In order to interpret the reaction behavior under various conditions it is necessary to consider various features and questions: (*i*) what are the mechanisms of transport of the reactants through continuous Cr_2O_3 scales? Where does the oxide formation take place? (*ii*) Why does the deformability of the Cr_2O_3 scales increase with decreasing partial pressure of oxygen? (*iii*) Does chromium transport across the gap between the metal and the scale limit the rate of reaction? An overall interpretation clearly must be based on a thorough knowledge of the defect structure and defect-dependent properties of Cr_2O_3. In this respect it is considered useful to review the properties of Cr_2O_3. This will be presented in Part II of this work (19).

At this stage it will be provisionally concluded from the results that transport of both chromium and oxygen through the scale is important during growth of continuous Cr_2O_3 scales. Furthermore, the transport may take place by lattice diffusion and along microcracks and grain boundaries in the scale. This conclusion is based on the observations that large growth stresses develop in the scale and that the oxide not only grows normal to, but also horizontally along the metal surface· *i.e.*, oxide formation also takes place within the oxide scale. The extensive deformations of the scales also suggest that both chromium and oxygen atoms are mobile species in the lattice. In previous studies of growth of Cr_2O_3 scales it has also been concluded that transport of the reactants may take place by various paths. Caplan *et al.* (6-10) have for instance suggested that Cr_2O_3 grows by both lattice and grain boundary diffusion and specifically propose that chromium diffuses outwards by lattice diffusion and that oxygen moves inwards along grain boundaries (9).

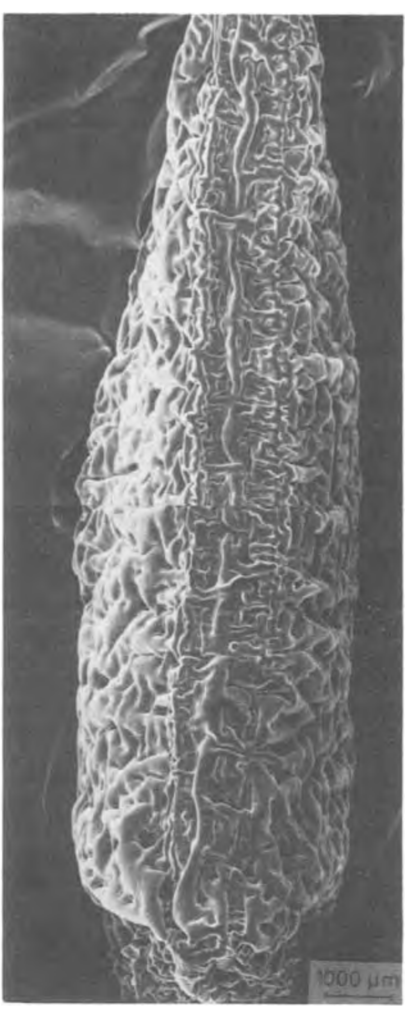

Fig. 19. Appearance of chromium specimen oxidized for 26 hr at 1075°C and $7 \cdot 10^{-2}$. The detached scale has deformed and given the specimen a pear-shaped appearance.

Without going into further details as to the defect-dependent properties of Cr_2O_3, two features of the oxidation behavior may be discussed at this point: (*i*) the mechanism of the logarithmic oxidation at 800°C and 10^5 Pa O_2, and (*ii*) Cr transport across the gap between the scale and the metal substrate.

Logarithmic oxidation at 800°C and 10^5 Pa O_2.—Logarithmic oxidation of chromium has been previously reported, but always for thin film formation of Cr_2O_3 at considerably lower temperatures (17). The unusual feature of the present results is that a logarithmic type behavior is observed at such a high temperature and for relatively thick scales (>1 µm

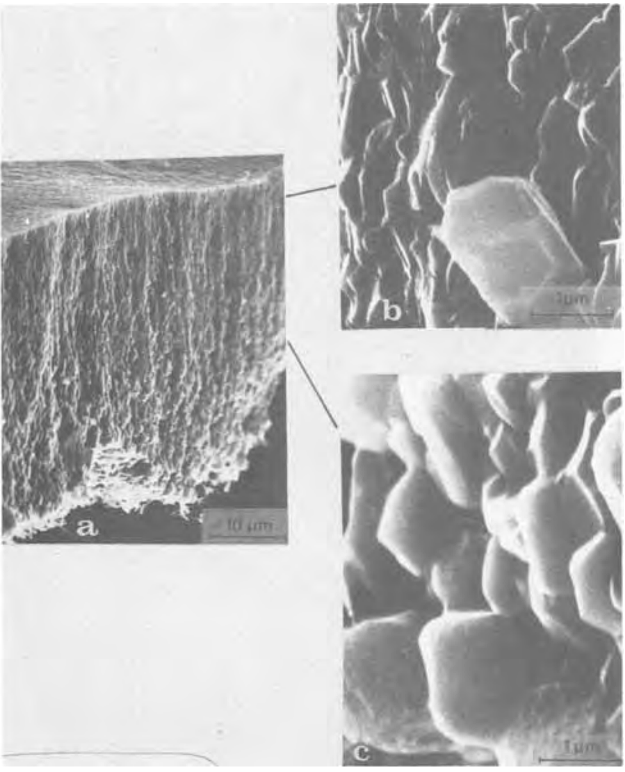

Fig. 20. Scanning electron micrograph of fractured edge of Cr_2O_3 scale after oxidation for 23 hr at 1075°C and $7 \cdot 10^{-2}$ Pa O_2; (b) detail of the outer part of the cross section in (a), (c) detail of the inner part of the cross section in (a).

thickness). This suggests that the thin film models, *e.g.*, the Mott-Cabrera theory (17), cannot be applied in the present case. Furthermore, important changes take place in the scale during its growth.

Various mechanisms have been advanced to explain logarithmic-type kinetics or behavior where the reaction rate decreases faster with time than for

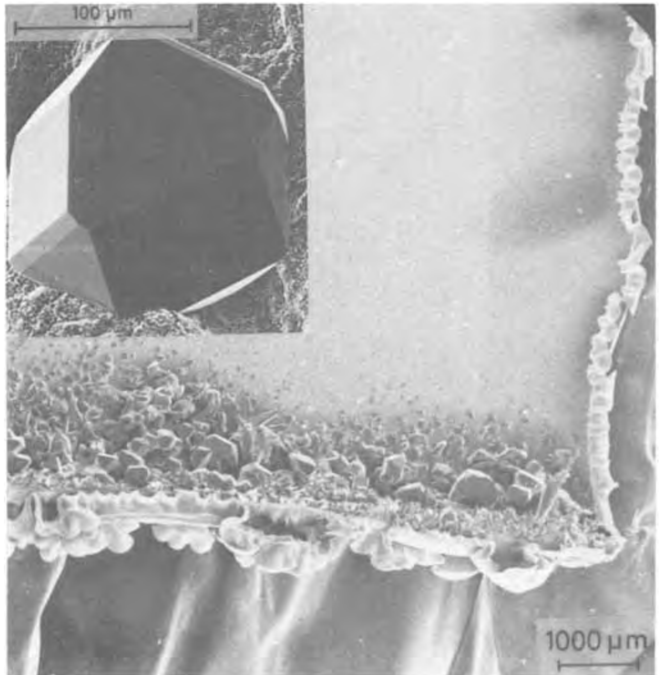

Fig. 21. Scanning electron micrograph of single crystals of chromium on the inner surface of detached Cr_2O_3 scale after oxidation for 72 hr at 1000°C and $7 \cdot 10^{-2}$ Pa (15×). The insert shows a single crystal at higher magnification (600×).

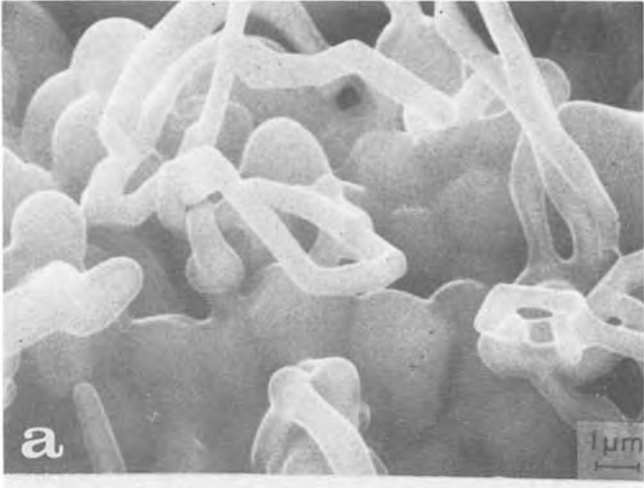

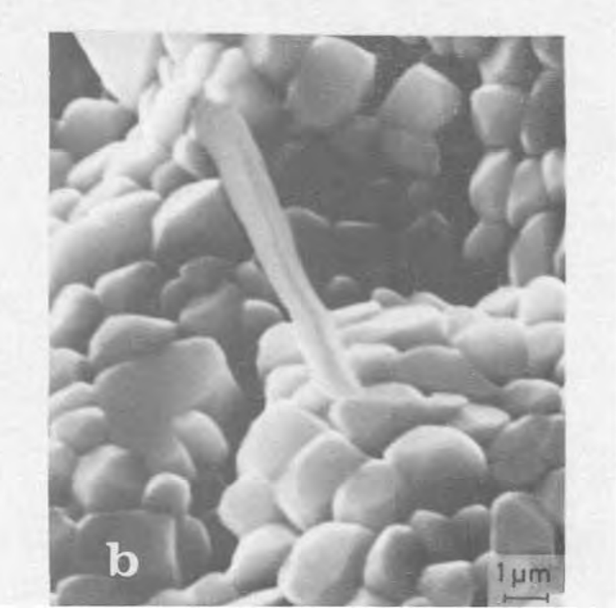

Fig. 22a. Scanning electron micrograph of threadlike oxide crystals on the inner surface of detached Cr_2O_3 scale after oxidation for 24 hr at 1075°C and $7 \cdot 10^{-2}$ Pa O_2; (b) different area of specimen shown in (a) with better developed crystal facets and whiskers.

parabolic oxidation. These models often involve transport of reacting atoms or ions along grain boundaries, dislocations, or lines of disarrayed atoms and that these diffusion paths gradually become blocked, deactivated, or annealed out with time (2, 29, 30). An alternative model by Evans (29) assumes that only part of the film thickens, as may occur, for instance, if cavities, voids, or obstructions develop during oxide growths and thereby continuously shrinks the area of the scale through which solid-state transport may take place. An example in case is development of cavities at the metal/oxide interface due to outward migration of cations through the scale.

The logarithmic type behavior in this study is associated with two main features as regards the scale growth: (*i*) a gradual detachment of the scale from the metal substrate, and (*ii*) an increased grain growth and developments of crystal facets on the grains during the oxidation. Both features may give rise to a rapidly decreasing reaction rate with time.

If the gradual detachment is the important factor that determines the kinetics, it is implied that the supply of gaseous chromium across the gap eventually becomes the rate-limiting factor. However, such an interpretation does not conform with the results at

the lower oxygen pressure ($7.2 \cdot 10^{-2}$ Pa) at 800°C. In this case the scale detachment is even more pronounced than at 10^5 Pa O_2; the oxidation rate is essentially linear and eventually becomes faster than at 10^5 Pa O_2. The results at the lower oxygen pressure thus suggest that a limited chromium supply is not the reason for the logarithmic type behavior.

An alternative interpretation is that the logarithmic type behavior is related to the grain growth in the scale during oxidation. This implies that transport via easy diffusion paths is particularly important during initial oxidation, and that their concentration gradually decrease with time through the grain growth. Such an interpretation is also qualitatively in accord with the fact that the initial oxidation is relatively high at 800°C compared to what would be expected if the oxidation rates at the higher temperatures are extrapolated to 800°C. Qualitatively one expects that the size of oxide nuclei and crystallites increase with increasing temperature.

Cr transport across the gap between the scale and the metal substrate.—The results at the lower oxygen pressure at 800°C and the latter interpretation of the logarithmic type behavior implies that there is sufficient chromium at the inner surface of the detached scale. In this respect it is of interest to estimate the rate of supply of gaseous chromium by chromium evaporation from the metal substrate.

At the highest temperatures (1000° and 1075°C) and reduced oxygen pressures single crystals of chromium are found on the inner surface of the oxide scale. Under these conditions the vapor pressure of chromium is sufficiently high to explain the oxidation rates. Thus at 1075°C the linear rate of oxidation at $7 \cdot 10^{-2}$ Pa O_2 is approximately 0.2 mg O/cm^2 hr. This corresponds to a consumption of 0.43 mg Cr/cm^2 hr. By use of the Herz-Langmuir equation an estimate of the rate of evaporation of chromium yields 0.47 mg/cm^2 hr. If the chromium metal surface is faceted, the rate of evaporation may be higher by at least a factor of 2. Thus the supply of chromium vapor is sufficiently large under these conditions.

At 800°C the situation is different. At $7 \cdot 10^{-2}$ Pa O_2 the linear oxidation rate is approximately $1 \cdot 10^{-2}$ mg O/cm^2 hr, while the estimated rate of evaporation of chromium by means of the Herz-Langmuir equation is only $8.7 \cdot 10^{-5}$ mg Cr/cm^2 hr. Thus even for a highly faceted chromium metal surface, the rate of supply of chromium metal vapor would not be sufficiently high to sustain the oxidation.

This discrepancy cannot be satisfactorily explained at present. One may speculate if an enhanced rate of evaporation from the chromium metal substrate in the form of a Cr-O molecule may take place at the low partial pressures of oxygen existing in the gap between the scale and metal. Is the presence of cubic oxide crystals (tentatively suggested to consist of CrO) at the inner oxide surface related to such an enhanced evaporation? According to available thermodynamic data for the vapor species of various chromium oxides in equilibrium with Cr and Cr_2O_3 such an enhanced evaporation would not be expected (23, 31, 32). However, when the scale is detached from the chromium metal over most of the surface, Cr and Cr_2O_3 are not necessarily in equilibrium, and conditions for enhanced evaporation could possibly exist. It may be noted that Fryburg *et al.* (25) observed enhanced oxidative vaporization of chromium at temperatures below 800°C in 15 Pa O_2 containing 2.5% oxygen atoms. The atomic oxygen is the "reactive" component, and these results cannot be directly translated to the conditions existing in the gap between the metal and the scale. But the study may indicate that an easily evaporated Cr-O specie can be formed at reduced pressures at temperatures below 800°C.

As regards the results of the present study it would be of interest to obtain further information on the conditions favoring the formation of the cubic oxide crystals, *e.g.*, by studies of oxidation of chromium at very reduced oxygen pressures.

On High Temperature Oxidation of Chromium

II. Properties of Cr_2O_3 and the Oxidation Mechanism of Chromium

P. Kofstad and K. P. Lillerud

Department of Chemistry, University of Oslo, Blindern, Oslo 3, Norway

ABSTRACT

Chromium specimens oxidized at 1000°-1100°C and at different oxygen pressures (10^5-$7 \cdot 10^{-2}$ Pa O_2) have been treated in high vacuum at temperature as a direct continuation of the oxidation runs. All specimens lost weight during the high vacuum treatment. During an initial period the rate of weight loss slowly decreased, but after longer time the loss rate became essentially linear. It is concluded that the weight loss is due to chromium evaporation due to chromium transport througn the scales by lattice diffusion and transport along paths of easy diffusion and microcracks. On the basis of the properties of Cr_2O_3 scales and available literature data on defect-dependent properties of Cr_2O_3, a defect structure model has been proposed for the oxide. It is proposed that interstitial chromium ions are the predominating point defects at partial pressures of oxygen near the Cr/Cr_2O_3 phase boundary. At near-atmospheric pressures the oxide is an intrinsic electronic conductor. Parabolic rate constants calculated from the diffusion data and the proposed defect structure model are compared with experimental values. The oxidation mechanism of chromium is discussed. Important factors are lattice diffusion, transport along paths of easy diffusion and microcracks through the scale, growth stresses in the scale, the ability of the scale to deform, and vapor transport from the metal substrate to detached scales.

Part I of this work describes studies of oxidation of annealed, thermally-etched chromium in the temperature range 800°-1100°C at different oxygen pressures ranging from 10^5 to $7 \cdot 10^{-2}$ Pa (1). This paper, Part II, presents results on high vacuum treatment of oxidized chromium specimens and discusses the properties and defect structure of Cr_2O_3 as a basis for an overall consideration of the high temperature oxidation mechanism of chromium.

A literature survey of oxidation of chromium and a description of materials and methods have been given in Part I (1).

High Vacuum Treatment of Oxidized Specimens

Thermogravimetric measurements.—If the oxidation runs at and above 1000°C (1) were discontinued by pumping high vacuum on the system while keeping the specimens at temperature, it was found that the oxidized specimens began to lose weight. A few specimens were therefore treated in high vacuum after oxidation and their weight losses were recorded for extended periods. During this treatment the vacuum, as measured with an ionization or Penning gauge located just outside the furnace region, was $<10^{-3}$ Pa.

Figure 1 shows an example of the weight loss as a function of time for specimens oxidized at 1100°C. During an initial period of the high vacuum treatment the rate of weight loss slowly decreased, but after longer time the loss rate became essentially linear with time. Provided sufficiently good vacuum was maintained, all specimens continued to lose weight within the time periods studied. The vacuum treatments were in some cases continued for several hundred hours.

All specimens lost weight irrespective of prior oxidation conditions. But differences in weight loss were observed. For instance, for specimens oxidized at 10^5 Pa and 1100°C the rate of weight loss was smaller if the high vacuum treatment was started before the first major breakdown of the scale [as noted by sudden weight gain in the oxidation curves (1)], than for specimens oxidized past the first "breakdown" stage.

If the temperature was increased (*e.g.*, from 1100° to 1200°C) during the high vacuum treatment, the rate of weight loss increased. But on return to the starting temperature (1100°C), the rate of weight loss was smaller than the original rate.

During the high vacuum treatment the cooler zones just outside the furnace were covered with a black-gray deposit, presumably consisting of chromium metal.

The rates of weight loss became too small to be detected accurately at temperatures below 1000°C.

Characterization of specimens.—Specimens which were oxidized in 10^5 Pa O_2 and subsequently high vacuum treated, exhibited no major change in surface

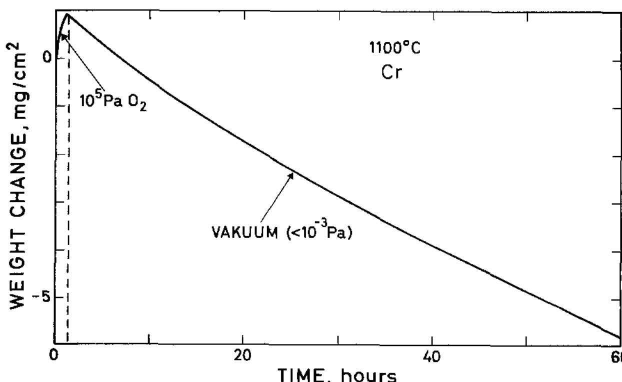

Fig. 1. Weight change of thermally etched Cr specimen during oxidation at 10^5 Pa O_2 at 1100°C and subsequent treatment in high vacuum.

Key words: metals, corrosion, SEM, mass transport.

and cross-sectional appearance as a result of the high vacuum treatment. But the specimens oxidized in $7 \cdot 10^{-2}$ Pa O_2 underwent marked changes in appearance. This is illustrated in Fig. 2a and b, which show specimens at the end of the oxidation and of the high vacuum treatment, respectively. During oxidation at $7 \cdot 10^{-2}$ Pa O_2 the oxide scale deforms and bulges away from the metal (1). During the high vacuum treatment this process continues. The oxide scale balloons out as shown in Fig. 2b. At the end of the oxidation the oxide at the scale/gas interface is extremely fine-grained (Fig. 3a), but after the subsequent high vacuum treatment the oxide grains have grown and have developed crystal facets (Fig. 3b). The same features are observed at the inner surface of the scale. This is illustrated in Fig. 4a and b.

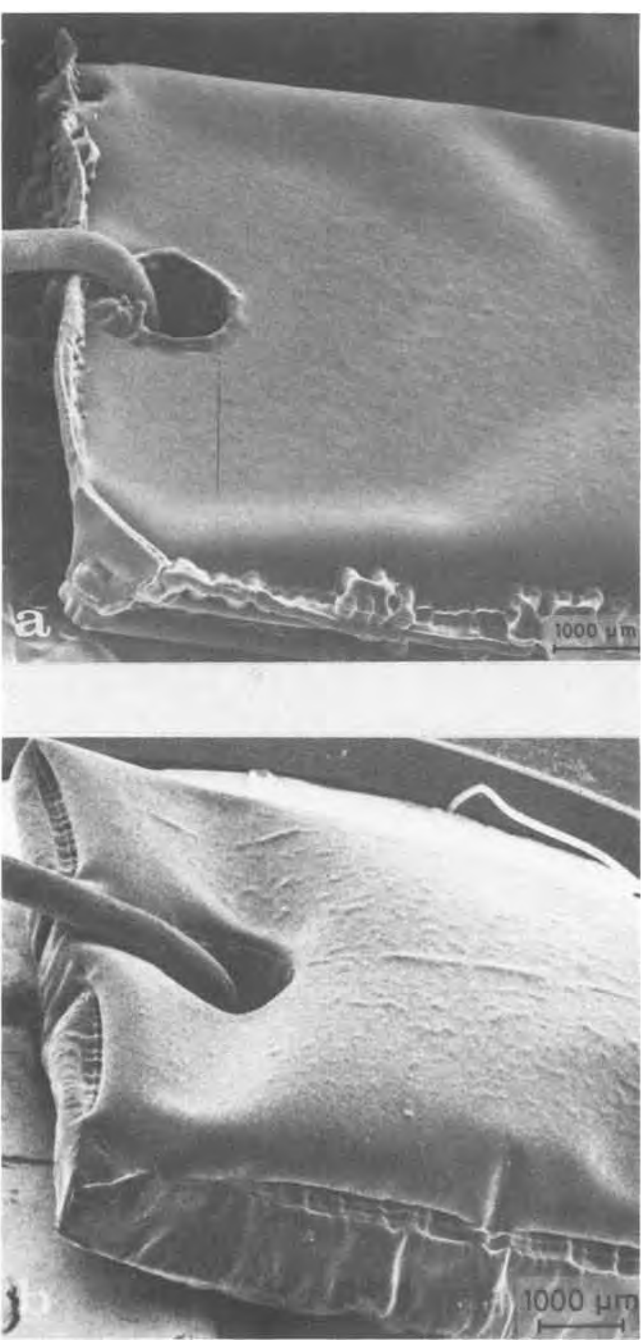

Fig. 2. Change in appearance of oxidized specimens after high vacuum treatment at temperature 15×. (a) Specimen appearance after oxidation at 1000°C and $7 \cdot 10^{-2}$ Pa O_2 for 72 hr; (b) appearance of a specimen after oxidation for 71 hr at 1000°C and $7 \cdot 10^{-2}$ Pa O_2 and subsequent treatment in high vacuum for 84 hr at the same temperature.

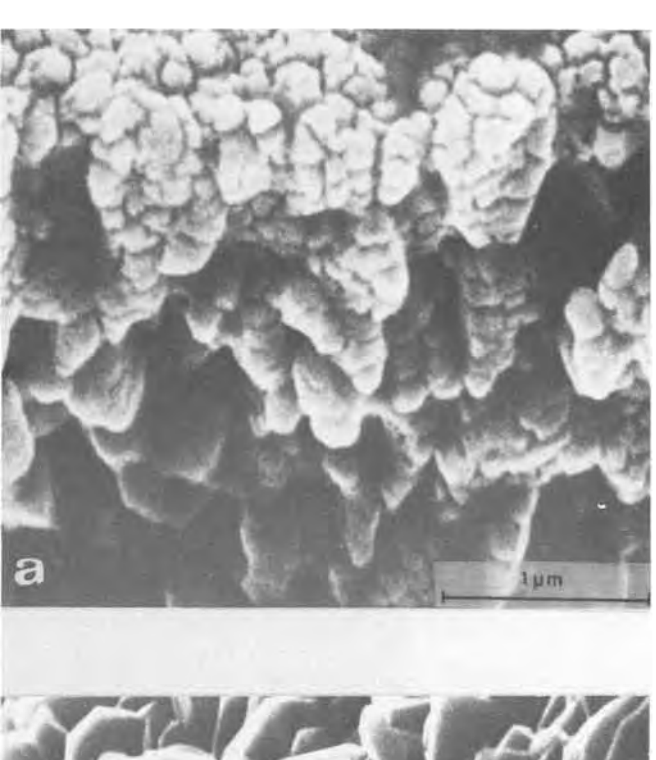

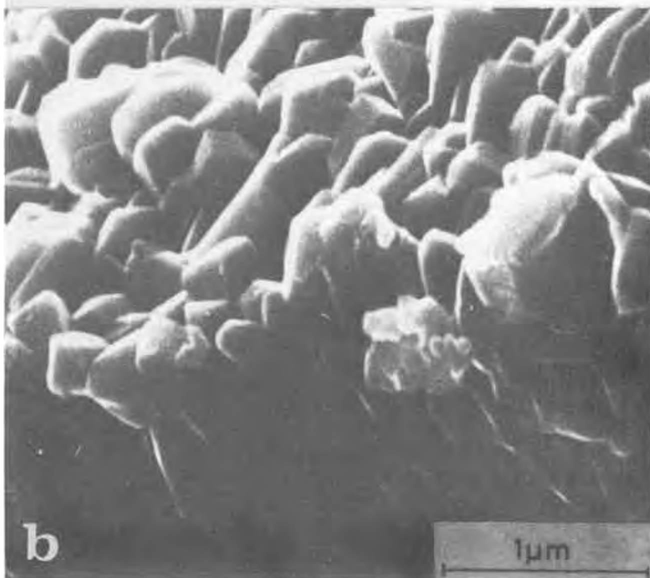

Fig. 3. SEM micrographs of the structure of the oxide scales at the gas/oxide interface after (a) oxidation for 25 hr at $7 \cdot 10^{-2}$ O_2 at 1075°C; (b) subsequent high vacuum treatment at 1075°C for 47 hr.

Discussion.—The deformation of the scale reflects further alleviation of growth stresses in the scale. During the high vacuum treatment the whole scale can be considered to be equilibrated with chromium metal, and the effective partial pressure of oxygen throughout the scale essentially becomes equal to the decomposition pressure of Cr_2O_3 in equilibrium with chromium metal. The results suggest that the ability of Cr_2O_3 to deform is even higher at this low partial pressure of oxygen than at higher ones.

The weight loss in all probability reflects loss of chromium metal. Chromium may penetrate the scale by lattice diffusion and by transport along grain boundaries, easy diffusion paths, and microcracks. The latter transport processes are concluded to be significant as evidenced by the gradual decrease in rate of weight loss during an initial period of the high vacuum

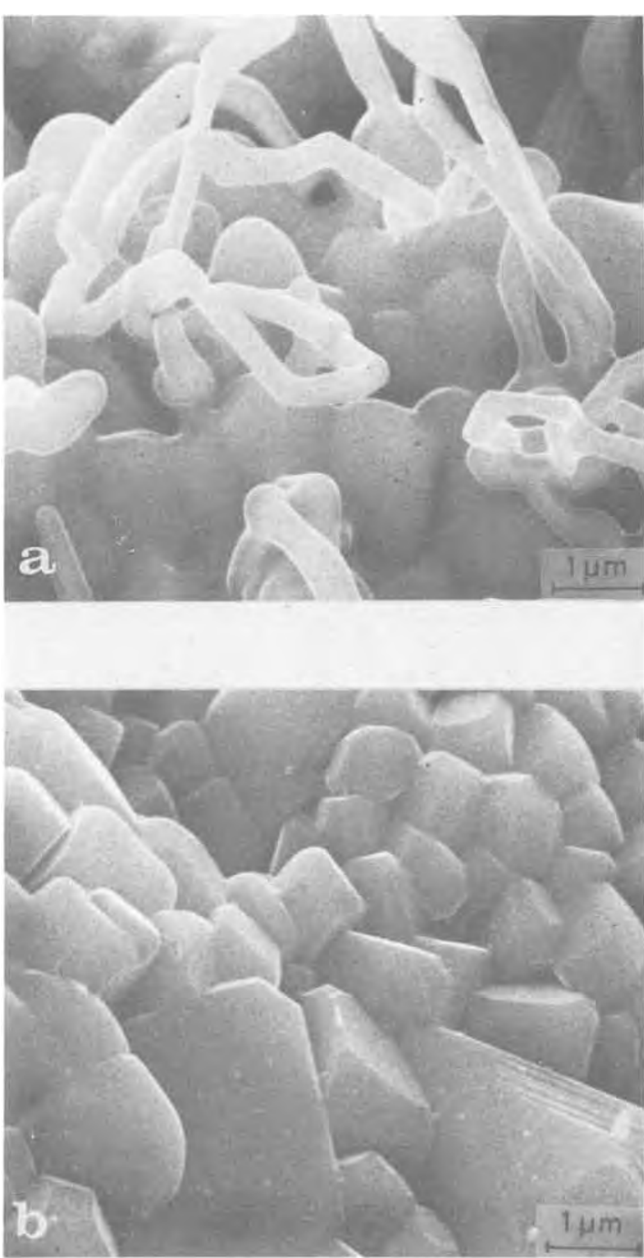

Fig. 4. SEM micrographs of the structure of the inner scale surface after (a) oxidation for 25 hr at 7 · 10^{-2} Pa O_2 at 1075°C; (b) subsequent high vacuum treatment at 1075°C for 47 hr.

treatment and the simultaneous increase in crystal perfection in the scale.

Defect-Dependent Properties of Cr_2O_3

An overall interpretation of the oxidation mechanism of chromium must be based on a thorough understanding of the defect structure and defect-dependent properties of Cr_2O_3. It is appropriate therefore briefly to survey available data on Cr_2O_3, and to attempt to interpret these in terms of a consistent model. A number of studies have been reported on electrical conductivity, diffusion, sintering, etc. (2).

Nonstoichiometry.—Variations in the deviation from stoichiometry in Cr_2O_3 at high temperatures and different partial pressures of oxygen are apparently small. So far it has proved difficult to determine experimentally (2). An added difficulty is that measurements at high oxygen pressures, where the largest weight changes are expected if chromium vacancies are the predominating defects, are also significantly influenced by evaporation of CrO_3.

Hay (3, 4) has attempted to measure variations in the deviation from stoichiometry at 950°-1200°C and near-atmospheric pressures by measuring the weight change of Cr_2O_3 specimens when changing the ambient oxygen pressure from one value to another. Small weight losses were observed when the oxygen pressure was decreased. The results were not sufficiently accurate to determine the exact oxygen pressure dependence of the weight loss, and accordingly no definite conclusion could be drawn as to the predominating defects. But by assuming that these are chromium vacancies, Hay estimated the extent of nonstoichiometry to be of the order of 10^{-4} vacancies per chromium site. It may be noted however, that regardless of whether the predominating defects are chromium or oxygen vacancies or interstitials, Cr_2O_3 specimens will lose weight when the partial pressure of oxygen is reduced. It appears that the only conclusion that can be drawn at this time is that the deviation from stoichiometry in Cr_2O_3 is "small" at near-atmospheric oxygen pressures.

Cojocaru (5) has reported that Cr_2O_3 produced by heating CrO_3 for 4 hr at 673°-1273°K exhibited nonstoichiometry up to $x = 0.12$ in $Cr_{2-x}O_3$. The "nonstoichiometry" increased with decreasing temperature. These results probably do not represent equilibrium values for Cr_2O_3.

Electrical conductivity (2, 5-14).—Cr_2O_3 is an electronic semiconductor. When the electrical conductivity is measured as a function of temperature at near-atmospheric oxygen pressures, the behavior may be divided into two main regions: (*i*) a high temperature region above about 1000°-1200°C with activation energies reported to range from 155 to 175 kJ/mole (1.6-1.8 eV) and (*ii*) a low temperature region where the activation energy is much smaller. While the different results for the high temperature region are in reasonably good agreement, the results for the low temperature show large discrepancies.

It is generally concluded that the high temperature region reflects the intrinsic electronic equilibrium in the oxide (2,10-13). [Fe_2O_3, which has the same crystal structure as Cr_2O_3, is also probably an intrinsic electronic conductor (2).] The electrical conductivity is independent of the partial pressure of oxygen at near-atmospheric oxygen pressures. If one as a first approximation neglects the activation energy associated with the mobility of electrons/electron holes, the measured activation energy should be expected to be one-half of the value of the bandgap. This is reported to be 330 kJ/mole (3.4 eV), in satisfactory agreement with the conductivity measurements.

Hay *et al.* (4) have from measurements of thermoelectric power on Cr_2O_3 estimated that the concentration of electron holes is $2 \cdot 10^{+17}$ mm^{-3} at 1500°C. They conclude from their studies that the high temperature electrical conductivity cannot be intrinsic electronic conductivity. However, the concentration of electron holes may also be estimated from the equation

$$p \cdot n = K_i = 4 \left(\frac{2\pi kT}{h^2} \right)^3 (m_e \cdot h_h)^{3/2} \exp \left(-\frac{E_g}{kT} \right) \quad [1]$$

where k is the Boltzmann constant, h is the Planck constant, m_e and m_h the effective masses of electrons and electron holes, respectively, and E_g is the bandgap. If m_e and m_h are set equal to the rest mass of the electron, Eq. [1] gives a value of $p = 9 \cdot 10^{16}$ mm^{-3}, which is in reasonable agreement with the measured value.

The reason for the transition to the low temperature region is not clear. For sufficiently low temperatures a possible explanation is that the concentration of electronic defects produced by the intrinsic electronic equilibrium becomes so small that their concentration is determined by unavoidable impurities. When specimens are exposed to high temperatures in ceramic

tubes or chambers (2, 11), the majority of such impurities are lower valent, *e.g.*, Na, Ca, etc., and their presence may determine the concentration of electron holes, *e.g.*

$$[Ca'_{Cr}] = p \quad \text{or} \quad 2[Na^{2'}_{Cr}] = p \qquad [2]$$

This may explain that "pure" Cr_2O_3 is found to be a p-type semiconductor in the low temperature region and that the measured electrical conductivities in this region may differ by several orders of magnitude from one study to another (2). It may also be noted that Cr_2O_3 becomes an n-conductor when doped with higher valent cations, *e.g.*, TiO_2 (11). This is the expected behavior if Ti is dissolved substitutionally, *e.g.*, $n = [Ti^{\cdot}_{Cr}]$.

In the low temperature region the electrical conductivity may be dependent on the oxygen pressure if the lattice solubility of impurities or dopants vary with the oxygen pressure. It has alternatively been suggested that the electrical conductivity at the lower temperatures reflects a defect structure which is "frozen in" at the low temperatures (12).

Regardless of a detailed interpretation of the electrical conductivity, it appears that such results do not provide any clear-cut information as to the predominating point defects in Cr_2O_3.

Self-diffusion.—Both ^{51}Cr- and ^{18}O-tracer diffusion studies have been made on Cr_2O_3 (12, 15-18). The reported values are summarized in Fig. 5.

Hagel and Seybolt (12) made their studies on hot-pressed and sintered specimens, respectively. The hot-pressing was performed in graphite dies. Owing to the strongly reducing conditions during the process, the hot-pressed specimens contained some chromium metal. This was chemically determined to be in amounts of 0.1-0.2 weight percent (w/o) (12). The hot-pressed compacts had a density of 99.5% of the theoretical limit.

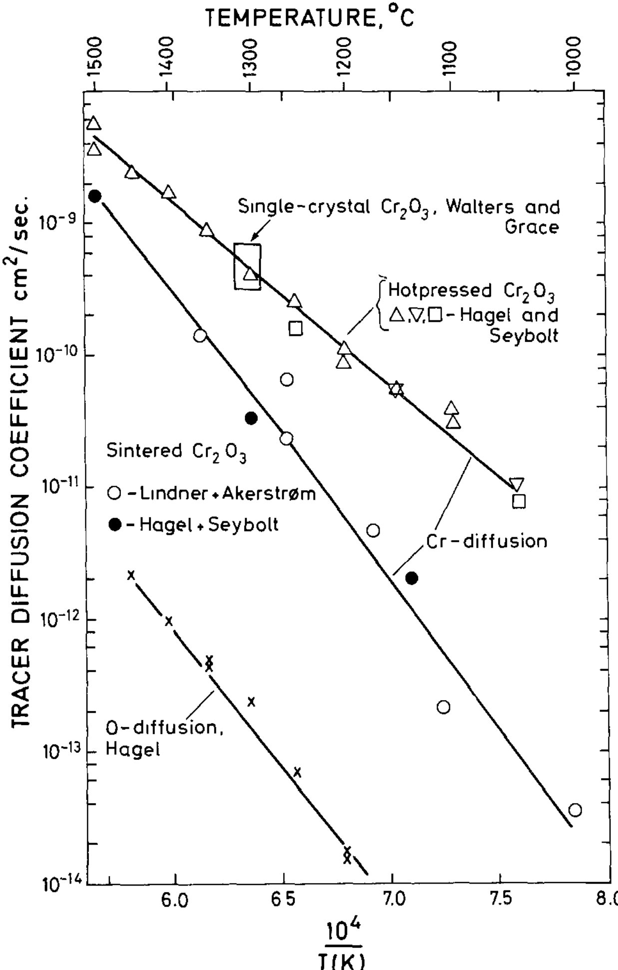

Fig. 5. Literature values of tracer self-diffusion of ^{51}Cr and ^{18}O in Cr_2O_3. Values of Hagel and Seybolt (12) (hot-pressed and sintered specimens), Lindner and Åkerstrøm (15) (sintered specimens), Walters and Grace (16), and Hagel (17) (O-diffusion).

The sintered specimens were prepared by sintering in argon (with reported partial pressure of oxygen of about 10^{-1} Pa O_2) at 1700°C and had a density approaching 93.7%. The diffusion anneals were made in high purity nitrogen atmospheres with a reported partial pressure of oxygen of about 10^{-2} Pa O_2. Thus the sintering and diffusion anneal were made at partial pressures of oxygen of 10^{-1}-10^{-2} Pa O_2.

As shown in Fig. 5 the self-diffusion coefficients of chromium were higher for the hot-pressed than for the sintered specimens. The activation energies were also different and amounted to 255 and 415 kJ/mole (61 and 100 kcal/mole), respectively. The tracer diffusion coefficients can be expressed as (12-15)

$$\text{sintered:} \quad D = 4.3 \cdot 10^3 \exp(-415{,}000/RT) \qquad [3]$$

$$\text{hot-pressed:} \quad D^* = 0.167 \exp(-255{,}000/RT) \qquad [4]$$

Lindner and Åkerstrøm (15) have also studied self-diffusion of Cr in sintered Cr_2O_3. As shown in Fig. 5 their results are in reasonable agreement with those of Hagel and Seybolt on the same type of specimens.

Hagel and Seybolt (12) believe that the results on the hot-pressed and more compact specimens represent the more correct value for the self-diffusion coefficient of chromium in Cr_2O_3. However, this conclusion is surprising considering that the self-diffusion in the hot-pressed specimens are considerably higher than in the sintered specimens. If grain boundary diffusion were important in the less compact, sintered specimens, it would be expected that diffusion in the sintered specimens were higher. Contribution from grain boundary diffusion should also have been noted in the tracer penetration curves.

We would like to suggest a possible alternative explanation for the difference between the two types of specimens. Hagel and Seybolt report that the hot-pressed specimens contained some chromium metal. This suggests that the hot-pressed specimens had a nonstoichiometry approximately corresponding to that of Cr_2O_3 at the Cr/Cr_2O_3 phase boundary, *i.e.*, the effective partial pressure of oxygen within the specimens was close to the decomposition pressure of Cr_2O_3 in equilibrium with chromium metal. The sintered specimens, on the other hand, were prepared and diffusion-annealed at partial pressures of oxygen of 10^{-1}-10^{-2} Pa O_2. If these are the important differences between the two types of specimens, one can conclude from these studies that the self-diffusion coefficient of Cr in Cr_2O_3 in this pressure range increases with decreasing partial pressure of oxygen. This cannot be explained by assuming that chromium vacancies are the predominating chromium point defects in Cr_2O_3. Rather, it is reasonable to assume that the important cation defects are chromium interstitials at partial pressures of oxygen close to the decomposition pressure of Cr_2O_3.

Walters and Grace (16) measured the self-diffusion in Cr_2O_3 single crystals at 1300°C in $H_2 + H_2O$ mixtures. The partial pressures of oxygen ranged from $1 \cdot 10^{-11}$ to $5 \cdot 10^{-11}$ Pa O_2, which is close to the decomposition pressure of Cr_2O_3 at this temperature, $p_{O_2}{}^* = 5 \cdot 10^{-12}$ Pa. As shown in Fig. 5 their values agree with those of Hagel and Seybolt for the hot-pressed specimens. This is consistent with the above interpretation. It may be added that Walters and Grace interpreted their data on the basis of a Cr-vacancy model. This was based on measurements of the self-diffusion coefficients in the narrow pressure range from $1 \cdot 10^{-11}$ to $5 \cdot 10^{-11}$ atm O_2. However, the scatter in their results is appreciable, and other interpretations seem possible (2).

Self-diffusion of oxygen in Cr_2O_3 at $p_{O_2} = 1.6 \cdot 10^4$ Pa O_2 have been studied by Hagel (18) by means of ^{18}O-exchange in the temperature range 1100°-1450°C. The data are included in Fig. 5. The oxygen tracer self-diffusion coefficient under these conditions can be expressed by

$$D_O{}^T = 15.9 \exp(-422{,}000/RT) \text{ (act. energy in J/mole)} \quad [5]$$

The oxygen self-diffusion coefficient at $p_{O_2} = 1.6 \cdot 10^4$ Pa is smaller than the chromium self-diffusion coefficient for sintered specimens (at p_{O_2} 10^{-1}-10^{-2} Pa) by about three orders of magnitude.

High temperature oxidation.—In discussions of the growth mechanism of Cr_2O_3 scales it is commonly assumed in the literature that the important lattice defects are chromium vacancies. If this were so, parabolic oxidation of chromium governed by lattice diffusion should exhibit a significant oxygen pressure dependence, *i.e.*, $k_p \propto p_{O_2}{}^{1/n}$ where n is determined by the defect structure. Such a pressure dependence has never been observed. Rather, available data suggest that the parabolic rate constant is approximately independent of oxygen pressure (1). This is the expected relationship if chromium interstitials are the predominating point defects.

Sintering (2, 19-24).—Sintering of Cr_2O_3 at atmospheric or near-atmospheric pressures of oxygen yields fine-grained, highly porous and partially sintered, structures with poor densification (20). However, when the partial pressure of oxygen is reduced, sintering rates are markedly increased (19-22). Thus Halloran and Anderson (21) found that the initial sintering, *i.e.*, the fractional shrinkage rate at 3% linear shrinkage at 1100°C, only was observed at partial pressures of oxygen <1 Pa O_2. The shrinkage rate increased with further decrease in oxygen partial pressure and reached a maximum at the decomposition pressure of Cr_2O_3. Ownby and Jungquist (20) studied final sintering of Cr_2O_3 at 1600°C. After a sintering time of 1 hr the theoretical density only reached 63% at 10^5 Pa O_2, while essentially 100% density was reached at partial pressures of oxygen close to the decomposition pressure of Cr_2O_3. A particularly rapid increase in densification took place at oxygen pressures close to the decomposition pressure were approached.

Without going into the details of sintering mechanisms, these results clearly demonstrate a markedly increased rate of transport (*i.e.*, increased concentration) of point defects with decreasing partial pressure of oxygen. Diffusion-controlled sintering is governed by the transport of the slower diffusion species, *i.e.*, the oxygen atoms. It is tentatively concluded that oxygen vacancies constitute the oxygen point defects, and that these are the minority defects in Cr_2O_3, at least at partial pressures of oxygen near the decomposition pressure of Cr_2O_3.

Discussion of defect structure and transport properties of Cr_3O_3.—Available data on electrical conductivity, self-diffusion, and sintering of Cr_2O_3 suggest that this oxide has a complex defect structure. But a few major conclusions may be drawn:

(*i*) Chromium point defects are the majority point defects in Cr_2O_3, at least at reduced oxygen pressures.

(*ii*) Chromium diffusion increases from specimens prepared and equilibrated in partial pressures of oxygen of 10^{-2} to 10^{-2} Pa O_2 (sintered specimens) to specimens containing small amounts of chromium metal (hot-pressed specimens) for which the effective partial pressure of oxygen is close to the decomposition pressure of Cr_2O_3 in equilibrium with chromium metal. This is inconsistent with Cr vacancies being the predominating chromium defects in this range of partial pressures of oxygen. Rather it is concluded that Cr interstitials are the predominating chromium point defects under these conditions. [The predominating iron defects in Fe_2O_3 have also been shown to be iron interstitials (25)].

(*iii*) Cr_2O_3 is an intrinsic electronic conductor at high temperatures (>1000°-1200°C) and at oxygen pressures from 1 atm O_2 down to partial pressures of oxygen existing in argon atmospheres (<10-10^{-1} Pa O_2 depending upon the purity of argon). The electrical conductivity has not been studied at partial pressures close to the decomposition pressure of Cr_2O_3. Cr_2O_3 is a p-conductor at atmospheric and near-atmospheric oxygen pressures. This suggests a higher mobility for electron holes than for electrons.

(*iv*) At lower temperatures (<1000°-1200°C) the factors affecting the electrical conductivity are more difficult to evaluate. The behavior may be caused by the presence of unavoidable impurities or that defect equilibria are "frozen in" and slow to be established.

As electronic defects predominate at near-atmospheric oxygen pressures, details of the point defect equilibria in this oxygen pressure range are as yet diffcult to ascertain.

Defect structure model.—All in all it appears reasonable to divide the stability range of Cr_2O_3 into two main regions:

(*i*) At near-atmospheric oxygen pressures Cr_2O_3 is an intrinsic electronic semiconductor.

(*ii*) At oxygen pressures near the decomposition pressure of Cr_2O_3 the oxide has excess metal; the predominating point defects are chromium interstitials. The minority defects are probably oxygen vacancies.

This model is illustrated schematically in Fig. 6. Let us first consider the low pressure region. Following the conclusions drawn above, the self-diffusion coefficient measured for the hot-pressed specimens represents diffusion in Cr_2O_3 in equilibrium chromium metal. This means that these results do not represent values of the self-diffusion coefficient at a constant partial pressure of oxygen, but at the decomposition pressure of Cr_2O_3 in equilibrium with chromium metal. The decomposition pressure of Cr_2O_3 changes with temperature according to

$$p_{O_2}{}^* = \exp\left(-\frac{2\Delta G^\circ(Cr_2O_3)}{3RT}\right) = \exp\frac{2\Delta S^\circ(Cr_2O_3)}{3R}\exp\left(-\frac{2\Delta H^\circ(Cr_2O_3)}{3RT}\right) \quad [6]$$

Fig. 6. Defect structure model for Cr_2O_3

where $\Delta G^\circ(Cr_2O_3)$, $\Delta H^\circ(Cr_2O_3)$, and $\Delta S^\circ(Cr_2O_3)$ represent, respectively, the standard free energy, enthalpy, and entropy of formation of Cr_2O_3 at temperature T. The value of $\Delta G^\circ(Cr_2O_3)$ is given by $\Delta G^\circ(Cr_2O_3) = \Delta H^\circ(Cr_2O_3) - T\Delta S(Cr_2O_3) = 111{,}300 + 250\ T$ J/mole (26). The decomposition pressures range from $p_{O_2} = 10^{-16.8}$ atm at 1000°C to $p_{O_2} = 10^{-8.2}$ at 1500°C.

If the diffusion coefficient of Cr at constant partial pressures of oxygen is to be estimated from the diffusion coefficient for the hot-pressed specimens, the defect structure of Cr_2O_3 near the decomposition pressure of Cr_2O_3 must be known. Let us for the sake of illustration assume that the predominating point defects under these conditions are chromium interstitials with three positive effective charges. Their formation may be written (2)

$$3/2\ O_O + Cr_{Cr} = Cr_i^{3\cdot} + 3e' + 3/4\ O_2 \qquad [7]$$

If the electroneutrality condition is given by $n = 3[Cr_i^{3\cdot}]$, the equilibrium concentration of chromium interstitials is given by (2)

$$[Cr_i^{3\cdot}] = \left(\frac{K_1}{27}\right)^{1/4} \cdot p_{O_2}^{-3/16} \qquad [8]$$

where K_1 is the equilibrium constant for Eq. [7].

The self-diffusion coefficient in Cr_2O_3 at the phase boundary Cr_2O_3/Cr (in hot-pressed specimens), D_{Cr}^*, is then related to the self-diffusion of chromium at constant partial pressure of oxygen, $D_{Cr} = D_{Cr}^\circ p_{O_2}^{-3/16}$, by the equation

$$D_{Cr}^* = D_{Cr}^\circ (p_{O_2}^*)^{-3/16} \qquad [9]$$

Experimentally D_{Cr}^* (hot-pressed specimens) is given by $D^* = 0.167 \exp(-255{,}000/RT)$.

The temperature dependence of D_{Cr} can be expressed by

$$D_{Cr} = D_{Cr}^\circ \exp(-\Delta H_{Cr}/RT) \qquad [10]$$

where ΔH_{Cr} is the activation energy for chromium self-diffusion at constant partial pressure of oxygen.

It may be shown that ΔH_{Cr} is given by (3)

$$\Delta H_{Cr} = 255 + \frac{2}{3}\frac{3}{16}\,\Delta H^\circ\ (Cr_2O_3) = 255 + 140 = 395\ \text{kJ/mole} \qquad [11]$$

This may be compared with the activation energy for the sintered specimens ($p_{O_2} \sim 10^{-1}$-10^{-2} Pa O_2) of about 415 kJ/mole. If it were assumed that the chromium interstitials were doubly charged, $Cr_i^{2\cdot}$, then the oxygen pressure dependence of $D_{Cr} \propto p_{O_2}^{-1/4}$ and the activation energy $\Delta H_{Cr} = 440$ kJ/mole. The approximate agreement in activation is consistent with this type of model.

The results of the model assuming that $Cr_i^{3\cdot}$ predominates may be illustrated in Fig. 7. The figure includes the experimental values for the hot-pressed and sintered specimens, and estimated diffusion coefficients of chromium at different partial pressures of oxygen in the low pressure region.

The model must also explain the markedly increased sintering rates in the low pressure region. This is assumed to be governed by transport of oxygen vacancies. Their formation may be written

$$O_O = V_O^{2\cdot} + 2e' + \tfrac{1}{2}\ O_2$$

For the electroneutrality condition $n = 3[Cr_i^{3\cdot}]$, it follows that the oxygen pressure dependence of the oxygen vacancies is given by $[V_O^{2\cdot}] \propto p_{O_2}^{-1/8}$. This would qualitatively explain the increased sintering rate with decreasing partial pressure of oxygen.

A Krøger-Vink diagram giving a qualitative picture of the variations of these point defects as function of the partial pressure of oxygen is shown in Fig. 6.

For the high pressure region with predominant intrinsic electronic equilibrium one may only speculate as to the important point defects. The electroneutrality condition is given by $n = p = K_i^{1/2}$, and this in turn means that the concentration of the chromium interstitials and oxygen vacancies vary as $[Cr_i^{3\cdot}] \propto p_{O_2}^{-3/4}$ and $[V_O^{2\cdot}] \propto p_{O_2}^{-1/2}$. Thus the concentration of both defect species decrease rapidly with increasing partial pressure of oxygen. But at sufficiently high oxygen pressure, other point defect structure situations may begin to predominate. Thus chromium vacancies may become important or a Frenkel or Schottky defect structure situation may predominate. In this latter case the concentration of chromium point defects will be independent of the partial pressure of oxygen. The same would then also apply to the concentration of oxygen vacancies.

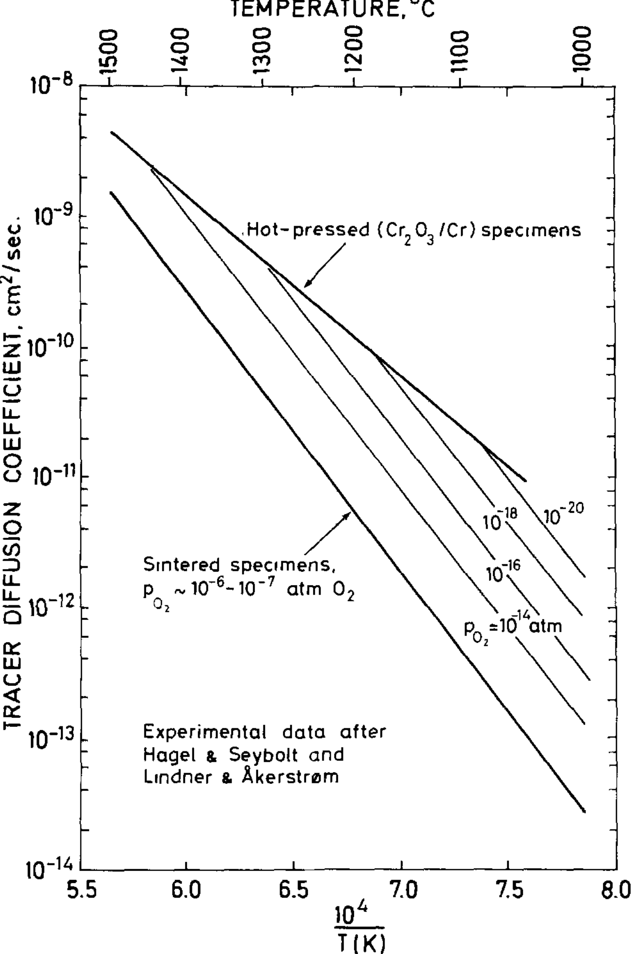

Fig. 7. Estimated values of the chromium self-diffusion in Cr_2O_3 at different partial pressures of oxygen. Fully drawn lines represent the experimental values for hot-pressed and sintered specimens (12, 15) (cpr. Fig. 5).

Such a defect structure situation is also illustrated in the Krøger-Vink diagram in Fig. 6.

The relative concentrations of the chromium point defects and oxygen vacancies cannot be ascertained and depend on the values of the equilibrium constants for the Frenkel and Schottky defect equilibrium. It is not obvious that the concentration of oxygen vacancies are much smaller than that of the chromium defects in this region.

As regards creep and stress-induced deformation of Cr_2O_3 at high temperatures it is expected that this will qualitatively follow the same oxygen pressure dependence as for sintering: creep rates are relatively small at near-atmospheric oxygen pressures and will increase rapidly in the region near the decomposition pressure of Cr_2O_3.

The authors would like to emphasize that the proposed model is not pretended to constitute a "final"

defect structure model for Cr_2O_3. It is, of course, realized that details of the interpretations may vary. It would, for instance, be valuable to confirm by electrical conductivity measurements whether the oxide is an excess metal semiconductor in the stability region near the Cr_2O_3/Cr phase boundary. The importance of the model lies in the major trends that are suggested for the defect structure as a function of partial pressure of oxygen and the implications on the properties of the oxide.

Mechanism of High Temperature Oxidation of Chromium

Chromium exhibits an extremely complex reaction behavior at high temperatures. A number of factors must be considered in order to make an overall description of the oxidation mechanism: transport of the reactants through the Cr_2O_3 scale in the form of volume diffusion and along grain boundaries, easy diffusion paths, and microcracks, the build-up of compressive stresses in the growing oxide scale, cracking and deformation of the scale, detachment of the scale from the metal surface and a possible rate-limiting supply of chromium vapor across the gap between the metal and the scale, evaporation of CrO_3 from the outer oxide surface at the higher oxygen pressures, etc. It is not surprising that the reaction kinetics may vary considerably with experimental conditions.

Oxidation at 900-1100°C.—Let us first consider oxidation at atmospheric pressure at and above about 900°C. Under these conditions the initial oxidation decreases with time; as the scale builds up, cracking occurs, and the overall kinetics can be considered to consist of a sequence of protective stages where new protective oxide is formed after cracking.

Volume diffusion. Comparison of experimental k_p's with values calculated from diffusion data.—The initial, protective oxidation conforms approximately with parabolic kinetics, and parabolic rate constants can be evaluated for this stage (1). It is reasonable to assume that the oxidation during this initial stage is governed by transport of the reactants through a thin scale, which initially grows as an approximately plane-parallel layer on the surface. In view of the discussion of the defect structure and transport properties of Cr_2O_3, it is of interest to compare experimentally observed rate constants with values calculated from the reported diffusion data by means of the Wagner theory. Such a comparison should only be considered an order of magnitude exercise to test the overall consistency of the diffusion and oxidation data. It is emphasized that the Wagner theory represents an ideal model that presupposes the growth of dense scales governed by lattice diffusion. For previously reported studies the k_p's have usually been evaluated for extended periods of oxidation where CrO_3-evaporation, a rate-limiting Cr-evaporation across the gap between the detached scale and the metal, grain boundary transport, etc. will affect the measured values.

For an oxide scale growing by volume diffusion the partial pressure of oxygen will change from the ambient oxygen pressure at the oxide/gas interface, p_{O_2}, to the decomposition pressure of the oxide in equilibrium with the metal at the inner surface of the scale, $p_{O_2}{}^*$. Following the proposed defect structure model the growing Cr_2O_3 scale can be considered to consist of two regions: an inner region where interstitial chromium ions predominate the lattice diffusion process and an outer region where intrinsic electronic equilibrium predominates. The lattice diffusion of chromium in the inner region will be much faster than the transport processes in the outer region. Accordingly the inner region will be assumed to be considerably thicker than the outer region. For the outer region it is not known whether chromium predominates or whether oxygen transport is also a contributing factor. As a first approximation an evaluation of k_p may be made assuming that the inner region comprises essentially the complete scale.

Let us consider the parabolic rate constant k_p in $\Delta X^2 = k_p t$, expressed in terms of cm²/sec. For Cr_2O_3 growing by lattice diffusion of interstitial chromium ions with an effective charge α (electroneutrality condition $\alpha[Cr_i^{\alpha\cdot}] = n$, k_p is related to the self-diffusion coefficient of chromium in Cr_2O_3 through the relation (2, 27)

$$k_p(\text{cm}^2/\text{sec}) = 2(\alpha+1)D_{Cr}{}^{\circ}\{(p_{O_2}{}^*)^{-3/4(\alpha+1)} - p_{O_2}{}^{a})^{-3/4(\alpha+1)}\} \quad [13]$$

where $p_{O_2}{}^*$ is the decomposition pressure of Cr_2O_3 in equilibrium with Cr and $p_{O_2}{}^a$ is the partial pressure of oxygen at the outer border of the oxide layer under consideration. When $p_{O_2}{}^* << p_{O_2}{}^a$, Eq. [13] reduces to

$$k_p = 2(\alpha+1)D_{Cr}{}^{\circ}(p_{O_2}{}^*)^{-3/4(\alpha+1)} = 2(\alpha+1)D_{Cr}{}^* \quad [14]$$

The self-diffusion coefficient of chromium at constant partial pressure of oxygen is given by $D_{Cr} = D_{Cr}{}^{\circ}p_{O_2}{}^{-3/4(\alpha+1)}$ and $D_{Cr}{}^*$ is the value of D_{Cr} at the Cr_2O_3/Cr phase boundary. As seen, k_p is determined by $D_{Cr}{}^*$.

Values of k_p [expressed in (weight gain of O)²/cm⁴ sec] have been calculated for $\alpha = 3$ and assuming that the diffusion data for the hot-pressed specimens are equal to $D_{Cr}{}^*$. As the details of the diffusion mechanism are not known, the correlation coefficient is neglected. The values are plotted in Fig. 8 and are compared with the experimental values of Hagel (28), Cadiou and Paidassi (29), and of this work (1). The calculated and experimental values are of the same order of magnitude. The calculated values are somewhat higher than those of Hagel and of Cadiou and Paidassi, but lower than the results of this study. In this connection it should be noted that the k_p's of this study have been evaluated from the initial oxidation, while those of the other studies after extended reaction. With regard to the calculated values of k_p it should be recalled that the values of $D_{Cr}{}^*$ involve considerable experimental error (12) and that k_p will be lower for lower values of α.

The approximate agreement between calculated and measured k_p's and that $D_{Cr}{}^*$ and essentially all measured k_p's have the same activation energies is consistent with the conclusion that lattice diffusion in general constitutes an important mode of transport in growth of Cr_2O_3 scales. Growth of Cr_2O_3 by interstitial chromium diffusion should also be independent of the ambient oxygen pressure.

A note should be added regarding the extremely low values of k_p estimated from metallographic cross sections by Caplan and Sproule (30). These values are lower than those of Hagel by almost two orders of magnitude. The values are estimated from small, local areas with special orientations where the oxide layer is proposed to be monocrystalline. The values are not corrected for oxide evaporation. From similar studies by other investigators this correction would be expected to be much larger than the oxidation involved in forming the thin monocrystalline layers. If the monocrystalline layers do reflect the total oxidation in these local areas, one may speculate if diffusion in Cr_2O_3 single crystals is highly dependent on crystal orientation.

Diffusion and oxide growth along grain boundaries.—In addition to volume diffusion, a number of other factors affect or significantly influence the oxidation behavior. An important factor is the development of compressive stresses in the growing Cr_2O_3 scales. This feature has earlier been emphasized by Caplan *et al.* (30-34). This behavior shows that oxide formation also

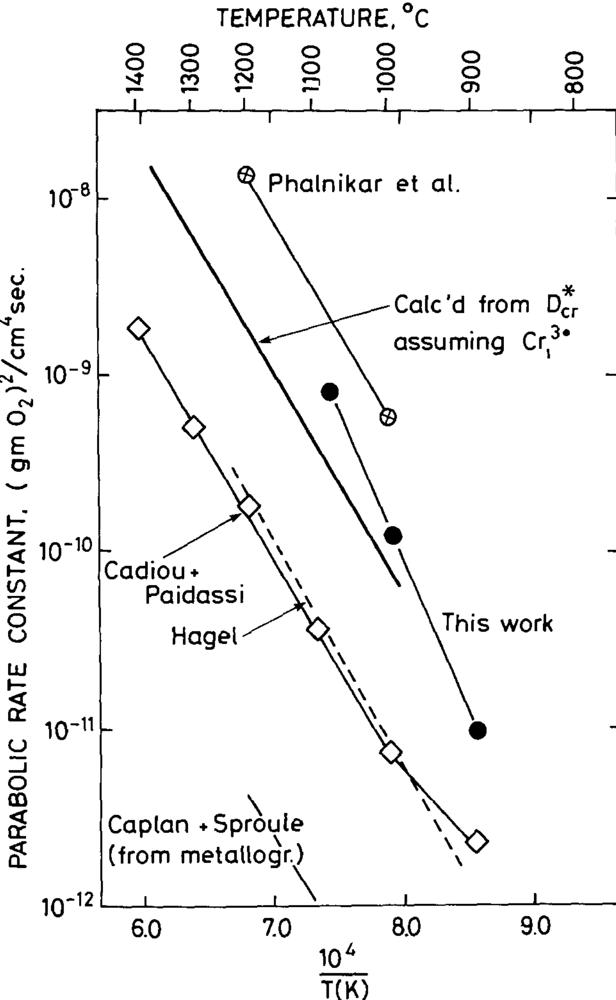

Fig. 8. Values of the parabolic rate constant for oxidation of chromium calculated from the self-diffusion coefficient of chromium compared with experimental values of Hagel (28), Cadiou and Paidassi (29), and of this work (1).

takes place within the scales. In addition to the increase in oxide thicknesses during oxidation, the oxide also grows along the metal surface. This in turn strongly suggests that the oxide scales grow by countercurrent chromium and oxygen diffusion. This may take place through volume diffusion processes in the oxide scale. But the important effect is concluded to be countercurrent grain boundary diffusion of both chromium and oxygen and the consequent oxide formation along grain boundaries. This would account for the development of large compressive stresses in the growing scales and also the very fine-grained oxide structure and the imperfect crystals observed in parts of the scales.

Due to the changing orientations and the disarray of atoms along grain boundaries, small and imperfect oxide crystallites are probably formed along grain boundaries. If sintering of these small oxide crystallites is slow, small amounts of porosity probably exist at such areas with newly formed oxide. These regions may as far as transport is concerned possibly be considered as microcracks or "channels." The rapid loss of chromium during high vacuum treatment after oxidation at $7 \cdot 10^{-2}$ Pa O_2, where the oxide is particularly fine grained, is proposed to reflect such a situation.

The relative importance of transport of chromium and oxygen along grain boundaries and microcracks is difficult to assess. It is believed, however, that such oxygen transport is most important at atmospheric oxygen pressure; this would account for the fact that the oxide crystals in an outer layer have relatively large, well-developed crystals, while the oxide crystals at the inner surface are small and imperfect under these conditions. But as the ambient oxygen pressure is lowered, the relative importance of oxygen grain boundary tranport is also reduced. As a first approximation, it may be postulated that the oxygen grain boundary transport is proportional to $p_{O_2}{}^{1/2}$ or p_{O_2} if the oxygen diffuses as atoms or molecules, respectively. At the very lowest oxygen pressure used in this study chromium diffusion along grain boundaries and microcracks is believed to predominate (see also further discussion below).

Formation of cavities and gap between the metal and the scale.—In addition to the development of compressive stresses, pores and cavities are formed, and these finally grow to form a gap between the metal and the scale. It is concluded that this is a result of the outward diffusion of chromium both along grain boundaries and by volume diffusion in the inner region of the scale. In all previously published discussions of chromium oxidation, this is assumed to reflect vacancy condensation. However, such cavity formation may also in general result from outward interstitial metal diffusion. Under conditions where the oxide is easily deformed (at the lower oxygen pressures), the gap may be dramatically increased after extended oxidation.

Scale deformation.—Another important factor, particularly as regards the oxygen pressure dependence of the oxidation behavior, is the ability of the oxide to deform. This is believed to take place by creep processes induced by the growth stresses in the scale. The rate-limiting factor in creep is the diffusion of the minority defects, *i.e.*, oxygen vacancies. Following the proposed defect structure model for Cr_2O_3, the creep rate is concluded to increase with decreasing partial pressure of oxygen, the increase being particularly large at the lower oxygen pressures.

For a continuous oxide scale the partial pressure of oxygen decreases from that of the ambient gas pressure at oxide/gas interface to the decomposition pressure of the oxide at the metal/oxide interface. Accordingly the creep properties of the scale vary significantly through the scale. For Cr_2O_3 scales the ability to deform will be smallest at the oxide/gas interface.

Cr_2O_3 scales formed at 1 atm O_2 show little or no tendency to deform. This is concluded to reflect that the creep in an outer region of the scale (the region with intrinsic electrons predominant) is small. In this region the ability to deform is small, and the oxide cracks abruptly giving kinetics with abrupt increases in oxidation rates. The resulting porosity of the scale is found in the outer layer of the scale. The scale easily spalls off by cooling to room temperature.

As the oxygen pressure is reduced to about 100 Pa O_2, the ability of the scale to deform increases. The oxide buckles and, as viewed from the surface, has wavy appearance. But the oxide cannot deform sufficiently rapidly in an outer layer; the oxide continuously cracks and heals in a large number of sites statistically distributed over the scale. During this cracking process oxygen penetrates the scale, and the metal beneath the scale becomes oxidized. The reaction is accordingly approximately linear, and the overall oxidation is faster than at 1 atm O_2. After extended oxidation, and as new oxide is formed in the metal, the surface oxide may essentially build up to form two or more layers. The oxidation rate may as a result of this slow down with time after extended oxidation.

With further decrease in oxygen pressure, the deformation of the scale increases. At the low oxygen pressure of $7 \cdot 10^{-2}$ Pa O_2 the deformation of the oxide is sufficiently high that no cracking occurs. Rather the oxide balloons away from the oxide surface. The stresses in the scale are sufficiently alleviated that there is no oxide spallation during cooling to room temperature.

As high vacuum is pumped on such oxidizing specimens, the ballooning continues further. Under these conditions the supply of oxygen at the surface becomes very small, and as chromium metal vapor is continuously supplied, the partial pressure throughout the entire scale becomes equal to that for Cr_2O_3 in equilibrium with chromium metal. Under these conditions the ability of the scale to deform is concluded to be at its maximum.

Temperature dependence of the oxidation at different oxygen pressures.—As discussed above, most studies of oxidation of chromium at atmospheric pressure yield parabolic rate constants with an activation energy of about 255 kJ/mole. In this work, the oxidation rates are higher than in most other studies and the activation energy determined from the k_p's at three temperatures amounts to 315 kJ/mole (1). The reason for this difference is not clear. But it appears to be related to a higher amount of easy diffusion paths and microcracks in the Cr_2O_3 scales when specimens are pretreated through thermal etching. The presence of such paths or cracks in the scales is clearly indicated by the results of the high vacuum treatments after oxidation.

Figure 9 shows the temperature dependence of the oxidation at 130 Pa O_2. The kinetics are different from that at 10^5 Pa O_2 (1). The amount of oxidation at 1000° and 1075°C is also larger at this pressure than at atmospheric pressure.

The results at $7 \cdot 10^{-2}$ Pa O_2 are presented in Fig. 10. In going from 1000° to 1075°C one observes an unexpected crossover in the weight gain curves, and after more than about 30 hr of oxidation the net weight gain at 1000°C becomes larger than at 1075°C. A possible explanation is that at such a low ambient oxygen pressure there is not sufficient oxygen absorbed on the Cr_2O_3 surface to react with all the chromium that is transported outwards through easy diffusion paths and microcracks, and that part of the chromium is lost as vapor. If this is the case the "oxidation" is higher than that indicated by the net weight gain. Furthermore, the loss of chromium will be higher at 1075° than at 1000°C as judged from the weight losses observed in high vacuum after evaporation. If approximate (but too high) corrections are made by adding the rates of weight loss observed in high vacuum after oxidation, a more "regular" increase in oxidation from 1000° to 1075°C is found. However, such an interpretation should be confirmed by other direct measurements, *e.g.*, mass spectrometric studies on oxidizing specimens.

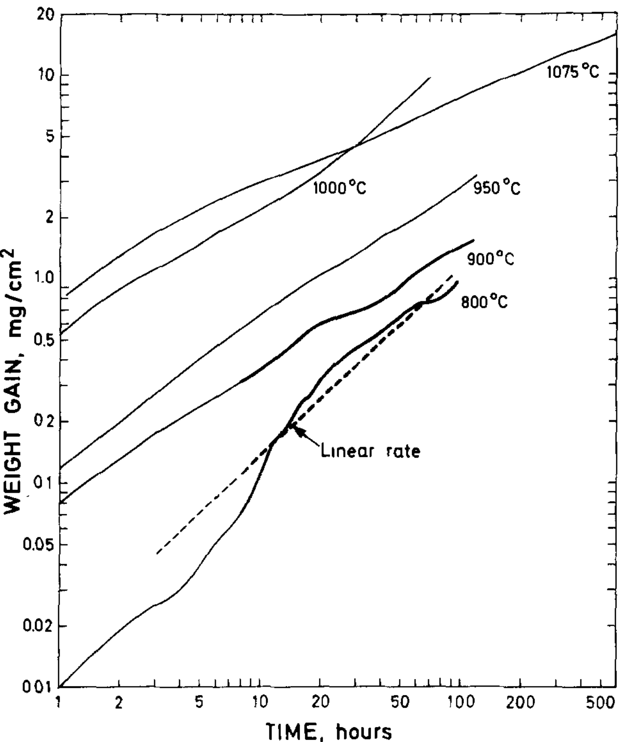

Fig. 10. Oxidation of chromium at $7 \cdot 10^{-2}$ Pa O_2 at temperatures from 800° to 1075°C.

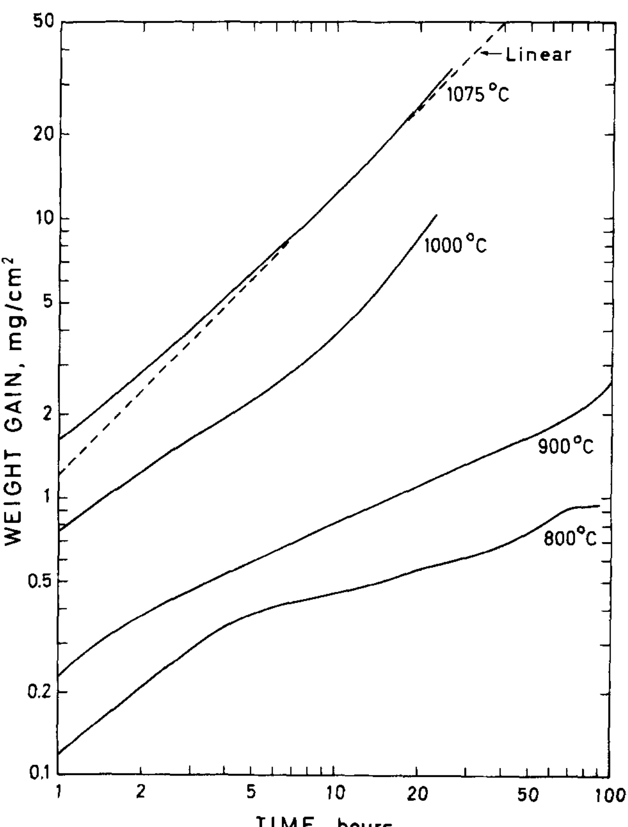

Fig. 9. Oxidation of chromium at 130 Pa O_2 at temperatures from 800° to 1075°C.

Oxidation at 800°C. Chromium transport across the gap between the scale and the metal substrate.—These aspects have been discussed in Part I (1). By way of summary it is concluded that the logarithmic type behavior observed at 800°C and 10^5 Pa O_2 involves rapid transport along easy diffusion paths during initial oxidation, but that these are gradually eliminated through grain growth as the oxidation proceeds. It is difficult to explain the observed results at lower oxygen pressures at 800°C without assuming an enhanced oxidative evaporation of chromium across the gap between the scale and the metal substrate (1).

Akcnowledgment

Part of this study has been carried out under a project supported by the Royal Norwegian Council for Scientific and Technical Research.

Manuscript submitted Dec. 26, 1980; revised manuscript received July 8, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Electrochemical Methods for Measuring Diffusivities of Hydrogen in Palladium and Palladium Alloys

Reiner Kirchheim[1] **and Rex B. McLellan**

Department of Mechanical Engineering and Materials Science, William Marsh Rice University, Houston, Texas 77001

ABSTRACT

A palladium bielectrode has been used in a viscous electrolyte consisting of glycerin and phosphoric acid. The transport of molecular hydrogen from and to the electrode is remarkably diminished in this electrolyte in comparison with aqueous electrolytes. Therefore, changes of the electrode potential are unambiguously related to concentration changes caused by diffusion within the electrode. A single current pulse and a potentiostatic technique were applied to determine the diffusion coefficients of H in Pd over a wide range of concentration and at different temperatures. New evaluation methods for current-time and potential-time curves also yield values of the initial concentration, which are in excellent agreement with the values calculated from previous coulometric titrations. A special arrangement of two bielectrodes also allows the measurement of small differences in the diffusivities of hydrogen in the two electrodes. Results for hydrogen diffusion in pure palladium are in excellent agreement with Gorsky effect measurements.

Because of the importance of hydrogen metal systems, a large variety of experimental methods are available to determine their thermodynamic and transport properties. The activity of dissolved hydrogen in metals is usually obtained from a direct measurement of the equilibrium pressure (1). The diffusivity of hydrogen has been measured by permeation, electrochemical, and anelastic measurements (2). Among these, the Gorsky effect, where the transport of hydrogen is caused by an elastic strain field, is an especially reliable method at room temperature because it is independent of surface properties.

Electrochemical methods are mostly used for the Pd-H system since the noble metal palladium is less vulnerable to surface contaminations and, although different surface preparation techniques are used (3-5) the results agree rather well with data from Gorsky-effect measurements (6). Electrochemical studies done before 1965 yield substantially lower diffusivities (2), which may be due to a less careful sample preparation (annealing, purity, and surface cleaning) or to making measurements at lower concentrations where an exchange of molecular hydrogen between electrode and electrolyte changes the boundary conditions of the diffusion experiment (1). The magnitude and the direction of this flux of molecular hydrogen in the electrolyte depends on the hydrogen activity and mobility in the electrolyte. This process is similar to an absorption or desorption of hydrogen for palladium exposed to a gas phase containing molecular hydrogen. Especially at low hydrogen contents in the electrode, the flux causes higher relative changes of the hydrogen concentration and reliable results are only expected for diffusion fluxes in the sample which are large in comparison with the flux of molecular hydrogen in the electrolyte. Another drawback of electrochemical studies is the limited

[1] Permanent address: Max-Planck-Institut fur Metallforschung, Institut fur Werkstoffwissenschaften, Stuttgart, Germany.

Key words: electrolyte, palladium, electrode.

temperature range over which they may be carried out.

In the present study, a viscous electrolyte was used in order to decrease the mobility of molecular hydrogen in the electrolyte. The reliability of this electrolyte was checked by the coulometric titration of hydrogen into high purity palladium and subsequent emf measurements. A single current pulse and a potentiostatic technique were applied to measure hydrogen diffusivities in palladium. Special evaluation procedures also enabled the determination of the initial hydrogen concentration before the diffusivity measurement and its comparison with the value obtained from coulometric titration.

Recently, a difference method has been developed to measure directly the difference in oxygen diffusivities between a pure metal and an alloy (7). A similar experimental setup and evaluation procedure for hydrogen diffusion is described in this study. The method is especially appropriate for measuring directly the influence of a metallurgical treatment (plastic deformation, alloying, etc.) on hydrogen activity and diffusivity. An example of this technique is presented showing the change of the diffusion coefficient effected by small concentrations of niobium in the palladium.

Experimental Procedure

Electrode.—The electrodes were prepared from high purity palladium of different stock (one was MARZ grade Pd from MRC and one was 5*N* Pd from Alfa Company). After rolling down to a final thickness of about 0.25 mm, the samples were annealed under high vacuum conditions for 30 min at 500°C. In some cases the surface was etched with nitric acid or covered with palladium black (3). However, no essential difference has been found in comparison with vacuum annealed surfaces. The area exposed to the electrolyte was 1 cm^2.

Electrolyte.—A highly viscous electrolyte was prepared by mixing two volume parts of glycerin with one volume part of phosphoric acid (85%). This electrolyte is hygroscopic and has, therefore, to be renewed after several measurements.

Cell.—Two bielectrodes (1) were mounted in a Plexiglas container, consisting of four electrolytic compartments as shown schematically in Fig. 1. The potentials at both sides of the samples (s_o, s_1) were measured against saturated calomel electrodes via Haber-Luggin capillaries (R_1, r_1, R_o, r_o). Auxiliary electrodes (a_1, a_o, A_1, A_o) were made with platinum wires. Although the cell is symmetric, only the compartments d_1 and d_o were used for carrying a hydrogen current to or from the one side of the working electrodes (w_o, w_1) which were connected to potentiostats or constant current sources in order to dope or deplete the samples with hydrogen. Open-circuit potential measurements were made in the compartments m_1 and m_o using the reference electrodes R_1 and R_o. The auxiliary electrodes were used from time to time in order to check the symmetry of the arrangement, *i.e.*, to show if a surface contamination was present at the other side of the bielectrode. Temperature was measured with precise thermometers in the electrolyte and was kept constant by immersing the whole cell in a temperature bath. Independent measurements with the samples s_o and s_1, as well as difference measurements, can be made using the double cell depicted in Fig. 1.

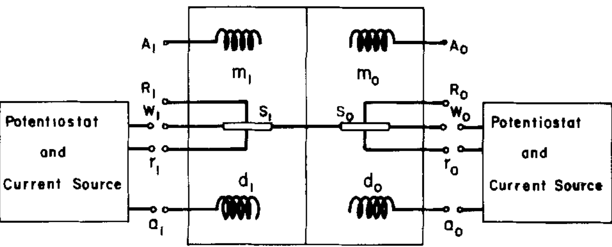

Fig. 1. Schematic outlay of apparatus

Voltage and current supply, meters.—The potentiostat and constant current source were combined in the "Electroscan 30" (Beckman Instruments, Incorporated), which could be run in a potentiostatic and galvanostatic mode. Digital voltmeters with infinite input impedance (potentiostatic technique) were used to measure voltages between W and R. Their analog output was connected to a chart recorder.

Evaluation

For an infinitely dilute solution of hydrogen in palladium, the relation between the hydrogen concentration c and the emf E is given by the following well-known equation

$$E = E_o + \frac{RT}{\mathbf{F}} \ln c \qquad [1]$$

where E_o is constant with respect to c and c is the concentration of hydrogen in the electrode at the electrolyte/electrode interface. Changes of c caused by diffusion are described by Fick's Second law

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \qquad [2]$$

Concomitant with different initial and boundary conditions, various solutions of Eq. [2] are known (8) and may be inserted into Eq. [1] to calculate the expected emf changes. Sometimes overpotentials restrict the validity of Eq. [1] and it becomes more convenient to measure the current, which is related to the concentration gradient at the electrode/electrolyte interface using the following relation

$$i = \mathbf{F} D \frac{\partial c}{\partial x} \qquad [3]$$

We are looking for solutions of Eq. [2] for two different sets of boundary and initial conditions which are fulfilled during a single current pulse or a potentiostatic procedure. The two boundaries of the bielectrode, of thickness s, are denoted by $x = o$ and $x = s$ describing the surfaces of the electrode facing the doping and measuring compartments of the cell respectively (see Fig. 1).

Single Current Pulse Technique

A single current pulse of height i_o and duration t_o is sent through the doping compartment of the cell. After switching off the current the following boundary conditions are fulfilled

$$\frac{\partial c}{\partial x} = 0 \quad \text{for} \quad x = o \quad \text{and} \quad x = s \quad \text{and} \quad t \geq t_o$$

With a homogeneous concentration distribution in the beginning, $c(x, o) = c_o$, and a sufficiently short pulse duration, Züchner (3) has obtained a solution of Eq. [2]. He defined a time t_d, which describes a time lag for the onset of emf changes (between w and R in Fig. 1) and which is caused by the diffusion of hydrogen through the bielectrode. This evaluation procedure was used in this study, together with a new one, which described the emf changes using a semi-infinite solution of Eq. [2]. Similar to Züchner, the hydrogen concentration distribution at $t = o$ to $t = t_o$ which is caused by the current pulse, will be described by a Dirac-Delta function

$$c(x) = Q\delta(x)$$

where Q is the amount of hydrogen doped by the current pulse

$$Q = \frac{i_o t_o}{\mathbf{F}}$$

The solutions of Fick's Second law for semi-infinite samples (planar source solution) is known (8)

$$c(x,t) = c_o + \frac{Q}{(\pi Dt)^{1/2}} \exp\left(-\frac{x^2}{4Dt}\right) \quad [4]$$

This function is shown in Fig. 2 as the solid line. According to Seith (9), the solution for a finite sample of thickness s is obtained by reflecting the concentration profile at $x = s$ (dashed curve 1' in Fig. 2) and superposing it on the original profile (line 1 + 1' in Fig. 2). Thus the concentration at $x = s$ can be written

$$c(s,t) = c_o + \frac{2Q}{(\pi Dt)^{1/2}} \exp\left(-\frac{s^2}{4Dt}\right)$$

which is valid for $t < s^2/\pi^2 D$ (dashed line 1' does not reach the other boundary $x = o$). Corresponding emf changes are given by Eq. [1] in the form

$$\Delta E = \frac{RT}{\mathbf{F}} \ln\left[1 + \frac{2i_o t_o}{Fc_o(\pi Dt)^{1/2}} \exp\left(-\frac{s^2}{4Dt}\right)\right]$$

For small emf changes (less than 3 mV), the second term in the argument of the logarithm is small in comparison with [1], and we have

$$\Delta E = \frac{2RTi_o t_o}{\mathbf{F}^2 c_o (\pi Dt)^{1/2}} \exp\left(-\frac{s^2}{4Dt}\right) \quad [5]$$

Straight lines are obtained by plotting $\ln(\Delta E t^{1/2})$ *vs.* reciprocal time, and these intersect the ordinate at $\ln(2RTi_o t_o/\mathbf{F}^2 c_o(\pi D)^{1/2})$ and have a slope of $-s^2/4D$. The diffusivity and the initial concentration can be evaluated from these quantities. Compared to the procedure used by Züchner, more information is obtained (initial concentration) and the diffusion coefficient is not only evaluated from one quantity (time lag) but from a set of data points. However, in order to utilize these advantages it is necessary to measure small emf changes and obviate emf drifts caused by absorption and desorption of molecular hydrogen.

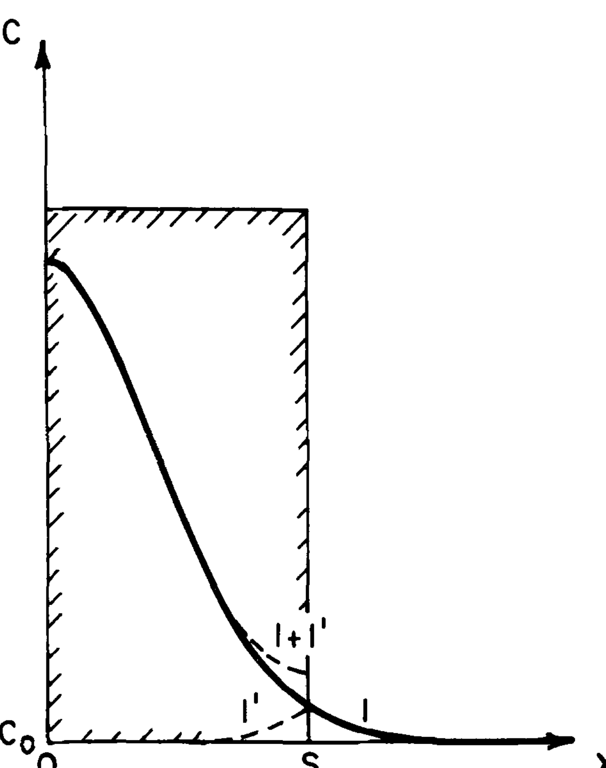

Fig. 2. Illustration of solution of Fick's Second law for samples of finite thickness.

Potentiostatic Technique

A constant potential is applied at the doping side of the bielectrode (wr in Fig. 1), which should be high enough to maintain a hydrogen concentration at $x = o$ close to zero. Or strictly speaking, $c(0, t)$ should always be very small compared with the mean hydrogen concentration in the sample. Assuming again a homogeneous concentration distribution before experiment, we have the following boundary conditions

$$c(x, 0) = c_o$$

$$c(0, t) = 0$$

$$\left(\frac{\partial c}{\partial x}\right)_{x=s} = 0$$

The corresponding solution of Eq. [2] is a series of exponential time functions with different time constants (8, 10). For $t > 4s^2/\pi^2 D$, all of them except the one with the highest constant can be neglected and we have

$$c(x,t) = \frac{4}{\pi} c_o \exp\left(-\frac{\pi^2 Dt}{4s^2}\right) \sin\frac{\pi x}{2s} \quad [6]$$

and the emf changes are $x = s$ are

$$\Delta E = \frac{RT}{\mathbf{F}} \ln\frac{4}{\pi} - \frac{RT\pi^2 Dt}{4\mathbf{F}s^2} \quad [7]$$

Plotting E directly with a strip chart recorder gives a straight line. The diffusion coefficient D is calculated from the slope of the straight line in accord with Eq. [7]. An obvious advantage of the potentiostatic technique is a lack of any intermediate evaluation and plotting procedure. Another advantage is the possibility of changing the temperature during the experiment. Thus values of D can be obtained from plots of the emf *vs.* time at a series of temperatures (10).

The emf changes described in Eq. [7] are caused by the current flowing from w to a in Fig. 1 and the corresponding depletion of the sample with respect to hydrogen. This current can be obtained from Eq. [3] and [6] in the form

$$i = \frac{2\mathbf{F}D}{s} c_o \exp\left(-\frac{\pi^2 Dt}{4s^2}\right) \quad [8]$$

Plotting ln i *vs.* t gives straight lines with the slope $-\pi^2 D/4s^2$. Diffusivities evaluated from this slope should agree with values obtained from the emf change at the other side of the bielectrode. The validity of Eq. [8] as well as Eq. [6] is restricted to $t > 4s^2/\pi^2 D$. For smaller times the sample can be treated as a semi-infinite sample (8) giving the following relations between current and time

$$i = \mathbf{F}c_o\left(\frac{D}{\pi t}\right)^{1/2} \quad [9]$$

which may be used to calculate either c_o or D, if one of these values is given from Eq. [8]. Thus the potentiostatic technique gives several values for D and c_o during one diffusion run and, therefore, enables systematic errors to be revealed, *i.e.*, those caused by surface contamination.

Difference Technique

For samples of the same thickness s and the same initial concentration c_o, but slightly different diffusivities D_1 and D_2, a direct measurement of the difference $\Delta D = D_1 - D_2$ is achieved by applying potentiostatic conditions to both electrodes at the same time (7). The emf changes w_1R_1 and w_oR_o in the

measuring compartments of the double cell (Fig. 1) are given by Eq. [7] again, where the voltage difference from R_0 to R_1 is described by

$$\Delta(\Delta E) = \frac{RT\pi^2 \Delta Dt}{4Fs^2} \quad [10]$$

There might be also a constant contribution resulting from slightly different potentials of the saturated calomel electrodes or diffusion potentials in salt bridges. If floating potentiostats are not used, w_0 and w_1 are both grounded.

Results

The high viscosity of the electrolyte used diminishes the influence of a flux of molecular hydrogen into or from the electrolyte, as the mobility of molecular hydrogen decreases with increasing viscosity according to the Stokes-Einstein relation. Stable emf values were obtained especially for hydrogen concentrations in the samples of less than 100 at ppm. In dilute sulfuric acid (1*N*) an emf drift towards positive values was observed, and usually a doped sample was totally depleted of hydrogen after some hours, depending on the initial concentration. The depletion is due to a flux of hydrogen atoms dissolved in palladium toward the surface subsequent to the formation of H_2 molecules and a flux of these molecules into the electrolyte. The last step is sensitive to the viscosity of the electrolyte. Doping of the samples with hydrogen was achieved by coulometric titration. For the viscous electrolyte, the emf of a pure palladium electrode measured against the SCE is shown in Fig. 3 for various concentrations at $T = 295°K$. As can be seen, Nernst's law, (Eq. [1]), is obeyed over a wide concentration range because the slope of the straight line in Fig. 3 has the theoretical slope RT/F. Deviations of the data points from the straight line behavior are expected at lower and higher concentrations and will be explained in the next section. It is a special feature of the viscous electrolyte and, therefore, of this study that the relationship between emf and hydrogen concentration in Pd is shown to obey Nernst's law. Because the electrolyte is hygroscopic it loses its viscosity and changes its pH and the values shown in Fig. 3 cannot be reproduced after a prolonged use of the same electrolyte.

Diffusivity measurements were made by using the current pulse and the potentiostatic technique as described above. For a single current pulse, a typical plot of $\ln \Delta Et^{1/2}$ *vs.* t^{-1} is shown in Fig. 4. According to Eq. [5], the data points can be represented by a straight line. Diffusion coefficients calculated from the slope of this line agreed excellently with values

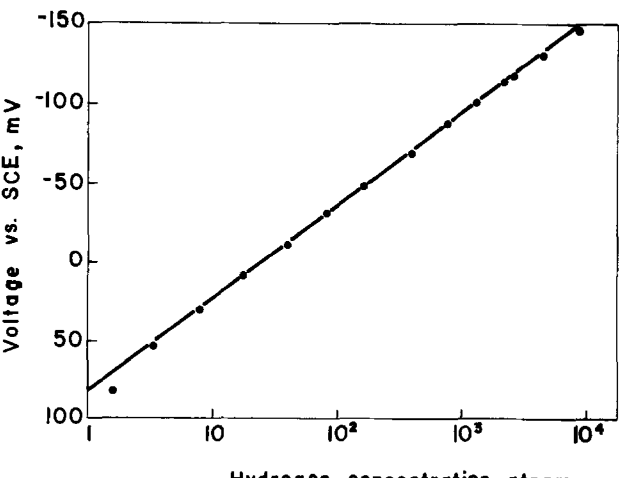

Fig. 3. EMF of pure Pd electrode at 295°K measured against SCE plotted against hydrogen concentration in the sample.

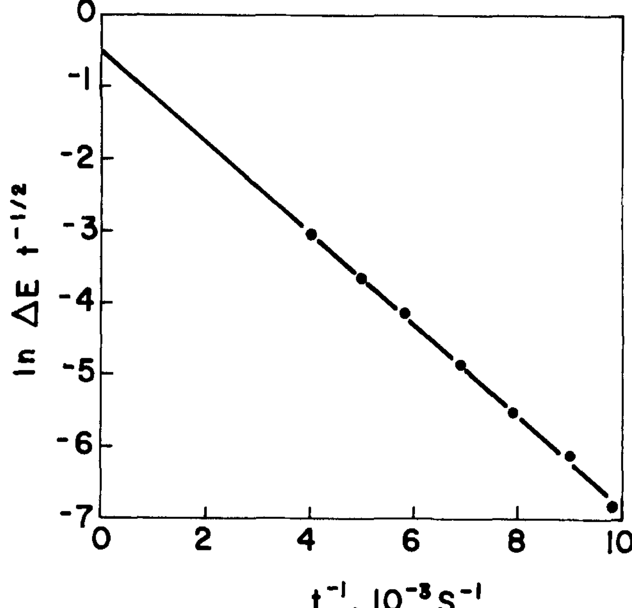

Fig. 4. Plot of ln $\Delta E\, t^{1/2}$ *vs.* reciprocal time

obtained by the time lag method (3). The initial concentrations evaluated from the ordinate intercept usually differ less than 10% from the values of the previous coulometric titration.

The current pulse technique is not very sensitive to the interaction with molecular hydrogen, if the change of hydrogen concentration is high enough and the time lag is short. Thus sulfuric acid may also be used as an electrolyte, although the mutual agreement obtained between the differently-evaluated results is not as good.

The use of a viscous electrolyte is however essential to the potentiostatic technique. Sulfuric acid never gave reliable results. Figure 5 shows that for the viscous electrolyte, a straight line is obtained for the emf *vs.* time curve as predicted by Eq. [7]. The D value from the slope is in agreement with the value from a current pulse experiment. Deviations were usually smaller than 5%. The chart recorder plot as depicted in Fig. 5 was made at 295°K and Eq. [7] gives a value of 6.2 mV for the difference between the extrapolated straight line and the actual emf at $t = 0$, which is in good agreement with the experimental value of 5.5 mV. This agreement was often even better. During the same diffusion run, the current delivered by the potentiostat was recorded. Figure 6 shows the logarithm of this current plotted *vs.* time. Deviations from the straight line (*cf.* Eq. [8]) at smaller times originate due to the neglect of exponential terms with smaller time constants in the exact solution. For small times, Eq. [9] is an appropriate description of the current, which decreases with the reciprocal square root of time, as can be seen in Fig. 7. Using D values calculated from the slopes of the straight lines in Fig. 5 and 6, the initial concentration c_0 is obtained either from the slope in Fig. 7 or from the current i_0, at which, in Fig. 6, the extrapolated straight line intersects the ordinate. A comparison of different D and c_0 values for one experimental run is given in Table I. The agreement of the c_0 values shows that the current yield was 100% for the coulometric titration ($i < 100$ mA/cm²).

A surface contamination of the electrodes was observed after the samples were exposed for more than two days to the electrolyte. Nonlinearities were seen in plots like those of Fig. 4-6 and the overpotential during a coulometric titration was increased remarkably. These effects vanished after cleaning the samples with xylol and carbon tetrachloride. The voltage applied to wr (Fig. 1) for a potentiostatic measurement

* Equation used for evaluation.

was 0.5V. At lower voltages, the results were more dependent on surface contaminations and at higher values of dissolution of the Pd-electrode was observed, increasing the current and changing the color of the electrolyte.

In order to study the influence of foreign solute atoms on the diffusivity of hydrogen in palladium, the methods described have been used for palladium alloys (11). The precision of these methods is high enough to reveal changes of the diffusivity of more than 20%. For smaller differences between pure and alloyed palladium, the difference technique should be used. An example is shown in Fig. 8, where pure palladium was used as the working electrode w_0 and Pd-0.1 at %Nb as w_1. Both samples had the same thickness and about the same initial concentration. From the recorder trace of R_0w_0, the diffusivity of H in pure Pd is obtained, while the simultaneously recorded voltage R_1R_0 gives the diffusivity difference. The diffusivity of hydrogen is decreased by the niobium atoms concomitant to the voltage R_1R_0 increasing with time. The ratio of the slopes in Fig. 8 is $2.5 \cdot 10^{-2}$ which is equal to the relative decrease of the diffusivity (*cf.* Eq. [7] and [10]).

The diffusion coefficient of hydrogen in high purity palladium was measured at different temperatures using the current pulse and the potentiostatic techniques. The results are compiled in Table II, where the D values are mean values of 2-5 measurements. Table III contains D values measured with the current pulse technique at different initial concentrations.

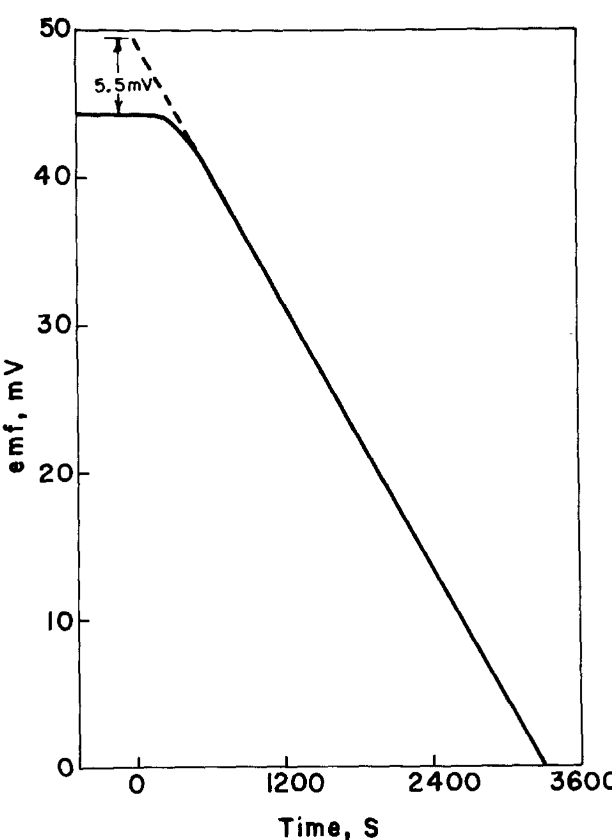

Fig. 5. Plot of EMF *vs.* time in seconds. The viscous electrolyte was used and $T = 295$°K. The diagram was drawn directly from a chart recorder trace.

Table II. Measured diffusivities of hydrogen in palladium

T (°K)	D (10^{-7} cm²/sec)	T (°K)	D (10^{-7} cm²/sec)
334	9.4	298	3.8
322.5	7.3	296.5	3.55
321.5	7.1	295.5	3.4
317	6.05	294.5	3.3
310	5.25	293	3.1
308	4.9	287.5	2.7
305.5	4.6	281	2.15
302	4.15	273	1.6

Table III. Diffusivity values measured at differing initial concentrations. The temperature was 295°K

C_0 (at ppm)	0.5	4	8	20	100	500	1000
D (10^{-7} cm²/sec)	2.2	3.2	3.2	3.1	3.1	3.05	3.1

Deviations from the straight line in Fig. 3 at lower and higher concentrations are explained by attractive interaction of hydrogen atoms with lattice defects (grain boundaries and dislocations), or with other hydrogen atoms. In both cases hydrogen activity is lowered compared with the ideal dilute behavior. Their influence on hydrogen mobility, however, could not be detected (*cf.* Table III).

Discussion and Conclusions

The results in Table II are shown in Fig. 9 in an Arrhenius plot, where the solid line is the best representation of different measurements proposed by Völkl and Alefeld (2). The frequency factor is $D_0 = 2.90 \cdot 10^{-3}$ cm²/sec and the activation energy is $Q = 22.2$ kJ/mole. Because of the excellent agreement with the data of the present study, no effort was

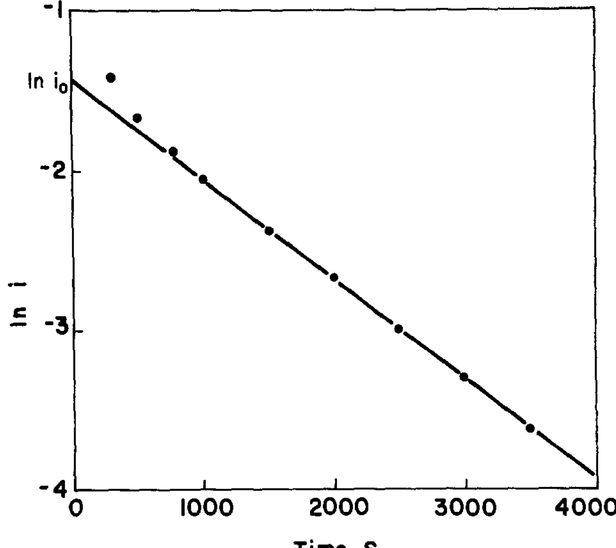

Fig. 6. Plot of ln *i* *vs.* time in seconds

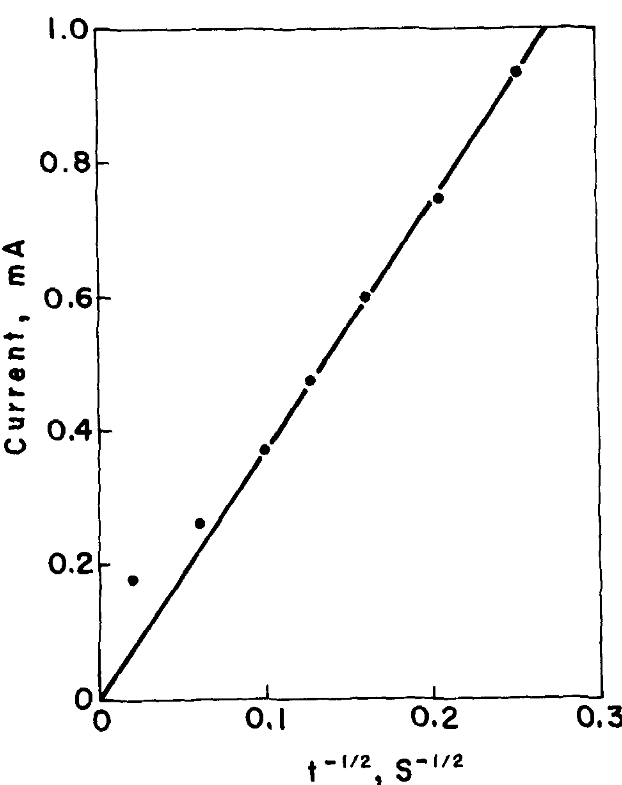

Fig. 7. Plot of current (mA) vs. $t^{1/2}$ in $sec^{-1/2}$

made to fit the current values to an Arrhenius equation. The current measurements, when extrapolated

to high temperatures, are in excellent agreement with permeability measurements of the diffusivity of H in palladium (14).

It has not been the aim of this study to add another set of diffusivity data to the already existing huge volume in the literature, but rather to demonstrate that electrochemical methods are precise and reliable. The improvement of electrochemical data becomes obvious in Fig. 9, where some results at room temperature are shown in filled squares. The scatter of these data may be explained by the interaction of molecular hydrogen between electrode and electrolyte, which, depending on the boundary conditions of the diffusion experiment, leads to more or less large systematic errors.

With the introduction of a new viscous electrolyte, this source of systematic errors was obviated in this study and it has been shown that reliable diffusivity measurements can be made over a wide concentration range. At concentrations of only a few at ppm H, the current pulse technique is still applicable and in conjunction with the difference technique, it may be used to study the influence of lattice defects on hydrogen diffusion. In regard to the extensive measurements which have to be made to study diffusion of hydrogen in alloys of different composition (11) the electrochemical methods offer another advantage: simple experimental setup and quick measurement and evaluation procedures.

Thermodynamic Stabilization of the Solid Electrolyte $RbAg_4I_5$

Nilo Valverde[1]

Forschungsinstitut Berghof GmbH, D-74, Tübingen, Germany

ABSTRACT

Partial substitution (up to about 6 mole percent) of iodine in $RbAg_4I_5$ by S, Se, or Te leads to solid solutions with the crystal structure of $RbAg_4I_5$ and with ionic/electronic conductivities much the same as the unsubstituted compound. While $RbAg_4I_5$ is thermodynamically unstable and decomposes rapidly when kept at low temperatures, the substituted compounds $RbAg_{4+y}I_{5-y}S_y$, $RbAg_{4+y}I_{5-y}Se_y$, and $RbAg_{4+y}I_{5-y}Te_y$ show no tendency to such decomposition under the same conditions. The partial substitution of iodine by S, Se, or Te, however, does not prevent the resulting compounds from very rapid decomposition in the presence of moisture. The final decomposition products in air saturated with water vapor are not in accord with the decomposition mechanism proposed by Owens (5).

Solid phases of the general composition MAg_4I_5 (M = K, Rb, NH_4, etc.) show the highest ionic conductivity at room temperature among all known solid electrolytes (1-3). The exceptionally high ionic conductivity of these compounds can be explained by the singular constitution of the elementary cell. According to Geller (4) there are 56 available sites for the 16 Ag^+ ions per unit cell, therefore, there is a large number of unoccupied silver sites in the elementary cell. This arrangement makes possible a great mobility of the silver ions.

The compounds KAg_4I_5 and $RbAg_4I_5$ are, however, thermodynamically unstable below 36° and 27°C and decompose according to the equations (1, 5)

$$2KAg_4I_5 = K_2AgI_3 + 7AgI \quad [1]$$

and

$$2RbAg_4I_5 = Rb_2AgI_3 + 7AgI \quad [2]$$

respectively.

It has been found experimentally (1) that the above-mentioned decomposition takes place very slowly at moderately low temperatures, especially in absence of water vapor in the air (6). It has not yet been studied, however, what happens when the mentioned compounds are kept for long periods of time at very low temperatures in dry atmosphere. For practical purposes it is desirable to extend the range of existence of these solid phases to lower temperatures so that the galvanic cells with $RbAg_4I_5$ as solid electrolyte could be operative at temperatures much below 0°C during long periods of time (several years).

The purpose of this work is, therefore, to find a method for extending the range of existence of $RbAg_4I_5$ at temperatures well below the decomposition point (< + 27°C). Simultaneously the influence of water vapor on the decomposition of $RbAg_4I_5$ at temperatures below its existence range has been investigated.

Theoretical Considerations

It is a well known fact that the range of existence of a molten phase can be extended to lower temperatures, if new components are added which show very little tendency to form solid solutions with the first segregated solid phase. The same principle can be applied to extend the stability range of $RbAg_4I_5$ to lower temperatures.

A partial substitution of I in the compound $RbAg_4I_5$ by Br or the chalcogenides S, Se, or Te should lead accordingly to solid solutions of the general composition $RbAg_4(I, Br)_5$ or $RbAg_{4+y}(I_{5-y}X_y)$ with greater thermodynamic stability, where X denotes S, Se, or Te. The decomposition Eq. [2] would consequently take the form

$$2RbAg_4(I_{5-y}Br_y) = Rb_2Ag(I_{3-0.6y}Br_{0.6y}) + 7Ag(I_{1-0.2y}Br_{0.2y}) \quad [3a]$$

or, respectively

$$2RbAg_{4+y}(I_{5-y}X_y) = Rb_2Ag_{1+0.6y}(I_{3-0.6y}X_{0.6y}) + 7Ag_{1+0.2y}(I_{1-0.2y}X_{0.2y}) \quad [3b]$$

The magnitude of the elastic energy in the solid solutions $Rb_2Ag(I, Br)_3$ and $Ag(I, Br)$ or $Rb_2Ag_{1+y}(I, X)_3$ and $Ag_{1+y}(I, X)$ with higher order of lattice and more dense packing of the anions in the crystal is presumably greater than in solid solutions of the type $RbAg_4(I, Br)_5$ or $RbAg_{4+y}(I, X)_5$, which have more cation defects and probably not such dense packing of the ions. This is schematically represented in Fig. 1.

[1] Present address: Instituto de Química-Física "Rocasolano," Consejo Superior de Investigaciones Científicas, Serrano 119, E-Madrid 6, Spain.

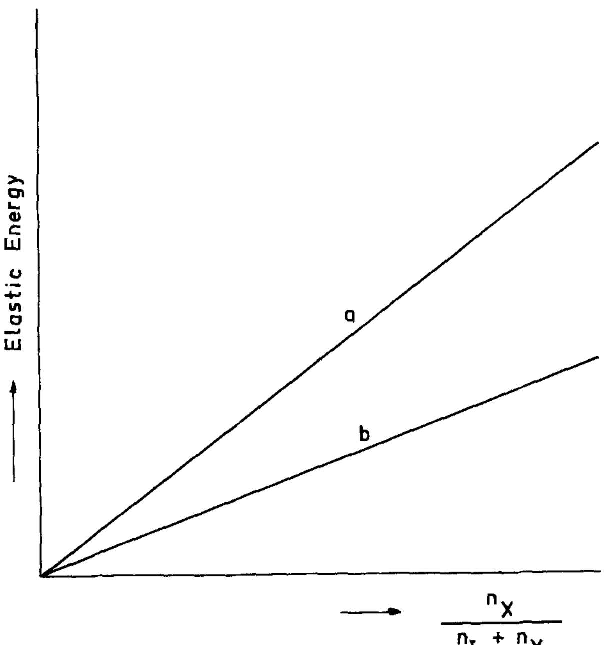

Fig. 1. Schematic representation of the variation of the elastic energy in solid solutions, with some of their ions partially substituted, as a function of the substitution mole fraction. Curve a, elastic energy for $Rb_2Ag_{1+y}(I, X)_3 + 7Ag_{1+y}(I, X)$; curve b, elastic energy for $2RbAg_{4+y}(I, X)_5$.

According to the above suppositions, the variation of the Gibbs energy of reactions [3a] and [3b] will be enhanced through the partial substitution of I by Br or X and consequently the range of existence of the phase with higher conductivity of the silver ions will be extended to the region of lower temperatures.

It is unlikely that iodine ions can be substituted in all proportions by Br, S, Se, or Te in the compound $RbAg_4I_5$, since phases of general composition $RbAg_4Br_5$ or $RbAg_4X_{2.5}$ do not exist. Moreover in the decomposition Eq. [3a] and [3b], the assumption has been made that the ratio Br/I or X/I in each of the resulting new phases is the same as in the primary compounds. This supposition is based on the very low exchange frequency of the anions at room temperature. The new resulting phases are probably in metastable equilibrium. It is expected that a redistribution of the ions with the time could take place gradually, and accordingly a decomposition of the new resulting products Ag(I, Br) or $Ag_{1+y}(I_{1-y}, X_y)$ into the secondary products AgI, AgBr, or Ag_2X, respectively, is likely to happen. The products resulting from the secondary reaction imply a diminution of the Gibbs energy and they are consequently thermodynamically more stable than the products resulting from the reaction [3a] or [3b]. It follows that the extension of the range of existence of the resulting phases $RbAg_4(I, Br)_5$ and $RbAg_{4+y}(I_{5-y}X_y)$ to lower temperatures is supposedly not quite so wide as it could be expected to be.

Preparation of Samples

The solid electrolyte $RbAg_4I_5$ and the corresponding solid solutions $RbAg_{4+y}(I_{5-y}S_y)$, $RbAg_{4+y}(I_{5-y}Se_y)$, and $RbAg_{4+y}(I_{5-y}Te_y)$ resulting from the partial substitution of I, respectively, by S, Se, or Te, were prepared according to the procedure described by Owens and Argue (3). The identification of the resulting products was carried out by means of x-ray diffraction.

Partial substitutions of I by S, Se, or Te (up to 6%) lead to solid solutions with the crystal structure of the compound $RbAg_4I_5$. When the substitution is beyond that amount, other compounds besides $RbAg_{4+y}(I_{5-y}X_y)$, such as AgI, Rb_2AgI_3, and Ag_2X, are originated. On the contrary, as long as the substituted compounds $RbAg_{4+y}(I_{5-y}X_y)$ with values of y between 0.05 and 0.3 were kept in inert dry atmosphere and protected from exposure to light, no evidence of decomposition was observed for periods of time longer than three years.

The Role of Water Moisture in the Decomposition of $RbAg_4I_5$ and Its Substituted Compounds

In order to study the influence of moisture on the decomposition of $RbAg_4I_5$ and its substituted compounds, samples of $RbAg_4I_5$ and of $RbAg_{4+y}(I_{5-y}X_y)$ were placed in a refrigerator at temperatures of 3° and −25°C, respectively. At appropriate time intervals the samples were removed from the refrigerator and analyzed with the help of x-ray diffraction. According to Eq. [2] the decomposition products Rb_2AgI_3 and AgI after a thorough decomposition of $RbAg_4I_5$ should be present in a ratio of about 28.4 weight percent (w/o) Rb_2AgI_3 to 71.6 w/o AgI.

In a first run of experiments samples of $RbAg_4I_5$ and of $RbAg_{4.1}(I_{4.9}S_{0.1})$ were investigated. After 15 days of exposure to the moist air of the refrigerator the decomposition was not completed (Table I).

In a second run of experiments, 7 samples of $RbAg_{4+y}I_{5-y}S_y$, with values of y between 0.1 and 0.7 were placed in a refrigerator at 3°C for 73 days. Similarly 7 samples of the same composition were placed in a refrigerator at −25°C for the same time. After that time the decomposition of the original compounds was completed. The results of the experiments conducted at 3°C confirmed the decomposition proposed in Eq. [2]. On the contrary, the mechanism of decomposition at −25°C seems to be somewhat different from that proposed in Eq. [2]. While the decomposition products β-AgI appear in much the same proportion in both series of experiments, corresponding approximately to the proportion of that compound in Eq. [2], no presence of Rb_2AgI_3 has been observed at all among the decomposition products. Instead, it appears as a new compound which has not been identified.

The two preceding experiments have been performed without considering the relative humidity of the air. In a third run of experiments the water vapor pressure in the air at one determined temperature was adequately fixed. Six samples of each of $RbAg_4I_5$ and $RbAg_{4.2}(I_{4.8}S_{0.2})$ were placed in a desiccator containing a saturated aqueous solution of NaCl on the bottom. The desiccator was closed and put in a refrigerator at 3°C. After periods of time one sample of each substance was taken out and analyzed with the help of x-ray diffraction. The results of these experiments have been summarized in Table II.

The presence of a nonidentifiable phase among the decomposition products at 3°C, with its diffraction lines identical to the unknown phase by the decomposition at −25°C in slightly wet air, excludes the possibility of a low temperature modification of Rb_2AgI_3.

Table I. Decomposition products (in weight percent) resulting after 15 days exposure of $RbAg_4I_5$ and $RbAg_{4.1}(I_{4.9}S_{0.1})$ to moist air at 3° and −25°C

Original compound	Exposure at 3°C				Exposure at −25°C			
	$RbAg_4I_5$	Rb_2AgI_3	β-AgI	γ-AgI	$RbAg_4I_5$	Rb_2AgI_3	β-AgI	γ-AgI
$RbAg_4I_5$	25	35	15	25	15	45	15	25
$RbAg_{4.1}(I_{4.9}S_{0.1})$	20	30	15	35	70	10	15	5

Table II. Decomposition products (in weight percent) of $RbAg_4I_5$ and $RbAg_{4.2}(I_{4.8}S_{0.2})$ in air containing well-defined water vapor pressure at 3°C

Time of exposure (days)	Experiments with $RbAg_4I_5$: $RbAg_4I_5$	Rb_2AgI_3	β-AgI	No identified phase	Experiments with $RbAg_{4.2}(I_{4.8}S_{0.2})$: $RbAg_4I_5$	Rb_2AgI_3	β-AgI	No identified phase
0	100	0	0	0	100	0	0	0
0.5	25	22	50	0-10	25	25	50	0
1	0	0	60-70	30	0	0	60	40
3	12	0	80	0-10	Above this time of exposure it was completely impossible to analyze the samples, since the intensities and position of the Debye-Scherrer lines were changing continuously during the determination.			
8	0	0	65-80	20-30				
15	0	0	80	20				
30	0	0	90	5-15				

The unknown phase is therefore most probably a hydrate of Rb_2AgI_3.

It seems that some of the primary decomposition products, especially the Rb_2AgI_3 hydrate, are not stable and a second decomposition reaction takes place simultaneously, the overall reaction being

$$2RbAg_4I_5 \xrightarrow{H_2O} 7AgI + Rb_2AgI_3 \xrightarrow{xH_2O} 10(Ag_{0.8}Rb_{0.2})\,I\cdot(H_2O)_x \quad [4]$$

Equation [4] is based on the fact that no lines of the Debye-Scherrer spectrum corresponding to RbI have been observed.

The Ionic Conductivity σ_i of $RbAg_4I_5$ and Its Substituted Compounds

The method used for the measurements of the electrical conductivity of the samples has been used previously by Miyatani (7), Rickert (8), and Valverde (9) and it has been called after Wagner the "*IR* drop method." With the help of the cell

$$\begin{array}{ccc} Ag(1) & /RbAg_4I_5/ & Ag(2) \\ | & & | \\ \text{Ag-grid } (1) & & \text{Ag-grid } (2) \end{array} \quad [I]$$

is measured the *IR*-drop = ΔE-drop (potential drop) between the silver-grids (*1*) and (*2*), originated by the passage of a direct current (d.c.) across the specimen placed between the two silver-disk electrodes (*1*) and (*2*). The samples were pressed cylindrical pellets of 8 mm diam and about 15 mm length.

Considering that the electronic conductivity of $RbAg_4I_5$ and its substituted compounds is almost negligible (see next section), the measured conductivity σ coincides practically with the ionic conductivity σ_i of the compounds. Two series of measurements have been performed. First of all the variation of the ionic conductivity σ_i as a function of temperature for $RbAg_4I_5$ as well as the substituted compounds was investigated. In the second series of experiments the variation of the ionic conductivity with the composition y of the sample has been studied. The temperature for the first series of experiments could be gradually regulated from about 150°C to −50°C. The measurements have always been performed first with decreasing temperature and afterward with increasing temperature. Some of the results of these measurements have been represented in the Fig. 2-4.

The conductivity-temperature plots for all tested $RbAg_4I_5$ samples always show an inflection point between about 15° and 27°C. Moreover the two curves obtained with decreasing and increasing temperature do not fall together (see Fig. 2). It seems that below the inflection point an irreversible decomposition process sets in. After one complete round the final conductivity of the sample (curve b) is much lower than the initial one (curve a) which may be attributed to the fact that low temperatures notably accelerate the decomposition of the compound $RbAg_4I_5$ even in absence of moist air.

An inflection point can likewise be observed in the electrical conductivity-temperature plots of the first series members of the substituted compounds $RbAg_{4+y}I_{5-y}S_y$ and $RbAg_{4+y}I_{5-y}Se_y$ (Fig. 3), but this inflection point is less pronounced and will be displaced toward lower temperatures with increasing amounts of I substituted by S or Se. Moreover the two curves observed with decreasing and increasing temperature fall together. By the substituted compounds of the series $RbAg_{4+y}I_{5-y}Te_y$ no inflection points in

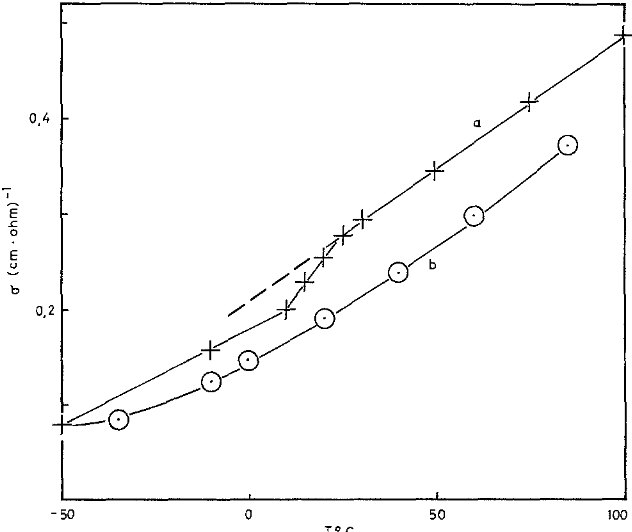

Fig. 2. Ionic conductivity σ_i of $RbAg_4I_5$ as a function of temperature. Curve a, measurements conducted with decreasing temperature; curve b, measurements conducted with increasing temperature.

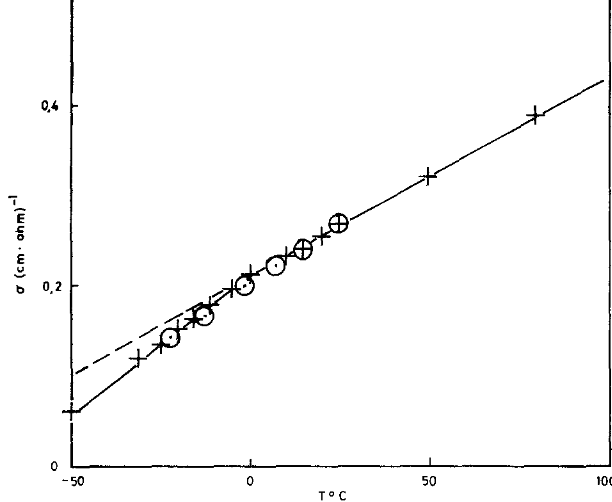

Fig. 3. Ionic conductivity σ_i of $RbAg_{4.2}I_{4.8}Se_{0.2}$ as a function of temperature. +—+, Measurements conducted with decreasing temperature; ⊙—⊙, measurements conducted with increasing temperature.

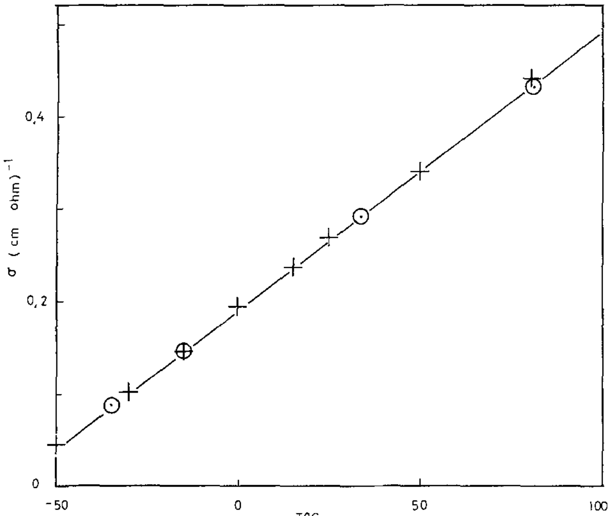

Fig. 4. Ionic conductivity σ_i of $RbAg_{4.1}I_{4.9}Te_{0.1}$ as a function of temperature. +—+, Measurements conducted with decreasing temperature; ⊙—⊙, measurements conducted with increasing temperature.

the electrical conductivity-temperature curves have been observed (see Fig. 4). The variation of the ionic conductivity σ_i with the composition y of the sample have been studied at 27°C in much the same way as the previous series of measurements. The results of these measurements for the compounds of the series $RbAg_{4+y}I_{5-y}S_y$ are shown in Fig. 5. The conductivity curves of the other two series $RbAg_{4+y}I_{5-y}Se_y$ and $RbAg_{4+y}I_{5-y}Te_y$ are very similar both qualitatively as well as quantitatively. Substitutions as large as 14% of the I by S, Se, or Te in the compound $RbAg_4I_5$ result in a decay in the electrical conductivity of only about 30% with respect to the value for pure $RbAg_4I_5$.

The Electronic Conductivity σ_e of $RbAg_4I_5$ and Its Substitution Compounds

The values reported for the electronic conductivity of $RbAg_4I_5$ vary between 10^{-8} $(\Omega\cdot cm)^{-1}$ (10, 11) and 10^{-11} $(\Omega\cdot cm)^{-1}$ (12, 13). The method used for this measurement has been the one first used by Hebb (14) and Wagner (15, 16) and has been called by the last author the polarization method.

Using the cell

$$- Ag/RbAg_4I_5/C + \qquad [II]$$

with the positive pole on the right side and applying a voltage below the decomposition potential of $RbAg_4I_5$, silver ions migrate at first from the $RbAg_4I_5/C$ interface toward the silver electrode and electrons in the opposite direction. At the $RbAg_4I_5/C$ interface a metal deficit originates since the first migrated silver ions are not replaced. That creates therefore a concentration gradient of silver ions across the sample of $RbAg_4I_5$. Due to the concentration gradient formed, silver ions migrate in the opposite direction. Finally, under steady-state conditions the two flows in opposite directions are balanced and the current is carried only by excess electrons or electron holes.

The intensity I of the current in cell (II) according to Wagner and Wagner (17) is

$$I = \frac{RT}{\mathbf{F}} \cdot \frac{A}{L} [\sigma_n{}^o(1 - e^x) + \sigma_p{}^o(e^x - 1)] \qquad [5]$$

where A is the cross-section area and L the thickness of the sample, $\sigma_n{}^o$ and $\sigma_p{}^o$ are the conductivities due to excess electrons and electron holes, respectively, (for $a_{Ag} = 1$) and finally x denotes $E\mathbf{F}/RT$.

Plotting the obtained values of I against the applied potentials E(V) one obtains curves like that in Fig. 6. Every obtained curve shows undoubtedly a plateau region, at which the value of the current I corresponds to a conductivity caused exclusively by excess electrons. Under these conditions the component of the electronic conductivity due to electron holes is negligible and Eq. [5] takes the form

$$\sigma_n{}^o = \frac{I(\text{plateau})}{RT/\mathbf{F}} \cdot \frac{L}{A} \qquad [6]$$

For values of $I >> I$(plateau) the electronic conductivity is essentially due to electron holes. One obtains likewise from Eq. [5]

$$\sigma_p{}^o = \frac{I}{RT/\mathbf{F}} \cdot \frac{L}{A} \cdot \frac{I}{e^x - 1} - \sigma_n{}^o \qquad [7]$$

the partial conductivity of the electron holes $\sigma_p{}^o$. The point where the prolonged two branches of the curve meet together gives approximately the decomposition potential of the compound (see Table III). The value found for the decomposition potential of $RbAg_4I_5$ (~ 0.65V) at 27°C is in good agreement with the value (0.67V) found by other authors (18). The de-

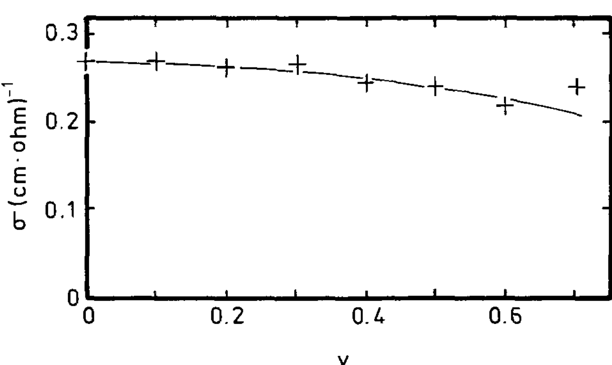

Fig. 5. Ionic conductivity σ_i at 27°C of the compound $RbAg_{4+y}I_{5-y}S_y$ as a function of the substituted mole fraction y.

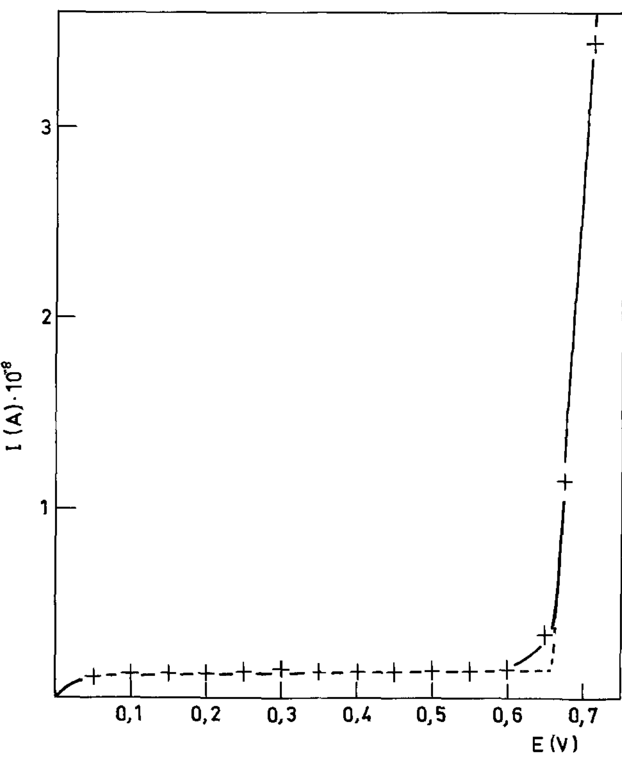

Fig. 6. Intensity-potential curve obtained by the determination of σ_e in $RbAg_4I_5$ at 27°C, using cell (II) and Wagner's polarization method.

Table III. Electronic conductivity and decomposition potential of $RbAg_4I_5$ and of several of its substitution compounds

Compound	Melting point (°C)	Electronic conductivity at 27°C $(\Omega \cdot cm)^{-1}$	Decomposition potential at 27°C (mV)
$RbAg_4I_5$	228	$6 \cdot 10^{-8}$	650
$RbAg_{4.1}I_{4.9}S_{0.1}$	225	$8.5 \cdot 10^{-9}$	575
$RbAg_{4.1}I_{4.9}S_{0.1}$	230	$3.2 \cdot 10^{-8}$	650
$RbAg_{4.2}I_{4.8}Te_{0.2}$	235	$3.6 \cdot 10^{-8}$	600

composition potentials of the other studied compounds are about the same as, or only slightly smaller than, that of $RbAg_4I_5$.

Concluding Remarks

The partial substitutions of iodine in $RbAg_4I_5$ by S, Se, or Te do not deteriorate the remarkably good ionic conductivity of this compound when the substituted amounts are ≤ 14%. These substitutions do not prevent the decomposition caused in $RbAg_4I_5$ by small amounts of water vapor in the air. The decomposition is very rapid in air saturated with water vapor. The final decomposition products under these conditions are not the ones corresponding to Eq. [2], as it can be seen by the results of Table II. Most probably the first originated compound Rb_2AgI_3 is not stable either under these conditions and the decomposition reaction proceeds further according to Eq. [4].

The ionic conductivity of $RbAg_4I_5$ is considerably deteriorated when samples of this compound are placed in inert dry atmospheres to low temperatures (up to −50°C) for prolonged periods of time. On the other hand, the substituted compounds behave quite differently under the same experimental conditions. No irreversible reaction has been observed. The curves are either straight lines over the whole range of temperature (Fig. 4) or, in a few cases, show a bending below the room temperature (Fig. 3). The position of the bend point is displaced toward lower temperatures with increasing amounts of substituted iodine. But even in those cases the samples recover their original conductivity when the temperature is increased again. These results are interpreted as sufficient evidence for a thermodynamic stabilization of the solid electrolyte $RbAg_4I_5$ by partial substitution of I by S, Se, or Te.

Crystallization of Amorphous Alloys of Rare Earths and 3d Transition Metals

K. H. J. Buschow and A. G. Dirks

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Amorphous rare earth rich alloys of 3d transition metals were prepared by melt spinning. Their crystallization behavior was studied by means of differential scanning calorimetry, x-ray diffraction, and transmission electron microscopy. In order to obtain an estimate of the relative importance of the rare earth component the thermal stability of various amorphous alloys of the type $R_{69}Ni_{31}$ has been studied. The role played by the transition-metal component was assessed by investigating the crystallization behavior of various $Gd_{1-x}M_x$ alloys. Finally, a series of amorphous $Tb_{1-x}Fe_x$ and $Er_{1-x}Fe_x$ alloys has been made in search of the influence of the R/M ratio upon the crystallization characteristics.

The low thermal stability of amorphous Gd-Fe alloys (1) contrasts sharply with the relatively high thermal stability ($T \sim 400°C$) of Zr-Fe or Th-Fe alloys (2) in which Fe is combined with metals having metallic radius and electronegativity similar to those of Gd. Furthermore the tendency to glass formation generally is highest near deep eutectics (3). The Gd-Fe system seems to be an exception (1) to this rule. This apparent anomalous behavior of the Gd-Fe alloys has prompted a more detailed investigation of the crystallization behavior of amorphous rare earth transition metal alloys.

In order to obtain an estimate of the relative importance of the rare earth component (R) some results obtained on alloys of the series $R_{69}Ni_{31}$ (R = La, Nd, Gd, Tb, Dy, Er) will be presented first. Various $Gd_{1-x}M_x$ alloys (M = Fe, Mn, Co, Ni) were also investigated making it possible to assess the role played by the transition metal component. In these alloys the 3d atom concentration was chosen to be equal to $x = 0.40$. In some cases also slightly lower and higher 3d atom concentrations were applied. Finally, the results obtained on the R-Fe systems (R = Tb, Er) will be discussed.

Experimental

Amorphous alloys were prepared by arc melting followed by melt spinning in a purified argon gas atmosphere. Small parts of each ribbon were investigated by means of x-ray diffraction. CuK_α radiation was applied in combination with an x-ray monochromator. The thermal stability of the alloys was studied by means of a differential scanning calorimeter (DSC) du Pont 910, again using an atmosphere of purified argon gas, we used a heating rate of 50°C/min. The origin of the observed heat effects has been studied by heating the ribbons to the distinct stages in the crystallization process followed by cooling and x-ray diffraction. Thin specimens of the samples, needed for transmission electron microscopy (TEM) were obtained by means of ion milling.

Results

DSC and x-ray diffraction.—The crystallization temperatures (corresponding to the first peak maximum in the DSC tracings) of various amorphous rare earth nickel alloys of the composition $R_{69}Ni_{31}$ are compared in Fig. 1. It is seen that T_{cr} increases steadily in going from La to the heavier rare earth elements. The change in thermal stability upon variation of the transition-metal species was investigated by DSC measurements of series of $Gd_{1-x}M_x$ ribbons. It was found that this stability increases in the sequence M=Fe, Mn, Co, Ni ($x = 0.4$) when x was kept constant.

Typical results of DSC tracings are shown in Fig. 2. The behavior of $Gd_{69}Ni_{31}$ is an example where the crystallization involves two stable crystalline phases (Gd_3Ni: $T_{cr} = 285°C$ and GdNi: $T_{cr} = 345°C$). Crystallization in amorphous $Gd_{65}Co_{35}$ first involves the phase Gd_8Co_3 and at slightly higher temperatures also the phase Gd_3Co. In amorphous $Gd_{55}Co_{45}$ crystallization entails the phase Gd_4Co_3. The amorphous alloy $Gd_{60}Co_{40}$ (not shown in Fig. 2) crystallizes at 310°C. The behavior of $Gd_{60}Mn_{40}$ is an example where the crystallization proceeds already slightly above room temperature and involves a metastable Gd-Mn compound. The broad peak centered around 300°C in the DSC diagram presumably reflects the increase with temperature of the amount of the material that has crystallized. This crystallization is not accompanied by a sharp thermal effect. The peak shown at 460°C in the DSC tracing (Fig. 2) is due to crystallization of the stable C15 compound $GdMn_2$. In the case of amorphous Gd-Fe alloys the first crystallizing phases are α-Gd and α-Fe. Crystallization of the cubic C15 phase $GdFe_2$ takes place again at much higher temperatures.

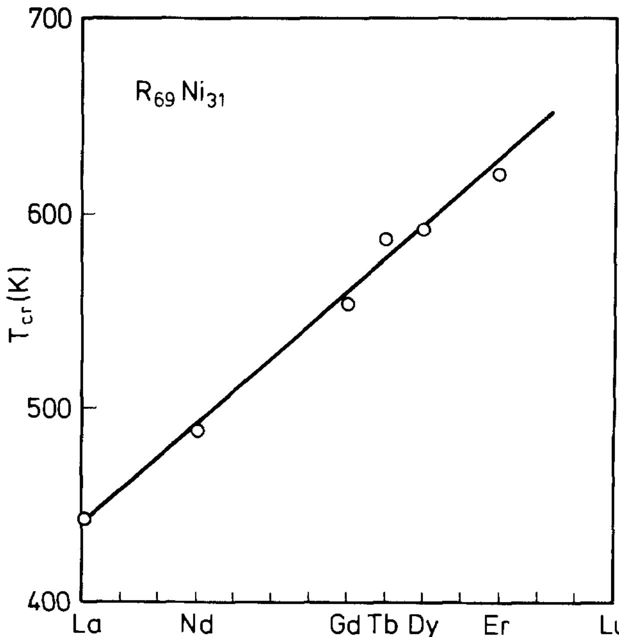

Fig. 1. Crystallization temperature in various amorphous rare earth nickel alloys.

Key words: crystallization, alloy, TEM.

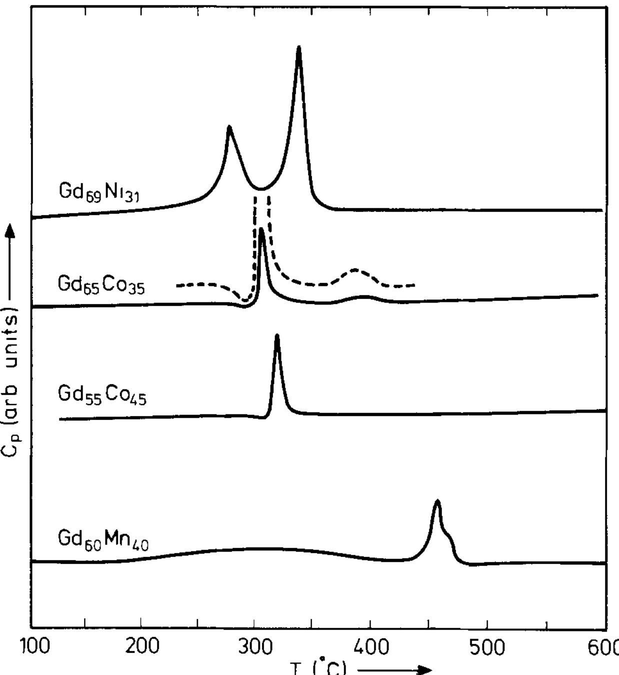

Fig. 2. DSC tracings of various amorphous alloys of Gd with 3d transition metals. The broken line in the case of $Gd_{65}Co_{35}$ was obtained by using a ten times higher sensitivity.

DSC data on series of Tb-Fe and Er-Fe ribbons are shown in Fig. 3. All Tb-containing alloys show up a similar behavior: at temperatures between 100° and 400°C the smeared-out thermal effect is due to the crystallization of α-Tb. The broadened x-ray diffraction lines of the α-Tb phase formed at low temperatures (circa 100°C) indicate the presence of rather small crystallites. According to the x-ray diagrams it can be concluded that the $Tb_{1-x}Fe_x$ ribbons heated to temperatures above 400°C are composed of a mixture of the crystalline phases $TbFe_2$ and α-Tb. This is in agreement with the expectations based on published data on R-Fe equilibrium diagrams (4, 5). The DSC data in Fig. 3 for the $Er_{1-x}Fe_x$ ribbons make it clear that in the Er alloys, too, crystallization sets in considerably below the temperature where the sharp crystallization peak is found in the DSC tracings. However, the first crystallizing phase is not the rare earth metal, as in Gd-Fe (1) and Tb-Fe alloys, but some metastable Er-Fe intermetallic compound. The smeared-out thermal effect is correlated with the formation of a metastable compound with unknown structure: only one diffraction peak corresponding to a spacing d = 2846Å is observed. Heating to temperatures over 300°C initiates the crystallization of another metastable compound (d = 2.919Å) and of α-Er. Diffraction lines due to the compound $ErFe_2$ (cubic Laves phase) occur together with those of α-Er in samples heated to temperatures higher than 500°C. These results can be summarized as follows. The two peaks in the DSC tracings near 350°C and 500°C are heat effects due to the formation of crystalline α-Er and $ErFe_2$, respectively. Minor precipitation of α-Er occurs already at temperatures somewhat below 350°C, but at much lower temperatures crystallization involves two metastable Er-Fe phases.

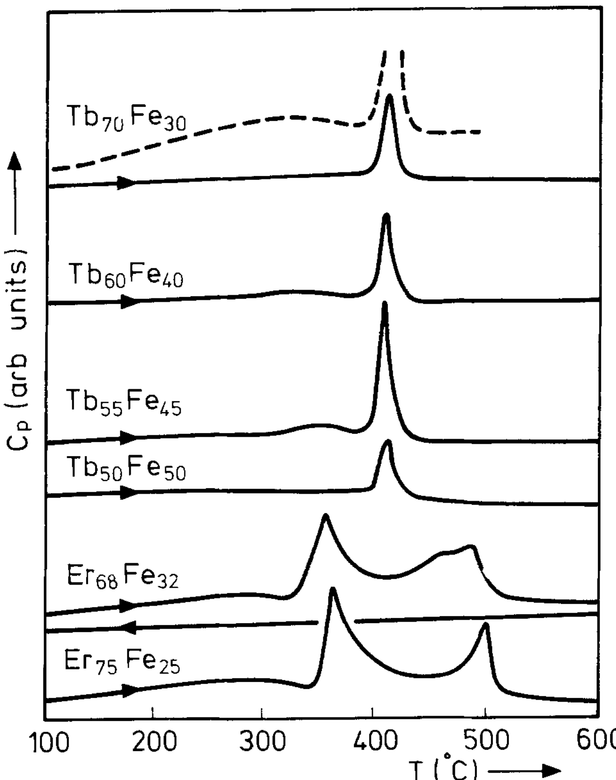

Fig. 3. DSC tracings of various amorphous terbium-iron and erbium-iron alloys. The broken line in the case of $Tb_{70}Fe_{30}$ was obtained with a ten times higher sensitivity.

TEM results.—The TEM investigations were restricted to a few representative examples. In all amorphous Gd-Co and R-Ni ribbons mentioned above primary crystallization involves a crystalline phase, present in the corresponding phase diagram, that has a composition not much different from that of the amorphous alloy. This crystallization is accompanied by a sharp peak in the DSC tracing (T_{cr}). Below T_{cr}, x-ray diffraction revealed no crystalline phases. Examination of a $Gd_{65}Co_{35}$ sample by TEM revealed the presence of still intact amorphous regions together with regions in which crystallization had taken place. The nature of the crystalline material was inferred from the corresponding SAD patterns. These patterns were quite complex and pointed to the presence of a low symmetry Gd-Co intermetallic compound rather than to α-Gd or α-Co.

A quite different picture emerges from the TEM investigation of R-Fe ribbons, represented by $Gd_{60}Fe_{40}$ and $Tb_{70}Fe_{30}$ heated to 250° and 100°C, respectively. The microstructure of these alloys consists of crystalline regions embedded in an amorphous matrix (see, for example, Fig. 4). Electron diffraction data made it clear that part of the crystalline material is α-Gd resp. α-Tb. In the Gd-alloy a second phase was

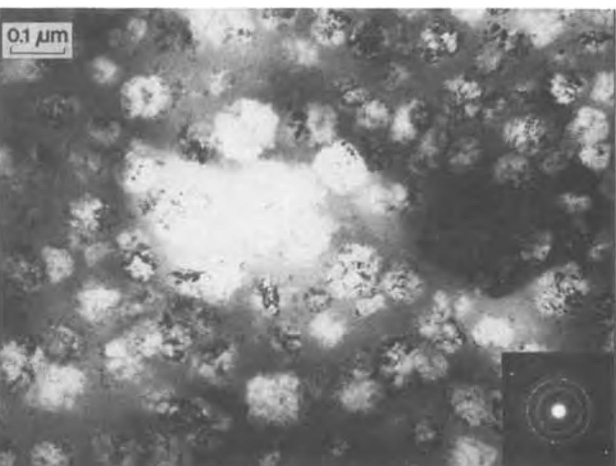

Fig. 4. Transmission electron micrograph of an ion-milled $Tb_{70}Fe_{30}$ ribbon after heating to 100°C. The bright field image shows primary crystallites in an amorphous matrix. The electron diffraction pattern in the inset shows both patchy rings (α-Tb crystals) and diffuse halos.

found to consist of α-Fe in the form of crystallites of rather small dimensions (diameter ≤ 100 μm); this might explain the absence of α-Fe peaks in the x-ray diagrams. In the Tb-alloy no evidence was found of the presence of α-Fe crystallites with electron diffraction techniques. These results seem to indicate that with increasing temperature part of the Tb can precipitate in amorphous $Tb_{70}Fe_{30}$, leaving an amorphous matrix of slightly higher Fe content.

Discussion

The above results can be reasonably well understood in terms of the cluster model of liquid structures (6,7). The occurrence of clusters can be considered as resulting from compositional fluctuations. The tendency to cluster formation between unlike atoms increases as the heat of mixing ΔH_m of the two composing elements becomes more negative (cluster formation between like atoms decreases in the same sense). The reason for this is the gain in free energy that is obtained if the coordination of a given atom with unlike atoms becomes higher than that associated with the random distribution of atoms in the amorphous state. It can be shown (8, 9) that for rare earth 3d alloys $Gd_{1-x}M_x$ (with $x < 0.5$) ΔH_m becomes more negative in the sequence M = Fe, Mn, Co, Ni. It is about −1 kJ/mole alloy in the case of Fe but larger than −30 kJ/mole alloy in the case of Ni. Clustering in the liquid state between unlike atoms will therefore be low in the case of Fe but will increase towards Ni. In the amorphous alloys such clusters can be regarded as embryos that facilitate nucleation. It is understandable therefore that nucleation of intermetallic compounds proceeds less easily in the case of the amorphous Gd-Fe alloys. On the other hand it was shown by Zielinski and Matyja (10) that large negative ΔH_m values lead to low interdiffusion constants and hence to low growth rates. As a result glass formation will be easier in alloys with large negative ΔH_m values.

Once an amorphous alloy has been obtained by means of rapid quenching from the melt, its thermal stability will be largely determined by the temperature dependence of the viscosity (11, 12). Crystallization will set in whenever the temperature is high enough to match ΔE. In previous investigations ΔE has been taken equal to the energy ΔH_{1v} needed to create a hole of the size of the smallest type of atom in the solid alloy (2). Using the results of an analysis of the enthalpies of formation of monovacancies in pure metals given by Miedema (13) it can be shown that the enthalpy of formation of a hole of the size of a 3d atom (ΔH_{3d}) in rare earth rich $R_{1-x}M_x$ alloys is considerably less than ΔH_{3d} in the pure 3d metals. Furthermore, in alloys of fixed composition x and fixed element M, the values of ΔH_{3d} increase if one proceeds through the rare earth series from La to Lu. This means that T_{cr} is expected to increase in the same sense. Inspection of the results in Fig. 1 shows that, qualitatively, good agreement exists with experimental findings.

The discussion of ΔH_{3d} given above refers to a situation where no account has yet been taken of a positive or negative interaction between the R atoms and the 3d atoms. One may expect that it will be more difficult to create a hole in the alloy if there exists a strongly attracting interaction between the R and 3d atoms. In other words, ΔH_{3d} will increase as ΔH_m becomes more negative in going from R = La to R = Lu and also in the sequence M = Fe, Mn, Co, Ni as already mentioned above. In the first sequence the effect of an increasingly negative ΔH_m is to reinforce somewhat the R dependence of T_{cr} mentioned above in connection with the results of Fig. 1. With regard to the second sequence we note that ΔH_m of Fe and Mn alloys is almost negligible whereas it is strongly negative in Co and Ni alloys.

Conclusions

It has been shown that there are appreciable differences in the crystallization behavior of amorphous rare earth transition metal alloys $R_{1-x}M_x$. The thermal stability is lowest in alloys of light rare earth elements but increases if one proceeds through the lanthanide series. It also increases in the sequence M = Fe, Mn, Co, Ni. It is proposed that the observed differences in the type of the crystallization originate primarily from differences in the heats of alloying, leading to nucleation difficulties in the case of small heats of alloying. In order to explain differences in the temperature of crystallization other heat effects also have to be taken into consideration.

Pattern Etching of CVD Si_3N_4/SiO_2 Composites in HF/Glycerol Mixtures

Cheryl A. Deckert*[,1]

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Solutions of concentrated (49%) aqueous HF in glycerol have been found to etch CVD Si_3N_4 films faster than thermally grown SiO_2 over a wide temperature range. Since silicon dioxide films are etched much faster than silicon nitride films in aqueous HF media, this result is quite surprising, and the mechanism for the etch rate reversal is not understood at present. HF/glycerol mixtures have been used to pattern a variety of $Si_3N_4/SiO_2/Si$ composite structures using either photoresist or metal masks.

Several types of integrated circuit devices are fabricated using multiple dielectric coatings. Structures bearing films of silicon nitride over silicon dioxide are useful in such applications as high reliability devices, localized nitride-masked oxidation processes, MNOS memory devices, etc.

In many cases, the composite structures consist of a high temperature, chemically vapor-deposited (CVD) Si_3N_4 film over either thermally grown SiO_2 or a densified CVD SiO_2 film on silicon (Fig. 1a). Depending on the particular application, an overlying film of undensified CVD SiO_2 may also be included (Fig. 2a). In order to pattern these composites, openings must be etched through the nitride and oxide films using a masking layer.

Dry etching techniques, such as plasma etching (1), have greatly increased in popularity over the past few years, and Si_3N_4/SiO_2 composites can be patterned in this manner, using, for instance, a CF_4 plasma. Plasma etching offers the advantage that only minimal mask-to-substrate adhesion is required, since the tendency for etchant undercutting is negligible; hence plasma etching is quite suitable for complex, high resolution pattern delineation.

The steep edge profiles characteristic of many dry etching processes do facilitate fabrication of high density microstructures, but patterning of multiple dielectric layers typically involves only the opening of contact holes. Ideally, for this step, the etching process should produce slightly tapered walls in the dielectric films (Fig. 1b and 2b), so that subsequently deposited metal films will cover the edges uniformly and completely. The usefulness of sloped dielectric layers in achieving metallization of high yield and reliability is well known, since thinning of the metal layer can occur over sharp corners in the dielectric (1, 2). Ideally a 45° taper should be used; however, lower angles are acceptable if resolution of the top surface of the dielectric is not critical. The lower surface of the delineated film, of course, will maintain the same dimension as the masking material unless either significant undercutting or overetching takes place. Thus use of tapering procedures does not typically require lithographic biases. Although it is possible, in some cases, to achieve tapered edges using plasma-assisted etching techniques (1), plasma etching processes generally involve poor selectivity and, hence, involve some etching of the layer beneath the one(s) being etched. Thus we centered our efforts toward achieving the desired type of edge profile on wet chemical procedures. Both for the sake of simplicity and to avoid formation of an undesirable film "lip," (3-5) it would be advantageous if the etching process could be carried out in a single step, using an etchant that would dissolve all the various layers sequentially.

In order to etch a multiple layer film so as to obtain a sloped edge, it is necessary that the etch rates of the various films decrease in the order $r_1 \geqq r_2 \geqq \ldots r_n$, where r_1 is the etch rate of the uppermost layer and r_n is the etch rate of the bottommost layer.

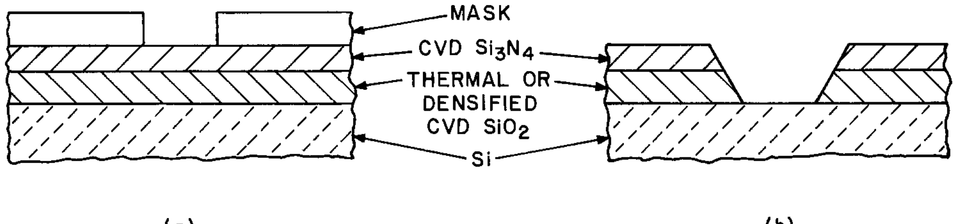

Fig. 1. (a) $Si_3N_4/SiO_2/Si$ composite structure bearing delineated mask film; (b) etched composite structure having desired sloped edges (vertical dimension exaggerated).

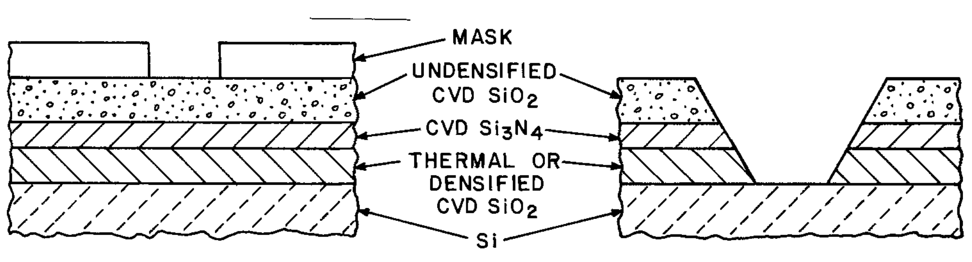

Fig. 2. (a) $SiO_2/Si_3N_4/SiO_2/Si$ composite structure bearing delineated mask film; (b) etched composite structure having desired sloped edges (vertical dimension exaggerated).

Thus, for the silicon nitride-silicon dioxide composite structures, a suitable wet chemical process should have r (undensified CVD SiO_2) $\geqq r$ (CVD Si_3N_4) $\geqq r$ (thermal or densified CVD SiO_2) $>> r$ (Si).

In general, CVD Si_3N_4 is a rather difficult material to etch at an appreciable rate. The use of hot (160°-180°C) orthophosphoric acid (85% H_3PO_4) (6) or phosphoric-sulfuric acid (4) mixtures are well-known methods, but decomposition of the etchants (loss of water and conversion into higher phosphates) occurs with prolonged heating. Thus, even if an appropriate reagent were added to promote simultaneous etching of SiO_2, control of the relative etch rates of the films would be very difficult to achieve.

Other systems have been proposed for simultaneous etching of Si_3N_4 and SiO_2 films (3, 5, 7). All these systems suffer from a combination of disadvantages, including the necessity of maintaining high temperatures (>90°C) in aqueous systems or the difficulty of achieving the desired etch rate ratio. In particular it is often difficult to etch the nitride film at a sufficiently fast rate because Si_3N_4 etching characteristics may vary considerably depending on the exact film deposition conditions used, specifically the deposition temperature and the ammonia/silane ratio in the reactant mixture.

The use of H_3PO_4-HBF_4 mixtures at 100°-110°C has been reported (7) to give r (CVD Si_3N_4) $\geqq r$ (thermal SiO_2), but in practice we have found that some typical nitride compositions etch more slowly than SiO_2 under these conditions. The system HF/H_2O at 90°-100°C gives (3, 5) the desired etch rate ratio at very low HF concentrations only ($\lesssim$ 0.1M); under these conditions evaporation of H_2O and HF tends to alter the relative and absolute etch rates (8). Another reported (9) etchant system for Si_3N_4/SiO_2 composites is high temperature water (>100°C), this requires use of a high pressure reactor, which is undesirable for a factory process.

From several recent studies (3, 5, 10), it is known that aqueous fluoride etchants can be made to etch CVD Si_3N_4 faster relative to thermal SiO_2 by increasing temperature. For this reason it was attempted to utilize, as a preferential Si_3N_4 etchant, moderately high temperature (100°-140°C) HF solutions in a relatively nonvolatile solvent resembling water in its ionization and solvation behavior. Glycerol (CH_2OH $CHOHCH_2OH$) [$K_a = 7 \times 10^{-15}$ (25°C, aqueous solution), bp = 290°C] was chosen as a suitable solvent for these studies, and this paper deals with the interesting etching characteristics of the HF/glycerol system.

Experimental

The substrates used in both the etch rate tests and the composite layer patterning tests were polished, single crystal silicon wafers.

For the etch rate tests, a single dielectric was produced on the wafers by one of the following methods: (*a*) Approximately 6000Å of thermally grown SiO_2 was produced at 1000°C in steam at atmospheric pressure. (*b*) Approximately 1 μm of undensified CVD SiO_2 was deposited from a silane-oxygen-nitrogen gas mixture at 450°C. (*c*) Densified CVD SiO_2 was prepared by baking undensified CVD SiO_2 at 800°C in dry nitrogen for 15 min.

Three different formulations of CVD Si_3N_4 were used as described below. In order to avoid excessive stress buildup, nitride film thicknesses were limited to about 2100Å. (*d*) The flow rates of SiH_4, NH_3, and N_2 were 0.55, 3.14, and 40 liters/min; the NH_3/Si molar ratio was therefore $\approx$6. A 750°C reactor temperature was employed. (*c*) The flow rate of N_2 carrier gas through $SiCl_4$ at 25°C was 110 cm^3/min, resulting in transport of 0.21 g/min $SiCl_4$. The flow rate of NH_3 was 600 cm^3/min. These conditions give NH_3/Si = 20. The nitrogen main flow was 225 liters/min and the reactor temperature was 875°C. (*f*) Using the same reactor as (*e*), the $SiCl_4$ supplied to the reactor = 0.22 g/min; NH_3 flow = 450 cm^3/min; N_2 main flow = 224 liters/min. Thus NH_3/Si $\approx$ 14.

The initial thicknesses of the SiO_2 films were measured by the interference fringe method utilizing a Beckman DB-G spectrophotometer. Initial thicknesses of the Si_3N_4 films were measured by a technique based on relative reflectivity of a monochromatic beam of light (11). Two different wavelengths of light were employed. All oxide and nitride samples were etched nearly to completion, and the final thicknesses were determined based on the interference color of the residual films. The order number was verified by masking off an area of each etched sample and stripping the remaining film. The estimated error in the etch rates was ±5-8%; this accuracy was thought to be sufficient for our purposes.

HF/glycerol solutions were prepared by mixing a specified volume (33, 67, or 100 ml) of concentrated (49%) aqueous HF with reagent grade glycerol (assay <0.4% water) to give 1, 2, or 3M solutions.

Other materials used in formulating etchants, as is described in the text, were also of reagent grade quality. Etchant temperatures were controlled to within ±0.5°C.

For the composite layer patterning tests, various types of Si_3N_4/thermal SiO_2 or undensified CVD SiO_2/Si_3N_4/thermal SiO_2 samples were prepared, masked as described below and etched in an HF/glycerol solution.

Etch Rates Studies

As discussed earlier, the original motivation for studying the HF/glycerol system was that relatively high (>100°C) etching temperatures were thought necessary to achieve r (CVD Si_3N_4) $\geqq r$ (thermal SiO_2). Initial experiments conducted at 110°C using moderately concentrated HF/glycerol solutions did, in fact, produce the desired etch rate ratios, (r (Si_3N_4)/r (SiO_2) > 1). However, the observed etch rates are anomalous in two respects, based on the rates in aqueous HF (3, 8). First, the nitride is etched much more rapidly, relative to the oxide, than would be expected at this temperature; and second, the absolute values of the etch rates for both nitride and oxide are considerably smaller than would be expected. Based on the first of these observations, it appeared that acceptable etch rate ratios could be achieved at even lower temperatures (<100°C), and indeed this was found to be the case. Etch rates were determined for undensified and densified CVD SiO_2 films, thermal SiO_2, and three different formulations of CVD Si_3N_4 (NH_3/Si molar ratio in gas mixture varying from 6 to 20) in 1, 2, and 3M HF/glycerol solutions at 25°, 70°, 80°, and 90°C. These etch rate data are summarized in Fig. 3-6. The following observations can be made: (*i*) In all cases, undensified CVD SiO_2 is etched faster than CVD Si_3N_4, which is etched faster than thermal SiO_2. (*ii*) All three types of CVD Si_3N_4 are etched at very similar rates. This fact is especially useful for utilization of the etchant in different manufacturing areas. (*iii*) Densified CVD SiO_2 is etched slightly faster than nitride at 25°C, but slightly slower at the elevated temperatures.

Based on these etch rates, it is seen that a wide range of temperatures and HF concentrations can be used to produce sloped edges in the two- or three-layer dielectric film composites of Fig. 1 and 2. The desired etch rates and edge contours will determine the exact parameters used. In practice, HF concentrations lower than ~1M lead to prohibitively long etching times for dielectric films of typical thicknesses, and concentrations greater than ~3M lead to handling problems. Similarly, the temperature range from 60° to 90°C is thought to be optimum.

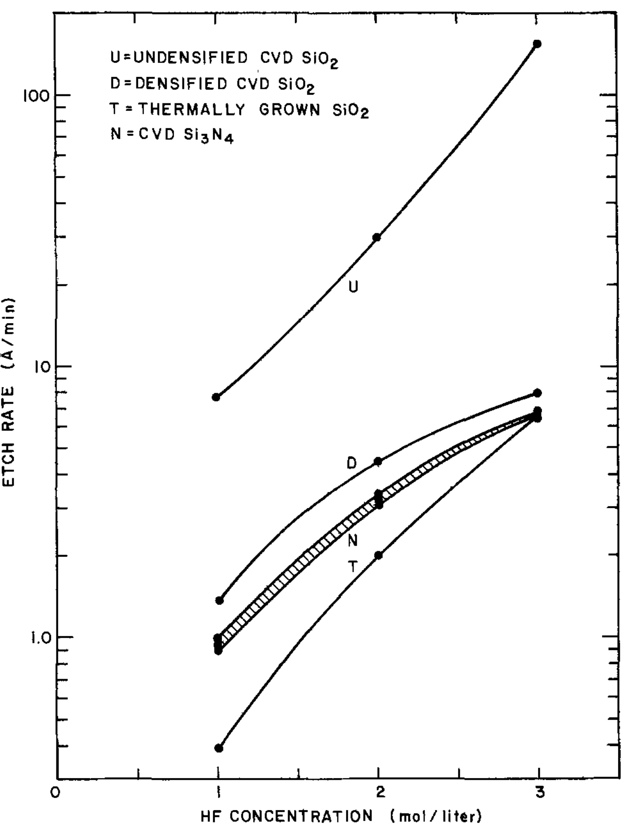

Fig. 3. Etch rates of Si_3N_4 and SiO_2 films in HF/glycerol solutions at 25°C.

Reversal of Nitride/Oxide Etch Rate Ratio

As mentioned above, both the absolute and relative etch rates of Si_3N_4 and thermally grown SiO_2 in HF/glycerol were unexpected, based on previous etch rate studies conducted using aqueous HF systems (3, 8). For ease of comparison, the etch rates for these two materials in HF/glycerol are summarized in Fig. 7, and etch rates in HF/water are shown in Fig. 8. The nitride etch rates shown in Fig. 7 and 8 were obtained using the deposition conditions listed as (*e*) in the Experimental section. Clearly, in the glycerol system, it is much easier to choose conditions giving r (CVD Si_3N_4) $> r$ (thermal SiO_2).

The mechanism for the unexpected reversal in the etch rate ratio and the decrease in absolute magnitudes of the etch rates is not clear. To elucidate the situation somewhat, HF solutions of several other high boiling solvents were tested. The results of etch rate tests, conducted at 80°C using 2M HF solutions, are summarized in Table I. It is seen that in aqueous solution, large absolute etch rates and a small etch rate ratio [r (Si_3N_4)/r (SiO_2)] are obtained, while in hydroxylated organic solvents the absolute etch rates are greatly reduced, but the SiO_2 etch rate is reduced more than the Si_3N_4 etch rate, leading to a relatively

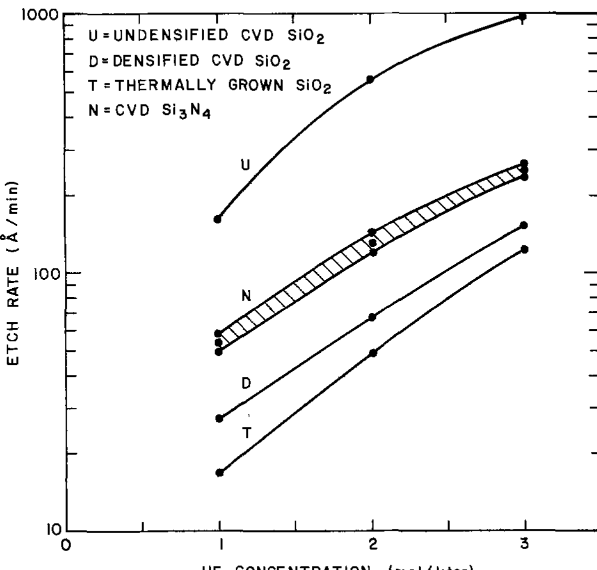

Fig. 5. Etch rates of Si_3N_4 and SiO_2 films in HF/glycerol solutions at 80°C.

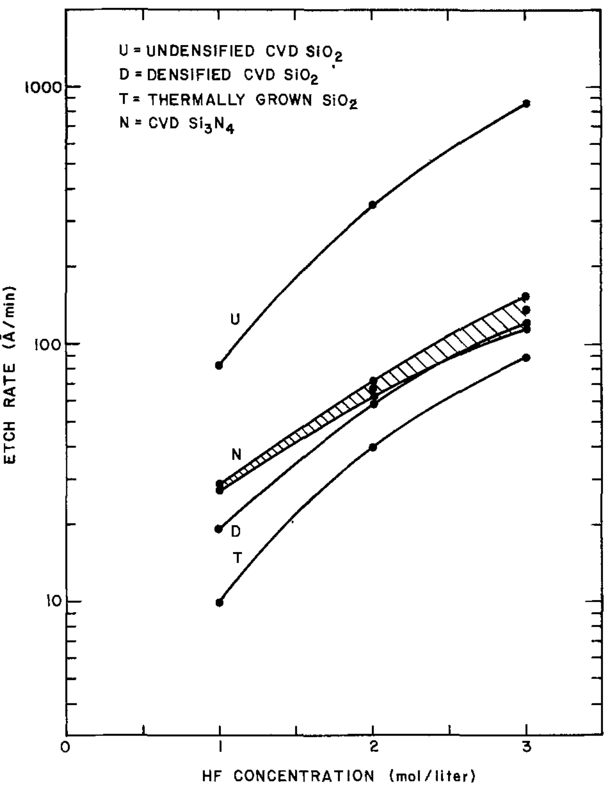

Fig. 4. Etch rates of Si_3N_4 and SiO_2 films in HF/glycerol solutions at 70°C.

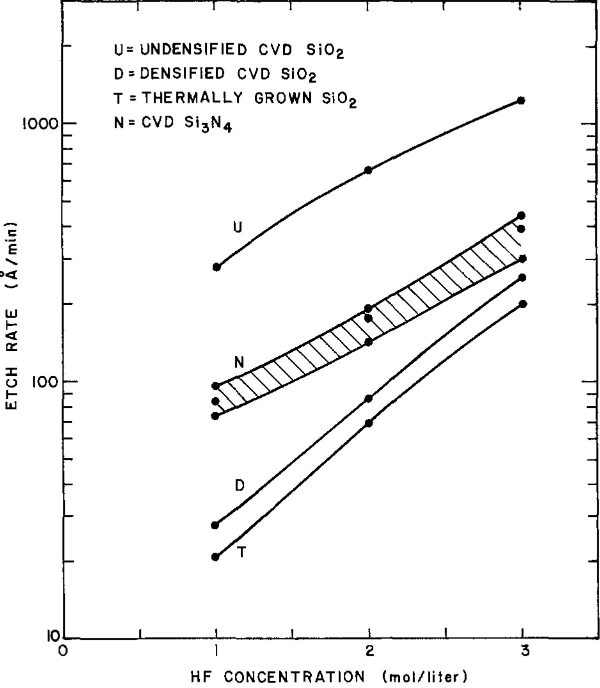

Fig. 6. Etch rates of Si_3N_4 and SiO_2 films in HF/glycerol solutions at 90°C.

large etch rate ratio. Finally, in DMF, the nitride etch rate is reduced even further, the SiO_2 etch rate is slightly larger, and a small ratio is obtained. (It should be mentioned that although these solvents were of reagent quality, no special attempts were made to remove residual water.)

These differences in etch rates and ratios of etch rates depending on solvent indicate that the dependence of SiO_2 and Si_3N_4 etch rates on the various equilibrium solution species is more complicated than had

previously been thought. It has been demonstrated (10, 12) that in dilute aqueous solution (*i.e.*, 1M ionic strength), etch rates of SiO_2 and Si_3N_4 depend on [HF] and [HF_2^-] only. Since the ionic strengths of the solutions used in the present study are well below those at which higher polymeric species have been observed in aqueous media, it seems likely that only monomeric species are involved in the etching mechanism. It does appear that large etch rate ratios, as required for patterning CVD Si_3N_4/thermal SiO_2 composites, can be achieved in HF solutions of numerous high boiling, hydroxylated solvents.

Although a relatively limited HF concentration range was used in this study (1-3M HF $\approx$ 2-6% HF by weight), it seems useful to use the observed temperature dependence of etch rates on HF concentration to calculate apparent activation energies. Over the 1-3M HF concentration range and the 70°-90°C temperature range, $\Delta E_A = 8.7$ kcal/mole for thermally grown SiO_2 and 12.5 kcal/mole for CVD Si_3N_4. These results can be compared with about 7.8 and 13.6 kcal/mole for SiO_2 and Si_3N_4, respectively, determined over a similar concentration and temperature range in previous etching studies (3) carried out in dilute aqueous HF solutions. Thus, the activation energies support our observation that the Si_3N_4 etching process is facilitated, relative to that of SiO_2, when HF/glycerol etchants are used rather than HF/water.

A quantitative analysis of the solution equilibria involved in the fluoride-water-glycerol system was not attempted because of the complexity of the required calculations. Qualitatively, it may be concluded that the presence of water enhances SiO_2 etch rate more than Si_3N_4 etch rate. Since previous mechanistic studies (10, 12) of SiO_2 and Si_3N_4 etching processes in fluoride media involved only aqueous systems, the effect of the solvent on etch rate was not demonstrated. Clearly, the complete rate law for etching of SiO_2 and Si_3N_4 must contain one or more terms involving solvent species, since the observed effects, in particular the etch rate ratio reversal, cannot be explained on the basis of solvent-induced concentration shifts.

Results of a few more experiments, which further highlight the complexity of the etching process, are listed in Table II. In these experiments it is seen that addition of NH_4F, either as a solid or as an aqueous solution greatly enhances the SiO_2 etch rate relative to the Si_3N_4 etch rate. Addition of NH_4F to aqueous HF would tend to raise the *p*H and shift the fluoride equilibrium towards HF_2^-, the species which predominates in SiO_2 etching processes in solutions of 1M ionic strength (12). However, the observed SiO_2 etch rate enhancement exceeds (by at least a factor of 10) that predicted simply on the basis of a moderate increase in solution fluoride content and a shift to the HF_2^- species. This enhancement is yet another feature which must be explained if the mechanism of SiO_2 and Si_3N_4 dissolution in fluoride media is to be eventually understood.

Patterning Studies

It was desired to demonstrate that Si_3N_4/SiO_2/Si composites similar to those shown in Fig. 1a and 2a

Table II. Etch rates (Å/min) of CVD Si_3N_4 and thermal SiO_2 in selected HF/glycerol systems

can be patterned in HF/glycerol solutions to produce the desired tapered side walls. Since composite structures of this type are typically used as dielectrics under metallization patterns in integrated circuit devices, contact openings are the usual pattern structure. Thus our test pattern consisted of various size holes (4-25 μm) on a planar background.

Several types of masking materials were tested, as were several types of dielectric composites. Naturally, a primary mask (photoresist) would be preferable to a secondary masking material (such as a metal or dielectric unaffected by HF), which would itself require patterning by photolithographic techniques. The patterning experiments described below are divided into these two categories. All the nitride layers used in the patterning experiments were prepared as in procedure (d) described earlier.

Photoresist masks.—Both positive-(Shipley AZ 1350 B or J) and negative-working (Kodak 747, Waycoat IC, HR200) photoresists were tested. In general it was found that the negative resists could not withstand the heated etchants long enough for the pattern etching to take place. Thus most of the work employing photoresist masks centered on AZ 1350 B or J. (When AZ 1350B was employed, a double coating of resist was spun on to improve pinhole resistance.) In each case described, the dielectric sandwich structure was treated with the adhesion promoter hexamethyldisilazane by an immersion technique prior to photoresist application.

A composite film consisting of 500Å CVD Si_3N_4 over 500Å of thermally grown SiO_2 on Si was patterned using AZ 1350B, in a 1M HF/glycerol solution at 80°C. The etch time employed was about 40 min. After resist removal, a scanning electron micrograph was obtained. This is shown in Fig. 9. The average angle of taper is about 35° in this case.

A composite film consisting of 7000Å undensified CVD SiO_2/500Å Si_3N_4/500Å thermal SiO_2 on Si was etched, using an AZ 1350B mask, in 1M HF/glycerol at 80°C for 85 min. The SEM-graph is shown in Fig. 10. A slope averaging about 25° was obtained. For this type of film, an alternate procedure is to etch through the upper SiO_2 in BHF, then use the glycerol etch.

In neither of these photographs can the interface between the Si_3N_4 and thermal SiO_2 be distinguished, but the gradual slope of the edge indicates that the desired etch rate ratio (r (Si_3N_4) $\geqq$ r (SiO_2)) has been achieved. In the latter example, the interface between the CVD oxide and Si_3N_4 is clearly distinguishable. Particles remaining in the etched areas are apparently due to the difficulty of wetting the surfaces in glycerol solution and can probably be eliminated by employing a predip in a surfactant solution, or by using a surfactant in the etchant itself, as is often done when SiO_2 is patterned.

Since the etching time required in 1M HF/glycerol can be excessive, a similar composite, consisting of

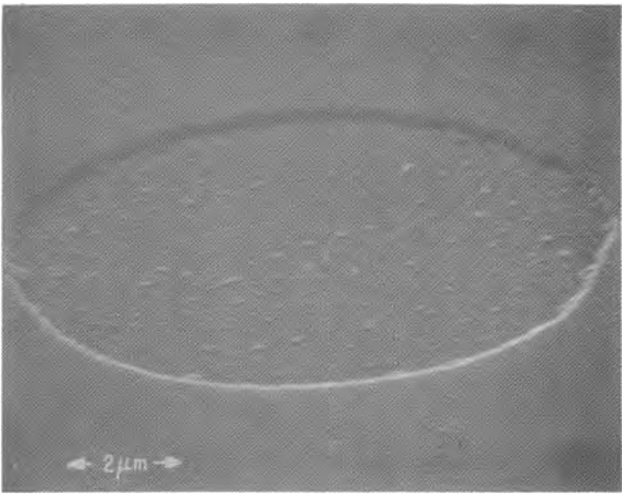

Fig. 9. Composite structure consisting of 500Å CVD Si_3N_4 over 500Å thermally grown SiO_2 on Si, patterned using AZ 1350B photoresist, and etched in 1M HF/glycerol at 80°C for 40 min.

7000Å undensified CVD SiO_2/1000Å Si_3N_4/500Å SiO_2 on Si was patterned using AZ 1350B in 3M HF/glycerol at 80°C. In this case, only 17 min etch time was required. A satisfactory sloped edge was also observed in this case.

As a final example, a composite consisting of 1000Å CVD Si_3N_4/500Å thermal SiO_2 on Si was patterned with AZ 1350J and etched in 1M HF/glycerol at 60°C for 160 min. A satisfactory pattern was again achieved.

Naturally it is desirable to utilize the highest temperatures and concentrations possible in these patterning processes in order to achieve as short as possible etch times. However, when photoresist is used as a mask, adhesion to the underlying substrate is always of concern, and thus somewhat lower than desirable HF concentrations and temperatures must be tolerated. In particular, when the uppermost dielectric film is Si_3N_4, and when the dielectric films are fairly thick, photoresist adhesion can be problematic; we found, for instance, that use of 3M HF/glycerol at 60°C or of 1 or 2M HF/glycerol at 70°C or higher caused adhesion failure of AZ 1350J when a composite comprised of 2000Å Si_3N_4/2000Å SiO_2 on Si was etched.

Metal masks.—A sputtered molybdenum mask was found to give very good results. A dielectric composite consisting of 2000Å Si_3N_4/2000Å SiO_2 on Si was coated with a (nominally) 1000Å film of sputtered molyb-

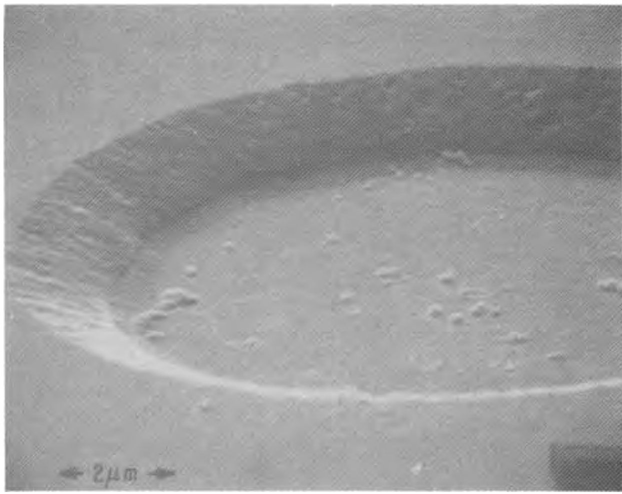

Fig. 10. Composite structure consisting of 7000Å undensified CVD SiO_2/500Å CVD Si_3N_4/500Å thermally grown SiO_2 on Si, patterned using AZ 1350B photoresist, and etched in 1M HF/glycerol at 80°C for 85 min.

denum. The Mo was patterned at room temperature using Kodak 747 photoresist, and employing an etchant of 1 part concentrated H_2SO_4, 1 part concentrated HNO_3, and 2 parts water. Only a few seconds immersion were required to etch the Mo film. After stripping the resist, the dielectric composite was etched at 80°C in 2M HF/glycerol for 60 min. The metal mask was then stripped. It was found that patterns of sloped edges were produced in the dielectric composite.

Another type of mask which has been tested is a lead fluoride/gold composite. This material reportedly (13) adheres very well to glass substrates; but unfortunately it did not adhere well to Si_3N_4 during our attempts at pattern etching.

Alternatively, secondary masks of dielectric materials which are unaffected by HF etchants (2) might be used. Some such materials are crystalline Al_2O_3 or sapphire, crystalline Ta_2O_5 (>500°C heat-treatment required), or spinel ($MgAl_2O_4$).

Conclusions

Mixtures of concentrated aqueous hydrofluoric acid in various high boiling, hydroxylated organic solvents such as glycerol appear to be suitable for chemical etching of CVD Si_3N_4/thermally grown SiO_2 on Si composite structures. Since the nitride etch rate is somewhat higher than the oxide etch rate over a wide temperature and HF concentration range, gradually sloped pattern edges are easily achieved. Undensified CVD SiO_2 films are etched even faster than Si_3N_4 films; thus similar composites bearing such a layer uppermost can also be pattern-etched using this method.

The exact mechanism for the etch rate ratio reversal, relative to that observed in aqueous media, is not understood at present.

If the etch times required for patterning a composite are not excessive, a positive photoresist such as AZ 1350J may be used as a masking material. A sputtered molybdenum film, patterned using a negative photoresist process, may also be used as a mask. If the Si_3N_4 and thermal SiO_2 layers are fairly thin, a thick film of a CVD SiO_2 film can be employed as a mask, with some of this uppermost oxide material being "sacrificed" during the nitride etching process.

AES Measurements on P-Doped Silicon Dioxide: Electron and Ion Beam Irradiation Artifacts

G. Queirolo* and G. U. Pignatel

SGS/ATES Componenti Elettronici S.p.A., Physics Department, Castelletto di Settimo Milanese, Milano, Italy

ABSTRACT

The phosphorus content of P-doped silicon dioxide films of various compositions was measured with Auger electron spectrometry. Electron and ion beam irradiation were found to severely affect both the energy and the shape of the P_{LVV} peak: for very low primary electron current densities a P_{LVV} peak, attributed to the phosphorus bonded to oxygen, was found at 110 eV; for higher current densities the 110 eV peak disappeared, and the well-known P_{LVV} peak of elemental phosphorus was found at 120 eV. A reduction effect was also noticed after an ion beam irradiation with 1 keV Ar^+ ions: in this case a reconstruction of the broken P-O bonds was found to take place after irradiation.

Phosphorus-doped silicon dioxide films are widely used in semiconductor device fabrication. The desired phosphorus content of these films, usually deposited by a chemical vapor deposition method, depends on the particular application and is typically between 2 and 12 mole percent (m/o). Several methods can be used to measure the phosphorus content in a P-doped silica glass (1, 2): dissolution rate in a suitable etchant, sheet resistance of the layer obtained in silicon when the film is used as a diffusion source, infrared absorption, x-ray microanalysis, neutron activation analysis,

* Electrochemical Society Active Member.

Key words: phosphosilicate glass (PSG), Auger electron spectrometry, phosphorus concentration measurement.

etc. In this paper we discuss the measurement of the phosphorus concentration in P-doped silica glass with Auger electron spectrometry and describe the effects of the electron and ion beam irradiation on both the P_{LVV} peak energy and shape.

Experimental

Sample preparation.—All the P-doped silicon dioxide films studied in this work were 1 μm thick and were CVD deposited on silicon slices within an AMT 2000, continuous silox reactor. The flows of the reactant gases (SiH_4, O_2, PH_3) and of the N_2 carrier were adjusted for every phosphorus concentration to obtain good thickness and doping uniformity along the boat. Czochralsky grown, 7.62 cm diam single crystal silicon wafers, (100) oriented, boron-doped ($N_A \simeq 10^{15}$ cm^{-3}) were used throughout. The polished wafers (SMIEL and Wacker Chemitronic) were cleaned in H_2SO_4 + H_2O_2 and HCl + H_2O_2 solutions prior to the deposition; after the film growth the wafers were cut in half in a clean hood and stored in dry nitrogen for neutron activation and Auger electron spectrometry analyses.

Neutron activation analysis. —The neutron activation analysis of the bulk phosphorus content of the P-doped silicon dioxide films were performed on the CESNEF reactor (Politecnico di Milano). The samples were irradiated for 10-15 min at a thermal neutron flux of 4 × 10^{11} cm^{-2} sec^{-1}; after the irradiation the P^{32} decay was followed, in order to eliminate the interference from other β^- decaying nuclides. Identical samples gave a 3% reproducibility, whereas a total absolute error of ±8% was estimated, a majority of which (±5%) came from uncertainties in the nuclear data used for computation of the phosphorus content. These samples were used as standards for the AES measurements.

Auger electron spectrometry.—AES measurements were performed with a Varian scanning Auger spectrometer equipped with a single pass CMA analyzer.

To obtain meaningful results, it was necessary to lower the electron current density on the sample by rastering the defocused primary beam over the acceptance area of the spectrometer. When the cylindrical mirror analyzer (CMA) was operated with the wider slits (energy resolution $\Delta E/E$ = 1.2% and 2.4%) it was possible to keep the current density in the range of 10^{-4} A/cm^2, while maintaining a relatively high total current (1 μA). At these $\Delta E/E$ settings the resolution of the low energy Si and P_{LVV} peaks was still good and, at the same time, the electron beam artifacts described above were avoided. A low energy electron gun (Varian Model 981-2781) was used to neutralize the positive charging of the samples when they were ion etched.

Chemical shift in AES measurements.—It is well known that the low energy Auger peaks involving electrons in the valence band are very sensitive for a number of elements to the chemical environment. This occurs, for instance, for boron, aluminum, and silicon in the respective oxides; the low energy LVV peaks are very similar [see Fig. 1 of Ref. (3) for B and Si], both in their shape, energy shift from the elemental peak, and separation of the satellite peak at the low energy side. For phosphorus the P_{LVV} peak, both for phosphorus implanted or diffused in silicon and for phosphorus in P-glass, is reported in the literature at 120 eV. Only recently a chemical shift has been observed in P-doped thermal oxide films grown on heavily doped polysilicon (4).

In the present work it is found that the P_{LVV} peak in the phosphosilicate glass (PSG) exhibits a 10 eV chemical shift from the elemental P_{LVV} peak at 120 eV and that the shape of this peak is very similar to that of the LVV peaks of oxidized B, Al, and Si.

Results

Auger electron spectrometry.—Measurements at low current density.—The results of the Auger measurements on the PSG system depend on the previous history of the sample and on the primary current density used during the analysis. A preliminary investigation was therefore necessary to establish the experimental conditions at which no electron beam artifacts could be observed for an irradiation time of several minutes, required for obtaining Auger spectra.

The following conditions were found to fulfill the requirement: primary energy, 1.5-2.0 keV; primary current, 1 μA; CMA modulation voltage, 2 eV. In addition the primary beam was fully defocused and rastered over an area of 640 × 640 μm^2; this area is comparable with the acceptance area of the spectrometer when operated at 1.2% energy resolution and well within it for the 2.4% setting. Measurements were performed either in high vacuum (p ~ 1 × 10^{-9} Torr), or in argon at a static pressure of 5 × 10^{-5} Torr.

The low energy region of the Auger spectrum obtained on sample 14, not previously ion etched, is shown in Fig. 1. This spectrum displays the usual Si_{LVV} peak of silicon bonded to oxygen at 76 eV, while the P_{LVV} peak is displayed at 110 eV, with a minor satellite peak at 94 eV.

The magnitude of the chemical shift of the P_{LVV} peak (10 eV) is very similar to that of B, Al, and Si in their oxides (respectively 11, 12, and 14 eV). Moreover, both the shape and the separation between the main and the satellite peaks are very similar for these four elements. We therefore assign the peak at 110 eV to the phosphorus bonded to oxygen.

The P (110 eV)/Si (76 eV) peak-to-peak height ratio is plotted in Fig. 2 as a function of the phosphorus content, as determined from activation analysis. A straight line passing through the origin is obtained, showing very good correlation between the two measurements. In this calibration curve several points are reported for sample 14; the measurements were taken at different times after the end of an ion etch. We will discuss this point in more detail later. A good reproducibility of the AES measurements was also found, as shown by the error bars in Fig. 2, provided no ion etching was performed. It was assumed that the P/Si

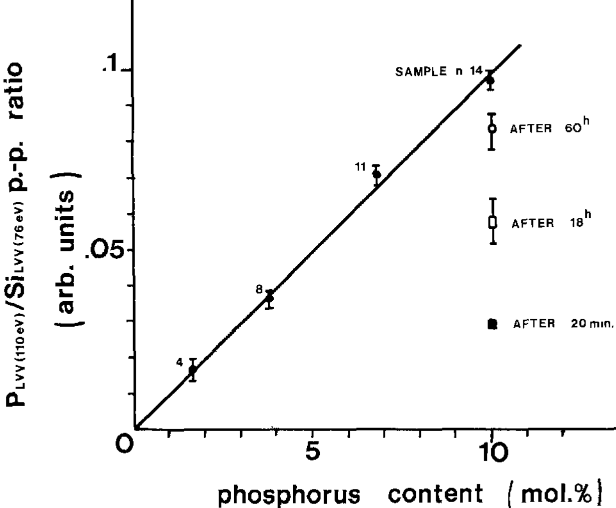

Fig. 2. Calibration curve of the P_{LVV} (110 eV)/Si_{LVV} (76 eV) peak-to-peak ratio vs. the phosphorus content (m/o) in P-doped silicon glass. The experimental points at the right-hand side represent the surface restoration with time after the ion beam irradiation.

ratio was relatively unaffected by the presence of the slight carbon contamination present on the samples, because both peaks will likely to be attenuated by the same amount.

Measurements at high current density: effect of the electron beam irradiation.—If the primary electron current density is increased, for instance by focusing the beam and decreasing the scan width, the P_{LVV} shifted peak disappears, while the unshifted, elemental phosphorus peak starts to increase after some "delay time." In Fig. 3 the p-p height of the P_{LVV} (120 eV) peak is reported as a function of the irradiation time. After the delay time the apparent surface concentration first increases linearly with the irradiation time, reaches a steady state, and then decreases to a very low value; finally the onset of charging occurs, which suggests that a variation in secondary emission coefficient has taken place. A similar variation of the P signal *vs.* irradiation time was also found by Chang in P-glass (5) and in silicon dioxide grown on heavily P-doped polysilicon (6).

The delay time, the steady-state value, and the onset of the final decrease of the P (120 eV) signal are functions of the current density. For a high enough current, the decrease can occur before the steady state is reached, or even shortly after the beam is turned on. These facts explain the measurement difficulties encountered in the early attempts in obtaining AES spectra of P-doped silicon dioxide.

Effect of the ion beam irradiation.—The bombardment with 1 keV Ar^+ ions causes a reduction effect in the PSG system. As shown in Fig. 4, the amplitude of the elemental phosphorus peak increases quickly with the irradiation time, reaching a steady state in a very short time; in the meanwhile the shifted phosphorus peak disappears. In contrast with the reduction effect caused by the electron beam irradiation, no delay time was found between the time the ion beam was turned on and the increase of the elemental peak amplitude.

When the ion beam is switched off, the elemental phosphorus peak decreases, while the shifted peak increases, as also shown in Fig. 4. The difference in the p-p height of the elemental peak before and after the ion beam was switched off is likely due to a charging effect or to an interference between the ion and electron beams. After the ion beam irradiation, the p-p amplitude of the shifted P_{LVV} peak does not immediately return to its original value but reaches a level which is only about 30% of the pre-irradiation value, showing that a partial phosphorus desorption is also induced by the ion irradiation. Nevertheless a nearly complete surface restoration was observed if the samples are left in the vacuum ambient for a long enough time. This is shown in the right-hand side of Fig. 2 where the P (110 eV)/Si (76 eV) peak amplitude ratio is reported, for sample 14, for different times after the irradiation experiment.

Discussion

Evaluation of the phosphorus content.—The AES measurements reported in this work show that the phosphorus in the PSG gives a P_{LVV} peak at 110 eV, which is chemically shifted from the elemental P peak at 120 eV. A direct evaluation of the phosphorus content from this peak and from the Si and O peaks was not possible, *a priori*, because no elemental sensitivity factors were available. In fact, the data obtained from activation analysis were used to generate the calibration curve of Fig. 2, which correlates the phosphorus content to the ratio between the shifted LVV peaks of phosphorus and silicon. This curve can now be used to obtain the phosphorus concentration in an unknown sample, provided that the electron and ion beam artifacts described above are avoided; moreover, from our data, we were able to obtain, *a posteriori*, an elemental sensitivity factor for the P_{LVV} (110 eV) relative to silicon in SiO_2 (76 eV) of 0.3.

A small carbon contamination does not hinder the phosphorus content evaluations because a similar at-

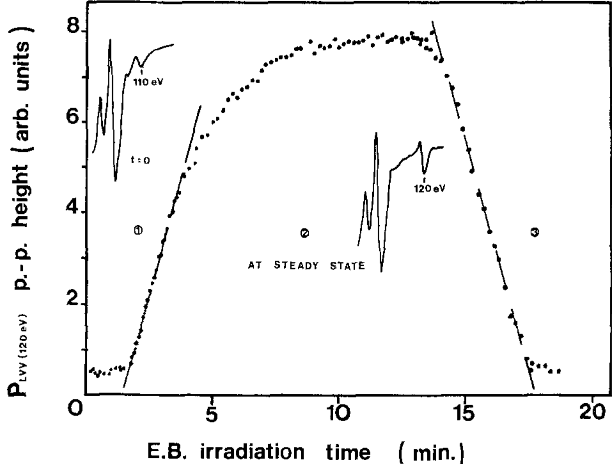

Fig. 3. Elemental phosphorus (120 eV) peak-to-peak height *vs.* electron beam irradiation time: region 1, surface accumulation; region 2, steady-state; region 3, desorption.

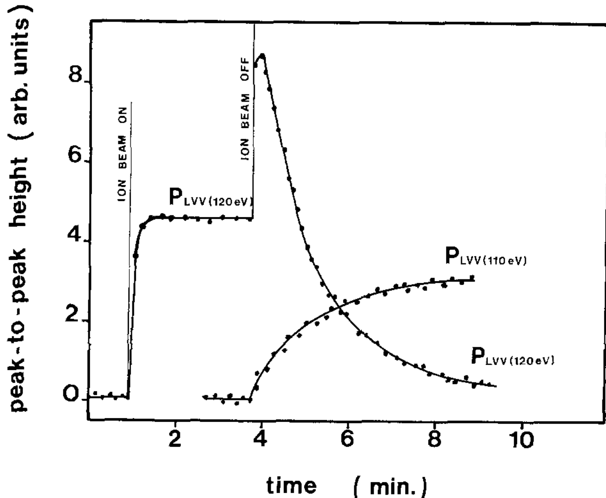

Fig. 4. Effects of ion beam irradiation (1 keV Ar^+) on the elemental (120 eV) and the oxidized (110 eV) phosphorus peaks.

tenuation of both Si and P peaks is expected. On the other hand, meaningful data can be also obtained after the removal of a heavy carbon contamination with ion beam etching if the sample is left in the vacuum ambient for a sufficiently long time.

Electron beam artifacts.—The effects produced by the electron beam irradiation are: a reduction of the phosphorus oxide, a P enrichment in the irradiated area, and a P desorption. At present the mechanism responsible for the phosphorus pileup in the electron irradiated zone is not well understood. A local thermal activation does not seem to justify the high mobility of P in PSG, since the temperature increase in the sample due to the energy dissipation of the electron beam was estimated to be a few degrees centigrade. Also not clear is the role of the "delay-time" which elapses between the electron beam switching on and the onset of the surface phosphorus enrichment.

Otherwise, in our experimental conditions the secondary electron yield is expected to be greater than unity (7). This means that a positive charge builds up in the oxide and a negative space charge, composed of low energy electrons, forms in front of the insulator. This space charge may be responsible for the surface phosphorus pileup found in region I of our irradiation experiment. The occurrence of a flat region after the surface accumulation denotes the onset of a steady-state condition in which the number of phosphorus ions reaching the sample surface is equal to the number of atoms leaving it. When no more P is available within a "diffusion length" from the irradiated volume, only the desorption mechanism is effective, as shown by the decrease of the P signal in region III of Fig. 3.

The phosphorus desorption is confirmed by the depth profile of Fig. 5, in which the p-p amplitude of the P_{LVV} peak at 120 eV is reported as a function of the sputtering time. To obtain this profile, it was necessary to take into proper account the effects of both the ion and electron beam irradiation. After the desorption step the primary current density was lowered by decreasing the beam current. The sputter etch rate during the sputtering was sufficiently high to avoid the P enrichment effect. The scanning width and the focus condition of the electron beam were left unchanged to avoid the collection of Auger electrons from areas not previously irradiated.

Another experimental evidence of the e-beam induced P desorption was obtained by etching the irradiated sample with a P-etch solution (1) which is known to be sensitive to the P concentration. The monochromatic light microphotograph of Fig. 6 shows a silicon-dioxide (nearly) phosphorus-free island of about 100 μm in diameter left on the silicon slice after the chemical etch. The etch rate of the irradiated zone was found to be very close to that of undoped CVD SiO_2 (~10 Å/sec) in contrast with a fast etch rate (~150 Å/sec) for the PSG. With additional chemical etch after removal of the PSG around the island, there was evidence of an increase of the chemical etch rate after a few seconds of overetch. This means that the P depleted zone is only near the surface, and likely equal to the energy dispersion volume of the primary e-beam in the oxide.

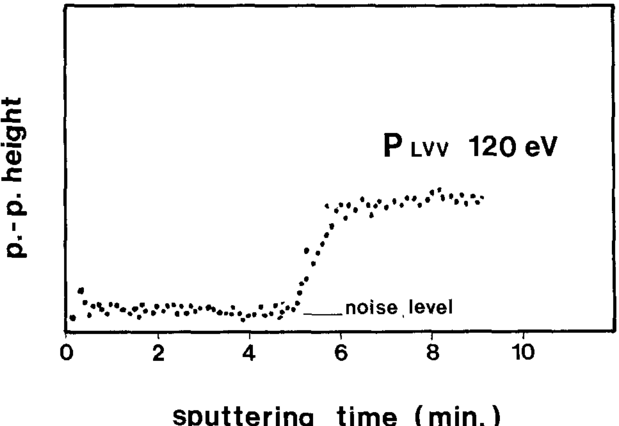

Fig. 5. P_{LVV} (120 eV) peak-to-peak amplitude from an irradiated area as a function of the sputtering time.

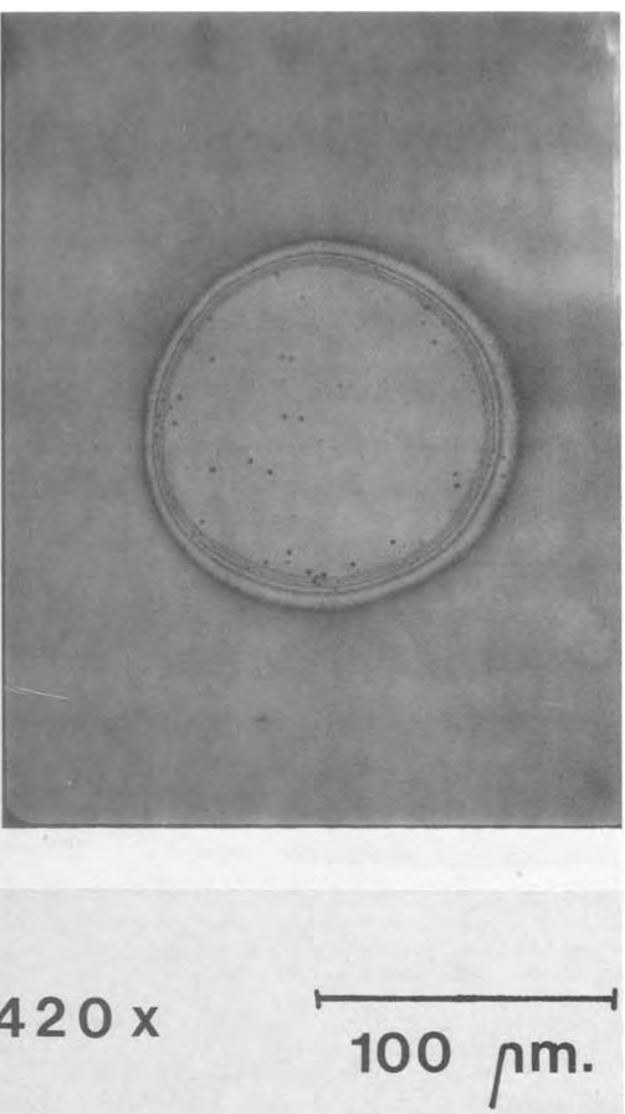

Fig. 6. Microphotograph showing a slow etching silicon dioxide island left after chemical etch of an electron beam irradiated sample.

It has to be mentioned that a glass sintering, which can occur during the e-beam irradiation, cannot explain the observed variation in etch rate. In fact, as already mentioned, only a very limited heating is expected with the primary current density used in the experiments; in addition we found that only a limited decrease in the etch rate was observed in the bulk of a P-doped CVD silicon dioxide film (about 10% phosphorus concentration) after a 2.25 hr annealing in dry nitrogen at temperatures ranging from 940° to 1050°C (8). In these annealing experiments, a noticeable variation in the etch rate was observed at the film/vacuum and film/silicon interfaces, which was attributed to a phosphorus depletion due to the P out-diffusion into the ambient and, respectively, the P diffusion into the silicon; these results also support the hypothesis that the electron beam induced variations in the etch rate are in fact due to the phosphorus desorption.

A numerical value for an "effective" diffusion coefficient of P^+ in PSG under electron irradiation can be obtained directly taking the conventional diffusion length $\lambda = 2\sqrt{Dt}$ equal to the range Rg of the primary electrons in the oxide, ignoring effects due to bulk or lateral boundary diffusion. From Ref. (9) and from Fig. 3 we have $Rg = 360Å$, $t = 10^3$ sec, and then $D = 3.24 \times 10^{-15}$ cm^2 sec^{-1}. For comparison, this value is nearly equal to the diffusion coefficient of P in SiO_2 at 700°C (10). Moreover our AES measurements show that in the PSG system, the P-O bonds are weaker than the Si-O bonds; in fact, while in our experimental conditions the silicon peak is practically unaffected by the e-beam, a complete reduction of the shifted P_{LVV} peak is noticed. So we can assume that in the PSG network the Si-O groups are the immobile constituents, while the P ions can move, for instance, under the influence of an electrostatic field. The fact that these ions, after the emission of an Auger electron, are double ionized can probably account for their very high mobility in the PSG system.

Ion beam effects.—In the ion beam irradiation experiments the increase of the peak-to-peak height of the elemental P_{LVV} peak and the occurrence of a steady state have a quite different meaning from the electron beam irradiation experiment. In fact, in this case the phenomenon is probably not connected with the P diffusion to the surface, but with a dynamical equilibrium between breaking of P-O bonds and their reconstruction. This is demonstrated by the disappearance of the elemental phosphorus peak at 120 eV and the concomitant appearance of the oxidized phosphorus peak at 110 eV after the ion beam is switched off. A similar effect has been recently reported by Chuang (11) for cobalt, iron, and nickel oxides.

Now let N_A be the number of the P-O broken bonds in the steady state and suppose that the P-O recombination follows a first-order kinetics law. After the ion beam is switched off we can write

$$\frac{dN}{dt} = -KN$$

and on integration, with the initial conditions $t = 0$, $N = N_A$, we obtain

$$N = N_A \exp(-Kt)$$

Provided that the peak-to-peak height in the Auger spectrum is proportional to the number of the emitting atoms, a plot in semilog coordinates of the peak-to-peak height of the elemental P_{LVV} peak (120 eV) *vs.* time should give a straight line. This was actually found experimentally as reported in Fig. 7 supporting the hypothesis of a first-order reaction kinetics.

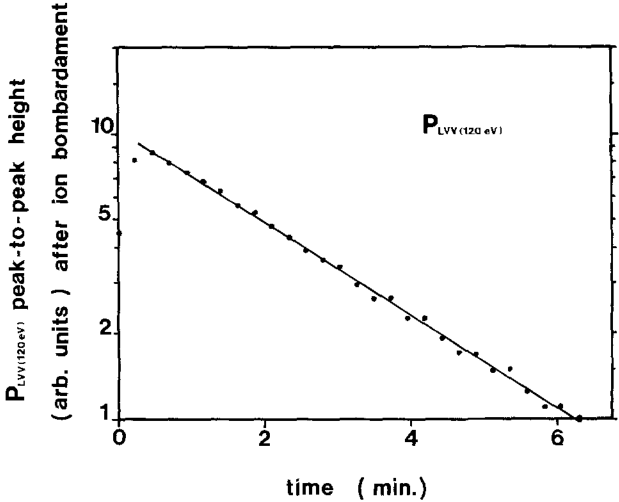

Fig. 7. Log-lin plot of the elemental phosphorus decay after the ion beam was switched off.

Conclusions

The following results were obtained in the present work.

1. The P_{LVV} peak in the PSG system has an energy of 110 eV. Its shape is very similar to that of LVV peak in oxidized B, Al, Si.

2. The ratio of the p-p amplitude of Si in SiO_2 and P in PSG peaks can be used to evaluate the phosphorus content of P-doped silicon dioxide.

3. The electron beam was found to induce, at high current density, a reduction effect, a diffusion-controlled phosphorus pileup, and finally a phosphorus desorption, which completely alters the oxide composition in the irradiated volume.

4. The ion beam was found to induce a reversible reduction effect, which recovers nearly completely if the sample is left in the vacuum ambient for long enough time.

All these artifacts demonstrate that great care must be taken when performing or interpreting depth profile experiments in P-doped silicon dioxide.

Effects of Conductor Stress on Bubble Propagation in Contiguous Disk Devices

I. L. Sanders and S. M. Kane

IBM Research Laboratory, San Jose, California 95193

and K. Y. Ahn

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Stress gradients associated with overlay conductors significantly degrade the propagation margins in ion-implanted contiguous-disk bubble devices. A study has been made of the influence of various conductor metallurgies, including Au, AlCu, and Cr deposited by vacuum evaporation and electroplating, on the bias margins of 1 μm bubble propagation along tracks with 5 μm circuit period. The conductors were 2.5 μm wide by 0.5 μm thick and were spaced 0.2 μm from the garnet surface. Annealing the devices at 250° and 350°C for 30 min in a helium atmosphere generally resulted in an increase in conductor stress and a further reduction in propagation margin. The bias margin loss due to the presence of the overlays depended upon track orientation, but for the so-called "good" tracks was typically 20% for evaporated Au and 27% for AlCu after the final anneal. A correlation between margin loss and the stress level in sheet films of the conductor metals was established and reveals a monotonic loss of margin with increasing stress. The results imply that for a margin reduction of no more than 10%, the conductor stress should not exceed $\sim 10^8$ dynes/cm^2.

It is known that metal stress effects can seriously impair the operation of magnetic bubble devices (1). Contiguous disk devices in particular are likely to be more sensitive to stress gradients at the edges of control conductors overlaying the propagation patterns than conventional permalloy devices. This is a consequence of the device structure which utilizes ion implantation to create a garnet drive layer with stress-induced planar anisotropy. The effect of the ion-implantation process is to place the garnet in a state of compression, so that providing the magnetostriction coefficient is negative (and sufficiently large), the stress-induced anisotropy predominates over the original perpendicular growth anisotropy. Charged domain walls in the garnet drive layer are responsible for bubble propagation. (2).

Stress interactions are of particular concern in the region of the transfer switches where a conductor may overlap the minor and major loops. If the conductor stress is too high, bubbles are frequently trapped preventing reliable minor loop propagation in addition to hindering the transfer function itself. Indeed, stress effects have been regarded so serious that considerable ingenuity has been exercised by device designers to produce novel chip layouts which do not require conductors that cross the propagation paths—these are the so-called self-aligned chips in which the control conductors and ion-implantation pattern are combined (3). Although it is too early at this stage in device development to be certain which approach, conventional or self-aligned, will find favor, it is clear that in either case a very low stress metallurgv must be sought in order to optimize contiguous disk technology.

In this paper, data are presented comparing the influence on bubble propagation of overlaid conductors of different metals deposited bv vacuum evaporation and electroplating. The effect of annealing is considered and the dependence of bias margin degradation on stress level in the overlay is discussed.

Device Fabrication and Materials

The composition and characteristics of the double layer garnet composites used in this study are given in Table I. In order to enhance domain contrast during visual testing, a thin reflective coating of chromium (500Å) was deposited by vacuum evaporation over a 200Å film of SiO_2 which served as a diffusion barrier between the garnet surface and the reflective layer, preventing interfacial diffusion during annealing (4). An additional 2000Å of SiO_2 was then sputtered onto the chromium as a spacer, simulating an actual device structure. The 5 μm period ion-implanted propagation patterns were defined with a 1.2 μm layer of Shipley AZ1350J photoresist. Prior to ion implantation, the photoresist was hardened by baking for 2 hr at 80°C; hardening of the resist image preserves the original pattern by preventing flow of the photoresist during the implantation process. The wafers were implanted with 3.5×10^{15} He^+/cm^2 at 135 keV, after which the resist mask was removed by ashing in an oxygen plasma.

Metallic stripes of chromium, aluminum-copper, and gold (2.5 and 5.0 μm wide and nominally 0.5 μm thick) running perpendicular to the direction of the propagation patterns, as shown in Fig. 1, were deposited by electron-beam evaporation using a lift-off technique. A 100Å film of niobium was evaporated beneath the gold to ensure adhesion to the SiO_2 layer. In addition, stripes of plated gold [BDT 510 and Pura 401[1]] were electrodeposited through a photoresist mask. Sheet films of the conductor metals were simultaneously deposited onto optically flat substrates to enable stress measurements to be made. The force due to the stress in these films produced bending of the

thin optical flats which was measured by the optical interference technique for observing Newton's rings (5).

Propagation margins were determined in the as-deposited state and after annealing for 30 min at 250° and 350°C in a helium atmosphere. The stress monitors were subjected to identical annealing conditions for the determination of stress levels.

Results and Discussion

Comparison of the effects of high stress Cr and low stress AlCu overlay conductors on quasistatic bias margins is made in Fig. 2, as a function of track orientation. Margins are also shown for similar propagation patterns over which there was no conductor. The data shown were taken after the sample had been annealed at 250°C. The dependence of propagation margins on track orientation with respect to the crystallographic axes of the drive layer has been discussed at length by Lin *et al.* (6) and will not be reiterated. It is sufficient here to note that good tracks are those in which the propagation axis is parallel to one of the bubble stripeout directions (that is, the $[\bar{1}\bar{1}2]$, $[\bar{1}2\bar{1}]$, or $[2\bar{1}\bar{1}]$ crystal directions), and that the super (bad) tracks are those having a stripeout direction pointing into (away from) the cusps. The variations in margins with track type shown in Fig. 2 are quite typical and are consistent with previously reported results.

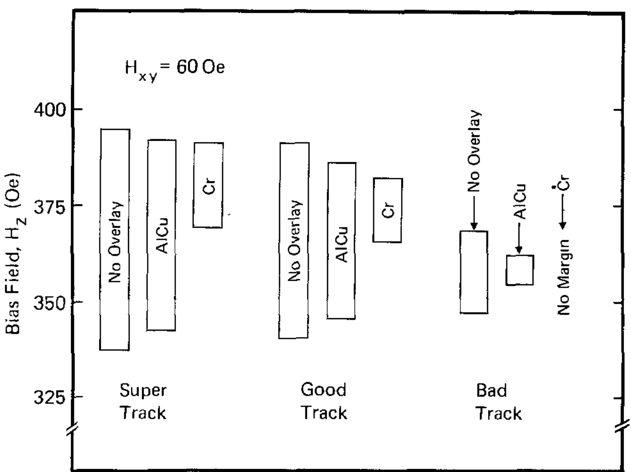

Fig. 2. Effect of high stress (Cr) and low stress (AlCu) overlay on margins for the three principal track orientations. Data taken after annealing device at 250°C for 30 min.

Although the data given in this section apply to conductors of 2.5 μm width, little difference could be detected with the wider (5.0 μm) overlays and suggests that conductor width is not critical in this range. The measured stress in sheet films of the Cr and AlCu was 92 × 10^8 and 17 × 10^8 dynes/cm^2, respectively, after annealing at 250°C. It is apparent that at 60 oe in-plane drive the highly stressed Cr significantly reduced the propagation margins on all tracks and actually prohibited any reliable bubble propagation on the bad track. As expected the effect of the AlCu conductors was much less severe, but was also most noticeable on the bad track where a 62% (13 oe) reduction in margin occurred. In contrast, a margin loss of only 12% (7 oe) was found for the super track, whilst the good tracks suffered a degradation of 29% (11 oe).

The failure mechanism at the lower limit of the margin due to the overlay was usually bubble hang-up at the point where the edge of the conductor crossed the propagation pattern. More rarely the bubble was observed to stripeout along the conductor edge to an adjacent propagation loop. At high bias the failure mode was invariably bubble collapse at the edge of the conductor. A roughly equal loss of upper and lower margin on the good track was typical.

A systematic study of the effect of varying the placement of the conductor with respect to the propagation patterns was not made. However, the overlay mask was designed such that the spacing between conductors was not an integral number of propagation periods. In this way the conductor edges did not coincide with any one particular point on the propagation track, but rather allowed a worst-case assessment of the margins to be made. On the good tracks it was found that, at low bias, the bubbles were most susceptible to hang-up when the conductor edge was slightly displaced from the center of the cusp, toward the direction of propagation. Under these conditions a bubble encounters the stress gradient just as it attempts to leave the cusp, where, it should be noted, the inherent edge affinity can sometimes cause hang-up (7) even in the absence of any external stress effects. This position of the conductor also seemed to be least favorable at the higher margin limit and resulted in early bubble collapse.

Isochronal annealing of the devices at 250° and 350°C for 30 min generally caused an increase in the conductor stress level and a consequent degradation of propagation margins. Propagation along tracks on which there was no overlay also suffered some reduction of margin; the data for the good tracks is summarized in Table II. For consistency, therefore, the relative margin loss due to conductor stress effects is referred to propagation margins determined on chips subjected to identical anneals. Figure 3 shows the dependence of this margin loss on annealing conditions for overlay conductors of evaporated AlCu, and evaporated and electroplated Au. In each case the margins steadily deteriorate with increased annealing temperature. Although wafer 1 was not tested in the as-deposited state, the close correlation with the data from wafer 2 for the AlCu overlay after annealing at 250° and 350°C is very encouraging. The BDT 510 plated Au and the evaporated Nb/Au metallurgies were found to be superior to AlCu from the point of view of stress effects and resulted in a margin loss of 20% after the final anneal, compared to ~26% for the AlCu. Pura 401 plated Au produced

the greatest margin loss at each stage of the annealing process.

The measured stress levels in sheet films of the metals considered above can be deduced from the numbered data points of Fig. 4 where margin loss is plotted *vs.* tensile stress. The figure reveals a monotonic loss of bias margin with increasing conductor stress in the range 1×10^8-90×10^8 dynes/cm^2, regardless of metal type or annealing condition. Although there is considerable scatter in the data, the correlation between margin degradation and stress

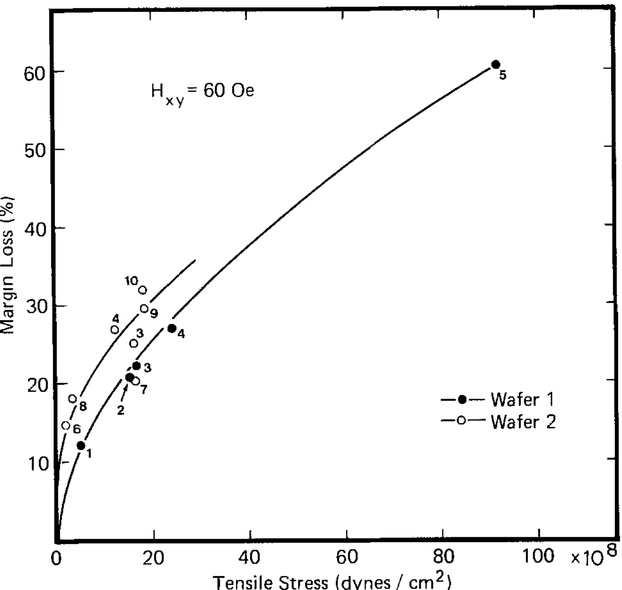

Fig. 4. Relationship between margin loss and tensile stress in sheet films. 1, Au, BDT 510-annealed 250°C; 2, Au, BDT 510-annealed 350°C; 3, AlCu-annealed 250°C; 4, AlCu-annealed 350°C; 5, Cr-annealed 250°C; 6, Nb/Au-as deposited; 7, Nb/Au-annealed 250°C/350°C; 8, Au, Pura 401-as deposited; 9, Au, Pura 401-annealed 250°C; 10, Au, Pura 401-annealed 350°C.

is nevertheless felt to be remarkable in view of the variables involved in an experiment of this nature. Wafer 1 appears to show a somewhat smaller margin loss than wafer 2 for comparable conductor stress levels; the reason for this difference is not obvious. However, for the type of device structure described here, the results imply that if a margin loss of greater than ~10% cannot be tolerated, conductor metallurgies with stress not exceeding 10^8 dynes/cm^2 are required.

Conclusions

The interaction between overlay conductors and bubble propagation in 5 μm period ion-implanted structures has been studied. The results which have focused on good track behavior, show that the presence of conductor stress is manifest as a bias margin loss at the upper and lower extremes. At high bias the conductor caused premature bubble collapse while at low bias bubble stripeout or hang-up was observed along the conductor edge. The loss of margin invariably became more significant after annealing samples at 250° and 350°C. Evaporated gold was found to produce less deterioration of bias margin than evaporated AlCu of the same thickness (~0.5 μm), both before and after annealing. A correlation between margin degradation and stress level in sheet films of the conductor metal has been established and indicates that a conductor stress of less than 10^8 dynes/cm^2 is necessary for a margin loss on the order of 10%. Clearly, low-stress metallurgies for contiguous disk device applications must be developed; there would seem to be a considerable amount of work still to be done in this area.

Stability of LPCVD Polysilicon Gates on Thin Oxides

S. P. Murarka,* A. K. Sinha,* and H. J. Levinstein

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Polysilicon films of thicknesses in the range of 1000-4700Å were characterized as regards (*i*) pinhole density and (*ii*) electrical properties of the fabricated MOS capacitors on 1000Å gate oxide. The effect of processing treatments were examined. It was found that (*i*) the phosphorus diffusion led to pinholes and higher freak population, the density of these being higher in thinner films, and (*ii*) the phosphorus glass flow caused lower median breakdown fields and higher freak population. On the other hand thermal oxidation and the exposure to window plasma etch did not have any effect on the breakdown field or freak population. High temperature anneal after aluminum deposition led to lower Q_{ss} and breakdown field in all films. It is concluded that polysilicon films thicker than 2000Å can be safely used as the MOS gate for VLSI devices.

The evolution towards higher levels of MOS-IC integration has led to the use of thinner polysilicon films and this raises concern about its integrity during processing. Degradation of the polysilicon films and consequently of the underlying gate oxide could result from pinholes formed either during the deposition of the film or during such processing steps which consume polysilicon, namely, phosphorus doping in an oxidizing ambient (1), oxidation (2, 3.), and aluminum silicon interactions (4-7) during low temperature hydrogen anneal. To the best of the authors' knowledge no similar studies have been reported except that Kamins *et al.* (8) have reported the results of their study of the structure of LPCVD [low pressure chemical vapor deposition (9)] polysilicon films and their stability during further heat-treatment.

The object of the present work was to characterize polysilicon films of various thicknesses as regards to (*i*) the pinhole density in such films and (*ii*) the electrical properties of the fabricated MOS gates. The effect of various processing treatments on these properties was evaluated. Polysilicon films of thicknesses from 1000 to 4700Å deposited on 1000Å gate oxide were used. It was found that polysilicon films more than 2000Å thick are stable under all individual processing conditions and are stable under most sequential processings required to produce MOS capacitors. Although the results are given for a 1000Å thick gate oxide, most of the results should be applicable to thinner oxides.

Experimental

Only (100) p-type 7.5 cm diam and nominally 8-12 Ω-cm Si wafers were used. After cleaning thermal dry oxide was grown at 1100°C to form 1000Å gate oxide which was annealed *in situ* for 30 min in argon at the same temperature. Low pressure CVD polysilicon films were then deposited at 630°C. Doping was carried out in PBr_3 at 1000°C for 30 min. The resulting phosphorus glass was approximately 300-400Å thick. The glass was removed in dilute HF solution. In some cases a second doping of the polysilicon films was carried out in a similar manner. The sheet resistance of doped films was measured using a four-point probe. Aluminum metal films (~7000Å thick) were evaporated though a shadow mask on the front surface giving 500 μm dots. The polysilicon films were then plasma-etched using the aluminum dots as mask. A back-aluminum contact was applied and the structure was annealed at 450°C in hydrogen for 30 min prior to electrical measurements.

Oxide breakdown measurements were made with negative applied fields (4), so as to keep the capacitor under accumulation. At least 100 breakdown measurements were made on each wafer using a General Automation minicomputer controlled test system (10) with increasing voltage ramp. The current was set at 2μA. Figure 1 shows a typical log-normal distribution plot of the breakdown voltage (BV). From this, the median dielectric strength, $\epsilon_{50\%}$, the standard deviation, σ [$= \ln \epsilon_{50}/\epsilon_{16}$] and the percent of freaks, f were obtained, freaks being defined as capacitors with a breakdown field of < 6 MV cm^{-1} (11). In many cases, the usual MOS characteristics (such as *C-V* plots, bias temperature effect etc.) were also measured to qualify the oxide.

Several kinds of treatments were given to the polysilicon films prior to metallization with Al. Tables I, II and IV describe these experimental procedures.

Results

Pinholes in Undoped and Doped Polysilicon Films

Experiment 1.—In employing the technique described in Table I, it was assumed that if there were pinholes in the polysilicon films, by immersing such wafers in buffered hydrofluoric acid (BHF) solution for a reasonably long time, the etching of the gate oxide underneath would reproduce the pinholes in oxide. KOH solution would then etch the substrate and thus reproduce the pinholes in oxide as etch pits. The etch pits have crystallographic features depending on the substrate orientation and thus are easily distinguished from any other pits or contaminants on surface.

No etch pits were observed on the undoped polysilicon films with thickness in the range of 1000-4700Å. On the other hand, etch pits were observed in thinner polysilicon films prior to metallization with Al Tables Figure 2 shows the SEM micrographs of the pinholes in 1000 and 2000Å polysilicon films doped once in

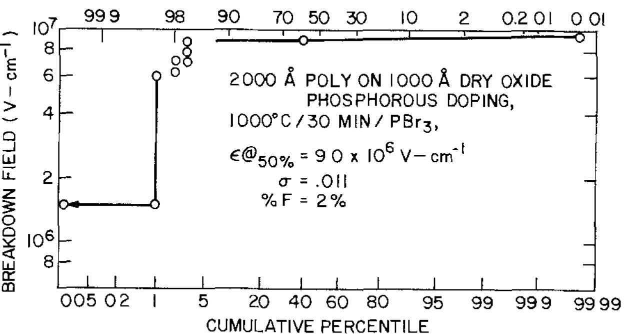

Fig. 1. A typical log-normal distribution plot of the breakdown field. The sample had 1000Å gate oxide and polysilicon film doped once at 1000°C with PBr_3 for 30 min and was annealed at 450°C in hydrogen for 30 min after aluminum.

Key words: films, electrical properties, MOS capacitors.

Table I. Experiment 1: direct observation of pinholes in polysilicon films

1. Various thicknesses of the film (1000, 2000, 3000, 4000, and 4700A) were used in this experiment. All were deposited on a 1000A thermal oxide on silicon substrates.
2. Samples were divided in various groups.
   a. Undoped films
   b. Single doping at 1000°C/30 min in PBr_3, P-glass removed in 50:1 HF
   c. Double doping, *i.e.*, a second 1000°C/30 min in PBr_3 (after the first and P-glass removal), P-glass removed in 50:1 HF
3. All exposed to 20 min in (10:1) BHF.
4. Polysilicon etched in all cases, in KOH solution, Exposure to KOH solution was always a minute or two longer than that required for etching polysilicon only.
5. Examine all oxides for holes.

PBr_3. The density of pinholes in 1000Å film was high and variable across the wafer surface as shown in Fig. 2A (high density) and in Fig. 2B (low density). Figure 2C shows the density of etch pits caused by pinholes in 2000Å polysilicon film. The halo around the dark pits is due to undercutting of the silicon under the oxide.

The pinhole density, represented by the etch pit density such as those shown in Fig. 2, decreased in going from 1000 to 2000Å polysilicon films. For 3000Å film, only a few pinholes were found near the edge of the wafer. For all practical purposes there were no pinholes in films with thicknesses of 3000, 4000, and 4700Å. Also the density of pinholes in thinner films was higher in those cases where two phosphorus diffusions were carried out as compared to films where only one phosphorus diffusion was carried out. This is due to conversion of a few hundred angstroms of polysilicon into SiO_2 during each diffusion step.

Electrical Measurements—Effect of Doping and BHF Exposure

Experiment 2.—If there are pinholes in polysilicon, which lead to holes in oxide during a BHF exposure, aluminum metallization of the polysilicon will cause substrate to metal shorts. Thus electrical measurements of the oxide breakdown characteristics provide a means to substantiate the findings of the previous section. As a result of the wafer processing described in Table II, we had 4 sets of wafers for measurements.

Figure 3 shows a plot of the sheet resistance as a function of the nominal polysilicon thickness for as-deposited films. Points for both singly and doubly doped films have been shown. The sheet resistance increased considerably for thinner films, and after the second doping the 1000Å film is no longer conducting. As suggested above, this was due to consumption of polysilicon during the two diffusions. For thicker films sheet resistance decreased as a result of the second phosphorus diffusion.

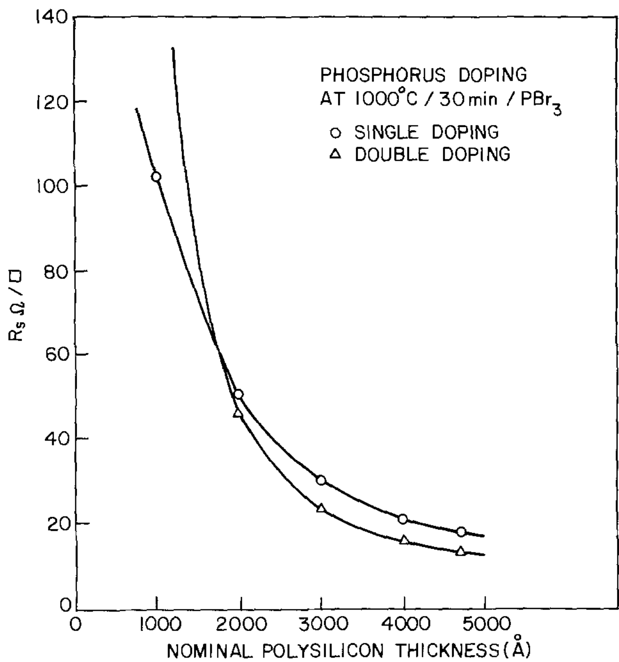

Fig. 3. Sheet resistance of various polysilicon films as a function of the thickness for one or two diffusions.

Table IIA summarizes the results of the breakdown measurements on the four sets of samples processed according to Table II. All devices, irrespective of the polysilicon film thickness, show excellent breakdown voltages. The freak population f is high for capacitors made on singly doped 1000Å film and there were no working capacitors on 1000Å polysilicon films in sets B, C, and D. Similarly the freak population increased after the second doping and after BHF exposure indicating an increase in the number of capacitors with premature breakdowns after these treatments. None of the thicker polysilicon devices showed these trends. These results clearly confirm the pinhole density results of the previous sections.

Effect of Phosphorus Glass Deposition and Flow

Experiment 3.—Samples for this experiment were processed as described in Table II, steps 1-4. This was then followed by a ~10,000Å P-glass deposition, glass

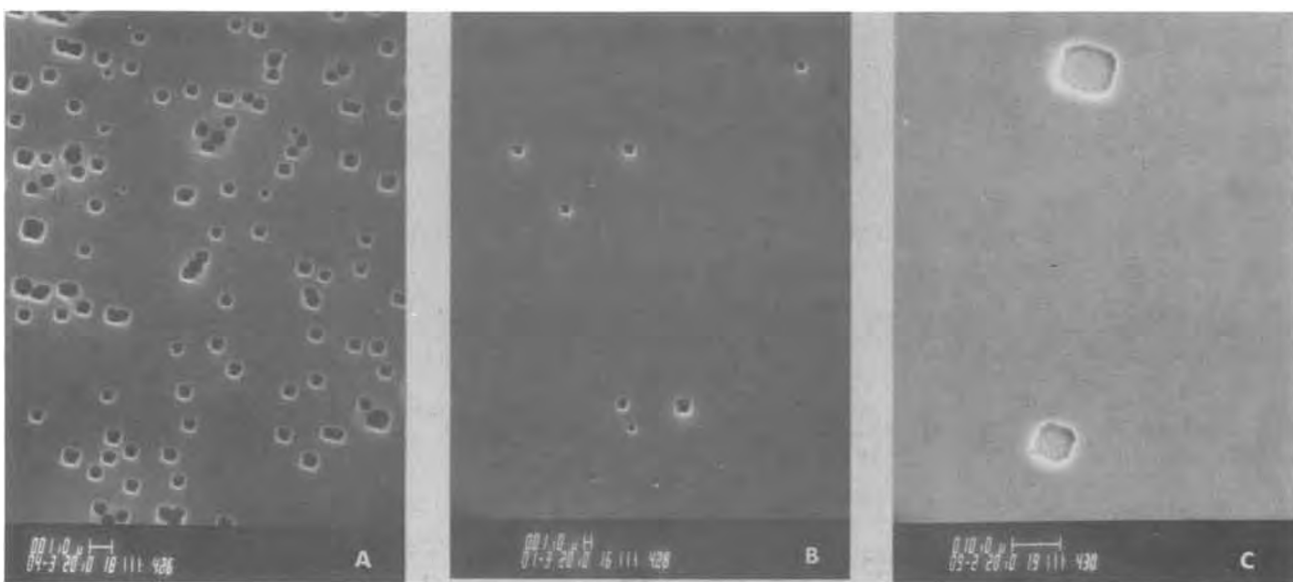

Fig. 2. SEM photographs of the holes in substrate silicon (and oxide). A and B show varying pinhole density across the surface of the wafer with 1000Å polysilicon film and C shows the pinhole density, in case of 2000Å polysilicon film (see Table I).

Table II. Experiment 2: effect of doping and BHF exposure on the electrical characteristics

1. All wafers, 1000°C/PBr_3/30 min. Remove p-glass in 50:1 HF. Measure sheet resistance. Remove controls (Set A) and those for second doping.
2. Expose wafers to 20 min in (10:1) BHF. Measure sheet resistance (set B).
3. Wafers from (1), for second doping, all these wafers, 1000°C/PBr_3/30 min. Remove p-glass in 50:1 HF. Measure sheet resistance. Remove controls (set C).
4. Expose these second group of wafers to 20 min in 10:1 BHF. Measure sheet resistance (set D).
5. All 4 sets of wafers: evaporate aluminum 7000A through a mask to form 500 μm dots. Evaporate Al on back for back contact. Etch polysilicon using Al dots as mask, clean, and anneal 450°C/30 min/H_2.
6. Electrical measurements.

reflow, removal of all P glass in (10:1) BHF, aluminum metallization (step 5, Table II), and electrical measurements. Table III presents the results. The effect of phosphorus glass deposition and flow is noticeable in the median breakdown voltage as is shown in Fig. 4. Only the results of singly doped films are shown. Results are similar (and worse) for doubly doped films. It is clear from these results that the use of phosphorus glass leads to lowering of the breakdown voltage in all the films.

A summary of all the data on freak population is shown in Fig. 5. In this figure A, B, C, and D on abscissa define the samples described by set A, B, C, and D, respectively, for each thickness of the polysilicon films. For thin films ($\lesssim$ 2000Å), the freak population increases with any additional processing following the first doping of the films. For thicker films, the freak population is invariant for all additional processings except for the phosphorus glass deposition and flow. In all cases the use of phosphorus glass led to a higher freak population.

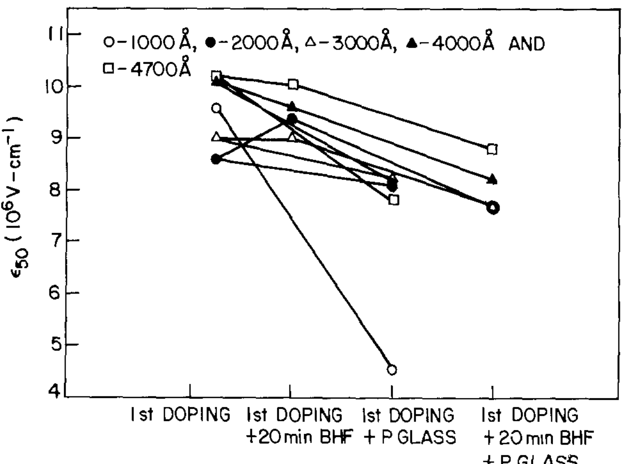

Fig. 4. Shows a plot of the median breakdown field as a function of various treatments given to polysilicon films of various thicknesses. A line between two points indicate direct jump from one process to another represented by those points.

Effect of Oxidation and Window Plasma Etch

Experiment 4.—During device processing polysilicon films go through oxidation, oxide removal, and are

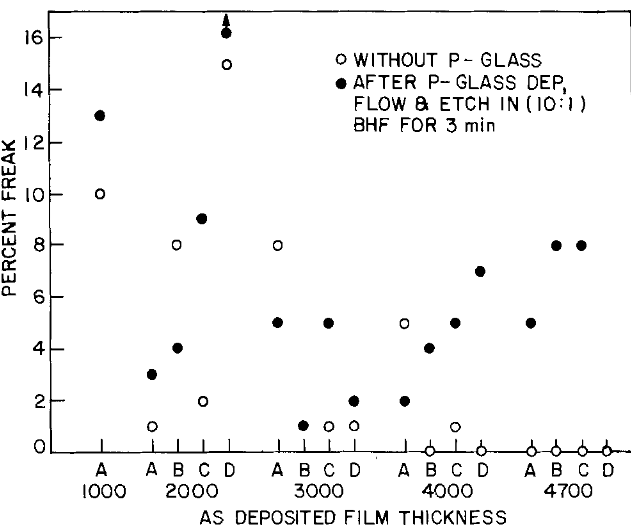

Fig. 5. Shows a plot of the freak population (f) as a function of the various processing and the polysilicon film thickness. Results for samples with and without phosphorus glass deposition and flow are shown. For 1000Å polysilicon films, no working capacitors were left after treatments B, C, and D.

exposed to window plasma etch. Experiment 4 was carried out (using 4700Å thick polysilicon films) to determine the stability of the gate oxide MOS capacitors exposed to these conditions.

The results of this experiment (Table IV) are presented in Table IVA. It is clear from these data that dry oxidation and exposure to phosphorus glass removal etch did not have any damaging effect on the breakdown characteristics of the gate oxide under the 4700Å polysilicon film.

Effect of 450°C vs. 550°C Hydrogen Anneal on the Stability of MOS Capacitors

Experiment 5.—Some of the samples, which were annealed at 450°C in hydrogen for 20 min, were reannealed (after electrical measurements) at 550°C in hydrogen for 30 min. This second anneal was carried out to evaluate the effect of aluminum-polysilicon interaction on the breakdown and MOS characteristics of the gate-oxide capacitors. Table V presents these results for polysilicon films of various thicknesses. Al-

though Q_{SS} (the fixed surface state charge, given in units electron charge) is highly variable for samples with different polysilicon film thicknesses, the important thing is that Q_{SS} and the breakdown field (ϵ_{50}) are lowered as a result of 550°C anneal. Freak population appears to increase in thin polysilicon capacitors and decrease in thicker (>2000Å) polysilicon capacitors. Similar results were obtained for MOS devices made from 4000Å thick polysilicon films subjected to 20 min BHF immersion and to second phosphorus diffusion with or without 20 min BHF immersion. Breakdown field was always lowered due to 550°C anneal.

Effect of Aluminum-Silicon Interactions on the Integrity of the Polysilicon Films

Aluminum and silicon interact at the device annealing temperatures, leading to a voluminous movement of silicon into the aluminum (4-7). As a result of this movement, holes are left in the silicon and precipitates of silicon are formed in aluminum. The surface of the polysilicon films on our samples of Experiment 3 was examined after the aluminum was etched off in hot (60°-70°C) phosphoric acid diluted with acetic acid, nitric acid, and water

$$(H_3PO_4:CH_3COOH:HNO_3:H_2O = 85:5:5:5)$$

SEM was used to examine the surface. Pinholes were found in all polysilicon films irrespective of thickness or the treatment prior to aluminum deposition and anneal. Figure 6 (A and C) shows the SEM micrographs of some of the samples which were all doped with phosphorus once (1000°C, 30 min, PBr_3). The density of holes is high for the thinner (2000Å) films. For thicker films the density appears to be lower. Prior to aluminum deposition, there were no pinholes in polysilicon films of 3000, 4000, and 4700Å films (Experiment 1). The hot aluminum etch, used for less than a minute, does not attack polysilicon films. Therefore, the holes in these films are solely due to the aluminum-silicon interaction.

In contrast to the results of Fig. 6 (A and C), we saw both holes and precipitates on polysilicon films which were doped twice at 1000°C in PBr_3. Figure 6 (B and D) shows the surface of the various polysilicon films after aluminum had been etched off. Once again hole density is larger in 2000Å films than in thicker films. The density of the precipitated particles appears to be more or less the same in all cases. Also as in case of Fig. 6 (A and C), we saw only holes near the edge of the capacitors. The density of the holes in the area near the edge was much larger than that in the rest of the capacitor surface.

The holes in the polysilicon never have a simple defined geometrical shape. It appears that holes always form at the grain boundaries in the polysilicon. We are not certain if they run through the whole thickness of the film to the oxide surface or through only a small part of the polysilicon. In the latter case, exposure to BHF will not lead to pinholes in oxide and consequently to aluminum substrate shorts.

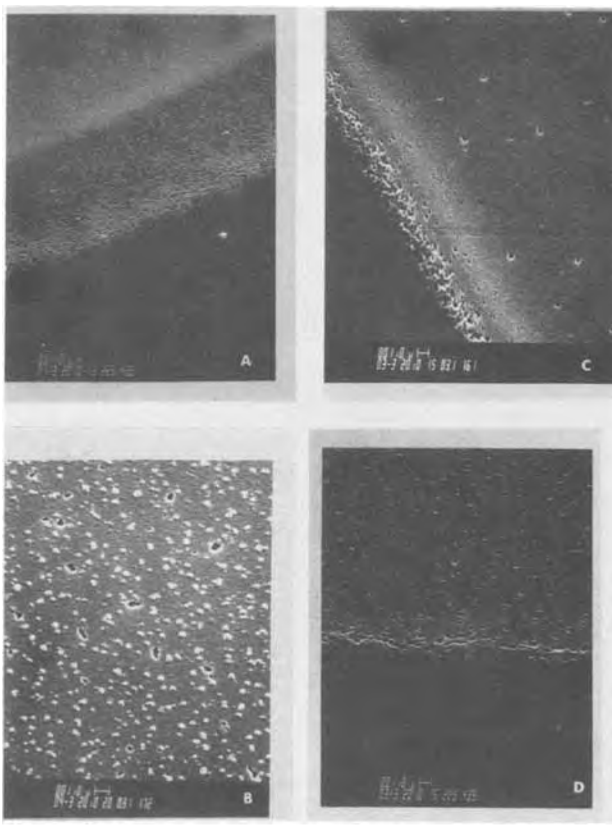

Fig. 6. Defects in polysilicon films formed as a result of the 450°C/30 min/hydrogen anneal after aluminum deposition. Aluminum was etched off prior to examination. A and C: Polysilicon was doped with phosphorus once at 1000°C for 30 min in PBr_3. B and D: Polysilicon in these samples was doped twice with phosphorus, each time at 1000°C for 30 min in PBr_3.

Discussion

Depending on the thickness, the polysilicon films may have pinholes (*i*) in as-deposited films, (*ii*) due to phosphorus diffusion which is known to cause preferential grain growth (13, 14) perpendicular to the substrate surface and consumption of silicon, (*iii*) during oxidation, which may oxidize the grain boundaries followed by BHF exposure which then etches out oxide from grain boundaries, (*iv*) during phosphorus glass deposition and reflow, the effect being similar to that during phosphorus diffusion; this treatment may also lead to diffusion of unwanted impurities into the active areas of the devices, (*v*) during plasma etching, which may preferentially etch along grain boundaries and also drive the impurities in the gate region, and (*vi*) during the hydrogen anneal with aluminum metal on, due to the ensuing Al-Si interactions.

The undoped polysilicon films even as thin as 1000Å thick, did not have pinholes through which BHF could etch the oxide underneath. On phosphorus doping, pinholes did form. The density of these holes decreased very rapidly with increasing film thickness (Experiment 1). This density increased due to second doping as is evidenced by the high resistivity (Fig. 2) of 1000Å film after second doping and higher failure rate of the capacitors in 1000 and 2000Å films. The second phosphorus doping did not affect the median breakdown field of the working capacitors. Similarly dry oxidation and/or exposure of polysilicon to phosphorus glass plasma etch (no phosphorus glass deposition or flow) did not affect the breakdown characteristics of the capacitors (Table IIA). Thus in the absence of pinholes, phosphorus diffusion or BHF exposure or P-glass plasma etch does not affect gate oxide breakdown characteristics.

Deposition of the phosphorus glass and the subsequent reflow seem to affect the breakdown characteristics. The median breakdown field was lowered and the freak population increased (Fig. 3 and 4). These results indicate that the phosphorus glass deposition and reflow, which is a high temperature process, cause damage to the gate oxide. Phosphorus glass could trap impurities which then diffuse to Al-gate-oxide polysilicon interface and which also get into the oxide grown on polysilicon. This leads to lower median breakdown fields. The increase in the freak population could both be due to the pinholes due to phosphorus diffusion as discussed earlier and due to entrapment of excessive impurities in some areas of the wafer.

The device degradation, as evidenced by the lowering of the median breakdown field due to 550°C anneal (Table V), could also occur due to the migration of aluminum to gate oxide-polysilicon interface and due to silicon dissolution into aluminum. In an independent study with aluminum alone as the gate metal, it was found that the 550°C anneal indeed decreased the median breakdown field. In view of the above our recommendations for the LPCVD polysilicon film, as gate material, would be to: (*i*) use films of thickness greater than 2000Å; (*ii*) dope the films with phosphorus preferably at lower temperatures and for lower time periods; (*iii*) avoid direct contact with phosphorus glass (which usually flows at 1100°C), a thermal oxide between polysilicon and phosphorus glass may act as a barrier to the diffusants which lower breakdown fields and cause higher failure rates; and (*iv*) use lower aluminum annealing temperatures, to avoid Ai-Si interactions.

Acknowledgments

The authors would like to thank C. Sarday for all the electrical measurement, W. S. Lindenberger for the SEM work, M. Grieco for polysilicon deposition, E. I. Povilonis for the processing help, and E. Kinsbron for discussions concerning grain growth in polysilicon.

Electrochromism in Solid Phosphotungstic Acid

B. Tell

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

The performance of electrochromic cells containing solid phosphotungstic acid including voltammograms, degradation, field-assisted bleaching, and open-circuit memory is presented.

We have previously discussed various aspects of the operation of electrochromic cells containing the heteropoly acids, such as phosphotungstic acid (PWA) (1, 2). These materials are hydrates forming a cubic structure (3) with representative formula $H_3PO_4(WO_3)_{12}:29H_2O$. PWA is a proton superionic conductor [$\sigma = 1\ (\Omega cm)^{-1}$ near room temperature] (4, 5) and an electronic insulator, which makes possible a self-contained electrochromic cell without the necessity of an additional electronic blocking layer. Our previous reports discussed various aspects of the electrochromic performance. In the present report, we present additional data of these effects, as well as voltammograms and a discussion of the open-circuit memory.

The basic arrangement is shown in Fig. 1. A powder of PWA containing a few percent of an opacifier such as TiO_2 is compressed to a thickness of 1-2 mm at ~150 kg/cm² in a ceramic tube against the working electrode, a transparent SnO_2 coated glass slide (2). The coloration mechanism is assumed similar to that of the WO_3[6] electrochromic cells and results from the reduction of W^{+6} under injection of electrons at the SnO_2 contact with simultaneous space charge neutralization by protons from the medium. The reaction, associated with the tungsten cage, is then

$$e + H^+ + W^{+6}O_3 \rightleftarrows HW^{+5}O_3 \quad [1]$$

$$\text{white} \leftrightarrows \text{blue}$$

The back or counterelectrode was usually a carbon powder with a carbon rod for contact to the external world. For comparison purposes, as will be discussed later, the PWA was also contacted directly with metal electrodes such as copper and stainless steel. While the SnO_2 working electrode is capable of electron injection only, the counterelectrode must provide charge neutrality by proton or other ion injection, or readily exist in several oxidation states.

Shelf-life degradation of these cells due to loss of water has been a major problem. This degradation is manifested by an increase in cell resistance along with nonuniform coloration at the viewing electrode. However, with more careful cleaning and encapsulation procedures, including encapsulating the carbon rod, adequate cell performance has been acheived after a shelf-life of two to three months. If a degraded cell is opened and placed for several days in a humidifier, approximately the original performance is regained. This indicates that the shelf-life degradation is still due to inadequate hermetical sealing permitting a slow loss of water from the cells.

Electrochromic Performance

Important factors concerning electrochromic cells include the achievable optical density change, the coloration and bleaching speeds, the efficiency, and the lifetime. In the present cells, which are compressed powders, the change in diffuse reflectivity at the viewing electrode is the quantity of interest. Optical density (OD) changes of -0.1 where $OD = \log_{10}(R/R_o)$ are observable in PWA in ordinary room light. OD changes ~ -0.3 are readily obtained at 0.6 μm in 25 msec with voltages of ~1V.

The optical coloration efficiency is defined as Eff $= OD/(Q/A)$ which is the optical density change divided by the injected charge per unit area in units of cm²/C. At the peak of the efficiency wavelength curve, the efficiency is typically in the range of 100-150 cm²/C. These values are comparable to or larger than those observed in WO_3 (6,7). A typical wavelength dependence is shown in Fig. 2 for a 1V, 25 msec pulse yielding an injected charge density of 2.7 mC/cm² (obtained from the average current times the time). In Fig. 3 is shown the OD change as a function of injected charge. It is seen that the efficiency is constant for OD changes below ~ -0.3, but decreases at higher injected charge. This decrease could be due to the coloration depth becoming greater than the optical penetration depth.

Although we have not been able to quantitatively fit the bleaching profiles, we wish to show that the

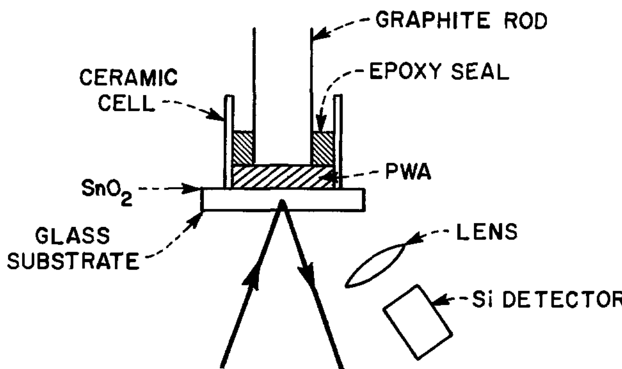

Fig. 1. The diagram of the experimental setup. The direct scattered light is blocked, while the diffuse scattered light is focused by a large diameter lens into an Si detector.

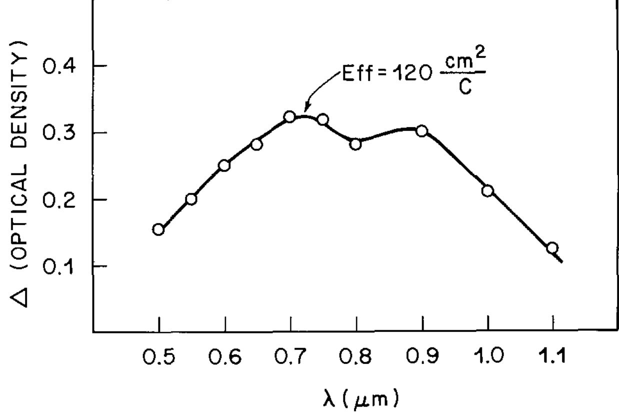

Fig. 2. Typical optical density change as a function of wavelength for a 1V, 25 msec coloring pulse and 1.3V bleaching pulse. The peak efficiency is indicated.

Key words: voltammograms, degradation, field-assisted bleaching, open-circuit memory.

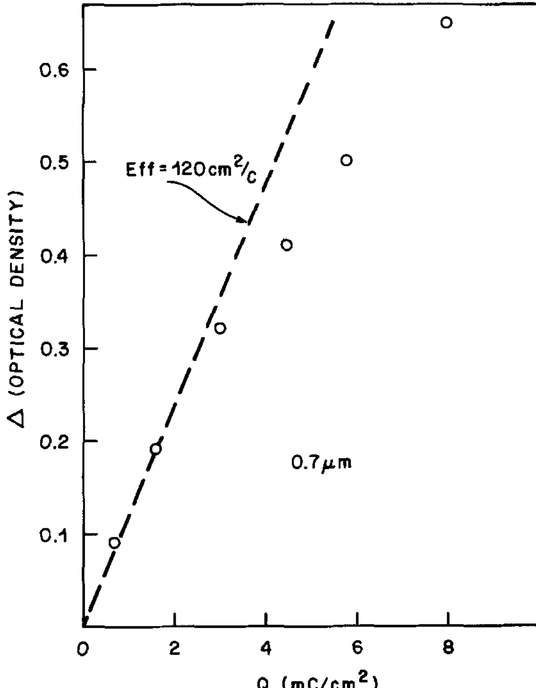

Fig. 3. The optical density change as a function of injected charge illustrating the deviation of the efficiency from linearity at higher optical density changes.

field-assisted bleaching is a diffusion-type phenomena. The bleaching time is insensitive to the magnitude of the bleaching voltage, at least for voltages above ~0.5V. However, the field-assisted bleaching time varies with the *OD* change, presumably due to an increase in coloration depth. This effect is illustrated in Fig. 4, where a PWA sample was colored in 25 msec to an *OD* of −0.26 (triangles) and −0.6 (circles), respectively, and bleached with a positive voltage of 1.2V applied between the SnO_2 viewing electrode with respect to a carbon counterelectrode. For purposes of comparison, the initial *OD* change has for both cases been normalized to unity.

The actual distribution of colored centers (*i.e.*, W^{+5}) due to electron injection at the SnO_2 contact is not known. However, it appears that for large initial *OD* changes, the coloration depth is larger than the optical absorption length. Then, a fit to the shape of the bleaching curve can be obtained by assuming diffusion in a semi-infinite medium with the SnO_2 boundary acting as a perfect sink. The distribution of reduced centers $N_R(x, t)$ is given by

$$N_R(x,t) = N_R(O) \operatorname{erf} \frac{x}{\sqrt{4Dt}} \quad [2]$$

where x is the distance from the SnO_2 contact, and $N_R(O)$ is the initial distribution of reduced centers which is assumed to be constant. The optical density change is proportional to the total number of reduced centers within an optical absorption length l. That is

$$OD \sim \int_0^l N_R(x,t)dx \quad [3]$$

The *OD* as a function of time can be obtained in terms of the parameter $l^2/4D$, and a fit to the bleaching profile can be obtained, as shown by the dashed line in Fig. 4. The shape is fit for times less than 700 msec, after which the experimental *OD* values become less than the calculated profile. This deviation results from the assumption of a constant density semi-infinite depth distribution, whereas the actual profile must peak near the origin and drop off in a finite distance. It is also seen in Fig. 4 that when colored to a relatively low *OD* (given by the triangles) the *OD* decreases significantly faster. For coloration depths shorter or comparable to the absorption length, the detailed distribution of reduced centers is important, and a fit of the bleaching curve has not been obtained

Another illustration of an increase in bleaching time is given in Fig. 5. Here, a PWA cell is colored to an *OD* change of −0.4 (*i.e.*, diffuse reflectivity 40% of its bleached value), and in one case immediately bleached (bleaching potential ~ 1.2V) and in the other case maintaining open-circuit conditions for 100 msec. The open-circuit condition produces a slower decay of the optical density, which can again be attributed to diffusion of the colored centers (*i.e.*, electrons) away from the SnO_2 contact during the open-circuit condition. The removal of the electrons from a greater coloration depth results in a longer bleaching characteristic.

As far as operating stability, we have obtained *OD* changes of −0.3 with 25 msec coloration time run at 2 Hz for more than 10^5 cycles, without noticeable degradation. We have found that provided the cell is not overdriven (so that large optical density changes followed by incomplete bleaching are not produced), the operating life does not appear limited. Even in the above, if high operating voltages (>2V) have not produced noticeable damage at the SnO_2 interface, cells with C electrodes can be revitalized by sustained bleaching. On the other hand, cells with metal electrodes can become irreversibly colored.

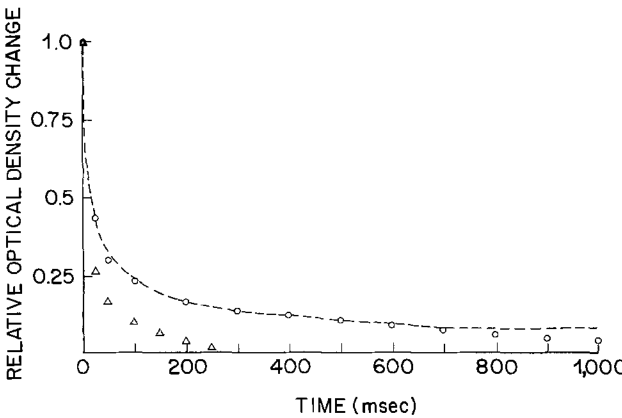

Fig. 4. Illustration of the increase in bleaching time for a cell colored to an initial OD of −0.6 (circles) compared to a cell colored to −0.26 (triangles), with the initial coloration normalized to unity.

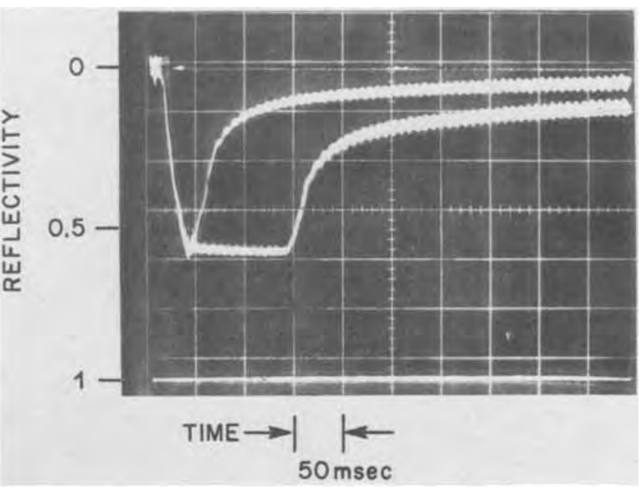

Fig. 5. Illustration of the increase in bleaching time for a cell maintained open circuit for 100 msec compared to a cell immediately bleached.

Voltammograms

The voltammograms for PWA were obtained with respect to an Ag reference electrode inserted in a hole drilled in the ceramic tube. The Ag had been previously anodized in H_3PO_4. Voltammograms are given for the SnO_2 working electrode and for carbon, copper, and stainless steel counterelectrodes as shown in Fig. 6a, b, and c, respectively. The purpose was to compare carbon electrodes with electrodes capable of injecting mobile foreign ions such as Cu^+, and noninjecting electrodes containing readily oxidizable elements such as Fe and Ni. The possibility of the carbon-containing surface groups to absorb the redox charge requirements while releasing H^+ has been previously discussed (2). It is seen that the carbon electrode is slightly anodic and maintains a nearly constant potential over the oxidation-reduction cycle. The Cu electrode is slightly cathodic and also exhibits only a small potential change over the entire cycle. The stainless steel electrode remains cathodic over the entire cycle, but exhibits a large potential variation. This electrode becomes highly cathodic under reducing conditions, *i.e.*, it must be brought to a large negative potential to be reduced, but readily oxidizes. It is also seen from these voltammograms that in the two electrode configuration (*i.e.*, working electrode and counterelectrode), the Cu and stainless steel cells will color under short-circuit conditions whereas the carbon cell will bleach, and that in the latter case, coloration requires application of a small negative potential to the SnO_2 electrode, *i.e.*, a slight coloration threshold. In addition to this short-circuit coloration, cells containing metal electrodes become significantly colored in about one week under open-circuit conditions. This is presumably due to the spontaneous reduction of tungsten by various metals, followed by a slow diffusion of the colored species to the viewing electrode. The coloration can be removed by application of a bleaching voltage, but returns when open-circuit conditions are reestablished. Both from the voltammograms and the discussions above, carbon electrodes are superior to the other electrodes discussed.

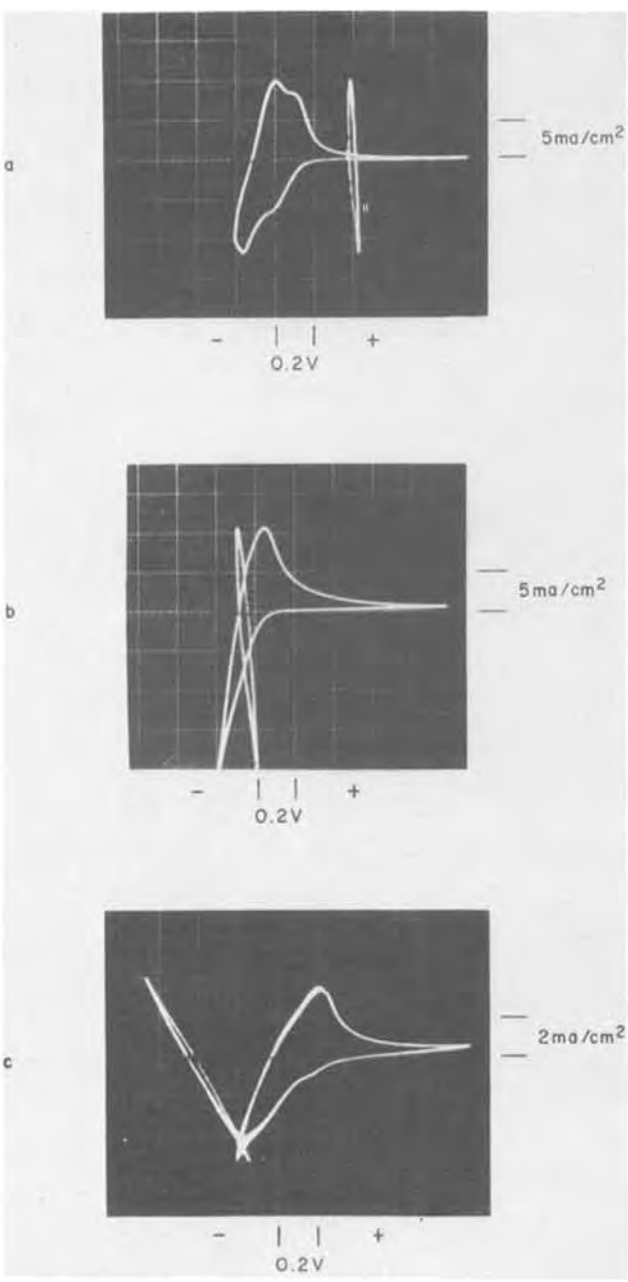

Fig. 6. Voltammograms of the SnO_2 working electrode and the counterelectrode (a, carbon; b, copper; c, stainless steel) with respect to the reference electrode for a sweep rate of 1 V/sec. The polarity with respect to the reference electrode is indicated.

Memory

The existence of open-circuit memory is a potentially attractive feature of electrochromic cells. Here, we wish to discuss the long-term memory in distinction from the short (~100 msec) memory discussed previously. Once a pattern has been impressed by means of an electric field, it may be retained without further expenditure of power for various times. The memory decay reported here does not appear to be an intrinsic property of the PWA, but is more likely due to the presence of residual oxygen. In WO_3 cells, the memory can be appreciably shortened as well as the efficiency being reduced by the presence of oxygen (8, 9). A possible reaction describing the loss of memory due to oxygen is

$$4HWO_3 + O_2 \rightarrow 2H_2O + WO_3 \quad [4]$$

$$\text{blue} \rightarrow \text{white}$$

In addition, the loss of efficiency during coloration could be due to a reaction such as

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O \quad [5]$$

This means that a percentage of the injected electrons and the accompanying protons are not available for reduction of tungsten as given by Eq. [1], but are instead expended in a parasitic reaction such as given above. When an oxidizing agent such as H_2O_2 or HNO_3 is intentionally added, we have found both a large reduction in the efficiency (factors of 2 or 3) and especially the open-circuit memory (~ orders of magnitude). However, simple techniques for reducing the residual oxygen, such as bubbling argon through the PWA during preparation have not given significant improvement.

In addition to the memory decay due to residual oxygen, a possible diffusion loss could occur since the colored depth is only a fraction of the sample length. Since the residual oxygen decay appears faster, we have not yet observed evidence for a diffusion mechanism.

The *OD* decrease has been various combinations of linear and exponential with time. An exponential decay indicates a simple loss mechanism, when the oxidizing agent is within the same geometrical region. A linear decay can indicate a loss mechanism in a porous medium when the oxidizing agent comes from outside the colored region (10). The loss of the reduced species N_R can be described by

$$\frac{dN_R}{dt} = -\frac{N_R}{\tau} - a \quad [6]$$

where τ is the loss time constant, which if due to tungsten oxidation by oxygen would be equal to a rate

constant per oxygen atom divided by the oxygen concentration, while a is the flux of oxygen entering the colored region from the PWA bulk. The solution is

$$N_R = N_R(0)\, e^{-t/\tau} - a\tau(1 - e^{-t/\tau}) \qquad [7]$$

where $N_R(0)$ is the reduced density at $t = 0$. When the oxygen density in the colored region is high compared to $N_R(0)$, the first term dominates and exponential decay occurs. If $N_R(0)$ is large compared to the immediate oxygen density, τ is long and the second term dominates, and the decay becomes linear. Also, as suggested above, the time constant τ is only constant if the oxygen density is large compared to the reduced tungsten density. If, during coloration, a significant fraction of the oxygen is depleted, as suggested by Eq. [5], the time constant will be different for successive colorations if the oxygen level has not returned to its original value. For a given cell, we expect the memory decay to be slower the higher the original optical density, and to be slower for successive cycles provided the residual oxygen has not been regenerated. An example of such memory behavior is shown in Fig. 7. The curve marked first cycle was bleached (~1.5V bias) prior to coloration and fits an exponential decay (solid curve) with a time constant of ~100 sec. After the initial *OD* change had decayed to near zero, the cell was maintained in open-circuit condition, and then colored a second time (second cycle). It is seen that the *OD* has increased compared to the first cycle, but more noticeable, the loss of memory is now characterized by a time constant or perhaps linear decay closer to 1000 sec. Finally, if the cell is now bleached, and then colored by two successive pulses spaced approximately a second apart, an initial fast memory decay occurs, followed by a slow decay which appears linear. Although there are cell-to-cell variations in the times involved, the general features of the memory are such as described above.

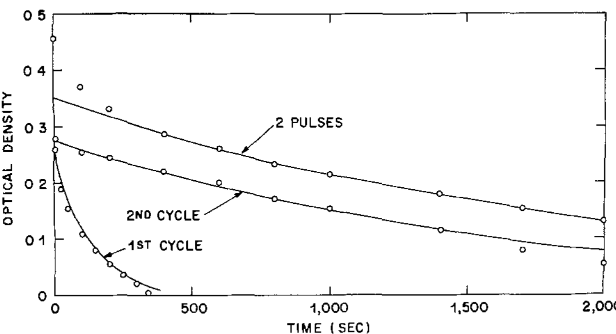

Fig. 7. Typical open-circuit memory for PWA as discussed in text.

Conclusions

In this paper, we have presented a fuller discussion of our results on PWA-type electrochromic cells. It is shown that these cells are simple to fabricate and are capable of reasonably efficient and fast electrochromic performance. However, the shelf-life is still unsatisfactory, while the open-circuit memory is complex and variable. Any further work on these cells should be concerned with increasing the shelf-life and removing all traces of residual oxygen.

A Novel Method for Measuring the Thermal Conductivity of Electrodeposited Gold Films

Peter G. Borden

Varian Associates, Incorporated, Corporate Solid State Laboratory, Palo Alto, California 94303

ABSTRACT

A simple method for determining the thermal conductivity, K, of electrodeposited gold films is described. Specifically, it is shown how a comparison of the resistance-temperature and resistance-current characteristics of a ribbon of the film leads to a unique determination of K. When applied to a film typical of those used in semiconductor device heat sink structures, the technique yields a value of $K = 2.50 \pm 0.13$ W/cm-°K, as compared to the value for bulk gold of 3.15 W/cm-°K.

Thick electrodeposited gold films are frequently used to heat sink power semiconductor devices such as FET's (1) and microwave diodes (2). The observed performance of such devices often indicates that the thermal conductivity of such films is well below that of bulk gold (3). It is quite surprising, then, that a thorough literature search, including computer searches

Key words: gold plating, thick gold films.

of NTIS and journal publications, has found no reported study of the thermal conductivity of electrodeposited gold since 1949 (4). Furthermore, the 1949 value of 2.96 W/cm-°K is incorrectly referenced, making confirmation impossible.

The present investigation considers the thermal conductivity of gold platings with respect to semiconductor device applications. Specifically, a simple, straightforward technique for the measurement of the thermal conductivity of such films is described. This is then applied to a film formed by methods typical of modern device fabrication, yielding a value about 20% below that of bulk gold.

Theory

The technique employs a comparison of the resistance-temperature and resistance-current characteristics of a self-supporting ribbon of the film to uniquely determine the thermal conductivity. A ribbon of the gold film, of length L and cross-sectional area A, is mounted between two supports of constant temperature T_o, as shown in Fig. 1. As a current I causes ohmic heating, the ribbon's resistance will rise due to its temperature coefficient of resistivity. Knowledge of this coefficient, the current, and the sample resistance at T_o allows determination of the thermal conductivity, K.

The conduction of heat generated by an electrical current in a wire has previously been considered (5). Here we follow similar procedures to find the resistance-current relation required to determine the thermal conductivity. Typically, the sample is long and of small cross section, so that the one-dimensional heat flow equation describes the temperature distribution; that is

$$KA\frac{\partial^2 T(x)}{\partial x^2} = -P \qquad [1]$$

Here, P is the dissipated power per unit length. The thermal conductivity is assumed constant in temperature and thermal expansion is ignored. For a sample resistivity ρ of the form

$$\rho(T) = \rho_0 + \rho_1 T \qquad [2]$$

Equation [1] takes the form

$$\frac{\partial^2 T}{\partial x^2} + \frac{I^2\rho_1}{A^2K}T + \frac{I^2\rho_0}{A^2K} = 0 \qquad [3]$$

It should be noted that the linear form of Eq. [2] is usually accurate for bulk metals, and, as will be seen, appears to hold for the electrodeposited gold considered here. This assumption allows a straightforward solution of Eq. [3] under the assumption of constant temperature at the ends ($T(x = -L/2) = T(x = L/2) = T_o$), yielding a temperature distribution in the ribbon of

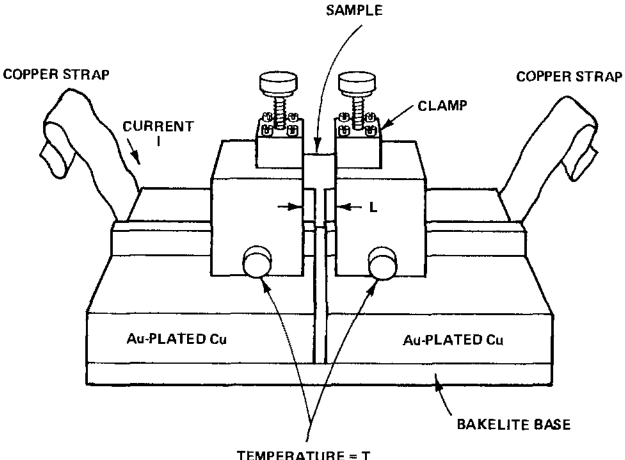

Fig. 1. The sample jig

$$T(x) = \left(T_o + \frac{\rho_0}{\rho_1}\right)\sec\frac{\alpha L}{2}\cos\alpha x - \frac{\rho_0}{\rho_1} \qquad [4]$$

where

$$\alpha = \frac{I}{A}\sqrt{\frac{\rho_1}{K}} \qquad [5]$$

Finally, the sample resistance is found from Eq. [2] and [4]

$$R(I) = \frac{1}{A}\int_{-L/2}^{L/2}\rho(x)dx = R_o\frac{\tan\left(\frac{\alpha L}{2}\right)}{\left(\frac{\alpha L}{2}\right)} \qquad [6]$$

with R_o the resistance at temperature T_o

$$R_o = (\rho_0 + \rho_1 T_o)L/A \qquad [7]$$

Thus, a measurement of $R(I)$ allows α to be found through Eq. [6]. An independent measurement of the temperature coefficient of resistance, ρ_1, gives the thermal conductivity K through Eq. [5].

As an example, a 1 cm long, 100 × 12.5 μm gold ribbon with $\rho_0 = -1.77 \times 10^{-7}$ Ω-cm and $\rho_1 = 8.05 \times 10^{-9}$ Ω-cm/°K (these values are obtained from a fit of published resistivity data (6)) has a resistance of $R_o = 0.179Ω$ at $T_o = 300$°K. With a current of $I = 0.2$A and a thermal conductivity of $K = 3.15$ W/cm-°K (7), $\alpha = 0.809$ cm^{-1} and the fractional change in resistance is 5.8%. The temperature rise at the center is 25°K.

The principal loss mechanisms are convection and blackbody radiation. Convective loss is difficult to estimate; for this reason, the experiment is conducted in a vacuum. Empirical results indicate that for pressures under 10^{-3} Torr, the resistance of a typical sample is independent of pressure. Blackbody losses are considered in the Appendix, where it is shown that a prudent choice of sample dimensions will minimize this effect.

Sample Preparation

The sample is prepared with techniques similar to those used in plating a heat sink structure to the back of a semiconductor device. A standard ohmic contact metallization of 40 nm Au-Ge, 7.5 nm Ni, and 60 nm Au is laid down on a GaAs wafer doped to 1 × 10^{18}/cm^3 with Te. The wafer is then held in a bath of Selrex 125, a pH-5 critic acid-based solution designed for fast plating of thick, high purity matte-finish films. The bath was held in a beaker at 60°C and kept under circulation with a magnetic stirrer. About 10 μm of gold were plated out at a current density of 0.3 mA/cm^2.

Ribbons are formed by photolithographic definition and etching in a KI-I_2 etch. After stripping the photoresist, the ribbons are separated from the substrate by etching the GaAs with a $5H_2SO_4$: $1H_2O_2$: $1H_2O$ etch.

Figure 2 shows top and side SEM views of a typical ribbon. The cross section, as determined by both weighing (assuming the density of bulk gold) and photography, is 60.0 × 9.7 μm. Figure 3 shows an SEM picture of the grain structure; the average size is 550 nm. Figure 4 is a Laue backscatter picture of the gold on the GaAs wafer, indicating that its crystallographic orientation is essentially random. This isotropy is significant, as it implies the thermal conductivity should be independent of direction. Thus, a longitudinal measurement is equivalent to a measurement through the thickness of the film.

Experimental Setup

The sample jig is made of gold-plated copper to ensure both good thermal conductivity and corrosion-free mechanical and electrical connections. Heavy copper straps are used as leads in order to minimize series resistance.

Initially, the jig with a mounted sample is placed in a vacuum oven. The resistance *vs.* temperature charac-

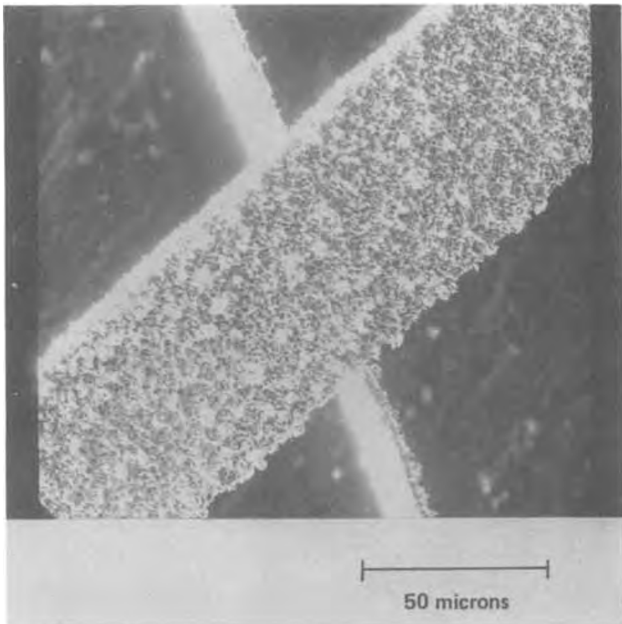

Fig. 2. Top and side views of a typical ribbon of electrodeposited gold.

teristic is measured. The jig is next removed from the vacuum oven and placed in a high vacuum system, where the resistance *vs.* current characteristic is determined. Analysis of the data, as already outlined, yields the thermal conductivity.

In the vacuum oven, temperature was monitored with a mercury thermometer. The wire resistance was found with a 5½ digit multimeter. Shorting the sample with a strap allowed measurement of the stray resistance. The current-resistance measurement used a PAR 172 precision current source, a 3½ digit DVM to monitor the current, and the 5½ digit multimeter to find the voltage drop at the sample. Samples are measured twice, once from low to high current and once from high to low. The resistance is found to be stable and reproducible for each value of current.

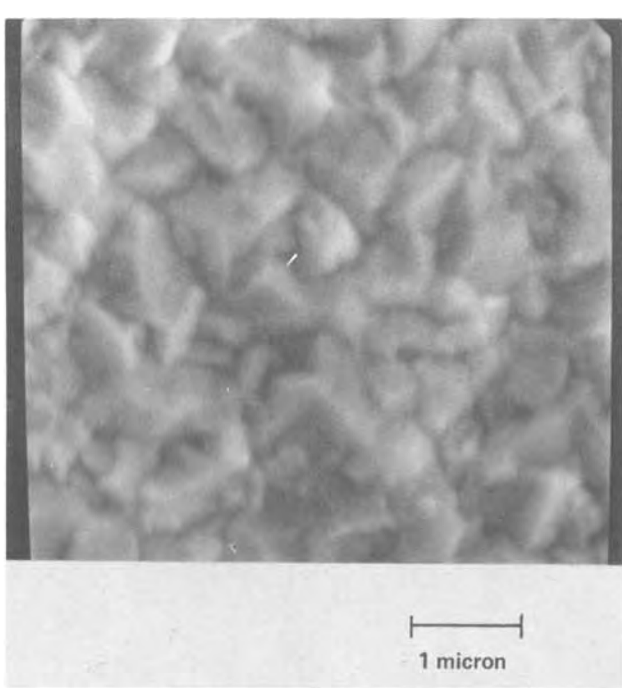

Fig. 3. An SEM view of the grain structure of a ribbon of electrodeposited gold. The average size is 550 nm.

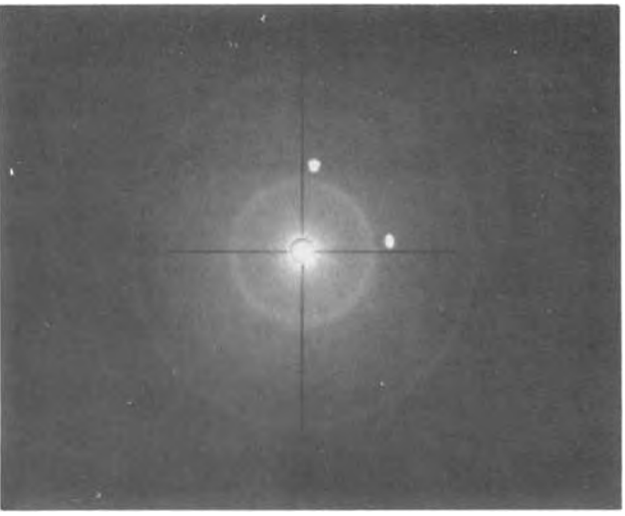

Fig. 4. A Laue backscatter picture of the electrodeposited film on the GaAs substrate. The concentric rings indicate isotropy of the film. The dots are due to the substrate.

Results

Measurements have been performed on both cold-rolled 11 × 100 μm bonding ribbons and ribbons of electrodeposited gold formed by the technique already described. Figure 5a shows a plot of the resistivity-temperature characteristic for a 1.07 cm length of the bonding ribbon. The thermal coefficient of resistivity $\rho_1 = 8.14 \times 10^{-9}$ Ω-cm/°K compares well to the tabulated value of 8.05×10^{-9} Ω-cm/°K (7). Differences in the value of ρ_0 from tabulated values are largely due to series resistance and do not have an effect on the thermal conductivity measurement.

Figure 6a shows the current-resistance characteristic for this ribbon. Analysis of these data yields a thermal conductivity of $K = 2.9$ W/cm-°K, in reasonable agreement with the bulk value of 3.15 W/cm-°K (6). Note also the excellent fit of the data to Eq. [6].

The resistivity-temperature characteristic of the electrodeposited gold ribbon is shown in Fig. 5b. The sample was 0.884-cm long with a cross-sectional area of 5.8×10^{-6} cm^2. The thermal coefficient of resistance is 9.93×10^{-9} Ω-cm/°K, 22% higher than for the bonding ribbon. The current-resistance characteristic is shown in Fig. 6b. The thermal conductivity of 2.50 ± 0.13 W/cm-°K is 20% below the bulk value. This is consistent with estimates obtained from the performance of microwave devices employing similar gold films in their heat sink structures.

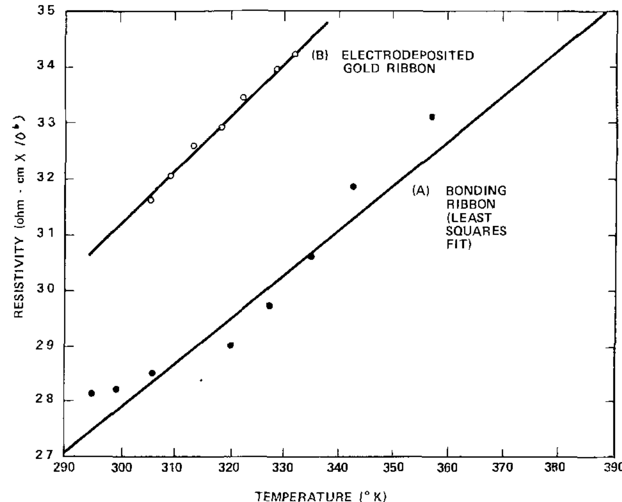

Fig. 5. Resistivity-temperature characteristics for (a) a gold bonding ribbon and (b) a ribbon made from electrodeposited gold.

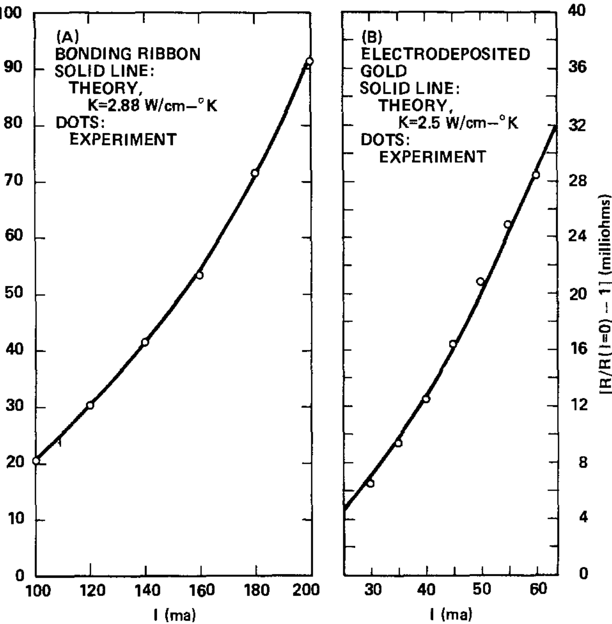

Fig. 6. The current-resistance characteristic of (a) the 1.07 cm long, 11 × 100 μm bonding ribbon and (b) the 0.884 cm long, 60.0 × 9.7 μm ribbon of electrodeposited gold. The theoretical characteristic, as determined by Eq. [6], is also plotted for both cases.

Conclusions

The great diversity in plating solutions and conditions in common use make the thermal conductivity of electrodeposited gold films quite variable. Nevertheless, because this property significantly affects the performance of devices employing plated gold in heat sinks, it is important to have available a technique for measuring the thermal conductivity of these films. This study has addressed this situation in two ways. First, a simple and straightforward measurement technique has been described. Second, a value has been found for a film typical of those used in semiconductor device plated heat sinks, showing that the thermal conductivity can indeed be significantly below the bulk value. This might be expected, both because of the large number of grain boundaries in the electrodeposited film and the possibility of the inclusion of impurities during formation.

It must be re-emphasized that the technique's simplicity to a large degree stems from assuming isotropy of the thermal conductivity. This appears to be valid on the basis of Laue backscatter photographs of the plated film, which show an essentially random crystal orientation.

Finally, it is noted that the technique may be applicable to other materials that are electrically conducting and can be formed as self-supporting ribbons, such as silver, nickel, and copper.

APPENDIX

Blackbody Losses

The blackbody loss per unit length for a ribbon with an arbitrary shaped cross section of perimeter p is

$$L_{BB} = \sigma e p (T^4 - T_o^4) \qquad [A\text{-}1]$$

with e the emissivity and σ the Stefan-Boltzmann constant. Writing the temperature $T = T_o - \Delta$. With $\Delta << T_o$, and using Eq. [4] to find the temperature change $\Delta = T - T_o$, the blackbody loss is

$$L_{BB} = 4\sigma e p T_o^3 \left(\frac{\rho_o}{\rho_1} + T_o\right)\left(\sec\frac{\alpha L}{2}\cos\alpha x - 1\right) \qquad [A\text{-}2]$$

The blackbody heat flux, F_{BB}, must be small compared to the heat flux through the ends of the ribbon, F_E. The former is given by

$$F_{BB} = \int_{-L/2}^{L/2} L_{BB} dX = 4L\sigma e p T_o^3 \left(\frac{\rho_o}{\rho_1} + T_o\right)\left[\frac{2}{\alpha L}\tan\frac{\alpha L}{2} - 1\right] \qquad [A\text{-}3]$$

and the latter by

$$F_E = KA\left[\frac{\partial T}{\partial x}\bigg|_{x=L/2} - \frac{\partial T}{\partial x}\bigg|_{x=-L/2}\right]$$

$$= \frac{8KA}{L}\left(T_o + \frac{\rho_o}{\rho_1}\right)\frac{\tan\frac{\alpha L}{2}}{\frac{\alpha L}{2}} \qquad [A\text{-}4]$$

For the case considered in the example below Eq. [7], assuming a worst case emissivity of $e = 1$

$$\frac{F_{BB}}{F_E} = 0.015$$

so that a prudent choice of the sample dimensions makes the blackbody loss small. It is also important to use currents small enough to avoid excessive heating of the sample.

Investigation of Energy Traps and Phosphorescence in Zinc Silicate Phosphors by Photostimulated Emission

I. F. Chang* and G. A. Sai-Halasz

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The manganese activated zinc silicates doped with or without arsenic are investigated using photostimulated luminescence technique in addition to conventional photoluminescence and phosphorescence measurements. The experimental results provide information about the energy levels of the Mn^{++} and the traps and how they interact during the luminescence process. Based on conclusions deduced from experimental data, a physical model is proposed for interpreting the zinc silicate luminescence and phosphorescence with some clues on the role of the arsenic doping and its effect on phosphorescence.

Manganese-doped zinc silicate is a useful phosphor in CRT applications due to its high efficiency and relatively long persistence. The green color emission is attributed to the spin flip transition of the d-orbital electron associated with the Mn^{++} ion (1). The Mn^{++} ion has been identified to be located on the two non-equivalent zinc sites in the rhombohedral crystal with a tetrahedral site symmetry (2). Thus, the luminescence transition is ascribed as $4T_{1g}$-$6A_{1g}$ transition, a forbidden one according to the selection rules (3). The intrinsic decay of the emission after u.v. excitation is exponential having a decay time constant (to $1/e$ point) on the order of 10 msec.

In addition to the intrinsic phosphorescence decay, one often observes in zinc silicate phosphors a long persistent phosphorescence with a much greater time constant(s). Often, this long persistence phosphorescence is too weak in intensity to be of any practical use. However, a properly tailored long persistent light decay can be utilized to reduce flicker (4) in a refreshed CRT display or in a illuminating light source.

There have been some empirical phosphor synthesis techniques reported in the literature (5, 6) for the purpose of enhancing or controlling this long persistence. One of the accepted and successful methods is to dope the manganese-activated silicate phosphor with a minute amount of arsenic (6). However, this technique has never been precisely described and the role of arsenic in the material has never been quite understood. Suggestions have been made that the long decay is mainly due to the fact that the excited electrons spend some appreciable time in traps before reaching the luminescent centers. Besides this type of qualitative description, we find surprisingly few facts or answers to the following questions: where are the electron-trap states and the Mn^{++} energy states located in relation to the energy bands of zinc silicate? How do they interact? What is the state of arsenic, where is it and its energy level and how does it prolong persistence?

We report here our early effort to find answers to the above questions. Taking a new approach we have carried out some photostimulated luminescence (PSL) experiments in addition to ordinary photoluminescence (PL) and phosphorescence (PP) measurements. The PSL is the luminescence stimulated by photons having energy lower than the emitted photons. This is possible if there were traps; then, the low energy photons can stimulate the trapped electrons (or holes) which have been previously excited and captured at the traps. The released electrons can then be captured by manganese ions. Such a process is expected to be a function of excitation energy. Thus, we expect that the PSL data can provide information about traps and how they interact with the luminescence process. In the following, we report the results of these experiments and other PL and PP measurements for manganese doped zinc silicates both with and without arsenic doping. We correlate these data with chemical analysis made on the materials and with other experimental data. Furthermore, based on these findings, we propose a physical model for interpreting the zinc silicate luminescence and phosphorescence.

Experimental Work

Phosphor materials investigated.—Numerous samples of commercial and laboratory synthesized zinc silicate phosphors have been investigated. The commercial phosphors are known as P1 (without As doping) and P39 (with As doping). The laboratory samples were synthesized (7) by solid reaction of $MnCO_3$, $ZnCO_3$, SiO_2, and/or As_2O_5 at temperatures between 1200° to 1450°C.

The laboratory samples give essentially the same luminescent properties as the commercial phosphors do. In Table I we list the chemical compositions of the materials that received detailed investigation in this work. The first three samples (A, B, and C) are P1-like materials which have no As doping. The remaining samples (D, E, and F) are P39-like materials which contain small amounts of arsenic doping and considerable less manganese than the P1 samples. Since the arsenic ions were more effectively introduced from As_2O_5 in the oxidizing atmosphere during synthesis, we assume that they remain as As^{+5} ions. All samples were identified by x-ray diffraction as zinc silicates and by chemical analysis as having slight excess of silica. Some high concentration manganese (>1%) zinc silicates have also been synthesized which exhibit a PSL intensity inversely proportional to the manganese concentration. This result will be reported elsewhere (8). The present work is mainly concerned with manganese concentration less than 1% which covers the doping range of commercial zinc silicate phosphors.

Table I. Chemical analysis of phosphor samples

Sample ID	C_{Mn} (w%)	C_{As} (ppm)	C_{Zn} (w%)	C_{Si} (w%)
A (P1)	0.523		51.8	16.1
B (P1)	0.605		52.2	16.3
C (P1)	0.431		55.4	14.7
D (P39)	0.048	330	52.8	15.8
E (P39)	0.033	76	51.5	17.2
F (P39)	0.063	88	52.6	15.9

Experimental procedure.—An experimental setup capable of making PL, PP, and PSL measurements is schematically shown in Fig. 1. The PL excitation sources used were a u.v. lamp with monochromator and an Argon laser tuned at 488 nm. The emission was measured with a Spex monochromator equipped with a GaAs detector and photon counter. For the PP decay curve and PSL measurements, the monochromator was set near the peak emission wavelength of the Mn^{++} green emission (~525 nm). Two laser sources (YAG-1.06μ and He-Ne-633 nm) were used to stimulate the green emission. The samples, all in powder form, were pressed into a sample holder which could be mounted on a heater stage capable of being heated up to 400°C. A fast electromechanical shutter with 1 msec response time was used to control the exposure of the laser lights on the phosphor samples. For PP spectral decay, an OMA (optical multichannel analyzer) was used in lieu of the monochromator.

Results and Discussion

In order to examine the excitation and emission processes involving the Mn^{++} ion and electron traps, we have selected two excitation energies, one being 488 nm which can directly excite the Mn^{++} ion and the other one being 254 nm which may excite the electrons from the Mn^{++} into the conduction band and cause filling of the traps. These above assumptions are consistent with the absorption (9) and excitation (10) data in zinc silicate which show only a set of characteristic absorption bands between 3000 to 5000Å corresponding to Mn^{++} ions and are also consistent with the photoconductivity data in willemite (11) which show strong excitation bands near 2800Å and below. However, one should point out an alternative possibility, *i.e.*, the 254 nm excitations may also excite the valence electron directly into the trap levels.

The spectra of photoluminescence and phosphorescence, decay curve, and photostimulated luminescence results are discussed below.

Photoluminescence spectra.—The PL spectra produced by these two excitations in zinc silicate are shown in Fig. 2. One notes that the two spectra have similar shape and identical peak wavelength, 525 nm (2.36 eV). This suggests that the final emitting state is the same for both excitations. It is also important to know at which excitation power density does the PL saturate so that we only use excitation power below the saturation level. Figure 3 shows the PL as a function of the 488 nm power density. One notes that the PL is approximately proportional to the power density up to 3 W/cm². Since the u.v. light source used in our experiments has much less power than the Argon laser, one can safely assume that both excitations used in our experiments are not causing any PL saturation effect.

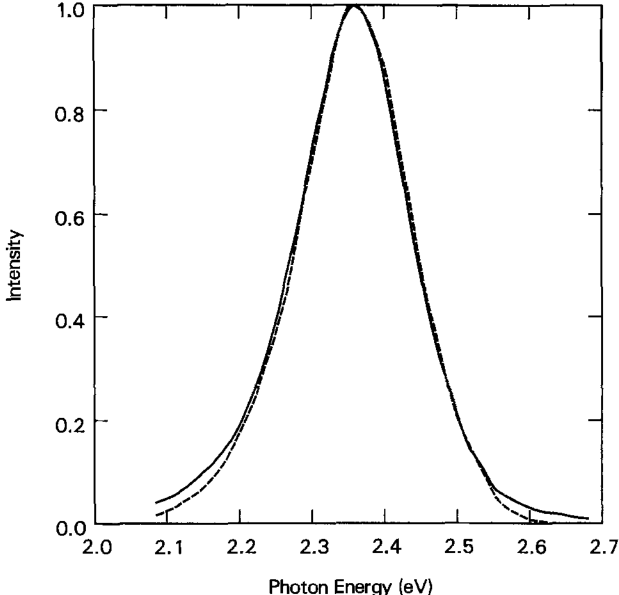

Fig. 2. Emission spectra of Mn^{++} in zinc silicate by 254 nm (solid line) and 488 nm (dash line) excitation.

Phosphorescence spectra.—The time resolved PP spectra was measured using an Optical Multichannel Analyzer (OMA) system. Only electron beam excitation can produce sufficient emission intensity to allow an unambiguous PP spectra measurement. Figure 4 shows the phosphorescence spectra taken at 1, 2, 3, 5, 10, and 30 msec with time integration interval of 200 μsec for a P1 sample. Again, the spectra exhibit identical shape and peak position. Thus it is reasonable to conclude that the final emitting state is also identical with the PL during PP decay. Similar conclusion can be made for the P39-like silicates.

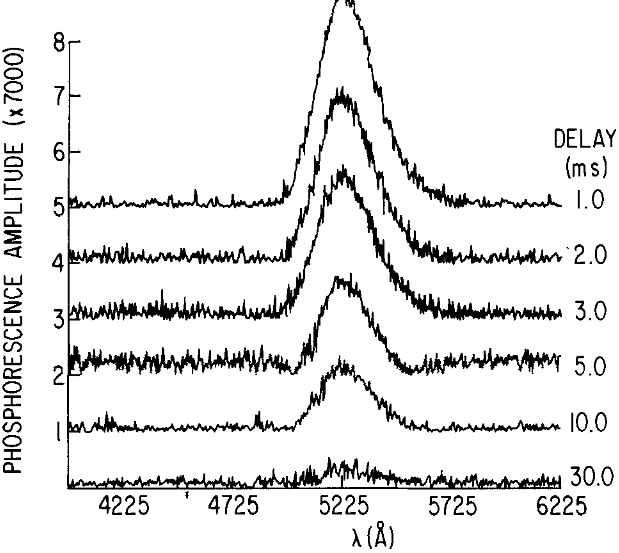

Fig. 4. Phosphorescence spectra for a P1 phosphor at the time of 1, 2, 3, 5, 10, and 30 msec after excitation removal. Spectra were recorded with a OMA having 200 μsec integration time.

Decay curve.—Although the PP spectra do not change with time for both P1 and P39-like samples, the PP decay curves are quite significantly different. The decay curves for the samples listed in Table I are shown in Fig. 5 for both 488 and 254 nm excitations. One notes that the P1-like samples (A, B, C) under 488 nm excitation show an exponential decay (left upper three curves of Fig. 5) with time constant, τ_e, being ~10 msec, a characteristic decay time of Mn^{++} emission in silicate. The same samples under 254 nm excitation also exhibit (right upper three curves of Fig. 5) similar decay time constant, however, with slightly more light output at longer decay time (much beyond 10 msec).

The decay curves of the arsenic-doped samples (D, E, F in Table I) by 488 nm excitation are shown in the left lower three curves of Fig. 5. One notes that the characteristic exponential decay is again observed. However, as shown in the right lower three curves of Fig. 5, a much slower decay is observed when excited by 254 nm. The decay curves do not show any 10 msec like decay time constant; instead they exhibit time constant on the order of a second. It is also noted that the initial decay time constant seems to be longer for higher arsenic content sample (sample D *vs.* E and F).

To probe where the arsenic level is, one should use excitation energies greater than 2.54 eV to find the threshold excitation energy for which the characteristic decay behavior changes to the long decay time constant attributed to arsenic trapping. This threshold excitation energy is found to be 3.96 eV (~313 nm) in P39-like material. This fact suggests that the arsenic level may be 3.96 eV above the manganese ground state or the valence band depending on where the electron is emitted from.

Photostimulated luminescence (PSL).—The PSL is a technique to probe the trap states in the zinc silicate material. The photostimulated green emission is obtained by exciting the zinc silicate phosphor with u.v. and then stimulating it with lower energy photon such as red or infrared. This effect is shown in Fig. 6 for a P1-like material. The samples are typically excited with 254 nm for 1 or 2 min and then exposed to a He-Ne laser (633 nm) light during or after the u.v. excitation. The sharp spike is the stimulated green emission. The PSL decays to equilibrium with fairly slow time constants (*i.e.*, not with the characteristic Mn^{++} decay time constant) as shown in Fig. 7. The area under the PSL spike represents the stored energy in the traps being released. The traps are apparently

Fig. 5. Decay characteristics of sample A, B, and C (P1-like) and samples D, E, and F (P39-like) by 488 and 254 nm excitations.

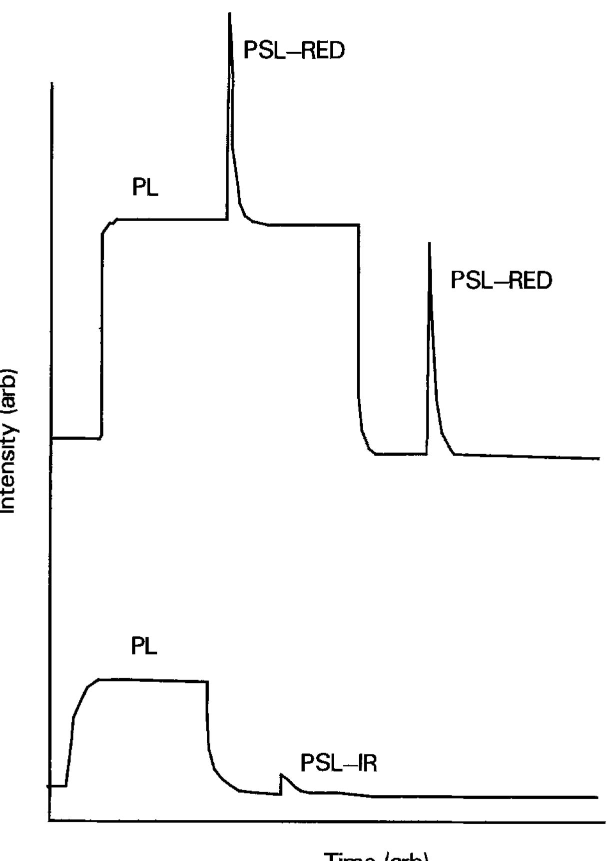

Fig. 6. The photostimulated luminescence effect by red (633 nm) and infrared (1.06μ) stimulation.

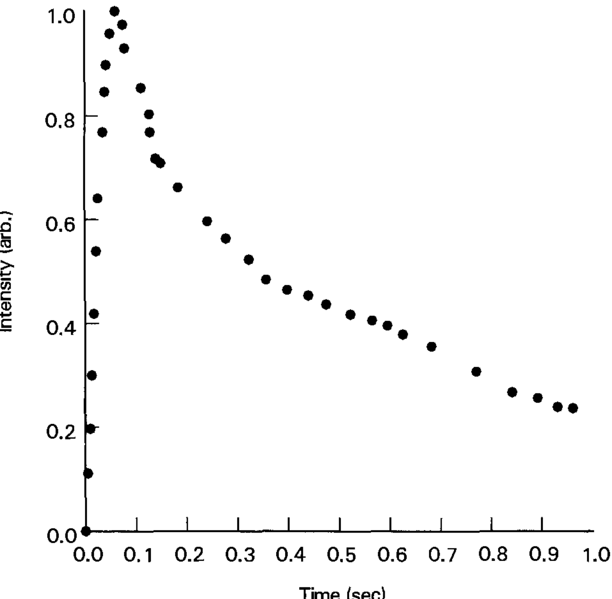

Fig. 7. Decay characteristics of the PSL-red

very stable at room temperature since the PSL can be observed hours later after the u.v. excitation is removed. The intensity of PSL depends on the u.v. excitation strength and duration and the stimulating power density. In general, more u.v. excitation and more intense stimulation produces greater PSL effect (8). One other important observation with PSL experiments is the threshold excitation energy for the PSL effect. The PSL-red is sufficiently intense to allow such an observation. Table II lists the PSL intensities measured at 2 min of continuous excitation (PSL-red-2) and after 30 sec excitation removal (PSL-red-2-30) for various excitation wavelengths. The PL intensities are also included for comparison. These results suggest that only the excitation energy greater than 3.65 eV is able to fill the intrinsic traps for red stimulation.

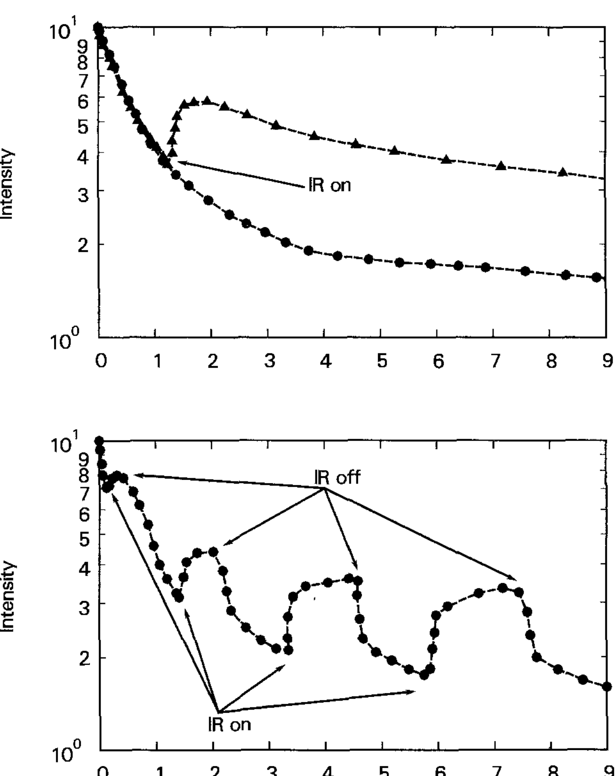
The PSL observed in P39 is generally much weaker in intensity. When stimulated with an infrared light source (1.06μ) (PSL-IR), the effect is even smaller. The PSL-IR is generally too weak to be observed during u.v. excitation. After u.v. removal (during PP decay), one can stimulate the PSL as shown in Fig. 8a and b for infrared stimulation in a P39 material. One notes that the PP decay shows its slow decay. As the infrared stimulation is applied, a slow buildup much slower than the buildup in red stimulation (Fig. 7) is observed. As the infrared stimulation is interrupted intermittently, one notes clearly that there are two time constants involved in the buildup and decay of PSL-IR.

The various PSL effects are summarized in Table III where the first column contains the PL intensity excited by 254 nm as a reference for the PSL effects. The different decay times to 10% point serve to qualitatively illustrate the time dependences of the decay

Table II. Dependence of PSL on excitation wavelength

Wavelength (nm)	254	280	300	320	340	366	420	440	480
PL[a]	10^5	10^3	10^4	10^4	10^3	10^3	10^3	10^3	10^4
PSL-2[b]	10^5	10^3	10^4	10^3	10^3	0	0	0	0
PSL-2-30[c]	10^4	10^3	10^4	10^3	10^3	1	10	5	5

[a] The intensities are given by order of magnitude only since light source, monochromator and filters are not calibrated precisely.
[b] PSL-2 means luminescence stimulated by 633 nm at 2 minutes of 254 nm excitation.
[c] PSL-2-30 means luminescence stimulated by 633 nm after 2 minutes of 254 nm excitation and 30 seconds of excitation removal.



Decay with 1060 nm excitation

processes involved. The PL of sample A (P1) and D (P39) reaches to 10% point at 25 msec and 1600 msec, respectively. The PSL-red decays to 10% point at 1.5 sec for sample A and 30 sec for sample D.

Discussions.—From Fig. 2 we can conclude that the final emitting state is the same for both the 254 and the 488 nm excitations. It is also evident from Fig. 4 that the final emitting state is also identical with the PL and PP decay. Similar conclusions can be made for both P1 and P39-like silicates. In the decay curves shown in Fig. 5, the slow component suggests that there are possibly some trapping states in the P1-like materials which can trap the excited electrons and have a very small probability of releasing them to the Mn^{++} emission. These traps may be intrinsic to the zinc silicates or may be induced by the half percent or so manganese doping. They should be distinguished from the traps induced by the arsenic doping as having different decay characteristics.

Since the 254 nm (4.88 eV) excitation produces no component of the characteristic decay in the arsenic-doped materials, it may be suggested that the luminescence decay is a cascading process of an electron being captured first in an As level, then transferred to one of the excited state of Mn^{++}, and finally reached the emitting state. Since in P39-like materials, the man-

ganese content is, comparable to that of the arsenic, on the order of several hundred parts per million (by weight), it is possible that the arsenic and manganese in the silicate may be paired in such a way that the arsenic energy states are coupled somewhat efficiently with the Mn^{++} excited states. If one assumes that the Mn^{++} and As^{+5} were randomly distributed in the lattice with respect to each other, then the probability would be so small (based on their concentrations) for an As^{+5} ion to transfer an electron to the Mn^{++} ion that one should observe the intrinsic decay of the Mn^{++} emission instead of the slow decay as shown in the right lower three curves of Fig. 5. Comparing PL efficiencies of P1 and P39-like materials, it is noted that the P39-like materials generally have efficiency about one-third of that of the P1 efficiency and yet have a manganese content reduction about one-tenth. This suggests that the introduction of arsenic actually increases PL efficiency on a per manganese ion basis probably because the arsenic has much greater capture cross section than the other intrinsic traps in the manganese doped zinc silicates. However, one cannot arbitrarily increase the arsenic content because it will reduce PL efficiency if exceeded 1000 ppm. One also cannot arbitrarily increase the Mn content since it will cause domination of the 10 msec manganese intrinsic decay if exceeded 1%. It appears that the optimal synthesis requires a comparable manganese and arsenic doping with a pair-like (efficient) coupling in the zinc silicate.

Referring to the PSL results presented above, it is interesting to point out that the threshold excitation energy (3.65 eV) and the red stimulation energy (1.95 eV) happen to be added up to be greater than the bandgap energy (9) (5.5 eV) of zinc silicate. This may suggest that it is the valence electrons that are excited into the traps. The holes left behind are then trapped somewhere else, perhaps in the Mn^{++} ground state. If this is true, one would expect a higher excitation threshold energy for the PSL-IR. Unfortunately, such experiments have not been conclusive due to difficulties in measuring very-weak PSL-IR effect.

On the other hand, if one assumes that the intrinsic traps are filled via conduction band electrons which are excited from the Mn^{++} ground state, then one could definitively assign the Mn^{++} ground state to be located at 3.65 eV below the conduction band. In this case, the threshold excitation energy will be constant for different stimulation energies.

Experimentally we have confirmed that the PSL-red can occur even after the PSL-IR is first exhausted (but not vice versa). Because of this result and the fact that the PSL-red is greater for higher energy u.v. excitation, one may suggest that the electron traps may not be a discrete level, rather that they have a distribution in energy which may undergo retrapping during stimulation (redistribution). Since the PSL-red decay rates are different for the samples with and without arsenic doping as explained in Table III, one may also suggest that the traps are not necessarily coupled with Mn^{++} excited states directly.

The PSL-IR in P39-like materials deserves more discussion. The PSL buildup shown in Fig. 8a is similar to the PL buildup in P39-like materials. This suggests that the buildup in both cases is due to filling up the arsenic traps. In the PL case, the 254 nm may excite electrons from the manganese ground states and fills them in the arsenic traps via conduction band, whereas in the PSL case, the infrared may stimulate the electrons from the intrinsic traps into the arsenic traps. As one notes in Fig. 8a, after reaching saturation (*i.e.*, the redistribution of trapped electrons reaches quasi-equilibrium), the decay resumes its initial decay which is attributed to the cascading decay process of transferring an electron from an intrinsic trap to an arsenic trap and then to the Mn^{++} causing emission. This interpretation is demonstrated by interrupting the infrared stimulation intermittently as shown in Fig. 8b. Clearly there are two time constants involved in the buildup and decay of PSL-IR. The first buildup is thought to be due to the filling of the arsenic states and the second buildup with slower rate (minutes) is thought to be due to the retrapping and redistribution of the intrinsic states with trapped electrons shifting to shallower states. The decay time constant associated with the arsenic state is smaller than that of the intrinsic states. Therefore, the PSL-IR first exhibits the refilling of the arsenic states, the first buildup curve, as shown in Fig. 8b. As time progresses, the arsenic states are filled to near saturation and then the redistribution of electrons in the intrinsic states also take effect, thus the PSL-IR exhibits the second buildup as seen in Fig. 8b.

As summarized in Table III, longer decay time of both PL and PSL are observed in the arsenic-doped sample. This is consistent with the cascade decay process discussed above. Similarly it is also true for the PSL-IR decay. The infrared stimulated luminescence have much longer decay time which may be attributed to the slower trap redistribution process under infrared stimulation.

One also notes that there are factors of 25 and 6 in intensity difference, respectively, for PSL-red and PSL-IR in samples A and D. This is likely due to the fact that the arsenic doping creates more trapping states which can shunt out the intrinsic traps in the capturing process in zinc silicates. This is supported by the thermoglow measurements made in P1 and P39-like materials (12). The glow peak near $T = 295°K$ in P39-like material is about 50 times larger than the corresponding peak in P1-like material. As suggested earlier, the arsenic states may be coupled with the Mn^{++} excited states. The arsenic state may be a discrete energy level and may not be stimulated efficiently by the red and infrared laser light, which may be responsible for the PSL intensity difference observed in samples with and without arsenic doping.

One further notes, in Table III, that the PSL-IR intensities are smaller by a factor of several hundred than the PSL-red intensities in both types of samples. This observation may be due to the reason that the 254 nm (4.88 eV) does not fill all the shallow traps (assuming valence electron excitation scheme) that the infrared can stimulate.

Physical Model and Conclusions

As stated earlier, the main questions are that we do not know where the Mn^{++} energy states and the electron-trap states, especially the arsenic states, are located in relation to the energy bands of zinc silicate. In the following, we list several conclusions deduced from the above described results which leads to a proposal of a physical model:

1. The ground state of Mn^{++} is located in the energy bandgap of zinc silicate—this is supported by the fact that the Mn^{++} ground state can stay empty for hours and allow long persistence PL, PP and long storage time of PSL.

2. The Mn^{++} emitting state is identical for PL (both directly excited by blue light or indirectly excited by higher energy photons) and for PP—this is borne out by the identical emission spectra of PL and PP.

3. There are intrinsic traps probably having an energy distribution which can be stimulated by the red and infrared photons—this is supported by the fact that the PSL intensity is greater for higher energy excitation and the fact that the PSL-red can occur even after the PSL-IR is exhausted.

4. The As^{+5} doping introduces an energy state which seems to be coupled with the Mn^{++} excited state and lies at least 2.54 eV above the Mn^{++} ground state perhaps about 3.96 eV—this is suggested by the fact that the blue excitation (2.54 eV) does not cause long persistence in an arsenic-doped sample and the change-

over of decay behavior occurs for excitation of 3.96 eV.

5. The As^{+5} ions probably form pairs with the Mn^{++} ions during material synthesis—this is because we have found that, in the samples having low Mn^{++} concentration (0.05%) the PL efficiency on a per ion basis is enhanced by the presence of comparable arsenic doping.

6. In the As^{+5} doped samples the energy transfer seems to proceed from the intrinsic traps through the As^{+5} to the Mn^{++} emitting state—this is suggested by the rise and decay behavior in the PSL-IR experiment (Fig. 8).

7. There is an uncertainty of reference point for the threshold energies determined—there exists a threshold excitation energy, 3.65 eV, for the PSL-red effect in all samples and a threshold excitation energy, 3.96 eV, for change over from short to long persistence decay in arsenic-doped zinc silicates, but whether they are measured from the valence band or the Mn^{++} ground state is not determined.

In considering a physical model, the uncertainty stated in 7 (above) leads to several possibilities. If the 3.65 threshold is measured from the Mn^{++} ground state to the conduction band, then the traps would be filled by the conduction band electrons which are excited from the Mn^{++} ground state by energy greater than 3.65 eV. The As^{+5} states could be filled the same way except they are coupled with the Mn^{++} excited states to exhibit long persistent decay. However, this picture is not consistent with the 3.96 eV threshold for decay behavior change. One cannot assign the As^{+5} states 3.96 eV above the Mn^{++} ground state (they would be in the conduction band) nor 3.96 eV above the valence band by assuming their excitation by the valence band electrons (they would be below the Mn^{++} emitting state). Therefore, one would prefer suggesting that the 3.65 eV threshold is measured from the valence band to the intrinsic traps and they would be filled by valence electrons during excitation [since 3.65 ev + 1.95 eV > 5.5 eV (bandgap)]. In this picture, the Mn^{++} ground level cannot be assigned precisely in relation to the conduction band. The Mn^{++} ground state is believed to be still above the valence band because they can stay empty for hours after excitation as exhibited by the PSL effect. The 3.96 eV threshold for decay behavior change can add some restrictions to the location of Mn^{++} ground state. This is shown schematically in Fig. 9 where (A) is based on the assignment of 3.96 eV being above the valence band and (B) is corresponding to the assignment of 3.96 eV being above the Mn^{++} ground state. Case (A) restricts the Mn^{++} ground state to be less than 1.6 eV above the valence band ($<3.96 - 2.36 = 1.6$) whereas case (B) does not limit the energy level of Mn^{++} ground state at all. Since the blue light excitation (2.54 eV) does not cause long decay in As-doped samples, the As^{+5} level must couple with one or more higher level excited state of the Mn^{++} ion. Both cases are consistent with our experimental results presented above.

In summary, using PSL experiments in addition to conventional PL, PP, and decay curve measurements, we have obtained some clues on the physical picture of the PL and PP mechanisms in zinc silicate phosphors. The long persistence on arsenic-doped zinc silicate phosphors seems to be attributable to a pair-like (perhaps Mn-O-As) coupling of the Mn^{++} and As^{+5} ions. Experimental findings suggest that in order to obtain long persistence one should incorporate comparable amounts of Mn^{++} and As^{+5} in the zinc silicate and the Mn^{++} concentration should be limited so that pairing or cluster of Mn^{++} will not dominate over the manganese-arsenic pairs. A preliminary physical model is proposed for the phosphorescence behavior of Zn_2SiO_4:Mn,As. Further work on the luminescence and excitation energy threshold for PSL effect and correlation with thermoglow peaks may provide a more precise picture of the luminescence processes and a quantitative account of the kinetics of the emission and decay processes.

LPE Growth of $(Nd,Y)P_5O_{14}$ Layers from Tin Melt

Hiroyuki Kasano and Yoshio Furuhata

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Metal fluxes such as Ga, In, and Sn are developed for liquid phase epitaxial growth of rare earth ultraphosphates in place of phosphoric acid flux. Solubility curves of NdP_5O_{14} for these fluxes are obtained. Using a tin flux, $(Nd,Y)P_5O_{14}$ layers having a few to twenty microns thickness are successfully grown both on the (100)-oriented NdP_5O_{14} and (001)-oriented $Gd_{0.33}Y_{0.67}P_5O_{14}$ substrates. A preliminary growth mechanism is also reported.

To date single crystals of rare earth ultraphosphates, which are favorable for miniature solid-state laser materials, have been grown only by the phosphoric acid flux method (1). This method is suitable for bulk crystal growth, through undesirable for thin film crystal growth with controlled micron-order thickness. This is because (*i*) crystal growth occurs and proceeds under the nonequilibrium state of dehydration of polyphosphoric acid, (*ii*) due to the high viscosity of the flux it takes a long time, *i.e.*, about 3 days to increase the degree of supersaturation to a level capable of sustaining crystal growth, and (*iii*) the very corrosive nature of the fluid and vapor of the flux makes it difficult to employ crucible materials suitable for multiple liquid phase epitaxy (LPE). To achieve a solid-state device system, it is desirable that a planer-type laser be formed on a common crystalline base together with both its exciting source, *i.e.*, an LD or LED array, and an electro-optical modulator (2). In this system, the optically pumped laser and waveguide are constructed from the same thin film. The top and back surfaces of this film are coated with a film having a smaller refractive index. These sandwich structures are preferable because propagation loss is reduced. These multilayer structures of rare earth ultraphosphates can be obtained by using the sliding boat technique (3) if a proper flux can be developed. This flux must produce low vapor pressure, be noncorrosive for the boat at growth temperatures, and have sufficiently large solubility for ultraphosphates (in practical use, more than 10^{-3} mole fraction at elevated temperatures).

This study presents pure metal fluxes having low melting points. One of these fluxes, *i.e.*, tin, was successfully employed in growing rare earth ultraphosphate films.

Experimental

Seed crystals as well as source crystals of rare earth ultraphosphates were prepared by using the phosphoric-acid flux method; 4 nines purified rare earth oxide powder (Nd_2O_3, Y_2O_3, Gd_2O_3, or CeO_2), manufactured by shin-Etsu Kagaku, was charged in a glassy carbon crucible with commercial orthophosphoric acid (85% H_3PO_4 + 15% H_2O). The ratio of oxide powder to orthophosphoric acid was 2.0-2.3% in weight. A crucible containing these starting materials was loosely sealed with a glassy carbon lid and was loaded in a quartz reaction tube set in an electric furnace. Wet argon was passed over the container at a rate 300 ml/min during the entire run. Before growth, the water component (~15%) in commercial orthophosphoric acid was removed by heating at 200°C for 2 days. Then, oxide powders were completely dissolved in dehydrated orthophosphoric acid at 300°C during the next 2 days. Ultimately, rare earth ultraphosphates were grown at 560°C for 12 days. Growth temperature was controlled to an accuracy of 0.1°C.

Crystal dissolution for measuring solubility and liquid phase epitaxy (LPE) using the metal fluxes were carried out in a dry argon atmosphere using a graphite boat as is shown in Fig. 1(a). For the metal fluxes, In, Ga, and Sn were chosen because both their melting points and vapor pressures below 1000°C were relatively low. In this study, a graphite block weight was used to sink the source crystals into the molten flux at elevated temperatures. To promote crystal dissolution, the molten metal was intermittently vibrated during heating. To measure solubility, the source crystals (~1.0g in weight) were held for 7 hr in the molten flux (~4 ml). This period was determined from experimental data at 650°C, where solubility was found to be independent of the heating time beyond 7 hr. After the 7 hr run, the flux was rapidly cooled. During cooling, the dissolved source recrystallized as slag and covered the flux surface as well as the residual source surface. The residual source weight was measured after the solidified flux was first removed with a hot HCl solution, and then the recrystallized slag was taken off in ethyl alcohol by utilizing ultrasonic vibration.

For LPE, only tin flux was used because solubility of NdP_5O_{14} in a relatively low temperature range was highest while the flux incorporation into NdP_5O_{14} was lowest among these fluxes. The LPE processes are as shown in Fig. 1. The system was purged with argon gas prior to increasing the temperature. At this stage, the surface of (100)-oriented NdP_5O_{14} and/or (001)-oriented $Gd_{0.33}Y_{0.67}P_5O_{14}$ substrates were exposed to the argon flow. Then, the temperature was increased. When the substrate temperature T_2 reached 400°C, the substrate surfaces were covered by the graphite boat upper wall by sliding the substrate-loaded graphite plate. The substrate was kept at 400°C until the growth conditions were fulfilled. The source temperature T_1 was further increased to 800°C where the NdP_5O_{14} or $Nd_{0.15}Y_{0.85}P_5O_{14}$ source crystals were dissolved. Five hours later, T_1 was decreased to the desired growth temperature at which substrates were put in contact with the tin melt by sliding the graphite

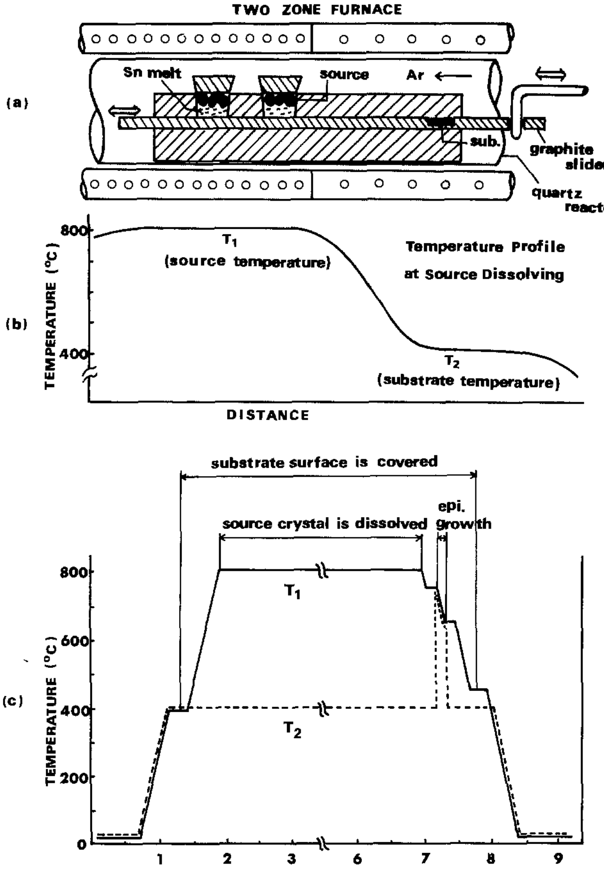

Fig. 1. Schematic diagrams for LPE growth of rare earth ultraphosphates. (a) Equipment used for LPE growth. (b) Temperature profile at source dissolving. (c) *T-t* diagram showing LPE growth program.

plate. At this stage, T_2 became nearly equal to T_1. Rare earth ultraphosphate was epitaxially grown in the course of the additional temperature decrease. At a temperature a hundred degrees lower than the one at contact, the substrates were removed from the tin melt while still covered by the graphite boat wall. When T_1 was decreased to 450°C, the substrates kept at 400°C were reexposed in an argon ambient and cooled to room temperature. Samples were then boiled in HCl solution. To measure epitaxial layer thickness, a cleaved face of the sample was etched for 10 min in phosphoric acid heated at 300°C. XMA and x-ray powder diffraction analyses were also carried out to obtain information on the compositions of the growth crystals.

To deduce a preliminary phase diagram of the system Sn:NdP_5O_{14}, differential temperature analysis (DTA) was performed at several Sn-rich compositions where the liquidus was clearly below the decomposing temperature (~1090°C) of NdP_5O_{14}, *i.e.,* in the compositional range where NdP_5O_{14} was less than 5 mole percent (m/o). For DTA apparatus a Rigaku Denki Model YGHD system was used. Starting materials, Sn and NdP_5O_{14}, were crushed and intimately mixed prior to being charged in an alumina cell. For a reference sample, α-Al_2O_3 powder (No. 2000 mesh) was used. The measurement (DTA) was carried out in N_2 ambient in a temperature range 20°-1250°C. Heating-cooling rate was 10 deg/min and a sensitivity was ±100 μV (full scale). Liquidus temperatures were determined from the heating curves, because the heating curves did not indicate significant overheating effects, while the cooling curves often indicated large supercooling effects.

Since Sn does not completely wet Nd_5O_{14} at elevated temperatures, a compositional error results. The magnitude of the error was estimated on a basis of the scanning XMA data of the differential temperature analyzed samples to be at most ±0.25 m/o; unreacted NdP_5O_{14} crystals had a diameter above 0.1 mm whereas that of recrystallized NdP_5O_{14} was less than 30 μm.

Results

Solubility curves of NdP_5O_{14} in the metal fluxes.—Solubility curves of NdP_5O_{14} for Ga, In, and Sn in a temperature range 620°-950°C are shown in Fig. 2. For comparison, $Nd_{0.15}Y_{0.85}P_5O_{14}$ was used as the source crystals in the tin flux case. A few data points in Fig. 2 indicate that solubility of $Nd_{0.15}Y_{0.85}P_5O_{14}$ is comparable to that of NdP_5O_{14} for the tin flux. This is similar to the phosphoric-acid flux case (4). The solubility curves for column III metals become steep at the higher end of the dissolution temperature, *i.e.,* 950°C for Ga and 800°C for In, while the solubility increase was still gradual for tin flux. Flux temperatures at which solubility reaches 1 [atomic percent (a/o)] are estimated from this curve to be nearly 990°, 780°, and 810°C for Ga, In, and Sn, respectively. From the gradient of the straight part of the solubility curves, the enthalpy of a dissolution reaction is estimated to be 1.35×10^5 J/mole (32.2 kcal/mole). This value is common for gallium, indium, and tin fluxes. Apparently, the fluxes are chemically free from the dissolving reaction of NdP_5O_{14}. Data scattering observed in the indium flux case may be due to the poorer wetting of indium and the source crystals as compared with the other two cases.

The body color of the undissolved core of the NdP_5O_{14} source crystals changed to reddish in the column III flux case, while it remained only slightly darkened in the tin flux case. The color of precipitates deposited on the undissolved cores was the same. The data of the x-ray diffraction analysis suggested that a few mole percent of the flux were incorporated in the recrystallized NdP_5O_{14} crystals in the gallium and indium flux cases. The incorporated Ga concentration is coincident with the reported value by Kruehler *et al.* [less than 2.2 a/o (5)]. However, no detectable amount (less than 1%) of the flux was observed in the tin flux case. Laser spectroscopic analysis results

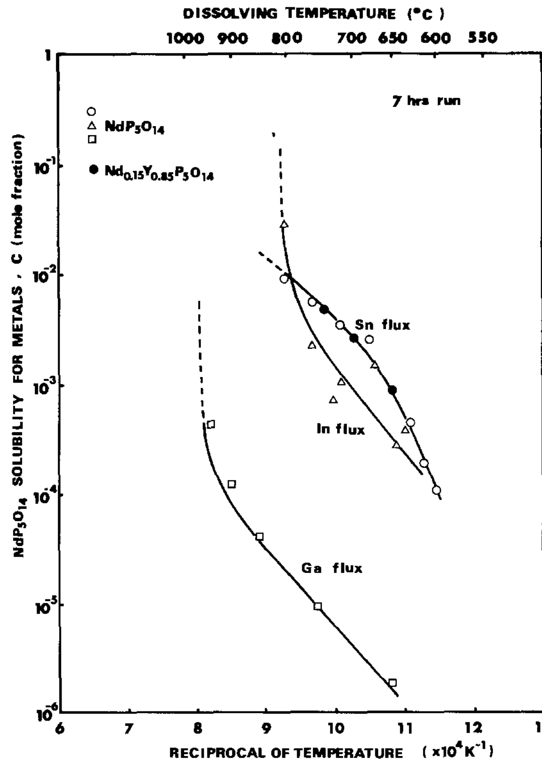

Fig. 2. Solubility curves of NdP_5O_{14} for metal fluxes

indicated the presence of only 100-500 ppm tin. Therefore, tin is judged to be the most suitable of these metals as a flux for LPE of ultraphosphates.

Liquid-phase epitaxy using tin flux.—Neodimium-yttrium pentaphosphates were epitaxially grown from the tin flux both on (001)-oriented $Gd_{0.33}Y_{0.67}P_5O_{14}$ and (100)-oriented NdP_5O_{14} substrates which were simultaneously charged in the same run. In this experiment, $Nd_{0.15}Y_{0.85}P_5O_{14}$ crystals were used as the source. Though $Gd_{0.33}Y_{0.67}P_5O_{14}$ and NdP_5O_{14} belong to different crystalline phases at growth temperature, *i.e.,* the space group C2/c of the monoclinic system for the former and the space group Pcmn of the orthorhombic system for the latter, the $Nd_{0.15}Y_{0.85}P_5O_{14}$ source can crystallize in both phases provided it is first dissolved or vaporized (6). As a result, LPE growth of $Nd_{0.15}Y_{0.85}P_5O_{14}$ can be achieved on these substrates. A combination of a $Nd_{0.15}Y_{0.85}P_5O_{14}$ epitaxial layer and a $Gd_{0.33}Y_{0.67}P_5O_{14}$ substrate is preferable because (*i*) the lattice parameter of the layer is well suited to that of the substrate (2), (*ii*) the optical refractive index of the layer is larger than that of the substrate (2), and (*iii*) the layer composition is out of the range of the ferroelastic species (7).

The surface of an epitaxial layer was slightly wrinkled and partly covered with a white precipitate. The origin of the precipitate was deduced to be $SnHPO_4$ on the basis of the x-ray diffraction analysis data. The hydrogen source may be water vapor which back diffused from a water vessel used as a gas trap. After removing the precipitate by lapping, the grown layers were confirmed to be epitaxial by an x-ray back Laue technique. Hence, these precipitates were probably formed during the cooling process from the residual tin flux stuck on the sample surface. A typical grown layer is shown in Fig. 3. The Nd/Y ratio of the epitaxial layer was examined by XMA and was found to shift slightly to the Y-rich side compared with the source crystals. The shift was 2-3% for the growth at 800°C. Grown layers were epitaxial at temperatures above 650°C. Layer thickness was measured as a function of the growth temperatures. The results obtained are shown in Fig. 4. The growth period in each run was limited to 100°C. The cooling rate in this period was controlled to 10 deg/min. The magnitude of the solubility difference caused by this cooling is calculated for NdP_5O_{14} and $Nd_{0.15}Y_{0.85}P_5O_{14}$ in the tin flux based on Fig. 2 data. This is also shown in Fig. 4 for comparison.

Discussion

Dissolving mechanism of NdP_5O_{14} in metal fluxes.—Solubility data of NdP_5O_{14} in the metals are presented for the first time in Fig. 2. However, the dissolving mechanism in the metal fluxes is still unknown. Based on the DTA data, a preliminary phase diagram for the system Sn-NdP_5O_{14} is proposed in a compositional range $x < 5$ (m/o), *i.e.,* in a very tin-rich region. During the temperature increasing process in DTA, only three peaks or knees were detected below 1200°C for each composition. These peaks or knees correspond in turn to a point on the solidus (the tin mp 232°C), a point on the liquidus, and the NdP_5O_{14} decomposing point (~1090°C), as is shown in Fig. 5. Though the data in the NdP_5O_{14}-rich side could not be obtained because liquidus temperatures exceed the decomposition temperature of NdP_5O_{14}, we believe that this diagram is reasonable. This is because (*i*) the NdP_5O_{14} layers recrystallized on the substrate along the liquidus curve during cooling (Fig. 4), and (*ii*) a point on the solidus was experimentally confirmed to be ~232°C even at very NdP_5O_{14}-rich compositions. That is, it is believed that any stable compound other than NdP_5O_{14} was not formed during heating. The x-ray diffraction analysis of the slag by which the surface of the metal flux was covered showed that the greater part was NdP_5O_{14}. The residual was metal oxide along with a slight amount of metal phosphate. As indicated above, metal phosphate was also found on the epitaxial layer. We consider that these residues were formed during cooling only at the surface of the melt as a result of chemical reactions among Sn, NdP_5O_{14}, and H_2O which came from the exhaust. The most probable mechanism is a simple diffusion such as $NdP_5O_{14}(s) \rightarrow NdP_5O_{14}(l)$. The case where a metastable compound is first formed in the molten flux heated at high temperatures and then decomposes to Sn and NdP_5O_{14} during the cooling stage is also conceivable.

Epitaxial growth process from tin melt.—The LPE growth mechanism from the tin melt is expected to be an ordinary spiral growth. From the grown-layer thickness data and the solubility difference curve shown in Fig. 4, the relationship between the growth rate V and the degree of supersaturation σ is readily obtained as is shown in Fig. 6. Though the data for the solubility decrease occurring during a hundred degree period were for the system Sn-NdP_5O_{14}, we consider that those for the system Sn-(Nd, Y)P_5O_{14} are consistent with the former on the basis of the data in Fig. 2. The quadratic dependence of V on σ is

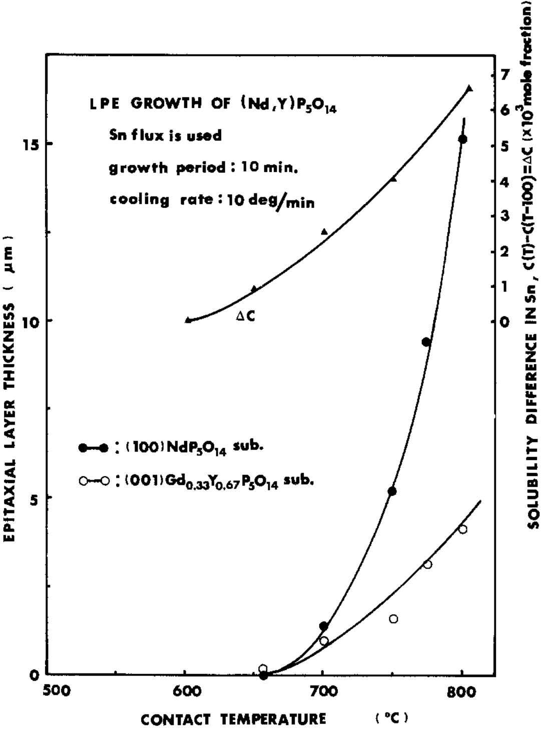

Fig. 4. Epitaxial layer thickness of $(Nd,Y)P_5O_{14}$ grown on (100)-oriented NdP_5O_{14} and (001)-oriented $Gd_{0.33}Y_{0.67}P_5O_{14}$ as a function of dipping temperature. Growth time was held to 10 min. In this period, flux temperature was linearly decreased by a hundred degrees. Magnitude of NdP_5O_{14} solubility decrease corresponding to this 100°C cooling is calculated from Fig. 2.

indicated both in the NdP_5O_{14} and $Gd_{0.33}Y_{0.67}P_5O_{14}$ substrate cases.

According to Elwell and Dawson (8), spiral growth from the flux is qualitatively explained using the Burton-Cabrera-Frank model modified by the diffusion effect. This gives

$$V = (A\sigma^2/\sigma_1)\tanh(\sigma_1/\sigma) \quad \text{(Bennema's modification)}$$

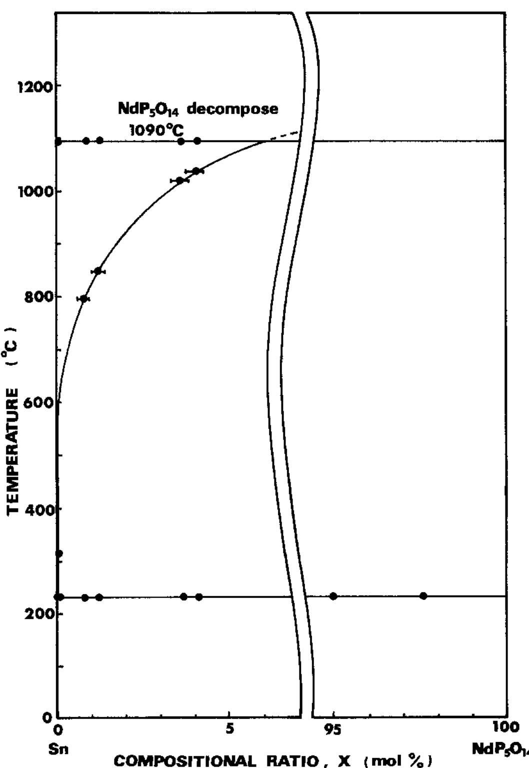

Fig. 5. Proposed phase diagram for $Sn\text{-}NdP_5O_{14}$ system

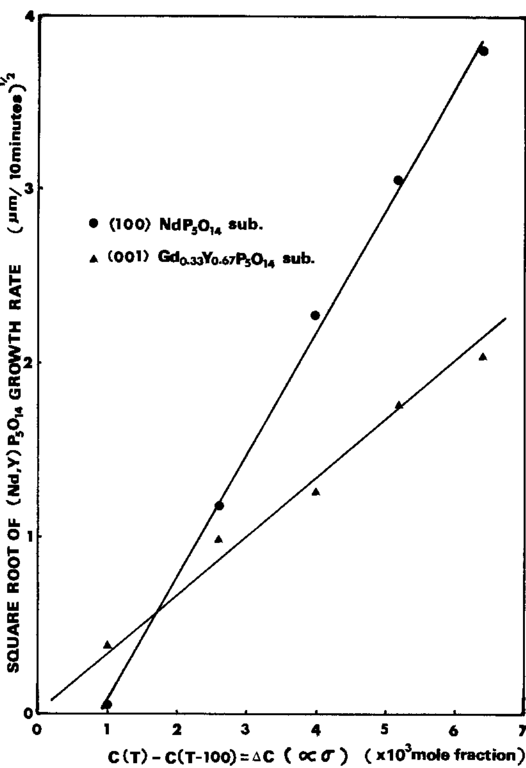

Fig. 6. Growth rate V of $(Nd,Y)P_5O_{14}$ as a function of the degree of supersaturation σ. $V \propto \sigma^2$ is indicated.

where σ_1 is the threshold of σ and A is a constant. Corresponding to the magnitude of the relative degree of supersaturation, this equation can be approximated in two cases

$$V \simeq A\sigma^2/\sigma_1$$

when $\sigma < \sigma_1$ (relatively low supersaturation) and

$$V \simeq A\sigma$$

when $\sigma \geqq \sigma_1$ (relatively high supersaturation). The fact that LPE growth of $(Nd, Y)P_5O_{14}$ took place under a relatively low degree of supersaturation in this study is suggested in Fig. 6.

Conclusions

Bearing thin film integrated optics in mind, metal fluxes adaptable to LPE growth of rare earth ultraphosphates have been developed. Metals with low melting points, *e.g.*, Ga, In, and Sn, were tested. It was found that ultraphosphates were soluble in these metals at relatively low temperatures (600°-800°C) and that the ultraphosphates were recrystallized during the cooling stage. The solubility curves of NdP_5O_{14} for these fluxes were experimentally obtained. Then, LPE growth of $(Nd, Y)P_5O_{14}$ was successfully carried out using the tin flux.

It is noteworthy that for multilayer growth with submicron order thickness control these metal fluxes are more suitable than phosphoric acid flux from the viewpoint of handling and stability.

A Method for Area Saving Planar Isolation Oxides Using Oxidation Protected Sidewalls

D. Kahng, T. A. Shankoff, T. T. Sheng, and S. E. Haszko

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A process has been developed to fabricate buried isolation oxide structures with a near-perfect topography. The method uses the combination of preoxidation silicon etching to the required depth with the added feature of sidewall oxidation protection used to control the profile at feature edges. The latter is achieved by the deposition of a second silicon nitride layer and a processing sequence of simple steps which are shown to be quite reproducible.

We have succeeded in fabricating buried isolation oxide structures with almost perfectly planar topography. The method borrows from the full-ROX (1, 2) technique in that the substrate is etched to a depth approximately 50% of the final, desired oxide thickness after silicon nitride patterning and prior to oxidation. It deviates from that technique in that sidewall oxidation protection is used to control the profile at feature edges and to eliminate the well-known form "bird's head and beak" and its abrupt, sharp and dimension robbing characteristics. The processing sequence itself involves the proper combination of simple steps and is quite reproducible.

Our concept of sidewall protection involves chemical vapor deposition of a second nitride layer after silicon substrate etching using the first nitride (or oxidation mask) as the etch mask; if the second nitride is etched after it is deposited using a straight-line method, then the sidewall will still contain the second nitride layer on the silicon quarter circles under the first nitride overhang after etching. The bulk of the to-be thick oxide device regions (isolation oxide) will be open to oxidation, but there will be masking at the sidewalls during oxidation. Thus for example, our initial experiments involved a straight-line process, ion implantation, which resulted in both etching and chemical conversion of nitride in the to-be oxidized regions. We implanted oxygen as O atoms into 300-500Å of the second nitride to a depth of 200-250Å (15 keV) so that whatever nitride that did not sputter off in the O atom implant would be converted to oxidizable oxynitride. Coupled with this set of experiments was the use of varying second nitride thicknesses arranged so that slight oxidation at the sidewalls would occur toward the end of the isolation oxidation in order to "smooth or round-out" the topography. The transmission electron micrographs in Fig. 1a and 1b respectively detail the full-ROX profile and the typical O atom implant result when the second nitride was thick enough so that no oxidation took place at the sidewalls. Experimentally we found that about 400Å of second silicon nitride is consumed during 10,000Å of wet isolation oxidation. Figure 2 shows the case where less than 400Å of nitride was used to allow some sidewall oxidation. In practice, we found that deposition control of silicon nitride composition and to a lesser extent thickness and uniformity control over a wafer essentially precludes consideration of the partial oxidation method on a practical basis.

Although the results using O atom implantation were encouraging, the process was fraught with variability. We always found some residual oxidation resistance in the presumed to be "opened" thick oxide silicon.

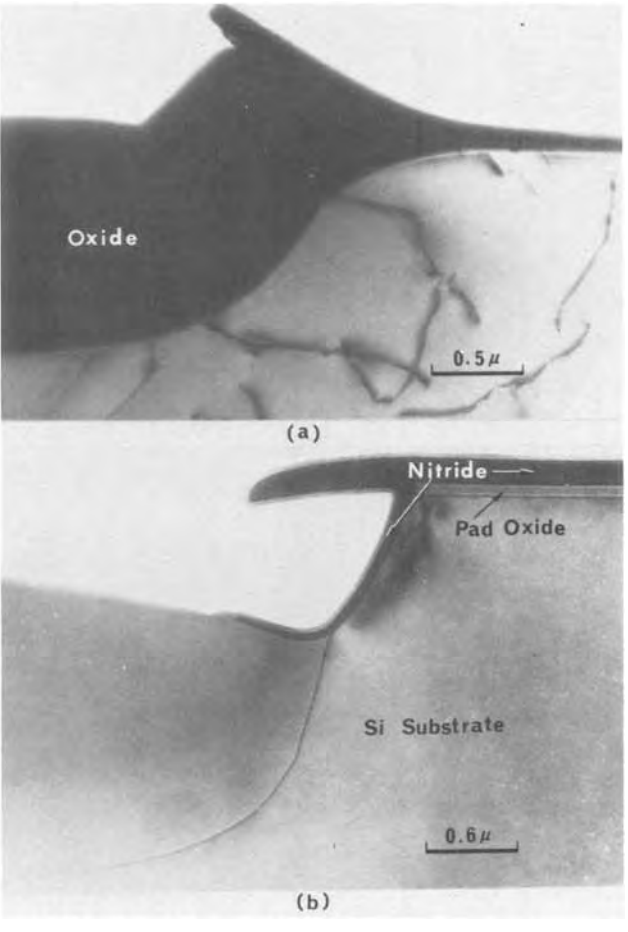

Fig. 1. (a) TEM profile of standard full-ROX structure. (b) TEM profile of O atom implant, 500Å second nitride method.

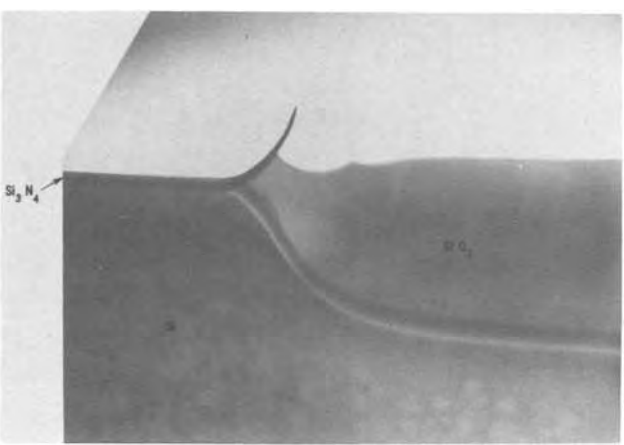

Fig. 2. TEM profile of O atom implant, less than 400Å second nitride method.

For example, in one case 7000Å of SiO_2 grew when 10,000Å was expected, while a 14.000Å oxidation time furnished the requisite 10,000Å. The important point was that we were on the proper track to achieving the desired end result. Processing details for the technique are set out in Table I using step 10a.

Our best results were achieved using reactive ion etching of the second nitride layer which is, if properly applied, a straight-line etching procedure. It was also decided to eliminate any attemps to use "thin" second nitride so that partial oxidation would be relied on to smooth-out the topology. Thus, for 10.000Å isolation oxidation, 500Å of second silicon nitride has been used and is reactive ion etched in anisotropic etching conditions so as to leave the entire feature-edge region coated with the full 500Å thickness at the isolation oxidation step. Silicon nitride in these thickness ranges is believed not to introduce stress during the oxidation (2). The processing sequence for this modification is included in Table I as step 10b. Typical results can be seen in Fig. 3. It is clear that too much sidewall protection is obtained with this method resulting in the sharp unoxidized notches at the feature edges. It became evident that the best situation would be achieved if oxidation is allowed to proceed up the sidewall, but in a controllable fashion in limited degree. A simple way to achieve the result is to use a pad oxide beneath the second nitride layer in much the same way that a pad oxide is employed beneath the first masking nitride film; the H_2O oxidant diffuses in the pad and allows some penetration of growing oxide further up the sidewall. Experiments were done with "second" pad oxide thicknesses of 100 and 300Å; the results can be seen in Fig. 4a and 4b. Clearly the 100Å case gives the best result. Use of a thin 100Å pad oxide beneath the 500Å nitride layer (which is too thick to be consumed during isolation oxidation) presents no control problem whatsoever since dry oxide thicknesses are relatively easy to control even at 100Å.

The only negative aspect of the pad oxide technique proves to be slight "spill-over" of the isolation oxide into the future thin oxide portions of the structure as evidenced by the thin, tapered elges in Fig. 4a and 4b

and Fig. 5a and 5b. A simple 30 sec oxide etchback in BHF to remove 500Å thermal oxide (30 sec removes more oxide than has spilled over by about a factor of 2, although this may be the only real variable connected with the process) easily solves this problem. After this BHF treatment, the structure which is finally achieved is essentially planar and contains no trace of "spilled-over" isolation oxide. Even more important, the intrusion of thick oxide into the thin oxide regions of a device chip stops at the edge of the original isotropically etched quarter circle formed in the silicon. Since this will typically be about 50% of the isolation oxide thickness in dimension at each feature edge, a significant saving of device real estate can be realized (note the intrusions of typically 15,000Å are found for selective-oxidation structures such as the semi-ROX structure owing to the "bird's beak"

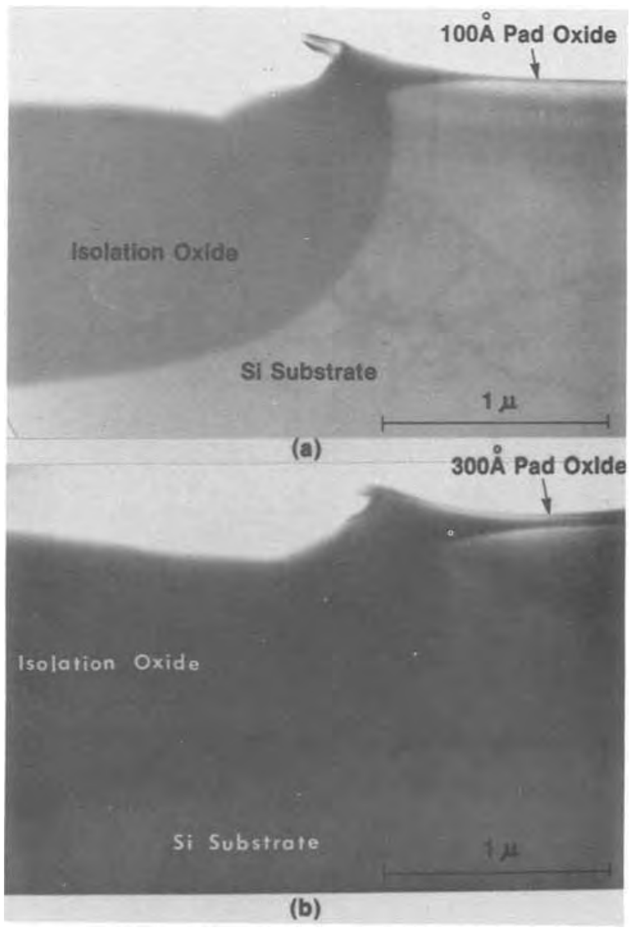

Fig. 4. (a) TEM profile of reactive ion etch of second nitride with 100Å second pad oxide. (b) TEM profile of reactive ion etch of second nitride with 300Å second pad oxide.

and close to 10,000Å for the full-ROX structure because of the bird's head).

A secondary, but important aspect of this work is the etchant used to achieve the desired isotropic quarter circle features used in this technique. It was found that the CrO_3-HF-H_2O etching system provides completely isotropic etching in the composition and etching thickness range studied during this program. The silicon substrate "floor" on which the isolation oxidation will be done is as defect-free and smooth as noted with any etching technique either dry or wet-chemical. The etching rate is sensitive to substrate doping, however, and calibration etching curves must be obtained for each new substrate doping used. Obviously, devices which have previously defined and doped structures will be difficult to process using this etchant, although a suitable etching alternative should not be difficult to find. The only parameter which will affect etching rate of the silicon for routine work, temperature, is readily controlled and inconsequential. Etch rate data for the CrO_3-HF-H_2O system in the applicable ranges are presented in Fig. 6.

In practice, it is important to use sufficient first nitride (perhaps 1200-1500Å) so that RIE of the second 500Å nitride with 25% overetch will not affect the oxidation masking by the first layer. Allowance also must be made for some loss of nitride in the CrO_3-HF-H_2O etchant (about 100Å per minute), perhaps increasing the original first nitride thickness to 1500-1800Å. Excellent etching results of the substrate are obtained when the CrO_3 concentration is in the 1 weight percent range (about 25Å/sec silicon etching rate for lightly boron-doped substrate and 1-2Å-sec for silicon nitride). The silicon etch depth can be controlled to within 100Å if desired and should be computed from the following considerations: 56% of thermal oxide growth is above the substrate, removal of the first nitride in 160°-180°C H_3PO_4 loses 5Å of thermal oxide per minute of etch time (30 min for 1500Å first nitride), removal of the first pad oxide (typically 300-400Å) with overetching in BHF for 30 sec costs 500Å of isolation oxide, and finally trimming the spilled-over oxide costs an added 500Å if BHF is used for 30 sec. Thus for 10,000Å final isolation oxide, an etching depth of 5100Å would be used and 11,150Å oxide grown, for a planar topography.

It came to our attention after much of this work was completed that the patent literature describes two attempts at sidewall oxidation protection to achieve the planar topography. In one method (3), "spin-on" oxide is used to preferentially fill the feature edges at the quarter circle; subsequent isolation oxidation is impeded at the feature edges because of this blocking oxide, giving the essentially planar structure. In the other technique (4), a second nitride layer is used, but instead of using a straight-line etching technique, photoresist is used to clog the feature-edge nitride overhang/quarter circles (spinning resist on forces resist into these crevices preferentially). Exposure and development should leave some thickness of resist in the quarter circles because of the thickness differential; subsequent nitride etching should leave nitride within the quarter circles to mask the sidewalls against the isolation oxidation. It was not possible to assess the degree of success with these approaches from the literature. However, it appears that the photolithographic exposure is difficult to control because of light diffraction at the quarter circles with the second method; the first method will have "spin-on" oxide within the device structure, seemingly undesirable from a contamination and quality control standpoint.

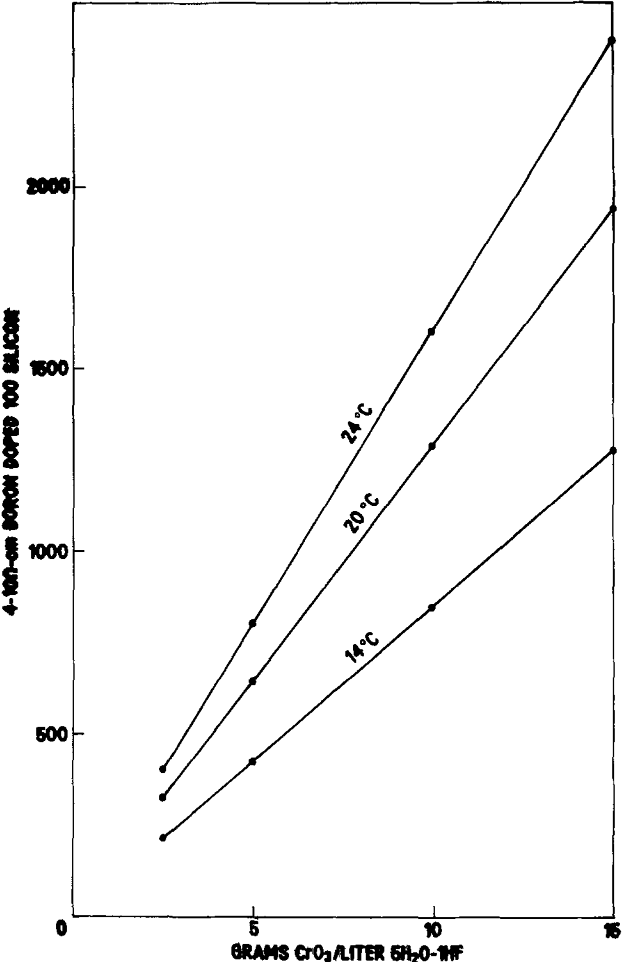

Fig. 6. Silicon etch rate curve for CrO_3-HF-H_2O system Å/min

Conclusions

We have demonstrated a method for achieving a planar isolation oxide structure based on a significant modification of the full-ROX technique for buried oxide. Sidewall masking with a second layer of silicon nitride prevents intrusion of the isolation oxide into the thin oxide regions to save real estate and to prevent formation of the bird's head. Use of a thin second pad oxide beneath the second nitride is a key step in achieving the planar structure. The CrO_3-HF-H_2O etching system provides a good means of isotropically etching the silicon substrate during processing.

The Role of Carrier Diffusion and Indirect Optical Transitions in the Photoelectrochemical Behavior of Layer Type d-Band Semiconductors

W. Kautek, H. Gerischer,* and H. Tributsch[1]

Fritz-Haber-Institut der Max-Planck-Gesellschaft, D-1000 Berlin 33, Germany

ABSTRACT

Photocurrents at n-type single crystals of MoS_2, $MoSe_2$, and WSe_2, with the van der Waals surfaces exposed to the electrolyte, have been studied by varying the voltage applied and the wavelength of the light. The experiments have been performed under conditions where a depletion layer is formed beneath the semiconductor surface and in the presence of I^--ions in the electrolyte which act as scavengers for the photogenerated holes and prevent corrosion of the electrodes. An evaluation of the quantum yield in relation to the absorption coefficient and the extension of the space charge layer shows that generation of minority carriers outside the space charge layer contributes to a large extent to the photocurrents. A mean diffusion length for holes of 1.4×10^{-4} cm (MoS_2) and 5×10^{-4} cm ($MoSe_2$) is derived from the experiments. The wavelength dependence of the photocurrent yield is analyzed in terms of light absorption for indirect transitions. This gives a measure of the bandgaps in these materials which turn out as 1.17 eV (MoS_2), 1.06 eV ($MoSe_2$), and 1.16 eV (WSe_2) in good accordance with optical measurements.

The theory of photovoltaic power conversion devices based on semiconducting materials like, *e.g.*, Si, Ge, GaAs, TiO_2, etc., shows that the efficiency is mainly determined by the diffusion process of the photogenerated minority charge carriers (1-3). The contribution of carriers generated in the space charge layer can be neglected because its extension in moderately doped samples mostly is several orders of magnitude smaller ($\sim 10^{-6}$-10^{-5} cm) than the minority carrier diffusion length which can reach the order of 10^{-4} cm [TiO_2, Ref. (2)], 10^{-3} cm (GaAs), or 1 cm (Ge, Si), respectively (4). We studied whether the situation is different or similar in layer type molybdenum and tungsten dichalcogenides which have also been shown to be interesting semiconductors for electrochemical (5-7) and solid-state (8) solar cells.

It was the aim of this investigation to distinguish between the extent of charge separation in the Schottky barrier and in the diffusion zone and to correlate the efficiency of energy conversion with the peculiar band structure of these systems. An electrochemical Schottky barrier is the easiest to fabricate and therefore has been employed for this study.

Transmission spectra with the incident light normal to the plane of the layers (electric field vector E normal to the c-crystal axis) have been known for a long time (9). Two peaks at the absorption edge, called A and B, have generally been accepted to be the result of ground state excitons with the separation A-B being a measure of the spin-orbit interaction.

There has been the idea that excitons exist in layer-type materials ($GaSe_2$, $MoSe_2$, etc.) in the hydrogen-like Wannier-Mott form (10) though these compounds exhibit very anisotropic physical properties. This has been confirmed for 2H-crystals in numerous experimental papers (11-17). The optical dissociation energy of these excitons lies between 0.04 and 0.06 eV which obviously is in the range of the lattice vibrational energy at room temperature (11, 12, 15, 17). It has been stated that the originally excited excitons dissociate inside the crystal to give free electrons and holes (18, 11, 19). An exciton-phonon ionization model was consequently proposed (20). The lifetime of excitons will therefore be extremely short at normal temperatures.

Intrinsic conduction measurements above 700°K of n-type MoS_2 and $MoSe_2$ yielded a thermal bandgap of the order of 1.1 eV (14, 21), which agrees well with the indirect bandgap suggested by band structure calculations (26), and is supported by photoemission measurements (27-34) and optical absorption measurements (35). On the other hand, there is still a valid discussion going on regarding the symmetry of the valence band involved in the direct and indirect optical transition. There has been a long tradition based on tight binding band structure calculations (36), optical absorption measurements (35), and consideration on EPR data (37, 38) to situate the direct A-exciton transition between the mainly p-like chalcogene valence

[1] Present address: Centre National de la Recherche Scientifique Laboratoires de Bellevue, F-92190 Meudon, France.

band and the d-like metal conduction band (25, 26). The fundamental indirect absorption edge however was associated with a d-d transition. In contrast to this picture, there is strong evidence from various band structure calculations (39, 22-26) and photoemission results (40, 33, 34) that both direct and indirect transitions are associated with the valence d- and conduction d-band of the transition metal.

Experimental and Materials

Materials.—All semiconducting materials used were n-type. Synthetic MoS_2 single crystals were obtained from Dr. F. Lévy (Laboratoire de Physique Appliquée, Ecole Polytechnique Fédéral de Lausanne, Switzerland) (41). The $MoSe_2$ and WSe_2 single crystals were prepared by J. Gobrecht (Fritz-Haber-Institut) by bromine transport from the gas phase (42). Molybdenum dichalcogenides crystallize in sandwich layers which are held together only by relatively weak van der Waals forces. The sandwiches are arranged in such a way that the molybdenum atom layer is placed between two layers of chalcogen atoms. The solid-state and crystal-chemical properties of transition metal dichalcogenides have been extensively reviewed (9, 43-48).

Electrode preparation.—The electrode preparation and the surface classification techniques have been described previously (49).

Electrolytes.—Electrolytes were prepared using reagent grade chemicals (Merck) and triply distilled water. A solution of 1M KCl served as supporting electrolyte. It was found that photocurrent spectra in electrolytes with and without 0.05M hydroquinone did not differ from the same experiment in 0.05M KI solution if the I_2- or I_3^--concentration was kept low enough. Therefore all the results presented here have been achieved with 0.05M KI electrolytes. The *p*H value was adjusted to 1 by addition of HCl and continuously monitored with a glass-electrode *p*H meter.

Experimental procedures.—Electrochemical quasistationary current-potential (*j*-*U*) characteristics and photocurrent spectra were determined in a Duran cell with an optical glass bottom. The platinum foil counterelectrode was located in a compartment separated by a glass diaphragm. In all cases a commercial-type saturated calomel electrode served as reference electrode, but all data have been transformed to the normal hydrogen electrode as the reference (U_H). All measurements have been performed at room temperature under controlled potential conditions. A monochromatic light source was used as described previously (49). It could be confirmed by means of a rotating electrode device that diffusion in the electrolyte never was determining the current.

The quotient of the charge carrier flux (anodic limiting photocurrent density) and the incident photon flux was taken as the apparent quantum efficiency Φ_a (value with no correction for light reflection).

Results

Figure 1 shows the characteristic *j*-*U* dependence which is practically identical for all absorption coefficients although α differs by four orders of magnitude. An anodic saturation current is reached within a band bending range of 0.2-0.4V independent of the wavelength of the light. The penetration depth of light increases proportionally to $1/\alpha$. One should therefore expect that the slope of the *j*-*U* dependence would gradually decrease with increasing wavelength if the main contribution to the photocurrent should come from light absorbed in the space charge layer, since a higher potential would have to be applied to collect the same number of photogenerated holes. Such a dependence cannot be observed with molybdenum and tungsten dichalcogenides. Figure 1c has been derived from measurements with a WSe_2 electrode showing an appreciable amount of surface not normal to the c-lattice vector. The consequences are discussed elsewhere (49, 60). The onset and slope of the anodic

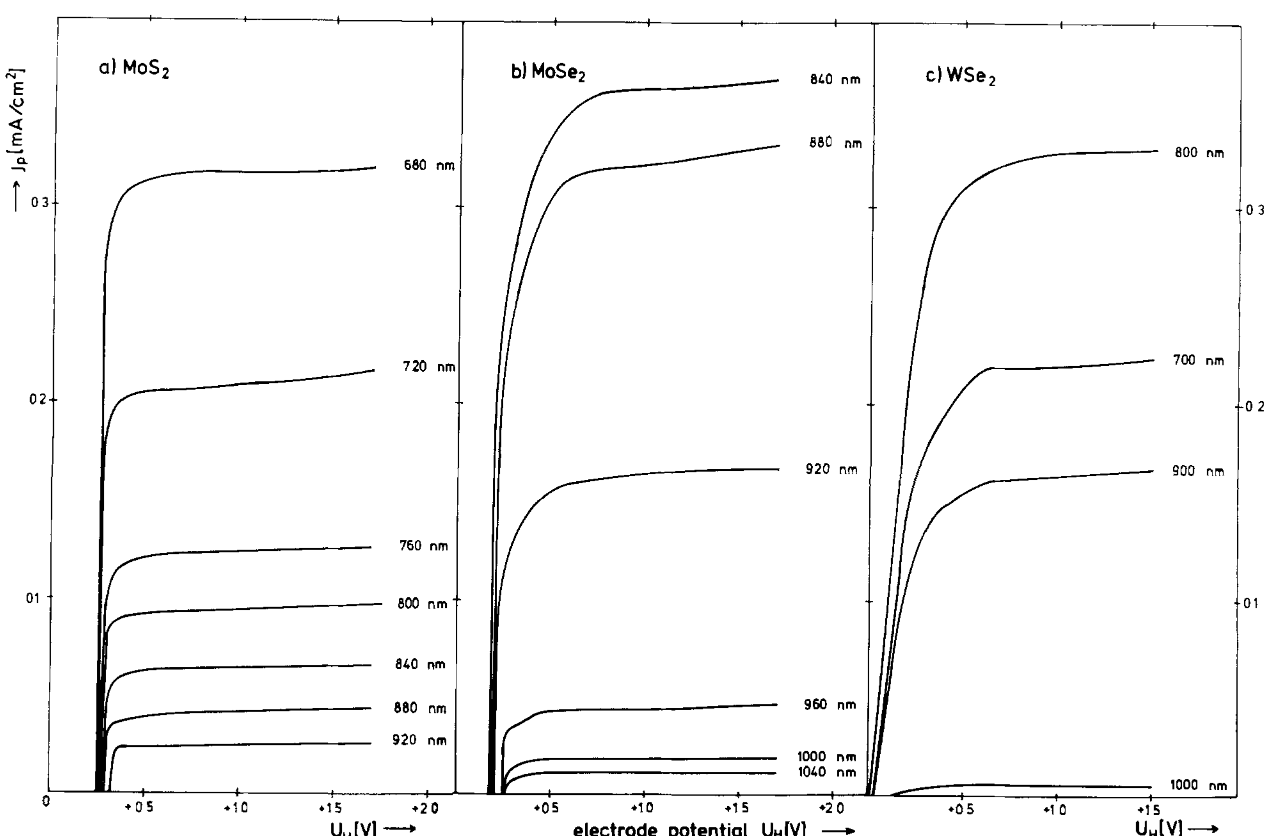

Fig. 1. Photocurrent-voltage curves of n-type transition-metal dichalcogenide semiconductor electrodes in contact with a redox electrolyte (0.05M KI, 1.0M KCl, *p*H = 1) at various wavelengths. Illumination intensity 1-2 mW/cm^2.

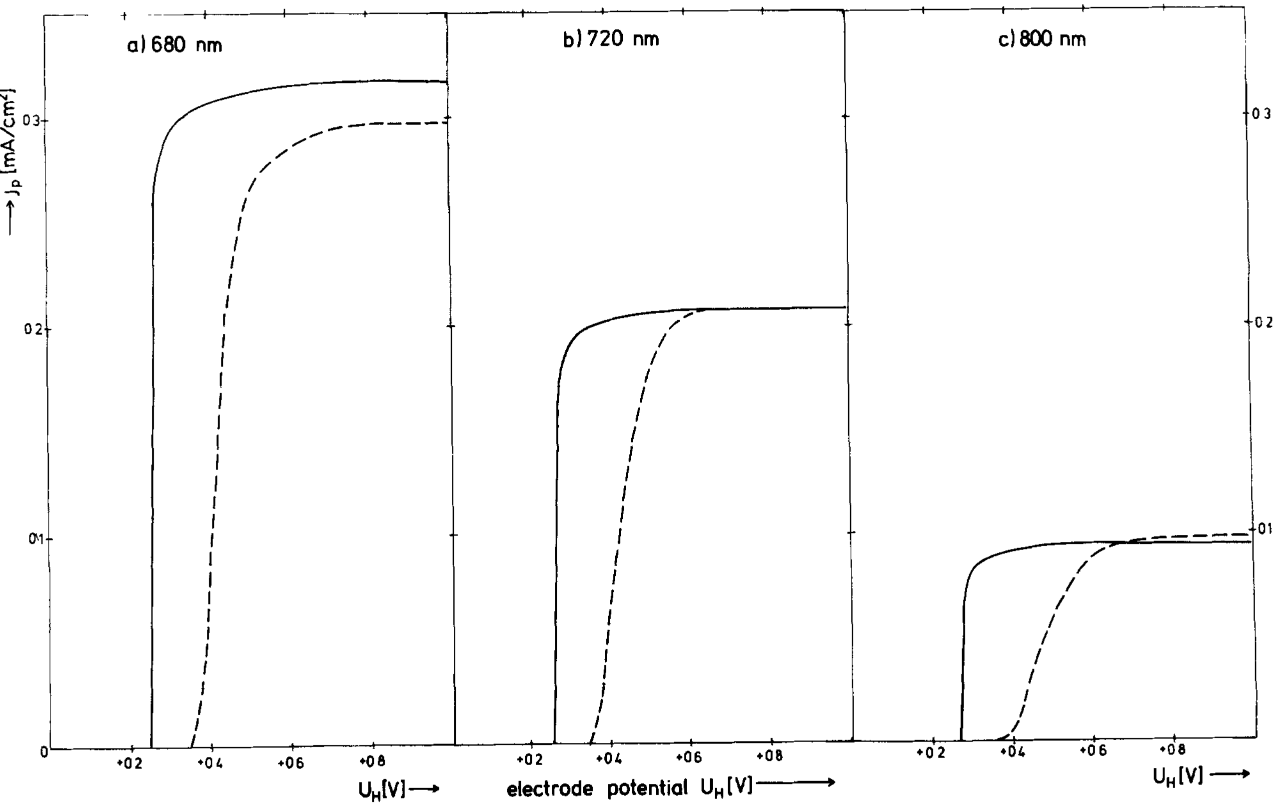

Fig. 2. Photocurrent-voltage curves of a n-type MoS_2 electrode in contact with a redox electrolyte (0.05M KI, 1.0M KCl, pH = 1) at three wavelengths corresponding to absorption coefficient values of (a) 10^5 cm^{-1}, (b) 10^4 cm^{-1}, (c) 10^3 cm^{-1}. Solid lines: practical ideal van der Waals surface; dashed lines: some surface fraction not normal to the c-lattice vector produced by anodic photoelectrochemical corrosion.

photocurrents depends to some extent on the quality of the electrode surface which is determined by the percentage of surfaces not normal to the c-lattice vector. The saturation current, however, is not greatly affected. Figure 2 shows the difference between a smooth and a corroded surface.

The photocurrent across a semiconductor-liquid interface does not necessarily reflect the absorption spectrum of the material. It is well known that there are intermediate processes, such as diffusion, migration, trapping and recombination of charge carriers, or transfer of excitation energy, which determine how many charge carriers can reach the electrode surface and undergo electrochemical reactions. A comparison of absorption spectra and photocurrent spectra in the saturation range is therefore a helpful means to identify intermediate processes. Figure 3 shows such a comparison for the layer-type semiconductors MoS_2, $MoSe_2$, and WSe_2 where the absorption coefficients plotted in a logarithmic scale are taken from data in the literature (35). A remarkable detail which can immediately be recognized is that the apparent quantum efficiency (Φ_a) still stays above 10% at wavelengths corresponding to light penetration depths two orders of magnitude deeper ($1/\alpha = 10^{-3}$ cm) than that of the wavelengths exciting the direct A-exciton (λ_A, $1/\alpha = 10^{-5}$ cm). With negligible diffusion the efficiency should decay abruptly at wavelengths beyond λ_A due to the difficulty of collecting the majority of holes generated outside the space charge layer. That means that field-independent diffusion of free charge carriers must play an important role.

Discussion

Photocurrent-potential relationships.—The prominent result is that the photocurrents are practically independent of the electrode potential in a wide polarization range (Fig. 1) even at wavelengths where the light penetrates deeply into the bulk. The meaning of this result can be derived from the traditional model for photocurrent-potential relationships of illuminated semiconductor electrodes (51). The n-type semiconductor-electrolyte half-cell is divided into four regions (Fig. 4): (*i*) a neutral electrolyte with redox couples present, (*ii*) the Helmholtz double layer between electrolyte and electrode surface, (*iii*) the space charge depletion region of width W across which charge carriers can migrate in the electric field of a potential drop $V_{sc'}$, and (*iv*) a neutral region in the bulk of the semiconductor in which the hole lifetime is τ and where the holes can diffuse with mobility μ_p. Light penetrates through the practically transparent electrolyte (very low concentration of I_2 and I_3^-) into the space charge region and the neutral bulk region to a depth given by the reciprocal value of the absorption coefficient, α, of the semiconducting material at a given wavelength.

We make the following assumptions in our model: (*a*) Absorption of the light quantum generates one electron hole pair. (*b*) The potential drop across the Helmholtz-layer is constant. (*c*) The doping level N_D is uniform. (*d*) The photoexcitation does not disturb the electric field in the space charge layer. (*e*) All holes in the depletion region can reach the surface, and the barrier height V_{sc} is large enough to prevent all surface recombination as well as the reverse electron transfer reactions. (*f*) The charge transfer rate across the Helmholtz layer is fast and not rate determining.

In the depletion approximation the depletion width (defined as distance x from the interface up to the plane where $dV/dx = 0$) is

$$W = \left(\frac{2\epsilon\epsilon_0 V_{sc}}{eN_D}\right)^{1/2} \quad [1]$$

with

$$V_{sc} = U - U_{fb} \quad [2]$$

where ϵ_0 is the permittivity of the free space, ϵ the relative dielectric constant, e the electric elementary

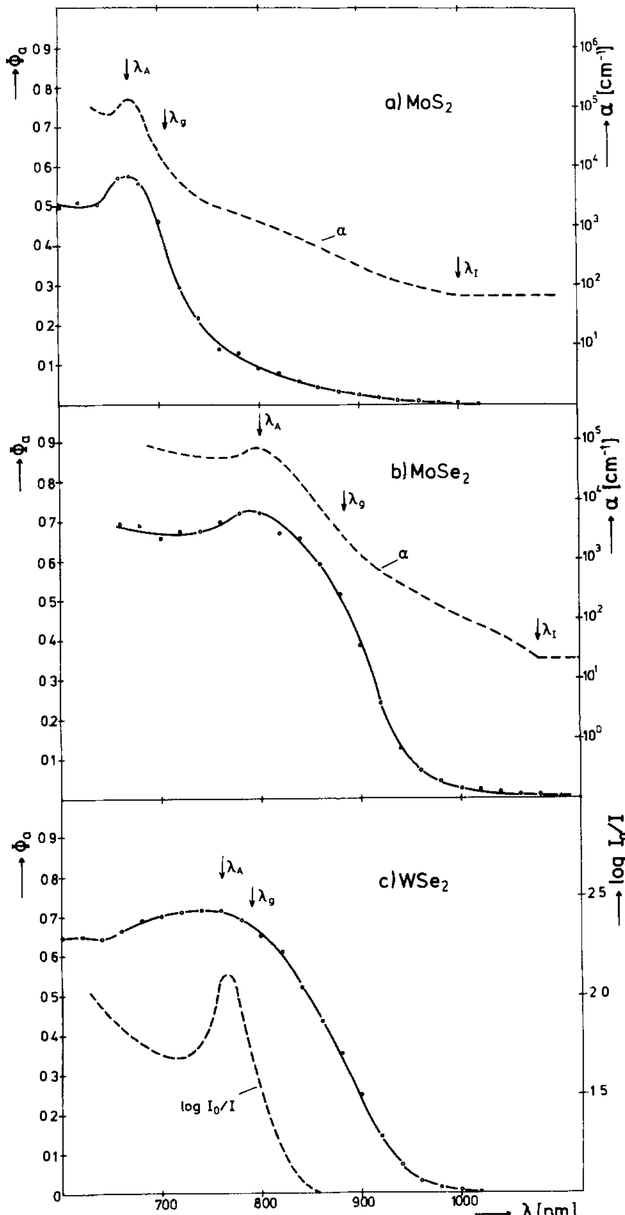

Fig. 3. Spectral dependence of the photoelectrochemical apparent quantum efficiency Φ_a depicted together with corresponding absorption spectra [α-values of MoS_2 and $MoSe_2$ from Ref. (35), log I_0/I values from Ref. (50)]. λ_g, assumed bandgaps in (a) Ref. (5), (b) Ref. (6), (c) Ref. (7) on the basis of energy conversion efficiency measurements. λ_A, wavelengths of the direct excitonic A-transition. λ_I, threshold wavelength of the indirect transition [Ref. (35)].

charge, N_D the donor concentration, and U_{fb} the flatband potential of the semiconductor. The diffusion length of the holes L_p is given by (4)

$$L_p = (D\tau_p)^{1/2} \quad [3]$$

where D_p, the diffusion coefficient of the holes, is related to the mobility μ_p by the Einstein relation

$$D_p = \frac{\mu_p kT}{e} \quad [4]$$

L_p therefore becomes

$$L_p = \left(\frac{\mu\tau_p kT}{e}\right)^{1/2} \quad [5]$$

With the above assumptions one obtains for the theoretical photocurrent j_p (51)

$$j_p = j_{sc} + j_D \quad [6a]$$

$$j_p = eI\,[1 - \exp(-\alpha W)] + eI\frac{\alpha L_p}{1 + \alpha L_p}\exp(-\alpha W)$$

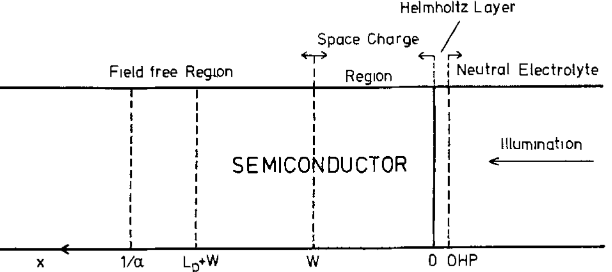

Fig. 4. Model of the illuminated semiconductor-electrolyte interphase region. $1/\alpha$, depth of light penetration; W, width of space charge layer; L_p, mean diffusion length of minority carriers; OHP, outer Helmholtz plane.

$$j_p = eI\left[\left(1 - \frac{1}{1 + \alpha L_p}\right)\exp(-\alpha W)\right] \quad [6b]$$

j_p is the sum of the currents of holes generated in the space charge region (j_{sc}) and the diffusion current of the holes generated in the adjacent bulk of the electrode (j_D), I designates the photon flux. Equation [6] expresses that minority charge carriers generated outside the depletion region (W) can only contribute to the photocurrent if they can reach the space charge domain by diffusion, *i.e.*, if they are generated within a distance of L_p behind the space charge layer. The rest of the photogenerated carriers recombine in the bulk.

We can calculate the depletion layer width W in the dependence of V_{sc} with Eq. [1] for our MoS_2 sample with $N_D = 2 \times 10^{17}$ cm^{-3} (52) and the dielectric constant for the electric field vector parallel to the c-lattice vector of the layer lattice $\epsilon = 4.9$ (16, 53). With $V_{sc} > 0.3$V, W is in the order of 10^{-5} cm for N_D above 10^{16} cm^{-3}. If L_p would be small compared with $1/\alpha$, that $\alpha L_p << 1$, we would get $j_p \approx j_{sc}$, and, therefore, a considerable potential dependence of j_p. This theoretical case is plotted in Fig. 5a and b as dashed lines. In Fig. 5c this case would give a negligible current. The graph does not show such a dependence and indicates that the observed photocurrents are mainly due to diffusive transport, particularly if $\alpha < 10^4$ cm^{-1}. This conclusion does not depend on the absolute values of α as long as $1/\alpha$ is not in the order of magnitude of W, which is certainly not the case for the range of the indicated bandgap.

The diffusion length of holes.—In such cases, the photocurrent can be used to calculate the diffusion length L_p at long wavelengths where space charge layer effects can be neglected ($\alpha W << 1$). Equation [6b] can be transformed using the quantum efficiency Φ

$$\Phi = \frac{j_p}{eI} \quad [7]$$

$$\frac{1}{\Phi} = \frac{1}{\alpha L_p} + 1 \quad [8]$$

According to this relation a plot of $1/\Phi$ *vs.* $1/\alpha$ should give a straight line the slopes of which should be the reciprocal diffusion length. This method gives relative deviations < 20% from the exact L_p value as long as $L_p < 0.5d$ (d: electrode thickness) (3). This relation was satisfied by our samples. In order to compare this theory with the experiment we have to correct our data for photon flux losses by reflection. The real efficiency will be given by

$$\Phi_r(\lambda) = \frac{\Phi_a(\lambda)}{T(\lambda)} \quad [9]$$

$\Phi_r(\lambda)$ is the real quantum efficiency at wavelength λ, $\Phi_a(\lambda)$ is the experimental apparent efficiency neglecting reflection losses, $T(\lambda)$ is the transmittivity. With assumption (a) that absorption of one light quantum

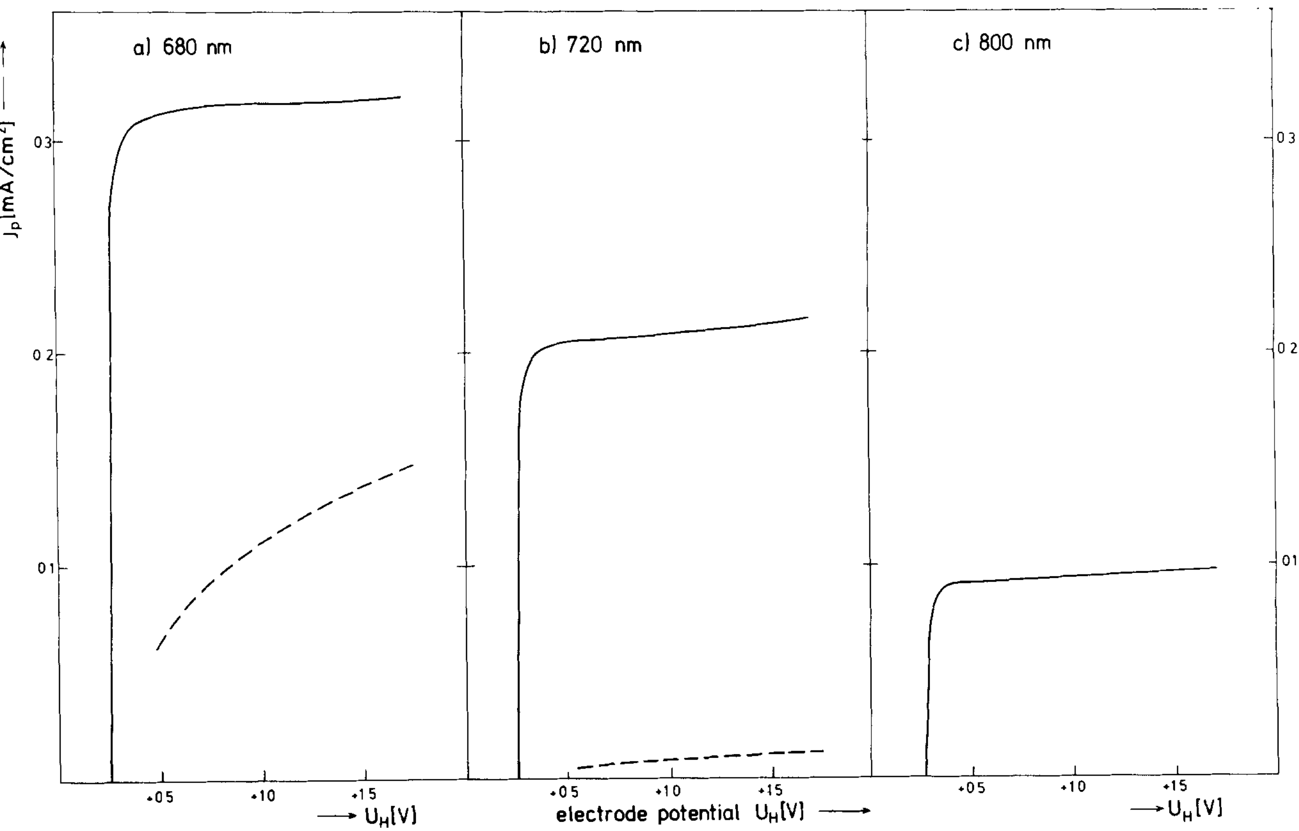

Fig. 5. Photocurrent-voltage relationship at a liquid junction of an n-type MoS_2 electrode (solid lines) compared with theoretical j_p-U curves according to Eq. [6b] neglecting diffusion of minority carriers (dashed lines).

generates one electron-hole pair we can set the real efficiency at the A-exciton wavelength, $\Phi_r(\lambda_A)$, equal to unity

$$\Phi_r(\lambda_A) \equiv 1 = \frac{\Phi_a(\lambda_A)}{T(\lambda_A)} \quad [10]$$

The relative wavelength dependence of the transmittivity can be taken from reflectivity measurements (54) and will be expressed by the factor $f(\lambda)$

$$f(\lambda) = \frac{T(\lambda)}{T(\lambda_A)} \quad [11]$$

Introducing Eq. [10] and [11] into [9] yields for the real quantum efficiency

$$\Phi_r(\lambda) = \frac{\Phi_a(\lambda)}{\Phi_a(\lambda_A)f(\lambda)} \quad [12]$$

One can see in Fig. 6 that the theory describes the experiment fairly well if one bears in mind that the accuracy of the available α-values is moderate and may vary from sample to sample in the range of low α-values. The slopes of the straight lines increase somewhat after considering the correction factor $f(\lambda)$. The corrected slopes for photon penetration depth ranges between 10^{-4} and 10^{-2} cm give mean diffusion length values for MoS_2, $L_p = 1.4\ (\pm\ 0.2) \times 10^{-4}$ cm and for $MoSe_2$, $L_p = 5\ (\pm\ 3) \times 10^{-4}$ cm.

The correctness of these figures depends on the accuracy of the α-values used in this treatment. Since we could not measure these data independently there remains a considerable uncertainty, which however, will not affect the order of magnitude.

With the knowledge of the hole mobility (μ_p) and the hole diffusion length (L_p) we can estimate the lifetime τ_p. Hole mobilities normal to c ($\mu_p\perp$) have been derived for p-type MoS_2 specimen with $N_D \approx 2 \times 10^{17}$ cm^{-3} around 200 cm^2/V sec (55). With an anisotropy of $\mu_p\perp/\mu_p\|| \approx 2200$ (56), the hole mobility along c ($\mu_p||$) would be around 0.1 cm^2/V sec. After Eq. [5] the mean hole lifetime would result in $\tau_p \approx 10^{-4}$ sec ($MoSe_2$) and $\tau_p \approx 10^{-5}$ sec (MoS_2). With a less pronounced anisotropy of about 10 due to lattice defects, we would obtain 10^{-6} sec ($MoSe_2$) or 10^{-7} sec (MoS_2). These results will be checked by direct lifetime measurements.

The indirect bandgap.—It is generally accepted that transition metal dichalcogenides are indirect bandgap semiconductors, as has been stated above, which should have serious consequences for the applicability of these compounds as energy converting electrodes. The photocurrent spectra in Fig. 3 show apparent quantum efficiencies up to 10% even at wavelengths corresponding to absorption coefficients almost three orders of magnitude smaller than that of the direct A-transition. If one assumes a sufficiently high density of states at the indirect conduction band minimum, ($N(E_c)$), the Fermi level will be located somewhat below in the n-type semiconductors of high enough doping levels as used here (Fig. 7). The decisive parameter for electrochemical regenerative and electrolysis cells is the distance between the Fermi energy at flatband condition and the valence band maximum, which determines the limit of the free enthalpy of the photogenerated holes which can be reached at high illumination intensities and can be used for electrochemical work.

A promising method for determining the size of this energy gap is based on the wavelength dependence of light absorption for indirect transitions, which is reflected in the photoresponse of the semiconducting electrode if the photocurrent is fully diffusion controlled. This condition is met for the present compounds at wavelengths near the onset of the indirect absorption (λ_I) (Fig. 3). There, αW and αL will be much less than unity so that Eq. [6b] and [7] simplify to

$$\Phi = \alpha L_p \quad [13]$$

The frequency dependence of the absorption coefficient α for an indirect transition is given by the relation (57, 58)

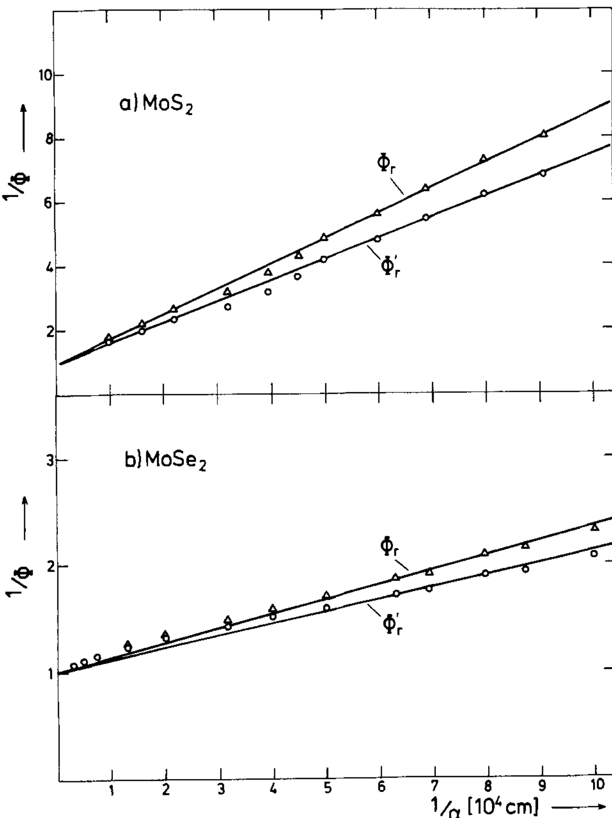

Fig. 6. The reciprocal of the quantum efficiency Φ is a linear function of the light penetration depth, $1/\alpha$ [α = absorption coefficient from Ref. (35)]. Φ_r', real quantum efficiency assuming constant transmittivity $T(\lambda) = T(\lambda_A)$; Φ_r, real quantum efficiency corrected for varying transmittivity, $T(\lambda)$, from Ref. (54).

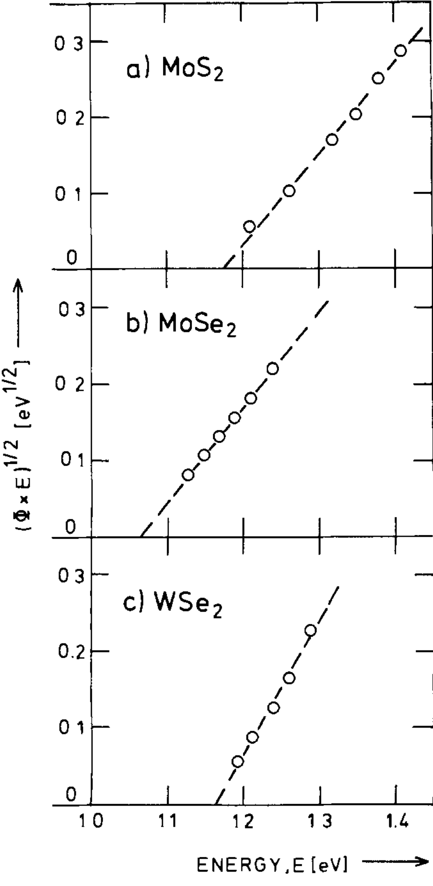

Fig. 8. Photoyield spectra near the energy threshold for electron injection from an iodide-containing electrolyte into the semiconductor valence band. The intercepts with the energy axis are taken as the fundamental energy gaps (see Table I).

$$\alpha = \frac{A(h\nu - E_g)^2}{h\nu} \quad [14]$$

where A is a constant, E_g is the energy gap. Inserting [14] into [13] yields

$$(\Phi h\nu)^{1/2} = (LA)^{1/2}(h\nu - E_g) \quad [15]$$

If this equation can be applied, a plot of $(\Phi h\nu)^{1/2}$ *vs.* $h\nu$ should be linear with the intercept of the photon energy axis being the bandgap edge.

This theory can describe our experimental finding well, as is depicted in Fig. 8. The real quantum efficiencies were used here after correction for reflection losses. The bandgap values derived from this figure are listed in Table I. The comparison with other data in this table shows that this method gives results in

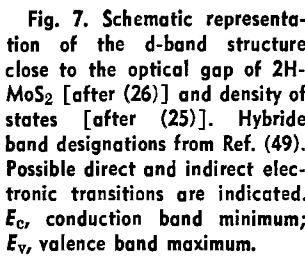

Fig. 7. Schematic representation of the d-band structure close to the optical gap of 2H-MoS_2 [after (26)] and density of states [after (25)]. Hybride band designations from Ref. (49). Possible direct and indirect electronic transitions are indicated. E_c, conduction band minimum; E_v, valence band maximum.

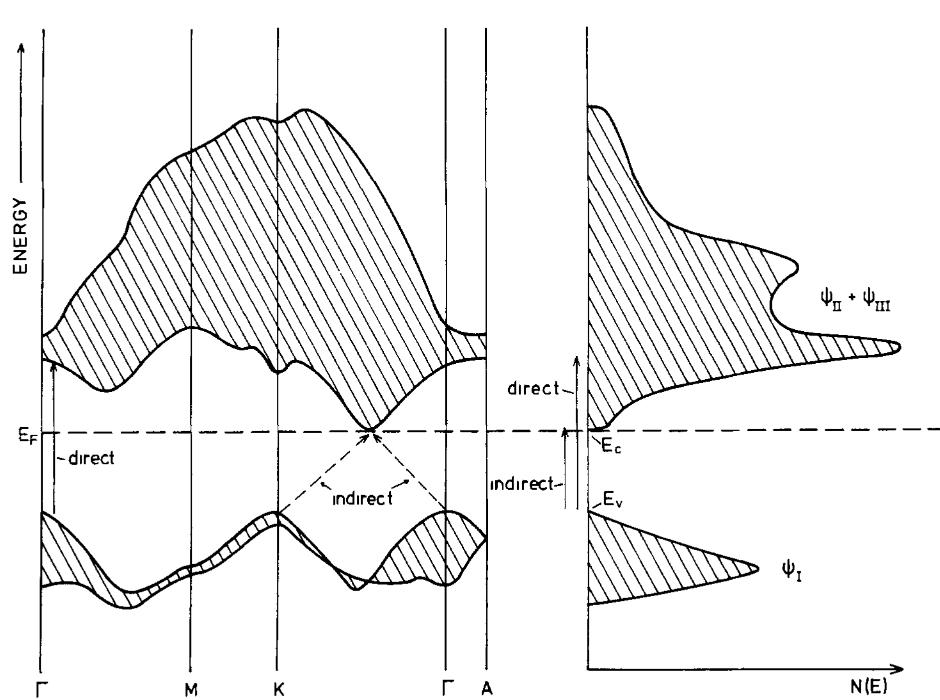

Table I. Fundamental indirect bandgap (eV)

	Photoelectrochemical	Optical absorption (35)	Photoemission (33)	"APW" calculation (25)
MoS_2	1.17 ± 0.03	1.13 ± 0.01	1.0 ± 0.2	1.16
$MoSe_2$	1.06 ± 0.03	1.09 ± 0.01	—	—
WSe_2	1.16 ± 0.03	—	—	—

good agreement with findings of other authors and methods. It should be mentioned that numerous photoemission experiments (29-34) indicated that the valence band maximum lies about 1 eV under the Fermi level on the energy scale in n-type semiconductors. This supports our conclusion that the electrochemicall effective bandgaps are substantially smaller (Table I) than has been assumed up to now on the basis of energy conversion efficiency measurements (λ_g's in Fig. 3: MoS_2 1.75 eV (5), $MoSe_2$ 1.4 eV (6), WSe_2 1.57 eV (7). Consequently, these photoelectrode materials can only catalyze redox processes with reaction enthalpies less than 1 eV. The photoelectrochemical splitting of water which needs 1.23 eV will be impossible without additional applied voltage. Solar cells on the basis of these layer-type materials will be very similar in their behavior to silicon and their efficiency will depend largely on the lifetime of the minority carriers.

We now also understand why photopotentials greater than 0.7V could never be measured. At electronic equilibrium, the maximum band bending is limited by the gap size. The loss in free energy of electron hole pairs generated by light absorption due to charge separation, electrochemical overpotentials, etc. (59) has been estimated to amount to ~ 0.5V. Substracting this value from the indirect bandgap (~ 1.2V) yields a maximum effective photovoltage of 0.7V in accordance with the experimental findings.

Acknowledgments

Diffusion of Dopants from Optical Coatings and Single Step Formation of Antireflective Coating and P-N Junction in Photovoltaic Cells

Bulent E. Yoldas

Westinghouse Research and Development Center, Ceramic and Glasses Department, Pittsburgh, Pennsylvania 15235

ABSTRACT

The p-n junction in a silicon chip and an antireflective (AR) oxide coating on the surface of the chip are formed simultaneously from a clear polymerized solution derived from alkoxides of titanium and a p or n dopant. The partially hydrolyzed and polymerized solution is applied to the surface of the silicon by liquid application methods. The silicon cell is then heated to convert the solution to a solid oxide coating which meets the antireflective optical film requirements and induces the migration of the dopants into the chip, forming a p-n junction in the chip. Other expected advantages of this method are: attainment of very uniform dopant diffusion on unusually large samples and polycrystalline substrates; deep diffusion while avoiding excessive surface carrier concentration; and multi-dopant diffusion in differential areas of a sample by a single heat-treatment.

In the conventional preparation of a photovoltaic solar cell, a p-n junction is formed by diffusion of either boron or phosphorus into a silicon base material. The diffusions are generally made from the vapor phase, in an oxidizing atmosphere at 850°-1000°C.

A separate step is required for the application of a quarter-wave optical thickness antireflective film to the surface of the cell. The antireflective coating may increase the efficiency of the cell by as much as 50% (1-5). Such optical coatings are applied by vacuum deposition, sputtering, or other techniques. Recently, it was discovered that polymerized titanium dioxide solutions could be made which would deposit optical coatings of the desired thickness and index of refraction by dipping, spinning, or spraying (1). A cost analysis of this new method suggests that in volume production the cost of applying the AR coating can be reduced to less than $0.01 W-package (1980$) (6).

When the above titanium-oxide based solution is doped with a p-type dopant compound such as boron, the dopant will diffuse into the n-type silicon and form a p-n junction during the baking of the antireflective coating. Thus the antireflective coating and the p-n junction are formed simultaneously. This eliminates several steps which are required for the present method of diffusion and junction formation. Tests using this method (where the boron diffusion source is the doped antireflective coating) have resulted in surface concentrations (C_o) of boron in silicon of $10^{19}/cm^3$ (as measured by the spreading resistance). Other boron diffusion techniques generally lead to C_o's of 10^{21} to $10^{22}/cm^3$. In photovoltaic devices, a lower C_o in the back-surface region is preferable, because of decreased carrier combination at the back-surface.

At high surface carrier concentrations, the junction depth is restricted due to the increasing number of recombinations. In this process, where the carrier concentration appears to be self-limiting at an ideal value, coupled with the passivated surface, the formation of deeper junctions with less shunting becomes feasible, and requirement for shallower junctions, *e.g.*, 0.3 μm, becomes less critical.

Key words: coatings, optics, doping.

Another advantage of this new process is that very uniform dopant diffusion and junction depth can be obtained on large devices, photovoltaic or otherwise. This is due to the fact that the dopant diffuses from an optical film which is homogeneous in composition at the molecule level and uniform in thickness below the wavelength of light, no matter how large the substrate. This fact coupled with the fact that the amount of dopant available for diffusion over a given substrate area is finite and well defined might make the method attractive for doping polycrystalline materials evenly.

It should also be obvious that diffusion on well-defined areas of a substrate may be accomplished without masking the rest of the sample, simply by coating only those areas where diffusion is desired. Multi-doping of a sample can be done in a single heat-treatment by applying solutions containing different dopants to those areas where the particular doping is desired.

Approach and Experiments

A clear titanium-oxide based solution, derived from the partial hydrolysis and polymerization of titanium alkoxides, is applied to obtain an antireflective optical coating on a silicon base material. Other alkoxides useful in preparing the solutions have the general formula $M(OR)_n$ where M represents a metal ion (for example, Ti), O is oxygen, R is an alkyl group, and n is the valence of M.

Metal alkoxides, in general, hydrolyze vigorously when brought into contact with water. They form oxides and hydroxides as represented by the following reactions

$$M(OR)_n + n/2\,H_2O \rightarrow MO_{n/2} + nROH \qquad [1]$$

$$M(OR)_n + n\,H_2O \rightarrow M(OH)_n + nR(OH) \qquad [2]$$

Whether the oxide or the hydroxide forms during the hydrolysis depends on the nature of the alkoxide. In either case, the resultant material is particulate and precipitates out; it is therefore not useful for optical coating. The alkoxides of titanium and tantalum show a particular tendency to form precipitates, even under insufficient water hydrolysis; under normal conditions, the formation of precipitates cannot be prevented. However, we have developed a method of preparing a soluble polymerized species, capable of forming a continuous oxide network, from these alkoxides (7, 8)

$$l\,\mathrm{Ti(OR)_4} + m\,\mathrm{H_2O} \rightarrow -\overset{\overset{\displaystyle OH}{|}}{\underset{\underset{\displaystyle O}{|}}{\mathrm{Ti}}}-\mathrm{O}-\overset{\overset{\displaystyle O}{|}}{\underset{\underset{\displaystyle OR}{|}}{\mathrm{Ti}}}-\mathrm{O}- + k\mathrm{R(OH)} \quad [3]$$

These polymerized solutions are somewhat different than those available commercially for dopant sources and passivation purposes. Precipitate formation and self-condensation (which would normally occur during the hydrolysis) are prevented by careful control of the molecular interaction during the hydrolysis, so that certain amounts of OR groups are left in the molecular structure. When applied to substrates, these solutions leave a film which, upon heat-treatment at temperatures as low as 325°C, converts to a glass-like oxide film. The dopants (such as boron) may be introduced into the coating solution either from soluble compounds or by chemical polymerization of dopant into the precursor solution, for example

$$\rangle\mathrm{B{-}OR} + \mathrm{OH}-\overset{|}{\underset{|}{\mathrm{Ti}}}-\mathrm{O}- \rightarrow \overset{|}{\underset{|}{\mathrm{B}}}-\mathrm{O}-\overset{|}{\underset{|}{\mathrm{Ti}}}-\mathrm{O}- + \mathrm{R(OH)} \quad [4]$$

The coating is applied by spinning and by dipping. Spin application is used for Czochralski-type round silicon wafers. For ribbon-like dendritic-web silicon, the spin method is not suitable; rather, the samples are coated by dipping. Extremely uniform AR coatings may be readily obtained by either method.

The antireflective coating on silicon solar cells in an air environment must have a refractive index of 2 and a thickness of about 750Å, as calculated from Fresnel's equations. An undoped TiO_2 coating baked in air gives an index slightly over 2.1; the same coating baked in vacuum has an index around 2.4 (1). The refractive index of the coating is controlled by the composition of the solution. For example, the index of refraction in the TiO_2-SiO_2 binary can vary from 1.4 to 2.4. The thickness of the coating is controlled by the properties of the solution (such as its concentration and viscosity) and also by the application rate (1).

The p- and n-type dopant compound may be added directly to these alkoxide-derived solutions. The most common n and p dopants are phosphorus and boron, but other dopants such as aluminum, arsenic, antimony, or gallium may be used. To prepare a boron-doped solution, a boron compound is added to the Ti solution; such compounds include boron trimethoxide, boron triethoxide, boron triisopropoxide, phosphorus pentabutoxide, phosphorus pentaethoxide, phosphoric acids, etc. Whichever dopant compound is used, it must be compatible with the alkoxide solution: that is, it may go into the precursor solution either by reaction with the metal alkoxide (as shown in Eq. [4]) or by dissolution, but it must not form a precipitate. When the deposited coating is baked, the boron or phosphorus dopant in the coating acts as a diffusion source. If the dopant is added from an alkoxide, it may be partially hydrolized with 1.0-1.5 moles of water per mole of alkoxide to prevent its vaporization or precipitation. However, this may not be necessary if the base solution contains enough hydroxyl groups.

The silicon substrate materials which are generally available and suitable for this method come in two forms: as wafers about 2-12 cm in diameter, and as strips (that is, dendritic web silicon) up to 4 cm wide. The nominal thickness is 125-250 μm. For the purposes discussed here, the silicon should have some base dopant, either p-type or n-type. Most of the work discussed here was carried out on n-type silicon, using the doped antireflective coating as a boron diffusion source.

The temperature range for boron dopant diffusion is about 850°-1100°C; below 850°C very little boron diffuses into the silicon, and above 1100°C the silicon properties deteriorate. A temperature of 900°C appears to be optimal. The oxide film (after heat-treatment) is continuous, has a uniform thickness to within several angstroms, and is tenaciously bonded onto the substrate.

The heat-treatment provides for boron diffusion into the substrate. After the heat-treatment, however, the coating must be able to meet the optical requirements for antireflectivity, as defined by the Fresnel equations, for photovoltaic devices. Since the coating is affected by the diffusion process, the initial composition and thickness of the coating must be tailored to give (using silicon as an example) an index of refraction equal to 2 and a thickness of about 750Å after the heat-treatment. Boron can be added to alter the index of refraction of the coating as well as be the source of substrate dopant.

Results and Discussion

At 850°C, very little boron diffused into the silicon. At 900°C, however, the diffusion was signficant and controlled; therefore most of the diffusion investigation was conducted at this temperature. A striking feature of the boron diffusion from the TiO_2 coating is that it results in very uniform, sharp, well-defined, and predictable diffusion depths. Figure 1 shows the spreading resistance diffusion profile from a 10% B_2O_3-90% TiO_2 coating, for various diffusion times,

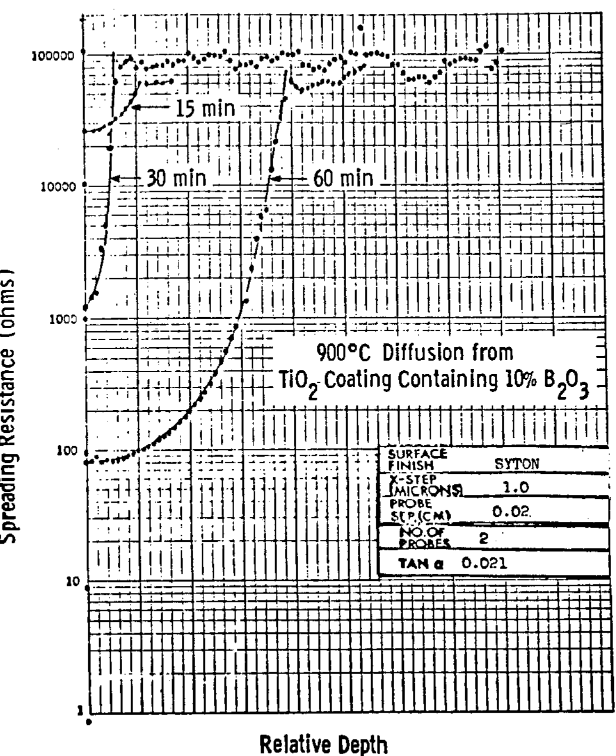

Fig. 1. Spreading resistance profiles as a function of time, at 900°C, for a 90% TiO_2-10% B_2O_3 optical coating on silicon.

baked at 900°C. The junction depths and surface concentrations reported here were obtained by simple spreading resistance profiles. Even though these measurements are not precise for a single sample, they provide comparison within a given set of samples, and established general trends. In these respects, the measurements were consistent to a degree that enabled us to predict these parameters, for a given condition, within a small error (usually less than 10%).

The concentration of boron in the coating affects the surface concentration and the junction depth in an n-type silicon substrate (10 Ω-cm resistivity). These effects are shown, for diffusion at 900°C for 1 hr, in Table I and Fig. 2 and 3. These figures are significant in that boron concentrations above 20 weight percent do not seem to affect either the carrier concentration or the junction depth. In this way boron diffusion from a TiO_2 coating differs from boron diffusion from conventional glass coatings. If this type of boron diffusion were used to produce a back-surface field in a p-type silicon, the stable C_o value of $\sim 10^{19}$ would approach the optimum value required for minimum recombination of the back-surface.

In order for the coating to meet the antireflective requirements, its index of refraction after the diffusion heat-treatment must be 2. Figure 4 shows the index of refraction of the coating, following heat-treatment for 1 hr at 900°C, as a function of B_2O_3 concentration in the TiO_2. It can be seen from the figure that over 50% B_2O_3 is needed to produce a coating with an index close to 2. This is acceptable, although for B_2O_3 concentrations greater than 40% the coating tends to become cloudy, and its chemical and environmental resistance may also drop.

A preferred method for adjusting the index of the coating to 2 is by limiting the boron addition to less than 30% (which is more in line with the diffusion requirement), and lowering the index by introducing another constituent with a low index—SiO_2, for example. The SiO_2 component may be added from alkoxides or partially hydrolized alkoxides by a process similar to the dopant introduction. Figure 5 shows the amount of equivalent SiO_2 required to lower the index of refraction to about 2, as a function of the amount of B_2O_3 dopant present in a titania-based AR coating subjected to 900°C vacuum treatment for 45 min. As an example, a precursor solution which would deposit a coating composed of 70% TiO_2, 20% B_2O_3, and 10% SiO_2 satisfies the index requirement for antireflectivity.

The spectral reflectivity curve in Fig. 6 shows zero reflection at 580 nm; this indicates the formation of an ideal single layer antireflective film on silicon, which meets the index of refraction and thickness requirements. When the boron diffusion measurements were done, it was found that this sample had a surface concentration of about 3×10^{19} and a junction depth of about 0.5 μm. Junction depth and carrier concentration on the entire sample were very uniform. The silicon samples, comprising an n-type dopant with 10-12 Ω-cm resistivity and a 10 cm silicon wafer, were spin-coated at 1000 rpm. The samples were baked at 900°C for 45 min and were divided into 1 cm² photovoltaic cells. The results of these unoptimized cells are shown in Table II.

Table I. Effect of boron concentration in coating on carrier concentration and junction depth (as determined by spreading resistance)

Weight percent B_2O_3 in AR coating (%)	Apparent surface concentration (C_o) (per cm³)	Junction depth (μm)
10	1×10^{19}	0.40
20	3×10^{19}	0.70
30	3×10^{19}	0.75
40	3×10^{19}	0.75
50	3×10^{19}	0.75

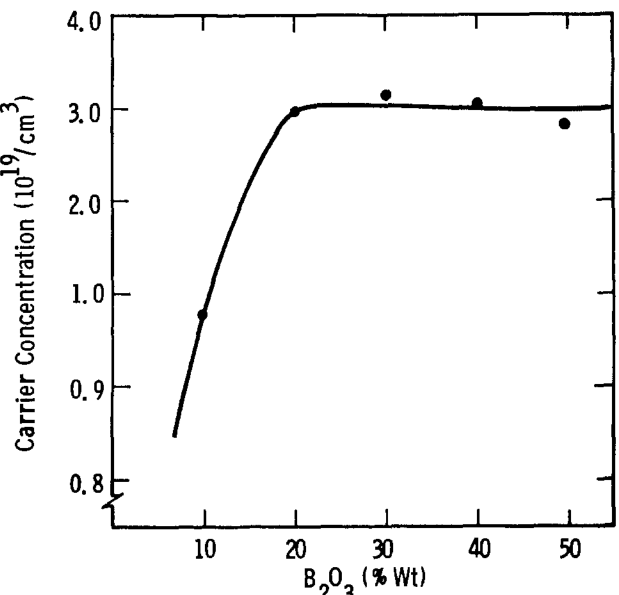

Fig. 2. Surface carrier concentration on a silicon chip as a function of boron presence in TiO_2 coating (as measured by spreading resistance).

These cells did not have a back-surface field. With the exception of sample 4, an OCD lifetime of 4-6 μsec is reasonable for the 10 Ω-cm n-type silicon used as a substrate. The low current density (J_{sc}) and fill factor (FF) are due to process related factors which, at the time of these experiments, were not optimized. When the process and structure design optimization is completed after the basic studies, back-surface field cells yielding current densities around 30 mA/cm² and efficiencies of ~15% are expected.

The experiments with phosphorus diffusion from the TiO_2 coating were less successful. There was no difficulty in obtaining antireflective coatings with phosphorus-containing TiO_2 coatings, however, diffusion into the silicon substrate required high temperatures. Understanding of the detailed diffusion mechanism from these coatings requires further studies including diffusion of dopants other than boron, use of optical coatings other than TiO_2, and use of polycrystalline substrates.

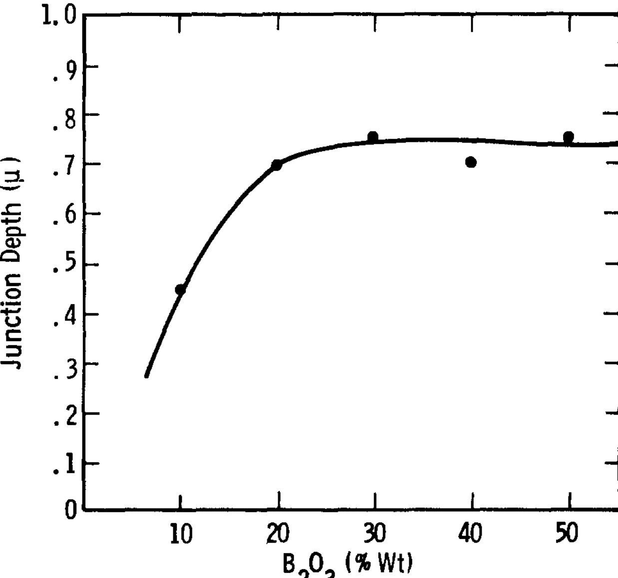

Fig. 3. Junction depth as a function of B_2O_3 concentration in the TiO_2 coating at 900°C for 1 hr.

Table II. Initial test results showing efficiencies of silicon solar cells whose p-n junctions were produced from the AR coating in a single step

Sample	$J_{sc}\left(\frac{mA}{cm^2}\right)$	V_{OC} (V)	FF	Eff. (%)	OCD (μsec)
1	24.60	0.515	0.734	9.83	5.60
2	24.60	0.515	0.738	9.89	5.60

ABSTRACT

The current-time characteristics of a polysilicon-polysilicon oxide-polysilicon structure were determined as a function of several MOS IC process parameters. We found a strong dependence of the current with the polysilicon oxidation temperature (900°-1100°C) in the case of an oxygen ambient. The data were empirically analyzed by an equation of the form $J = At^{-n}$ where "A" and "n" are constants; the current and "n" factor dependencies with measurement temperature (23°-135°C) and MOS bias (reference) electric field (1-3 $\times$ 10^6 V/cm) will be discussed. Interpretation of the data within the framework of surface asperities at the polysilicon-polysilicon oxide interface and a Fowler-Nordheim injection model will be discussed.

The understanding and control of defects in both semiconductor and dielectric materials are becoming more important for improved semiconductor device performance. Such device systems often involve wide bandgap amorphous and/or polycrystalline materials in conjunction with hot electron injection. In the double level poly floating gate Electrically Alterable Read Only Memory (abbreviated as EAROM henceforth), for example, programming is accomplished by the transport of hot electrons from the high electric field surface channel region adjacent to the drain through the gate oxide to the first level polysilicon floating gate. This procedure is identical to the programming of the Electrically Programmable Read Only Memory (EPROM) in that a high positive voltage is applied to both the drain and the second polysilicon control gate. Erase, however, is achieved by electron transport from the first level polysilicon floating gate through the thermally grown inter-level oxide on the floating gate to the second level polysilicon control gate. This is made possible by applying a higher positive voltage on the control gate while maintaining the source and drain at ground potential.

A desirable characteristic of the polysilicon oxide grown on the floating gate is a large gradient of current with respect to electric field. In this manner, the current through the polysilicon oxide is negligible at the relatively low electric field present during programming and reading (to minimize polysilicon oxide wear-out as well as read-disturb) and yet is high enough at the relatively high electric field present in the polysilicon oxide during the erase cycle. In all cases, it is desired that the current exhibit a minimum decay with time under constant voltage applied across the polysilicon oxide.

We shall present below several results of our investigation of the oxide thermally grown on the polysilicon floating gate. The impact of the oxidation temperature on the current conduction through the polysilicon oxide will be emphasized. Interpretation of the data within the framework of surface asperities at the polysilicon-polysilicon oxide interface (1-3) and a Fowler-Nordheim injection model will be discussed.

Experimental Procedures

Slice preparation.—Three in. diam, (100) oriented, 11-15 Ω-cm boron and 6-9 Ω-cm phosphorus-doped dislocation-free Czochralski crystals grown in resistance-heated pullers were used throughout the investigation. The final polished slice was 18 ± 1 mil thick; saw damage was removed by chemically etching one and a half mils off the slice prior to a single-sided free-floating polish by silica slurry in an alkaline medium.

Device fabrication.—Slice clean-up was performed via a sequence of dipping in organic and inorganic solutions prior to gate oxidation at 1100°C in an OHCl ambient utilizing 8 volume percent (v/o) HCl in these experimental tests.[4] Oxidation was followed by an *in situ* 10 min nitrogen anneal at temperature, prior to a 15 min cool down in nitrogen. Push/pull rates for these tests were between 7-10 in./min; the slices were loaded perpendicular to the gas stream (120 mil spacing). After photolithographic patterning and selective etching of the gate oxide, a 5000Å LPCVD polysilicon film was deposited at 622°C by the thermal decomposition of SiH_4. The polysilicon contacted the silicon substrate in selected areas thus permitting study of the transport process between poly I and poly II through the polysilicon oxide (see Fig. 1). The polysilicon was ion-implanted with either singly charged boron (35 (keV) or phosphorus (50 keV) ions at a dose of 1 $\times$ $10^{14}/cm^2$ in the case of a p- or n-type substrate, respectively.

Polysilicon oxidation was performed at either 900°, 1000°, or 1100°C with an oxygen ambient containing less than 1 ppm water (in the same furnace); similar preoxidation clean-up and furnace procedures were performed as for the gate oxidation case. A second polysilicon film was deposited as above, prior to doping with phosphorus at 1000°C via $POCl_3$ in a standard silicon IC procedure and subsequent electron beam aluminum evaporation. Several variously shaped and sized capacitor structures were fabricated by standard photolithographic techniques; the structure mainly utilized in this study was 1500 mils^2. The slices were then annealed in hydrogen at 450°C for 30 min prior to removal of the back-surface polysilicon and oxide layers.

[4] Before insertion of the slices into the furnace, the boat sat at the furnace end for approximately 1 min, enabling both warm-up of the slices and volatization of residual water, etc. The gate oxide was 950 ± 50A.

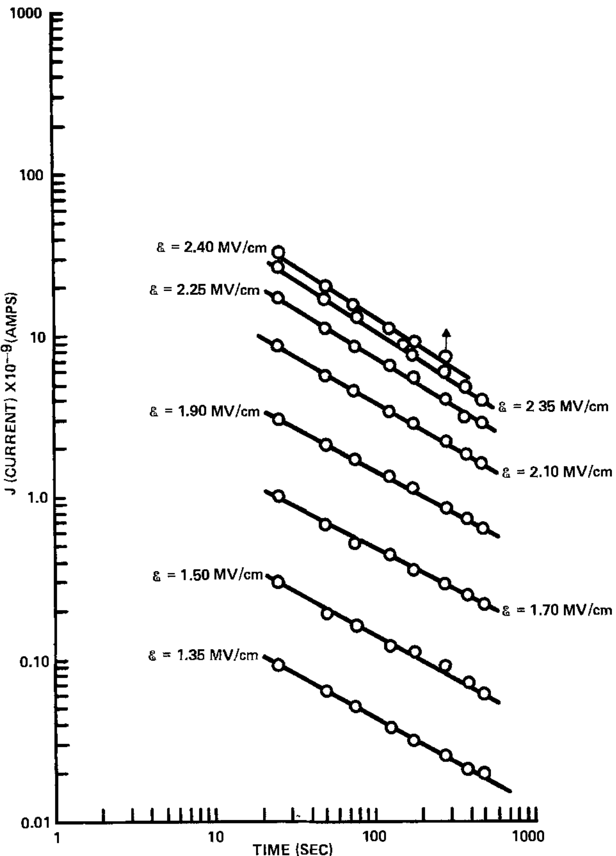

Fig. 2. Log current-log time graph for 1000°C polysilicon oxidation temperature. Poly I doping-phosphorus, $1 \times 10^{14}/cm^2$, 50 keV. Lot A, slice No. 7.

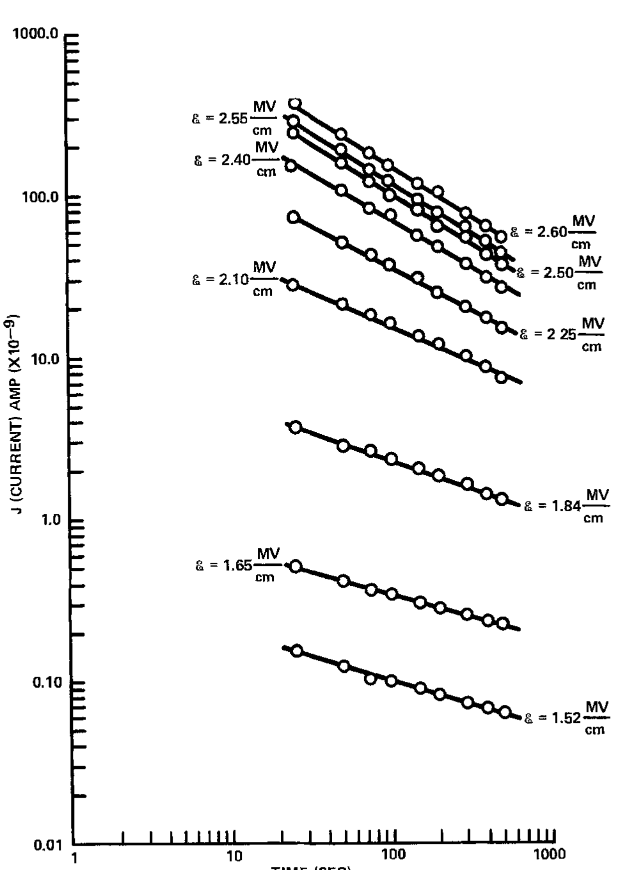

Fig. 3. Log current-log time graph for 1000°C polysilicon oxidation temperature. Poly I doping-boron, $1 \times 10^{14}/cm^2$, 35 keV. Lot B, slice No. 9.

Device measurement/analysis procedure.—A negative voltage was applied to the back-surface of the slice (aluminum contact on the front-surface was ground) to reduce spurious noise pickup. The voltage range was chosen to obtain a reference electric field of 1-3 $\times$ 10^6 V/cm across the polysilicon oxide. The current through the oxide was monitored as a function of time using a Keithley instrument logarithmic picoammeter and a chart recorder. A large displacement current flowed at $t = 0^+$, the transient typically expiring within 10 sec. Log current (J)-log time (t) curves were graphed from which the linearly extrapolated current at 1 sec, J_1, and the slope n, degradation constant, were derived.

A total of 172 measurement runs from 60 slices processed through 4 split lots constituted the basis of the room temperature experimental data. In addition, a number of experiments were performed at various measurement temperatures to obtain some estimates of the energy levels of the traps. A number of other experiments addressing the polysilicon surface condition and multiple ion implantations of the first polysilicon film were performed but shall not be discussed in this communication.

Experimental Results and Analysis

Figure 2 illustrates the log J-log t plot for a 1000°C polysilicon oxidation temperature in the case of a phosphorus implantation of poly I. It is observed that the current decreases and does not saturate with time and may be fitted by an equation of the form $J = At^{-n}$, where "A" and "n" are constants. Both the current level and the degradation exponent "n" increase as the reference electric field increases. The current level was asymmetric under polarity inversion of the aluminum contact. That is, the current is lower by a

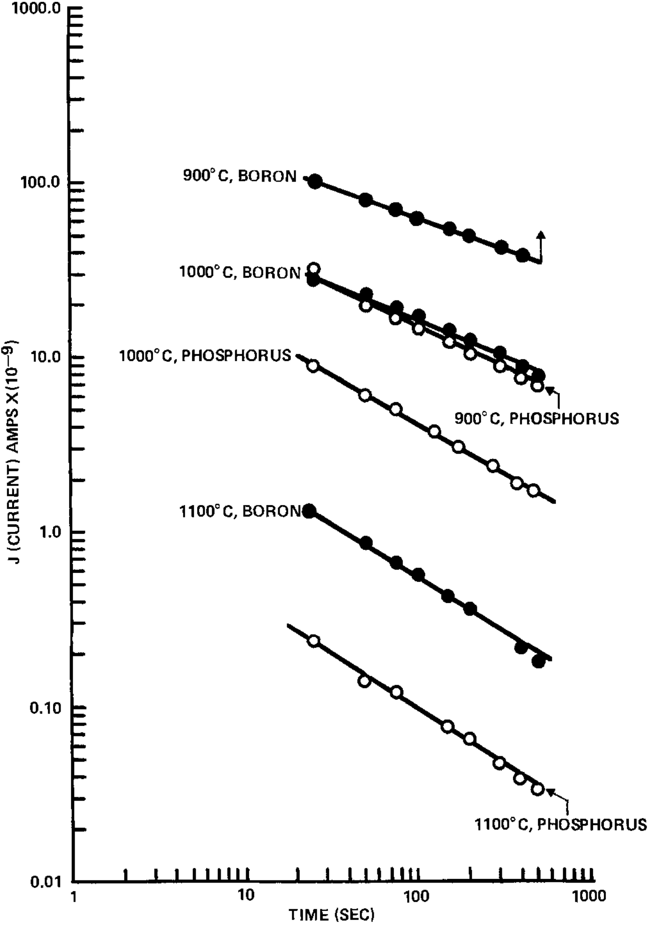

Fig. 4. Log current-log time representative summary graph for 900°, 1000°, 1100°C polysilicon oxidation temperatures. Poly I doping-boron (●)—lot B. Poly I doping-phosphorus (○)—lot A. Reference electric field equals 2.1 MV/cm.

factor of approximately 10^{+3} when the aluminum contact was made negative. Similar data are presented in Fig. 3 for boron doping of poly I, except that the current level, for a given reference electric field, was higher.

Figure 4 summarizes the influence of the polysilicon oxidation temperature for samples from the same split lots noted in Fig. 2 and Fig. 3. The current J_1 through the polysilicon oxide increases and the degradation exponent n decreases with decreasing inter-level oxidation temperature for a given polysilicon I doping (in the case of a reference electric field of 2.1×10^6 V/cm). Figures 5 and 6 summarize the influence of the polysilicon oxidation temperature on the current J_1 and degradation exponent "n", respectively.

The degradation exponent is a relatively weak function of reference electric field at room temperature for phosphorus-doped poly I and a 1000°C polysilicon oxidation temperature. In the case of boron doped poly I, however, the degradation exponent significantly decreases as the reference electric field decreases (see Fig. 7). Similar phenomena as above for both phosphorus and boron-doped poly I were also observed for 900° and 1100°C polysilicon oxidation temperatures.

A series of experiments were performed to monitor the current with time as a function of measuring temperature (23°-135°C) and reference electric field ($1\text{-}3 \times 10^6$ V/cm) in order to clarify the conduction mechanism responsible for the emission/transport of current through the polysilicon oxide. Figure 8 illustrates the Fowler-Nordheim characteristic[5] for phosphorcus-doped poly I and polysilicon oxidation temperatures of 1000° and 1100°C (4). One notes the tight packing of characteristics—slight increase of current as measuring temperature increases from 23° to 135°C—for the 1000°C case and the significant reduction in current level (for a given electric field) in the case of the 1100°C polysilicon oxidation. Nevertheless, the barrier height deduced from the Fowler-Nordheim curves was essentially constant at 0.48-0.52 eV, in good agreement with the 900°C oxidation data for the same lot and with that of another independent run (see Table I).[6]

[5] An electron effective mass of 0.4 m_o was used for these calculations.

[6] The barrier heights quoted are to be regarded as merely parameters (see Discussion).

* Poly I doped with phosphorus, followed by additional (undoped) polysilicon layer: Slice 12 (1000A); Slice 17 (1500A); Slice 23 (2000A)—Total poly thickness = 4500A.

A Frenkel-Poole analysis of the same data was also performed, although this interpretation does not appear as clear as that of the Fowler-Nordheim analysis. Figure 9 illustrates the log $J/\mathcal{E}$ *vs.* T^{-1} characteristic, for which a barrier height of 0.80-0.89 eV is derived for reference electric fields in the range of 1.6-2.35 $\times$ 10^6 V/cm (see Table I). In a similar fashion, a log $J/\mathcal{E}$ *vs.* $\mathcal{E}^{1/2}$ characteristic (Fig. 10) yields a dielectric constant of approximately 4, in poor agreement with the optical value of 2.2 (see Table I).

Similar analyses were performed for the boron-doped poly I samples. The Fowler/Nordheim characteristics increase slightly with measuring temperature for the 900°C polysilicon oxidation; the current significantly decreases (for a given electric field) in the case of the 1100°C oxidation. The barrier height was essentially constant at 0.57-0.69 eV (see Fig. 11 and Table II). The 1000°C data from another lot yielded

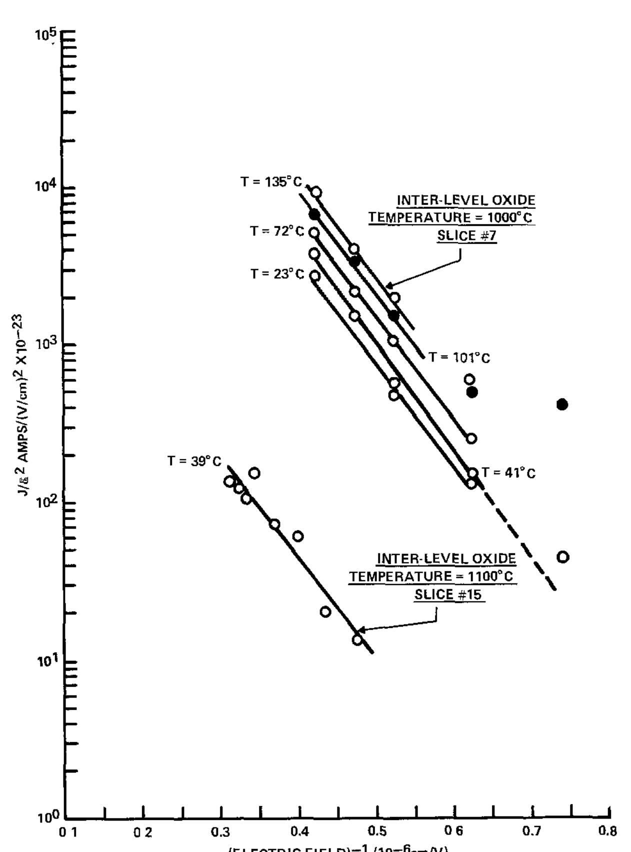

Fig. 8. Fowler-Nordheim characteristic for phosphorus-doped poly I. Lot A.

similar barrier height (see Table II). A Frenkel-Poole analysis yielded a dielectric constant of 1.2-4.5, in poor agreement with the optical value of 2.2 (see Fig. 12 and Table III). The barrier height derived by a log $J/\mathcal{E}$ vs. T^{-1} analysis exhibited a rather complicated temperature dependence and will require further experimental analysis (see Table III).

Discussion

The experimental observation of the decrease of current through the polysilicon oxide with respect to time, under the condition of a fixed voltage across the polysilicon oxide, implies a trap-related loss mechanism. Unfortunately, our understanding of traps in electrically stressed silicon dioxide films remains far from clear (5-10). Differentiation between models emphasizing the continuous generation of electron traps during large current flow in silicon dioxide subjected to high electric fields or the filling of previously existing traps, however, is not straightforward. Further complications as to the trap characteristics—shallow, large cross section and/or deep, small cross section—surely complicate the situation. Our discussion below is essentially an empirical interpretation of the experimental data within the framework of surface asperities at the polysilicon-polysilicon oxide interface and a Fowler-Nordheim injection mechanism.

The current transported through the polysilicon oxide increased strongly with decreased oxidation temperature in oxygen ambient (<1 ppm H_2O), consistent with recent observations (2, 11, 12). Scanning electron micrograph (SEM) analysis revealed pronounced surface asperities, similar to those data previously published in the literature (1-3), on the poly I surface after oxygen oxidation at 900°C while a rather smooth poly I surface was observed after an 1100°C oxygen oxidation.[7] It may be that at higher oxidation temperatures, the transport of the oxidizing species through the oxide my be the limiting factor and the poly I surface irregularities may be effectively obliterated. On the other hand, the lower temperature (900°C for example) may accentuate the surface dominated reaction, i.e., the (110) dendrites in the poly I surface (13) exhibit higher oxide growth rate, resulting in fingers of poly grains of other orientations protruding into the oxide. The enhanced electric field around the tips of these fingers shrinks the potential barrier width and thereby increases the carrier injection locally at the interface.

For all polysilicon oxidation temperatures, the current was observed to decrease with time for a constant voltage applied across the oxide similar to previously published data (11, 12, 14). A reference electric field was defined, for convenience, as the applied voltage divided by the polysilicon oxide thickness.[8] The degradation exponent "n", i.e., the slope of the current-time curve on a log-log graph, was observed to increase considerably with the reference electric field for the boron-doped poly I, while it

[7] These oxidations were performed in the same furnace tube.

[8] The polysilicon oxide thickness was estimated by measuring the oxide thickness of several single-crystal silicon slices which were phosphorus-implanted and oxidized concurrent with the test slices.

increased only slightly for the phosphorus-doped poly I. It was observed that the current always returns to the previous end point if one resumes the current-time measurement after an interruption of the measurement. It was also observed on separately processed device structures on circuit slices that although a transient recovery in the current level was achieved by a u.v. erase, the current rapidly decayed to the previous pre-u.v. level. This phenomenon suggests that some detrapping of electrons without annihilation of the traps occurs during the u.v. erase (14). On the other hand, a 450°C H_2 anneal was observed to recover the current to its virgin characteristic. One interpretation of this may be that the 450°C H_2 anneal annihilates those traps previously present.

It was observed that upon voltage polarity reversal, the current decreases significantly, suggesting that the dominant mechanism governing current flow is electrode-limited injection from the interfaces, rather than bulk-limited transport (1, 2, 11). The emission of

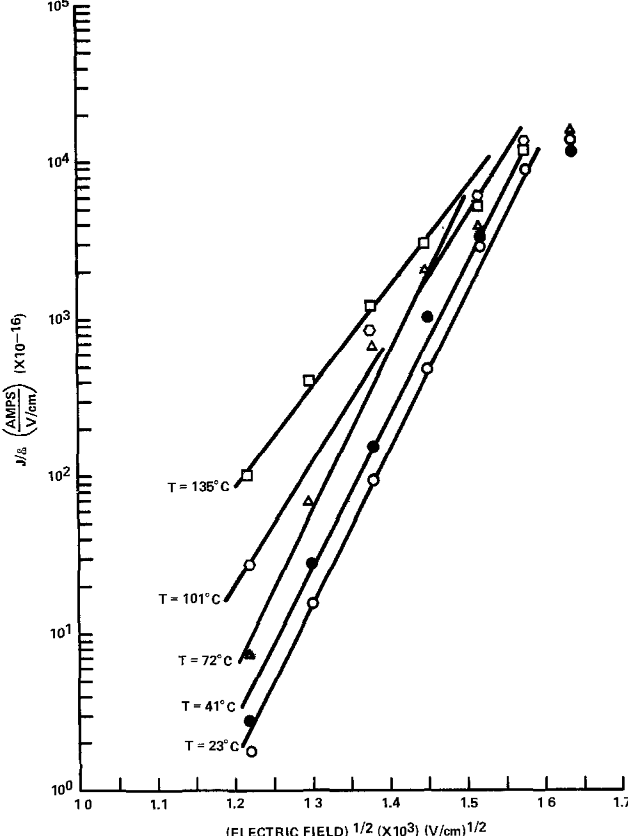

Fig. 12. Frenkel-Poole characteristic for boron-doped poly I. *Polysilicon oxidation temperature of 1000°C. (Log $J/\mathcal{E}$ vs. $\mathcal{E}^{1/2}$).* Lot B, slice No. 9.

current from single crystal silicon into thermally-grown silicon dioxide has previously been shown to occur by a Fowler-Nordheim process (15). The present polysilicon-polysilicon oxide data appear to be consistent with such a model, although we have not quantitatively corrected for the electric field enhancement at the polysilicon-polysilicon oxide interface due to the effects of the asperities and the space-charge at the interface. Therefore, the barrier heights deduced by the present Fowler-Nordheim analysis are to be regarded as merely parameters. Although these barrier heights do not represent "true" interface energy levels—such as observed by optical probing or deduced by utilization of the effective interface electric field—they may nevertheless be useful for comparison to similar data in the literature.

Shatzkes (16) has recently noted that the distribution of trapped electrons in the insulator can play an important role in the interpretation of the experimental data. Not only does trapped charge partially terminate the applied reference electric field, thereby reducing the effective electric field magnitude at the polysilicon-polysilicon oxide interface, but the barrier shape itself becomes distorted. Therefore, corrections to the barrier width for tunneling should be included to account for the field dependence and current decay observed. The negative charge trapped within the barrier provides an alternate explanation for the interpretation of reduced barriers derived from a Fowler-Nordheim analysis (16).

Probably a combination of both enhanced electric field at asperities and electron trapping within the barrier region apply in our case. Unfortunately, we are still unable to provide clear differentiation between electron traps previously present and "activated" by the electron transport through the oxide—such as perhaps the case for steam grown oxides (17, 18)—and continuously generated traps during at least a portion of the current transport. Clearly, further experimentation will be required for elucidation of the interfacial trap characteristics of the polysilicon-polysilicon oxide system.

Oxide-Substrate and Oxide-Oxide Chemical Reactions in Thermally Annealed Anodic Films on GaSb, GaAs, and GaP

G. P. Schwartz,* G. J. Gualtieri, J. E. Griffiths, C. D. Thurmond, and B. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A fundamental pattern of oxide-substrate reactions has been identified in thermally annealed anodic films on GaSb and GaAs through the use of Raman scattering and ternary phase diagrams. The relevant reactions on GaAs and GaSb yield interfacial deposits of As and Sb via $As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As$ and $Sb_2O_3 + 2GaSb \rightarrow Ga_2O_3 + 4Sb$. The failure to observe elemental P generation in annealed anodic films on GaP in conjunction with an estimate of the Ga-P-O phase diagram suggests that oxide-oxide reactions occur in the film instead. Formation of either ortho or metaphosphate will depend on the Ga_2O_3/P_2O_5 ratio in the film according to $P_2O_5 + Ga_2O_3 \rightarrow 2GaPO_4$ and $3P_2O_5 + Ga_2O_3 \rightarrow 2Ga(PO_3)_3$.

The current and future utilization of III-V compounds in the semiconductor industry reemphasizes the need for a more definitive understanding of the chemical and physical phenomena that occur at oxide-semiconductor interfaces. The factors affecting the initiation and propagation of chemical reactions at such interfaces, the nature and spatial distribution of the products formed, and their effect on the electronic properties of such structures are inadequately characterized. Moreover, little is known about the effects of such processes on the long term stability of these interfaces. Of special interest is the presence or absence of elemental constituents of the semiconductor in the oxide-semiconductor interfacial region, largely because it has often been assumed that their presence may have a deleterious effect on the electronic properties of III-V solid-state devices.

In the present work, anodic oxide films that were electrochemically grown in aqueous solutions at room temperature on GaAs, GaSb, and GaP were examined by reflection Raman scattering for evidence of elemental deposits of As, Sb, or P in the as-anodized state and for evidence of interfacial oxide/substrate reactions induced by thermal annealing. Estimates of the ternary phase diagrams for the Ga-As-O, Ga-Sb-O, and Ga-P-O systems were derived from binary phase stability experiments, thermodynamic calculations, and Raman scattering. The resulting phase diagrams indicate that the interfacial chemical constituents which can exist in thermodynamic equilibrium with GaSb and GaAs are Ga_2O_3/Sb and Ga_2O_3/As, respectively. Neither Sb_2O_3 nor As_2O_3 or their higher oxides are thermodynamically stable in the interfacial region. Oxidation processes which produce sharply delineated oxide-substrate interfaces containing these latter products are indicative of oxide growth under conditions far from thermodynamic equilibrium. Thermal annealing provides the necessary energy to overcome the reaction barriers associated with the reactions $2GaSb + Sb_2O_3 \rightarrow Ga_2O_3 + 4Sb$ and $2GaAs + As_2O_3 \rightarrow Ga_2O_3 + 4As$, thus depleting the group Vb oxides in the interfacial region with subsequent generation of elemental deposits of antimony or arsenic.

Similar work involving Raman scattering from anodic oxides on GaP coupled with thermodynamic estimates of the Ga-P-O system revealed a quite different pattern. No evidence was found for the generation of elemental phosphorus in the anodic films in either the as-grown or annealed conditions. The oxide-oxide reaction $Ga_2O_3 + P_2O_5 \rightarrow 2GaPO_4$ was verified in bulk mixtures. Some doubt as to the proper Ga-P-O phase diagram still remains.

Experimental

Sample preparation.—N-type substrates of GaP ($4\text{-}8 \times 10^{17}$ cm^{-3}, $(\bar{1}\bar{1}\bar{1})$ oriented), GaAs ($2\text{-}5 \times 10^{18}$ cm^{-3}, (100) oriented), and GaSb ($1\text{-}3 \times 10^{17}$ cm^{-3}, $(\bar{1}\bar{1}\bar{1})$ oriented) were prepared first by an alumina lapping (0.2 μm) and then by bromine-methanol polishing to a mirror finish. The electrochemical anodizations were carried out at room temperature

* Electrochemical Society Active Member.

Key words: Raman scattering, ternary phase diagrams.

under white light illumination in an AGW (1) electrolyte. This electrolyte consists of 3% H_3PO_4, adjusted to a *p*H of 6.2 with NH_4OH, which is then diluted in a 1:2 volume ratio with ethylene glycol. Post-anodization treatment involved rinsing the wafers in methanol followed by drying under a stream of nitrogen gas. The wafers were anodized at constant current (1 mA/cm^2) up to 50V. Film growth factors of approximately 10, 20, and 30 Å/V result under these conditions on GaP, GaAs, and GaSb, respectively. Thermal annealing of anodized wafers at 250° and 300°C took place in a nitrogen-purged oven. For temperatures exceeding 300°C, the samples were routinely sealed into evacuated (5×10^{-7} Torr) quartz tubes before treating at the appropriate temperature. Encapsulation served merely to avoid the dissemination of potentially toxic materials; the Raman scattering results are not affected by the choice of annealing under an inert atmosphere or under vacuum.

Samples of Ga_2O_3, GaOOH, Sb_2O_3, As_2O_3, and P_2O_5 were purchased in the form of finely divided powders. The latter three products were individually encapsulated in quartz, taken to their boiling points, and then cooled slowly in order to obtain samples of vitreous Sb_2O_3, As_2O_3, and P_2O_5. An amorphous gallia gel was prepared by the addition of dilute ammonium hydroxide to an aqueous gallium nitrate solution (2).

Raman scattering.—Surface reflection Raman spectra were obtained by coupling the incident laser light (5145Å, argon ion) into the films at Brewster's angle and detecting the light scattered normal to the sample surface. The optical constants given by Aspnes *et al.* (3) for anodized films on the respective substrates were used in the calculation of Brewster's angle. An Instrument S. A. Ramanor monochromator (Model HG-2S) equipped with holographic gratings and f/1.8 collection optics was used to analyze the scattered light. The analyzed light was detected with a cooled Hammamatsu R-928P photomultiplier coupled to conventional photon counting electronics.

A polarization rotator was inserted into the excitation beam path so that the electric vector of the incident light could be adjusted to be either in the scattering plane (H) or perpendicular to it (V). The polarization properties of the Raman scattered light emitted normal to the surface could be analyzed by inserting a polarization filter before the entrance slit. For most of the reported work this filter was omitted, and the scattered light is designated as unanalyzed (U). A polarization scrambler in the pre-slit optical path was present during the acquisition of all spectra to insure that the grating response did not distort the relative intensities of the polarized spectra.

Phase diagrams.—A series of binary mixture phase stability experiments were performed in order to check critical sections of the ternary phase diagrams for the Ga-Sb-O, Ga-As-O, and Ga-P-O systems. Powdered mixtures of the III-V substrates and their respective group V oxides (Sb_2O_3, As_2O_3, or P_2O_5) were sealed in evacuated quartz tubes and heated to elevated temperatures. The P_2O_5 was sublimed at 10^{-5} Torr prior to use to remove contaminant traces of P_2O_3 and H_2O and was subsequently handled under dry conditions.

The reaction products were analyzed by x-ray powder diffraction and Raman scattering. The latter technique is particularly useful for identifying vitreous phases (Sb_2O_3, As_2O_3, and P_2O_5) which would otherwise go undetected. Raman scattering can also supplement x-ray diffraction results for the positive identification of crystalline phases. In Fig. 1, for example, the reaction products for an initial mixture of 2:1 Sb_2O_3/GaSb display Raman peaks associated with β-Ga_2O_3 (labeled G_n) and unreacted Sb_2O_3 (senarmonite, labeled S_n) which was originally present in excess. Crystalline Sb is not particularly obvious due to interferences from Ga_2O_3 (G_1, G_2), but pellets of that material could be picked out of the mixture and easily identified by x-ray techniques. The broad Raman band between 300-500 cm^{-1} indicates that the reaction conditions have left vitreous as well as crystalline Sb_2O_3. Better spectra of the vitreous form were obtained from material adhering to the walls of the quartz tube in places where there were no other reaction products.

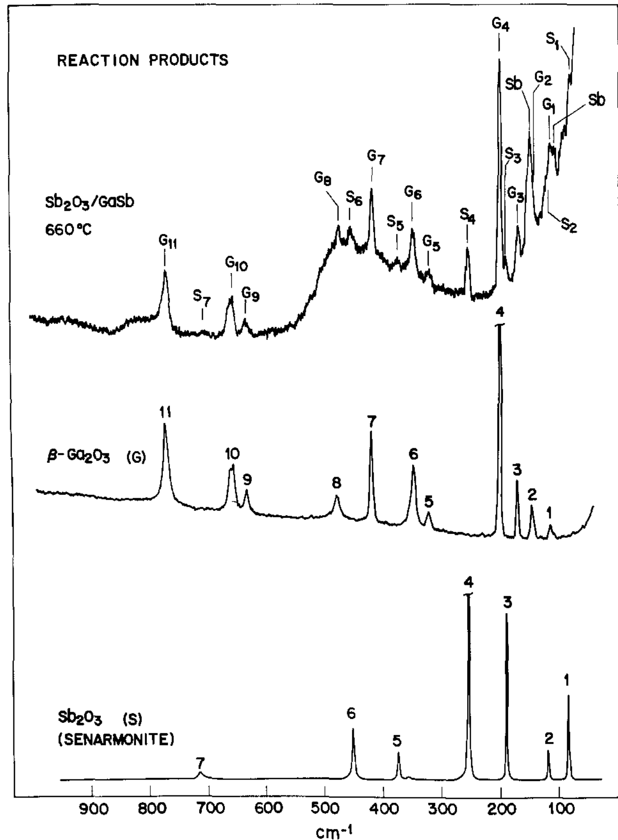

Fig. 1. Raman scattering analysis of a reaction product mixture containing crystalline Ga_2O_3. Sb_2O_3, and Sb along with vitreous Sb_2O_3. The latter species contributes the broad band between 300-500 cm^{-1}.

Detailed results for the Ga-As-O phase diagram have been reported previously (4). Tables I and II summarize the data for the pseudobinary GaSb/Sb_2O_3 and GaP/P_2O_5, Ga_2O_3/P_2O_5 systems. Reaction temperatures above 680°C exceed the congruent evaporation temperature of GaP (5). Nevertheless, we did not observe thermal decomposition of the GaP which leads us to suspect that a thin oxide layer has formed in insufficient quantity to be detected but in sufficient quantity to prevent thermal decomposition of the GaP. The application of the data in Tables I and II to the

determination of the Ga-Sb-O and Ga-P-O phase diagrams are discussed in the next section.

Results

General

Since the reflection Raman spectra should, in principle, contain contributions from the bulk oxide as well as from the interfacial layer and substrate, some preliminary comments are in order concerning the detection of the relevant chemical species. Anodic oxide films on GaP, GaAs, and GaSb are currently believed to consist of mixtures of Ga_2O_3 and either P_2O_5, As_2O_3, or Sb_2O_3, respectively. These films are both amorphous and optically transparent (3) in the region between 1.5 and 4 eV. It is this optical transparency at the excitation wavelength ($\sim$2.4 eV) and the limited number of molecules in these thin ($500 \leq d \leq 1500$Å) films that allow effective penetration of the laser beam to the oxide/semiconductor interface. It is thus possible to observe resonance enhanced Raman signals from minute amounts of arsenic and antimony that may be present in the interfacial region.

The group V oxides P_2O_5, As_2O_3, and Sb_2O_3 are well-known glass formers whose vitreous spectra are shown in Fig. 2. Amorphous Ga_2O_3 is not a well-characterized material; we have prepared a gallium oxide gel in order to obtain some idea of where the bands might be expected to occur. The Raman spectrum of this gel along with crystalline β-Ga_2O_3 and GaOOH are shown in Fig. 3. Crystalline spectra for P_2O_5, As_2O_3, and Sb_2O_3 have also been reported in the literature (6). Neither the crystalline nor vitreous Raman peaks associated with any of these oxide species is observed in surface reflection scattering from films ranging from 500 to 1500Å thickness. The normal Raman cross sections for inelastic light scattering from these films are apparently too low to allow their detection in such thin layers. Similarly, the conversion of amorphous Ga_2O_3 (gallia gel) to either GaOOH or β-Ga_2O_3 cannot be detected following the 250°C thermal anneal which is typically employed to remove loosely bound water. Analysis of Raman scattering from 8000Å anodic oxides on GaAs further indicates that there is insufficient cross section for oxide component identification even at this thickness. High temperature annealing ($T = 600$°C) of the 8000Å structures did not result in observable Raman peaks for β-Ga_2O_3.

In contrast to the anodic film components, the group V metalloids P, As, and Sb all possess electronic absorption bands which overlap the excitation frequency (7-9). Resonance enhancement of the Raman cross sections occur under such conditions with a concomitant increase in the detection sensitivity for these chemical species. A review of resonance enhanced Raman scattering in III-V semiconductors and the group V semimetals has recently been presented by Richter (10).

The relative resonance enhanced Raman cross sections for the A_{1g} and E_g modes of As and Sb have been measured by Renucci *et al.* (9) in the range from 1.6 to 2.7 eV. Examination of the data at $\sim$2.4 eV (5145Å) provides a measure of the relative detection sensitivity between Sb and As, *i.e.*, $\sigma_{Sb}/\sigma_{As} = 5.6$. Comparable data for elemental phosphorus do not appear to be available. Estimates of the minimum detection level for crystalline arsenic have recently been obtained from a comparison of internal standards and correlations with ellipsometric determinations of the absorptive component of these anodic films (11). The available data currently indicate a detection level of approximately 10-20Å of crystalline arsenic in the present experimental configuration. The detection of antimony should be 5-6 times more sensitive. Although the detection sensitivity for phosphorus is probably less favorable than for As and Sb, we are currently unable to provide a reasonably firm estimate of the detection limit for this material.

Raman Scattering and Ternary Phase Diagrams

GaSb.—Raman.—For <111> oriented substrates crystallizing with a zincblende structure, both longitudinal and transverse optic modes (LO, TO) are

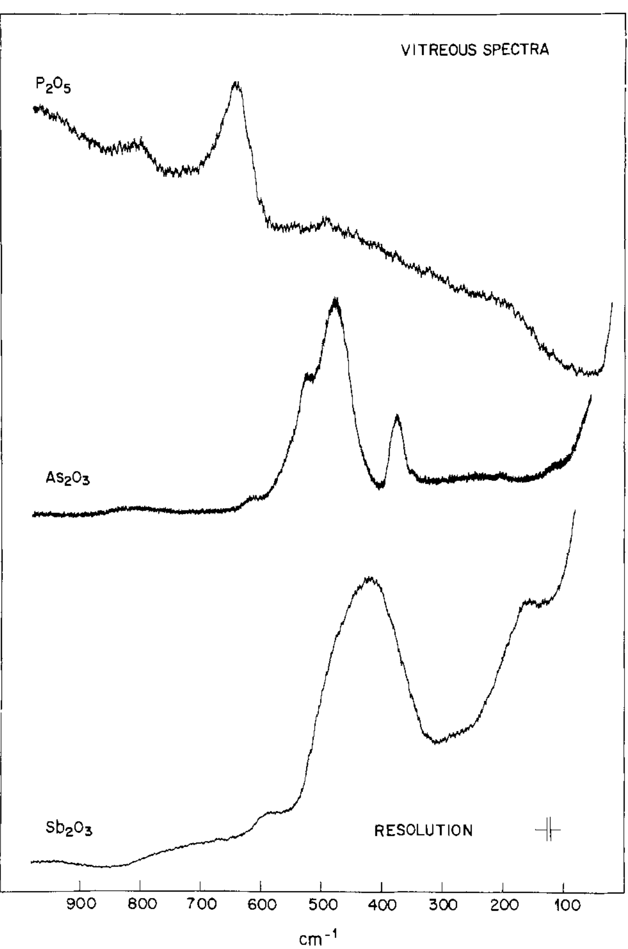

Fig. 2. Raman spectra of the vitreous glasses P_2O_5, As_2O_3, and Sb_2O_3 between 100-1000 cm^{-1}.

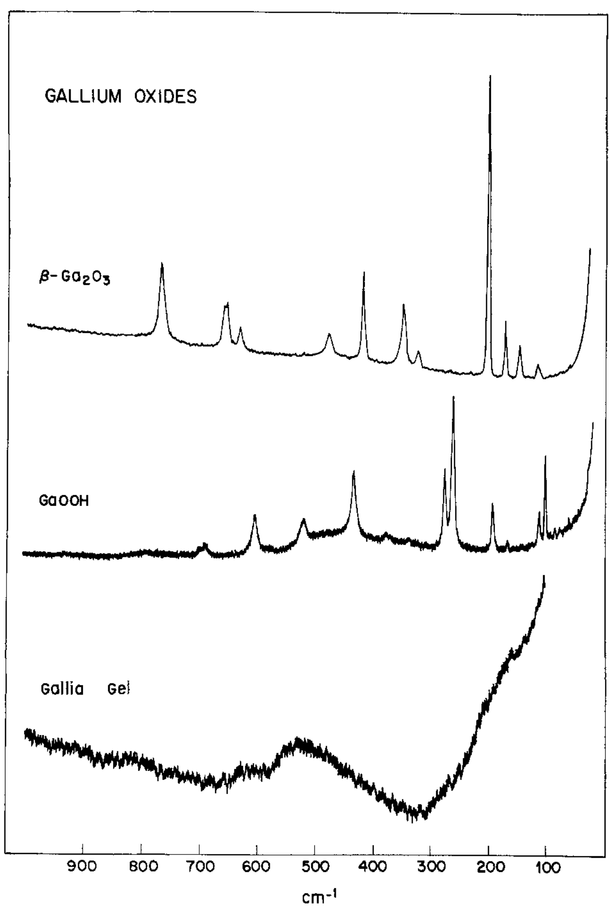

Fig. 3. Raman spectra of amorphous (gel) and crystalline forms of gallium oxide which would be anticipated in thermally annealed anodic films.

Raman allowed by the selection rules (12). Combination and overtone bands derived primarily from two-phonon processes will also be active. The two-phonon continuum shows sharp structure in its phonon frequency distribution at certain critical points in the Brillouin zone. In the case of the zincblende structure the relevant critical points allowed by the selection rules occur at the zone center Γ (0, 0, 0), the face center L (1/2, 1/2, 1/2), and X (1, 0, 0), the coordinate peak W (1, 1/2, 0), and the zone edge K (3/4, 3/4, 0).

The surface reflection Raman spectra for anodized samples (oxide thickness ~1500Å) in the as-anodized (A) and thermal annealed (B, 450°C/1 hr) states are shown in Fig. 4. The positions of the crystalline antimony bands (13, 14) for the trigonally distorted cubic A7 structure are denoted by S_1 and S_2. S_1 (150 cm^{-1}) corresponds to the symmetric A_{1g} mode of this structure, whereas S_2 (115 cm^{-1}) is the doubly degenerate E_g mode. Amorphous antimony (15) displays a broad, featureless band between ~120-170 cm^{-1}. The numbered peaks (n =1, 16) in Fig. 4A can be rigorously assigned (16, 17) to one and two-phonon scattering from the substrate (Table III). Part of the two-phonon GaSb spectrum (n = 1-3) overlaps the region in which elemental Sb (crystalline or amorphous) would be found if it were present in the as-anodized film. Within the peak-to-peak noise (~30 c/sec) in the vicinity of 150 cm^{-1}, no differences were detected between the bare substrate (not shown) and the anodized GaSb wafer (Fig. 4A). The estimated detection limit for crystalline Sb is an equivalent thickness of ~5Å; detection of the amorphous allotrope will be somewhat less sensitive.

Annealing the anodized sample of Fig. 4A *in vacuo* (5×10^{-7} Torr) at 450°C for 1 hr leads to dramatic changes in the spectrum. The presence of crystalline antimony now dominates the spectral features. The LO and TO modes of the GaSb substrate are now nearly totally attenuated by optical absorption of the excitation beam by the thermally generated Sb. Farrow *et al.* (18) have previously observed similar spectra for the case of thermally oxidized samples of GaSb. Cross polarized spectra (VH) attenuated the 150 cm^{-1} band by a factor of ~200, which is consistent with their assignment of this band as the A_{1g} mode of crystalline antimony.

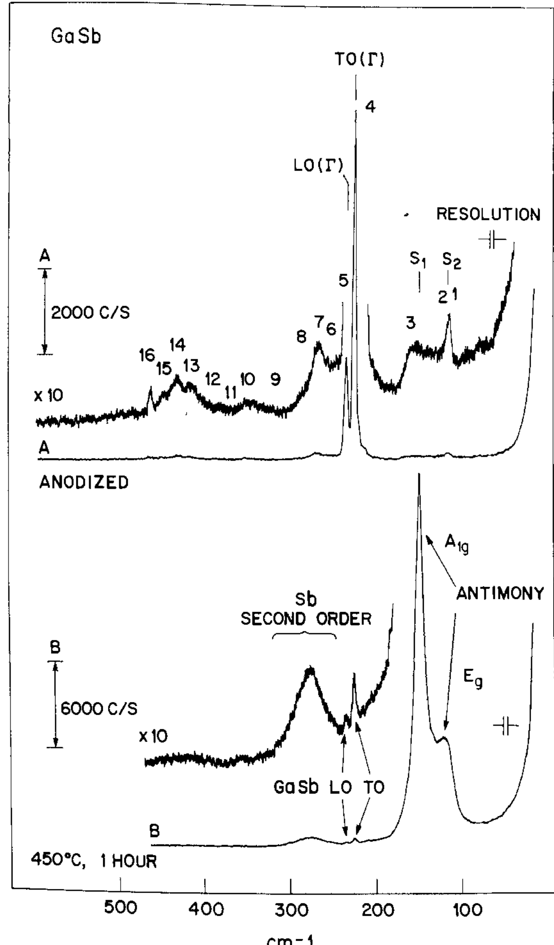

Fig. 4. Raman scattering intensity from as-anodized (A) and thermally annealed (B) films on GaSb. S_1 and S_2 denote the positions of crystalline Sb modes, the numbered features 1-16 correspond to substrate scattering. The scattered light polarization is unanalyzed.

The thermally induced formation of elemental Sb in electrochemically anodized films on GaSb is consistent with the pseudobinary phase stability experiments involving Sb_2O_3/GaSb mixtures insofar as Eq. [1] was observed to occur

$$Sb_2O_3 + 2GaSb \rightarrow Ga_2O_3 + 4Sb \qquad [1]$$

Figure 5 provides some idea of just how readily this reaction occurs in anodic films (typically ~2000Å) as a function of temperature. Elemental Sb is not readily detected after a 250°C bake for 2 hr (Fig. 5A). The spectral feature at ~117 cm^{-1} is a superposition of a laser plasma line and part of the two-phonon structure of the substrate. The E_g mode of crystalline Sb appears at a slightly lower wavenumber position and is typically broader. After a thermal treatment of 300°C for 1 hr (Fig. 5B), an antimony signal can be detected in the form of an amorphous deposit. After heating at 350°C for 1 hr, well-defined crystalline A_{1g} and E_g modes of Sb become clearly visible (Fig. 5C).

In order to verify that the reaction proposed in Eq. [1] is actually occurring in these films at the oxide/GaSb interface, a series of chemical etching experiments were performed in which the oxide film was successively dissolved in a dilute methanol/H_3PO_4 solution and the remaining film thickness was monitored by interference colors. The results are shown in Fig. 6, in which one observes no decrease in the signal associated with Sb down to a film thickness of ~300Å, at which point interference colors are no longer visible. The strong increase in the Rayleigh wing which causes marked changes in the shifting background scattering appears to be due to surface roughening effects occurring during etching. The Sb formed during annealing at 350°C for 1 hr is thus found to be localized within an interfacial layer whose position lies no more than 300Å from the actual oxide-semiconductor interface.

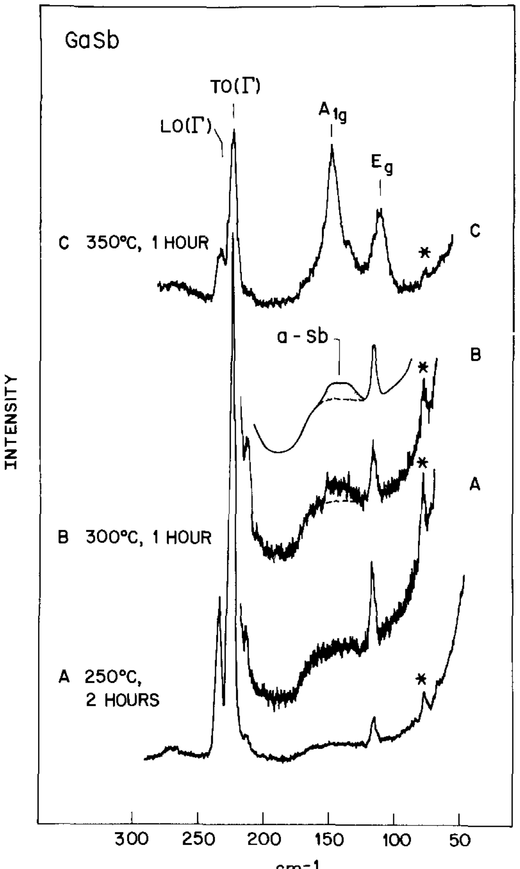

Fig. 5. Thermal evolution of the interfacial reaction which generates elemental Sb as detected by Raman scattering. Plasma lines are denoted by an asterisk. In frames A and B, the peak at ~117 cm^{-1} is a superposition of a plasma line and a two-phonon substrate peak.

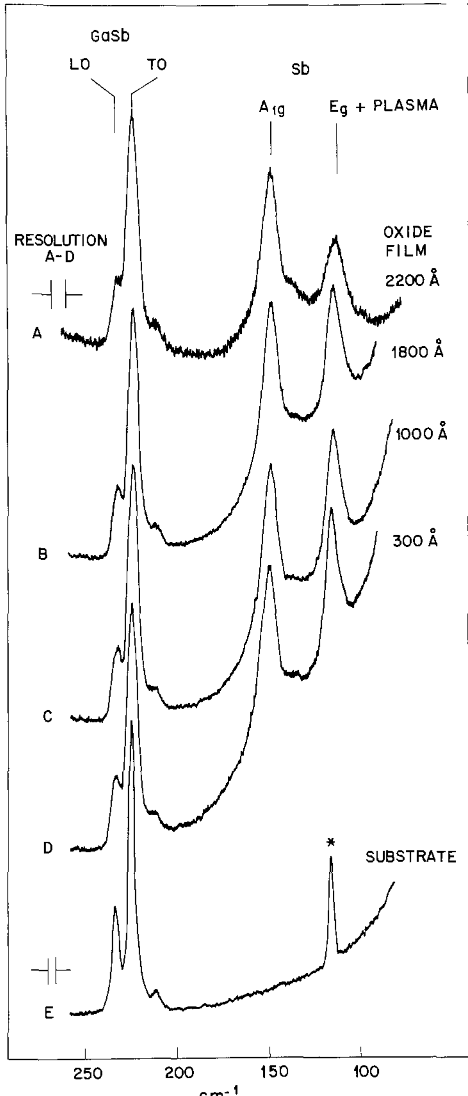

Fig. 6. Chemical etching and Raman scattering of a thermally annealed anodized GaSb wafer. The thermally generated Sb is seen to be localized within 300Å of the substrate. Plasma lines denoted by an asterisk.

The Raman scattering experiments on as-anodized GaSb thus show that there is no evidence for either amorphous or crystalline Sb anywhere in these films down to the detection limits of this technique. Thermal annealing results in the generation of strong antimony Raman signals (primarily as a crystalline phase), and chemical etching experiments show that antimony deposits are within 300Å of the oxide/GaSb interface.

Phase diagram.—An estimate of the lower section of the Ga-Sb-O phase diagram was generated from a combination of binary mixture experiments and thermodynamic calculations. Many aspects of this diagram were guided by prior results on the Ga-As-O system (4), which is shown for comparison in Fig. 7. All equilibria are assumed to be pseudobinary, *i.e.*, the phase fields are composed of mixtures of pure components in which mutual solid solubility is ignored.

The constituents in phase field I (Fig. 7) at equilibrium were obtained from the binary mixture results in Table I for initial Sb_2O_3/GaSb mole ratios greater than 1:2. The observed products were Ga_2O_3, Sb, and Sb_2O_3. The latter component was initially present in quantities sufficient to consume all the initial GaSb

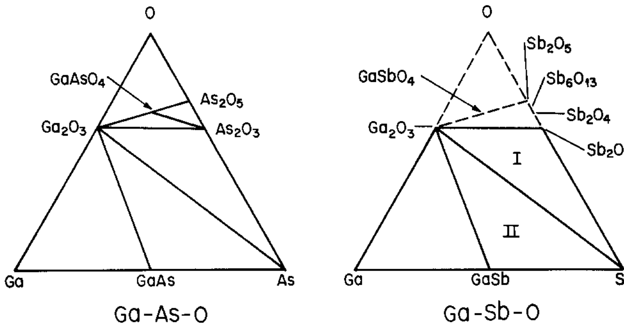

Fig. 7. Ternary phase diagrams for the Ga-As-O and Ga-Sb-O systems. The upper regions of the latter diagram have not been fully determined (dashed lines).

and still be present in excess. The absence of GaSb in the final product mixture indicates that the reaction has gone to completion, *i.e.*, the minor component (GaSb) has been totally consumed. In addition, no evidence could be found for the formation of $GaSbO_4$, which would have indicated the existence of a tie line between $GaSbO_4$ and Sb. The tie line instead connects Ga_2O_3 and Sb_2O_3 as shown in the phase diagram.

For reaction mixtures which initially contain excess GaSb ($Sb_2O_3/GaSb < 1/2$), the materials at the apexes of phase field II should be observed. Table I indicates that the products are Ga_2O_3, Sb, GaSb, as would be anticipated from Fig. 7. The total consumption of the Sb_2O_3 from the initial mixture again shows that the reaction has gone to completion. The crossing point between the Ga_2O_3-Sb tie line and an imaginary line connecting GaSb and Sb_2O_3 is represented by the reaction in Eq. [1].

The only part of the upper diagram which has been determined is the reaction between Ga_2O_3 and Sb_2O_5 to yield the intermediate product $GaSbO_4$ (2). Only the lower section of the diagram need concern us, however, since current evidence suggests that anodic oxides consist of Ga_2O_3/Sb_2O_3 mixtures.

A thermodynamic check on the correctness of the lower section of the phase diagram is made possible by calculating the relative stability of the various possible tie lines. The principle of the method is illustrated in Fig. 8.

An equation involving mass balance is written at any point at which two tie lines can intersect. Only one of these tie lines can be stable, its determination is made by calculating the Gibbs free energy for reaction for the balanced equation at the intersection point. Table IV presents the balanced equations which occur at intersection points 1, 2, and 3 on Fig. 8 along with the calculated free energy of reaction. The standard states

GaSb (c)	−9.3	±2.0
Sb_2O_3 (cubic)	−151.5	±4.0

Reference states: Ga (s), Sb (s), O_2 (g).

were obtained from Ref. (19). Our estimates of probable errors in these free energies are also included. Considerations of such factors as the spread in ΔG values encountered in crystalline modifications of the substances guided the error assignments. The quantity listed under "error sum" in Table IV is a summation of the assigned errors in the individual products for the reactions as listed and should thus represent an upper limit in the uncertainty in ΔG for the reaction.

Crossing point Eq. [1], (see Table IV and Fig. 8) for instance, indicates that the tie line which connects Ga_2O_3-GaSb is more stable than the Ga-Sb_2O_3 tie line by -105.7 ± 22 kcal. The negative sign of ΔG for the reactions shows that the tie lines associated with the binary couples on the right-hand sides of Eq. [1]-[3] (Table IV) are stable. These thermodynamic calculations thus predict tie lines connecting Ga_2O_3-GaSb and Ga_2O_3-Sb, a result consistent with the observed phases generated in the binary mixture experiments (Fig. 7).

GaAs.—Raman.—Raman scattering results from as-anodized and thermally annealed samples have been previously reported (11, 20) so that only a brief synopsis of the results are given here. A polished <100> oriented substrate was anodized to 50V (~1000Å anodic film) in an AGW electrolyte. Figure 9 shows the Raman spectra for the as-anodized (Fig. 9A) and annealed (Fig. 9B, 450°C/1 hr) samples. As before, the numbered peaks ($n = 1$ to 11) are associated with one and two-phonon scattering from the substrate. A detailed comparison of bare and anodized substrates is available in Ref. (20). Table V contains a compilation of the observed peaks and the assignments given by Sekine *et al.* (21). The positions of the totally symmetric A_{1g} (257 cm^{-1}) and doubly degenerate E_g (195 cm^{-1}) modes of crystalline arsenic (13, 14, 20) in its A7 structure are denoted by A_1 and A_2. Amorphous arsenic (15, 20) also has a characteristic spectrum in

this region in the form of a broad band between 200-250 cm^{-1}.

Whereas the as-anodized spectrum of Fig. 9A does not indicate the presence of arsenic within the present limits of detectability, annealing at 450°C for 1 hr (Fig. 9B) results in a spectrum dominated by crystalline arsenic. The origin of this signal has been related to the interfacial reaction given in Eq. [2]

$$As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As \qquad [2]$$

and the localization of the thermally induced arsenic deposits at the oxide/GaAs interface has been verified by chemical etching experiments (11).

Phase diagram.—The ternary phase diagram for the Ga-As-O system has already been developed (4) and was presented earlier in Fig. 7. The important point which should be reiterated is that the phases which are thermodynamically stable in the interfacial region are Ga_2O_3, As, and GaAs, not Ga_2O_3, As_2O_3, and GaAs. The thermally induced interfacial reaction given by Eq. [2] and observed in Raman scattering provides the pathway for the transition from an unstable to a thermodynamically stable interfacial mixture. This is discussed in the Discussion section.

GaP.—Raman.—N-type <111> GaP wafers were anodized at 50V (~500Å of oxide) in an AGW electrolyte at constant current density. The one- and two-phonon assignments of Sushchinsky *et al.* (22) were used to identify and tabulate (Table VI) individual spectral features n = 1-16 in Fig. 10A. The first order LO mode at ~403 cm^{-1} is not sharply defined on any of our wafers; we believe this to be due to LO-plasmon coupling which broadens and shifts this mode in the strong coupling regime.

Phosphorus is known to exist in white, red, black, and amorphous allotropic forms. Raman spectra from black phosphorus and amorphous phosphorus (23) have been reported by Lannin and Shanabrook. White phosphorus is a molecular crystal consisting of P_4 tetrahedra whose spectrum we have observed to be similar to data reported for P_4 gas phase species (6). Neither white nor black phosphorus allotropes are anticipated however; the former converts rapidly to red phosphorus above 260°C and the latter occurs only at very high temperatures or pressures or when its lattice is stabilized by small additions of Hg or other heavy metal impurities. Quite recent Raman experiments aimed at detecting phosphorus in thermally oxidized films in InP (24) corroborate that

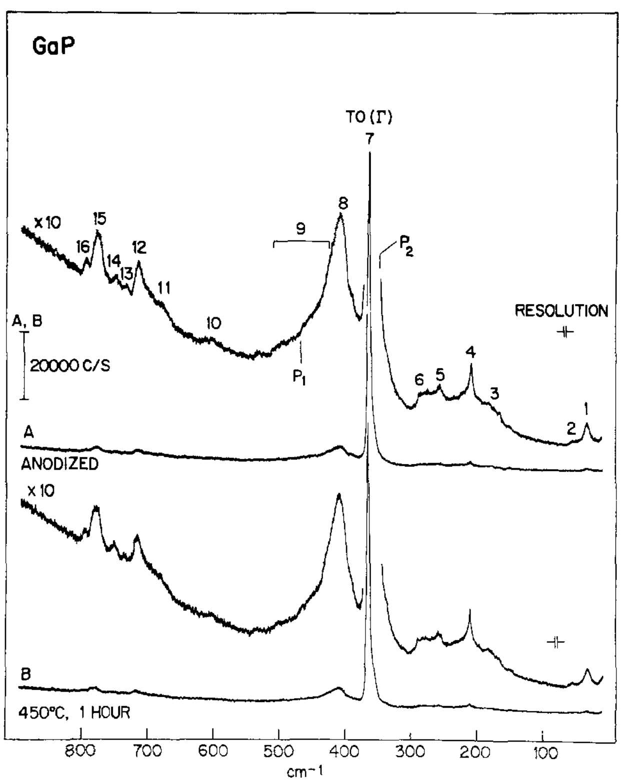

Fig. 10. Raman scattering from as-anodized (A) and thermally annealed (B) anodic films on GaP. The dominant crystalline red phosphorus peaks would occur at P_1-P_2, the numbered peaks 1-16 in A arise from substrate scattering. The scattered light polarization is unanalyzed.

either crystalline or amorphous red P will be the stable allotropes. For the annealing temperatures employed in these studies ($T \geq 450°C$), only crystalline red P is anticipated.

Data (24) on red phosphorus crystallized at $\sim$500°C indicate that there are no fewer than 35 observable Raman lines lying between 20 and 500 cm^{-1}. Their intensities are somewhat dependent on thermal treatment, but the two strongest modes consistently occur at $\sim$467 and 349 cm^{-1}. The two dominant modes are denoted as P_1 and P_2 in Fig. 10A.

Comparison of the bare substrate (not shown) and anodized spectra (Fig. 10A) showed the two to be virtually superimposable. No evidence could be found for the presence of either crystalline or amorphous phosphorus in the as-anodized films, although it should be noted that the broad line shape (23) anticipated for amorphous P could be masked by the two-phonon and coupled plasmon features of the substrate. Annealing the anodized sample at 450°C for 1 hr leads to no observable changes in the Raman spectrum (Fig. 10B). These experiments were extended to 650°C for 1 hr (not shown), but in no case was any structure observed which could not be associated with the GaP substrate.

Crossed polarization (VH) spectra were also analyzed in order to reduce the background interference from the two-phonon and coupled-plasmon scattering of the substrate. The results for as-anodized and thermally annealed (450° and 650°C) anodic films are presented in Fig. 11. Except for a gradual reduction in the overall intensity as one employs more severe annealing conditions, there is no evidence for any changes in the spectra consistent with the formation of any allotropic form of phosphorus. Consequently neither the detectable presence of elemental P in the as-anodized state nor its thermally induced growth were observed.

Phase diagram.—Thermodynamic calculation of the condensed phase portion of the Ga-P-O diagram is subject to considerable uncertainty. The upper limit for the temperature of an isothermal section representative of solid condensed phases is set by the melting point of P_2O_3, *i.e.*, 23.8°C. The latter product disproportionates above its boiling point (173°C) to form red phosphorus and a range of polymeric phosphorus oxides of variable composition (25). There is currently insufficient data appropriate to a binary P-O phase diagram to determine with certainty whether such chemical species as P_4O_8, P_4O_7, or P_4O_9 exist as thermodynamically stable compounds. Without definitive evidence in favor of such a proposition, we will assume that the condensed phases comprising the Ga-P-O diagram consist of Ga, GaP, P, Ga_2O_3, P_2O_3, P_2O_5, $GaPO_4$, and $Ga(PO_3)_3$. There are 24 possible phase diagrams associated with these 8 condensed phases.

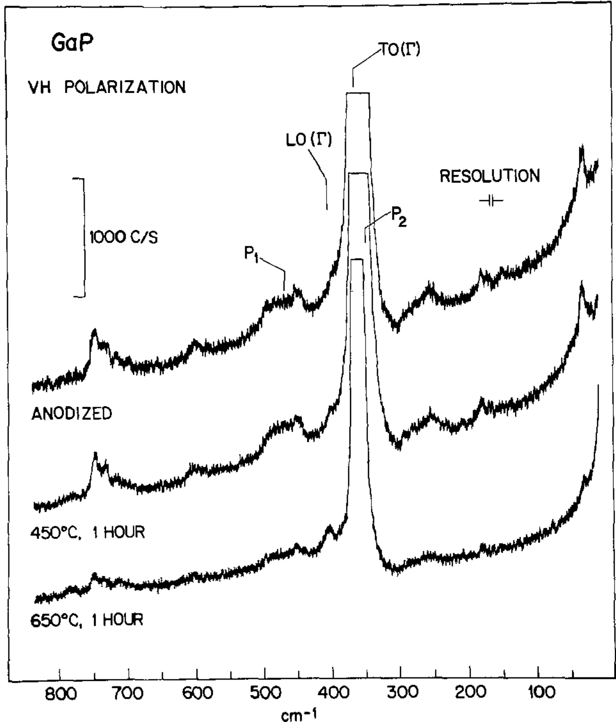

Fig. 11. Raman scattering in a crossed polarization configuration for anodized and thermally ann-aled films on GaP. The selected Raman scattered light is polarized in the plane of incidence.

Crossing point stability equations were examined for all relevant binary combinations of the condensed phases for which thermodynamic data are available. There are no data for $Ga(PO_3)_3$ to the best of our knowledge, and the data for $GaPO_4$ are relatively uncertain. The appropriate equations, reference states, and estimated errors are presented in Table VII. For P_2O_3, the ΔG value was calculated using the tabulated (19) ΔH value and by observing the trends between ΔH and ΔG for the series Sb_2O_3, As_2O_3, and P_2O_3. The large estimated uncertainty in the ΔG value for $GaPO_4$ is associated with a $\pm 9\%$ deviation present in the original solubility product data which formed the basis for the calculation of this free energy in Ref. (19). The error assigned to P_2O_5 primarily reflects the known variation between crystalline and amorphous structures. As in Table IV, the column designated as "error sum" is a worst case value assuming all errors to be additive and to scale with the appropriate number of moles of each product involved in the reaction.

Figure 12 shows the manner in which the stable tie lines were calculated. The condensed phase portion of all 24 diagrams lies below the tie line which connects Ga_2O_3 to P_2O_5. Gas phase equilibria bounded by the Ga_2O_3-P_2O_5-O triangle were not studied and are an excluded part of the phase diagram. Crossing point Eq. [1] through [3] occur as shown in Fig. 12 (top) and indicate the relative stability of the Ga_2O_3-GaP couple to crossing originating at the Ga apex of the diagram. No connections to $Ga(PO_3)_3$ are shown in Fig. 12 due to lack of thermodynamic data. It should be noted, however, that, if the Ga-$GaPO_4$, Ga-P_2O_5, and Ga-P_2O_3 couples cannot intersect the Ga_2O_3-GaP tie line, then neither can the Ga-$Ga(PO_3)_3$ couple. Unlike the calculations encountered in the Ga-As-O and Ga-Sb-O systems, the large values of the error sums relative to the calculated reaction Gibbs free energies for many of the crossing point equations reflect the uncertainty present in the form of the Ga-P-O diagram.

In our estimation, the most critical tie line of the phase diagram involves the $GaPO_4$-GaP couple. Ac-

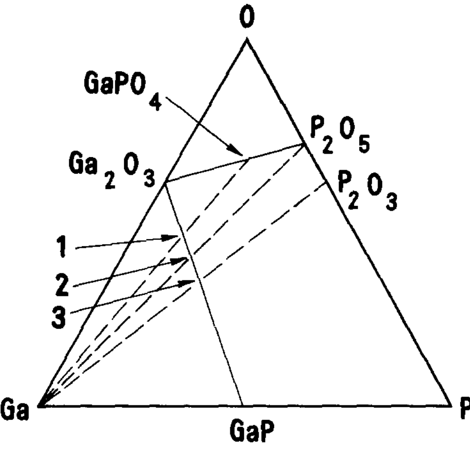

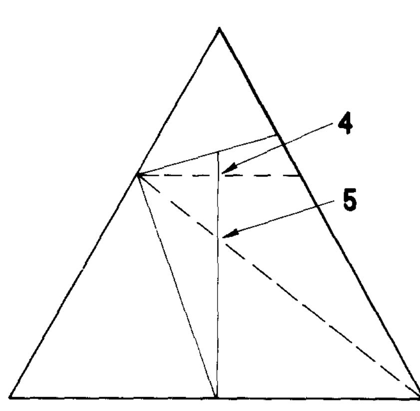

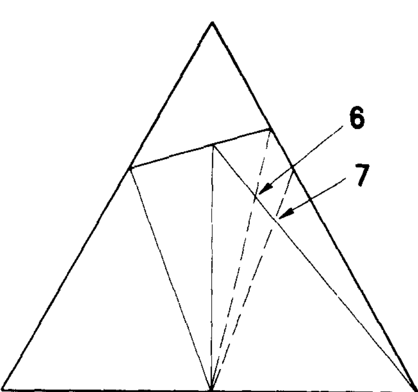

Fig. 12. Crossing point positions used in the calculation of the stable tie lines for the Ga-P-O system.

cording to Table VII and crossing point Eq. [4] and [5] of Table VII (see Fig. 12, center), the $GaPO_4$-GaP tie line is stable to crossing by the couples Ga_2O_3-P and Ga_2O_3-P_2O_3, although the uncertainty is large. Crossing by the Ga-P_2O_5 and Ga-P_2O_3 couples is excluded by the presence of the proposed Ga_2O_3-GaP tie line. In any case, the stability to crossing from these latter lines was calculated to be -323.3 ± 118 and -345.3 ± 111 kcal, respectively. The stability of the $GaPO_4$-GaP tie line implies that O_2 oxidation should yield a single phase oxide composed of $GaPO_4$. This expectation is consistent with the high temperature thermal oxidation studies of Rubenstein (26), in which $GaPO_4$ was identified as the primary reaction product (95%) by x-ray diffraction. $GaPO_4$ has also been identified as the oxide formed at lower temperatures (600°-950°C) in photoemission experiments (27).

Establishing the Ga_2O_3-GaP and $GaPO_4$-GaP tie lines serves to eliminate 18 of the 24 possible phase diagrams. The remaining 6 are shown in Fig. 13. At this point the calculations are severely hampered by the lack of thermodynamic data for $Ga(PO_3)_3$ and the uncertainty in the $GaPO_4$ data. One notes that only one of the 6 diagrams (Fig. 13, top, center) contains a tie line which connects P_2O_5 and GaP. The presence of this tie line is consistent with the binary mixture experiments involving the absence of reaction between P_2O_5 and GaP (Table II). The failure to observe phosphorus in the Raman experiments on annealed wafers also suggests the elimination of the bottom 3 diagrams. Equations [6] and [7] (Table VII), however, are at variance with the stability of the P_2O_5-GaP and P_2O_3-GaP couples relative to the $GaPO_4$-P tie line. A $GaPO_4$-P tie line, however, requires that the 4:5 molar mixture of P_2O_5 and GaP should have reacted to yield phase products which include $GaPO_4$ and P. Neither product was observed in the binary mixture experiments even after reaction at 850°C for 1 day.

There are a number of possible explanations which might account for this discrepancy. The simplest of these is kinetic in origin, *i.e.*, the solid-state reaction between P_2O_5 and GaP is sufficiently slow even at 850°C that the thermodynamically stable phases do not form. Alternatively, one might argue that the uncertainty in the available thermodynamic data (especially in $GaPO_4$) precludes an accurate description of the system. The failure to observe elemental phosphorus in thermally annealed films using Raman scattering may have still another explanation since there is a competing reaction channel involving P_2O_5 and Ga_2O_3 to yield $GaPO_4$ or $Ga(PO_3)_3$. If the kin-

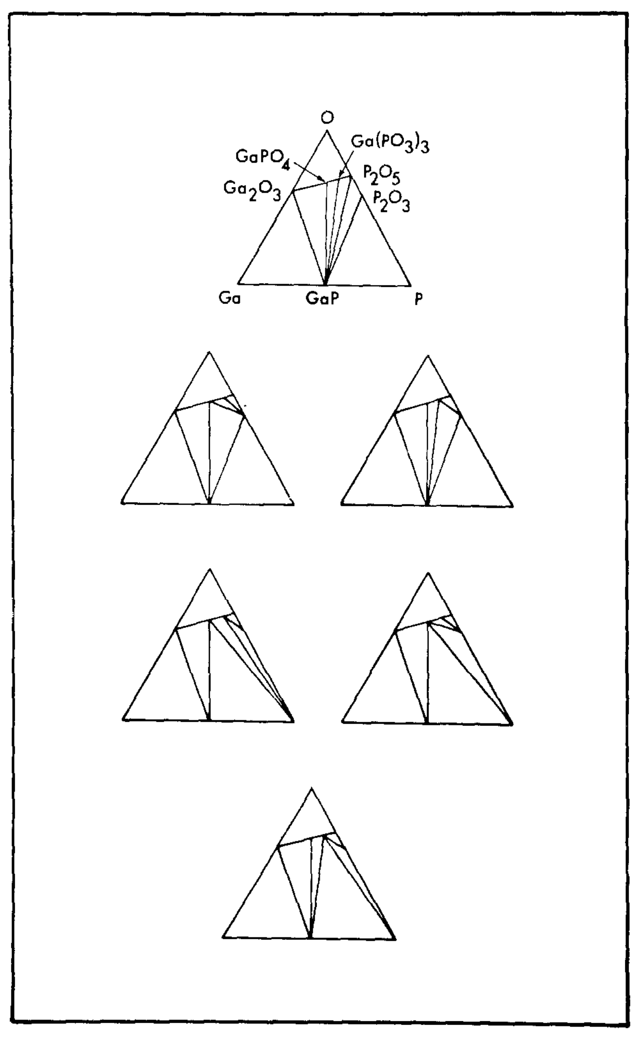

Fig. 13. Six possible choices for the Ga-P-O phase diagram

etics of those reactions were fast compared to reaction between P_2O_5 and GaP, the P_2O_5 would be removed from the film before it could react to generate phosphorus. In addition, direct volatilization of P_2O_5 will also deplete that component from the film. In view of the uncertainties involved in both the calculations and experiments, it is difficult to assess the relative merit of the final choices for the Ga-P-O condensed phase diagram ($T < 23.8°C$) shown in Fig. 13.

Discussion

The ternary phase diagrams can be used to specify the oxide phase composition if film growth has occurred under near equilibrium conditions. A comparison of the thermodynamically anticipated phases with those observed in anodic oxides provides the basis for understanding the interfacial reactions observed in thermally annealed anodic films.

The thermodynamic predictions for the oxide phase compositions utilizing O_2 as the oxidant are shown in Fig. 14 for GaSb, GaAs, and GaP. This figure was constructed from the phase diagrams in the following manner. A line connecting oxygen to the appropriate substrate is constructed, and the oxide components present in the film are read from the apexes of the various phase field triangles cut by the oxygen-substrate line. Movement along the oxygen-substrate line toward oxygen is equivalent to movement in the direction of increased oxygen chemical potential, *i.e.*, for the isothermal section represented by the diagram this would mean increasing the O_2 partial pressure in the gas phase. The progression from weak (W) to intermediate (I) to strong (S) oxidizing conditions qualitatively describes movement along the oxygen-substrate line toward oxygen. The molar ratios of the oxide film components can be determined by examining the intersection of the oxygen-substrate line with the phase field boundary. The molar ratios of oxide products are presented in Fig. 14 at the left of the various oxide regions found under different oxidizing conditions. The thickness of each layer is only a schematic representation of that region; kinetic parameters generally control these features in real oxide growth.

The stable interfacial phase products are of primary interest. On GaSb and GaAs the stable phases which grow in equilibrium with those substrates are Ga_2O_3/Sb and Ga_2O_3/As, respectively. From a strictly thermodynamic point of view, one anticipates interfacial deposits of the elemental group V component to be present. On GaP, the tie line which connects $GaPO_4$ to GaP admits to only one oxidation product ($GaPO_4$) under all oxidizing conditions using O_2 as the oxidant. Since all the phase diagrams in Fig. 13 contain this tie line, it is not possible to distinguish among them from experimental oxidation studies using O_2 or air.

The experimental determination of composition profiles on anodic films is summarized in Table VIII and Fig. 15 and in Ref. (28-40). Although the available data are somewhat sketchy for GaSb and GaP, a number of essential features emerge from the literature. The ellipsometric and Raman scattering results indicate that the bulk films are essentially nonabsorbing in a spectral region in which elemental Sb, As, or P would be detected if present at a level of 1-2 volume percent or greater. This result is in contrast to the phase diagram predictions for the Ga-Sb-O and Ga-As-O systems. Thermally oxidized films on GaSb and GaAs have in fact already been shown to contain substantial deposits of elemental Sb and As, respectively (18, 30, 31).

The variability with electrolyte composition and pH of the Ga/P ratio in bulk anodic films on GaP (34, 39-40) demonstrates that $GaPO_4$ is not the unique product evolved during anodic oxidation. These films

are believed instead to consist of an amorphous mixture of Ga_2O_3 and P_2O_5 whose ratio in the film is sensitive to selective dissolution of these components in the electrolyte.

A comparison of the film compositions appropriate to thermodynamic equilibrium (Fig. 14) and those found experimentally (Fig. 15) in electrochemically anodized films suggests that in the latter case oxide growth has not occurred under near equilibrium conditions. Some support for this point of view is available from observations that the oxide-GaAs interfacial composition and width are both dependent on the current density (growth rate) (35, 41). This interface can be quite narrow when grown under optimal conditions (41). Thermal annealing provides the necessary energy to overcome diffusion and reaction barriers. At sufficiently high temperatures the appropriate group V oxide component can react with the substrate on GaSb and GaAs according to Eq. [1] and [2] (Fig. 15). The products of this reaction yield an interfacial region composed of Ga_2O_3 and either Sb or As. For anodized GaP, the failure to observe P in thermally annealed films suggests either that the P_2O_5-GaP tie line is stable or that the P_2O_5 is either volatilized or reacted with Ga_2O_3 to form the phosphate or metaphosphate. The latter product is anticipated only if the P_2O_5/Ga_2O_3 ratio of the film is greater than one.

Summary

Interfacial oxide-substrate reactions have been observed on thermally annealed samples of electrochemically anodized GaSb and GaAs. This phenomenon involves diffusion of the group V oxide component of the film to the substrate followed by subsequent reaction to yield the thermodynamically stable interfacial phases. Estimates of the Ga-Sb-O and Ga-As-O ternary phase diagrams indicate that the phase constituents in thermodynamic equilibrium with GaSb and GaAs will be Ga_2O_3/Sb and Ga_2O_3/As, respectively. The interfacial reactions thus generate deposits of elemental Sb or As whose slow growth with time may prove deleterious in device applications involving native oxides on those substrates. Since the driving force for the interfacial reaction is thermodynamic in origin, native oxides produced via plasma oxidation techniques will also be subject to their occurrence whenever there is sufficient energy available to overcome the diffusion and reaction barriers. The reaction rate at a fixed temperature was observed to be much faster on GaSb than on GaAs.

An analogous reaction between P_2O_5 and GaP was not observed either in anodic films or powdered mixtures. Both $GaPO_4$ and $Ga(PO_3)_3$ can form, however, as a consequence of the reaction between P_2O_5 and Ga_2O_3. The actual product will depend on the P_2O_5/Ga_2O_3 ratio present in the film, this latter parameter being sensitive to the details of the anodization.

Intermediate Oxide Formation in Double-Polysilicon Gate MOS Structure

Hideo Sunami, Mitsumasa Koyanagi, and Norikazu Hashimoto

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

An intermediate insulator formation technique is realized using the concentration-dependent oxidation (CDO) of the phosphorus-doped first polysilicon gate. Utilizing the CDO effect, that is, heavily doped Si is oxidized faster than lightly doped Si, a thick intermediate oxide is formed to cover the first gate with its own oxide and a substrate surface to form the second gate oxide with simultaneous wet oxidation at 700°-900°C. Electrical properties of the intermediate insulator are discussed in terms of the formation conditions and topographical structures of the overlapped region. It is found that oxidation temperatures of around 900°C and moderate oxide thicknesses produce superior electrical properties and preferable geometries. In response to these requirements a dry-wet-dry oxidation (D-W-D) technique is successfully developed. A 5-17-5 min D-W-D oxidation at 900°C causes a 50 nm oxide to be formed on single crystal (100) silicon and a 210 nm oxide on the phosphorus-doped polysilicon. The autodoping effect of phosphorus atoms incorporated in the polysilicon gate is also discussed. It gives rise to harmful threshold voltage lowerings for the second gate n-channel transistors.

Following the application of the double-polysilicon gate MOS structure to CCD's (1), it is currently being extensively applied to large scale integration of MOS memories (2). These structures require an intermediate insulator between the two gates, which are electrically isolated at small capacitance to maximize circuit speed. Conventional techniques to realize the structure consist of CVD oxide formation on the first polysilicon gate, patterning of the double layer of the CVD oxide and the polysilicon gate, thermal oxidation of the gate edge, and subsequent second gate deposition. This structure has the disadvantages of possible shorts between adjacent second gates due to residual polysilicon under overhangs of the CVD oxide (3) and of lowering of the dielectric breakdown between the two gates by the thin oxide at the second gate edge.

SELOCS (selective oxide coating of silicon-gate) technology (4-6) has been introduced to reduce these drawbacks in the conventional CVD technology. Differences in processing sequences and the topographical structures of these two technologies are shown in Fig. 1. This SELOCS technology utilizes concentration-dependent oxidation (7-10), in which heavily doped silicon is oxidized faster than lightly doped silicon, thus producing simultaneous formation of the intermediate thick oxide and the second gate thin oxide at low temperature wet oxidation. Instead of the wet oxidation, a low temperature dry oxidation technique called differential oxidation, developed by Barnes,

Key words: concentration-dependent oxidation, double polysilicon, dielectric breakdown, autodoping effect.

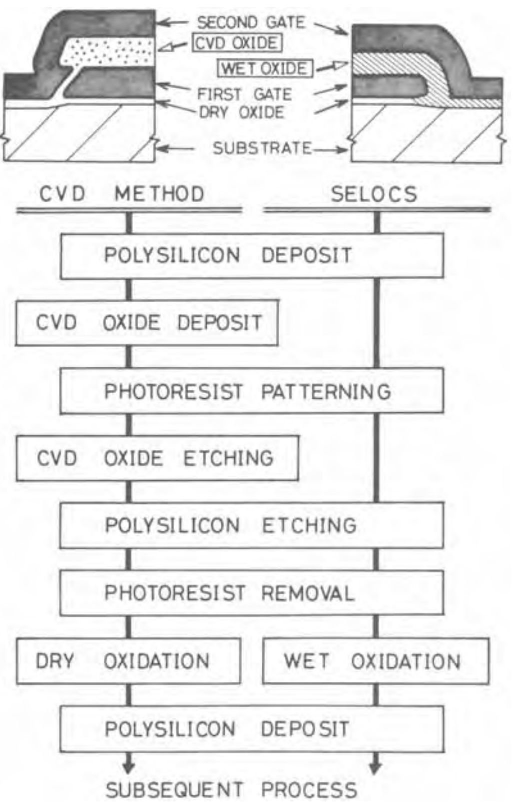

Fig. 1. Process sequences and resulting topographical structures for a conventional CVD oxide method and for SELOCS. A polysilicon film of the first gate is doped by phosphorus predeposition with a $POCl_3$ source.

DeBlasi, and Deal (11), also gives the identical structure, particularly concerned with the shallow junctions and thin oxide.

Even though SELOCS features a reduction in the number of processing steps, as previously shown in Fig. 1, and less probability of electrical shorts from the CVD oxide overhang, dielectric breakdown of the intermediate oxide between the two gates is still possible unless the processing conditions are appropriately chosen. Besides the dielectric breakdown SELOCS technology may have other limitations such as difficulties in formation of intermediate oxide of thicker than around 300 nm, inferior oxide integrity of the polysilicon oxide itself compared with that of single silicon oxide due to surface asperity of the polysilicon (12, 13), and increased sheet resistance due to the reduced thickness of the polysilicon gate.

The purpose of this study was to characterize parameters affecting oxide integrity and to choose better formation conditions for the coming VLSI double or triple level polysilicon devices. This paper presents the results of an empirical study on oxide formation and electrical properties affecting MOS transistors.

Experimental

A 400 nm thick polysilicon film was deposited by thermal decomposition of SiH_4 at 625°C onto a p-type (100) wafer with a resistivity of around 10 Ω-cm, on which a 50 nm oxide had been grown at 1000°C in a dry oxygen ambient. Then the film was doped with P using either a gaseous predeposition at 1000°C for 5-60 min using a $POCl_3$ source or P-ion implantation. Resultant sheet resistivity of the film was 15-60 Ω/square, depending on the P concentration. Initial grain size of the film of around 50 nm was increased to around 1 μm by P predeposition just as in the case of ion implantation with subsequent annealing (14). There was no significant structural or electrical differences between predeposition and ion implantation. A PSG film grown on the polysilicon film during the predeposition in an oxidizing ambient was removed by HF-buffered solution prior to subsequent processing. Then, the polysilicon film with patterned AZ1350 photoresist was etched by a conventional plasma etching technique using $CF_4 + 4\%O_2$ gas at 0.1 Torr in a barrel-type etching machine. The etching was automatically shut off by a plasma probe monitor (15) so as to obtain better reproducibility of the edge shape of the film. An etch rate of around 100 nm/min was obtained with 100W input rf power. In most cases, the 50 nm thick first gate oxide was etched off with HF-buffered solution to expose the substrate surface.

After the wafer was spin-dried, SELOCS oxidation was performed in a hydrogen-burning type furnace. A three-zone, resistance-heated furnace with a high purity alumina liner was used in this study. The oxidation chamber was a single wall, fused silica tube. Flow rates of oxygen and hydrogen for wet oxidation were 1.0 and 1.8 liters/min, respectively. The oxygen flow rate was 3.0 liters/min for the dry oxidation in the same furnace. Oxide thicknesses were determined by an ellipsometer for oxides on single crystal silicon and by a Talystep meter or a scanning electron microscope (SEM) for those on polysilicon films.

Currents flowing through the oxides were measured with a Model 26000 Keithley logarithmic picoammeter by the *I-V* method. A 3 V/sec ramp voltage was applied to the samples to characterize the oxide quality. All *I-V* measurements were made at room temperature while the samples were being blown with dry nitrogen in an electrostatic shield box used to block out the light.

Cross-sectional configurations of the samples were observed by field emission type SEM. Polysilicon gates were lightly etched after cleaving the samples to obtain clear images for SEM observation. The etching also removed small amounts of the high P content oxide film.

Results

Concentration-dependent oxidation.—Arrhenius plots of oxide thickness *vs.* the inverse of oxidation temperature are shown in Fig. 2 for polysilicon film which was doped with P ($C_B = 3 \times 10^{20}$ cm^{-3}) by the gaseous predeposition and 10 Ω-cm (100) single crystal silicon with wet oxidation (10). The P concentration was evaluated by a chemical method. The ratio of the thickness of the oxide on the polysilicon to that of the oxide on the single crystal shows a remarkable increase in the lower oxidation temperature region. Extrapolation of the experimental data in Fig. 2 gives 1050°C as the temperature at which the two oxides would be equally thick. To maximize circuit speed, larger values of the ratio are preferable when the second gate oxide thickness is kept constant. However, relatively low oxidation temperatures and thicker polysilicon oxides often give rise to dielectric breakdown between the two gates. This failure phenomenon is discussed in a later section.

Double-polysilicon gate structure.—The typical double-polysilicon gate structure shown in Fig. 3 was obtained by dry oxidation at 1000°C for 45 min subsequent to wet oxidation at 750°C for 90 min in two different furnaces. Of the 50 nm thickness of the second gate oxide, 30 nm was produced by the wet oxidation and 20 nm by the subsequent dry oxidation. The cross-sectional structure was mostly determined by the initial wet oxidation. The purpose of adding the dry oxidation was not primarily to improve the edge shape, but to improve the wet oxide of the second gate MOS transistors, since the wet oxide was relatively leaky compared to the dry oxide in this study.

As shown in Fig. 3, the second gate oxide became thinner in the vicinity of the gate edge. This phenomenon may well be the same as the "gate oxide thinning at the isolation wall" described by Sheng and Marcus (16).

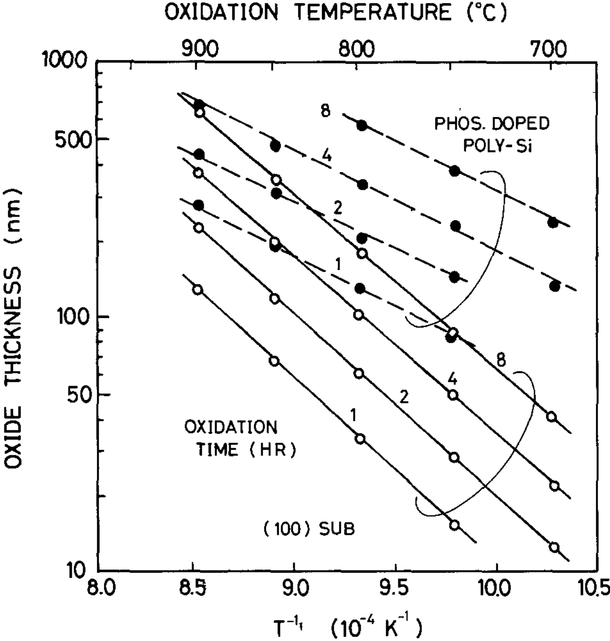

Fig. 2. Arrhenius plots of wet oxidaton for 10 Ω-cm (100) silicon substrates and polysilicon films phosphorus doped (C_B) = 3 × 10^{20} cm^{-3}) by $POCl_3$ gaseous predeposition.

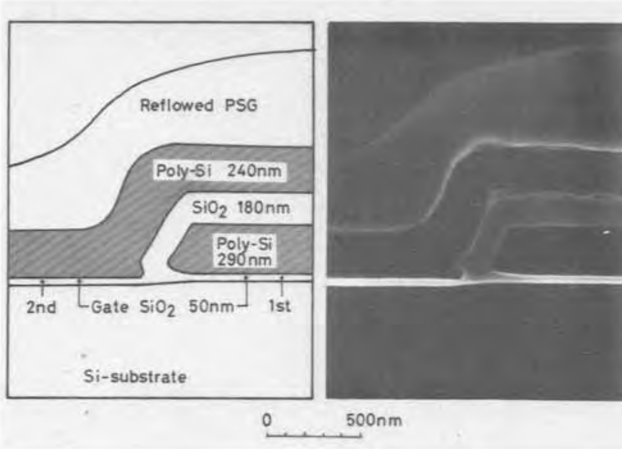

Fig. 3. Typical double-polysilicon gate structure realized by dry oxidation at 1000°C for 45 min subsequent to wet oxidation at 750°C for 90 min. The phosphorus concentration of the first gate measured 4.5 × 10^{20} cm^{-3}. The role of the dry oxidation was to electrically cure the oxide; the structure was mainly determined by the wet oxidation.

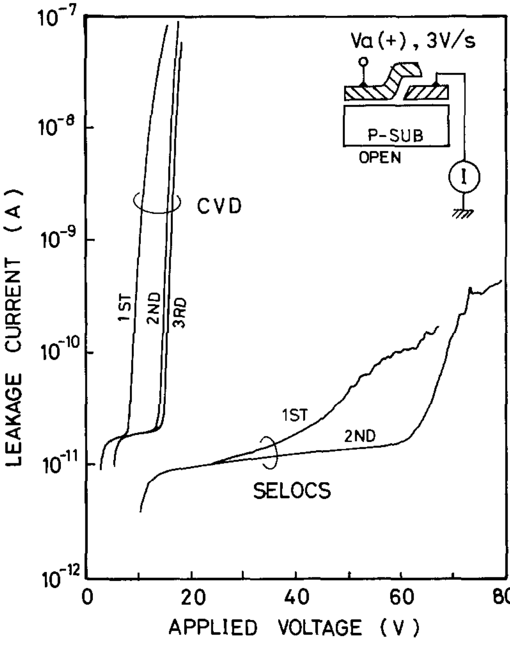

Fig. 4. Leakage currents through intermediate oxides obtained by a conventional CVD method and by SELOCS. The ramp rate of the applied voltage was 3 V/sec. Constant levels of the leakage currents in low voltage area are displacement currents. The area between the first and the second sweeps correspond to the amount of traps filled by electrons composing the leakage currents.

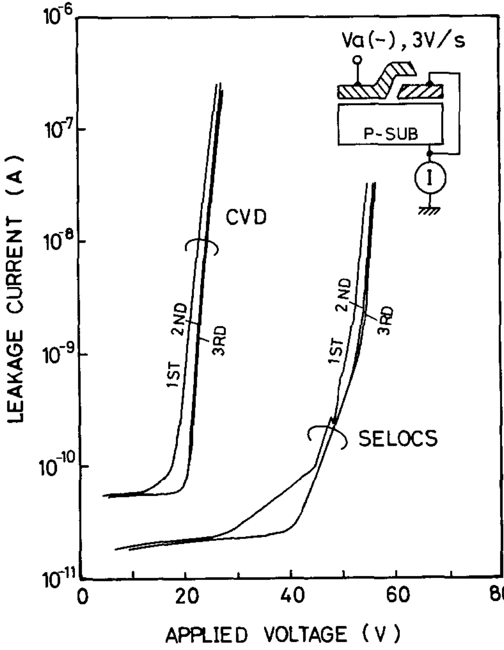

Fig. 5. Leakage currents for 50 nm thick second gate oxides and the intermediate oxides obtained by conventional CVD method and SELOCS.

Leakage current.—Results of the leakage current measurements for an intermediate oxide and a second gate oxide are shown in Fig. 4 and 5, respectively. Structures measured were striped first polysilicon gates covered with their own oxide on which a plane second gate was overlayed and were designed to be 455 μm in edge length and 1680 μm^2 in plane area. Cross sections of the obtained structures were previously shown in Fig. 1. To pick up effects caused by topographical features independent of the oxide quality second gate oxides in both structures were produced by the same dry oxidation in the same furnace. Process sequences were as follows:

1. CVD structure: The sample to be oxidized had patterned double layers of polysilicon gates and 400 nm thick CVD oxides. The first gates were delineated by the automatically shutoff plasma etcher using the patterned CVD oxides as etching masks. Substrate surfaces were made bare and exposed to the ambient by etching off the oxide except in the regions where the first gates were deposited. Then a 50 min dry oxidation was done at 1000°C to produce a 50 nm thick second gate oxide on the bare substrate surface and slightly thicker oxide on the edges of the first gates.

2. SELOCS structure: The samples to be oxidized had patterned first polysilicon gates. Substrate surfaces were bare just as in the CVD structure formation. Then a 4 hr wet oxidation at 800°C was made on the sample to produce a 120 nm thick oxide on the bare substrate surface and a 300 nm thick oxide on the first gates. Then an HF-buffered solution was used to etch off the 120 nm thick oxides. Consequently, the initial 300 nm thickness of the polysilicon oxides was reduced to around 200 nm. Then the same dry oxidation as in the CVD structure was done, resulting in a 50 nm thick second gate oxide on the substrate surface.

The constant levels of the leakage currents in the low applied voltage region, clearly shown in Fig. 4 and 5, are displacement currents defined by the equation: $I = dQ/dt = C(dV/dt)$. As the ramp rate was 3 V/sec, capacitances are evaluated from the curves shown in Fig. 4 to be about 6 and 3 pF for the CVD and the SELOCS structures, respectively.

The areas between the first and the second curves, also shown in Fig. 4 and 5, correspond to the amounts of traps filled by electrons composing the leakage currents. Thus the trap density can be evaluated by the *I-V* measurements. The trap density was evaluated to be on the order of 10^{12} cm^{-2} from these results.

For good circuit performance, thicker intermediate oxides are required. However, it was clear that the SELOCS method was markedly superior to the CVD method from the electrical point of view. Furthermore, breakdown voltages of the oxide in the CVD structure were lower than the expected value of 40V for 50 nm thick SiO_2 (calculated from the electric field of the dielectric breakdown of dry SiO_2: 8×10^6 V/cm). The electrical inferiority of the CVD structure may originate from an electric weakness of the polysilicon oxide itself. The breakdown voltage obtained for the polysilicon oxide is about half that of single silicon oxide of the same thickness. It is fairly consistent with expectations, since the dielectric breakdown between the second gate and the substrate electrically connected to the first gate occurred at about 20V, as shown in Fig. 5, and the voltage was limited mostly by the polysilicon oxide at the first gate edge for the CVD structure.

Failure of overhang formations.—Extreme oxidations in the SELOCS structure gave rise to an overhang of the intermediate oxide at the first gate edge. A cross section of a typical overhang is shown in Fig. 6. This structure resulted from 4 hr wet oxidation at 750°C. The overhang was caused by oxide forming beneath the first gate edge as if it were penetrating under it, raising the edge. A speculated sequence for the overhand formation is schematically shown in Fig. 7.

Since the thickness of an SiO_2 formed from polysilicon is nearly twice that of the original polysilicon, the front edges of the polysilicon oxide expand by approximately the same thickness of the polysilicon converted to SiO_2. Thus the polysilicon oxide edge begins to expand out over the substrate oxide surface as shown in (2) in Fig. 7. Furthermore, the oxide growing on the heavily P-doped polysilicon is thicker than that growing on the lightly doped silicon substrate. This expansion and lifting of the polysilicon oxide edge produces the overhang shown in (3) in Fig. 7. The overhang resulted in a very thin intermediate oxide at the gate edge, much like a previously reported process (16), giving rise to low dielectric breakdown voltages and shorts. In this study, it was found that thicker oxides and lower oxidation temperatures caused these failures. We found an empirical relationship between elec-

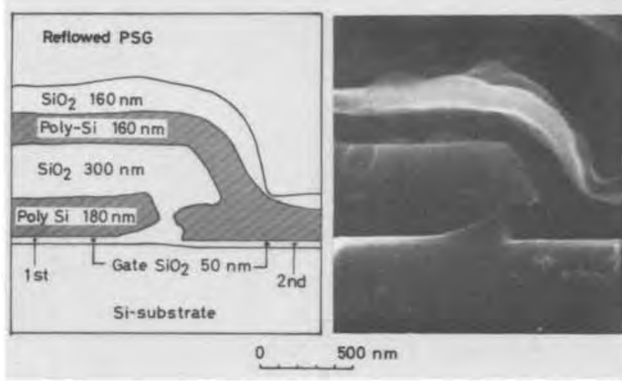

Fig. 6. An extreme case obtained by 4 hr wet oxidation at 750°C. An overhang of a 300 nm thick intermediate oxide was formed at the first gate edge.

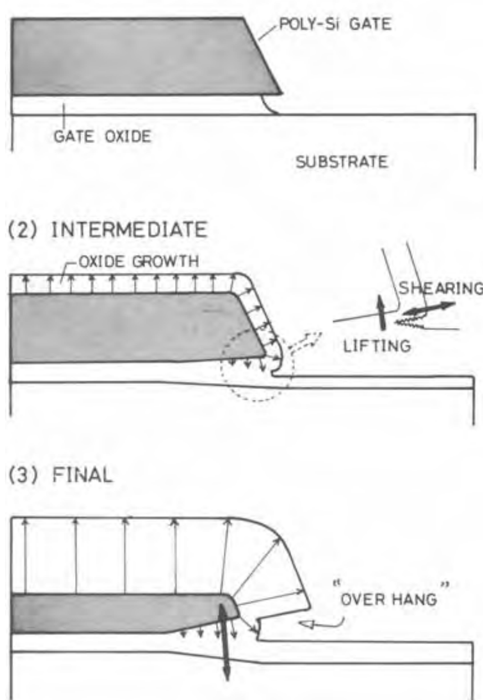

Fig. 7. Speculated sequence for overhang formation during oxidation of the first polysilicon gate.

trical properties and structures, on the one hand, and oxide thickness and oxidation temperature, on the other, as shown in Fig. 8. Preferable electrical performances, which mean sufficiently high and reproducible dielectric breakdown voltage, less time-dependent degradation of oxide integrity, and overhangless structures, are marked by o, failures by x, and intermediate by △. Thus the shaded region should give desirable performances for double polysilicon structures.

Discussion

Mechanism of overhang formation.—To characterize overhang formation the overhang wedge model shown in Fig. 9 was introduced. Parameters which seem to affect the formation were polysilicon gate thickness *Tg*, impurity concentration in the gate *Cg*, pad oxide thickness *Tp*, length of the pad oxide undercut *Lp*, intermediate oxide thickness $Ti \cdot ox$, and second gate

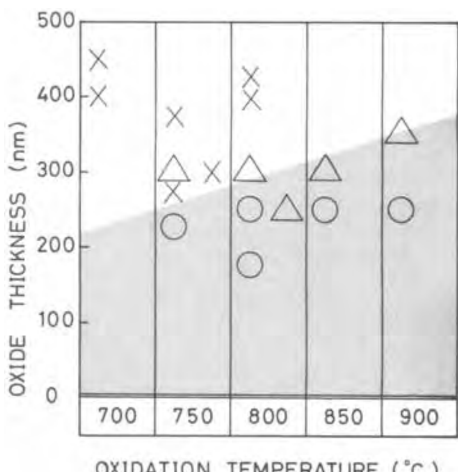

Fig. 8. Empirical relationship between electrical and structural integrity and both oxide thickness and oxidation temperature. Open circles denote preferable electrical and structural properties, × marks unpreferable, and triangles intermediate. Processing conditions in the shaded region give preferable performances.

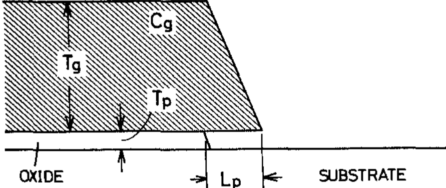

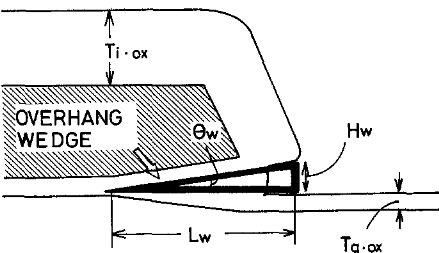

Fig. 9. Proposed model to explain the overhang formation. *T* is thickness, *C* impurity concentration, *H* height, *L* length, and *θ* angle, respectively.

thickness $Tg \cdot ox$. Wedge height Hw was defined as a figure of merit for the intermediate oxide formation. It was found that smaller Hw led to better dielectric performances. Large values of Hw led to formation of relatively thin intermediate insulator and electrical shorts between adjacent second gates because of a residual polysilicon underneath the overhang. To shorten Hw, wedge length Lw and/or wedge angle θw must be small according to the equation, $Hw = Lw \tan \theta w$ (Lw and θw were not absolutely independent but had mutual influence).

Parameters influencing Hw were thus qualitatively analyzed as follows.

Oxidation temperatures.—According to the general relationship (17) for thermal oxidation, relatively low temperatures lead to surface reaction controlled oxidation. In fact, this oxidation theory also fits that of P-doped polysilicon (10). Surface reaction controlled oxidation gives a linear increase in oxide thickness x with respect to the oxidation time t: $x = (B/A)t$. A parabolic increase is obtained in the diffusion-controlled regime: $x = (Bt)^{0.5}$. Here, A and B are the oxidation rate constants (17). Since oxidant transportation is thus not the rate-limiting process in surface reaction controlled oxidation, *i.e.*, at lower temperatures, oxidants can penetrate deeper than at higher temperatures, resulting in greater Lw.

Besides the effect of increasing Lw, surface reaction limited oxidation also has the effect that once a thin oxide layer at the first polysilicon gate edge is produced by the overhang formation and so forth, the thin place remains thin even after subsequent oxidation. This is because oxide thickness increasing rates are equal in spite of differing oxide thicknesses of the starting materials when oxidation is assumed to be absolutely surface reaction controlled. Unlike the surface reaction, in diffusion-controlled oxidation the thickness of the thin oxide formed at the first gate edge increases faster than that of thick oxide, resulting finally in equal oxide thicknesses for the entire area. To summarize the above, low oxidation temperatures lead to possible dielectric breakdowns between the two gates.

Oxide thickness.—Fundamentally the same as the above, an increase in oxide thickness $Ti \cdot ox$ also causes an increase in Hw when the thickness exceeds some optimum value which seems to depend strongly on the oxidation temperature. While increases in the gate oxide thickness $Tg \cdot ox$ decrease Hw, the ratio of $Ti \cdot ox$ to $Tg \cdot ox$ is a substantial parameter affecting breakdown. In this sense, higher temperatures also cause preferable small values of the thickness ratio.

The effect of pad oxide thickness Tp on Hw was somewhat complicated. It was found that increases in Tp did not necessarily result in an increase in Hw, but in small decreases in Hw. It seemed that since lifting of the first gate edge region occurred deeper from the edge due to increased oxidant supply, the bending angle of the gate edge became smaller, resulting in smaller Hw. In fact, breakdown voltages were higher for the structures on thick field oxides than for those on thin gate oxide.

Impurity concentration of doped polysilicon.—Since the oxidation is closer to the ideal diffusion-limited oxidation with increases in P concentration (10), heavy doping is expected to decrease Hw. However, the oxide thickness increases with the increase of impurity concentration and Hw tends to increase. These two effects on dielectric breakdown oppose each other, and substantial resultant effects on dielectric performance have not yet been found.

Undercut of pad oxide.—The undercut of the pad oxide Lp had a considerable influence on Hw. Increasing Lp caused an increase in Lw. In this sense it might be preferable not to remove the pad oxide prior to a subsequent second gate oxidation if the second gate oxide was allowed to be thicker than the pad oxide and was sufficiently cleaned prior to the subsequent oxidation.

To summarize these considerations, the empirical tendency in the relation between oxidation temperature and oxide thickness shown in Fig. 8 can be qualitatively explained with respect to oxidation temperature, oxide thickness, and the impurity concentration. Since the thick intermediate oxide resulted in the formation of thin oxide at the first gate edge, oxide thickness of the intermediate oxide among these factors seemed to have the strongest influence on the topographical configuration in connection with electrical performance.

Enlarged grain effect.—Heavy doping of the polysilicon gate caused grain growth up to several microns in diameter even for 0.5 μm thick polysilicon film (14). Enlarged grains were found to have a great influence on patterning of the gate by plasma etching with CH_4 gas. Gate edge shapes are shown in Fig. 10 for both undoped and P-doped (1×10^{21} cm^{-3}) polysilicon films. Fjord-like edges were obtained for the P-doped gate which seemed to reveal the grain boundaries of the gate. Maximum depth of the Fjord measured about 0.3 μm, as shown in the photograph. Since plasma etching using 0.1 Torr CH_4 gas provided an essentially isotropic chemical reaction, grain boundaries having more active silicon bonds, defined by dangling bonds, were likely to be attacked much more strongly than nearly single crystalline grains.

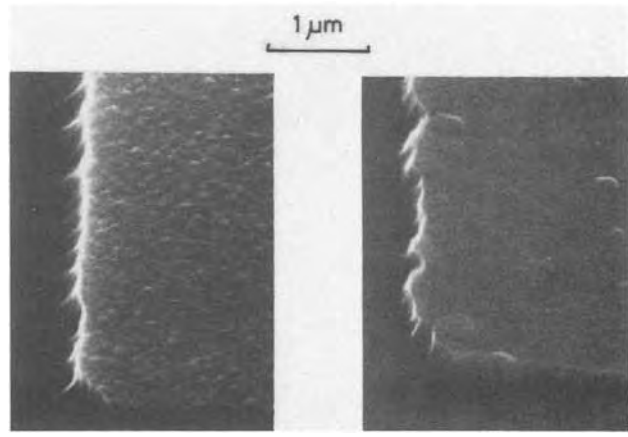

Fig. 10. Edge shapes delineated by plasma etching using CH_4 gas for undoped polysilicon and phosphorus-doped ($C_B = 1 \times 10^{20}$ cm^{-3}) films. (a, left), as deposited; (b, right), phosphorus doped.

It is considered that these Fjord-like edges cause the electric field concentration resulting in the lowering of dielectric breakdown. In addition, these edges made definition of gate length more difficult for scaled down MOS transistors. These points make strongly directional dry etching, such as reactive ion etching (18) or microwave plasma etching (19), preferable to isotropic plasma etching. These grains also gave rise to chipping and/or rising of the grains themselves similar to earthquake faults at the gate edges. This also degraded the electrcal performance of the double-polysilicon devices.

Autodoping of phosphorus atoms.—Phosphorus concentrations greater than 1×10^{21} cm^{-3} caused very rapid oxidation resulting in "initial oxide." It was previously speculated that the initial oxide consisted of P-rich SiO_2, or possibly phosphosilicate glass (10). In fact, SIMS depth profiles (Fig. 11), obtained in this study, clearly indicate the existence of a P-rich SiO_2 surface (20). The total amount of phosphorus in the polysilicon films was evaluated by chemical methods. The matrix effect between P and Si both in the oxide and in Si was found to be about 2 for evaluation of concentrations from the SIMS signals. These profiles were obtained for oxidized polysilicon films of which initial concentration of P were 2×10^{21} and 1×10^{21} cm^{-3} for (a) and (b), respectively. The oxidation was carried out in wet oxygen at 900°C for 5 min. This phenomenon that P concentration increases toward the oxide surface is highly reproducible. At present it is speculated that P atoms which exceed a solid solubility at the oxidation temperature came out from the polysilicon at the very early stage of the oxidation.

One polysilicon film of P concentration 2×10^{21} cm^{-3}, (a) in Fig. 11, caused a concentration of about 1×10^{21} cm^{-3} at the oxide surface, while another P concentration 9×10^{20} cm^{-3} caused a concentration of 2×10^{20} cm^{-3} at the surface. Thus the P concentration ratio at the oxide surface was 4.5 ($= 9 \times 10^{20}/2 \times 10^{20}$), while that of polysilicon films was 2 ($= 2 \times 10^{21}/1 \times 10^{21}$). Furthermore, the P profile in the oxide for (a) was clearly distinguished by the higher P concentration near the surface, though effective segregation coefficients (ratio of impurity concentration in silicon to that in oxide at oxide-silicon interface) under nonequilibrium conditions did not differ as much as the surface concentrations in the profile. The effective segregation coefficients were evaluated to be around 10 for both (a) and (b) from the curves shown in Fig. 11. The ratio of P surface concentration C_S to bulk concentration C_B had been reported to be 4 at 900°C wet oxidation for single silicon (21). The ratio of 1.5 was obtained for (a) in this experiment. The difference between these two values may be validly attributed to strongly enhanced diffusion of P in polysilicon (22).

Higher P concentration toward the oxide surface implies that P atoms can be vaporized into the oxidation ambient, causing harmful autodoping into bare silicon surfaces where second gate transistors will be subsequently formed. Threshold voltage lowerings of 0.1-0.5V were observed for n-channel transistors with phosphorus-doping concentrations greater than 2×10^{21} cm^{-3}. It was also found that the lowering depended on various conditions such as relative wafer locations in an oxidation furnace, gas flow rates, distance between adjacent wafers, and oxidation temperatures. Thus autodoping effects depend on detailed oxidation conditions and sample preparations may be extremely complex, quantitative analysis has not yet been done.

Dry-wet-dry (D-W-D) oxidation.—Among the various oxidation conditions tried in this study, the best results regarding oxide breakdown characteristics were obtained with dry-wet-dry (D-W-D) oxidation at 900°C. The results are shown in Fig. 12 compared to the next best results obtained from 750°C wet + 1000°C dry oxidations. The effective influence of high temperature oxidation was obviously observed in 900°C D-W-D oxidation in the same furnace, particularly for double polysilicon structures (B) on a 50 nm thick gate oxide. The initial 5 min dry oxidation improved oxide thickness uniformity due to uneven temperature rising within wafer surfaces and among different wafers to be simultaneously oxidized. The last 5 min dry oxidation was intended not to eliminate the overhang formation but to improve the wet oxide produced by the intermediate wet oxidation. In fact, a much longer 40 min, 1000°C dry oxidation in wet-dry

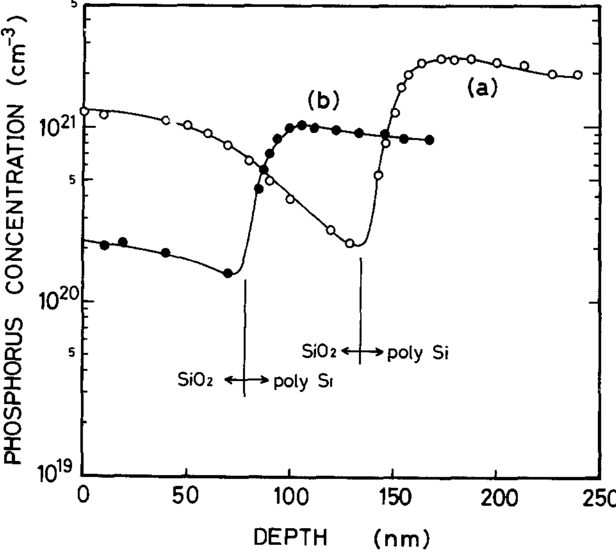

Fig. 11. SIMS depth profiles of phosphorus atoms in polysilicon films which were doped with P by implatation and their oxides obtained by 5 min wet oxidation at 900°C. Initial concentrations of implanted P were 2×10^{21} cm^{-3} for (a) and 1×10^{21} cm^{-3} for (b) prior to the wet oxidation.

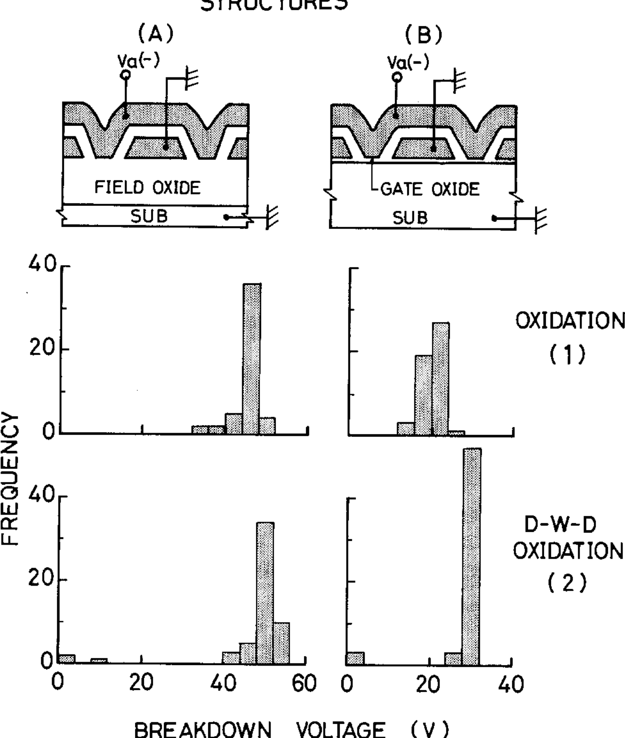

Fig. 12. Measured breakdown voltages of structures (A) and (B) for oxidations 1 and 2. Oxidation 1 = 750°C wet 90 min + 1000°C dry 40 min. Oxidation 2 = 900°C (D-W-D), 5-17-5 min. Around 50 samples were measured for 5 μm wide, 10 mm long striped gates. The cumulative total area and edge length were 25 mm^2 and 5m, respectively.

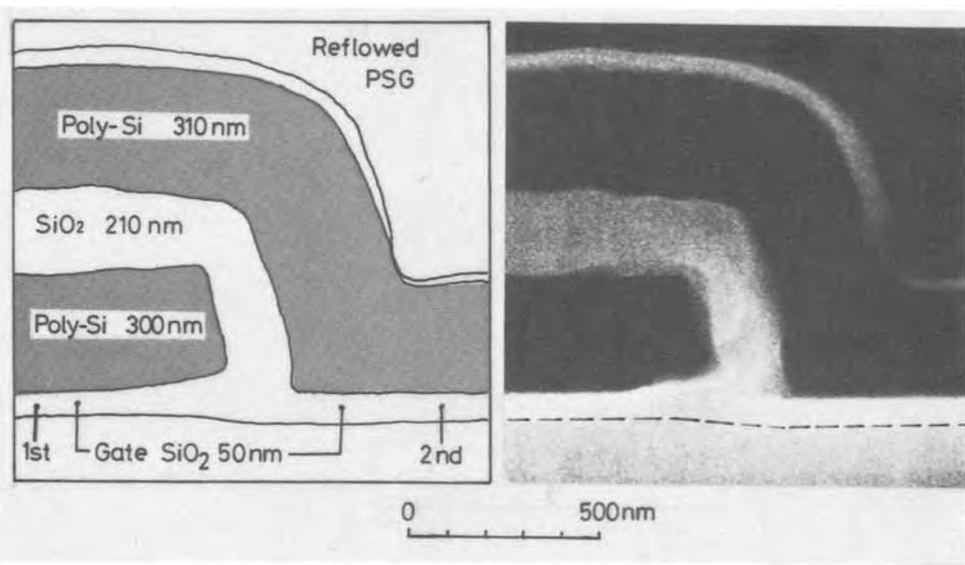

Fig. 13. Nearly perfect structure obtained by the D-W-D oxidation previously shown in Fig. 12 as Oxidation 2. The broken line has been added to the photograph to indicate the oxide-substrate interface.

oxidation (Fig. 12, (oxidation 1)) improved the breakdown field strength, but not to the level of the D-W-D oxidation.

A cross section of a double polysilicon structure realized by the D-W-D oxidation is shown in Fig. 13. Both a 50 nm gate oxide and a 210 nm intermediate oxide were formed by the D-W-D oxidation (Fig. 12, 2). A very smooth edge shape was obtained with no resulting overhang due to moderate intermediate oxide thickness of 210 nm and relatively higher temperature of 900°C. Oxidation temperatures higher than 900°C are expected to be more preferable, however, an oxidation temperature of around 900°C is a maximum one in a case that an intermediate oxide of thicker than 200 nm and a second gate oxide of thinner than 50 nm are needed.

Summary

An intermediate oxide formation technique has been realized using the concentration-dependent wet oxidation of phosphorus-doped first polysilicon gates at 700°-900°C for application to multilevel polysilicon devices. This technique, named SELOCS, gave significantly improved breakdown field strength and easier delineation of the overlayed second gate polysilicon. In particular, topographical effects regarding the overhang formation of the intermediate oxide were considered.

In this study, it was found that higher oxidation temperatures and moderate intermediate oxide thicknesses gave desirable electrical performances and topographical structures. According to this guiding principle, D-W-D oxidation was introduced to significantly improve performances. For a 5-17-5 min sequence at 900°C D-W-D oxidation, a 50 nm gate oxide and 210 nm intermediate oxide were formed on single crystal 10 Ω-cm (100) silicon and on P-doped ($C_B = 1 \times 10^{21}$ cm^{-3}) polysilicon, respectively. Anomalously thin intermediate oxide due to overhang is eliminated from relatively higher temperatures of around 900°C and the second gate oxide integrity is improved by the additional 5 min dry oxidation. In device structures realized by the D-W-D technique, a breakdown voltage of more than 25V between the first and the second gates on the gate oxide was obtained. In addition, the fact that autodoping of P atoms incorporated in the first polysilicon gate was pronounced when P concentration exceeded about 1×10^{21} cm^{-3} in the gate was discussed.

A Simple Model for the Deposition of Boron in Silicon by Using a BN Diffusion Source

S. F. Guo*

Institute of Electronics, National Chiao Tung University, Hsinchu, Taiwan, China

ABSTRACT

A physical model based on the multiple charge state vacancy statistics is proposed to express the boron diffusivity in silicon during the deposition step using the BN disk as a diffusion source in an inert ambient. The diffusion equation with concentration dependent diffusivity is solved numerically. A universal shape of the normalized profiles is observed. The surface concentration of the deposited layer has been determined experimentally. The calculated sheet resistance as a function of deposited time and temperature is in good agreement with the measured data. With a slight modification, this simple vacancy statistics model can also be applied to other deposition sources.

One of the most important advantages of the boron nitride (BN) source deposition process is its high reproducibility. It is also possible to describe the deposition sheet resistance in mathematical terms (1). High surface concentrations are generated by the BN diffusion system and anomalous effects have been observed under different diffusion conditions (2). To explain concentration-dependent diffusion in an inert atmosphere, Fair (3) proposed a donor-type monovacancy diffusion model and showed that the boron profiles fit a normalized universal curve which is a polynomial approximation to the solution of the diffusion equation with linear concentration-dependent diffusivity.

Recently, it was reported that vacancies in silicon can exist in V^+, V^-, and $V^=$ charge states, each having a definite energy level in the forbidden bandgap (4). Based on the multiple charge state vacancy statistics, Ho and Plummer (5) have successfully explained the commonly observed enhanced oxidation rates of heavily doped silicon. The purpose of this paper is to illustrate that the same statistics can also be applied to the behavior of high concentration boron deposition in a dry nitrogen ambient.

Although Fair (6) has examined the contribution of each charge state to the total diffusivity, it will be a good approximation that the diffusion coefficient of boron in silicon under an inert atmosphere is directly proportional to the total vacancy concentration. Furthermore, the enhanced diffusions in oxidized ambients can be explained by a surface space charge effect. The electric field factor generally encountered in the diffusivity expression will be omitted, since its variation is very small (from 1.45 to 2) and the localized Fermi level involved in the vacancy statistics might include the localized electric field effect.

As found by Armigliato *et al.* (7) , although dopant concentration is much higher than the solubility value at deposition temperature, precipitation is hard to occur. It is reasonable to assume that each boron atom in silicon provides a free hole in the diffusion coefficient and sheet resistance calculations. The hole mobility deduced by Antoniadis *et al.* (8) will be used in the surface concentration and sheet resistance calculations.

* Electrochemical Society Active Member.

Key words: diffusion model, boron deposition, BN source, vacancy statistics.

Experimental

The diffusion source employed in this work was Carborundum BN-975 boron nitride disks. The silicon materials used were 2 in. diam (111) oriented, one-side polished, high resistivity (>20 Ω-cm) n-type wafers. The source and silicon wafers are edge-stacked in the deposition carrier face to face with a spacing of approximately 1 mm. The diffusion furnace used was Thermco-Ranger Type-3000. The furnace ambient was dry nitrogen at a flow rate of 1 liter/min.

The sheet resistance of deposited layers was measured using a Veeco Model FPP-100 four-point probe. In order to obtain information on the dopant profile, the surface concentration was determined from a differential sheet resistance measurement. The thickness of anodic oxides was measured using a Rudolph Auto EL-II ellipsometer. The volumetric ratio of 0.4 for silicon converted to silicon dioxide and the concentration-dependent hole mobility value of Antoniadis *et al.* (8) were used in the concentration calculation. The measured results of surface concentrations as a function of temperature is shown in Fig. 1 along with other reported data for both BN solid source (2) and BBr_3 liquid source (7).

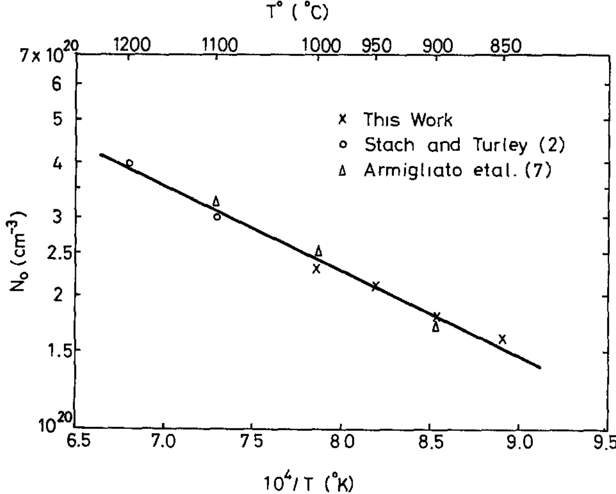

Fig. 1. Surface concentration of boron in silicon as a function of temperature.

Diffusion Model

The atomic theory of diffusion for substitutional impurities in silicon is based on the lattice vacancy diffusion mechanism. The effect of equilibrium vacancy concentration variation on the impurity diffusivity was first considered by Hu and Schmidt (9), and an expression of concentration-dependent diffusivity based on single charged state had been derived.

At the present time, it is known that silicon vacancies exist in neutral V^x and multiple charged states V^+, V^-, and $V^=$. The charged vacancy states have definite energy levels in the bandgap (4). The donor level E tracks the valence bandedge E_v

$$E^+ = E_v + 0.37 \text{ eV} \quad [1]$$

while the acceptor levels E^- and $E^=$ track the conduction bandedge E_c

$$E^- = E_c - 0.57 \text{ eV} \quad [2]$$

$$E^= = E_c - 0.11 \text{eV} \quad [3]$$

as the bandgap narrows with increasing temperature

$$E_G = E_c - E_v = 1.17 - 4.73 \times 10^{-4} \left(\frac{T^2}{T + 636} \right) \quad [4]$$

From the Shockley-Last theory (10), the thermal equilibrium concentrations of vacancies at various charged states C^r (r: $+,x,-,=$) are related to the Fermi level E_F by

$$C^+ : C^x : C^- : C^= = \exp \frac{E^+ - E_F}{kT} : 1 : \exp \frac{E_F - E^-}{kT} : \exp \frac{2E_F - E^- - E^=}{kT} \quad [5]$$

where the degeneracy effects have been neglected. It has been argued by Shockley and Moll (11) that the equilibrium concentration of neutral vacancies is a function of temperature only while the concentration of charged vacancies is a function of the Fermi level as well. The total vacancy concentration normalized to the neutral vacancy concentration is thus given by

$$C^T = 1 + \exp \frac{E^+ - E_F}{kT} + \exp \frac{E_F - E^-}{kT} + \exp \frac{2E_F - E^- - E^=}{kT} \quad [6]$$

By the use of Boltzmann approximation

$$\exp \frac{E_i - E_F}{kT} = \frac{p}{n_i} \quad [7]$$

where E_i is the intrinsic Fermi level

$$E_i = \frac{F_G}{2} - \frac{kT}{4} \quad [8]$$

and n_i is the intrinsic carrier concentration approximately given (12) by

$$n_i = 3.87 \times 10^{16} T^{3/2} \exp \left(- \frac{0.605}{kT} \right) \quad [9]$$

Equation [6] can be expressed as

$$C^T = 1 + \beta^+ \left(\frac{p}{n_i} \right) + \beta^- \left(\frac{n_i}{p} \right) + \beta^= \left(\frac{n_i}{p} \right)^2 \quad [10]$$

where

$$\beta^+ = \exp \frac{E^+ - E_i}{kT}$$

$$\beta^- = \exp \frac{E_i - E^-}{kT} \quad [11]$$

and

$$\beta^= = \exp \frac{2E_i - E^- - E^=}{kT}$$

On the assumption that the effective diffusivity is directly proportional to the total vacancy concentration (9), one gets

$$\frac{D}{D_i} = \frac{1 + \beta^+ \left(\frac{p}{n_i} \right) + \beta^- \left(\frac{n_i}{p} \right) + \beta^= \left(\frac{n_i}{p} \right)^2}{1 + \beta^+ + \beta^- + \beta^=} \quad [12]$$

where D_i is the intrinsic diffusivity. The value of D_i for boron in silicon has recently been determined by Antoniadis *et al.* (8) as

$$D_i = 0.55 \exp \left(- \frac{3.42 \text{ eV}}{kT} \right) \text{cm}^2/\text{sec} \quad [13]$$

under nonoxidized atmosphere.

Numerical Analysis

The classical solution of diffusion equation with constant diffusivity and constant surface concentration is a well-known complementary error function. However, for a high-concentration deposition, the diffusion coefficient is concentration-dependent and no analytic solution is available. Most recently a great deal of attention has been given to the use of computer simulation to determine dopant profiles (13).

For a concentration-dependent diffusivity, the diffusion equation is

$$\frac{\partial N}{\partial y} = \frac{\partial}{\partial y} \left(D \frac{\partial N}{\partial t} \right) \quad [14]$$

This problem should be solved numerically by discretizing the space y and time t coordinates

$$y = y_j = j\Delta y \qquad j = \ldots, -2, -1, 0, 1, 2, \ldots$$

$$t = t_i = i\Delta t \qquad i = 0, 1, 2, \ldots$$

and writing the differential Eq. [14] as a set of difference equation (14)

$$N(y_j, t_{i+1}) = M[D(y_{j+1}, t_i) N(y_{j+1}, t_i) + D(y_{j-1}, t_i) N(y_{j-1}, t_i)] + [1 - 2MD(y_j, t_i)] N(y_j, t_i) \quad [15]$$

where $M = \Delta t/(\Delta y)^2$ is called the mesh ratio and $D(y_j,t_i)$ is evaluated from Eq. [12] by letting $p = N(y_j,t_i)$ for $N(y_j,t_i) > n_i$ and $p = n_i$ for $N(y_j,t_i) \leq n_i$. The boundary condition for a constant surface concentration deposition is $N(y_0,t_i) = N_0$ and the corresponding diffusivity is D_0. The numerical calculation can be performed on a TI 59 programmable calculator. It would take about 2 hr to generate a profile, if a mesh ratio M of $1/4 D_0$, a space interval Δy of $\sqrt{4D_0t}/10$, and a time interval Δt of $t/100$ are chosen.

The calculated profiles of N/N_0 *vs.* $y/\sqrt{4D_0t}$ for several deposition temperatures are shown in Fig. 2. These normalized curves show a universal shape in the high concentration region ($N > n_i$) and a complementary error function tail in the low concentration region ($N < n_i$). It is interesting to note that the universal curve can be expressed as

$$\frac{N}{N_0} = 1 - 0.631 \left(\frac{y}{\sqrt{4D_0t}} \right) - 0.214 \left(\frac{y}{\sqrt{4D_0t}} \right)^2 \quad [16]$$

which is in good agreement with the approximate solution for arsenic diffusion in terms of Chebyshev polynomials (15). As a matter of fact, Fair's normalized boron profile [Fig. 3 of Ref. (3)] can also be approximated by Eq. [16] if the space coordinate is normalized to the surface diffusion length $\sqrt{4D_0t}$.

Results and Discussion

The experimental result of sheet resistance as a function of deposition time at various temperatures are

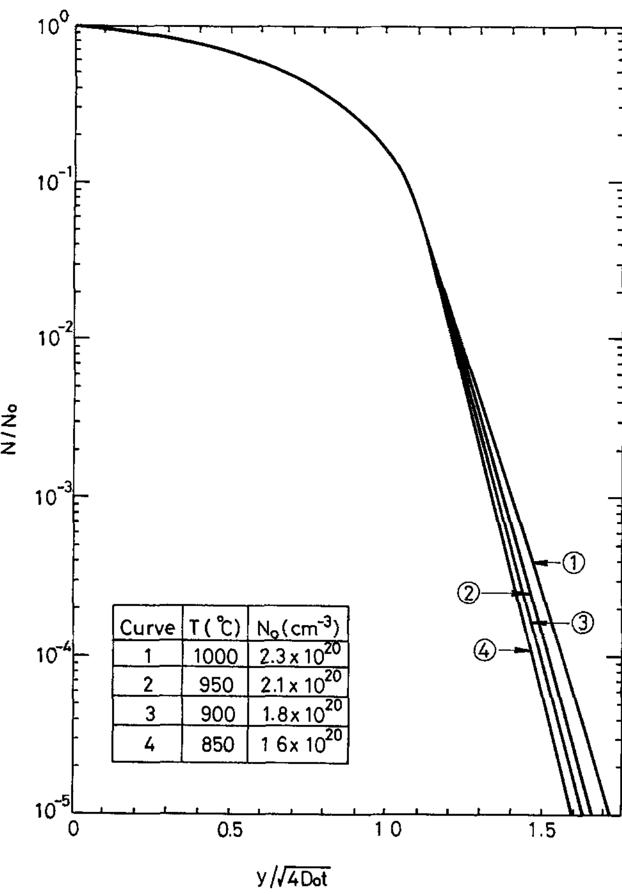

Fig. 2. Normalized profiles of N/N_0 vs. $y/\sqrt{4D_0t}$ for various temperatures.

shown in Fig. 3 along with data reported by Rupprecht and Stach (16). Assuming that boron atoms in the diffused layer are fully ionized, the deposited sheet resistance R_s can be calculated from

$$R_s^{-1} = \int q\mu_p N dy \quad [17]$$

where μ_p is the concentration-dependent hole mobility given (8) by

$$\mu_p = 49.7 + \frac{418}{1 + (N/1.6 \times 10^{17})^{0.7}} \quad [18]$$

As shown in Fig. 3, the numerically calculated results of sheet resistance are in good agreement with measured values.

Alternatively, Eq. [17] can be expressed as

$$R_s^{-1} = q\bar{\mu}_p Q \quad [19]$$

where $\bar{\mu}_p$ is the average hole mobility and Q is the deposited quantity of boron atoms in silicon per unit area. From numerical calculations it has been found that $\bar{\mu}_p \simeq 54$ cm²/Vsec for $N_0 \simeq 2 \times 10^{20}$ cm^{-3} and $Q \simeq 0.628\, N_0 \sqrt{4D_0t}$ for all deposited temperatures used in this work. Therefore, the sheet resistance expression [19] becomes

$$R_s = 9.2 \times 10^{16}/N_0 \sqrt{D_0t}\ \Omega/\text{sq} \quad [20]$$

where N_0 and D_0 are temperature dependent.

If the junction depth was defined as the distance from the surface at which N/N_0 had fallen to 10^{-2} in Fig. 2, then

$$y_j \simeq 2.4\sqrt{D_0t} \quad [21]$$

This is in approximate agreement with Fair's approximation [Eq. [12] of Ref. (3)].

It is suggested from Eq. [20] and [21] that the surface diffusivity D_0 can be determined experimentally by profile fitting or sheet resistance and surface concentration measurements. Some experimentally determined values of D_0/D_i and theoretically calculated curves of D/D_i vs. N/n_i are shown in Fig. 4. The multiple charge state vacancy model proposed in this work gives a result for the low temperature deposition using BN disks as diffusion source in a dry nitrogen ambient. For comparison, the D_0/D_i values for BBr_3 sources (7) as deduced from profile fitting are also shown in Fig. 4. Enhanced diffusion is observed. This phenomenon may be explained as follows.

The BBr_3 liquid source deposition is generally carried out in an oxidized ambient. This may result in some negative ions in the oxide layer. This surface charge causes the energy band of silicon to bend upward at the surface and the hole concentration p is then enhanced by a Boltzmann factor

$$\frac{p}{N} = e^{\Delta} \quad [22]$$

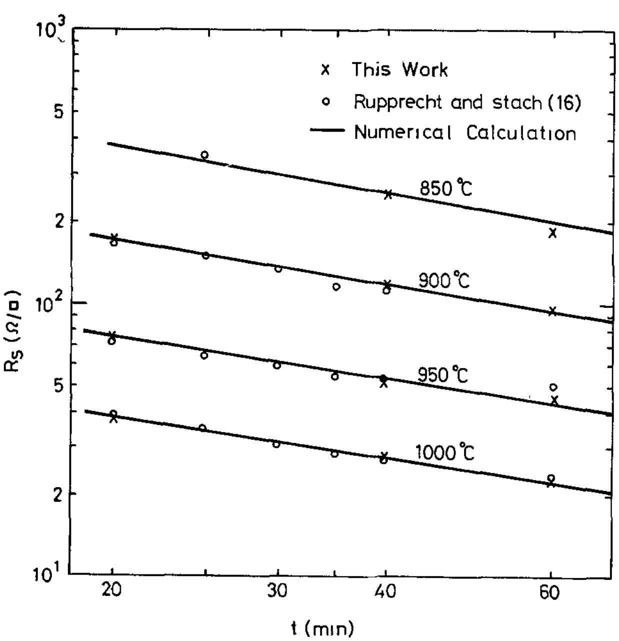

Fig. 3. Sheet resistance vs. deposition time for several temperatures.

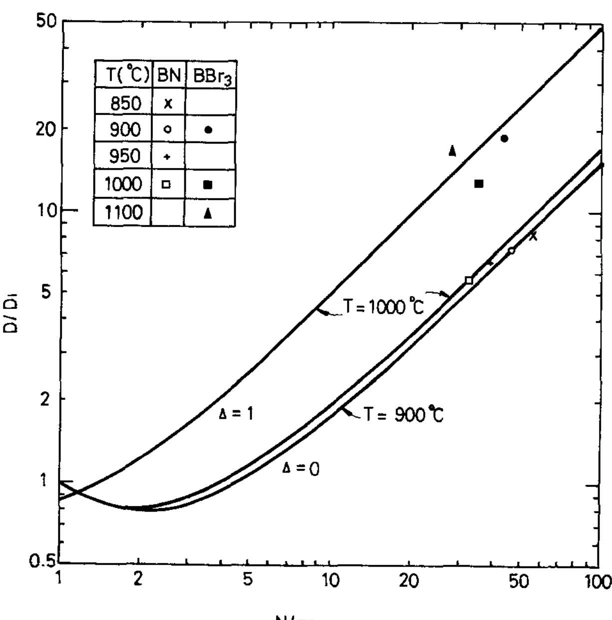

Fig. 4. Normalized diffusivity vs. normalized boron concentration under different conditions.

where Δ is the amount of energy band bending upward normalized to the thermal energy kT and N is the boron concentration. Taking this into account, the effiective diffusivity, Eq. [12], is modified to

$$\frac{D}{D_i(0)} = \frac{1 + \beta^+ e^{\Delta}\left(\frac{N}{n_i}\right) + \beta^- e^{-\Delta}\left(\frac{N}{n_i}\right)^{-1} + \beta^= e^{-2\Delta}\left(\frac{N}{n_i}\right)^{-2}}{1 + \beta^+ + \beta^- + \beta^=} \quad [23]$$

where $D_i(0)$ is the intrinsic diffusivity without energy band bending given by Eq. [13]. In Fig. 4, a band bending of 1 kT shows a good fit for the surface diffusivity of the BBr_3 source deposition.

In addition to the neutral vacancy concentration, the intrinsic diffusivity at the surface also depends on the band condition

$$\frac{D_i(\Delta)}{D_i(0)} = \frac{1 + \beta^+ e^{\Delta} + \beta^- e^{-\Delta} + \beta^= e^{-2\Delta}}{1 + \beta^+ + \beta^- + \beta^=} \quad [24]$$

The effect of band bending on the intrinsic diffusivity is shown in Fig. 5. Due to negatively charged vacancies, the intrinsic diffusivity decreases slightly with a small upward band bending. The values used in this work and the data reported by Fair (6) are also shown in Fig. 5. It is interesting to note that the increase of the enhancement of intrinsic diffusivity in oxidizing ambient with decreasing temperature (8) can be explained by the band bending effect. It is well known (17) that the positive oxide charge near the silicon dioxide-silicon interface increases with decreasing temperature. This positive surface charge will cause a downward band bending and the magnitude of band bending will increase with decreasing temperature. Therefore, Eq. [24] gives a good explanation for the diffusivity enhancement.

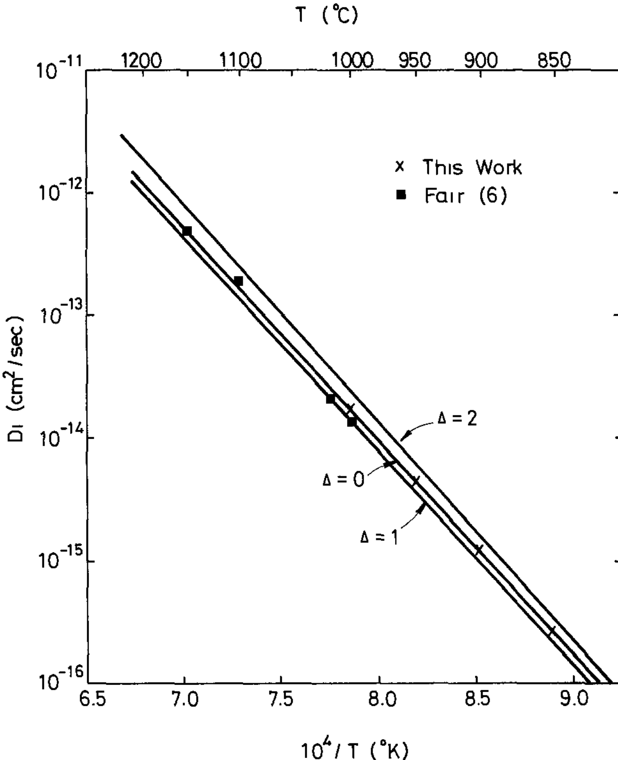

Fig. 5. Intrinsic diffusivity of boron in silicon with and without band bending.

Conclusion

A simple diffusion model based on the vacancy statistics gives a satisfactory prediction of the behavior of BN source deposition. Although the charged state of lattice vacancies might have a different contribution to the diffusion coefficient, the different behaviors for different diffusion conditions can be explained by a band-bending effect.

Preliminary Evaluation of Copolymers of Methyl Methacrylate and Acyloximino Methacrylate as Deep U.V. Resists

C. W. Wilkins, Jr., E. Reichmanis, and E. A. Chandross

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Copolymers of methyl methacrylate and acyloximino methacrylate esters have been evaluated as deep u.v. (200-250 nm) resists. Poly (methyl methacrylate-co-3-methacryloyl-oximino-2-butanone) has been found to be ~5 times faster than PMMA at $\lambda > 240$ nm and capable of submicron resolution. It has been found that the acetyl group of the 3-oximino-2-butanone substituent is more effective than the related species containing t-butyl, phenyl, or benzoyl groups in promoting polymer degradation. The copolymers have also been exposed to 20 kV electron beam radiation and have been found to be about as sensitive as PMMA (5×10^{-5} C/cm^2).

Deep (200-250 nm) u.v. photolithography is gaining a great deal of interest as a method of achieving small feature size (~1 μm) with high aspect ratios (1-7). The reduction in exposure wavelength from 400 to 250 nm should reduce diffraction effects and improve resolution (1). However, the technique requires the development of new resist materials. The ideal resist for deep u.v. lithography should possess good photosensitivity in the 200-250 nm region with little or no absorption at longer wavelengths to eliminate the need for the difficult task of removing the long wavelength light from a conventional mercury source. Additionally, the resist should be capable of high resolution, and be compatible with conventional microstructure fabrication.

Delzenne (8) has reported that copolymers of poly(methyl methacrylate) (PMMA) and acyloximino methacrylate esters undergo grafting in the presence of the other monomers, but that they degrade rapidly in monomer-free benzene solution upon irradiation with light of $\lambda = 365$ nm. We decided to investigate the solid-state photodegradation of similar copolymers and their possible utility as deep u.v. photoresists, and also as electron beam resists. The acyloximino ester chromophore has a strong absorption at ~225 nm ($\epsilon \sim 10^4$ M^{-1} cm^{-1}, Fig. 1) and the tail of this band is strong enough to give useful sensitivity at ~240 nm. These copolymers undergo a rapid photolytic decomposition involving cleavage of the N—O bond (scheme 1), yet they are sufficiently thermally stable to be compatible with conventional IC processing. Additionally, they should retain the high resolution properties of PMMA provided that the oxime methacrylate ester mole fraction is low.

Key words: ultraviolet, copolymers, degradation.

Experimental

Polymer preparation.—Polymers were prepared in toluene solutions at 60°C using azobisisobutyronitrile as initiator. They were isolated by two precipitations from methyl ethyl ketone solution into methanol, and dried under vacuum. Molecular parameters for the polymers evaluated are listed in Table I.

Preparation of 3-oximino-2-butanone methacrylate.—To a cold (0°) stirred solution of butane dione

a Elvacite 2010 (du Pont) "high molecular weight."

monoxime (54.5g, 0.54 mole) and triethylamine (120 ml, 1.1 mole) in ether (100 ml) under N_2 was added methacryloyl chloride (56.2 ml, 0.54 mole) in ether (250 ml) during the course of 1 hr. Stirring was continued at 0° under N_2 for 3 hr, after which the mixture was filtered, the filtrate washed with water (300 ml), dried, concentrated, and recrystallized from cyclohexane to afford 45g (50%) of product. (mp 38.5°-39°C).

Other monomers were prepared by the same general procedure as for the preparation of 3-oximino-2-butanone methacrylate.

Resolution.—The resolution capability of the materials was determined by proximity printing with a Kasper Model 2001 printer modified for deep u.v. exposure. The materials were exposed to the full output of a 200W xenon cadmium lamp.

Materials.—Poly(methyl methacrylate) (Elvacite 2010), a high molecular weight polymer available from du Pont, was used as the standard for measuring sensitivities.

Sensitivity.—Polymers were dissolved in methyl cellosolve acetate (10% solution) and were coated onto silicon substrates with a Headway Research spinner. Films were prebaked for 60 min at 100°C.

Photon sensitivities are reported relative to PMMA and were obtained by imaging a slit for varying exposure times across substrates coated with resist. Exposure times were recorded as the time necessary to completely remove the resist in the irradiated area, using methyl isobutyl ketone as the developer under conditions where there was essentially no thinning of the unirradiated areas. A 1000W high pressure mercury lamp was used as the exposure source. Absolute sensitivities were determined by using a monochromator and a thermopile to measure light flux.

Electron sensitivities were obtained by writing rectangular bars at different doses. The bar patterns were developed and the thickness remaining at each dose was measured. Figures 2 and 3 show plots of normalized resist thickness *vs.* dose for the polymers exposed at 20 kV.

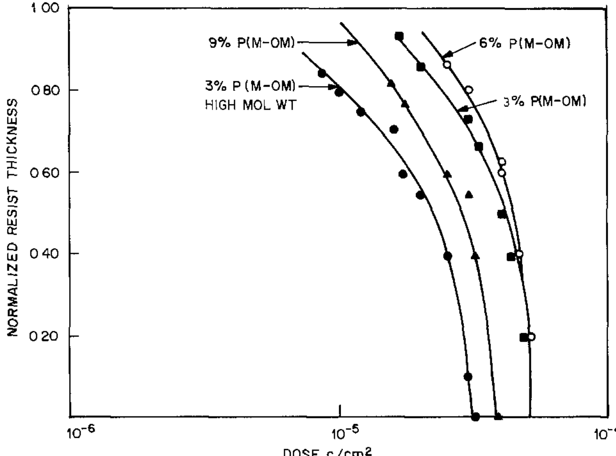

Fig. 2. Plots of normalized resist thickness vs. electron-beam dose for copolymers of methyl methacrylate and 3-oximino-2-butanone methacrylate.

Results and Discussion

Sensitivity.—We have found that incorporation of small (3-9 mole percent) amounts of 3-oximino-2-butanone methacrylate into PMMA renders the copolymers approximately 5 times more sensitive than PMMA, the standard material for deep u.v. lithography. In this section, we report the effect of both photosensitizer concentration and copolymer molecular weight on sensitivity.

Figure 1 reveals that the 3% 3-oximino-2-butanone copolymer has an optical density of 0.1 at 240 nm. This weak absorption allows light to be absorbed uniformly through the polymer film and results in patterns with high aspect ratios, but the materials are only marginally sensitive. Figure 1 shows the absorption spectrum of the copolymer as a function of acyl-oxime chromophore fraction. The OD of the 3% copolymer at 240 is 0.1, while that of the 9% copolymer is 0.3, but this approach is only marginally effective in improving sensitivity. Inspection of Table

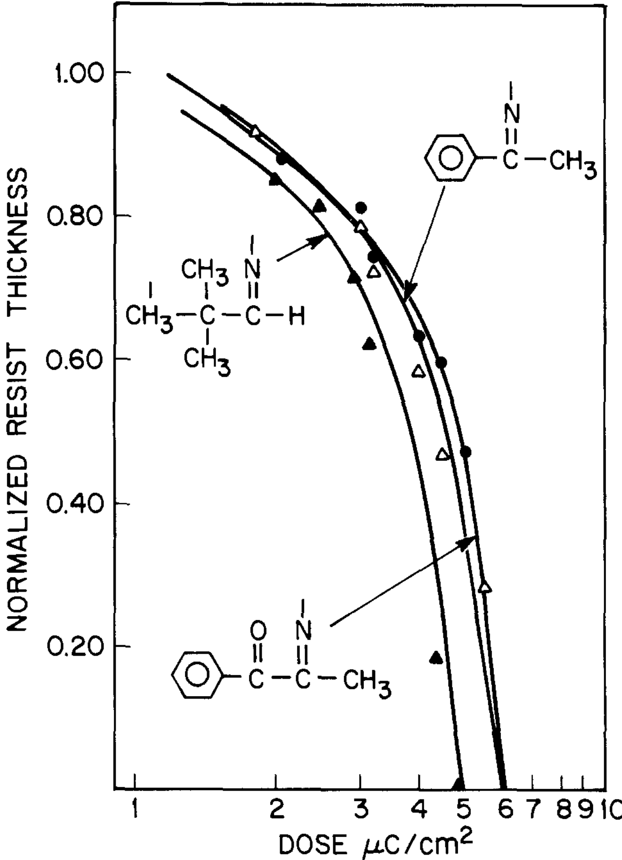

Fig. 3. Plots of normalized resist thickness vs. electron-beam dose for copolymers of methyl methacrylate and acyl-oxime methacrylate esters.

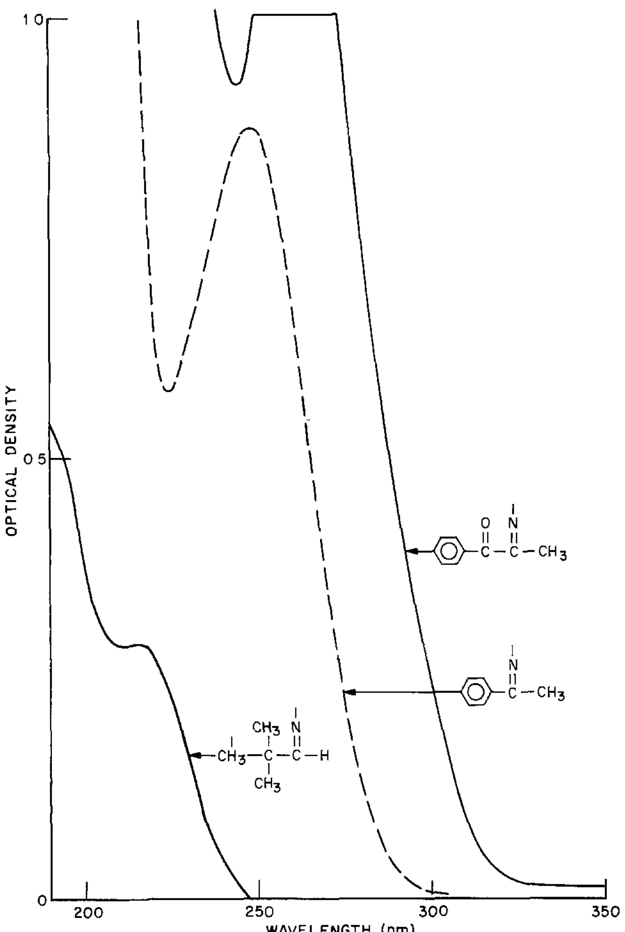

Fig. 4. Absorption spectra of copolymers of methyl methacrylate and oxime methacrylate esters.

I reveals that upon exposure to the full output of the mercury lamp the 6% acyl-oxime copolymer is more sensitive than the 9% copolymer. However, the 6% material has a monochromatic sensitivity at 240 nm of 1.3 J/cm^2 while the 9% copolymer has a sensitivity of 0.7 J/cm^2, compared to 3.4 J/cm^2 for PMMA. The effect of increasing the acyl-oxime content still further is under study and will be reported in the future.

Inspection of Table I reveals that only a minor improvement in sensitivity of the 3% copolymer was realized by increasing the polymer molecular weight, and that this effect was not realized with the 6% acyl-oxime copolymers.

Oxime structure.—We have also examined the effect of changing the structure of the oxime or acyl-oxime chromophore. We incorporated pivalaldehyde oxime methacrylate as well as species in which the acetyl group of 3-oximino-2-butanone has been replaced by phenyl or benzoyl substituents. The latter two groups push the absorption spectrum to longer wavelengths (Fig. 4), thus enabling a closer match with the emission spectrum of the high pressure mercury lamp for exposure at longer wavelengths.

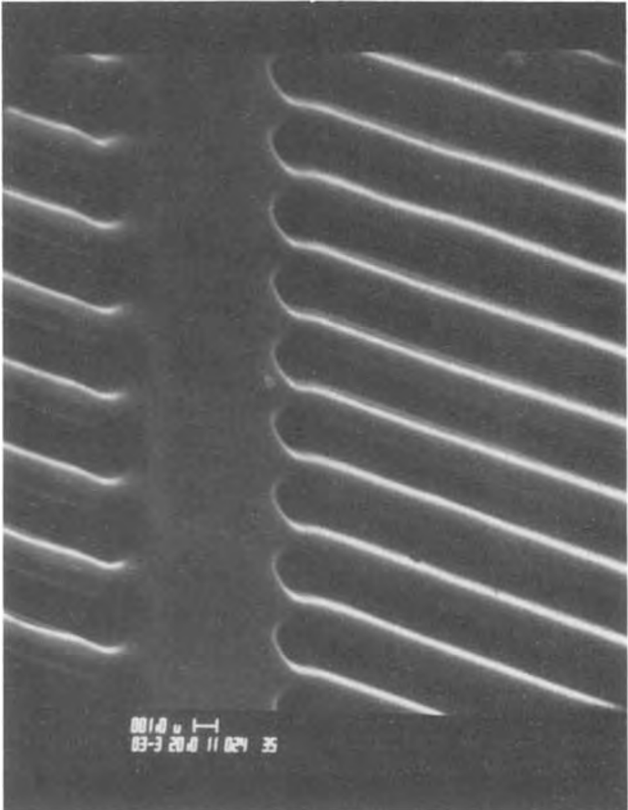

Fig. 5. Lines and spaces (1.25 μm) obtained in poly (methyl methacrylate-co-3-oximino-2-butanone methacrylate).

Figure 4 shows the absorption spectra of the polymers investigated. Table II shows that these substituents were not as effective as the 3-oximino-2-butanone chromophore in promoting PMMA degradation.

Resolution.—PMMA is known to be an extremely high resolution material. We found that by keeping the co-monomer concentration low we were able to improve the polymer's sensitivity at $\lambda > 230$ nm without any concurrent loss in resolution. Figure 5 shows 1.25 μm lines and spaces obtained routinely in poly (methyl-methacrylate-co-3-oximino-2-butanone methacrylate) (P(M—OM)). Electron beam exposure experiments (Fig. 6) reveal that the material is inherently capable of still higher (0.5 μm) resolution.

Electron beam irradiation.—Several workers have attempted to improve the sensitivity of PMMA to electron beams by copolymerization with other types of monomers, and we have also evaluated our polymers for their e-beam response. Figure 2 shows the effect of incorporating 3-9% 3-oximino-2-butanone methacrylate into PMMA. The most sensitive material is the 3% copolymer which requires a dose of 3.1×10^{-5} C/cm^2. This result is not understood, for

Table II.

Polymer	Mole percent acryl-oxime (%)	M_w ($\times 10^5$)	M_w/M_n	Relative sensitivities[a] Air	Relative sensitivities[a] N_2	T_g (°C)	Electron sensitivities ($\times 10^{-5}$ C/cm^2)

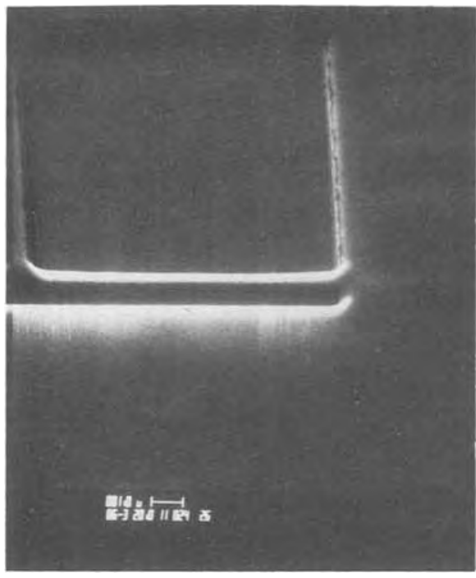
[a] Sensitivities are reported relative to PMMA.
P(M-t-BO)—poly (methyl methacrylate-co-1-oximino-2, 2-dimethyl-propyl methacrylate).
P(M-AO)—poly (methyl methacrylate-co-acetophenone oxime methacrylate).
P(M-BO)—poly (methyl methacrylate-co-1-phenyl-1, 2-propanedione-2-oxime methacrylate).



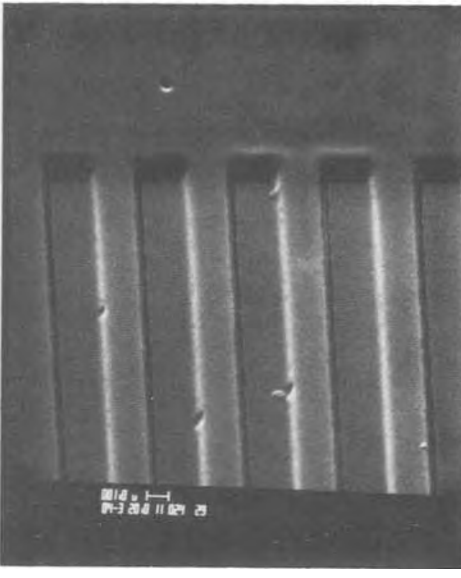


Fig. 6. Electron beam exposure patterns of poly(methyl-methacrylate-co-3-oximino-2-butanone methacrylate).

the higher acyl-oxime concentration copolymers of comparable molecular weight are not as sensitive. Additionally, the materials cannot be made appreciably faster than PMMA (5×10^{-5} C/cm^2) by changing the structure of the acyl-oxime monomer. Figure 3 shows that the acetophenone and 1-phenyl-1, 2-propanedione oxime polymers are slower than PMMA.

Conclusion

Copolymers of methyl methacrylate and acyl-oxime methacrylate esters have been evaluated as deep u.v. photoresists.

1. Poly(methyl methacrylate-co-3-oximino-2-butanone methacrylate) (94:6) is approximately 5 times faster than the base resin.
2. Sensitivity can only be marginally improved by increasing the polymer molecular weight.
3. The acetyl group of the acyl-oxime chromophore is more effective than t-butyl, phenyl or benzoyl groups in promoting polymer degradation.
4. Copolymers of methyl methacrylate and acyl-oxime methacrylate have about the same sensitivity as PMMA to 20 kV electron beams.

The Effect of Sensitizers on the Photodegradation of Poly (Methyl Methacrylate-co-3-Oximino-2-Butanone Methacrylate

E. Reichmanis, C. W. Wilkins, Jr., and E. A. Chandross

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

With the prospect of shorter wavelength photolithography, the need has arisen for new resist materials that will work efficiently at wavelengths where conventional resists are optically opaque. Poly(methyl methacrylate-co-3-oximino-2-butanone methacrylate) (P(M-OM)(94:6)), a resist that absorbs in the 220-250 nm range, has been sensitized for both this and the 280-320 nm range (an area where the new Perkin Elmer Printer is capable of making exposures). Its inherent sensitivity can also be improved by the incorporation of methacrylonitrile. Sensitized P(M-OM-CN) has a sensitivity of 75 mJ/cm^2 and is capable of better than 1 μm resolution.

The use of conventional photolithography becomes severely limited with the current trends towards increased device complexity. By the use of shorter wavelength (200-300 nm) u.v. light, diffraction effects will be reduced, and thus higher resolution should be obtainable (1). However, new resist materials that will work efficiently in the "deep u.v." need to be developed.

We have previously reported our efforts to improve the photosensitivity of poly(methyl methacrylate) (PMMA) in the 200-250 nm region (2) by the incorporation of oxime and α-keto-oxime methacrylate esters as co-monomers. These units contain a moderately labile N—O bond which, when cleaved, could lead to a carboxylate radical and subsequent polymer degradation. Of the materials examined, the 3-oximino-2-butanone group had the greatest positive effect on the overall photosensitivity of the polymer. Poly(methyl methacrylate-co-3-oximino-2-butanone-methacrylate) (P(M—OM)) (94:6) was found to be five times more sensitive than PMMA at λ = 220-250 nm.

We have extended the above work through the addition of external sensitizers and the incorporation of other monomer units into the polymer in an effort to increase its photosensitivity still further.

Experimental

Monomers and polymers were prepared as described previously (2).

Materials.—Poly(methyl methacrylate) ((PMMA); Elvacite) is a high molecular weight polymer available from du Pont which was used as a standard for measuring sensitivities.

The benzoic acid sensitizers, triphenylamine, and dibenzothiophene were purchased from Aldrich Chemical Company, while the acylcarbazoles were synthesized by known procedures (3).

Sensitivity.—Poly(methyl methacrylate-co-3-oximino-2-butanone methacrylate) (P(M—OM)) copolymer solutions were prepared as described previously, Poly(methyl methacrylate-co-3-oximino-2-butanone methacrylate-co-methacrylonitrile) (P(M—OM—CN)) terpolymers were dissolved in chlorobenzene or cyclohexanone (10% solution). Where appropriate, the specified amount of sensitizer was added to the solutions before coating onto a silicon substrate with a Headway Research spinner. Films were prebaked for 60 min at 110°C.

Key words: deep u.v. resists, photoresists, photodegradation.

Photon sensitivities are reported relative to PMMA and were obtained by imaging a 1 mm wide slit, illuminated by a 1000W Hg arc lamp focused through quartz condenser optics, for varying times across the substrate coated with resist, or by isolating either the 313 or 240 nm line from a 1000W Hg-Xe lamp with a monochromator (Jarrell Ash Model 82-410) and using a 1 mm diam circular contact mask. Exposure times were recorded as the time necessary to allow complete removal of the resist in the irradiated areas. The irradiated films were developed with methyl isobutyl ketone (MIBK) in the case of the copolymers, and with MIBK/isopropanol (8:2 v/v) in the case of the terpolymers.

Resolution.—Resolution was determined by proximity printing on a substrate coated with 1 μm of resist using a Kasper Model 2001 Proximity Printer fitted with a Xe-Cd lamp (output from 200-500 nm).

Results and Discussion

As discussed earlier (2), photochemically induced cleavage of the N—O bond in P(M—OM) can lead to decarboxylation followed by chain cleavage, the "usual" mechanism for PMMA chain scission. The absorption tail of the keto-oxime chromophore is sufficiently strong that addition of the 3-oximino-2-butanone group as the methacrylate ester confers added photosensitivity to the polymer in the range of 230-260 nm. Generally, it was found that the sensitivity of the copolymer increased with oxime ester concentration up to ~6 mole percent (m/o) OM. The effect of molecular weight on the system appeared minimal.

An additional, potential advantage of the keto-oxime chromophore is that it possesses a low-lying excited state ($\lambda \approx$ 350 nm) which could be sensitized. We proposed to test this by "externally" sensitizing P(M—OM) to promote degradation at longer wavelengths (300-330 nm, a region which would match the output of a Model III Perkin Elmer Printer with modified optics). The sensitizer must satisfy a number of criteria: (*i*) its excited state energy must match (or be greater than) that of the keto-oxime chromophore; (*ii*) it must transfer energy efficiently; (*iii*) it must not absorb at longer wavelengths than the range desired; (*iv*) it must be sufficiently nonvolatile to remain in the polymer film during the initial baking; and (*v*) it must be compatible with the polymer. The materials which were tested and satisfied the above criteria, were triphenylamine, N-acetyl and N-benzoylcarbazole, and dibenzothiophene. The absorption spectra of P(M—OM) (94:6) films containing 10

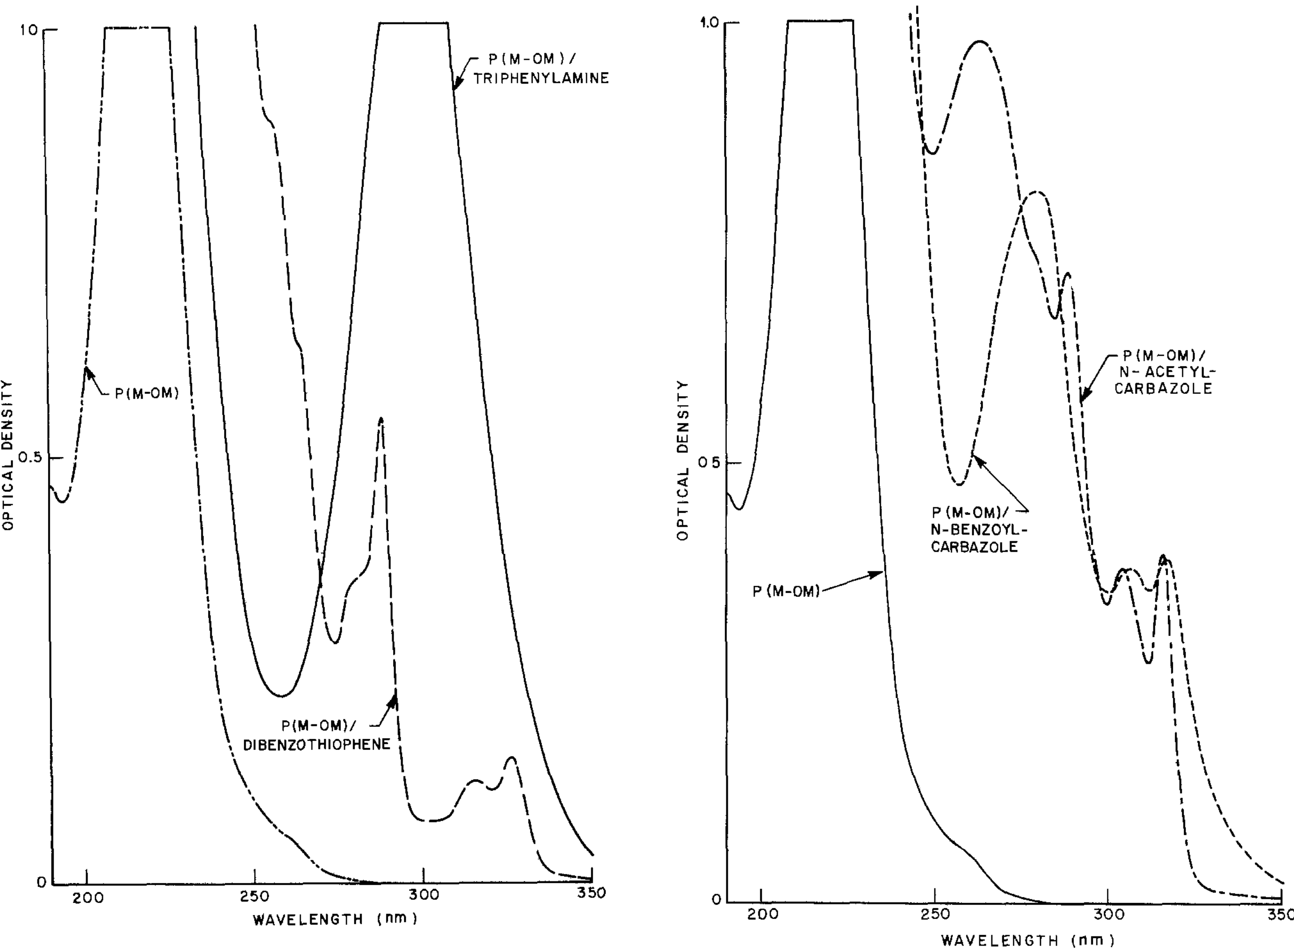

Fig. 1. Ultraviolet absorption spectra of 1 μm films of P(M-OM) and P(M-OM) containing (a, left) 10 w/o of triphenylamine or dibenzothiophene, (b, right) 10 w/o N-acetylcarbazole or N-benzoyl carbazole.

weight percent (w/o) of each of the above materials are shown in Fig. 1 and the results are given in Table I.

Clearly, addition of a sensitizer enhanced the sensitivity of the copolymer at longer wavelengths. Note that at 313 nm, where the copolymer has no significant absorption (see Fig. 1) and is quite insensitive to irradiation, a dramatic improvement in monochromatic sensitivity is observed upon the addition of sensitizer (see Table I). The most efficient sensitizer at 313 nm is N-acetylcarbazole. Upon irradiation with the full output of the Hg lamp, all of the materials examined become 4-5 times faster than the unsensitized copolymer under the same conditions (Table I). That the film containing triphenylamine is insensitive to 313 nm light but does degrade more rapidly when exposed to the full output of the Hg lamp may be explained by the observation that while it is opaque at 313 nm, longer wavelength light, up to $\lambda \approx 360$ nm, does penetrate the bulk of the film and may effect sensitization. The absorptions of the carbazole containing films are relatively flat across the region of 280-320 nm.

The optimum sensitizer concentration is about 10 w/o. A lower percentage has no effect on polymer sensitivity, while larger amounts provide no additional effect.

While these materials do sensitize P(M—OM) to longer wavelengths (300-350 nm), they are not usable at shorter wavelengths due to too large an absorption coefficient which, at the concentrations required, results in too high an optical density. Substituted benzoic acids which were found to sensitize poly(methylisopropenyl ketone) (PMIPK) (4), should have both singlet and triplet energy levels sufficiently high that either could effect sensitization of the keto-oxime chromophore. Also, their extinction coefficients would afford usable absorbances at ~250 nm in polymer films containing 10% of the acid. Three materials were tested. The absorption spectra of P(M—OM) films containing each of the sensitizers are shown in Fig. 2 and the results are tabulated in Table II. The film containing p-t-butylbenzoic acid proved to be most sensitive. Sensitivity was enhanced by a factor

Table I.

Polymer	Sensitizer (w/o)	Sensitivity: Absolute at λ313 nm (J/cm²)	Sensitivity: Relative from λ200 to 400 nm
P(MMA)	—	—	1.00
P(M-OM)[a]	—	4.6	0.25

Table II.

Polymer	Sensitizer (w/o)	Sensitivity: Absolute at λ240 nm (mJ/cm²)	Sensitivity: Relative from λ200 to 400 nm
P(MMA)	—	3400	1.00
P(M-OM)[a]	—	1300	0.25
P(M-OM)	p-t-butylbenzoic acid(10)	150	0.10
P(M-OM)	p-t-butylbenzoic acid(20)	—	0.10
P(M-OM)	p-methoxybenzoic acid(10)	—	0.20
P(M-OM)	3,4-dihydroxybenzoic acid(10)	—	0.25

[a] P(M-OM)(94:6), M_w: 2.87 × 10⁵, M_w/M_n = 1.86.

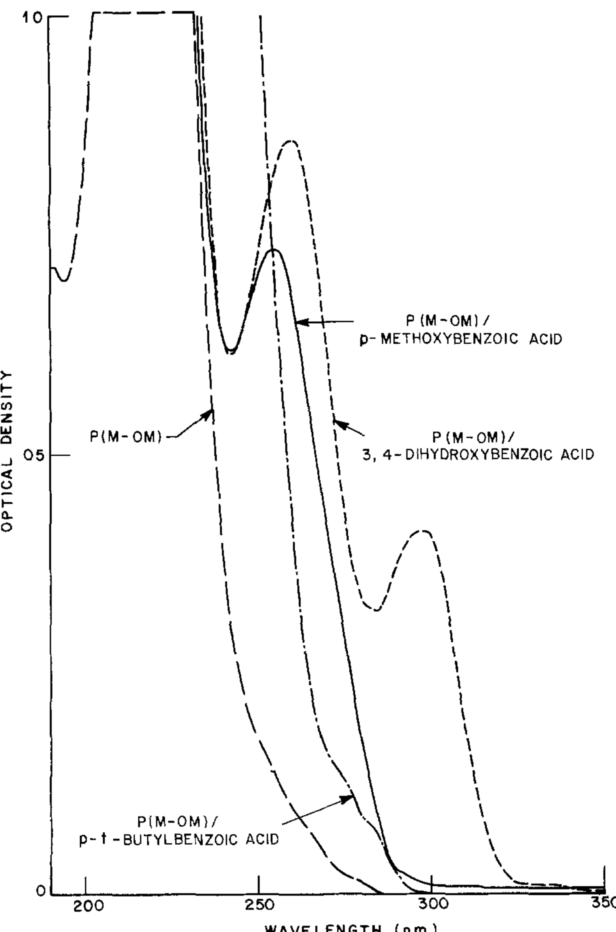

Fig. 2. Ultraviolet absorption spectra of 1 μm films of P(M-OM) and P(M-OM) containing 10 w/o p-t-butybenzoic acid, p-methoxybenzoic acid, and 3,4-dihydroxybenzoic acid.

of 2.5 over the unsensitized sample, employing the full output of the Hg lamp. Monochromatic sensitivity at 240 nm increased by a factor of ~9. The two other species studied have little or no effect on the sensitivity of the polymer.

An additional means of improving sensitivity is to incorporate methacrylonitrile (CN) into the copolymer. It is generally accepted that conjugation with a nitrile group stabilizes a radical. One might then expect the polymer backbone to break more easily at a point adjacent to a nitrile substituent, thus improving the sensitivity. Since incorporation of CN into PMMA affords an increase in sensitivity to electron beam exposure (5), we were prompted to examine its effect on the u.v. sensitivity of P(M—OM).

Examination of the data in Table III shows that the incorporation of 14 m/o MACN into P(M—OM) containing 6 m/o OM affords a fourfold increase in sensitivity. Somewhat anomalously, the polymer containing 28 m/o CN is slower, *i.e.*, its sensitivity over (P(M—OM) is only doubled. This effect is not readily rationalized. [It may, however, be noted that a similar effect was observed for poly(methyl methacrylate-co-methacrylonitrile) (P(M—CN)) copolymers on electron beam exposure (5).] In addition to being more sensitive, the resolution remains excellent. As may be seen in Fig. 3a, 1.5 μm lines and spaces obtained by proximity printing are clearly resolved.

Further enhancement of sensitivity is obtained by addition of p-t-butylbenzoic acid. The absorption spectra of the unsensitized and sensitized terpolymer are depicted in Fig. 4, and the sensitivity data are given in Table III. Employing the full output of the mercury lamp, P(M—OM—CN)/10% p-t-butylbenzoic acid is 30 times as fast as PMMA. At 240 nm, the material requires an exposure of 75 mJ/cm^2. As may be seen in Fig. 3b, addition of a sensitizer does not alter the high resolution characteristics of the polymer. A resolution of 1 μm is readily obtained by proximity printing.

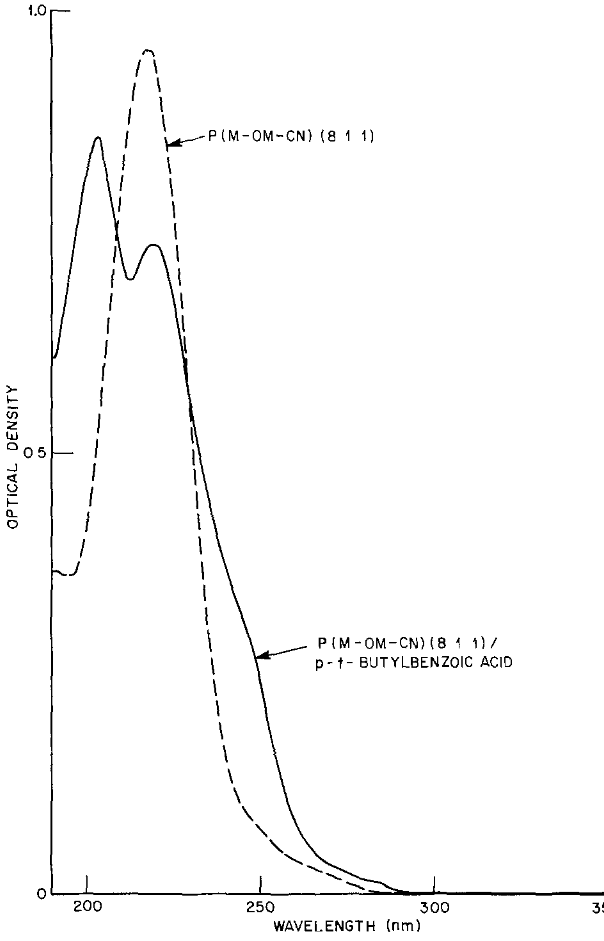

Fig. 4. Ultraviolet absorption spectra of P(M-OM-CN) (8:0.6:1.4) and P(M-OM-CN) (8:0.6:1.4)/10% p-t-butylbenzoic acid. (The films are obviously not of the same thickness but are shown to illustrate the effect of the addition of sensitizer on the absorption spectrum of the material.)

Conclusion

Incorporation of small percentages of 3-oximino-2-butanone methacrylate into PMMA affords added photosensitivity to the polymer. An additional four-fold increase in sensitivity is obtained by incorporating methacrylonitrile into the copolymer. Further addition of external sensitizers more than doubles the rate of polymer degradation. At 240 nm, the exposure required for (P(M—OM—CN)) (8:0.6:1.4) containing 10 w/o p-t-butylbenzoic acid is 75 mJ/cm², compared to 3400 mJ/cm² for PMMA. In addition,

Table III.

On the Nature of CVD Si-Rich SiO_2 and Si_3N_4 Films

E. A. Irene,* N. J. Chou,* D. W. Dong,* and E. Tierney

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10958

There are several published studies on the preparation of Si-rich SiO_2 (1-7) and Si_3N_4 (6-11) films. An early report (5) on chemically vapor deposited (CVD) Si-rich SiO_2 films described the material as "semi-insulating," because the material displayed an electrical conductivity intermediate between SiO_2 and Si. The implication is that the bandgap of the material is also intermediate and therefore that a homogeneity range exists in this system. Work at our laboratory (6) showed evidence that both Si-rich SiO_2 and Si_3N_4 are composed of two phases: silicon and either oxide or nitride. Later studies (7, 12) on Si-rich SiO_2 supported the multi-phase proposition but also suggested that the oxide phase is something other than normal CVD SiO_2. In the present study, our transmission electron microscopy (TEM), and x-ray photoelectron spectroscopy (XPS) observations are presented as a comparison of stoichiometric and Si-rich SiO_2 and Si_3N_4 films. From this comparison of CVD films, we conclude that the Si-rich films are indeed two phase materials: one phase Si and the other either normal CVD oxide or nitride. The nature of the so-called normal CVD oxide and nitride is not addressed in this study.

Experimental Procedures

CVD was used to prepare 100 nm films for this study. The films were deposited at 700°C onto cleaned single crystal Si substrates via the reaction SiH_4 with N_2O for the Si-rich SiO_2 and with NH_3 for Si-rich Si_3N_4. The gas phase ratios N_2O/SiH_4, R_o, and NH_3/SiH_4, R_N, were used to control the solid phase compositions. The details of this CVD procedure and preparations for TEM were previously discussed (6). The stoichiometric films were prepared using a large excess of N_2O for SiO_2 ($R_o = 25$) and NH_3 for Si_3N_4 ($R_N = 100$).

X-ray photoelectron spectra (XPS) of the nitride and oxide films were obtained using a UHV system with an Mg K_α source and PHI Model 255 double pass analyzer. The surfaces of both as-deposited and annealed specimens were chemically cleaned in lieu of the conventional ion etching technique which is known to have preferential sputtering effects. The annealed specimens were found to be surface oxidized, and a 200Å thick top layer was chemically removed to obtain a truly representative spectrum. The surface charging effect was minimized by an electron flood gun, and the work function of the spiraltron detector was corrected with the Au $4f_{7/2}$ line at 84.0 eV. A Gaussian curve fitting computer program[1] was used to resolve the measured spectra.

Results and Discussion

Transmission electron microscopy (TEM).—Figure 1 shows that the as-deposited Si-rich SiO_2 is nearly

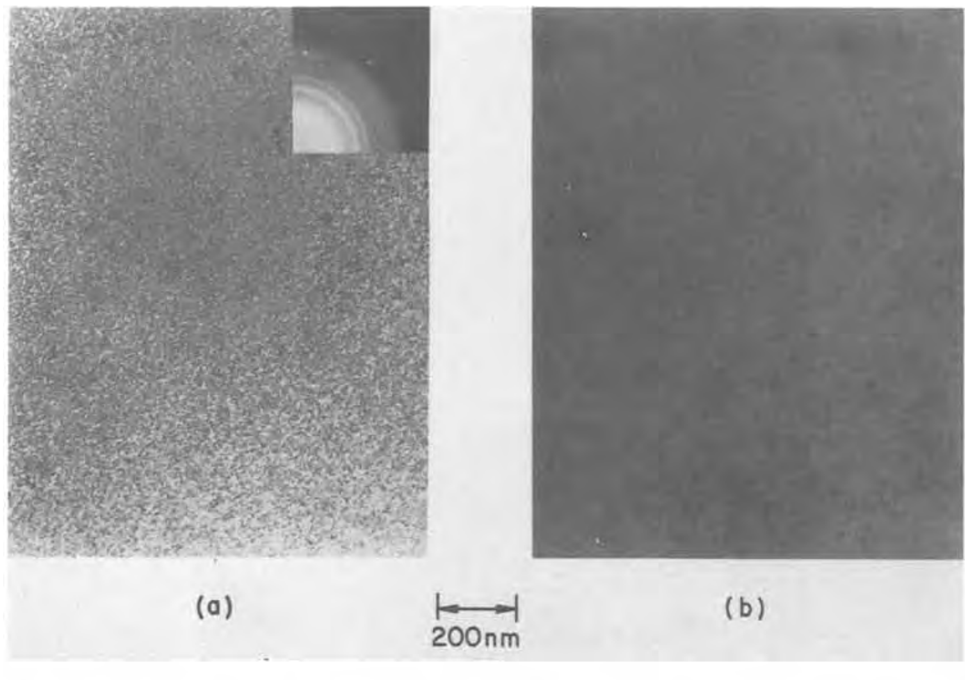

Fig. 2. Si-rich SiO_2 with R_o = 3 or about 10% excess Si, annealed 1000°C in N_2, 15 min (a) bright field with diffraction, (b) dark field.

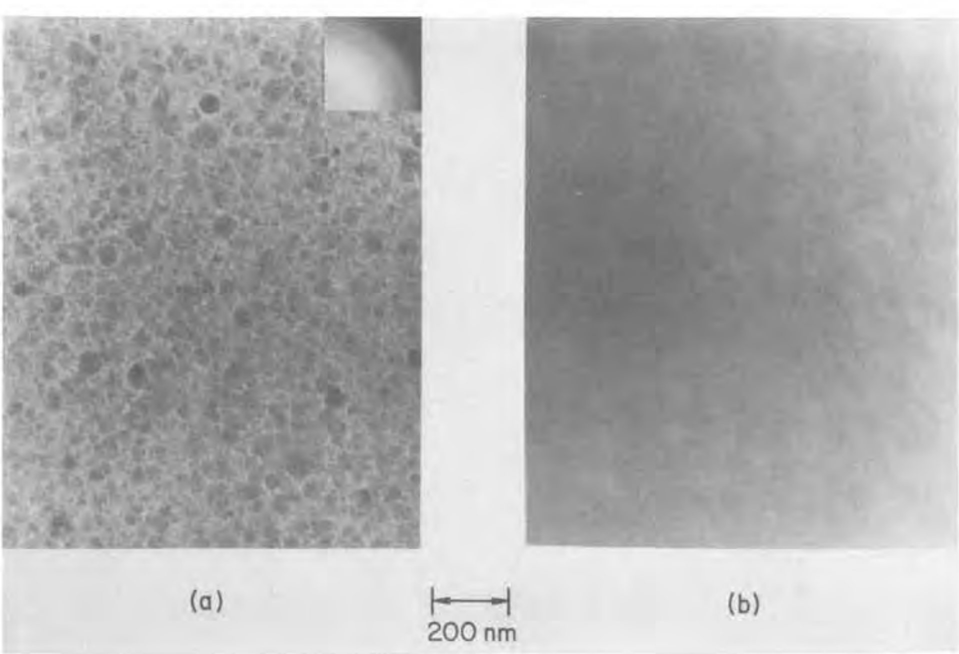

Fig. 3. Si-rich Si_3N_4, with R_N = 0.5 or about 8% excess Si, unannealed (a) bright field with diffraction, (b) dark field.

entirely amorphous. A careful look at the dark field micrograph reveals small (2 nm) and widely separated crystallites. Figure 2 shows that upon annealing, the excess Si crystallizes to form 10 nm randomly oriented grains. Both bright and dark field TEM show [as was previously reported (6)] that these films have a rough texture presumably due to differential attack by the etchant used to prepare these compositionally inhomogeneous films for TEM. Figures 3 and 4 show similar results for Si-rich Si_3N_4 except that there are more and larger (5 nm) Si crystallites in the as-deposited material, which grow to more than 10 nm after the 1000°C anneal.

ESCA.—The XPS of our stoichiometric CVD oxide films shown in Fig. 5 exhibited a single peak at 102.5 eV, which shifted to 103.5 eV upon annealing, and therefore these peaks may be identified with Si(2P) electrons associated with possibly incomplete or disordered Si—O bonds for the as prepared samples that are converted into tetrahedral Si—O bonds when annealed (7). As shown in Fig. 6(a), the unannealed Si-rich SiO_2 shows broad peaks which can be decomposed into three Gaussian peaks at 97, 99, and 102 eV. Figure 6(b) shows that upon annealing, the two peaks at 98.6 and 102.5 dominate the spectrum. Figure 7(a) shows that Si-rich Si_3N_4 contains a broad peak decomposed into two Gaussians at 97.5 and 102 for as-deposited samples and Fig. 7(b) shows that after annealing there is little change in the spectrum.

The TEM and ESCA results are understood by considering that both Si-rich oxide and nitride are composed of two phases: Si and either CVD SiO_2 or Si_3N_4. Since the overall stoichiometry does not change after annealing, the shifts in the Si and oxide and nitride peak is likely due to ordering of the as-deposited phases. This is illustrated best by the (TEM) observation of predominantly amorphous Si in the as-deposited Si-rich oxide presumably with the 97 eV ESCA peak. Upon annealing, this peak shifts to higher energy which yields the reported 99 eV for crystalline Si (7). The insulator peaks in the Si-rich films correspond to the normal stoichiometric CVD SiO_2 and Si_3N_4 films whatever is the details of the bonding in these films. For the Si-rich Si_3N_4 films, the as-deposited film already contains considerable crystalline

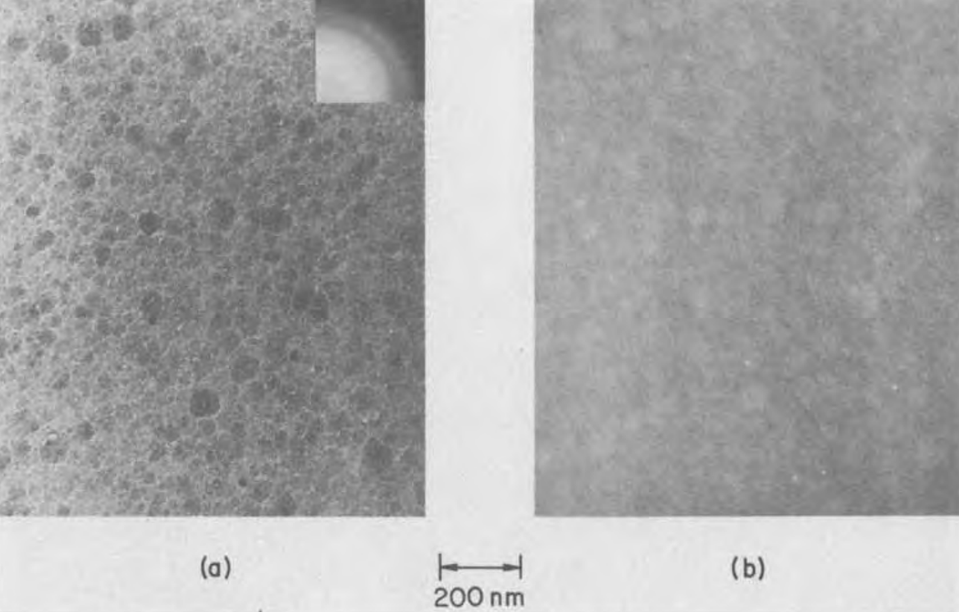

Fig. 4. Si-rich Si_3N_4, with $R_N = 0.5$ or about 8% excess Si, annealed 1000°C N N_2, 15 min (a) bright field with diffraction, (b) dark field.

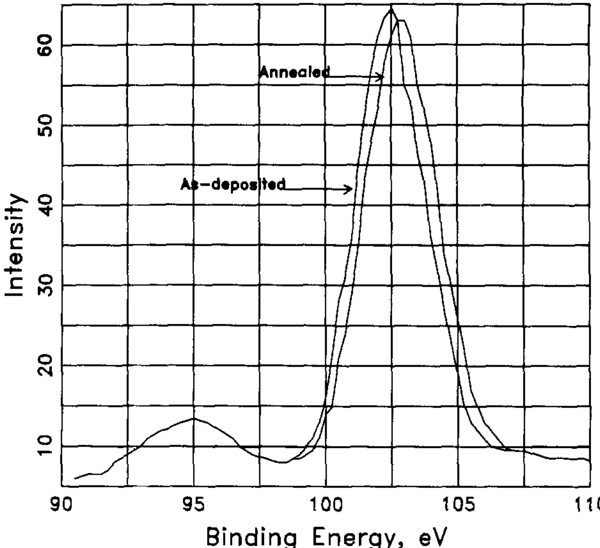

Fig. 5. ESCA spectrum of normal stoichiometric CVD SiO_2 as-deposited and annealed.

Si, thus, the spectrum does not change substantially upon annealing.

The higher conductivities for these materials (5-7) is probably attributable to localized field enhancement effects caused by the inhomogenous material rather than a smaller bandgap (7) or filamentary conduction (6).

Surface Roughness Studies of Native Oxides of GaAs

N. Bottka and J. H. Dancy

Naval Weapons Center, Physics Division, Michelson Laboratories, China Lake, California 93555

The native oxide of GaAs is of significant technological importance to warrant a detailed study of its physical properties. A significant amount of work has already been done in developing the various techniques to grow these oxides on GaAs surfaces (1-3). Their optical and electrical properties have been determined and the interface of the GaAs/oxide region well characterized by various surface probe techniques (4-7).

Although much is known about the surface and the GaAs/oxide interface chemistry, little information is available about the surface roughness and morphology of these oxides and their GaAs interfaces. The objective of this work was to obtain such surface-related information of thick native oxides of GaAs by means of surface roughness measurements, reflection electron diffraction, and transmission electron microscopy (TEM), using single-stage Pt/C surface replicas. Emphasis has been placed on oxides grown anodically from an aqueous solution. The surface properties were studied both as a function of substrate surface preparation and growth conditions (such as the current density for anodization and the thickness of the grown oxide).

Experimental

The samples under investigation were n-type GaAs both Te- and Sn-doped to $N_D \sim 10^{18}$ cm^{-3}. The surface orientation of all the samples was {100}.

Care was taken in preparing the surface of the GaAs substrates prior to oxidation. With the exception of a few samples, most of the GaAs substrates in this study were mechanically polished to a 1/4 μm finish and then polished chemically in a 0.4% bromine-methanol solution on a Buehler Microcloth. After proper rinsing in methanol and deionized water, they were cleaved into 1 cm^2 working units. The individual samples were then anodically oxidized in an aqueous solution (pH 2.7) (3) under various constant current density conditions. The anodization constant for the growth of the native oxide of GaAs was about 20 Å/V (3).

Key words: gallium arsenide, anodic oxide, oxide structure, interface.

Table I summarizes the surface preparation and oxidation conditions for the various wafers used in the experiment. The last three entries in this table refer to wafers that have been repeatedly oxidized and stripped with a solution of 1:1 NH_4OH:H_2O. This was done to determine the effect of repeated oxidation on the surface roughness both for thick and thin oxides.

Surface roughness measurements on the polished GaAs substrate, the grown oxide, and the GaAs/oxide interface after oxide stripping were made with a Talystep profilometer utilizing a special conical diamond stylus with a radius of 1 μm (8).[1] The stylus loading is continuously adjustable from about 50 mg to less than 1 mg. A loading of 2 mg is generally used with the standard stylus. This is adequate to make good contact and does not permanently mark surfaces. When using the sharper styluses the loading is generally reduced to about 0.5 mg. The total possible stylus travel across the sample is 2 mm, but 1-mm-long scans are generally used for the surface statistics. Three stylus traverse speeds are available; the slowest one, 3 μm/sec, is used for the surface statistics. When the data are sampled every 20 msec, the spacing between adjacent points on the surface is 0.061 μm.

The output of the amplifier of the Talystep is fed into a Hewlett-Packard Model 5480B signal averager which digitizes the signal and stores it in a block of 1000 data points. These data can be transferred to a Hewlett-Packard Model 2100A minicomputer with 32K memory for computation of the autocovariance function, height and slope distribution functions, and other surface statistics. The output from the minicomputer can be plotted on 10 × 15 in. graph paper using a Hewlett-Packard Model 7210A digital plotter, punched

on paper tape, or printed on a teletype. Depending on the roughness of the surface being measured, different gains can be used on the Talystep amplifier and signal averager input. Using the maximum gain on the Talystep, the instrument has a noise equivalent to an rms roughness of 1Å. To obtain this type of sensitivity, the instrument is mounted on a vibration isolation table which in turn rests on a granite slab. An acrylic plastic box encloses the entire instrument (excluding the amplifier, control unit, and recorder). Measurements are generally made after the sample has become temperature stabilized, and noise generated by the rest of the equipment in the laboratory is at a minimum. The instrument is microphonic on the most sensitive scale and will pick up frequencies in the audio range. Thermal drifts are generally linear and can be eliminated from the surface statistics by putting a least squares straight line through the measured data. During stable periods, instrumental drifts are about 10 Å/min or less, and drift rates as low as 3 Å/min have been obtained. Depending on the settings on the signal averager, sampling distances can be varied from 1.5 μm to less than 0.06 μm. The lateral resolution achievable with a stylus profiling instrument depends on the radius of the stylus and the slope of the surface. With a small surface slope, lateral resolution much less than the stylus radius is possible. The rms slopes of most surfaces we have studied are under 1°, so that the lateral resolution is of the order of 0.1 μm when using the sharper styluses. Thus, a sampling distance of 0.06 μm is adequate to show all the surface detail the instrument is capable of detecting.

All roughness measurements were made on center areas away from edges. An effort was made to measure surface areas that were representative of the sample studies. On both the oxide and GaAs areas of each sample, a 15 μm and a separate 610 μm scan were made. On most of the samples an additional set of 3 μm scans (10 scans encompassing an area of about 5 × 0.1 mm²) were made. These scans allowed us to observe any variation across the surface. Generally speaking, the 610 μm scans represent the figure of merit of our polished surface; whereas, the 15 and 3 μm scans represent the actual surface roughness.

Results and Discussion

After measuring the surface roughness of the first six wafers (the first six entries in Table I), it became evident that the thickness of the grown oxide and not necessarily the current density, *J*, of anodization controlled the resulting surface roughness of the oxide and the underlying GaAs surface at the GaAs/oxide interface. No noticeable change in surface roughness was observed between the initial GaAs surface and the oxide surface grown on it when the oxide thickness was 1000Å or less. This was true even for the oxides grown at relatively large current densities (10 mA/cm² or larger).

There was a systematic degradation of the surface (the surface becoming rougher on the 3 μm and 15 μm scale) observed both on the oxide surface and the underlying GaAs/oxide interface when the oxide was grown thicker than 1000Å, even for moderate current densities (3 mA/cm² or less). This condition of surface deterioration continued even after the oxide was stripped with an ammonia solution and a new thick oxide grown on it. The reverse of this process was observed when the grown oxide was thin (less than 1000Å), *i.e.*, thin oxides produced smoother oxide surfaces and GaAs/oxide interfaces. Moreover, this smoothing process continued after the oxide was stripped, and a new thin oxide was grown on it. The stripping of the oxide with the 1:1 $NH_4OH:H_2O$ solution did not deteriorate the underlying GaAs surface.

An interesting application of this smoothing action of anodic oxidation of GaAs surfaces is indicated by the experiment performed on wafer EM 1/Te, results of which are summarized in Fig. 1. This wafer was polished by the manufacturer to a very fine finish. It had a good figure of merit (9Å rms surface on the 610 μm scale) and a very smooth short-range surface roughness rms (2.1Å on the 3 μm scale). Electron diffraction studies showed this GaAs surface to be polycrystalline, thus indicating that the layers underlying the surface were damaged by the polish. This damage was revealed after the first oxide growth. Both the oxide surface and the underlying GaAs/oxide interface (after oxide stripping) showed a substantial surface deterioration both in the short- and long-range scale roughness measurements (point A in Fig. 1). Successive oxide growth and stripping removed the crystal damage. Continued thin oxide growth followed by stripping smoothed the surface by a factor of three. A final thick oxide reversed this process and deteriorated the surface almost by a factor of four (point B in Fig. 1). Aside from the absence of crystal damage, similar results were observed on the chemically polished samples, C5-30/Sn and CS-4/Sn.

The surface roughness deterioration process observed in thick anodically-grown native oxides of GaAs may have its origin in the chemical nature of the GaAs/oxide interface. It is known from Auger electron spectroscopy (7) that this interface is not abrupt but has a graded composition extending as much as 700Å in a 2000Å thick oxide (7). Most likely,

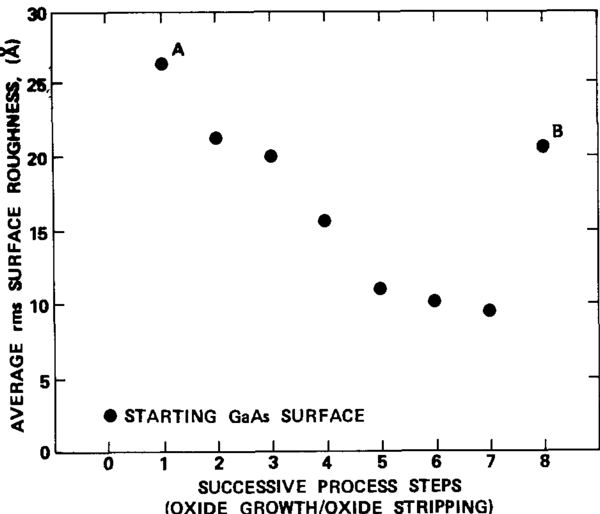

Fig. 1. Average rms surface roughness of GaAs sample EM-1/Te on the 15 μm scan after successive thin (1000Å or less) oxide growth and oxide stripping with 1:1 $NH_4OH:H_2O$. Points A and B indicate the surface roughness after stripping the thick (>1000Å) native oxide layers.

the width of this interface is proportional to the thickness of the grown oxide. We would expect, therefore, that during NH_4OH stripping of the oxide the etch rate of this interface is highly nonuniform, causing additional roughness to occur on the newly exposed GaAs surface. Subsequent growth of a thick oxide on this new surface would replicate the surface roughness. Further stripping would continue this process of surface degradation. For thin oxides (and more abrupt GaAs/oxide interfaces), the action of this nonuniform etching rate would be less severe and might even reverse the process of surface degradation.

The electron diffraction studies on these native oxides indicate that, with the exception of sample BH-2E/Te, all oxide films were amorphous even for the high current densities (10 mA/cm^2 and higher). No polycrystalline β-Ga_2O_3 phase was observed as reported by other workers (5). The oxide on sample BH-2E/Te was polycrystalline. Its surface was polished by the manufacturer of the wafer, and had an initial average rms roughness of 11Å on the 15 μm scale. No attempt was made by us to improve the quality of this surface prior to oxide growth. After oxide growth, surface roughness measurements and transmission electron micrograph on BH-2E/Te showed that this sample had a much rougher surface than any of the other samples measured. This seems to indicate that the formation of the polycrystalline phase (at least for GaAs, having a net carrier concentration of 10^{18} cm^{-3} or larger) during the oxide growth is determined primarily by the initial surface roughness of the substrate rather than the oxide thickness or current density of anodization.

In summary, surface roughness measurements, TEM, and reflection electron microscopy were made on thick native oxides of GaAs and correlated with oxide growth conditions and substrate surface preparation. Results indicate that the growth of polycrystalline Ga_2O_3 is more a result of surface roughness than anodic growth conditions. The polycrystalline oxide surface is rougher than the initial substrate surface. Substrate surfaces polished to an rms finish of 5Å or better and anodically oxidized in an aqueous solution give rise to an amorphous oxide film even for large current densities. The short-range rms roughness both for the oxide surface and the underlying GaAs/oxide interface depends more on the thickness of the oxide than the current density of anodization. Successive thick oxides (1000Å or thicker) grown on polished or oxide-stripped GaAs surfaces show successive deterioration in the short-range surface roughness. Successive thin oxides (1000Å or thinner) reverse this process and act to smooth the oxide surface and the underlying GaAs/oxide interface.

Room Temperature CVD Process for Preparing Boron Diffusion Sources

Károly Dobos

Budapest Technical University, 1521 Budapest, Hungary

A room temperature CVD method has been developed for forming homogeneous layers of boron oxide, silicon dioxide, borosilicate, and phosphosilicate glass diffusion sources. A procedure suitable for industrial applications is proposed which is based on a reactor developed for this purpose. In recent work the properties of B_2O_3 x n H_2O diffusion source layers have been investigated.

Key words: coating process, diffusion in silicon, diffusion of boron, silicon devices.

Boron nitride disks are often used to attain maximum solid solubility in the silicon diffusion process (1). To satisfy special requirements, such as the preparation of precisely controlled surface concentrations, the use of silane plus gas phase dopants has been used widely, (2-4). Alternatively, the simpler

liquid dopant sources can be used; these are normally applied to the substrate by centrifuging methods. The method developed by us combines the advantages of both of these techniques, the deposition is going on from the gas phase, but at room temperature and during a very short time, with the same simplicity as obtained by the liquid source method.

The halide compounds BBr_3 and $POCl_3$, frequently used in semiconductor technology, are known to be readily decomposed in the presence of water, and the hydrolytic reaction goes on spontaneously, owing to the negative charge of free energy. The reaction velocity coefficient is generally very high, particularly in the hydrolysis of BBr_3. The final product of reaction is the corresponding acid to be used as diffusion source. The present paper describes the method developed by us which is based on these reactions.

Experimental Equipment

For carrying out controlled gas phase hydrolysis the following equipment, shown in Fig. 1, has been developed.

BBr_3 saturator (Fig. 1A).—In this unit nitrogen carrier gas containing BBr_3 is produced. The nitrogen has to be desiccated to avoid premature hydrolysis in the saturator. The nitrogen gas generated from liquid nitrogen is adequate for this purpose. The gas is streaming through the glass saturator over the BBr_3 surface while it is entraining BBr_3 vapor. The quantity of the carried BBr_3 can be controlled by the temperature and the geometry of the saturator, and by the carrier gas flow rate.

Water saturator (Fig. 1B).—The nitrogen gas flowing through this part of the system is saturated with water vapor at a rate controlled by the temperature in the saturator.

Gas mixing head (Fig. 1C).—The gas mixing head is placed in a small enclosure flushed with nitrogen. The substrate slices are placed into this closed space through a lock by a simple moving mechanism. The whole system can be made of Plexiglas as well, since the reaction does not require an elevated temperature.

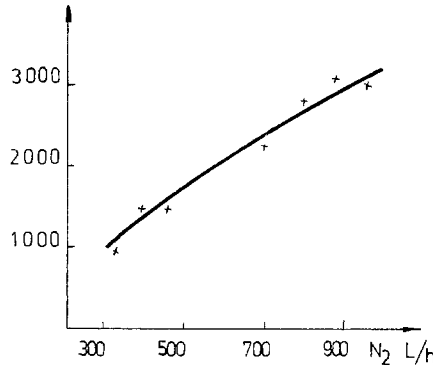

Fig. 2. Deposition rate vs. nitrogen carrier flow rate

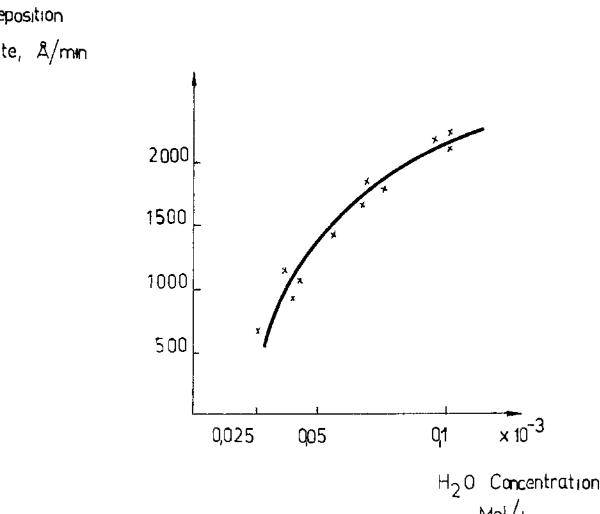

Fig. 3. Deposition rate vs. water concentration

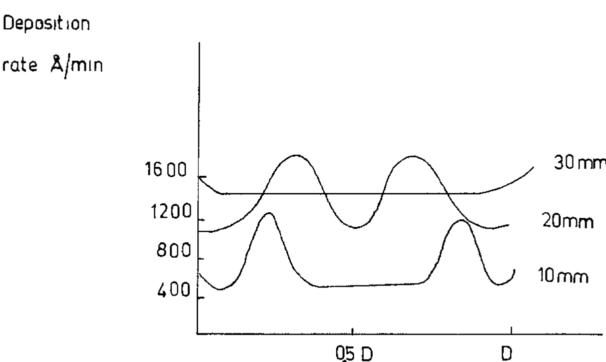

Fig. 4. Deposition rate variation along the 5 cm diameter of a silicon slice with the gas mixing head to substrate distance as parameter.

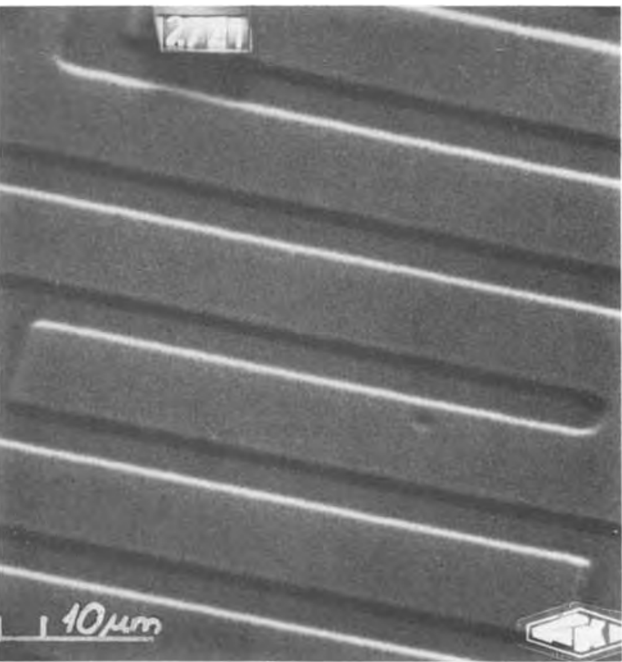

Fig. 5. Scanning electron micrograph of a deposited and heat-treated layer.

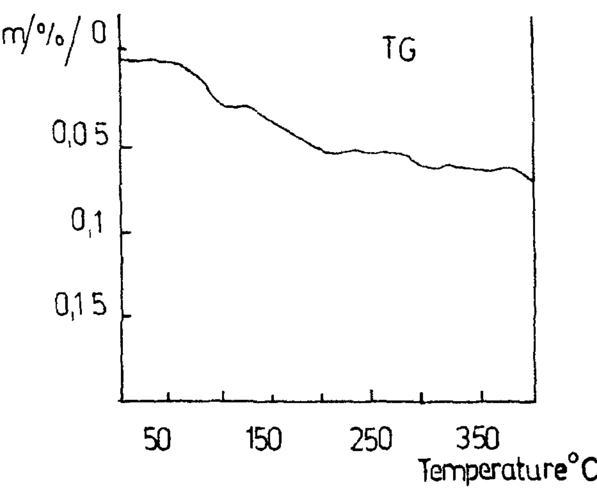

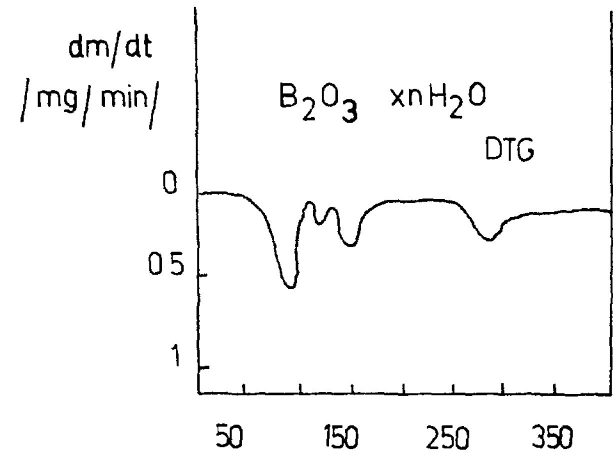

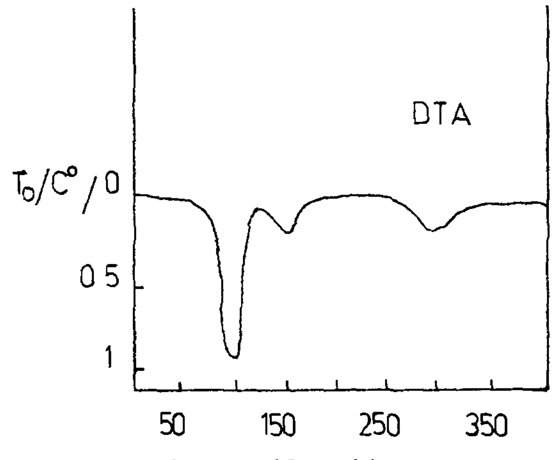

Fig. 6. Curves of thermogravimetry (TG), differential thermogravimetry (DTG), and differential thermal analysis (DTA) of a B_2O_3 x *n* H_2O layer.

Kinetics of Deposition

During the deposition process the following chemical reactions take place in the gas phase

$$2H_2O + BBr_3 \rightarrow HBO_2 + 3HBr$$

$$HBO_2 + H_2O \rightarrow H_3BO_3$$

In addition, some other reactions are possible on the surface of a silicon slice in the reactor

$$HBO_{2(solid)} + H_2O \rightarrow H_3BO_3$$

$$2H_3BO_{3(solid)} + BBr_3 \rightarrow 3HBO_2 + 3HBr$$

$$2H_2O_{(on\ the\ surface)} + BBr_3 \rightarrow HBO_2 + 3HBr$$

Accordingly, on the silicon surface a film of HBO_2 and H_3BO_3 mixture will be deposited. The composition of this film depends on the concentration of the materials taking part in the reaction and the geometry of the reactor. The adhesion, the optical, and morphological properties of this mixture layer are more favorable than those of the pure H_3BO_3 film. The thickness increases with the advancement of the reactions in the gas and on the surface of the boron acid layer. It would be difficult to determine the growth of the layer by calculation, but the layer thickness is easy to determine from the interference color of the film, which can be measured during the deposition process. The resulting deposition rates, gas flow rates, and water concentration are shown in Fig. 2 and 3, respectively.

If the gas mixing head is a simple tube, as shown in Fig. 1, and the substrate is not moved during the deposition, the variation of the deposition rate depends on the distance between the gas mixing head and the substrate (Fig. 4).

Examination of the Deposited Layers

The deposited layers to be used as a diffusion source for a small 4 × 4 μm area have to be homogeneous of max. 0.1 μm or less grain size. Figure 5 shows the layers to satisfy this requirement before diffusion. The method of thermal analysis has been applied for testing the water content of the boron acid layer. The water loss of the layers, that is, the $H_3BO_3 \rightarrow B_2O_3$ conversion, can be readily followed by thermogravimetry (TG), differential thermogravimetry (DTG), and differential thermal analysis (DTA). Results are shown in Fig. 6. The HBO_2:H_3BO_3 ratio determined from DTG (from m = weight loss) in Fig. 6 was approximately 1:1. Because of the small quantity of material the error of the measurements was about ±30%.

Diffusion from the Deposited Layers

The properties of the B_2O_3 x n H_2O layer diffusion sources from the aspect of the diffusion process differ only by their looser structure from those of B_2O_3 layers deposited at higher temperature. Therefore they are more hygroscopic and they contain more water. Be-

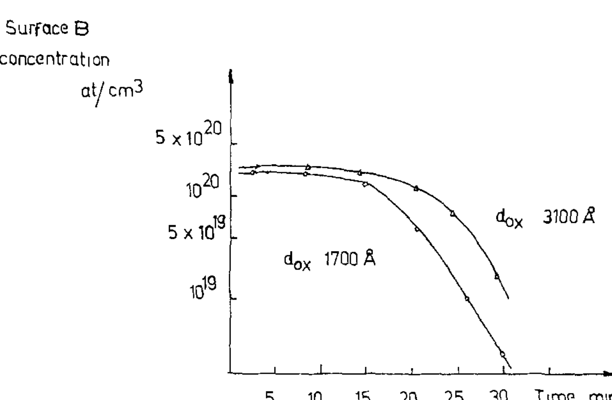

Fig. 7. Surface boron concentration in silicon vs. initial oxidation time for two different B_2O_3 x *n* H_2O thicknesses.

cause of their looser structure and higher water content they can be applied in a thicker layer without forming a so-called "boron skin." In the diffusion furnace these layers soften at about 500°C forming B_2O_3 melts similar to layers produced by other methods. Diffusion experiments have been performed with layers of various thicknesses on silicon substrates at 1100°C by first flowing dry oxygen and then nitrogen through the system.

The diffusion time was 30 min throughout. The surface boron concentration calculated from the Irvin curves *vs.* initial oxidation time is plotted in Fig. 7. The layers deposited by this method were used for the isolation diffusion of silicon bipolar integrated circuits and for special diffusions in opto-electronic devices.

Summary

A room temperature CVD method has been developed for producing B_2O_3 layers and layers for silicon diffusion sources. The properties of $B_2O_3\ x\ n\ H_2O$ diffusion source layers have been investigated. From the aspect of appropriate surface concentration these layers are equivalent to B_2O_3 layers produced at a high temperature.

Anion Effects in the Stress-Corrosion Cracking of Copper and Brass

R. C. Newman* and G. T. Burstein**

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge, England

Recently the stress-corrosion cracking (SCC) susceptibility of an admiralty brass has been studied in neutral electrolytes using slow strain rate and controlled potential (1). Transgranular SCC was observed in many electrolytes, and occurred most rapidly in the following order of severity with respect to anion: $NO_2^- > NO_3^- > ClO_3^-$. Subsequently transgranular SCC of slowly strained copper was observed in aerated 1M $NaNO_2$ solution at open circuit (2), at present the only unambiguous instance of transgranular SCC in a pure metal. The present communication attempts to account for the severity of these anion effects.

Many copper alloys undergo SCC in ammoniacal environments. The potency of ammonia is associated with its ability to form stable soluble complexes with Cu(I) (3). In SCC of copper alloys, the rate of cracking is probably controlled by dissolution at bare metal surfaces. Localisation of the attack is ensured by a stable film on the crack walls (3), and the most severe cracking generally occurs when the repassivation of bare metal is slow but ultimately complete. The open circuit potential of cracking of copper in 1M $NaNO_2$ is +160-190 mV (nhe) (2): in this range the reaction $Cu = Cu(II)(aq) + 2e^-$ would rapidly approach equilibrium within the confines of a crack whether the soluble species is taken as $Cu^{2+}(aq)$ (4) or $CuNO_2^+$ (aq) (5). Thus the possible production of ammonia during the bare surface reaction has been investigated, as this would enable cracking to proceed by dissolution of copper as Cu(I) (aq) (3). The behaviour of ClO_3^- at bare copper and brass surfaces has also been examined.

Abrasion at open circuit was used together with qualitative and quantitative electrolyte analysis. Rods of copper and α-brass were abraded by hand for ∿2 min in 6 ml pools of electrolyte lying on 120 grit emery paper, or immersed for 24 h without abrasion. Control electrolyte samples were obtained by abrading in doubly distilled water and by sampling the original electrolyte. The solutions used were high purity 1M $NaNO_2$, $NaNO_3$ and $NaClO_3$. After abrasion the electrolytes were filtered and tested quantitatively for ammonia using Nessler's reagent (6) and a set of standard NH_3 solutions, or qualitatively for Cl^- using acidified $AgNO_3$ solution. Both copper and brass produced high levels of ammonia from $NaNO_2$ and somewhat lower levels from $NaNO_3$. For the Cu/NO_2^- system, 500 single scrapes of a 0.2 cm^2 area produced $\sim 10^{-5}$ moles of NH_3 - even with a roughness factor of 10 for the rod and filings, this represents $\sim 10^{-8}$ moles NH_3 per cm^2 of bare surface, or ∿5 monolayers of Cu dissolved as $Cu(NH_3)_2^+$. The process is therefore quite efficient. All control tests were negative for these solutions, and similar results were obtained by abrading with a sapphire blade. In $NaClO_3$ significantly higher levels of Cl^- were detected after abrasion of both metals than before : crude quantitative comparison suggested a somewhat less efficient reduction of the anion in this case.

*Electrochemical Society Student Member.
**Electrochemical Society Active Member.

The preliminary experiments described above highlight a possible role of anions which act both as cathodic reactants ($NO_2^- + 7H^+ + 6e^- = NH_3 + 2H_2O$; $ClO_3^- + 6H^+ + 6e^- = Cl^- + 3H_2O$) and as sources of complexants ($Cu + 2NH_3 = Cu(NH_3)_2^+ + e^-$; $Cu + 2Cl^- = CuCl_2^- + e^-$ (5). The specificity of such processes to the bare surface may provide an additional localisation of attack which in the case of Cu/NO_2^- is sufficient, and perhaps necessary, to cause SCC of a pure metal. Anions which complex directly (e.g. Cl^-) may well cause blunting of incipient cracks in pure metals but can cause SCC in alloys owing to additional features such as dealloying, coarse slip and grain boundary chemical heterogeneity. The Cu/NO_2^- system is particularly favourable in that the open circuit potential lies in a potential range where the metal is in a borderline state of passivity ; this may be another necessary condition for SCC to occur in a pure metal. The bare surface will undergo a negative pulse of potential in the presence of a local cathodic reactant, whether or not the potential is externally controlled, particularly in brass where transient dezincification current densities of >10 A cm^{-2} are possible (7) and must lead to large ohmic potential changes : this in itself will enhance the reduction of the anion to the aggressive complexant. It is significant that Devardas' alloy (Cu-45Al-5Zn) is used in analytical chemistry to reduce NO_2^- quantitatively to NH_4^+. Prediction of other pure metal - environment combinations likely to exhibit SCC is in progress.

Analysis of the Gases Evolved during the Pitting Corrosion of Aluminum in Various Electrolytes

C. B. Bargeron and R. C. Benson

The Johns Hopkins University, Applied Physics Laboratory, Laurel, Maryland 20810

This paper contains a preliminary report of the composition of the gases evolved during the pitting corrosion of aluminum in aqueous electrolytes containing respectively KCl, KSCN, or $NaNO_3$. We believe the rather surprising results will bear positively on understanding pitting mechanisms and reactions. First, each electrolyte has a unique set of gases. Second, using a light microscope (1, 2), it was observed in each system that the gas evolution begins when the potential is increased above the pitting potential, E_p, and ceases when the potential is decreased below E_p. E_p has been determined to be about -0.8 V (all potentials are referred to the saturated calomel electrode) for 1 M Cl^- electrolytes by many investigators (e.g., 3-5). Galvele, et al have published pitting potentials of about 1.46 V and 0.96 V for 1 M $NaNO_3$ and 1 M KSCN, respectively (6, 7). Kaesche has observed that gas evolution occurs only above E_p for chloride electrolyte (8). Bargeron and Givens have observed blister formation, which requires gas production at the oxide-metal interface, as a step in the breakdown of the passivating oxide in chloride solutions (1, 2). As will be shown, the gases evolved from the NO_3^- and SCN^- electrolytes can only be explained by direct reaction of the anion with the metal. These results may also imply that Cl^- reacts directly with the metal.

The aluminum used for observations under the light microscope was 0.25 mm thick discs of purity 99.999 percent. The discs were placed in an electrode holder as described previously (1, 2). For the gas collection, aluminum of purity 99.99 percent was machined into a cylinder about 1 cm high and 1 cm in diameter. Samples were degreased in acetone and pickled briefly in 1 N NaOH. The samples used in the gas analysis experiments were screwed onto a Teflon holder which sealed the electrical connections from the electrolyte. Deionized water of resistivity 18 MΩ-cm and A.C.S. reagents (highest purity available) were used to prepare electrolytes. The electrolytes were deaerated with high purity argon before gas collection. The gas collection apparatus (a glass tube with a bell-shaped piece on the end) was evacuated and filled with electrolyte. The evolved gases displaced the electrolyte in the tube, and 1-2 cm^3 of gas was collected. Before entering the gas analyzer (VEECO Model SPI-10), the gases passed through a trap at -50°C (alcohol and dry ice) to remove water. After an experiment the trap was warmed to room temperature, and gases from it were analyzed. Only water was detected from the trap.

The sample potential was potentiostatically controlled. The reference electrode was a saturated calomel electrode connected by a bridge of the electrolyte through a Luggin capillary placed about 1 mm from the sample surface (the O.D. of the capillary was also about 1 mm).

The mass spectrum of the gas collected from pitting aluminum at a potential of 1.5 V in 1 M KCl is shown in Figure 1a. The spectrum shows the presence of H_2 and the deaeration gas Ar which is always present (Ar^+ at m/e = 40 and Ar^{++} at m/e = 20, where m/e is the mass-to-charge ratio). Potentials between -0.5 V and +1.5 V were investigated. The gas evolution increased with increasing potential (increasing current). For all potentials above E_p, only H_2 and Ar were detected. This is a surprising result since hydrogen production via the normal route of $2H^+ + 2e \rightarrow H_2$ should be impossible at an anode potential of 1.5 V. Oxygen production (via $2H_2O \rightarrow O_2 + 4H^+ + 4e$) is to be expected at this potential as assumed by others investigating pitting corrosion (9, 10). However in all cases O_2 was not observed above the weak background signal. Pickering and Frankenthal (11) also observed hydrogen evolution at controlled high potentials (1.2 V) during the pitting corrosion of iron and

Key words: gas evolution, pitting mechanism, pitting reactions, aluminum

stainless steels. Their explanation includes a high-resistance path resulting from a constriction in the pit caused by a gas bubble. Using a microelectrode they also measured much lower potentials within the pit.

The mass spectrum of the gas collected from pitting aluminum in 1 M KSCN at a potential of 1.2 V is shown in Figure 1b. The main components were H_2 and CH_4 (see Figure 1c for the cracking pattern of CH_4) with weaker peaks at 28, 32, 33, and 34 m/e. (It should be noted that the background signal was negligible at this sensitivity.) The distinctive odor of H_2S was present, and qualitative analysis of the solution after pitting was positive for sulfide (13). Hence, the 32-34 m/e peaks are probably due to the small amount of H_2S that escapes the water. The 28 m/e peak could be either N_2 or CO.

In Figure 1d the mass spectrum from gases evolved from pitting aluminum in 1 M $NaNO_3$ at a potential of 2.0 V is shown. In this case the gases are H_2, N_2, NO, and a peak at 44 m/e (likely N_2O). De Wexler and Galvele have previously noted briefly that gas is evolved during pitting in nitrate solutions and that the main component determined by gas chromatography was nitrogen. However, no further details are given (7). Adams, Eagle, and Foley have detected ammonia in mixtures of Cl^-/NO_3^- electrolytes in general corrosion tests (no potential control)(13). Qualitative analyses for NH_3 (12) in solution were positive. Ammonia is not present in the mass spectrum presumably because it is highly soluble in water.

The above results in which gas is evolved only at potentials above E_p strongly suggests that gas evolution is intimately involved in the pitting process. The mechanism by which these gases are formed is not known, but the fact that CH_4, H_2S, N_2, NO, and NH_3 are produced indicates that SCN^- and NO_3^- must interact directly with the metal. Furthermore, in the SCN^- and NO_3^- electrolytes, gas evolution only occurs above the pitting potentials of about +0.96 V and 1.46 V, respectively. Yet, in these instances there is concomitant H_2 production which requires a much lower potential. Thus, if H_2 is formed in the usual way, the potential difference across the electrified interface which controls the rate of the electrodic reaction (14) must fluctuate because of bubble constriction (11), even though the potential on the metal is constant.

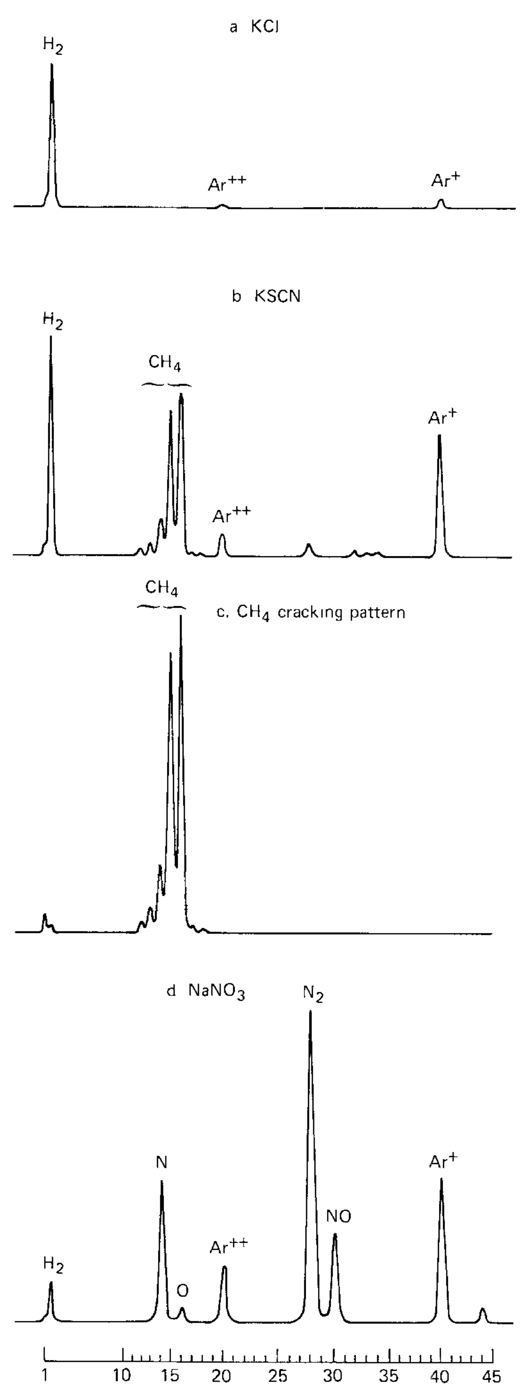

Figure 1

Mass spectra of the gases evolved during the pitting corrosion of aluminum under the conditions indicated: a) 1 M KCl at a potential of 1.5 V, b) 1 M KSCN at a potential of 1.2 V, c) cracking pattern of methane, and d) 1 M $NaNO_3$ at a potential of 2.0 V.

Regarding the metal-anion interaction, intermediate species may form which lead to gaseous products and metal dissolution. For example, in the pitting of aluminum in chloride solutions, aluminum chloride species have been proposed as intermediates (15, 16) which then hydrolyze. Similarly, during pitting in other solutions aluminum carbide, sulfide, or nitride species may be formed which then hydrolyze to CH_4, H_2S, and NH_3, respectively. (See *Handbook of Chemistry and Physics*.) Since these intermediate species are unstable in water, they would necessarily be formed on the metal surface which could provide some stabilization.

It should be noted that even the highest purity reagents that are commercially available contain chloride impurity. Therefore, it is possible that this Cl^- contaminant is involved in the H_2 production in the SCN^- or NO_3^- electrolytes. Experiments are being conducted to determine if trace amounts of chloride are significant.

In summary, the results reported here indicate that pitting of aluminum is accompanied by evolving gas which has a composition dependent on the anion and that a primary step in the pitting mechanism involves a direct interaction of the anion with the aluminum.

We wish to acknowledge the assistance of R. B. Givens.

Cyclic Voltammetric and Spectroscopic Studies of $SOCl_2$ Solutions

H. V. Venkatasetty*

Honeywell Incorporated, Corporate Material Sciences Center, Bloomington, Minnesota 55420

The lithium-thionyl chloride ($Li/SOCl_2$) battery has the highest energy density of any known electrochemical system today (1-2). The solvent thionyl-chloride is also the cathode active material and this battery system has the potential for applications needing high rate discharge. Though the overall cell reaction is known to some extent, there is very little information on the reaction intermediates and the chemical reaction(s) following electrochemical reaction during the cell discharge process (3-6). The $Li/SOCl_2$ battery has shown a tendency to explode under a variety of conditions such as short circuit, forced over discharge and resistive load overdischarge (3,4,6). It has been postulated that during the discharge of $SOCl_2$, the radical SO is formed according to $SOCl_2 + 2Li \rightarrow SO + LiCl$ and SO may dimerize and then decompose to S and SO_2(7). $2SO \rightarrow (SO)_2 \rightarrow SO_2 + S$. There is no definite experimental evidence for the formation of SO during electrochemical reduction and the following chemical reaction.

This paper presents cyclic voltametric data on $SOCl_2$ carried out as a function of $SOCl_2$ concentration and scan rate in different aprotic organic solvents such as dimethylsulfite (DMSI), dimethylformamide (DMF) and acetonitrile (ACN) with lithium aluminum chloride and tetrabutylammonium hexafluorophosphate as supporting electrolytes. The cyclic voltammetric data have been treated using the diagnostic criteria of Nicholson and Shain (8) and the plots of current function versus voltage sweep rate are consistent with an irreversible charge transfer followed by chemical reaction. Studies have also been carried out using constant potential electrolysis and ultraviolet spectroscopy of solutions of $SOCl_2$ in acetonitrile with 0.1M tetrabutylammonium hexafluorophosphate.

Experimental Procedure.--The cyclic voltammetry and constant potential electrolysis were carried out in a three compartment cell with fritted disc separator using a PAR 173 potentiostat/galvanostat and PAR 175 universal programmer and PAR 179 digital coulometer. The working electrode was glassy carbon, the counter electrode was platinum spiral and the reference electrode was lithium. The solvents DMF and ACN were Burdick and Jackson distilled in glass. The solvent DMSI was Eastman Kodak. All these solvents were redistilled using Perkin Elmer Spinning band column and the water content was found to be between 50 and 70 ppm as determined by an aquatest. Spectroscopic measurements were carried out using Beckman spectrometer. The supporting electrolytes were dried under vacuum and weighed inside a drybox. All experiments were carried out under dry and inert conditions.

Results and Discussion.--The cyclic voltammograms of 40 mM $SOCl_2$ in DMF containing 0.1M $(C_4H_9)_4NPF_6$ and 10 mM $SOCl_2$ in DMSI containing 0.1M $LiAlCl_4$ are shown in Figures 1 and 2 respectively. Similar voltammograms have been obtained with different concentrations of $SOCl_2$. In the case of $SOCl_2$ reduction in DMSI with 0.1M $LiAlCl_4$, there are three reduction peaks, peak I at 2.5V, peak II at 2.25V and a small peak III around 1.5V VS Li. On increasing the scan rate to 200mV/sec the peak at 2.5V becomes the shoulder of the large peak at 2.25V and the peak positions shift to more negative values. In the case of $SOCl_2$ reduction in DMF with 0.1M $(C_4H_9)_4NPF_6$, at slow scan rates, there are three peaks, one around 2.5V, the major peak around 2.1V and a small peak around 1.5V vs Li. Similar voltammograms are observed for $SOCl_2$ reduction in acetonitrile with $LiAlCl_4$ and $(C_4H_9)_4NPF_6$ supporting electrolyte. The reduction peaks I and II observed in these solvent systems are due to diffusion controlled processes as they show a linear relationship between the cathodic peak current versus square root of the voltage scan rate. The peaks I and II can be attributed to the two step reduction of $SOCl_2$ and the third peak around 1.5 can be attributed to the reduction of SO_2.

A detailed mathematical analysis of the shape of the voltammograms for reversible and irreversible electrochemical reactions, preceded or followed by chemical reactions is given by Nicholson and Shain (8). One of the diagnostic criteria proposed by these authors is a plot of the current function $\frac{i_p}{\eta A F D^{1/2} V^{1/2} C^*}$ against the voltage sweep rate V, where i_p is the peak current, D is the diffusion coefficient, V is the voltage scan rate and C^* is the concentration of $SOCl_2$ and η is the number of electrons transferred. F is the Faraday constant and A is the area of the working electrode. For uncomplicated charge transfer reactions such as reversible and irreversible charge transfer processes, horizontal straight lines are obtained (8). However, the plots of current function versus the voltage sweep-rate for all the solutions studied in different solvents with different supporting electrolytes show that the reaction mechanism is consistent with results for an irreversible charge transfer followed by catalytic chemical reaction (Figures 3,4,5) (8).

$$O + \eta e \xrightarrow{k} R$$

$$R + Z \xrightarrow{k_f} O$$

Similar relationships have been found for different concentrations of $SOCl_2$ in DMF and DMSI containing 0.1M supporting electrolytes such as tetrabutylammonium hexafluorophosphate and tetrabutyl ammoniumtetrafluoroborate.

The ultraviolet spectrum of a freshly prepared solution of 0.1M tetrabutylammonium hexafluorophosphate in acetonitrile (UV grade) containing 5 mM $SOCl_2$ shows two medium intensity peaks at 232nm and 202nm. This solution, when left standing for several hours in the drybox, a new peak appears at 281nm whereas the peak at 232nm disappears and the peak at 202nm remains unchanged. On electrolyzing the solution using platinum electrodes at 1.75V vs Li the potential past the second reduction wave till most of $SOCl_2$ has been used up and examining the UV spectrum of the electrolyzed solution, three peaks are observed, a shoulder of medium intensity at 291nm, and two intense peaks, one at 256nm and the other at 202nm. The new high intensity peak at 256nm can be attributed to a new compound formed during electrolysis. Solutions of 0.1M tetrabutylammonium hexafluorophosphate in acetonitrile containing small amounts (≃5mM) of sulfur, sulfur monochloride (S_2Cl_2), Sulfur dichloride (SCl_2) and sulfurylchloride (SO_2Cl_2) were studied by UV spectroscopy. The solution containing sulfur shows four peaks, two medium intensity peaks at 277nm and 263nm and two high intensity peaks at 222.5nm and 206.5nm. The solution containing S_2Cl_2 shows three peaks, two medium intensity peaks at 262.5nm and 201nm and a weak intensity peak at 305nm. The solution containing SCl_2 shows three peaks of medium intensity at 256nm, 242.5nm, and 202nm. The solution containing SO_2Cl_2 shows three intense peaks at 281nm, 239nm, and 214nm. The absorption spectra of the vapors of SCl_2, S_2Cl_2, $SOCl_2$ and SO_2Cl_2 have been investigated in the visible and ultraviolet regions (9). In the case of SCl_2, there are two absorption peaks in the UV region appearing at 228nm and 261nm whereas S_2Cl_2 shows one absorption peak appearing at 258nm. $SOCl_2$ shows one absorption peak at 245nm and SO_2Cl_2 shows a continuous peak from 260nm to 108.6nm. These peak positions observed for the vapor state will be shifted generally to lower wavelength in solutions. The new medium intensity peak appearing at 256nm in electrolyzed solution of $SOCl_2$ can be attributed to the chlorides of sulfur SCl_2 and/or S_2Cl_2 produced during electrolysis.

The two step electrochemical reduction of $SOCl_2$ in solutions of organic aprotic solvents such as DMSI, DMF and ACN can be explained in terms of donor-acceptor approach. The ions and neutral species generated during electrochemical reduction process are expected to be stable in solvents of high donor strength.

The Donor Number (DN) of a solvent is a measure of the donor properties of the solvent and is defined as the numerical value of the heat of adduct formation between the donor molecule and the reference acceptor $SbCl_5$, in dilute 1,2-dichloroethane Solution (10). The Acceptor Number (AN) of a solvent is the ratio of the ^{31}P NMR Chemical Shift of triethylphosphine oxide (Et_3PO) in the solvent to that of 1:1 $SbCl_5$ Et_3PO in 1.2 dichlorethane multiplied by 100 (11-12).

The 'Donor Numbers' (DN) of thionylchloride, acetonitrile and dimethylformamide are 0.4, 14.1, and 26.6 and dimethyl sulfite is expected to show medium donor properties in comparison with the donor number of 15.3 for ethylene sulfite (10). Therefore, $SOCl_2$ is expected to form a donor-acceptor type complex with the aprotic solvents studied. A possible mechanism for the two step electrochemical reduction of $SOCl_2$ followed by chemical reaction can be written by the following reactions:

$$SOCl_2 + (\text{org-solvent})n \xrightarrow[\text{electrolyte}]{\text{supporting}} (\text{org-solvent})\eta \cdot SOCl_2$$

$$(\text{solvent})\eta \cdot SOCl_2 + e \longrightarrow (\text{solvent})\eta \cdot SOCl^{2} + Cl^-$$

(solvent)η·SOCl + e ⟶
(solvent)η·SO + Cl$^-$

(solvent)η·SO ⟶
½SO$_2$ + ½S + ηsolvent

This kind of exothermic chemical reaction taking place following electrochemical charge-transfer process in Li/SOCl$_2$ battery may be important in relation to safety problems. Detailed investigations are in progress and will be reported in future papers.

ABSTRACT

Electroanalytical methods have been employed to investigate the cathodic deposition of $Cd(OH)_2$ on a nickel substrate from $Cd(NO_3)_2$ solution. Evidence for two distinctly different deposition products is given, depending on the potential of the deposition. At potentials positive of $-0.6V$ *vs.* SCE a gray noncrystalline form of $Cd(OH)_2$ appears to be deposited on the nickel substrate, presumably via a precipitation mechanism using the OH^- that is electrogenerated in the reduction of NO_3^-. At potentials negative of $-0.8V$ *vs.* SCE, a black precursor to $Cd(OH)_2$ is deposited. This black material forms at the same potentials as one of the further reduction processes of NO_3^- and NO_2^- that is reported herein; hence, it is believed to involve a cadmium complex of a nitrate reduction product. X-ray diffraction studies indicate that either of these materials is readily converted to crystalline hexagonal $Cd(OH)_2$ during the electrochemical formation process. However, since the gray material is deposited with minimal concurrent gas evolution or metallic cadmium deposition, its utility in achieving high $Cd(OH)_2$ loadings of a uniform material within the pores of nickel plaque material is stressed by this work. When low current densities (0.2 A/in.^{2} plaque) are employed (such that the potential of the nickel substrate never becomes more negative than $-0.65V$ *vs.* SCE) in the deposition; a high loading is achieved of a uniformly distributed product that requires no formation to reach maximum capacity. This work is supported by a series of scanning electron micrographs of impregnated plaque material. Some voltammetric evidence is presented that indicates somewhat reversible hydrogen adsorption on the negative cadmium-impregnated nickel electrode during overcharge.

The manufacturing methods for the cadmium electrodes used in alkaline cells which have been reported in the patent literature generally fall into two categories; vacuum deposition or electrochemical impregnation. In either method, porous (>75%) nickel plaque material is employed as the electrode substrate. In the former method, the nickel plaque material is placed in a chamber and the chamber is evacuated. A cadmium salt solution is then allowed to flow into the chamber so that the plaque becomes immersed within it. The soaked plaque material obtained in this manner is removed from the chamber and immersed in an alkaline solution to precipitate cadmium hydroxide within the pores. This process is sometimes repeated to achieve higher $Cd(OH)_2$ loadings than would be possible in a single vacuum deposition cycle. In the latter method, a cadmium salt solution is reduced at the nickel plaque electrode to produce hydroxide ion which, in turn, precipitates cadmium hydroxide within the pores of the plaque material. Electrodes prepared by this single immersion process are generally less expensive than those prepared by the time-consuming vacuum deposition process, and they often exhibit superior performance characteristics with respect to cycle life and fading. However, the results obtained with electrochemically impregnated cadmium electrodes are not consistent and appear to be highly dependent on the experimental variables employed during the impregnation. These variables include the properties of the plaque material (thickness, porosity, and pore structure), the properties of the cadmium salt solution (composition, concentration, pH, and temperature), and

Key words: voltammetry, deposition, electrode, films.

the electrochemical parameters (applied voltage, current density, and time of electrolysis). A recent review (1) provides a compilation of some studies of these variables which have been undertaken by battery manufacturers. The basic electrochemistry of the cathodic deposition of cadmium hydroxide has not received much attention, even though this developed patent literature exists and emphasizes various control conditions of the cathodic process for nickel and cadmium electrodes [(1), and references contained therein]. This study was undertaken, then, to provide this fundamental electrochemical information about the cadmium process using the techniques that were employed in this laboratory during a recent investigation of the nickel process (2). Nickel microelectrodes were cathodized under controlled potential conditions to study the deposition process under various cadmium solution environments. Some cadmium hydroxide electrodes prepared in this manner (either by voltammetry or chronoamperometry) were also subjected to charge-discharge studies in 32% KOH. The information gained from these studies indicates that, even though the cadmium process is somewhat more complicated than the nickel process, the conditions for deposition may be controlled to produce cadmium electrodes that have consistently high utilization characteristics with minimum surface buildup. Because a thorough understanding of the mechanism of cathodic deposition of cadmium hydroxide is necessary to control these conditions properly, the elucidation of this mechanism which follows is believed to be essential to the further development of electrode fabrication technology.

Experimental

A Princeton Applied Research Model 170 Electrochemical System (PAR) was used in all electrochemical studies; digital chronocoulometry experiments were carried out using this instrument in conjunction with a Hewlett-Packard Model 2401C Integrating Voltameter. All electrochemical experiments were conducted in quiescent deareated solution contained in a covered 400 ml beaker under a maintained atmosphere of helium. The *p*H of the solution was controlled by adding the required amount of the acid of the cadmium salt employed in the experiment; no buffers were used. The nickel working electrode and saturated calomel reference electrode (SCE) used in these studies have been described previously (2). A 1.0 × 15.0 cm strip of cadmium was used as the counterelectrode. In some experiments a cadmium working electrode was used; this was made by imbedding a strip or wire of the desired metal in a sheath of Lucite or Teflon to form a microelectrode of area less than 0.1 cm^2.

X-ray diffraction patterns were obtained using a Philips XRG-3000 diffractometer employing Ni-filtered CuK_α radiation at a typical 2θ scan rate of 1°/min. Samples for these x-ray studies were prepared electrochemically on a 1.0 × 2.5 cm nickel foil that was used in place of the nickel microelectrode for this purpose; a correspondingly larger counterelectrode was employed with this nickel foil working electrode.

Scanning electron micrographs were obtained for cadmium electrodes which had been prepared by impregnating sintered nickel plaque material using the deposition technique that was suggested as a result of the microelectrode studies. (This method is outlined below.) The ETEC Scanning Electron Microprobe that was used for this purpose was equipped with a Kevex 5100C Analyzer for the x-ray energy dispersive analysis used to determine cadmium and nickel content Gold-palladium sputtered samples were employed.

Results and Discussion

In a preliminary attempt to elucidate the mechanism of cadmium hydroxide cathodic deposition, cyclic voltammetry studies of 1M KNO_3 solutions in the presence and absence of 2M $Cd(NO_3)_2$ were carried out at controlled *p*H using both nickel and cadmium microelectrodes. The results of these preliminary studies at a nickel electrode are shown in Fig. 1. The upper multiscan voltammogram shows the processes that take place in a solution containing both cadmium and potassium nitrate when the electrode potential is scanned in a negative direction, reversed, and reversed again; the lower (background) curve shows at the same sensitivity those processes that occur in the absence of $Cd(NO_3)_2$. From this voltammetry it is clear that the participation of the cadmium ion is necessary for the electroactivity exhibited in the upper graph. The most prominent feature of this electroactivity is the large reduction wave at −0.63V *vs.* SCE that is obtained only during the initial negative scan. Plausible causes for this wave include the reduction of Cd^{+2} to electroplate metallic cadmium on the nickel surface or the reduction of a solution species to liberate OH^- in the presence of Cd^{+2} to precipitate a cadmium hydroxide on the electrode surface; evidence presented below indicates that the latter explanation is correct. When this portion of the sweep is followed by a further potential excursion into the background reduction process for the nitrate solution and then reversed, a second reduction process is observed at −0.62V *vs.* SCE during the reverse scan. Evidence presented below indicates that this wave is due to the reductive formation of metallic cadmium from some cadmium oxide or hydroxide that was deposited on the electrode surface during the forward scan. This contention is supported by the observation of the oxidation wave at −0.56V *vs.* SCE at the end of the first full cycle. This wave at the anodic stripping potential of cadmium is observed only if the preceding reduction wave is obtained in nitrate solution; therefore, it probably corresponds to the anodic stripping of the cadmium metal that is formed when the deposited material is reduced. That these processes (or one of them) effectively passivate the electrode to further electroactivity is evidenced by the lack of any significant reduction current at potentials positive of −0.75V *vs.* SCE during the second half-cycle. The reduction process at −0.63V causes a gray film to be deposited on the nickel electrode whereas the sweep past −0.75V results in the deposition of a black film. Evidence presented below indicates that the formation of the gray material at −0.63V *vs.* SCE is sufficient

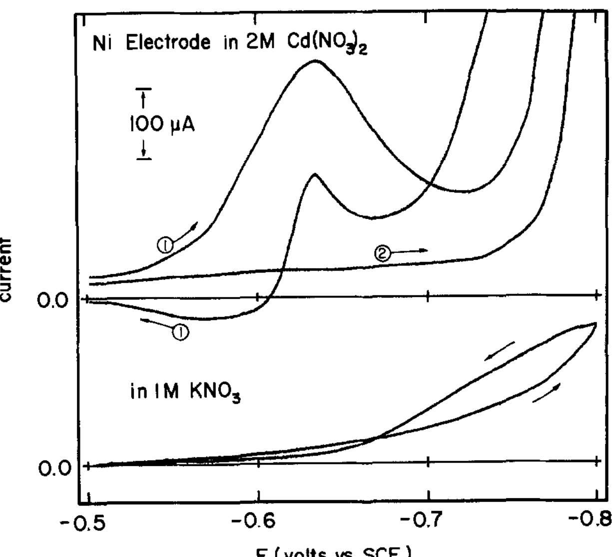

Fig. 1. Voltammetry of nitrate solutions at a nickel electrode. In addition to 2M $Cd(NO_3)_2$ the solution used for the upper voltammetry contained 1M KNO_3. In both runs pH = 2.6. A = 0.013 cm^2, and v = 0.1 V/sec. Scans were initiated at the solution rest potential (−0.15V vs. SCE, not shown, for the upper voltammogram).

to passivate the electrode to the extent exhibited during the second scan.

The corresponding voltammetry at a cadmium working electrode is shown in Fig. 2. As is evident from this figure, the large reduction wave that is present at −0.63V *vs.* SCE on nickel is absent on cadmium during the initial scan. If this wave on nickel is due to passive film formation, its absence on cadmium could indicate that this film is already present on the cadmium electrode at the start of the scan. In acid solution ($pH = 2.6$) the oxidation of cadmium metal is thermodynamically feasible. On the other hand, the absence of this wave on cadmium could be caused by the overvoltage of the species responsible for it being higher on cadmium than on nickel. Since the voltammetry of the KNO_3 solution in the absence of $Cd(NO_3)_2$ is essentially the same at either electrode, there is no evidence that the solution is reduced more readily on nickel than on cadmium. Thus, the pre-existence of a passivating film on cadmium in acid solution is presumed to be the reason for the absence of this wave on cadmium. This hypothesis is supported by the observation that the rest potential of a cadmium electrode in acidified $Cd(NO_3)_2$ solution is, at first, rather poorly defined. This suggests that spontaneous film formation begins to occur at the instant that the electrode is immersed in the solution and only ceases when the electrode is passivated to any activity at −0.63V *vs.* SCE.

The reversal of the initial scan on cadmium (following a potential excursion to −0.8V *vs.* SCE) reveals three additional reduction processes as opposed to the one observed on nickel. These are probably due to the reduction of different complexes of Cd^{+2} to metallic cadmium in the rapidly changing pH environment of the working electrode. Scan 2, which was begun without ever entering the potential region where anodic stripping of cadmium would occur, reveals a new reduction process at −0.68V. This probably corresponds to the same cathodic film formation that is observed on the initial scan at −0.63V on nickel. This explanation is plausible because the reduction processes observed at the end of the first scan probably deposit a fresh cadmium surface on the electrode so that it is no longer passivated to additional film growth.

The reductive formation of cadmium metal following potential excursions into cathodic background is supported by the upper voltammetry shown in Fig. 3. This voltammogram shows the effect of reversing the scan direction on the second half-cycle before reaching the potentials where anodic stripping of cadmium occurs. That the second scan exhibits a shoulder at −0.69V *vs.* SCE that is reminiscent of the wave seen at the start of the second scan on cadmium (see Fig. 2) indicates that the behavior of the nickel electrode is not unlike the behavior of a cadmium electrode under these conditions. Since this behavior is not at all like that seen during the second scan on nickel following anodic stripping (see Fig. 1), one can only infer that the reduction process at −0.62V on the reverse scan is responsible for the cadmium which forms on the electrode surface. Because this might appear to be contrary to the laws of thermodynamics, it is prudent at this point to rationalize this observation.

Let us assume that the species deposited on the electrode at −0.6V is $Cd(OH)_2$. (X-ray evidence is presented below indicating that this species is a noncrystalline form of cadmium hydroxide.) This species could form on the electrode if the rate of solution decomposition is sufficiently fast to generate enough hydroxide ion to precipitate $Cd(OH)_2$ ($K_{sp} = 1.2 \times 10^{-14}$) on the electrode surface, rather than allowing Cd^{+2} to be directly reduced. The reduction of $Cd(OH)_2$ to metallic cadmium is pH dependent

$$2e + Cd(OH)_2 \rightleftarrows Cd + 2\,OH^- \quad [1]$$

and would occur more readily in acid medium. As the electrode potential is being swept in a positive direction from −0.8V *vs.* SCE where maximum hydroxide ion generation occurs, that is exactly what happens: the solution in the vicinity of the working

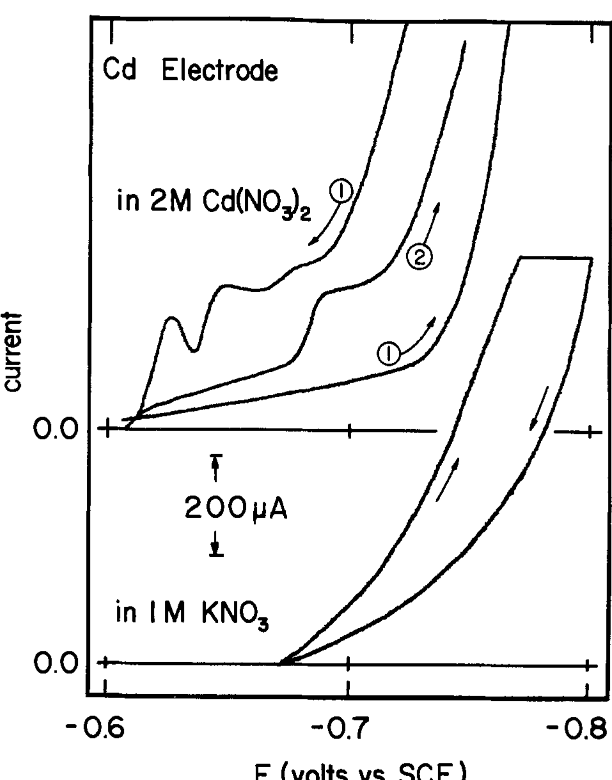

Fig. 2. Voltammetry of nitrate solutions at a cadmium electrode. Experimental conditions were identical to those given in Fig. 1 except that $A = 0.064$ cm^2. Potentials positive of −0.6V vs. SCE were avoided to prevent electrode oxidation.

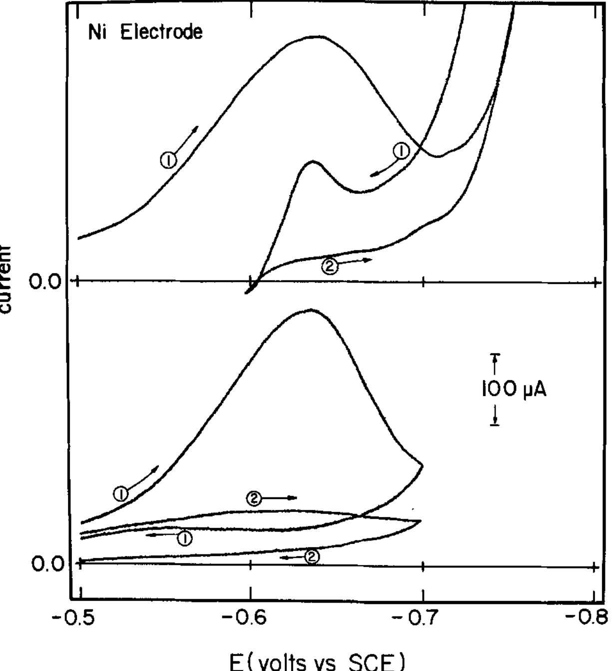

Fig. 3. The effect of potential variation in the voltammetry of $Cd(NO_3)_2$ solutions at a nickel electrode. Experimental conditions are given in Fig. 1. In the upper curve, the potential was swept from the rest potential to −0.8V vs. SCE, reversed, and reversed again at −0.6V. In the lower curve, each scan was initiated at the rest potential and reversed at −0.7V vs. SCE.

electrode approaches bulk acidity. At some potential, the generation of hydroxide ion diminishes to the point that reaction [1] may occur. When this happens, the cathodically deposited cadmium hydroxide is reduced to cadmium.

The lower voltammetry in Fig. 3 illustrates that the first reductive process that occurs at −0.63V *vs.* SCE is sufficient to passivate the electrode to additional electroactivity at this potential. Because the scan direction was reversed before the onset of solution decomposition, the process occurring at −0.63V is shown to be responsible for the passivation that is observed during the second scan. This process is believed to be the cathodic deposition of $Cd(OH)_2$.

This deposition occurs by a diffusion-controlled process, however. Evidence for this observation may be found in Table I which shows the linear sweep voltammetry $i_p/v^{1/2}$ data for the peak at −0.63V. The near constancy of this quantity over the range of given scan rates indicates that the rate of the deposition process is controlled by the diffusion of a solution species, at least in the early stages of the deposition (before film formation causes passivation).

The *p*H dependence of this process is illustrated in Fig. 4. As the bulk solution becomes more acidic the reduction process that results in electrode passivation occurs at less negative potentials. In addition, even though the peak current is higher at *p*H 6.0 than it is at *p*H 1.5, there is a general decrease in area under the voltammetric peak with increasing *p*H (about 18% reduction in going from *p*H 1.5 to *p*H 6.0). This indicates that the reduction process occurs more readily in acid media and points to a *p*H-dependent redox reaction as a cause of this process. This data suggests that passivating film formation is not due to direct Cd^{+2} reduction in nitrate solution

$$Cd^{+2} + 2e \rightleftarrows Cd \quad [2]$$

Instead, it appears more likely that this wave is due to solution reduction coupled with $Cd(OH)_2$ precipitation. Solution reduction may occur either by solvent reduction

$$2H_2O + 2e \rightleftarrows 2\,OH^- + H_2 \quad [3]$$

or by electrolyte reduction. In the latter case, the nitrate ion $N(V)O_3^-$ would either be reduced to another "mononegative" ion $N(n)O^-_{1/2(n+1)}$ (such as NO_2^- or $N_2O_2^{-2}$) or to a molecular compound of nitrogen $N(n)O_{1/2n}$ or $N(n)H_{-n}$ (such as NO_2, N_2O_3, NO, N_2O, N_2, NH_2OH, N_2H_4, or NH_3) where *n* is the oxidation state of the nitrogen in the compound so formed. In general the electrode reaction for these NO_3^- reduction processes may be written

$$\tfrac{1}{2}(5-n)H_2O + NO_3^- + (5-n)e \rightarrow N(n)O^-_{1/2(n+1)} + (5-n)OH^- \quad [4a]$$

$$\tfrac{1}{2}(6-n)H_2O + NO_3^- + (5-n)e \rightarrow N(n)O_{1/2n} + (6-n)OH^- \quad [4b]$$

$$(3-n)H_2O + NO_3^- + (5-n)e \rightarrow N(n)H_{-n} + (6-n)OH^- \quad [4c]$$

Either reaction [3] or [4] produces OH^- which may precipitate $Cd(OH)_2$

Table I. Current-scan rate data for linear sweep voltammetry at *p*H 3.5

Sweep rate v (mV/sec)	Peak current i_p (μA)	$i_p/v^{1/2}$
10	164	51.9
20	210	47.0
50	320	45.3
100	446	44.6
200	700	49.5

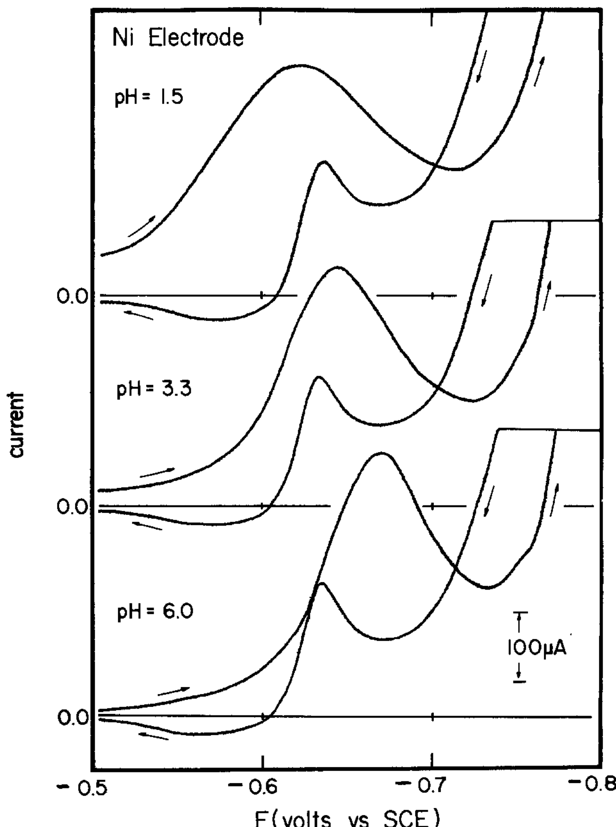

Fig. 4. The *p*H dependence of the voltammetry of $Cd(NO_3)_2$ solutions at a nickel electrode. Experimental conditions other than *p*H are given in Fig. 1.

$$Cd^{+2} + 2\,OH^- \rightarrow Cd(OH)_2 \quad [5]$$

on the electrode surface (or within the pores of the plaque material). Alternately, since the presence of the Cd^{+2} appears to be necessary to observe the NO_3^- reduction process, a concerted deposition reaction may be obtained by combining Eq. [3] or Eq. [4] with Eq. [5]. For example, by combining Eq. [4a] with Eq. [5]

$$\tfrac{1}{2}(5-n)H_2O + NO_3^- + \tfrac{1}{2}(5-n)Cd^{+2} + (5-n)e \rightarrow N(n)O^-_{1/2(n+1)} + \tfrac{1}{2}(5-n)Cd(OH)_2 \quad [6]$$

is obtained. Comparison of this deposition stoichiometry with the charge-discharge stoichiometry (Eq. [1]) results in the conclusion that one equivalent of chargeable $Cd(OH)_2$ is deposited by each equivalent of charge passed during the concerted deposition represented by Eq. [6]. The different reduction products given in Eq. [3], [4b], and [4c] result in different concerted deposition stoichiometries, but in no case would more than two or less than one equivalent of chargeable $Cd(OH)_2$ be deposited by one equivalent of charge passed during deposition. Any of these deposition mechanisms would occur more readily in acid medium and exhibit the voltammetry of Fig. 4.

Voltammetric scans in the absence of NO_3^-, shown in Fig. 5, not only rule out reaction [2] as a source of OH^-, but also indicate that NO_3^- reduction is responsible for the behavior in question. The first three scans, done in 0.76M $CdCl_2$ at *p*H 2.0 adjusted with HCl show clearly that the onset of Cd^{+2} reduction is at potentials negative of −0.7V *vs.* SCE. No electroactivity is observed between −0.6 and −0.7V where the primary passivation wave occurs in nitrate solution. When the deposition threshold potential is crossed on the reverse scan, the anodic stripping of electrodeposited cadmium is observed. The behavior of 0.67M $CdSO_4$ at *p*H 2.0 adjusted with H_2SO_4 is essentially the same; this is shown in curve d. Only when nitrate ion is added (in the form of HNO_3 to maintain the *p*H in curves e and f) is there any electroactivity at poten-

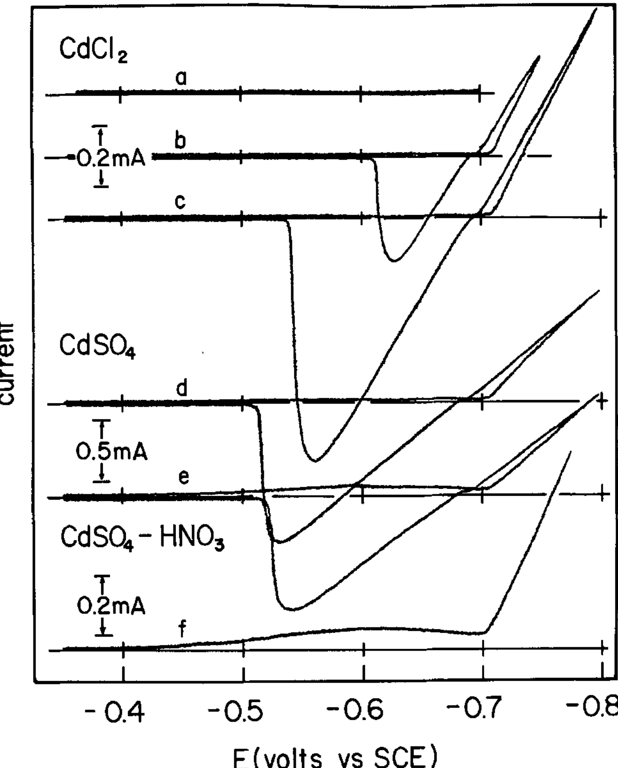

Fig. 5. Cadmium solution voltammetry in the absence of nitrate. Curves a, b, and c: 0.76M $CdCl_2$ at a nickel electrode; $v = 20$ mV/sec. Curves d, e, and f: 0.67M $CdSO_4$ at a nickel electrode; $v = 50$ mV/sec. The bulk pH was maintained at 2.0 using HCl for curves a, b, and c and H_2SO_4 for curve d; for curves e and f, this pH was maintained with HNO_3.

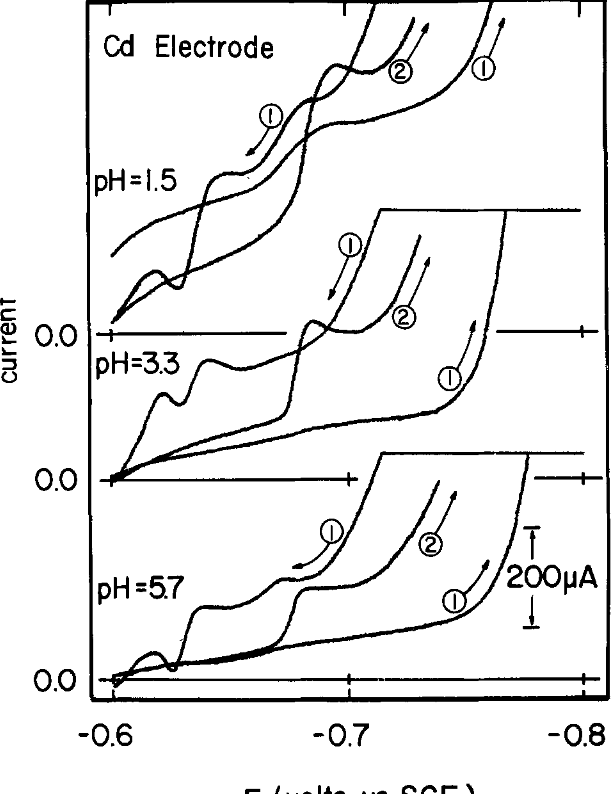

Fig. 6. The pH dependence of the voltammetry of $Cd(NO_3)_2$ solutions at a cadmium electrode. Experimental conditions other than pH are given in Fig. 2.

tials positive of $-0.7V$ *vs.* SCE. Even small quantities of NO_3^- (less than 0.01M), however, are sufficient to produce a discernible wave in the vicinity of $-0.6V$ (see curve f). This experiment demonstrates conclusively that the wave observed at $-0.63V$ *vs.* SCE on nickel in $Cd(NO_3)_2$ solution is due neither to the direct reduction of Cd^{+2} nor to the cathodic deposition of $Cd(OH)_2$ from solvent decomposition. Instead, this work indicates that nitrate ion reduction followed by cathodic deposition of $Cd(OH)_2$ (reactions [4] and [5]) is responsible for this wave.

The voltammetry of $Cd(NO_3)_2$ on cadmium at various levels of *p*H is shown in Fig. 6. These voltammograms confirm the absence of the cathodic deposition reaction on cadmium and illustrate variability of the rest potential in acidified nitrate solution. This suggests that the passive film forms spontaneously on cadmium immersed in nitrate solution at any *p*H studied. Regardless of *p*H, more electroactivity is observed on cadmium following excursions into cathodic background than is observed on nickel. These results merely tend to confirm the observations associated with Fig. 2.

These results indicate that it is electroanalytically possible to gain some information about the mechanism of cathodic deposition of a cadmium hydroxide film on a nickel electrode in nitrate solution. At potentials positive of $-0.7V$ *vs.* SCE, the film is gray in color; it forms via nitrate reduction with little detectable gas evolution at a microelectrode; it effectively passivates the electrode to further film deposition; and it neither is metallic cadmium nor is it readily converted to metallic cadmium by making the electrode potential more positive (to decrease the local *p*H in vicinity of the film). At potentials negative of $-0.7V$ *vs.* SCE, either a different kind of deposition occurs, or the film that was deposited at more positive potentials is transformed. At these potentials a black deposit forms on the surface of the electrode. Considerable gas evolution takes place concurrently with the deposition of the black film. Even though the electrode potential is sufficiently negative to deposit metallic cadmium at the potential of black film deposition, there is no evidence of cadmium deposition. Instead, metallic cadmium appears to be formed from the reduction of $Cd(OH)_2$ that has been deposited on the electrode; this reduction seems to take place readily when the electrode potential is changed in a positive manner from the black film deposition potential so that the electrode experiences a rapid decrease in local *p*H. The black film is not nearly as effective as the gray film in passivating the electrode to further activity at the deposition potential. (Excessive gas evolution at the more negative potential may serve to suppress any uniform film growth on the electrode surface, thereby minimizing passivation.) Practitioners of the deposition art, then, have the ability to electrochemically deposit two different cadmium forms on a nickel substrate, depending on the potential of the deposition. Further investigations were carried out to characterize these two cadmium forms and to assess their utility as battery active material.

Macroelectrodes of the size necessary for x-ray diffraction studies were prepared potentiostatically from $Cd(NO_3)_2$ solution at -0.6 and $-0.8V$ *vs.* SCE. During the deposition of the gray material at $-0.6V$ (material A) minimal gas evolution was observed at the larger electrode; excessive gas evolution occurred with the deposition of the black material at $-0.8V$ (material B). X-ray powder patterns for these two materials are given in Table II. The patterns for these materials were compared with ASTM reference patterns for hexagonal $Cd(OH)_2$, metallic Ni, and metallic Cd (also given in Table II) and for several known cadmium compounds: monoclinic $Cd(OH)_2$, CdO $Cd(O_2)_{0.88}(OH)_{0.24}$, $Cd(NO_3)(OH) \cdot H_2O$, and $Cd(NO_3)(OH)$ (not given). Even though the patterns for materials A and B were in general poorly defined, it was clear from these comparisons that these materials could not be positively identified as any of these

known compounds. (Because material A has some characteristics in common with hexagonal $Cd(OH)_2$, it is believed to be a noncrystalline form of this compound.) Material A was then subjected to a few charge-discharge formation cycles in 32% KOH. Material B was allowed to stand in neutral water for 30 min. Either of these treatments produced a material having a pattern that agreed quite well with that of hexagonal $Cd(OH)_2$. Thus, either of these materials may be readily converted to the crystalline form of battery active hexagonal $Cd(OH)_2$. The ease with which material B is converted to $Cd(OH)_2$ suggests that it undergoes a simple redox or ligand exchange reaction when removed from the acid environment of the deposition solution and placed in neutral (or basic) water. The fact that the powder pattern of material B does not agree with the pattern of either of the reported nitrate complexes of $Cd(OH)^+$ indicates that this material is not a nitrate complex, however.

To gain further insight as to the nature of the complex believed to be formed at −0.8V, the voltammetry of a dilute KNO_3-$Cd(NO_3)_2$ solution was carried out in the presence of saturated KCl supporting electrolyte. The presence of the KCl allowed for the proper assignment of voltammetric peak potentials for the nitrate reduction processes by eliminating the ionic migration effects observed in the absence of supporting electrolyte. In addition, as shown in Fig. 7, the KCl presence gave clear indication that two nitrate reduction processes are possible in this system, one occurring at −0.71V and the other occurring at −0.83V in the presence of supporting electrolyte. The wave at −0.71V corresponds to the wave at −0.62V in the absence of supporting electrolyte in Fig. 1. Note that by the tenth cycle, the electrode is passivated to further activity at this potential, just as is observed in two or three cycles on a more concentrated solution. The wave at −0.83V does not exhibit this effect. The product of this reduction appears to be relatively stable and undergoes oxidation at −0.76V on scan reversal.

The appearance of this wave at −0.83V is observed in each of the three voltammograms shown in Fig. 8; again, fairly good stability of the reduction product is indicated by the corresponding oxidation wave. The curve a reduction wave at −0.71V, which is present only in nitrate solution, is believed to be the one associated with the deposition of $Cd(OH)_2$ from $Cd(NO_3)_2$ solution. If the reduction process associated with this

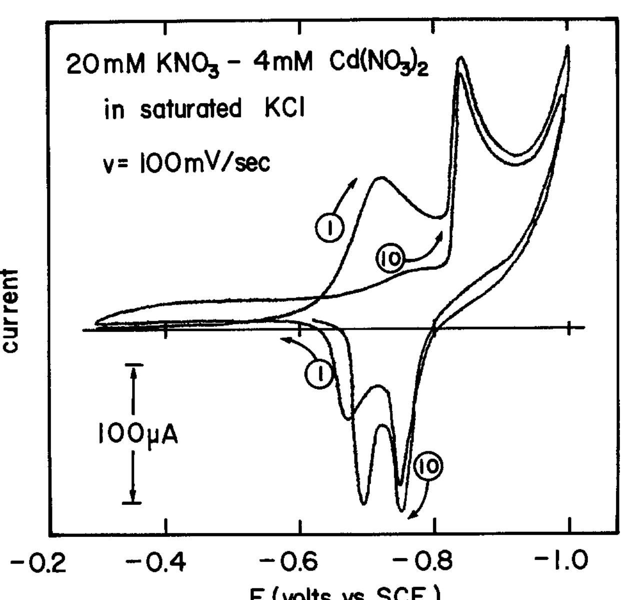

Fig. 7. Cyclic voltammetry of a dilute KNO_3-$Cd(NO_3)_2$ mixture in saturated KCl at a nickel electrode. The first and tenth cycles (as indicated by those numbers) are shown.

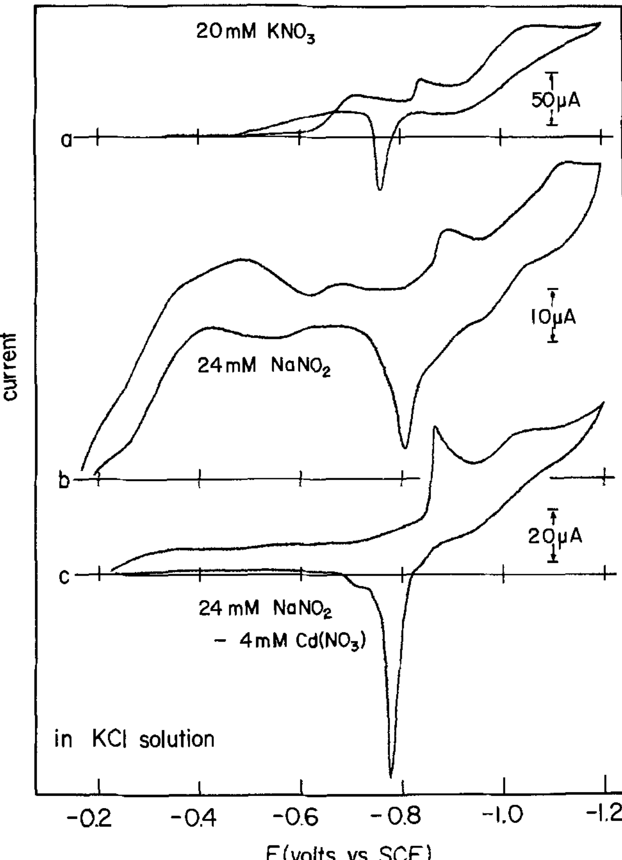

Fig. 8. Nitrate and nitrite voltammetry in saturated KCl. The composition of each solution is indicated in the figure. The scan rate was 10 mV/sec in each case.

wave leads to nitrite production, it is clear from the voltammetry in curve b that the NO_2^- produced in this manner will undergo further reduction at these potentials to some unspecified nitrogen product. This product of NO_2^- reduction is responsible for the wave at $-0.83V$ which is common to all three voltammograms. It is possible that the product of this common reduction process is one of the molecular compounds mentioned above in the development of Eq. [4]. This would then be available in the vicinity of the electrode to form a complex cadmium hydroxide precipitate of the sort believed to be responsible for the black material formed at potentials negative of $-0.8V$ in nitrate deposition solution. The voltammetry in curve c indicates that it may be possible to deposit the $Cd(OH)_2$ from nitrite solutions, also. The presence of the Cd^{+2} in curve c appears to suppress the evolution of gaseous product that is believed to be responsible for the displaced voltammetry obtained in curve b.

This voltammetry suggests that the gray cadmium hydroxide material that is cathodically deposited from nitrate solution at potentials between -0.6 and $-0.8V$ *vs.* SCE is caused by the reduction of NO_3^- to some product other than NO_2^-. Moreover, the black material which is deposited at potentials negative of $-0.8V$ *vs.* SCE appears to be formed at potentials corresponding to a second reduction process common to products of both NO_3^- and NO_2^- reductions. The products of this reduction would be available to form a complex cadmium hydroxide on the electrode surface either by reaction with an existing $Cd(OH)_2$ film or by complexation of Cd^{+2} followed by precipitation. Both materials are easily converted to crystalline hexagonal $Cd(OH)_2$ by subjecting the electrode to formation cycles in KOH. However, since the gray material is deposited at less negative potentials with minimal concurrent gas evolution, a higher degree of $Cd(OH)_2$ loading should be achieved within the nickel plaque material under these conditions. This could be achieved by operating at low current density in a controlled current process. In addition, since the gray form of $Cd(OH)_2$ is not readily converted to metallic cadmium at more positive (less basic) electrode potentials, current reversal techniques may be employed during the cathodic deposition, if the deposition is carried out at low current density. (Such reversal techniques are sometimes used to clean the counterelectrode or to aid in the introduction of fresh solution within the pores of the plaque material.) Reversal techniques could not be used at current densities high enough to produce the black precursor to $Cd(OH)_2$; the metallic cadmium that is often formed when the electrode potential is made more positive during current reversal can be anodically stripped from the electrode during the reversal process unless careful potential control is exercised. Thus, this voltammetry indicates that it would be clearly self-defeating to employ current reversal techniques with any high current density cadmium deposition process.

Some experiments were also conducted to demonstrate that the low current density deposition product was battery active in concentrated KOH. A film of the gray $Cd(OH)_2$ was deposited on the nickel working electrode from nitrate solution by sweeping the electrode potential from the rest potential to $-0.6V$ *vs.* SCE and instantaneously ceasing the electrolysis. During this potential sweep the charge was measured and found to be 0.58 mC; this is illustrated in Fig. 9. The electrode was then removed from the acidified $Cd(NO_3)_2$ solution, washed, and placed in 32% KOH where it was subjected to several charge-discharge formation cycles. Two of these are illustrated in Fig. 10. As shown in this figure, the electrode was charged potentiostatically for 500 sec at $-1.4V$ *vs.* SCE and discharged potentiostatically at $-0.21V$ *vs.* SCE for the same period. During the discharge, the current fell essentially to zero. As the electrode was subjected to repeated charge-discharge cycles, the current that passed during each half-cycle increased. By the fourth formation cycle, 95.6 mC passed during the charging half-cycle; this was indicative of the considerable amount of hydrogen evolution that was taking place at the charging potential. Of this charge, 29.3 mC were "recovered" on discharge. Since only 0.58 mC were used in the deposition of the $Cd(OH)_2$ film, no more than 1.16 mC of active $Cd(OH)_2$ could be available on the nickel substrate if the development associated with Eq. [4] and [5] is correct. Voltammetric investigations were carried out in an attempt to resolve this apparent discrepancy.

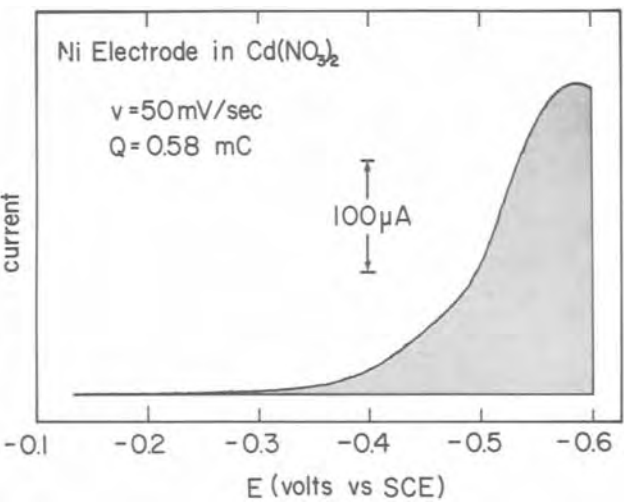

Fig. 9. Linear sweep voltammetry of the cathodic deposition of gray $Cd(OH)_2$. The charge represented by the shaded area is given in the figure.

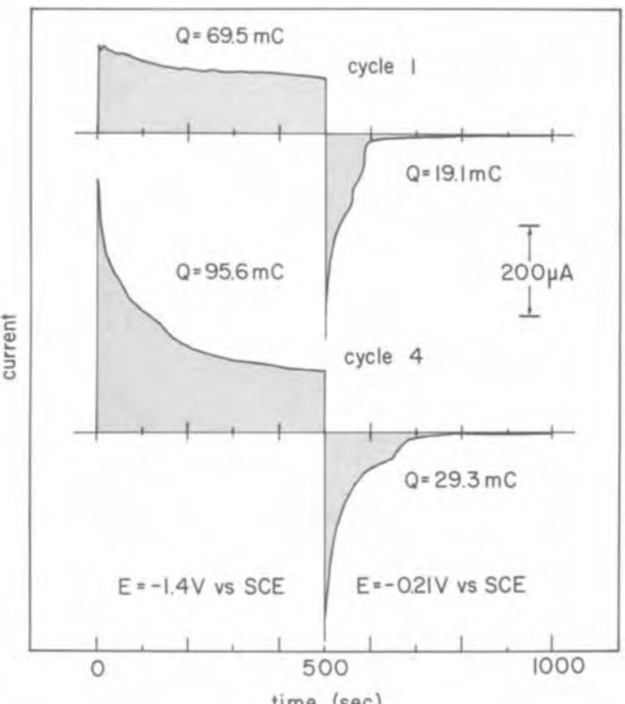

Fig. 10. Chronoamperometry of $Cd(OH)_2$ in 32% KOH. The electrode used in these studies was the same one prepared by the cathodic deposition of Fig. 9. Charges represented by the shaded areas are given in the figure.

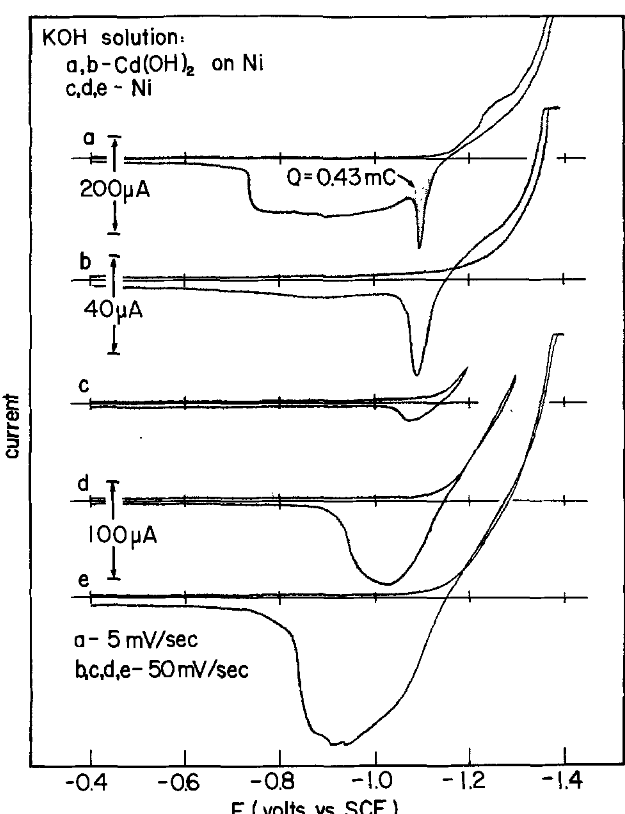

Fig. 11. Cyclic voltammetry studies in 32% KOH. The electrode used in curve a was the same one used in Fig. 9 and 10. Curve a was obtained after the fourth cycle of Fig. 10; curve b was obtained prior to any formation cycles on another $Cd(OH)_2$ electrode; curves c, d, and e were run on a bare nickel electrode.

This slow scan voltammetry is shown in curve a of Fig. 11. Prominent in this voltammetry is a shoulder at −1.25V during the negative scan; this wave, which was concomitant with the hydrogen evolution process corresponds to the cadmium electrode charging process. After the potential scan direction was reversed, a broad discharge wave was obtained; this wave commences with a spike at −1.1V *vs.* SCE and continues with the passage of considerable current to −0.7V. The area under the spike corresponded to a discharge of 0.43 mC as shown in the figure. It is believed that this spike was caused by the discharge of the 0.58 mC of $Cd(OH)_2$ that was deposited on the electrode in Fig. 9 and charged during the hydrogen evolution process of the forward scan. Based on the assumption that this admittedly crude current integration is an effective measure of the amount of deposited cadmium (by the reverse of Eq. [1]), the deposition process (represented by Eq. [4] and [5]) is seen to be between 37% and 74% efficient. That is, between 37% and 74% of the current that is used in the low current density deposition process goes to produce chargeable $Cd(OH)_2$ on the microelectrode surface. However, the accurate measurement of this cadmium discharge is obscured by the broad discharge wave that accompanies it. Clearly, it is this secondary discharge that accounts for nearly all 29.3 mC of discharge that was observed during the second half of the fourth cycle of the chronoamperometry in Fig. 10. The amount of this secondary discharge current increases as the electrode is subjected to repeated charge-discharge cycles.

This may be seen in curve b of the same figure which was run on a $Cd(OH)_2$ filmed nickel electrode that had not been subjected to any previous charge-discharge studies. The sweep rate used in obtaining curve b was ten times that used in curve a, so that the electrode was subjected to potentials negative of −1.2V *vs.* SCE for less than 10 sec. [When this is done, the relative amount of the secondary discharge process is greatly diminished, but the likelihood of completely charging the $Cd(OH)_2$ film in this short time period is also decreased.] The near absence of the secondary discharge process in curve b, therefore, supports the contention that it is related to the amount of time that the electrode experiences the overcharge condition, but this experiment does not suggest an easy electrochemical way to determine the quantity of deposited $Cd(OH)_2$.

Evidence that the secondary discharge process is caused by the oxidation of hydrogen generated on overcharge is provided by curves c, d, and e, which were obtained on a nickel electrode in the absence of any $Cd(OH)_2$ film. These three curves which have negative limits of −1.2, −1.3, and −1.4V *vs.* SCE, respectively, show that the oxidative current on reversal is dependent on the overcharge potential achieved. Even a brief excursion to −1.2V produces a significant oxidative current on scan reversal. This observation points out the difficulty in attempting to measure the amount of $Cd(OH)_2$ deposited on the electrode surface by subjecting the electrode to charge-discharge studies: any potential that is sufficiently negative to charge the $Cd(OH)_2$ will cause sufficient hydrogen evolution and adsorption on the nickel substrate to prevent the unambiguous determination of the amount of deposited cadmium through discharge current measurement. The adsorbed hydrogen will be oxidized either concurrently with the cadmium film or at potentials just positive of cadmium oxidation.

This voltammetry provides support for the hypothesis that the stepped discharge curve that is sometimes observed from cadmium-limited nickel-cadmium cells that have been subjected to considerable overcharge is due to the oxidation of adsorbed hydrogen on the negative plate during discharge (3). This oxidation takes place somewhat less readily than the oxidation of cadmium; thus, when the supply of cadmium is exhausted, the cell voltage would fall but the cell would continue to discharge until the adsorbed hydrogen was also used up. (The cell would operate as a nickel-hydrogen cell.) Other investigators have attributed this stepped discharge behavior to excessive carbonation

of the electrolyte (4) and to Ni_5Cd_{21} alloy formation (5). While these processes may also contribute to a stepped discharge curve, it is clear from the voltammetry in Fig. 11 that hydrogen adsorption on overcharge would play a primary role in this behavior in cadmium-limited cells. Of course, in the more conventional nickel-limited cell composition, such behavior can be properly attributed to nickel electrode characteristics.

Applications

The information obtained in the studies above was used to suggest modifications in the procedure for the cathodic deposition of cadmium hydroxide in sintered nickel plaque electrodes. These observations and the corresponding suggestions for the manufacturing process are given below:

1. It is possible to deposit two distinctly different cadmium compounds for use as battery active material on nickel from $Cd(NO_3)_2$ solution depending on the deposition potential and the pH. The material deposited at less negative potentials (low current density in a controlled current process) appears to be deposited as a uniformly dense film. This is presumably due to the fact that the nitrate reduction process responsible for this deposition does not evolve any H_2 gas. The deposition at more negative potentials (high current density) may take place with H_2 gas evolution and probably involves cadmium complex formation with one of the products of NO_3^- reduction. Thus, the deposition at high current density is not only expected to be less dense, but also its pre-formation cadmium content is probably lower. For high loadings of a uniform $Cd(OH)_2$ deposit, the deposition should be carried out at low current density so that the potential of the nickel electrode never becomes more negative than $-0.65V$ *vs.* SCE.

2. The material deposited at low current density neither is metallic cadmium nor is it readily converted to metallic cadmium at less negative deposition bath electrode potentials. The material deposited at higher current densities may contain some metallic cadmium when the potential of the electrode is changed in a positive direction; this metallic cadmium can undergo anodic stripping when the electrode potential is changed in a positive manner as it would be in a current reversal deposition technique. Thus, if current reversal techniques are to be employed during the deposition either to introduce fresh solution within the pores of the nickel plaque material or to clean the surface of the electrodes, the low current density deposition is again recommended to avoid the buildup of strippable metallic cadmium on the electrode surface.

3. At low current density there is no H_2 gas evolution and the stoichiometry of the sequence given by Eq. [4] and [5] gives an approximation of the amount of active $Cd(OH)_2$ that is actually deposited on the electrode surface. An exact determination of the efficiency of the cathodic deposition process cannot be made without further studies to identify the product(s) of the NO_3^- reduction process. However, if these products are mononegative ions or if they are molecular species containing nitrogen in a low positive or negative oxidation state, the number of equivalents of charge passed during deposition should nearly equal the maximum number of equivalents of $Cd(OH)_2$ available for use in alkaline cell operation.

4. Either of the two materials investigated herein may be converted to battery active hexagonal $Cd(OH)_2$ by subjecting the electrode to charge-discharge formation cycles in concentrated KOH. In either case, however, subjecting the electrode to a high overcharge either during formation or in actual use will produce deleterious results. Hydrogen evolved on overcharge is adsorbed on the nickel surface and is available for reaction when the cell is discharged. Unfortunately, this adsorbed hydrogen appears to dislodge the $Cd/Cd(OH)_2$ that is in contact with the nickel surface so that the amount of the available negative plate material is diminished. Care should be exercised during formation and use so as to minimize hydrogen evolution during the charging of the negative plate. If the electrode is to be used in the usual nickel-limited battery configuration, it might be advisable to eliminate any electrochemical formation whatsoever of the cadmium electrode.

In order to see if these recommendations could be related to the practical process, the cathodic deposition of $Cd(OH)_2$ in some sintered nickel plaque material was attempted by controlled current techniques (6). A cadmium impregnation bath for porous nickel plaque was assembled as described by Pickett (7). The plaque material used in the deposition had a porosity of 78% and was 0.031 in. thick. The bath contained an SCE reference electrode so that the potential of the nickel plaque electrodes could be controlled by controlling the current density. It was found that a deposition potential positive of $-0.65V$ *vs.* SCE could be maintained by not allowing the current density to exceed 0.2 A/in.^{2} of single surface plaque area. (Deposition took place on both surfaces, however.) A high quality $Cd(OH)_2$ electrode was obtained using this method. During the process, it was found to be useful (but not necessary) to alternate the direction of current flow for short periods of time to clean the surfaces of the electrodes. Cadmium electrodes prepared in this manner had a high initial capacity and did not have to be subjected to an electrochemical formation process to achieve a higher apparent capacity. This observation confirms the belief that an uncomplexed form of $Cd(OH)_2$ is deposited at low current density so that the initial density of the active material is quite high.

This observation is supported by the scanning electron micrographs of a sample electrode shown in Fig. 12 and 13. These SEM results were obtained using an impregnated electrode prior to being subjected to any charge-discharge cycles in alkaline solution. Figure 12 shows the detail of the $Cd(OH)_2$ that was deposited at low current density within the pores of the nickel sinter. Figure 13 is a composite of seven such micrographs that have been selected to show the cross-sectional distribution of the $Cd(OH)_2$ from the outer surface of the impregnated plaque material to the nickel grid fracture surface in the center of the electrode. This composite shows the kind of loading that can be achieved by carrying out the deposition at low current density. The fact that larger $Cd(OH)_2$ platelets are

Fig. 12. Scanning electron micrograph of nickel plaque impregnated with $Cd(OH)_2$. Low current densities (0.2 A/in.^{2}) employed in this deposition never allowed the electrode to become more negative than $-0.65V$ vs. SCE. $Cd(OH)_2$ platelets are seen to be imbedded within the pores of the sintered nickel plaque material.

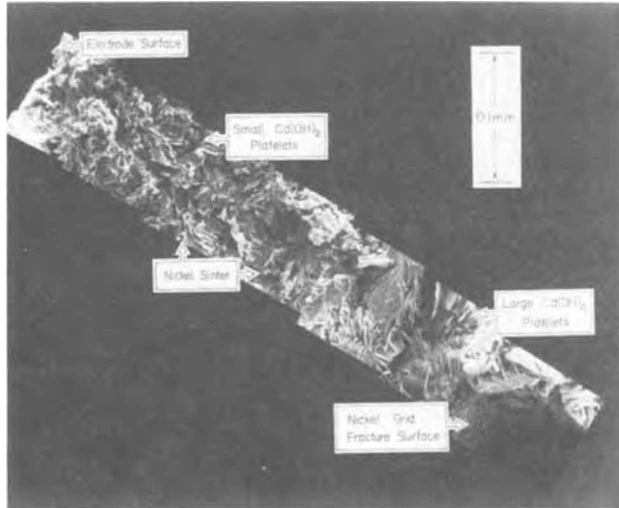

Fig. 13. Composite cross-section photomicrograph of $Cd(OH)_2$ impregnated nickel plaque material. Seven different micrographs have been assembled to show this view of the fracture surface from outer electrode surface to the inner Ni grid wire contact. Larger platelets are evident in the interior of the plaque material.

found in the interior of the plaque material enforces the belief that deposition proceeds by a precipitation mechanism. Larger crystals are indicative of the slow crystal growth process that would occur in the diluted environment of unreacted cadmium ion that would be found in the solution in the interior. These concentration effects no doubt contribute to the minimal passive film formation that is observed on the highly irregular surface of the porous electrode material.

Figure 14 demonstrates that a uniform deposition of cadmium is achieved by this low current density method. This figure shows the impregnated plaque material in the vicinity of one of the nickel wires (shown in cross section) used in the support grid. In the upper left and right quadrants are the backscattered electron and secondary electron micrographs of this material. In the lower left and right quadrants are the x-ray energy dispersive analyses on the same material for cadmium and nickel, respectively. These results indicate clearly that cadmium-containing material is well distributed within the plaque, even deep in the interior. Electrodes having this characteristic are believed to resist capacity fading much better than electrodes having a high surface distribution of active material.

Electrodes prepared in this manner were also subjected to cycle life testing in cadmium-limited and conventional nickel-cadmium cells. The results of this testing are to be the topic of a future communication.

Moderate Temperature Sodium Cells

I. Transition Metal Disulfide Cathodes

K. M. Abraham,* L. Pitts, and R. Schiff

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

A moderate temperature, rechargeable Na cell having the configuration

Liquid Na/β-Al_2O_3/Na^+-conducting electrolyte/Transition metal disulfide

is described. The cell operates at ~130°C. Three transition metal disulfides, TiS_2, VS_2, and $Nb_{1.1}S_2$, have been evaluated as cathode materials. A 1M solution of NaI in 1,2-Bis(2-methoxy-ethoxy)ethane, (triglyme), served as the electrolyte. The mechanism of discharge in all the three cathode materials involves Na intercalation. Experimental results are presented on cathode capacity, rate capability, and rechargeability.

Recently, there has been considerable interest in high energy, secondary batteries with alkali metal anodes for applications such as electric vehicles. electrical load leveling and space modules. Secondary Li batteries utilizing transition metal chalcogenide (1, 2) or oxide (3) cathodes have shown considerable promise in this respect. A secondary sodium battery utilizing molten Na polysulfide cathode and operating at temperatures above 300°C is presently in advanced developmental stages (4). Recently, we described (5) a moderate temperature secondary Na cell which operates at the temperature range of 100°-150°C and utilizes a β-Al_2O_3 solid electrolyte in conjunction with a soluble S cathode. In the continued search for suitable cathode materials for this moderate temperature Na battery, we have evaluated several transition metal chalcogenides. In this paper our findings on TiS_2, VS_2, and $Nb_{1+x}S_2$ cathodes are reported.

The transition metal disulfides of interest here crystallize with layered structures (1). The unit building block of the disulfides consists of two hexagonally close-packed chalcogen layers between which reside the metal ions. The metal ions occupy either sites of octahedral (Oh) symmetry as in TiS_2 and VS_2 with 1T-CdI_2 structure (1) or trigonal prismatic (TP) symmetry as in 2H-NbS_2 (1). Bonding within the layers is strong, while between adjacent layers it is weak. Consequently, it is possible to form intercalation compounds under rather mild conditions by insertion of atoms, molecules, or ions between the weakly bound layers. It is the intercalation and deintercalation of the alkali metals (Eq. [1]) which form the basis of the cathode reactions in rechargeable cells

$$xA^+ + xe^- + MS_2 \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftarrows}} A_xMS_2 \qquad [1]$$

Lithium intercalation into the disulfides often proceeds with very little structural change in the host lattice (1) so that the reaction is readily reversible. A rechargeable cell based on the Li/TiS_2 couple has been shown to have very long cycle life (1, 2). While there have been several prior studies dealing with the structural chemistry of Na intercalates of TiS_2 (6, 7), VS_2 (8, 9, 10), and NbS_2 (11), very little is known about the reversibility of the reaction. The available structural data on the Na intercalates of these transition metal disulfides show that structural changes of the host lattice occur with Na intercalation. Often, in a given Na_xMS_2 ternary, more than one crystallographically distinct phase appears with the degree of intercalation (1, 6-11). A prior study (12) on the ambient temperature electrochemical intercalation of Na into TiS_2 showed that the equilibrium potential-Na composition curve exhibits three plateaus which closely correlate with the three phases in the Na_xTiS_2 ternary at the Na composition ranges of $0.17 < x \leq 0.33$, $0.38 < x < 0.72$, and $0.8 < x \leq 1$. The implication of these phase changes on the rechargeability of the cathode, especially at elevated temperatures, is unknown.

The three disulfides, TiS_2, VS_2, and $Nb_{1+x}S_2$, were evaluated as cathode materials in a cell of the configuration

Liquid Na/β-Al_2O_3 / Na^+-conducting electrolyte / Transition metal disulfide

The cell operates at ~130°C and utilizes as electrolyte a 1M solution of NaI in 1,2-Bis(2-methoxy-ethoxy) ethane, (triglyme).

Experimental

All the experiments were carried out in the absence of air and moisture using standard techniques employed for the manipulation of air-sensitive compounds (13). Wherever appropriate, the handling and transfer of reagents were also carried out in an argon-filled dry box (Vacuum Atmospheres Corporation).

Synthesis and Characterization of Metal Disulfides

TiS_2.—The disulfide was prepared by the direct reaction of stoichiometric amounts of Ti metal powder (−100 mesh, Ventron) and S (Ventron, random pieces) at ~700°C (14). The material was characterized by x-ray (1) and elemental analysis. Composition of the material was established as $Ti_{1.02}S_2$. Its x-ray pattern was consistent with the 1T-CdI_2 structure (1).

VS_2.—The compound was prepared by the reaction of either $LiVS_2$ (15, 16) or $NaVS_2$ (15) with CH_3CN/I_2 solution (16). Its x-ray data and elemental analysis confirmed material purity. X-ray data showed that the material had the 1T-CdI_2 structure (16).

$Nb_{1.1}S_2$.—The compound was synthesized by direct reaction of Nb powder (−60 mesh, Ventron) and S (random pieces, Ventron) at 950°C (17). The composition of the material was determined by combustion analysis as the oxide and found to be $Nb_{1.1}S_2$. X-ray pattern of the material showed that a major fraction belonged to the 3S-polytype (17).

Electrolyte Preparation

1,2-Bis(2-methoxy-ethoxy)ethane, (triglyme), obtained from Aldrich Chemical Company, (Cat. No. P-6952) was passed twice over Fisher neutral alumina. A 1M NaI solution was prepared by dissolving ultrapure NaI (Ventron) at room temperature. The 1M NaI

* Electrochemical Society Active Member.

Key words: sodium cells, TiS_2, VS_2, $Nb_{1.1}S_2$.

solution has a specific conductivity of 2.55×10^{-3} Ω^{-1} cm^{-1} at 25°C and 4.5×10^{-3} Ω^{-1} cm^{-1} at 130°C. Infrared and visible-u.v. spectral analyses of electrolyte stored for 2 months at 130°C showed no evidence for decomposition. Also, the electrolyte exhibited no background current in the potential limits between 1 and 2.5V *vs.* Na^+/Na, the region of interest in the present study.

Electrochemical Measurements

The electrochemical cell incorporating β-Al_2O_3 tube was of the same type discussed previously (5). The transition metal sulfide cathodes were fabricated in the form of pressed electrodes. Initially an intimate mixture consisting of ~50 weight percent (w/o) metal sulfide powder, 40 w/o carbon (AGM-2100 graphite or Shawinigan 50% compressed carbon), and 10 w/o Teflon (du Pont 7A) was prepared in a blender. The mixture was then pressed onto an expanded Ni grid (Exmet Corporation, 5Ni5-5/0) at a pressure of ~5000 lb/in². The pressed electrode typically had an area of 8 cm²/side and a thickness of 0.60-1.0 mm. In some cells the electrodes were fabricated from a mixture of 90 w/o sulfide and 10 w/o Teflon without any carbon. The electrode areas were also varied in some cells. The pressed electrode was wrapped tightly around the β-Al_2O_3 tube and secured in position with another wrap of expanded Ni over the electrode. The wrap of expanded Ni over the electrode helped retain the active materials on the grid during cycling. The cell was completed by filling it with an appropriate amount of electrolyte. Before cycling, the cells were thermostated to 130°C. The cells were cycled galvanostatically or potentiostatically using standard instrumental techniques (2, 5).

Results and Discussion

The Sodium-Titanium Disulfide Cell

Galvanostatic tests.—The Na/TiS_2 cell has an open-circuit potential (OCV) of 2.15V at 130°C. Typical discharge curves are shown in Fig. 1. The first discharge corresponds to $0.85e^-$/moleTiS_2. The discharge curve is characterized by two plateaus spanning the Na composition (x) ranges at $0 < x \leq \sim 0.30$ and $0.37 < x \leq 0.8$. The end of discharge is indicated by a clear potential drop. There is a gradual decrease in discharge capacity in the early cycles (≤ 4) and this appears to result from an incremental inefficiency in cathode rechargeability in these cycles (vide infra). The first full cycle is shown in Fig. 2. There is a close similarity between the potential profiles of discharge and charge. Discharge/recharge reactions involving intercalation and deintercalation of Na as shown in Eq. [2] could explain this type of behavior

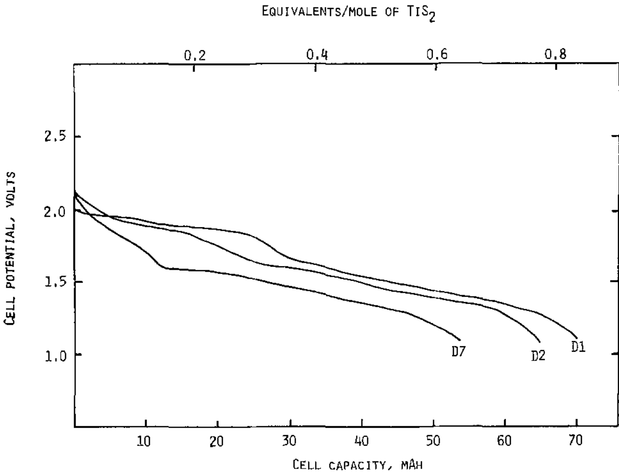

Fig. 1. Galvanostatic discharges of the cell, liquid Na/β-Al_2O_3/triglyme/1M NaI, TiS_2 at 130°C. The cathode was fabricated from 50 w/o TiS_2, 40 w/o C, and 10 w/o Teflon. Current, $id = ic = 4$ mA. Current density $= 0.5$ mA/cm². Curves D1, D2, and D7 are the first, second, and seventh discharges.

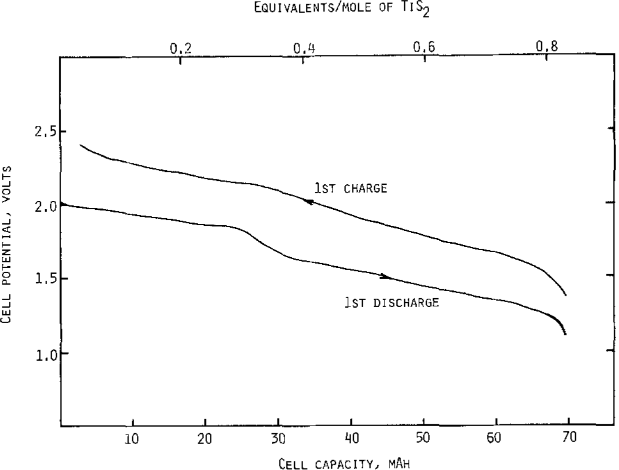

Fig. 2. The first full cycle of the TiS_2 cell shown in Fig. 1

$$TiS_2 + xNa^+ + xe^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftarrows}} Na_xTiS_2 \quad [2]$$

This is substantiated by x-ray data on discharged cathodes. The C-lattice parameter of an electrochemically obtained Na intercalate of composition $Na_{0.8}TiS_2$ was found to be 6.68Å, in agreement with previous observations (6).

The phase diagram of the Na_xTiS_2 ternary has been described (6, 7). There are three phases as x is varied from 0 to 1. The first phase covering the Na composition range, $0.17 < x < 0.33$ is a second-stage trigonal prismatic (TP) phase with Na in trigonal prismatic and Ti in octahedral co-ordination sites. The Na occupies approximately every other layer in the crystal lattice. The second phase covering the region $0.38 < x < 0.72$ is a first-stage TP phase. The third phase for $0.8 < x \leq 1$ is trigonal antiprismatic (TAP) in which both Na and Ti occupy octahedral sites.

The two regions in the discharge curve (Curve D1, Fig. 1) appear to correlate with two TP phases. The sharp cutoff in the discharge curve at an Na composition of ~0.80 suggests that it is difficult to intercalate Na into the TAP phase at potentials above 1.0V *vs.* Na^+/Na. This is in agreement with the observations of Whittingham *et al.* (6) who found that in the preparation of Na_xTiS_2 from TiS_2 and Na-naphthalide, even with a large excess of the latter reagent, the ternary with the maximum Na content that could be prepared was $Na_{0.8}TiS_2$. The difficulty in obtaining Na_xTiS_2 with $x > 0.8$ is probably due to the lower diffusion coefficient of Na in the TAP phase (6). In the TAP phase, Na^+ has to pass through small 4 co-ordinate sites, whereas in the TP phase such sites are much larger, facilitating better Na diffusion.

Cathode rechargeability.—Figure 3 summarizes the capacities corresponding to the first and second phases in each discharge as a function of cycle number. The capacity in the second phase remains essentially constant whereas that in the first phase gradually decreases in the early cycles. At present we do not know why Na is only partially reversible in the first phase. However, it is noteworthy that the irreversibility is brought about gradually with cycling. This tends to suggest that under the conditions of the cathode cycling, a new phase is formed and irreversibly stabilized at low values of x in Na_xTiS_2. It would be necessary to carry out a detailed study of the structural and electronic properties of Na_xTiS_2 at various stages of cycling. This is beyond the scope of the present work. The data suggest that in long-term cycling a fraction of the capacity in the first phase

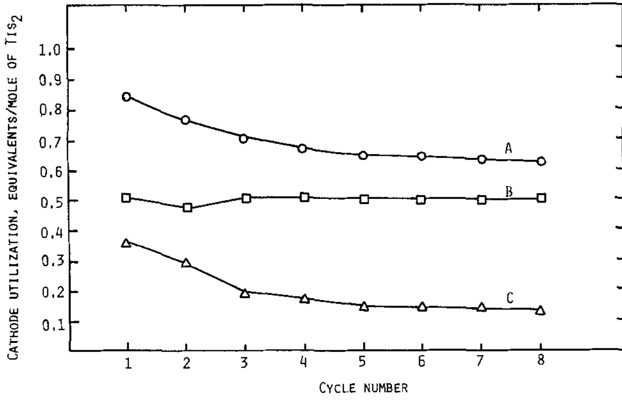

Fig. 3. Cathode utilization vs. cycle number for the TiS_2 cell shown in Fig. 1. Curve A represents the total capacity. Curve B represents the capacity in the second phase. Curve C represents the capacity in the first phase plus the transition region.

and all the capacity in the second phase would be rechargeable. A reasonable estimate for the average rechargeable capacity of the TiS_2 cathode is $\sim 0.65\ e^-/TiS_2$.

The presence of carbon on the electrode matrix was found to be necessary for good cathode rechargeability. This was indicated by the cycling behavior of a cell in which the cathode composition was 90 w/o TiS_2 and 10 w/o Teflon. The first discharge corresponded to $0.8e^-/TiS_2$, as in the case of the cell with carbon. However, the capacity decreased rapidly in the next three cycles. Thus capacities of 0.64, 0.45, and $0.37e^-/TiS_2$ were obtained in the second, third, and fourth discharges, respectively. It was apparent from the discharge curves that the rapid loss in capacity in these cycles occurred from both of the phase regions. This seems to suggest that with cycling a fraction of the cathode material gets physically isolated in the electrode and not utilized electrochemically. The capacity loss was more gradual in subsequent discharges and was mostly attributable to the irreversibility in the first phase. Thus it was $0.33e^-/TiS_2$ in the fifth discharge and $0.26e^-/TiS_2$ in the seventh discharge. Evidently the isolation of the material occurs in the initial cycles. The TiS_2 crystallites show a largely reversible expansion and contraction upon intercalation and expulsion of Na. Thus an initially optimized electrode structure changes even after the first discharge-charge cycle, since bonded powder electrodes used in these studies do not show ideal elastic behavior. In the absence of C in the electrode matrix, a loss of particle to particle contact occurs, leading to diminished performance. We have observed a similar, but less drastic, phenomenon in the cycling of high capacity Li/TiS_2 cells (2).

Potentiostatic tests.—Potentiostatic discharge of TiS_2 cathode was carried out to obtain information on its rate capability. For discharge the potential was set at 1.3V and the current was monitored as a function of time. The current-time curves were incrementally integrated and Fig. 4 shows the capacity expressed as charge equivalents per mole of TiS_2 as a function of current density. At current densities ≤ 1 mA/cm^2, the cathode utilization is $\sim 0.8e^-/TiS_2$. A capacity of $0.48e^-/TiS_2$ has been obtained in the first 60 min of discharge during which time the minimum current density was 4.1 mA/cm^2. Since the cathode or the cell was not optimized for best performance, it appears that current densities higher than these with good utilization should be possible for the TiS_2 cathode.

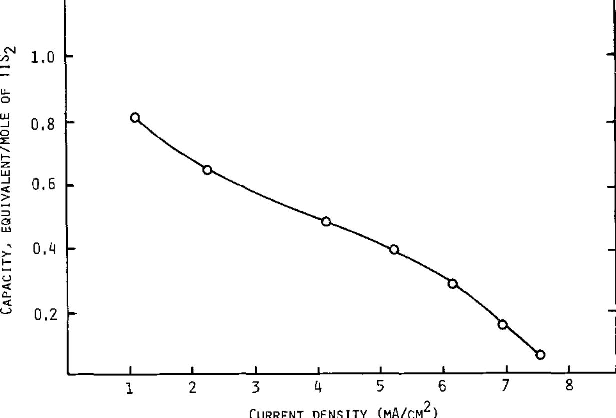

Fig. 4. Capacity vs. current density of TiS_2 cathode potentiostated at 1.3V. Temperature = 130°C.

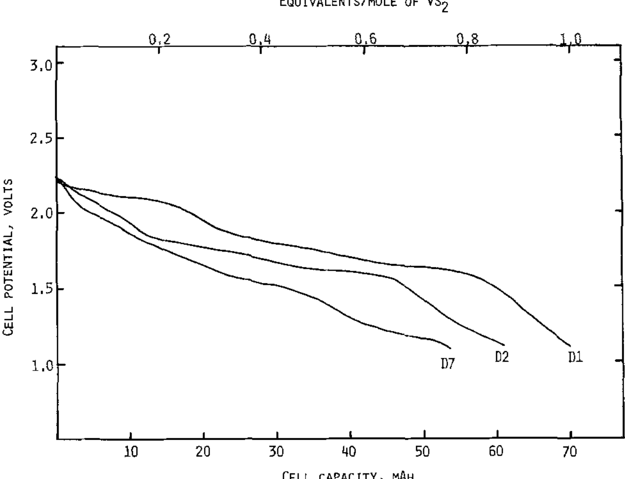

Fig. 5. Galvanostatic discharges of the cell, liquid Na/β-Al_2O_3/triglyme/1M NaI, VS_2 at 130°C. The cathode was fabricated from 50 w/o VS_2, 40 w/o C, and 10 w/o Teflon. Current, *id* = *ic* = 4 mA. Current density = 0.5 mA/cm^2. Curves D1, D2, and D7 are the first, second, and seventh discharges.

The Sodium-Vanadium Disulfide Cell

Galvanostatic tests.—The Na/VS_2 cell has an OCV of 2.30V at 130°C. Typical discharge curves are shown in Fig. 5. The first discharge corresponds to a capacity of $1.0e^-/VS_2$. The discharge curve is mainly characterized by three regions, spanning the Na composition (x) ranges approximately at $0 < x \leq 0.28$, $0.3 < x \leq 0.85$, and $0.85 < x \leq 1$. There is a decrease in cathode utilization with cycle number, but much of this loss occurs in the second discharge and seems to mostly involve the capacity in the first plateau. The first full cycle is shown in Fig. 6. Apparently, the capacity encompassed in the first plateau is only fractionally recharged in the first charge.

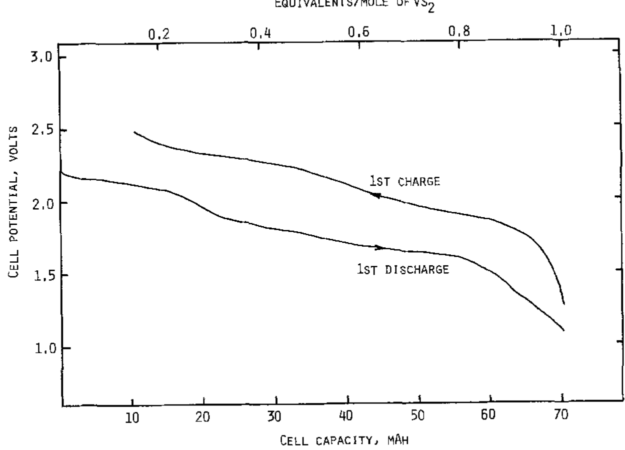

Fig. 6. The first full cycle of the VS_2 cell shown in Fig. 5

The x-ray diffraction pattern of a discharged cathode established that the mechanism of discharge involves Na intercalation into VS_2. A discharged cathode of composition $Na_{\sim 1.0}VS_2$ exhibited a C-lattice parameter of 7.31Å as opposed to 5.72Å in VS_2. Structural studies of Wiegers (8) has shown that Na intercalation of VS_2 is accompanied by phase transformations as the Na composition is varied from 0 to 1. However, a precise phase diagram of the Na_xVS_2 ternary is not known. Rouxel has suggested (9), on the basis of a generalized model for the phase diagrams of Na_xMS_2 ternaries, where MS_2 has the 1T-CdI_2 structure as in VS_2, that in the Na_xVS_2 ternary, there would be three phases spanning the Na compositions, x, at $0 < x < 0.3$ (second stage TP), $0.30 < x \leq 0.85$ (first stage TP), and $0.86 < x \leq 1.0$ (TAP). The three potential regions found in the first discharge of the Na/VS_2 cell shown in Fig. 5 correlate fairly well with these phase regions. The structure of the ternary, $Na_{1.0}VS_2$, we have obtained from the electrochemical cell at the end of discharge appears to be identical to that of the TAP $Na_{1.0}VS_2$ described by Wiegers with crystal lattice parameters of a = 3.22Å and C = 7.30Å. We have further established Na intercalation by VS_2 from the x-ray patterns of Na_xVS_2 compositions prepared from VS_2 and Na-naphthalide (6). The C-lattice parameters for $Na_{0.4}VS_2$ and $Na_{0.8}VS_2$ intercalates have been found to be 7.08 and 6.94Å, respectively, in agreement with the observations of Wiegers (8).

Cathode rechargeability.—Rechargeability of the VS_2 cathode was investigated by extended cycling of a cell with a pressed cathode (0.8m thick) containing 62 w/o VS_2, 30 w/o C, and 8 w/o Teflon. Cathode utilization as a function of cycle number is shown in Fig. 7. An average capacity of $0.70e^-/VS_2$ was obtained in the first 40 cycles. The capacity then gradually decreased. The average capacity for the last 15 cycles was $0.6e^-/VS_2$. The 22nd cycle is shown in Fig. 8. Detailed analysis of the discharge curves suggests that the capacities involved in the second and third phases are rechargeable during extended cycling. However, it appears from the potential profiles of later discharges, for example the 22nd discharge shown in Fig. 8, that the structural differences between these two phases gradually disappear. The latter discharge curves exhibit more or less linear profiles. A possible reason for some of the decrease in capacity after the 40th cycle is mechanical loss of materials from the cathode matrix. This was evidenced by visual observations. The cycling data demonstrate that the Na/VS_2 cell could deliver an average rechargeable capacity of $0.7e^-/VS_2$.

The cathode utilization in the first discharge of cells without carbon in the electrode matrix was only $\sim 0.70e^-/VS_2$. The potential profiles of the discharge curves suggested that Na intercalation into the third

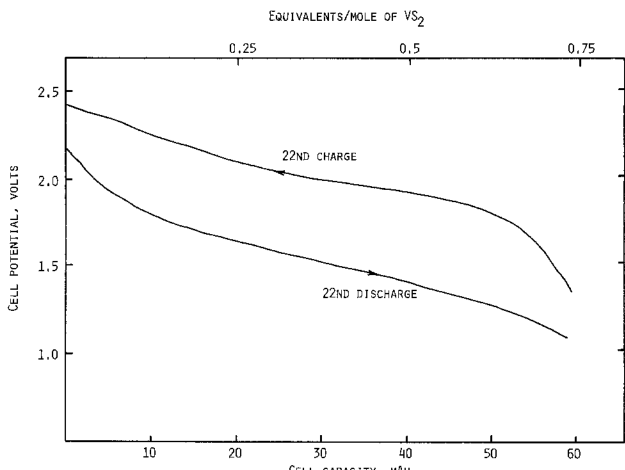

Fig. 8. The 22nd cycle for the VS_2 cell depicted in Fig. 7

phase was not achieved when carbon was absent. The resistivity data for VS_2 and Na_xVS_2, x = 0.65, 0.8, and 1, shown in Table I, suggest that this may be due to decreased electronic conductivity of Na_xVS_2 compositions for $x \geq 0.8$. The data in Table I show that no significant increase in resistivity occurs until $x = 0.8$. When $x = 1$, the material becomes low conducting. The exact break-point to lower conductivity is not known, but may be associated with the TAP phase with $x \geq 0.8$. It has been shown by Wiegers *et al.* (10) that $Na_{1.0}VS_2$ could exist in two crystallographic modifications, namely, the TP and TAP forms. The TAP modification is semiconducting, while the TP form is metallic. The x-ray data we have obtained for $NaVS_2$ samples prepared electrochemically are in good agreement with a TAP modification. These results seem to suggest that the capacity limiting factor in the TAP phase in VS_2 is electronic conductivity whereas that in TiS_2 is Na diffusion. The activation energy for Na intercalation usually decreases with increasing c/a ratio of the crystal lattice. The c/a ratio for the TAP phase in VS_2 is 2.26 whereas that for the TAP phase in TiS_2, *i.e.*, in $Na_{0.8}TiS_2$, is 1.9 (6, 8).

In extensive cycling, rechargeable capacity of VS_2 cathode without carbon in the electrode matrix would be $\sim 0.4e^-/VS_2$.

Potentiostatic cycling of VS_2.—A VS_2 cathode was potentiostatically cycled with the potential for discharge set at 1.3V and for charge at 2.3V. The cycling curves are shown in Fig. 9. The total integrated capacity in the first discharge corresponds to $0.95e^-/VS_2$. The capacities in the first charge and the second discharge are slightly lower than the capacity in the first discharge; however, they are about 10% higher than the values found in the corresponding galvanostatic cycles. Analysis of the first discharge curve shows a capacity of $0.58e^-/VS_2$ in the first 60 min of discharge during which time the minimum current density was 4.3 mA/cm^2. The comparable rate capabilities of the VS_2 and TiS_2 cathodes are in conformity with their similar crystal structures.

The Sodium-Niobium Disulfide Cell

Typical galvanostatic cycles for a cell with $Nb_{1.1}S_2$ cathode are shown in Fig. 10. The open-circuit po-

Table I. Resistivity data for Na_xVS_2; x = 0.0, 0.65, 0.8, and 1.0

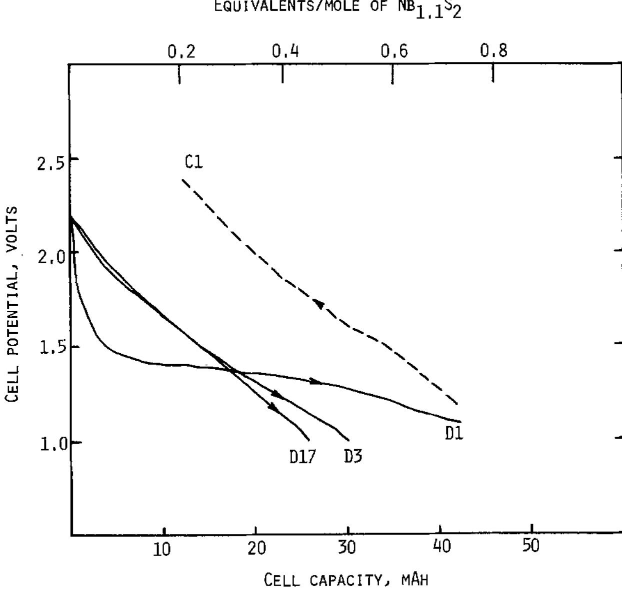

Fig. 10. Galvanostatic cycling curves for the cell, liquid Na/β-Al_2O_3/triglyme/1M NaI, $Nb_{1.1}S_2$ at 130°C. The cathode was fabricated from 50 w/o $Nb_{1.1}S_2$, 40 w/o C, and 10 w/o Teflon. Current, $i_d = i_c = 4$ mA. Current density = 0.5 mA/cm^2. Curves D1, D3, and D17 are the first, third, and 17th discharges. Curve C1 is the first charge.

tential of the cell was 2.20V. However, the first discharge proceeds from 1.7V with the potential remaining at ~1.4V during most of the discharge. The first discharge corresponds to $0.72e^-/Nb_{1.1}S_2$. The first charge exhibits a more linear voltage-time behavior, with a much higher slope than the discharge. The charge corresponds to $0.54e^-$. All subsequent discharges and charges have slopes similar to the first charge. It appears that in the first discharge as Na is intercalated, $Nb_{1.1}S_2$ undergoes a phase change and the "new phase" retains the structures during subsequent cycling. Average cathode utilization in 17 cycles was $0.5e^-/Nb_{1.1}S_2$.

A wide variety of structural types are known in the Nb-S binary system (17). The x-ray pattern of our material of average stoichiometry $Nb_{1.1}S_2$ could not be indexed to a single homogeneous phase, although a considerable fraction of the material appeared to belong to the 3S-$Nb_{1+x}S_2$ structural type (17). A cathode was cycled once and then treated with CH_3CN/I_2 solution to remove all the residual Na. Its x-ray pattern appeared to be similar to that of the 2H-$Nb_{1+x}S_2$ structural type (17). It appears that intercalation of Na initially converts the 3S-$Nb_{1+x}S_2$ structure to the 2H-$Nb_{1+x}S_2$ structure which does not undergo further change with cycling. The potential profiles of the charge/discharge curves after the first discharge closely resemble the previously reported (18) EMF-Na composition curve of the Na_xTaS_2 ternary (18) where the parent disulfide belongs to the 2H-polytype.

Table II. Energy density of Na/MS_2 couples calculated from experimentally obtained capacities and voltages

Metal sulfide	Equiv./mole of MS_2	Mid-discharge voltage	Specific energy (W-hr/kg)
TiS_2	0.65	1.7	215
VS_2	0.70	1.8	258
$Nb_{1.1}S_2$	0.50	1.5	119

Summary and Conclusions

Three transition metal disulfides, TiS_2, VS_2, and $Nb_{1.1}S_2$, have been evaluated as possible cathode materials for a moderate temperature rechargeable Na cell operating at ~130°C. Discharge and charge reactions in all the three cathodes involve Na intercalation and deintercalation, respectively. Our data seem to indicate that the cycling reactions proceed with phase transformations of the host lattice.

The first discharge of TiS_2 results in a capacity of 0.85 equiv./mole. It may be inferred from the discharge data that the Na_xTiS_2 ternary encompassing the Na compositional range, $0 < x \leq 0.85$ involves two phases. About half of the Na in the first phase spanning the Na compositional range, $0 < x \leq 0.30$ and practically all the Na in the second phase spanning the compositional range, $0.37 < x \leq 0.80$ are rechargeable.

Vanadium disulfide intercalates up to one mole of Na/mole of VS_2 in the first discharge. The resulting Na_xVS_2 ternary encompasses three phases at $0 < x \leq 0.28$, $0.3 < x \leq 0.85$, and $0.85 < x \leq 1$. Extended cycling data suggest that virtually all the Na in the last two phases are rechargeable. The Na involved in the first phase is practically irreversible.

Niobium disulfide appears to undergo a phase change in the first discharge. The new phase, however, retains the structure during subsequent cycling. The average rechargeable capacity in extended cycling of this cathode appears to be about 0.50 equiv./mole.

Energy densities of Na/MS_2 couples calculated from experimentally determined average capacities and mid-discharge voltages are presented in Table II. The energy density projection recently made by Rao (19) for an Na-TiS_2 cell is in close agreement with our results.

A Pulse Technique Employed for Studying Egress of Hydrogen from Iron Polarized Cathodically in As^{3+}-Containing Solutions

P. Kedzierzawski, Z. Szklarska-Smialowska, and M. Smialowski*

Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

Triangular pulses were applied to one side of an iron membrane polarized cathodically in As^{3+}-containing solution of 0.1*N* H_2SO_4 or 0.1*N* NaOH, and changes in the rate of the hydrogen ionization occurring at the diffusive side of the membrane were recorded. The results indicated that in both solutions the egress of hydrogen from iron at the polarized side of the membrane was hampered by some surface effects related to the presence of As^{3+} in the electrolyte. The probable nature of these effects is discussed.

In a study of the electrochemical extraction of hydrogen from iron membranes polarized cathodically on one side, Nanis and Namboodhiri (1) analyzed theoretically the transient current of hydrogen removal from iron following steady-state permeation. Two limiting conditions were considered: 1, the fastest possible decay caused by a rapid egress of hydrogen at both sides of the membrane; and 2, slow hydrogen removal occurring only at the diffusive side of the membrane. In case 1, the concentration of hydrogen at the input (polarized) side is considered to drop instantaneously to zero on polarization current interruption, whereas in case 2, the input side is thought to become impermeable to hydrogen removal. The theoretical analysis has shown that for the fastest possible decay (condition 1) the amount of hydrogen extracted at the diffusive side of the membrane is one-third of the total amount of hydrogen present at steady-state permeation. The remaining part of hydrogen diffuses out through the input side. In the second case (condition 2) the total quantity of hydrogen escapes at the diffusive side.

Experiments conducted with Armco iron membranes polarized cathodically in 0.1*N* H_2SO_4 or 0.2*N* NaOH solution proved (1) that after interruption of the charging current about 33% of the total quantity of hydrogen present at steady-state permeation escapes through the diffusive side indicating that condition 1 is fulfilled.

More generally, if v_{in} is the stationary rate of hydrogen ingress and v_{eg} is the rate of hydrogen egress at the polarized side of the membrane, then for condition 1

$$v_{in} \approx v_{eg} >> \frac{C_H^\circ \cdot D}{L} \quad [1]$$

and for condition 2

$$v_{in} \approx \frac{C_H^\circ \cdot D}{L} >> v_{eg} \quad [2]$$

where $(C_H^\circ \cdot D)/L$ is the rate of hydrogen permeation through the membrane.

In case 1 each variation of polarization conditions, for example of the cathodic current density i_c, induces immediately an appropriate change in C_H°. Therefore, changes in i_c and C_H° with time are determined by the same function. In case 2, however, variations of polarization conditions produce relevant changes in the value of $(\partial c/\partial x)_{x=L}$, *i.e.*, of the concentration gradient of hydrogen at the entry side of the membrane.

Apart from the data reported by Nanis and Namboodhiri (1) there also are in the literature some other results suggesting that for sufficiently thick membranes charged with hydrogen evolved from acid or alkaline solutions condition 1 is satisfied. For example, on the basis of permeability measurements performed by Devanathan and Stachurski (2) on Armco iron membranes of different thicknesses polarized cathodically in 0.1*N* H_2SO_4 the following values were calculated:[1] at $E = 600$ mV_{SCE} the stationary rate of hydrogen ingress was $v_{in} \approx 10^{-9}$ mole $H/cm^2 \cdot sec$, and for $L = 0.77$ mm the steady-state permeation was 5.7×10^{-11} mole $H/cm^2 \cdot sec$. At $E = 650$ mV_{SCE} the re-

* Electrochemical Society Active Member.

Key words: cathodic polarization, iron, hydrogen diffusion, hydrogen permeation, hydrogen ionization.

[1] Calculations of v_{in} were made by extrapolating the steady-state permeation to zero thickness of the membrane ($L = 0$).

spective values were $\approx 10^{-9}$ mole $H/cm^2 \cdot sec$ and 8.3×10^{-11} mole $H/cm^2 \cdot sec$. Similar experiments carried out by Kim and Wilde (3) on Ferrovac iron charged with hydrogen in $10^{-4}M$ NaOH led to following values: $v_{in} \approx 5 \times 10^{-10}$ mole $H/cm^2 \cdot sec$ and permeability through a 0.77 mm thick membrane = 6.2×10^{-11} mole $H/cm^2 \cdot sec$.

The above results indicate that under stationary conditions of electrolytic charging of iron membranes with hydrogen evolved from pure, *i.e.*, promoter-free solutions, the permeability is by one to two orders of magnitude lower than v_{in}. Hence, in conformity with condition 1, v_{eg} is almost as high as v_{in}.

Similar conclusions follow from measurements performed by Kedzierzawski *et al.* (4). In their experiments high purity zone-refined Battelle iron was polarized with alternating currents in $0.1N$ H_2SO_4. The results indicated that the diffusivity of hydrogen calculated from either amplitude or phase relationships was independent of frequency. This led to the conclusion that at the input side of the iron membrane the current was in phase with $C_H°$; hence again, condition 1 was fulfilled.

Different results were obtained for palladium membranes. Thus, according to Fullenwider (5), the permeability-time relationships obtained experimentally were close to those based on the assumption that each change in the potential applied to the Pd electrode induced an immediate change in the concentration gradient of hydrogen at the input side of the membrane; and Sekine (6) argued that in permeability measurements conducted with alternating currents the cathodic current was in phase with the concentration gradient of hydrogen at the input side of the Pd membrane. These results fit in with condition 2.

The present paper provides experimental evidence that in As^{3+}-containing solutions pure iron behaves accordingly to condition 2.

It has been found in previous studies (7, 8) that compounds of arsenic, and also those of phosphorus, antimony, sulfur, selenium, and tellurium, promote the entry of hydrogen into iron only in such regions of the electrode potential and pH in which the hydrides of these elements coexist in trace amounts at the polarized cathode surface. On the other hand, it has been suggested (9) that in the presence of the compounds, which promote entry of hydrogen into metals, the reverse process, *i.e.*, the egress of hydrogen from the metal, is hampered.

In order to verify the above suggestion experimentally, a pulse technique was employed. The experiments were carried out by applying triangular pulses to the entry side of the iron membrane and measuring for each applied pulse the quantity of hydrogen ionized at the diffusive side of the membrane. This technique permitted evaluation to be made of the rate at which hydrogen egressed from iron at defined values of the electrode potential and current density applied to the entry side of the membrane. Also, measurements of the cathodic current after pulse application enabled conclusions to be drawn on the desorption of the promoting species from the cathode.

Theoretical Basis of the Method Employed

Changes in the ionization rate of hydrogen that occur at the diffusive side of the membrane when a potential pulse is applied to the polarized side can be analyzed considering that the egress of hydrogen at the latter side is controlled either by condition 1 (diffusion control), or by condition 2 (kinetic control).

The anodic current P at the diffusive side of the membrane is given by the expression

$$P(t) = DF\left(\frac{\partial c_H}{\partial x}\right)_{x=0} \quad [3]$$

To calculate $(\partial c_H/\partial x)_{x=0}$ it is necessary to know the concentration of hydrogen as a function of time and space coordinates. For this, Fick's second law with defined initial and boundary conditions must be solved.

Case 1. Diffusion controlled process.—The system of equations to be solved is of the form

$$\frac{\partial^2 c_H}{\partial x^2} = \frac{1}{D}\frac{\partial c_H}{\partial t} \quad [4]$$

$$c_H(0, t) = 0 \quad [5]$$

$$c_H(L, t) = C_H° + \lambda\delta(t) \quad [6]$$

$$c_H(x, 0) = \frac{C_H° x}{L} \quad [7]$$

The use of Dirac's delta function $\delta(t)$ is justified by the fact that the duration of the pulse (both potential and current) is less than 0.1 sec, hence much shorter than the time during which permeation of hydrogen is recorded (10-100 sec).

By substituting $c = c_H - C_H° x/L$ one obtains

$$\frac{\partial^2 c}{\partial x^2} = \frac{1}{D}\frac{\partial c}{\partial t} \quad [8]$$

$$c(0, t) = 0 \quad [9]$$

$$c(L, t) = \lambda\delta(t) \quad [10]$$

$$c(x, 0) = 0 \quad [11]$$

Above substitution eliminates the steady-state component of the permeation rate. Changes in the permeation rate ΔP registered in this work are related to the transient component of concentration c by

$$\Delta P = \mathbf{F}D\left(\frac{\partial c}{\partial x}\right)_{x=0} \quad [12]$$

Equation [12] may be solved using Laplace's transformation method. By transforming both sides of [8] and for boundary conditions as above one gets

$$\frac{d^2Y}{dx^2} - \frac{1}{D}sY = 0 \quad [13]$$

$$Y(0, s) = 0 \quad [14]$$

$$Y(L, s) = \lambda \quad [15]$$

where $Y = \alpha[c]$, s = Laplace transformation parameter.

Equation [13] has a solution

$$Y = \frac{\lambda \sinh(x\sqrt{s/D})}{\sinh(L\sqrt{s/D})} \quad [16]$$

Inverse transformation of [16] gives

$$c = -\frac{2\pi D\lambda}{L^2}\sum_{n=1}^{\infty}(-1)^n n \sin\frac{n\pi x}{L}\exp\left(-\frac{n^2\pi^2 D}{L^2}t\right) \quad [17]$$

and

$$\Delta P = \mathbf{F}D\left(\frac{\partial c}{\partial x}\right)_{x=0} = -\frac{2\pi^2 D^2\lambda\mathbf{F}}{L^3}\sum_{n=1}^{\infty}(-1)^n n^2 \exp(-n^2k) \quad [18]$$

where

$$k = \frac{\pi^2 Dt}{L^2} \quad [19]$$

Therefore changes in the permeation rate with time are proportional to the factor

$$K_1 = -\sum_{n=1}^{\infty}(-1)^n n^2 \exp(-n^2k) \quad [20]$$

The plot of K_1 *vs.* k is given in Fig. 1. Calculations indicate that in this case the half-peak width is equal to 1.4.

Case 2. Kinetically controlled process.—The system of equations to be solved has the form

$$\frac{\partial^2 c_H}{\partial x^2} = \frac{1}{D}\frac{\partial c_H}{\partial t} \quad [21]$$

$$c_H(0, t) = 0 \quad [22]$$

$$\frac{\partial c_H}{\partial x}(L, t) = \frac{C_H{}^\circ}{L} + \mu\delta(t) \quad [23]$$

$$c_H(x, 0) = \frac{C_H{}^\circ x}{L} \quad [24]$$

By substituting

$$c = c_H - \frac{C_H{}^\circ x}{L}$$

one obtains

$$\frac{\partial^2 c}{\partial x^2} = \frac{1}{D}\frac{\partial c}{\partial t} \quad [25]$$

$$c(0, t) = 0 \quad [26]$$

$$\frac{\partial c}{\partial x}(L, t) = \mu\delta(t) \quad [27]$$

$$c(x, 0) = 0 \quad [28]$$

As in the previous case the transient concentration component c is related to the transient component of the permeation rate by Eq. [12]. The above system of equations can again be solved using Laplace's transformation method. Transformation of both sides of [25] and of boundary conditions leads to the equation

$$\frac{d^2 Y}{dx^2} - \frac{1}{D} sY = 0 \quad [29]$$

with boundary conditions

$$Y(0, s) = 0 \quad [30]$$

and

$$\frac{dY}{dx}(L, s) = \mu \quad [31]$$

Equation [29] has the solution

$$Y = \frac{\mu\sqrt{D}\sinh(x\sqrt{s/D})}{\sqrt{s}\cosh(L\sqrt{s/D})} \quad [32]$$

Inverse transformation of [30] gives the expression for c

$$c = -\frac{2D\mu}{L}\sum_{m=1}^{\infty}(-1)^n \sin\frac{(2n-1)\pi x}{L^2} \exp\left[-\frac{(2n-1)^2 k}{4}\right] \quad [33]$$

Differentiation of [33] *vs.* x gives the expression for the transient component of the permeation rate

$$\Delta P = FD\left(\frac{\partial c}{\partial x}\right)_{x=0} = -\frac{\pi D^2\mu F}{L^2}\sum_{n=1}^{\infty}(-1)^n(2n-1) \exp[-(2n-1)^2 k/4)] \quad [34]$$

Therefore changes in the permeation rates are proportional to

$$K_2 = -\sum_{n=1}^{\infty}(-1)^n(2n-1) \exp[-(2n-1)^2 k/4] \quad [35]$$

The plot of K_2 *vs.* k is shown in Fig. 1. According to calculations, in this case the half-peak width is 4.3.

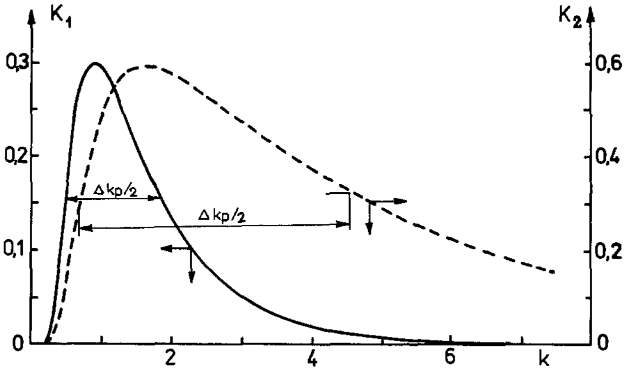

Fig. 1. Variations in K_1 and K_2 with k according to Eq. [20] (diffusion control, $\Delta k/2 = 1.4$; full line) and Eq. [35] (kinetic control, $\Delta k/2 = 4.3$; dashed line).

Experimental

A schematic drawing of the apparatus employed is shown in Fig. 2. The electrolytic permeability cell was based on the design similar to that used in Ref. (3). The Pt counterelectrode in the diffusion compartment, E_{p2}, was sheltered by a glass frit to minimize access of hydrogen from that source. As reference electrode, E_{02}, a Pt foil plated with Pt sponge bubbled with H_2 and immersed in 0.1N NaOH was used. The E_{01} reference electrode was either $Hg/HgSO_4$/0.1N H_2SO_4 or Hg/HgO/0.1N NaOH, this being dependent on the composition of the catholyte employed in the given experiments: either acid or alkaline.

The membranes were in shape of caps machined from a bar of Battelle ultrapure iron with 5 ppm nonmetallic and 23 ppm metallic impurities. The cap's bottom, 0.8 cm in diameter, 0.077 cm thick, served as the membrane and its side part was clamped between the two compartments of the electrolytic cell which were made of Plexiglas. The membranes were ground with 600 grit abrasive paper, polished with diamond paste, degreased with benzene, heated in vacuo for 2 hr at 700°C, and furnace cooled. Before measurements the internal side of the cap which served as the diffusive side of the membrane was electroplated with a thin coat of palladium.

The measurements were performed at room temperature in either 0.1N H_2SO_4 or 0.1N NaOH. The solutions were pre-electrolyzed for several hours in an auxiliary cell between smooth Pt electrodes at a voltage of 1.6V.

As established in Ref. (7 and 8), in both acid and alkaline solutions the presence of arsenic compounds greatly increases the permeation rate of hydrogen

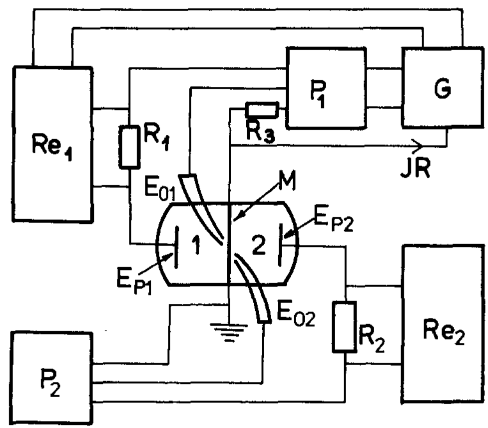

Fig. 2. Schematic drawing of the apparatus. through iron polarized cathodically to potentials at which arsine is produced in trace amounts together with hydrogen evolution. The permeability of hydrogen increases with increasing As^{3+} concentration to a maximum at about 10^{-3}M and then decreases. The present experiments were carried out at 10^{-5}M or 5×10^{-4}M As^{3+}.

Two types of experiments were performed: (*i*) measurements of polarization curves and permeabilities of hydrogen during galvanostatic polarization in As-free and As-containing solutions, and (*ii*) cyclic perturbation measurements in As-containing solutions.

Polarization and permeability measurements.—The iron membrane coated on one side with palladium was clamped between the two parts of the electrolytic cell. The cathodic polarization compartment was filled with either 0.1*N* H_2SO_4 or 0.1*N* NaOH, either without or with the addition of As_2O_3 at concentrations previously given. The diffusive compartment of the cell was filled with 0.1*N* NaOH and the potential of the membrane was set at -70 mV_{NHE}. Under these conditions all the hydrogen permeated through the membrane was ionized at the Pd-coated iron surface. Measurements of the cathodic polarization curves were made by changing the potential every 30 min by 50 mV in the negative direction. Simultaneously, the hydrogen ionization current was recorded.

Cyclic perturbation measurements.—These experiments were conducted only in As-containing solutions, because in the absence of As^{3+} the hydrogen ionization currents were too small to be recorded accurately enough.

Initially the polarized side of the membrane was kept at a constant "starting potential" E_i (Fig. 3) of either -500 mV_{NHE} (in 0.1*N* $H_2SO_4 + As^{3+}$) or -1300 mV_{NHE} (in 0.1*N* NaOH $+ As^{3+}$). Under these conditions the cathodic current densities and the hydrogen ionization rates were recorded. After the steady state was established, a potential pulse, either cathodic or anodic, was applied to the entry side of the membrane. The triangular pulse lasted for 0.01-0.03 sec. After attaining the peak at E_z (Fig. 3), the potential returned to its initial value of E_i. The change in the hydrogen ionization current occurring at the diffusive side in response to the potential pulse was recorded.

Results of Polarization and Permeability Measurements

Figures 4 and 5 show the cathodic polarization curves obtained for iron membranes exposed to As-free and As-containing electrolytes. It is seen that in the whole range of potentials examined the current density is less in the presence of As^{3+} than in its absence. This is probably due to adsorption of As and/or of its compounds on the cathode.

Figures 6 and 7 illustrate the dependence on potential of the steady-state ionization current of hydrogen permeating through the membrane polarized, respectively, in 0.1*N* H_2SO_4 and 0.1*N* NaOH with either 10^{-5}M or 5×10^{-4}M of As^{3+}. In the range of potentials studied, higher permeabilities are observed for

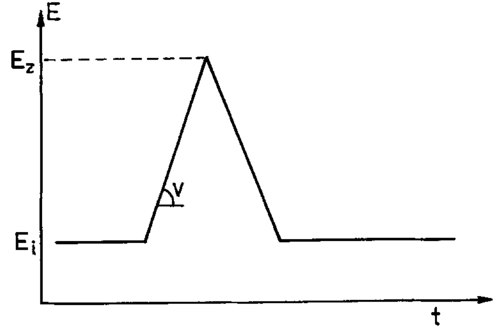

Fig. 3. Shape of the potential pulse applied. E_i, starting potential; E_z, reversal potential; $v = (dE/dt)$, sweep rate.

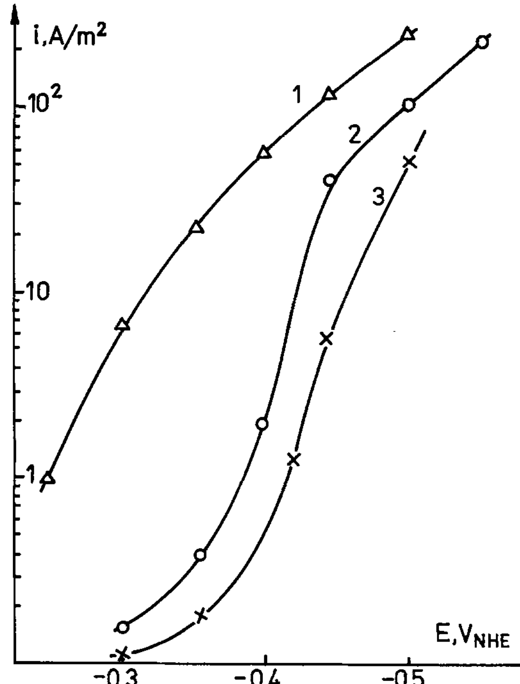

Fig. 4. Polarization curves for iron in 0.1*N* H_2SO_4. Curve 1, without As^{3+}; curve 2, with 10^{-5}M As^{3+}; curve 3, with 5×10^{-4}M As^{3+}.

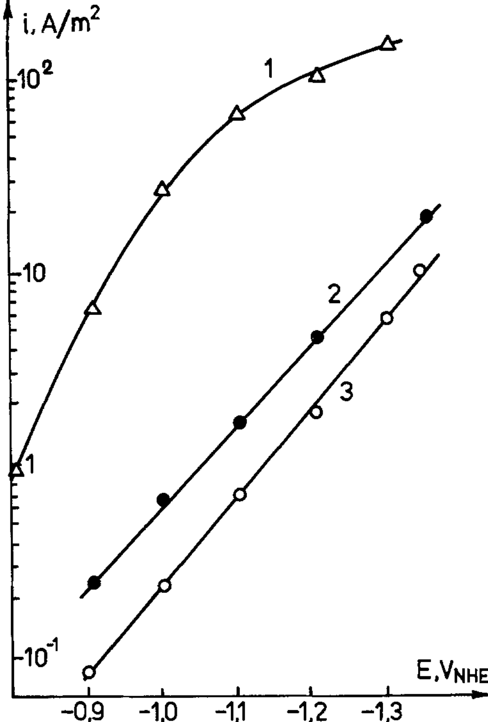

Fig. 5. Polarization curves for iron in 0.1*N* NaOH. Curve 1, without As^{3+}; curve 2, with 10^{-5}M As^{3+}; curve 3, with 5×10^{-4}M As^{3+}.

both solutions at 10^{-5}M than at 5×10^{-4}M As^{3+}. Also, higher permeabilities occur when iron is charged cathodically in acid than in alkaline solution. This fits in with the results found in Ref. (3 and 4).

Results of Perturbation Measurements

By recording the response of the hydrogen ionization current to the potential pulse one obtains *P-t* curves with maxima or minima, this being dependent on the direction of the pulse. As follows from theoretical considerations given above, the shape of the response curve, and especially the half-peak width,

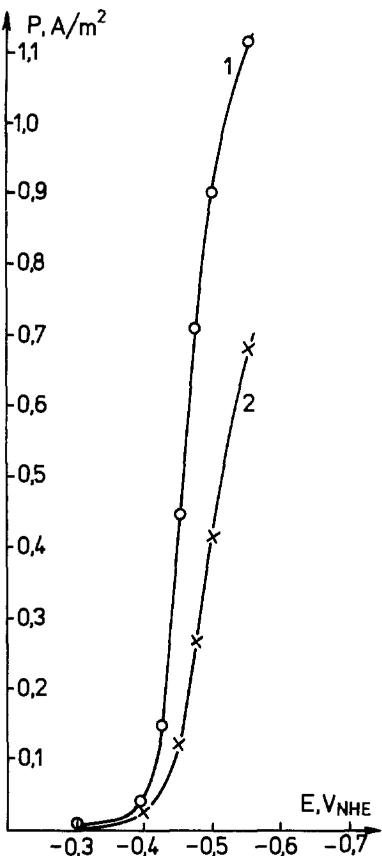

Fig. 6. Steady-state permeation rate vs. potential in 0.1N H_2SO_4. Curve 1, with 10^{-5}M As^{3+}; curve 2, with 5 $\times$ 10^{-4}M As^{3+}.

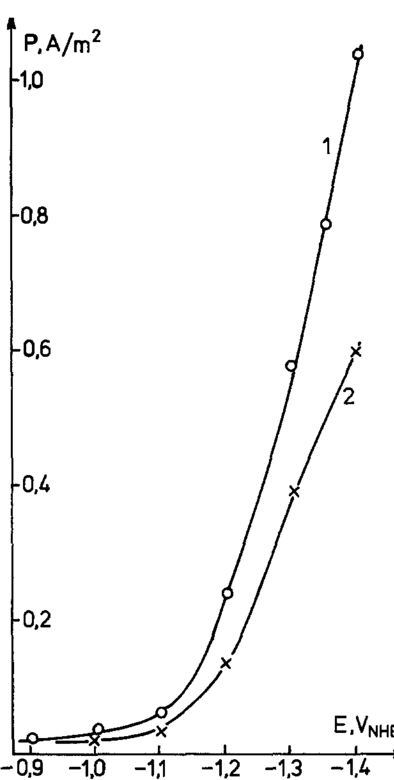

Fig. 7. Steady-state permeation rate vs. potential in 0.1N NaOH. Curve 1, with 10^{-5}M As^{3+}; curve 2, with 5 $\times$ 10^{-4}M As^{3+}.

permits conclusions to be drawn regarding kinetics of hydrogen extraction. Namely, if the removal of hydrogen were controlled by diffusion (condition 1), the dimensionless term

$$\Delta k_{P/2} = \frac{\pi^2 D}{L^2} \Delta t_{P/2}$$

would be equal to 1.4, whereas in the case of kinetic control (condition 2) this term would be equal to 4.3. By substituting $D = 8.3 \times 10^{-5}$ cm²/sec (6) and $L = 0.077$ cm one obtains for the diffusion controlled removal $\Delta t_{P/2} = 10.1$ sec and for the kinetically controlled removal 31.1 sec.

As shown in Fig. 8 and 9, in 0.1N H_2SO_4 + As^{3+} at E_z potentials less positive than 0.15 mV_{NHE}, and also in 0.1N NaOH + As^{3+}at E_z potentials more negative than −0.5 mV_{NHE} the time corresponding to the half-peak width is close to the value calculated for the kinetically controlled removal of hydrogen. At more anodic E_z potentials of the pulse wider peaks are observed.

Discussion

The above results indicate that the egress of hydrogen from iron exposed to As^{3+}-containing solutions is hampered by some kinetic impediments dependent on the electrode potential.

Let us consider electrode processes which might be thought responsible for these effects.

Both in 0.1N H_2SO_4 + As^{3+} and 0.1N NaOH + As^{3+}, at potentials at which, according to the previous results (7, 8), arsine occurs as a by-product of the hydrogen evolution reaction, the ingress of hydrogen into iron is accelerated (Fig. 6 and 7), but the egress of hydrogen from iron is restrained (Fig. 8 and 9). These effects are probably due to co-adsorption of arsenic hydride molecules or radicals with hydrogen

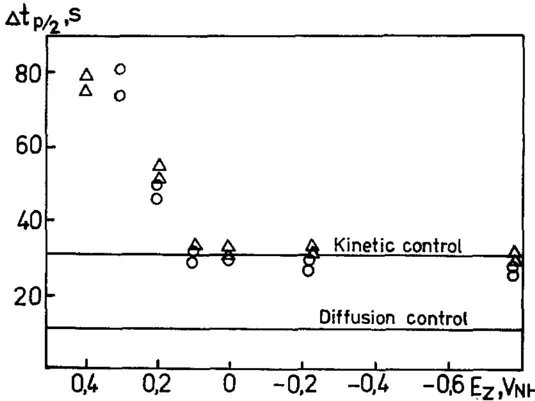

Fig. 8. Effect of reversal potential on width of half-peak of the ΔP-t curve for membranes polarized in 0.1N H_2SO_4. Circles, 10^{-5}M As^{3+}; triangles, 5 $\times$ 10^{-4}M As^{3+}.

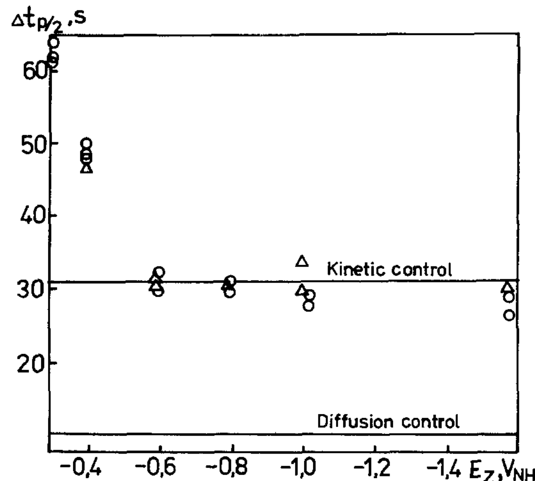

Fig. 9. Effect of reversal potential on width of half-peak of the ΔP-t curve for membranes polarized in 0.1N NaOH. Circles, 10^{-5}M As^{3+}; triangles, 5 $\times$ 10^{-4}M As^{3+}.

atoms at the metal surface. For some as yet unexplored reasons this promotes ingress of hydrogen into metal bulk and inhibits the reverse process.

At E_z potentials not exceeding $+150$ mV_{NHE} in $0.1N$ $H_2SO_4 + As^{3+}$ (Fig. 8) or -500 mV_{NHE} in $0.1N$ NaOH $+ As^{3+}$ (Fig. 9), the duration of the half-peak width is about 31 sec, which corresponds to the value calculated for the kinetically controlled removal of hydrogen from iron (condition 2). Within the above E_z potential regions the cathodic current density has been found to return to its initial value. As follows from Fig. 10 and 11, more positive (or less negative) potential pulses result in longer times necessary to restore the initial current density. The higher E_z the slower is the return of the cathodic current to its initial value. Slower restoration and higher time lags are observed in alkaline than in acid electrolytes.

These effects are probably due to a rapid desorption of the promoting species (arsine?), which occurs if a relatively high anodic potential pulse is applied, followed by a slow re-adsorption of arsenic and/or of some of its compounds, the rate of these processes being dependent on E_z.

Because a part of the experiments was performed under conditions under which the entry side of the membrane was submitted to anodic potential pulses, a detailed analysis was undertaken to check whether anodic reactions, such as oxidation of iron, of arsenic, or of hydrogen, could affect the cathodic current density after the pulse was applied. However additional measurements of chronovoltammetric curves have shown that electric charges consumed by these reactions are about 10^3 times smaller than those found in the main series of our experiments. This indicates that the effect of these oxidation reactions is negligible and that the desorption of the promoting species is responsible for the increase of the cathodic current density observed after application of the anodic pulse.

Conclusions

A pulse technique was used to study the removal of hydrogen from iron membranes whose one side was polarized cathodically in the presence of small amounts of As^{3+} in either $0.1N$ H_2SO_4 or $0.1N$ NaOH. In contrast with the results of Nanis and Namboodhiri (1), and others (2-4), who found that in pure (*i.e.*, As^{3+}-free) solutions the egress of hydrogen from iron at the polarized side of the membrane was unhampered and almost as rapid as the ingress of hydrogen into iron, the results of the present study indicated that As^{3+} added to the catholyte at a concentration of the order of 10^{-5}M caused a nearly complete interception of the egress of hydrogen from iron. Under these conditions almost all the hydrogen which entered into iron at the polarized side of the membrane diffused out through its other side.

It is suggested on the basis of the present and previous (7, 8) results that arsine produced in trace amounts during the cathodic process promotes the entry of hydrogen into iron and inhibits the reverse reaction. These effects are probably related to co-adsorption of arsenic hydride molecules or radicals with hydrogen atoms on the surface of the cathode.

LIST OF SYMBOLS

c_H	concentration of hydrogen in the metal
$C_H°$	concentration of hydrogen at the polarization side
c	nonstationary component of hydrogen concentration in metal
D	diffusivity of hydrogen in metal
E	electrode potential
E_i	starting potential
E_z	reversal potential
F	Faraday constant
i_c	cathodic current density
k	dimensionless parameter $= \pi^2Dt/L^2$
K_1, K_2	sums of series of Eq. [20] and [35]
L	membrane thickness
P	ionization rate of hydrogen at the diffusive side of membrane
ΔP	nonstationary component of P
s	Laplace transformation parameter
t	time
v	sweep rate
v_{in} and v_{eg}	rates of ingress and egress of hydrogen at the polarized side, respectively
Y	$\alpha[c]$
λ, μ	proportionality coefficients
$\delta(t)$	Dirac's delta function
$\Delta k_{p/2}$	half-peak width of K_1, K_2 *vs.* k curve
$\Delta t_{p/2}$	half-peak width of ΔP *vs.* t curve

Auger Analysis of the Passivation of Gadolinium by Electropolishing

A. J. Bevolo, B. J. Beaudry, and K. A. Gschneidner, Jr.

Ames Laboratory and Departments of Physics and Materials Science and Engineering, Iowa State University, Ames, Iowa 50011

ABSTRACT

A method of electropolishing has been developed at the Ames Laboratory which produces a shiny surface on gadolinium that remains untarnished for years at 20°C. Auger depth profiles have revealed the presence of a chlorine bearing layer on top of the native oxide after electropolishing with a chilled methanol-perchloric solution. Even though this passivating film is only a few monolayers thick it is continuous and stable for at least two years under room temperature air exposure.

Gadolinium metal does not turn completely into its oxide as the light rare earth metals do with extended exposure to air at room temperature, but it does tarnish so that within a period of weeks its original silvery metallic appearance is replaced by a darkened surface. At high temperatures >400°C gadolinium oxidizes more rapidly, exhibiting both linear and parabolic behaviors (1-4). A method of electropolishing has been developed at the Ames Laboratory (5) which produces a shiny surface on gadolinium which remains untarnished for years at 20°C. Auger electron spectroscopy was used in combination with ion beam sputtering to investigate the surface composition of electropolished gadolinium. We have been unable to find any Auger depth profiles of the native oxide of gadolinium in the literature. However, Farber and Braun (6) did investigate the effects of oxygen exposure up to 380 Langmuir (1L = 10^{-6} Torr-sec) on sputter-etched gadolinium.

A 1g sample was prepared from a batch of gadolinium metal which had the following impurities (all given in atomic parts per million): oxygen 2650, hydrogen 934, nitrogen 420, carbon 288, aluminum 8, silicon 8, chlorine 4, phosphorus 4, thorium <3, tantalum 2, copper 1, and zirconium 1. All other elements were below one ppm atomic. This sample was cut into two pieces with a low speed diamond saw. One piece was simply rinsed in acetone and no further treatment was done before its surface was analyzed. We call this the as-cut sample. The other piece was electropolished in a 6% perchloric acid solution in methanol held at −78°C and then rinsed in acetone.

The surface composition was analyzed by Auger electron spectroscopy in combination with ion beam sputtering to produce depth profiles. The Auger spectrometer utilized a Physical Electronics Incorporated Model 10-155 single pass cylindrical mirror analyzer with a coaxial electron gun. The electron beam had an energy of 3.0 keV with a total current of 10 μA into a spot size of about 50 microns and made an angle of 60° with the surface normal. The ion beam, which was produced by a 3M Minibeam I ion gun, was parallel to the sample normal and consisted of 2.5 keV Ar^+ ions at a current of 50 nA. The ion beam spot size was approximately 0.3 mm in diameter and it was rastered over a 2 × 2 mm^2 area. The vacuum chamber, with a base pressure of 5 × 10^{-10} Torr, was backfilled to 7 × 10^{-5} Torr argon gas during the Auger depth profiles.

Figure 1 shows an Auger depth profile of the as-cut gadolinium sample through the native oxide. This profile was taken within a few days after the surface was exposed by the diamond saw and it still retained its high metallic luster. The data shown in Fig. 1 are the peak-to-peak amplitudes of the first derivative spectrum of the Gd(138), O(510), Cl(181), and C(272) Auger transitions plotted *vs.* sputtering time. There is a very thin, low coverage chlorine layer at the very top of the sample surfa_e (near zero sputter time) followed by a thicker carbon layer and then by the native oxide layer. We estimate the native oxide layer to be 200Å thick. The oscillations in the Gd(138) signal for sputter times longer than 25 min are reproducible and represent lineshape changes that occur as one proceeds through the oxide layer.

Figure 2 shows an Auger depth profile of the electropolished gadolinium sample taken under the same experimental conditions as those used for the as-cut sample. The major difference between the two samples is the presence of a high density of chlorine in the layer on the very top surface of the electropolished sample. We estimate that this chlorine bearing layer is 10Å thick and represents tens of percent of the surface composition at its maximum concentration. The

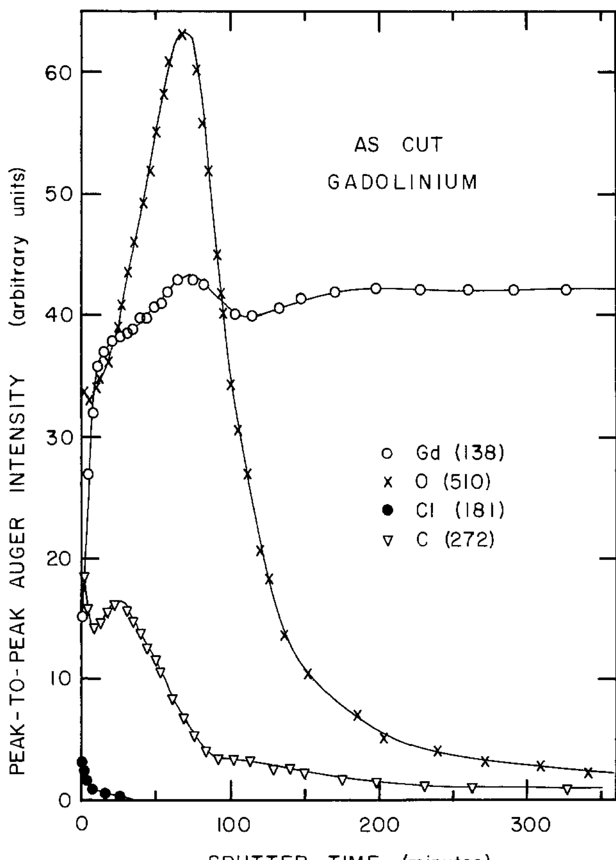

Fig. 1. Auger depth profile of the as-cut gadolinium sample

Key words: metals, electropolishing, AES.

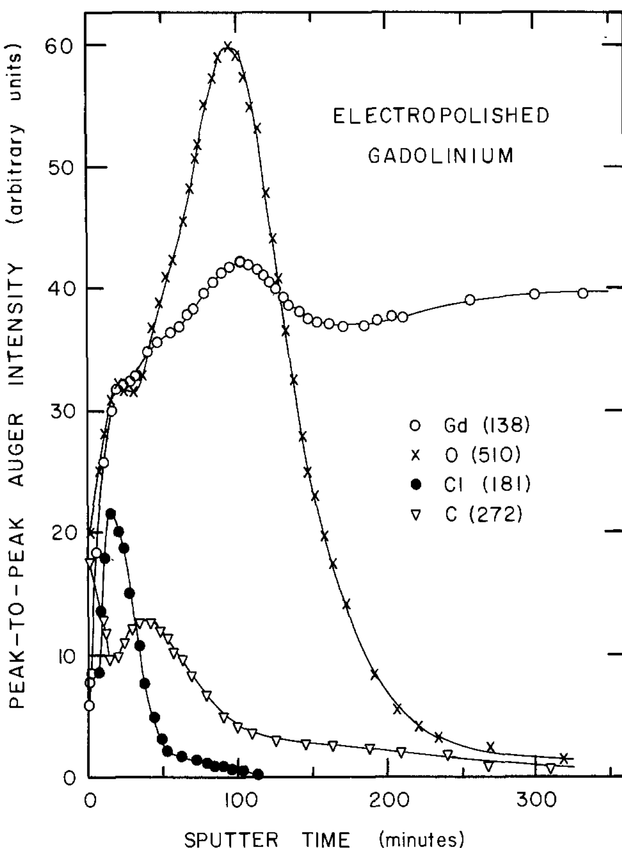

Fig. 2. Auger depth profile of the electropolished gadolinium sample with the chlorine bearing film occurring on top of the native oxide layer.

carbon and oxygen signals are nearly identical in both samples.

Both of these samples were Auger depth profiled again 22 months after their initial exposure to air. The electropolished sample had retained its high metallic luster (except at the site of the original ion bombarded area) while the surface of the as-cut sample had acquired a darkened surface coloration. Little change was found in the surface composition of the unsputtered electropolished sample. Specifically, the thickness and compositions of the chlorine, carbon, and oxygen layers remained the same. On the other hand the as-cut sample exhibited an oxide layer that was five times thicker than that originally observed for this sample.

The results of this investigation permits the following conclusions. The tarnishing of the as-cut gadolinium is due to a slow but progressive oxidation of its surface. Electropolishing in the chilled methanol-perchloric bath suppressed this continuous air oxidation by forming a passivating chlorine bearing layer on top of the native oxide. This passivating layer is probably a gadolinium oxychloride phase. Although only a few monolayers thick this passivating film is continuous and stable for at least two years under air exposure. Finally, it is concluded that the methanol-perchloric electropolishing provides a viable technique for preventing continuous oxidation of gadolinium and should provide a useful procedure for those investigating the optical properties of gadolinium.

ABSTRACT

Densities of porous anodic aluminum oxide coatings have been measured to range from 1.1 to 2.2 g/cm^3, values approximately 0.3-0.6 times those of bulk Al_2O_3. These measurements are obtained by using two independent techniques for determining film parameters, Rutherford backscatter (RBS) of MeV protons and alpha particles and optical or scanning Auger microscopy. The former gives areal densities in units of g/cm^2 and the latter two thicknesses in units of cm. Additional information on the composition of the films studied using ion-induced x-ray analysis simultaneously with RBS is: (*i*) the compositions are mainly Al_2O_3 with small amounts of SO_3 or CrO_3 for those anodic layers grown in H_2SO_4 or H_2CrO_4 electrolytes, respectively; (*ii*) sulfur is present as a contaminant in layers grown in H_2CrO_4 electrolytes; (*iii*) there is a reduction in the concentration of the alloying elements in anodized films grown on 7075 T-73 Al; (*iv*) atoms from the cathode are deposited on the film surfaces during anodization; (*v*) chlorine is present throughout the surface of alumina samples severely corroded in NaCl solutions.

The need to improve the corrosion resistance of aluminum parts and components is particularly important to naval applications in light of the corrosive salt-laden air and saltwater environments which are regularly encountered. The application of alumina coatings by anodization is one of the standard methods by which corrosion protection is provided. However, corrosion still occurs! Thus, there is a need to understand the corrosion process more fully in order to develop methods which may extend material lifetimes and reliability. In support of our metallurgical studies we have initiated a program of ion-beam analysis to investigate the composition and structure of anodized Al layers before and after exposure to corrosive salt environments. This investigation concentrates on the analysis of the composition of porous anodic oxide coatings which are obtained from chromic and sulfuric acid electrolytes. Although these coatings are softer and more porous than barrier-type anodic oxide films, they can be grown considerably thicker, and they can be sealed for added corrosion protection. These two characteristics have made them more desirable for naval applications.

Several ion beam and electron beam techniques are available for materials surface layer analysis. We have selected Rutherford backscattering spectroscopy (RBS) and positive ion-induced x-ray (PIX) techniques for this study. RBS allows in-depth profiling of relatively thick surface layers in which the stoichiometry for several material constituents are determined. Simultaneous PIX measurements permit specific elemental identification of high and middle atomic weight components in the film when RBS cannot uniquely determine the scattering atom because of limited mass resolution. This elemental identification is thus made on the same sample area used in the RBS analysis. In addition, trace element analysis is determined from the intensities in the x-ray spectra. Both techniques are nondestructive to the extent that removal of target matter by sputtering is negligible although areas the size of the beam diameter receive radiation damage.

Other techniques which are often used for surface analysis are secondary ion mass spectroscopy (SIMS), scanning Auger microscopy (SAM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). SIMS and SAM depend on the removal of target material by sputtering and hence destroy the target. They are often unreliable for the analysis of thick insulating targets such as the alumina layers studied here. In this case the charging of the insulating layer during sputtering can cause uncertainties in the measurement of the secondary ions emitted from the target. In addition, other uncertainties arise from the possibility of preferential sputtering rates from the components of a composite target, enhanced diffusion of the oxygen at the sputter site, or surface reoxidation during sputtering. SEM analyses are limited to thin surface layers while TEM techniques are limited to the study of thin self-supporting films. Moreover, TEM requires target destruction to produce specimens for study. The x-ray analysis associated with SEM (EDAX) has poor depth resolution. This drawback is also true for PIX, but EDAX is not as sensitive for trace element analysis as PIX because of the larger bremsstrahlung backgrounds encountered with electron beams.

Ion beam analysis has been used by various groups to study the growth of anodic films and the anodization process. RBS studies have been directed mainly to the determination of mobilities of ion implanted species during the anodization process (1-3). Investigations have also been made using SIMS to study the effects of ions in the growth of oxide layers (4). Those studies had been conducted mainly on thin anodic layers with areal densities of less than 0.05 mg/cm^2. The anodic films studied for this report had areal densities from 0.2 to 0.5 mg/cm^2.

The principal and unexpected result of this study has been the determination of film densities which are substantially less than previously reported. Whereas most density measurements are made from independent measurements of mass and volume, other techniques can be used. Independent measurements can be made of the areal density (units of g/cm^2) and thickness (units of cm) of the anodic oxide films. The density is then determined by dividing the former by the latter. In RBS measurements areal densities are determined directly from the energy difference of positive ions scattered from the front and back surfaces of a thin film and from the stopping power [units of energy/(g/cm^2)] for the projectile in the target material. The stopping power for the projectile in the anodized film is obtained from Bragg's

* Electrochemical Society Active Member.

Key words: corrosion, anodization, Rutherford backscatter, aluminum, anodization density.

rule by which energy loss is determined from the weighted average of the stopping power of the compound constituents. Since for high velocity protons this rule is valid to about 1% (5), differences between the stopping powers as determined for Al_2O_3 and an anodic film composed of the same proportions of Al and O are negligible. Independent measurements of film thicknesses are obtained directly from optical, SEM, or SAM techniques. The film densities obtained in this manner are approximately 0.3-0.6 times the density of bulk Al_2O_3 and are lower than densities of porous anodic oxide films reported by others (6, 7). This lower density is not consistent with the 15% porosity of the films grown.

Although information concerning chemical binding and composition is not obtainable in the ion beam analysis techniques used here, we are able to obtain general information on the stoichiometry of the anodic films. Results for the atomic composition of the films including pickup of the anions from the electrolyte, the reduction of the alloying elements of the bulk Al, and the presence of surface impurities from both the electrolyte and the cathode are reported.

Experimental Approach

Ion beams from NAVSWC's 2.5 MV Van de Graaff accelerator were used for the materials analysis. The backscatter spectra were obtained using both incident protons and ^4He ions. The protons have the advantage that their lower stopping power allows the analysis of thicker samples and in the targets studied here more clearly marks the interface between the anodic layer and the bulk Al. Helium has the advantage of better mass resolution for making stoichiometric determinations at the surface. The incident particles were collimated through 1.0 mm apertures and passed through an annular surface barrier detector which detected the particles after being scattered through 178.4°. In addition to the Rutherford backscattering measurements, the x-rays produced by these beams were simultaneously analyzed. The x-rays were detected by an Si(Li) x-ray detector with a 196 eV resolution of an ^{55}Fe source. It was mounted at 90° to the beam direction. The x-rays were collimated with a 2.5 mm aperture placed directly in front of the 25 μm Be detector window. In order to reduce the intensity of the low energy x-rays from the Al a 100 μm polyethylene absorber was placed in front of the window. The use of this absorber allows greater sensitivity for trace element analysis of elements with atomic number greater than Al but a considerably lower sensitivity for elements with atomic number less than Al. Both the backscatter spectra and the x-ray spectra were recorded simultaneously on a multichannel analyzer.

Anodic samples were prepared from both 7075 T-73 commercial Al and Marz grade (99.9995% pure) Al. In preparation for anodization all samples were polished mechanically with 600 grit SiC. They were then washed and rinsed in acetone or alcohol, etched for 30 sec in Keller's etch ($HF + HNO_3 + HCl$), and finally washed in deionized water. The anodization conditions given in Table I produce films which are approximately 2 μm thick with a porosity of approximately 15% (8).

Thickness measurements were obtained using three methods, optical, SEM, and SAM. Although these measurements destroy the specimen, it was possible to correlate the thickness obtained with these methods using samples prepared under identical conditions. The optical and SEM thickness measurements were made from an edgewise cross section of the anodized layer. The sectioning was done by carefully sawing the sample perpendicular to the surface with a slow speed cutoff wheel. The samples were then mounted in a room temperature curing epoxy containing alumina particles and polished metallographically for edge retention. The film thicknesses from the SAM measurements were obtained by knowing the sputter rate in Å/min and the elapsed time at which a sharp increase in the Al concentration occurred. This increase is due to the increased Al concentration at the alumina/aluminum interface. The film thicknesses in both methods are measured in units of length.

Table I. Anodization conditions to produce ~2 μm films. The anodic films were grown on 7075 T-73 and 99.9995% pure Al

Sample	Electrolyte	Voltage (VDC)	Time (min)	Current density (A/m²)	Cathode
7075Al	H_2SO_4	13.5	4	130	Stainless steel
7075Al	H_2CrO_4	40	55	130	Pb
Pure Al	H_2CrO_4	40	55	130	Pb
Pure Al	H_2CrO_4	40	55	130	Pt

Results and Discussion

A typical energy spectrum of 1.0 MeV protons scattered from pure Al anodized in H_2CrO_4 electrolytes is shown in Fig. 1. The position of the front surface of the anodized layer and the Al_2O_3-Al interface can be identified from the energies of the protons scattered from both the aluminum and the oxygen. These energies are indicated in Fig. 1. Computer analyses by Niiler (9) were made on this spectrum and on a spectrum obtained from the same target with ^4He projectiles. Using a computer program by which film parameters are varied to reproduce the measured spectra, he obtained good fits to the data for a film 0.34 mg/cm² thick. The Bragg rule was used to determine the stopping power. The thickness measured optically with a microscope at 800× magnification is 2.3 μm. The average film density must be 1.5 g/cm³ for these two measurements to be consistent. This value is considerably lower than the density of bulk Al_2O_3 (3.5-3.9 g/cm³) and the densities of alumina layers measured by others. Similar RBS studies by Bauer and Muskett (3) on anodic films produced in an aqueous solution of CP ammonium nitrate show that 48.4 μg/cm² films have a thickness of 1300Å. The resulting density of 3.72 g/cm² agrees with the bulk values. However, the film thus produced is a barrier-type film which is expected to be more dense than the porous films studied here.

Similarly, we determined densities of other films using proton RBS coupled with optical, SEM, or SAM measurements on the same alumina layers. The alumina films were made from 99.9995% pure or 7075

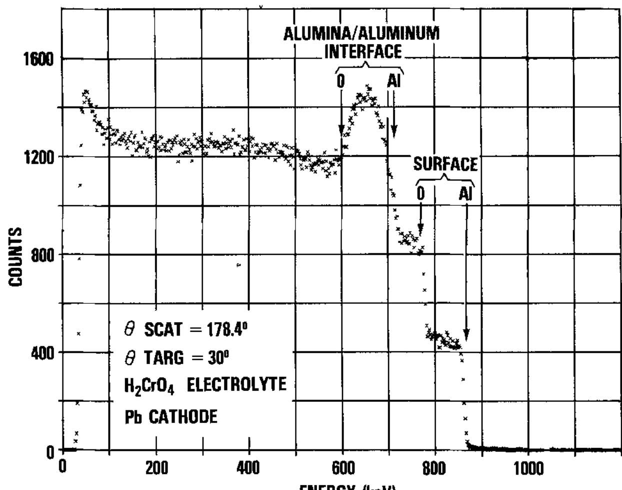

Fig. 1. Energy spectrum of 1.0 MeV protons RBS from 99.9995% pure Al anodized at 40 VDC in an H_2CrO_4 electrolyte for 55 min. Features due to scattering from O and Al at the front surface and at the alumina/aluminum interface are identified. The areal density is determined from the energy difference from scattering from the O or the Al at the front surface and at the interface and from proton stopping powers in Al_2O_3.

T-73 Al anodized in H_2CrO_4 or H_2SO_4 electrolytes. The results of the density measurements are given in Table II. The densities range from 1.1 to 2.2 g/cm^3. In those cases using 7075 Al two samples were made under similar conditions of current density, voltage, electrolyte concentration, electrolyte temperature, and target preparation (see Table I). One was then sealed in boiling water for 10-20 min. The densities of the sealed films are lower than those of their companion unsealed films although the differences obtained for those prepared in the H_2CrO_4 electrolyte are within the experimental error. The densities obtained for those samples whose thickness is determined optically and by SEM are more accurate than those for which SAM was used. We estimate an error in thickness of about 15% for the optical measurements and about 20% for SAM. For the measurement of the areal density using RBS we use the Bragg rule to obtain the proton stopping power for Al_2O_3 in which the stopping powers for aluminum and oxygen are given by Andersen and Ziegler (10). The resulting stopping powers are accurate to within 10%. Thick target calculations as described by Foti *et al.* (11) were followed. The determination of the energy differences for protons scattered from the front and back surfaces of the alumina films are also accurate to approximately 10%. The densities of the alumina layers as obtained from the RBS/optical combination have an error of 20% while those using the RBS/SAM combination have a 25% error. We determined these errors by accumulation in quadrature .The RBS measurements were made at three proton energies; 1.0, 1.2, and 1.4 MeV. The targets at three different tilt angles to the incident beam; 0°, 30°, and 45°. The film thickness for individual targets was found to be the same within experimental error for all angles and beam energies. Since the film thickness scales with angle, the pore size must play an insignificant role in these measurements.

An advantage of the ion beam studies described here is that they quickly yield a variety of information which ordinarily may require separate measurements to obtain. Thus, in addition to the average film densities, information concerning the surface stoichiometry and the presence and qualitative distribution of trace elements is obtained. To determine surface stoichiometry RBS spectra using ^4He ions are used since better mass resolution and more accurate scattering cross sections are available. Typical spectra from 2 MeV ^4He scattered from alumina layers produced from anodized pure Al in an H_2CrO_4 electrolyte are shown in Fig. 2. A Pb cathode was used during anodization From the features of these spectra O, Al, S, Cr, and probably As can be readily identified to be on the surface of the samples. In addition traces of a high-Z material are seen, probably Pb from the cathode. The surface composition of the constituents of these samples was obtained using standard calculational tech-

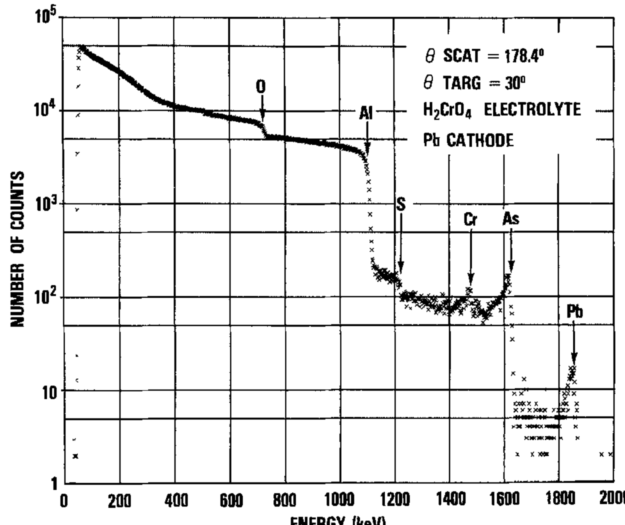

Fig. 2. Energy spectrum of 2.0 MeV ^4He RBS from 99.9995% pure Al anodized in an H_2CrO_4 electrolyte. The identified elements appear at the front surface. The sample was anodized with a Pb cathode.

niques with Rutherford scattering cross sections and He stopping powers of Ziegler (12). The atomic fractions determined from these spectra along with those for other samples which will be discussed below are given in Table III. The computer analysis of Niiler (9) indicates that the Cr distribution is approximately uniform throughout the alumina film. The As and Pb appear as thin layers on the surface; their thickness is difficult to determine since the energy width is within the resolution of the detection system. Similar results are obtained for the films anodized in an H_2CrO_4 electrolyte using a Pt cathode instead of a Pb cathode.

The x-ray spectra obtained from this target by 1.2 MeV protons is shown in Fig. 3. This spectrum confirms that the feature which was attributed to As in the RBS spectra is indeed As, in addition to corroborating the existence of Al, S, and Cr in the target. The x-ray spectra from the films made with a Pt cathode also show x-rays from trace amounts P and Cl; the origin of these impurities is not known.

The anodized 7075 Al samples were corroded potentiostatically in 3.5 weight percent NaCl solutions. In those cases in which a small amount of corrosion occurred as indicated by the potentiostatic measurements, there was no appreciable change in the backscatter spectra. At this early stage of corrosion it is not possible to determine the corrosion site from the RBS spectra. The x-ray spectra, however, show the addition of Cl to the sytsem. In the case of extreme corrosion, as observed visually by deep pits into the anodized layer, the uptake of Cl into the surface is

quite apparent both from the RBS spectra and the x-ray spectra as shown in Fig. 4 and 5, respectively. The proton RBS spectrum of these heavily corroded samples no longer shows the existence of a thin alumina layer on a bulk aluminum substrate. Instead, the appearance is that of a bulk target containing O, C, Al, Cl, and the alloying additives of 7075 Al. All of these constituents appear to be uniformly distributed with regard to depth into the target.

Conclusions

The density of various porous aluminum films has been measured with values ranging from 1.1 to 2.2 g/cm^3. These values are based on a combination of film thickness determinations using RBS with optical or SAM measurements. The densities obtained in this study are substantially lower than those which are based on Archimedes Principle. For instance, in studies by Mason (6) the mass and volume of alumina films are obtained from differences of mass and volume measurements made of alumina films on their aluminum substrates and from the aluminum substrates after the films had been stripped off. These measurements thus based on Archimedes Principle are obtained from the ratio of numbers each of which is a small difference of large numbers. The measurements reported here are made more directly from the alumina films *in situ*. Since the beam diameter of 1.0 mm is considerably larger than the size of the pores in these samples, the densities measured are averaged over many cell diameters. The thickness obtained by the RBS measurements scale with target angle with respect to the incident beam; hence the layers cannot have large porosity. The films studied here have approximately 15% porosity (8). Thus, it is concluded that the lower densities reported here are not accounted for by the porous nature of the films. The errors in the density which were determined from the optical thickness is about 20% while the errors for those determined from the SAM thickness was larger (approximately 25%) due to reduced accuracies in the SAM measurement.

The surface compositions of representative samples analyzed by ^4He RBS are given in Table III. The values of the ratio of the atomic fraction of O to Al are greater than the expected value of 1.5 for Al_2O_3. Our measurements on thin evaporated Al_2O_3 samples yield the proper ratio of O:Al. Thus, there is a larger fraction of oxygen in the anodized layers than expected from

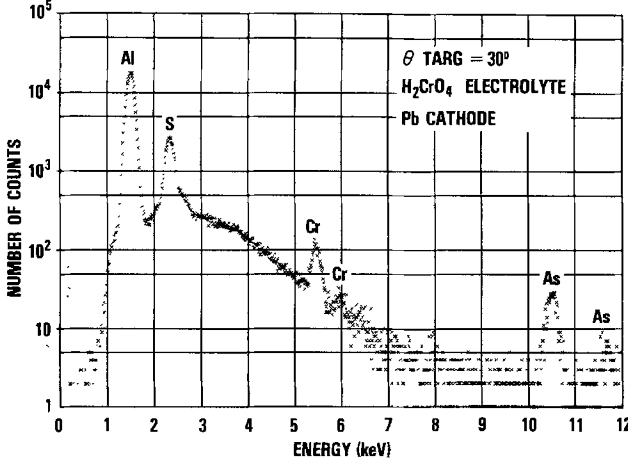

Fig. 3. X-ray spectrum induced by 1.2 MeV protons from pure Al anodized in an H_2CrO_4 electrolyte. The sample is the same one as shown in Fig. 2.

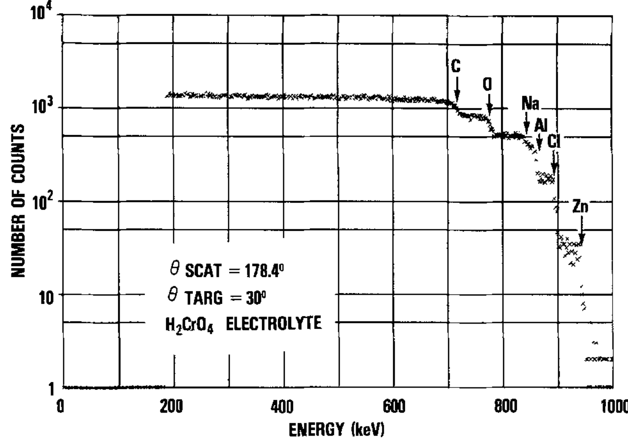

Fig. 4. Energy spectrum of 1.0 MeV protons RBS from anodized 7075 Al which had been heavily corroded in a 3.0 w/o NaCl solution. The identified elements appear at the target surface and are apparently distributed uniformly into the target to depths comparable to the proton range.

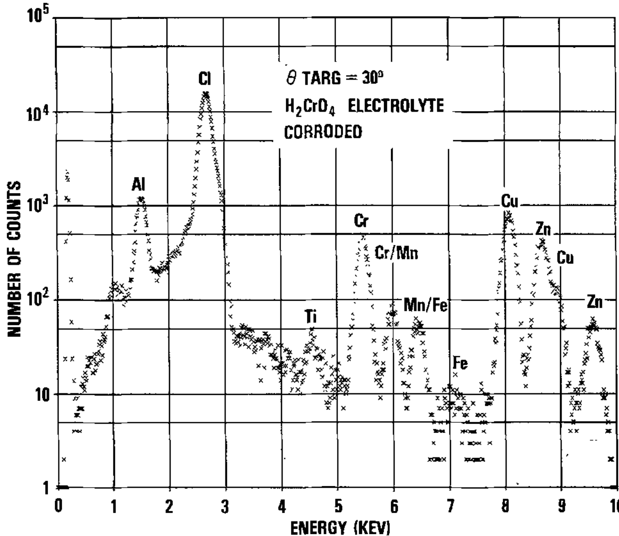

Fig. 5. X-ray spectrum induced by 1.0 MeV protons on the same target as shown in Fig. 4.

pure Al_2O_3. Sulfur and chromium are also picked up into the alumina layers from their respective electrolytes. Their depth distribution appears to be uniform throughout the alumina layer. This result is in general agreement with those found by other methods (13). The amount of oxygen in excess of that needed to form Al_2O_3 is in the proper proportion for combination with the S (or Cr) in the films in the form of SO_3 (or CrO_3) anions. The films are thus composed mainly of Al_2O_3 with the addition of SO_3 (or CrO_3) anions from the electrolyte. This result is in agreement with those found by other methods (13). Additional conclusions on the composition of these films obtained from this analysis are: (*i*) There is a reduction of the atomic fraction of the alloying additives in the anodic layers by a factor of 5-10 as compared with those in the bulk aluminum. This value is obtained from the backscattering measurements on the concentration of the Zn additive and x-ray measurements which show that the relative x-ray production between the Zn and the other additives is the same in the alumina layers as in 7075 aluminum. This study does not indicate whether these additives are transported into the electrolyte or into the bulk aluminum during the growth of the oxide layer. From the ion implantation studies of Mackintosh *et al.* (1) and Towler *et al.* (2), it is more likely that they accumulate at the alumina/aluminum interface with some fraction being transported across the barrier interface as the layer growth continues. This model qualitatively accounts for a lower atomic fraction in the alumina layer.

(*ii*) The alumina layers also contain S which is present primarily when Pb (and to a lesser extent Pt) cathodes are used with H_2CrO_4 electrolytes. The atomic fraction is less by an order of magnitude from that when H_2SO_4 electrolytes are used.

(*iii*) Lead or platinum atoms from their respective cathodes are also transported to the anode surface (see Table III). The mechanism of transport for both S and the cathode atoms is not clear from this study.

(*iv*) Chlorine is picked up into the alumina layer after it has been corroded potentiostatically in an NaCl solution. In the cases of light corrosion (invisible to the eye), the addition of Cl is only apparent from the x-ray measurements, and it is not possible to determine its location from the RBS measurements. However, in the case of extreme corrosion, the structure of the alumina layer appears to be destroyed and Cl (10 atomic percent in the sample illustrated in Table III) is seen to extend from the surface of the corroded sample into the bulk Al. The proton RBS spectra indicate the removal of the alumina layer from the surface of the aluminum substrate and the incorporation of Cl into the aluminum to depths which are beyond the RBS analysis of protons (approximately 2-3 μm).

Acknowledgments

The authors would like to express their thanks to F. Rider for his work in preparing the anodized samples and to P. Cady for his assistance in taking the data. We are particularly thankful to Dr. A. Niiler, Army Ballistic Research Laboratory, for his computer calculations on the RBS spectra. The SAM measurements were made at the Naval Weapons Support Center, Crane, Indiana. This work was supported in part by the Naval Surface Weapons Center under the Independent Research Program and in part by NAVAIR Project No. SF54592.

Manuscript submitted March 10, 1980; revised manuscript received *ca.* July 15, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the Naval Surface Weapons Center.

The Chemical Nature of Aluminum Corrosion

III. The Dissolution Mechanism of Aluminum Oxide and Aluminum Powder in Various Electrolytes

T. H. Nguyen and R. T. Foley*

Department of Chemistry, The American University, Washington, D.C. 20016

ABSTRACT

Attention was focused on the first steps in the pitting process, the adsorption of aggressive anions and the dissolution of aluminum oxide. The adsorption of chloride on alumina and aluminum powder are quite similar and show a saturation plateau at high chloride concentration; the amount of chloride adsorbed is proportional to the weight of alumina. The amount of "free" aluminum ions dissolved from alumina is inversely proportional to the chloride concentration while the amount dissolved from aluminum powder appears to be independent of chloride concentration. Nitrate ion is reduced by aluminum metal but not by alumina. Alumina will greatly reduce the amount of "free" aluminum in solutions of $AlCl_3$, $Al(NO_3)_3$, and $Al_2(SO_4)_3$. These results support the idea that the first steps in aluminum pitting in aggressive solutions involve adsorption of the anion on the oxide film followed by chemical interaction to form a soluble species resulting in a thinning of the film and direct contact with the metal surface.

It is universally accepted that the exceptional corrosion resistance of aluminum depends to a great extent on the oxide film which is formed on its surface (1). When a fresh aluminum surface is exposed to air, it oxidizes rapidly (2), and, as a result, a compact, adherent protective film of aluminum oxide (alumina) is formed. In aqueous solutions, surface layers, which for the greater part consist of crystalline hydrates of alumina, are developed (3). Aluminum oxide is relatively inert chemically, and it is on this inactivity that the passive behavior of aluminum depends (4). If the oxide film dissolves, the metal corrodes uniformly and Lorking and Mayne (5, 6) have shown that corrosion was associated with the initial rate of solution of the anhydrous oxide. On the other hand, when the film is damaged under conditions that prevent normal self-repairing, localized corrosion ensues (7).

Pitting is one type of localized corrosion which appears on a metal surface that otherwise shows a very low dissolution rate. Its importance in the corrosion of aluminum, in particular, has been manifested by a number of investigations by various workers on this subject (8-10). Several explanations or theories have been proposed for the breakdown of the passive film (11, 12). However, there is not as yet a unanimously recognized explanation with respect to the mechanism by which an oxide film loses its protective character.

It has been postulated (13) that the initiation of pitting of aluminum in halide solutions proceeds in four consecutive steps, (*i*) the adsorption of the aggressive anion on the oxide film; (*ii*) the chemical reaction of the adsorbed anion with the Al^{+++} in the oxide lattice

$$Al^{+++} \text{ (in } Al_2O_3 \cdot nH_2O \text{ lattice)} + Cl^- \rightarrow Al(OH)_2Cl$$

or

$$Al^{+++} \text{ (in } Al_2O_3 \cdot nH_2O \text{ lattice)} + 2Cl^- \rightarrow Al(OH)_2Cl_2^-$$

the lower stoichiometric number (one or two) applicable to neutral solution; (*iii*) the thinning of the oxide film by dissolution, (*iv*) the direct attack of the exposed metal by the aggressive anion with the formation of transient complexes which rapidly undergo hydrolysis

$$Al^{+++} + 4Cl^- \rightarrow AlCl_4^-$$

$$AlCl_4^- + 2H_2O \rightarrow Al(OH)_2Cl + 2H^+ + 3Cl^-$$

* Electrochemical Society Active Member.
Key words: corrosion, films, oxidation.

In this mechanism the chemical properties of aluminum oxide proper, as distinguished from oxide-covered aluminum, assume major significance in the overall aluminum pitting reaction. The purpose of the present work is to investigate the reactivity of aluminum oxide toward an aggressive environment and compare it to the behavior of purified aluminum powder subjected to the same treatment.

Experimental

Adsorption-type alumina (Fisher A-540, Chromatographic grade α-Al_2O_3, 80-200 mesh) and purified aluminum powder (Apache Chemical, 0093) were used throughout this work. Solutions were prepared with water doubly distilled from a quartz still and salts of reagent grade.

In a typical experiment, 100 ml of a salt solution was mixed with 10g of alumina or aluminum powder in a 150 ml flask. The mixture was shaken several times at constant intervals and then allowed to stand and settle for a fixed time (16 hr). The supernatant liquid was then filtered and analyzed for the presence of aluminum ions in solution. The quantitative analysis of aluminum ions was done spectrophotometrically with Eriochrome Cyanine-R as a dye reagent at the wavelength of 530 nm (14). This method is accurate to better than 6% in the absence of iron or manganese and the sensitivity is up to 1 μg per 50 cm^3 of solution. The concentration of chloride anions before and after adsorption was determined by the Mohr method with sodium dichromate as an indicator. At 25°C the sensitivity of $4 \times 10^{-5}N$ silver is equal to the indicator blank. This corresponds to an excess of 0.08 ml of 0.1*N* silver nitrate in the titration of 100 ml of 0.1*N* NaCl or to an error of 0.08%. In our titration, an amount of 0.1 ml is subtracted from the volume of $AgNO_3$ read on the burette in order to account for the indicator correction. The reported concentration of chloride adsorbed is an average value of three different sets of NaCl solution. It is observed that the difference in the amount of chloride adsorbed between two different runs is around 10%.

Results and Discussion

Adsorption isotherm of chloride.—The uptake of chloride as a function of solution concentration is shown in Fig. 1. The plot in Fig. 2 shows that the amount of chloride adsorbed from a solution of 1*N*

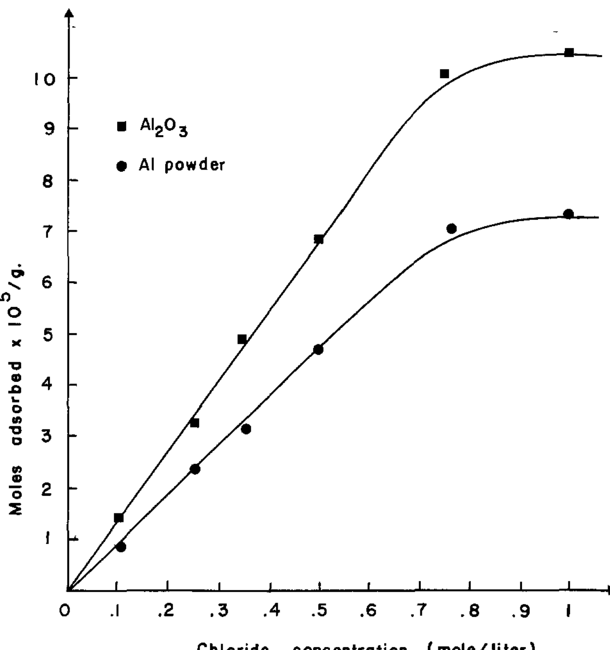

Fig. 1. Adsorption isotherm (24° ± 1°C) of chloride on alumina, ■, on purified aluminum powder ●.

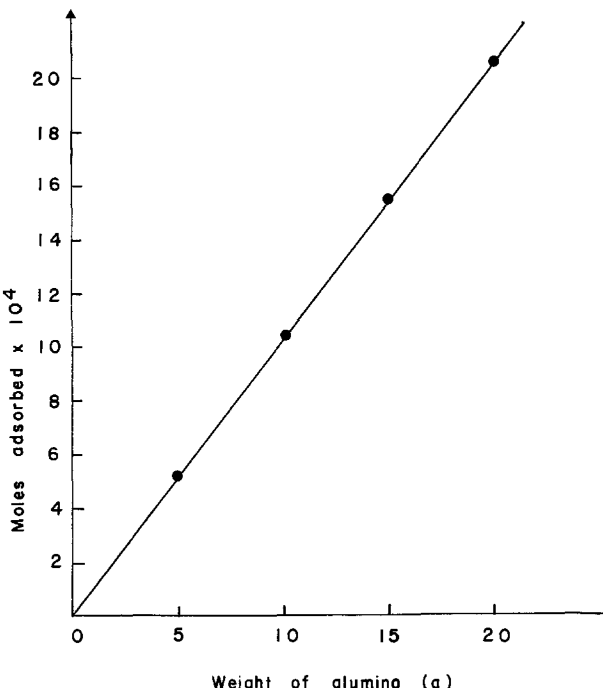

Fig. 2. Adsorption of chloride as a function of weight of alumina (24° ± 1°C).

NaCl varies linearly with the weight of alumina present. It can be seen that the adsorption isotherm of chloride on aluminum oxide and on aluminum powder are quite similar. At low concentration adsorption is linear with concentration and, at high concentration, reaches a plateau on which adsorption is independent of concentration. These adsorption isotherms resemble characteristic Langmuir type isotherms but the mechanism must be different from that encountered in conventional chemisorption experiments involving ions on solid substrates which yield monolayers. First, is the question of available surface area. The "surface area" of the alumina or aluminum powder has no significance in the conventional sense, as established, for instance, by a BET measurement. In contact with an aqueous solution the powder will hydrolyze to give a number of equilibrium and nonequilibrium species. These systems have been studied in some depth by Smith (15) who classifies the types of aluminum species as follows: Al^a as monomeric species, Al^{+++}, $Al(OH)^{++}$, $Al(OH)_2^+$, and $Al(OH)_4^-$; Al^b as polynuclear material containing 20-100 Al atoms; Al^c as large, solid $Al(OH)_3$ particles.

Thus, the "surface" of the powder must be seen as a dynamic, reacting system. An individual particle would very rapidly lose its original shape and surface area. The second important difference is the achievement of equilibrium. It has been established (15) that true equilibrium in these aluminum oxide systems is only achieved after several months or several years. The time frame in which we are working is that of a typical corrosion experiment that covers a few days or weeks. This means that the plateaus in Fig. 1 represent an approximate steady-state condition in which the particle interface is saturated with the product of the reaction between adsorbed chloride and aluminum oxide.

The initial surface charge on alumina is positive as shown by electrophoresis measurements and flocculation by a negatively-charged gold sol (15). The point of zero charge or the isoelectric point is about 8.9-9.2 and seems to be independent of the type of alumina in the absence of some drastic prior treatment being given the compound (16, 17). Table I shows the pH change of the solution before and after adsorption. The final pH in the chloride solution containing alumina is very close to the reported isoelectric point for alumina. The pH of the chloride solution in contact with the aluminum powder is approximately 8.0 independent of the chloride concentration. In the absence of chloride the pH is higher; approximately 10, but potentials of zero charge this high have been observed before and assumed to be caused by the adsorption of monomeric species (Al^a-type).

Solubility of aluminum oxide and purified aluminum powder.—The concentration of dissolved aluminum ions in solution from alumina and aluminum powder in the presence of different aggressive aqueous environments is reported in Table II and III. This analysis measures "free" aluminum, *i.e.*, such species as Al^{+++}, $Al(OH)^{++}$, and $Al(OH)_2^+$, but not aluminum tied up as a complex polymer with unit structure $[Al(OH)_2Cl]$. The concentration of such aluminum in H_2O solution is highest in the absence of electrolyte.

Table I. pH values of different test solutions before and after adsorption

Solution	Initial pH	Final pH in Al_2O_3	Final pH in Al powder
0.1*N* NaCl	6.5	9.1	8.0
0.5*N* NaCl	5.9	8.9	8.0
1.0*N* NaCl	6.0	8.8	7.8
1.0*N* Na_2SO_4	6.2	9.7	7.7
1.0*N* $NaNO_3$	6.7	8.9	12.3
1*N* NaCl + 0.01*N* $AlCl_3$	4.1	7.4	4.5
1*N* NaCl + 0.01*N* $Al(NO_3)_3$	4.1	7.8	4.5
H_2O	6.9	10.3	9.8

Table II. Amount of aluminum ions dissolved in 100 ml of different NaCl concentration solutions

Concentration of NaCl	Aluminum powder (10g)	Alumina (10g)
1.00*N*	41 ± 2 μg	231 ± 14 μg
0.75*N*	54 ± 3 μg	258 ± 15 μg
0.50*N*	65 ± 4 μg	322 ± 19 μg
0.35*N*	54 ± 3 μg	358 ± 21 μg
0.25*N*	54 ± 3 μg	433 ± 28 μg
0.10*N*	67 ± 4 μg	476 ± 28 μg

Table III. Amount of aluminum ions dissolved in 100 cm^3 of different salt solutions

Solution	Al powder (10g)	Alumina (10g)
H_2O	247 ± 15 μg	1245 ± 74 μg
1N $NaNO_3$	NH_3 formation	230 ± 14 μg
1N Na_2SO_4	169 ± 10 μg	308 ± 18 μg
1N NaCl + 0.01N $AlCl_3$ (8.28 mg Al^{3+})	14.00 ± 0.84 mg	329 ± 20 μg
1N NaCl + 0.01N $Al(NO_3)_3$ (8.30 mg Al^{3+})	8.75 ± 0.52 mg	540 ± 32 μg
1N NaCl + 0.02N $Al_2(SO_4)_3$ (16.85 mg Al^{3+})	19.16 ± 1.15 mg	211 ± 12 μg

At different concentrations of NaCl it is found that the apparent solubility of aluminum ions from alumina decreases with increasing concentration of NaCl. On the other hand the concentration of aluminum ion in solution from aluminum powder does not seem to follow any particular pattern and is practically the same regardless of the concentration of NaCl present. In the presence of water, aluminum oxide will undergo hydration and when chloride anions are available, the positive surface charge will attract chloride to forn a soluble complex of the type $Al(OH)_2Cl_2^-$ (18). With increasing chloride concentration the amount of chloride adsorbed increases. On the other hand, with increasing chloride concentration, the amount of "free" aluminum ion decreases. This suggests that the hydroxy-chloride species formed is a relatively stable species and probably remains attracted to the aluminum oxide lattice. This interaction is much more pronounced in the mixture with aluminum powder because of a possible reaction with the underlying aluminum metal.

Nitrate reaction.—Sodium nitrate has a surprising effect on aluminum powder. When a solution of $NaNO_3$ is brought in contact with aluminum powder, the formation of ammonia can be recognized after 16 hr. Upon shaking the suspension vigorously, the formation of NH_3 is quickly accelerated and within a few minutes, the heat generated by the reaction brings the whole solution to complete ebullition. Since there is no such formation of NH_3 in the case of alumina, it is concluded that NH_3 is the product of the chemical reaction between NO_3^- and the underlying aluminum metal.

It is known that nitrate is reduced by elemental aluminum in alkaline solution (19)

$$8Al^\circ + 3NO_3^- + 5\,OH^- + 18H_2O \rightarrow 8Al(OH)_4^- + 3NH_3$$

Alternately, NO_3^- can be reduced to NH_3 by nascent hydrogen, usually zinc and caustic soda is used (20). The reduction potential for the couple NO_3^-/NH_4^+ is only 0.47V (21).

In order to confirm the chemical role of the nitrate anion, a 0.5M solution of aluminum nitrate was mixed with aluminum powder. After 40 days of contact with regular shaking, there was still no perceptive odor of ammonia. However, when the mixture was shaken very vigorously for a while, the NH_3 odor became noticeable within the next day. And, after a few days, the aluminum powder was almost completely dissolved and a milky white precipitate was formed. The grinding process and perhaps even the abrasion between particles caused by the energetic stirring motion of the mixture will remove any protective film from the film surface and thus allow the reduction of NO_3^- by the suddenly unprotected aluminum metal. Whatever the mechanism, the reduction of NO_3^- to NH_3 is taken as evidence that the electrolyte is, at that point, in direct contact with the metal surface.

Adams, Foley, *et al.* (22, 23) have reported the formation of NH_3 in the accelerated corrosion of aluminum alloys 2024 and 7075 by certain mixtures of chloride and nitrate. It was concluded that the presence of Cu or Zn as alloying elements was necessary perhaps by the formation of a local alkaline cathodic site. Aluminum alloy 1199, which is essentially pure aluminum, does not exhibit the synergistic effect in which chloride promotes the dissolution of the film. Moreover, the existence of specific concentrations and anion ratios in which corrosion is accelerated is likely due to a competitive reaction between nitrate and chloride anions on the aluminum oxide leading to a formation of an inert (nitrate case) or labile (chloride case) hydrolyzed aluminum species. If the anion ratios are in favor of the formation of a labile complex, the synergistic effect will likely occur unless the nitrate anion present is too small. On the other hand, if there is a predominant formation of an inert complex at the surface to block the Cu or Zn reaction site, the synergistic effect will not be observed.

Mixtures of NaCl and aluminum salts.—The mixture of 1N NaCl with various aluminum salts has some interesting effects on the dissolution of alumina and aluminum powder. Table III shows that when a mixture of 1N NaCl and aluminum salt is in contact with alumina, the concentration of "free" aluminum ions in solution decreases considerably compared to the initial amount present. For example, the $AlCl_3$ solution contained 8.28 mg Al^{+++} initially in the 100 ml volume. After reaction with alumina the concentration dropped to 329 μg. Similar results were obtained with aluminum nitrate and aluminum sulfate. It was also observed that after the reaction ensued a heavy gelatinous precipitate was developed. On the other hand, the same solution in contact with aluminum powder greatly enhanced the solution of aluminum ions. The explanation for this difference in the two cases is that when aluminum salt is in contact with aluminum oxide it undergoes a hydrolysis reaction

$$AlCl_3 + 2\,OH^- \rightarrow Al(OH)_2Cl + 2Cl^-$$

According to Sillen (24), the nucleus $Al(OH)_2Cl$ is the basis of the product of hydrolysis; other authors, by using Raman and NMR spectroscopy to study aqueous solutions of aluminum chlorides (25) have indicated an equilibrium between different forms of oxychlorides such as $Al(OH)Cl_2$, $Al(OH)_2Cl$, and $Al_2(OH)_5Cl$. Whatever the composition or structure of the product it is evident that the Al is tied up as a stable complexed species.

Conclusions

These experiments have shed some light on the first two steps in the aluminum corrosion process postulated above. They imply that the corrosive or noncorrosive state of a metal in a given environment depends on the stability of the complex species formed on the film and on the affinity of the anion present to react with the exposed metal. Nitrate is highly reactive with elemental Al to form ammonia. However, due to the ability of the complex species formed on the oxide film to remain attracted to the surface makes it behave in some cases like an inhibitor.

The ability of aluminum salts to activate the corrosion of aluminum have been reported by different authors (26, 27). This is a direct consequence of the hydrolysis of the salts by the hydroxyl from the aluminum oxide which help to accelerate the thinning process. However, it is not necessary that all aluminum salt solutions should activate the corrosion of aluminum. From step three it can be seen that it all depends on the ability of the anion to form a transient complex with the exposed metal. This is consistent with the idea that the hydrolysis reaction itself does not determine the corrosive nature of the solution (28).

As a result of this investigation, it can be concluded that the rate of dissolution or degree of passivity of a metal is directly correlated to the behavior and stability of the complex species formed, as predicted by the complex ion theory of corrosion (29).

Oxidation and Polarization Measurements on Zirconium and Zircaloy-2 in Molten Nitrite and Nitrates at 573°K

N. Ramasubramanian*

Atomic Energy of Canada Limited, Materials Science Branch, Chalk River Nuclear Laboratories, Chalk River, Ontario, Canada K0J 1J0

ABSTRACT

Oxidation and polarization measurements were carried out on zirconium and Zircaloy-2 samples in molten KNO_3-$NaNO_3$, KNO_3-$NaNO_3$-$NaNO_2$, and $NaNO_2$ at 573°K. Good agreement between the rates of oxidation calculated from the weight gain and polarization data was found for zirconium and Zircaloy-2 samples in the three melts. The various steps leading to the oxide growth were identified as: (*i*) attainment of a highly negative immersion potential initially due to the existing thin insulating air-formed oxide film, (*ii*) lowering of the resistance of the oxide resulting from the growth of a doped conducting oxide film on the intermetallic and impurity precipitates and the shift in the sample potential in the anodic direction, and (*iii*) oxygen-ion migration in the oxide under the driving force of the anodic shift in the potential.

Molten alkali nitrates and nitrites and and their eutectics are simple and convenient media for oxidation studies on metals and alloys because (*i*) the oxide ion activity at temperatures $\geqq$ 500°K is sufficiently high and (*ii*) cathodic reduction of the anions occurs at potentials negative to -1V and anodic oxidation of the ions occurs at potentials positive to about 0.1V so that a potential span of at least a volt is available for polarization measurements during the oxidation.

The electroanalytical chemistry of the molten nitrates and nitrites has been investigated in detail recently. Such studies have been mainly concerned with the salt decomposition reactions and the effect of various additions to the melt on these reactions (1). Passivation and oxidation studies on iron, nickel, and mild steel in these melts have also been reported (2, 3). Here, the type of oxide grown was related to the reactions occurring at various potentials; but the rate of oxide growth from an independent measurement and its relation to the polarization behavior in the melt has not been explored. Unlike the oxides on the metals referred to in (2) and (3), the oxide grown

* Electrochemical Society Active Member.
Key words: fused salts, oxidation, polarization.

on zirconium and its alloys is highly resistive. Therefore, the potential applied during the polarization measurements might be expected to be mainly across the growing oxide and hence the measured currents are a consequence of charge transport in the oxide. Thus, the resistivity of the zirconia formed would also extend the available potential span to more than a volt during the polarizations.

In an earlier report, on the oxidation of Zircaloy-2 at 673° and 573°K in molten $NaNO_3$-$NaNO_2$-KNO_3 eutectic, an attempt was made to relate the oxidation currents obtained from the polarization data to the instantaneous oxidation rates calculated from the kinetics of weight gained (4). The results were inconclusive because of a lack of sufficient kinetic data, especially at the lower temperature of 573°K. We have, therefore, extended the investigation in the ternary nitrate-nitrite eutectic to oxidation and polarization measurements in $NaNO_2$ and the binary KNO_3-$NaNO_3$ eutectic. The rates of oxidation obtained from the polarization and kinetic data in the three melts are compared and related to the different reactions occurring in the melts.

Experimental

Paddle-shaped samples, with a surface area of $\simeq$ 10 cm^2, were cut and prepared according to a standardized procedure of mechanical polishing followed by pickling in a bath of hydrofluoric and nitric acids. The zirconium and Zircaloy-2 samples were in the as-received (rolled and annealed) condition. The nitrates were 99.99% pure reagent grade chemicals and the nitrite was "chemically pure" at 97%. The molten salt baths, *i.e.*, ternary eutectic $NaNO_2$(40)-$NaNO_3$(7)-KNO_3(53), binary eutectic $NaNO_3$(41)-KNO_3(59) and $NaNO_2$(100) were made up without further purification of the chemicals; the numbers in the parentheses refer to percentages by weight.

The molten salt cell and the experimental apparatus used for current *vs.* potential measurements have been described in detail elsewhere (4). The only modification was the use of a Hewlett-Packard logarithmic converter so that semilog plots of current against voltage could be traced. Current *vs.* time transients were obtained using the pulse generator in the Universal Programmer, Model 175, supplied by Princeton Applied Research.

The kinetics of oxidation of a sample in a melt were followed. At predetermined times, the sample was polarized in the melt, withdrawn, washed, weighed, and returned to the melt for further oxidation. Oxidation and polarizations were carried out at 573°K and the polarization rate usually employed was 2 V/hr; the polarization always commenced with the cathodic forward and finished with the anodic reverse sweep. When tracing voltammograms, a rate of 15 mV/sec was used. A platinum wire fused in glass was used as a general reference electrode; its potential was frequently checked against an Ag/Ag^+ (0.07M in KNO_3-$NaNO_3$) reference electrode. All the potentials are quoted relative to this silver electrode. The oxidized samples were examined on a scanning electron microscope and characteristic x-ray energy spectra were also taken.

Results

Unalloyed zirconium.—Experiments were carried out in the binary and ternary eutectics. Hysteresis effects were observed mainly in the anodic portions of the polarization curves; therefore, the cathodic reverse and anodic forward portions in the curves were analyzed. A typical curve trace after 20 hr oxidation in the ternary melt is shown in Fig. 1. The linear anodic plateau was characteristic of all the polarizations carried out on zirconium. When the plateau was extrapolated to the rest potential, as shown by the dashed line in the figure, the equivalent amount of oxygen obtained from the current was found to be in agreement with the rate of oxidation calculated from the kinetic data. The rest potential was taken as the potential of zero current during the cathodic reverse and anodic forward sweep. This was slightly different, shifted towards anodic values, from the rest potential prior to the polarization. In Fig. 2, the oxidation rates calculated from the weight gain data are compared with the corresponding rates calculated from the oxidation currents (extrapolated currents at the rest potentials) obtained from the polarization data at various stages during the oxidation. The agreement is found to be generally good for oxidation in the binary as well as the ternary eutectics. The kinetics of oxidation also showed transitions similar to those in Fig. 2 and the oxidation of zirconium in the two melts was quite similar.

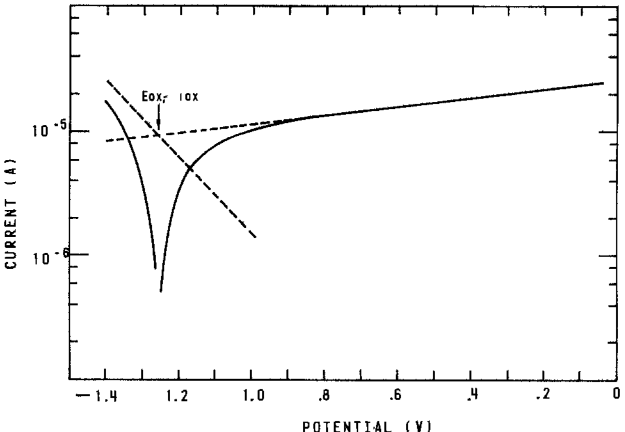

Fig. 1. Polarization curves for zirconium oxidized 20 hr and polarized in the ternary eutectic melt at 573°K; weight gain 1.2 mg/dm²; solid lines—curves obtained experimentally, dashed lines—curves obtained from analysis, E_{OX}—rest potential, and i_{OX}—oxidation current.

The cathodic portions obtained from analyzing the polarization curves traced, are shown in Fig. 3. When the two sets of curves are compared, a distinct difference in the rest potentials and the resistance to cath-

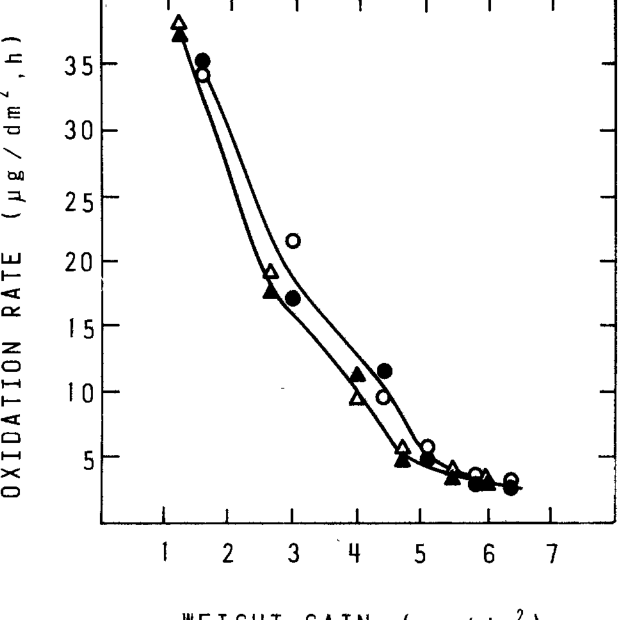

Fig. 2. Comparison of oxidation rates calculated from the kinetic and polarization data; zirconium oxidation in ○: $NaNO_2$-$NaNO_3$-KNO_3 and △: $NaNO_3$-KNO_3 melts at 573°K; solid symbols—kinetic and open symbols—polarization data.

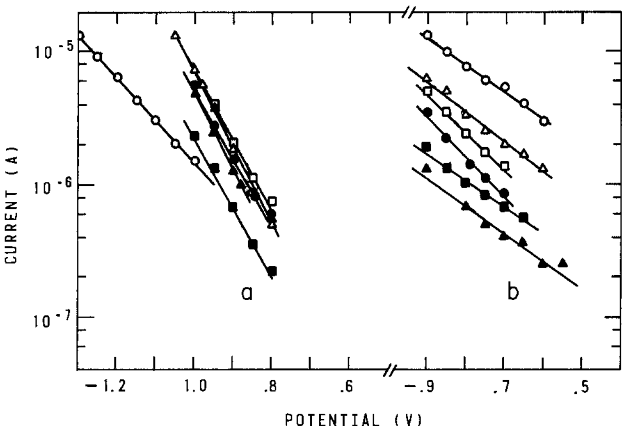

Fig. 3. Cathodic portions of the polarization curves after analysis; the corresponding weight gains are shown in Fig. 2 by the open or shaded points. Zirconium oxidized and polarized at 573°K in (a) the ternary eutectic and (b) the binary eutectic melts. Time of oxidation in hours: ○, 20; △, 86; □, 182; ●, 300; ▲, 500; and ■, 670.

odic current flow is seen; except for the curves corresponding to the 500 hr oxidation. In the case of the samples oxidized in the ternary melt the rest potential changed from −1.24 to −1.0V initially and stayed steady at ~ −0.9V during the rest of the oxidation; the resistance showed a decrease initially followed by a gradual increase with increasing oxidation. The rest potential stayed steady at ~ −0.85V and the resistance increased gradually during the oxidation for samples oxidized in the binary melt.

Zircaloy-2.—Oxidation followed by polarizations were carried out in all the three melts. A typical set of polarization curves obtained in the three melts following a 24 hr oxidation is shown in Fig. 4. When compared to the curves shown in Fig. 1 for unalloyed zirconium, the anodic plateaus covered a shorter range of potentials and the rest potentials were more anodic; the curves obtained with the nitrite and ternary melts showed negative resistance regions in the cathodic portions. Such cathodic negative resistance (CNR) peaks were observed during the forward cathodic sweeps also and were present in the curves traced in both the nitrite containing melts, after various times of oxidation. The rates of oxidation calculated from the kinetic data and the corresponding rates from the oxidation currents obtained from the polarization data are compared in Fig. 5. In each melt, the agreement between the two was quite good throughout the oxidation. The oxidation rates were different in the three melts in the initial stages but there was a tendency towards attaining a similar rate at high weight gains. In all the three melts, an increase in the oxidation rate was observed at the beginning; then the rates in the nitrite were nearly twice those in the other two melts. The amount of oxidation also varied as $NaNO_2$ > ternary > binary.

The cathodic portions of the analyzed polarization curves are shown in Fig. 6; unlike the curves shown in Fig. 3 for zirconium, the change in the resistance with increasing oxidation was small. In the case of the

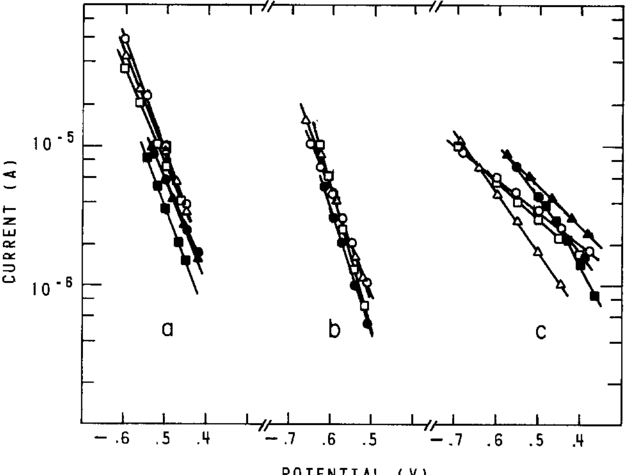

Fig. 6. Cathodic portions of the polarization curves after analysis. Zircaloy-2 is oxidized and polarized at 573°K in (a) sodium nitrite, (b) ternary, and (c) binary melts. Time of oxidation in hours: (a) ○, 24; △, 62; □, 85; ●, 135; ▲, 185; and ■, 255; (b) and (c) ○, 24; △, 72; □, 170; ●, 325; ▲, 500; and ■, 670.

samples oxidized in the nitrite and ternary melts, a slight increase in the resistance to the cathodic current flow is seen with increase in oxidation; the rest potentials have stayed nearly steady at about −0.5 and −0.6V, respectively. A slight decrease in the resistance with increasing oxidation is noticed for samples oxidized and polarized in the binary melt; the rest potentials also showed a change from −0.65 to −0.45V and a tendency to become steady towards the later stages of oxidation. In general, the oxides grown in the nitrite were found to be more conducting than those grown in the ternary and binary melts when their resistances to cathodic current flow were compared.

Ionic and electronic transport in growing zirconia films.—When the anodic portions of the polarization curves were plotted linearly, plateaus similar to those obtained on the semilogarithmic plots shown in Fig. 1 and 4 were obtained and the oxidation currents were also nearly identical to those from the latter curves. The immersion potentials of zirconium and Zircaloy-2 samples at the start of the oxidations varied from −1.8V in the binary and ternary to −1.6V in the sodium nitrite melt, and with oxidation, the rest potentials shifted in the anodic direction. Therefore, the ionic conductance of the growing oxide at any time during the oxidation was calculated from the ratio of the oxidation current, obtained from the corresponding polarization data, to the anodic shift in the rest potential relative to the immersion potential. The variation of the ionic conductivities, of the oxides grown on zirconium and Zircaloy-2, with weight gained is shown in Fig. 7. In the case of oxides grown in the binary and ternary melts on zirconium the conductivity values and their dependence on weight gain were almost the same, *i.e.*, initially independent of weight gain with a gradual decrease to about a third of the initial value. On Zircaloy-2 the conductivities of the oxides grown in the binary and ternary melts were quite similar, whereas that of the oxide grown in the nitrite melt was two times higher than the former. The conductivities of the oxides grown on Zircaloy-2 in the three melts showed an increase initially, followed by a gradual decrease with oxide growth; a behavior similar to the variation of the oxidation rates with increasing oxidation shown in Fig. 5. There was a tendency, however, towards reaching more or less the same value at high weight gains.

During cathodic polarization, in nitrate and nitrite melts containing sodium ions, it is known that the precipitation of sodium oxide on the electrode surface inhibits the reduction reaction leading to the appearance of reduction peaks in the current-voltage curves (6, 7). When such voltammograms for a platinum wire electrode in the three melts were compared, the cathodic reduction peak, located at $\simeq -1.5$V, was most well defined in the ternary melt. Therefore, voltammograms were traced in the ternary melt for oxidized zirconium and Zircaloy-2 samples. A broad and well-defined reduction peak was observed at −1.4 to −1.6V only in the case of the Zircaloy-2 samples; no systematic change in the size or the potential of the peak was observed with increasing oxidation and the voltammograms of samples oxidized in any of the three melts showed the presence of this reduction peak.

The ternary eutectic has a lower melting point than the binary and nitrite melts; therefore, current-time transients were obtained in the ternary melt on oxidized Zircaloy-2 samples at 573°K, the oxidation temperature, and at 473°K. D-C voltage pulses up to ±30 mV relative to the rest potential and 20 sec in duration were applied and the resulting current-time transients were recorded. At 473°K the transients obtained on oxidized Zircaloy-2 samples, 8.5 cm^2 in area, were nearly identical to those on a platinum microelectrode, 0.1 cm^2 in area. At 573°K the curves for Zircaloy-2 were very different from those of platinum. On platinum the current decay was similar to that observed at 473°K, whereas on Zircaloy-2 the current decayed very slowly indicating that contributions from an ionic component were also present in the total current measured. A set of curves obtained for the platinum microelectrode and an oxidized Zircaloy-2 sample is shown in Fig. 8. From a comparison of the conducting area in oxidized Zircaloy-2 to that of platinum the density of the electronically conducting inter-

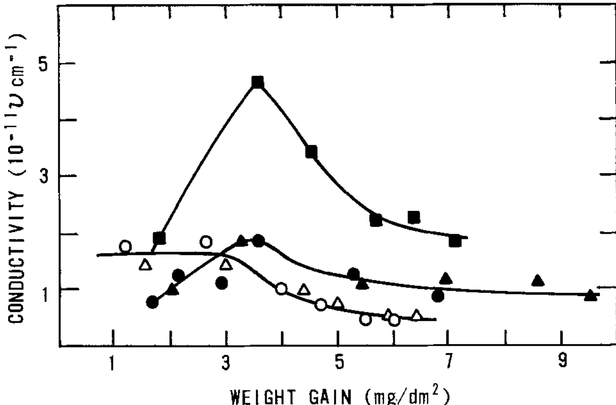

Fig. 7. Variation of ionic (oxygen ion) conductivity of zirconia films at 573°K with the weight gained during oxidation. Zirconia films grown on zirconium in ○—ternary and △—binary melts; on Zircaloy-2 in ●—ternary, ▲—binary, and ■—sodium nitrite melts.

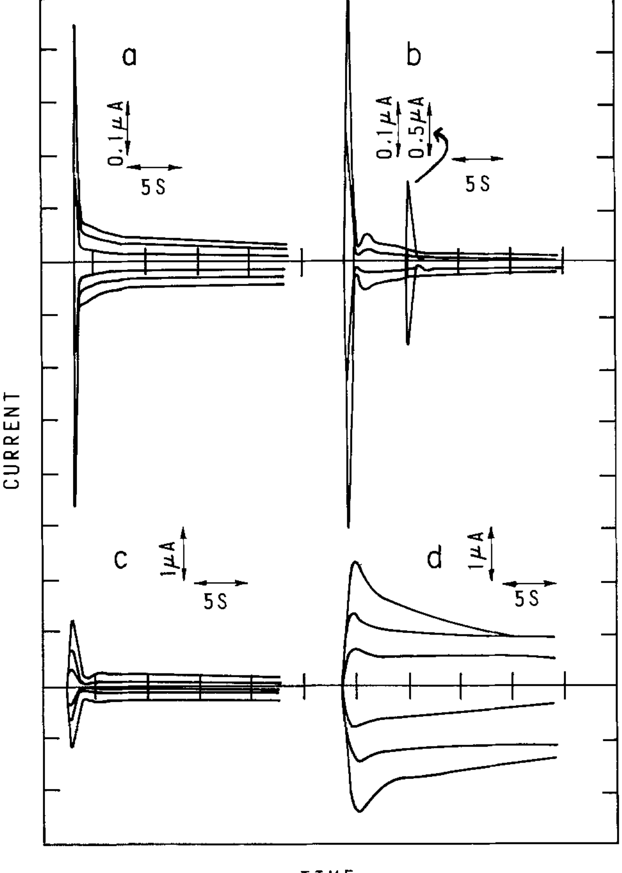

Fig. 8. Current vs. time transients obtained, on application of ±10, 20, and 30 mV d-c pulses 20 sec in width, for platinum 0.072 cm^2 in area and Zircaloy-2 8.5 cm^2 in area in the ternary melt. Zircaloy-2 was oxidized in the ternary melt and had a weight gain of 3.5 mg/dm^2. Curves a and b traced at 473°K and c and d at 573°K; curves a and c—platinum and b and d—oxidized Zircaloy-2. metallic precipitates in the alloy can be estimated as $1.6 \times 10^6/cm^2$, assuming an average diameter of 1 μm for the precipitates. This estimate is in good agreement with a density of $1 \times 10^6/cm^2$ obtained from optical examinations.

Discussion

Reactions in the molten salt.—In molten nitrite and nitrate the oxygen ions originate by self-dissociation according to the equilibria

$$NO_3^- \leftrightarrows NO_2^+ + O^{2-} \quad [1]$$

and

$$NO_2^- \leftrightarrows NO^+ + O^{2-} \quad [2]$$

The concentration of the oxygen ions can be calculated from the equilibrium constants; for example, at 573°K it is $\simeq 10^{-12}$ mole/liter for reaction [1] (8). Marchiano and Arvia have worked out Pourbaix type potential *vs.* pO^{2-} ($pO^{2-} = -\log [O^{2-}]$) diagrams for molten nitrite and nitrate (9). It is seen from these diagrams that, at such an oxygen ion concentration at 600°K, the various cathodic reactions leading to the formation of oxygen ions occur at potentials negative to -1V. The corrosion potentials during the oxidation of zirconium and its alloys were in the range of -1 to -0.4V; therefore, cathodic reduction reactions of the nitrate and nitrite ions do not play a role in the oxidation. The oxygen ion concentration in the melts, at the oxidation temperature of 573°K used in the present study, would thus be extremely low. But the observation that the oxidation of zirconium and the alloys proceeds equally well in the three melts and the kinetics are comparable to those in other oxidizing media, indicates that the oxygen ion concentration and its mobility are not low enough to be rate limiting. The reactions leading to the oxidation of zirconium and the alloys are thus

$$Zr \leftrightarrows Zr^{4+} + 4e \quad [3]$$

$$Zr^{4+} + 2\,O^{2-} \leftrightarrows ZrO_2 \quad [4]$$

followed by the cathodic reactions

$$NO_2^+/NO^+ + e \leftrightarrows NO_2/NO \quad [5]$$

Since the melts used in the present investigation were not extensively purified, water as a contaminant is very likely to be present; therefore, reduction of water to produce hydroxyl ions, reported to occur at $\simeq -0.6$V, is another cathodic reaction to be considered in addition to reaction [5] (7).

During polarization measurements, at applied anodic potentials ≥ 0.1V, anodic discharge of NO_2^- and OH^- is possible in addition to the reactions, discussed above, occurring during oxidation (7).

Anodic plateaus.—In the case of zirconium and Zicaloy-2 samples, anodic plateaus during the polarizations were observed throughout the period of oxidation. The currents obtained at the rest potentials corresponded to the kinetic rates derived from the weight gain data. These currents must therefore be the oxidation currents and the plateaus represent the variation of the ionic (oxygen ion) current flow, through the growing zirconia, with the applied potential. It is also implied that in the plateau region of the polarization curve, there is negligible contribution to the current from any other anodic or cathodic reaction and that the applied potential is across the growing zirconia. When compared to Zircaloy-2, the plateaus covered a wider range of potentials during polarization of oxidized zirconium. This can be attributed to the presence of intermetallic precipitates in the former, which act as electron conduction sites, as will be discussed later.

Under the conditions of temperature and oxide thickness investigated the ionic current would be expected to follow the low field approximation of the Tafel relation, and give a linear relationship with the potential (10). Anodic plateaus were indeed observed on linear current *vs.* voltage plots, though slightly less well defined than on the semilog plots, and the oxidation currents were nearly identical to those obtained from the latter. However, for the sake of convenience and also because the other cathodic and anodic reactions (at the electron conduction sites in the oxide) obey a semilogarithmic relationship, the data are shown on semilog plots.

Electron conduction sites.—It has been established, from a comparison of the oxidation and polarization behavior of Zircaloy-2 in various metallurgical conditions and zirconium-tin and zirconium-iron binary alloys, that the oxidized intermetallic precipitates, mostly of zirconium and iron in Zircaloy-2, are localized high-conduction sites for electron transport during oxidation (4). This is further confirmed by the results of cathodic voltammograms and the current-time transients (Fig. 8) obtained in the present study. The inhibition by precipitated sodium oxide results in the formation of a broad peak at $\simeq -1.5$V; a potential nearly the same as that observed for a number of other metals (5). The oxide on the intermetallics must therefore be a good conductor; otherwise, one would have expected this reduction peak to occur at a much more negative potential than -1.5V.

The current-time transients obtained at a temperature much lower than the oxidation temperature, where contributions from the ionic current flow through the oxide would be negligible, were nearly identical to those on platinum; another indication that the oxide grown on the intermetallics is a good electronic conductor. In the case of unalloyed zirconium, the cathodic voltammograms did not show reduction peaks; however, there is evidence for localized conduction sites (11). These are associated with impurities (*e.g.*, iron) in the material. These impurity sites are smaller in size, fewer in number, and less uniformly distributed than the intermetallic precipitates in Zircaloy-2. Thus, the intermetallic precipitates in Zircaloy-2 and impurity centers in unalloyed zirconium are the localized conduction sites for electron transport. The cathodic reduction of NO_2^+, NO^+, and H_2O during oxidation and polarization and in addition the anodic discharge of NO_2^- and OH^- during polarization, discussed previously, are facilitated by the electron transport at these sites. When the resistance to the cathodic current flow at these sites is compared (*e.g.*, Fig. 3 and 6) the impurity centers in zirconium are found to be more resistive than the intermetallics in Zircaloy-2. This may be due to differences in size, density, and distribution. With increasing oxidation, only slight changes in the resistance to cathodic current were observed on Zircaloy-2; occasionally, even a decrease was noticed. This may be attributed to the growth of a doped oxide, of increasing conductivity, on the intermetallic precipitates.

Mechanism of oxide growth.—A highly negative potential, ~ -1.8V, was attained by zirconium and Zircaloy-2 on immersion in molten alkali nitrates, nitrites, and their eutectics. The oxide growth during the first few minutes after immersion was estimated to be only about 0.2-0.4 nm, the higher value being in the nitrite melt. These values were obtained from extrapolations of the thin film growth in the initial stages monitored by observing the changes in the interference colors. The highly negative immersion potentials and negligibly small oxide growth on immersion indicate that the air-formed oxide film existing, prior to the oxidation in the molten salt, on all surfaces is highly resistive and remains so during the first few minutes following immersion. The reaction occurring at the metal-oxide interface is the oxidation and dissolution of zirconium in the air-formed oxide film

$$Zr + nZrO_2 \leftrightarrows \left[(n+1)\, ZrO_2 \left(\frac{n}{n+1} \right) \right]^{4+} + 4e^- \quad [6]$$

resulting in a positive space charge associated with the anion vacancies in the oxide and a negative charge, responsible for the immersion potential, on the metal or alloy. At the oxide-salt interface oxygen ions from the melt are incorporated into this modified air-formed oxide film, according to the reaction

$$\left[(n+1)\,ZrO_2\left(\frac{n}{n+1}\right)\right]^{4+} + 2\,O^{2-} \leftrightarrows (n+1)\,ZrO_2 \quad [7]$$

This reaction reinforces the highly negative immersion potential attained by the metal or alloy. Electron flow from the latter could occur, to a small extent, by emission over the insulating zirconia barrier. Thickening of the air formed oxide film, by a few angstroms, occurs mainly by reactions [6] and [7].

The immersion potential measured may be nearly identical to $-E_a$, where E_a is the electrochemical potential associated with the anodic reaction [6] because of the condition that there is practically no oxide growth (12). The immersion potential will be, however, slightly anodic to $-E_a$ by an amount proportional to any *IR* drop across the oxide. Thus, the unique feature of the molten nitrates and nitrites, *viz.*, the availability of O^{2-} ions directly from the melt without recourse to a reduction step, and the high resistance of the air-formed zirconia films, enables the measurement of a potential close in value to E_a. With time of oxidation, however, the insulating oxides on the intermetallics and impurity precipitates become increasingly conducting due to doping by transition metal ions from the alloying additions or impurities. This results in a gradual lowering of the internal resistance of the cell, zirconium/Zircaloy-2-oxide-molten salt, and the rest potential shifts in the anodic direction with oxidation. The driving force for the ionic current flow through the growing zirconia is then the anodic shift in the rest potential from the initial immersion potential. Thus, the basic features are essentially the same as those proposed initially by Cox (5), *viz.*, the anodic reaction (oxygen-ion migration) occurs in the zirconia matrix and the electron transport for the cathodic reactions (which complete the oxidation) is localized at intermetallic and impurity sites.

Oxidation and polarization behavior.—During oxidation the metal or the alloy acquires a rest potential when the current due to electron transport at localized impurity or intermetallic sites is balanced by that due to the oxygen ions through the zirconia. It has been pointed out (13), and is also evident from the polarization curves reported here, that the anodic oxygen-ion current is more polarizable or less sensitive to a change in the potential than the cathodic electron current at the intermetallic sites. However, when comparing the oxidation behavior of zirconium and its alloys in a melt or different melts, the effect of a change in the rest potential and its relation to the rate of oxidation has to be considered in conjunction with the relevant resistances for ionic and electronic transport and their variation with oxide thickness. At comparable weight gains the electronic conductances of the oxides on zirconium are found to be less than those of the oxides on Zircaloy-2. Therefore, the rest potentials attained by zirconium are more negative and hence the rates of oxidation are less than those obtained for Zircaloy-2. Similarly, during polarization, because of a greater contribution to the current measured from the electron transport at the intermetallic sites, the anodic plateaus are shorter in the case of Zircaloy-2. When the oxidation of Zircaloy-2 in each of the three melts is compared, the rates in the nitrite melt are faster than those in the other two melts. This has to be related to the increased ionic conductivity of the zirconia grown in the nitrite melt because the rest potentials attained, the resistance to cathodic current flow, and the variation of these parameters with increasing oxide growth are similar in the three melts.

The reason for a higher ionic conductivity of zirconia grown in the nitrite melt is not clear. An important observation is that a large increase in the conductivity is seen when the oxide is 0.1-0.3 μm thick (1 mg/dm^2 weight gain $\equiv$ 67.3 nm); therefore any mechanism proposed should also account for this dependence on the oxide thickness. The mechanism of oxide growth has been treated in detail by Cox (5). Oxygen-ions are transported mainly by a line diffusion process via the oxide crystallite boundaries and the oxide crystallites nucleate at the metal or alloy-oxide interface. Therefore, the cause for the increased ionic conductivity must originate at the oxide-salt interface. One possibility is the incorporation of impurities from the melt, in the outer layers of oxide, which inhibits the crystallite growth and imparts a high conductivity. Such impurity uptake might be dependent on the rest potential of the alloy. With increasing weight gain these outer oxide layers would form a diminishing proportion of the total oxide thickness. Therefore, an increase in the conductivity is observed in the initial stages and this is followed by a decrease at high weight gains.

The ionic conductance of zirconia was calculated from the ratio of the oxidation current to the anodic shift in the rest potential from the immersion potential because the low-field approximation, which assumes a linear relationship between the current and the potential, is expected to apply to films thicker than 0.1 μm (4). In calculating the ionic conductivities, the measured immersion potentials were used. However, there could be some minor differences between these measured values and the true values to be used due to one or more of the following reasons: (*i*) a depolarization caused by the thermal emission of electrons at the start of the oxidation might have lowered the immersion potential slightly; (*ii*) using an Ag/Ag^+ in KNO_3-$NaNO_3$ as a reference electrode might have contributed to small potential differences, arising from junction potentials due to different solvents, in the nitrite melt; and (*iii*) during oxide growth Sn, Fe, Cr, and Ni in small quantities but varying amounts are oxidized along with Zr; these might correspond to small deviations from the immersion potential that is characteristic of pure zirconium.

Conclusions

When zirconium and Zircaloy-2 are oxidized in molten alkali nitrites, nitrates, and their eutectics, it is seen that (*i*) the rates of oxidation calculated from the kinetic data of weight gain are in good agreement with those calculated from the oxidation currents obtained from the polarization data; (*ii*) the oxides grown on the intermetallic and impurity sites are good conductors and the electron transport, completing the oxidation, occurs mainly at these sites; and (*iii*) the ionic (oxygen) conductivity of the zirconia grown in the nitrite melt is higher than in the other two melts. The electronic conductivity, per unit area of the samples, of the intermetallic precipitates in the alloy is higher than that of the impurity sites in the metal and the relative ease of transport of the ions and electrons determines the rest potentials. The molten nitrites and nitrates are thus convenient and suitable media for studying the mechanism of oxide growth on zirconium and Zircaloy-2.

Electroplated Lead Collimator for Gamma Ray Imaging

Clinton J. Beuscher* and Christopher H. Tosswill

Galileo Electro-Optics Corporation, Sturbridge, Massachusetts 01518

ABSTRACT

A gamma-ray imaging collimator for the use in diagnostic radiology has been fabricated by applying electroplating techniques onto a glass structure. The substrates, an outgrowth of the microchannel plate technology, have a honeycomb geometry with hexagonal channels of 16 mm in length, 0.75 mm across opposing sides, and a surface area of 90 × 90 mm. The glass substrate was enveloped with a thin electroless nickel film followed with lead plating yielding a metal ratio of about 2:1.

The collimators to be described in this paper were prepared for the formation of gamma-photon images in the branch of radiology known as nuclear medicine. Gamma ray images are formed by photon selection in multi-channel collimators, because high energy radiation cannot be efficiently reflected or refracted. These images present the physician with two-dimensional projections of radionuclide distributions established within the patient under examination. The images are created by a collimator mounted in close proximity to an array of detectors responsive to gamma photons with wavelengths in the order of 0.1Å.

The typical collimator is a honeycomb structure with parallel walls of septa of a mass sufficient to absorb uncollimated incident photons. The assembled septa enclose a multiplicity of channels arranged in some regular pattern: the channel cross sections may be circular, square, or triangular, and in the main are chosen to simplify the task of construction. Collimator performance is measured in terms of spatial resolution, which depends upon the center-to-center dimensions of the channel structure; and of transmission efficiency, which depends upon the relative frontal areas of the septa and of the channels. The gamma-photon absorption coefficients of the elements grow very rapidly with rising atomic numbers; thus, making the ideal collimator an assemblage of very thin septa formed from one of the heaviest elements. Lead and steel collimators both have been widely used in nuclear medicine, but neither can be used with septa thinner than about 1 mm. Lead, despite its excellent absorption, is too soft, and steel is unsatisfactory because of its inferior absorption. A collimator with 1 mm septa affords an acceptable transmission level for center-to-center dimensions down to about 3 mm.

Key words: collimators, electroless plating, electroplated lead, microchannel plate (MCP), honeycomb structure, radiology.

Until very recently the detector array to which the collimator was coupled took the form of a mosaic of photomultiplier tubes located behind a single massive crystal, usually of sodium iodide. The spatial resolution of this configuration was also 3 mm at best and there was obviously no great incentive to improve the collimator resolution without a matching improvement in detector resolution. This situation has now changed, because there are now in active development clinical radionuclide cameras employing semiconductor arrays, with both liquid-filled and gas-filled ionization detectors. All these new detector arrays will have intrinsic spatial resolution of the order of 1 mm, and will create a demand for collimators of at least equal performance.

Collimators with 1 mm resolution have recently been constructed by two very different techniques. In the first; a myriad of short pieces of small-bore tubing are stacked together and then cemented into a single rigid mass: although this procedure may not be practical for the assembly of full-size collimators, which require a total diameter of some tens of centimeters, successful small-area collimators have been assembled during the past year in this fashion. The second technique which the authors have developed, is based upon microchannel plate (MCP) technology, a process in which minute holes are etched through a thin glass disk.

MCP's were first developed to simplify electron fluxes in Night Vision image intensifier tubes. Glass, containing a small portion of lead was chosen to furnish the surface electrical conductivity and secondary electron emissivity necessary for electron multiplication within the channels, and fortuitously was an effective absorber of low energy x-rays and gamma-rays. Consequently, it was found that thick slabs cut from standard MCP boules could be used in some x- and gamma-ray collimator applications. To build a

collimator which performs well across the entire clinical energy range (several hundred keV) a far higher proportion of lead, or of some other heavy element, is needed. Because the absorption process is related to the quantum levels of the inner electron shells, there are sharp discontinuities in the absorption energies and thus a lighter element may almost perform as well as a heavier one at some energy levels. In Fig. 1, tin comes close to matching lead at about 85 keV or tungsten at about 70 keV. However, tin does not span our range of interest.

Experimental

Collimator fabrication.—Collimator fabrication involves two distinctly different steps: (*i*) the manufacture of the glass capillary array substrate; and (*ii*) the metallization of the entire surface area of the substrate with a radiation absorbing layer.

The most obvious approach to obtain the collimator was to increase the lead content of the glass. Uncollimated radiation can readily pass through transparent glass, therefore, an absorbing type of glass such as Corning Glass Works 8161 (14% lead by volume; 51% lead by weight) was used. This glass can only absorb 10.2% of the radiation of an equivalent strip of lead of the same thickness. However, uncollimated stray radiation passing down the length of the glass column would be readily absorbed. Hexagonal microchannel plate geometry was selected for the matrix because of its inherently high, thin-walled strength and efficient packing density. The "staggering" of the channels aids to overcome the passage of uncollimated photons found in some collimator geometries. It is the author's belief that this approach offers a decided advantage over the previously described methods.

Microchannel plate manufacture is an outgrowth of fused fiber optic faceplate technology. A description of the various processes involved are found in the literature (2, 3). For those that are unfamiliar with this process Fig. 2 serves as an illustrative example.

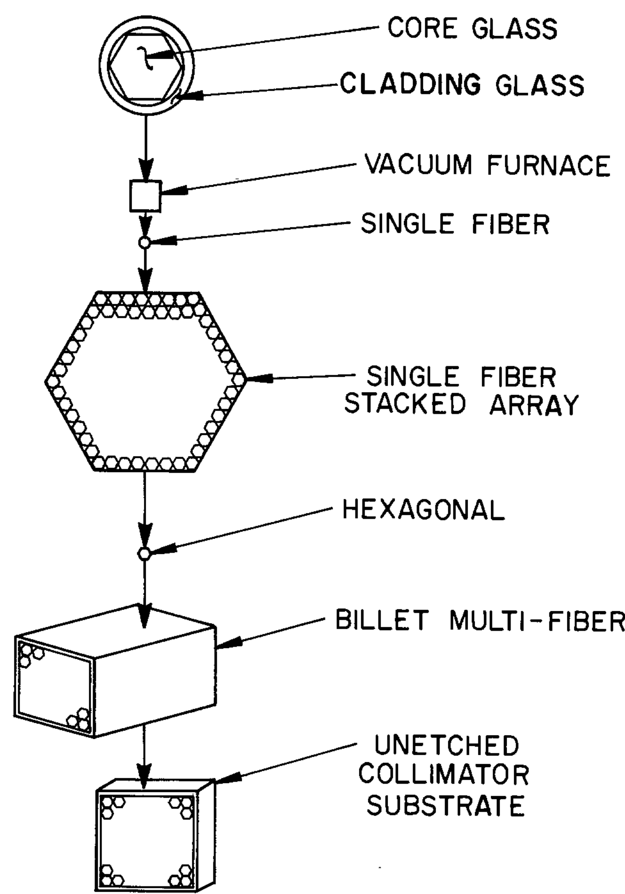

Fig. 2. Diagram of hexagonal draw

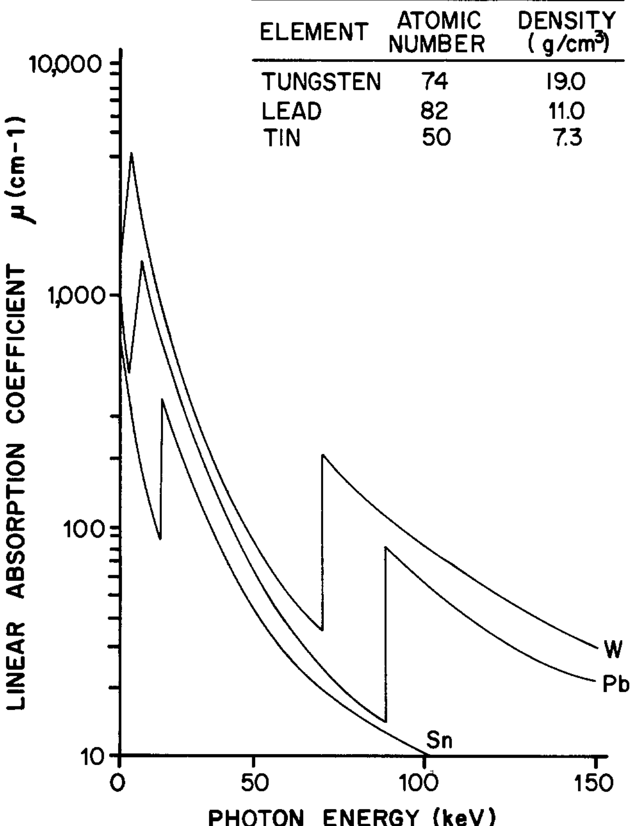

Fig. 1. Gamma photon absorption coefficients

MCP's and fiber optic plates are normally fabricated in a repetitive cycle of drawing, stacking, and fusing operations. The process begins with the passage into a drawing furnace of a single etchable glass rod within a nonetchable tube assembly. To produce the hexagonal geometry the combination is drawn through a vacuum furnace. Progressively larger numbers of smaller and smaller elements are heated and drawn down until the required dimensions are reached in the final boule. Channels less than 10 microns in diameter are readily achieved by this procedure, with dimensional uniformity of a few percent. Mosaics, thus fabricated, are wafered from the boules into slices 16 mm thick whose parallel surfaces are ground, but not polished, for good electroless plating adhesion. The substrate is etched in a 1.2M hydrochloric acid solution and dried for storage.

Electroless.—A dried glass substrate was mounted in a specially designed Teflon frame and was placed in a beaker of water and a vacuum drawn to fill the channels. The combination was then attached to the dunking unit as illustrated in Fig. 3. The variable speed unit was designed to have 8 cm of travel and a range of 2.5-60 rpm. It was found that 30 rpm produced an excellent exchange of solution through the holes and became the standard speed.

The electroless plating system was chosen over the various methods of coating nonconductors because of its excellent uniformity, high electrical conductivity, and plating solution compatibility. Shipley's CP-70 electroless copper system was initially tried. Film uniformity was satisfactory, however, adhesion to the 8161 glass was poor and peeled rather easily. The Enthone Ni-416 electroless nickel system adhered quite

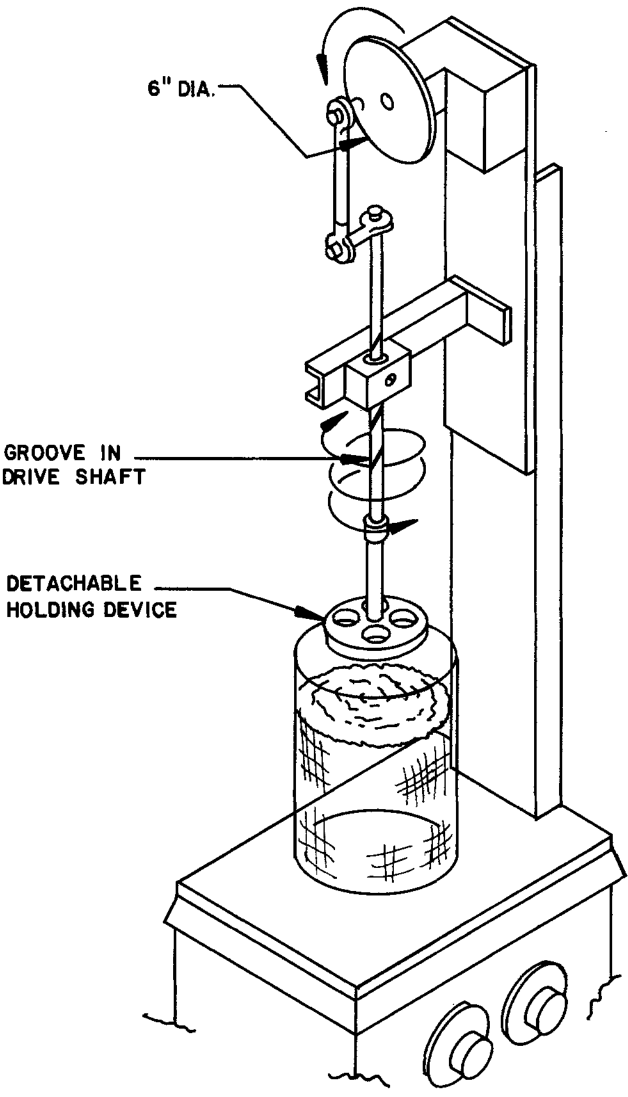

Fig. 3. Sketch of dunk-twist apparatus

well to the glass but their activators would not produce a continuous and uniform film.

A combination of the two systems gave excellent results and was used as follows:

1. Conditioner 1160 (19 parts deionized water, 1 part 1160) 3-5 min at room temperature (Shipley Company, Newton, Massachusetts).
2. Three 5 min deionized water rinses.
3. 15% hydrochloric acid (by volume) 2-3 min.
4. Catalyst 6F (2 parts deionized water, 3 parts hydrochloric acid, 1 part catalyst) 3-5 min at room temperature (Shipley Company, Newton, Massachusetts).
5. Three 5 min deionized water rinses.
6. Accelerator 19 (5 parts deionized water, 1 part catalyst) 3-5 min at room temperature (Shipley Company, Newton, Massachusetts).
7. Three 5 min deionized water rinses.
8. Electroless nickel (1 part Enthone Ni 416, 2 parts deionized water) raised to 80°C, *p*H 4.5-5.5. (Enthone Company, New Haven, Connecticut).

Applying these parameters, a deposit of between 5 and 8 microns of nickel was attained in 10-12 min. This was enough to provide a good conductive surface, yet not too much to interfere with absorption. The temperature of the final rinses was 80°C and the subsequent rinses were lowered in 20°C increments to prevent shock to the substrate.

Metal Absorbing Layer

In choosing a metal coating one is somewhat limited to the high Z numbered and high density metals. A list of the various candidates and appropriate parameters appears in Table I. All options were weighed in eliminating candidates from within this group. Cost, a major concern, eliminated gold and the noble metals. Tungsten was investigated and abandoned because of the difficulty in plating as reported by Sarojamma and Rama Char (4). Although tantalum tubes have been used to assemble small area collimators by hand it is a very difficult element to plate. Cadmium and tin, both very plateable and inexpensive were considered, but were borderline candidates for energy attenuation characteristics (range of interest being 50-140 keV). This left lead, an extremely good choice from the standpoint of energy attenuation range, plateability, and cost.

Electroplated lead has been used as a protective coating over steel, for bearings, on water pipes, for refrigeration tanks, and storage battery parts (5). Most of these coatings were on the order of 60 microns, or about half the amount anticipated for the collimator. The vast majority of lead plating work has been performed on flat or slightly curved surfaces, and, in a few cases slightly recessed surfaces. Very little lead plating effort has been directed towards channels except for a stuly reported by Greco (6) (in conjunction with 105 mm gun barrels).

It was apparent that the success of this undertaking might well lie in the throwing power and covering power of the lead plating bath selected. A careful review of the literature on throwing power (7-13) suggested that another exercise along this line was unnecessary. The theory has been well documented by Foulke and Kardos (14, 15).

The concerning factor of solution replenishment within the long channels was within the limits as suggested by Irvine (16). It became clear, however, that throwing and covering power were related to a number of parameters as recorded by numerous authors (17-21): (*i*) solution resistivity, (*ii*) current efficiency/current density relationship, (*iii*) cathode potential/current density relationship, (*iv*) primary and secondary current distribution. These parameters were easily adjusted by changing the tank geometry, plating bath formation, agitation, grain refiners, etc.

Seth (22) outlined 13 lead plating baths and gave compositions (acid, neutral, and alkaline) as well as comments on each. However, of these baths only the fluoborate has been universally used because of numerous advantages. The most important of these were thickness of deposit, numerous available specific grain refiners, high conductivity of solution, and ease of bath control.

Test Procedures

All of the experimental tests were run in a slightly enlarged Hull-type cell with 100% pure lead anodes. The work was performed at room temperature (22°-28°C) and the solution agitated using a magnetic stirrer. Brass tubing with various diameters (1.6, 2.5, and 4.5 mm) all cut in 16 mm lengths were used for test samples giving aspect ratios of 10.2, 6.2, and 3.5, respectively. As the throwing power was improved small sections of a round hole collimator (500 μm diam) were used to extend the aspect ratios to 15 and 21.

A profiling system was adopted for the plated samples as shown in Fig. 4. One-half of the length of the interior of the brass tube is illustrated with one-half of the lead plate shown under the dashed line. The other half is shown with the solid line. The buildup of the plate on the ends and variation within the channel were easily discernible from the plots. The plating thickness was measured at 2 mm increments, starting at each end of the brass tube. A point 0.5 mm in from both ends was also plotted to check the "dog-bone" effect that generally occurs with

Table I. Possible elements for collimator layer

Element	Septa Density	Septa Z	Throwing power*	Plating parameters: Plateable	Control	Cost	Literature**	Usable Final candidate
Gold	19.3	79	10	Yes	Easy	Extremely expensive	+	No
Tungsten	19.0	74	2	Difficult	Difficult	Expensive	–	No
Tantalum	16.7	73	?	Difficult	Difficult	Expensive	0	No
Lead	11.0	82	4	Yes	Easy	Cheap	+	Yes
Cadmium	8.65	48	7	Yes	Easy	Moderate	+	No
Tin	7.3	50	3-6	Yes	Easy	Moderate	+	No

"in-hole" plating. In some cases the plating at the face of the sample had to be estimated because of the carry over of the plating to the exterior. For each bath, triplicate samples were run on three different test samples. The data gave us a spread from which we plotted the S/H (surface to center of hole thickness) ratio against T/D (substrate thickness to hole diameters) ratio.

A list of plating baths appears in Table II. The tin/lead bath was used to compare our data to Rothschild's (23), with the resultant curves fairly close. The amperage was lowered increasing the lead content, but no noticeable differences were observed in the throwing power. Hull cell testing was performed prior to each of the subsequent baths to provide a plating range for the best current density.

The initial test samples were the 4.5 mm tubes using baths No. 1 and No. 2 (24). Treeing and whiskering were more pronounced in bath No. 1. Periodic reverse (PR) plating was introduced and these baths were rerun, practically eliminating these faults. The efficiency cycle (25) was 78% and accounted for the small amount of treeing that appeared.

After experimenting with efficiency cycles ranging from 39 to 78% and plate to deplate time cycles of up to 4:1, a 50% efficiency cycle was established as the norm. The No. 2 bath was somewhat better in throwing power than the Sn/Pb bath, a decided increase in throwing power using the PR cycle. In baths No. 4, 5, and 6, peptone was added and the formulation altered. The results were not greatly different, although the No. 6 bath was the best of the three. The deposits were fairly fine grained and one can see the buildup of the lead from the cross-sectioned 1.6 mm brass tube illustrated in Fig. 5.

In baths 7, 8, and 9, the peptone was replaced with Shinol LF-3 (26) along with variations in bath formulations. The No. 7 bath was made up to Harstan's specifications and yielded extremely fine grained, almost lustrous deposits. The bath exhibited excellent throwing power and displayed the narrowest spread for each of the test sample ranges. No noticeable improvement was observed in baths 8 or 9, although the latter was slightly cloudy during the test runs. Mechanical agitation was used in all baths, and the first 6 baths were filtered prior to use. In baths 7, 8, and 9, continuous filtering and agitation was used as suggested by the Harstan Company. From the test a metal ratio of 1.65:1 with a 21:1 aspect ratio was attained, and plotted with some of the other baths shown in Fig. 6. The solid lines represent our accumulated data, while the dashed lines represent the projected S/H ratio at an aspect ratio of 21:1. Our No. 2, 6, and 7 baths are shown along with Rothschild's Sn/Pb and acid gold data.[1]

Collimator plating.—With the data gathered from the tests, general parameters were established to plate the collimators. A 7 liter container was used for the plating vessel. The bath was both constantly filtered and stirred, the anode/cathode distance was 10.5 cm, anode/cathode ratio was 1.5:1, and the work performed at room temperature. The hexagonal honeycomb structure with 75% open area, contains 2.5 times more sur-

face area than the 500 μm round hole collimator samples. This structure has about 25 times greater surface area than a normal flat slice having the same exterior dimensions. The lead coating raised the mean fraction of lead within the collimator structure to approximately 50% by volume, and the performance of the collimator approached that of a homogeneous glass structure containing the same overall dimensions and fraction of lead. A calculation showed that a minimum of 5 times more lead, by weight, was needed than the total weight of the substrate materials. This afforded an easy control for our plating end point.

After the electroless nickel plate was accomplished an initial forward plate of 5 A/dm² completely enveloped the unit with lead in 30 min. The collimator was then removed and a lead plated copper "thief" was attached and a gap of 2 mm was allowed to separate the two. The substrate was then plated at an efficiency cycle of 50% using a current density of about 0.2 A/dm². The required amount of lead was deposited in about 42 hr.

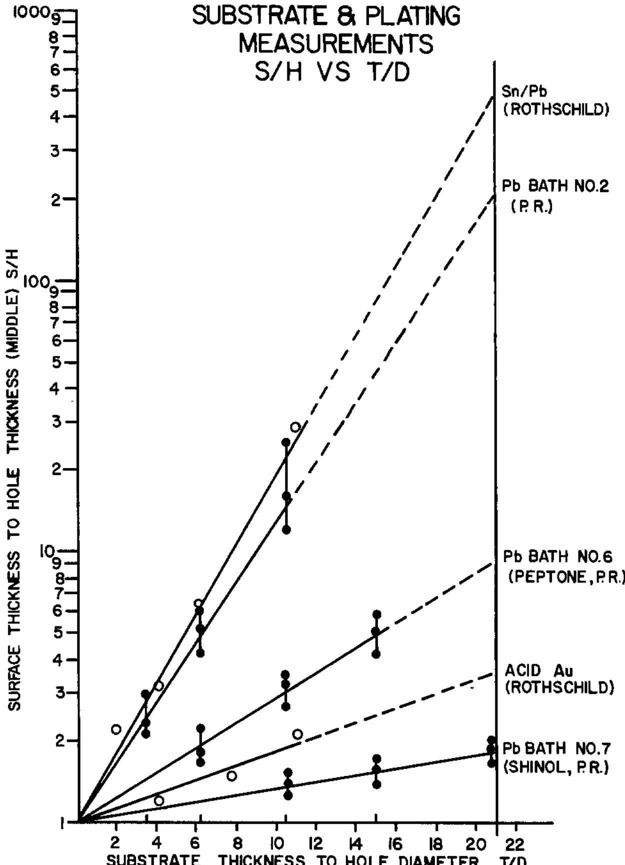

Fig. 6. Substrate thickness and plating measurements (S/H vs. T/D).

Figure 7 illustrates a transverse (perpendicular to the axis) cross section of the collimator with ideal dimensions. Figure 8 is an actual photograph of a similar cross section, the combined glass walls being about 145 μm while the metal plate is about 95-120 μm. Figure 9 shows a longitudinal (parallel to the axis) cross section, a different collimator section. Note the four plated channels visible; the channels closest to the center show the plating on the surface to be about 135 μm. The ends of the channels (on the photo) are less than half the distance to the midpoint, or about 3.25 mm long. The actual plating at the center of the channel was 105 μm for a metal ratio of 1.6:1.

A total of 8 collimators, 90 × 90 × 16 mm thick were plated, and from the best four, 75 mm squares were

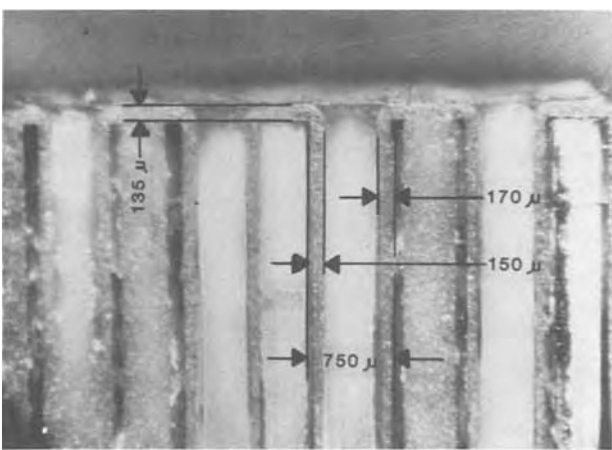

Fig. 9. Photograph of cross section of actual collimator (parallel to axis).

extracted from each. These four units had two surfaces milled square and were bonded together using an epoxy adhesive impregnated with tungsten powder 84% (by weight), to absorb stray radiation. The 15 cm square unit tested at The University of Florida exhibited the predicted resolution of about 1 mm using technetium 99^m as the radioactive source. A patent No. 4,125,776 entitled "Collimator for X and Gamma Radiation" was issued November 14, 1978.

Summary

A parallel hole, high resolution collimator for radionuclide cameras has been fabricated by combining microchannel plate technology with lead plating. The aspect ratio of 21:1 (length of hole to diameter) was obtained with a minimum of 0.10 mm of lead in the channel giving an average metal ratio of 1.85:1. This was accomplished by using a combination of periodic reverse plating with an efficiency cycle of 50% and Shinol LF-3 (Harstan Company) grain refiner. Resolution at the face of the collimator was 0.9 mm, open area of 50%, sensitivity was 40% of a conventional high resolution collimator (which can resolve 3 mm) and septal penetration for 140 keV photons using technetium 99^m was 0.1%.

Variation of Contact Resistance of Electroless Ni-P on Silicon with the Change of Phosphorous Concentration in the Deposit

B. K. Singh and R. N. Mitra

Institute of Radio Physics and Electronics, Calcutta University, Calcutta 700009 India

ABSTRACT

Ohmic contacts to n-type silicon having resistivity of the order of 5 Ω-cm and orientation (111) by electroless Ni-P process were investigated under two different conditions, *i.e.*, keeping operating temperature constant and *p*H variable and vice versa. It was found that the formation of Ni-P alloy during deposition resulted in low resistance ohmic contacts to silicon with increase of P-concentration and with heat-treatment after deposition in both cases.

Of the various methods used for making ohmic contact to silicon, the electroless nickel plating technique to achieve quick-to-solder and reliable low resistance ohmic contact is simple and economical. Basically, the process (1) is a type of chemical reduction of a metal salt such as nickel chloride to the metal with simultaneous oxidation of a reducing agent (sodium hypophosphite). The chemical reactions during electroless nickel plating are

$$Ni^{++} + (H_2PO_2^-) + H_2O — Ni^\circ + 2H^+ + (H_2PO_3^-) \quad [1]$$

$$H_2PO_2^- + H_2O — H(HPO_3^-) + H_2 \quad [2]$$

Reactions [1] and [2] occur simultaneously. Reaction [1] is responsible for the nickel reduction and the formation of H^+ ions. As the H^+ ion concentration increases, nickel deposition stops when the *p*H falls below 3.0 (2). Therefore, in order to maintain the required *p*H some buffering and alkali agent are added. Reaction [2] is responsible for the evolution of molecular hydrogen which cleans the surface of the sample. The resulting deposit so obtained is not pure nickel but it is a mixture of nickel and phosphorous. It has been observed (2, 3) that the percentage of phosphorous in the nickel deposit is inversely proportional to *p*H containing about 3-15% phosphorous when the operating temperature of the bath is kept at about 95°C. It has been reported that the percentage of phosphorous in the deposit is directly proportional to the operating temperature of the bath if the *p*H of the same is kept constant. This observation was reported by Feldstein (4) who obtained about 2.5 and 5% phosphorous in the deposit when the bath was operated at 25° and 70°C, respectively. This means that by using electroless technique one might expect to obtain low resistance ohmic contact to n-type silicon if the conditions are such that more phosphorous can diffuse or alloy into silicon. Considering the advantage of the facts discussed above some attempts have been made to study the following observations: (*i*) variation of contact resistance (C_R) with sintering temperature keeping operating temperature of the bath constant and *p*H as parameter and (*ii*) variation of C_R with sintering temperature keeping *p*H constant and operating temperature as parameter. It has been observed that the contact resistance decreases as the phosphorous content in the deposit increases with the heat-treatment.

Experimental

n-Type silicon of resistivity 5 Ω-cm and orientation (111) were used. Samples were first lapped with 600 mesh carborundum powder, washed thoroughly with deionized (DI) water, and then warmed in conc HNO_3 for a few minutes. Samples were then boiled in DI water, degreased in organic acids followed by washing in water. Next, samples were etched in caro's etch (5) for a few minutes. After washing, samples were treated in 48% HF solution for 1 min. Finally samples were rinsed. Immediately after this, samples were dipped first in sensitizing solution and then in activation solution (6) in steps for a few minutes. After each step samples were rinsed in water. It is believed that stannous ion reduces the palladous ion to metallic palladium, which act as palladium nuclei for electroless Ni-P deposition. Now, the samples were ready for deposition of nickel by immersing in the electroless plating bath. The compositions of the plating baths which were used in the present work are given in Table I. *p*H of the acidic and alkaline type of bath were maintained by adjusting the amount of HCL and NH_4OH, respectively. All the reported *p*H values were estimated to be within +0.5. The optimum operating conditions for obtaining an adherent, bright, and dense deposit of nickel on silicon are also given in Table I. All chemicals used in this investigation were of laboratory grade except for sodium hypophosphite which was 99% pure.

Key words: resistivity, alloy, electroless Ni-P.

Contact Resistance Studies

The electrical measurements were made by soldering leads to opposite faces of Ni-plated samples. The nickel plate was removed from all edges by grinding. The resistance of each sample was measured from its d-c *V/I* characteristics. Bulk resistance contributed by the silicon itself was calculated from silicon resistivity. The bulk resistance of the silicon plus the series resistance associated with the leads were deducted from the measured value which is called here the contact resistance (in Ω-cm^2). All measurements were taken at room temperature.

Results and Discussions

The plated samples were sintered in N_2 atmosphere for about half an hour between the temperature range 500°-800°C. Sintering leads to the formation of a diffusion-like zone between silicon substrate and the plating. After sintering the samples were replated in order to facilitate taking the leads and measurements. Figure 1 shows the variation of contact resistance (C_R) with sintering temperature keeping operating temperature of the bath constant and *p*H as parameter and Fig. 2 shows the variation of C_R with sintering temperature keeping *p*H constant and operating temperature as parameter. For each temperature, three samples were used and the average value of C_R is plotted.

From Fig. 1, it is clear that as the *p*H of electroless bath decreases the P-concentration in Ni-P alloy increases, resulting in a decrease in contact resistance

Table I. Compositions and operating conditions of baths

Bath used	Composition of the bath used	Operating conditions of the bath: pH	Temp. in °C	Immersion time in min	Control
Bath I	Solution A				
	$NiSO_4$, $6H_2O$—50 g/liter	10	25	30	pH was maintained by adding NH_4OH
	$Na_4P_2O_7$, 10 H_2O—100 g/liter				
	NH_4OH—45 cm³/liter	10	70	3-4	pH was maintained by adding NH_4OH
	Solution B				
	NaH_2PO_2, H_2O—50 g/liter				
	Solutions A and B were taken in the ratio 1:1				
Bath II	$NiCl_2$, $6H_2O$—30 g/liter	3	95	60	pH was maintained by adding HCl and NH_4OH according to desired pH value
	NaH_2PO_2, H_2O—10 g/liter				
	$(NH_4)_2HC_6H_5O_7$—10 g/liter	4	95	45	pH was maintained by adding HCl and NH_4OH according to desired pH value
		5	95	10	pH was maintained by adding HCl and NH_4OH according to desired pH value
		10	95	2-3	pH was maintained by adding HCl and NH_4OH according to desired pH value

with sintering temperature. The contact resistance gradually decreases up to 700°C. In all cases the contact resistances were found to be minimum between the temperature range 600°-700°C. This minimum value decreases steadily with increase of phosphorous concentration. Beyond this, the contact resistance slightly increases. This increase in C_R is probably due to the outdiffusion of phosphorous during heat-treatment. Again, from Fig. 2, it can be seen that the contact resistance decreases as the operating temperature of the bath increases from 25° to 70°C because at high operating temperature (70°C) the deposited Ni-P alloy contains more phosphorous than the samples prepared at 25°C which contains low P-concentration.

Conclusion

Two electroless baths, I and II, were used in this work; when operated under two different conditions as described above they yield an adherent, bright, and dense deposit of Ni-P alloy which when sintered at higher temperature gives a low value of contact resistance. From the practical point of view for obtaining a low contact resistance, it may be concluded that the most favorable temperature range of heat-treatment is between 600°-700°C. Heat-treatment above 700°C slightly increases the contact resistance due to outdiffusion of P from Ni-P alloy.

ABSTRACT

Coulostatic-flash irradiation of semiconductor/liquid-junction cells with a pulsed laser source has allowed time-resolved measurements of photopotential transients in the submicrosecond time domain. In 1.0*M* electrolyte ~12 nsec rise times were observed with several different n-TiO_2 electrodes. The dependences of transient photopotentials on the initial potential, pulsed laser intensity, and nature of electrolyte have been studied, and the measurement limitations defined by experimental and instrumental parameters have been described. Most importantly, the time dependence of photopotential transients has been characterized. Four possible contributions to the transient behavior are discussed: electron-hole recombination, photoinduced charge transfer at the solution interface (oxidation), subsequent back-reaction of photoproducts (reduction), and a transient expansion of the space charge layer due to rapid photoinduced charge injection.

A large number of studies have been conducted in recent years to characterize the photooxidation of water at n-type semiconductor electrodes (1-4). Most of this work has involved continuous irradiation with the purpose of determining final photoproducts, quantum yield, energy conversion efficiency, electrode durability, wavelength response, voltage dependence, intensity effects, etc. Photooxidation of water was first demonstrated at n-TiO_2 electrodes (5), but a wide variety of other electrode materials has been investigated in attempts to achieve improved performance. Recently, it has been shown that a solar-to-electrical conversion efficiency of ~12% could be obtained with n-GaAs electrodes using a regenerative Se_n^{2-}/Se^{2-} redox couple for photooxidation (6). Such polychalcogenide solutions also generally enhance the durability of the electrode (*i.e.*, resistance to electrode photodissolution). On the other hand, the efficiency of the water-splitting photoprocess (leading to the production of hydrogen fuel), originally described by Fujishima and Honda (5), has been achieved with an overall solar energy conversion efficiency of only ~1% (1-4). The production of hydrogen has some very desirable attributes, obviously, in that a storable combustible fuel is produced. Thus, it is one goal of our studies to examine mechanistic aspects of the photooxidation process which may dictate overall efficiency. To achieve a new perspective on these photoinduced electrode processes we have developed a time-resolved photoelectrochemical technique that allows meaningful measurements of photoeffects in a time domain several orders of magnitude shorter than previously reported.

We have reported previously on the limited time-resolution of potentiostatic photocurrents measured with pulsed irradiation (7, 8). At best, one can achieve resolution of ~500 nsec, with ~50 μsec more typical if correction for induced charging currents is made (8). Barker and co-workers (9) proposed coulostatic-flash measurements to obtain microsecond time resolution in photoemission studies with mercury electrodes. We recently achieved 200 nsec time resolution in coulostatic-flash mercury photoemission studies (10). The present work demonstrates that we can observe photopotential transients at semiconductor electrodes with at least 15 nsec time resolution. We have analyzed the electrical and electronic characteristics of photoelectrochemical cell and measurement circuitry to ensure the validity of short-time measurements; and we have suggested possible interpretations for the observed behavior. Our studies reported here have concentrated on observations with single crystal n-TiO_2 electrodes in various aqueous electrolytes, since such systems have been well characterized previously with CW light sources (1-4).

Key words: electrochemistry, semiconductor electrochemistry, photochemistry.

Experimental

Instrumentation.—The basic ingredients of the photoelectrochemical instrumentation have been described previously (10-13). A Princeton Applied Research Corporation (PAR) Model 174A polarograph was used for controlled-potential flash experiments as well as for cyclic voltammetry and voltage scans with CW irradiation. A 4-electrode cell was used (10), in which the fourth electrode is a platinum quasi-reference electrode. The pulsed laser source was a Molectron Model UV 1000 nitrogen laser (337 nm) with 10 nsec pulse width. The Molectron Model DL 200 dye laser was used to provide a pulsed source of subbandgap irradiation. The CW laser source was a Spectra-Physics Model 171 krypton ion laser (u.v. lines at 351/356 nm, visible lines at 531 and 647 nm). The coulostatic-flash instrumentation has been described also (10), but some modifications to the measurement approach have been made for this study. They are as follows: (*i*) for photopotential transients in a time domain from 10 nsec to 10 μsec, the working electrode and Pt quasi-reference electrode were directly connected (and a-c coupled) to a Tektronix Type 7A13 (105 MHz bandwidth) differential amplifier plug-in which was mounted in a Tektronix Model 7623A oscilloscope. All control/monitoring electronics were located inside the Faraday cage enclosing the cell. The y-axis output from the scope back panel was connected externally to a Type 7A19 (500 MHz bandwidth) plug-in amplifier (50Ω input, a-c coupled), mounted in a Tektronix Model 7844 oscilloscope. (*ii*) For photopotential transients in the time domain from 1 μsec to seconds, the Pt quasi-reference electrode was capacitively coupled (0.47 μF) to the saturated calomel reference (SCE) electrode; the SCE and working electrode potentials were input to a wideband-pass (5 MHz) high input impedance ($10^{11}\Omega$) differential amplifier (4.6×), with d-c offset bias so that the d-c level of transients could be conveniently measured. Its output was in turn connected to a Tektronix Type 7A16-A amplifier plug-in, with 1 MΩ input impedance, and 225 MHz bandwidth. Traces were recorded photographically. The philosophy behind the above measurement approaches is documented elsewhere (10, 14). The important point is that the Pt quasi-reference electrode reflects accurately any transient changes in the cell potential in a time domain of $<$10 μsec. Capacitive coupling of the two reference electrodes allows measurements of photopotential transients referenced to the SCE for times exceeding 1 μsec. However, when only the magnitude of photopotential transients was required the quasi-reference electrode could be monitored directly, without coupling to the SCE.

A General Radio Model 1650-A impedance bridge was used to obtain cell impedance measurements for Mott-Schottky plots (15, 16). The cell bias voltage was provided by the polarograph, by connecting the working and counterelectrode terminals from the polarograph to the bias terminals of the bridge, through two 30 mH inductors. The reference electrode terminal of the polarograph was connected to the SCE in the cell. The working and counterelectrodes were connected to the "unknown" terminals of the bridge. The 1 kHz oscillator signal was used, with ~15 mV peak-to-peak amplitude. The cell equivalent circuit for the purpose of this measurement was assumed to be a simple series *RC* combination.

Cell impedance measurements were also made using a Hewlett-Packard Model 4800A Vector Impedance Meter. This instrument conveniently measures both the complex impedance and phase angle as a function of frequency (5 Hz to 500 kHz). Consequently the cell resistance R_s could be measured at high frequency where the cell capacitance has a negligible contribution to the total impedance. The resistance measured at high frequency is the more significant figure for calculating fast rise times. The values measured at 1 kHz compared favorably to those calculated from the bridge measurements made for the Mott-Schottky plots at 1 kHz.

Cell and electrodes.—The photoelectrochemical cell design is basically as described previously (10-13), except that the platinum counter and reference electrodes were constructed of a fine mesh. The Pt reference formed a cylinder of 1.7 cm in diameter and 1.5 cm in height around the working electrode; the Pt counterelectrode formed a half-cylinder around the Pt reference electrode, with the same surface area as the reference. The large surface area electrodes were desirable in these studies to help minimize cell impedance and hence minimize response delays related to the source impedance of the measurement circuit. In addition, for measurements to be related only to the interfacial capacitance of the working electrode, it is necessary that the counter and/or reference electrodes have much higher capacitance. The n-TiO_2 electrodes used in this work were prepared from a boule of single crystal TiO_2 (Commercial Crystal Laboratories, Incorporated, South Amboy, New Jersey). The procedure involved slicing the boule perpendicular to the c axis (with alignment by x-ray diffraction) with a diamond wafering blade. The resultant 1 mm slices were reduced in a hydrogen furnace at 500°C for varying times. The crystal slices were then boiled in concentrated H_2SO_4 for 1 hr, and indium metal was rubbed onto one side until a shiny metallic surface was obtained. Indium was melted onto the shiny surface and a 12 gauge copper wire was then silver-soldered to the surface. The entire assembly was then mounted to a glass tube with epoxy (Dexter Epoxi-patch), with care taken to expose only the flat crystal surface.

The electrodes were used unpolished.[1] Prior to each series of runs they were etched in 1:1 H_2O/H_2SO_4 for 10 min.[2] Four different electrodes were used, representing a range of resistivities and donor densities. These were designated as electrodes A-D, and their characteristics are summarized in Table I.

Photoelectrochemical procedures.—The coulostatic-flash experimental procedure has been described in detail elsewhere (10). It involves first adjusting the cell voltage to the desired initial potential, E_i, for the semiconductor working electrode using the polarograph. A solid-state electronic switch which opens the cell circuit is triggered at 5 sec intervals. After ~30 μsec time delay the pulsed laser is triggered and the open-circuit potential difference between the working and reference electrodes monitored as described above. After a 2 sec interval the cell circuit is closed again and the initial potential reimposed by the polarograph.

With CW irradiation the cell voltage is controlled or scanned with the polarograph. A-C photocurrent signals were measured by chopping the laser source at 500 Hz and using a PAR HR-8 Lock-in amplifier synchronized with the chopper. Details have been published elsewhere (10-13). D-C photocurrents were measured by monitoring the PAR 174A output directly.

Pulse photocurrent measurements were made directly from the PAR 174A polarograph as described previously (10-13).

All solutions were deaerated with high purity nitrogen for at least 10 min before photoelectrochemical studies were conducted. The nitrogen was allowed to flow over the solution surface during experiments.

Results and Discussion

Semiconductor electrode characteristics.—Table I summarizes the physical and photoelectrochemical features of the various n-TiO_2 electrodes used in this work. The Mott-Schottky (M-S) plots, from which much of the data are taken, were linear in every case over the range of -0.5 to $+1.0$V *vs.* SCE in 1.0*M* KNO_3.

[1] Polishing is likely to introduce surface states (17).
[2] Etching of TiO_2 by concentrated H_2SO_4 is common in the preparation of photoelectrochemical electrodes, *e.g.*, Ref. (18).

Table I. Summary of electrode characteristics. (n-TiO_2)

R_s ($E = +1.0V$), Ω	330	29	38	~86
Area, cm^2	0.11	0.14	0.20	0.21

All data obtained with 1.0M KNO_3 electrolyte. E_{FB} = flatband potential; E_{TH} = threshold potential; N_D = donor density; M-S = Mott-Schottky plot; CW/u.v. refers to photocurrent *vs.* E experiments with CW/u.v. laser source; a.c. refers to lock-in detection; d.c. refers to direct current measurements; C-F refers to coulostatic-flash experiments; R_s, C_s refer to impedance bridge measurements of cell resistance and capacitance at 1 kHz.

* E_{TH} (CW/u.v.) and E_{TH} (pulse i_p) were obtained by extrapolating the rising portion of the i_p *vs.* E plot back to zero current.

† E_{TH} (C-F) was defined as the most negative potential at which a measurable negative photopotential transient was observed.

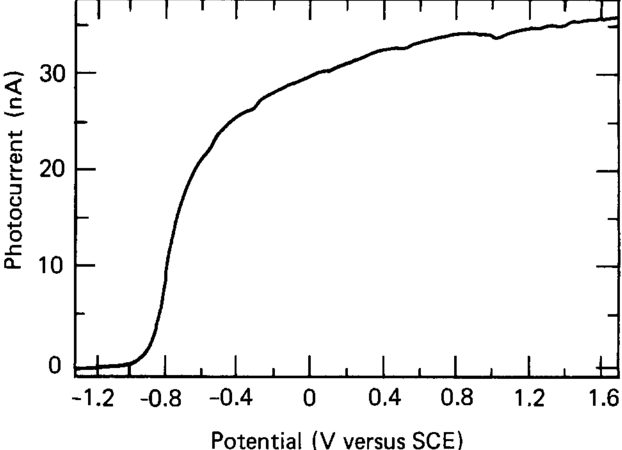
The magnitude and range of the features obtained from the M-S plots are both generally consistent with the observations of others (19). It should be pointed out, also, that the variation in donor density, N_D, was significant and deliberately created. There was also a corresponding range of resistance and capacitance of the electrodes at 1 kHz. Note that the value of R_s includes the solution resistance, which was ~15Ω for the 1.0*M* KNO_3; thus, the resistance of the semiconductor electrode alone can be calculated in each case. However, it is the total resistance, R_s, which affects the time response in coulostatic and potentiostatic measurements, as discussed below. It is important to note that the measured values of R_s and C_s depend on the frequency used in the measurement. The values in Table I were taken from Mott-Schottky plots made at the usual frequency of 1 kHz. However, whenever pulse photocurrents or rapid coulostatic measurements were interpreted, values of R_s and C_s obtained with the vector impedance meter at high frequency (>1 kHz) were used. The range of electrode characteristics exhibited in Table I was desired so that the effects on time-resolved photopotential/photocurrent transient behavior could be observed.

A significant observation in these characterization studies was that photoeffect threshold potentials usually did not agree with the flatband potential, E_{FB}, derived from Mott-Schottky plots (see Table I). Such discrepancy is not totally unexpected in correlating Mott-Schottky data to transient measurements. Some discussion of these discrepancies is presented below.

Photocurrent observations.—The dependence of photocurrent (i_p) on electrode potential with a continuous source irradiation is consistent with the previous literature (1-4). A typical curve is shown in Fig. 1. All electrodes behaved similarly, except for slight differences in E_{TH} (see Table I). Similar shapes were obtained for the a-c and d-c photocurrent, except a more noticeable "foot" was observed when monitoring the d-c photocurrent (Fig. 1). For the d-c current the rising portion of this lower intensity feature was extrapolated to zero current to yield E_{TH} (Table I). Finally, the quantum efficiency (photocurrent/incident photons) for d-c CW/u.v. experiments was approximately 0.1. This value is on the low side, probably because the high intensity laser source results in a lower fraction of photons absorbed in the depletion layer.

Thermal effects were easily distinguished by irradiating the electrode with subbandgap light (647/676 nm). The resulting a-c photorelated current observed was more than one order of magnitude lower in intensity and had a different shape (i_p *vs.* electrode potential) than the a-c photocurrent resulting from irradiation with u.v. light (351/356 nm). The corresponding d-c photorelated current was more than four orders of magnitude lower in intensity than the d-c photocurrent resulting from u.v. irradiation. In each case the observed visible/u.v. photocurrent ratios were made using comparable laser intensities.

Photocurrent measurements with the pulsed laser source yield essentially the same type of photocurrent-potential behavior shown in Fig. 1. However, the time-resolved photocurrent pulse behavior is of primary interest here. As pointed out previously (7, 8), potentiostatic photocurrents with pulsed irradiation follow a time dependence dictated by the cell time constant (R_sC_s), as long as the pulse width is short compared to R_sC_s and the photoinduced charge transfer processes are complete within a time frame short compared to R_sC_s. Figure 2 shows a typical photocurrent pulse. The decay times of these pulses compare favorably with the values of R_sC_s obtained from Table I for each electrode. Thus, no information on the dynamics of



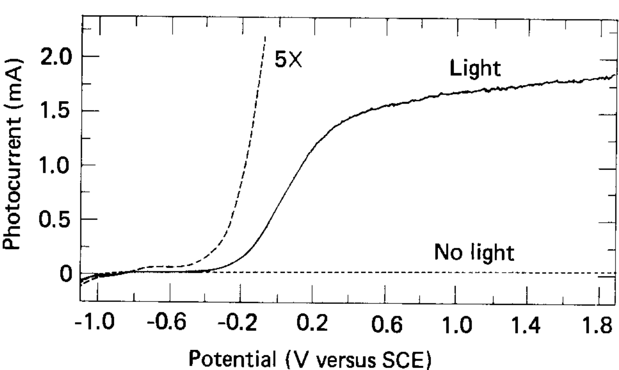


Fig. 1. Photocurrent-voltage curves with CW laser source. Electrode C; 1.0*M* KNO_3; wavelength = 351/356 nm; sweep rate = +20 mV/sec. (a, top) synchronous a-c detection, laser intensity = 0.15 mW/cm^2; (b, bottom) d-c current, laser intensity = 270 mW/cm^2.

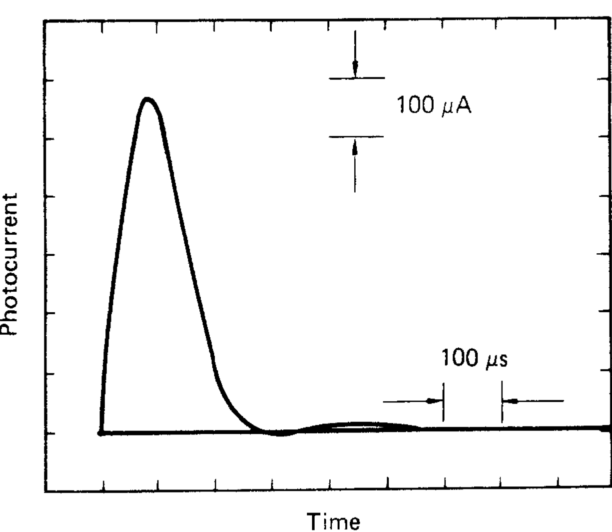

Fig. 2. Photocurrent-time behavior with pulsed laser source. Electrode C; E_i = +1.5V vs. SCE; 1.0M KNO_3; light intensity = 10 kW/cm².

photorelated processes can be obtained from pulse photocurrent measurements when R_sC_s is long compared to the time frame of interest. However, it is possible to obtain a measure of the total photorelated charge (Q_p), simply by integrating the photocurrent pulse. Such information is useful, of course, for quantum efficiency calculations. It is also useful for determining the electrode capacitance by combination with coulostatic measurements, as discussed below.

The differences in E_{TH} (a-c i_p, d-c i_p, pulsed i_p, C-F) reflect the differences in the experimental measurement technique and the quantity being measured. For example, the pulsed i_p measurement has a longer time constant than the coulostatic-flash experiment (vide infra), and only measures the net charge transferred. The actual number of photons per pulse in the pulsed measurement is far less (by a factor of 10^{-4}) than the number of photons per second in the CW experiment; consequently the more positive E_{TH} observed for pulsed i_p may reflect a lower sensitivity or photon threshold.

Coulostatic-flash studies.—Time dependence.—In contrast to pulse photocurrent measurements, coulostatic (open-circuit) photopotential (E_p) measurements made with a pulsed laser source are not limited in response time by the cell time constant (R_sC_s) (9, 10). The response is limited by the RC time constant defined by the cell impedance (R_s) and the combined value of the interelectrode stray capacitance, the input capacitance of the measurement electronics, and cable capacitance. This combined value, C_M, is typically less than 100 pf. Thus, for electrodes A to D, respectively, R_sC_M <4, <3, <4, and <5 nsec, where R_s is the value measured at high frequency with the vector impedance meter in 1.0M KNO_3. These response time constants are comparable to or less than the pulse width of the laser source (10 nsec), thus allowing time-resolved studies in a time domain of ≥10 nsec as shown below.

Figures 3 and 4 show typical photopotential (E_p)-time behavior for coulostatic-flash experiments in 1.0M KNO_3, using the nitrogen laser (337 nm). Irradiation with subbandgap energy light using the nitrogen pumped dye laser (520 nm) resulted in photopotential excursions at least four orders of magnitude lower (using comparable laser intensities).

Table II summarizes the time-dependent behavior of all four electrodes. Several features are worth noting. First of all, it is clear that the rise time ($t_{95\%}$) is ~12 nsec, which suggests that it is limited by the laser pulse-width and/or the bandwidth of the measurement electronics. The potential changes sharply in a

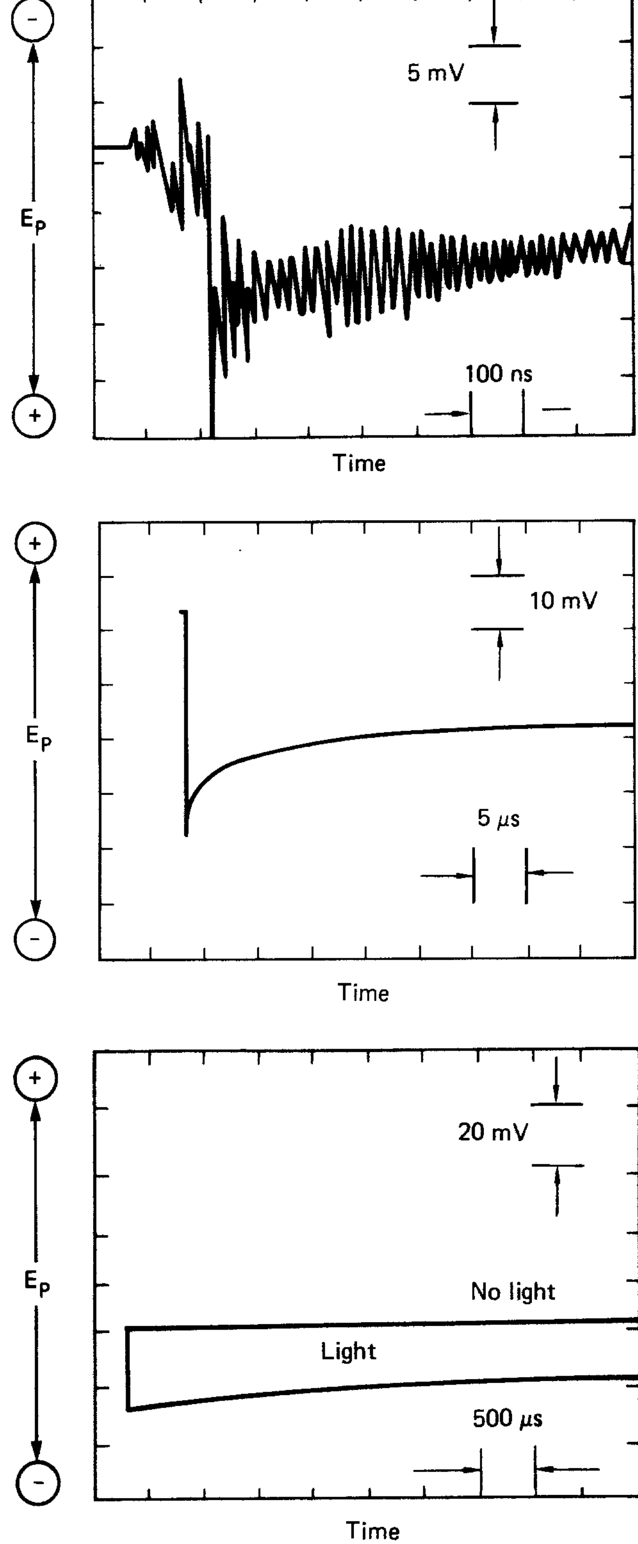

Fig. 3. Coulostatic-flash photopotential transients at positive potential for three different time domains. Electrode C; E_i = +1.0V vs. SCE; 1.0M KNO_3; light intensity 10 kW/cm². The 10 nsec laser pulse occurs at the onset of the negative potential transient; (a, top; b, center; c, bottom).

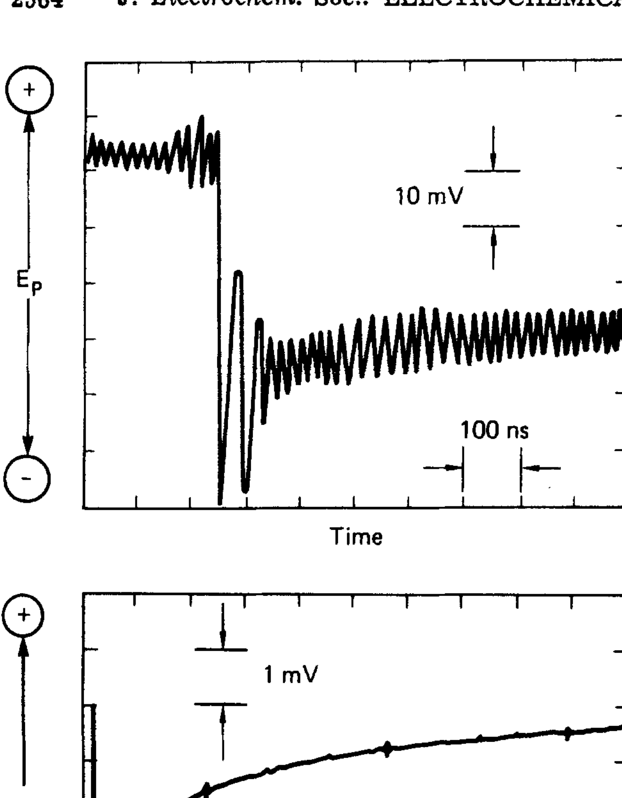
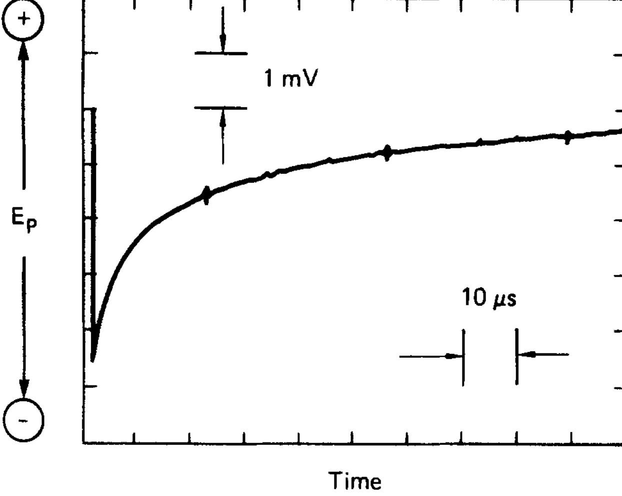
more negative direction, but then decays back toward the initial potential, E_i. When E_i is very positive of E_{FB}, the final photopotential, $(E_p)_F$, is reached after ~1 to 20 msec for the electrodes studied here. When E_i is near E_{FB}, not only is there a much smaller initial excursion of the photopotential, but $(E_p)_F$ approaches E_i; also $(E_p)_F$ is reached in < ~1 msec.

The net magnitude of photopotential excursion achieved after the decay, $(\Delta E_p)_F$, is taken to be in-





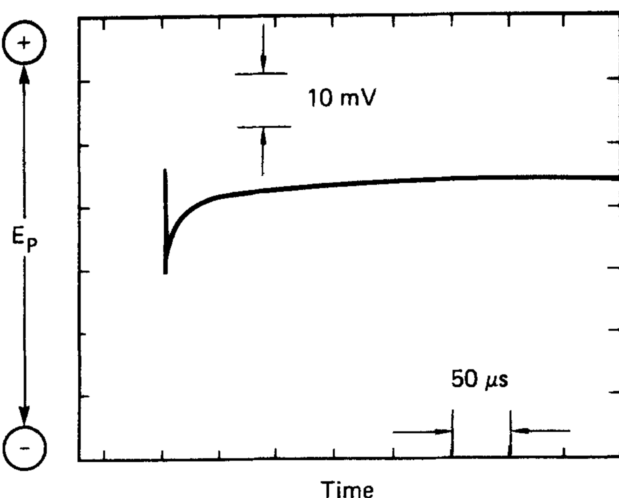


Fig. 4. Coulostatic-flash photopotential transients near E_{FB} for three different time domains. Electrode C; $E_i = -0.5V$ vs. SCE; 1.0M KNO_3; light intensity $\simeq$ 10 kW/cm^2. The 10 nsec laser pulse occurs at the onset of the negative potential transient; (a, top; b, center; c, bottom).

dicative of the net quantity of charge transferred, or "photocharge" (Q_p). Q_p can be calculated from the relationship, $Q_p = C_s \cdot (\Delta E_p)_F$. (In general C_s depends on the cell potential, so Q_p has to be calculated from the integral of C_s and E_p for large photopotential excursions). An indication of the efficiency of the photoelectrolysis process can be obtained from the ratio, Q_p/A, where A is the electrode area. The data in

Table II. Summary of time-dependent behavior of several n-TiO_2 electrodes with pulsed-laser coulostatic-flash experiments in 1.0M KNO_3

† $Q_p = (\Delta E_p)_F \cdot C_s$; A = working electrode area in cm^2. (The C_s value used was taken from M-S plots or was taken as the maximum measured value from the M-S plot when $E_i < E_{FB}$.)

Table II clearly show that electrode B is the most efficient and electrode A is the least efficient. By comparison with Table I, the trend in efficiency correlates well with the donor density. (However, because the laser pulse intensity varied ± 25% due to optical alignment, and because N_D values for electrodes B, C, and D are similar, the efficiency trends can only be interpreted semiquantitatively.)

The times, t_F, required for the photopotential to decay to $(\Delta E_p)_F$ were only estimated from visual inspection of photographic traces, but do indicate a qualitative inverse correlation between t_F and the donor density. Finally, the quantum efficiency (Q_p/total photons incident) can be estimated to be ~10^{-2}. This value is somewhat low, but certainly includes the uncertainties in measuring the total charge transferred and the number of photons absorbed in the depletion layer during each 10 nsec laser pulse.

The nature of the E_p decay is certainly of interest (Fig. 5A). Several different factors may be involved (Fig. 5B-E). The first factor (Fig. 5B) is that the initial photopotential excursion is due to space charge layer contraction caused by electron-hole generation and separation. The narrower space charge layer has a larger capacitance, while the total charge remains the same, thus the excursion is toward E_{FB}. The subsequent decay is caused by electron-hole recombination (Fig. 5B). The rates of such processes in the bulk for highly doped semiconductor materials are typically found to be in the submicrosecond time domain (20). However, longer lifetimes might occur in the space charge region at a semiconductor/electrolyte interface (band bending at the interface facilitates the separation of electrons and holes).

The second factor (Fig. 5C) is oxidation (of either the solvent or species at the electrode surface) by holes migrating to the surface. Note that this process would tend to increase ΔE_p with time. An opposite effect would be due to the dark reduction of photoproducts (Fig. 5D); *i.e.*, the photopotential decay represents the dark back reaction of photooxidation products produced by the flash. We have some evidence from other controlled-potential, pulsed photocurrent studies (21) that such back reactions may occur, probably via surface states, even when the electrode potential is quite positive of E_{FB}. The rate (or efficiency) of the back reaction appears to increase as the potential is made less positive (21), and this is consistent with the observation here that the decay time constant decreases as E_i approaches E_{FB} (Table II).

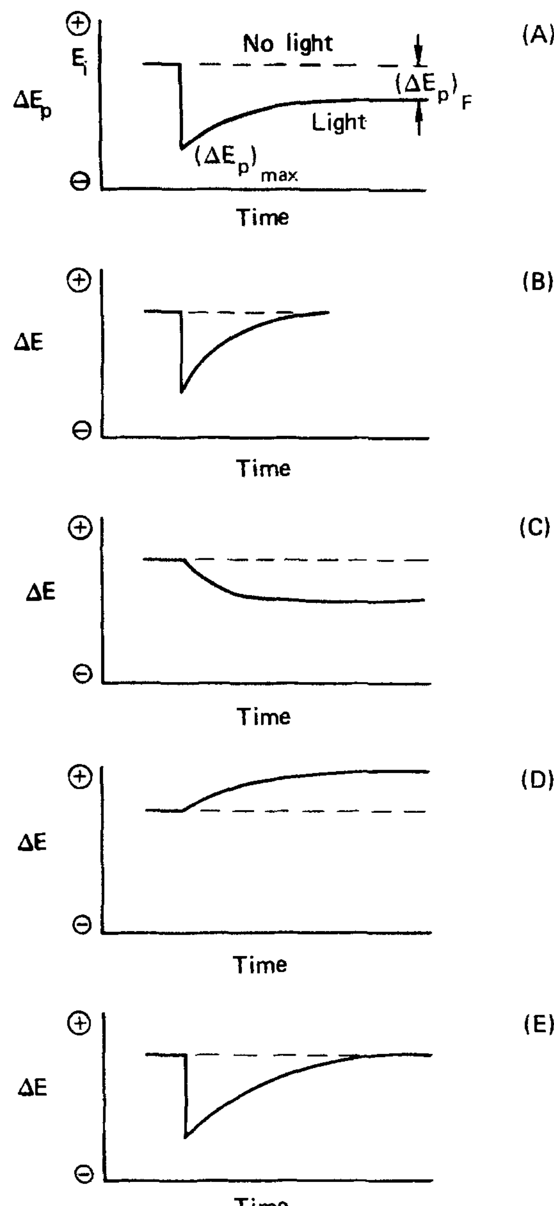

Fig. 5. Pictorial representation of four factors which may influence the observed transient photopotential: (A) experimentally observed behavior; (B) electron-hole separation and recombination; (C) photoinduced oxidation; (D) dark reduction; (E) expansion and relaxation of the space-charge layer. In all cases the vertical (ΔE) and horizontal (time) scales are arbitrary.

The fourth possible factor is that the very high rate of negative charge injection due to photooxidation caused by the intense 10 nsec laser pulse forces a transient nonequilibrium expansion of the space charge region in the semiconductor, followed by a relaxation back to its equilibrium dimensions, with associated overshoot and decay of the photopotential (Fig. 5E). (This decay may or may not involve hole-electron pair recombination, depending on the survival of excess surface holes.) Such a relaxation effect has been observed with coulostatic electrical charge injection at a mercury/dilute-electrolyte interface (22, 23) and has been described theoretically (24-26) in terms of a transient overexpansion of the diffuse-double layer (interfacial) followed by a relaxation back to an equilibrium thickness, with corresponding changes in the measured double layer voltage analogous in nature and time dependence to those observed here.

The nature of steady-state photopotentials generated under conditions where charge transfer to solution is blocked has been described previously (27-29); and experimentally observed instantaneous photovoltaic response has been described (30, 31). Gerischer (32) suggested that short light pulses should be used for these measurements to obtain a better characterization of the space charge region free from charge transfer and surface effects. However, no reliable measurements have been reported on a time scale comparable to our studies. The possibility that a transient photopotential overshoot and decay might be observed has been suggested previously (33, 34). Laser and Bard (35) also pointed out that the response of the semiconductor space charge layer to coulostatic electrical charge injection is analogous to that predicted by Feldberg (26) for diffuse double layer relaxation, except that it should occur in a much shorter time domain. Unfortunately, the pulsed laser-induced photopotentiometry experiments performed here do not correspond exactly to the electrical coulostatic charge injection situation described by Laser and Bard (35). Nor do the conditions agree with those used to simulate steady-state photopotentials (29) or to simulate the relaxation of photogenerated free carriers (33). However, Ref. (33) does demonstrate that distinct transient minima and maxima in the concentration-distance profiles of minority and majority charge carriers can be generated, perhaps leading to the kind of relaxation processes observed here. The time scale of the transient behavior predicted (33) is several orders of magnitude shorter than observed here. However, the conditions chosen for the simulations correspond to light fluxes and donor densities several orders of magnitude lower than those used here.

To investigate further the merits of the fourth possible factor influencing the photopotential decay (transient expansion and contraction of the space charge layer due to photocharge injection), the time dependence was compared to that predicted theoretically for diffuse double layer relaxation (26). In that case, assuming equal mobilities for positive and negative charge carriers, theory predicts that the observed double layer potential should follow a $t^{-2/3}$ dependence during the latter part of the decay when the potential is near E_{PZC} (potential of zero charge). By analogy, the same essential, theoretical concepts can be imposed on the response of the semiconductor space charge region to an instantaneous light-induced charge injection. Holes and electrons are considered to replace cations and anions, with their associated mobilities and concentrations; the thickness of the depletion layer replaces the double layer thickness, and E_{FB} replaces E_{PZC}.

The suggestion that double layer relaxation could also contribute to the time dependence observed here is of course appropriate. However, the effects have not been observed at mercury electrodes with concentrated electrolyte ($> \sim 0.05M$) and relatively small charge injection (22). Thus, we should not expect to see Helmholtz layer relaxation effects here, with $1.0M$ KNO_3 electrolyte and $Q_p/A < 1\ \mu C/cm^2$.

A typical plot of E_p *vs.* $t^{-2/3}$ is shown in Fig. 6 for electrode D. The value of E_i for the experimental data in Fig. 6 was near E_{FB}. The data plotted are for only the latter part of the decay, where a linear dependence on $t^{-2/3}$ was observed. This behavior is analogous to double layer relaxation observations (22), where linear dependence of cell potential on $t^{-2/3}$ is predicted after coulostatic charge injection when E_i is near E_{PZC} (26). The behavior shown in Fig. 6 was typical of all the electrodes used in these studies. Nonlinear dependence on $t^{-2/3}$ was observed at short times, as indicated in Table III. Nonlinear dependence on $t^{-2/3}$ was observed at all times when E_i was very positive of E_{FB} (*e.g.*, at +1.0V *vs.* SCE) for all electrodes; the slope of a linear least squares fit on a log-log plot of E_p *vs.* t becomes increasingly more positive as E_i becomes more positive of E_{FB}.

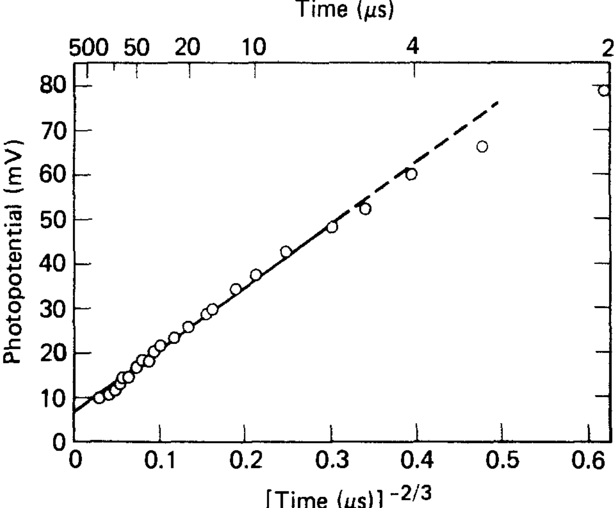

Fig. 6. Transient photopotential vs. $t^{-2/3}$ for E_i near E_{FB}. 1.0M KNO_3, electrode D, −0.5V vs. SCE, gain = 4.6.

In order to investigate further the observed time dependence of the transient photopotentials the slopes of the E_p *vs.* $t^{-2/3}$ plots were compared to the theoretical predictions of Feldberg (26). While an absolute correlation is not feasible without an accurate knowledge of the carrier mobilities and the internal potential gradient, it is possible to examine the observed slopes with regard to predicted correlations. Feldberg's theory predicts that the slope, S, is related to q, the injected charge density, C_Z, the bulk concentration of charge carriers, and D, the diffusion coefficient of charge carrier, by a linear function shown in Eq. [1]

$$S = (\text{constant}) \cdot q^{5/3} \cdot C_Z^{-3/2} \cdot D^{-2/3} \quad [1]$$

Because the diffusion coefficient in solution is analogous to the carrier mobility in a semiconductor, the relationship defined in [1] predicts that the product, $S \cdot C_Z^{3/2} \cdot q_p^{-5/3}$, should be a constant for any particular semiconductor electrode, as q_p is varied experimentally. Thus, Eq. [2] defines a parameter, γ, which can be calculated for each electrode from the slope and intercept of various experiments where q_p is varied. ($q_p = (\Delta E_p)_F \cdot C_s/A$)

$$\gamma = S \cdot C_Z^{3/2} \cdot q_p^{-5/3} \propto D^{-2/3} \quad [2]$$

(It should be pointed out that the values of q_p/C_Z in our experiments are 1 or 2 orders of magnitude lower than what Feldberg found necessary for Eq. [2] to hold.)

The values of γ obtained from several different experiments are given in Table III. Note that the two values for electrode B agree reasonably well as q_p varies. Also, note that the magnitude of γ increases with the donor density from electrode to electrode.

Table III. Summary of $t^{-2/3}$ analysis of photopotential decay for E_i near E_{FB}

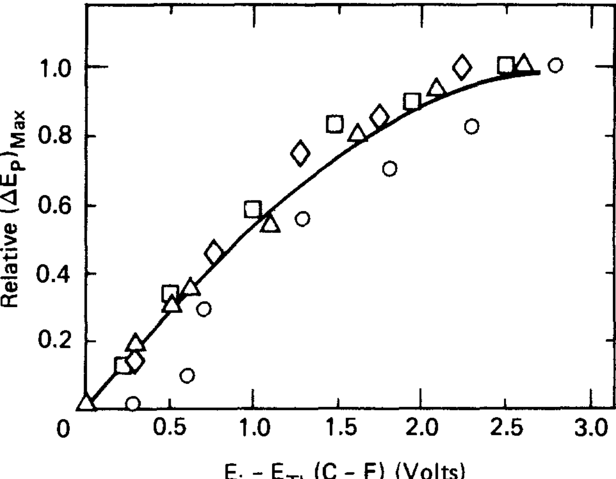
	Electrode				
	A	B		C	D
E_i, V *vs.* SCE	−0.7	−0.6	−0.7	−0.5	−0.8
S, V-μsec$^{+2/3}$*	0.089	0.012	0.0025	0.027	0.013
t_s, μsec	~30	~4	~4	~15	~15
$(\Delta E_p)_F$, mV	3.6	2.7	0.78	2.8	2.0
q_p, μC/cm^2	0.017	0.067	0.021	0.044	0.032
C_Z, cm^{-3} (× 10^4)	0.027	5.0	5.0	2.33	2.5
γ (× 10^5)	0.22	1.21	1.74	1.75	1.59

* S = slope of (ΔE_p) *vs.* $t^{-2/3}$ plot; t_s = time at which linear dependence on $t^{-2/3}$ begins; $(\Delta E_p)_F$ = intercept of (ΔE_p) *vs.* $t^{-2/3}$ as $t \to \infty$; q_p = photocharge density = $C_s \cdot (\Delta E_p)_F/A$ (see Tables I and II for C_s, A); $C_Z = N_D/A_v$, where A_v = Avogadro's number = 6×10^{23}; $\gamma = S \cdot C_Z^{3/2}/q_p^{5/3}$.

This is consistent with the fact that the carrier mobility decreases with increasing donor density (20), and Eq. [1] predicts that the slope, S, should increase with decreased carrier mobility; thus, γ should increase with increased donor density, as indicated in Table III. Such results support our speculation that space charge relaxation is a possible factor in the observed transient time dependence of the photopotential.

Additional support is seen in the fact that the magnitude of the photopotential overshoot diminishes with increasing N_D (Table II-A). This behavior is consistent with Feldberg's theory (26). Moreover, the fact that lowering the solution electrolyte concentration does not change the long-term photopotential decay, but only increases the initial rise time (as discussed below), indicates that Helmholtz-layer relaxation is not contributing significantly to the observed potential excursions.

Potential dependence.—The dependences of $(\Delta E_p)_{max}$ and $(\Delta E_p)_F$ on E_i are shown in Fig. 7. The observed photopotential excursions were normalized with respect to the values obtained at the most positive potential for each electrode so that the responses for all electrodes could be plotted on the same vertical scale despite variations in laser intensity, optical alignment, and photoelectrolysis efficiency. The voltage axis uses the threshold potential (E_{TH}(C-F)) observed in coulostatic-flash experiments as the individual reference points for each electrode. Thus, the potential ref-



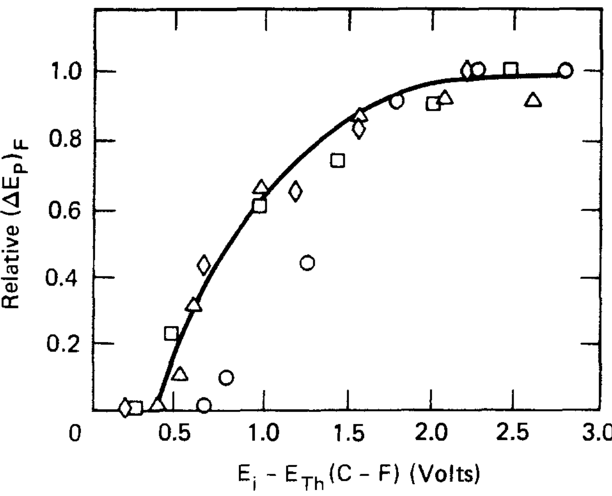


Fig. 7. Dependence of maximum (a, top) and final (b, bottom) coulostatic-flash photopotential on initial potential. 1.0M KNO_3; light intensity ≃ 10 kW/cm^2. Electrodes: A (△), B (○), C (◇), and D (□).

erenced to the SCE for each electrode can be determined from Table I. Also, the relationships between $(\Delta E_p)_F$ and $(\Delta E_p)_{max}$ at potentials near to, and very positive of E_{FB} can be obtained from Table II.

It is interesting to note from Fig. 7 that $(\Delta E_p)_F$ appears to achieve a plateau for $[E_i - E_{TH}(C\text{-}F)] > \sim 1.3V$, whereas $(\Delta E_p)_{max}$ increases continuously with potential. This difference in dependence on potential is probably a reflection of the fact that $(\Delta E_p)_F$ is indicative of the net "photocharge" involved in the photoelectrolysis, whereas $(\Delta E_p)_{max}$ would be related to all of the previously discussed factors which contribute to the initial photopotential excursion. Note also that the shape of Fig. 7B is similar to that seen for i_p (Fig. 1).

The fact that $(\Delta E_p)_F$ decreases as E_i approaches $E_{TH}(C\text{-}F)$ reflects a decrease in the efficiency of the photoelectrolysis process. This may be due to the occurrence of a dark back reaction, which becomes more favorable near E_{TH}. However, the back reaction must be very rapid, essentially complete before time, t_s, where the observed linear $t^{-2/3}$ dependence begins (Table III). We note that as E_i approaches $E_{TH}(C\text{-}F)$, the value of $(\Delta E_p)_F$ reaches zero before $(\Delta E_p)_{max}$ (Fig. 6). That is, the observed photopotential pulse was not due, apparently, to a net photooxidation process for $(E_i - E_{TH}(C\text{-}F)) < \sim 0.5V$. This corresponds roughly to the potential region negative of E_{FB}. Thus, the apparent early thresholds $(E_{TH}(C\text{-}F))$ reported in Table I may be related to a transient laser-induced charge redistribution in the space-charge layer which allows minority carrier charge transfer to the solution, despite an equilibrium potential gradient opposing the flow of holes to the surface. The observation that $(\Delta E_p)_F$ approaches zero as E_i approaches E_{FB} suggests that the charge transfer is reversed as the equilibrium potential gradient in the space-charge region is approached. A similar argument may explain the early thresholds observed with chopped CW irradiation (Table I). The closer agreement between E_{TH} (pulse i_p) and E_{FB} may be attributed to the fact that the dynamics of the electrode process are not reflected in the pulse photocurrents, as discussed earlier. Of course, all of these observations at negative potentials must be tempered with the fact that for all four electrodes a gradual rise in background dark current was observed with cyclic voltammetry for E negative of $\sim -0.9V$ *vs.* SCE. It is not clear whether this influences the early threshold observations.

Intensity effects.—The effects of laser pulse intensity are summarized in Fig. 8. There is an apparent saturation effect when the light intensity exceeds 10 kW/cm^2. Thus, all studies of potential and time dependence described here utilized a lower intensity laser pulse, as indicated in the figure legends and elsewhere. Another observation is that there is a somewhat different dependence of $(\Delta E_p)_{max}$ and $(\Delta E_p)_F$ on light intensity. This different dependence is probably explained, as pointed out above, by the fact that $(\Delta E_p)_{max}$ reflects the transient expansion of the space-charge layer as well as the net photoelectrolysis charge.

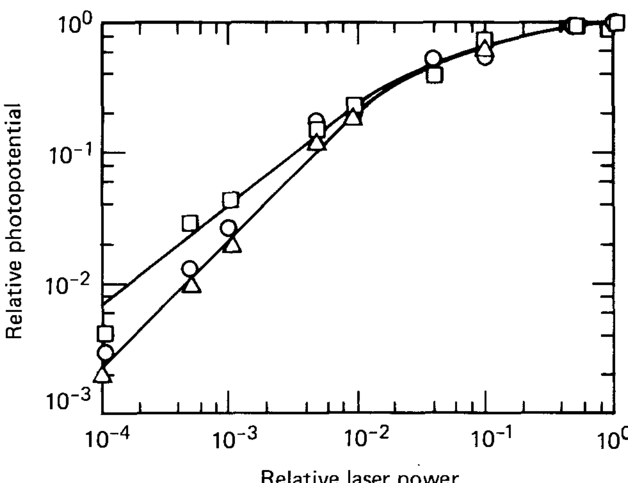

Fig. 8. Intensity dependence of photopotential $(\Delta E_p)_{max}$ for coulostatic-flash experiments. Electrode A; 1.0M KNO_3; I_o = 1 MW/cm^2. E_i = +1.0V *vs.* SCE (△); E_i = 0.0V *vs.* SCE (○); E_i = −0.6V *vs.* SCE (□).

Electrolyte effects.—The effects of using a more dilute electrolyte, as well as using other electrolytes, have been examined. When more dilute electrolytes are used, the long-term time dependence remains the same, but the rise time of the transient increases. For example, for electrode C the observed rise times were ~12, ~20, and ~150 nsec, for 1.0, 0.1, and 0.01*M* KNO_3 solutions, respectively. Essentially the same trend in rise times was observed for all of the electrodes for various electrolyte concentrations. Thus, the rise time can be related primarily to the measurement limitations. That is, the rise time of the potentiometric circuitry is limited by R_sC_m, where R_s is the total cell resistance. [$t_{95\%} = 3(R_sC_m)$.] The value of C_m is estimated to be <100 pf. R_s values were measured at high frequency using the vector impedance meter for the three different electrolyte concentrations. Thus, the rise times ($t_{95\%}$) are predicted to be <8, <34, and <180 nsec for 1.0, 0.1, and 0.01*M* KNO_3, respectively, based on R_s values of 26, 112, and 600Ω for electrode C in these solutions. The trend is consistent with the observed data; in addition, using the observed rise times and R_s values, the calculated values of C_M are 60 and 80 pf, respectively, for 0.1 and 0.01*M* KNO_3 solutions (the measured value for 1.0*M* KNO_3 is limited by the laser pulse width and amplifier bandwidth).

The influence of other electrolytes was also studied. We observed no significant differences from all the above results of voltage, intensity, and time studies when 1.0*M* KCl or 1.0*M* Na_2SO_4 were substituted for 1.0*M* KNO_3. With 1.0*M* NaOH there was an expected negative shift in the observed value of E_{FB}. Moreover, the expected trend in E_{FB} with pH was observed over the pH range of 1-13, as predicted by Eq. [3]

$$E_{FB} = E_{FB}(pH = 0) - (0.059)pH \qquad [3]$$

It may be significant that unbuffered solutions were used; consequently local pH changes at the interface during photooxidation of H_2O may cause E_{FB} to vary. Further experiments need to be performed to see if buffering the solution has a significant effect and what buffers can be expected to respond rapidly enough to eliminate any contribution from a "pH jump" effect.

Correlation of flash photocurrent and photopotential measurements.—Another useful perspective on the photoinduced electrode process can be obtained by correlating the total photocharge in a photocurrent pulse obtained potentiostatically with the photopotential excursion observed coulostatically under the same conditions of laser pulse intensity, electrode potential, etc. The relationship, $Q_p/(\Delta E_p)_F = C_s$, should be approximately true.

For example, the value of C_s calculated in this way for electrode C with 1.0*M* KNO_3, E_i = 1.0V *vs.* SCE, was 3.5 μF. This value compares favorably with the value of C_s (3.3 μF) obtained from vector impedance meter measurements at 1.6 kHz (which is approximately the frequency of the photocurrent pulse, see Fig. 2). This agreement suggests that the interpretation of $(\Delta E_p)_F$ as relating to the net photooxidation charge transfer is correct.

Conclusions

These studies demonstrate for the first time that photoinduced electrode processes can be observed re-

liably in the nanoseconds to milliseconds time domains. The observed limitations on time resolution are consistent with those predicted. The time dependence of transient potentiostatic photocurrents is clearly related to the cell time constant (microseconds); whereas the time dependence of transient coulostatic photopotentials can be studied with ~10 nsec time resolution. The fact that the rise time is ~12 nsec in 1.0*M* electrolyte may indicate that photoinduced transfer of charge to the electrolyte solution is essentially instantaneous with a 10 nsec laser pulse. While the pulsed experiment may only be accessing a monolayer or so on the surface, these initial experiments suggest that the electron transfer rate is proportional to the excitation rate. This observation is definitely a desired attribute for any stoichiometric photochemical process (*e.g.*, solar energy conversion).

The observed subsequent photopotential decay may be related to a phenomenon of space charge relaxation which exhibits a decay time varying from ~1 to ~20 msec as the potential becomes more positive of E_{FB}. A significantly shorter and less dramatic decay is observed with increased doping density. Alternative explanations suggested here include photoproduct back reaction or hole-electron recombination. Because these other processes are known to occur to some extent, their possible contributions to the initial photopotential transient behavior should be investigated further.

These studies have provided a foundation on which to base further investigations of transient behavior with other semiconductor photoelectrodes and other photoelectrolysis processes. It should be possible to study the dynamics of redox stabilized photoelectrodes as well as dye-sensitized photoelectrolysis on a previously inaccessible time scale. Modification of the local environment (*e.g.*, nonaqueous solvents) may be necessary to fully exploit this technique for studying chemical processes as opposed to processes inherent to the semiconductor electrode.

ABSTRACT

The effect of nickel impurity in zinc sulfate electrowinning solutions was studied using voltammetry techniques. The reactions occurring at various points on the polarization curve are proposed and comparisons made for both pure electrolyte and those containing nickel. A nickel-activated hydrogen evolution peak was found to occur at low current densities during the anodic sweep portion of the curve, the height of which was found to be proportional to the nickel concentration in solution. The influence of certain operating parameters such as zinc ion concentration, potential scan limit, and scan rate on the nickel activated peak was also determined.

The primary industrial process for the production of metallic zinc is the electrolysis of acid sulfate solutions containing approximately 60 g/liter zinc ion and 200 g/liter H_2SO_4 (1, 2). Zinc has a rather negative potential (-0.76V *vs.* SHE) but it also exhibits a high hydrogen overvoltage, thus making aqueous electrolysis possible. Unfortunately, the system is then very susceptible to the presence of any impurities with lower hydrogen overvoltages which might co-deposit with the zinc. Reductions in current efficiency will result if the concentration of certain impurities is too high, and extensive electrolyte purification is required prior to electrolysis to minimize this occurrence.

The problem is compounded by two factors. First, the levels of impurities that can affect deposition efficiency are very low, being in the range of 20 ppb to 10 ppm, depending on the impurity (3). In addition, synergistic interactions are common among various impurities, making it difficult to evaluate the quality of an electrolyte by chemical analysis alone. Both organic and inorganic compounds are added to assist in deposit growth control, which adds to the complexity of the solution chemistry (4). There have been numerous reports on the observed effects of impurities in zinc electrowinning (5-11) and inferences to the reasons for this behavior, but there is surprisingly little data on the more quantitative aspects of the mechanism involved.

Cyclic voltammetry techniques have been previously developed and successfully used to monitor the relative glue and antimony concentrations in zinc electrolytes (12, 13). During this research, it became apparent that other valuable information might also be derived from electrochemical testing of this type (14-17). One potential use of a more applied nature included the ability to evaluate the electrolyzability of a solution, *i.e.*, to provide an indication of the concentration of active impurity present in solution. The process also offered interesting possibilities in establishing the fundamental behavior of many of the chemical species present in zinc electrolytes and of the zinc deposition process itself.

In order to determine the feasibility of this approach, studies were made on a "pure" or reference electrolyte and the results were compared with those obtained with nickel in solution. Nickel was chosen because it is one of the most common, harmful impurities found in zinc sulfate solutions. Furthermore, it has been extensively studied in previous electrolysis tests.

* Electrochemical Society Active Member.

Key words: electrowinning, zinc, voltammetry, impurities.

The objectives of this research were to determine the applicability of cyclic voltammetry to testing deposition efficiency in the presence of impurities such as Ni and to gain insight into the mechanism of impurity behavior in the zinc electrowinning process.

Experimental

The electrolyte was prepared by acidifying neutral, purified zinc sulfate (supplied by AMAX, Sauget, Illinois) with sulfuric acid to give a final composition of 60 g/liter Zn and 200 g/liter H_2SO_4. For each experiment, 300 ml of electrolyte was introduced into a Pyrex "H" cell. When studying the effects of nickel additions, the desired amount of nickel sulfate was mixed with the electrolyte in a beaker before introducing it into the "H" cell.

The electrode was prepared by wet grinding on 600 grit paper, then water washed in an ultrasonic cleaner, rinsed and dried in an air stream, and immediately put into the "H" cell. An alternate preparation included a wheel polishing step using 0.05 μm γ-alumina following grinding on 600 grit paper. The cleaning and drying procedures were the same as described previously.

The cyclic voltammetry experiments were conducted in a Pyrex "H" cell, open to the atmosphere, and a three-electrode setup was used. The working electrode (test electrode) was Al (supplied by Cominco Limited, Trail, B.C., Canada), the exposed surface area of which was 1 cm^2. The counterelectrode consisted of platinum gauze, and the reference electrode of Hg/Hg_2SO_4 (2M H_2SO_4). The entire cell assembly was immersed in a constant temperature water bath in order to maintain the electrolyte at the test temperature.

Cyclic voltammograms were obtained using a Petrolite Potentiodyne Analyzer M-4100. The current display is logarithmic which is useful in the microamp ranges encountered in the initial portion of the curve.

The cycle was set to begin at -0.53V *vs.* SHE, with the upper cathodic limit set to a value capable of producing a total current of 50 mA (in some runs, 10 mA). At this point the process was reversed and driven anodically to the original potential. Figure 1 shows a zinc deposit obtained using parameters typical for those used in this study.

Results and Discussion

Voltammograms of a zinc electrolyte containing Ni^{+2} impurities.—Figure 2 shows the typical voltammogram of a zinc electrolyte which contains no nickel additions and Fig. 3 was obtained from an identical solution except for the addition of 5 ppm Ni^{++}.

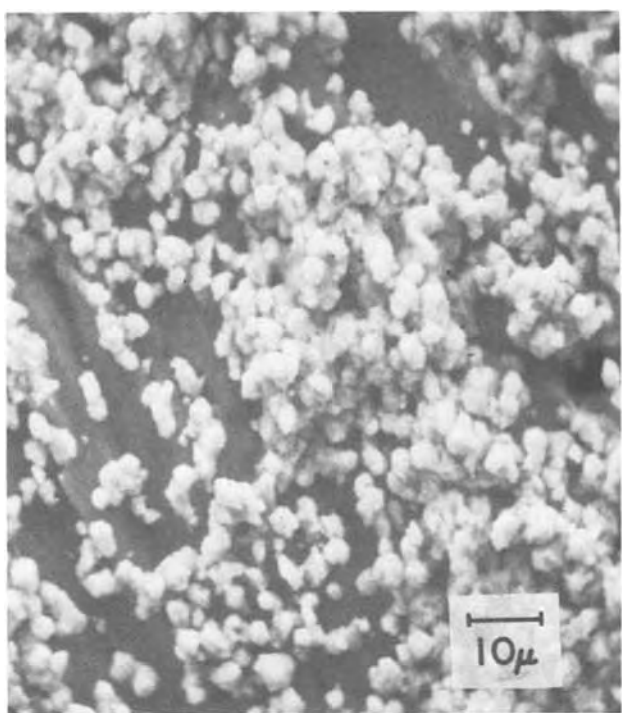

Fig. 1. SEM micrograph of a typical Zn deposit produced by cycling at 1 mV/sec to a current density of 50 mA/cm², reversing the scan until the 5 mA/cm² is attained and immediately removing from solution.

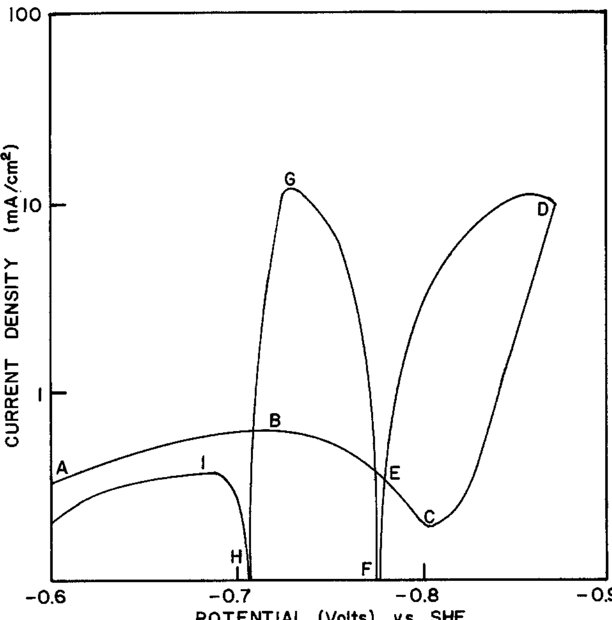

Fig. 2. Voltammogram for electrolyte containing 60 gpl Zn^{++} and 200 gpl H_2SO_4. Aluminum cathode.

The more probable electrochemical reactions involved during the scan are proposed to be as follows

Cathodic reaction:

$$H^+ + e \rightarrow \tfrac{1}{2} H_2 \text{ (Al substrate)} \quad [1]$$

$$Ni^{++} + 2e \rightarrow Ni \text{ (Al)} \quad [2]$$

$$Zn^{++} + 2e \rightarrow Zn \text{ (Al)} \quad [3]$$

$$H^+ + e \rightarrow \tfrac{1}{2} H_2 \text{ (Zn)} \quad [4]$$

$$Ni^{++} + 2e \rightarrow Ni \text{ (Zn)} \quad [5]$$

$$Zn^{++} + 2e \rightarrow Zn \text{ (Zn)} \quad [6]$$

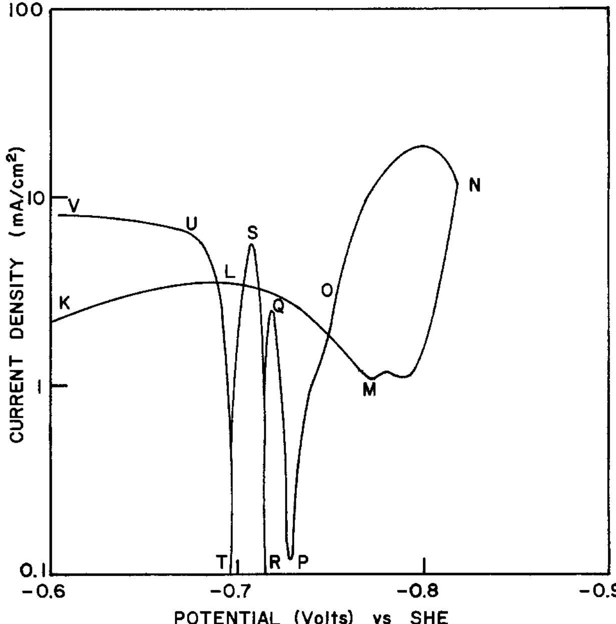

Fig. 3. Voltammogram for electrolyte containing 60 gpl Zn^{++}, 200 gpl H_2SO_4 and 5 mg/l Ni^{++}. Aluminum cathode.

$$H^+ + e \rightarrow \tfrac{1}{2} H_2 \text{ (Ni)} \quad [7]$$

Anodic reaction:

$$Zn \rightarrow Zn^{++} + 2e \quad [8]$$

Since the Ni addition was less than 20 mg/liter, deposition of Ni should be diffusion controlled; i_2 and i_5 are the diffusion-limited currents.

The voltammogram for the electrolyte containing no Ni^{2+} is divided into 7 sections for the benefit of discussion. The numbered subscripts refer to the current for the reactions listed previously and i_c and i_a are net cathodic and anodic currents, respectively.

Region AB — ($i_c = i_1$).—Hydrogen ion reduction appears to be the main reaction occurring, but the magnitude of the current is affected by the chemical nature of the zinc solution. The potential of zero charge (PZC) for Al is approximately −0.6V (SHE). As the electrode potential becomes more negative, adsorption of zinc ions on the aluminum surface can occur. This blocks the access of H^+ to the cathode for discharge. The hydrogen current for an electrolyte containing only H_2SO_4 (200 g/liter) is of a much higher value than for the same acid strength solution containing zinc ions. The effects of zinc ions on the initial hydrogen reduction current will be discussed in the latter part of this paper.

Region BC — ($i_c = i_1$).—Hydrogen ion reduction continues to be the dominant reaction until the potential where the minimum in current (point C) occurs. Some spot-checks have been conducted by holding the electrode at constant potential in this region for 20 min, removing it from the cell, and examining its surface with the scanning electron microscope (SEM) and energy dispersive x-ray attachment. There was no evidence of zinc deposition. As the electrode potential is made more negative, the contact absorption (specific ion adsorption) of zinc ions becomes more pronounced. This surface blockage by zinc ions contributes to the decrease in hydrogen current.

Region CD — ($i_c = i_1 + i_3 + i_4 + i_6$).—The overpotential is sufficient to initiate zinc deposition at point C. From C to D, there is simultaneous reduction of zinc and hydrogen ions. The co-deposition occurs on both the aluminum and the freshly nucleated zinc, with the latter predominating with increasing potential.

Region DE — ($i_c = i_1 + i_3 + i_4 + i_6$).—At point D the scan direction is reversed. From D to E. zinc and hydrogen ions discharge on both Zn and Al surfaces. Zn deposited on Zn requires less activation overpotential, so the current is higher than that measured from the front sweep when compared at the same potential value. The cathodic current decreases with decreasing reduction potential. If a constant potential is maintained in the region D to E, the current will increase and reach a steady-state value. However, at point E (approximately 5-10 mV from the crossover potential for cathodic to anodic current) the current fluctuates. This instability is indicated by dissolution followed by partial deposition of zinc in a cyclic pattern. The exact pattern followed at this point is dependent on the purity and nature of the electrolyte. The potential at E can be considered as a type of reversible potential for Zn for the particular solutions under investigation.

Region EF — ($i_c = i_1 + i_4 - i_8$).—As the potential becomes less negative, i_8, Zn dissolution increases. In the meantime, i_1 and i_4 decrease, so the net cathodic current i_c decreases. At point F, $i_1 + i_4 = i_8$ or $i_c = 0$; this condition is referred to as the crossover potential.

Region FGH — [$i_a = i_8 - (i_1 + i_4)$].—As the potential becomes more positive, i_8 increases and i_1, i_4 decrease, so from F to G, Zn dissolution predominates but hydrogen ion reduction is still evident. As the anodic zinc process proceeds, the surface is eventually depleted, thus causing the drop of i_a from G to H. At point H, $i_a = 0$ and accordingly $i_8 = i_1 + i_4$.

Region HIJ — ($i_c = i_1 + i_4 - i_8$).—As the deposited zinc approaches complete dissolution, i_8 will approach zero, $i_c = i_1$, and the cathodic current results mainly from the hydrogen discharge reaction. Some notable changes in the curve occur when Ni^{2+} impurity is present in the solution, as shown in Fig. 3.

Region KL — ($i_c = i_1 + i_2$).—i_2 is very small and perhaps negligible, thus the amount of nickel deposited is insufficient to cause any increase in the hydrogen reduction current.

Region LM — ($i_c = i_1 + i_2$).—The drop of the hydrogen reduction current again is caused by the increasing coverage on the Al surface of zinc contact-adsorbed ions.

Region MNO — ($i_c = i_3 + i_1 + i_6 + i_4 + i_2 + i_5$).—Zinc starts to deposit at M. The surface area increases as the deposition process proceeds. As a result the nickel deposition current (the nickel diffusion current density is constant in this potential range) is higher. However, the nickel in the deposit is bridged over or covered by the massive deposition of zinc and is unable to serve as active sites for the hydrogen ion discharge reaction. The cathodic current from M to N increases with increasing negative potential. At point N the scan direction is reversed. From N to O the cathodic current becomes smaller as the potential becomes more positive. With the presence of nickel in the deposited layer, zinc dissolution begins at a more negative potential, O than the potential *E* when nickel ion is absent.

Region OPQR — ($i_c = i_7 + i_1 + i_4 - i_8$).—As the scan goes from O toward a more positive direction, partial dissolution of zinc begins from the outer layer, probably at selected imperfection sites. Nickel and hydrogen ions can also be discharged by a localized spontaneous displacement reaction. As some of the surface-layer zinc dissolves, the underlying nickel accumulated from the previous cathodic process is exposed to the solution. In this potential region, net zinc deposition stops, and zinc ion contact-adsorption becomes less severe due to the increasing positive potential. The presence of the additional active nickel sites and the reduction in blockage from the more massive deposition of zinc increases the hydrogen reduction current sharply from P to Q. From Q to R the decrease in cathodic current is due to the relative increase in zinc dissolution compared to hydrogen evolution from the available nickel sites. At point R, $i_8 = i_7 + i_1 + i_4$, the net current is zero.

Region RST — [$i_a = i_8 - (i_7 + i_1 + i_4)$].—The net anodic current is due to the dominance of the zinc dissolution, but there is still considerable hydrogen reduction occurring.

Region TUV — ($i_c = i_1 + i_4 + i_7 - i_8$).—This part of the cathodic current is much higher than that from the front scan. There is an indication that some nickel still remains on the surface. However, when the cathode is left at open circuit for a few minutes and the second scan started, the hydrogen reduction current drops to a normal value. The probable cause is flushing or removal of the nickel deposits from the Al substrate surface by the hydrogen bubbles.

The presence of nickel is indicated by a cathodic current peak near the crossover potential at Q. Other findings for the voltammograms of electrolytes with Ni^{2+} additions (nickel voltammograms for short) are as follows:

1. The nickel peak appears only after some zinc has been deposited. If the cathodic sweep direction is reversed before the zinc deposition potential is attained, the nickel peak is not observed.
2. H_2 evolution is considerably more vigorous from the cathode surface at point Q on the voltammogram than for a comparable potential in the pure solution.
3. A continuous scan trace of the previous curve indicates that nickel does not accumulate nor remain on the Al substrate.
4. Table I shows the effects of zinc ion concentration on the nickel voltammograms. The nickel peak potential shifts toward less negative values with increasing Zn concentration in the electrolyte; the same trend holds for the Zn deposition potential. This indicates that the Ni peak potential is dependent on the Zn concentration in the electrolyte. Also the Ni peak current increases with decreasing Zn ion concentration.

Effects of test parameters on results.—The aims of the test parameter study were to develop procedures to maximize the nickel detectability in zinc electrolytes, and to investigate the behavior of nickel in zinc electrowinning processes.

Cathode surface preparation.—The height of the nickel peak current (point Q) is greater with a 600 grit polished electrode than for one which is wheel polished. The rougher surface, with higher effective area, enhances the effect of and sensitivity to the presence of the nickel impurity. Additional work on the cathode material and its preparation seems warranted, since it can influence the variations noted in polarization behavior in the presence of impurities.

Upper scan limit.—The results of this study are shown in Table II. There is a fivefold increase in the nickel peak current when the upper scan limit is raised from 1 to 10 mA/cm^2, but it remains fairly constant at higher limits, up to 50 mA/cm^2. The peak current is related to the Ni/Zn ratio in the deposit, and this ratio decreases with increased current density.

Scan rate.—Scan rates in the range of 0.1-10 mV/sec were studied and the results are tabulated in Table

Table I. Effects of zinc ion concentration on the nickel-type voltammograms, 200 g/liter H_2SO_4, 20 ppm Ni^{2+}, Al cathode, 600 grit polished, 30°C, scan rate 0.5 mV/sec, upper scan limit 10 mA/cm^2

Zinc ion concentration (g/liter)	Nickel peak potential V(SHE)	Nickel peak current (mA)	Zn deposition potential measured at 1.5 mA/cm^2 on the cathodic sweep V(SHE)
20	−0.770	100	−0.841
60	−0.753	37	−0.823
100	−0.742	12	−0.805

Table II. Effect of upper scan limit on the nickel peak current densities, 60 gpl Zn, 200 gpl H_2SO_4, 5 mg/liter Ni^{+2}, aluminum cathode, 600 grit-polished, 30°C, scan rate 0.5 mV/sec

Upper scan limit (mA/cm^2)	Ni peak height (mA/cm^2)
1	2.7
5	8.6
10	12.7
50	13.8

Table III. Effect of scan rates on the Ni voltammograms, 60 g/liter Zn, 200 g/liter H_2SO_4, 5 ppm Ni^{+2}, Al cathode, 600 grit-polished, 30°C, upper scan limit 10 mA/cm^2

Scan rate (mV/sec)	Ni peak height (mA/cm^2)	Time required for completing one cycle (min)
0.1	50	95
0.5	12	20
1.0	2	11
10.0	No Ni peak	1

III. The scan rate at 0.1 mV/sec gives the highest peak, and hence greatest sensitivity to the presence of nickel. The time for completion of a test approaches 2 hr at this scan rate, and would be too long if used for monitoring plant operations. However, for basic data generation it is acceptable and combinations of scan limits and rates must be tested to determine the optimum values for these parameters.

Electrolyte composition.—The effect of Zn ions on the voltammogram is shown in Fig. 4. The hydrogen discharge reaction appears to be depressed by the presence of Zn ions in the electrolyte. The adsorption of Zn ions on Al becomes pronounced at about 80 mV less cathodic than the Zn deposition potential. Also, the Zn deposition potentials shift to less negative potentials with increasing Zn ion concentration.

The effect of acid strength on Ni detectability was studied using a 60 g/liter Zn solution and the acid strength was varied from 50 to 200 g/liter. All solutions were doped with 3 mg/liter Ni, and the tests were conducted at 30°C. The voltammograms revealed

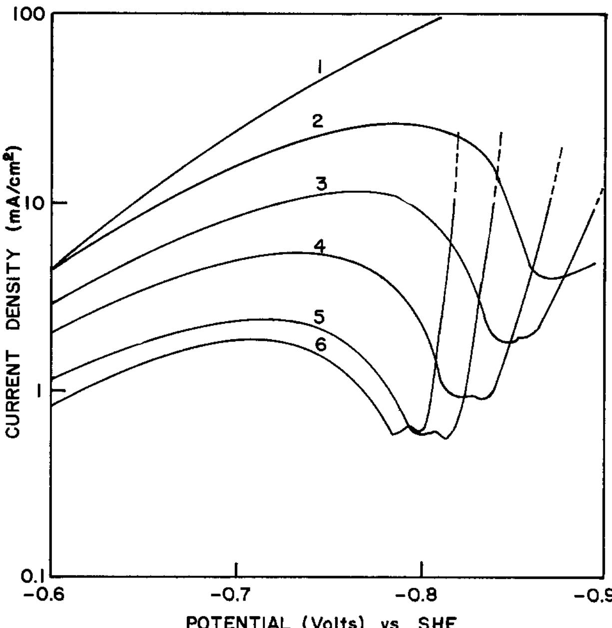

Fig. 4. Effect of Zn^{++} content on voltammograms containing 200 gpl H_2SO_4 plus curve 1, no Zn^{++}; curve 2, 1 gpl Zn^{++}; curve 3, 5 gpl Zn^{+2}; curve 4, 20 gpl Zn^{+2}; curve 5, 60 gpl Zn^{+2}; curve 6, 100 gpl Zn^{+2}.

that the characteristic peak indicating the presence of Ni was present only at high acid contents (200 g/liter).

Electrolyte temperature.—Increasing the temperature did increase the sensitivity for Ni ion detection. With 1 mg/liter Ni in the electrolyte, no Ni peak appeared on the anodic sweep at 30°C. An Ni peak of 2 mA appeared at 55°C. Most Zn electrowinning plants operate in the temperature range of 30°-40°C.

Ni detectability study.—The detectable limit for nickel in the electrolyte of 60 g/liter Zn, 200 g/liter H_2SO_4 is 3 mg/liter at 30°C and 1 mg/liter at 45°C, using test parameters discussed previously. Values of the Ni potential and the Ni current as a function of Ni ion concentration are given in Table IV. It can be seen that the Ni peak potential is independent of the Ni^{2+} concentration, while the height of the Ni peak current density is proportional to Ni^{2+} concentration. A straight line relationship exists for the Ni peak current density *vs.* the Ni concentration as shown in Fig. 5. This indicates that the Ni deposition from the Zn electrolyte is a diffusion-controlled process.

Better detectability of nickel can be achieved by diluting the Zn ion concentration with 200 g/liter H_2SO_4. Starting from 60 g/liter Zn, 200 g/liter H_2SO_4 solution, the electrolyte was doped with 0.5 mg/liter Ni^{+2}. Normally, 0.5 mg/liter would not show up on the voltammogram with the 60 g/liter Zn electrolyte; however, by one-tenth dilution with 200 g/liter H_2SO_4 solution, the Ni peak corresponding to 0.05 mg/liter appeared on the voltammogram as shown in Fig. 6.

The Ni concentration and peak current relationship for the 6 g/liter Zn electrolyte is shown in Table V.

Conclusions

By using cyclic voltammetry techniques, it is possible to elucidate the manner in which nickel is activated in zinc electrolytes. The behavior observed is also consistent with that found to occur for long term zinc deposition (6). Current efficiency decreases with increased nickel ion concentration, temperature, acid level, and time of deposition. The nickel peak current is shown to be sensitive to these parameters as well, and in the same approximate proportions, with higher nickel peaks indicating poorer efficiency. Once conditions on the electrode surface allow a critical content of nickel to be exposed, such as at the bottom of a recess in a rough deposit, preferred hydrogen evolution is initiated at this point. Zinc deposition is less

Table IV. Effects of Ni^{++} concentrations on the nickel peak potential and current on the voltammograms, 60 gpl Zn, 200 gpl H_2SO_4, aluminum cathode, 600 grit-polished, 30°C, scan rate 0.5 mV/sec

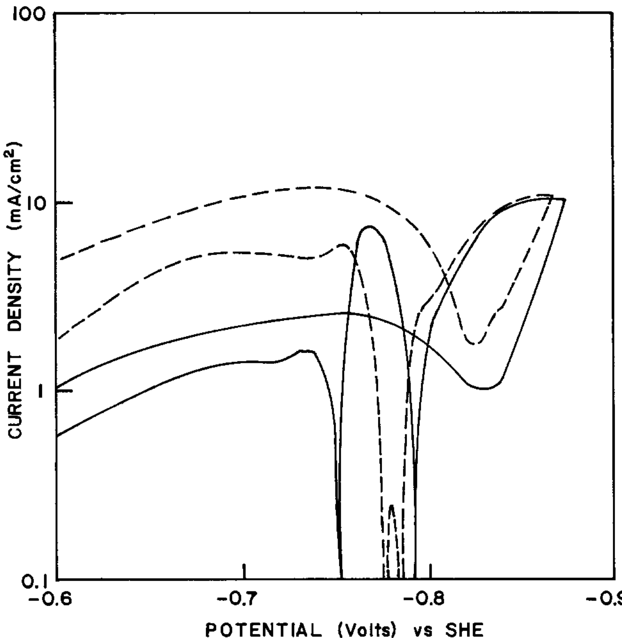

Fig. 6. Voltammograms for electrolyte containing 6 gpl Zn^{++} and 200 gpl H_2SO_4 (solid line) and 6 gpl Zn^{++}, 200 gpl H_2SO_4 plus 0.05 mg/liter Ni^{++}.

feasible, and an unstable condition is generated which allows zinc to dissolve. The condition is probably similar to a local cell reaction encountered in corrosion. It might also be expected that, with time, an autocatalytic reaction can occur, since even more nickel becomes exposed as the zinc dissolves. If such were the case, pitting might be expected, and although this was not investigated in these short time studies, pits have been noted in zinc deposits galvanostatically produced from electrolyte containing nickel.

In addition to providing for some insight into the mechanism for nickel behavior, this technique might also be used to monitor the level of nickel present in solution. Additional tests would have to be conducted using other known detrimental impurities such as cobalt, copper, antimony, germanium, and arsenic. If there are common mechanisms involved in their behavior, it may be that only a total effect will be indicated, rather than a differentiation between individual impurities. This technique might also be used to advantage when attempting to find a means of combating the influence of nickel impurities. Screening tests could be run with the nickel peak height being used to indicate the effectiveness of the control method chosen.

The determination of the quality of zinc sulfate electrolyte prior to electrolysis has always been a major challenge in industrial operations. Polarization techniques of the type described appear to offer some promising opportunities to the solution of this problem and, if properly developed, might become a useful analytical tool in commercial practice.

Acknowledgments

The authors are particularly grateful for the contributions of Harlan Rice, Kenneth Allison, and Jack Smart during this investigation and the helpful technical discussions and suggestions of Dr. R. Kerby, Cominco Limited, and Dr. E. Cole, USDI, Bureau of Mines.

The financial and technical assistance of Cominco Limited and AMAX throughout this program is also acknowledged.

Particular thanks are extended to the U.S. Department of Interior, Bureau of Mines, for their continued support of this research under contract GO-264029.

Manuscript submitted Nov. 19, 1979; revised manuscript received *ca.* June 27, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the University of Missouri.

Low Temperature Polarography of Alkyl Halides in Dimethylformamide

Adsorption onto Mercury of Complex Species Composed of Tetramethylammonium and Halide Ions

William F. Carroll, Jr.[1] and Dennis G. Peters

Department of Chemistry, Indiana University, Bloomington, Indiana 47405

ABSTRACT

At relatively negative potentials and at temperatures below −29°C, a prominent current minimum is observed in polarograms for the reduction of alkyl halides in dimethylformamide containing tetramethylammonium perchlorate. This minimum is attributed to the formation and subsequent adsorption onto mercury of complex ionic species which block reduction of the alkyl halide; these adsorbed species appear to be positively charged aggregates consisting of supporting electrolyte cations and halide ions released upon electrolysis of the starting material. If a small amount of tetramethylammonium halide is added to a solution of an electroactive substance other than an alkyl halide in dimethylformamide containing tetramethylammonium perchlorate, the same low temperature current minimum is seen. Further, in dimethylformamide containing only tetramethylammonium perchlorate at concentrations greater than 0.08F, there is evidence that a species derived from the supporting electrolyte itself is adsorbed onto mercury at temperatures lower than −33°C.

In three previous papers dealing with the electrochemistry of 1-halonorbornanes (1) and 1,4-dihalonorbornanes (2, 3) in dimethylformamide containing tetramethylammonium perchlorate, we have reported that low temperature polarograms exhibit unusual current minima. At temperatures below −29°C, a conspicuous depression of the current is observed on the diffusion plateau of the single polarographic wave for 1-iodonorbornane; this minimum becomes more severe as the temperature is lowered, obscuring a region of potentials as wide as 250 mV at −36°C. Similar behavior is seen for 1-bromonorbornane, although the polarographic minimum does not appear until the temperature reaches −33°C. Two polarographic waves are observed for 1,4-diiodonorbornane at room temperature, but at temperatures less than −28°C, the current corresponding to the second step of reduction is depressed to a level equal to that of the first wave. At −34°C the diffusion current for 1,4-dibromonorbornane is suppressed almost completely over more than a 200 mV range of potentials.

Phenomena responsible for these current minima, seen in low temperature polarograms for 1-halonorbornanes and 1,4-dihalonorbornanes only when tetramethylammonium perchlorate is employed as supporting electrolyte, manifest themselves in other ways. Thus, in the potential region corresponding to the polarographic minima, the shape of current-time curves for individual mercury drops is characteristic of adsorption onto the electrode surface of an electroinactive substance (4). Moreover, faradaic and capacitive currents observed by means of three-electrode, phase-sensitive a-c polarography (5) are likewise indicative of the adsorption of electroinactive species on the mercury cathode.

On the basis of the preceding kinds of experimental evidence, we conclude, as discussed in this paper, that when any of the aforementioned halogen-substituted norbornanes is reduced at low temperature in dimethylformamide containing the tetramethylammonium cation, the latter combines with the liberated iodide or bromide to form a complex ion aggregate which is adsorbed onto mercury at certain potentials, thereby causing the anomalous polarographic minima. In addition, in the absence of an electroactive alkyl halide, it appears that a species derived from tetramethylammonium perchlorate itself may undergo adsorption at temperatures below −33°C.

[1] Present address: Firestone Plastics Company, Pottstown, Pennsylvania 19464.

Key words: adsorption, alkyl halides, 1,4-dihalonorbornanes, 1-halonorbornanes, low temperature polarography.

Experimental

Reagents.—Dimethylformamide used as solvent and tetramethylammonium perchlorate employed as supporting electrolyte were handled as described in a previous paper (1). Modified procedures devised in our laboratory (1) were utilized for the synthesis of 1-bromonorbornane and 1-iodonorbornane, and the preparation of 1,4-dibromonorbornane and 1,4-diiodonorbornane was done according to a method outlined earlier (3). Commercially available 1-iodododecane (Chemical Samples Company, 95%) and 1-bromodecane (J. T. Baker & Company, 97%) were purified by means of vacuum distillation; fractions used for electrochemical experiments were determined with the aid of gas chromatography to be greater than 99% pure (6).

Preparation of 1,10-diiodododecane was accomplished by treatment of 1,10-dibromodecane with sodium iodide in acetone at 30°C. Sodium bromide precipitated immediately, and the reaction mixture was stirred until peaks due to bromine-containing compounds were absent from gas chromatograms. Upon recrystallization from pentane, the product was found to be identical to an authentic sample of 1,10-diiodododecane purchased from ICN Pharmaceuticals, Incorporated, Plainview, New York.

Apparatus and procedures.—Figure 1 is a picture of the cell used for polarography. A nitrogen gas inlet tube and a reference electrode are mounted in horizontal 12/18 standard-taper ground-glass joints (A and B). An alcohol thermometer is inserted through a plastic adapter and sealed with a rubber O-ring into a screw-type glass joint (C). Extending from the bottom of the inner compartment of the cell are two standard-taper stopcocks (D); mercury drops can be trapped in the space between the stopcocks, and the lower stopcock can be opened to permit collection of the mercury.

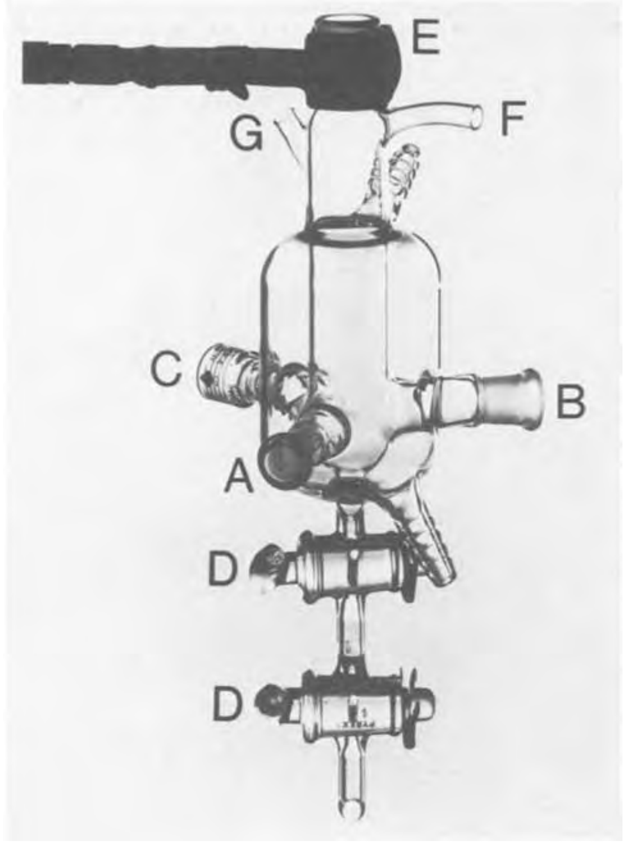

Fig. 1. Polarographic cell; see text for detailed discussion

A dropping mercury electrode is inserted through the 14/20 standard-taper ground-glass joint (E) at the top of the cell and is secured with a Teflon fitting. Nitrogen gas, used to stir and deaerate the solutions, escapes by way of a sidearm (F) near the top of the cell. A second sidearm (G) allows insertion of a platinum wire anode as well as introduction or removal of solution. To keep the temperature of the solution constant to within ±0.1°C, a 1:1 methanol:water mixture was circulated through the jacket surrounding the cell by use of an FTS Systems, Incorporated, Stone Ridge, New York, MC-2-60 refrigerated bath equipped with FTS cryogenic pump and FTS TCH-1 controller. Polyurethane foam plumbing insulation was wrapped around both the polarographic cell and the solid polyurethane tubing used to carry the coolant.

Conventional d-c polarography was performed with the aid of a Princeton Applied Research Corporation (PAR) Model 175 Universal Programmer, a PAR Model 173 potentiostat/galvanostat, and a PAR Model 176 current-to-voltage converter capable of *iR* compensation. All of the a-c polarography was carried out by use of a PAR Model 174 Polarographic Analyzer equipped with a Krohn-Hite Model 5200A signal generator and a PAR Model 5101 lock-in amplifier; an a-c signal of amplitude 100 mV and frequency 600 Hz was used. All potentials are reported with respect to a reference electrode consisting of a saturated cadmium amalgam in contact with dimethylformamide saturated with cadmium chloride and sodium chloride (7, 8); this electrode has a potential of −0.750V *vs.* the aqueous saturated calomel electrode.

Results and Discussion

Low temperature polarography of alkyl halides.—Shown in Fig. 2 are polarograms recorded at various temperatures for the reduction of 1-iodonorbornane in dimethylformamide containing 0.1F tetramethylammonium perchlorate. Characteristic of the polarographic reduction of many alkyl halides at room

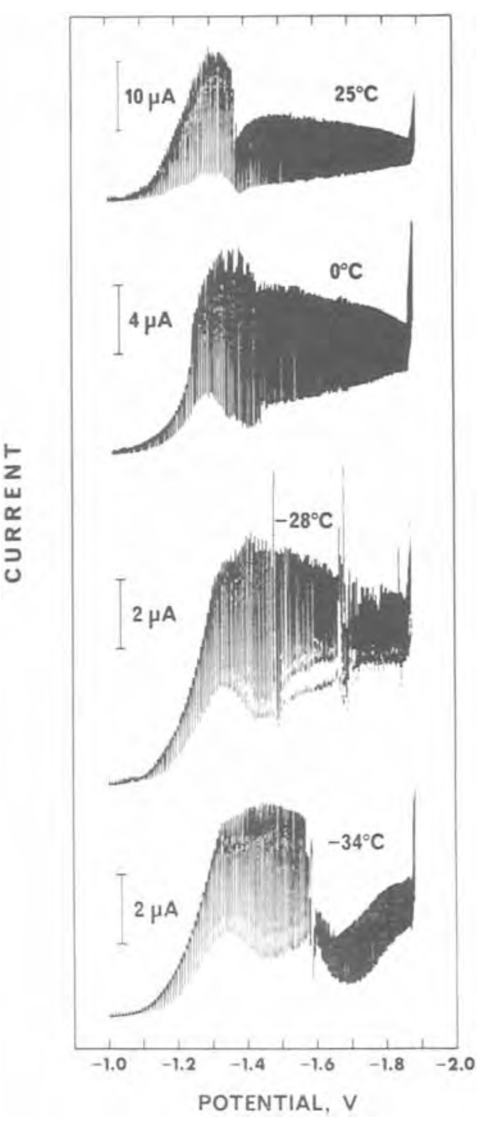

Fig. 2. Effect of temperature on polarograms for reduction of 0.0025M 1-iodonorbornane in dimethylformamide containing 0.1F tetramethylammonium perchlorate.

temperature is the appearance of a current maximum,[2] which diminishes in size and finally vanishes as the temperature is lowered. On the other hand, at temperatures below −29°C, the polarogram for 1-iodonorbornane exhibits a pronounced minimum which becomes more severe as the temperature is decreased. As revealed in Fig. 3, similar behavior is seen for 1,4-diiodonorbornane. Figure 4 demonstrates that a low temperature minimum can be observed for alkyl bromides as well as for alkyl iodides, although temperatures below −32°C are needed to cause the phenomenon. A set of low temperature polarograms showing current minima for 1-bromodecane, 1-iododecane, and 1,10-diiododecane is illustrated in Fig. 5, so the appearance of the minimum is not unique to norbornyl halides. Most significantly, the minima appear at low temperatures only when tetramethylammonium perchlorate is employed as supporting electrolyte.

Polarography of dimethylformamide solutions of tetramethylammonium perchlorate.—Even in the absence of an electroactive alkyl halide, solutions of tetramethylammonium perchlorate in dimethylformamide exhibit unusual polarographic behavior at low

[2] This polarographic maximum does not exhibit the usual response to added suppressors. Although further investigation of this phenomenon is underway, we believe that it is related to reduction of adsorbed alkylmercury radicals.

temperature. A plot of mercury drop-time *vs.* potential for a 0.1F solution of tetramethylammonium perchlorate in dimethylformamide at −33°C is illustrated in Fig. 6A, in which the most notable feature is the sharp discontinuity at −1.64V. Presented in Fig. 6B are d-c polarograms for the same system that were recorded at two sensitivities; these residual-current curves show a depression in the region of potentials between −1.64 and −1.83V. Such a depression is seen more clearly both in the faradaic current ($\phi = 15°$) and charging current ($\phi = 105°$) monitored by means of phase-sensitive a-c polarography; the phase angles needed to optimize the effects depicted in Fig. 6B differ from the theoretically ideal values of 0° and 90°, respectively, undoubtedly because the resistance of the solution alters the desired phase relationships. These observations suggest that some species in solution, namely, the tetramethylammonium cation, tetramethylammonium perchlorate, or an ion aggregate derived from the supporting electrolyte, is adsorbed onto the surface of the mercury electrode at potentials between −1.64 and −1.83V.

Effects of temperature as well as the concentration of supporting electrolyte are shown in Fig. 7. An inspection of the faradaic and charging currents reveals that the anomalous depression is first observed in a-c polarograms recorded at −31°C and is fully developed at −33°C. Interestingly, when the concentration of tetramethylammonium perchlorate is decreased from 0.1 to 0.08F, a current depression is no longer seen at −33°C (Fig. 7E).

Tetramethylammonium and halide ions are both required to cause the low temperature polarographic minimum for alkyl halides.—Polarograms for a 0.003m solution of anthracene in dimethylformamide containing 0.1F tetramethylammonium perchlorate are depicted in Fig. 8A. At a temperature of −29°C, the d-c polarogram exhibits the expected two-step reduction, the half-wave potentials being −1.21 and −1.72V,

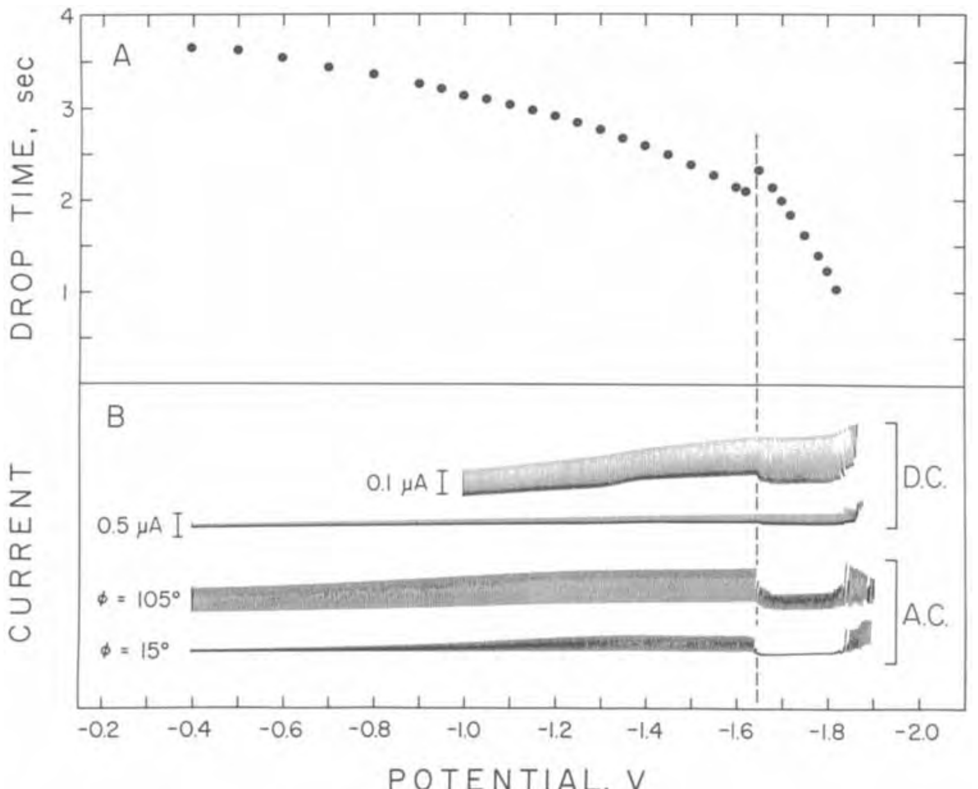

Fig. 6. Polarography of 0.1F tetramethylammonium perchlorate in dimethylformamide at −33°C. (A) Plot of mercury drop time *vs.* potential. (B) D-C and a-c polarograms.

respectively; a-c polarographic observations of the faradaic current at a phase angle of 6° and of the charging current at a phase angle of 96° are compatible with the d-c polarographic behavior of anthracene. When a small amount (0.0025F) of tetra-*n*-butylammonium iodide is dissolved in the anthracene-containing system, Fig. 8B reveals that the d-c and a-c polarograms change dramatically in the region of potentials from −1.64 to −1.86V; the second stage of reduction is

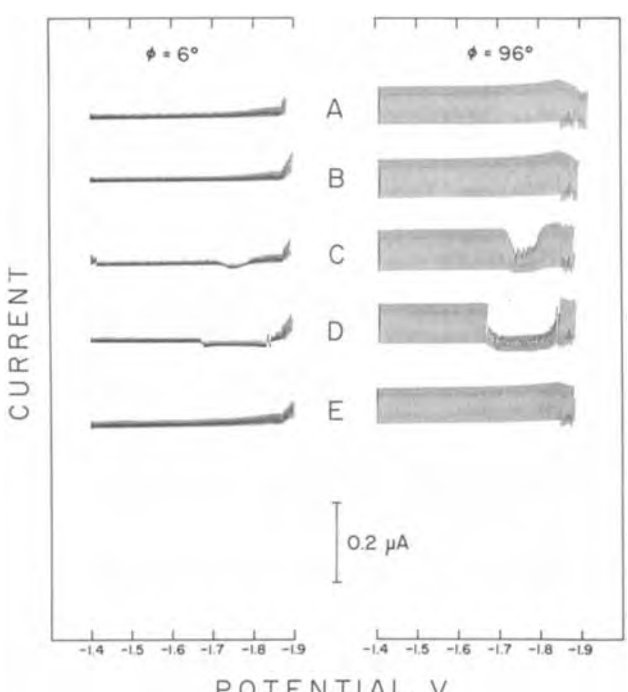

Fig. 7. Effects of temperature and of concentration of tetramethylammonium perchlorate on a-c polarograms. Temperatures are (A) −29°C, (B) −30°C, (C) −31°C, (D) −33°C, and (E) −33°C. Concentration of tetramethylammonium perchlorate is 0.1F for curves A through D and is 0.08F for curves E.

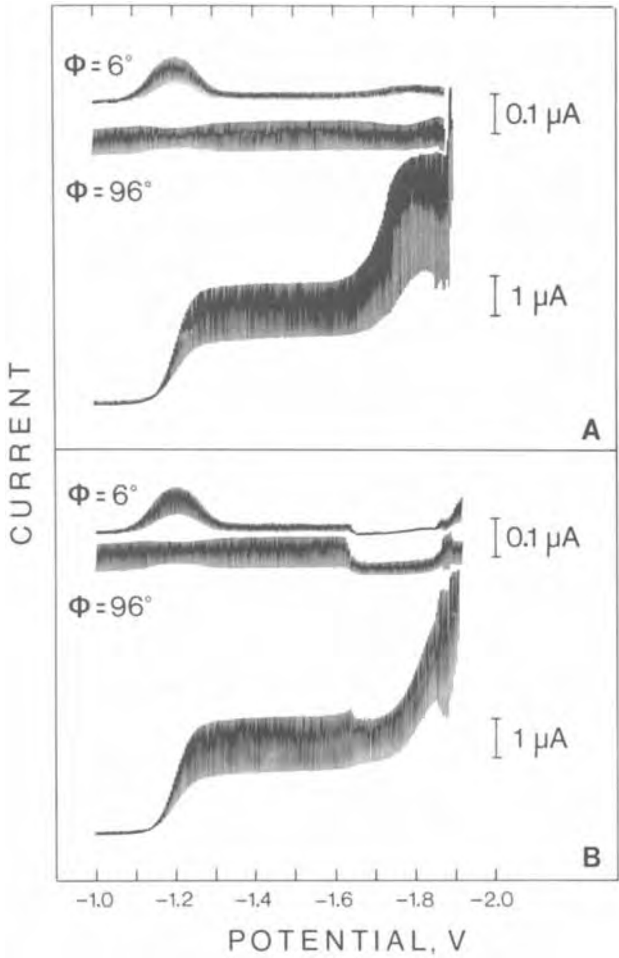

Fig. 8. D-C and a-c polarograms for reduction of 0.003M anthracene in dimethylformamide containing 0.1F tetramethylammonium perchlorate at −29°C. (A) no tetra-*n*-butylammonium iodide present. (B) 0.0025F tetra-*n*-butylammonium iodide present.

almost obliterated from the d-c polarogram, and pronounced depressions appear in the faradaic- and charging-current components of a-c polarograms. Clearly, these phenomena must be attributed to the presence of both the tetramethylammonium and the iodide ion, because the supporting-electrolyte cation alone does not cause such current depressions at −29°C, as is shown in Fig. 7A.

Additional evidence for the conclusion reached in the preceding paragraph is the set of polarograms in Fig. 9 for the reduction of 1-bromonorbornane in dimethylformamide containing 0.1F tetramethylammonium perchlorate. Figure 9A is a polarogram recorded at −33°C, showing the start of a wave at approximately −1.6V, but most of the rising portion of the wave between −1.66 and −1.86V is obscured by a current depression. As demonstrated by Fig. 9B, when the temperature is raised slightly to −30°C, the wave for reduction of the carbon-bromine bond is unmasked. However, if the temperature is kept at −30°C and if tetra-n-butylammonium iodide (0.0025F) is added to the solution, the polarogram in Fig. 9C is obtained. These observations confirm that at −30°C a small concentration of iodide, in combination with the tetramethylammonium cation, inhibits electron transfer to 1-bromonorbornane. Moreover, even the bromide ion released by reduction of 1-bromonorbornane interacts with the supporting-electrolyte cation to form a species, apparently adsorbed onto mercury, which can cause a current depression, although a lower temperature (−33°C) is needed to produce the effect.

Current-time curves for individual mercury drops change shape as a function of potential over the region corresponding to the polarographic minimum. Figure 10 shows some of these traces for the reduction of 1-iodonorbornane at −34°C. At a potential of −1.50V, which, as can be seen in Fig. 2, is before the beginning of the minimum, the current-time curves have a normal appearance. At a potential (−1.58V) near the onset of the minimum, the current decreases toward the end of each drop lifetime. Across the region of potentials corresponding to the polarographic minimum, the curves are characterized by an initial rise, severe depression, and eventual recovery of the current. At potentials more negative than the minimum, the current-time traces once again appear normal, but the final current is lower than that in a comparable electrochemical system which does not exhibit a polarographic minimum. For all curves in Fig. 10, the initial rise in current is due to reduction of the alkyl halide. Between approximately −1.58 and −1.64V, the temperature and solution composition are favorable for the formation of complex ionic species that are adsorbed onto the mercury drop; these adsorbed species block electron transfer to the alkyl halide, as evidenced by the decline in current which follows the initial rise. However, the adsorbed species appear to be imperfect insulators, because reduction of the alkyl halide resumes toward the end of the lifetime of a mercury drop.

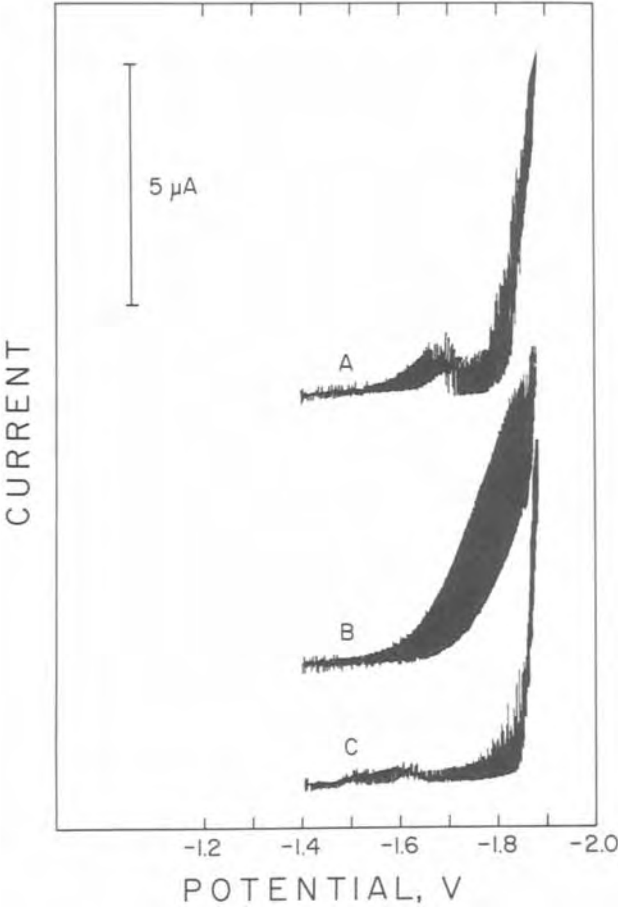

Fig. 9. Polarograms for reduction of 0.001M 1-bromonorbornane in dimethylformamide containing 0.1F tetramethylammonium perchlorate. (A) −33°C. (B) −30°C. (C) −30°C with 0.0025F tetra-n-butylammonium iodide present.

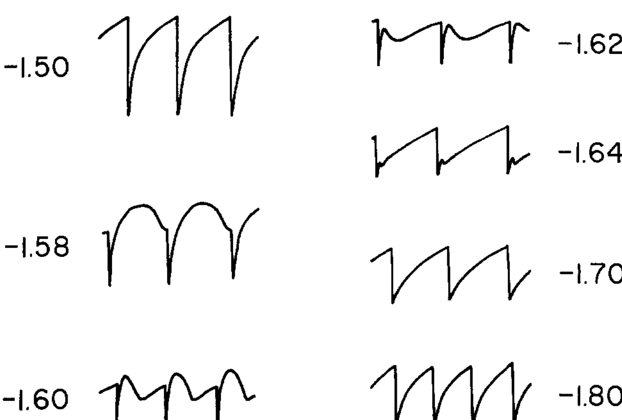

Fig. 10. Polarographic current-time curves for individual mercury drops as a function of potential for reduction of 0.0025M 1-iodonorbornane in dimethylformamide containing 0.1F tetramethylammonium perchlorate at −34°C.

Nature of the adsorbable species.—Adsorption of tetraalkylammonium ions onto mercury from aqueous media has been investigated extensively (9-14). Devanathan and Fernando (9) used a capillary electrometer to examine the behavior of several tetraalkylammonium iodides at 25°C and concluded, for tetramethylammonium iodide as well as the other salts, that there exists a mid-cathodic region of potentials within which the cation and anion are both specifically adsorbed and that the cations probably form "bridges" with the anions. In a later study by Piro, Bennes, and Bou Karam (10), tetramethylammonium bromide was observed to be less strongly adsorbed onto mercury than the iodide salt.

Although there have been no previous reports dealing with the adsorption of tetramethylammonium salts from dimethylformamide onto mercury, evidence offered in the present paper indicates that such species are adsorbed at low temperatures. In dimethylformamide containing only tetramethylammonium perchlorate, it appears as shown earlier (Fig. 6 and 7) that the low temperature polarographic minimum can be attributed to adsorption of the tetramethylammonium cation, tetramethylammonium perchlorate, or possibly an ion aggregate. However, when halide ions are either present initially or generated electrolytically, the phenomenon responsible for the minimum is more complicated.

Figure 11 illustrates conditions necessary for onset of the halide-induced current minimum for the polarographic reductions of 1-bromodecane and 1-iododecane

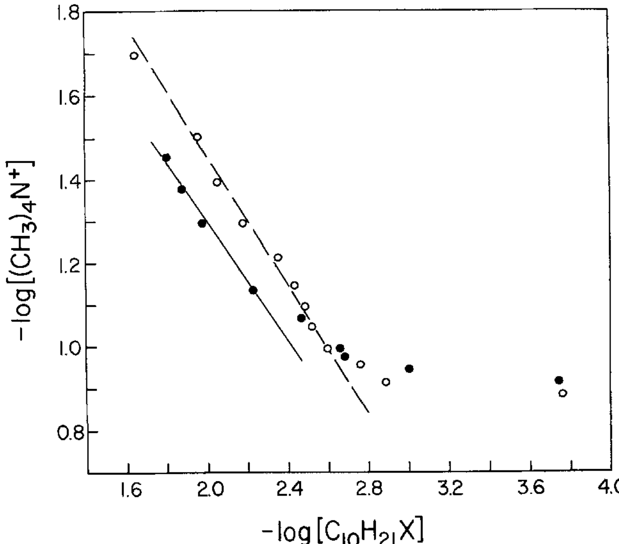

Fig. 11. Plot of logarithm of concentration of tetramethylammonium cation *vs.* logarithm of concentration of 1-bromodecane (filled circles) or 1-iododecane (open circles) needed to cause onset of polarographic minimum in dimethylformamide at −33°C.

at −33°C in dimethylformamide containing tetramethylammonium perchlorate. For these experiments, we varied the concentrations of supporting electrolyte and decyl halide to determine what combination of these parameters causes the minimum to appear; arbitrarily, we defined the onset of the minimum as a 10% diminution of the normal, unattenuated diffusion current. If the logarithm of the concentration of supporting electrolyte is plotted against the logarithm of the concentration of decyl halide, a linear correlation between these two variables is observed at intermediate concentrations of tetramethylammonium perchlorate. Graphical analysis of the slope of the line for each system indicates that the onset of the minimum is more highly dependent on the concentration oi tetramethylammonium ion than of decyl halide. Moreover, if it is iodide or bromide ions liberated upon electrolytic reduction of a decyl halide which combine with the tetramethylammonium cation to form a surface-active species, we can conclude that the current minimum results from adsorption of one or more unipositive aggregates consisting of tetramethylammonium and halide ions in a ratio lying between 3:2 and 5:4.[3] Such discrete species, if they exist, should be almost impossible to isolate and identify, especially because they might prevail only under the influence of a polarized electrode. Nevertheless, it is intriguing that the crude picture so far developed of the cooperative adsorption of tetramethylammonium and halide ions onto mercury in dimethylformamide bears a remarkable resemblance to the model invoked by Devanathan and Fernando (9) in which halide ions and tetramethylammonium cations form bridged species adsorbed at the mercury-water interface.

[3] It can be shown (15) that the straight lines passing through the experimental data for 1-bromodecane and 1-iododecane in Fig. 11 fit the general relation $a \log[(CH_3)_4N^+] + b \log[C_{10}H_{21}X]$ = constant or $[(CH_3)_4N^+]^a[C_{10}H_{21}X]^b$ = constant′. For 1-bromodecane, a/b is 1.39 which lies between a ratio of 4:3 and 3:2; for 1-iododecane, a/b is 1.28 which lies between a ratio of 5:4 and 4:3.

Currently, we are completing the construction of a computer-controlled capillary electrometer, based on the design of Mohilner and co-workers (16). Our goal is to utilize this instrumentation to study in detail the electrical double layer at the mercury-solution interface in nonaqueous solvents containing various tetraalkylammonium salts in the presence and absence of electroactive organic compounds.

Acknowledgments

Appreciation is expressed to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for financial support of this work. We thank Alan McQuarrie for assistance in recording polarograms as well as Brian Willett and Daniel La Perriere for many helpful discussions.

Voltammetric and Chronopotentiometric Studies of Na_2O-NaCl Melts

M. L. Deanhardt[1] and Kurt H. Stern*

Chemistry Division, Naval Research Laboratory, Washington, DC 20375

ABSTRACT

The oxidation of Na_2O in molten NaCl was studied in the presence of oxygen (<10 Torr) at 830°C by two electrochemical techniques: cyclic voltammetry and chronopotentiometry. The results indicate the following reaction pathway

$$2\,O^{2-} + O_2 \rightleftharpoons 2\,O_2^{2-}$$

$$2\,O^{2-} \rightleftharpoons O_2^{2-} + 2e^-$$

$$O_2^{2-} \rightleftharpoons O_2 + 2e^-$$

The partial conversion of O^{2-} to O_2^{2-} in the melt results in two oxidizable species. Experimental data indicate that superoxide is absent from the Na_2O-NaCl melts.

In previous studies of the Na_2O-NaCl system (1), several types of experiments were reported which indicated that oxide ion (O^{2-}) dissolved in molten NaCl is partially oxidized to peroxide (O_2^{2-}) and perhaps to superoxide (O_2^-). The motivation for this work was the previous finding (2) that O^{2-} is oxidized by two distinctly different kinds of reactions in molten nitrates: by molecular O_2 in oxygen-containing atmospheres and by the reduction of nitrate to nitrite in the (near) absence of oxygen. Since halide anions were considered difficult to reduce, it was thought likely that O^{2-} would be stable in NaCl in the absence of O_2. The results of manometric experiments, chemical analyses of quenched melts, and potentiometric studies with O^{2-}-specific zirconia electrodes gave consistent results. When the atmosphere contained oxygen, Na_2O-NaCl melts take up O_2 reversibly, chemical analysis showed a species which reduces permanganate, and the potentiometric experiments indicated that a large fraction of any added Na_2O disappeared rapidly. These observations are all consistent with substantial conversion of O^{2-} to O_2^{2-}, presumably by the reaction $O^{2-} + \frac{1}{2}\,O_2 \rightleftharpoons O_2^{2-}$. The experiments did not allow any conclusions to be drawn about O_2^- formation, but thermodynamic calculations indicate that its equilibrium concentration is much less than that of O_2^{2-}.

Results in a low O_2 atmosphere were more puzzling. In a helium-filled glove box whose nominal O_2 content was 1-10 ppm, similar chemical and potentiometric studies also indicated peroxide formation, although at a slower rate. None of the several possible explanations examined appeared satisfactory.

The current work was therefore undertaken to (*i*) determine the number of species to which O^{2-} transforms and (*ii*) to shed further light on the remaining unresolved anomalies. Voltammetric and chronopotentiometric techniques had already been used successfully by several workers (3-6) to study oxide species in halide melts and were therefore used in this study.

Experimental

Apparatus.—The molten salt furnace, temperature controller, and helium-oxygen dry boxes have been previously described (1). High purity gold crucibles were used as containers for the melt.

Current-voltage and voltage-time curves were obtained with a Princeton Applied Research Corporation Model 173 potentiostat/galvanostat. A triangle wave generator (PAR Model 175) was interfaced to the Model 173 to obtain cyclic sweep voltammograms. Fast voltammetric scan rates were recorded with a transient recorder (Biomation Model 802).

Electrodes.—The reference electrode consisted of a silver wire in contact with ~10 mole percent AgCl in NaCl. The reference melt was placed in a mullite tube which was immersed in the melt. The gold container served as the counterelectrode. Since gold is less susceptible to corrosion by the Na_2O-NaCl melt than is platinum, a gold wire (area ~0.50 cm^2) was used as the working electrode.

Reagents.—Reagent grade NaCl was vacuum dried at 500°C before use. Reagent Na_2O (Alfa Inorganics) (94% Na_2O by analysis) containing ~2% Na_2O_2 impurity, and reagent Na_2O_2 were used without pretreatment. All weighing and transfer operations involving these substances were carried out in the dry box in which the experiments were done.

Procedure.—The temperature of the melt was maintained at 830° ± 5°C. Sodium oxide was added directly to the sodium chloride melt by means of a glass funnel and approximately 5 min were allowed for the oxide to dissolve before electrochemical measurements were made. Na_2O concentrations were kept as low as possible (<50 mM) in order to minimize corrosion effects on the electrodes and cell container. As will be discussed below, Na_2O is unstable at high oxygen pressures, resulting in the formation of Na_2O_2. Therefore studies were made at oxygen pressures generally below 10 Torr.

Results and Discussion

The oxidation of Na_2O in molten NaCl was studied by two electrochemical techniques, voltammetry and chronopotentiometry. Typical voltammograms of the oxidation of Na_2O are shown in Fig. 1. The reduction limit occurs at ~ −1.3V and the oxidation limit at ~ +0.3V (probably the oxidation of the gold electrode). Two oxidizable species are observed when Na_2O is added to the melt; the first anodic wave (wave I) occurs at −0.47V *vs.* the Ag/AgCl reference electrode and the second (wave II) occurs at ~ +0.12V. Additions of Na_2O immediately increase the peak current of wave I; therefore, this wave is attributed to the oxidation of oxide ions in the melt. Wave II does not immediately increase in peak current with added Na_2O; however, the peak current does increase with time as shown in Fig. 1, and is believed to be due to the oxidation of peroxide ions formed by the following

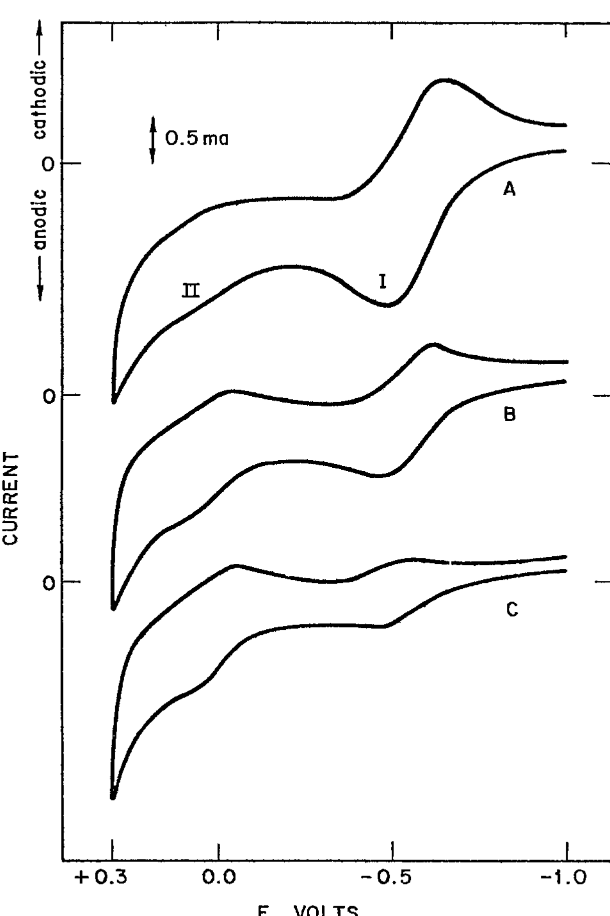

Fig. 1. Cyclic voltammograms for the oxidation of O^{2-} in molten NaCl. $[O^{2-}] = 7.2 \times 10^{-3}$M, Au working electrode ($A \approx 0.50$ cm^2), $T = 830$°C, O_2 pressure = 2.3 Torr, scan rate = 0.5 V/sec. Curve A: scan taken 8 min after addition of Na_2O. Curve B: scan taken 32 min after addition of Na_2O. Curve C: scan taken 59 min after addition of Na_2O.

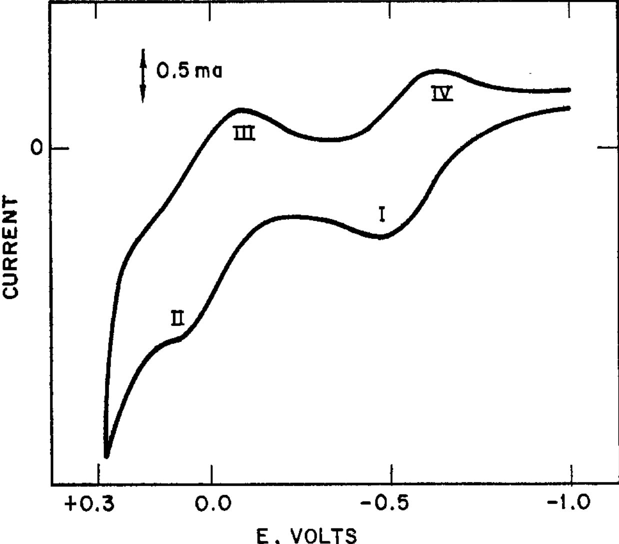

Fig. 2. Cyclic voltammogram for the oxidation of O^{2-} in molten NaCl. Cumulative $[O^{2-}] = 1.58 \times 10^{-2}$M, Au working electrode ($A \approx 0.50$ cm^2), $T = 830$°C, O_2 pressure = 2.3 Torr, scan rate = 0.5 V/sec, scan taken 2.3 hr after first addition of Na_2O.

reaction

$$2\,O^{2-} + O_2 \rightleftharpoons 2\,O_2^{2-} \qquad [1]$$

The decrease in peak current of wave I with time can also be accounted for by reaction [1]. Measurement of this decrease indicated that the oxide concentration decreased in a first order fashion with a half-life of approximately 30 min.

The voltammogram in Fig. 2 was taken 2.3 hr after the first addition of Na_2O to the melt (at a higher total oxide concentration than in Fig. 1). This indicates that the O_2^{2-} concentration becomes appreciable when Na_2O remains in the melt for long periods of time. Loss of oxide ion and peroxide ion due to vaporization and reaction with container, electrodes, etc., also occurs in the melt but is a slow process that takes many hours (1). Attempts were made to enhance the peak current of wave II with additions of Na_2O_2. The results were the same as for the addition of pure Na_2O. Most likely, solid Na_2O_2 decomposes to Na_2O before it dissolves in NaCl.

The reversibility of wave I was determined by measuring the separation of its peak and half-peak potential. $(E_p - E_{p/2})_a$ was found to be 120-135 mV at slow scan rates which is in reasonable agreement with the theoretical value of 105 mV for a reversible 2-electron process at 1103°K (7). The potential difference between wave I and its corresponding cathodic wave, $(E_p)_a - (E_p)_c$, was 125-150 mV which is also in reasonable agreement with the theoretical value of 105 mV for a reversible 2-electron process (7). The slightly higher experimental values could be attributed to quasi-reversible behavior; however the higher values are probably due, in part, to uncompensated *IR* effects in the melt.

The peak potential of a reversible charge transfer should be independent of scan rate. The approximate constancy of peak potential with scan rate, ν, for wave I is shown in Table I. The peak potential changes only by ~50 mV for a hundredfold increase in scan rate. The shift in peak potential is probably due, in part, to larger *IR* drops at fast scan rates.

The second anodic wave (wave II) was not as well defined as the first anodic wave since it appears as a shoulder on the oxidation limit of the electrode. Therefore measurements of the peak potential of wave II were only approximate. Values of $(E_p - E_{p/2})_a$, $(E_p)_a - (E_p)_c$, and the constancy of peak potential with scan rate were similar to those of wave I and would suggest a 2-electron process for the oxidation of O_2^{2-} in the melt.

Chronopotentiometry was also used to study the oxidation of Na_2O in the melt. Typical anodic and current reversal chronopotentiograms for the oxidation of O^{2-} are shown in Fig. 3. Plots of E *vs.* $\ln\left(\frac{\tau^{1/2} - t^{1/2}}{t^{1/2}}\right)$ were linear with slopes ranging from −64 to −74 mV; the theoretical slope for a reversible 2-electron process is −48 mV (8). Using current reversal chronopotentiometry, t_f/τ_r values were found to be 3-4, which reasonably agrees with the theoretical value of 3 for a reversible electron transfer process (8). Chronopotentiograms for the oxidation of O_2^{2-} in the melt were ill defined due to their proximity to the oxidation limit of the melt. Therefore, no quantitative information was obtainable for the peroxide oxidation.

Based on these results and results reported earlier (1), we postulate the following reaction mechanism

$$2\,O^{2-} + O_2 \rightleftharpoons 2\,O_2^{2-} \qquad [2]$$

$$2\,O^{2-} \rightleftharpoons O_2^{2-} + 2e^- \qquad [3]$$

Table I. Variation of $(E_p)_a$ and $(E_{p/2})_a$ with scan rate for the oxidation of O^{2-} in molten NaCl $[O^{2-}] = 1.61 \times 10^{-2}$M

Scan rate (V/sec)	$(E_p)_a$ (mV)	$(E_p - E_{p/2})_a$ (mV)
0.1	−474	121
0.5	−475	135
1.0	−464	128
5.0	−431	156
10.0	−425	163

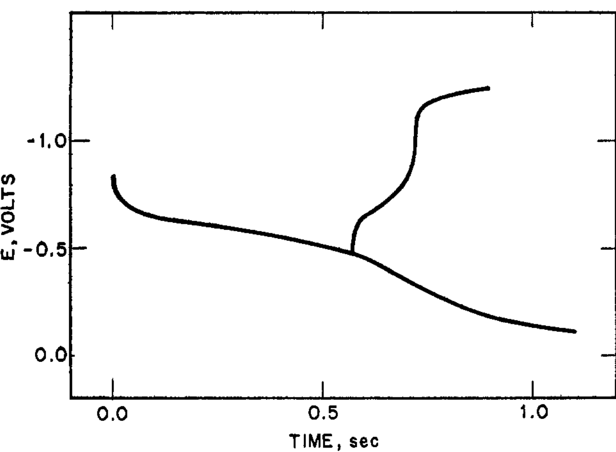

Fig. 3. Anodic and current reversal chronopotentiograms for the oxidation of O^{2-} in molten NaCl. $[O^{2-}] = 1.31 \times 10^{-2}M$, $T = 830°C$, O_2 pressure = 2.3 Torr, forward current density = reverse current density = 36 mA/cm^2.

$$O_2^{2-} \rightleftharpoons O_2 + 2e^- \quad [4]$$

Thus in Fig. 2, the first anodic wave (I) represents the oxidation of oxide to peroxide and the second anodic wave (II) represents the oxidation of peroxide to oxygen. On reversing the scan, the first cathodic wave (III) represents the reduction of oxygen and the second cathodic wave (IV) represents the reduction of peroxide.

The theory of cyclic voltammetry for multistep charge transfer systems has been derived and verified by Polcyn and Shain (8). When two electroactive species are reduced or oxidized at sufficiently different potentials ($\Delta E° > 118/n$ mV), the multistep charge transfer reactions can be considered as resulting from separate reactions and will exhibit two separate voltammetric waves. The oxidation potentials for oxide and peroxide differ by several hundred millivolts and appear as uncomplicated charge transfer reactions as previously indicated.

Values of $i_p/\nu^{1/2}$ were measured as a function of scan rate to check for possible chemical reactions coupled to the multistep charge transfers. The invariance of $i_p/\nu^{1/2}$ with scan rate would indicate charge transfers with no chemical complication (7). Our mechanism proposes a chemical reaction, the oxide/peroxide equilibrium (Eq. [2]), coupled to multistep charge transfers, the oxidation of oxide to peroxide to oxygen (Eq. [3] and [4]). However the equilibrium reaction [2] appears to be a slow process so that essentially no chemical reaction takes place during the time interval of a voltammetric scan (<10 sec). In this case, charge transfer reactions [3] and [4] would occur with no chemical complications. Values of $i_p/\nu^{1/2}$ for the oxidation of oxide (wave I in Fig. 2) at various scan rates are listed in Table II. The times at which the voltammograms were measured with respect to the addition of Na_2O to the melt are also given. The initial decrease in $i_p/\nu^{1/2}$ is due to the loss of oxide in the melt. The decrease in i_p with time holding ν constant is illustrated in Fig. 1. Once the oxide/peroxide equilibrium is established, $i_p/\nu^{1/2}$ approaches a constant value within experimental error. Similar results were observed with the oxidation of peroxide (wave II in Fig. 2) except for an initial increase rather than decrease in $i_p/\nu^{1/2}$ due to the gain of peroxide in the melt. The results indicate that the multistep charge transfer reactions of

Table II. Variation of $i_p/\nu^{1/2}$ with scan rate for the oxidation of O^{2-} in molten NaCl; before addition, $[O^{2-}] = 2.67 \times 10^{-2}M$; after addition, $[O^{2-}] = 4.03 \times 10^{-2}M$

Scan rate (V/sec)	$i_p/\nu^{1/2}$ (mA/sec$^{1/2}$/V$^{1/2}$)	Time elapsed after oxide addition (min)

20.0	3.0	25
0.5	2.8	57

oxide to peroxide to oxygen proceed with no chemical complications. This interpretation is further supported by the following observations: with voltammetry, the approximate constancy of peak potential with scan rate for both waves I and II; and with chronopotentiometry, the t_f/τ_r value of ~3.

The presence of only two oxidizable species, O^{2-} and O_2^{2-}, would tend to rule out the presence of O_2^- in the melt. Increasing the O_2 pressure would tend to favor the formation of superoxide in the melt (1). Experiments were carried out in O_2 pressures as high as 60 Torr; however, no additional waves were observed.

According to reaction [2], the formation of peroxide should be minimal at low O_2 pressures. Experiments were carried out in He atmospheres containing less than 1 ppm O_2. Voltammograms of the oxidation of Na_2O at this O_2 pressure were similar to those at higher O_2 pressures; however, the decrease in peak current of the first anodic wave was considerably slower than in the case of higher O_2 pressures. Since O_2 is produced by the oxidation of O_2^{2-}, it was impossible to study the formation of O_2^{2-} at very low O_2 pressures. The second anodic wave would produce O_2 in the vicinity of the electrode in the melt that would eventually react with O^{2-} to form O_2^{2-}.

In conclusion, we have shown that when Na_2O is dissolved in molten NaCl in the presence of oxygen, oxide ions react slowly with oxygen to form peroxide ions. The oxidation of oxide ion at a gold electrode results in two multistep charge transfers, the oxidation of oxide to peroxide followed by the oxidation of peroxide to oxygen.

On the Short Time Solution for the Concentration Step at the Surface of a Rotating Disk

Daniel A. Scherson, Pier Filippo Marconi,* and John Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The first thirty coefficients of a proposed series solution for a fundamental problem in nonsteady diffusion to a rotating disk have been evaluated. The results obtained raise serious questions not only with respect to potential practical applications of such a solution, but also in regard to the claimed convergence character of the series. Certain difficulties related to the numerical determination of these coefficients are discussed in detail.

The use of transient techniques in conjunction with forced convection systems, such as a rotating disk, seems to be one of the most valuable tools in the analysis of electrode processes. In particular, the a-c impedance method has found a multiude of applications in the characterization and study of detailed mechanisms of electrochemical reactions.

From a theoretical standpoint, an expression for the Warburg impedance for a rotating disk was recently derived (1) by a formal space transformation of the solution for the step potential method. As a means of fully utilizing this particular property, previous mathematical treatments of the step potential problem, leading to analytic solutions, were carefully examined.

The transient concentration profile, under step potential conditions at the surface of a rotating disk electrode, has been investigated by Selman (2). Within the framework of approximations specified elsewhere (2, 3), this author developed a series, up to third order, by means of a classical perturbation expansion. Krylov and Babak (3), on the other hand, have independently derived a generalized form of the same series by introducing parabolic cylinder functions. This latter approach allows a recurrence relation for the coefficients to be obtained without resorting to solving the resulting differential equations individually. Based on this solution, these workers arrived at an analytic expression for the flux at the surface and indicated that the series converged for any finite value of the dimensionless time.

In order to extend the accuracy of these results beyond the limits imposed by the first three coefficients reported, a numerical evaluation of the first thirty coefficients was performed. Given that the flux at the surface is intimately connected to the Warburg impedance through its Laplace transform, a series solution for the real and imaginary parts of the impedance can be easily obtained.

The purpose of this note is twofold. First, to report the results obtained and examine certain problems encountered in the calculations and second, to discuss, based on the former, the convergence character of the series in relation to potential practical applications.

Mathematical Formalism

A thorough derivation of the series under study will not be pursued here. Although the mathematical details are interesting in themselves only the results will be presented.

According to Krylov and Babak, the transient behavior of the flux at the surface is given by

$$j(\tau) = \frac{c_0(AD^2)^{1/3}}{\sqrt{\pi\tau}} \left\{ 1 - \pi \sum_{n=1}^{\infty} \sum_{k=-3n-1}^{3n-1}{}^{**} \frac{2^{k/2} b_k^{(n)}}{\Gamma\left(-\frac{k}{2}\right)} \tau^{3n/2} \right\} \quad [1]$$

where c_0 and D are the bulk concentraiton and diffusion coefficient of the electrochemically active species, respectively. The dimensionless time τ, is related to the time t, the angular velocity Ω, and the kinematic viscosity of the solution ν by

$$\tau = (DA^2)^{1/3} t \quad \text{where} \quad A = a\left(\frac{\Omega^3}{\nu}\right)^{1/2} \quad [2]$$

The double asterisk in the right upper corner of the summation sign in Eq. [1] indicates that "k" involves values which are only even, for odd n, or only odd, for even n.

The first four coefficients $b_k^{(1)}$ are given by

$$b_2^{(1)} = \frac{2}{3\sqrt{\pi}}, \quad b_0^{(1)} = \frac{1}{\sqrt{\pi}}, \quad b_{-2}^{(1)} = 0, \quad b_{-4}^{(1)} = \frac{-1}{\sqrt{\pi}} \quad [3]$$

which serve as a basis for calculating higher order coefficients through the recursion formulas specified below (for $n = 2, 3, 4, \ldots$)

$$b_k^{(n)} = -\frac{2\sqrt{2}}{3n+k+1}\left[(k+1)(k+2)b_{k+1}^{(n-1)} + (2k+1)b_{k-1}^{(n-1)} + b_{k-3}^{(n-1)}\right] \quad \text{for } -3n+5 < k < 3n-5 \quad [4]$$

$$b_{3n-1}^{(n)} = -\frac{\sqrt{2}}{3n} b_{3n-4}^{(n-1)} \quad [5]$$

$$b_{3n-3}^{(n)} = -\frac{\sqrt{2}}{3n-1}\left[b_{3n-6}^{(n-1)} + (6n-5)b_{3n-4}^{(n-1)}\right] \quad [6]$$

$$b_{-3n+1}^{(n)} = -3\sqrt{2}(n-1)(3n-2)b_{-3n+2}^{(n-1)} \quad [7]$$

$$b_{-3n+3}^{(n)} = \frac{\sqrt{2}}{2}\left[(6n-7)b_{-3n+2}^{(n-1)} - (3n-5)(3n-4)b_{-3n+4}^{(n-1)}\right] \quad [8]$$

$$b_{-3n-1}^{(n)} = -\frac{3n}{2}\Gamma\left(\frac{3n}{2}\right) \sum_{k=-3n+1}^{3n-1}{}^{**} \frac{2^{(3n+k+1)/2}}{\Gamma\left(\frac{1-k}{2}\right)} b_k^{(n)} \quad [9]$$

* Electrochemical Society Active Member.

Key words: convection, diffusion, impedance.

Based on this formalism, the real and imaginary parts of the Laplace transform of the flux at the surface, $\mathcal{L}\{j(\tau)\}$, which prescribe the value of the Warburg impedance, are given by

$$\mathrm{Re}[\mathcal{L}\{j(\tau)\}] = K^{1/2}\frac{\sqrt{2}}{2} - \frac{1}{\sqrt{\pi}}\sum_{n=1}^{\infty} \Theta_n \frac{\Gamma\left(\frac{3n+1}{2}\right)}{K^{1/2(3n-1)}} 3^n \sin\frac{1}{4}(3n-1)\pi \quad [10]$$

$$\mathrm{Im}[\mathcal{L}\{j(\tau)\}] = K^{1/2}\frac{\sqrt{2}}{2} + \frac{1}{\sqrt{\pi}}\sum_{n=1}^{\infty} \Theta_n \frac{\Gamma\left(\frac{3n+1}{2}\right)}{K^{1/2(3n-1)}} 3^n \cos\frac{1}{4}(3n-1)\pi \quad [11]$$

where the coefficients Θ_n are defined by

$$\Theta_n = -\pi \sum_{k=-3n-1}^{3n-1}{}^{**} \frac{2^{k/2} b_k^{(n)}}{\Gamma\left(-\frac{k}{2}\right)} \qquad n = 1, 2, 3 \ldots \quad [12]$$

$$\Theta_0 = 1 \quad [13]$$

and $K = \omega\nu(3D/a\nu)^{2/3}/\Omega D$, is the dimensionless frequency.

Computation Method

Preliminary calculations based on Eq. [1] showed that even for small values of n, the computed coefficients, Θ_n, were appreciably altered by choosing π, arising from $\Gamma(k/2)$ for odd k, with an increasing number of significant figures. Moreover, noticeable changes were observed by merely performing the required arithmetic operations in a different order. This behavior was apparently induced by round-off errors, which may become extremely significant upon addition and substraction of a collection of terms which are many orders of magnitude larger than the Θ_n itself.

This problem can be successfully overcome by multiplying the original $b_k^{(n)}$ coefficient by $\pi^{1/2}$, modifying the recursion formulas by a factor of $2^{1/2}$, and expanding the gamma functions. The newly generated set of $b_k^{(n)}$ coefficients can therefore be conveniently represented as the ratio of two integer numbers. Consequently, Θ_n or $\Theta_n\pi^{1/2}$, can be expressed in the same exact fashion, depending on whether n is even or odd.

Based on these considerations, a computer program which performs all the calculations by integer arithmetic was developed. Θ_n's up to $n = 29$ were evaluated by effectively using up to 387 bits for storing the numerator and denominator of the $b_k^{(n)}$ coefficients. The results obtained, as well as the values for the flux at $\tau = 1$ are listed in Table I.

A comparison *a posteriori* indicated that floating-point representation and arithmetic could give reliable values of Θ_n up to $n = 7$ or $n = 16$ by using single-precision (48 bits exclusive of sign and exponent) or double-precision (96 bits) calculations, respectively.

Discussion and Conclusion

The different values for the flux at $\tau = 1$, obtained by taking an increasing number of terms in the Krylov-Babak series do not seem to improve the accuracy of the result. Actually, a careful inspection of Table I shows that an oscillatory departure from an arbitrary intermediate value is generated. Moreover, the fact that the coefficients do not seem to approach zero as n increases clearly suggests that the series diverges for all τ. This remark should be regarded as purely empirical, for no analytic proof of convergence has been presented. However, even if the series converged, the computational effort involved and the number of terms that would be required to obtain an acceptable answer, certainly make the use of this solution highly impractical.

Voltammetric and Electrochromic Behavior of N-Heptylviologen on Chemically Modified Metal Oxide Electrodes

R. C. Cieslinski and N. R. Armstrong*

Department of Chemistry, University of Arizona, Tucson, Arizona 85721

ABSTRACT

Voltammetric and spectroelectrochemical results are presented for the one-electron reduction of n-heptylviologen dibromide on clean and silane-modified, tin oxide, and on indium tin oxide metallized-plastic optically transparent electrodes (MPOTE). The amount of n-heptylviologen dibromide reduced and the rate of coloration due to the formation of the cation-radical film can strongly be influenced by the state of the electrode surface. The initial 200-500 msec of viologen deposition are not mass transport controlled. Calculations for the amount of viologen deposited vary, depending on whether a spectrophotometric or coulometric estimated is used. Spectrophotometric data indicate that the amount of viologen deposited in the first 200 msec of chronoamperometric reduction from a concentrated viologen solution is *ca.* 10-14 monolayers and is increased at least 60% by the addition of a monolayer of the silane modifier to the electrode surface. In the case of the metallized plastic films, the increase in coloration rate may be attributed to the presence of nonpolar surface groups present at the surface of the conductive film.

Permanent attachment of various chemical species to electrode surfaces to change their surface properties is now widely recognized (1-19). These chemically modified electrodes have been tested for numerous reasons, with potential applications to electrocatalysis (9, 10, 13, 14, 19) and photosensitization (3, 4, 8). Their use as predictable and controllable electrochromic display materials is also another interesting possibility (17, 20). The present study presents the result of some spectroelectrochemical investigations of the reduction of a film-forming viologen on chemically-modified SnO_2 glass and In_2O_3/SnO_2 (ITO) metallized plastic films (21). The use of viologens (dialkyl and diaryl 4,4′ bipyridinium compounds) in redox chromic displays is well known with a number of papers and patents discussing their use (22-27). The ability to vary the coloration rates of electrochromic reactions of these compounds through chemical modification of the electrode substrate will be demonstrated. The use of silanes to alter the behavior of an electrochemically adsorbed molecule is not new. Evidence that silane-modified SnO_2 electrodes exhibit appreciably different electrochemical behavior towards oxidation of xanthene-type dyes such as erythrosin and fluorescein has already been noted (3). With these xanthene dyes, where adsorption accompanies oxidation, anodic peak potentials have been shown to shift to lower overpotentials, and the total oxidative charge transferred increased at the silane-modified electrodes. The investigations reported here have shown that the silane-modified metal oxide surface probably promotes a higher surface concentration of nucleation sites for the viologen. In most cases, reduction of the viologen at the silanized SnO_2 electrode or ITO metallized plastic optically transparent electrodes (MPOTE) resulted in faster coloration rates. Occasionally several monolayers of the viologen were retained on the electrode surface following oxidation of the viologen film. Surface analysis studies indicated that increased coloration rates of the viologen films on the modified SnO_2 electrodes, and on the ITO MPOTE's resulted from an increase in the nonpolar nature of the electrode surface.

Key words: deposition, nucleation.

Experimental

A basic spectroelectrochemical cell design was used to measure the electrochromic properties. This design allows sandwich-like positioning of the electrodes to a Lucite body with a cell volume of approximately 5 ml. A circular brass contact recessed in the Lucite block and separated from solution by an O-ring allowed uniform distribution of current to the metal oxide electrodes. The geometric area of the electrode was 0.5 cm². The cell was placed in a Baush and Lomb Spec 210 u.v.-visible spectrophotometer from which single beam or dual beam absorbance/time or transmittance/time measurements were made. The voltammetric measurements were performed using a potentiostat of conventional design. The recording instruments were either a Houston 2000 recorder, a Tektronix 5441 storage oscilloscope, or a PAR Model 4202 signal averager, used in the transient recorder mode.

In a typical double potential step chronoabsorbance experiment, absorbance or transmittance was monitored at the wavelength maximum for the viologen cation radical as a function of time while stepping to and from the deposition potential. During this time interval, both current and the total charge and the true potential of the working electrode *vs.* the reference electrode were recorded ($E_{work} - E_{ref}$).

N-heptyl viologen dibromide (1,1′-Diheptyl-4,4′-bipyridinium dibromide) was used as obtained from Aldrich Chemical Company. Reagent grade potassium bromide (Baker) was recrystallized twice from water which had been distilled three times from alkaline $KMnO_4$. The deaerated electrolyte solutions were made just prior to investigation and stored under nitrogen. Toluene (Drake) was dried in magnesium sulfate and distilled from potassium metal under a nitrogen atmosphere prior to use. All silanes were purchased from Petrarch Systems Incorporated, and used as obtained from the manufacturer.

Fluoride-doped SnO_2 on glass was manufactured by Pittsburgh Plate Company. The electrodes were cleaned in an ultrasonic bath, using successive washings of alcoholic KOH, ethanol, and distilled water. Metallized plastic optically transparent electrodes (MPOTE) were obtained from Sierracin/Sylmar (Sylmar, California) under the trade name Intrex-K (indium-tin oxide,

ITO) films (21). These electrodes were ultrasonically cleaned with ethanol and then with water before use. The sheet resistance of the SnO_2 electrodes was *ca.* 15-30 Ω/sq and that of the ITO films 100-300 Ω/sq.

For silane modification, the SnO_2 electrodes were refluxed in a 1-5% silane-dry toluene solution under nitrogen for 30 sec to 2 hr after which the excess silane was removed by rinsing the electrodes in dry toluene. The silanized electrodes were then stored in an inert atmosphere prior to use.

The presence of the silane or of n-heptyl viologen dibromide was confirmed by surface elemental analysis using either a GCA-McPherson ESCA 36 spectrometer (base pressure *ca.* 10^{-7} Torr) or a Physical Electronics, Incorporated (PHI) TFA Auger spectrometer (base pressure *ca.* 10^{-9} Torr).

Results and Discussion

Viologen deposition on unmodified SnO_2 electrodes.— A working model for redox processes of n-heptyl viologen films on transparent tin oxide (SnO_2) electrodes has been formulated by Jasinski (25, 26) and others (22-24). An initial cleaning/hydrolysis step with alcoholic KOH to remove carbonaceous material, generates hydroxyl-type entities on the surface. The next step calls for a modification of these entities, presumably through an ion exchange process with the viologen counter ion (Br^- in many cases), to produce a surface on to which the viologen may be deposited. The third step involves a nucleation of the radical cation film on these sites. After nucleation, the film grows at a rate limited by diffusion. The last step in the overall mechanism is equilibration of the radical cation salt deposited with the bulk of solution.

Some initial investigations of the viologen reduction indicated that diffusion control was achieved soon after (less than 100 μsec) the initiation of deposition (25, 26). Other reports (27) and the experiments described below, however, show that in a potential-controlled reduction of the viologen, diffusion control is not achieved instantly, and that the amount of viologen reduced in the first 100-500 msec can be strongly influenced by the state of the electrode surface. Figures 1 and 2 show the double potential step, current/time, charge/time, and transmittance (at 595 nm)/time measurements for 1×10^{-2}M solution of n-heptyl viologen dibromide in 0.5*N* KBr electrolyte. In these experiments, an SnO_2 electrode was biased between −0.7 and −0.8V *vs.* the Ag/AgCl reference electrode (just positive of the potential for reduction to the neutral viologen) and after approximately 3 sec (Fig. 1) the bias voltage was changed to +0.4V. The current/time profile, from 1 to 3 sec of reduction, shows that the growth of the n-heptyl viologen radical cation film on the tin oxide substrate appears diffusion controlled. The transmittance/time plot shows that the color change occurs through two distinct time regions, linear changes from 0 to 400 msec and then a nonlinear change from 1 to 3 sec. The behavior at longer electrolysis times is representative of spectroelectrochemical behavior for a diffusion-controlled process (28). A spectrophotometric assay of the deposited viologen concentration after 400 msec of deposition (assuming the molar absorptivity to be *ca.* 1.5×10^4 M^{-1} cm^{-1}, and a projected surface area of the viologen to be *ca.* 50Å^2) showed the surface excess to be *ca.* 15 monolayers. A coulometric assay at this same electrolysi time (corrected for charging current with or without viologen present) indicated a deposition of *ca.* 34 monolayers. The variation in the two numbers can be assumed to arise in an overestimation of the extinction coefficient for the viologen in the film or poor estimation of the projected area of the molecule.

When the bias voltage was changed to +0.4V after 3.75 sec, the oxidative current was constant as a function of time during the first 500 msec of decoloration.

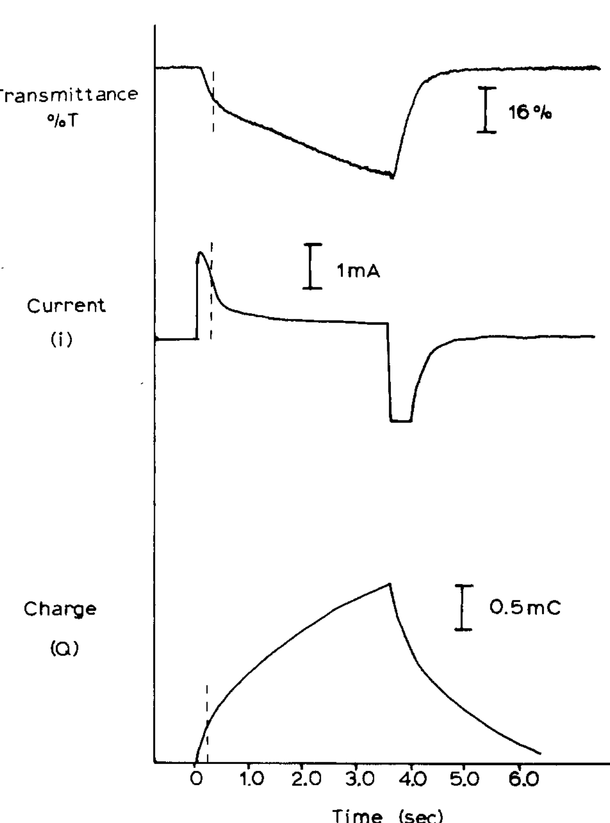

Fig. 1. Double potential step, transmittance (at 595 nm)/time, current/time, and charge/time measurements for a 1×10^{-2}M solution of n-heptyl viologen dibromide in a 0.1*N* KBr at a clean SnO_2 electrode. Total elapsed time: 6 sec. Dashed line indicates the passage of 200 msec of electrolysis time (see Fig. 2).

Decoloration therefore appears to be kinetically limited. Measurement of $E_{work} - E_{ref}$ simultaneously in the chronoabsorptometric experiment indicated that the applied deposition or reduction potential (−0.8V) was reached within 10 μsec after initiation but that the oxidation potential (+0.4V) was reached only after 500-1000 msec, following application of that potential. We believe that this delay in controlled potential response is due to the inherent resistivity of the cation radical film (25-27) and the inability of the potentiostat to comply with the current/voltage characteristics necessary to achieve fast dissolution of the film. The resistivity of the viologen film toward oxidation may be due to low rates of electron transfer through the films, back to the electrode substrate. Saturation of this region with the newly formed dication may also impede electron transfer. The rectifying nature of the cation-radical film requires further study.

Reduction in the time region from 0 to 200 msec was examined in more detail with a series of double-potential step experiments shown in Fig. 2. Both the transmittance change and total reductive charge increased linearly over this time region. Absorbance change *vs.* (time)$^{1/2}$ and charge *vs.* (time)$^{1/2}$ plots therefore show a positive deviation from linearity. Even though potential control was achieved within 10 μsec, the reduction current was virtually constant with time throughout deposition. The deposition during the initial 200 msec is apparently not mass transport controlled (28). This initial reduction corresponds to approximately 1.8×10^{-9} moles/cm^2 or *ca.* 6 monolayers (determined spectrophotometrically). The decoloration or stripping of viologen in this time interval is also resistively controlled similar to the longer time measurements. Since the first several monolayers of viologen are deposited at rates not controlled by mass

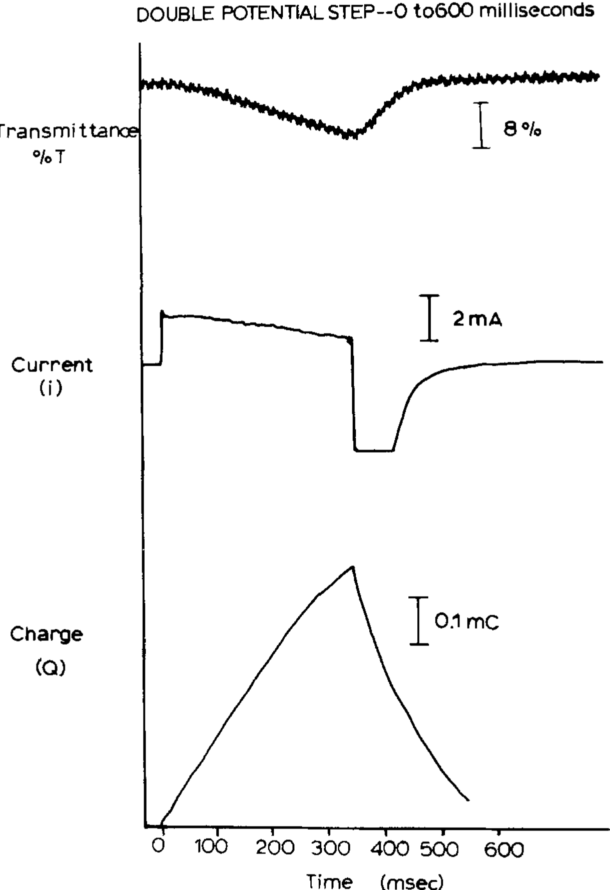

Fig. 2. Double potential step, transmittance (at 595 nm)/time, current/time, and charge/time measurements for a 1×10^{-2}M solution of n-heptyl viologen dibromide in 0.1N KBr electrolyte at a clean SnO_2 electrode. Total elapsed time: 600 msec.

transport, we concur with Bruinink and Kregting (27) that nucleation of the cation-radical film is very important to film growth (22-26). Fletcher, Duff, and Barraclas have recently confirmed this nucleation hypothesis for the initial deposition of the cation-radical n-heptylviologen film on SnO_2 (29). Their results were obtained at low concentrations of the viologen (10^{-5}-10^{-4}M) where nucleation can be expected to be more dominant in the growth of the film than the results presented here. Similar conclusions have been reached regarding electrodeposition of metals (30). In our experiments, it appears that nucleation can be expected to dominate film growth from concentrated solutions of viologen for times up to 1 sec when reduction is carried out potentiostatically. This observation also leads to the conclusion that modification of the electrode surface should dramatically change the viologen deposition process by changing the number and type of nucleation sites.

Viologen deposition on chemically modified electrodes.—Most metal oxide electrodes have shown reactivity to silane coupling agents which can be used to alter the various electrochemical responses (1-8). We have found that those electrodes which possess short, nonpolar groups such as a dimethyl functionality (from dimethyldiethoxy silane, dmde-silane) or a phenyl functionality (from phenyltriethoxy silane, phensilane) or a metallized plastic film electrode (MPOTE) improve the coloration behavior of the n-heptyl viologen.

Preliminary results for dilute (10^{-3}M) solutions of n-heptyl viologen dibromide in 0.1N KBr had indicated an increase in coloration rates with increased nonpolar nature of the electrode surface (20). Unmodified SnO_2 electrodes were compared with amine-silane-modified SnO_2 electrodes and ITO metallized plastic film electrodes. The amine-silanes included γ-aminopropyl triethoxy silane (pr-silane) and aminoethylaminopropyl triethoxy silane (en-silane) both of higher molecular weight and chain length than in the studies reported here. A slight increase in current density for the reduction and oxidation waves of the cyclic voltammograms of n-heptyl viologen was noted on the modified SnO_2 electrode and the MPOTE. An increase of the coloration rate of the viologen film (1-30 sec) of up to 50% was noted on the modified SnO_2 electrode in chronoabsorptometric experiments. In the case of the SnO_2 electrodes, the increase in coloration rate was hypothesized to be due to the presence of the organic functionality on the electrode surface. In the case of the MPOTE electrodes, surface analytical data has indicated that the surface is carbon-rich, due to the admixture of the metal oxides and the polymer undercoating (21). Also of note was that the reduction prewave in the cyclic voltammograms of the viologen was missing on the chemically modified SnO_2 electrode. The prewave is typical of reactions where the product of the electroreduction is adsorbed on the electrode surface (31, 32). The absence of the prewave indicates the alteration of the adsorption surface site. Further exploration of this effect is necessary.

In spite of the encouraging results obtained with the pr-SnO_2 and en-SnO_2 electrodes, we found it difficult to control the surface concentration of the modifier so that optimum coloration and decoloration behavior was obtained. High surface concentrations of the modifier promoted excessive decoloration rates. It was decided that the propylamine or ethylamine-propylamine groups were not of the optimum type to promote a favorable change in the n-heptyl viologen deposition and dissolution. Dimethyl diethoxy silane and phenyltriethoxy silane were explored next, to add smaller, nonpolar functional groups to the SnO_2 surface.

Double potential step, transmittance/time plots, (5×10^{-2}M viologen, 0.1N KBr) from 0 to 5 sec, are shown in Fig. 3, comparing an unmodified SnO_2 electrode with a dmde-modified SnO_2 electrode. Several features are apparent in these plots. On the modified electrode surface the amount of coloration at 2 sec is *ca.* 30% greater than on the unmodified surface, consistent with the results presented previously for the more dilute solutions of viologen. On both electrodes, the initial viologen deposition (0-500 msec) is not mass transport controlled. On the modified surface in the first 500 msec of deposition the transmittance change is increased over that of the unmodified surface by *ca.* 60%. On both surfaces the rates of decoloration were kinetically controlled and were not significantly changed on the modified electrode surface. On those electrodes with large molecular weight silanes attached, or with surface concentrations of the silane consistent with a siloxane polymer (1, 2, 32), the decoloration rates were lengthened relative to the unmodified surface.

The effect of surface concentration of the silane on the electrochromic process is explored in more detail in Fig. 4. Cyclic voltammograms and chronoabsorbance behavior are shown for n-heptyl viologen (10^{-3}M) on unmodified SnO_2, and SnO_2 electrodes exposed to dmde-silane at 20 and 100 min, respectively. The amount of silane found on the SnO_2 surface when examined by XPS is found to be a direct function of the exposure time of the SnO_2 electrode to the silane during modification. Both silanized electrodes show greater coloration rates when compared to an unmodified SnO_2 electrode, and the cyclic voltammograms show a greater current response due to the increase in surface concentration of viologens. The optimum coloration rate was achieved when the SnO_2 electrode was silanized for 20 min. Further exposure to silane solution caused a greater reduction current,

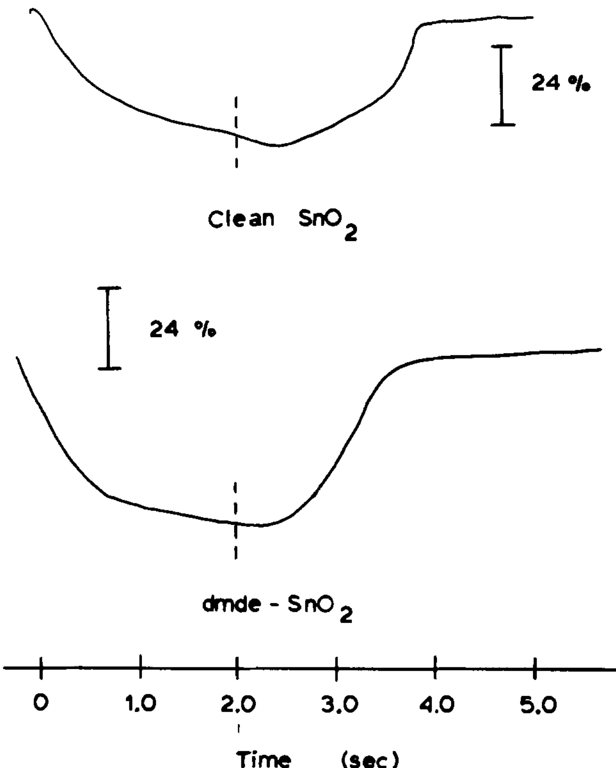

Fig. 3. Double potential step, transmittance (at 595 nm)/time plots comparing an unmodified SnO_2 electrode with a dmde-modified SnO_2 electrode for 5×10^{-2} solution of n-heptyl viologen dibromide in 0.1N KBr electrolyte. Total elapsed time: 5 sec. Dashed line indicates the point at which chronoabsorptometric behavior was compared.

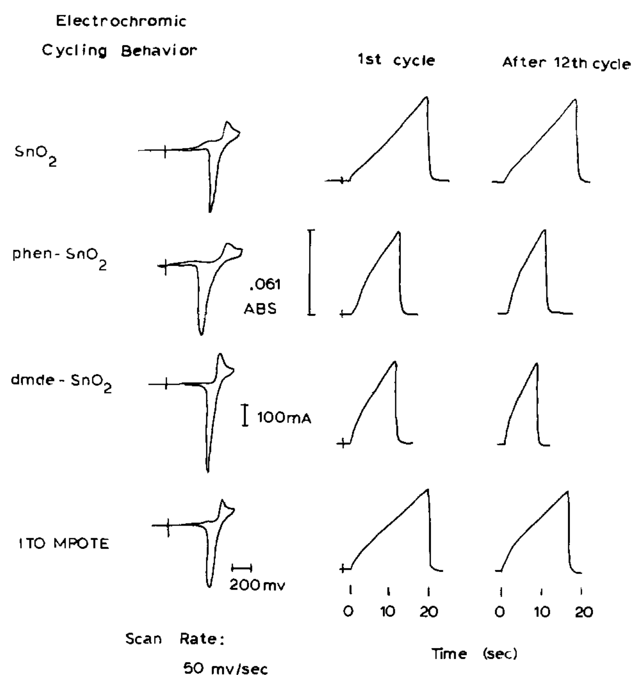

Fig. 5. Cyclic voltammograms and double potential step chronoabsorbance plots for a 1×10^{-3}M solution of n-heptyl viologen in 0.1N KBr electrolyte on clean unmodified SnO_2 electrode, SnO_2 electrodes modified with phenyl dimethoxysilane and dimethyldiethoxysilane, and an ITO metallized plastic electrode film. Behavior monitored as a function of number of times the electrode potential was cycled to and from the reduction potential.

but slowed down the coloration rate for that electrode. We believe that too much attached silane restricts the nucleation of viologen at the electrode surface and possibly forms an insulating surface layer (1, 2). This point is further illustrated in Fig. 5. Comparisons of unmodified dmde-modified and phen-modified SnO_2 electrodes and an ITO, MPOTE are shown. Upon potential cycling to and from the deposition potential, both the dmde-SnO_2 and the phen-SnO_2 electrodes show improved coloration rates after the 12th cycle. This can be attributed to some activation of the modified electrode surface, possibly by electrochemical stripping of the unbound silane, or irreversible deposition of monolayers of viologen. No additional changes were noted for voltammetric cycles beyond the 12th cycle. Good stability of the film is apparent for 30-50 cycles. Further studies of film stability are in progress. Only minor amounts of improvement were observed upon potential cycling the SnO_2 and ITO MPOTE electrodes. Auger analysis of a surface removed from solution after the 12th cycle shows that the silane is still present on the surface, but its surface concentra-

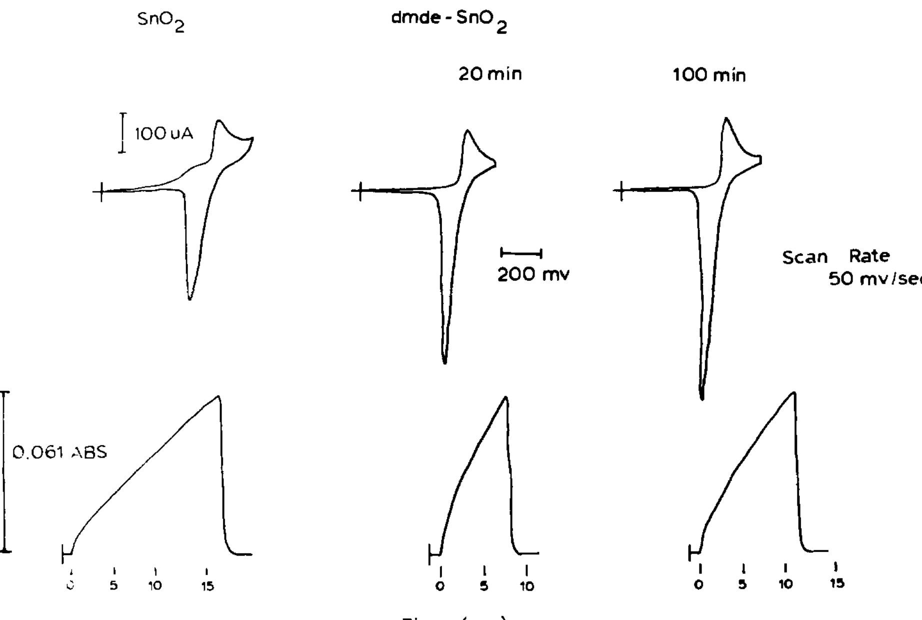

Fig. 4. Cyclic voltammograms and double potential step, chronoabsorbance curves for a 1×10^{-3}M solution of n-heptyl viologen in 0.1N KBr electrolyte on unmodified SnO_2 and SnO_2 exposed to dmde-silane at 20 and 100 min, respectively.

tion is half that found after one cycle. Even after potential cycling the electrode, the coloration rates on the modified surfaces are still faster than on the unmodified electrodes.

Conclusions

It is clear that the amount of n-heptyl viologen electrochemically reduced and its rate of precipitation can be strongly influenced by the state of the electrode surface. Figure 6 is a schematic of the electrodeposition process for unmodified SnO_2 electrodes. The top picture represents an unmodified SnO_2 electrode whose surface is viewed to consist of hydroxyl groups which can be exchanged with a counter ion such as bromide (25, 26). Viologen undergoing electrochemical reduction precipitates in a configuration producing a partially conductive film. For chemically modified electrodes as shown in the bottom picture, the role of the counter ion is uncertain. Several recent studies have shown that only a fraction of the available surface hydroxyls are involved in silane bonding, so that ion exchange processes are still possible (33, 34). We believe that by providing a nonpolar site on the surface through attachment of the silane, that a more preferred nucleation site is obtained for the deposition of the first monolayers of viologen. The spectroelectrochemical data indicates that the amount of viologen deposited in the first 200-500 msec of the reduction is increased at least 60% by the addition of a monolayer concentration of the silane to the electrode surface. We have seen little effect on the reduction of methyl viologen using silane-modified electrodes and conclude that the heptyl group on the viologen is the major source of the interaction with the surface modifier. The role of the n-heptyl groups in the viologen reduction must be to reduce the solubility of the cation radical and to increase the tendency toward aggregation of the deposited molecules. We picture the role of the silane modifier as a facilitator in the solvation of the nonpolar portions of the viologen. The surface functional groups cannot be too bulky, or the surface concentration of the modifier too large, to avoid excessive decoloration times for the viologen film. In the case of the metallized plastic films, it seems that the increase in coloration rate can be attributed to the presence of nonpolar surface groups which are present on the surface of the conductive film and interact with the viologen. XPS and AES analysis confirmed the higher surface concentration of carbon on these films compared to normal SnO_2 thin film electrodes (21, 36). Favorable nucleation sites are present on the MPOTE, but not of the same chemical type as those on the silane-modified SnO_2 surface.

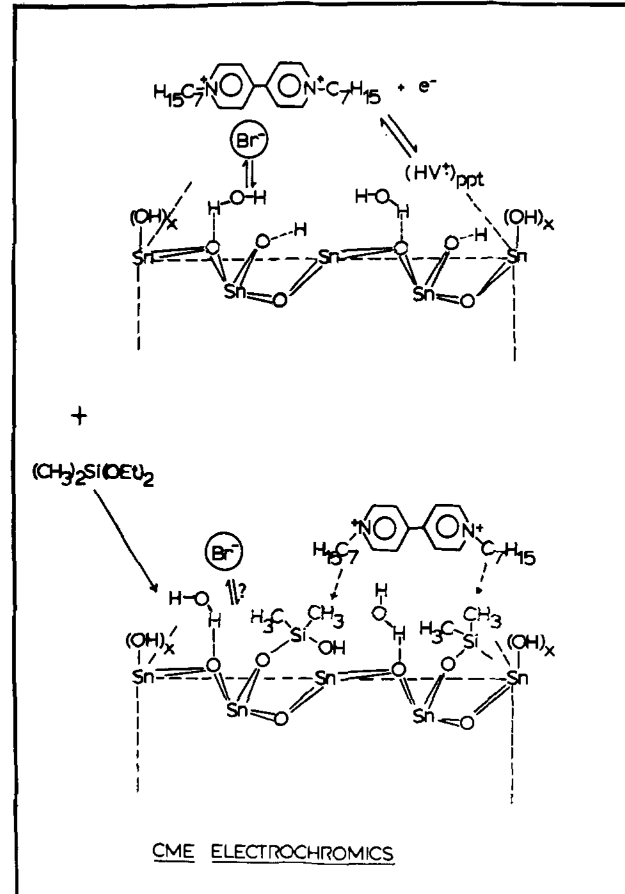

Fig. 6. Schematic representation of the viologen electrodeposition process on unmodified and chemically modified (CME) SnO_2 electrodes.

Several questions remain under investigation regarding the viologen electrochromic reactions. The role of the anion in the deposition reactions is important and unexplored on the modified surfaces. Understanding of the nature of the interaction of Br^- with the metal oxide surface as well as other anions may lead to further optimization of the electrochromic response of the viologens. It would also be desirable to hold the viologen in a more rigid matrix next to the electrode surface to further enhance coloration rates, the stability of the viologen cation-radical film, and possibly reduce resistive effects on the decoloration process (37).

An Investigation of Electrode Materials for the Anodic Oxidation of Sulfur Dioxide in Concentrated Sulfuric Acid

P. W. T. Lu* and R. L. Ammon

Westinghouse Electric Corporation, Advanced Energy Systems Division, Pittsburgh, Pennsylvania 15236

ABSTRACT

The kinetic studies and electrochemical evaluation of catalysts for the SO_2 oxidation reaction have been carried out in concentrated (50 weight percent) sulfuric acid solutions using the steady-state potentiostatic method and cyclic voltammetry. Palladium and palladium oxide have been identified to be better catalysts than platinum for this reaction. The polarization potential for SO_2 oxidation on a preanodized Pd anode decreases with increasing temperature, while the reaction mechanism is independent of temperature. The electrochemical oxidation of SO_2 commences at an anodic potential where the formation of adsorbed oxygen-containing species is initiated. On the Pt, Ru, Ir, and Rh anodes, the chemical transformation of the adsorbed species to metal oxides at higher potentials creates passivated layers which partially cover the electrode surface and inhibit the SO_2 oxidation reaction.

The sulfur cycle hydrogen production process is being developed for the electrolytic generation of hydrogen from water (1-4). This cycle is essentially composed of an electrochemical and a thermochemical reaction. In an electrolysis cell, sulfur dioxide dissolved in aqueous solutions is electrochemically oxidized at the anode while hydrogen gas is evolved at the cathode. Sulfuric acid produced in the electrolyzer is concentrated, using thermal energy from a high temperature heat source, and then catalytically decomposed to form sulfur dioxide, water, and oxygen. The hybrid cycle is completed by circulating the sulfur dioxide to the electrolyzer. The partial reactions for the cycle may be represented as follows

$$\text{Electrochemical:} \quad SO_2 + 2H_2O \rightarrow H_2SO_4 + H_2 \quad [1]$$

$$\text{Thermochemical:} \quad H_2SO_4 \rightarrow H_2O + SO_2 + \tfrac{1}{2} O_2 \quad [2]$$

It has been noted (5) that the thermodynamic reversible potential for the reaction [1] is only 0.29V [in 50 weight percent (w/o) sulfuric acid at 25°C] as compared to 1.23V for water electrolysis. Consequently, the sulfur-based cycle, through the anodic oxidation of sulfur dioxide (in place of the anodic evolution of oxygen), utilizes theoretically ~24% of electric energy required in the conventional water electrolysis.

In acid media, the electrochemical oxidation of sulfur dioxide has been intensively investigated on platinum (6-13), gold (8, 11, 14, 15), graphite (16), and platinum-gold alloys (14). In a view by Zhdanov (17), the mechanism of the SO_2 oxidation reaction has been discussed. Nevertheless, a majority of electrochemical studies on this reaction were carried out in dilute sulfuric acid solutions (less than 5 w/o). Quantitative information regarding the anodic oxidation of sulfur dioxide in concentrated electrolyte or on metals and alloys other than platinum and gold is sparse (12). As has been pointed out (2, 4, 18), however, high concentration of sulfuric acid solution in the electrolyzer is of crucial importance to maximize the overall energy efficiency of the cycle.

The objective of the present study is to understand the kinetics of the SO_2 oxidation reaction in concentrated sulfuric acid solutions. A number of candidate materials such as palladium, gold, ruthenium, rhenium, iridium, and rhodium, which are chemically stable in

* Electrochemical Society Active Member.

Key words: oxidation, catalysis, kinetics, depolarization, inhibition.

the electrolyte environment, were investigated as catalysts for this reaction. Effects of temperature on the electrode kinetic parameters were examined. In addition, cyclic voltammetric studies were conducted on smooth metal electrodes to determine the influence of oxygen-containing surface layers on the reaction kinetics. Attempts were also made to find alternate catalysts of low cost and promising activity to substitute for platinum in the electrochemical oxidation of sulfur dioxide in concentrated acid media.

Experimental

Electrode preparation.—A wire or rod of candidate materials was electrically connected to a platinum wire by spot welding. Each electrode was then sealed in a shrinkable Teflon tubing such that a surface area approximately 1 cm^2 was exposed to the electrolyte.

The porous carbon plates used in the fabrication of PdO_x/C electrodes were pretreated in concentrated (13.5*N*) nitric acid at 80°C for 4 hr, followed by ultrasonic cleaning. The resulting carbon substrates were rinsed thoroughly in distilled water and then dried in air at 125°C. An appropriate amount of aqueous $PdCl_2$ solution was applied to the pretreated carbon substrate by a vacuum filtration method. After thermal decomposition at 600°C under a hydrogen atmosphere, the catalyzed carbon electrode was oxidized at ~450°C in a stream of helium of gas containing 5 w/o oxygen. In preparing Pt-black/C electrodes, an aqueous solution of H_2PtCl_6 was applied and the oxidation process was eliminated. The catalyst loading of these electrodes was about 10 mg/cm^2.

Two dimensionally stable anodes (DSA), composed of RuO_x-TiO_2 and IrO_x-TiO_2, respectively, on titanium substrates, were obtained from Electrode Corporation. The PdO_x-TiO_2/Ti electrode was prepared by a thermal decomposition method. A flat titanium substrate was mechanically roughened, degreased, pickled (in 20 w/o oxalic acid at 90°C), and cleaned ultrasonically. An appropriate amount of the solution comprising palladium chloride ($PdCl_2$), titanium chloride ($TiCl_3$), isopropyl alcohol, and hydrochloric acid, was coated on the substrate. After a heat-treatment in air, a catalyst layer of mixed oxide was formed on the substrate. Prior to an experiment, each test electrode was degreased using acetone and then pretreated cathodically at 10 mA/cm^2 in SO_2-free sulfuric acid solutions for 10 min.

Electrolyte preparation.—The measuring solutions (50 w/o H_2SO_4) were prepared from Fisher analyzed reagent grade sulfuric acid and distilled water. With a view to minimizing impurities, each measuring solution was further purified by pre-electrolysis at a current density of about 2 mA/cm^2 on a Pt-gauze cathode for at least 24 hr, followed by bubbling a highly pure nitrogen gas to eliminate traces of oxygen and hydrogen dissolved in the electrolyte.

Apparatus.—Electrochemical studies were conducted in a three-compartment cell as described in the work by Miles and co-workers (19). A platinum spiral positioned in a small compartment served as a counterelectrode. A reversible hydrogen electrode (RHE) with sulfuric acid of the same concentration as the measuring solution was used as the reference. The working electrode was placed about 0.5 mm from the tip of a Luggin capillary. Electrochemical measurements were made using a PAR Model 371 potentiostat coupled with a PAR Model 175 programmer. While performing voltammetric studies, cyclic voltammograms were recorded on an X-Y recorder. A quartz tube furnace was used in the preparation of oxide and mixed oxide electrodes. The microstructures of these electrodes were examined by scanning electron microscopy (ISI Model SUPER IIIA).

Electrochemical measurements.—Tafel plots were determined for SO_2 oxidation on test electrodes in 50 w/o sulfuric acid solutions at 25°C, using the steady-state potentiostatic method. During each experiment, the electrolyte within the main compartment was a stirred solution deaerated with purified SO_2. At a constant polarization potential, the observed currents on the freshly prepared metal electrode gradually decayed with time. A similar phenomenon has also been reported in the literature (7). Therefore, each pretreated metal electrode was further potentiostated at 1.0V in SO_2-saturated solution for about 30 min. This preanodization process resulted in the formation of stable surface layers on the electrodes. Thus, steady currents were generally observed in the direction of decreasing potential. Electrochemical studies of the temperature effect on electrode kinetic parameters were performed on a smooth palladium electrode at temperatures of 25°, 50°, 70°, and 90°C.

Cyclic voltammetric studies were conducted on the smooth electrodes of Pt, Pd, Ru, Ir, and Rh. In the measuring solution, each freshly prepared electrode was initially potentiostated at 0.3V for 5 min. By applying a linear potential sweep of 100 mV/sec, the first ten traces of continuous cyclic voltammograms were recorded for a test electrode.

Results and Discussion

Kinetic studies on metal electrodes.—Electrocatalytic activities of preanodized electrodes of Pt, Pd, Au, Ru, Re, Ir, and Rh were investigated for SO_2 oxidation in 50 w/o sulfuric acid at 25°C and atmospheric pressure. As identified in an earlier analysis, the concentration of SO_2 in the saturated solution was approximately 1.2M under these conditions. Three separate studies were carried out on each electrode. It was found that the preanodization of a test electrode resulted in reproducible data. The potential-current density relationships shown in Fig. 1 represent the averaged results for the three individual studies. Well-defined Tafel regions were generally observed on these electrodes. Kinetic parameters such as Tafel slope, transfer coefficient, and limiting current density for SO_2 oxidation are summarized in Table I.

The performance characteristics of the Pt electrode is considered as a baseline for comparison. As illustrated in Fig. 1, Pd is a better catalyst than Pt for the SO_2 oxidation reaction. At 1 mA/cm^2, the polarization potential on the electrode is approximately 120 mV lower than on the Pt electrode. Under the identical experiment conditions, the Pd electrode exhibits a limiting current density of 4.0×10^{-2} A/cm^2 as compared to 1.2×10^{-3} A/cm^2 for Pt (see Table I). In addition, Au and Ru show approximately the same catalytic activities as Pt. However, Ir, Re, and Rh electrodes were relatively inactive for the anodic oxidation of sulfur dioxide.

There have been a number of investigations on the reaction mechanism for SO_2 oxidation, with most of these studies being conducted in dilute sulfuric acid solutions (6-12). In concentrated acid media, Appleby and Pichon (12) first proposed a reaction mechanism

Table I. Electrode kinetic parameters for the SO_2 oxidation reaction on various candidate materials in 50 w/o H_2SO_4 solutions at 25°C

Electrode	Tafel slope (mV/decade	Transfer* coefficient	Current density at 0.6V (A/cm^2)	Limiting current density (A/cm^2)
Pt	67	0.88	1.8×10^{-5}	1.2×10^{-3}
Pd	54	1.09	1.2×10^{-4}	4.0×10^{-2}

Ir	66	0.89	3.3×10^{-6}	5.1×10^{-4}
Rh	82	0.72	1.9×10^{-6}	4.0×10^{-4}

* Transfer coefficient = 2.303 RT/bF where b is the Tafel slope.

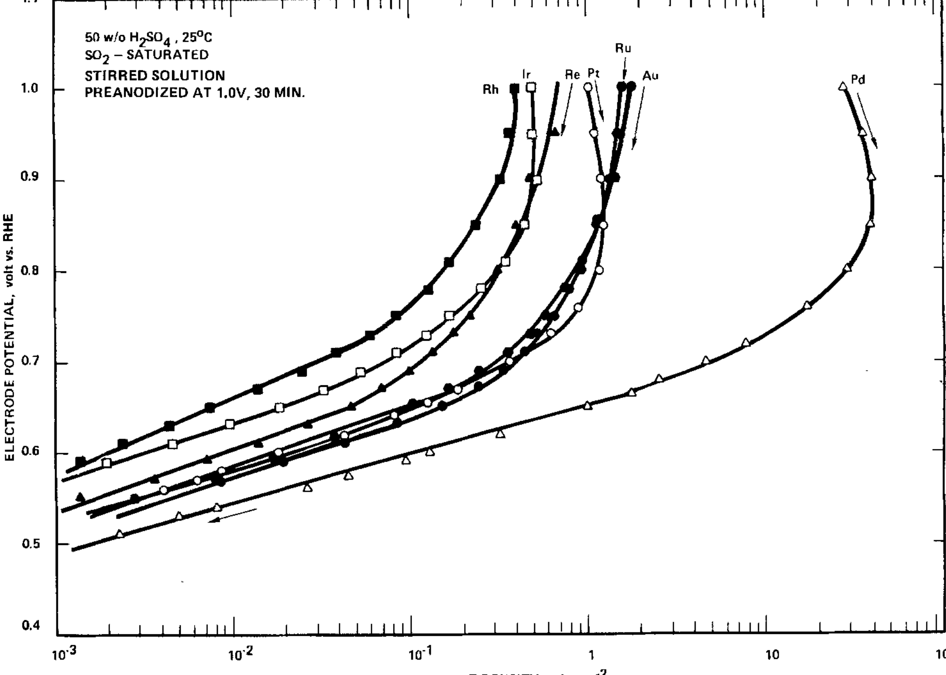

Fig. 1. Tafel plots for SO_2 oxidation on smooth electrodes of Pt, Pd, Au, Ru, Re, Ir, and Rh in 50 w/o sulfuric acid at 25°C.

for Pt electrode which may involve the following steps

$$Pt + H_2O \rightarrow PtOH + H^+ + e^- \quad [3]$$

$$PtOH \rightarrow PtO + H^+ + e^- \quad [4]$$

$$SO_2 + PtO \rightarrow SO_3 + Pt \quad [5]$$

This reaction scheme is only applicable to interpret the SO_2 oxidation at potentials above 0.95V, the potential at which the formation of PtO film commences (20). As seen from Fig. 1, however, the linear Tafel regions for this reaction are normally found at potentials below 0.7V. Therefore, the measured kinetic parameters are not suitable for use to explain the oxidation mechanism by following the above reaction paths.

As shown in Table I, the observed Tafel slopes on the Pt, Pd, Au, Ru, Re, and Ir electrodes are close to RT/F (that is, transfer coefficients being close to unity). On the Rh electrode, a slightly higher Tafel slope of $\sim$1.4 RT/F is measured. By use of the observed Tafel slopes alone, it is difficult to determine uniquely the reaction mechanism. In 50 w/o sulfuric acid saturated with SO_2, however, the measured open-circuit potentials at 25°C are $\sim$0.49 and $\sim$0.20V on the Pt and Pd electrodes, respectively. Since the standard potential for the formation of $H_2S_2O_6$ is as high as 0.564V (17), it seems unlikely that in such a concentrated sulfuric acid, the SO_2 oxidation reaction takes place via the intermediate $S_2O_6^{-2}$ ions.

According to Robertson and Dunford (21), the measured concentrations of SO_4^{-2} and HSO_4^- ions in 50 w/o sulfuric acid are approximately 1.86 and 5.14M, respectively. It is thus highly uncertain (12) whether the overall electrochemical reaction for SO_2 oxidation is represented by

$$SO_2 + 2H_2O \rightarrow SO_4^{-2} + 4H^+ + 2e^- \quad [6]$$

or

$$SO_2 + 2H_2O \rightarrow HSO_4^- + 3H^+ + 2e^- \quad [7]$$

As a result, the reversible electrode potential for SO_2 oxidation cannot be obtained unambiguously. Thus, exchange current densities on the candidate materials are not determined from the observed Tafel plots. In Table I listed are the current densities at a polarization potential of 0.6V.

Temperature dependence of electrode kinetic parameters.—The effect of temperature on Tafel plots for SO_2 oxidation on a preanodized Pd electrode is shown in Fig. 2. Distinct linear Tafel regions of approximately three decades are observed at temperatures of this study. Electrode kinetic parameters for SO_2 oxidation at the four experimental temperatures are presented in Table II. The observed Tafel slopes (being close to RT/F) are approximately constant at various temperatures, indicating that the mechanism of the SO_2 oxidation reaction is independent of temperature.

There is very little or no improvement in the limiting current density arising from the temperature in-

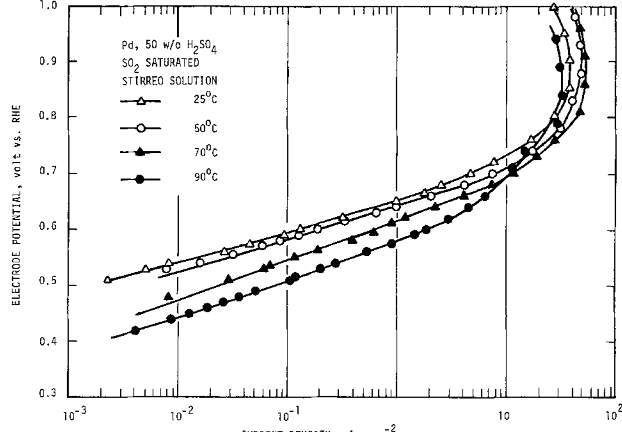

Fig. 2. Tafel plots for SO_2 oxidation on a smooth Pd electrode in 50 w/o sulfuric acid at temperatures of 25°, 50°, 70°, and 90°C.

Table II. Electrode kinetic parameters for the SO_2 oxidation reaction on preanodized palladium electrodes in 50 w/o H_2SO_4 solutions

Temperature (°C)	Tafel slope (mV/decade)	Transfer* coefficient	Current density at 0.6V (A/cm²)	Limiting current density (A/cm²)
25	54	1.09	1.2×10^{-4}	4.0×10^{-2}
50	59	1.09	2.0×10^{-4}	4.9×10^{-2}
70	72	0.92	6.0×10^{-4}	5.4×10^{-2}
90	70	1.03	1.9×10^{-3}	3.3×10^{-2}

crease. Under atmospheric pressure, the solubility of SO_2 in the electrolyte decreases significantly with increasing temperature (11, 12, 22, 23). Therefore, in the limiting current density region, any improvement in the electrode kinetics is probably marred by the reduction of SO_2 solubility. In the linear Tafel regions, however, the temperature increase results in a distinct decrease in the polarization potential. As illustrated in Fig. 2, an improvement of ~100 mV in the anodic overpotential at 1 mA/cm^2 is achievable by increasing temperature from 25° to 90°C. The current density for SO_2 oxidation at 0.6V increased by one order of magnitude from 1.2×10^{-4} A/cm^2 at 25°C to 1.9×10^{-3} A/cm^2 at 90°C (see Table II).

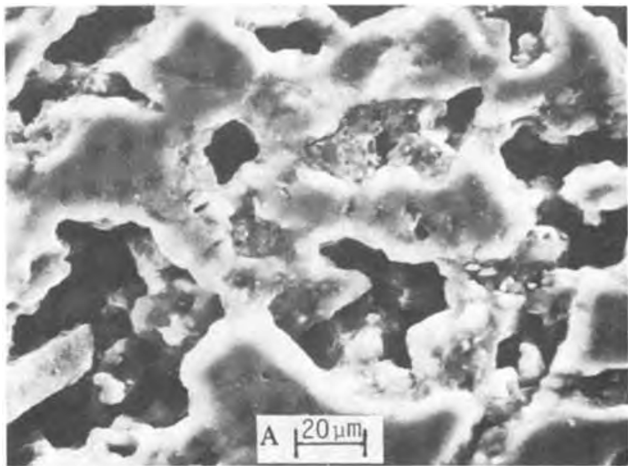
Electrochemical evaluation of alternate catalysts.—A number of oxides and mixed oxides have attracted considerable attention for use as catalysts. Ruthenium oxide (RuO_x) on titanium, for instance, is highly active for the anodic evolution of chlorine and has found wide application as an electrocatalyst in the chlor-alkali industry (24-26). This DSA-type electrode also shows low anodic overpotentials for oxygen evolution from acid (27) and alkaline (28) media. In addition to metal electrodes, the present work has been extended to investigate oxides and mixed oxides as catalysts for SO_2 oxidation. The anode in an SO_2-depolarized electrolyzer is normally operating at potentials below 0.7V *vs.* RHE (5). Apparently, a majority of noble metal oxides or mixed oxides are electrochemically stable under this operating condition.

The microstructure of a pretreated porous carbon plate used in the fabrication of PdO_x/C and Pt-black/C electrodes is illustrated in Fig. 3A. The mean pore diameter in this substrate is ~9 μm prior to the pretreatment. Nevertheless, a maximum pore diameter ~60 μm is observed in the scanning electron micrograph. A catalyst layer was applied to the surface of the pretreated carbon plate using a proprietary fabrication process. The microstructure of the resulting electrode is shown in Fig. 3B. Obviously, the density of catalyst particles on the PdO_x/C electrode is high and the particle distribution is rather uniform.

The potential-current density relationships for SO_2 oxidation on pure carbon, PdO_x/C and Pt-black/C electrodes are given in Fig. 4. The carbon substrate itself is extremely inactive for the anodic oxidation of SO_2. The PdO_x/C electrode exhibits higher limiting current density and lower polarization potentials as compared to the Pt-black/C electrode. At 1 mA/cm^2, for example, the anodic overpotential on the former is approximately 50 mV less than on the latter.

The PdO_x-TiO_2 electrode was prepared by a thermal decomposition method as described elsewhere (29). The microstructure of the electrode surface is shown in Fig. 5. The distribution of catalyst particles is uniform with a maximum particle size of ~3 μm. Illustrated in Fig. 6 is the electrochemical properties of the mixed oxide electrodes in SO_2-saturated sulfuric acid solutions. The PdO_x-TiO_2/Ti electrode exhibits an electrocatalytic activity quite comparable to the Pt-black/Ti electrode for the SO_2 oxidation reaction. A polarization potential of ~0.60V was measured on this electrode at 10 mA/cm^2. Ruthenium oxide and iridium oxide on titanium substrates are excellent catalysts for the anodic evolution of chlorine (24-26) and oxygen (27, 28). As seen from Fig. 6, however, both RuO_x-TiO_2/Ti and IrO_x-TiO_x/Ti electrodes are very ineffective for the electrochemical oxidation of SO_2 in acid media.

Cyclic voltammetric studies.—The voltammetric method has been extensively used to investigate the reaction mechanism of SO_2 oxidation on platinum (8-10, 14) and gold (8, 14, 15). The previous studies were, however, carried out only in dilute acid media. According to the work by Seo and Sawyer (8, 30), an activated electrode surface can be achieved by cycling the potential of a platinum or gold electrode between



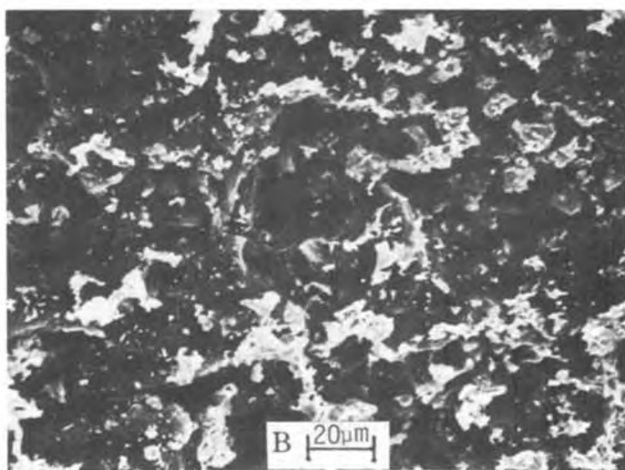


Fig. 3. Scanning electron micrographs of (A) a polished carbon substrate after treatment, and (B) a PdO_x-catalyzed carbon electrode (loading: 10 mg-PdO_x/cm^2).

−0.15 and 1.50V *vs.* SCE (saturated calomel electrode) directly in an SO_2-containing electrolyte. In the cathodic sweep, the SO_2-containing species in the solution is electroreduced in the potential region for hydrogen adsorption. As a result, the reduction reaction may lead to the formation of adsorbed sulfur and H_2S on the electrode surface (14, 31, 32). With a view to eliminating the adsorbed impurities, this study was carried

out at potentials above 0.30V, where hydrogen adsorption does not occur.

Figure 7 shows the first traces of cyclic i-V curves on a freshly prepared Pt electrode in both SO_2-free and SO_2-saturated sulfuric acid solutions. It should be noted that the current density scales for the two voltammetric curves are significantly different. In the SO_2-free electrolyte, the formation of adsorbed oxygen-containing species on the bare electrode surface commences at an anodic potential of ~0.55V (see Fig. 7). Ellipsometric studies (20) indicated that starting at ~0.95V in the 0.1N sulfuric acid, the adsorbed oxygen-containing species on a Pt anode is converted to platinum oxide, PtO, by the "place exchange mechanism" (33). Subsequently, the coverage and thickness of PtO species on the electrode surface increases with potential. It has been pointed out (34) that, in 2N sulfuric acid, the surface adsorbed oxygen is not converted to the so-called "dermasorbed oxygen," Pt-O, until potentials above 1.0V are reached. In this study, the

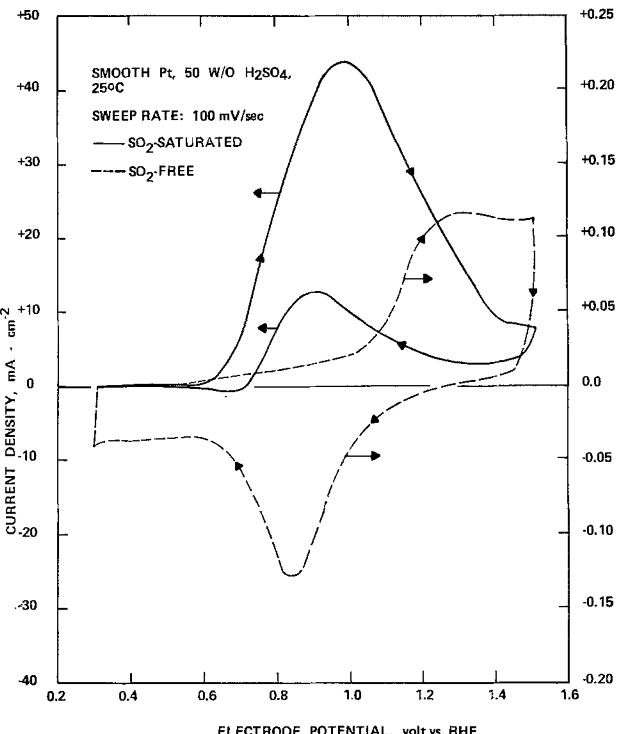

Fig. 7. Cyclic voltammograms on a smooth Pt electrode at 100 mV/sec in SO_2-free and SO_2-saturated sulfuric acid solutions at 25°C.

anodic and cathodic peaks observed at 1.30 and 0.83V, respectively, are probably attributed to the formation and reduction of the PtO film. According to the work by Thacker and Hoare (34), a complete layer of oxide film may be reached at about 1.6V.

In the SO_2-saturated acid solution, the anodic and cathodic peaks corresponding to the formation and reduction of oxide film are entirely obscured by the relatively high currents for the SO_2 oxidation reaction. As shown in Fig. 7 this reaction commences at approximately the same potential (~0.55V) as that for the formation of absorbed oxygen-containing species. It is assumed that the presence of SO_2-containing species in the electrolyte does not change significantly the potentials for the formation and chemical conversion of the surface film. In the anodic i-V curve, the observed current density decreases significantly with a further rising potential after reaching the peak maximum at ~0.98V. As discussed previously, the conversion of adsorbed oxygen-containing species to PtO film takes place at potentials above 0.95V (20). The appearance of the anodic peak is thus attributed to the formation of the PtO film, which partially covers the electrode surface, and the subsequent increase of its coverage with potential. At 1.40V, the observed current density is reduced to less than ¼ of the peak-maximum value.

In the cathodic i-V curve, no detectable reduction peak is observed, indicating that the SO_2 oxidation reaction is highly irreversible. As seen from Fig. 7, the electroreduction of the PtO film in the cathodic sweep starts at ~1.25V. The complete reduction of the oxide film occurs at potentials below 0.6V. Nevertheless, on the partially reduced Pt electrode, an anodic peak for SO_2 oxidation appears at ~0.90V. It is noted[1] that, in the Tafel plots shown in Fig. 1, the measured current density on a preanodized Pt electrode increases slightly

[1] Ellipsometric results (20) revealed that the coverage of the PtO film on the Pt anode is much less than a monolayer at 1.0V. In oxygen-saturated acid solution, the measured coverage of oxide film on the surface of a Pt electrode is ~30% at the open-circuit potential of 1.06V (34). Therefore, on the Pt electrode preanodized at 1.0V, the SO_2 oxidation reaction takes place only at the active sites that are not covered by the PtO species.

with decreasing potential in the range of 0.85-1.0V, essentially due to the gradual reduction in the coverage of PtO species on the electrode surface. These observations indicate that the electrocatalytic activity of an oxide-covered Pt anode for the anodic oxidation of SO_2 is rejuvenated by the electroreduction of PtO film to adsorbed oxygen-containing species.

On the basis of voltammetric results, it is concluded that the electrochemical oxidation of SO_2 commences at the potential (~0.55V) where the first adsorbed oxygen-containing species appears on a bare Pt anode. At potentials higher than 0.98V, the adsorbed species is chemically converted to a passivating PtO film which partially covers the electrode surface and inhibits the SO_2 oxidation reaction.[2]

The first traces of cyclic i-V curves on a freshly prepared Pd electrode are illustrated in Fig. 8. In the SO_2-free electrolyte, two anodic peaks are detected at 1.03 and 1.14V. It has been found experimentally (35) that, in dilute acid solutions, palladium oxide, PdO, is formed on a bare Pd electrode at potentials above 0.79V by the following reaction

$$Pd + H_2O \rightarrow PdO + 2H^+ + 2e^- \quad [8]$$

In addition, the standard potential for the formation of hydrated palladium oxide, $Pd(OH)_2$, is ~0.896V. Therefore, in the anodic sweep up to 1.2V, the chemical transformation of adsorbed oxygen-containing species to palladium oxide films should take place.

In the SO_2-saturated electrolyte, the cyclic voltammogram on the Pd electrode is somewhat different from that on the Pt electrode. On a bare Pd anode, the SO_2 oxidation reaction also commences at a potential where the formation of adsorbed oxygen-containing species is initiated (being ~0.60V as identified in Fig. 8). The observed current density for this reaction, however, increases distinctly with rising potential up to 1.2V and then decreases gradually with reducing potential. No oxidation peak is detected in either the anodic or the cathodic i-V curve. It is obvious that the formation of oxide films on the Pd anode does not inhibit the electrochemical oxidation of SO_2. More precisely, an oxide-covered Pd electrode exhibits high electrocatalytic activity for SO_2 oxidation.

Figure 9 shows the cyclic i-V curves on the freshly prepared electrodes of Ru, Ir, and Rh in SO_2-saturated sulfuric acid solutions. Like the Pt anode, broad anodic peaks are normally observed on these electrodes. At the potential sweep rate 100 mV/sec, the peak-maximum potentials on Ru, Ir, and Rh electrodes are approximately 1.12, 1.08, and 0.88V, respectively, in the anodic i-V curves. As observed on the Pt anode, the conversion of adsorbed oxygen-containing species to metal oxides on these electrodes also creates passivated surface layers which inhibit the SO_2 oxidation reaction.

[2] There is possibly an alternative interpretation that the adsorbed SO_2 blocks the formation of PtO, which is a reaction intermediate for SO_2 oxidation (12). As a result, the overall SO_2 oxidation reaction is retarded by the gradual decrease of PtO species on the electrode surface. In this case, it is purely coincidental that the peak-maximum potential for SO_2 oxidation as shown in the anodic i-V curve in Fig. 7 is identical with the potential at which the formation of PtO species is initiated.

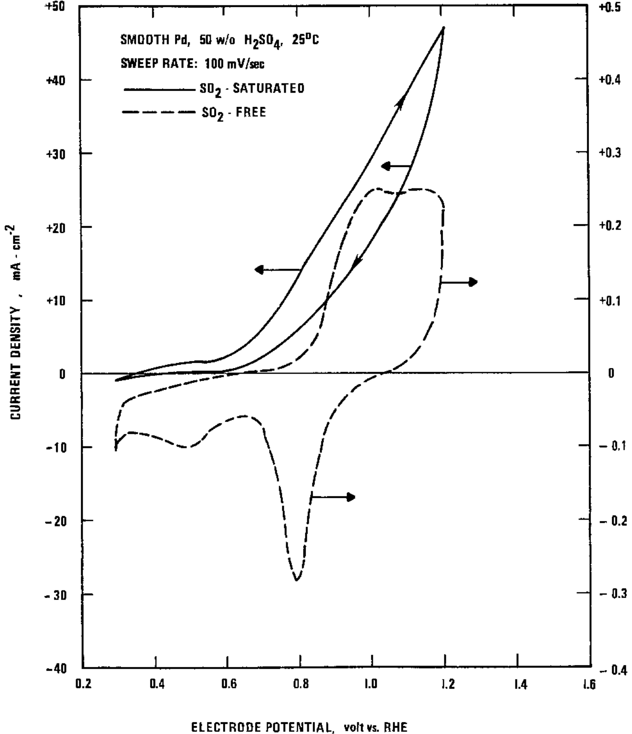

Fig. 8. Cyclic voltammograms on a smooth Pd electrode at 100 mV/sec in SO_2-free and SO_2-saturated sulfuric acid at 25°C.

Conclusions

For the anodic oxidation of SO_2, palladium and palladium oxide are better catalysts than platinum. The DSA-type electrodes such as RuO_x-TiO_2/Ti and IrO_x-TiO_2/Ti are inactive for this reaction. Increasing temperature results in remarkable improvements in the anodic overpotential for SO_2 oxidation on a pre-anodized Pd electrode. The reaction mechanism is, however, independent of temperature. In the anodic sweep, the SO_2 oxidation reaction commences at potentials where the formation of adsorbed oxygen-containing species is initiated. On most metal electrodes, the chemical transformation of the adsorbed species to metal oxides at higher potentials creates passivated surface layers which partially cover electrode surfaces and inhibit the SO_2 oxidation reaction. However, the oxide-covered Pd electrode exhibits high electrocatalytic activity for SO_2 oxidation.

Effects of the Gaseous Environment on Propagation of Anodic Reaction Boundaries in Lutetium Diphthalocyanine Films

M. M. Nicholson* and F. A. Pizzarello

Rockwell International, Electronics Research Center, Anaheim, California 92803

ABSTRACT

Influences of the gaseous environment on the anodic oxidation of lutetium diphthalocyanine films contacted by aqueous Na_2SO_4 or KCl were investigated with a moving-boundary technique. Ambient water vapor was required to propagate the red/green boundary from both electrolytes. Oxygen was also required with the sulfate solution but not with the chloride. The results suggest that the diphthalocyanine oxidation product containing sulfate may bind oxygen reversibly at room temperature.

Recent papers from this laboratory have described color-boundary propagation in lutetium diphthalocyanine films due to anodic oxidation of the dye (1, 2). The film was supported on a strip of alumina, with the lower end immersed in an aqueous electrolyte and the upper end contacted by gold. Under constant applied current, the color conversion from green to red began at the dye/electrolyte interface and moved upward through the film. The electrochemical reaction was shown, approximately, to be a two-electron oxidation of the diphthalocyanine. Charge compensation occurred by migration of anions from the electrolyte through the red phase under the influence of the electric field. An ionic mobility of 4×10^{-6} cm²/Vsec was determined in the solid oxidation products formed with both chloride and sulfate electrolytes. In radiotracer experiments with Cl^{36} and S^{35}, the chloride product gradually lost chlorine and reverted to green in ambient air, but the sulfate product retained its red color and its radioactivity more than a month (2). It was also found that dry and moist elemental chlorine reacted immediately with lutetium diphthalocyanine films to form a red product (3).

In this paper, we report pronounced dependences of the faradaic boundary propagation on the composition of the gas in contact with the dye film. Specifically, the effects of water vapor and oxygen on the velocity of propagation from chloride and sulfate electrolytes were determined. The results are examined in relation to crystal structures of related actinide diphthalocyanines and the known abilities of certain phthalocyanines and porphyrins to form oxygen adducts. The interesting possibility of oxygen-carrier activity in diphthalocyanine derivatives is noted.

Experimental

Film specimens of lutetium diphthalocyanine [LuH(Pc)$_2$] were prepared by vacuum sublimation of the dye onto single-crystal sapphire strips 1.25 cm wide and approximately 5 cm long (1, 2). The film thickness was estimated from its optical density at 670 nm in the initial green state.

Quantitative measurements of the boundary position as a function of time were made with the cell shown in Fig. 1. The container was a Klett colorimeter cell, open at the top, with an inlet for blanketing the film with the selected gas. The electrolyte was 1M Na_2SO_4 or 1M KCl. In the sulfate solution, the reference and counterelectrodes were $Pb/PbSO_4$; in the chloride, they were Ag/AgCl.

Details of the cell assembly and measurement procedures were described previously (1). Constant anodic currents were applied with a Princeton Applied Research (PAR) 173 galvanostat. The total voltage between the working and reference electrodes was monitored with a Keithley 610C electrometer and strip-chart recorder. With total applied currents in the microampere range, the current density through the cross section of the film ranged from approximately 20 to 50 mA/cm². An open cell, illustrated in Fig. 2, was used to determine effects of the gases impinging directly on the red film. The container then was a Klett cell with a portion of the front wall removed, as indicated by the dashed line. In the open-cell experiments, the boundary was characterized as moving or stationary by observing it under a low power microscope, and the corresponding instantaneous voltages were noted.

The gases included in the study were ambient air, dry and wet oxygen, and dry and wet helium. In addition to cells with flowing helium, some of the partially enclosed cells were set up in a helium-atmosphere glove box where the oxygen content did not exceed a few ppm.

Results and Discussion

Qualitative observations of the boundary movement and voltage changes are summarized in Table I. The results were consistent through many experiments performed with a number of cells. Striking ambient effects occurred under certain conditions. For example, dry helium introduced above the sodium sulfate solution could drive the galvanostat to its full compliance of approximately 95V in a few seconds. Quantitative data for the two electrolytes in partially enclosed cells are presented in Fig. 3 and 4, where the propagation distances and voltages are plotted as functions of time.

It is apparent from the table that some water in the ambient gas was essential for propagation of the color change from both chloride and sulfate electrolytes; dry helium or dry oxygen impinging directly on the red film stopped the boundary movement in each case and caused a major increase in electrical resistance. Moreover, the water content of the film above the liquid could not be attributed to capillary action. The meniscus against the dye was nonwetting, and the previous tracer study had shown the uptake of anions to be stoichiometric (2). It is possible that water also combines with the dye stoichiometrically or that it accompanies the anion in some definite proportion.

The responses of the film to oxygen were quite different with the two electrolytes. Figure 3 represents the behavior in sodium sulfate. The boundary propagation, which had begun in air at point A, stopped completely on introduction of dry helium at B, and the voltage rose essentially to the compliance of the instrument. On addition of air at C, the voltage dropped abruptly, and normal propagation continued. Wet (water-saturated) helium, introduced at D, also arrested the boundary propagation, but the voltage then gradually fell instead of increasing as it did with dry helium. Again, the propagation resumed in the usual voltage range on addition of air at E. This figure establishes the important point that oxygen is necessary for propagation of the boundary from a sulfate solution. Although dry helium stopped all anodic processes, wet helium apparently transferred enough water to the outer surface of the film to support an electrolytic side reaction at low voltage. Oxidation of the dye was then effectively shunted by the lower faradaic resistance.

Table I. Summary of gaseous environment effects on boundary propagation[a]

Electrolyte / Ambient gas	1M Na_2SO_4 Boundary movement	1M Na_2SO_4 Voltage change[b]	1M KCl Boundary movement	1M KCl Voltage change[b]

[c] Open cell as in Fig. 2.
[d] Partially enclosed cell as in Fig. 1.

The contrasting results obtained with potassium chloride are illustrated by Fig. 4. Dry helium, introduced at point B, caused a gradual rise in voltage, but the boundary propagation still continued at the rate observed in ambient air (A-B and C-D). Wet helium, beginning at D, caused a sharp voltage drop and a pronounced decrease in the boundary velocity. This was attributed to electrolytic shunting by a film of water, as in the sodium sulfate experiment. The film in Fig. 4 probably remained somewhat wet, even after the final addition of air at point E.

In summary, an oxygen-containing atmosphere was required to propagate the boundary from sulfate solution, but not from chloride. Dry helium increased the resistance of the film system, and very dry oxygen or very dry helium could stop the boundary propagation from either electrolyte.

These points are borne out by observations of the initial reaction site under different conditions. Figure 1 shows a scribe line in the dye, which was placed just below the meniscus to limit any downward propagation of the red color. In sodium sulfate solution, the dye reaction always began at the meniscus. It then travelled upward with oxygen present, but with oxygen absent, it proceeded downward only and stopped at the scribe line. The dye reaction below the liquid level probably was sustained by anodically-formed oxygen. Any oxygen escaping into the gas phase was highly diluted, however, so that upward propagation was prevented. In the chloride electrolyte, the red color first appeared within the small submerged area and then continued upward, with or without oxygen present.

The effects of the gas environment were found to be associated almost entirely with the red region, rather than the green. This was apparent from the anion specificity in the case of oxygen. It was indicated in the case of water by Fig. 5, which shows a current-voltage plot determined on a strip of green dye film between two gold contacts. The relationship was ohmic in air to at least 93V (~20 V/cm). Wet and dry helium, passed over the film for more than an hour, produced significant resistance changes, but none approaching the magnitude of those in the propagation experiments. It should be noted in this context that other investigators have reported very large ambient effects of water and oxygen on electronic conduction in divalent-metal phthalocyanines (4). However, such compounds generally have resistivities several orders of magnitude higher than those of the rare-earth diphthalocyanines (5) and hence may be more susceptible to ambient effects.

We shall now consider the anodic reactions of the dye, some requirements for migration of anions into the film, and the possibility that the oxidation product containing sulfate could be an oxygen carrier at room temperature.

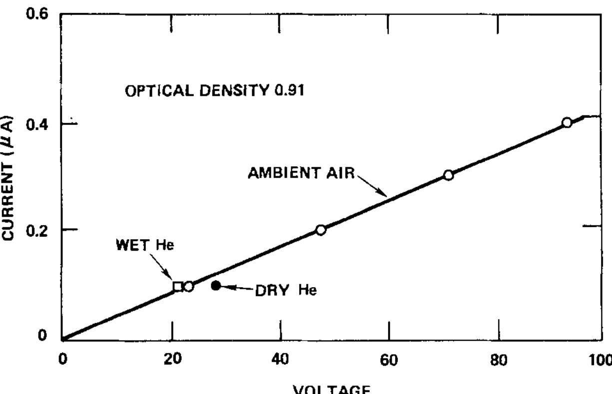

Fig. 5. Current-voltage characteristics of green film between two gold contacts.

Moskalev and Kirin originally suggested that the electrochromism of $LuH(Pc)_2$ at anodic potentials in KCl was due to complexing with oxygen or water (6). It is now clear that both of these substances are involved with a sulfate electrolyte and that water, but not oxygen, is needed for the anodic process in chloride solution. In addition to any direct addition reactions, charge compensation must accompany the loss of electrons by the dye. Our previous work showed that this was accomplished by migration of anions A^{-z} into the film (1, 2)

$$\underset{\text{(Green)}}{LuH(Pc)_2} + yA^{-z} \rightarrow \underset{\text{(Red)}}{LuH(Pc)_2 \cdot yA} + ne^- \quad (n = yz)$$

The experimental n values were approximately 2 for KCl and Na_2SO_4. Further work will be required to determine whether water and oxygen also participate stoichiometrically in the electrode process and how they are bonded within the organic structure.

The mobility of anions within the red phase may be examined in relation to the space available in the organic solid. The crystal structures of $U(Pc)_2$ and $Th(Pc)_2$ have been known for some time (7, 8), and that of a neodymium diphthalocyanine complex was recently investigated (9). These crystals contain open spaces great enough to accommodate unsolvated chloride ions, with a radius of 1.8Å. Hence it is plausible that oxidation of $LuH(Pc)_2$ in a chloride electrolyte could occur and be reversed without a major change in lattice dimensions. This is in keeping with the high solid-state chloride-ion mobility of 4×10^{-6} cm²/Vsec.

The similar mobility of larger, polyatomic anions such as sulfate in the red phase seems to require further explanation. An attractive possibility, consistent with the ambient-atmosphere dependence, is the formation of an oxygen adduct by $LuH(Pc)_2 \cdot SO_4$. It has long been known that certain organic crystals can expand on addition of oxygen. For example, Calvin *et al.* observed pronounced dimensional changes along one crystallographic axis in cobalt^{II}bis-(salicylaldehyde) ethylenediamine during cyclical absorption and desorption of oxygen (10). Such a lattice expansion of lutetium diphthalocyanine might provide the additional space needed for the sulfate ions. This mechanism requires the presence of oxygen throughout the red film, not just at the red/green interface. The very large voltage change that occurred on introduction of helium also suggests an effect in the bulk of the red film.

Thus it is quite possible, but not proved, that the sulfate oxidation product of $LuH(Pc)_2$ is an oxygen carrier, *i.e.*, a compound that binds oxygen reversibly at room temperature. Although much work has been done in recent years on synthetic and natural oxygen carriers (11-15), this could be the first instance of carrier activity controllable by anions or (one may predict) by anion exchange. The natural hemoproteins achieve reversible oxygen binding by virtue of complicated structures attached to the porphyrin ring. Among simpler molecules, manganese(II) tetraphenylporphyrin forms a reversible dioxygen complex near −79°C in the presence of pyridine (13), but this is unstable at room temperature. However, manganese(II) phthalocyanine binds oxygen in pyridine at much higher temperatures (14, 15). Generally, it appears that oxygen-carrier behavior in the porphyrins and phthalocyanines results from a special balance of conditions that is not easily achieved. This balance may exist in a product such as $LuH(Pc)_2 \cdot SO_4$ or in a solid hydrate of that product. Further investigations of the diphthalocyanine-oxygen systems are in progress.

Steady-State D-C Polarization Characteristics of the O_2, Pt/Stabilized Zirconia Interface

Turgut M. Gür, Ian D. Raistrick,* and Robert A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Four-probe d-c polarization studies were carried out on the Pt/stabilized zirconia interface between 600° and 900°C in the presence of 10^{-6}-1 atm of oxygen partial pressure. Three types of polarization effects were observed. At high currents, the oxygen flux density is limited by diffusion of molecular oxygen in the gas phase through a boundary layer near the interface. At intermediate currents, porous Pt electrodes are almost completely nonblocking to oxygen, and the primary impedance present is due to ionic resistivity in the electrolyte. At low overvoltages, a limiting current plateau is observed at 600° and 700°C, which disappeared completely at 800°C and above. Two alternative mechanisms involving slow diffusion of either atomic oxygen or an electronic species are proposed to account for the observed behavior.

Although electrical conduction due to ionic motion was observed in oxides by Nernst (1) in 1899, the potential of the widespread use of solid oxides as electrolytes has been exploited only in the last two decades. Efforts have also only recently been made to better understand electrode/solid electrolyte interfaces and their polarization effects (2-5).

Early work on stabilized zirconia indicated that only ohmic polarization is present when suitable electrodes and current densities are used (6, 7). Further information on polarization effects under a broader range of conditions was obscured to a large extent by lack of proper characterization of the electrode/electrolyte interfaces being studied. This led to considerable variations in performance (8-12), even under apparently identical conditions. There is now sufficient evidence to believe that both the electrode material (10, 13) and the electrode morphology (14-22) play a very important role in the interface behavior. Experiments carried out in very oxygen deficient environments or under heavy polarization have resulted in readily observable structural changes, such as the "blackening" of the zirconia (19, 22-24).

Although the oxygen electrode/zirconia interface has been the subject of numerous investigations, there is considerable disagreement among them. This is seen in Table I, which summarizes the major studies in this field in chronological order.

* Electrochemical Society Active Member.

Key words: interface polarization, solid electrolyte, zirconia, porous electrodes, platinum.

The first attempt to rationalize these apparently conflicting results was by Kröger (30), who showed that the differences may be due to a change in the rate-limiting mechanism with changes in temperature, oxygen pressure, and electrode morphology. However, his calculations involved the use of the solubility product of oxygen in Pt estimated by Brook *et al.* (18). Recent measurements of this product by Velho and Bartlett (31) give values many orders of magnitude smaller, and thus Kröger's calculations may be misleading.

Pizzini *et al.* (29) and Casselton (21) contended that a limiting current proportional to $[P_{O_2}]^{1/2}$ is characteristic of cells operating at low temperatures with small electrode areas (14, 17-19, 28, 29). On the other hand, a limiting current proportional to P_{O_2} is often observed at high temperatures with larger electrode areas (9, 15, 21).

Such attempts to resolve the disparate results were constrained by a lack of characterization of the electrode/electrolyte interface in many of the experiments to date. *In situ* determination of various parameters relating to the interphase morphology, such as the porosity, tortuosity, and pore size distribution of the electrode material and the effective area of the contact between the electrolyte and the electrode material, are certainly not easy. The physical situation is further obscured by time-dependent morphological changes induced by thermal and faradaic effects (22).

The earliest evidence of the importance of electrode morphology came from Karpachev and Filyaev (32).

* A-C impedance.
† Sputtered.

They showed that cathodic overvoltages can significantly be reduced by scratching the surface of a Pt electrode, thus providing access for oxygen to a three-phase boundary. Similarly, Bauerle (25) utilized heavy current treatments on initially nonporous electrodes to induce artificial porosity which reduced electrode polarization effects.

Coupled effects of current and heat-treatments on Pt electrode morphology were demonstrated by Pizzini *et al.* (28, 29) using SEM. Current-voltage characteristics were found to be dependent on such morphological changes. More recently, Pizzini *et al.* (33) used model electrochemical cells and showed that the macroscopic polarization behavior also varies with cell geometry.

This work represents an attempt to further understand polarization effects pertinent to Pt/zirconia interfaces in an oxygen ambient by careful investigations made under a wide range of experimental conditions. Great care was given to the preparation of the interface.

Experimental Arrangements

Detailed descriptions of the experimental apparatus and procedures have been given elsewhere (34). A wide range of O_2-He mixtures was supplied to the interfacial region at a rate of 90-100 cm^3/min. The oxygen content of the streaming gas was analyzed by two separate oxygen sensors, placed upstream and downstream of the zirconia pump. Oxygen analysis was also independently made using a Varian Aerograph Model 142010 gas chromatograph. Excellent agreement was obtained between the two analytical techniques.

Mixtures of high purity He (Matheson) and zero grade oxygen (Air Products) were prepared in a lecture bottle by monitoring the oxygen pressure with a high precision Heise gauge. Traces of moisture and other possible impurities (*e.g.*, CO_2) in the streaming gases were removed by appropriate traps. The entire experimental system was evacuated (2×10^{-5} Torr) and lightly baked prior to each polarization experiment.

The oxygen sensors were made from one-end closed yttria-stabilized zirconia tubes (Zircoa) featuring gold paste (Hanovia, UR No. 01-FM) electrodes scratched to improve response time. The sensors were operated at 650°-700°C and the oxygen partial pressures were calculated using the Nernst equation.

The schematic design of the zirconia pump is shown in Fig. 1. A 12 × ½ in. OD calcia-stabilized zirconia (CSZ) tube (Zircoa) was used to support the 8 mole percent (m/o) $Sc_2O_3 \cdot ZrO_2$ electrolyte disk (Applied Electrochemistry). The faces of the disk were polished with a 1 μm diamond paste. The CSZ tube and the disk were ultrasonically cleaned and then heated for a few hours in air at about 800°C.

Pt electrodes were deposited onto both faces of the disk by etch-sputtering. The disk was then sealed leak-

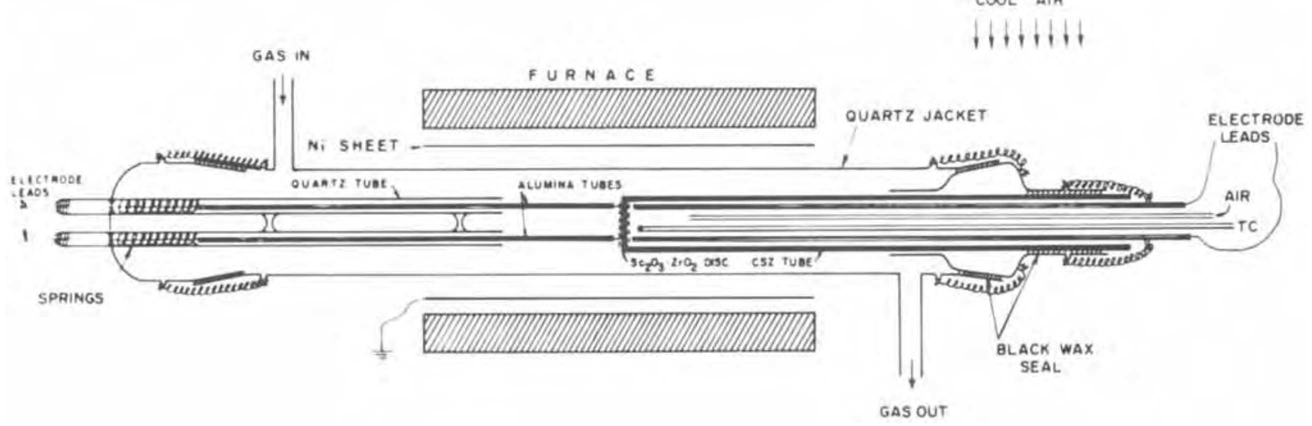

Fig. 1. Schematic design of the zirconia pump

tight on one end of the CSZ tube using a high temperature glass. Four electrode connections (two on each side of the disk) were made by spring-loaded Pt wires. Air was blown onto the inner electrode to avoid diffusional effects.

The basic electrical circuit used in the four-probe d-c experiments is shown in Fig. 2. Voltage across the electrolyte/electrode assembly was supplied by a d-c power supply. Current was measured by the voltage drop across a fixed resistor and a strip-chart recorder was employed to assess steady-state conditions. The applied, E_{appl}, and monitored, E_{mon}, voltages and the open-circuit emf's of the two oxygen sensors were measured with a potentiometric microvoltmeter.

Polarization Experiments

Four-probe d-c polarization studies were carried out on the cell

$$(-)\ P_{O_2}, Pt/8\ m/o\ Sc_2O_3 \cdot ZrO_2/Pt, Air\ (+) \quad [I]$$

between 600° and 900°C in the oxygen partial pressure range of 10^{-6}-1 atm. Scandia-stabilized zirconia was chosen for its superior ionic conductivity. Sputtered Pt electrodes 1 μm thick and 0.66 cm^2 in area were used. These electrodes were initially essentially nonporous. Artificial porosity was generated by a novel progressive current treatment (22) which eliminates the possibility of blackening or mechanical failure of the electrolyte frequently observed when Bauerle's technique (25) is used. The new technique involves slowly cycling the potential of the cell between 0 and 2V at the highest working temperature using small voltage increments until no hysteresis is observed. The advantage of this technique is that it approximates a near-equilibrium process if sufficient time is allowed for the changes in surface morphology to keep up with variations in the faradaic current.

The results obtained in the polarization experiments following the progressive current treatment were completely reproducible. Data points on the polarization curves can easily be reproduced during ascending or descending voltages.

Results of D-C Polarization Experiments

Cathodic polarization.—Steady-state current-overvoltage characteristics of cell [I] were studied, with the overvoltage, η, defined as

$$\eta = E_{mon} - E^{\circ} - I_{ss}R_b$$

where, E_{mon} is the voltage drop across the electrolyte measured by a potentiometer in a circuit which carries no current, as opposed to E_{appl}, where the external circuit carries the observed steady-state ionic current, I_{ss}; R_b is the electrolyte bulk resistance obtained from a-c admittance measurements (35). Thus $I_{ss}R_b$ represents the voltage drop across the electrolyte and E° is the reversible potential of cell [I] given by the Nernst equation. Consequently, η represents the interfacial overvoltage.

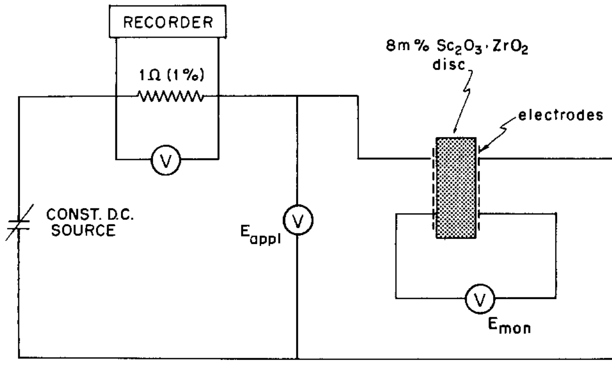

Fig. 2. Electrical circuit used in four-probe experiments

The steady-state current-overvoltage behavior of cell [I] between 600° and 900°C in the oxygen partial pressure range of 10^{-4}-1 atm is shown in Fig. 3 and 4. Two distinct characteristics at low η are immediately evident. At 600° and 700°C well-defined current plateaus extend to about η = 250 mV, above which the current increases rapidly in an exponential-like manner. The low overvoltage region at 600°C is expanded in Fig. 5 to show the limiting current plateau more clearly. The low η current plateaus, however, did not appear in the experiments at 800° and 900°C. This abrupt change in behavior occurs throughout the entire oxygen concentration range.

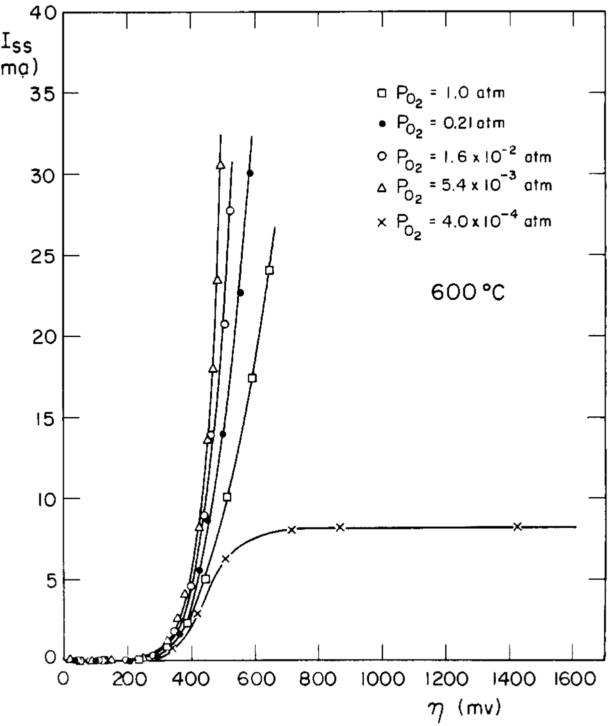

Fig. 3. Characteristic current-overvoltage behavior at 600°C

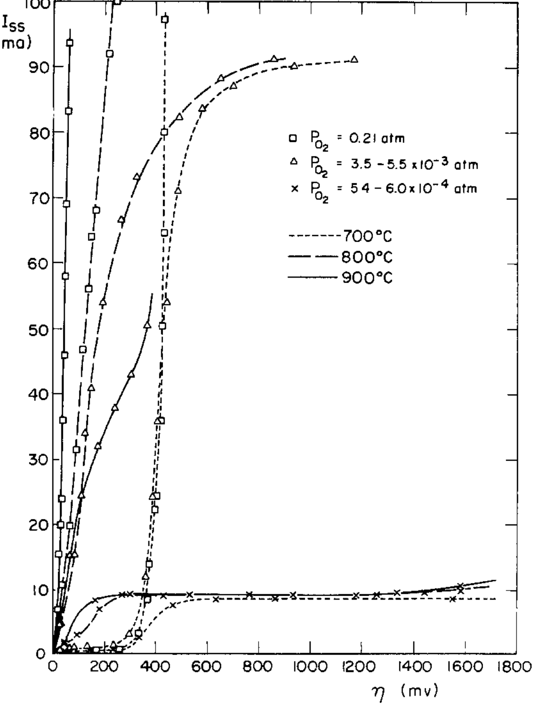

Fig. 4. Characteristic current-voltage behavior at 700°, 800°, and 900°C.

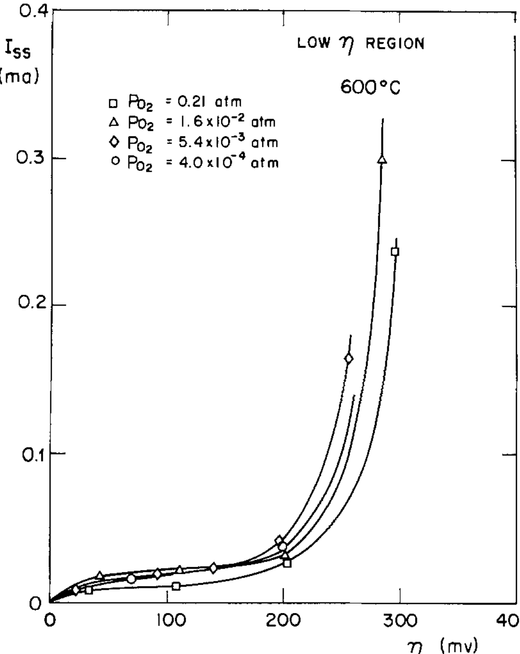

Fig. 5. Limiting current behavior in the low overvoltage region at 600°C.

The single plateau, observed at high temperatures and sufficiently low oxygen pressures, eventually gave way to mixed conductivity where the electronic contribution to the total current became more and more significant with increasing overvoltage. This situation is depicted in Fig. 6, where the ionic transference number t_i (calculated from oxygen sensor analysis) is plotted against voltage. At low temperatures (*e.g.*, 600°C) all the observed current is predominantly ionic, whereas mixed conduction appears at large overvoltages at higher temperatures, as expected.

Effect of flow rate.—The double plateau phenomenon shown in the current *vs.* overvoltage plots (Fig. 3 and 4) has not previously been reported for the Pt/zirconia system. A survey of previous studies suggested that one of these plateaus might be due to mass transport constraint in the boundary layer in the gas. Thus a series of d-c experiments was conducted at different flow rates of the gas mixtures. If the mass transport involves diffusion through the solid electrode, no flow rate dependence of the limiting current plateaus should be observed. Conversely, if the rate is limited by mass

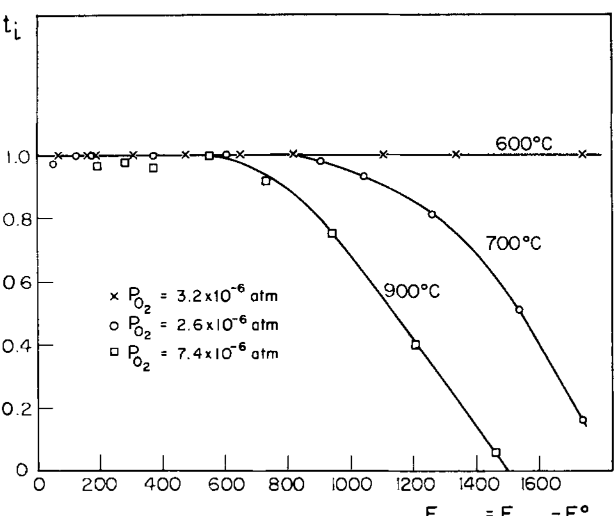

Fig. 6. Voltage and temperature dependence of ionic transference number, t_i, for oxygen.

transport in the gas phase, then it should be affected by the flow rate.

Figure 7 shows that the flow rate has virtually no effect on the low overvoltage limiting-current plateau, whereas it drastically affects upper plateaus in the higher overvoltage region. The latter effect is also observed at high temperatures. Gas chromatographic data indicated that the further increase in the current beyond the upper plateau region is due to the onset of electronic conduction as depicted in Fig. 8. Here the deviation from the predominantly ionic nature is given by the lateral distance between the solid and the dashed lines. The former represents the ionic current and the latter includes the electronic contribution, which increases rapidly with increasing overvoltage.

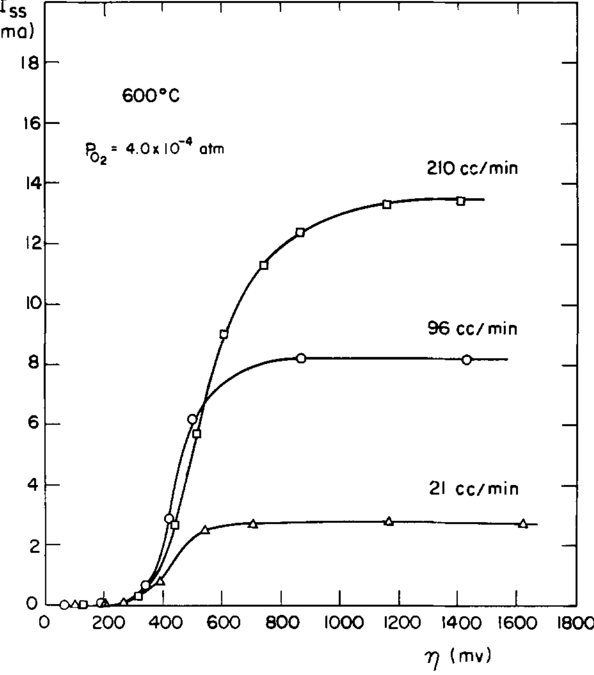

Fig. 7. Effect of flow rate on limiting current at 600°C

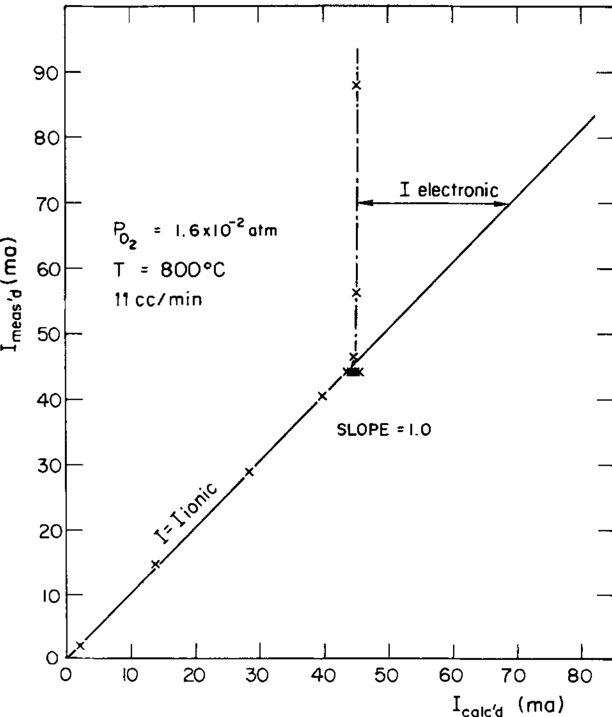

Fig. 8. Comparison of calculated ionic current with the experimentally measured current.

Effect of H_2O.—The influence of residual moisture is expected to be significant only when the P_{H_2O} becomes comparable to or greater than the oxygen partial pressure.

Studies carried out at 10^{-4} atm oxygen partial pressure with both wet and dry O_2-He mixtures indicated that the polarization behavior was not significantly altered by the presence of moisture.

The situation drastically changed for P_{O_2} values of 10^{-6} atm, where the limiting current plateau was raised to almost twice its dry mixture value by the presence of H_2O, as depicted in Fig. 9. Furthermore, the polarization curve for the dry gas mixture was predominantly ionic in nature, while the increased current in the presence of the wet mixture involved an electronic contribution.

Discussion

The characteristic current-overvoltage plots indicate three distinct regions of behavior at high, intermediate, and low overvoltage values. Throughout, it is assumed that the overall polarization behavior is governed by phenomena occurring at the cathode/electrolyte interface; the potential drop at the anode/electrolyte interface is assumed to be negligible (19, 21).

The overall cathode reaction for oxygen incorporation is

$$\frac{1}{2} O_2(g) + V^{oo}_O (ZrO_2) + 2e'(Pt) = O_O^x(ZrO_2) \quad [1]$$

where V^{oo}_O denotes an oxygen vacancy with an effective charge of +2, and O_O^x is a normal oxygen species on an oxygen site in the electrolyte. Since this reaction involves species from all the three phases, it must occur at a site which is accessible to all of the reacting species. Therefore, this "electrochemical reaction site" (ERS) should be located at or near a boundary where the three phases meet.

Scanning electron microscope pictures of the cathode surface indicated that the electrode was quite porous. Huge voids, about 1-2 μm in width and up to 6 μm in length, exposed the zirconia surface directly to the gas phase.

Consequently, three possible paths can be visualized by which the oxygen can arrive at the ERS; namely, from the surface of the electrolyte or either through or along the surface of the platinum.

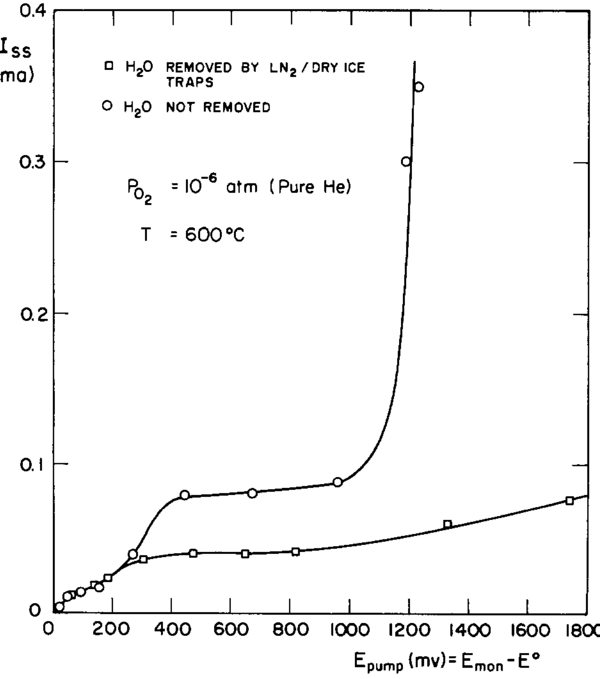

Fig. 9. Effect of H_2O on the limiting current at low oxygen partial pressures.

Mechanism of oxygen transport to ERS.—Information about surface diffusion of oxygen on zirconia is scarce. Smith (36) studied oxygen adsorption on pure zirconia at 400°-900°C. He concluded that 90-95% of the surface is covered with irreversibly adsorbed oxygen atoms and the remaining by weakly adsorbed mobile O_2' species. The "irreversibly adsorbed" oxygen was likely simply incorporated into the zirconia to make up for the stoichiometric loss (22, 34) due to the H_2 pretreatment given to the sample.

A rough estimate shows that surface diffusion of O_2' is not likely to be rate determining. At 900°C, the values of the surface exchange and bulk diffusion coefficients are about 4×10^{-6} cm/sec and 2×10^{-8} cm²/sec, respectively, (37). Assuming a surface density of 10^{15} sites/cm² and complete surface coverage, the limiting current density would be about 10^{-5} A/cm² for a diffusion distance of 1 μm. This agrees well with the value of 4×10^{-6} A/cm² estimated by Casselton (21). For 600°C, the limiting current density would be about 10^{-6} A/cm².

These values are much too low to account for the limiting current values observed in the present work.

If bulk diffusion of oxygen through the Pt were rate determining, the corresponding limiting current would be

$$i_{lim} = n\mathbf{F}AJ_O = n\mathbf{F}AD_{O,Pt}\frac{C_{s,O}}{\delta} \quad [2]$$

where J_O is the oxygen molar flux, $D_{O,Pt}$ is the diffusion coefficient of oxygen in Pt, $C_{s,O}$ is the molar oxygen concentration on the Pt surface, δ is the diffusion distance (taken as the thickness of the Pt layer, 1 μm), and A is the area (assumed to be equal to the geometric area of the electrode, *i.e.,* 0.66 cm²).

The values of $D_{O,Pt}$ and $C_{s,O}$ at 900°C can be extrapolated from the data of Velho and Bartlett (31) to give 3×10^{-14} cm²/sec and 3×10^{-11} weight percent, respectively. Substitution into Eq. [2] gives a limiting current value of about 10^{-17}A at 900°C. Casselton (21) estimated limiting current densities of 10^{-10} A/cm² through 0.2 cm thick Pt electrodes at 1400°C.

Clearly, these estimated values are many orders of magnitude lower than those actually observed. Therefore, a transport path involving bulk diffusion through Pt is also improbable.

A third possibility is that oxygen arrives at the ERS primarily by adsorption and transport along the surface of the Pt. The surface diffusion coefficient for oxygen on Pt can be estimated to be about 10^{-6} cm²/sec at 900°C (38). For a diffusion area of 1×1 μm, a current density of about 10^{-1} A/cm² can be expected, assuming complete coverage of the surface, with 10^{15} sites/cm². This agrees well with the values observed in the present experiments.

Thus, it is proposed that oxygen gets to the ERS by transport along the surface of the Pt rather than by either bulk diffusion through the Pt or by dissociation and surface migration on the electrolyte.

Possible rate-determining steps.—Thermodynamic studies by Ngo (39) established that Pt does not form a stable bulk oxide at elevated temperatures below 1 atm oxygen pressure. PtO_2, which is the most stable oxide of Pt, exists only up to 583°C at 1 atm oxygen pressure.

Oxygen, however, readily adsorbs on Pt with a low activation energy, about 3 kcal/mole (40, 41). The initial heat of adsorption for molecular oxygen is about 10-17 kcal/mole (38, 42, 43), and molecules readily dissociate into oxygen atoms, with a dissociative heat of adsorption of about 53-70 kcal/mole (44-46).

In view of the preceding considerations the overall cathode reaction can be divided into intermediate steps as follows

$$1/2\ O_{2(g)}\ (\text{bulk gas}) = 1/2\ O_{2(g)}\ (\text{boundary layer}) \quad [3]$$

$$1/2\ O_{2(g)}\ (\text{boundary layer}) = 1/2\ O_{2(g)}\ (\text{Pt micropore}) \quad [4]$$

$$1/2\ O_{2(g)}\ (\text{Pt micropore}) = 1/2\ O_{2(ad)}\ (\text{Pt}) \quad [5]$$

$$1/2\ O_{2(ad)}\ (\text{Pt}) = O_{(ad)}\ (\text{Pt}) \quad [6]$$

$$O_{(ad)}\ (\text{Pt}) = O_{(ad)}\ (\text{ERS}) \quad [7]$$

$$2e'\ (\text{Pt}) = 2e'\ (\text{ERS}) \quad [8]$$

$$V^{oo}_{O}\ (ZrO_2) = V^{oo}_{O}\ (\text{ERS}) \quad [9]$$

$$O_{(ad)}\ (\text{ERS}) + 2e'\ (\text{ERS}) + V^{oo}_{O}\ (\text{ERS}) = O^{x}_{O}\ (\text{ERS}) \quad [10]$$

$$O^{x}_{O}\ (\text{ERS}) = O^{x}_{O}\ (ZrO_2) \quad [11]$$

For reactions [9] and [11], only bulk transport conduction is assumed for the arrival and departure of V^{oo}_{O} and O^{x}_{O} to and from the ERS. A unit reaction obviously cannot proceed unless the reaction product O^{x}_{O} is removed from the ERS and is replaced by a V^{oo}_{O}, so that the ERS is reset for the next unit reaction to take place.

Within the framework of this sequence of steps, the three overvoltage regions of interest will be discussed, and the most likely mechanism controlling the overall rate within each regime will be arrived at by a process of systematic elimination of the others.

High overvoltage region.—The applied voltages had to be kept below 2V in order to avoid electrolysis of the electrolyte [$E_{decomp.} = 2.27$V at 900°C (50)]. One would expect to see a limiting current behavior below that voltage only when the oxygen partial pressure was sufficiently low that the rate of reaction at the ERS was limited by the rate at which oxygen arrived from the gas phase.

Assuming the ideal gas law, the rate of oxygen arrival at the ERS can be estimated from Fick's first law of the form

$$J_{O_2} = D_{O_2} \frac{\Delta[C_{O_2}]}{\delta} = 7.5 \times 10^{-6} \frac{D_{O_2}}{\delta} [P_{O_2(g)} - P_{O_2}\ (\text{ERS})] \quad [12]$$

for diffusion of molecular oxygen in the gas phase. Here D_{O_2} is the diffusion coefficient of molecular oxygen and δ is the diffusion length.

The molar oxygen flux, J_{O_2}, is also related to the current by Eq. [2], so that

$$i = 7.5 \times 10^{-6}\, n\mathbf{F}A \frac{D_{O_2}}{\delta} [P_{O_2(g)} - P_{O_2}\ (\text{ERS})] \quad [13]$$

where A is the cross-sectional area. Thus, it is clear that a constraint due to molecular oxygen transport will be inversely proportional to the oxygen partial pressure at constant temperature.

Similar equations can be written for the case of diffusion of atomic oxygen. The limiting current would then exhibit a $P_{O_2}{}^{1/2}$ dependence.

In order to assess the nature of the constraint at high voltages the limiting current is plotted against P_{O_2} in Fig. 10. The unit slope clearly indicates that gas phase diffusion of molecular oxygen causes this phenomenon, so that the phenomena related to Eq. [6]-[11] in the reaction sequence are not rate controlling in this regime. Similarly, Eq. [5] can also be eliminated because it represents a thermally activated process, whereas Fig. 10 virtually shows no temperature dependence (also see Fig. 11).

One expects that diffusion through the boundary layer would be strongly dependent on the gas flow rate and cell geometry, but independent of electrode morphology, whereas diffusion through micropores in the electrode structure should be dependent on the electrode morphology and the local P_{O_2} within the micropore, but practically independent of macroscopic flow rate.

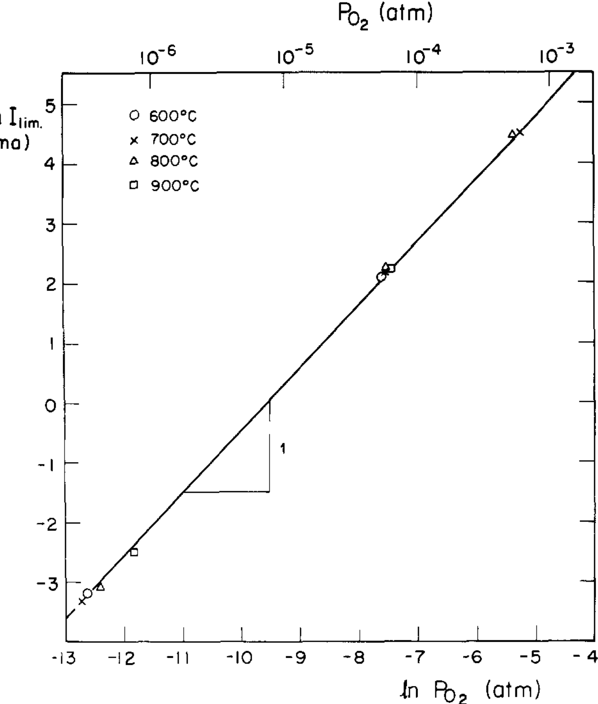

Fig. 10. Oxygen partial pressure dependence of high overvoltage limiting current.

The pronounced effect of flow rate on the high voltage limiting current was demonstrated in Fig. 7. A plot of limiting current *vs.* flow rate indicated a 0.6th power dependence. This is in good agreement with Bobb and Mason (47) who showed that a limiting current resulting from a slow diffusional process in a boundary layer should vary as the square root of the fluid velocity in a laminar flow system with stagnation flow geometry, similar to the conditions employed in the present work.

Consequently, the rate-determining mechanism in this overvoltage region is gas phase diffusion of molecular oxygen through the boundary layer (*i.e.*, Eq. [3]), rather than diffusion within the micropores. This agrees with some of the findings reported in the literature (9, 15, 21).

The $P_{O_2}{}^{1/2}$ dependence of the limiting current observed by other authors (see Table I) has been attributed to oxygen bulk diffusion through Pt electrodes (17-19, 27). However, the activation energies of about 22-27 kcal/mole (17, 18, 27) for the limiting current are too low to account for bulk diffusion in Pt which involves 117 kcal/mole (31).

Actually, the measured temperature dependence is in much better accord with the activation energy of about 27-34 kcal/mole for surface diffusion of oxygen on Pt reported by Lewis and Gomer (38). The oxygen partial pressure dependence of surface diffusion also is consonant with the observed $P_{O_2}{}^{1/2}$ dependence. This, in fact, was proposed as the rate-determining mechanism by Kleitz (13, 14) and Pizzini *et al.* (28, 29) who reported activation energies of about 33-35 kcal/mole for the high voltage limiting current.

The effect of H_2O.—Although H_2-H_2O mixtures have been used in various fuel cell applications (6, 51-54), little effort has been made to investigate their polarization behavior. There seems to be general agreement that ohmic polarization due to the ionic resistance of the ZrO_2 dominates the overall cell performance (6, 53), but the possibility of concentration overvoltage has also been reported (9).

The effect of water vapor would become noticeable only when $P_{O_2} \leq P_{H_2O}$ under conditions of gas phase polarization. It would, however, become important at much lower concentration levels if oxygen chemisorp-

tion were rate limiting, because it is known that water vapor and oxygen adsorb competitively on Pt (55).

The effect of H_2O on the limiting current was demonstrated by using dried and undried O_2-He mixtures. For $P_{O_2} = 4 \times 10^{-4}$ atm, the effect of H_2O was found to be insignificant, suggesting that the partial pressure of water vapor present was less than that of the oxygen. This is to be expected since diffusion of O_2 and H_2O in the boundary layer are comparable.

The situation, however, was quite different when pure He containing only a few ppm of O_2 was used. Undried He exhibited a significantly higher limiting current plateau than dried He, as depicted in Fig. 9. For this case $P_{O_2} << P_{H_2O}$ and the oxygen was present mainly in the form of H_2O molecules, owing to the large equilibrium constant, K_{H_2O}, for the reaction

$$1/2\ O_{2(g)} + H_{2(g)} = H_2O_{(g)} \qquad [14]$$

which has a value of about 10^{12} atm$^{-1/2}$ at 600°C. This suggests that the rate-limiting mechanism in this case is due to the transport of H_2O rather than O_2.

If one assumes that chemisorption of H_2O is rate determining, one expects to see a lowering of the limiting current plateau due to competition between O_2 and H_2O, as observed by Pizzini *et al.* (29). If surface migration were rate determining, one should obtain a $P_{O_2}^{1/2}$ dependence.

The observed behavior, however, was contradictory to both of these considerations. Thus, the rate-limiting mechanism was gas phase diffusion of water molecules through the boundary layer.

Intermediate overvoltage region.—At moderate voltages, and when $P_{O_2} \geq 10^{-3}$ atm, polarization curves showed a purely ohmic behavior, the current being determined by the bulk electrolyte resistance. Pancharatnam (17) also observed ohmic behavior with sputtered and paste Pt electrodes at intermediate voltages. Similar behavior has also been reported for other ionically conducting electrolytes (56).

There is, however, a slight oxygen partial pressure dependence of the ohmic slopes, especially at low temperatures (see Fig. 3). Theoretically, the bulk electrolyte resistance should be independent of P_{O_2} within the range of experimental conditions used in the present work.

A weak P_{O_2} dependence was also reported by Casselton (57) when the oxygen vacancy transport and ambient gas flow were not in the same direction. In the present work, gas flow and vacancy transport were in opposite directions. Thus, the observed P_{O_2} dependence is consistent with Casselton's results. However, the origin of this behavior is still unresolved.

Low overvoltage region.—The existence of double current plateaus was recently suggested by Fabry and Kleitz (58). They associated the first plateau with the depletion of adsorbed oxygen at the interface and the second plateau with the depletion of adsorbed CO_2. This may be valid in some cases but is obviously not applicable to the present situation.

The limiting current plateaus at low voltages are observed up to 700°C but disappear completely at higher temperatures (see Fig. 3 and 4). The plateaus are due to a process which is thermally activated and disappear, as the overvoltage is increased, into the ohmic region where the current remains entirely ionic. The temperature dependence of both the high and low overvoltage current plateaus are depicted in Fig. 11. The apparently high activation energy of about 61 kcal/mole associated with the low overvoltage limiting current agrees well with the activation energy value of >56 kcal/mole for the interface resistance obtained by the a-c admittance measurements (35). It matches, within experimental error, both the heat of molecular dissociation of oxygen on zirconia (36), about 58 kcal/mole, and on Pt (45, 46), 53-70 kcal/mole. No clear partial pressure dependence was found for the limiting current density in this low overvoltage region.

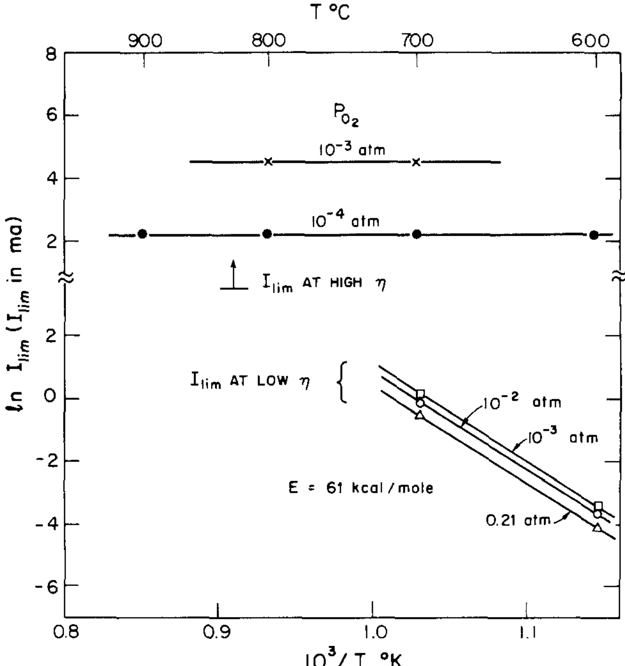

Fig. 11. Variation of limiting current with reciprocal of temperature.

Assuming that the current in this region is limited by the diffusion of some electroactive species, the available parameters do not allow an unambiguous assignment of the rate-determining step. Diffusion of oxygen on ZrO_2 itself or through Pt appear to allow too low a current density. Rate-limiting surface diffusion on the platinum [7], however, is of the right order of magnitude, and also predicts the correct temperature dependence when preceded by the molecular dissociation step [6]. This mechanism, also proposed by Kleitz (14), would predict a $P_{O_2}^{1/2}$ dependence.

An alternative process might be the rate-limiting diffusion of an electronic species from the Pt electrode along the zirconia electrolyte toward the electrochemical reaction site represented by reaction [8]. It is implicitly assumed that the electrochemical reaction site is located in the first few atomic layers of the electrolyte, since oxygen vacancies can exist only in the zirconia side of the three-phase boundary. It is very likely that the electrochemical reaction sites are actually zones rather than restricted microscopic sites along the three-phase boundary. Otherwise, extremely large current densities would be involved. A rate-limiting mechanism involving diffusion of electronic species would predict a current independent of the oxygen partial pressure and may well explain the disappearance of the plateaus as the overvoltage is increased.

Little information is available in the literature regarding electron diffusion in zirconia. Weppner (48-50) reported activation energies of about 12.9 and 32.3 kcal/mole for electron and hole bulk diffusion coefficients in zirconia. The activation energy for electron conductivity in 10 m/o $Y_2O_3 \cdot ZrO_2$ was found by the same author to be 94.5 kcal/mole. The comparable value for hole conductivity was 42.7 kcal/mole. These values are within 10% of those found by other investigators (59-61). None of these values, however, correspond to those observed experimentally in the present study.

The disappearance of the low voltage limiting current behavior beyond 700°C suggests a sudden change in the interface mechanism. A-C admittance measurements (35) conducted on cell [I] also indicated a sudden change at about 700°C in the activation energy of the interface resistance associated with the electrode

reaction. Pizzini (28) reported a significant decrease in charge transfer overvoltage around this temperature.

The shift in interface mechanisms around 700°C may be related to a characteristic behavior of the O_2/Pt system known as "surface reconstruction." This is commonly observed when a strongly exothermic surface reaction (*e. g.*, chemisorption of oxygen) occurs on Pt (40), Ni or other metal surfaces (46). The reconstructed surface is composed of both Pt and chemisorbed oxygen atoms in periodic arrays (38). This raises the work function of Pt by 1.2 eV (46) thus imposing an additional barrier for electrons to leave the Pt electrode to participate in the charge transfer reaction. As the voltage across the cell is increased, the potential energy barrier can be distorted in such a way as to allow tunneling. However, the estimated limiting current density due to the "tunneling effect" is much too low to account for the low voltage current plateau.

Surface reconstruction can occur even at temperatures as low as 200°C, but the original Pt surface can be restored either by exposing the Pt to high temperatures (38, 41) or to H_2. The "restored" clean Pt surface is obviously more reactive. Strong evidence of this came from Ngo (39) who found a sudden increase of Pt catalytic activity toward NO_2 at 750°C and above. At this temperature the adsorbate on Pt becomes unstable and desorbs as O_2 or PtO_2 whereby the "restored" Pt surface becomes appreciably more active in decomposing NO_2.

So, it is possible that the transformation of the Pt electrode surface from a reconstructed to a restored state may be responsible for the disappearance of the lower current plateaus as the result of a change in interface mechanism above 700°C observed in the present work.

Conclusions

It has been shown that at high particle fluxes the current is limited by diffusion of molecular oxygen through the gas phase boundary layer. This has been substantiated by temperature, flow rate, and oxygen partial pressure dependence measurements. It has also been shown that the effect of water vapor on the polarization behavior in this regime becomes noticeable only when the partial pressure of water vapor is comparable to or greater than that of oxygen.

At intermediate rates, the interfaces are nearly nonblocking, and the major impedance is the ohmic resistance of the solid electrolyte to oxide ion migration.

In the low overvoltage region, current plateaus are observed at $T \leq 700°C$ which disappear at higher temperatures. The disappearance may be due to a property of Pt surfaces in an oxygen environment which changes their surface structure from a reconstructed to a restored state around this temperature.

The physical phenomenon responsible for the observed limiting current behavior in this region could not be fully resolved. However, it seems like either electron diffusion through the ZrO_2 from Pt electrode to the ERS or oxygen surface diffusion on the Pt electrode may be rate determining.

Acknowledgments

The authors are indebted to Dr. J. Weissbart of Applied Electrochemistry, Incorporated, for kindly providing the scandia-stabilized zirconia samples. Financial support from the Environmental Protection Agency under Contract 5 R01 R 801337, as well as Stanford University, is also appreciated.

The Activation of Polycrystalline Gold to the Hydrogen Electrode Reaction Promoted with Repetitive Potentiodynamic Perturbations

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Sucursal 4, Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The activation of gold electrodes toward the hydrogen electrode reaction is studied using the polycrystalline gold/1M H_2SO_4 interface at 25°C. The electrode activation is promoted by potentiodynamic aging in the potential range where the O-electrosorption/O-electrodesorption takes place. The activation effect is comparable to that earlier described when gold electrodes are cathodized for a relatively long time in the potential range of the net evolution of hydrogen. The activation effect is revealed through the appearance of a remarkable increase of current associated with the hydrogen ion discharge and an anodic current related to the electrooxidation of hydrogen. For the latter, different contributions are distinguished, namely, the molecular H_2 diffusion and those related to adsorbed and probably absorbed hydrogen. The electrochemical characteristics of the gold/1M H_2SO_4 interface are related to a large extent to the restructuring of the metal surface.

The energetic characteristic of the electrode surface is crucial in electrochemical kinetics. There are numerous experimental procedures described in the literature to activate particular metal electrodes such as the application of certain types of either current or potential pulses, the addition of traces of some particular species to the electrolyte solution, the production of electrodes with a determined size of particles, etc. Sometimes the activation or deactivation of metal electrodes depends to a large extent on the proper electrode history. This is the case of the mechanism of the hydrogen evolution reaction on gold which is very sensitive to the quality of the gold surface (1-3).

In this respect it has been recently shown that the surface structure of polycrystalline gold electrodes immersed in aqueous H_2SO_4 solutions changed when the electrochemical interface was subjected to several hundred potentiodynamic cycles in the 0-1.9V (NHE) range (4, 5). The electrochemical treatment transformed the originally disturbed surface into a structured surface with the appearance of grain boundaries and faceting (4-7) as in the thermal etching (8). It is clearly elucidated that crystal orientation of gold electrodes influences the capacity of the electrical double layer (4, 6, 9, 10). On the other hand, repetitive polarization cycles in the −0.8 to 1.2V (*vs.* SCE) potential range produces a systematic and progressive change of the electrode surface from a (111) to a (110) structure as revealed through electron microscopy and electron diffraction and changes the potential of zero charge (4). The structural surface change is reflected in an increase of electrode activation of gold to the hydrogen electrode reaction (5-7, 11) as compared to the adsorption of hydrogen on nonactivated gold (2, 12, 13). Values between 3% and 4% of a hydrogen adsorbed monolayer have been reported. The capacity maximum at about −0.2V (SCE) found at the (100) gold face, but not at the (110) face, was ascribed to hydrogen adsorption (6).

It has also been demonstrated that the surface restructuring requires the electrosorption and electrodesorption of oxygen on the metal surface (4, 5, 7, 11), but the influence of the perturbation variables on the efficiency of the electrode surface activation concerning the hydrogen electrode reaction is still not completely known. Therefore, in order to elucidate the problem of the gold electrode activation, the type of perturbation described in the literature to promote the potentiodynamic aging of layers of different species electrochemically formed on electrode surface (14-16), was systematically applied to the gold/1M H_2SO_4 interface. The corresponding results are relevant to understand, at least in part, the relationship between

the electrode surface activation and the surface restructuring provoked by potential perturbations such as the combined complex repetitive triangular potential sweeps.

Experimental

The experimental procedure was based on that described in previous works (14, 15). The working electrode (0.38 cm^2 apparent area) consisted of a polycrystalline spectroscopic quality wire (Johnson, Matthey) mounted on a Teflon holder. The following electrode pretreatments were independently applied: (*i*) The gold electrode was polished with a 300 mesh Al_2O_3 powder-water suspension. The electrode was then immersed in 1:1 HNO_3-H_2SO_4 mixture and finally rinsed for a long time in water. (*ii*) The gold electrode was dipped without any polishing in a 5*N* HNO_3 solution. The first procedure gave the more reproducible results but the second one was particularly useful to emphasize the memory effect of the used electrodes which is described further on. The counterelectrode (7 cm^2 apparent area) was made with the same material and adequately separated to eliminate any diffusion of the products from the counterelectrode section of the cell to the working electrode compartment. An Hg/Hg_2SO_4 electrode properly protected to avoid Hg(I) diffusion into the electrolysis cell was used. Teflon tubing and stopcocks and joints lubricated with the electrolyte solution contained in the cell were employed. The electrode potentials are referred to the reversible hydrogen electrode (RHE).

The electrolyte was 1M H_2SO_4 solution prepared from triply distilled water and A.R. 98% H_2SO_4 (Merck). The distilled water was systematically tested to satisfy the purity requirements described in the literature (17). Platinum or any other possible electrode contaminant were carefully avoided. The experiments were made with purified gas saturation, either N_2 or H_2, and employing either quiescent or stirred electrolytes. The temperature was fixed at 25°C. The activation of gold electrodes to the hydrogen electrode reaction by means of the potentiodynamic aging in the O-electrosorption/O-electrodesorption potential range was studied by applying different potential/time perturbation programs. Runs were made covering different switching potentials ($E_{\lambda,a}$, $E_{\lambda,c}$, and $E'_{\lambda,c}$), potential sweep rates (v_a, v_c, and v_i) and durations (τ) of the intermediate perturbation. The subscripts a, c, and i stand for the positive going (anodic) and negative going (cathodic) potential excursions and for the intermediate repetitive triangular potential scan (RTPS), respectively. Both electrode handling and cell assembling were made taking precautions to prevent any possible contamination through the laboratory atmosphere. The electronic circuitry is the same as employed in previous works (14, 15).

Results

Quiescent N_2-saturated electrolyte.—The *E/I* profiles resulting at 0.2 V/sec within $E_{\lambda,a} = 1.67V$ and $E_{\lambda,c} = -0.2V$, obtained with and without the potentiodynamic aging between $E_{\lambda,a}$ and $E'_{\lambda,c}$, are comparatively depicted in Fig. 1. The potentiodynamic aging at 0.2 V/sec was confined to a potential range ($E_{\lambda,a} = 1.67V$ and $E'_{\lambda,c} = 1.26V$), where about one-half of the O-containing layer was involved in each electrodesorption/electrosorption cycle. The potential sweep run immediately after the intermediate RTPS between $E_{\lambda,a} = 1.67V$ and $E_{\lambda,c} = -0.2V$ distinguishes the following features, as compared to the stabilized RTPS: (*i*) The shift of the O-electrodesorption current peak toward more negative potentials and its simultaneous slight increase in charge. The cathodic current peak becomes more symmetric and thinner than the corresponding current peak recorded in the stabilized RTPS. (*ii*) A remarkable increase of the hydrogen evolution current. (*iii*) A net anodic current in the 0.1-0.4V potential range which is attributed to the hydrogen electrooxidation (1, 5, 11). The potential of the anodic current peak recorded during the positive going potential sweep is located in the 0.120-0.165V range. The charge $Q_{H,a}$ related to the hydrogen electrooxidation under fixed values of $E_{\lambda,a}$, $E_{\lambda,c}$, and $E'_{\lambda,c}$ depends on the time τ and on the frequency of the intermediate RTPS (Fig. 2). The maximal $Q_{H,a}$ value is obtained at *ca.* 2 V/sec. Within the $E'_{\lambda,c}$ range indicated in the figure and within the 0-30 min range, $Q_{H,a}$ increases with τ. The $Q_{H,a}$ value recorded during the negative going potential sweep, reveals a composite current peak involving at least two contributions. The more positive contribution is in the 0.3-0.5V range, while the more negative one is in the 0.15-0.17V range. The potentials of the anodic current peak during successive potentials sweeps are reproducible within ±10 mV.

The $Q_{H,a}$ value depends strongly on $E'_{\lambda,c}$ and correspondingly on the percentage of the O-containing species being removed during the intermediate RTPS (Fig. 3). The maximal $Q_{H,a}$ value results at *ca.* 80% of the electrosorbed oxygen involved in the intermediate RTPS. This percentage is referred to the charge of the O-electrodesorption current peak in the stabilized *E/I* profile. The gold electrode, which became activated toward the hydrogen electrode reac-

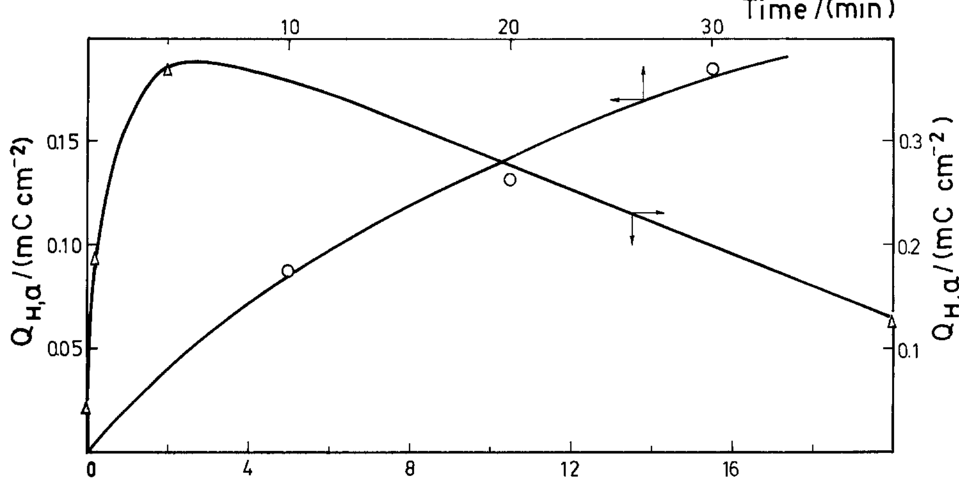

Fig. 2. Dependence of $Q_{H,a}$ on v_i and on τ. N_2-saturation. $E_{\lambda,a}$ = 1.7V; $E_{\lambda,c}$ = −0.05V; $E'_{\lambda,c}$ = 1.09V; and $v_a = v_c = v_i$ = 0.2 V/sec.

tion, progressively deactivates with a further potential cycling between $E_{\lambda,a}$ and $E_{\lambda,c}$.

The rate of decrease of the electrode activation can be followed through the change of the relative charge $(Q_{H,a})_n/(Q_{H,a})_1$ (Fig. 4) where $(Q_{H,a})_n$ is the hydrogen electrooxidation charge after the nth RTPS between $E_{\lambda,a}$ and $E_{\lambda,c}$ and $(Q_{H,a})_1$ refers to the same charge for the first potential sweep immediately after the intermediate RTPS carried out between $E_{\lambda,a}$ and $E'_{\lambda,c}$. The charge related to hydrogen electrooxidation decreases more rapidly when $E_{\lambda,a}$ becomes more negative than the potential which corresponds to the O-electrosorption. This result reveals the influence of the O-electrosorption on the activation for the hydrogen electrode reaction. For a constant set of perturbation conditions the charges $Q_{H,a}$ and $Q_{H,c}$ recorded during the triangular potential sweep run immediately after the electrode activation increase as $E_{\lambda,c}$ becomes more negative, but for a fixed $E_{\lambda,c}$, $Q_{H,a}$ is larger than $Q_{H,c}$ (Table I). There is, however, an optimal $E_{\lambda,c}$ value ($E_{\lambda,c} = -0.05$V for $v_a = v_c$ = 0.2 V/sec and v_i = 2 V/sec) at which $Q_{H,c}$ practically compensates $Q_{H,a}$.

On the other hand, under the same potentiodynamic aging conditions in the O-electrosorption region, $Q_{H,a}$ decays according to a rate law of the form $Q_{H,a} \sim t^x$ (Fig. 5) where the exponent x depends on the switching potentials of the triangular potential perturbation following the intermediate RTPS. Analogously $Q_{H,a}$ also decreases with τ_p, the time at which the electrode is held at $E_{\lambda,c}$ after its potentiodynamic activation. The decay of $Q_{H,a}$ fits a reasonable linear $Q_{H,a}$ *vs.* log τ_p plot (Fig. 6).

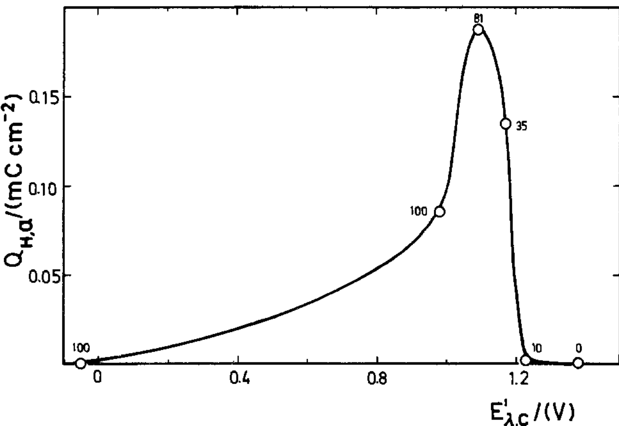

Fig. 3. Dependence of $Q_{H,a}$ on $E'_{\lambda,c}$. N_2-saturation. $E_{\lambda,a}$ = 1.67V; $E_{\lambda,c}$ = −0.05V; $v_a = v_c$ = 0.2 V/s:c; v_i = 2 V/sec; τ = 30 min. For each experimental point the percentage of the O-electrodesorption at $E'_{\lambda,c}$ in the first intermediate negative potential going sweep is indicated.

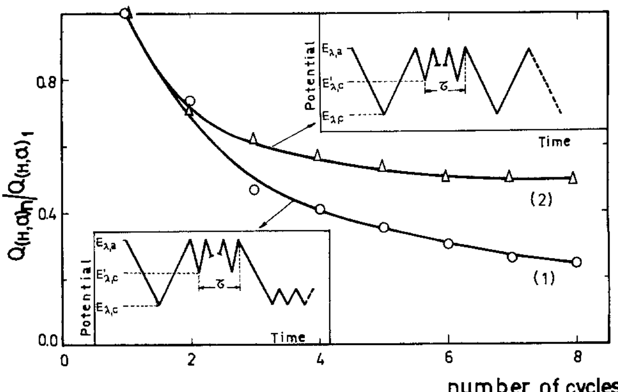

Fig. 4. Relative change of $Q_{H,a}$ as a function of the number of RTPS operating after the potentiodynamic aging. N_2-saturation. $E_{\lambda,a}$ = 1.7V; $E_{\lambda,c}$ = −0.05V; $E'_{\lambda,c}$ = 1.09V; τ = 30 min; $v_a = v_c$ = 0.2 V/sec. v_i = 2 v/sec. Curve 1, without covering the O-electrosorption potential range during the potential cycling. Curve 2, the O-electrosorption potential range is covered.

Quiescent H_2-saturated solution.—In the H_2-saturated electrolyte the increase of $Q_{H,a}$ is already observed for $E_{\lambda,c}$ = 0.0V, a potential at which no macroscopic H_2 gas evolution is produced (Fig. 7a and 7b). The electrode subjected to the potentiodynamic aging in the O-electrosorption/O-electrodesorption potential range exhibits an anodic current contribution in the negative potential going sweep before reaching $E_{\lambda,c}$, with two anodic current peaks at 0.39 and at 0.19V, respectively. The returning positive going sweep exhibits a single anodic current peak. During the triangular potential cycling as $Q_{H,a}$ decays, a gradual shift of the anodic current peak potential toward more negative potentials is observed. The heights of the anodic current peak decrease, particularly the one

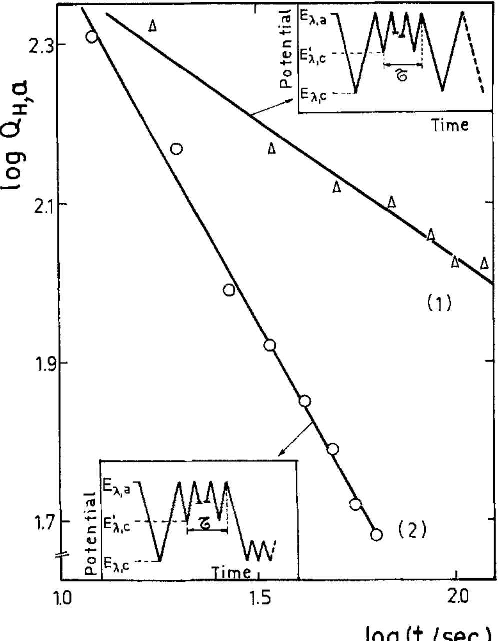

Fig. 5. Log-log plot for the $Q_{H,a}$ decay. N_2-saturation. The time counting starts immediately after $\tau = 30$ min. $E_{\lambda,a} = 1.7V$; $E_{\lambda,c} = -0.05V$; $E'_{\lambda,c} = 1.09V$; $v_a = v_c = 0.2$ V/sec; $v_i = 2$ V/sec. Curve 1, the O-electrosorption potential range is covered, $E_{\lambda,a} = 1.7V$. Curve 2, without covering the O-electrosorption potential range during the potential cycling.

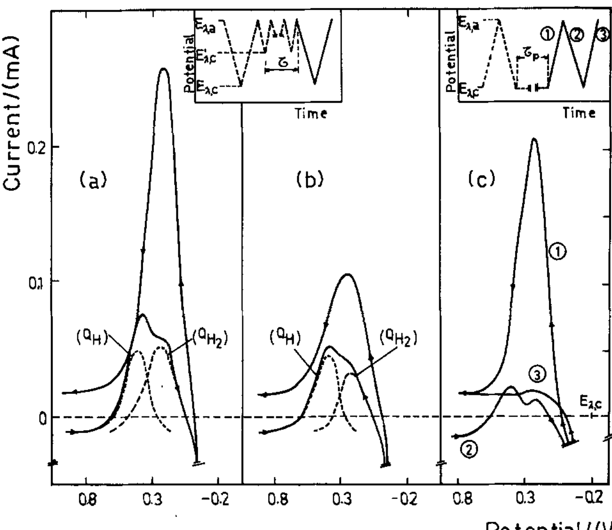

Fig. 7. Comparative E/I displays obtained after the electrode activation process with the potential/time perturbation programs indicated in the figure. H_2-saturation. $E_{\lambda,a} = 1.7V$; $E_{\lambda,c} = 0.0V$; $E'_{\lambda,c} = 1.09V$; $v_a = v_c = 0.2$ V/sec; $v_i = 2$ V/sec; $\tau = \tau_p = 30$ min. (a) The triangular potential sweep after the potentiodynamic aging initiates toward positive potentials. The dashed lines correspond to the estimated contributions of H-adatoms and H_2 in the E/I profile during the negative potential going half-cycle. Still solution. (b) The same as (a) but with solution stirring. (c) Comparative successive E/I displays (curves 1, 2 and 3) run with the electrode activated by holding the potential at $E_{\lambda,c}$ during τ_p. With solution stirring.

located on the more positive potential side. A similar qualitative E/I response results when the electrode is held at $E_{\lambda,c} = 0.0V$ during $\tau_p = 30$ min (Fig. 7c) although the charge is smaller than that observed under the potentiodynamic aging.

The gold electrode activation in the H_2-saturated electrolyte is greater than that observed in the N_2-saturated electrolyte under comparable perturbation conditions.

Influence of the solution stirring.—The influence of stirring is determined under preset potential perturbation conditions. Thus, either for H_2- or for N_2-saturated stirred solution, the hydrogen-electrooxidation current gradually decreases when $E_{\lambda,c}$ is between 0.0 and $-0.2V$ and it increases again if the potential cycling continues and the stirring is interrupted.

Under the same potential perturbation conditions a remarkable decrease of $Q_{H,a}$ due to stirring is noticed in the E/I display run immediately after the potentiodynamic activation of the gold electrode. This effect, however, is significantly less in the negative going potential excursion than in the preceding positive going potential scan (Fig. 7a and 7b).

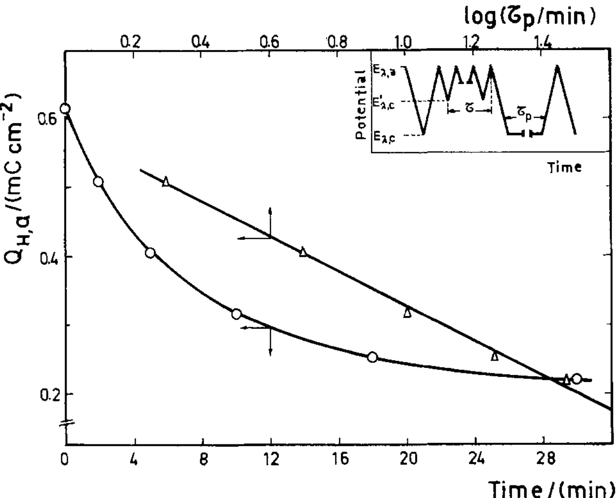

Fig. 6. Decay of $Q_{H,a}$ as a function of τ_p. N_2-saturation. $E_{\lambda,a} = 1.7V$; $E_{\lambda,c} = -0.2V$; $E'_{\lambda,c} = 1.09V$; $\tau = 30$ min; $v_a = v_c = 0.2$ V/sec; $v_i = 2$ V/sec.

When the gold electrode activation is produced by cathodization at $E_{\lambda,c} = -0.2V$, the solution stirring produces a net decrease of the electrode activation. The decrease continues during the repetitive potential cycling, especially when $E_{\lambda,a}$ is more negative than the O-electrosorption/O-electrodesorption potential range. When $E_{\lambda,a}$ exceeds this value the E/I display recorded during the negative going potential scan then exhibits the anodic doublet previously reported (Fig. 7).

Memory effect.—Gold electrodes, which were repetitively activated through potentiodynamic aging followed by storing for a long period of time in a 5*N* HNO_3 solution, exhibit a residual activation when they were cycled by a triangular potential signal in quiescent, H_2-saturated 1M H_2SO_4 solution between $E_{\lambda,c} = -0.2V$ and $E_{\lambda,a} = 1.3V$. Under these conditions, the positive going potential excursion shows an anodic current peak related to hydrogen electrooxidation. The negative going potential excursion after a progressive increase of $E_{\lambda,a}$ repeats the complex multiple E/I display previously described. The stable RTPS E/I profile is attained after about 10-15 cycles. The effect can be reversed simply by changing $E_{\lambda,a}$ to more negative potentials. Thus, the stable RTPS E/I profile of the activated electrode (Fig. 8a) changes to that shown in Fig. 8b when $E_{\lambda,a}$ decreases to 0.6V. Now the charge involved in the successive E/I profile in both directions decreases, as indicated by the arrows, to attain the new stable RTPS E/I profile shown in Fig. 8c (dashed line). Under these circumstances, an increase of $E_{\lambda,a}$ to 1.7V, the E/I profile first shows an increase of the current peaks up to a maximal value and afterward a slight decrease to attain again the stable profile depicted in Fig. 8d (dashed line). Finally,

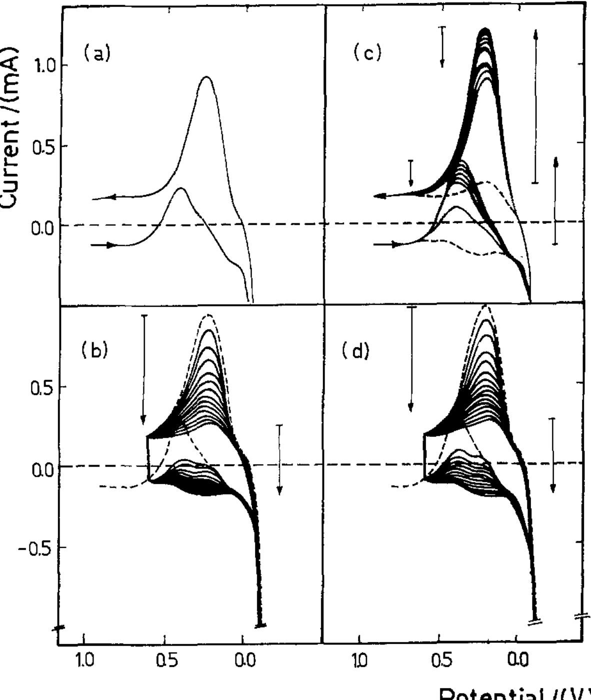

Fig. 8. Potentiodynamic *E/I* displays ($E_{\lambda,c}$ = −0.16V; $v_a = v_c$ = 0.2 V/sec; $\tau = \tau_p$ = 20 min; H_2-saturation) run according to the following sequence. (a) *E/I* profile run immediately after the potentiodynamic activation. (b) Stabilized *E/I* profile from (a) (dashed trace) and successive *E/I* displays after fixing $E_{\lambda,a}$ = 0.6V (full traces). (c) Stabilized *E/I* profile from (b) (dashed trace) and successive *E/I* displays after fixing $E_{\lambda,a}$ = 1.7V (full traces). (d) Stabilized *E/I* profile from (c) (dashed line) and successive *E/I* displays after fixing $E_{\lambda,a}$ = 0.6V (full traces).

a decrease of $E_{\lambda,a}$ from 1.7V back to 0.6V produces again a decrease of the electrode activation.

The memory effect disappears or it is appreciably attenuated after mechanically polishing the electrode with a water-Al_2O_3 suspension.

Discussion

The gold/aqueous acid interface can be activated for the electrooxidation of hydrogen under either potentiostatic cathodization or after potentiodynamic aging in the O-electrosorption potential range. In the former case, the effect depends on $E_{\lambda,c}$ and on τ_p (3-5) while in the latter it is influenced by $E_{\lambda,a}$, $E'_{\lambda,c}$, τ, and the frequency of the repetitive triangular potential perturbation between $E'_{\lambda,c}$ and $E_{\lambda,a}$. The values of $E_{\lambda,a}$ and $E'_{\lambda,c}$ determine the amount of electrosorbed oxygen which is alternatively electroformed and electroreduced during the intermediate RTPS. The maximum effect corresponds to a charge which is about 80% of the O-monolayer charge on gold. Although both activation procedures give comparable results, the activation of the hydrogen electrooxidation on gold produced through the potentiodynamic aging is already noticed by holding the potential of the electrode at $E \approx$ 0V.

The activation of the gold electrode toward the hydrogen electrode reaction implies both an increase of the overall cathodic current related to the evolution of hydrogen and the appearance of two anodic current peaks associated with the electrooxidation of hydrogen on gold. The possibility that the cathodic current increase is due to the increase of the electrode roughness is, in principle, disregarded because the charge related to the O-electrodesorption before and after the electrode activation remains practically the same.

The two anodic current peaks present a different response to the solution stirring. Thus, the height of the main anodic peak located at more negative potentials decreases strongly by stirring the solution, as one should expect for a diffusion-controlled redox reaction. This current peak should be related to the electrooxidation of molecular hydrogen, supersaturating the diffusion layer (18, 19). This local supersaturation is only observed with previously activated gold electrodes. The largest degree of H_2 supersaturation at the electrode surface is achieved through the cathodic potentiostatic activation and it depends both on the potential applied to the interface and on the time τ_p. The corresponding current peak potential is displaced toward the positive potential side from the H_2/H^+ equilibrium potential due to the irreversibility of the redox reaction. Most of the *E/I* profile recorded during the positive going potential scan after cathodic potentiostatic activation can be reproduced using the equation of a redox process (20) with the exchange current density, $i_o \approx 10^{-5}$ A/cm² (2) and the estimated hydrogen supersaturation 10^{-1} mole/liter (19).

The smaller anodic current peak at *ca.* 0.3V appears as independent of the stirring of the solution. The *E/I* profile also indicates a possible third anodic current contribution at *ca.* 0.2V although it is mostly overlapped by the main diffusion-controlled current peak already discussed. The charge of the anodic current peak at *ca.* 0.3V as estimated from the negative potential going *E/I* display, is always less than the charge expected for the H-adatom monolayer (210 μC/cm² for polycrystalline platinum) (21). This charge can be associated with the presence of H-adatoms whose surface concentration should depend on available active metal sites promoted on the surface by the potentiodynamic aging in the O-electrosorption potential range.

The gold electrode activation process for the hydrogen electrode reaction can be interpreted on the basis of the data reported for the dependence of the hydrogen overvoltage with the type of gold electrode used (2). The hydrogen overvoltage obtained with smooth gold electrodes are similar and rather high. They agree with calculation for $E_{Au\text{-}H} \approx$ 46 kcal (22, 23). For a smooth gold electrode, the cathodic Tafel slope is *ca.* 0.1 V/decade or slightly higher and some evidence has been obtained for a lower slope at lower overvoltages (24, 25). Otherwise, for electrolytic gold deposits, smaller overvoltages and lower Tafel slopes are reported (24-26) especially for electrodes subjected to anodic-cathodic activations (1, 27). These results make it difficult to draw definite conclusions regarding the mechanism of the reaction under stationary conditions. But they correlate with the present data if one admits that the restructuring of gold electrode surfaces, which was demonstrated through optical methods (4-8), plays a significant role in defining their degree of activation.

To develop a qualitative formalism of the reactions at the gold electrode, let us first consider that it consists of a clean gold surface structure which remains practically unaltered during the potential perturbation and that no H_2 is dissolved into the electrolyte. Because of the (H)Au bond energy value, the hydrogen adatom concentration on the metal is probably very low. Therefore, the following reaction steps of the electrochemical process can be proposed

$$\mathrm{Au} + (\mathrm{H}^+)_s = \mathrm{Au} + (\mathrm{H}^+)_e \overset{+e}{=} \mathrm{Au(H)}_{ad} = \mathrm{Au} + \tfrac{1}{2}\mathrm{H}_2 \qquad [1]$$

where s, e, and ad denote the bulk of the solution, electrode surface, and adsorbed species, respectively. The reaction sequence [1] has been considered to interpret earlier experimental results with the assumption that the concentration of adsorbed H is negligible and the adsorbed species is written as a postulated reaction intermediate (22). The rate-determining step under stationary conditions has been assigned to the

discharge plus H-desorption step. However, it is claimed that a fraction of the hydrogen atoms electrochemically produced can penetrate into the metal through a slow diffusion process. The diffusion coefficient of hydrogen in gold is estimated, at 25°C, equal to 4×10^{-12} cm^2/sec (5). Then, this means that reaction sequence [1] should be written as follows

$$Au + (H^+)_s = Au + (H^+)_e$$

$$+e = Au(H)_{ad} \nearrow Au + \tfrac{1}{2}H_2 \quad [2a]$$

$$\searrow Au(H)_{ab} \quad [2b]$$

where ab stands for the absorbed hydrogen. The electrooxidation of absorbed hydrogen would occur through a reaction which may be either under activation or diffusion control.

The participation of sorbed hydrogen in the electrochemical process is appreciably influenced by the O-electrosorption/O-electrodesorption processes occurring at more positive potentials. These processes modify the crystallographic order at the first layers of the metal lattice (7, 14). Through the mobility of metal atoms out of the lattice assisted by their rearrangement during the O-electrodesorption stage and by the anisotropy of the surface energy due to the incomplete removal of the O-containing layer (7). These changes in the metal lattice should depend both on the frequency (ν) and duration (τ) of the intermediate RTPS and attains a maximal value for a particular set of perturbation variables as shown in Fig. 2 and 3.

The precedent discussion and the already reported data on the O-electrosorption/O-electrodesorption on gold (28) suggest that the overall processes occurring in the $E_{\lambda,a}$-$E_{\lambda,c}$ potential range on the activated gold electrode under potentiodynamic conditions can be ascribed by the following reactions

$$Au + H_2O = Au(OH)_{ad} + (H^+)_e + e \quad [3]$$

$$Au(OH)_{ad} = Au^*(O) + (H^+)_e + e \quad [4]$$

$$Au^*(O) \xrightarrow{k_a} Au(O) \quad [5]$$

depend on the values of k_a, k_6, k_7, and the characteristics of the perturbation program applied to the electrode. The H_2-discharge reaction occurring on Au and Au* are explained by steps [8] and [9], respectively. The Au* sites are those which exhibit toward the hydrogen adatoms a reactivity higher than the Au sites. Reactions [8a] and [8b] should be responsible for the changes produced in the potentiodynamic E/I display after the potentiodynamic aging.

When the electrolyte layer adjacent to the electrode is saturated with H_2, the H_2 electrooxidation should preferentially occur at the Au* sites (reaction [10]). The presence of the Au* sites should favor the existence of hydrogen adatoms either electrochemically formed as well as produced from the dissociation of molecular hydrogen. Then, the surface concentration of H-adatoms should depend on the surface concentration of Au* sites. The potential of the corresponding electrooxidation current peak indicates a slight increase in the average Au*(H) bond energy as compared to that of the Au(H) bond. Under these circumstances the behavior of the activated gold electrode with respect to the hydrogen electrode reaction approaches that of the platinum electrode. The overall processes represented by reactions [3]-[10] under potentiodynamic conditions imply either the M-O and M-M or the M-H and M-M bonds changing simultaneously.

The effect of the activation process depends on the time spent to achieve it. Thus, when the activation process operates during a short time the electrode activation decays linearly with the logarithm of time (Fig. 5 and 6), a relationship commonly obtained in electrodesorption of different species from solids (29). This suggests that the activation effect is predominantly associated with the first layers of the metal lattice. On the other hand, when the time of the activation process is sufficiently large, the electrode acquires an activation memory with respect to the hydrogen electrode reaction which can be interpreted as a deeper and longer lasting change of the electrode surface structure resulting from the processes taking place over the O-electrosorption/O-electrodesorption potential range. This effect is probably assisted by

$$Au^*(O) + (H^+)_e + e \underset{k_7}{\overset{k_6}{\rightleftharpoons}} Au^*(OH)_{ad} + (H^+)_e + e \rightleftharpoons Au^* + H_2O \quad [6]$$

$$\downarrow \qquad \downarrow \qquad \downarrow$$

$$Au(O) + (H^+)_e + e \rightleftharpoons Au(OH)_{ad} + (H^+)_e + e \rightleftharpoons Au + H_2O \quad [7]$$

$$Au^* + (H^+)_e + e = Au^*(H) \nearrow Au^*(H)_{ab} \quad [8a]$$

$$\searrow \tfrac{1}{2}H_2 + Au^* \quad [8b]$$

$$\downarrow \qquad \downarrow$$

$$Au + (H^+)_e + e = Au(H)_{ad} = \tfrac{1}{2}H_2 + Au \quad [9]$$

$$2Au^* + H_2 = 2Au^*(H)_{ad} \nearrow Au^*(H)_{ab} \quad [10a]$$

$$\searrow Au^* + H^+ + e \quad [10b]$$

$$\downarrow$$

$$Au$$

Reactions [3] to [5] explain the main processes involved in the potentiodynamic O-electrosorption/O-electrodesorption on gold (28). Reactions [3] and [4] are the initial steps related to the O-electrosorption occurring on the nonactivated gold electrode. Reaction [5] represents the aging of the O-electrosorbed species, k_a is the corresponding rate constant. This reaction plays an important role during the potentiodynamic aging covering the potential range of the O-electrosorption/O-electrodesorption processes. Reactions [3] to [5] imply at least the occurrence of two different surface sites, denoted as Au and Au*. Then, the O-electrodesorption may occur through the series of reactions [6] and [7] which also imply possible deactivation processes of the Au* species (dashed arrows). The relative surface concentration of Au and Au*

the possible accumulation of adsorbed oxygen in the metal as was suggested earlier to explain the discrepancy observed between the complex evolution of the optical properties of the metal associated with restructuring of its surface and the prediction of the simple faceting model (30). The resulting effects can be related to the penetration of hydrogen into the metal.

Electrochemical Reactions at Multiple Interfaces

The Nickel Hydroxide Electrode Formed by Precipitation on a Platinum Surface

M. E. Folquer, J. R. Vilche,* and A. J. Arvía*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Sucursal 4, Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The formation of a multiple interface consisting of a platinum-base electrode covered by a chemically produced $Ni(OH)_2$ layer is investigated in alkaline electrolytes. The potentiodynamic response of the multiple interface is relatively complex but can be interpreted as the sum of two main contributions, namely, the processes related to the electrosorption and electrodesorption of hydrogen and oxygen on platinum and the conjugate redox processes related to the nickel hydroxide electrode. The mutual interference of the oxygen electrosorption and electrodesorption reactions with those of the nickel hydroxide electrode is inferred from the change of the aging characteristics of the oxygen electrodesorption process. The overall electrochemical reaction is interpreted through a reaction model involving two limiting planes dividing the electrochemical interface in two main regions associated with the two processes referred to above.

In a recent publication the concept of the multiple electrochemical interface was applied to explain the potentiodynamic behavior of iridium in different acid electrolytes (1, 2). A multiple electrochemical interface involves at least three different phases, namely, the base metal, the conducting or semiconducting film which covers the base metal either partially or totally, and the electrolyte. The cations or atoms of the metal in the film forming chemical species are different from those of the base metal electrode. Various electrochemical processes take place at the multiple electrochemical interface. The sites of each reaction within such an interface are differently located so that a reaction plane proper to each reaction can be assigned. During the electrochemical reaction the different planes move at rates which depend on the characteristics of the reactions, whether they refer to a corrosion of the base metal, a monolayer formation, a thickening of the anodic film, or a proton transfer process occurring through the film. The reaction model, which proved useful for interpreting the abovementioned reaction, may have a more general application. In this sense, it is interesting to test it through coupling the characteristics of both the nickel hydroxide electrode and the platinum/alkaline solution interface and further to attempt to elucidate some of the questions regarding the kinetics of the former process.

Recent studies on the nickel hydroxide electrode have shown that the overall electrochemical reaction

* Electrochemical Society Active Member.
Key words: metals, potential, voltammetry.

involves complications previously disregarded since both the reactants and the products that usually enter electrochemical reactions correspond to composite mixtures of different species (3, 4). These species generally expressed in terms of simple limiting stoichiometries, involve different structures with their own energetic characteristics which are revealed through the electrochemical response under complex potentiodynamic conditions (5). In spite of the fact that the potentiodynamic results furnish information on the possible reaction pathways some important questions referring to these reactions are still unsolved. One of them concerns either the influence or the interference of the metal side of the interface on the overall electrochemical processes including the aging process which takes place in the composite nickel hydroxide film.

To achieve a stabilized hydroxide electrode, such as the nickel hydroxide electrode on an apparently inert base metal, the physicochemical properties of colloid films associated with proton transfer reactions are of special interest. These films may exist on the metal substrate with a sufficiently firm mechanical adhesion and a high electrochemical activity. The experimental data derived through the formation of a multiple electrochemical interface after the use of complex potentiodynamic perturbations indicate the mutual influence of the various processes assigned both to the nickel hydroxide electrode potential range and to the potential range where the platinum metal is covered with either an oxygen or a hydrogen electrosorbed monolayer. This is clearly envisaged through the straightforward comparison of the electrochemical behavior of the multiple interface and the electrochemical characteristics of the separate interfaces.

Experimental

The experimental arrangement including the electrolysis cell, solution preparation, and perturbation techniques are the same as those previously described in different publications (3-5). The working electrode, in the present case, was a platinum wire (Johnson-Matthey, spec-quality) of 0.4 mm diam and 0.22 cm^2 apparent area.

The following electrolyte solutions were employed: $0.01N$ KOH + $0.66N$ K_2SO_4 (blank solution) or blank solution with $Ni(OH)_2$ saturation. The solutions were prepared from analytical grade Merck reagents and thrice distilled water. The $Ni(OH)_2$ saturation was achieved using the following different procedures. (*i*) By addition of $10^{-3}N$ $NiSO_4$ to the blank solution and separation of the saturated solution from the precipitate. (*ii*) By addition of the $NiSO_4$ solution as indicated in (*i*) without separation of the precipitate. (*iii*) By forming the $Ni(OH)_2$ on the electrode outside the cell by alternatively and repetitively immersing first in the blank solution and then in a $10^{-2}N$ $NiSO_4$ solution. After the preparation stage the electrode was immersed on the cell containing freshly prepared, previously deoxygenated blank solution. The ionic strength was kept practically constant and close to one. The nickel ion concentration in these solutions was of the order of 10^{-8}M, since for $Ni(OH)_2$ at 25°C, $K_s = 1.5 \times 10^{-16}$ (mole/liter)^3 (6, 7).

Experiments were run under different potential sweeps at 0.03 V/sec $\leq v \leq$ 0.30 V/sec and 25°C under 1 atm pressure N_2 gas saturation. The electrode potentials in the text are referred to the SCE scale.

The base platinum metal was prepared by using the two following different cleaning procedures. (*i*) Mechanical polishing with a fine grade pure alumina powder suspension in water to produce a mirror surface followed by immersion in an HNO_3 + H_2SO_4 (1:1) mixture for 15 min. (*ii*) Immersion in the acid mixture as indicated in (*i*).

Electrodes differently cleaned were tested with the blank solution by running repetitive triangular potential sweeps (RTPS) in the potential range of the hydrogen and oxygen electrosorption, between the anodic ($E_{\lambda,a}$) and the cathodic ($E_{\lambda,c}$) switching potentials. Procedure (*i*) requires a time longer than procedure (*ii*) to attain the stable *E/I* display at 0.3 V/sec. Although both procedures finally gave the same results, the latter was preferentially used.

Results

Preliminary information was obtained by comparing the potentiodynamic RTPS *E/I* displays run in the $E_{\lambda,c} = -0.90$V to $E_{\lambda,a} = +0.65$V potential range, at 0.3 V/sec, with the blank solution (Fig. 1) and with the solution containing Ni(II) after a previous potentiostatic cathodization of the platinum electrode at potentials ranging from -0.9 to -1.2V during a fixed period of time (1 min $\leq t \leq$ 5 min). Thus, for the Ni(II) containing solution, after a 5 min cathodization at -1.2V (Fig. 2) the RTPS potentiodynamic run in the -0.9 to $+0.2$V range repeats the main features already known for the blank solution, namely, the positive going potential excursion involves the anodic current peaks IHA and IIHA related to the electrodesorption of hydrogen adatoms and the IOA, IIOA, and IIIOA which correspond to the oxygen electrosorbed layer on platinum. During the negative going potential excursion the following cathodic current peaks are recorded: IOC, pertaining to the electrodesorption of the oxygen layer, and IIHC and IHC related to the electrosorption of the hydrogen adatoms. The charge related to the current peaks IHA + IIHA is approximately equal to the charge involved in current peaks IHC + IIHC. Those charges are of the order of the charge of one monolayer of hydrogen adatoms, which for a smooth polycrystalline platinum surface is taken as 210 $\mu C/cm^2$ (8-10). The same charge balance extends also to the sum of current peaks IOA + IIOA + IIIOA which equals that of IOC. At potentials higher than 0.25V, however, the *E/I* displays are different. The presence of the nickel hydroxide species on the platinum electrode is reflected in the conjugated redox couple characterized by the current peaks INiA and INiC, which are recorded in the 0.30-0.65V range.

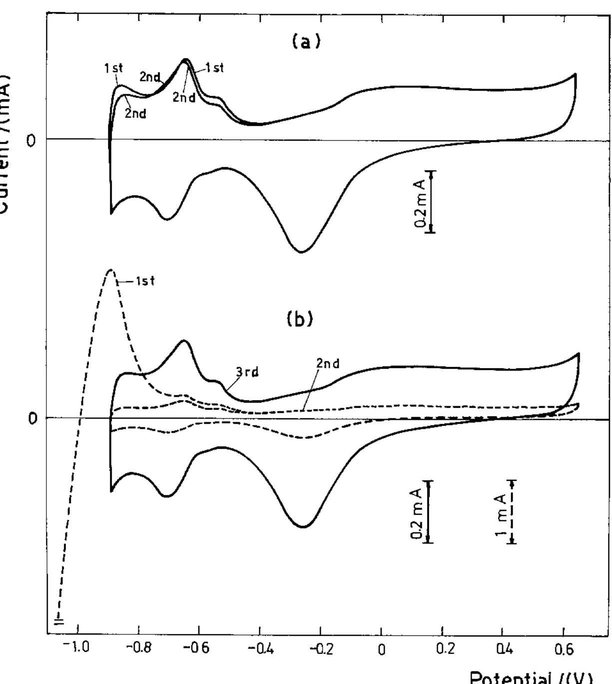

Fig. 1. Potentiodynamic *E/I* displays obtained under RTPS at 0.3 V/sec for platinum in the blank solution after a previous cathodization at different potentials. (a) 30 sec at -0.9V; (b) 1 min at -1.1V.

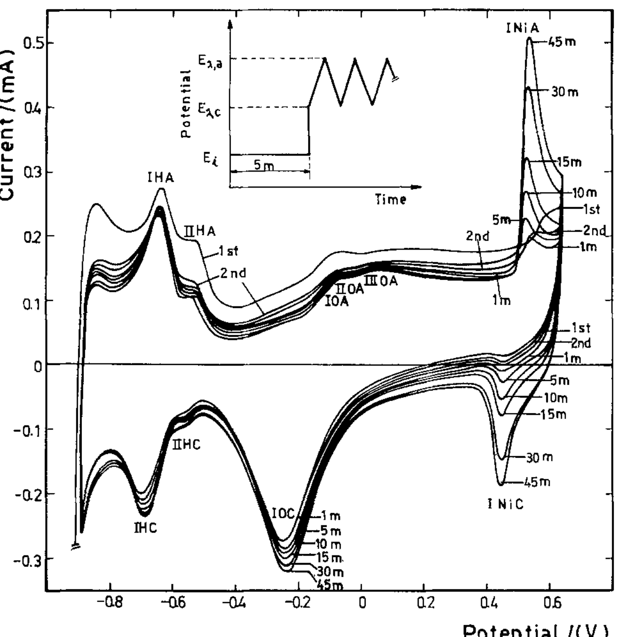

Fig. 2. Potentiodynamic displays run at 0.3 V/sec for platinum in the blank solution containing Ni(II) species after a previous cathodization at —1.2V during 5 min.

During the potential cycling obtained with a new electrolyte solution immediately after $NiSO_4$ additions the gradual change of the *E/I* profile is more noticeable in moving from the first to the second sweep, particularly in the positive going potential excursion. The latter exhibits a constant anodic current contribution throughout the whole potential range, but the currents of the redox couple related to the nickel hydroxide electrode are then more poorly defined. For the electrodes prepared according to either (*i*) or (*ii*), the potential of the anodic current peak is near 50 mV more positive than the peak potential in the stabilized *E/I* profile. The latter is recorded after about 60 min potential cycling and the corresponding charge, either anodic or cathodic, after the proper double layer charging and baseline corrections, is comparable to that of the hydrogen adatom current peaks. Within the -0.9 to $+0.4$V range the *E/I* display reaches a stable situation much faster than the portion of the *E/I* display related to the nickel hydroxide electrode. But, although the charges of the hydrogen and oxygen electrosorption regions remain unaltered during further potential cycling, the charge of the current peaks related to the nickel hydroxide electrode still increases to reach a constant value only after about 60 min.

When $0V \leq E_{\lambda,c} \leq 0.3V$, that is, $E_{\lambda,c}$ is more positive than the potential of the cathodic current peak IOC, the main effect produced in the *E/I* display is a slight shift of the anodic current peak potential INiA toward more positive value as $E_{\lambda,c}$ decreases (Fig. 3). Simultaneously, the cathodic current contribution of current peak IOC in the 0 to 0.3V range is appreciably reduced as $E_{\lambda,c}$ decreases. This corresponds to the potentiodynamic aging of the oxygen-containing monolayer on platinum already known (11).

The *E/I* profile of the nickel hydroxide redox couple is influenced by the anodic ($E_{\lambda,a}$) and cathodic ($E_{\lambda,c}$) switching potentials as depicted in Fig. 4. When $E_{\lambda,c}$ becomes more positive, within the potential range of current peak INiC, the positive going excursion exhibits the splitting of the anodic current peak INiA into two peaks. This behavior is the same as already described for the nickel hydroxide electrode on a nickel base which was attributed to the aging processes of the $Ni(OH)_2$ species (4, 5). The stabilized *E/I* profile, particularly during the negative going

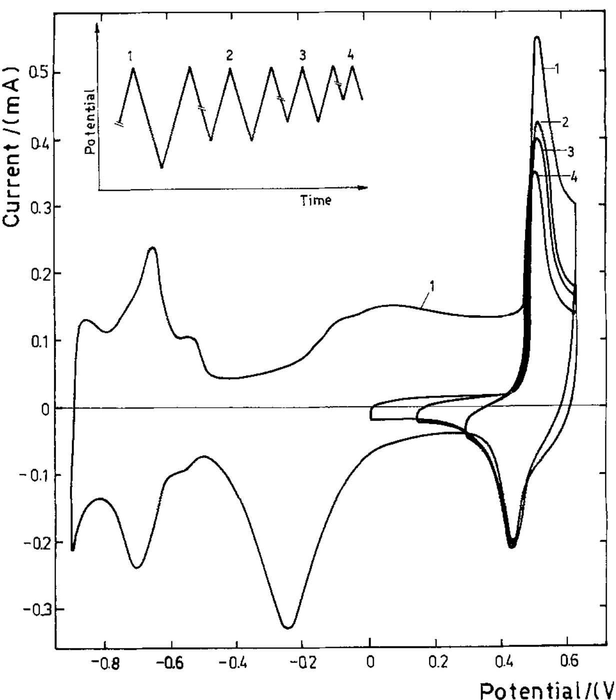

Fig. 3. Influence of the cathodic switching potential on the stabilized *E/I* profile at 0.3V/sec.

potential excursion, is slightly modified when $E_{\lambda,a}$ becomes more positive within the potential range exceeding that of the current peak INiA. The current peak INiC shifts toward more negative values as $E_{\lambda,a}$ increases. By further increasing $E_{\lambda,a}$ into the potential range of the oxygen evolution reaction one noticed that the latter reaction had no appreciable influence on the nickel hydroxide current peaks, with the ex-

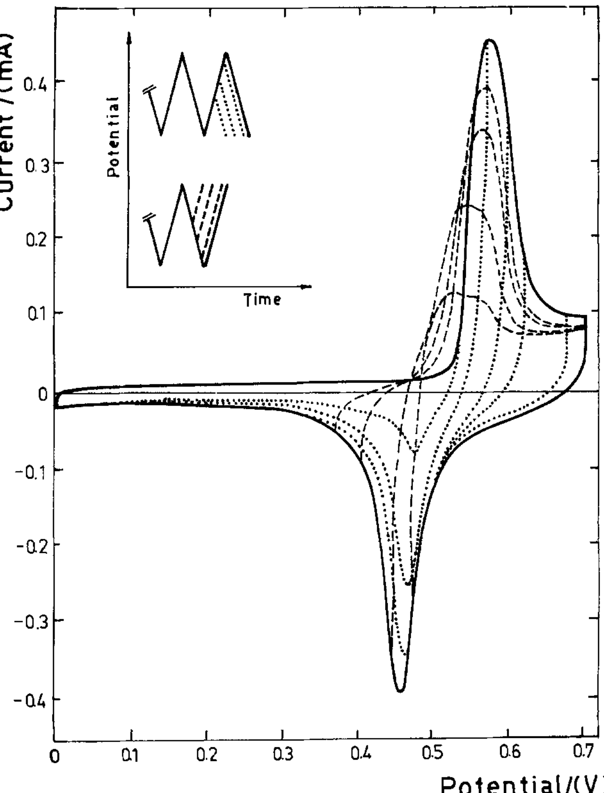

Fig. 4. Influence of the anodic and cathodic switching potentials on the *E/I* profile at 0.1 V/sec run with the platinum electrode in the potential range of the nickel hydroxide redox couple.

ception of changing the baseline cathodic current contribution predominantly in the potential region more negative than that of current peak INiC.

When platinum electrodes are left overnight in electrolyte solution in contact with the $Ni(OH)_2$ precipitate the resulting *E/I* profiles show a poor electrochemical response associated with the nickel hydroxide redox couple. To decide whether the formation of the nickel hydroxide redox couple is due either to the deposition on the platinum surface of $Ni(OH)_2$ out from the solution or to the $Ni(OH)_2$ produced by the alkalinization of the interface during cathodization in the presence of Ni(II) in solution, experiments were made with a freshly decanted $Ni(OH)_2$ saturated solution and with a solution that had been decanted for three days. The *E/I* displays obtained with the fresh solution show only small current peaks while practically no current peaks are recorded with the latter. By adding to the fresh solution the previously separated $Ni(OH)_2$ precipitate, small current peaks are observed but the charge corresponding to the nickel hydroxide electrode shows no further increase during the potential cycling. In contrast, after the addition of $NiSO_4$ solution to the electrolyte in the cell, the *E/I* profiles exhibit the features already described but without requiring the cathodization in the hydrogen evolution region.

The greatest charge contribution of the $Ni(OH)_2$ redox couple is achieved when the $NiSO_4$ solution is added to the blank just in the vicinity of the electrochemical interface. Under these circumstances, if the $Ni(OH)_2$ layer is now rapidly removed from the electrode and the latter is put back into the same solution without a further addition of $NiSO_4$, the contribution of the nickel hydroxide current peaks are much lower than those previously observed. The first situation, however, can be reproduced by a further addition of $NiSO_4$ to the electrolyte. These experiments show, therefore, that the efficiency of the solution to produce $Ni(OH)_2$ species on platinum, decreases relatively rapidly after the $NiSO_4$ addition. The precathodization of the interface seems to be less important than the nucleation and growth of the first $Ni(OH)_2$ layer to accomplish the formation of the nickel electrode redox couple on the platinum electrode. To confirm those results the $Ni(OH)_2$ film was prepared according to procedure (*iii*) (Fig. 5). The electrode was immersed for 15 min in the $HNO_3 + H_2SO_4$ mixture, then, washed in thrice distilled water, dipped for 5 min in the alkaline solution, and immediately afterward immersed in the $NiSO_4$ solution for another 5 min. Finally, the electrode was cathodized at $-0.8V$ in the blank solution during 30 sec before running the RTPS between -0.8 and $+0.7V$. The first *E/I* display at 0.3 V/sec shows all the features already described, but the overall charge increases rapidly during the four first triangular potential sweeps. Later the rate of the charge increase diminishes to attain a stable charge after 5-10 min potential cycling. Further potential cycling produces net shifts of current peaks INiA, INiC, and IOC toward more positive values. The same effect is also observed on current peak IIHC and probably also on the baseline related to the oxygen evolution reaction. Furthermore, the longer the time of the potential cycling the larger the current peak INiA potential shift toward more positive potentials. If the INiA current peak involves the contribution of two current peaks whose separation is about 50 mV, then, initially the one at more negative potentials prevails while as the potential cycling continues the one at the more positive potential side becomes more important. The amount of charge playing a part in the nickel hydroxide electrode potential range attains a limiting value with the potential cycling as described above. The limiting charge slightly increases with the immersion time in the solutions involved in procedures (*iii*) (Fig. 6), but it increases dramatically with the

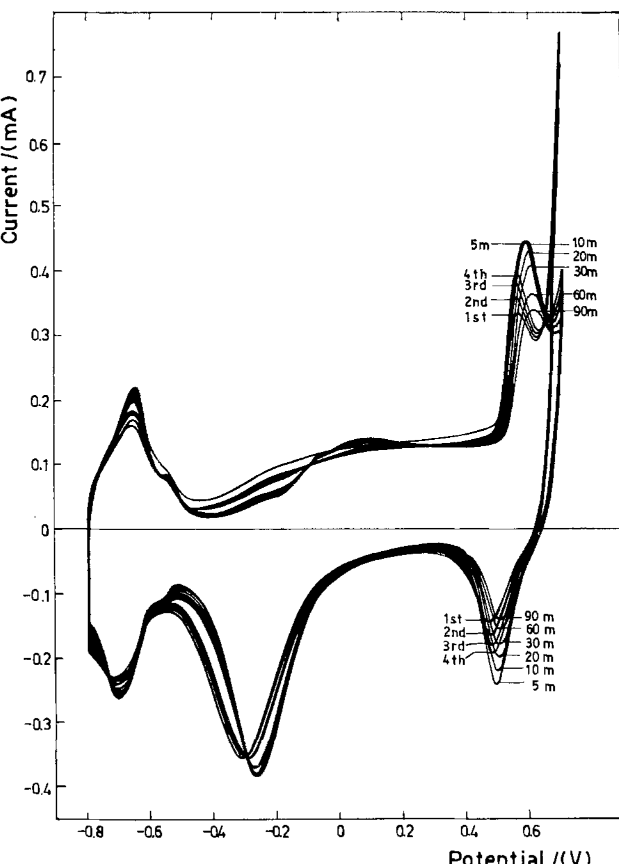

Fig. 5. Successive potentiodynamic *E/I* displays obtained under RTPS at 0.3 V/sec after a previous cathodization at −0.8V during 30 sec. The nickel hydroxide electrode was prepared by dipping the platinum electrode during 5 min in the blank solution and immediately afterward in the $NiSO_4$ solution for another 5 min.

number of the alternative immersions performed at a constant immersion time (Fig. 7). The charge increase is accompanied by shifts of the potentials of current peaks INiC and INiA. Although the potential shift of the INiC current peak follows no simple dependence on the number of immersions, that of peak INiA becomes more negative as the number of immersions increases. The charge increase of current peaks INiC and INiA has no appreciable influence on the rest of the potentiodynamic current peaks under the conditions depicted in Fig. 7.

The complexity of the *E/I* profile related to the nickel hydroxide electrode is also revealed by running stabilized RTPS potentiodynamic *E/I* profiles in the 0.3-0.7V range, at different potential sweep rates v (Fig. 8). The current peak heights, either INiA or INiC after correction for double layer charging and baseline effects, increase almost linearly with v. The charges involved are independent of v. The INiA current peak moves toward more positive values as v increases, but no definite shift is observed for current peak INiC. Nevertheless, the peak potential dependence on v is certainly more complex because of the composite characteristics of the potentiodynamic current peaks associated with the nickel hydroxide electrode (3-5).

The nickel hydroxide electrode perpared by any of the above described procedures remains active after having been removed from the electrolyte, washed with water, and again placed into the electrolysis cell.

Discussion

The potentiodynamic response of the platinum-nickel hydroxide-electrolyte multiple interface in the potential range of the electrochemical stability of water, reveals that there are three net potential ranges where

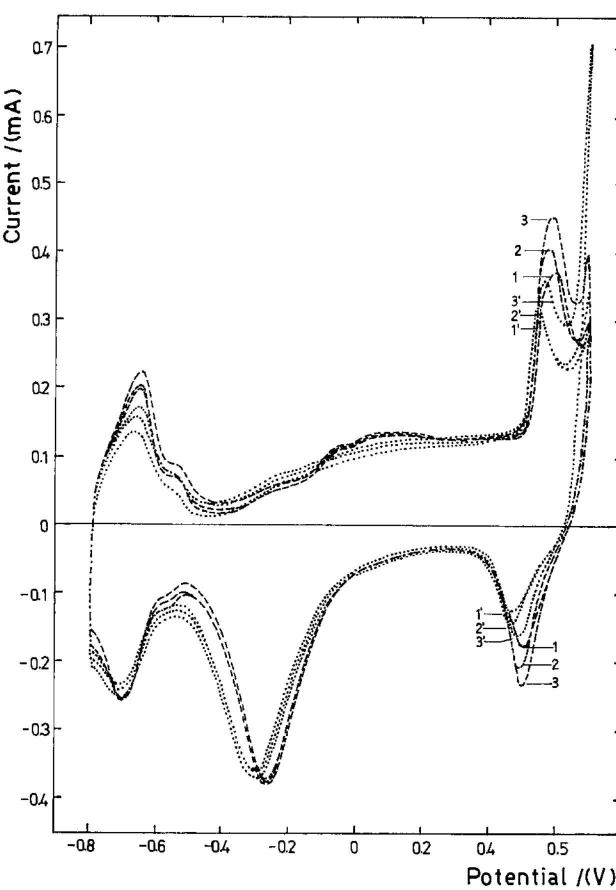

Fig. 6. Influence of the time (τ) spent during a single immersion of the platinum electrode in both the blank solution and the $NiSO_4$ solution on the potentiodynamic *E/I* displays run at 0.3 V/sec. The *E/I* displays 1, 2, and 3 are recorded during the second RTPS. The *E/I* displays 1′, 2′, and 3′ are recorded after 5 min RTPS. $\tau = 10$ sec (1 and 1′). $\tau = 1$ min (2 and 2′). $\tau = 5$ min (3 and 3′).

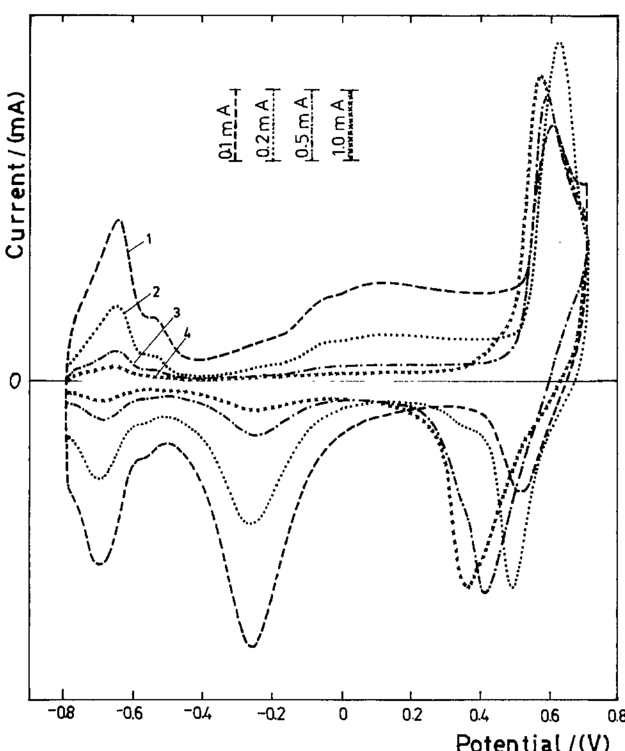

Fig. 7. Influence of the number of alternative immersions of the platinum electrode in the blank and in the $NiSO_4$ solution ($\tau = 10$ sec) on the potentiodynamic *E/I* displays run at 0.3 V/sec after 15 min RTPS. 1, 2, 3, and 4 correspond to a single, twice, ten times, and fifty times immersion in each solution, respectively.

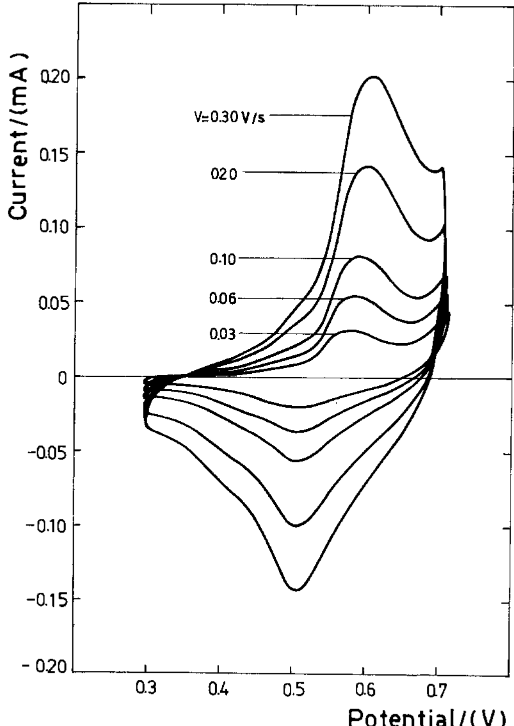

Fig. 8. Potentiodynamic *E/I* displays run with the stabilized nickel hydroxide electrode at different potential sweep rates.

the following three conjugated electrode processes are successively taking place along with the progressive potential excursions. In the −0.8 to −0.5V range

$$Pt(H) = Pt + H^+ + e \quad [1]$$

in the −0.5 to 0.2V range

$$Pt + H_2O = PtO + 2H^+ + 2e \quad [2]$$

and in the potential range just preceding the electrochemical evolution of oxygen

$$Ni(OH)_2 = NiOOH + H^+ + e \quad [3]$$

Reactions [1] and [2] have been discussed in detail both in acid and alkaline electrolytes in numerous recent publications (11-19). They include, together with the proper electrochemical reactions, chemical and structural transformations of the various reactants and products participating in the overall reactions in both directions, which were described under the general term of aging processes. They exhibit time-dependent electrochemical spectra as expected for the gradual formation of species of more stable configuration on the electrode surface. Reaction [3] exhibits practically the same characteristics already described for the nickel hydroxide electrode on nickel, comprising the same type of splitting of the anodic and cathodic current peaks. Those splittings are assigned to the aging of both the $Ni(OH)_2$ and NiOOH species due to chemical transformations, so that at least two different $Ni(OH)_2$ species and two different NiOOH species participate in the electrochemical processes. The instantaneous ratio of the two species for both $Ni(OH)_2$ and NiOOH depends on the time elapsed since each species started to be either cathodically or anodically formed. This means that chemical transformations occur both under open-circuit conditions and also simultaneously with both electron transfer processes. So, the simplest reaction scheme can be put forward as follows

$$\begin{array}{ccc} [Ni(OH)_2]_u & \rightleftarrows & [NiOOH]_s + H^+ + e \\ \downarrow & & \uparrow \\ [Ni(OH)_2]_s & \rightleftarrows & [NiOOH]_u + H^+ + e \end{array} \quad [4]$$

where u and s denote unstable and stable species, respectively. Reaction scheme [4], however, neglects the occurrence of crossed electrochemical reactions as recently reported under special perturbation conditions (20).

The present data, besides confirming recently reported results concerning reaction (4), are important for the interpretation of the nickel hydroxide conjugate reactions without the uncertainty of the changing roughness factor which occurs when the nickel hydroxide species are produced by corrosion of the nickel base metal. The roughness factor of the base platinum electrode is otherwise known either through the charge of the hydrogen adatoms monolayer or through the charge required to electrodesorb the oxygen layer formed on platinum, which for the switching potential limits of the present experiments, is exactly twice the charge of the former.

Two clearly different limiting cases can be distinguished depending on the overall charge involved in the potentiodynamic electroformation of the nickel hydroxide electrode. When the charge participating in the process is of the order of the hydrogen adatom monolayer the first potentiodynamic sweep depicts predominantly one anodic and one cathodic current peak associated with the conjugated nickel hydroxide reactions. The corresponding current peaks suggest then that the prevailing reaction is

$$[Ni(OH)_2]_u = [NiOOH]_u + H^+ + e \quad [5]$$

that is, the electrochemical reaction involves the more reactive $Ni(OH)_2$ and NiOOH species. On the other hand, the transformation of the $[Ni(OH)_2]_u$ species into the $[Ni(OH)_2]_s$ species is facilitated when the charge involved in the nickel hydroxide electrochemical reaction gradually increases to exceed that of the hydrogen adatom monolayer. Hence, the present results demonstrate that under the conditions of a low surface coverage by the $Ni(OH)_2$ species, the interpretation of the electrooxidation of $Ni(OH)_2$ can be approached by the single electron transfer represented by reaction [5].

When the amount of nickel hydroxide exceeds several times the hydrogen adatom monolayer and the $Ni(OH)_2$ species constitutes an actual phase, then its average composition depends on the type and time constants of the potential perturbation program applied to the interface. A comparison of the different *E/I* profiles during the successive potential cycling shows the increasing contribution of the reactions indicated in scheme [4]. In case (*ii*) the electron transfer reactions occurring in the multiple interface can be assigned to two different limiting reaction planes according to the model previously described (1). The plane related to the $Pt/Ni(OH)_2$ (hydrated) interface is the site of reactions [1] and [2]. Another plane is ascribed to the $Ni(OH)_2$/solution interface. The proton (or OH^-) transfer process associated with reaction [3] occurs both through the latter plane and through the $[Ni(OH)_2\text{-}NiOOH]$ layer located between the two limiting planes. For the latter reaction the oxidized platinum electrode surface acts mainly either as an electron source or an electron sink. Hence, the reactions taking place in the metal plane, when the positive going potential excursion starts from the hydrogen adatoms potential range up to the nickel hydroxide electrode potential range, can be put forward as follows

$$Pt_x[PtH][Ni(OH)_2 \cdot nH_2O]^* + OH^- = Pt_x[Pt][Ni(OH)_2 \cdot (n+1)\,H_2O]^* + e \quad [1a]$$

$$Pt_x[Pt][Ni(OH)_2 \cdot (n+1)\,H_2O]^* + 2\,OH^- = Pt_x[PtO]^*[Ni(OH)_2 \cdot (n+2)\,H_2O]^* + 2e \quad [2a]$$

where n is the number of hydration water molecules in the nickel hydroxide layer and x refers to bulk platinum. At more positive potentials, in the nickel hydroxide layer

$$Pt_x[PtO]^*[Ni(OH)_2 \cdot (n+2)\,H_2O]^* + OH^- = Pt_x[PtO]^*[NiOOH \cdot (n+3)\,H_2O]^* + e \quad [3a]$$

Analogously, during the negative going potential excursion within the same switching potential range, the complementary overall reactions can be written as follows. In the nickel hydroxide layer

$$Pt_x[PtO]^{**}[NiOOH \cdot (n+3)\,H_2O]^{**} + e = Pt_x[PtO]^{**}[Ni(OH)_2 \cdot (n+2)\,H_2O]^{**} + OH^- \quad [3c]$$

and at the metal plane, at more negative potentials

$$Pt_x[PtO]^{**}[Ni(OH)_2 \cdot (n+2)\,H_2O]^{**} + 2e = Pt_x[Pt]\,[Ni(OH)_2 \cdot (n+1)\,H_2O]^{**} + 2\,OH^- \quad [2c]$$

and

$$Pt_x[Pt][Ni(OH)_2 \cdot (n+1)\,H_2O]^{**} + e = Pt_x[PtH][Ni(OH)_2 \cdot nH_2O]^{**} + OH^- \quad [1c]$$

Reactions [1a]-[3a] and [3c]-[1c] also involve the corresponding OH^- ion transfer processes from the solution side of the interface to the multiple interface or the reverse, respectively. The brackets indicate the two different reaction regions, namely, the metal surface and the nickel hydroxide film. The single and double asterisks denote that the average energetic configuration of reactants and products, either in the anodic or the cathodic reactions, are different because of the aging processes.

The formation of the nickel hydroxide electrode on platinum produces a simultaneous decrease of the aging effect of the PtO species. This means that the PtO monolayer aging is coupled to some extent to the nickel hydroxide electrode reactions through a pseudostabilization of the PtO transient species with either the $Ni(OH)_2$ or the NiOOH species on the electrode surface. The stabilization can be assisted through a structural unit such as either a $[PtO + Ni(OH)_2]$ or a $[PtO + NiOOH]$ surface complex unit. These structures involve the innermost layer of the $[Ni(OH)_2 + NiOOH]$ film which is just in contact with the PtO surface. According to recent results, the PtO aging is principally related to a surface reaccommodation process (11) formally written as

$$[Pt]_x[Pt_yO_z]_u \rightleftarrows [Pt]_x[Pt_yO_z]_s \quad [6]$$

where x refers to the bulk metal and $z \leq y$ and $z \rightleftarrows y$ when the monolayer is formed. Therefore, through a binding between $[Pt_yO_z]_u$ with either the $[Ni(OH)_2]$ or the [NiOOH] species different surface structures are achieved. Hence, the place exchange mechanism according to reaction [6] is partially impeded by the adsorption of either the $[Ni(OH)_2]$ or the [NiOOH] species on the Pt(O) surface. The stabilization of the surface species can be accounted for, at least in part, through the participation of hydrogen bonding.

The fact that the nickel hydroxide electrode on platinum is formed without requiring a simultaneous cathodization before running the potentiodynamic experiments and that the solution where $Ni(OH)_2$ precipitates loses its property of generating the electrochemically active redox couple deserves a further comment in terms of the chemistry of the colloidal system involved. Those systems are unstable in the thermodynamic sense causing the accustoming of colloidal system (21), the coarsening or ripening of precipitates (22), as well as other aging effects (23, 24). All these effects are strongly dependent on the solution composition, pH, time of aging, nature of anions present and other topological transformation, and preparation conditions. Unfortunately, despite numerous investigations

little is still known about the mechanism of metal hydroxide and oxide precipitation (23).

However, under the conditions prevailing during the $Ni(OH)_2$ precipitation on platinum one should recognize that most of those variables are also involved. Thus, it seems that the largest efficiency of the nickel hydroxide electrode, as measured through the charge involved in the *E/I* profile, is attained when the $Ni(OH)_2$ precipitation occurs from fresh solutions and as close as possible to the electrode surface. If the nucleation of the precipitate can occur either on the metal surface or in the bulk of the solution, the former situation is largely favored in the conditions where the greatest efficiency has been attained. The coarsening and aging of the precipitate adversely influence the yielding of the nickel hydroxide electrode formation. Therefore, besides the study of the proper electrode processes, the present results offer the possibility of establishing promising relations between the multiple interface electrode systems and the physicochemical characteristics of colloidal systems.

Some Electrochemical Properties of Strong Organic Acids for Use as Fuel Cell Electrolytes: Methane Sulfonic, Methane Di-sulfonic, Trichloroacetic, Chloro-Difluoroacetic, Pentafluoropropanoic, Benzoic, and Benzene Sulfonic Acids

ABSTRACT

Several organic acids have been evaluated as possible electrolytes for the oxidation of hydrogen. The tests performed included electrical resistivity and vapor pressure measurements at various temperatures. Current-potential relations were obtained at both platinized-platinum rotating disk electrodes and Teflon-bonded, platinum-black gas diffusion electrodes. Most of the acids underwent chemical or electrochemical breakdown. Out of the electrolytes tested, the only one holding any promise as a fuel cell electrolyte is methane sulfonic acid. As a result of this work certain classes of compounds should be ruled out as candidates, *e.g.*, halogenated fatty acids and certain aromatic acids, *e.g.*, benzoic and benzene sulfonic acids.

This paper presents the results of a search for organic electrolytes which perform better than phosphoric acid as an electrolyte in fuel cells using H_2 or H_2-CO mixtures. There are several obvious requirements for the "ideal" electrolyte (1) as follows: (*i*) availability of suitable ions for fuel oxidation at the anode and oxygen reduction at the cathode, (*ii*) high ionic conductivity, (*iii*) good solvent, that is, high values of solubility-diffusivity products for fuel and oxidant, (*iv*) chemically inert toward fuel, oxidant, and reaction products (CO_2 and water), (*v*) stability over the voltage ranges involved, (*vi*) since water must be removed from the cell, the electrolyte must have a low vapor pressure (high boiling point) to avoid a complicated condensing-separation system, (*vii*) negligible absorbability on, and poisoning of, the electrode materials, and (*viii*) noncorrosive toward cell and electrode materials.

With the above requirements in mind, we performed a literature search which suggested a number of classes of organic acids as possible electrolytes on the basis of their melting and boiling points. Table I shows the properties of seven acids selected for study.

The tests performed include ionic conductivity and vapor pressure as a function of temperature and electrochemical performance with H_2 or H_2-3%CO as reactant. Two types of electrochemical tests were performed. Use of a gas diffusion electrode with the electrolyte gives a directly revelant measure of fuel performance. Tests with a rotating disk electrode in electrolyte saturated with H_2 indicate whether the reaction rate is controlled by mass transfer or by electron transfer kinetics.

Experimental Techniques

The resistivity of the various electrolytes was measured at various temperatures using a microconductivity cell (3403 Yellow Springs Company, cell constant = 1 cm^{-1}) and a digital conductivity bridge (Barnsted PM-70CB). The temperature was adjusted using an oil bath. The isoteniscope technique (2) was chosen for measuring the saturated vapor pressure of the liquid.

The rotating disk electrode (RDE) assembly is shown in Fig. 1. The electrode was a disk of platinum force-fitted into the Teflon head. Best results were obtained with the disk lightly platinized. Double layer capacity measurements in 85% H_3PO_4 at 135°C in the range of 250-450 mV *vs.* a dynamic hydrogen electrode

Table I. Melting and boiling points of selected electrolytes

Electrolyte	Formula	MP (°C)	BP (°C)	Manufacturer
Benzene sulfonic acid-hydrate	$C_6H_5SO_3H \cdot 1.5H_2O$	45-46	—	Eastman Kodak
Methane disulfonic acid	$CH_2(SO_3H)_2$	—	220	Eastman Kodak
Trichloroacetic acid	CCl_3CO_2H	54-58	196	Aldrich
Pentafluoropropanoic acid	$C_2F_5CO_2H$	—	96	ICN Pharmaceutical Incorporated
Chlorodifluoroacetic acid	$ClCF_2CO_2H$	24-26	122	Aldrich
Benzoic acid	$C_6H_5CO_2H$	118	249	Baker
Methane sulfonic acid	CH_3SO_3H	20	—	Eastman Kodak

(3) gave a capacity of 6.7×10^3 μF/cm^2, suggesting a surface roughness of about 270 (using 25 μF/cm^2 for bright platinum). Rotation speed was measured with a phototachometer. The cell used with the gas diffusion electrode and the RDE (Fig. 2) was designed to meet the requirements: (*i*) small total volume (~15 ml) in view of the cost and availability of some of the electrolytes, (*ii*) separate compartments for the reference, working and auxiliary electrodes to prevent contamination of the electrolyte in the working electrode compartment with products of the reactions taking place in the other compartments, (*iii*) compatibility with an RDE assembly, with sufficient depth of electrolyte to avoid nonideal circulation of liquid to the rotating surface, (*iv*) ensurance of continuous saturation of the electrolyte with the fuel gas. The cell incorporated a dynamic hydrogen reference electrode (3) which is maintained at a small steady potential by passing a cathodic hydrogen evolution current of 1 mA cm^{-2} provided by an auxiliary circuit.

The designs of the porous gas-diffusion electrode and its holder were those described by Almaula and Austin for sulfuric acid (4). The electrode holder was made of two Teflon parts. The bottom part exposes one side of the electrode to the electrolyte and the other to the reactant gas. The top part has two concentric glass tubes through its length; the inner is the inlet of the gas (which is kept slightly above atmospheric pressure) and the outer is the outlet of the unreacted gas. The porous gas diffusion electrodes were made by pressing an homogenous paste of Pt-black and Teflon dispersion (du Pont 30) into a disk in a steel die to 18,000 psi for 2 min. It was dried at 50°C

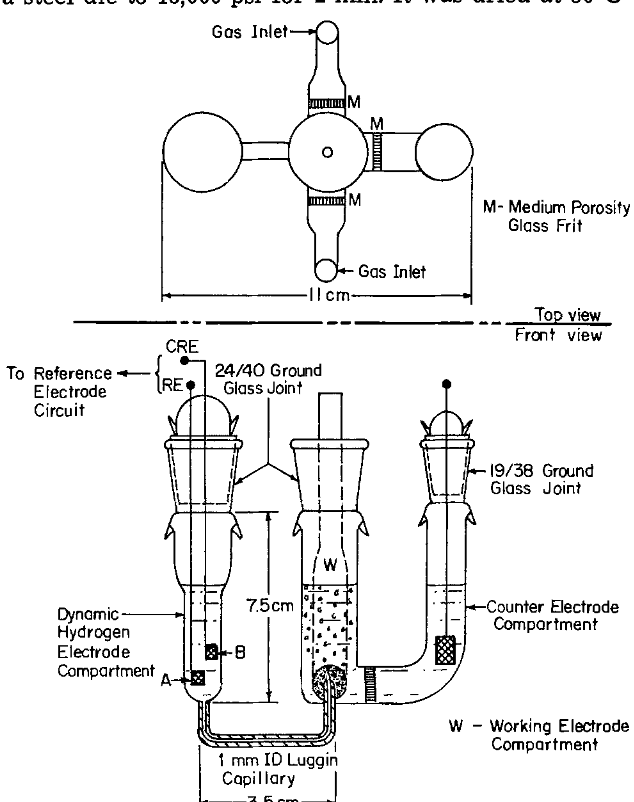

Fig. 2. Schematic of electrochemical cell

for 1 hr, taken to 350°C over 5 min, and sintered for 2 min at 350°C. Electrodes prepared with a platinum screen were found to crack when heated in concentrated phosphoric acid at 135°C and gave irreproducible *IR* corrections. This has been attributed to the recrystallization of the Pt-black on the Pt screen (5, 6). More stable electrodes were obtained by pressing the Pt-black and Teflon paste onto a tantalum screen (45 U.S. mesh) (6).

Current densities at a desired potential between test and reference electrodes were measured with a Wenking or an Aardvark potentiostat. Corrections were made for the *IR* drop in the electrolyte path between the Luggin tip and the test electrode face by using the blanked-out portion of an oscilloscope trace after current interruption. The oscilloscope was connected to measure the test-reference potential at a steady current and the current interrupted with a rapid switching circuit which also triggered the trace.

Due to experimental difficulties encountered with obtaining reproducible results from phosphoric acid, and the differences in the properties of various electrodes, a comparison technique was used. Before each electrolyte was run at the desired temperature on a certain electrode, the electrode was tested with H_2 fuel in 1*N* H_2SO_4 at 25°C. This system gives well-defined limiting currents for Teflon-bonded electrodes which are not flooded (4). The ratio of the limiting current obtained in the particular electrolyte at a certain temperature to that obtained in sulfuric acid at 25°C was taken as a measure of the efficiency of the electrolyte. This ratio was found to be about 1.6 for 85% H_3PO_4 at 135°C. Table II lists the properties of the various electrodes used in this work. Figure 3 shows the current-potential relations obtained in 1*N* H_2SO_4 at 25°C and in 85% H_3PO_4 at 135°C using H_2 gas as fuel at the same electrode. The limiting current was taken to be the current at 500 mV *vs.* DHE.

Fuel gas was supplied to the cell through a train consisting of columns of Ridox (oxygen scavenger, Fisher Scientific), KOH, and Drierite. The phosphoric acid was purified using the H_2O_2 treatment recommended by Appleby (7), and the organic electrolytes were used as supplied.

Results and Discussion

Figure 4 shows the plots of log conductivity *vs.* 1/*T* for the electrolytes tested. Measurements were performed in both the ascending and descending direc-

tions with respect to temperature. No significant hysteresis was observed except when significant amounts of water existed in the electrolyte and only when measurements were taken at high temperatures as, for example, with the 90% aqueous solution of CCl_3CO_2H. The straight lines shown are least squares correlations of the data. The results on the 85% H_3PO_4 agree well with the literature values (8). Table III lists the straight line equation, the correlation coefficient, and the temperature range over which the measurements were taken. In the case of the 90% aqueous solution

of CCl_3CO_2H, hysteresis occurred due to loss of water, and the correlation is based on the low temperature results. It was concluded that methane disulfonic acid was the only electrolyte tested which had sufficient conductivity to compare with phosphoric acid.

The system for vapor pressure measurement was tested using benzoic acid, giving the result shown by curve 1 in Fig. 5. Although there is some scatter in the data points, the overall results agree with the accepted literature values, and the apparatus is considered adequate for the purpose of the present study.

Figure 5 also shows plots for benzene sulfonic acid, both 10% aqueous solution and anhydrous pentafluoropropanoic acid, and trichloracetic acid. The results satisfactorily fit straight lines over the studied range of temperatures. Table IV summarizes the results.

Background Currents

Methane sulfonic acid gave the lowest background current of all the tested electrolytes (about 6% of the measured current at the limiting current at various temperatures for both the gas diffusion and the rotating disk electrodes). The corresponding percentages for the other electrolytes are: pentafluoropropanoic acid, 3% at low potentials increasing to 60% at the limiting current; chlorodifluoroacetic acid, 10% of the measured current at all potentials for both 23° and 50°C; benzene sulfonic acid hydrate, 20% at 60°C; methane disulfonic acid, less than 10%. All the acids tested (except one) gave anodic background currents. Trichloroacetic acid was the only acid which gave a

cathodic background current up to 500 mV DHE, increasing in magnitude with decreasing anodic potential.

The experimental results obtained on the various electrolytes are presented below, along with the relevant experimental observations. All the electrolytes were tested with H_2 and some were also tested with H_2-3% CO to see whether CO poisoned the electrode. The results are as follows.

Pentafluoropropanoic acid (90 weight percent aqueous).—The ratio of limiting currents was less than 10^{-3}. The resistivity of this solution at 25°C is 335 Ω cm. The electrolyte underwent polymerization on heating to 50°C. This electrolyte also had an undesirably high vapor pressure (see Fig. 5).

Trichloroacetic acid.—This electrolyte had to be diluted with water to give reasonable resistivity. The measured resistivities were 1240 and 23 Ω cm at 25°C for the 90% and 70 weight percent (w/o) aqueous solutions, respectively. Figure 6 shows the current-potential relations obtained on the 70% acid solution at 25°C. The ratio of limiting currents is 0.22. It was noticed that chlorine gas evolved on heating this electrolyte. The acid itself (without dilution) also has an excessively high vapor pressure (see Fig. 5) and it is known to be hygroscopic.

Chlorodifluoroacetic acid.—Measurements were performed on this acid at 23° and 50°C, see Fig. 6. The ratio of limiting currents was less than 10^{-3}. The decomposition of the acid leading to production of chlorine was also evident. The resistivities were 168 and 140 Ω cm at 23° and 50°C, respectively.

Benzene sulfonic acid hydrate.—At 60°C the limiting current ratio is 0.06, see Fig. 6. The acid resistivity was 108 Ω cm at 60°C and the vapor pressure is fairly high. The acid decomposed, turning from the light brown color into a black color, on heating to higher temperatures in presence of the Pt-black electrode.

Methane disulfonic acid (50% aqueous).—Figure 7 shows the results obtained in this acid at two different temperatures for H_2 fuel. The limiting current ratios were 0.33 and 0.47 at 27° and 54°C, respectively. The electrical resistivities were quite low; 3 and 2.5 Ω cm at 27° and 54°C, respectively. Measurement at 80°C gave irreproducible results due to the excessive loss of water. The nonaqueous acid is a very hygroscopic material which boils at 220°C. The only commercially available form is the 50% aqueous solution.

Benzoic acid.—Although this acid has a reasonable vapor pressure, it was ruled out because of its extremely high electrical resistivity; the values obtained were 2.1×10^7, 2.0×10^7, and 1.9×10^7 Ω cm at 135°, 141°, and 153°C, respectively. The acid is also insoluble in water.

Methane sulfonic acid.—This electrolyte was chosen on the basis of its low vapor pressure, 10 mm Hg at 167°C (9), and relatively low resistivity of 66 Ω cm at 135°C. It is also available in reagent (>98%) and practical (>95%) grades, the latter being much cheaper than the former. Figure 8 shows the results obtained on the practical grade acid for the oxidation of both H_2 and H_2-3% CO fuels at 50°, 90°, 135°, and 145°C. The limiting current ratios for H_2 oxidation are 0.14, 0.09, 0.55, and 3.7, respectively. Similar results were obtained with H_2-3% CO, but the presence of CO poisoned the electrode surface and caused continuous decrease in the current. The results on H_2-3% CO were obtained by allowing the electrode to rest at open circuit between each current and potential reading; the current was recorded before the start of the excessive drift.

There were several reasons for also using the rotating disk electrode technique in this work: (*i*) it clearly distinguishes between chemical and mass transfer-limited reactions and (*ii*) it provides for well-defined and reproducible hydrodynamic conditions at the electrode surface regardless of the electrolyte or the fuel gas used. For mass-transport limited reactions,

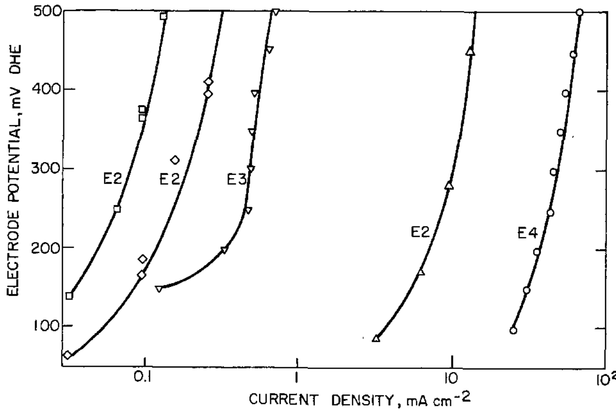

Fig. 6. Current-potential relations for H_2 oxidation at a platinum black, Teflon-bonded gas diffusion electrode in: E_2 chlorodifluoroacetic acid; at 23° and 50°C., respectively; E_3 pentafluoropropanoic acid (90 w/o aqueous) at 26°C; E_2 benzene sulfonic acid hydrate at 60°C; and E_4 trichloroacetic acid (70 w/o aqueous) at 27°C (see Table II).

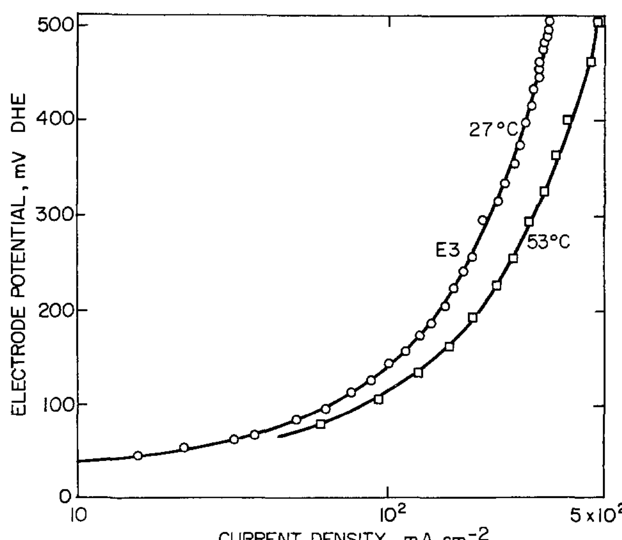

Fig. 7. Current-potential relations for H_2 oxidation at a gas diffusion electrode in methane disulfonic acid (50 w/o aqueous) at 27° and 53°C; i_L (1N H_2SO_4) is 950 mA cm^{-2}.

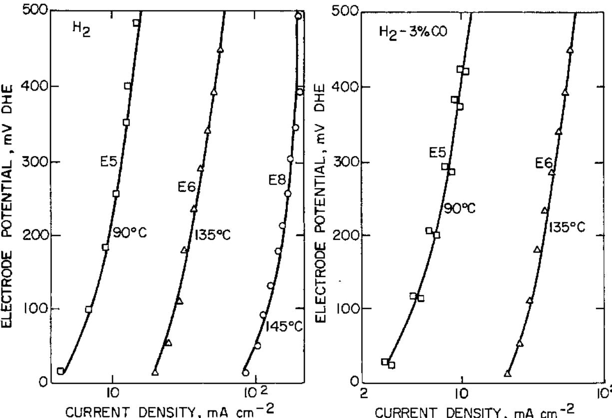

Fig. 8. Current-potential relations for the oxidation of H_2 and H_2-CO in methane sulfonic acid at a gas diffusion electrode at 90° and 135°C, curves 1 and 2, respectively. Curves 1 are to be compared with an i_L (1N H_2SO_4) of 167 mA cm^{-2}.

it is possible to estimate the solubility-diffusivity product of the fuel gas in the particular electrolyte, using the Levich equation (10) and independent measurements of solubility and kinematic viscosity

$$i_L = 0.62\, n\mathbf{F}D^{2/3}\omega^{1/2}\nu^{-1/6}C$$

where i_L is the mass-transfer limiting current density, n is the number of electrons transferred per molecule, **F** is the Faraday constant, D is the diffusion coefficient, $\omega = 2\pi N$, where N is the number of rotations per second, ν is the kinematic viscosity, and C is the equilibrium concentration of the fuel gas in the electrolyte at the test temperature and gas pressure.

Figure 9 shows current-potential relations for H_2 oxidation at a platinized-platinum electrode at 135°C in both 85% H_3PO_4 and the technical grade methane sulfonic acid (MSA) at various rotation speeds. Clearly at the same potential and the same (or a comparable) rotation speed, methane sulfonic acid supports currents that are more than an order of magnitude higher than those obtainable in phosphoric acid. In fact, the currents obtainable at 500 mV in this acid at 35°C are

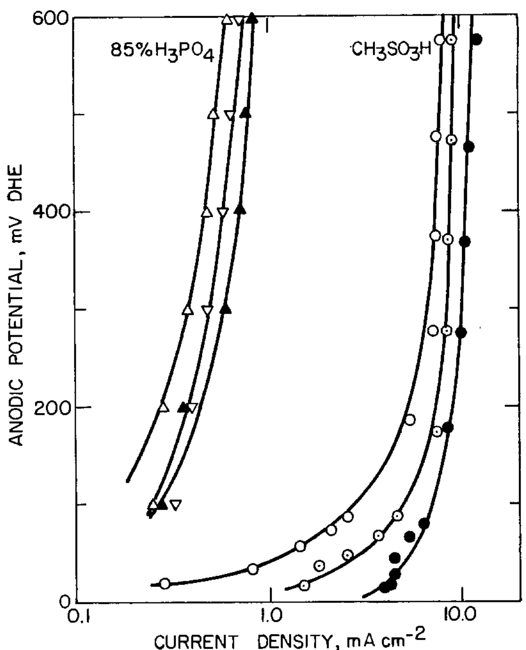

Fig. 9. Current-potential relations for the oxidation of H_2 at a platinized Pt rotating disk electrode in both methane sulfonic acid (at 800, 1000, and 1650 rpm) and 85% H_3PO_4 (at 800, 1000, and 1500 rpm) both at 135°C.

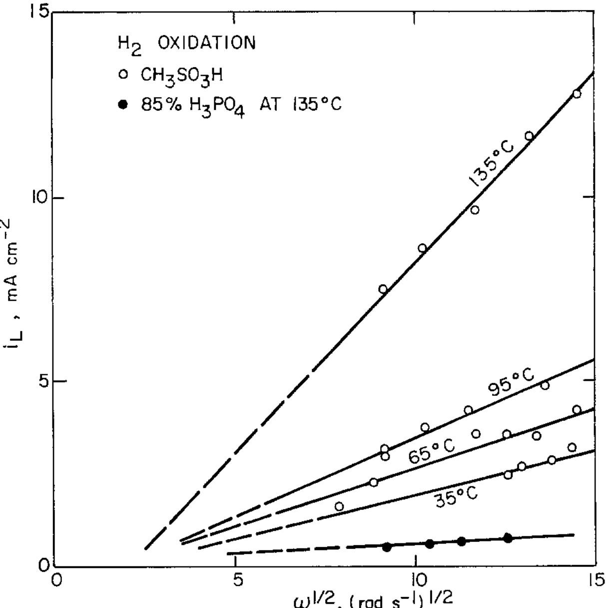

Fig. 10. Plots of the limiting current for H_2 oxidation at a platinized Pt RDE in methane sulfonic acid at various temperatures and in 85% H_3PO_4 at 135°C.

comparable to those obtained in 85% H_3PO_4 at 135°C, see Fig. 10. This figure shows the results obtained in MSA at various temperatures and rotation speeds, plotted according to the Levich equation. Although satisfactory straight lines are obtained, extrapolation of the lines does not go through the origin as required by the Levich equation. This does not seem to be caused by the relatively small size of the cell as compared to the electrode diameter, since the samé cell gave equivalent plots passing through the origin for the redox couple of ferri-ferrocyanide and for H_2 oxidation in 1N H_2SO_4 at 25°C. It is concluded that the limiting currents are a combination of mass transfer and chemical-limiting current effects.

Figures 11a and 11b show Arrhenius plots for the rates of hydrogen oxidation in MSA (a) for the ratio of limiting current densities at a porous gas-diffusion electrode and (b) for $i_L/\omega^{1/2}$ at an RDE. The error bars in Fig. 11b refer to the extent of the scatter of the data points obtained at 5 or 6 rotation speeds ranging from 700 to 2000 rpm. Both figures show regions of temperature where the rate of hydrogen oxidation is either: (*i*) insensitive to temperature changes (below 90°C), (*ii*) moderately temperature dependent (90°-135°C), or (*iii*) extremely temperature dependent (at and above 135°C). Figure 11b can be split into two regions: the first between room temperature and

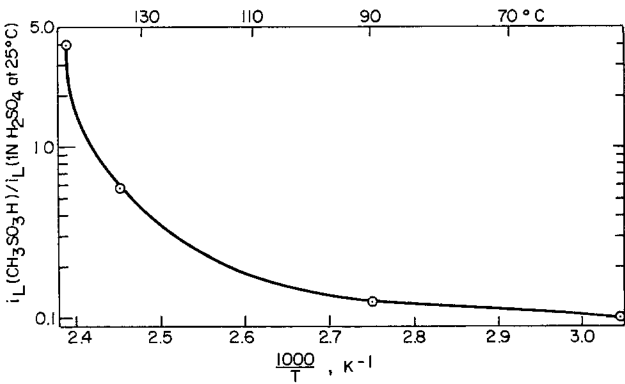

Fig. 11a. Arrhenius plot of the normalized limiting currents for H_2 oxidation in methane sulfonic acid at a Teflon-bonded Pt black gas diffusion electrode.

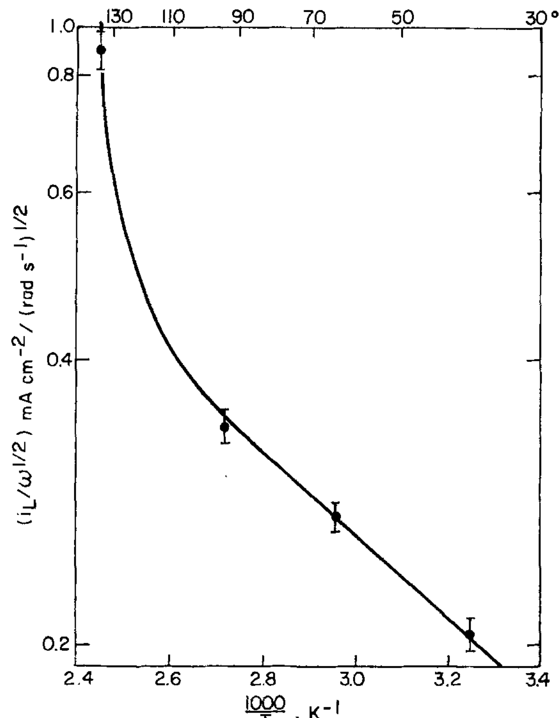

Fig. 11b. Arrhenius plot of the normalized limiting current for H_2 oxidation at an RDE. The error bars refer to the extent of the scatter of the data points obtained at 5 or 6 rotation speeds between 700 and 2000 rpm.

90°C where the slope of the Arrhenius plot gives an activation energy of 2.0 kcal/mole, which is characteristic of diffusion limited processes. Above 90°C, there is a steeper increase in reaction rate with temperature.

Conclusions

It is concluded that only methane sulfonic acid has any promise as a fuel cell electrolyte out of the seven organic acids tested. The electrical resistivity and vapor pressure of the electrolytes vary with temperature according to the expected forms, but the mass transfer and electrochemical kinetics of H_2 oxidation at rotating platinized-platinum disk electrodes are not simple in these electrolytes. This could be due to impurities in the electrolytes, although the background currents in methane sulfonic acid were not significant compared to the measured currents (around 6% at the limiting current).

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 126, No. 5, 7, and 8, May, July, and August 1979 and Vol. 127, No. 1, 2, 3, 5, and 7, January, February, March, May, and July 1980.

The Stability of Trifluoromethane Sulfonic Acid as an Electrolyte in Fuel Cells

A. A. Adams and R. T. Foley (pp. 775-778, Vol. 126, No. 5)

V. B. Hughes and B. D. McNichol:[1] In this article Adams and Foley described the use of trifluoromethane sulfonic acid monohydrate (TFMSM) as an electrolyte in fuel cells using low relative molecular mass hydrocarbons as fuel. A reference therein to our paper[2] implied that we had concluded that the monohydrate was thermally unstable. This in fact is incorrect since our paper referred to the instability of TFMSM in aqueous solutions, in the presence of methanol. We were surprised to read further that Adams and Foley ascribed the so-called instability observed by us as due to the source or purity of the acid or the use of a carbon counterelectrode in our system. Our paper had included a reasonable explanation for the instability of this aqueous acid under the particlar conditions in which we were interested. We would therefore emphasize that we claimed instability only with respect to aqueous TFMSM systems and not with respect to the pure monohydrate. Furthermore, the instability was linked to specific concentrations [see Fig. 13 of Footnote 2]. Thus in the presence of methanol, at temperatures above 60°C using high activity catalysts, certain concentrations of aqueous TFMSM are unstable. Also, in pure aqueous solutions, at concentrations between 25-50 weight percent, and during potentiodynamic cycling, sulfur is produced (presumably during the cathodic sweep).

With regard to the pure monohydrate, we found no evidence for decomposition above 80°C but did imply that falloff in activity at temperatures in excess of 80°C

[1] Shell Research Limited, Thornton Research Centre, Chester, England CH1 3SH.

[2] V. B. Hughes and B. D. McNicol et al., *J. Appl. Electrochem.*, 7, 161 (1977).

could perhaps be attributed to a reaction (as yet undefined) between the monohydrate and methanol.

That the source of our material should be called into question was surprising since it was stated in our paper that the acid was obtained for us by Fluorochem Limited, who bought it from the 3M Corporation, from whom Adams and Foley also obtained their material. The purity of our acid was also questioned yet in our paper we quite clearly recorded that the pure acid and the monohydrate were both triply distilled under nitrogen, showed correct boiling points, and in the case of TFMSM monohydrate showed the correct sharp melting point. The remarks concerning the purity of the acid used by us are therefore completely out of order.

Both graphite and platinum-gauze counterelectrodes were used in our studies and in both cases sulfur formation was found above 60°C with aqueous acid. At this point it should be emphasized (as we have done previously[2]) that the stability of TFMS is kinetic rather than thermodynamic and it is therefore perfectly feasible that in the presence of finely divided catalysts the temperature of decomposition could be lowered, especially if the agent responsible for the decomposition, *viz.* water, is present in significant quantities, *e.g.*

$$CF_3SO_3^- + 2H_2O + H^+ \rightarrow 3HF + H_2SO_3 + CO_2$$

then

$$3H_2SO_3 \rightarrow 2HSO_4^- + S + H_2O + 2H^+$$

This reaction has been discussed in some detail by Fabes and Swaddle.[3] Furthermore the role of methanol in promoting this decomposition is as yet unknown.

For the benefit of other readers, not already acquainted with our work, we are primarily interested in methanol electro-oxidation. As might be expected, the use of TFMSM monohydrate as an electrolyte for the methanol/air fuel cell resulted in low activities for both smooth and finely divided catalyst.. This is perfectly understandable since there is simply not enough water available for the reaction (*cf.* methanol electro-oxidation in 96% H_3PO_4 which is also low[4]) and water is an important agent involved in the electro-oxidation of CH_3OH. Confirmation of this followed from our studies of aqueous systems which showed high activities, explained by us in terms of the higher water activity in such systems. Above 60°C, sulfur was formed from several possible sources, *e.g.*, the decomposition of the acid anion catalyzed by platinum as outlined above or from reaction with hydrogen at the counterelectrode (though both platinum and carbon counterelectrodes produced the same result).

In conclusion therefore we do feel that the reference to our work is completely out of context in this paper since (*i*) Adams' and Foley's paper does not deal with methanol electro-oxidation, and (*ii*) does not deal with aqueous TFMS solutions. We feel it is important therefore to emphasize these points in print.

A. A. Adams[5] and R. T. Foley:[6] The reference to the Shell work[7] was made because that laboratory was the only one to report chemical instability of trifluoromethanesulfonic acid, or its monohydrate, at temperatures as low as 60°C. This is implied for the monohydrate: "We found also that at temperatures higher than 80°C the activities of the catalysts decreased. A possible reason for this was decomposition of the electrolyte producing S species which could poison the catalyst. However, cyclic voltammetry studies showed no evidence of sulfur poisoning of the catalysts (Fig. 4). Thus, for the moment the reason for the fall-off in performance above 80°C remains unclear."

Several other laboratories have worked with aqueous solutions of the acid over the temperature range of 60°-100°C but there has been no report of chemical instability. Appleby and Baker[8] studied oxygen reduction at 62°C on Pt black electrodes in 1.1M solution. Full fuel cells have been run at 200 mA/cm^2 at 60°C in 6M TFMSA over 2000 hr.[9] We have run half-cell tests in monohydrate at 135°C for weeks without a decrease in performance which would be very quickly seen if there was sulfur produced. Cells have been run with 6M electrolyte for months from 60° to 75°C without poisoning the catalyst electrode.[10] There is no evidence to suggest that the chemical stability of aqueous solutions would differ from that of the monohydrate.

The importance or lack of importance, of methanol has not been resolved by the Shell reports. In the review by Howells and McCown[11] they mention "The exothermic reaction of alcohols with trifluoromethanesulfonic acid leads to esters, but ethers and olefins may also be formed." In our work with methanol we concluded that we did, in fact, see esterification but the Shell authors disputed our interpretation of NMR experiment on which we based the conclusion.

The proposed mechanism for the decomposition of the $CF_3SO_3^-$ anion is difficult to accept for several reasons. The first step leading to the production of sulfur is the hydrolysis of the C-F bond. All the literature reports indicate that this does not occur under the conditions imposed here. (A more likely source of H_2SO_3 would be an SO_3 impurity in the original acid.) Apparently, the reaction proposed takes place only in methanol solution. But no role of methanol is indicated in either of the two steps given by these authors.

We suspect that the production of sulfur came from either (*i*) the reduction of trace amounts of SO_3 carried over from the original 97% acid, or (*ii*) voltage transients at the counterelectrode. The voltage transients would have to be greater than 1.5V (probably close to 2.0V) because we regularly cycle our electrodes to 1.5V to clean them before a voltammetry run.

Minority Carrier Lifetime: Correlation with IC Process Parameters

H. R. Huff and T. L. Chiu (pp. 1142-1147, Vol. 126, No. 7)

G. F. Cerofolini and G. Ferla:[12] In this article, Huff and Chiu report an extensive correlation of minority carrier lifetime with IC process parameters.

Their results can be summarized as follows: lifetime is reduced by high temperature annealing; the higher the temperature, the sharper the decrease. Phosphorus diffusion alone is insufficient to increase lifetime. Phosphorus diffusion followed by "an extended *in situ* anneal and a subsequent additional proprietary nitrogen anneal" is very efficient to increase lifetime.

We wish to point out that similar results have been obtained by us by using a phosphorus diffusion followed by an anneal at moderate temperature.

These results have been extensively published[13-17] and if the "proprietary anneal" quoted by Huff and

Chiu is nitrogen anneal in the temperature range 700°-900°C, their results are confirmations to our theory.

The Potentiostatic Current Oscillations at Iron/Sulfuric Acid Solutions Interfaces

J. J. Podesta, R. C. V. Piatti, and A. J. Arvia
(pp. 1363-1367, Vol. 126, No. 8)

C. Gabrielli, M. Keddam, C. Rakotomavo, and H. Takenouti:[18] In this paper J. J. Podesta *et al.* accumulated a number of quantitative data on the oscillations of the iron/H_2SO_4 interface. However, as far as, according to the authors themselves, emphasis is put on the "correlation of the potential range of the periodic effect to the passivity potential," their results and discussion deserve, we believe, the following remarks.

1. Although claimed to be coincident with literature, the E/I curves (their Fig. 1) are somewhat apart from data obtained under well-defined mass transport conditions (RDE). (*i*) Their E/I curves do not exhibit a clear diffusion plateau. (*ii*) Their E/I curves show a stable negative slope at the active-passive transition. (*iii*) Their E/I curves show an abnormally high passive current density, by one or two orders of magnitude when compared to the typical standard values under such conditions (5-10 μAcm^{-2}).[19]

(*i*) and (*ii*) could be explained by the recording procedure itself, the stirring conditions being not elucidated. Did the authors use an RDE? (*iii*) is likely to arise from a poor contact between iron and the embedding material which induces an undermining active dissolution. Cl^- ions from the SCE can also be harmful to the passive layer. Did the authors use a Haber-Luggin capillary?

2. In spite of mentioning our work on localized attack [Ref. (21) in the paper under discussion], the authors completely disregard the accompanying Z-shaped E/I profiles involving a multiplicity of steady states (MSS).[20] Both effects were strictly correlated as established in a most recent interpretation.[21] In view of the transition evidenced in the paper around 1.5N, our experiments previously performed in 2N H_2SO_4[20] were repeated in 1N solution. Figure 1 below shows the most typical features of the E/I curves recorded with an RDE. The primary electric field distribution keeps the ohmic resistance (16Ω at a layer free surface) close to the working disk electrode. The reference electrode is located in the bulk of solution. The potential E actually measured between reference and working electrodes includes the ohmic drop ReI. The curves plotted by thin lines are obtained by means of a fast response potentiostat. By using a negative impedance converter (NIC) the working electrode can be grounded across an adjustable negative resistance ρ[20] (see insert in Fig. 1), which counter balances the corresponding part of the electrolyte resistance. Under these conditions Z-shaped curves are recorded (bold lines), dotted lines indicate oscillations quite similar to those under discussion. This behavior is very close to that obtained previously in 2N H_2SO_4.[20] The potentiostatic curves exhibit a bistability (hysteresis) at the active-passive and passive-active transition. The plateau is diffusion controlled and obeys the Levitch law. These statements are also valid for 0.5N solution though the plateau is not so clearly seen. No fundamental change in the steady-state behavior and transport properties can be detected in this range of concentration. In fact, Fig. 2 and 4 of the paper under discussion show that the authors considered on both sides of 1.5N quite two different kinds of oscillations. The true passive state can be regarded as reached only in concentrated solutions (Fig. 2, 3, and Fig. 4, f through i) so that the comparison is hardly relevant.

3. Discussing the origin of oscillations in terms of steady-state behavior is certainly an extremely difficult task. However, the consideration of the respective positions of the E/I curve and of the load line imposed by the regulating device provides some clarification. The discussion of the stability can be restricted to the regions of the E/I profile where the system switches from one state to another. Figure 1b gives the steady-state polarization curve (Fig. 1a) near the point C with expanded current and voltage scales. During the passive part of the oscillation, the polarization point is located on the E/I curve at the potential E_0 controlled by the potentiostat. Triggering to the active state occurs suddenly when M reaches a position such as C where the load line becomes tangent to the E/I curves.[22] Therefore, the succession of active and passive states and the slow increase of current during the passive period supports a periodic displacement of the Flade potential. Oscillations may occur if the potential is held within the narrow range of this displacement. However, as stated by Podesta *et al.*, the detailed mechanism is certainly far more complicated. Ohmic drop contribution can hardly be neglected as proved by the dependence of the frequency on both E_0 and ρ. Values of ρ locating the load line between PQ and PR (Fig. 1a) give the best conditions for obtaining sustained oscillations. In agreement with previous data,[23] potentiostatic oscillations were found difficult to reproduce, unless ohmic drop effects are partially compensated for by a Haber-Luggin capillary. As emphasized, $FeSO_4$ precipitated along with various hydrated oxides is likely to contribute in the relaxation process. More than one species should be considered in the transport phenomena to solve the apparent inconsistency between the hindrance of passivity leading to Z-shaped E/I curves and the cathodic shift of the passivation potential needed by the periodic effect.

and with iron RDE at rotation speeds from 168 to 425 rpm using the same type of perturbation technique already described in the literature. These curves allowed an adequate choice of the working potential region.

The magnitude of the passive current density cannot be attributed either to the undermining active dissolution or to the traces of chloride ion coming from the SCE. The Luggin-Haber capillary tip arrangement was used. The effect of chloride ion increases the frequency of the oscillations in the Fe/1N H_2SO_4 and Fe/1.5N H_2SO_4 interfaces under a potentiostatic step. The magnitude of the current density is referred to the apparent electrode area. The estimated electrode roughness factor is probably close to 10 as deduced from SEM data. Therefore, in this sense the coincidence between the E/I curves given in Fig. 1 and those reported in the literature is reasonably good within one order of magnitude. This is sufficient to evaluate the magnitude of the proper potential step to produce the periodic oscillations. There is a good correlation between the passive current density change with the H_2SO_4 concentration as given in Fig. 1 and 4.

The fact that no fundamental change of the Z-shaped E/I profiles involving a multiplicity of steady states is noticed in the 0.5-2.0N H_2SO_4 concentration range, does not preclude concentration effects on the t_d/t_p ratio as shown in Fig. 7 of the paper. Since both measurements correspond to a different time-scale, straightforward comparison is hardly relevant.

It is possible that the film involved during each period of the oscillating cycle is a nonstabilized film where the electric field assists the restructuration of iron oxides yielding more compact structures. But this situation which corresponds to an aging-type process is undistinguishable under the conditions of the paper in discussion, but it has to be considered in deriving conclusions from passive films formed under definite perturbation conditions that are involved in the periodic current oscillations.

Investigation of Two- and Three-Phase Fields in the Ga-As-Sb System

M. F. Gratton and J. C. Wooley (pp. 55-62, Vol. 127, No. 1)

Robert F. Brebrick:[25] The authors have made a valuable contribution to the experimental knowledge of the phase diagram for this ternary system. However, they have overlooked two references that are pertinent to the theoretical analysis they present. A systematic investigation of fits to III-V pseudobinaries,[26] made when the experimental data for Ga-As-Sb were less extensive, showed that a simple solution model with interaction coefficients linearly dependent upon T gave a calculated peritectic temperature at least 12° below the experimental value of 745°C. It was concluded at that time that, if the experimental peritectic temperature was correct, that a simple solution model for the pseudobinary solid is inadequate. This discrepancy still exists in the authors' analysis, in addition to the poor fit to the pseudobinary miscibility gap they mention, and the authors have correctly concluded a simple solution model for the pseudobinary solid is inadequate. In a later analysis of III-V binary systems,[27] including GaSb and GaAs, it was shown that the simple solution liquid model was inadequate in that it could not simultaneously provide an adequate simultaneous fit to the thermochemical data and liquidus lines. It was also shown that a liquid model in which the interaction coefficient was a linear function of both T and atom fraction was adequate in terms of the experimental data then available.

[25] Department of Mechanical Engineering, Marquette University, Milwaukee, Wisconsin 53233.

[26] R. F. Brebrick and R. J. Panlener, *This Journal*, 121, 933 (1974).

[27] R. F. Brebrick, *Metall. Trans. A*, 8, 403 (1977).

Table I.

AB	$-\Delta H°_f$ (J/mole AB)		$-\Delta S°_f$ (J/K-mole AB)	
	Calc	Exp.	Calc	Exp.
GaSb(s)	54,197	68,208	39.41	54.81
GaAs(s)	92,803	118,213	39.80	54.60

Thus the authors have used a liquid model that has been previously demonstrated to be inadequate. As one example of this inadequacy we cite the following. The zero Gibbs free enthalpy for the congruent melting of GaSb and GaAs leads to two equations for each binary (Eq. [13] and [14] of Footnote 27) which link the thermodynamic properties of the liquid phase with the enthalpy and entropy of formation, $\Delta H°_f$ and $\Delta S°_f$, of the narrow homogeneity-range compound from its pure liquid elements and at its melting point. The values calculated for these latter quantities from the authors' liquid model parameters and the experimental values are shown in Table I above. Although the calculated values are of the right sign they are too small in magnitude by an amount that, in our opinion, exceeds the uncertainties in the experimental quantities.

The Warburg Impedance in the Presence of Convective Flow

Daniel A. Scherson and John Newman (pp. 110-113, Vol. 127, No. 1)

Eugène Levart[28] and Daniel Schuhmann:[29] The aim of this paper was to establish approximate analytical expressions for the real and imaginary parts of the reduced Warburg impedance of an RDE, valid for very large Schmidt numbers only.

The results found at high frequencies are close to the numerically computed exact values. As correctly stated by the authors, they do not differ significantly from those reported by us [Ref. (7) in the paper under discussion]. Incidentally, it is to be pointed out that our expressions $\mathrm{Re}(-1/\Theta'(0)) = 1/\sqrt{2K} + 3/4K^2$ and $\mathrm{Im}(-1/\Theta'(0)) = -1/\sqrt{2K}$ are much simpler than Eq. [11]-[13] in the paper under discussion.

At low frequencies, the authors derive Eq. [14]-[16] in the form of an infinite series of the reduced frequency K, containing the known eigenvalues and the related coefficients of the Sturm-Liouville system. Their Table II summarizes the results found and compares them to the few exact values available to the authors ($K \geqq 1.5$) and to the values obtained by the Nernst layer approximation. This part of the paper requires some comments.

First of all, it should be recalled that in our previous paper [Ref. (5) in the paper under discussion] we have treated a very general case of the concentration impedance of an RDE. Series form solutions, valid for every finite value of the Schmidt number encountered in electrochemistry, have been given for all frequencies. The results relative to the limiting case Sc $= \infty$ at HF have then been developed in detail in Ref. (7) where it has been emphasized that our LF results agree perfectly with the exact solution from $K = 0$ to $K = 30$ at least. Surprisingly, in presenting their Table II, the authors make no mention of our LF solution. Perhaps because we used reduced quantities different from theirs, or because our Eq. [52] in Ref. (5) is not directly usable for Sc $= \infty$, or even because our Eq. [53] contained a small printing error (μ instead of u).

In any case, we take the opportunity to recall our Eq. [52] in Ref. (5) for the reduced impedance $M°$. For large values of Sc and in the absence of chemical

reaction, this expression simplifies to its first term $m = 1$ and becomes

$$M^\circ(\mathrm{Sc}, j\sigma) = \lambda_1{}^\circ(j\sigma)\mathrm{Sc}^{-1/3} \quad [1]$$

Dividing Eq. [1] by the value of M° at zero frequency, $M^\circ(\mathrm{Sc}, \mathrm{O}) = (3/0.510233)^{1/3}\Gamma(4/3)\mathrm{Sc}^{-1/3}$ and replacing the ratio $M^\circ(\mathrm{Sc}, j\sigma)/M^\circ(\mathrm{Sc}/0)$ by its equivalent $-1/\theta'(0)\Gamma(4/3)$, we get

$$-1/\theta'(0) = \lambda_1{}^\circ(j\sigma)(3/0.51233)^{-1/3} \quad [2]$$

where $\sigma = K/3^{2/3}$ and $\lambda_1{}^\circ$ is a continued fraction of $j\sigma$

$$\lambda_1{}^\circ(j\sigma) = 1/(f_{1,0}{}^\circ + j\sigma/(f_{1,1}{}^\circ + j\sigma/(f_{1,2}{}^\circ + \ldots))) \quad [3]$$

with known values of $f_{1,n}{}^\circ$, the coefficients $f_{m,n}{}^\circ$ having been computed and published for $m = 1$ to 4 and n = 0 to 14 [Ref. (5), Table II]. More precise values for $m = 1$ to 6 and $n = 0$ to 24 are also available on request from us. The number of divisions to be effected in Eq. [3] depends on σ and on the precision desired, but it is of the same order of magnitude as the number of terms in Scherson and Newman's series.

Table I above summarizes the results found using our LF solution and compares them to the corresponding values reported by Scherson and Newman. It is to be recalled once more that our results are identical to the exact values computed by the finite difference method over the range of K from 0 to 30 within 5 significant digits. These results overlap to a great extent the region of validity of the HF solutions which become exact within 5 digits for $K \geq 20$. In contradistinction, the LF results given in the paper under discussion are noticeably different from these exact values which were not given by the authors.

We complete Table I above with the values computed for Sc = 1000 and Sc = 100, which make clear that the Scherson-Newman LF approximation is unable to describe the physical reality with an error smaller than about 5%. Like our Eq. [3] which is infinitely more precise, it requires the knowledge of a great number of numerical coefficients. The only apparent disadvantage of our equation is that it is not easily separable into analytical expressions for the real and imaginary parts of the impedance. However, such an objection is not serious because using modern computer techniques, operations on complex quantities are not more difficult than those on real numbers.

Investigation on the Kinetics of Electroreduction Processes at Dark TiO_2 and $SrTiO_3$ Single Crystal Semiconductor Electrodes

J. Vandermolen, W. P. Gomes, and F. Cardon
(pp. 324-328, Vol. 127, No. 2)

P. Salvador:[30] The authors postulate an interesting two-step mechanism involving bandgap surface states as intermediates of a process of electron transfer from the conduction band to the electrolyte oxidizing species. Under conditions of high enough concentration of the oxidizing agent the capture of C.B. electrons by surface states is shown to be the rate-limiting step of the overall reaction. Then a cathodic dark saturation current

$$J_{\mathrm{sat}} = -eNk_1n_s \quad [1]$$

is reached, which is determined by the density of surface states, N, their coefficient of electron capture, k_1, and the electron density at the semiconductor surface, n_s.

As shown by Morisaki *et al.*,[31] an identical result is obtained from Nishida's theoretical treatment[32] of the charge transfer, via surface states associated with the photoinduced evolution of oxygen, at the n-TiO_2/electrolyte interface, with the difference that in this case the process of charge transfer involved photogenerated holes from the valence band instead of conduction band electrons. According to Wilson,[33] we believe it is reasonable to assume that the same surface states are involved in both processes of charge transfer, since there is direct evidence that those surface states that are oxidized by valence band holes can also be reduced by conduction band electrons.

As predicted by Eq. [1], the saturation current is found to be independent of the oxidizing agent, but very sensitive both to the electrolyte pH and to the applied voltage, which is attributed to variations of n_s. However, the authors, conclusion that Nk_1 is a constant for a given material seems to us a little adventurous. In our opinion this statement might be correct in the case of preexisting surface states created, for instance, by pretreatment or semiconductor doping. Nevertheless, the possibility that surface states might result from the interaction of the semiconductor surface with the electrolyte must not be overlooked, in which case the density of surface states could be influenced by the electrolyte composition and pH.

From experimental values of J_{sat}, the authors estimate a density of surface states of 4×10^{11} cm^{-2} and 10^{10} cm^{-2} for TiO_2 and $SrTiO_3$, respectively. These values are exceedingly low by comparison with that of about 10^{14} cm^{-2} corresponding to processes of charge transfer at TiO_2, involving either conduction band electrons[33,34] or valence band holes.[35] The discrepancy is due to the very high value assumed for the electron-capture cross section ($S_n = 10^{-12}$ cm^{-2}). In fact, from the quantitative analysis of the growth and decay of the peak corresponding to the reduction by conduction band electrons of bandgap surface states, Wilson[33] has been able to calculate the actual cross section of these states for interaction with electrons. He obtained a value of the order of 10^{-16} cm^2, which is considerably smaller than the geometric cross section of a state localized on a single atom, probably

[35] P. Salvador, Communication presented to the "Third International Conference on the Photoelectrochemical Conversion and Storage of Solar Energy," Boulder, Colorado (1980).

because of the poor electronic or phonon coupling between the surface state and the semiconductor.[33] On the other hand, there is indirect experimental evidence that surface hydroxyl groups are involved in the process of charge transfer through the interface semiconductor/electrolyte. For instance, Parkinson *et al.*[34] observed that surface pretreatment with a strong base enhanced the oxygen cathodic reduction via surface states at TiO_2. A similar effect is reported by Wilson[33] with respect to the enhancement of the peak corresponding to the reduction of the surface states by conduction band electrons when, instead of acidic electrolyte (H_2SO_4), a strongly basic one (KOH) is used. Wagner and Somorjai[36] also observed that the photocatalytic production of hydrogen on an illuminated surface of $SrTiO_3$ increased with the concentration of the NaOH solution surrounding the crystal. Finally, we have recently observed[35] that the quantum efficiency of water photo-oxidation at n-TiO_2 electrodes is noticeably dependent on the electrolyte *p*H. Surface OH^- groups probably act as centers for trapping and transfer of charge between the semiconductor and the electrolyte. For oxidation reactions involving valence band holes the mechanism could be

$$Ti^{+4}\text{—}OH^- + h_{vb}^+ \rightarrow Ti^{+4}\text{—}OH^\circ$$

$$Ti^{+4}\text{—}OH^\circ + [Red]_{solv}^- \rightarrow Ti^{+4}\text{—}OH^- + [Ox]_{solv}$$

while, for conduction band electrons involving reduction reactions a simplified mechanism might involve the following steps

$$Ti^{+4}\text{—}OH^- + [Ox]_{solv}^+ \rightarrow Ti^{+4}\text{—}OH^\circ + [Red]_{solv}^\circ$$

$$Ti^{+4}\text{—}OH^\circ + e_{cb}^- \rightarrow Ti^{+4}\text{—}OH^-$$

The position of the energy levels corresponding to active surface hydroxyls should be somewhere in the bandgap (*i.e.*, between the top of the valence band and the bottom of the conduction band). This requirement should be better fulfilled by the basic OH groups (bonded to one Ti atom) than by the acidic OH groups (bonded to two Ti atoms).

The surface density of OH^- active centers should depend on the electrolyte concentration of OH^- ions. The maximum density of basic surface hydroxyl groups in TiO_2 is of about 10^{14} cm^{-2},[35,37] which is in good agreement with the density of surface states obtained by several authors for different oxidation and reduction reactions.[33-35] From structural considerations this value should be, in general, lower for $SrTiO_3$ than for TiO_2, which agrees with Vandermolen *et al.*'s observation that for a given n_s value J_{sat} is lower for $SrTiO_3$ than for TiO_2.

This charge transfer model involving surface OH^- groups predicts, therefore, a new effect of the electrolyte *p*H upon the behavior of the cathodic current density, which is ascribed to the variations of N. However, this effect is masked by that due to the variations of n_s, since $dn_s/dp\text{H} >> dN/dp\text{H}$.

The experimental fact that surface hydroxyls play a decisive role in TiO_2 and $SrTiO_3$ photochemistry at the gas/solid interface,[37-39] gives support to the identification of surface OH groups with the surface states involved both in photoassisted and dark reactions at the electrode/electrolyte interface.

J. Vandermolen, W. P. Gomes, and F. Cardon:[40] It is indeed interesting to remark that our experimental value of the product NS_n for TiO_2 is roughly in agreement with Wilson's recent results[41] which lead to the conclusion that, in his experiments, a nearly complete coverage of the surface by acceptor-type centers is involved. Hence, it might well be that the same centers are responsible for the cathodic current in both cases. In contrast to Salvador's statement, we did not estimate N to be 4×10^{11} cm^{-2}, but merely used this number to illustrate, by the example of a donor-type center, the fact that the observed saturation current is quantitatively interpretable on the basis of a charge transfer mechanism through surface states.

In our opinion, a kinetic study like the one under discussion does not allow the determination of the chemical nature of the centers participating in the proposed mechanism. It may be remarked in this context that Salvador's suggestion, that these centers might originate from the interaction between the semiconductor surface and the electrolyte, is not supported by our experimental results, since they do not exhibit any significant dependence of Nk_1 on the nature of the oxidizing agent or on *p*H. Therefore, we think that independent studies would be needed in order to establish whether surface hydroxyl groups are indeed involved in the process discussed.

High Rate Discharge Characteristics of Li/SOCl₂ Cells

K. A. Klinedinst and M. J. Domeniconi
(pp. 539-544, Vol. 127, No. 3)

M. H. Miles:[42] The authors present an interesting study relating to the discharge of Li/$SOCl_2$ cells at high current densities. The results show that higher discharge voltages and discharge capacities can be obtained with cells containing pure $AlCl_3$ rather than the conventional $LiAlCl_4$ electrolyte. The authors point out that the direct reaction of Li with $SOCl_2$ deposits a protective LiCl film on the anode that, in turn, reacts with $AlCl_3$ to produce soluble $LiAlCl_4$. These reactions continue until either Li, $SOCl_2$, or $AlCl_3$ is exhausted. The formation of $LiAlCl_4$ by these reactions accounts for sufficient electrolyte conductivity to support the cell discharge. How long, approximately, does it take in terms of time per unit volume of $SOCl_2$ per unit area of exposed lithium for the reactions of Li, $SOCl_2$, and $AlCl_3$ to produce sufficient conductivity? The authors mention a 10 min stand on open circuit before beginning cell discharge experiments.

Although the cell discharge was cathode limited due to LiCl precipitating within the cathode pores, it would be interesting to know the coulombic efficiency for the lithium anode in the pure $AlCl_3$ electrolyte. What is the ratio of Li reacting electrochemically *vs.* that reacting directly with $SOCl_2$? This may be a critical factor in designing practical batteries since considerable heat may be produced by the direct reaction of Li with $SOCl_2$ as well as by I^2R heating that takes place during cell discharge. The direct reaction of Li with $SOCl_2$ could also greatly decrease the energy density obtained from such cells. Using the reported 0.75 mm thickness for Li and assuming a 1 cm^2 area (Fig. 1 in the paper under discussion suggests an even larger anodic area), the results for 4.5M $AlCl_3$ in Fig. 4 in the paper under discussion indicate that less than 4% of the Li present reacts electrochemically. It is realized that the authors purposely used large excesses of both Li and $SOCl_2$; nevertheless, data regarding the relative amounts of Li reacting electrochemically *vs.* that reacting directly with $SOCl_2$ is needed to judge the practicality of such cells. The anode efficiency is an important parameter in any cell that uses an oxidizing electrolyte. In thermal battery cells utilizing molten nitrates as the oxidizing electrolyte, direct reaction of the electrolyte with the calcium anode occurs.[43,44] In thermal battery systems, however, the

heat generated by the direct reaction might be useful in maintaining the high temperature of the molten salt.

K. A. Klinedinst[45] **and M. J. Domeniconi:**[46] The authors wish to thank M. H. Miles for a very thoughtful response to this paper. With regard to the use of pure $AlCl_3$ rather than $LiAlCl_4$ to form the $Li/SOCl_2$ electrolyte, it should first be pointed out that such $AlCl_3$ solutions are suitable only for batteries to be operated in the reserve mode. Thus, the cell is filled with the $AlCl_3$ solution just before the beginning of its discharge. Tests have shown that, when $Li/SOCl_2$ cells are activated by the addition of a 4.5M $AlCl_3$ solution, between 1 and 2 sec are required to reach acceptable operating voltages (for cells discharged at room temperature with a 30 mA/cm^2 discharge rate). It is clear, therefore, that enough $LiAlCl_4$ is formed immediately to sustain a moderately high discharge rate.

It is presumed that the further direct reaction between dissolved $AlCl_3$, $SOCl_2$, and Li to produce $LiAlCl_4$ is primarily controlled by the rates of diffusion of $AlCl_3$ to the anode surface and of the reaction products away from the anode surface. We presently have no data on the coulombic efficiency for the lithium anode in pure $AlCl_3$ electrolyte. It is important to note that this efficiency will be a function of both the rate of discharge and the operating temperature. It is also noted that the heat resulting from the production of the $LiAlCl_4$ by this direct reaction may help to attain a somewhat elevated temperature which will provide even a greater efficiency of operation of the battery. Alternatively, some solid LiCl may be stored within the battery (*e.g.*, within the porous separator or cathode). The presence of such solid LiCl would hasten the achievement of the minimum $LiAlCl_4$ concentration required to support a high rate discharge, and the heat produced by the $LiAlCl_4$ formation reaction could be used to attain the desired operating temperature.

A Study on Activation and Acceleration by Mixed $PdCl_2/SnCl_2$ Catalysts for Electroless Metal Deposition

Tetsuya Osaka, Hideki Takematsu, and Kohji Nihei
(pp. 1021-1029, Vol. 127, No. 5)

Rudolph J. Zeblisky:[47] This paper evaluated the characteristics of mixed $PdCl_2/SnCl_2$ catalysts used in electroless plating, and concluded that catalytic activity is exhibited only by colloidal systems. A major reason for this conclusion was spectrophotometric data (Fig. 3 in the paper).

I have also conducted similar spectrophotometric measurements on these $PdCl_2/SnCl_2$ catalysts solutions and have additional information that assists in understanding the nature of these solutions. My spectrophotometric measurements of $PdCl_2/SnCl_2$ catalyst solutions diluted with water similar to Osaka *et al.* produced the same spectra as that described in the paper. I also found that these water-diluted catalysts were unstable and were no longer effective for catalyzing plastics for electroless metal deposition. This would indicate that the water diluted catalyst solutions had decomposed and were no longer representative of the original catalyst solutions.

It is not possible to measure the spectra of undiluted commercial solutions due to spectra intensity. From the above it is clear that the dilution procedure is an important consideration. I have found that the stability of these $PdCl_2/SnCl_2$ catalysts is dependent on their environment. Therefore as outlined in several U.S. patents,[48] they require sufficient excess chloride ions, excess stannous ions, and acid to maintain solubility and stability of the catalyst complex. Even local or temporary dilution with water can cause catalyst instability and some decomposition. To avoid this decomposition it is usual to use an acidic chloride solution,[48] *e.g.*, HCl or an acidic chloride stannous solution[49,50] $HCl\text{-}Sn^{++}$ predip to avoid the drag-in of water, which would result in decomposition of the catalyst solution.

In addition to maintaining the stability and solubility of the $PdCl_2/SnCl_2$ catalyst, the hydrolysis[48,50,51] of excess tin compounds present in the catalysts must be avoided to prevent precipitates which will interfere with spectrophotometric measurements. Insoluble tin compounds can form at a *p*H of about 2 depending on the tin compound present, excess chloride ion, oxygen concentration, and other factors. Water dilution of catalysts can raise the *p*H, and cause hydrolysis of tin. The dissolved oxygen in the water can also oxidize the Sn(II) to Sn(IV) reducing the excess Sn(II) and chloride ion concentration of the catalysts which cause precipitates in the diluted samples.

Therefore, in order to determine the spectra of $PdCl_2/SnCl_2$ solution, I diluted $PdCl_2/SnCl_2$ catalyst solutions using the principles outlined in U.S. Patents 3,672,923 and 3,672,938 to maintain catalyst stability. A blank was prepared with the identical composition of the catalyst less the palladium component. A diluting solution consisting of 215 g/liter NaCl and 10 ml/liter HCl (37%) was used to dilute the catalyst and the blank. The $PdCl_2$ concentration in the diluted sample was 0.01 g/liter. The diluted catalyst produced very sharp, well-defined absorption peaks at 310, 340, and 410 nm, using a Perkin Elmer 552 spectrophotometer. The diluted catalyst also proved effective for catalyzing plastic for subsequent electroless copper deposition, with longer immersion times of 30 min to compensate for the dilution.

In view of the retention of both sharp, well-defined peaks in the spectrophotometric measurements and the catalytic effectiveness of the diluted catalyst, I feel that the nature of the catalyst is different than the results indicated in the paper. The additional work reported here indicates that it is possible to dilute the catalysts and still retain the complex nature of the $PdCl_2/SnCl_2$ complex. I propose that the loss of absorption peaks in the water diluted samples was due to decomposition of the catalyst complex in an unstable environment.

T. Osaka:[52] Dr. Zeblisky discussed the spectrophotometric data shown in Fig. 3 of the paper. He claims that the water diluted catalyst solutions do not give the true nature of the catalysts because of their giving no longer catalyst activity.

We have obtained additional information about the spectrophotometric measurements as shown in Fig. 1. Catalysts A, B, and C which show lower catalytic activity became unstable, close to greenish brown color solutions, and finally colorless solutions after several hours when they were diluted 100 or 200 times with 1M HCl. Absorption spectra of samples A, B, and C diluted 200 times with 1M HCl are shown in Fig. 1 as 1, 2, and 3, where the absorption spectra are measured within 1 hr after dilution. They lost the feature of high extinction coefficient conditions and the spectra of 1 and 3 showed wavy curves which seemed to contain very small absorption peaks around $320 \sim 330$, $410 \sim 430$, and $610 \sim 620$ nm. The spectrum of 2 diluted with HCl, which decomposed the fastest, gave a clear ab-

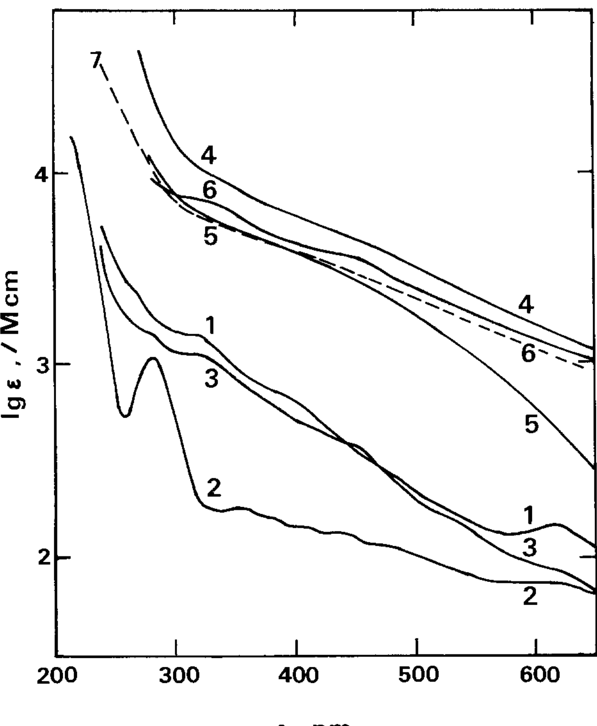

Fig. 1. Absorption spectra of $PdCl_2/SnCl_2$ catalysts diluted with various conditions. Curve 1, catalyst A diluted 200 times with 1M HCl (*i.e.*, $PdCl_2$ 0.005 g/liter); curve 2. catalyst B diluted with 1M HCl (*i.e.*, $PdCl_2$ 0.00125 g/liter); curve 3, catalyst C diluted with 1M HCl (*i.e.*, $PdCl_2$ 0.005 g/liter); curve 4, catalyst D diluted 100 times with distilled water (*i.e.*, $PdCl_2$ 0.01 g/liter); curve 5, catalyst D diluted 100 times with 1M HCl (*i.e.*, $PdCl_2$ 0.01 g/liter); curve 6, catalyst D diluted 100 times with 215 g/liter NaCl and 10 ml HCl (37%) (*i.e.*, $PdCl_2$ 0.01 g/liter); curve 7, (dashed line) catalyst D diluted 200 times with water (the same as D in Fig. 3 of the paper).

sorption peak of 280 nm with lasting high extinction coefficient. Samples A, B, and C, however in the case of water dilution, gave the linear high extinction coefficient as shown in Fig. 3 of the paper.

In the case of catalyst D which has higher catalytic activity, the solutions of three different dilution (shown as 4, 5, and 6 in Fig. 1) are stable in contrast to those of samples A, B, and C and their absorption spectra show the feature of high extinction coefficient absorption similar to those of Fig. 3 of the paper (data in the paper are diluted 200 times with water). The high extinction coefficient absorption spectrum of 6 which is diluted with the same dilution solution as that of Dr. Zeblisky seems to contain small absorption peaks around 320 $\sim$ 330 and 420 $\sim$ 430 nm. The sample D solution diluted with HCl or (NaCl + HCl) was stable until about one day and after one day the solution decomposed completely and gave the colorless solution (in this case the precipitates were not noticed because of small amount of palladium concentration). The water diluted catalyst D solution gave the same conditions as dark brown color solution with high extinction coefficient absorption for a long time.

As for the results of the functionality test of the diluted catalysts using electroless nickel deposition (bath composition was already shown in the paper), the HCl or (NaCl + HCl) diluted sample D solution (5 or 6 in Fig. 1) initiated the nickel deposition after immersion time of 10 min with HCl acceleration of 30 sec on copper sheet and also glassy epoxy plastic board. The water diluted sample D solution did not activate the nickel deposition as pointed out by Dr. Zeblisky using electroless copper plating. We found, however, very interesting results that the catalytic activity of water diluted sample D solution is restored by the addition of several drops of HCl (37%) even though HCl is added after one day and that the water diluted solution with the addition of HCl initiates the nickel deposition.

The water diluted catalyst solution is considered to no longer give the catalytic activity because of the formation of stannous or stannic hydroxide on colloidal particle surfaces due to the change of solution pH, but the addition of HCl is considered to activate the water diluted catalyst solution because of the dissolution of stannous or stannic hydroxide on colloidal particle surfaces which covers the active core. It is concluded from the above results that a large excess of Cl^- ion environment accelerates the decomposition of the dark brown intermediate and the reformation of green intermediate, and that it finally enhances the formation of black precipitate of palladium metal. The data of the absorption spectrum by Dr. Zeblisky which produces well-defined absorption peaks at 310, 340, and 410 nm are considered to result from the solution conditions where both the green and dark brown intermediates coexist. This is also supported by the fact that the solution color of catalyst changes immediately from dark brown to greenish brown when the catalyst solution is diluted with HCl. Since the freshly prepared catalyst B, which has greenish dark brown color and gradually becomes dark brown with several minutes, showed much lower catalytic activity in our functionality test, the green color intermediate may have lower catalytic activity, and it is also the other possibility in the long time immersion experiment of diluted catalyst solution by Dr. Zeblisky that the palladium metal particles of precipitate which are produced by long-term immersion accelerate the metal deposition.

The functionality test of acidic mixed $PdCl_2/SnCl_2$ solution was reported by Nagai *et al.*[53] using electroless copper plating and they concluded that the intermediate with dark brown color gives active sites rather than that with green color whose absorption spectrum shows three or four peaks at 290, 325, 420, and 640 nm,[54] where the absorption peak at 290 nm is due to palladium ions. We also investigated this catalyst system using electron diffraction analysis[55] and found that the particle sizes adsorbed on substrate become larger with the aging process which enhances the catalyst activity (*cf.*, the difference of catalyst preparations between A and D).

Therefore, we can conclude that the catalyst solution having higher activity is relatively stable against environment and that the feature of absorption spectrum with high extinction coefficient, which is observed in all cases of water, HCl, and (NaCl+ HCl) diluted catalyst D solutions, informs the true nature of the catalyst solution with dark brown color which gives the higher catalytic activity, and we can finally conclude that the dark brown intermediate should be colloidal states and that the colloidal particles adsorbed on substrate give active sites rather than soluble complexes. The above final conclusion can also be supported by the fact that the aging process, which is an important procedure in the preparation to enhance the catalytic activity, produces the distribution of well-defined larger colloidal particles in solution.

Mixed Potential Analysis of Sulfation of Molten Carbonate Fuel Cells

Dan Townley, Jack Winnick, and H. S. Huang
(pp. 1104-1106, Vol. 127, No. 5)

Thomas E. Tang[56] and J. R. Selman:[57] Townley *et al.* present a thermodynamic model to estimate the effect

of H_2S on molten carbonate fuel cell performance. They make use of six experimental data points reported by the Institute of Gas Technology [IGT, Ref. (2)] and by United Technologies Corporation [UTC, Ref. (1)].

We would like to point out that several experimental results in these reports clearly invalidate the assumptions used by Townley *et al.* We refer in particular to the following.

1. Thermodynamic equilibrium relations (Eq. [39-c]) are used to calculate the potential shifts due to H_2S in the anode gas, at a given current load. Not only is this logically inconsistent, it is also in contradiction to experimental observations. The open-circuit potential of the anode is negligibly affected by moderate H_2S levels in the fuel gas, however, anode overpotential (polarization) is strongly affected [see, for example, Ref. (1) of the original paper, pp. 5-22 and Ref. (2), pp. 5-12]. This points not to thermodynamic, but to kinetic or mass-transfer limitations, which cannot be interpreted in a physically meaningful way by shifts in equilibrium ("mixed") potential and a pseudo-thermodynamic Henry coefficient for H_2S.

2. Sulfation of the electrolyte is assumed to be mainly responsible for the effect of H_2S. The sulfate [6a] and sulfide [6b] equilibria, if applied consistently in a thermodynamic reaction model, may indeed predict a considerable degree of sulfation (>75%) of the carbonate electrolyte, as Townley *et al.* indicate in their Table III. The conditions which favor sulfation have been discussed extensively in the IGT and UTC reports referenced by the authors (3, 4 of the original paper). However in actual fuel cells such a high degree of sulfation is simply not found; see, for example, Table 3-3 of Ref. (3). Therefore, it appears groundless to ascribe the potential loss upon introduction of H_2S to an equilibrium sulfation process.

We conclude that the concept of a pseudo-Henry coefficient put forward by Townley *et al.* is of very limited utility for predicting performance loss. Certainly, much more extensive data than they used (Fig. 1) would be necessary to verify the concept. That the applicability of a pseudo-constant to the experimental data may have an entirely different cause, is suggested by the similarity of the Nernst relations [39-c] and the Tafel relation written for constant current density

$$\eta = \text{constant} - \frac{RT}{\alpha_a \mathbf{F}} \ln i_o$$

Here i_o (of hydrogen oxidation) may be assumed to depend on p_{H_2S}. For example, the IGT data presented in Fig. 1 are correlated quite well by

$$\eta_{H_2S}(\text{mV}) = -47.5 + 91.5 \log p_{H_2S} \text{ (ppm)}$$

which would suggest a reaction mechanism with $\alpha_a = 2$ and $i_o\ (H_2) \sim p_{H_2S}^{-1}$.

Our intention here is not to speculate about such a reaction mechanism but to caution against "simple," but equally speculative, correlations and models which ignore important experimental information. Also, more systematic experimental work is needed to make analysis fruitful.

Furthermore, we believe that the term "mixed potential" should remain reserved for the potential of an electrode at which multiple electrode reactions proceed, each at a finite rate. The potential analyzed by Townley *et al.* is the common equilibrium potential of electrode reactions [29-c].

Finally, the free energy changes for the sulfation reactions [6a] and [6b], quoted as taken from an IGT report [Ref. (3) of original paper], are not correct. The IGT data (3) are, for [6a] + 20.5 kcal/mole, and for [6b] − 0.6 kcal/mole (M = Na). This is substantially different from, respectively, + 7.7 kcal/mole and −1.7 kcal/mole. It is nowhere mentioned that these and other data are for 923 K (650°C) only.

Dan Townley,[58] Jack Winnick,[58] and H. S. Huang:[59] The main criticism of Tang and Selman (TS) relates to the fact that our treatment predicts a high sulfur-species thermodynamic activity at the anode. Yet chemical analysis has found little in the electrolyte from fuel cells run with H_2S contaminant at ppm levels. As we suggested the activity may be strongly affected by the presence of the electrode and matrix materials, neither of which were present during the equilibrium measurements. The condition of interest is that at the electrolyte-electrode-gas interface. In a recent study Energy Research Corporation (ERC), following a sulfur tolerance test, analyzed the bulk electrolyte, the layer adjacent to the anode, and the electrolyte within the anode structure.[60] The total quantity of sulfur found is not great. However, they find a gradient in sulfur species, increasing as the anode is approached. No technique has yet been capable of analyzing the material in the immediate vicinity of the actual interface. Here it is expected that, under closed-circuit conditions, the gradient is very steep and the interfacial electrolyte has a high sulfur-species activity.

In the ERC chemical analysis, furthermore, little insoluble (*i.e.*, Ni or Co) sulfide was found.[60] These sulfides are expected if the anode material, composed of metallic Ni and Co, were being sulfided by the H_2S present in the fuel gas. This information provides even more support for the conclusion that the main cause of the loss of voltage is the alteration of the electrolyte at the interface.

The observation that the open-circuit potential is unaffected by H_2S is entirely consistent with our treatment. As stated in our note, the value of H^{-1} calculated is a function of the current density. This dependence is based on the diffusion of reacting species to and from the interface. The gas diffusion portion of H^{-1} can be removed by finding, as a function of current density, the partial pressures of the reacting species at the interface. Wilemski *et al.*[61] have developed a sophisticated model of the processes occurring at the anode. We have used their gas-phase physical property data as well as their effective diffusivities through the electrode to carry out these calculations. These values for the partial pressures are then used in our Eq. [1], [3a-c], and [4] to calculate a value of H^{-1} which does not depend on current density. A much smaller value is found and the calculations then show little effect of H_2S at open-circuit conditions.

For example, at a current density of 160 ASF, for 75% utilized low BTU fuel, the ratios of activities at the surface, a_e, and in the bulk, a_b, for hydrogen and water, are calculated at about

$$(a_{W,e}/a_{W,b}) = 1.2 \quad \text{and} \quad (a_{H_2,e}/a_{H_2,b}) = 0.5$$

The electrolyte composition is seen to be strongly dependent on the partial pressures of hydrogen and water. The activity of carbonate ion, as expressed in Eq. [3a-c] and [4], depends upon $(a_{H_2,e}/a_{W,e})^4$. The above calculated values cause this ratio to be around 3% of the ratio in the bulk gas. At open circuit, however, the ratios are identical. The net effect of this calculation is to show that very little sulfation of the electrolyte occurs at open circuit, in complete agreement with experiment.

TS's criticism of the free energy values used for reactions [6a] and [6b] is more puzzling. Those preferred by Tang and Selman are taken from the JANAF tables

for M = Na. These values do not agree with the experimental results reported on pages 3-11 in the same reference for M = 0.62 Li, 0.38 K. These free energies were obtained by bubbling the gas through free electrolyte. In an operating cell there are two additional phases, $LiAlO_2$ and the electrode, which we feel may alter the activity coefficient of the H_2S through surface effects. Furthermore, as stated in the note, the free energy changes used for the reactions need not be accurate to predict the proper η_{H_2S}-P_{H_2S} curve. They do have a large effect on the calculated activities of sulfide and sulfate in the electrolyte and on H^{-1}, but very little effect on the calculated η_{H_2S}. All data used are indeed for 650°C.

Finally, we agree with TS that, in many instances of limited experimental information, a kinetic interpretation may yield a description equivalent to a thermodynamic one. That however, is not the case here. Our treatment involves but one empirical parameter to adequately characterize two independent sets of data, run with quite different fuel utilizations. On the other hand, a kinetic expression, uniquely defined in terms of H_2S concentration, can characterize only that one data set from which its two empirical parameters are determined.

Voltage Losses in Fuel Cell Cathodes

R. P. Iczkowski and M. B. Cutlip (pp. 1433-1440, Vol. 127, No. 7)

Philip N. Ross, Jr.:[62] The authors are to be commended for the scope of the analysis of transport processes in polytetrafluoroethylene (PTFE)-bonded air cathodes, particularly the use of the Stefan-Maxwell equations for multicomponent gaseous diffusion. Their analysis is also the first to include the possible variation in Galvani potential within the electrolyte-filled agglomerates due to the effective resistivity of the electrolyte. As the authors show in Fig. 4, the resistive component is the largest component of voltage loss in a particular electrode to which they applied their analysis. They have, however, done very little to justify the physical model of the electrode structure to which their mathematical analysis was applied. The importance of establishing the physical validity of the model is appreciated by the authors who state: "This model is useful to evaluate how much voltage loss is caused by each of the basic transport processes . . . identification of the most important sources of voltage loss allows research and development efforts to be directed towards the minimization of these voltage losses." The model will be useful in directing structure development only if the adjustable parameters of the model are truly related to real physical characteristics of the structure. Otherwise the model is just another example of parametric curve-fitting. The authors have done both themselves and electrochemical science an injustice by not properly exercising the model. Instead of applying the model to a single electrode (whose structural characteristics are not described), the model should have been applied to electrodes of variable structure and electrolytes of variable conductivity to determine whether the adjustable parameters relate to physical properties in a meaningful way. For example, Klinedinst *et al.*[63] have shown that the structure of the PTFE-carbon black composite, *i.e.*, the radius of flooded agglomerates, can be controlled by variation of the weight fraction of PTFE solids and the curing time and temperature. One would expect, for example, that as the weight fraction of PTFE solids varies, the effective agglomerate radius would change, and the voltage loss due to dissolved oxygen diffusion in the agglomerate should vary proportionately. Klinedinst *et al.*[63] have also demonstrated analytical methods for independently measuring the effective agglomerate radius. In a Vulcan XC-72R/TFE-30 composite containing 50 w/o TFE solids cured at 610 K the independently measured[63] agglomerate radius is *ca.* 10^{-6}m. It would be of great interest to know whether the value of r_a determined by application of the model to polarization curves from this type of electrode is of the correct magnitude. According to the model, changing the conductivity of the electrolyte should decrease the "ohmic" component of the voltage loss. Again, exercising the model with the same electrode in phosphoric acid of variable concentration, and therefore variable conductivity, would provide a more adequate test for validity of the analysis, particularly the suspect treatment of ionic conduction in the catalyst layer.

The treatment of ionic conduction within the agglomerate, and its effect on electrode polarization, is over-simplified and the conclusions related to it misleading. The authors simply write Ohm's law to relate the Galvani potential in solution (in their notation E_i) to the ionic current, and then assume the electrochemical reaction rate depends only on $(E_e - E_i)$, the catalyst-solution Galvani potential difference. This treatment is incorrect. Physically, the process they attempt to describe is actually an ionic diffusion polarization due to the absence of excess supporting electrolyte. Hydrogen ion is consumed at the catalyst surface via the reaction

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

The appropriate diffusion equation is that for a binary electrolyte where one of the two ionic species is electroactive. For this case, it can be shown[64] that the gradient in hydrogen ion concentration is related to the ionic current by

$$-I_i(z) = n_+ \left(1 + \frac{n_+}{|n_-|}\right) D_+ \mathbf{F} \frac{dC_+}{dz} \quad [1]$$

where z is the spatial variable in the author's Eq. [33] and [34], n_+ and D_+ are the hydrogen ion valence and diffusivity, respectively, n_- is the anion valence, and C_+ the hydrogen ion concentration. The ionic concentration at any point is related to the Galvani potential in solution from the equilibrium condition of the (inert) anions

$$\bar{\mu}_- = \mu_- + RT \ln C_- + |n_-| \mathbf{F} E_i = \text{constant} \quad [2]$$

and the electroneutrality condition

$$n_+ C_+ = |n_-| C_- \quad [3]$$

Equations [1]-[3] must be solved simultaneously with the diffusion equations for the dissolved neutral species and the kinetic rate equation. It is also important to note the coupling between hydrogen ion concentration and reaction rate was neglected. In fact, the rate of oxygen consumption at any point z in the agglomerate is given by[65]

$$N_i(z) = \left(\frac{K}{4\mathbf{F}}\right) (C_+) \exp\left[-(E_e - E_i)/T_s\right] \quad [4]$$

where C_+, E_e, and E_i are functions of z, and not by the simpler expression used by the authors

$$N_i(z) = \left(\frac{K'}{4\mathbf{F}}\right) \exp\left[-(E_e - E_i)/T_s\right] \quad [5]$$

The stronger coupling of ionic conductivity with the oxygen consumption rate implied in Eq. [4] *vs.* Eq. [5] would mean, in principal, an even larger effect of internal resistance on the total polarization for an electrode than would be computed in the model presented.

[65] A. Damjanovic, D. Sepa, and M. Vognovic, *Electrochim. Acta*, 24, 887 (1979).

In work at our laboratory, we have used the current ratios for varying oxygen partial pressure to separate ionic diffusion losses from molecular diffusion losses in air cathodes. We have found[66] that ionic diffusion losses of 5-10 mV per 100 mA/cm² current density are observed only when the acid concentration exceeds 98 w/o, *e.g.*, 99 w/o acid shows a 7.5 mV resistance polarization at 200 mV/cm² but only *ca.* 2 mV is observed in 95 w/o acid. We postulate that the dramatic appearance of this internal resistance polarization is due to a change in the majority proton species from $[H_9O_4]^+$ to $[H_4PO_4]^+$ in this region of concentration.

In their discussion on optimum electrode thickness, the authors express a very interesting rationale for the variations in voltage loss with PTFE content (at fixed Pt loading). In their model increasing PTFE content increases E_a, the agglomerate tortuosity factor, reducing diffusion losses (see Eq. [28] of the paper) but increasing voltage loss due to the "ohmic" component. Too little PTFE results in large diffusion losses and too much PTFE results in excessive "ohmic" loss, the optimum PTFE probably occurring at the crossover point for these competing effects. The conventional wisdom concerning the increase of voltage loss with PTFE content above the optimum has been that the structure has "dry" catalyst above a certain PTFE level. The authors present a new and more compelling explanation.

Finally, two assumptions were made in applying the model to phosphoric acid fuel cell cathodes that appear questionable, and further affect the general applicability of the breakdown of the losses shown in Fig. 4. Inside the gas pore, water vapor is assumed to be in equilibrium with the electrolyte at every point z.

[66] P. Ross, Lawrence Berkeley Laboratory Report, Materials and Molecular Research Division, LBL-10799 (May 1980).

If this were always the case, the polarization curve at zero oxygen utilization would not depend on the partial pressure of water in the bulk air stream (in back of the substrate). This is in fact not the case, as we have observed that polarization curves for purely dry oxygen and for oxygen presaturated to the water vapor pressure of the bulk electrolyte are significantly different, *e.g.*, the dry gas curve shows lower polarization. The magnitude of the diffusion losses determined by application of this model to polarization curves will depend critically on the kinetic parameters for oxygen reduction that are used, particularly the Tafel slope. The breakdown of voltage losses shown in Fig. 4 were produced by use of a 90 mV/decade Tafel slope, referring to the work of Kunz and Gruver[67] as having determined this parameter independently. Careful reading of the cited article reveals a circular argument, since PTFE-bonded electrodes were used in the cited work to arrive at the 90 mV/decade Tafel slope with transport modeling employed to "deduce" this kinetic parameter. The definitive determination of the kinetic parameters for smooth platinum in concentrated H_3PO_4 appears to be the recent work by Yeager and co-workers,[68] and shows that the Tafel slope is 120 mV/decade. For platinum clusters dispersed on carbon black, we have found[69] that the true Tafel slope depends on the microstructure of the clusters (105-115 mV/decade), but for a catalyst like that used by Kunz and Gruver the true Tafel slope is 105 ± 5 mV/decade, instead of 90 mV/decade. It would be of interest to know how the analysis of losses in real fuel cell electrodes changes in light of these new kinetic parameters.

A Titanium Dioxide Hydrogen Detector

L. A. Harris

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

Sputtered films of titanium dioxide several thousand angstroms thick and sandwiched between a layer of titanium and a layer of platinum are highly selective detectors of hydrogen. The resistance of the device decreases on exposure to hydrogen. At concentrations above 0.5% H_2 in air, the response is rapid and limited by lead resistance. At lower concentrations the response is proportional to concentration but relatively slow at room temperature. Moderate increases in temperature quicken the response. The detectors may be used as effective alarm devices at room temperature, with a-c or d-c circuitry that requires negligible power in the absence of hydrogen.

It is well known that reducing gases can donate an electron to the conduction band of some normally insulating oxides, thereby greatly increasing the conductivity of the oxide (1-7). This principle has formed the basis of several solid-state detectors for a variety cf gases (5-12). Most of these detectors exhibit changes in conductivity along their surface due to surface adsorption of the reacting gas and thus frequently respond to a variety of gases.

If the detector response depended on diffusion of a particular species within the solid then it could be made specific for those gases that give rise to the diffusing species. A case in point is titanium dioxide (TiO_2) in its rutile form, in which the diffusion of hydrogen (protons) is a much studied phenomenon (13-16). Here, H atoms can enter the lattice and in doing so become ionized to produce a mobile interstitial proton and a conduction electron, a process that can readily occur even at room temperature (3, 4).

For these reasons, and encouraged by an earlier suggestion of Johnson *et al.* (16), some simple experimental crossed-film detectors were constructed and tested. This paper describes some of the characteristics of these devices in which the current flows through, instead of along the surface of, the thin insulating or semiconducting film.

Construction

The devices were made by successive depositions of thin films on standard glass microscope slides. The first film was a 3000Å layer of TiO_2 sputter deposited onto the clean slide. This layer was covered by a 1000Å film of Ti metal which, in turn, was covered by a second sputter deposited layer of TiO_2 in thicknesses ranging from 500 to 3000Å. The sputtering was done in an rf system in argon for Ti and in 50% argon, 50% O_2 for TiO_2. The gas pressure was approximately 2.5 Pa (18-20 microns) and the rf power was 500W. With the target voltage raised to 1700V the deposition rate was approximately 90 Å/min. The slides rested on a water-cooled support which kept plasma heating of the substrates to about 200°C. X-ray diffraction showed the films to be principally anatase, with a trace of rutile.

Key words: titanium dioxide, hydrogen detectors, hydrogen sensors, gas detectors, instruments, sensors, indicators.

All of the above films covered the entire slides except for two small areas of Ti metal left uncovered near the ends of the slide for contacts to that film.

A coating of lacquer (Hunt Waycoat negative photoresist) was painted by hand over the second TiO_2 layer except for a 2-3 mm strip down the center of the slide and the two Ti contact areas. This configuration was chosen as the simplest one that would prevent gas-induced conduction on the TiO_2 surface between the Ti contacts and the Pt cross strips to be applied later. These cross strips, 200Å thick and 1 mm wide, were electron-beam evaporated after the lacquer was thoroughly dried and polymerized by exposure to u.v. light. Figure 1 shows schematically the disposition of the various layers comprising the detector slide.

The first film of TiO_2 was included to balance the stresses on the base metal layer (Ti) after earlier attempts using noble metals (Au and Pt) on glass

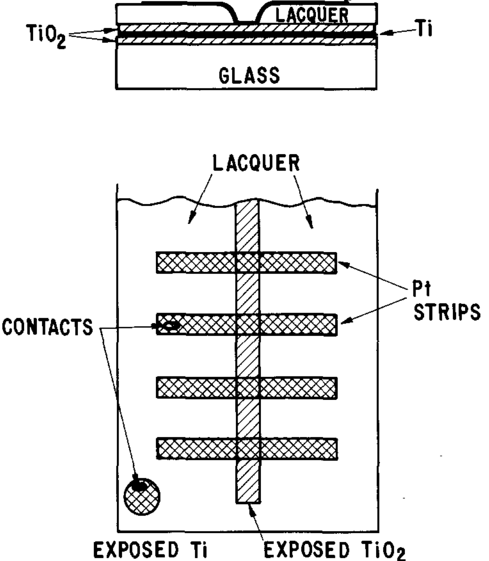

Fig. 1. Schematic illustration of hydrogen detector construction

failed by peeling. The TiO_2 layer improved the situation, but noble metals were still unstable. Ti and Cr films were found to be stable, but Cr films showed no sensitivity to hydrogen, presumably because of the highly insulating layer of Cr_2O_3 on its surface. With Ti films it may be possible to omit the first TiO_2 layer.

Platinum was chosen for the top film for its ability to dissociate molecular hydrogen to the atomic form that can diffuse into the TiO_2.

Detectors made in this way were not uniformly successful. On some slides most of the junctions had excessive conductance even at very low voltages, while other junctions exhibited extremely low conductances. The junctions tested were selected from the latter group having typical junction conductances of the order of 10^{-7} mhos or less, measured in the absence of hydrogen.

Experimental

Samples were tested by attaching leads to the Ti and Pt films with indium solder, after first applying contact pads of silver paint. A potentiostat (Pine Instruments Company RDE 3) acted as a regulated power supply and current converter. For logarithmic current plots, a Keithley Model 26000 Logarithmic Picoammeter in series with a resistor measured the output voltage of the potentiostat's current indicator. The voltages (V) applied for testing were scaled roughly with TiO_2 layer thickness (d) to keep the average field (V/d) less than about 10^5 V/cm. In what follows the voltage or bias is that of the Pt film with respect to the Ti film.

The detector slides were mounted inside a jar or a small metal oven through which the test gas could be flowed and then vented to air. When the oven was used, the slide rested on a thin stainless steel tray to which a Chromel-Alumel thermocouple was attached.

The test gas was made by mixing hydrogen with air or nitrogen through a two-stage dilution system consisting of the valves and flowmeters indicated in Fig. 2. The mixed gas passed through a drying (Drierite) tube and a small three-way valve mounted near the test chamber. This arrangement allowed the gas flow to be diverted to the room while it was adjusted to the desired mixture, and after the feed lines had equilibrated the gas was directed to the test chamber. Usually hydrogen was mixed with air because it was found that the current decreased only very slowly after hydrogen removal if oxygen was not present in the ambient gas.

To the extent possible the flow rate through the test chamber was held at about 2.5 SCFH ($\approx$20 cm^3/sec) as indicated by the flowmeters. At this rate the largest test chamber had a complete change of gas in about 12 sec. The concentrations of H_2 in air quoted in this paper are only approximate because of instabilities in the gas flow and the imprecise nature of the small plastic meters and their associated valves. An approximate correction for the flow of H_2 through flowmeter B (Fig. 2) was applied after measuring flow rates with a bubble meter.

Qualitative tests of the sensitivity of detectors to gases other than H_2 were made by flowing undiluted chemically pure gases from lecture bottles through the test chamber and noting any change in response from that for dry air.

Some brief experiments were done in a humidity chamber to assess the value of these devices as humidity sensors. Though some response was obtained, it was so slight as not to warrant further investigation.

Except for one test, all of the measurements were made under d-c or slow sweep conditions (100 mV/sec). In that one case the complex admittance of the detector was measured with a Hewlett-Packard Model 3042A Network Analyzer at frequencies from 100 Hz to 10 MHz both in air and in pure H_2 at room temperature.

Results

The volt-ampere characteristics of a detector with a 3000Å (TiO_2) thickness are shown in Fig. 3, both in the absence and in the presence of hydrogen. Generally similar results were obtained with thinner specimens, but the slope or conductance of the curve at the origin tended to increase as the thickness decreased. Owing to the variability of junctions even on the same slide it is not possible to quantify any thickness dependence reliably.

Notable features of Fig. 3 are the asymmetrical or rectifying nature of the curves both with and without H_2 present, the marked hysteresis of the positive segment of the curve with H_2 present, and of course the very large increase in current for H_2 for both polarities. (Note the scale change indicated on Fig. 3.) All of these features are discussed in the section to follow.

Figure 4 shows the current response and recovery times for exposure of a 1000Å detector to pure H_2 for several negative and positive biases. The rapid current onset and the delay in current fall after H_2 flow ceased suggest that the current response is triggered by much lower partial pressures of H_2 than the atmospheric pressure used in this test.

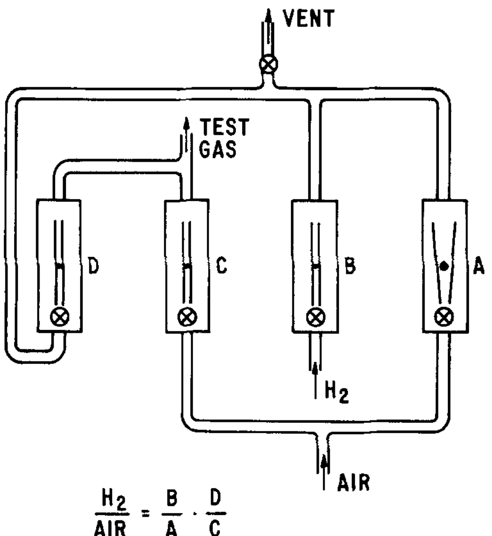

Fig. 2. Arrangement of valves and flowmeters for two-stage dilution of hydrogen in air.

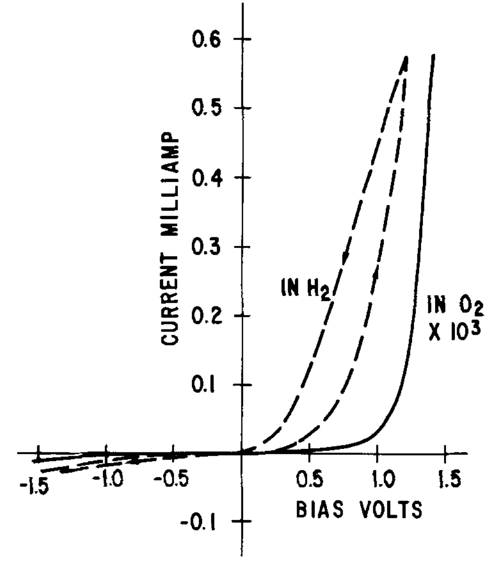

Fig. 3. Current-voltage characteristics of detector 4A, 3000Å thick, in oxygen and in hydrogen. Voltage scan rate was 100 mV/sec.

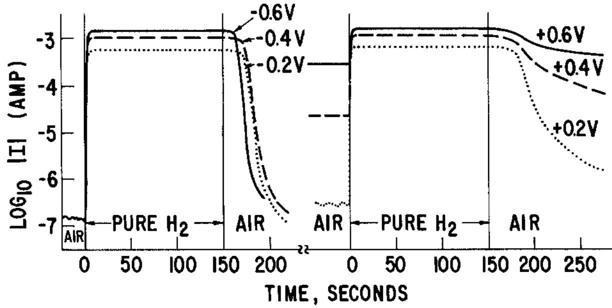

Fig. 4. Response and recovery of detector 2B, 1000Å thick, to 100% hydrogen for several negative (left) and positive (right) bias voltages at room temperature.

Figure 5 shows the corresponding responses of the same device to 4500 ppm (0.45%) of H_2 in air. About the same saturation values are reached as for 100% H_2, but the response time is longer and the recovery time shorter, consistent with more rapid dilution to subsaturation levels of H_2. Figure 5 shows more clearly than does Fig. 4 that the response when H_2 is introduced is quicker for positive bias than for negative, but the converse is clearly true with respect to recovery.

The saturation currents in Fig. 4 and 5 correspond to a total device resistance of roughly 350Ω. If the resistance of the thin Pt film between the contact and the overlap area is estimated by taking half the measured resistance of the Pt film from the contact to its other end a similar magnitude is obtained. This crude correspondence suggests that with H_2 present most of the device resistance is associated with the Pt connection and not with the TiO_2 layer between Pt and Ti.

The slow response to lower concentrations of H_2 (900 ppm in air) at room temperature is more dramatically shown in Fig. 6. Although the response with positive bias is notably faster, in neither case does it give a meaningful indication of H_2 concentration in reasonable observation times (less than 10-15 min). The momentary drop in current for positive bias at about 20 sec on the time scale is related to the internal

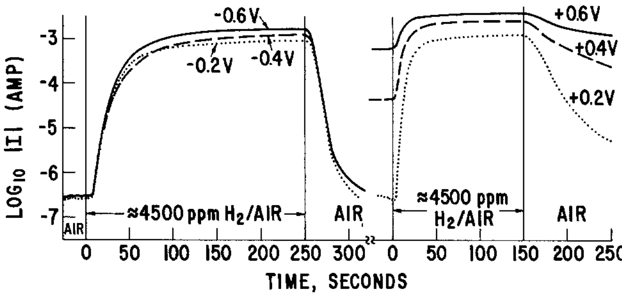

Fig. 5. Response and recovery of detector 2B to 0.45% H_2 in air at room temperature.

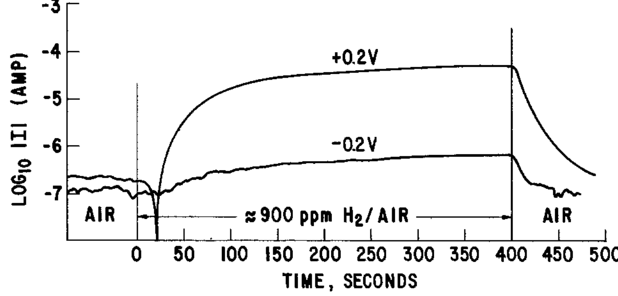

Fig. 6. Response of detector 2B to 0.09% H_2 in air at room temperature.

fields in the TiO_2 layer and is discussed in the section to follow.

Response and recovery times might be expected to depend on thickness and temperature. As noted above is was not possible to make reliable quantitative measures of thickness dependence, but some qualitative features may be noted. There appeared to be little significant difference in rates or saturation levels with thickness though the thickest films 3000Å may have been somewhat slower. The principal result of increasing thickness was a lowering of the background current, which in effect lowers the threshold of detectable current changes. Thus, given enough time, a 3000Å detector gave an observable response to as little as 20 ppm H_2 in air, when the background current in air was about 10^{-9}A.

In contrast to thickness, temperature had a dramatic effect on the speed of responses. Figure 7 shows how the risetime decreased as temperature was raised, even for the low concentration of 900 ppm H_2 in air (cf. Fig. 6) and for a small negative bias. (The data of Fig. 7 were obtained from a different junction from the one used in Fig. 6, but both were nominally 1000Å thick.) So far as can be judged, given the rough reproducibility of the gas mixture from test to test, the steady-state response of the detector was relatively independent of temperature. It was observed to shift quite readily with minor adjustments of the gas mixture.

This steady-state response, now observable at elevated temperature, was approximately linearly dependent on H_2 concentration, as Fig. 8 shows, down to about 500 ppm below which the response was not

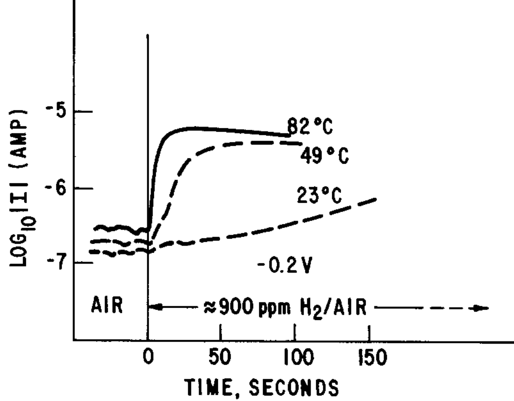

Fig. 7. Response of detector 11B, 1000Å thick, to 0.09% H_2 in air at several temperatures.

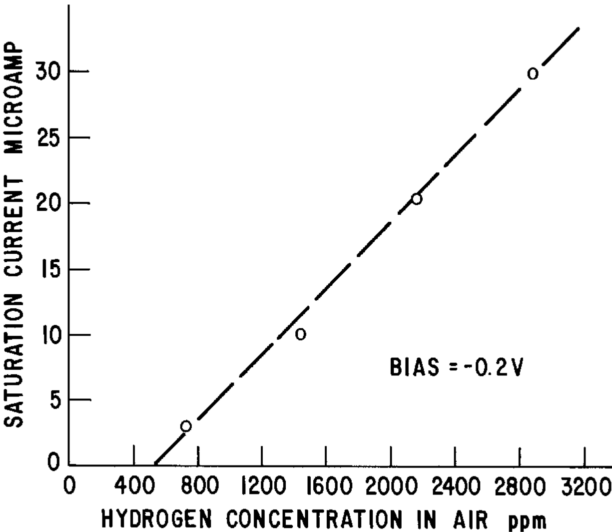

Fig. 8. Dependence of saturation current on hydrogen concentration in air for detector 11B, with —0.2V applied, at 82°C.

detectable. These data were obtained with negative bias only, as that was judged to be the more useful mode of operation.

Failure of the detector current to recover from H_2 exposure in the absence of oxygen was noted earlier. This behavior is illustrated in Fig. 9, in which pure H_2 was used for about 58 sec followed by pure N_2 for another 172 sec, at which time the gas was changed to pure O_2 and the current returned to its base value of 4×10^{-7}A.

In order to clarify some features of detector operation its photoresponse was observed both in the absence and presence of hydrogen. Similar results were obtained with bright light from a xenon lamp and with the 350 nm component of that light obtained from a monochromator. Figure 10 shows the volt-ampere characteristics observed with the detector dark and illuminated for both kinds of ambient gas.

The results of the a-c admittance test noted in the previous section are shown in Fig. 11. Interpretation of these results is deferred to the following section.

Response of the detectors to gases other than H_2 was observed qualitatively using pure gases, alternating with O_2 to flush the test chamber while maintaining a negative bias to ensure restoration of the normal background current. These tests were done at room temperature and at 71°C with both positive and negative biases. The results are summarized in Table I. They show that at room temperature and negative bias the response to most of the gases tested is negligible compared to that for H_2, though H_2S does provide a clearly measurable effect. With positive bias, CO, CO_2, and H_2O respond very weakly while NH_3 and H_2S have moderate responses (5-10% of that for H_2). At elevated temperatures the detector is not so selective, and it responds much more strongly to most gases when biased positively.

Discussion

Sputtered TiO_2 films, which are polycrystalline, largely anatase, and highly disordered, differ markedly from the single crystal rutile on which many diffusion studies have been made. Despite these differences the behavior of these hydrogen detectors is generally consistent with that deduced from earlier electrochemical and other observations using the single crystal material.

According to this view, H_2 is dissociated on the Pt top layer into H atoms, some of which cross the interface into the TiO_2. Once inside the TiO_2, the H atoms ionize to produce a conduction electron and an intersitial proton (3). Depending on the direction of the field at the TiO_2-Pt interface and other factors, either electrons or protons are driven toward the Ti base layer while the other carrier is driven back to the interface.

The photoresponse of the device in the absence of H_2, particularly its displacement from the origin (Fig. 10, left) indicates the existence of a Schottky barrier at the Pt-TiO_2 interface. Figure 12 (left) shows a presumed band structure when no bias is applied and no H_2 is present. Band bending within the TiO_2 pro-

vides a field at the interface which may not be overcome by a small positive bias. The momentary drop in current noted in connection with Fig. 6 can be attributed to a reverse current of conduction electrons from the first H atoms to enter the TiO_2 film. These are moved toward the base layer by the built-in field of the depletion region, but as we shall see this field does not persist as more H enters the insulator.

When H_2 is present, the intercept of the current with illumination (Fig. 10, right) shifts to zero bias, suggesting that the Schottky barrier is no longer effective (17). This situation might be represented by the band structure shown on the right of Fig. 12. The change in band structure can be expected because the H atoms are electron donors converting the poorly conducting TiO_2 to an n-type semiconductor. The Fermi level of the TiO_2 is thus moved closer to its conduction band and electron transfer between the Pt and TiO_2 is greatly facilitated. In thick films or crystals of TiO_2 nonuniform distributions of H can result in significant band bending and internal fields due to this effect, and these fields can complicate the resultant electron and proton flow rates (2, 13).

The increased current due to illumination, even when H_2 is present, may be attributed to photoconductivity of the TiO_2. The light absorbed in the TiO_2 produces both mobile holes and electrons which move in opposite directions as determined by the field in the material.

The comparable sensitivities observed with bias of either polarity suggest that the principal conduction mechanism is electronic rather than ionic. With sufficient negative bias, protons are held near the Pt side of the TiO_2 layer so ionic conduction cannot play a significant part, but the electronic conductivity arises from the presence of ions in this layer.

The ionic current contribution can be seen in cases of positive bias when H_2 is present. The significant hysteresis in the positive portion of the curve of Fig. 3 with H_2 may be attributed to the motion of protons into the TiO_2 during the positive voltage excursion. The 10 sec duration of the 1V upward sweep in Fig. 3 provides some notion of the rate at which ions can enter the TiO_2 and move within it. The recovery times (Fig. 4-6) are considerably longer, but they are governed by the rate at which H atoms can be removed from the surface, as discussed below, as well as by proton motion toward the surface. This motion is enhanced by negative bias and retarded by positive bias.

The a-c admittance measurements shown in Fig. 11 are consistent with this view of electronic conductivity. The approximately semicircular locus of admittance with frequency roughly corresponds to an equivalent circuit consisting of a 135Ω resistance in series with a 0.016 uf capacitance (8). These values correlate with the approximate measured resistance of the Pt film and the capacitance of the junction area if a dielectric constant of 62 is assumed for the TiO_2. When the detector is exposed to H_2 its admittance locus collapses to a virtually constant value corresponding to the lead resistance, suggesting that the capacitor has been shunted by a very high conductance that is essentially independent of frequency.

Even when the current is primarily electronic and not ionic, it arises from electrons donated by H atoms to the conduction band. This current must therefore be related to the density and distribution of protons within the TiO_2 layer. These quantities are governed by the applied and internal fields in the material, the concentration gradients of protons, and the surface boundary concentration, which is determined by the rates at which H atoms are supplied to and removed from the surface.

The principal source of H atoms is dissociation of H_2 molecules, with lesser contributions from other dissociable molecules, *e.g.*, H_2O, H_2S, NH_3. On recovery after H_2 exposure, accumulation of protons near the surface from within the bulk of the TiO_2 also provides H atoms. The sinks for H atoms are diffusion into the bulk, reaction with oxygen to form water, or recombination to form H_2. In the presence of oxygen, the formation of water is undoubtedly predominant.

Bearing these competitive processes in mind, it is easy to understand why the recovery rate is negligible in the absence of oxygen (Fig. 9), why the response is faster and the recovery slower with positive bias (Fig. 5 and 6), and why increasing temperature accelerates the response significantly.

These considerations lead us to expect a dependence of sensitivity and response time on the carrier gas. Indeed it was observed that for a given concentration of H_2 the sensitivity and speed of response was least in O_2, somewhat greater in air, and greater still in N_2. By the same token we might expect a high relative humidity to increase the sensitivity and response speed, not because the water vapor dissociates (which it does only very slowly) but because it shifts the reaction away from water formation.

Optimum thicknesses of the TiO_2 and Pt layers have not been determined in this work. It seems clear, however, that excessively thin TiO_2 layers are not advantageous because they have relatively high background currents and high threshold levels of detection thus limiting their dynamic range. Excessive thickness, on the other hand, will eventually result in slowed response and recovery.

The saturation current of the detectors described in this work was determined by the Pt lead resistance, the resistance of the TiO_2 layer becoming negligible at about 0.5% H_2 in air. The saturation current, and with it the measurable H_2 concentration range, might be raised by reducing the resistance of Pt film. This course might carry with it the danger of thermal damage to the detector due to higher current in localized "hot spots." The existence of thin spots or localized regions of higher conduction is strongly suggested by the generally higher background currents observed with thinner TiO_2 layers, even with constant applied field.

Conclusions

The TiO_2 devices described here are effective detectors of hydrogen at concentrations of a few hundred parts per million in air, though some units have detected less than 1/10 of this value with slower response. The preferred mode of operation is with the Pt film negative with respect to the base film of Ti because this provides a greater dynamic range and considerably faster recovery when hydrogen is removed. This polarity also makes the detector virtually unresponsive to other gases at room temperature, and almost so even at higher temperatures.

Air or oxygen is generally needed to remove hydrogen from the detector once the source of H_2 is cut off. The response rate but not the sensitivity is strongly increased by a moderate rise in temperature.

The d-c voltages applied in this work are generally smaller than those available from batteries, so that appropriate series resistors, doubling as current sensing elements, would be needed if the detectors are battery operated. Nevertheless low and moderate frequency a-c methods are also applicable so that a considerable variety of instrumentation circuitry can be devised.

At very low hydrogen concentrations the detector responses can be quantitative, but they saturate at concentrations above about 0.5% H_2 in air, making them excellent alarm devices specific to hydrogen. (Though the detector does not respond to pure CH_4, natural gas apparently has sufficient hydrogen in it to produce a strong response.)

The operation of the device depends on the relative rates of hydrogen dissociation and reformation, hydrogen atom diffusion into and out of the dielectric, and reaction between hydrogen and ambient oxygen to form water vapor, all of which are catalyzed by the platinum film.

The diffusion of hydrogen into and out of the detector appears to be quite reversible, at least for the duration of the experiments reported here. It is not known, however, what the lifetime of these devices might be and how it would be affected by temperature. Temperatures above about 300°C might come dangerously close to effecting a permanent reduction of the TiO_2 to a highly conducting state (4).

Significant advantages of this detector are its effectiveness as an alarm for hydrogen operable at room temperature and requiring simple circuitry that uses negligible power in the absence of hydrogen.

Acknowledgment

The author is grateful to R. H. Wilson for useful discussions, to J. Briant for the admittance measurements, and to R. O. Carlson for assistance with humidity measurements. Construction of the detectors was accomplished through the work of A. Golab and I. Mullin.

A Model on the Mechanism of Room Temperature Interfacial Intermixing Reaction in Various Metal-Semiconductor Couples: What Triggers the Reaction?

Akio Hiraki

Department of Electrical Engineering, Osaka University, Suita, Osaka 565, Japan

ABSTRACT

Metal films such as Al, Au, Cu, and Pd exhibit an intermixing reaction at room temperature with semiconductors of energy gaps (E_g) of less than ~2.5 eV or dielectric constants (ϵ) larger than ~8. The semiconductors are mostly covalent ones. A model of the mechanism, especially the triggering mechanism, of this room temperature interfacial intermixing reaction is proposed. One of the bases of the model is the consideration of the role of metal on the covalent semiconductor from the theoretical view point to induce instability in the cohesive mechanism resulting in facilitating the reaction. The other is our slow deposition experiment of Au film onto Si (111) surface in ultrahigh vacuum.

We previously found and reported (1, 2) that when metal films (~500Å) such as Al, Au, Cu, and Pd are vacuum evaporated onto clean surfaces of semiconductors with energy gaps (E_g) less than 2.5 eV or dielectric constants (ϵ) larger than ~8, they react and intermix at the interfaces with each other readily even at room temperature, as summarized in Table I. However, insulators like SiO_2 and NaCl, which do not satisfy the above criterion, exhibit no reaction. As a result of the intermixing reaction, a very thin alloyed layer is introduced irrespective of the deposited metal

Key words: films, semiconductor, metals.

Table I. Summary of the room temperature interfacial reaction in various metal-semiconductor couples studied by Hiraki *et al.* (1, 2)

Semiconductors	E_g (eV)	Interface reaction	Surface atom(s)	Dielectric constant
Ge	0.67	Yes	Ge	16
InSb	0.18	Yes	In,Sb	15.2
Si	1.11	Yes	Si	12
GaAs	1.35	Yes	Ga	10.5
InP	1.26	Yes	In,P	9.5
GaP	2.24	Yes	Ga	8.4
SiC	2.9	No		6.4
SiO_2	6.5	No		3.5
NaCl	7.7	No		2.5

forming with the semiconductor stable compounds (like Si-Pd) or not (Si-Au). Then the reaction is called the room temperature interfacial intermixing reaction. In many cases the constituent atoms of the semiconductors are released from the alloyed interfacial region and they migrate through the metal films to accumulate on the top of the films under high vacuum. As an example, Fig. 1 demonstrates the surface accumulation of In and P atoms on Au film observed in an InP-Au couple.

Since most of the semiconductors (listed in Table I) which readily intermix with the metals are classified as covalent semiconductors with fairly large bond energy (the bond energy of Si, for example, is ~2 eV/bond), without the presence of such an effect of metal as to induce instability in the bonding (or cohesive) character of the semiconductor adjacent to the metal, the above interfacial intermixing reaction can hardly occur.

We postulate that the physical origin of this instability is due to the ability of metal to screen Coulomb interaction by its mobile free electrons. Although there may be other possible mechanisms of the present room temperature interfacial intermixing reaction, we think the above postulated possibility of the metal induced instability in the semiconductor bonding character is very likely from the following experimental facts and theoretical considerations.

Using ELS, AES, LEED, and ion sputtering techniques, Okuno *et al.* (3) of our group performed the experiment on the slow deposition (~0.1 monolayer/min) of Au film onto clean Si(111) surface with 7 × 7 LEED structure at ultrahigh vacuum (~ 5 × 10^{-10} Torr). As illustrated schematically in Fig. 2, the results indicate an abrupt onset of the room temperature interfacial intermixing or alloy-forming reaction between the deposited Au film and the Si substrate at the thickness of ~4 monolayers, the presence of a critical film-thickness for the reaction. Namely, 1-2 monolayers of Au induce no intermixing reaction either at room temperature or at an elevated temperature of ~800°C, although the ELS signal shows that the deposited Au atoms eliminate the surface states indicating that the atoms relax the reconstruction existing on the Si(111) clean surface. However,

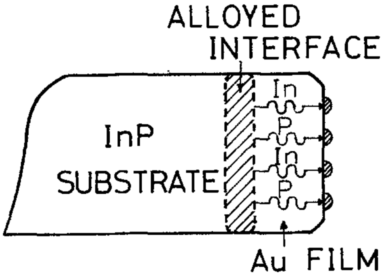

Fig. 1. Schematic illustration of the room temperature accumulation of In and P atoms on top of Au film caused by the interfacial intermixing reaction between InP and Au.

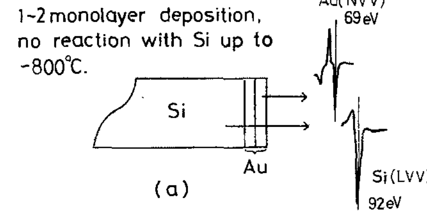

more than 4monolayers of Au quickly react with Si to convert to Si-Au alloy at room temperature

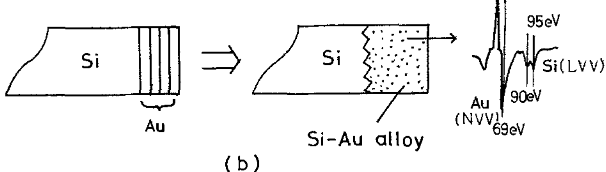

Fig. 2. Schematic illustration of the results on the slow deposition experiment by Okuno *et al.* (3) of Au film on clean Si(111) surface under ultrahigh vacuum.

more than four monolayers of Au immediately react with the substrate and the Au film intermixes with Si to convert into a layer of amorphous Si-Au alloy which can be clearly identified from the definite chemical shift of the Si(LMM) Auger signal with characteristic double peaks at 90 and 95 eV [Fig. 2(b)] (4). The amorphous layer thus produced is unstable against temperature rise and easily decomposes into Au and Si grains at ~200°C. This is an obvious contrast to the tough thermal stability of two monolayers of Au film up to ~800°C which is far above the Si-Au eutectic point (~370°C).

Similar experimental results were reported for the AES-LEED study on the first stage condensation of Au film on Si(111) surfaces by Le Lay *et al.* (5). Also the recent result of the MeV He^+ ion backscattering/channeling study by Narusawa *et al.* (6) on Si(111) and Si(100)-Au systems under ultrahigh vacuum is consistent with our observation (Fig. 2). They observed a steep increase of the surface peak intensity of Si at ~4 monolayers of Au and interpreted that this was due to the abrupt appearance of an amorphous gold silicide film as a result of the intermixing reaction.

We interpret the above facts on our slow deposition experiment as follows. For Au film to function as a metal, a highly polarizable medium which is expected, as mentioned already, to induce instability in the covalent bonding of Si at the interface, its thickness must be more than four monolayers, the critical thickness: this criterion is generally accepted for most of metal films to behave as intrinsic metal. On the other hand, 1-2 monolayers of Au do not act as metal in the above sense but as nonmetal, probably due to covalent interaction with underlying covalent Si through the dangling bonds: this statement is in agreement with both the ELS and AES studies on monolayer Ga on Si by Rowe *et al.* (7) and monolayer Al on Si by Kobayashi *et al.* (8).

Moreover, the definitive role of an intrinsic metal to trigger the interfacial intermixing reaction can be demonstrated by the following experiment. We deposited onto a clean Si surface 500Å of nonmetallic (or covalent) Ge film in high vacuum and heated the specimen up to ~500°C and detected no intermixing reaction by RBS (9). But, if we convert this nonmetallic film into metallic by depositing ~2000Å of thick Au film on the thinner (~500Å) Ge film followed by heat-treatment at ~200°C to produce metallic Ge-Au alloy, Si reacts with the metal (or Ge-Au alloy) readily and consequently metallic Si-Ge-Au alloy appears. These results are schematically shown in Fig. 3.

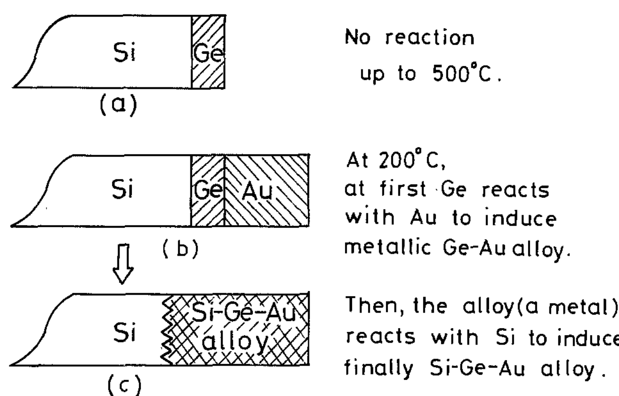

Fig. 3. Schematic illustration of the results on the experiment by Hiraki *et al.* (9) to show that Ge(nonmetal) does not react with Si, but metallic Ge-Au alloy does to produce Si-Ge-Au alloy.

The modification or instabilization of bonding character in covalent semiconductors by metal has been investigated theoretically by Phillips (10), Inkson and Anderson (11) to understand the metal-independent Schottky barrier height in place of the familiar concept of Bardeen's surface state. Okiji *et al.* (12) using the Hubbard model took the effect of metal into account on narrow gap nonmetal whose gap is caused by the many body effects or electron correlation.

Inkson and Anderson's calculation suggests the band closure of covalent semiconductor energy gap in the region of 2-3 monolayers of semiconductor side in contact with the metal and therefore the region converts to metal from semiconductor (11). Theory by Okiji *et al.* also concludes the possibility of the transition of nonmetal to metal in several layers (12). Figure 4 is a schematic illustration of the proposals of these theories, where S and M denote semiconductor (or nonmetal) and metal, respectively. In the figure, to avoid confusion, the temperature is set at ~0°K [Fig. 4(b)], because we already know that by the metal (or M) deposition even at room temperature S reacts immediately to induce S-M alloyed layer [Fig. 4(c)]: however, due to the presence of activation energy for the interfacial intermixing reaction as evidenced by our previous experiment on GaP-Au couple at 22°C and 200°C (1), only very low temperature (or ~0°K) may guarantee the unreacted but converted (to metal from S) layer designated by M(S) of 2-3 monolayers thick.

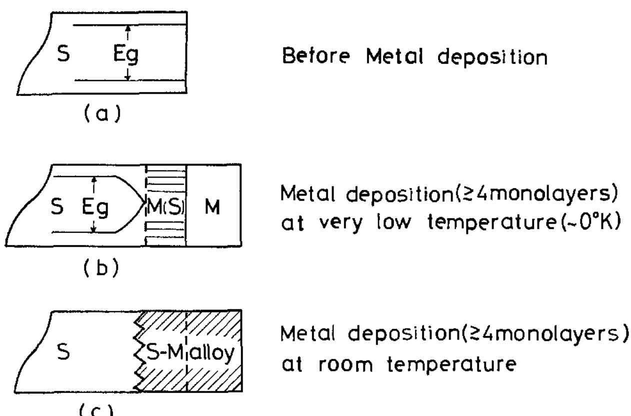

Fig. 4. Schematic illustration of the effect of metal (M) deposition on covalent semiconductor (S) to provide situation for easy S-M interfacial reaction. (a) Before metal deposition; S with energy gap (E_g) $\lesssim$ 2.5 eV. (b) Metal deposition ($\gtrsim$ 4 monolayers) at very low temperature (~0°K). Band closure of several monolayers of S to convert to metal [M(S)] due to presence of M ($\gtrsim$ 4 monolayers), see text for the reason for setting the temperature to 0°K. (c) Metal deposition at room temperature. Converted metal layer [M(S)] readily reacts with M at room temperature to induce S-M alloy.

From our slow deposition experiment illustrated in Fig. 2, we know that four monolayers of Au induce the interfacial intermixing reaction and the cause can be attributed to the effect of intrinsic metal. This effect of metal is expected by the above theories to convert S into M(S) which is schematically illustrated in Fig. 4(b). So the next question may be the reason why once a part of S converts to M(S) as Fig. 4(b) shows, it reacts and intermixes with M to form an alloyed interface at such a low temperature as room temperature. Before answering this question, it may be more convincing to refer to experimental data indicating ready low temperature intermixing or interdiffusion in metal-metal (M-M) couples (13). The most important factor to facilitate the low temperature M-M intermixing may be the cohesive mechanism of metal which is quite different from that of the covalent semiconductor (14), since from the consideration of the cohesive mechanism of metals, both in the metal films and at the interface, we can expect the ready atomic motion which is requisite for the intermixing or interdiffusion reaction to take place. In other words, the cohesive energy of metal, roughly speaking, is determined mostly by the density of its mobile free electron or electron gas, and so long as the atomic motion of metal ions does not increase the electron density, the Fermi energy of the electron gas exerts no restriction against the atomic motion. Therefore, it is understandable that for the metal layer M(S) to intermix with M through the atomic motion is in general far easier than in the case where the region of S adjacent to M does not convert into M(S) and still stays as covalent semiconductor (or nonmetal).

The resistance against the atomic motion in metal films is due mainly to atomic size, perfection of the films, and so on, to suggest that in or into defect-rich metal films, such as evaporated films, atomic motion may be quite easy. So the easiness of the intermixing reaction which proceeds from atomic motion is expected to greatly depend on the perfectness of the deposited metal layer and, therefore, deposition condition. Many complicated factors control the deposition condition and then determine the perfectness of the deposited films. They are deposition rate, deposition temperature, surface geometry (such as, orientation and lattice spacing) of the substrate, surface energy and so on.

Therefore, with a few exceptions, it is not possible to deposit defect-free or single crystalline metal film (M) on the semiconductor substrate (S). Consequently, almost all room temperature metal (M) deposition on S helps low temperature interdiffusion between M(S) and M to take place inducing the S-M alloy as shown in Fig. 4 and resulting in the interfacial intermixing reaction of the S-M couple.

However, we must point out that on GaAs(001) it has been reported that it is possible to deposit Al film epitaxially (15) suggesting no mutual intermixing. In this GaAs(001)-Al case, in addition to the suitable geometrical fitness, *i.e.*, lattice matching and so on, for epitaxial growth to be satisfied in the couple, both a high enough deposition temperature and slow enough deposition rate may be generally necessary to allow deposited Al atoms to arrange themselves into a perfect epitaxial layer.

Also it may be crucial and relatively easier to control if this arrangement of Al atoms is perfect in the first two monolayers so defects are not induced which would assist intermixing between Al and GaAs to occur when the Al film thickness exceeds more than four monolayers. As mentioned and illustrated already in connection with Fig. 2(a), 1-2 monolayers of de-

posited Al film are expected not to intermix with GaAs substrate as in the case of Si-Au couple. Otherwise, epitaxial deposition of Al on GaAs is impossible: we already know the GaAs(111) intermixes even readily with deposited Al film (~500Å) when the evaporation is performed with the conventional deposition rate at room temperature (2). Such determinative role of defects or the perfection of the deposited film in the low temperature interdiffusion or interfacial intermixing reaction in metal-metal couples is clearly shown by Kirsch *et al.* in the case of an Ag-Au couple (16).

More detailed description of the present model on the role of intrinsic metal triggering the low temperature interfacial intermixing reactions taking place in S-M couples will be published elsewhere soon (9) with experimental and theoretical discussion.

Plasma-Developed X-Ray Resists

Gary N. Taylor* and Thomas M. Wolf

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A novel plasma-development method using an oxygen plasma and new materials which optimize sensitivity have been evaluated as x-ray resists at the 4.37Å $Pd_{L\alpha}$ wavelength. Both negative and positive tone images can be obtained upon plasma development. To date, negative tone images are more technologically important. X-ray absorbing host polymers and moderately volatile guest monomers are used. Images are developed after exposure and low temperature fixing under vacuum by differential development in an oxygen plasma. Examples are presented for monomers which are locked by free radical and cationic mechanisms. One composition which has optimum properties is a mixture of 81 weight percent poly(2,3-dichloro-1-propyl acrylate) and N-vinyl carbazole. With it features as small as 0.3 μm were resolved for a short 1.5 min exposure time. These resists and processes are suitable only for multilevel resist processing schemes which are demonstrated.

One of the fundamental problems of high resolution lithography using polymeric negative resist materials is the limit to resolution caused by swelling of the polymeric resist during solution development of the exposed pattern (1). Positive resists of either the novolac-quinonediazide type (2) or of the poly(methacrylate) family (3) are virtually free of swelling problems. Both classes of materials appear to develop in an etch-like manner by selective dissolution of material in the exposed areas. For the novolac-quinonediazide resists the difference in wetting properties of the exposed and unexposed areas and the very small size of the host novolac resin and quinonediazide sensitizer molecules minimizes swelling. For the poly(methacrylates) the unique mobility of the chain segments associated with the methacrylate structure is believed to control and minimize developer permeation leading to swelling and dissolution (4) even though the molecular weight of polymer in the exposed areas is still high. For these reasons positive resists are considered to have far superior resolution.

For conventional solution-developed negative resists, swelling is a necessary consequence of the development process in which uncrosslinked material is dissolved in unexposed areas and is extracted from crosslinked gel in the exposed areas. The crosslinked gel is itself swelled by the developing solvent. Swelling can be minimized by a judicious choice of developer and rinsing solvents and conditions (5). However, resolution is still limited to about 2 μm (gap) in 5000Å final resist thickness for many negative resists. Recent results by Feit (6) with poly-(chlorostyrene) electron resist have indicated that improved resolution to ~1.0 μm can be achieved if resist contrast is sufficiently high ($\gamma > 2.0$). Moran and Taylor have shown that higher resolution can be achieved with a negative

* Electrochemical Society Active Member.

Key words: oxygen plasma, high resolution lithography.

x-ray resist mixture containing 92.5 weight percent (w/o) poly(2,3-dichloro-1-propyl acrylate) and poly-(glycidyl methacrylate-co-ethyl acrylate) when it is exposed in the presence of trace amounts of oxygen (7). However, resolution is at best only 1 μm in 5000Å final resist thickness.

Clearly, it would be very useful if negative resists could be developed which would not be swelled during the development process. Hofer, Kaufmann, and Kramer have recently described one new type of negative resist which minimizes swelling. This involves conversion of the resist to a highly ionic state by electron or x-ray irradiation of charge-transfer organic metalloid polymers (8). Herein we describe another new means to avoid limitations due to swelling. These are new negative x-ray resist materials and development processes which develop the resist image by plasma etching. The materials are mixtures of a host polymer and a moderately volatile monomer which is locked into the host by the impinging radiation. Pattern development is accomplished by subsequent heating (fixing) and exposure to an oxygen plasma. Recently a similar process has been described for photoresist compositions by workers from Motorola (9, 10). However, no chemical details of their process were presented.

Experimental

Materials.—Poly(vinyl chloride) (Aldrich), poly-(chloroprene) (du Pont), and poly(epichlorohydrin) (Hercules) were used as received. Poly(butene-1 sulfone) was obtained from Mead Chemical Company. The chlorinated acrylates and methacrylates were prepared in house using techniques analogous to those previously reported (22). Monomers were obtained from either Monomer-Polymer Laboratories, Polysciences, or Aldrich. 2-(1-naphthyl)ethyl acrylate and methacrylate were prepared in house.

Equipment.—X-ray exposures were conducted with a $Pd_{L\alpha}$ exposure system which was previously described (17). X-ray masks were of the polyimide membrane type. Fabrication details have also been disclosed (23). All x-ray exposures were conducted under a nitrogen atmosphere. Plasma development was accomplished in an oxygen plasma contained in a Dionics, Incorporated, Model 2005T plasma etcher at 0.40 Torr and 100W without a Faraday cage.

Results and Discussion

Initial results.—While investigating x-ray resist mixtures of poly(2,3-dichloro-1-propyl acrylate), DCPA, and poly(glycidyl methacrylate-co-ethyl acrylate), COP, we observed an interesting phenomenon. When a 1 μm thick film of the polymer mixture on an Si wafer was exposed to 10-20 mJ/cm^2 of $Pd_{L\alpha}$ x-radiation and was then heated at 100°C and 50 mTorr pressure for 1-2 hr, a faint relief image was visible. No image was evident immediately after exposure. The relief image was shallow, of the order of several hundred angstroms, and appeared to be thinner where the resist had been exposed. The relief image appeared to be an exact copy of the gold absorber pattern on the x-ray mask although submicron dimensions could not be measured accurately because of low optical resolution. In order to establish the dimensions more accurately, the sample was placed in a barrel-type plasma etching apparatus. The polymeric film was removed by etching in an oxygen plasma until the bare Si substrate surface was first reached. Surprisingly, the substrate was first cleared of polymeric material in the unirradiated regions which had initially been thicker than the irradiated regions. The final resist thickness in the irradiated regions was approximately 500Å.

These results indicated that the irradiated regions had etched more slowly than the unirradiated regions and that the enhanced relief image was the result of different removal rates for polymer in the two regions. Attempts to increase the final relief image either by increasing the x-ray dose, the heating time, or changing the composition proved unsuccessful. However, it was possible to obtain thicker films after heating in vacuum and oxygen plasma etching when the COP was replaced by a moderately volatile polymerizable monomer containing aromatic functionality.

Polymer host: monomer guest mixtures.—Our choice of moderately volatile aromatic polymerizable monomers in a polymeric host binder as x-ray resist compositions having the possibility of high resolution was derived from several inputs. First, Broers and co-workers (11) had demonstrated extremely high resolution (~80Å) by contamination writing in a scanning transmission electron microscope. They "locked" extremely small amounts of "monomer" pump oil contaminants as very thin films on gold and used the fine resist lines thereby created as a mask for the ion milling of the fine patterns into the thin gold film contained on a carbon foil substrate.

Their results prompted us to think of a more practical method of locking monomers. The basis for this lies in two articles by Chandross and co-workers (12) who made optical waveguide circuits, directional couplers, and grating couplers by photolocking 2-(1-naphthyl)ethyl acrylate into a 1:1 copolymer of methyl methacrylate and glycidyl methacrylate, functionalized with cinnamic acid or monoethyl fumarate, by exposure to ultraviolet and visible radiation. For x-ray locking the analogous processes are radiation grafting and polymerization (13). One example is the high energy electron irradiation of mixtures of poly(vinyl chloride) and multifunctional acrylic and methacrylic monomers now used in the manufacture of telephone frame wire (14).

A third input was the general knowledge that resist materials containing aromatic functionality are generally more resistant to plasma etching than their aliphatic analogues. This coupled with our observations of differential removal of exposed and heated conventional x-ray resist mentioned above suggested that the locking process, followed by a fixing step using heat and vacuum to remove unreacted monomer, would provide a film having different types and amounts of chemical bonds in the irradiated and unirradiated regions which would be removed at different rates when a plasma was applied. Since oxygen plasma etching is utilized to strip resist materials (15) we have found it very useful in achieving differential removal of the imaged and nonimaged regions. Recently we reported relative rates of removal for 40 polymers in an unshielded oxygen plasma (16). We have used the data generated to design resist compositions which would hopefully optimize differential removal in the plasma treatment (development) step.

The process which has been realized experimentally for resists exposed to x-rays is schematically outlined in Fig. 1. In the first step, exposure of a mixture of monomer m and polymer P in the region indicated by the impinging radiation designated by the vertical arrow, presumably causes locking by chemical reactions as grafted (P-m bonds) and polymerized (m-m bonds) material. The second step, fixing, is accomplished by heating the exposed resist under vacuum thus removing the unreacted monomer chosen to have moderate volatility. Since more material is removed in the unirradiated regions a relief image is generated. In the third step plasma treatment removes material from the imaged and nonimaged areas. However, because of the different chemical nature of the two regions the rates of removal can be substantially different. In the case of plasma A, which is typically an oxygen plasma, the imaged regions are removed at a lower rate than the nonimaged regions thus enhancing the initial relief image obtained after fixing and affording a fully developed negative tone pattern when the substrate is bared. For plasma B the unimaged regions are removed at a significantly lower rate than the imaged regions thus inverting the tone obtained at the

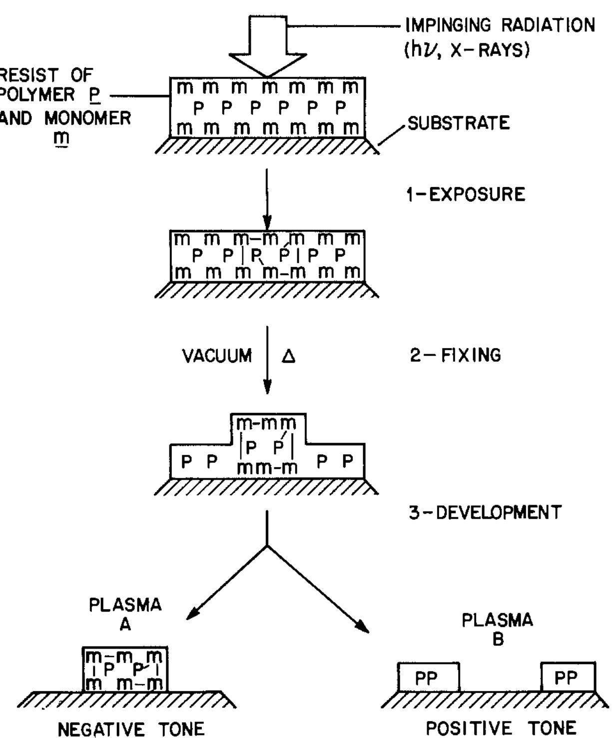

Fig. 1. Schematic diagram of plasma-developed resist showing the resist film composed of polymer host P and moderately volatile monomer m. The three processing steps are (a) exposure which locks monomer in place by grafting and polymerization, (b) fixing which removes unlocked monomer from all regions, (c) plasma development where plasma A is an oxygen plasma. Plasma B will be described elsewhere (18).

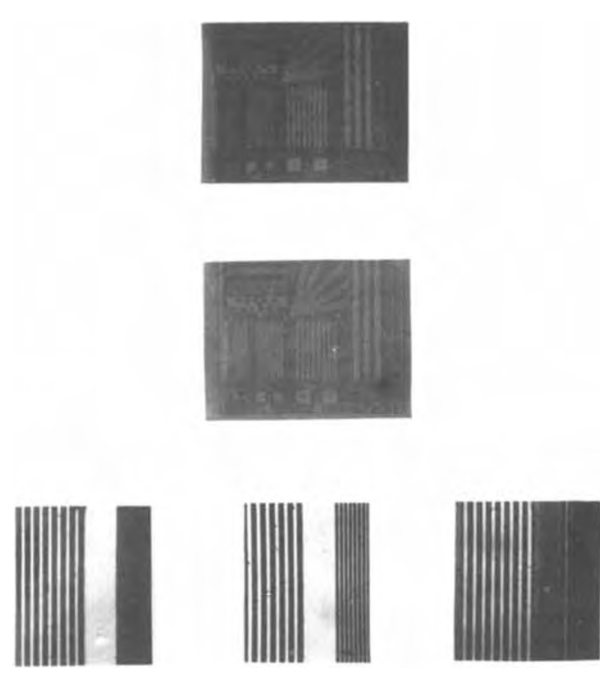

Fig. 2. Photomicrographs of plasma-developed resist patterns in 80 w/o poly(2,3-dichloro-1-propyl acrylate) and 20 w/o N-vinyl carbazole at various processing steps: (a, top) immediately after exposure for 2.5 min, (b, middle) after fixing at 90°C and 0.10 Torr for 1 hr, (c, bottom left) 2500Å negative-tone image after O_2 plasma treatment of magnified 1 and 2 μm lines and spaces, (d, bottom right) 6400Å positive-tone image obtained after treatment with plasma B, (e, bottom middle) corresponding features on the mask.

fixing stage and providing a positive tone pattern upon complete development when the substrate surface is reached.

Experimental realization of these processes is provided in Fig. 2. Photomicrograph 2A shows a shallow relief image seen immediately after exposure of a 1.0 μm thick film comprised of 80 parts by weight poly (2,3-dichloro-1-propyl acrylate) **1** and 20 parts by weight N-vinyl carbazole **2**

$$—(CH_2—CH)_n— \quad C{=}O \quad O \quad CH_2\,CHCl\,CH_2\,Cl$$

1 **2**

The patterned regions were exposed to 12 mJ/cm^2 of $Pd_{L\alpha}$ x-radiation [4 min exposure on a 4 kW x-ray exposure system described by Zacharias and co-workers (17)]. Photomicrograph 2B shows the enhanced relief image obtained after fixing by heating at 75°C and 0.05 Torr for 1 hr. The resist thickness in the exposed regions was 8700Å and in the unexposed regions was 7800Å. The relief image was, therefore, 900Å. Upon treatment with an unshielded 100W O_2 plasma at 0.55 Torr generated in a Model 2005T Plasma Etcher obtained from the International Plasma Division of Dionics, Incorporated, the resist was completely removed in the unexposed regions by etching for approximately 3 min thus affording the magnified patterns of 1 and 2 μm lines and spaces 3200Å thick shown in Fig. 2c. A comparison of identical features on the x-ray mask is shown in Fig. 2E. Figure 2D shows a similar pattern but with the positive resist tone obtained after treatment with other plasmas. The resist thickness in 2D was 6400Å in the unexposed regions compared to bare substrate in the exposed regions. The details of the positive tone process will be presented elsewhere (18). The remainder of the present report is concerned with the negative tone process.

In order to discuss our results we must first define several terms relating to sensitivity. This is necessary since the usual terms employed to define the sensitivity of solution-developed negative resists, D_g^i and $D_g^{0.5}$, no longer apply since plasma-developed resists are not gelled or crosslinked by the low doses of incident radiation used. We find that plots of normalized thickness *vs.* log dose for both the relief and plasma developed images to be useful aids in examining resist properties as a function of composition. Such plots are presented in Fig. 3 for an 85:15 mixture by weight of poly(2,3-dichloro-1-propyl acrylate) and N-vinyl carbazole.

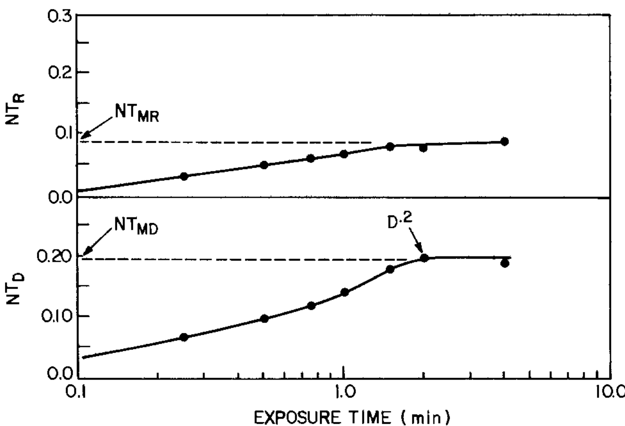

Fig. 3. Sensitivity curves for an 85:15 mixture by weight of poly(2,3-dichloro-1-propyl acrylate) and N-vinyl carbazole. The top curve plots normalized relief image thickness NT_R obtained after fixing *vs.* log exposure time (dose). The lower curve plots normalized thickness of the plasma-developed image NT_D *vs.* log dose.

Here NT_R is the normalized thickness of the relief image

$$NT_R = NT_{RE} - NT_{RU} \quad [1]$$

and NT_{RE} and NT_{RU} are the normalized thickness of the exposed and unexposed regions after fixing, respectively. In the lower portion of the plot NT_D is the normalized thickness of the plasma-developed image

$$NT_D = NT_{DE} - NT_{DU} \quad [2]$$

where NT_{DE} and NT_{DU} are the normalized thickness of the exposed and unexposed regions after plasma development, respectively. Plasma development is continued until the substrate is bared or $NT_{DU} = 0$ such that

$$NT_D = NT_{DE} \quad [3]$$

At all points on the lower curve resolution is equal and usually closely approximates the features on the mask. The slope of the linear portion of the lower curve is called γ, the contrast. Another parameter which we employ is $D^{0.2}$ or the dose required to give $NT_D = 0.2$. This is useful because starting from a 1.5 μm film we obtain 3000Å final thickness which is typically the minimum required for subsequent trilevel processing (22).

Several additional parameters are instructive. Certain compositions such as that shown in Fig. 3 exhibit plateaus at high doses for both NT_R and NT_D. These maximum normalized thicknesses we call NT_{MR} and NT_{MD}. In all cases we find that NT_{MR} is less than the theoretical NT_R expected for the case in which all monomer initially present is locked. The theoretical NT_R is assumed to be given by $1 - NT_{RU}$ for zero exposure time. One parameter not given in Fig. 3 is the differential removal rate for oxygen plasma treatment called R_D. It is given by

$$R_D = (NT_{RU} - NT_{RE} + NT_D)/t = (NT_D - NT_R)/t \quad [4]$$

where t is the plasma etching time required to clear the unexposed regions. This value is dependent on dose since the x-ray mask permits exposure beneath the nominally masked regions. Thus, longer etch times are required at higher doses. Typical differential removal rates for the 85:15 mixture are 220 Å/min for a 2 min exposure and 140 Å/min for a 1 min exposure.

We have examined a large number of monomer-polymer mixtures as x-ray resists. In Table I we present data for ten monomers in poly(2,3-dichloro-1-propyl acrylate) host. They can be divided into two classes. Monomers 1-5 are polymerized by both cationic and free radical initiators whereas monomers 6-9 are polymerized only by free radical initiators. Monomer 10, N-phenyl maleimide, is presumably locked not by polymerization but by a free radical chain-transfer process.

Within each class the monomers are ordered according to sensitivity. With the exception of N-vinyl carbazole the two classes of materials have comparable locking efficiencies as judged by the NT_R values for the 2.5 min exposure time (5.5 mJ/cm^2). 9-vinylanthracene is observed to have an abnormally low NT_R value. This arises because the NT_{RE} and NT_{RU} values are >0.90 indicating that thermal locking during the fixing step is overwhelming that due to the radiation locking.

Comparing NT_D to NT_R we observe that the inclusion of aromatic functionality reduces plasma removal rate and optimizes the differential removal rate. The exceptions are examples 7 and 8. Both monomers are locked efficiently. This is particularly true for 8 which contains chlorine functionality and hence absorbs the $Pd_{L\alpha}$ x-rays efficiently. A reason for the low differential removal rates is not apparent. Since the acrylate corresponding to 8 behaves in an identical manner the lower rates do not appear to result from the presence of methacrylic functionality. Also, the methacrylate ester of 9 does have the protective property expected of aromatic groups.

The dependence of properties on monomer concentration is detailed for N-vinyl carbazole, naphthylethyl methacrylate and acrylate, and N-phenyl maleimide. The complete sensitivity curves are given in Fig. 4-6, respectively. For 5 the sensitivity is observed to increase with increasing N-vinyl carbazole concentration. At high doses a plateau is reached in each case. The NT_{MR} values in the plateau region for the various N-vinyl carbazole concentrations are always less than the theoretical NT_R values expected if all monomers were locked in each case. For example, in Fig. 2 NT_{MR} is 0.08 or about 53% of the theoretical amount. This implies that only a certain fraction of monomer is present in reactive sites and suggests a microscopic incompatibility which is not observed at 0.1 μm dimensions in patterned samples. Above 20 w/o the mixture becomes macroscopically incompatible and crystallization results. Similar phenomena occur for acenaphthalene and hydroquinone dimethacrylate above 20 w/o monomer.

Table I. Properties of poly(2,3-dichloro-1-propyl acrylate)-monomer mixtures

[b] Monomer rapidly exuded from the film.

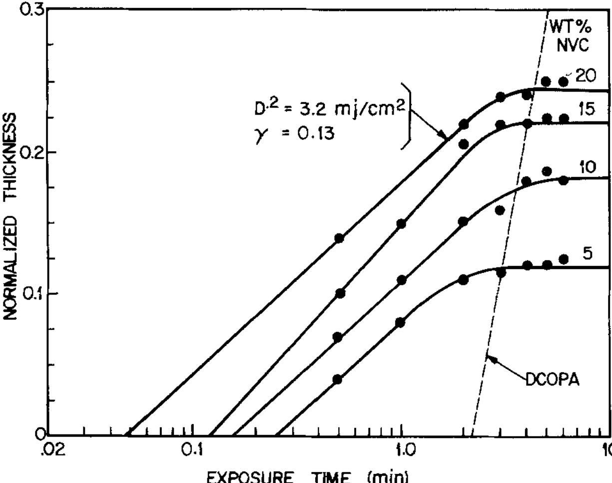

Fig. 4. Sensitivity curves for mixtures by weight of poly(2,3-dichloro-1-propyl acrylate) and N-vinyl carbazole.

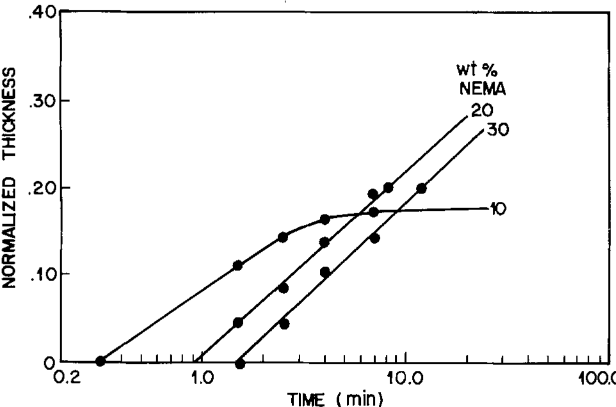

Fig. 5. Sensitivity curves for mixtures by weight of poly(2,3-dichloro-1-propyl acrylate) and 2-(1-naphthyl)ethyl acrylate.

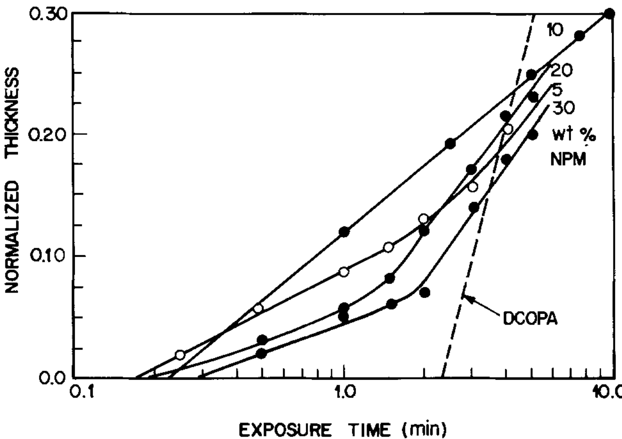

Fig. 6. Sensitivity curves for mixtures by weight of poly(2,3-dichloro-1-propyl acrylate) and N-phenyl maleimide.

Monomer volatility can also be a problem. Both acenaphthalene and 2-vinylnaphthalene exude too rapidly from spun films. Others such as 1,3-dimethoxystyrene, phenyl acrylate, and 4-chlorostyrene are also too volatile, while materials such as bis-phenol-A-dimethacrylate are too involatile and are partially polymerized during the higher temperature fixing step required. As a general rule of thumb we have found that monomers having a molecular weight ranging from 190-350 g/mole have appropriate volatility when mixed with poly(2,3-dichloro-1-propyl acrylate). The lower end of the range can be extended if a suitable glassy host polymer were used or if a highly polar monomer or a monomer containing hydrogen bonding groups were used. An example of the polar monomer case is N-phenyl maleimide, molecular weight 173 g/mole, which is less volatile than N-vinyl carbazole. Conceivably the upper part of the range could be extended by the use of monomers which are less subject to thermal polymerization.

The dependence on monomer concentration exhibited by N-vinyl carbazole is not mimicked by examples 9 and 10 for which free radical species are presumably involved. In other cases a maximum sensitivity is observed at about 7.5 w/o monomer. Similar results are obtained for many other materials locked by free radical mechanisms. It appears that these monomers are self-inhibiting, *i.e.*, less monomer is locked at high monomer content. This is in part due to the monomer's low x-ray absorption. However, at 30 w/o monomer, estimates based on calculated mass absorption coefficients predict only a 27% reduction in absorbed dose. This contrasts with a 75% reduction in sensitivity observed for 9 and a 40% reduction for 10. Since reduced absorption cannot account for these results, significant chemical quenching must be occurring.

We note that N-vinyl carbazole and 2-(1-naphthy)-ethyl methacrylate exhibit nearly identical differential removal rates for equivalent NT_R values. In contrast, N-phenyl maleimide is locked least efficiently but exhibits the highest differential removal rates. At 10 w/o composition $NT_D > 5NT_R$ for it whereas $NT_D \approx 3NT_R$ for N-vinyl carbazole and naphthylethyl methacrylate for $NT_R = 0.02$.

For all three monomers the contrast γ given by the slopes in Fig. 4-6 is low. However, resolution is high because of the differential removal process. It appears limited mainly by the mask and the electron range of secondary electrons produced in the resist. Unlike conventional wet-developed resists resolution is identical for all points along each sensitivity curve. The linewidth appears to be independent of exposure.

For comparison purposes in Fig. 4-6 we present the sensitivity curve for a high speed conventional wet-developed negative resist termed DCOPA. It is a 92.5:7.5 w/o mixture of poly(2,3-dichloro-1-propyl acrylate) and poly(glycidyl methacrylate-co-ethyl acrylate). Its properties were recently described by Moran and Taylor (7). For present x-rays masks with 6000Å Au and 1000Å Ta and a 25°-30° sloped edge, the proper exposure for 1 μm resolution and good linewidth control occurs at $D_g^{0.5}$, the 50% dose. For slightly lower doses resolution is adequate but linewidth is less than desired. For exposures at $<D_g^{0.4}$ resolution is inferior. For exposure $>D_g^{0.55}$ both resolution and linewidth control are worse. With plasma-developed resists underexposure or overexposure results in a shorter or longer plasma development time, respectively. Although final resist thickness is altered resolution remains identical. For N-vinyl carbazole and N-phenyl maleimide the sensitivity is higher for exposure to $D_g^{0.2}$. These materials thus offer considerable sensitivity advantages. Resolution also is much improved.

To date the most reactive monomer we have investigated is N-vinyl carbazole. We have studied it in a variety of polymer hosts which are absorbing at the PdL_α wavelength. Our results are presented in Table II and are listed in order of increasing sensitivity. Results are given for that monomer composition which afforded optimum sensitivity. Sulfur, bromine, and chlorine containing host polymers were studied. A broad range of sensitivities is observed. They are dependent on the specific bonding and polymer phase. The importance of polymer phase is best seen by comparing poly(2,3-dichloro-1-propyl acrylate) and the corresponding methacrylate. Both polymers are removed in an oxygen plasma at an identical high rate. The locked compositions exhibit nearly identical differential removal rates. The considerable difference in

Table II. Influence of polymer host on the properties of plasma developed negative x-ray resist containing N-vinyl carbazole monomer

Polymer	Phase[a]	Relative[b] plasma removal rate	Monomer (w/o)	Exposure time (min)	NT_R	NT_D	$D^{0.3}$ (mJ/cm²)	γ

Poly(2,3-dichloro-1-propyl acrylate)	R	12.22	20	1.0	0.07	0.18	3.2	0.14

[a] G = glass and R = rubber.
[b] Relative to the removal rate for poly(styrene) in an oxygen plasma (270Å/min) at 35°C.

sensitivity thus appears to be related solely to the locking efficiency which is four times less efficient for the harder glassy methacrylate.

Locking efficiency also appears to be controlled by the type of chemical bonds present. Most striking is the very long exposure time required to lock monomer into poly (2,3-dibromo-1-propyl acrylate). This is further aggravated by the tendency of the locked portions of the film to etch faster than the unlocked regions thus providing the sole example for which $NT_D < NT_R$. Perhaps in this case locked carbazole sensitizes the decomposition of the brominated acrylate.

Vinylic chlorine found in poly(chloroprene) appears to have low locking efficiency whereas aliphatic C-Cl bonds have much greater reactivity which is highly dependent on structure. The most sensitive compositions appear to be those which can form the most stable carbonium ion intermediates. The 1,3- and 2,3-dichloro-1-propyl acrylate polymers can both yield such stabilized species. In the case of the 1,3-isomer the primary carbonium ion can be stabilized by intramolecular participation with the carbonyl oxygen as depicted below (**11**). The 2,3-isomer can be similarly

—CH₂—CH— ; C=O ; O ; ⊕ ; CH—CH₂ ; CH₂Cl ; Cl⊖

—CH₂—CH— ; C=O ; O ; ⊕ ; CH₂—CH—CH₂Cl ; Cl⊖

11 **12**

stabilized (**12**) but in addition is a more stable secondary ion. Its expected greater stability could be responsible for the initiation of N-vinyl carbazole locking by a cationic polymerization mechanism.

Poly(2,3-dichloro-1-propyl acrylate)-N-vinyl carbazole mixtures.—Our best results to date have been obtained using a mixture of 81 parts by weight poly-(2,3-dichloro-1-propyl acrylate) (DCPA) and 19 parts by weight N-vinyl carbazole (NVC). The sensitivity curve for this composition is given in Fig. 7. An exposure time of 1 min affords a normalized thickness of 0.14-0.15 when developed in an oxygen plasma. The sensitivity curve is independent of thickness for 3 μm or less initial thickness films. Figure 8 plots final resist thickness *vs.* initial thickness for a 1 min exposure time. The linear plot is equivalent to a constant normalized thickness of 0.18. It results from the very nearly uniform absorption of x-rays by the resist having an absorption of 11%/μm at the 4.37Å $Pd_{L\alpha}$ line. Resolution for each point is identical. Thus, although the normalized thickness is rather low, the final thickness can have a practical value which of course is obtained by using a film having a greater initial thickness.

The reader may have noticed that the NT_D at 1 min exposure time for Fig. 7 is lower than that obtained in Fig. 8. This results from slight environmental and processing variations which can be both controlled and optimized. First, exposure to ambient fluorescent light causes resist exposure with consequent locking of significant NVC in nominally unexposed regions and affords a reduction in sensitivity. This results from absorption of light below 3700Å by the N-vinyl carbazole as shown in Fig. 9. DCPA is not absorbing at wavelengths >2300Å. The locked product, Fig. 9c, also is absorbing at the longer wavelengths. From the difference in absorbance of curves 9b and 9c at 3440Å we calculate that a 2.5 min exposure followed by fixing locks approximately 20% of the total monomer present assuming no variation in the extinction co-

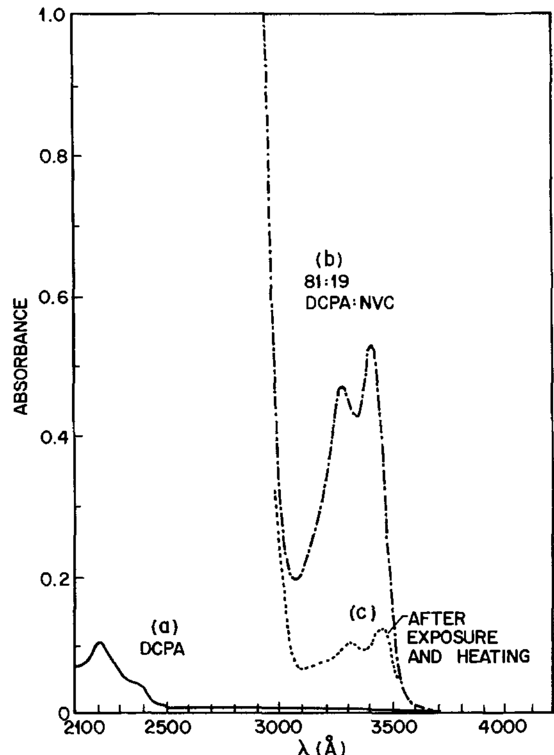

Fig. 9. Absorbance as a function of wavelength for (a) poly(2,3-dichloro-1-propyl acrylate), (b) 81 parts (a) and 19 parts N-vinyl carbazole, (c) (b) after 2.5 min exposure and fixing for 1 hr at 90°C and 0.1 Torr.

efficients for monomer and polymer. Use of yellow safelights and black wafer handling boxes has eliminated problems arising from ambient light exposures.

A second factor is fixation temperature and fixation time, a time temperature superposition. Results of a study of NT_D for a 1.5 min exposure as a function of fixing conditions are given in Table III for a 1.5 μm initial thickness film. The ultimate vacuum in the vacuum oven was 0.1 Torr. At the lowest temperature (23°) NT_D in large patterned areas was very high. However, development was microscopically nonuniform. Large unpatterned areas cleared before small unpatterned features. This was minimized by vacuum treatment for much longer time at 23° or by fixing at higher temperatures. At the highest temperature, NT_D values were lower than the optimum value obtained at 70°. Presumably, at the higher temperatures thermal locking of NVC becomes significant during the time required for removal of the unlocked NVC thus leading to a smaller difference in etch rates in the exposed and unexposed regions. A complete explanation of the phenomenon occurring at lower temperatures is not yet apparent.

Table III. Affect of fixing conditions on final thickness for 81:19 DCPA-NVC

Temp (°C)	Fixing time (hr)	Final[a] thickness (μm)	Remarks
23	0.50	0.47	Very nonuniform development
23	1.00	0.53	Very nonuniform development
23	16.00	0.36	Slight nonuniform development
45	0.50	0.32	Slight nonuniform development
60	0.50	0.30	Very slight nonuniform development
70	0.75	0.30	Uniform development
83	0.50	0.28	Uniform development
118	0.25	0.25	Uniform development
118	1.00	0.25	Uniform development

[a] The initial thickness was 1.5 μm and the exposure time was 1.5 min.

A third factor is loss of NVC from spun films by slow exudation of this slightly volatile material. A plot of spun thickness *vs.* time is given in Fig. 10 for the 81:19 mixture and a 1 μm initial film thickness. Thickness loss became significant for standing times longer than 4 hr at which time <5% of the NVC was lost. After 8 hr 12.5% was lost. In thicker films the rate of loss of NVC was less. At long setting times (≧ 16 hr) microcrystal formation was observed. After exposure the wafer may sit for times as long as 2 days before fixing. However, immediate processing is recommended.

A fourth factor constitutes the influence of plasma processing conditions on developed image thickness, uniformity, and quality. Center-of-table-mounted single 3 in. wafer samples were developed most uniformly at 0.40 Torr. Thickness uniformity across the wafer was 500Å. At lower and higher pressures uniformity was worse. At low pressure (0.10 Torr) the center of the wafer cleared first whereas the edges cleared first at 1.00 Torr. The NT_D values were optimum at 0.40 Torr. Temperature variations from 25°-70°C did not appear to affect NT_D. The combination of high temperature and high pressure did lead to deposition of polymer on the wafer which was worst at wafer edges. At high temperatures the film removal rate was at least a factor of 2 greater than at 25°C. At the optimum pressure of 0.40 Torr, power variations by ±200% had little effect on NT_D but did alter film removal rate and uniformity. The optimum power was 100W in the 13 in. barrel reactor.

These variations with plasma conditions are a consequence of the well-known loading effect in plasma etching (19). It is observed when the lifetime of the reactive intermediates responsible for etching is long, as is the case with oxygen atoms thought to be responsible for the oxygen plasma stripping of photoresists (20). Uniformity of plasma development is essential in order to maintain both adequate resist thickness for further etching steps as well as to maintain linewidth control. In the hope of achieving better development uniformity, patterns were developed using a radial flow plasma reactor with floating bias. Results with the radial flow etcher were worse than those obtained with the barrel reactor. Uniformity was at best 1200Å and NT_D values were lower.

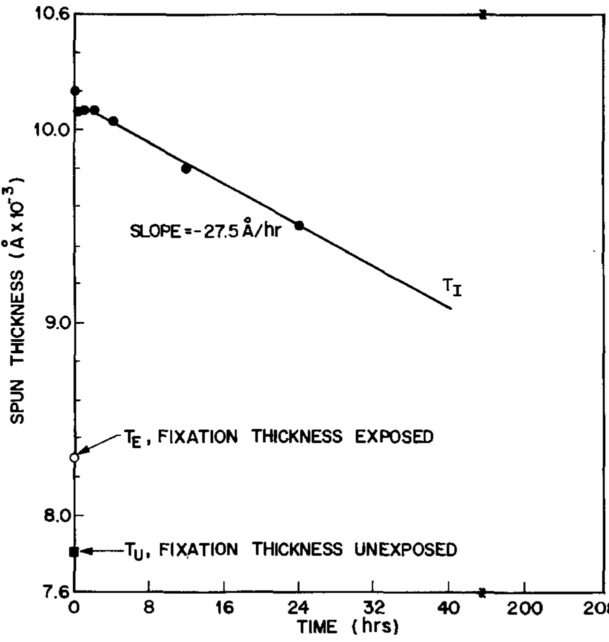

Fig. 10. Spun film thickness vs. standing time after coating of 81:19 DCPA-NVC.

Etch gas composition also has a considerable affect. Of all the gases and gas mixtures with and without oxygen that we have studied, only oxygen gave superior results. The other gases tried included CF_4, CHF_3, CF_3Cl, C_2F_6, N_2, He, Ar, NO_2, and CO_2. At low oxygen pressures traces of background air and pump oil hydrocarbons reduced NT_D. Thus plasma development afforded significant differential development only for oxygen containing plasmas.

A final factor is host molecular weight. Unlike many conventional negative resists in which sensitivity is dependent on the reciprocal of $\overline{M}_w$, we find no similar dependence for plasma-developed resists since crosslinking is not involved. Identical sensitivity curves were obtained for DCPA host having $[\eta] = 2.05$ and 0.80 dl/g. Thus, the molecular weight of the host can be designed to optimize processing properties. To date DCPA with molecular weight considerably lower than that used in conventional resist formulations has been found to be superior. Present DCPA properties are: $[\eta] = 0.80$ dl/g in ethyl acetate at 30°C, $\overline{M}_w = 764{,}000$ g/mole, $\overline{M}_n = 244{,}000$ g/mole, $P = 3.13$, and weight percent solids $= 12$ in chlorobenzene. Unlike conventional, negative crosslinking resists polydispersity has no influence on resist contrast.

Resolution.—In principle, the resolution of plasma-developed resists should be superior to that of conventional negative resists because of the absence of solvent-induced swelling. Consistent with this, we find that the resolution is better than 0.5 μm. SEM photomicrographs of thin (2500Å) patterns on silicon are shown in Fig. 11. The 0.5 μm gap is resolved including the proximity effect variations on the mask at the end of the gap. Resolution appears equally good in the partially developed 1 μm lines and spaces shown in Fig. 11d. Patterns in 6000Å thick resist are shown in Fig. 12. The lines are undersized in the line and space features due to overexposure in the mask resulting in greater gap widths as seen in the 0.5 μm gap (Fig. 12d) which is 1 μm wide in the print. Different masks were used to make the prints in Fig. 11 and 12.

Comparison of the pictures in Fig. 13 establishes the lower limit of resolution. SEM photomicrographs were taken of plasma-developed patterns exposed to 1.5 min of x-irradiation and further processed by trilevel techniques (21) to give high aspect ratio structures (Fig. 13a, 13b, and 13c). The exactly corresponding patterns in the x-ray mask are shown in Fig 13d, 13e, and 13f. It was necessary to destroy the mask and remove the topmost protective organic layer on it by plasma etching in order to obtain samples for SEM evaluation. The resist patterns are negative images of the mask pattern. Note that the particular mask chosen had very poor 0.5 μm features and only fair 1.0 μm features. Evaluation of resist resolution must be examined by comparison to the poorly resolved mask features having corrugated edges. In this regard, the fine structure at mask feature edges appears to be well resolved. This fine structure was copied to a great extent with about 0.1 μm of additional edge roughness being introduced. During pattern transfer to the intermediate 1200Å SiO_2 layer, only 300Å of the protective resist was lost. The change in linewidth from this loss is too small to measure by the techniques used here. The conventional DCOPA negative x-ray resist is not capable of resolving the poor 0.50 μm features on this mask. The plasma developed resist can resolve these features if development is continued for slightly longer time. This causes a 500Å thinning of resist and a consequent loss of linewidth for the larger features which is within the linewidth variation desired for the larger features.

This type of resolution can only be achieved on flat surfaces. On a surface having topography, the spun resist film will not cover all features to a uniform thickness. Consequently, during development the thinnest regions will clear first and the thickest regions last. The thickness difference due to topography may approach 0.70 μm in the worst case. In such cases plasma-developed resists having the present composition will be completely removed in the thinner regions thus offering no protection during subsequent process-

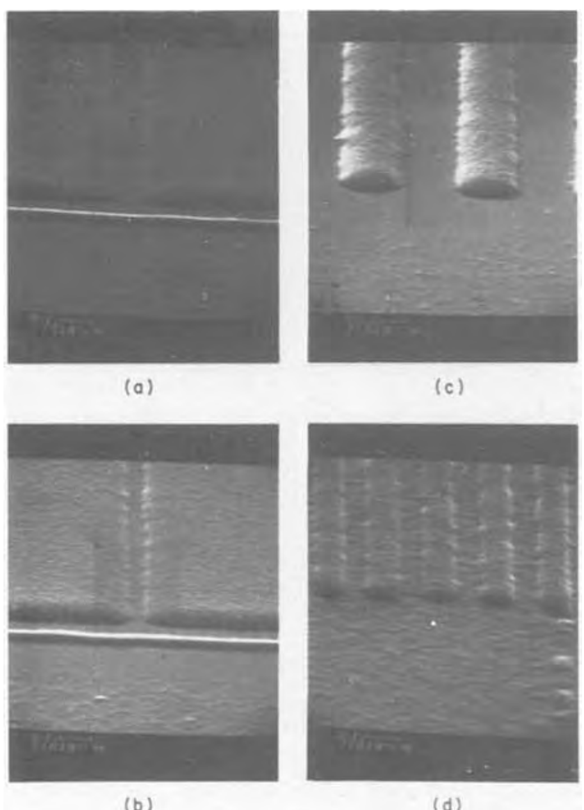

Fig. 11. Plasma-developed resist patterns from 81:19 DCPA-NVC in 2500Å thick resist after exposure for 1.5 min and plasma development. Initial thickness was 1.5 μm. Fully-developed patterns are shown in (a), (b), and (c). A 2000Å thick partially developed pattern is shown in (d).

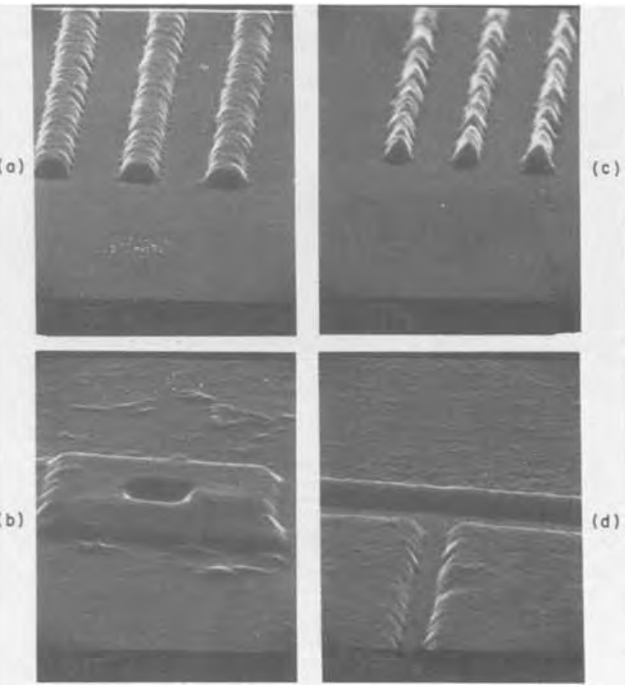

Fig. 12. 6000Å thick plasma developed resist patterns in 81:19 DCPA-NVC. The initial thickness was 3 μm and the exposure time was 1.5 min.

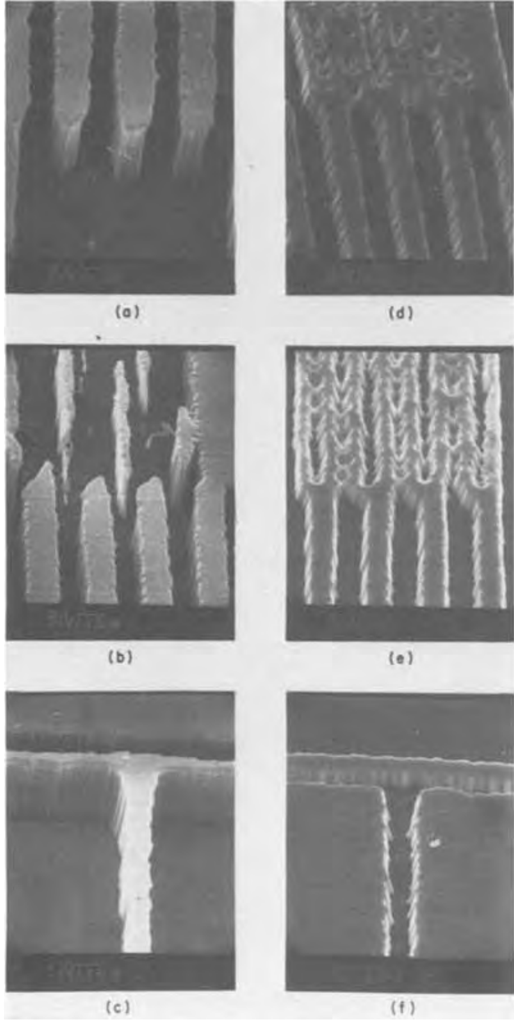

Fig. 13. Comparison of trilevel resist pattern resolution in 2.0 μm thick resist obtained from a plasma-developed resist top layer (a), (b), (c) to the exactly corresponding mask patterns in 7000Å thick Au (d), (e), (f). The limit to resolution seen by matching up the sharpest edges in the resist and mask patterns is about 0.3 μm.

ing steps. For reduced topographic variations, linewidth control will suffer. The trilevel process provides a means for circumventing the above difficulty. Using it and a higher resolution mask, line and space features as small as 0.3 μm should be resolved. Thus, it appears that plasma-developed x-ray resists are readily capable of submicrometer resolution.

General processing properties.—It was mentioned previously that the 81:19 DCPA-NVC composition provided a very good mask for etching the SiO_2 film used in the trilevel process. It also functions as an excellent etch mask for the dry etching of Si_3N_4 using 92% CF_4 and 8% O_2. Less than 500Å was lost in the latter case when 1200Å of Si_3N_4 was etched. Plasma etch resistance has not been evaluated for plasma etching conditions used to etch P-glass, polysilicon, and aluminum since trilevel resist processing must be used in conjunction with pattern transfer operations on these substrates.

In general, plasma developed resists have better processing properties than conventional negative x-ray resists. The former are easily filtered through 0.2 μm pores. The present formulation of 81:19 DVPA-NVC using 764,000 $\overline{M}_w$ DCPA affords excellent spun 1.5 μm initial thickness films by coating at 2450 rpm. A complete spin curve is given in Fig. 14. At spin speeds less than 2200 rpm a nonuniformity of the coating is observed which becames worse at lower spin speeds. The nonuniformity appears as thickness variations of as

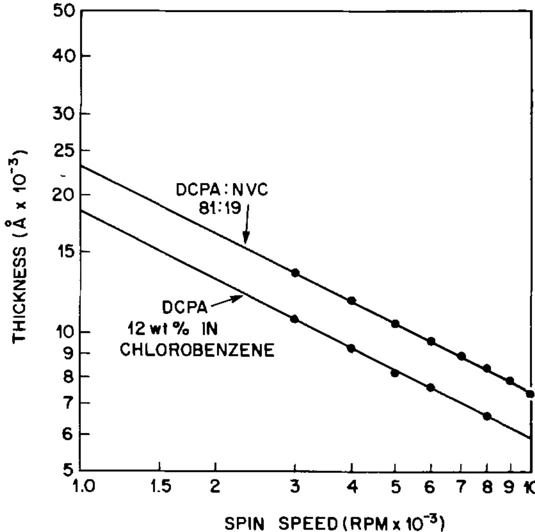

Fig. 14. Log-log plot of coated thickness in angstroms vs. spin-coating speed in rpm for 12 w/o 764,000 g/mole DCPA in chlorobenzene and the same solution admixed with NVC to give 81:19 DCPA-NVC solution by weight.

much as 1000Å over areas as large as 2500 μm^2 and results in ragged feature edges. We believe it arises from channel formation in the very rubbery intermediate phase formed as the solvent plasticizer exudes from the film during spin drying. At high spin speeds the lifetime of this semifluid phase is probably short enough to preclude formation of the regions with undulating thickness.

Conclusions

We have shown that it is possible to obtain sensitive negative x-ray resists that are developed by oxygen plasma etching. They do not suffer from the limitations to resolution imposed by distortions caused by wet solvent development of conventional negative resists. The differential removal of exposed and unexposed regions amplifies the initial relief images obtained by radiation locking moderately volatile monomers into a host polymer. The host polymer serves as a container and binder for the monomer and also functions as the main x-ray absorber and polymerization initiator. It has a high removal rate in an oxygen plasma. The most preferred monomer, N-vinyl carbazole, is not highly absorbing, but is readily polymerized presumably by a cationic mechanism. It has a volatility which offers optimum processing characteristics. The optimum 81:19 w/o composition of DCPA and NVC provides final resist thicknesses of 0.30 μm for a 1.5 min exposure time and submicrometer resolution. Flat substrate surfaces are required for good thickness and linewidth control. The resist is thus ideally suited to sequential trilevel processing. Total sequential processing by dry methods has been demonstrated for trilevel processed wafers.

Optimum and reproducible developed thickness has been found to be dependent on ambient light, fixing conditions, and plasma processing conditions as well as resist composition. All of these processes can be readily controlled thus assuring excellent reproducibility. Presently, initial spun thickness uniformity, etch uniformity, and end point control limit resolution to the submicrometer regime. Because the mechanism of action of this new type of resist is different, it is possible to tailor the molecular weight of the host polymer to give optimum processing properties. Low molecular weights are desired.

We believe that plasma developed x-ray resists offer superior properties relative to those of solution-developed resists. The most important of these are resolution, sensitivity, latitute of molecular parameters, and perhaps ultimate cost.

Chemical Vapor Deposition of Single Crystalline β-SiC Films on Silicon Substrate with Sputtered SiC Intermediate Layer

Shigehiro Nishino, Yoshikazu Hazuki, Hiroyuki Matsunami, and Tetsuro Tanaka[1]

Department of Electronics, Faculty of Engineering, Kyoto University, Kyoto 606, Japan

ABSTRACT

A single crystal of β-SiC was grown by chemical vapor deposition using an SiH_4-C_3H_8-H_2 system on a silicon substrate with a sputtered layer. The grown layer of 4 μm thickness was confirmed as a single crystal by examination with reflection electron diffraction and x-ray diffraction. To reduce the large mismatch between β-SiC and a silicon substrate, a sputtered β-SiC layer was employed as a buffer layer. Even though the sputtered layer was polycrystalline, the subsequent layer deposited by CVD was a single crystal. The crystallinity of the deposited layer was strongly affected by the thickness of the sputtered layer, the substrate temperature during sputtering, and the temperature of chemical vapor deposition.

Silicon carbide (SiC) is an interesting material for electronic and optical device applications because of its high temperature stability and large energy gap. The cubic form, β-SiC, has a bandgap energy of 2.35 eV (1) at room temperature, an electron mobility of 1000 $cm^2/V\cdot sec$ (2), and a drift velocity of 2.7×10^7 cm/sec (at 2×10^5 V/cm) (3). These properties are particularly attractive for minority carrier as well as majority carrier device applications. However, a large area substrate is not available because of the difficulty of crystal growth. Crystals of β-SiC obtained by a sublimation process (Lely method) have small size and irregular shapes, thus complicating wafer processing for device fabrication. In order to obtain β-SiC single crystals of large area, it is desirable to grow β-SiC on foreign substrates.

Epitaxial growth of β-SiC on foreign substrates has been reported by many investigators with chemical vapor deposition (CVD) (4-6), chemical conversion (7-9), evaporation (10), or rf sputtering methods (11-13). They, however, reported only very thin films of β-SiC. By the chemical conversion method. Nakashima *et al.* (9) have obtained single crystal films of β-SiC less than 100 nm thick on an Si substrate. Examination with reflection electron diffraction (RED) showed the change of the crystal structure from single crystal to polycrystal with increasing film thickness. Rohan *et al.* (5) showed oriented β-SiC layers grown on sapphire substrates by CVD and reported that the growth of single crystal films was not possible because of relatively large lattice mismatch.

[1] Present address: Takuma Radio Technical College, Takuma, Mitoyo-gun, Kagawa 769-11, Japan.

Key words: silicon carbide, CVD, epitaxial films, thin films, sputtering.

Difficulty with heteroepitaxial growth comes from the lattice mismatch between the grown layer and the substrate (a_{SiC}: 4.358Å, a_{Si}: 5.430Å, $a_{sapphire}$: 4.75Å, $c_{sapphire}$: 12.95Å). One of the approaches to overcome this difficulty is to introduce a buffer layer between substrate and deposit. This approach is well known in the crystal growth of III-V compounds by liquid phase epitaxy. A few examples are reported for CVD systems such as GaP/evaporated P/Si (14), ZnO/sputtered ZnO/sapphire (15), β-SiC/evaporated Ni/α-SiC (16), and α-SiC/sputtered AlN/W (17).

We previously reported the preparation of β-SiC on Si substrates by a sputtering method and suggested that the sputtered β-SiC layer might be attractive as a substrate in the CVD process (18). In the CVD process, we reported the optimum conditions for epitaxial growth of β-SiC on Si substrates with an $SiCl_4$-C_3H_8-H_2 system (19). In this report, chemical vapor deposition of single crystal β-SiC films on Si substrates with sputtered β-SiC intermediate layers is described. Chemical vapor deposition was carried out using an SiH_4-C_3H_8-H_2 system. The crystallinity of the deposited layer was found to be strongly affected by the thickness and the crystalline structure of the sputtered layer. The surface morphology and crystallinity of the layer grown by CVD are described. The growth mechanism of β-SiC is also discussed.

Experimental

Sputtering.—Thin films of β-SiC were deposited on Si substrates by rf sputtering. The target material was an SiC disk from Union Carbide Company. The distance between the target and the substrate was 4.5 cm. The Si substrate was heated by a molybdenum strip heater and the temperature was measured by means of an optical pyrometer.

After preliminary evacuation of the reaction chamber to 1×10^{-6} Torr, argon gas was introduced up to a pressure of 1×10^{-2} Torr. Rf power of 200W (peak voltage of 2 kV and frequency of 13.5 MHz) was applied. Substrate temperatures were varied between 800° and 1000°C. Sputtering time was varied from 100 sec to 60 min. The thickness of the thin film was determined by using an interference microscope at a step made by masking a portion of the substrates during sputtering.

Chemical vapor deposition.—The deposition of β-SiC by pyrolysis of silane (SiH_4) and thermal decomposition of propane (C_3H_8) in a hydrogen flow system was carried out using the apparatus shown in Fig. 1. The reaction tube of 30 mm ID and 440 mm length was made of clear fused quartz with a water-cooled jacket. The thickness of the sputtered layer was 30-80 nm. After being rinsed in acetone and dried, the substrate was put on an SiC-coated graphite susceptor ($24 \times 5 \times 30$ mm^3). To obtain a uniform grown layer, the susceptor was tilted at an angle of 10° from the horizontal. The linear velocity (defined as the ratio of the carrier gas flow rate to the cross section of the reaction tube) of the system was approximately 2 cm/sec. The temperature was measured by observing the Si substrate through the water-cooled wall of the reaction tube with an optical pyrometer. The measured temperature was calibrated taking account of the emissivity of Si, but no correction was made for absorption by the water-cooled quartz jacket. The entire system was evacuated by a rotary pump and backfilled with H_2. After H_2 flowed for 10 min, the substrate was heated externally by an rf generator and kept at 1000°C for 5 min before deposition of β-SiC.

The deposition of the β-SiC was carried out at a substrate temperature in the range of 1000°-1360°C with the standard gas composition: H_2-750 cm^3/min, SiH_4-0.6 cm^3/min, C_3H_8-0.2 cm^3/min, Si/H_2-0.7×10^{-3}, and Si/C = 1. The deposition time was usually 30-180 min. The thickness of the deposited β-SiC films was determined by direct observation of the cross section of fractured specimens with a scanning electron microscope (SEM). To study the crystallinity of the β-SiC films, the grown layers were examined by reflection electron diffraction with an acceleration voltage of 80 kV. The lattice parameters of the grown layers were determined from a spot pattern using the diffraction pattern of gold as a reference.

Experimental Results

Preparation of substrates.—The relation between the thickness of the sputtered SiC film and sputtering time is shown in Fig. 2. The sputtering rate depends on the substrate temperature. The higher the substrate temperature, the lower the sputtering rate obtained. The temperature dependence is explained by a reduced sticking coefficient of sputtered atoms at high substrate temperatures, or by decreased sputtering yield resulting from high target temperature due to thermal radiation from the heated substrate (20).

Since the substrate with the sputtered layer is kept at high temperature during the CVD process, the crystallinity of the sputtered layer could be changed by the heating process. Consequently, the crystallinity of the sputtered layer before and after annealing was examined by RED analysis. Thermal annealing was carried out in an Ar ambient at 1270°C for 30 min. Diffraction patterns of the sputtered layer before and after annealing are shown in Fig. 3. Before annealing, every RED pattern showed haloes which implies an amorphous state. This was true even if a high substrate temperature was employed during sputtering, as shown in Fig. 3(b) and (c). After annealing, the RED pattern showed Debye rings which imply a polycrystalline state. The Debye rings became stronger

when the substrate was kept at high temperature during sputtering. The sputtered layer was verified as being polycrystalline β-SiC by analyzing the RED pattern.

Temperature dependence of the CVD growth rate.—The growth rate as a function of the substrate temperature is plotted in Fig. 4. Vertical bars in the figure define the thickness difference from run-to-run. The mole ratio of the reactant gas (SiH_4, C_3H_8, Si/C = 1) to hydrogen is shown in the figure. The open circles indicate a higher mole ratio than that for the solid circles. While the higher mole ratio gave higher growth rate, it also gave an irregular surface and poor crystallinity, so the layer grown with the higher mole ratio is not favorable for device applications. The lower mole ratio gave a smooth surface and good crystallinity; therefore the ratio represented by a solid circle in Fig. 4 was chosen as a standard gas composition. The growth rate is expressed by an exponential function of the reciprocal substrate temperature above 1200°C, which indicates that the growth rate is limited by surface reaction. The activation energy for the formation of β-SiC calculated from the slope of the line is about 15 kcal/mole. An activation energy of 20-25 kcal/mole was obtained for the growth of β-SiC on an Si substrate without a sputtered layer when using the $SiCl_4$-C_3H_8-H_2 system (19). Two reasons may be given for the two activation energies. First, the growth of β-SiC on an Si substrate is heteroepitaxial growth, while the growth of β-SiC on a buffer layer (polycrystalline β-SiC) is homoepitaxial growth to some extent. The activation energy for homoepitaxial growth is generally smaller than that for heteroepitaxial growth. Second, $SiCl_4$ was used for the Si source in the previous work (19), while SiH_4 was used in this work. Since the temperature of decomposition of SiH_4 is lower than that of $SiCl_4$, a smaller activation energy might be expected.

The growth rates appear to be constant at substrate temperatures lower than 1200°C. The deposition mech-

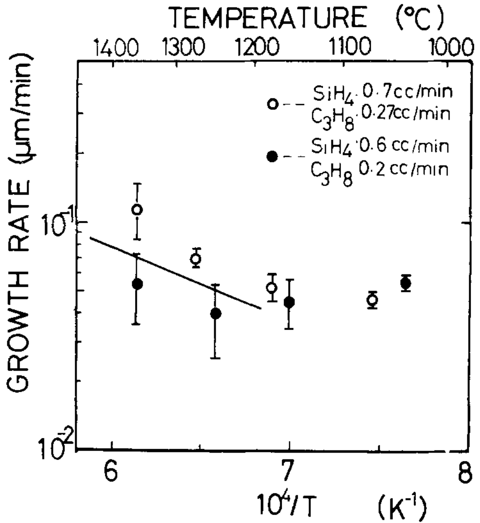

Fig. 4. Temperature dependence of the CVD growth rate

anism might be different in the high substrate temperature and low substrate temperature regions. Although the sputtered layer originates many nucleation sites for subsequent CVD growth, the layers grown by CVD at low temperatures tend to be polycrystalline because of short migration length of adatoms on the surface.

Surface morphology.—Surface morphology of the layers grown at three substrate temperatures is shown in Fig. 5. When the deposition was done at 1070°C, the surface was covered with rounded grains of size less than 0.2 μm. On the surface grown at 1250°C, the size of the rounded grains became larger. When the film was deposited at 1360°C, the surface was strongly influenced by the crystal habit of the substrate. Although the size of the grains became larger at a substrate temperature lower than 1360°C, the layer showed a bumpy surface resulting from incomplete coalescence of the grains. When the substrate temperature was above 1360°C, coalescence of the grains was fully developed and a replica of the crystal habit of the substrate appeared in the grown layer. Figures 6(a) and (b) show surface morphology of the layer grown at 1360°C. Square crystallites with a side of 1 μm were observed on the layer grown on the (100)Si substrate, while triangular crystallites with a side of 2 μm were observed on the layer grown on the (111)Si substrate.

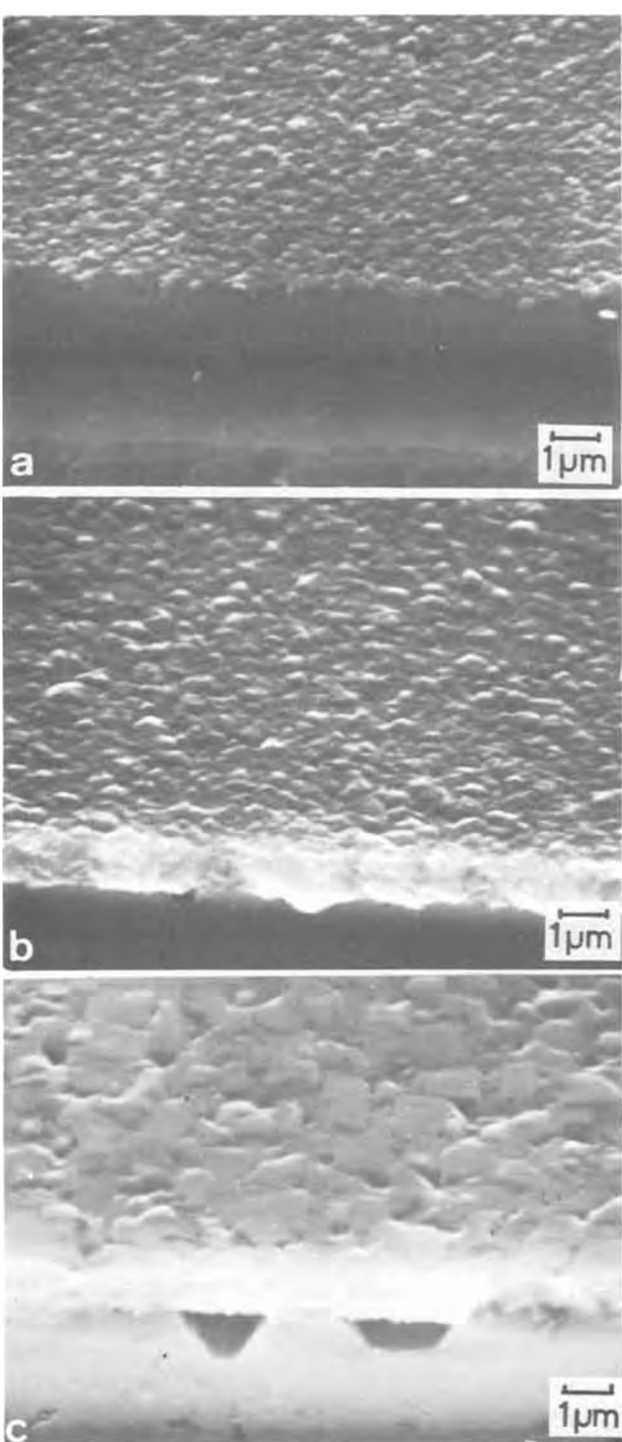

Fig. 5. Morphology of the grown layer for different substrate temperatures: (a) 1070°C, (b) 1250°C, (c) 1360°C.

Crystalline properties of β-SiC films.—The crystallinity of growth obtained by the CVD process was strongly affected by the thickness of the sputtered SiC layer and the substrate temperature during sputtering. The layer grown by CVD was not a single crystal when the sputtered layer was thicker than 100 nm, even if a high substrate temperature was employed during sputtering. When the sputtering was done at a substrate temperature lower than 800°C, the subsequent layer grown by CVD was not a single crystal in spite of keeping the substrate at high temperature during the CVD process. From these experiments, it was found that the Si substrate should have a sputtered β-SiC overlayer with a thickness of 30-80 nm prepared at a substrate temperature of 1000°C.

The growth temperature for CVD is one of the important parameters which determines the crystallinity of the grown layer. The crystallinity of a layer of about 4 μm thickness was examined by the RED method. The diffraction pattern of β-SiC prepared at 1160°C showed so-called Debye rings which indicate a polycrystalline structure. Spots were superimposed

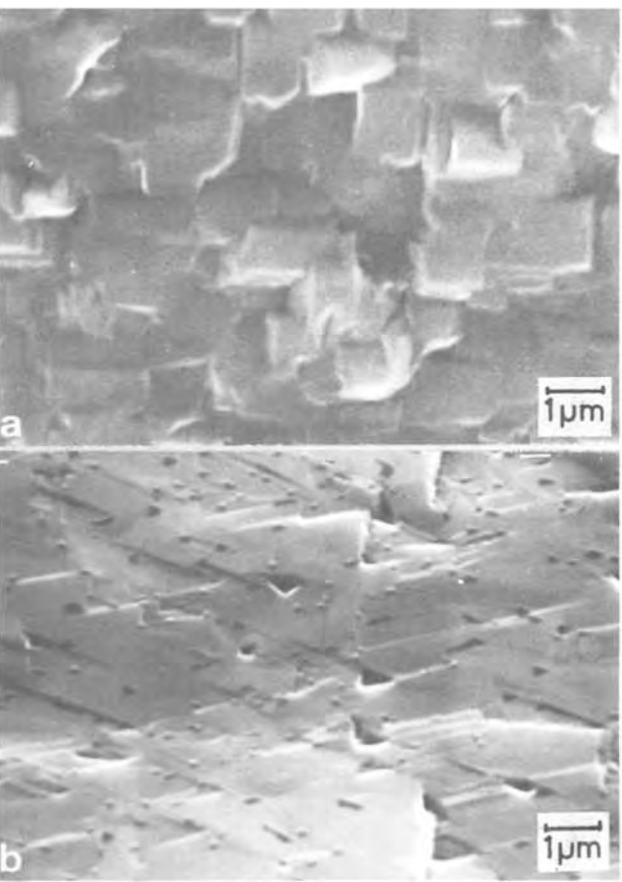

Fig. 6. Morphology of the grown layer reflecting the crystal habit of the substrate. (a) Layer grown on (100)Si substrate with a sputtered layer. (b) Layer grown on (111)Si substrate with a sputtered layer.

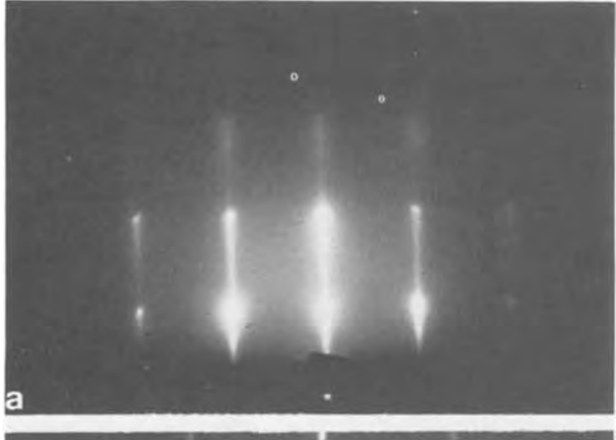
on the faint Debye rings for the film prepared at 1250°C, but the diffraction pattern was not changed when the direction of the incident electron beam was changed. The grown layer was therefore considered to have a preferred orientation. For the film prepared at 1360°C, the diffraction pattern consisted of strong spots. Consequently, it may be concluded that a change from polycrystalline to single crystal structure occurred with increasing substrate temperature. Good single crystals seem to be obtained at approximately 1360°C.

To investigate the substrate-orientation dependence of the growth, substrates with (111) or (100) surface planes were used. The CVD growth of β-SiC was carried out on the two substrates simultaneously using the standard gas composition at 1360°C. The diffraction patterns from the layers grown on the two substrates are shown in Fig. 7. Strong spots indicate that the layers are single crystalline. The orientation relationship between the overgrowth and the substrates is as follows

$$\beta\text{-SiC}(111)//\text{Si}(111), \beta\text{-SiC}[\bar{1}10]//\text{Si}[\bar{1}10],$$

$$\beta\text{-SiC}(100)//\text{Si}(100), \beta\text{-SiC}[001]//\text{Si}[001]$$

Since the RED measurement gives information on crystallinity very near the surface, the layer was examined by x-ray diffraction with a copper target for further crystal analysis. Figure 8 shows typical diffraction charts for the β-SiC layers. A strong peak appeared at $2\theta = 41.40°$ for the layer grown on the (100) substrate. A peak for the Si substrate also appeared due to the thin β-SiC layer. A strong peak also appears at $2\theta = 36.65°$ for the layer grown on the (111) substrate. Furthermore, the β-SiC film without a substrate was also examined by x-ray transmission Laue method. The Si substrate was removed by chemical etching using an HNO_3-HF solution. The Laue photographs are shown in Fig. 9 for the layers grown on the (100) and (111) substrates. The Laue pattern for the layer grown on the (100) substrate shows fourfold symmetric spots with faint Debye rings as shown in Fig. 9(a). The Laue pattern for the layer grown on the (111) substrate shows threefold symmetry with diffuse spots and faint Debye rings, as in Fig. 9(b).



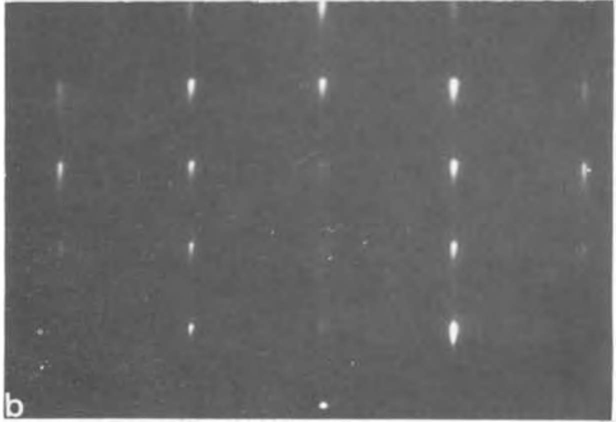


Fig. 7. Reflection electron diffraction patterns from layers grown on (a) (100)Si and (b) (111)Si substrates with sputtered layers.

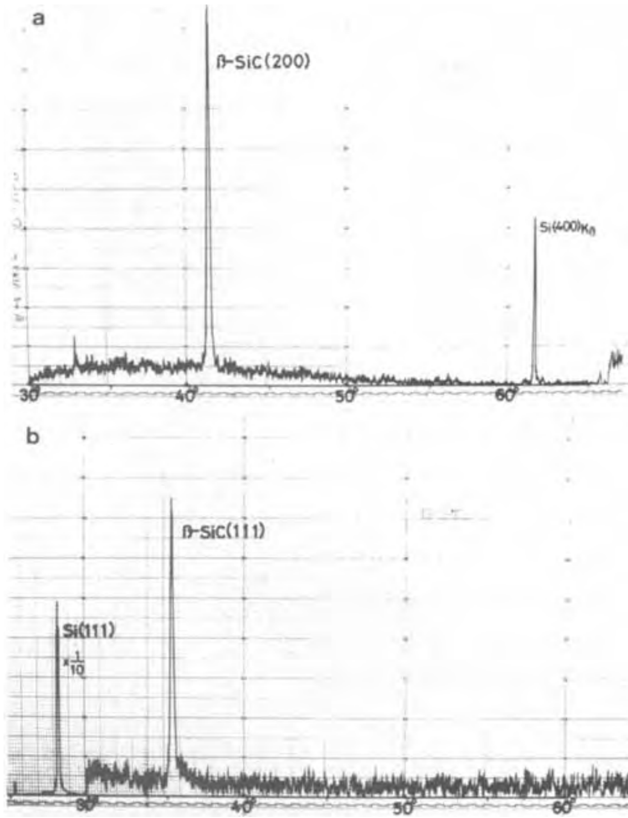

Fig. 8. X-ray diffraction spectrum obtained from layer grown on (a) (100)Si and (b) (111)Si substrates with sputtered layers.

The faint Debye rings are found to arise from the polycrystalline layer contiguous to the Si substrate. The underside of the β-SiC film was observed by SEM and examined by RED. A triangular morphology was observed on the underside surface of the layer grown on the (111) substrate, as shown in Fig. 10(a). In this figure, the length of the side of the triangles was scattered from 0.1 to 0.4 μm. The RED pattern from the underside of the layer shows Debye rings of polycrystalline β-SiC, as shown in Fig. 10(b).

Discussion

When a β-SiC film is deposited directly on an Si substrate, it is difficult to grow single crystals of β-SiC thicker than 100 nm, as reported by most researchers. The difficulty arises from the large lattice mismatch and stresses between the grown layer and the substrate. In this work, by introducing an intermediate layer as a buffer layer, stresses caused by the lattice mismatch could be released. The buffer layer should have an appropriate film thickness and crystallinity, because the crystal field of the substrate must be transferred through the buffer layer.

We speculate that the nature of the polycrystalline β-SiC layer obtained by sputtering is different from the one obtained by CVD. In the CVD system, the grown layer is formed under a condition of thermodynamic equilibrium, so that nucleation and growth are strongly dependent on the surface treatment of the substrate. The initial stage of growth is influenced by parameters difficult to control, such as surface roughness and dislocations. An adatom moves toward favorable sites of the substrate, so the density of nu-

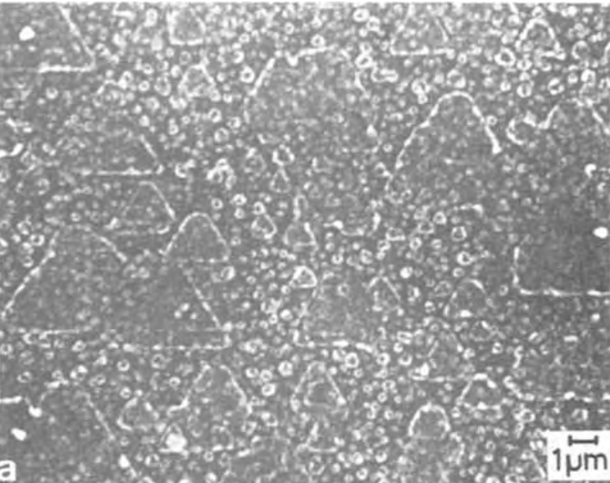

Fig. 10. Crystal structure of the underside of β-SiC after removal of the Si substrate. (a) SEM photograph and (b) RED pattern.

cleation on the surface might be nonuniform atomically. As a result, single crystal growth of β-SiC on an Si substrate by the CVD process needed careful preparation including SiC coating of the susceptor and etching of the substrate before the crystal growth. Furthermore, reproducibility of single crystal growth was not good. In the sputtering method, deposition is carried out under a nonequilibrium condition. Sputtered atoms uniformly hit the whole area of the substrate and nucleation may occur more uniformly over the surface. Therefore, the intermediate layer of β-SiC prepared by sputtering can be more uniform than that by CVD. Consequently, the initial stage of growth in the subsequent CVD process is not strongly dependent on the surface and single crystals of β-SiC are reproducibly obtained. When the CVD deposition was done at a substrate temperature higher than 1360°C, single crystalline β-SiC was also obtained in cases where the film thickness was less than 4 μm.

Conclusion

Single crystals of β-SiC were obtained reproducibly by CVD at a substrate temperature of 1360°C on Si substrates by using sputtered SiC layers as buffer layers. Crystallinity of the β-SiC layer so grown was examined by the RED and x-ray diffraction transmission Laue methods. The epitaxial relation between the β-SiC film and the Si substrate was obtained. Sputtering should be done at a substrate temperature between 800° and 1000°C. To obtain a single crystal by CVD, the thickness of the sputtered layer must be less than 100 nm. It is speculated that the growth of the single crystalline β-SiC was controlled by the crystal field of the Si substrate through a polycrystalline intermediate layer formed by sputtering.

Application of the Langmuir Probe in Sputtering Techniques

H. Norström, R. Olaison, S. Berg, and L. P. Andersson*

Institute of Technology, Uppsala University, S-751 21 Uppsala, Sweden

ABSTRACT

During sputtering the plasma potential of the glow discharge may be influenced by unprotected electrodes situated in the vicinity of the plasma region. A positive electrode potential (V_a) is known to shift the plasma potential by a value of V_a in the positive potential direction. A negative electrode potential has no such influence on the plasma potential. A consequence of this behavior of the plasma potential is that all grounded parts of the vacuum system will establish a substantial ($\sim V_a$) negative potential with respect to the plasma if a positive electrode is introduced. This effect may cause excess contamination of the sputtered films since sputtering during this condition takes place both from the grounded vessel surfaces and from the sputtering target. Also, grounded substrates will then be subjected to unintended bombardment by energetic ions. This is especially important to consider in planar magnetron sputtering, where no energetic bombardment of substrates is supposed to take place. Introducing a negatively biased Langmuir probe into the plasma makes the probe current very sensitive to plasma conductance without affecting plasma potential conditions during sputtering. It is thus possible to monitor the sputter-cleaning of targets. During cleaning of an Al target the secondary emission factor of electrons caused by ion impact changes considerably. Thus the conductance of the plasma changes. This is detected by the Langmuir probe.

Numerous papers have been published in the field of Langmuir probe studies of glow discharges (1-3). We will restrict ourselves to the region of interest during sputtering. It has been reported that during sputtering of Ta and TaO it is necessary to reproduce not only pressure and bias conditions but also plasma conditions in order to obtain reproducible results.

This points out the importance of knowing and understanding plasma conditions during sputtering. It is well known that the plasma potential follows the potential of a positive electrode introduced into the plasma. In this way Holland (4) used the effect for treating and passivating vacuum systems. Coburn and Kay (5) measured the energy of ions extracted from a plasma and showed that the ion energy increased by the same value as a positive bias applied to an electrode exposed to the plasma. Both of these observations strongly confirm that the plasma I-V characteristic is indeed affected by an extra electrode introduced into the plasma in a sputtering system.

In some plasma applications it is very important to avoid any possible sputter bombardment of the substrates. If such bombardment takes place it may ruin the performance of the device. We are going to point out some possible sources causing such (unintended) bombardment of the substrates during sputtering.

Experimental Results and Discussion

A system such as that shown in Fig. 1 was used during the probe I-V measurements. A single Langmuir planar probe was inserted into the sputtering plant. The upper electrode in Fig. 1 formed the cathode and consequently operated as the target during sputtering. A metal screen was inserted inside the glass bell jar. This metal screen was insulated from ground and a positive or negative voltage may be applied.

Consider the experimental I-V characteristics shown in Fig. 2. Here the Langmuir probe characteristics have been measured under different conditions wherein voltage is applied to the metal screen inside the vacuum chamber during sputtering. The I-V characteristic clearly shifts to more positive potentials with a value equal to that applied to the metal screen. Since the plasma is quite conductive, the plasma potential V_p follows the potential of the positive metal screen as expected. The implication of this effect is clearly demonstrated by applying a very high positive value to the metal screen. If so, a "dark space" region is observed over grounded areas inside the vacuum cham-

ber. These areas are then subjected to sputter bombardment of argon ions. This effect has earlier been used by several authors, *e.g.*, Holland (4) to clean grounded stainless steel vacuum chambers. It is also a well-known fact that this effect causes outgassing of the system (6) and speeds up pumping time. This coupling of the plasma potential to the most positive potential in the vacuum chamber also exists in a planar magnetron system. Figure 3 shows the photograph of the *I-V* characteristics of the Langmuir probe in a magnetron sputtering equipment. Figure 3 clearly demonstrates the described coupling effect. Since many commercially available magnetron plants are equipped with a positive anode ring it is important to realize the effect of this anode on the plasma potential. In certain applications this positive anode may cause unintended bombardment of grounded substrates by energetic ions. If a positive bias is applied the ground to plasma potential difference may exceed the threshold value for sputtering. The yield is of course still low, but this effect may under severe circumstances cause excess film contamination from chamber walls.

This is in accordance with the results from Coburn and Kay (5) who showed by mass spectrometric studies that grounded areas really are bombarded by energetic particles if the plasma potential is raised by introducing a positive electrode.

We also want to report on a quantitative way to make use of the Langmuir probe. We have found that the probe operates as an end-point detector in sputter-etching experiments. The probe was used with a negative bias of 15V so as to collect only ions, not influenc-

ing the sputter conditions. In Fig. 4 the collected ion-current to the probe is monitored during cleaning of an Al target in d-c-sputtering equipment. Here the ion-current *vs.* time is shown to decrease to a steady-state level. In the same figure the cathode current of the Al target is also recorded. These two curves have a very strong correlation. What is demonstrated is that Al_2O_3 is removed from the surface. The secondary electron coefficient by ions is lower for Al than for Al_2O_3. Thus the target current decreases. Since fewer secondary electrons are generated at the target surface when the oxide is removed, the conductance of the plasma decreases. Thus the ion concentration in the plasma will be smaller. The ion-current collected by the probe thus decreases, indicating that the oxide is removed. The Langmuir single planar probe thus offers the possibility of simple end-point detection in a d-c-sputtering system.

Preliminary results on rf-sputtering and on d-c-magnetron sputtering showed no such simple and reliable results. The reason why end-point detection cannot be observed by a single Langmuir probe under these conditions is probably due to the differences in ionization mechanisms compared to simple d-c-sputtering. Here the ionization is not directly dependent on the target electron secondary emission coefficient. Instead plasma conductance depends on frequency, magnetic flux, etc. Thus the change in plasma conductance may be too small to be ensured. However further work will be carried out to investigate the usefulness of Langmuir probe as end-point detectors.

Summary

The plasma potential in d-c-sputtering equipment will be determined by the most positive electrode exposed to the plasma. This may cause unintended bombardment of grounded substrates by energetic ions. The plasma conductance changes when an oxide is removed from an Al-target in a d-c-sputtering system. This effect is used to detect target cleaning with a single Langmuir planar probe.

Manuscript submitted Dec. 26, 1979; revised manuscript received May 23, 1980. This was Paper 128 presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Electrostriction in Anodic Oxides: Comparison with Macroscopic Theory

Jack L. Ord*

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

ABSTRACT

Optical studies of the anodic oxidation of tantalum, niobium, and tungsten have recently found that application of the anodizing field increases the oxide film thickness by between 0.1 and 1% and decreases both the optical and low frequency dielectric constants by about the amount predicted by the Clausius-Mossotti relation between dielectric constant and density. These results are shown to contradict the predictions of the macroscopic theory of electrostriction, and the reasons for the conflict are examined. Energy conservation is shown to require the dielectric constant to have an explicit dependence on the electric field, and this requirement invalidates both the Clausius-Mossotti relation and the form of the energy density used in the macroscopic theory. A modified theory using an energy density of the form used in the theory of ferroelectrics is shown to give results consistent with all of the experimental results including the observation that at large strains the dependence on field is not quadratic.

The current physics literature on electrostriction is characterized by complaints from experimentalists that "disagreements exist as to the proper form of the (Maxwell) stress tensor in material media" (1), and complaints from theoreticians that "there exists very little information on detailed numerical values of the electrostrictive tensor ... most references are very old ..." (2). The problem has been that electrostrictive effects in most materials are so small that they are of little interest to the experimentalist, and as a consequence there are insufficient data available to test competing theories.

The electrochemical literature, on the other hand, contains a small but growing number of recent papers (3-10) which report extraordinarily large electrostrictive effects in anodic oxide films. Although there is some disagreement concerning the form of the field dependence, there is no argument about the three main features of the results: (*i*) the strains are very large, as large as 1%, (*ii*) the strains are positive, *i.e.*, film thickness increases with field, and (*iii*) the effects appear to be universal, having been observed directly in the anodic oxides of tantalum, niobium, and tungsten, and indirectly in the anodic oxides of vanadium (11) and molybdenum (12). Although no explanation has been offered for the occurrence of a large positive strain instead of the small negative strain expected to

Key words: dielectrics, capacitance, ellipsometry, ferroelectricity.

result from coulomb attraction between the opposing charge layers, the optical and low frequency dielectric constants have been shown to vary with field in approximately the manner predicted by the Clausius-Mossotti relation between dielectric constant and density.

In this paper we begin by summarizing the experimental results and outlining the development of the macroscopic or phenomenological theory of electrostriction. We then show that the experimental results contradict the predictions of the theory, and we examine the reasons for the disagreement. Finally we show how the theory can be brought into agreement with the results of experiment, and we discuss the physical significance of the modifications required.

The Experimental Results

The anodic oxides of tantalum and niobium have a number of properties which make them ideal from an experimental viewpoint for a study of electrostriction: (*i*) they support high electric fields without appreciable leakage current; (*ii*) they have high dielectric constants; (*iii*) they can be studied over a wide range of film thickness; (*iv*) they are insoluble in the electrolytes of interest; (*v*) the high-field growth process keeps their thickness uniform. Further, they have two properties which make them ideal also from a theoretical point of view: (*vi*) their vitreous structure is isotropic at zero applied stress and field; (*vii*) the massive metal substrate applies the boundary condition that the transverse strain be zero. The anodic oxides of tungsten, vanadium, and molybdenum are progressively less ideal, and metals such as iron which cannot be anodized beyond the oxygen evolution potential have anodic oxides which are far too thin for direct optical strain measurements. The only way in which the anodic oxides of tantalum and niobium differ significantly from ideal films of elastic dielectric is a consequence of the fact that they are grown in a high electric field. The large-scale atomic migration during film growth tends to relax stress in the film and when the field is removed the film is not left in a stress-free state, whereas all simple models assume that the film starts out in a stress-free state at zero field. We will deal no further here with this problem nor with the related problem of stress relaxation beyond noting that both introduce uncertainties into the analysis of the optical data.

The main experimental technique used to study electrostriction in anodic oxides is ellipsometry. This optical technique, based on the analysis of the change in polarization produced on reflection of light incident at an oblique angle on a film-covered interface, is capable of measuring and distinguishing between small changes in refractive index and film thickness. The two laboratories which have been involved in the optical studies of electrostriction in anodic oxides use similar self-nulling ellipsometers linked along with the anodization circuitry to minicomputer systems. Although the original study (3) treated the oxide films as optically isotropic, in all of the more recent work (4-6, 9, 10) the analysis takes account of the field-induced birefringence.

In all of our investigations the optical measurements have been complemented by measurements of the field dependence of the dielectric constant of the oxide film. In our original work (3) we used an a-c technique similar to that used on tantalum film capacitors (7, 8), but recently (9, 10) we have used a technique based on the analysis of open-circuit transients (13). This latter technique is primarily an analysis of the ionic conductivity of the oxide film and is based on the assumption that the logarithm of the ionic current density is proportional to the product KE, where E is the electric field in the oxide film and K is its dielectric constant. The technique was developed more as a test of the influence of electrostriction on the ionic conductivity than as a technique for determining the field-dependence of the dielectric constant. If the electrical equation of state relating the dielectric constant of the oxide to its density is known, the dielectric constant data can be used to calculate a relation between strain and field which can be compared directly with the optical data. The equation of state which we have used in all of our work is the Clausius-Mossotti relation which "gives the correct dependence of K on density for a wide class of solids and liquids" (14)

$$(K-1)/(K+2) = A\rho \qquad [1a]$$

where A is a constant and ρ is the density of the oxide. If the transverse strain is zero, the relation can be rewritten in the form

$$u = 3\,(K_0 - K)/((K_0+2)(K-1)) \qquad [1b]$$

where K_0 is the value of K when u, the strain in the field direction, is zero. For large values of K, Eq. [1b] can be rewritten, to a very good approximation, in a form which shows that the Clausius-Mossotti relation "amplifies" the effect of strain by a factor of $K_0/3$

$$K_0/K = 1 + (K_0/3)u \qquad [1c]$$

Although the Clausius-Mossotti relation can be used to link dielectric constant measurements to optical strain measurements, it is of no direct use in the analysis of open-circuit transient or a-c data where one needs instead a relation between dielectric constant and field. In our analysis of open-circuit transient data (9, 10) we have fitted the data to the empirical form

$$K = K_0\,(1 - \gamma(E/E_1)^n) \qquad [2]$$

where γ is the fractional change in K when the field is raised from 0 to E_1, the oxidation field. An expression of this form can be used in the analysis of a-c data also provided one is careful to take account of the fact that the a-c technique involves the derivative of the dielectric constant. In fitting our original a-c data (3) to Eq. [2] for inclusion in the figures which follow, we had insufficient information to determine all three parameters, and were forced to assume a value for n. Since our most recent values (10) for n were 1.85 for niobium and 1.75 for tungsten, we took their average, 1.8, and applied it to the a-c data from original study.

The experimentally determined dependences of strain on field for the anodic oxides of tantalum, niobium, and tungsten are shown in Fig. 1, 2, and 3. All of the optical results plotted in the figures were obtained by analysis techniques which take account of the birefringence induced in the oxide film by the field, and the source of the data is indicated in each case. The dielectric constant data were all obtained in our laboratory, and strains were calculated from them using the Clausius-Mossotti relation as described above. Although we shall see that the Clausius-Mossotti relation is not actually applicable to our data, it does provide a convenient means of reducing dielectric constant data to a dimensionless, frequency-independent form suitable for comparison with strain data.

Although the tantalum system was the first one to be studied, it has received little recent attention because the electrostrictive effects are smaller than in the other two systems. The optical results plotted in Fig. 1 were taken directly from the paper by Cornish and Young (4), and the dielectric constant data for the second curve were calculated from our original a-c capacitance data (3) using the procedure described above.

The niobium system has received more attention than the others because it combines large electrostrictive effects with ideal electrochemical behavior. The results of optical studies by Yee and Young (5), Wang (6), and Ord and Lushiku (10) are shown in Fig. 2. In the case of niobium, both a-c (3) and open-circuit

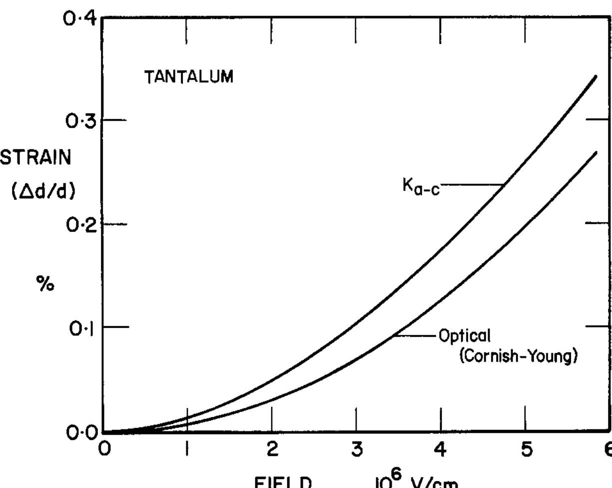

Fig. 1. The dependence of strain on field for the anodic oxide of tantalum as measured optically and as calculated from a-c dielectric constant data using the Clausius-Mossotti relation.

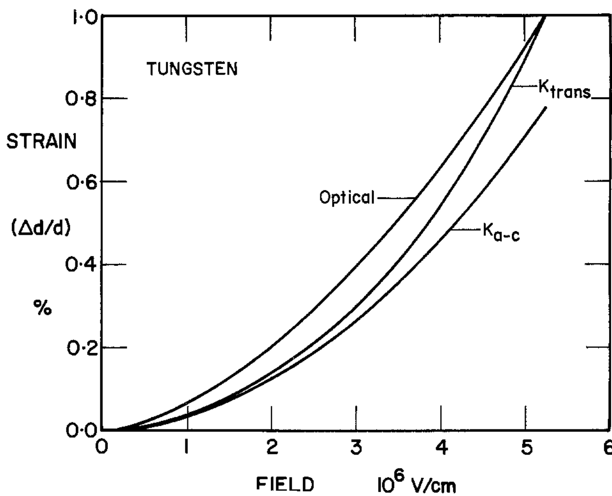

Fig. 3. The dependence of strain on field for the anodic oxide of tungsten as measured optically and as calculated from a-c and open-circuit transient dielectric constant data using the Clausius-Mossotti relation.

transient (10) dielectric constant data are available for strain-field calculations, and the two curves are shown in the figure.

The tungsten system exhibits larger electrostrictive effects than do the tantalum or niobium systems, but the solubility of the oxide in the low-resistance electrolytes convenient for electrical measurements, and the relatively low breakdown potential combine to make it a more difficult system to study. Figure 3 shows the results of the one optical study which has been undertaken (9) and curves calculated from a-c (3) and open-circuit transient (10) dielectric constant data.

There is little one need say about Fig. 1, 2, and 3 because the results speak for themselves, establishing the large positive strains and corresponding changes in dielectric constant as experimental facts for which the theory of electrostriction must account.

The Macroscopic Theory

Traditional textbook treatments of electrostriction (15) write the stress due to electrical forces exerted on the surface of a dielectric slab in a parallel-plate capacitor as the sum of three terms: (*i*) the internal pressure in the dielectric created by the field, (*ii*) the stress on the surface polarization charge layer, and (*iii*) the stress on the charge layer on the surface of the plate in contact with the dielectric. The internal pressure is calculated by relating the force on a dipole in a nonuniform field to the pressure gradient in the dielectric. Since the force involves the field gradient, both expressions can be integrated directly, and the internal pressure in a uniform field is found to be $\sigma_p E/2$, where E is the field in the dielectric, and σ_p is the polarization charge density on surfaces perpendicular to the field. The stress on the surface polarization charge, if there is a gap between the slab and the plates, is $\sigma_p (E_o - E)/2$, where E_o is the field in the gap, and hence the internal pressure and the stress on the polarization charge sum to give a tensile stress equal to $\sigma_p E_o/2$ or $K(K - 1)\epsilon_0 E^2/2$ on the surface of the dielectric. For a slab not in contact with the plates, the stretching along the field lines in response to this tensile stress is known as electrostriction, and is quadratic in the field. If, as is the case in our system, the slab is in contact with the plates, the stress on the surface charge layer, $K^2\epsilon_0 E^2/2$, is transmitted to the dielectric, and the net stress on the surface of the dielectric is a compressive stress equal to $K\epsilon_0 E^2/2$. If the slab has a stiffness constant c, the strain, u, which results from the compression exerted by the electrical forces is

$$u = - K\epsilon_0 E^2/2c \qquad [3]$$

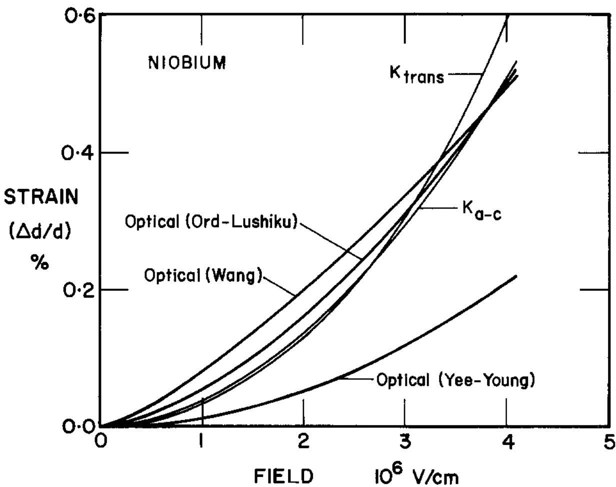

Fig. 2. The dependence of strain on field for the anodic oxide of niobium as measured optically and as calculated from a-c and open-circuit transient dielectric constant data using the Clausius-Mossotti relation.

The small compressive strain predicted by this expression was what was expected before large strains of the opposite sign were found experimentally. As we shall see, the more advanced theoretical treatment of electrostriction fares no better when compared with experiment.

The treatment of electrostriction outlined above neglects effects due to the variation of the dielectric constant with density, and hence cannot be expected to apply to high dielectric-constant materials which are expected to be quite sensitive to density variations. The variation of dielectric constant with density can be dealt with by introducing an additional stress, but in order to determine the form of the stress we must formulate the problem in terms of energy rather than in terms of force. There is considerable controversy in the literature over what constitutes a proper nonlinear theory of the elastic dielectric, but fortunately we can avoid the controversy because all of the competing treatments give identical results when applied to a system as simple as the one we are studying. The simplicity of our system results from the fact that to a very good approximation the field is uniform and confined to the oxide film. We get the same results

using a model with a thin spherical dielectric shell on a massive metal sphere as we get using a model with a thin slab constrained to have zero transverse strain, but the slab model is much simpler mathematically, and is the one we use here.

We can extract a solution for our system from a more general solution (16) by setting numerous tensor components equal to zero, but we get a better picture of what is involved by restricting our attention to the isotropic slab with zero transverse strain at the outset, and following through the steps in the solution. Grindlay (17) and Juretschke (2) have published treatments of the dielectric slab problem which attempt to present the theory in a form which treats the coupling between elastic and dielectric effects properly, yet is free of cumbersome mathematics. Grindlay's treatment, which emphasizes the variational technique used to solve the problem, is more suitable for our purposes than Juretschke's treatment which emphasizes the tensor nature of the coupling. Grindlay's treatment, however, is not self-contained, and we must refer to his more general treatment of electrostriction (16) for an explicit expression for the energy density.

In order to set up a problem for a solution based on energy considerations, it is usually necessary to have an expression for the energy density at all points in space, but in our system the field is confined to the slab, and the substrate is unstrained, so we need only an expression for the energy density in the dielectric. In order to avoid having to distinguish between energy density per unit volume and per unit mass, we will write instead an expression for the internal energy, U, of a square slab of side l and unstrained thickness z. The internal energy is represented by a power series in the strain, u, and the electric displacement, D, carried to fourth order in D (assuming u of order D^2)

$$U = [cu^2/2 + (q + b/2)\, uD^2 + bD^2/2]\, zl^2 \qquad [4]$$

where c and q are the elastic stiffness and electrostrictive constants of the oxide film, and $b = 1/K_o\epsilon_o$. This expression for the internal energy reduces to the correct form for a capacitor with a vacuum between the plates when q and c are zero, and it can be used to describe a capacitor with a spring between the plates when q is zero and c is nonzero. [Note that if $q = 0$, $(1 + u)$ can be factored out of the entire expression since the elastic energy term is unchanged to second order in u when it is divided by $(1 + u)$.] The internal energy does not contain the fourth-order term in D used in the theory of ferroelectrics, and as a consequence we will find that the dielectric constant depends on the density but not on the field, a result which is consistent with the Clausius-Mossotti relation.

The fundamental relation in Grindlay's treatment is the principle of conservation of energy

$$\delta U = \delta W \qquad [5]$$

where δU is the change in internal energy when charge δQ is added to the capacitor, changing the electric displacement by $\delta D = \delta Q/l^2$ and the strain by δu, and δW is the external work done. In charging a capacitor with no externally applied stress, the only external work done is the electrical work $V\delta Q$, where V is the potential difference across the capacitor. If we expand δU in terms of δu and δD, Eq. [5] takes the form

$$\{[cu + (q + b/2)\, D^2]\, \delta u + [(2q + b)\, uD + bD]\, \delta D\}\, zl^2 = Ez\, (1 + u)\, l^2 \delta D \qquad [6a]$$

where E is the electric field in the oxide film. Collecting terms in δu and δD, we can rewrite Eq. [6a] in the form

$$[cu + (q + b/2)\, D^2]\, \delta u = [E\, (1 + u) - (2q + b)\, uD - bD]\, \delta D \qquad [6b]$$

In a variational calculation, δu and δD are treated as arbitrary independent variations, and hence their coefficients in Eq. [6b] must vanish, yielding

$$u = -(2q + b)\, D^2/(2c) \qquad [7]$$

$$E\, (1 + u) = [(2q + b)\, u + b]\, D \qquad [8a]$$

These equations constitute a complete solution to the dielectric slab problem. Equation [7] gives the dependence of the strain on the electric displacement, and Eq. [8a] is an electrical equation of state which defines the dielectric constant. The equation of state can be compared with the Clausius-Mossotti relation by rewriting Eq. [8a] in the form of Eq. [1c]

$$K_o/K = 1 + (2q/b)\, u \qquad [8b]$$

Note that if q equals zero, the dielectric constant is independent of density, and the expression for the strain in Eq. [7] reduces to the expression given earlier in Eq. [3]. On the other hand, if the Clausius-Mossotti relation is valid, q must equal $1/6\, \epsilon_o$, and the strain will be larger by a factor of $(1 + K_o/3)$ than predicted without taking the variation of dielectric constant with density into account.

We can use the results we have obtained to write our original internal energy expression in three alternate forms which will be useful in the discussion which follows

$$U = [cu^2/2 + (1 + u) ED/2] zl^2 \qquad [9a]$$

$$U = (cu^2/2) zl^2 + QV/2 \qquad [9b]$$

$$U = [bD^2/2 - (2q + b)^2 D^4/8c] zl^2 \qquad [9c]$$

Comparison Between Theory and Experiment

The electrostrictive constant q, unlike the elastic stiffness c, can be either positive or negative, and we might expect the choice of sign to provide the degree of freedom needed to fit theory to experiment, but this is not the case. Equation [7] can account for the observed positive strain if q is negative and sufficiently large, but Eq. [8b] which must account for the observed decrease in dielectric constant with increasing field involves the product qu and requires that q be positive to agree with experiment.

We can see how this conflict arises by considering the implications of using the internal energy expression given in Eq. [9b] to describe the charging of a capacitor whose dielectric constant varies during the charging process. Equation [9b] states that the internal energy is the sum of the electrostatic term $QV/2$ and an elastic term $(cu^2/2)zl^2$. There is nothing unreasonable about this statement, and it is something we might well have assumed at the outset. It does, however, dictate the shape of charging curves. Figure 4 shows charging curves for capacitors with the same low-field dielectric constants and same total charge, but whose dielectric constants (a) remain unchanged, (b) increase by 25%, and (c) decrease by 25% during the charging process. The external work done in each case is the area under the charging curve, and the electrostatic term in the internal energy is the area under the line joining the endpoints of the charging curve. If the dielectric constant does not change during the charging process, the external work done and the electrostatic energy stored are equal, and hence the elastic energy is zero. If the dielectric constant increases during the charging process, the charging curve will curve toward the charge axis, the external work done will exceed the stored electrostatic energy, and the difference will be stored as elastic energy. This is the prediction of our theory, and it is the direction of the change in dielectric constant which is critical, not the sign of the strain which appears squared in the elastic energy term.

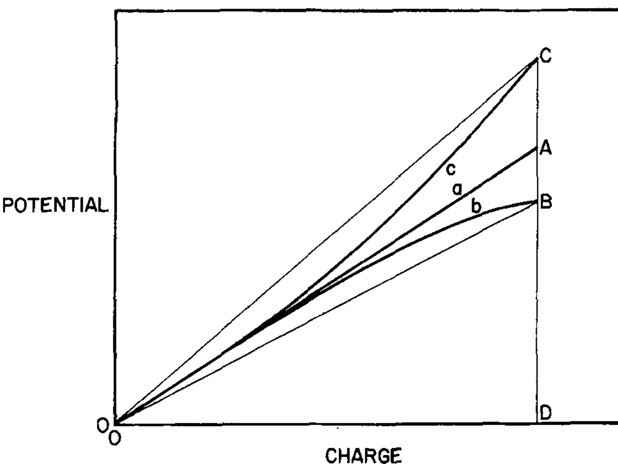

Fig. 4. Charging curves for capacitors with dielectrics whose dielectric constants have the same low field value, but (a) remain unchanged, (b) increase by 25%, (c) decrease by 25% during charging.

If the dielectric constant decreases during the charging process, the charging curve will curve away from the charge axis, and the external work done will be less than the electrostatic energy stored—a clearly impossible situation because the elastic energy cannot be negative. This then is the extent to which theory and experiment disagree: the apparently reasonable expression we derived for the internal energy of a capacitor makes it impossible for the experimentally observed decrease in the dielectric constant to occur without violating the principle of energy conservation. Since the principle of energy conservation is not seriously open to question, there must be something wrong either with the experimental results or with the theory.

All experimental results can be questioned, and more measurements correlating dielectric constant variation with strain need to be made, but it is unlikely that an effect which has been seen in both *in situ* anodic oxidation studies at room temperature and tantalum film capacitor studies at liquid nitrogen temperature will prove to be an artifact of the widely different measurement techniques. If we accept as fact the experimental observation that the dielectric constant can decrease when the field is applied, then we must reject the theory we derived in the previous section. We could, of course, argue that our theory constitutes a definition of electrostriction, and that other effects may mask its experimental observation, but a theory of electrostriction which applies to neither electrolytic nor film capacitors is sterile at best.

The conflict between theory and experiment can be resolved by looking carefully at what both theory and experiment are saying. If we look at the charging curve in Fig. 4 for a capacitor whose dielectric constant decreases on charging, we can, without assuming a form for the internal energy, determine whether or not the decrease is a consequence of the strain in the film. If the decrease in dielectric constant results from the strain, then if we clamp the capacitor and charge it without allowing the film thickness to change, the charging curve will be linear, and the external work will be less than for charging a free capacitor. If we disconnect the charging supply before releasing the clamp, the external work done during the release will be negative no matter what the sign of the strain because the force exerted by the clamp must oppose the displacement to the strained state. Hence the external work done in charging a clamped capacitor then releasing it is less than the work done by the free capacitor when it is subsequently discharged. Conservation of energy therefore forces us to conclude that if the dielectric constant decreases during charging it cannot be due to strain in the film, no matter what its sign. We can, in fact, conclude that more work must be done to charge a clamped capacitor than a free one, and hence the effect of strain must actually oppose the observed decrease in the dielectric constant, not produce it.

We can reach the same conclusions without reference to the experimental results simply by requiring that the theory apply to large electrostrictive effects as well as small. (Perhaps "large" is an inadequate term to apply to effects which are many orders of magnitude larger than anticipated.) The solution we derived in the previous section is only stable if the effects are small, and hence we should not be surprised that it conflicts with the experimental results on anodic oxides. The instability shows up clearly both in the internal energy expression and on a charging curve. The internal energy expression in Eq. [9c], which was obtained by substituting the solution for the strain back into the original internal energy expression, is the sum of a positive term in D^2 and a negative term in D^4. (The sign of the D^4 term is inherent to the theory and does not depend on the sign of q.) This means that although the energy increases with D at small D, as D gets larger it decreases without bound. This effect shows up in a different way on the charging curve in Fig. 4 for a capacitor whose dielectric constant increases on charging. The curve is drawn for a quadratic dependence on D with an overall change of 25% in the dielectric constant. Note that the charging curve is almost flat at its top end, and if charging is continued the potential across the capacitor will actually begin to decrease as additional charge is added. Hence the increase in the dielectric constant required by the theory guarantees its instability, and the experimentally observed decrease in the dielectric constant is actually a necessity if the system is to be stable.

Once the stability problem is recognized, and it is realized that the decrease in the dielectric constant cannot be due to the strain in the film, it is not difficult to modify the theory to ensure stability at high fields. Our expression for the internal energy is a power series in even powers of D with a lead term of second order, and fourth-order terms of the form u^2 and uD^2. As we noted at the outset, there is the additional explicit fourth-order term, and this term is needed for a stable fourth-order theory. If we write the internal energy in the form

$$U = [cu^2/2 + (q + b/2)uD^2 + gD^4/4 + bD^2/2]zl^2 \quad [10]$$

and follow the same procedure we used in the last section, our expression for the strain in Eq. [7] remains unchanged, but Eq. [8b] which defines the dielectric constant becomes

$$K_0/K = 1 + (2q/b)u + (g/b)D^2 \quad [11]$$

and Eq. [9c] for the internal energy becomes

$$U = [bD^2/2 + (g/4 - (2q + b)^2/8c)D^4]zl^2 \quad [12]$$

For stability we require the coefficient of D^4 in Eq. [12] to be positive, and hence

$$g > (2q + b)^2/2c \quad [13]$$

As we expected, the sign of q does not affect stability, and we are free to choose q negative a fit the sign of the observed strain. Equation [11] bears out the conclusion we reached by considering a clamped capacitor: the decrease in dielectric constant is due to an explicit field-dependence, and the strain in the film acts to oppose the change in dielectric constant. If it were not for the sign of the strain term, Eq. [11] could be thought of as an extension of the Clausius-Mossotti relation to allow for field-dependent polarizability, but with the sign as it is, we are forced to conclude that the Clausius-Mossotti relation is simply not valid

for the valve-metal oxides. We reach this conclusion reluctantly, for we have made extensive use of the Clausius-Mossotti relation in the past to relate dielectric constant variation to strain, but the conclusion is a direct consequence of energy conservation applied to the observed decrease in dielectric constant with increasing field, and is inescapable.

The quadratic dependence of strain on displacement predicted by the theory serves to resolve the minor controversy in the literature over the form of the field dependence. A quadratic dependence on KE will appear quadratic in E up to fields at which the decrease in K becomes significant, and beyond this point the dependence on E will appear slower than quadratic. For tantalum, therefore, the dependence should appear quadratic almost all the way to the anodizing field, but for niobium and tungsten the dependence should appear quadratic over no more than half the region to their anodizing fields. This prediction is consistent with our experimental findings and with the different ranges used to fit the reported quadratic dependences for tantalum (4) and niobium (5).

Bilayer Taper Etching of Field Oxides and Passivation Layers

Lawrence Keith White

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

As geometries and design rules become more stringent for multilayer devices, precise taper control is essential to insure high reliability products. A bilayer process appears to provide precise taper control and the ability to adjust the taper angle as various IC designs may require. The taper control layer of a bilayer process minimizes the effect of the photoresist-oxide interface properties on the tapering process. Control of the taper is determined by the etch ratio of the underlying layer's etch rate to the taper control layer's etch rate. Examples presented here show that thermal SiO_2 can be tapered with control layers of CVD SiO_2 and 6% densified PSG can be tapered with an undensified PSG layer of similar phosphorus concentration. Optimum control layer thickness ranges from 500 to 1000Å. Taper angles are relatively insensitive to etch temperature and buffer composition changes for buffered HF etchants. Taper slopes were estimated by a combination of Tencor Alpha-Step profilometry or interference fringes obtained from optical microscopy. SEM analysis was used to verify these results.

Properly tapered steps for multilayered devices are essential for high reliability products. Smooth and gradually sloped steps for field oxides, and for under metal passivation layers promote good metallization coverage and minimize buried channel and void formation. One tapering process used now for IC production is undercutting at the photoresist-oxide interface. The process is based on photoresist adhesion and is highly sensitive to environmental factors that influence the photoresist-oxide interface properties, such as temperature, humidity, photoresist lot, and surface contamination. Although this process is workable, precise control of taper angle is difficult. Precise control of taper angle is becoming more critical for the anticipated reduced geometries and tighter design rules for IC's.

Key words: etching, slope angle, silicon dioxide, phosphosilicate, CVD.

Tapering processes were investigated that had the potential to provide tighter control for thermal oxides or passivating PSG layers. The processes are based on good photoresist adhesion, as this variable appears easier to control than varying degrees of poor adhesion. Consequently, a photoresist primer, hexamethyldisilazane (HMDS), has been used for all these studies. The literature describes several techniques

that can be used to taper steps during chemical pattern etching. These include etch temperature variation (1-3), buffer composition variation (2-4), ion-implant techniques (5, 6), and bilayer control process (7-9). In many respects the ion-implant technique is similar to a bilayer process. The ion-implant process step can be viewed as a way of producing a fast-etching taper control layer on top of a field oxide. Although ion-implant techniques would appear to provide excellent taper control, according to the literature, the economics of the process would appear to be unattractive and control of ion-implant parameters could be difficult. Thus, our efforts have concentrated on etch temperature variation, HF buffer composition, and the bilayer control processes. Early in our study, it became apparent that both the etch temperature and HF buffer composition tapering techniques depended on interface properties. Since these properties are inherently difficult to control, most of the work here deals with the bilayer tapering process.

The determination of the average taper is not trivial. Several methods were used to monitor the performance of the tapering process. They include Tencor profilometry, interference microscopy, and SEM analysis. Comments on the use and applicability of these methods in a production environment are included.

Experimental

A number of dielectric layers were deposited or grown on polished, single crystal silicon wafers. The methods for each type of layer are summarized as follows: (*i*) Thermal SiO_2 was grown at 1000°C in steam at (atmospheric) pressure to a thickness of 1 μm. (*ii*) CVD SiO_2 used for taper control layers was deposited from a silane-oxygen-nitrogen gas mixture at 450°C. (*iii*) PSG layers were deposited from a silane-phosphine-oxygen-nitrogen gas mixture at 450°C, and in some instances at 300°C.

Densification of CVD SiO_2 and PSG were carried out in a nitrogen ambient for 30 min at the desired densification temperature. Thicknesses of CVD SiO_2, CVD PSG, and thermal oxide films were measured with a Tencor Alpha-Step Profilometer. Etch rate measurements and pattern etching were done in a constant temperature bath controlled within ±0.2°C. Pattern etching times through field oxide or passivating layers were determined by observing the repellency point of the etchant on the underlying silicon of an unpatterned control sample or from previously determined etch rate and thickness measurements. The etchants used for these studies were all buffered HF compositions that were made from reagent grade 40% aqueous NH_4F and 49% aqueous HF. Volume to volume compositions of the NH_4F and HF solutions used for these studies ranged from 6:1 to 30:1.

Photoresist masking for pattern etching was done with Kodak 747 negative photoresist. The adhesion promotion priming treatment consisted of a 5 min immersion in neat (100%) HMDS.

The determination of average taper for patterned etched samples is discussed in a following section. A combination of SEM analysis, Tencor profilometry, and interference optical microscopy was used.

Temperature and Buffer Composition Taper Etching Studies

Initial taper etching studies examined the effects of the etch temperature and buffer composition. These effects have been examined in the literature by Parisi *et al.* (1). Since both these methods of tapering are based on enhanced etch rates at the photoresist-oxide interface, careful control of interface properties is necessary to produce meaningful results. These experiments have been repeated with the use of an adhesion primer to insure that the photoresist-oxide interface has good adhesion. A single type of negative photoresist, Kodak 747, was used throughout the study. These experiments were structured to determine whether enhanced etching of the interface was still operative even with good photoresist adhesion.

Figure 1a and b display a schematic of the expected taper for conditions of "good" and "poor" photoresist adhesion at the interface. If adhesion is "good," an isotropic etchant etches at the same rate in every direction. The classic quarter circle profile for the step is the expected result (Fig. 1a). Although the taper at the bottom of this step is smooth, the top portion of the step is sharp and steep, and thus undesirable. In practice, the full quarter circuit profile is not usually observed, because most etching processes employ some degree of overetching. Under overetch conditions, the arc of the profile is less than that of a quarter circle giving steeper and still less desirable average tapers. If adhesion is "poor," enhanced etching occurs at the interface, and the etch rate in the lateral direction is greater than that in the vertical direction, producing a smooth taper both at the top and bottom of the step. The taper angle is determined by the increased magnitude of the lateral etch rate relative to the vertical etch rate. Because the magnitude of the lateral etch rate is highly sensitive to interface properties, the slope of the taper is difficult to predict or reproduce.

Figure 2 plots the average taper for thermal oxide as estimated from interference microscopy *vs.* the HF buffer composition. The estimated average tapers displayed here are not necessarily smooth. Taper profiles approaching a quarter circle are expected for the steeper slopes. The average taper displayed here is more a relative measure than an absolute measure of the taper profile. A discussion of estimation of average taper is presented in a later section of this report. The compositions of the various volume-to-volume mixtures of 40% NH_4F and 49% HF have been converted to molarity of HF. The 6:1, 10:1, and 20:1 compositions are marked on the HF axis. The "[HF]" concentration shown is not the actual composition of the etchant, since other etching species are present, notably HF_2^-. Figure 2 shows that higher etching temperatures and higher buffer compositions produce shallower tapers for the oxide step. An exact comparison of our results to the Parisi study (1) is difficult, since average taper angles were not reported for every etching condition and their evaluation methods were somewhat different. However, the present results appear to be in reasonable agreement with Parisi. It should be emphasized that the results dis-

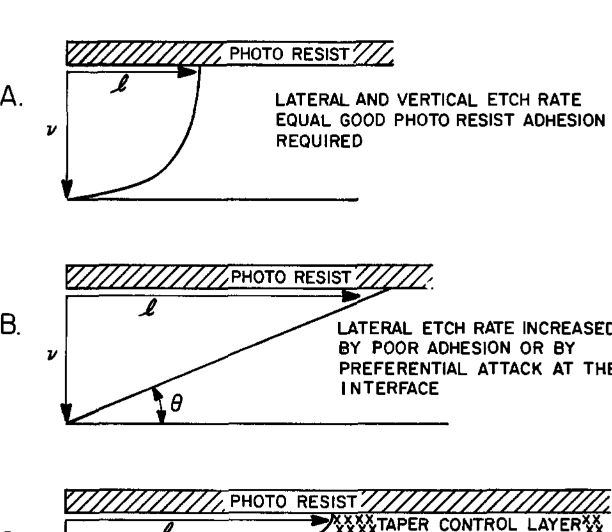

Fig. 1. Tapering processes

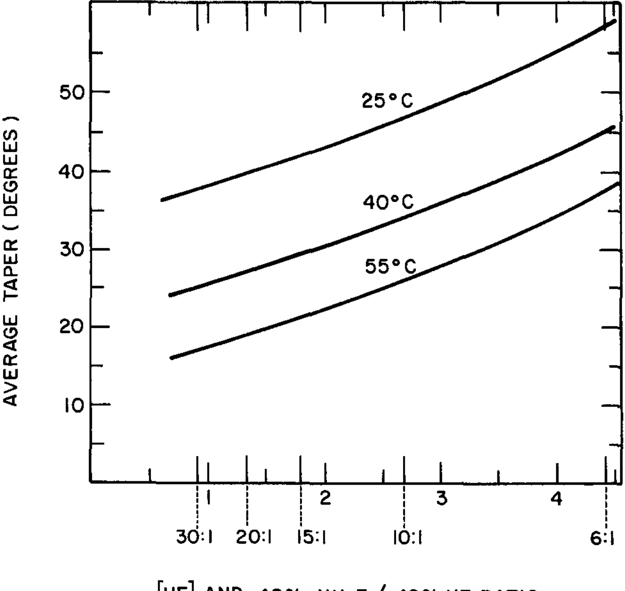

Fig. 2. Observed taper vs. HF buffer composition

played in Fig. 2 should not be considered exact or reproducible. A different photoresist lot or somewhat different processing conditions could dramatically change the observed taper. For example, on occasion the degree of lateral undercut has been observed to increase by factors of two to three times with no intentional or obvious change in processing conditions.

The results shown in Fig. 2 illustrate that the taper of field oxide can be varied through variations in the etchant composition or the etching temperature. Both these processes can provide some degree of taper control, but both are still based on the properties of the photoresist-oxide interface. Obviously, etchant temperature changes influence the etchant composition or the interface properties to vary the undercutting (*i.e.*, the lateral etch rate at the interface). Buffer composition changes also have a similar effect.

Both of these processes are still subject to variations in interface properties. After all, at constant buffer composition, temperature changes affect the taper angle and vice versa. Even in the presence of good adhesion, some preferential attack at interfaces occurs under a variety of conditions. Also, these results demonstrate that etch temperature and buffer composition variation can be used to determine how sensitive a tapering process is to interface properties and photoresist undercutting. The studies of the bilayer taper control process make use of similar experiments to test the sensitivity of the taper angle to interface properties and undercutting effects. Taper processes that do not rely on interface properties should be easier to control.

Bilayer Taper Control Process

Multilayer processing of IC's requires that top layers etch faster than underlying layers to produce a smooth taper. The bilayer taper process investigated here makes use of this observation to taper individual field oxide or under-metal passivating layers. A faster etching taper control layer is deposited on the layer to be tapered. Several literature reports (7-9) have used this technique to taper steps of a variety of compositions.

Figure 1c shows a schematic of the bilayer process. The taper control layer is deposited on top of the underlying layer to be pattern etched. The ratio of the etch rate of the taper etched layer to that of the control layer determines the taper angle. Our initial study used a CVD SiO_2 taper control layer deposited at 450°C to taper etch thermal oxide. To test the process sensitivity to photoresist-oxide interface properties and undercutting, several experiments were done varying the etching temperature and the etchant buffer composition.

Figure 3 summarizes etch rate data for 450°C deposited CVD SiO_2 and thermal SiO_2 as a function of etchant composition. Data was collected for two etching temperatures, 25° and 40°C. Note that, as previously described, the buffer composition is expressed as an HF concentration and 6:1, 10:1, and 20:1 compositions are marked on the axis. Assuming that the relative etch rates of the control layer to the underlying layer (*i.e.*, the etch ratios) determine taper angles, some change in taper angle may be expected just from the etch ratio variations. Figure 4 plots the etch rate ratio of various CVD control layers on thermal oxide against buffer composition. The changes in the etch ratio are slight, even for different etching temperatures. Thus, the taper slope using a CVD SiO_2 control layer is expected to be relatively insensitive to etch temperature and buffer composition, provided that undercutting effects at the interface are insignificant. Comparisons of tapers obtained using the bilayer process show that variations of the temperature or buffer composition do not change the observed taper significantly. Figure 5 displays interference fringes for a thermal oxide etched at 25° and 40°C. The change in the distance from bottom of step to

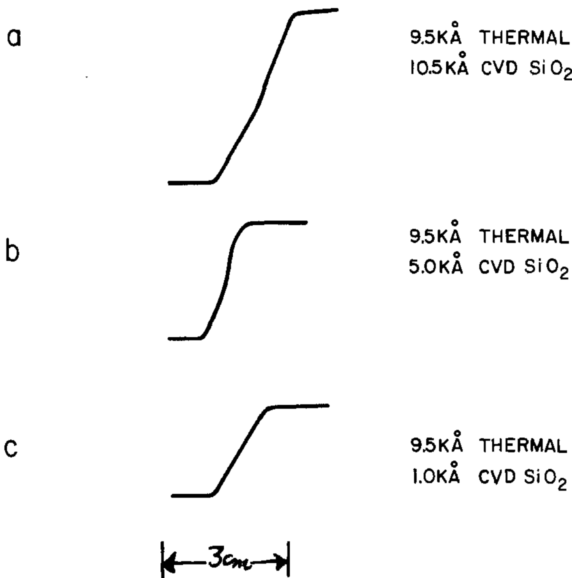

Fig. 6. Tencor traces of tapered profiles

top of step is small, indicating only minor changes in the taper angle have occurred. Similar results have been obtained using various etchant compositions. This insensitivity to environmental factors that normally produce taper angle changes in the absence of a control layer indicates that the effects of interface properties and undercutting are indeed insignificant or small for the bilayer tapering process. Evidently, control of the tapering process has been transferred from the photoresist-oxide interface to the taper control layer. In addition, contrary to undercutting processes, we do not expect the average taper angle produced from a bilayer process to be significantly affected by the degree of overetching.

The effect of the thickness of the taper control layer on the taper slope of the step was also examined. CVD SiO_2 taper control layers ranging in thickness from 1 to 20 kÅ were deposited on a 10 kÅ thermal oxides. Profiles of the pattern etched slopes were recorded on a Tencor Alpha-Step Profilometer. These results are displayed in Fig. 6. Two slopes are apparent in the profile, one corresponding to the thermal oxide and the other to the taper control layer. The slopes of steps with taper control layer thicknesses less than 2000Å appear smooth. However, this observation is an artifact of the Tencor Alpha-Step Profilometer. SEM's of these samples do detect a small lip for the taper control layer. Figure 7 shows an example of the lip for a 1000Å SiO_2 CVD layer on top of a 10 kÅ thermal oxide layer.

Generally, the slope of the taper control layer is steeper than that of the underlying field oxide. An etch profile of an arc less than a quarter circle is expected for the control layer, while the ratio of the etch rates should determine the slope of the underlying oxide. The Tencor traces and interference fringe analysis indicate that the taper of the underlying oxide is relatively insensitive to the control layer's thickness.

The lip produced by the taper control layer could interfere with metallization coverage. Thinner taper control layers produce less substantial and less noticeable lips. Thus, thin taper control layers are more desirable. A taper control layer of 500-1000Å thickness should provide good coverage of the underlying oxide and keep the control layer's lip small. We also believe that this thickness is sufficient to insure that the undercutting and interface attack have minimal effect on the taper angle. Should the small lip on the taper control layer present coverage problems, dip etching can be employed to completely remove the taper control layer. Since the bilayer taper con-

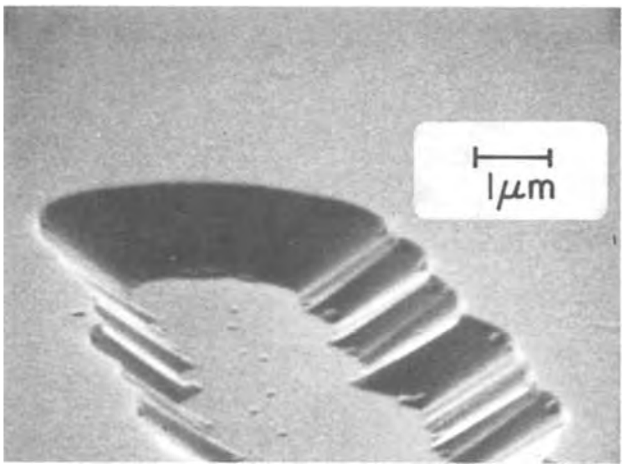

Fig. 7. Taper control layer on thermal oxide, 1 kÅ CVD SiO_2, 10 kÅ thermal oxide, SEM angle 80°.

trol process is insensitive to taper control layer thickness, etch temperature, and buffer composition, some other parameter must be used to alter the taper angles. The etch rate properties of control layer can be modified to control the angle of the taper slope. Two examples of a bilayer process are presented here that use various methods to vary the etch rate of the control layer.

Bilayer Etching Results

The etch rate of the CVD SiO_2 control layer used to taper etch patterned thermal oxide can be altered by densification at the appropriate temperature. Figure 8 plots the etch rate of CVD SiO_2 deposited at 450°C *vs.* densification temperature, where the densification is carried out in dry nitrogen for 30 min. The etch temperature is 25°C and buffered HF (6:1 v/v 40% NH_4F:49% HF) is the etchant. The etch rate of thermal SiO_2 is included for a reference. Figure 9a, b, c, show SEM's of the taper of the field oxide for the various CVD SiO_2 control layers. The tapers estimated from interference optical microscopy are 13° for the 450°C CVD SiO_2 (as deposited), 24° for the 625°C densified CVD SiO_2, and 37° for the 800°C densified CVD SiO_2. Figure 10 plots these estimated tapers *vs.* densification temperature.

Etch rate data for the control layer and underlying oxide can provide some predictive ability for the expected taper angle. The arc tangent of the etch rate ratio would appear a reasonable approximation. The predicted taper from etch rate data is also shown in Fig. 10. The arc tangent function consistently predicts lower taper angles than those estimated for our experiments. Also, the maximum theoretical angle possible is 45°. This maximum angle would correspond to the average slope of the quarter circle profile, but the estimated average angle could be much steeper. Since the bottom of the step has a shallow taper, optical detection methods may not discern the true bottom of the step. This difficulty could lead to estimated average tapers steeper than the actual average slope for the quarter circle profiles. Also, the quarter circle implies zero overetch; in practice, an overetch time must be used and thus angles greater than 45° are likely.

Literature references (1, 10) report that the arc sine of the etch ratio can be used to approximate the observed taper. The predicted taper using the arc sine function is also displayed in Fig. 10. Although some improvement for predicting our estimated aver-

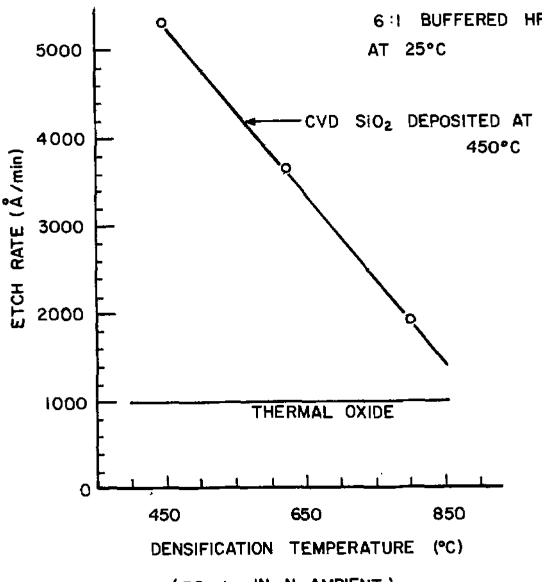

Fig. 8. Etch rate *vs.* CVD SiO_2 densification temperature

age tapers is apparent, particularly for the steeper tapers, our estimated taper angles still are higher than the predicted ones. This discrepancy is not thoroughly understood. Uneven taper slopes and the experimental error for the estimated average taper may account for part of the discrepancy. However, other factors may play a role. Etchant depletion in occluded regions produced during pattern etching could lead to variations in the vertical and lateral etch rates. Oxide thickness and the extent of pattern delineation could influence the etchant depletion within occluded regions. In spite of these apparent discrepancies between the predicted and observed average taper slopes, the arc sine functional form appears to be a good starting point for predicting taper angles for untried control layers from etch rate data alone. After initial taper determinations, adjustments in the etch ratio to alter the taper slope can be made as required.

Phosphosilicate glasses are being used more frequently in device fabrication for their gettering capability or flow properties. Taper etching of these glasses may require taper control layers that etch

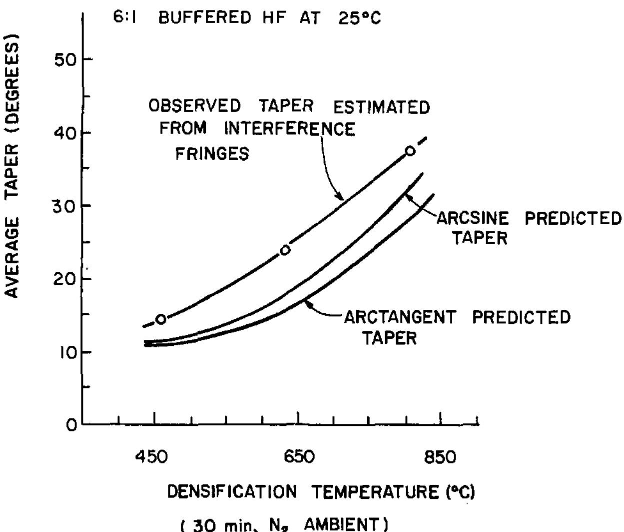

Fig. 10. Average taper vs. CVD SiO_2 densification temperature

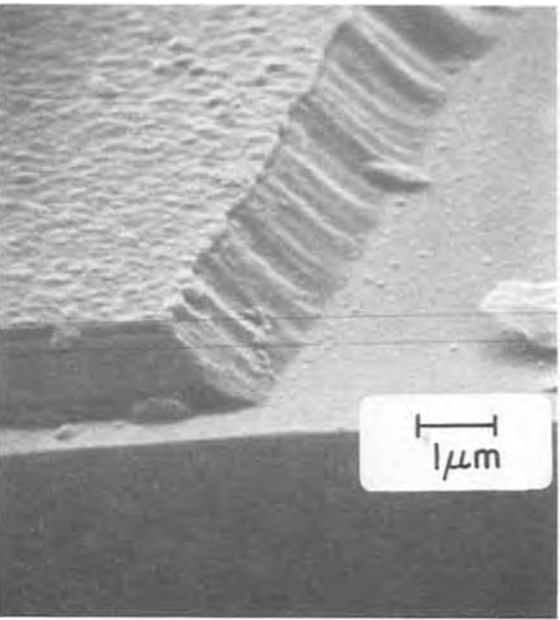

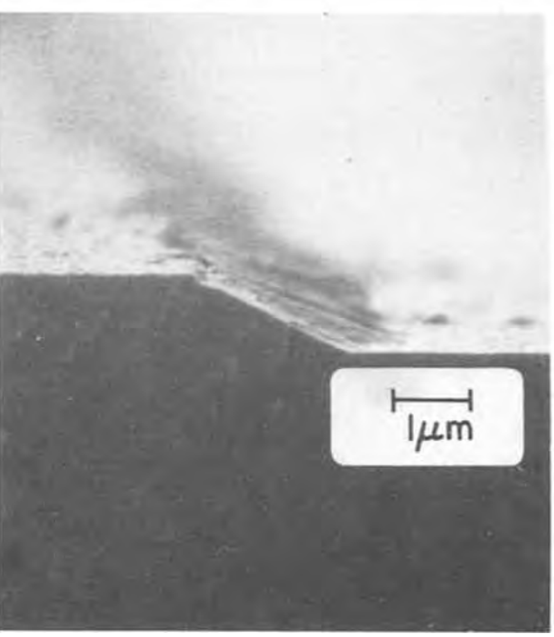

Fig. 11. SEMS of tapered 6% densified PSG layers. a. 6:1 buffered HF at 25°C, undensified 6% PSG, control layer deposited at 450°C. b. 6:1 buffered HF at 25°C, undensified 6% PSG, control layer deposited at 300°C.

faster than a CVD SiO_2. PSG passivating layers are typically densified before pattern etching. Thus, faster etching undensified PSG can be used as a taper control layer. Densified 6% PSG has been tapered with an undensified PSG layer of similar phosphorus composition (deposited at 450° or 300°C). Figure 11 displays SEM photographs of some tapers obtained using an undensified control PSG layer of similar phosphorus composition in buffered HF at 25°C. Suitable tapers are obtained using the undensified PSG control layer (10). Phosphorus composition of the layer or the deposition temperature can be used to vary the etch rate of the taper control layer. If, however, a phosphorus content greater than 6% is used, or if the 6% taper control layer is not subsequently densified, the layer should be removed before metallization to reduce susceptibility to metal corrosion (11).

The previous examples show that a bilayer process can be tailored into specific IC designs to provide the desired taper. The transfer of the taper control from the photoresist-oxide interface to the taper control layer makes it possible to alter the taper angle. CVD deposited layers, however, are only one possible candidate for a taper control layer. Since the taper angle is largely controlled by the etch rate of the control layer relative to the underlying layer to be patterned etch, several types of taper control layer compositions and deposition techniques appear possible. LPCVD deposited layers show promise as taper control layers. These rapidly deposited, uniform layers will provide scale-up production advantages over the conventional atmospheric pressure CVD deposition.

Determination of the Taper Angles

Accurate and rapid determination of the taper angle for a process in a production environment is not a trivial task. The taper angle is not necessarily smooth, as pointed out in previous discussions. In the classic quarter circle profile for pure isotropic etching, the taper angle ranges from 0° at the bottom of the step to 90° at the top of the step. Small lips encountered for the bilayer process, and for various undercutting processes, also produce deviations from a smoothly tapered step. In spite of these excursions from a smooth taper angle, we believe that an average taper of a step provides a simple and useful characterization of a tapering process.

Since most thin-film layers used in IC manufacture have thicknesses of one micron or less, average taper angle determinations require the measurement of distances of a similar magnitude. Both the thickness of the step and the span between the top and bottom of the step need to be estimated to obtain an average taper angle. Two rapid methods of taper estimation were used in our studies: interferences fringes obtained from optical spectroscopy and Tencor Alpha-Step profilometry. SEM photographs at low angles were used to check the accuracy of our taper angle determination.

The Tencor profilometry technique involves the use of a stylus to trace the profile of the step. The vertical step is expanded and an excellent thickness determination is obtained. The lateral distance determination going up the step is on a less expanded scale and can be distorted by the point of the stylus (12).

Profiles have been examined using styli of different radius (12). The smaller radius stylus points produce profiles that are less sensitive to distortions produced by the stylus point. The smallest stylus available, nominally a 2 micron stylus radius, can detect differences in the profile slope provided the slope is less than 35° for a 1 μm step. This technique cannot measure any slopes greater than 35°, and taper angles

approaching this angle are not detected with good sensitivity, due to the effect of the stylus radius (12). Also, the maximum detectable taper angle decreases as the step height decreases (12).

The use of interference fringes obtained with an optical microscope has different disadvantages. The fringe count for a layer of known refractive index can be used to determine the thickness. Also, the distance from the bottom fringe to top fringe is usually a good measure of lateral distance from the top to bottom of the step. The accuracy of the thickness determination is reduced from that obtained of a profilometer, since a single fringe represents ~1900Å for most SiO_2-type thin films. Fractions of a fringe are difficult to determine. Steep tapers present more serious problems. Fringes begin to overlap and it becomes virtually impossible to measure the layer thickness from a fringe count. The distance from top to bottom of a step is more difficult to determine, because a fraction of a millimeter difference at 760× microscope power is necessary to obtain accurate taper measurements. However, for tapered layers of known thickness, we have been able to estimate lateral distances for one-micron steps corresponding to an estimated average taper ~55°. Either the Tencor Alpha-Step Profilometer with 2 μm stylus radius or interference fringes obtained from optical microscopy alone can be used to estimate average tapers of 35° or less for a 1 μm step. Tapers greater than this can be estimated using interference fringes provided the thickness of the layer is known accurately. The Tencor profilometer could provide this thickness determination with relative ease. A combination of both instrumental techniques could be used to estimate average tapers above 35° up to about 60°.

Conclusions

As geometries and design rules become more stringent for multilayer devices, precise taper control is essential to insure high reliability products. A bilayer process appears to provide precise taper control and the ability to adjust the taper angle as various IC designs may require. The taper control layer of bilayer process minimizes the effect of photoresist-oxide interface properties on the taper process. Control of the taper is determined by the etch ratio of the underlying layers etch rate to the taper control layers etch rate. Examples presented here show that thermal oxide can be tapered with control layers of CVD SiO_2, and 6% densified PSG can be tapered with an undensified PSG layer of similar phosphorus concentration. Adjustments in the taper slope can be made for the thermal oxide through etch rate ratio changes produced by different densification temperatures for the CVD SiO_2 control layer. Taper adjustments for a 6% densified PSG layer can be made by varying the phosphorus content or deposition temperature of the PSG control layer. Optimum control layer thicknesses range from 500 to 1000Å. The apparent advantages of the bilayer process include: precise control of the taper angle through the etch rate of the control layer, minimal effects on the taper angle from undercutting at the photoresist-oxide interface, and the taper angle's relative insensitivity to etch temperature and HF buffer composition. Although a taper control layer does introduce additional processing steps, this disadvantage does not appear serious. Only the etching properties of the layer are important. Precise control of the layer thickness is not critical. Removal of the taper control layer is accomplished with a dip etch.

Estimation of the average taper for 1 μm steps can be accomplished for tapers less than 35° using either Tencor Alpha-Step profilometry or interference fringe microscopy alone. Interference fringe microscopy can be used to estimate taper greater than 35° and up to 60° provided that the thickness of the step is known accurately.

Acknowledgment

The author thanks George Schnable and Werner Kern for critically reviewing the manuscript and for many valuable technical discussions. The technical assistance provided by Robert Vibronek is also deeply appreciated.

Manuscript submitted April 22, 1980; revised manuscript received June 23, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by RCA Laboratories.

On Predicting the Maximum Efficiency of Phosphor Systems Excited by Ionizing Radiation

D. J. Robbins

Royal Signals and Radar Establishment, Great Malvern, Worcestershire, England WR14 3PS

ABSTRACT

A model allowing theoretical prediction of the maximum possible efficiency for any cathode-ray or x-ray phosphor is proposed, based on an earlier statistical analysis of e-h pair generation by van Roosbroeck. The model is independent of the detailed band structure of a particular solid, and predicts the limiting yield of e-h pairs, Y, in terms of an energy loss ratio for energetic particles K = (energy lost to phonons per ionization event/ionization energy). The novelty of the model lies in the emphasis placed on competitive phonon losses during the carrier avalanching process, and it is probably successful because of the dominant role played by carriers with energies a few times greater than threshold where electrons and holes may be expected to behave similarly. A quantitative estimate of the average energy per e-h pair in a particular phosphor can be made by reference to an index of efficiency $\mathfrak{R}$, which is proportional to van Roosbroeck's parameter K but which is defined in terms of accessible physical constants of the phosphor host lattice: ϵ_x, ϵ_S, E_g, and ω_{LO}. The predicted efficiencies η_{max} are in good agreement with measured values for widely different phosphor types, suggesting that the model is quite generally applicable and may be used in a predictive fashion in the search for new and efficient phosphor systems. Finally, the relationships between the present theory and previous approaches involving plasmon excitation are discussed.

The past forty years have seen intensive development of a wide variety of phosphor systems, for both consumer and professional applications (1-3). However there is still no theory which can explain in a satisfactory manner the relative power efficiencies observed for different CRT or x-ray phosphor materials. Empirical "rules of thumb" are legion; for example it is known that the efficiencies of CRT phosphors tend to decrease in the order: sulfides > oxysulfides > oxides, and that there is some (rather obscure) relationship between the limiting efficiency of a particular phosphor host lattice and its bandgap. The reasons for these observations are not known, and yet a successful theory capable of explaining such observations could clearly have great value. In the first place, it would allow prediction of those solids likely to generate efficient phosphor hosts, thereby facilitating the search for new materials and eliminating considerable empirical development work. Secondly, it would provide an estimate of the maximum efficiency for a particular host-activator combination, allowing development to terminate as soon as optimum performance had been achieved. Clearly the difficulties involved in developing a reliable predictive theory of this kind are considerable, not least because of the very wide variety of rather complex solids which can be used as phosphor host lattices. However it is the purpose of this paper to make an initial attempt in this direction by putting forward a semi-empirical treatment of phosphor efficiency which is at least capable of rationalizing the relative limiting efficiencies of a wide range of phosphor systems in a consistent way. As will be seen, the theory appears to give sufficiently good correlation between calculated and observed efficiencies for known phosphor systems that it may be used in a cautiously predictive fashion.

The excitation mechanisms for both cathode-ray (CR) and x-ray (XR) phosphors are similar in that high energy ionizing radiation is absorbed by the phosphor lattice, giving rise to an avalanche of secondary carriers which ultimately excite the luminescent activator (4). In what follows we shall concentrate on CR phosphor systems, but the theory is also applicable to XR materials. It is well known that the power conversion efficiencies of CRT phsophors decrease at high power densities (4), but we neglect all such saturation effects and consider only the efficiency at lower loadings where the response is linear. We shall also adopt the generally accepted model (4) of the phosphor excitation process which assumes that the energy of the incident high energy radiation is rapidly converted into thermalized electron-hole (e-h) pairs, and that the recombination energy of these pairs is transferred to the activator center where it is finally emitted as a photon. One e-h pair can therefore give rise to one quantum of radiation emitted by the activator. With these assumptions the efficiency of the CRT phosphor system can be written as follows (4-6)

$$\eta = (1 - r_b) \cdot \left(\frac{h\nu_m}{\xi} \right) \cdot S \cdot Q \qquad [1]$$

where r_b is the primary back scattering coefficient, $h\nu_m$ is the mean energy of the luminescent photons, ξ is the average energy required to generate one e-h pair, S is the efficiency for transfer of carrier recombination energy to the activator emitting state, and Q is the quantum efficiency for the final luminescent process.

The efficiency of the energy transfer process, S, has been discussed in earlier publications from this laboratory (7-9). The backscattering coefficient r_b depends on the average atomic number of the phosphor material and on the morphology of the phosphor layer; we shall assume that this factor does not vary greatly amongst practical phosphor systems. The maximum efficiency for any host-activator combination will therefore be reached when conditions can be adjusted to that $S = Q \sim 1$ in Eq. [1] *i.e.*

$$\eta_{max} \sim \text{constant} \cdot \left(\frac{h\nu_m}{\xi} \right) \qquad [2]$$

The key to calculating this maximum limiting efficiency for different phosphor systems is clearly the parameter ξ, the average energy per e-h pair generated in the lattice by high energy radiation. This energy is greater than the bandgap energy E_g, as can be seen from Fig. 1, which illustrates schematically the

Key words: cathodoluminescence, solids, x-rays.

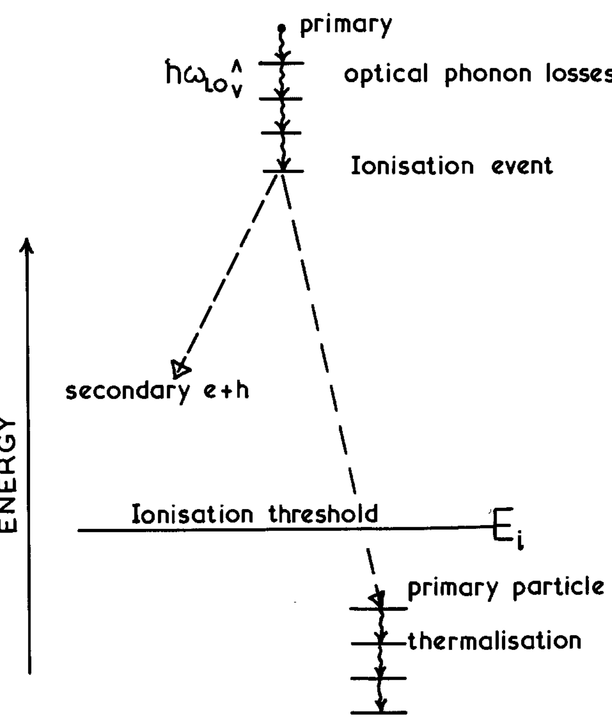

Fig. 1. Schematic sequence of energy loss processes for an energetic electron or hole as it nears the ionization threshold. Particles falling below E_i can lose further energy only by phonon emission or recombination.

energy loss processes for a primary particle (e or h) with an energy in excess of the ionization threshold. The fast particle can lose energy either by creation of optical phonons or by impact ionization. As soon as its energy falls below the ionization threshold E_i it is unable to create further secondaries and simply emits phonons until equilibrium with the lattice is established. The average energy required to produce each e-h pair therefore includes various phonon losses in addition to the intrinsic pair recombination energy. For semiconductor radiation counters, in which the same mechanisms operate, it has been found empirically that the following relationship holds over a range of semiconductor materials (10)

$$\xi = \beta E_g \quad [3]$$

with $\beta \sim 3$.

Theoretical estimates of ξ have been made by a number of workers, including Shockley (11), Klein (10), and van Roosbroeck (12). These calculations generally assume a simple parabolic band structure with equal masses and equal division of excess energy between secondary electrons and holes generated in the ionization process. The average energy per pair can then be written as the sum of three terms (see Fig. 1)

$$\xi = E_i + E_{op} + 2E_f \quad [4]$$

where E_{op} is the average energy lost to optical phonons for each ionization event during the avalanching process and E_f is the average energy of a carrier when first it falls below threshold and cannot produce further ionization. In order to calculate E_f both Shockley (11) and Klein (10) assume an initially uniform distribution of carriers in momentum space up to the threshold energy E_i, which leads to the conclusion that phonon losses during final thermalization are more significant than optical phonon generation by particles above threshold. On the other hand the statistical analysis by van Roosbroeck (12) suggests that for realistic optical phonon loss rates the distribution of carriers as they fall below threshold is not uniform, but is peaked at low energy. This implies that optical phonon loss by ionizing particles may be more significant than suggested by Shockley or Klein, and that the competition between phonon generation and ionization for fast particles will be important in governing the average energy per pair, ξ.

Lehmann (6) has used Eq. [1] and [3] to estimate the parameter β for a range of phosphor materials, not restricted to the more covalent elemental and binary semiconducting compounds for which Eq. [3] was established. However he found that this "3 $\times$ E_g" rule is quite inadequate for many phosphor systems, especially for oxide materials where β can take values in the range 4-13 when fitting measured efficiency data to Eq. [1]. In order to tackle this problem Klein (13), Kingsley and Ludwig (5), and subsequently Rothwarf (14), have discussed ionization in semiconductors and phosphors in terms of plasmon creation by fast particles. These workers have pointed out that the electron energy loss function is not uniform above threshold, and should be peaked at the zero in the dielectric function corresponding to the frequency of the collective valence-electron plasmon oscillation

$$\omega_p = \left(\frac{4\pi n_v e^2}{m}\right)^{1/2} \quad [5]$$

where n_v is the valence electron density. Phonon losses were neglected in the calculations of Kingsley and Ludwig and of Rothwarf and it was suggested that differences in efficiency for phosphor materials could be correlated with the calculated plasmon frequency. The reasoning is that if the high energy particles lose energy primarily by plasmon creation, and the plasmons then decay into e-h pairs, one expects the average energy per pair, ξ, to be determined by the plasmon energy. Some correlation between η and $(\omega_p)^{-1}$ was observed, but only for a limited number of phosphor materials. However the usefulness of the plasmon concept is open to question in the wider-gap phosphor materials, where the energy of the single-particle excitations is comparable to the calculated plasmon energy. The distinction between these excitations then becomes blurred, and in fact, when the calculated frequencies ω_p are replaced by measured plasmon energies for some of the more efficient phosphor systems, the correlation between η and $(\omega_I)^{-1}$ disappears (15, 16).

Thus none of the theories so far advanced has proved capable of rationalizing the relative efficiencies of the full range of phosphor systems. Attempts to modify the "3 $\times$ E_g" rule have emphasized differences in the ionization process for different materials by introducing the plasmon concept, but have neglected any competitive phonon losses. On the other hand the majority of e-h pairs are generated near the end of the branching process, by particles with energies only a few times the ionization threshold. For such particles optical phonon losses can constitute a significant fraction of their total excess energy, and any realistic model must take into account the competition between optical phonon generation and ionization in the overall de-excitation of these fast particles. Clearly as the ratio (energy lost to optical phonons/energy lost in ionization) increases then the yield of secondary e-h pairs must fall and the average energy per pair, ξ, must rise.

Fortunately van Roosbroeck's statistical treatment of e-h pair generation in solids (12) takes account of this competitive energy loss in a natural way, and allows prediction of the secondary yield in terms of an energy loss ratio K. The model is independent of details of band structure and quite general in its application; it will therefore be used as the starting point in estimating the parameter ξ for a range of phosphor materials. We shall show that η_{max} calculated according to Eq. [2] using the theory developed here correlates well with the observed efficiencies for many

optimized phosphor systems. In the next section the basis of van Roosbroeck's "crazy carpentry" model will be outlined. In the section "The Loss Parameter K" a method is developed for calculating the loss ratio K in terms of the physical properties of a phosphor host material. This parameter is used in the section "The Average Energy per e-h Pair Generated by Ionizing Radiation" to calculate the average energy per pair, ξ, for typical phosphor host lattices. In the section "The Maximum Efficiency of CRT Phosphors" the measured efficiencies of a number of optimized phosphor systems are compared with the calculated values, and in the last section the relationship between the present theory and the results of previous treatments is discussed.

The "Crazy-Carpentry" Model (12)

Van Roosbroeck has called his statistical treatment of e-h pair generation the "crazy-carpentry" model because it can be formulated in terms of the equivalent problem of cutting boards of a given length (see Fig. 2). We begin with a board of length L (in units of E_i), and the rules are as follows. For all boards greater than unit length, remove with probability r a length $x_r << 1$. This represents creation of an optical phonon, so that $x_r = (\hbar\omega_{Lo}/E_i)$. With a probability $(1 - r)$ remove a length unity, to represent e-h pair generation, and then make a random cut in the remainder (at Z in Fig. 2). The random length Z now represents energy remaining in the primary particle after ionization, and the excess energy transmitted to the secondaries (represented by the right-hand length $L - Z - 1$) is equally divided between the electron and hole, giving each a KE equal to $(L - Z - 1)/2$. These steps are repeated for all remaining pieces of greater than unit length, and boards shorter than unity are discarded. The number of boards of unit length produced at the end of this process represents the number of e-h pairs produced by the initial particle of energy $(L \times E_i)$. The limiting yield of e-h pairs, Y, is defined for large L

$$Y = \frac{\text{(No. of boards of unit length)}}{L} = \frac{\text{(No. of e-h pairs)} \times E_i}{\text{initial particle energy}} \quad [6]$$

The average energy required to produce a e-h pair, ξ, is given by

$$\xi = \frac{E_i}{Y} \quad [7]$$

$$= E_i + KE_i + 2L_fE_i \quad [8]$$

where L_f is the average length of a waste board ($L_f < 1$) (or the energy of a particle when first it falls below threshold)

$$K = Nx_r \quad [9]$$

and

$$N = \frac{r}{(1 - r)} = \frac{\lambda_i}{\lambda_{op}} \quad [10]$$

the ratio of the mean free path for ionization to the mfp for optical phonon generation.

The limiting yield can be obtained from the crazy-carpentry model either analytically or by Monte Carlo techniques. The yield Y is determined largely by the parameter K, although it would be modified to some extent by assuming a different division of excess energy between secondary carriers produced in an ionization event. K is essentially a ratio of energy loss rates for a fast particle

$$K = \frac{\text{rate of energy loss to optical phonons}}{\text{rate of energy loss in ionization}} \quad [11]$$

and the term KE_i in Eq. [8] represents the average energy lost to optical phonons for each ionization event during the avalanching process. The yield Y is plotted as a function of K in Fig. 3, using data taken from van Roosbroeck's paper.

The crazy-carpentry model should be quite generally applicable to the problem of excitation by high energy radiation as long as "all the incident unreflected energy is ultimately accounted for by secondary electrons and holes, and by phonons" (12). Of course it involves a number of idealizations. The random cutting involved in division of energy between primary and

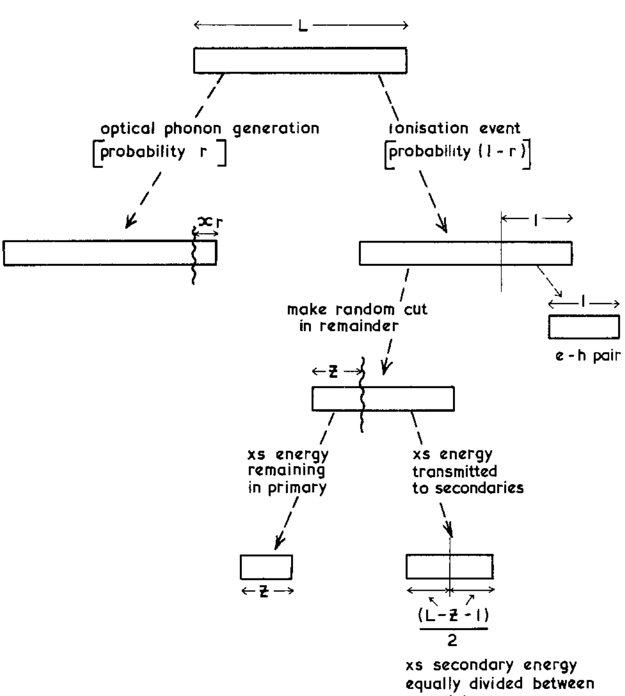

Fig. 2. Competitive energy loss processes for energetic particles formulated in terms of the "crazy-carpentry" model of van Roosbroeck [Ref. (12)]. The initial board length L is defined in units of the ionization threshold E_i. Each board of unit length produced in this way represents the generation of one e-h pair by impact ionization. The equal division of excess kinetic energy between secondary electrons and holes is a simplification which is discussed in the text.

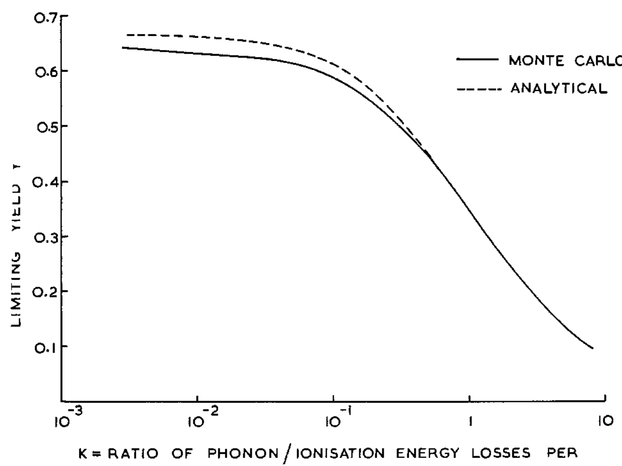

Fig. 3. The e-h pair limiting yield, Y, plotted as a function of the energy loss ratio $K = rx_r/(1 - r)$ for the "crazy-carpentry" model illustrated in Fig. 2. Solid line: Monte Carlo results. Broken line: analytic solution [after van Roosbroeck, Ref. (12)].

secondary particles at each ionization event assumes a uniform probability distribution for excitation, and neglects discrete loss processes such as plasmon creation. Equal division of excess energy between secondary electrons and holes is also open to question, since a narrow valence band would limit the energy of mobile holes. In addition the probability of optical phonon loss, r, is assumed constant for all particle energies $> E_i$, and this is unlikely to be strictly true (17). The saving grace lies in the fact that the limiting yield Y is approached rapidly for initial particle energies $\gtrsim 4E_i$. This means that the overall yield is determined largely by particles with energies only a few times E_i, where electrons and holes might be expected to behave somewhat similarly and the assumption of constant r may not be too bad. Clearly the phonon loss rate becomes very significant in determining the ionization yield when the particle energies approach the threshold E_i.

The Loss Parameter K

The average energy per e-h pair, ξ, can be obtained from Eq. [7] when Y and E_i are known. It is therefore necessary to calculate a value of the loss parameter K for a given material, so that Y can be read from the theoretical curve in Fig. 3. The loss parameter K can be written as

$$K = \frac{\text{optical phonon generation rate}}{\text{ionization rate}} \cdot \frac{(\hbar\omega_{opt})}{E_i} \quad [12]$$

In order to calculate K we make a number of simplifying assumptions. These are simply stated here, and will be discussed further below: (*i*) the particle energies are sufficiently large and the lattice temperature sufficiently low that only phonon generation need be considered, and phonon absorption from the lattice neglected; (*ii*) the fast charged particles couple principally to the LO phonon modes; (*iii*) phonon dispersion is neglected; (*iv*) the ionization rate for particles appreciably above threshold is assumed constant for all materials; (*v*) the energtic electrons and holes above threshold are well-removed from the band extrema and are therefore assumed to have the free electron mass; and (*vi*) the ionization threshold $E_i = 1.5\ E_g$. With these assumptions the loss parameter reduces to

$$K \sim \frac{(\text{optical phonon generation rate})}{\text{constant}} \cdot \frac{(\hbar\omega_{LO})}{1.5E_g} \quad [13]$$

We estimate the phonon generation rate in the following way. A free primary or secondary charged particle in a solid polarizes the lattice atoms in its vicinity, the particle and polarization cloud propagating as a single quasi-particle, the polaron (18). In the limit of narrow bandwidth and very polar materials with strong short-range forces the polarization may be so strong as to induce self-trapping, as in the V_k center in alkali halides (19). In general, however, the particle will remain mobile in the lattice, but will exhibit an increased effective mass. At any instant the polarization surrounding a low-energy particle near the band extrema can be considered as a cloud of virtual phonons (20), the average number of phonons in the cloud being of the order $\sim \alpha/2$, where α is the polaron coupling constant appropriate for a polar material

$$\alpha = \frac{e^2}{\hbar} \cdot \left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_S}\right)\left(\frac{m}{2\hbar\omega_{LO}}\right)^{1/2} \quad [14]$$

and where ϵ_∞, ϵ_S are the high frequency and static dielectric constants, respectively. For the higher energy charged particles of interest here we shall assume that the instantaneous deformation of the lattice can again be described by the polaron coupling constant, but that now the fast particle loses energy by the creation of real phonons at a rate proportional to the coupling constant multiplied by the phonon frequency, *i.e.*

$$(\text{optical phonon generation rate}) \propto \frac{\alpha\omega_{LO}}{2}$$

$$= \text{constant} \cdot \frac{1}{\bar{\epsilon}} (\hbar\omega_{LO})^{1/2} \quad [15]$$

where

$$\frac{1}{\bar{\epsilon}} = \left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_S}\right) \quad [16]$$

and we have used the free electron mass $m = m_e$ for the charged particle, which is now well removed from the band extrema. Introducing Eq. [15] into [13] gives the expression for the relative energy loss parameter K which we are seeking

$$K \sim \text{constant} \cdot \frac{1}{\bar{\epsilon}} \cdot \frac{(\hbar\omega_{LO})^{3/2}}{1.5E_g} \quad [17]$$

The rate of energy loss to optical phonons included in this expression contains the same functional dependence on phonon frequency and effective dielectric constant as that given by Ulbrich (21) for the loss rate averaged over a Maxwellian distribution of hot electrons for which the electron temperature $T_e >> (\hbar\omega_{LO}/k)$.

From Eq. [17] it is possible to calculate the loss parameter, K, and hence the e-h pair yield Y, in terms of four physical constants of any material: (*i*) the LO phonon frequency, ω_{LO}; (*ii*) the bandgap (or absorption edge), E_g; (*iii*) the static dielectric constant, ϵ_S; (*iv*) the high frequency dielectric constant, ϵ_∞ (or the refractive index at optical frequencies in a region of negligible absorption, when $\epsilon_\infty = n^2$). Before going on to this stage, however, it is necessary to justify some of the assumptions made in establishing Eq. [17].

The restriction to LO phonon modes is commonly made in polaron coupling theory, and since these are among the highest energy phonons in a solid they are likely to dominate the rate of phonon energy loss. The assumption of a constant ionization rate for all energetic particles (electrons and holes) is more sweeping, but fortunately some insight can be obtained from studies of carrier avalanching in semiconductor devices such as avalanche photodiodes and IMPATT diodes (22, 23). The problem here is to obtain a carrier distribution function in an applied field in order to calculate the ionization rate. Baraff (24) has developed a theory for the ionization rate per unit distance traveled in the field which rests on the following assumptions: (*i*) the energy bands are parabolic; (*ii*) optical phonon generation is the only important dissipative process for the hot carriers which competes with ionization; (*iii*) a single phonon energy for the optical modes; (*iv*) the mfp for optical phonon scattering (λ_{op}) is independent of carrier energy; (*v*) the mfp for ionization (λ_i) is a step function, rising at the threshold E_i and constant for energies $> E_i$. These assumptions are similar to those made earlier in this section.

Much of the experimental work on avalanche multiplication in a range of semiconductor materials has been fitted using Baraff's theory (22, 23), with the assumption that the ionization rate for electrons, α_i, is equal to the ionization rate for holes, β_i. More recent work (25) has indicated that at low fields ($\leq 4 \times 10^5$ V cm^{-1}) in GaAs the ionization rates are sensitive to band structure; β_i is roughly isotropic, but α_i varies strongly with the crystallographic direction along which the field is applied. At high fields ($> 5 \times 10^5$ V cm^{-1}), however, it is apparent that $\alpha_i \sim \beta_i$ in all directions, a result confirmed by Ito *et al.* (26). Similar ionization rates for both electrons and holes are observed in Si and GaP at comparable fields (27). The fact that $\alpha_i \sim \beta_i$ at high fields, where a larger fraction of carriers have energies appreciably above

threshold, supports the idea that details of band structure or differences in effective mass for carriers near the band extrema are not significant in determining ionization rates for more energetic particles. A similar conclusion may be drawn from the work of Kane (28), who calculated the pair production rate in Si using pseudopotential energy bands and wavefunctions. For electron energies >8 eV above the VB the calculated ionization rate approaches the value calculated using a free-electron approximation with an electron density appropriate for Si. If carrier energies are measured from midgap the calculated hole ionization rate gives a curve almost identical to that obtained for energetic electrons. The implication is that for particle energies appreciably above threshold the ionization rates are not very sensitive to details of band structure, density-of-states, or carrier masses. Since a free-electron approximation gives a good estimate of the ionization rate for energetic particles in Si, the assumption of a constant ionization rate for hot carriers in the solids of interest here is probably not unreasonable.

At first sight it might appear surprising to suggest that hot electrons and hot holes can be treated similarly. A hole is simply the absence of an electron, and if created in a deep core band level it will be immobile with an essentially atomic-like wavefunction. It cannot therefore cause ionization directly by propagation through the lattice, like a hot electron of the same energy. However the energy of the core hole is stored as useful potential energy which can be released by subsequent relaxation of the atom, for example by x-ray fluorescence or by emission of an Auger electron. This energetic secondary particle (photon or electron) has only a small probability of escaping from the lattice, and the bulk of this secondary energy will be reabsorbed in creating lower energy (but still hot) e-h pairs. This relaxation will continue until the potential energy of the original core hole is converted into the energy associated with holes in the valence band and electrons in the conduction band. At this stage the hot VB holes have sufficient mobility to create further secondaries by impact ionization. Thus the relaxation of a very high energy immobile hole can be considered to take place through intermediate electron states, until its potential energy is converted partly into the energies of electrons and holes a few times greater than the ionization threshold, and partly into phonons generated during the relaxation process. Taken overall, therefore, the relaxation of a core hole proceeds via processes which are essentially similar to those for a high energy electron, and it is not unreasonable as a first approximation to treat energy losses for these two kinds of particles in the same way. Towards the end of the relaxation process, in an energy range a few times above threshold, the competitive phonon losses assume greatest significance and then the assumption of similar ionization behavior for electrons and holes receives support from the fitting of experimental data to Baraff's theory.

The best value of the ionization threshold in fitting avalanche data to Baraff's theory is generally found to be $E_i = 1.5\,E_g$, as assumed in the derivation of Eq. [17] (22, 23). This is actually the calculated threshold for a direct gap material with simple parabolic bands and equal carrier masses; the boundary conditions which set the minimum threshold are that the group velocities of the three final particles in the ionization event should be equal, and that energy and momentum are conserved (25). As noted above the details of band structure are important when the carrier distribution is peaked well below threshold, but for higher carrier energies a threshold which is independent of such specific material properties gives adequate description of the experimental results.

The Average Energy per e-h Pair Generated by Ionizing Radiation

In Table I are collected together the physical constants necessary to calculate the relative loss parameter K for a range of phosphor materials of interest. In column 6 is shown the value of the material coefficient $\mathcal{R}$, defined as

$$\mathcal{R} = \left(\frac{1}{\epsilon_\infty} - \frac{1}{\epsilon_s}\right)\frac{(\hbar\omega_{LO})^{3/2}}{1.5E_g} \qquad [18]$$

From Eq. [17] $\mathcal{R}$ is seen to be proportional to K, and we shall therefore use this as an index of relative efficiency for phosphor host materials. In order to obtain the constant of proportionality between $\mathcal{R}$ and K use is made of experimental evidence which suggests that the archetypal phosphor host materials, ZnS and CdS, obey the "$3 \times E_g$" rule (4, 6, 10). For such materials, with $\xi = 3E_g$ and $E_i = 1.5E_g$, we deduce from Eq. [7] that

$$Y = 0.5 \qquad [19]$$

and hence, using the Monte Carlo values of yield in Fig. 3, that

$$K = 0.30 \qquad [20]$$

Setting the mean value of $\mathcal{R}$ for ZnS and CdS (*i.e.*, $\mathcal{R} = 1.23 \times 10^{-4}$) equal to this value gives

$$K = (0.244 \times 10^4)\mathcal{R} \qquad [21]$$

This constant of proportionality will be used for all phosphor hosts, in accordance with [17]. The choice of ZnS and CdS as reference compounds is natural because of our particular interest in the relative efficiencies of phosphor materials, but is somewhat arbitrary in that other semiconducting compounds (such

Bracketed values for ϵ_∞ are obtained from the square of the refractive index at ~1 μm.

as GaAs and GaP) might equally well have been chosen. However the principal conclusions would not be greatly affected by a change of reference since the yield Y does not vary strongly with K (or $\mathcal{R}$) in the range covering this group of binary semiconductors.

In Fig. 4 is shown a plot of β *vs.* $\mathcal{R}$, where β is defined from Eq. [3] and [7] as

$$\beta = \frac{\xi}{E_g} = \frac{3}{2Y} \qquad [22]$$

and Y is obtained from Fig. 3 via Eq. [21]. The average energy per e-h pair can be obtained from Eq. [3] by making use of the data in Table I. For small phonon losses ($\mathcal{R} \to 0$) the factor β tends to a limiting value ~2.35. The magnitude of β initially increases only slowly with $\mathcal{R}$ as the relative losses to phonons become more significant, but the increase is much more rapid when $\mathcal{R} > 1 \times 10^{-4}$ corresponding to a relative phonon loss parameter $K \sim 0.25$. At the top of Fig. 4 are indicated the values of $\mathcal{R}$ appropriate to materials of phosphor interest. As expected, the binary semiconductors for which the "$3 \times E_g$" rule was established cluster in the center of the curve, with values of β in the range 2.6-3.0. It should be noted that CaS, although being highly ionic, is predicted to behave in a manner analogous to the IIB-VI compounds ZnS and CdS since it has similar dielectric properties and a comparable LO phonon frequency.

For the conventional phosphor materials it can be seen that β increases in the order sulfides < oxysulfides < oxides. Since phosphor efficiency $\eta \propto \beta^{-1}$ this ordering of the phosphor hosts according to the index $\mathcal{R}$ is clearly consistent with the observations made in the introduction to this paper. It is worth noting that the alkali halides CsI and NaI fall at the LH side of the diagram mainly because of their low frequency phonon modes; conversely the "molecular" oxides such as Zn_2SiO_4, $CaWO_4$, and YVO_4 have the largest values of the index $\mathcal{R}$ principally because of the high vibrational frequencies introduced by the strong intramolecular bonding in the $[MO_4]$ tetrahedra within the lattice structure. In such materials excitation of these high frequency modes carries away a greater proportion of the particle energy near the end of the avalanching process and greatly reduces the e-h pair yield.

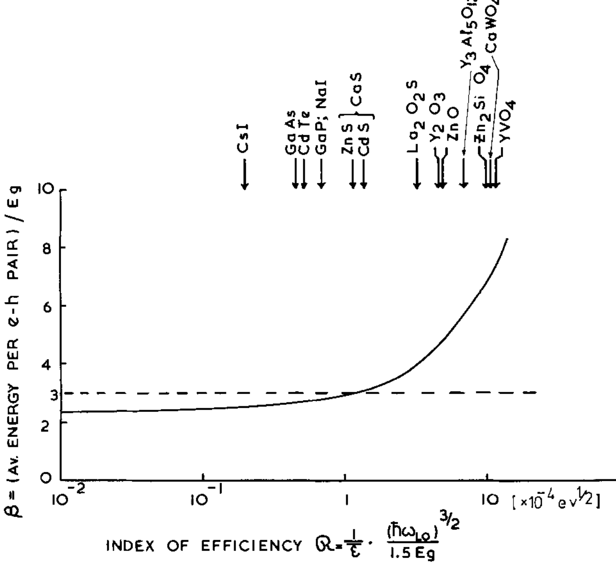

Fig. 4. The parameter $\beta = \xi/E_g$ as a function of the index of efficiency $\mathcal{R}$ defined in Eq. [18]. The index $\mathcal{R}$ depends on basic physical constants of a particular material and is proportional to the energy loss ratio K in Fig. 3: $K = (0.244 \times 10^4)\,\mathcal{R}$. The line $\beta = 3$ corresponding to the "$3 \times E_g$" rule for the average energy per e-h pair is indicated. At the top of the diagram values of $\mathcal{R}$ for several phosphor host materials are shown. The average energy per pair for oxides is predicted to be much higher than that for the sulfides.

The data in Table I for GaAs and GaP also lend support to the assumption that details of band structure can be neglected in estimating the energy loss parameters. The mean free paths for optical phonon generation in the low temperature limit obtained from fitting ionization data to Baraff's theory are $\lambda_{op} = 58$ and 42Å for GaAs and GaP, respectively (52). The same parameter is applicable for both electron and hole scattering in each material. Assuming similar velocities for energetic carriers in the two materials λ_{op} is inversely proportional to the optical phonon generation rate, so that the ratio of mfp's $\lambda_{op}(GaAs)/\lambda_{op}(GaP)$ can be obtained from Eq. [15] and Table I. This calculated ratio is ~1.75, compared with the experimental ratio (52) ~1.38 under conditions in which only phonon creation is significant. Applying this reasoning to the oxide materials in Table I suggests $\lambda_{op} \sim$ 3-5Å, *i.e.*, a distance on the order of a unit cell or between the tightly bound MO_4 units in the lattice.

The Maximum Efficiency of CRT Phosphors

The maximum efficiency which might be expected from any host activator combination, η_{max}, was defined in Eq. [2] in terms of the mean luminescence photon energy, $h\nu_m$, and the e-h pair energy parameter, ξ. In Table II η_{max} is calculated for a number of important phosphor systems, neglecting backscattering and using values of β and E_g from Table I. Figure 5 compares these calculated values of η_{max} with measured values of efficiency reported in the literature for the same phosphor systems.

It is gratifying to find that the experimental points cluster about the line of perfect correlation in Fig. 5. There are many reasons why the measured efficiency for a particular phosphor might fall below the predicted value η_{max} (for example the neglect of backscattered primaries, or a reduction in the energy transfer efficiency S or the quantum efficiency Q in Eq. [1]), but it does appear that the best reported values correlate well with the theoretical predictions. The most serious deviation occurs for CaS:Ce, which has a much higher reported efficiency than we predict (6); the behavior of CaS:Mn and CaS:Pb on the other hand is more consistent with the theory. In some cases, notably Zn_2SiO_4, there is a lack of reliable physical data so that certain parameters have been estimated in evaluating the index $\mathcal{R}$. Agreement between predicted and measured efficiencies may be improved when better data are available.

For most phosphors there is good agreement between the efficiencies measured under CR and XR excitation. An exception to this rule is $CaWO_4$, which has an XR efficiency ~8% but an optimum CR efficiency of only half this value (56). As one might expect, theory predicts a maximum efficiency close to the higher of the measured efficiencies, $\eta_{max} \sim 9\%$. The reasons for the lower limit to the CR efficiency are not clear, but may

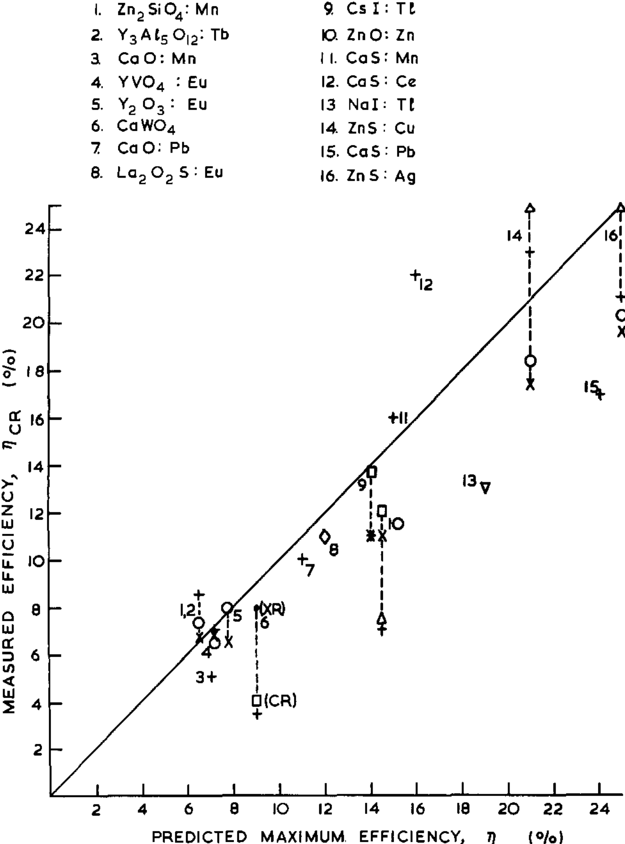

Fig. 5. The correlation between measured values of phosphor efficiency and the theoretical maximum efficiency predicted by the model. The measured value for a particular phosphor will fall below the line of perfect correlation if the energy transfer and radiative processes in the phosphor are not optimized. However the best reported values of efficiency for a wide range of phosphor types show good agreement with the predictions. Data points: △ [Ref. (53)]; ○ [Ref. (54)]; + [Ref. (6)]; × [Ref. (55)]; ▽ [Ref. (4)]; ● [Ref. (56)]; □ [Ref. (57)]; ✲ [Ref. (58)]; ◇ [Ref. (59)].

for example reflect the increased importance of surface deactivation for the less-penetrating electron radiation.

Discussion

A calculation of the maximum efficiency to be expected from particular host-activator phosphor combinations has been made using a model which is very idealized, but which should be quite general in its application. The theory draws heavily on van Roosbroeck's statistical analysis of the e-h pair generation problem in semiconductors (12), but in the context of phosphor materials the approach adopted in this paper is novel in emphasizing the competitive phonon loss processes which occur during the carrier ionization cascade. The relative phonon loss parameter K appearing in van Roosbroeck's analysis is here translated into an index of efficiency, $\mathcal{R}$, which can be calculated from accessible physical constants of a particular material: ω_{LO}, E_g, ϵ_∞, ϵ_S. The many simplifications in the model are probably successful because the yield of secondary e-h pairs, which is a critical factor in the limiting efficiency, is determined largely by carriers with energy only a few times greater than the ionization threshold, E_i. In this energy range, covering higher valence and conduction band states, the ionization rates are governed by excess particle energy and are insensitive to details of band structure or carrier charge and mass. In the final analysis, however, it is the good agreement between measured phosphor efficiencies and the maximum value η_{max} calculated from the theory which must be considered the principal justification for the many assumptions made during the development.

The degree of correlation with experiment evident in Fig. 5 suggests that the index $\mathcal{R}$ may prove a useful tool in the search for new and efficient phosphor host materials. The model should be applicable generally to those polar semiconducting and insulating materials for which polar optical mode scattering is expected to dominate the phonon energy dissipation, and this includes the materials of primary interest as phosphor hosts. If the index $\mathcal{R}$ is calculated for any potential phosphor lattice according to Eq. [18], the average energy per e-h pair for these materials can be read from Fig. 4 and the limiting efficiency estimated using Eq. [2]. However it must be realized that this maximum efficiency represents only one ingredient in the recipe for a useful phosphor system (it is also necessary that the lattice have the requisite damage-resistance), and that an efficient activator center can be incorporated so that the parameters S and Q in Eq. [1] are optimized.

At a somewhat simpler level it is clear from Fig. 4 that the index places the more common phosphor hosts in an order which is in satisfying agreement with experience; the more efficient sulfides to the left hand, the oxysulfides in the center, and the less efficient oxides to the right of the figure. The important parameters which determine $\mathcal{R}$ are the effective dielectric constant $\bar{\epsilon}$ (defined in Eq. [16]) and the LO phonon frequency (or at least the ratio $\hbar\omega_{LO}/E_g$). The effective dielectric constant $\bar{\epsilon}$ arises from relaxation of the lattice atoms alone, and relates the lattice polarization field to the electric displacement associated with the free charge carriers (18)

$$\bar{P}_{\text{lattice}} = \frac{1}{4\pi\bar{\epsilon}}\bar{D} \qquad [23]$$

If $\bar{\epsilon}$ is large the lattice deformation induced by the free carriers is relatively small, and the phonon coupling is reduced. Both oxides and alkali halides have small values for $\bar{\epsilon}$; phonon coupling is therefore strong, but in the case of the heavier halides the LO phonon frequency is low so that the total energy carried away by phonons is small and the index $\mathcal{R}$ as a whole is reduced. This is consistent with the well-known use of the heavier alkali halides as the host lattices for efficient scintillator devices (4). In the majority of oxides, on the other hand, the combination of the light O atom and tighter, more covalent bonding produces high phonon frequencies and therefore larger values for the index $\mathcal{R}$. The large pair energy ξ, and the corresponding modest efficiency, for oxide-based materials are therefore to be understood as the consequences of a low effective dielectric constant $\bar{\epsilon}$ coupled with a high lattice phonon frequency.

As a final point it is worthwhile to consider the relationship between the present theory and previous attempts to rationalize the relative efficiencies of different phosphor materials. Alig and Bloom (16) have emphasized that the correlation between CR efficiency η and the inverse plasmon frequency $(\omega_p)^{-1}$ originally proposed by Kingsley and Ludwig (5) is only valid when calculated plasmon frequencies are used; no correlation exists for measured values of ω_p. From Eq. [5] it is therefore clear that the foundation of Kingsley and Ludwig's observations must lie in a correlation between η and $(n_v)^{-1/2}$, where n_v is the valence electron density. For those phosphor lattices which can be considered to have a similar ratio of ionic to covalent bonding (*i.e.*, specifically neglecting the alkali halides) Alig and Bloom have demonstrated that there is indeed a relationship between η and n_v; in fact they have plotted η *vs.* $(n_v)^{-1}$ and have shown that some degree of correlation does exist between these quantities.

In this work we predict an inverse relationship between η and the index $\mathcal{R}$, *i.e.*, from Eq. [18] we expect some positive correlation between η and the product of the quantities $\bar{\epsilon}$ and $(\hbar\omega_{LO}/E_g)^{-1}$. The observations discussed in the previous paragraph would therefore be understandable if these exists a correlation between $\bar{\epsilon}$ and/or $(E_g/\hbar\omega_{LO})$ and the inverse valence electron density $(n_v)^{-1}$. These quantities are listed in Table III and plotted in Fig. 6 using the reported values of n_v; this figure demonstrates that both $\bar{\epsilon}$ and the ratio $(E_g/\hbar\omega_{LO})$ do indeed vary as $(n_v)^{-1}$, and that the correlation with their product is even stronger. The reasons for this dependent behavior are as follows. The quantity $(n_v)^{-1}$ tends to be larger for lattices containing the bigger anions, such as S^{2-} and Se^{2-}, than for the oxides. The presence of heavy ions in a lattice reduces the vibrational frequency $\hbar\omega_{LO}$, so that the ratio $(E_g/\hbar\omega_{LO})$ also tends to be larger for the sulfides and selenides. As noted previously this ratio is particularly low for oxides containing tightly bound molecular anions. The effective dielectric constant can be rewritten as

$$\bar{\epsilon} = \frac{\epsilon_\infty}{(1 - \epsilon_\infty/\epsilon_S)} \qquad [24]$$

and for the more polar materials of interest here it is most sensitive to variation in the high frequency dielectric constant ϵ_∞. According to the Clausius-Mossotti relation (60) ϵ_∞ increases with the electronic polarizability of the ions in the lattice. Since the anion polarizability is dominant, and for the chalcogenides has the order $Se^{2-} > S^{2-} > O^{2-}$, it is again apparent that $\bar{\epsilon}$ will be larger for those compounds containing the bigger anions for which $(n_v)^{-1}$ is also larger.

We therefore suggest that the explanation of the earlier observations of Kingsley and Ludwig and of Alig and Bloom is as follows. For a particular phosphor host our theory predicts a positive relationship between the maximum phosphor efficiency η_{max} and the product of two quantities, $\bar{\epsilon}$ and $(E_g/\hbar\omega_{LO})$. As long as we restrict our attention to compounds with similar bonding properties, *e.g.*, the chalcogenides, we find that both these quantities tend to increase with increasing anion size, for reasons discussed above. For lattices containing the larger anions the inverse valence electron density, $(n_v)^{-1}$, is also large. Hence the previously reported appearance of correlation between η and $(n_v)^{-1}$ [and implicitly between η and $(\omega_p)^{-1}$] arises simply because for the compounds of interest the product of the effective dielectric constant $\bar{\epsilon}$ and the energy ratio $(E_g/\hbar\omega_{LO})$ for a particular compound tends to be large in those lattices containing the larger anions, for which $(n_v)^{-1}$ is also larger.

Acknowledgments

The author is grateful to a number of colleagues, particularly Dr. P. J. Dean, for valuable comments on this work.

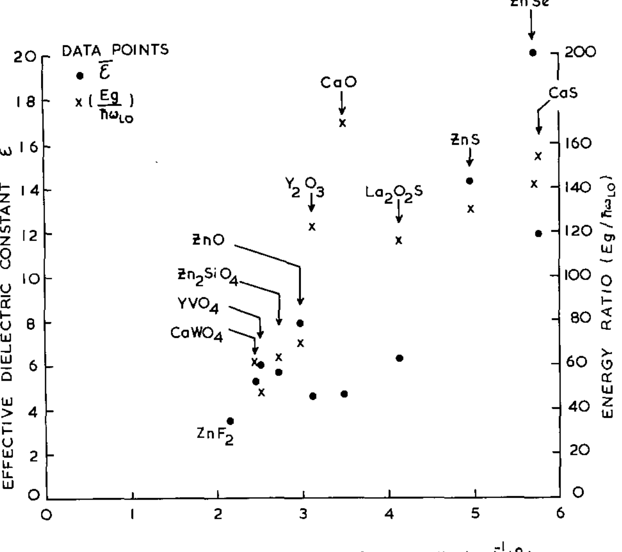

Fig. 6. The effective dielectric constant $\bar{\epsilon}$ and the ratio $(E_g/\hbar\omega_{LO})$ for a number of phosphor host materials plotted against the inverse valence electron density $(n_v)^{-1}$ taken from Ref. (16). A positive relationship between phosphor efficiency η and the product $\bar{\epsilon}$ $(E_g/\hbar\omega_{LO})$ is expected on the basis of the theory developed in this paper. The evident correlation between these quantities and $(n_v)^{-1}$ is the origin of a previously noted correlation between η and the calculated plasmon frequency $\omega_p = (4\pi n_v e^2/m)^{1/2}$.

Investigation of Contact Metallization Systems for Solar Cells

R. B. Campbell and A. Rohatgi

Westinghouse Advanced Energy Systems Division, Pittsburgh, Pennsylvania 15236

ABSTRACT

In conventional solar cells, evaporated Ti-Pd-Ag metallization system has been found reliable. However, for low cost terrestial applications, its cost effectiveness may be questioned. Electroplated Ag and Cu have been investigated as replacements for evaporated Ag and have given results comparable to the evaporated Ti-Pd-Ag system.

Reliable contact systems are required if solar cells are to meet the operating lifetime goal. Evaporated Ti-Pd-Ag is the most widely used contact system due to its overall satisfactory performance and it has been qualified for space cells. However, this system may not be cost effective due to: (*i*) the use of expensive Ag, (*ii*) vacuum techniques, and (*iii*) inefficient use of evaporated material. A second problem, relating to operating life, is the interaction between the interconnect strap and the contact metallization. If these are different metals, there could be problems arising from galvanic corrosion effects and formation of intermetallics.

In this paper we will describe several alternate contact systems which ease processing, are suitable for a single metal interconnect system, and which are less costly than the evaporated Ti-Pd-Ag system.

Key words: solar, electroplating, metallization.

Systems Studied

The following contact systems were studied: (*i*) evaporated Ti-Pd-Ag (baseline system); (*ii*) evaporated Ti-Pd + electroplated Ag; (*iii*) evaporated or electroplated Cu; (*iv*) evaporated Pd + electroplated Cu; and (*v*) evaporated Ti-Pd + electroplated Cu.

Evaporated Ti-Pd-Ag was used as a baseline contact system against which all other systems were evaluated. The evaporated Ti-Pd electroplated Ag system (No. *ii*) should be more cost effective than No. *i* since the Ag is deposited only on the well-defined grid area. The evaporated Ti-Pd electroplated Cu system (No. *iii*) has the advantages of No. *ii* as well as using a less expensive metal. In addition, a system with a top layer of copper may permit a single metal contact-interconnection system using copper foils. The Pd-Cu system was investigated to determine the role of the diffusion barrier metal, Ti, in the system. The evaporated Cu on Si sys-

tem was studied to show that even at very moderate operating conditions copper on silicon is unsatisfactory.

These contact systems were studied by fabricating 1 × 1 cm n^+ p p^+ solar cells on either float zone or dendritic web silicon. The base material was 10-15 Ω-cm boron-doped. The cell parameters were determined by a combination of dark and lighted *I-V* measurements. The open-circuit voltage (V_{OC}), short-circuit current (I_{SC}), fill factor (*FF*), and cell efficiency were determined for the AMI spectrum using a quartz-iodine simulator. The bulk and junction responses were determined by transforming the measured dark *I-V* data by removing the effects of series and shunt resistances as described by Davis *et al.* (1). The upper segment of the transformed *I-V* curve (Fig. 1) represents the bulk performance (ideality factor of unity) and the lower segment is indicative of the junction response. If the upper segment moves to the left it indicates a loss of bulk lifetime and the upward movement of the lower segment suggests increased recombination in the junction or junction recombination current (2, 3). The lifetime was determined by the open-circuit decay (OCD) technique using 20 mA current. The junction current (I_j) dominates at low voltages and is indicated in this paper by the current in the lower segment at $V \simeq 0.3$V. The junction excess current can reduce the fill factor and cell performance if it becomes appreciable in relation to the current at the operating point.

Experimental Results and Discussion

Table I shows a comparison of the evaporated Ti-Pd-Ag system *vs.* the evaporated Ti-Pd electroplated Ag system. These data were obtained by removing the evaporated Ag from the samples in the first column and then electroplating an Ag layer. The data show no essential difference between the two systems. The electroplated Ag system will be less costly since the Ag is deposited only on the grid structure, and not over the entire cell (as in the evaporation technique).

The evaporated copper system resulted in extremely poor yields. The main failure mechanism was a low shunt resistance of the order of few ohms as compared to the normal 30 KΩ or greater. This was most probably due to the Cu diffusing into the silicon, and shunting the junction. This occurred at the moderate processing temperatures of about 100°C.

Table II shows a comparison of the baseline system with evaporated Pd-electroplated Cu. The specific data

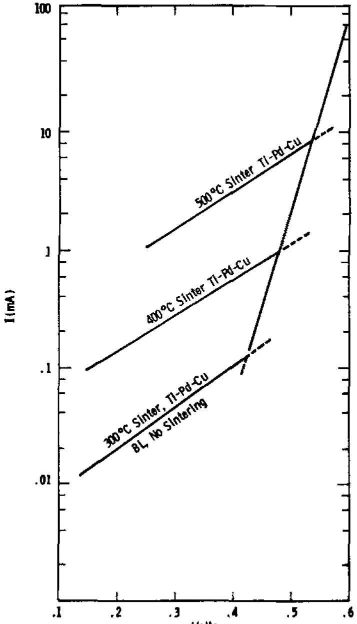

Fig. 1. Transformed *I-V* curves of baseline system and Ti-Pd-Cu system.

Table I. Evaporated Ti-Pd-Ag vs. evaporated Ti-Pd-plated Ag

	Evaporated Ag	Plated Ag
η (%)	14.4	14.3
I_{sc} (mA)	34.6	35.1
V_{OC} (V)	0.572	0.578

in Table II is for a Pd layer of 0.03 μm, although layers from 0.08 to 0.3 μm were tested with the same results. The unsintered Pd-Cu system is equivalent to the baseline system. However, the system cannot withstand sintering as shown in the last two columns. The sintering was carried out in H_2 at the noted temperature for 15 min. The degradation is due to an increase in the junction excess current, again presumably due to the Cu diffusing through the Pd to the junction.

Although not indicated in the table, the experiments were repeated using sintered Pd as a base for plating the Cu. Pd layers from 0.08 to 0.3 μm were studied. In these tests the Pd was sintered for 15 min at 300°C to form Pd silicides prior to plating 4 μm of Cu. Initial cell characteristics were good but when these samples were sintered at 300°C they showed the same degradation as the cells in Table II, *i.e.*, excess junction current. We, therefore, conclude that Pd, either sintered or unsintered, does not serve as a barrier to Cu.

Table III shows the comparison of evaporated Ti-Pd-Ag system and the evaporated Ti-Pd electroplated Cu system. All cells were fabricated on dendritic web silicon. As seen from the table, this system is equivalent to the baseline system and can be sintered to

Table III. Evaporated Ti-Pd-Ag vs. evaporated Ti-Pd-plated Cu

above 300°C. There is only a slight decrease in performance when sintered at 400°C, but a significant degradation when sintered at 500°C. The degradation was due to increased junction current with no significant effect on the bulk properties.

This is indicated in Fig. 1 which shows the transformed *I-V* curves of the Ti-Pd-Ag baseline system (unsintered) and the Ti-Pd electroplated Cu system after sintering at 300°, 400°, and 500°C. As the sintering temperature is increased, the cell degrades by an increase in the junction current until at 500°C it noticeably affects the cell parameters. For example, the efficiency drops from 14 to 10.5%. This increase in junction current can be due to impurities or defects in the depletion region, such as Cu precipitates.

These data indicate that evaporated Ti-Pd electroplated Cu is a promising contact system from both a performance and cost standpoint. Its long term reliability under realistic cell operating conditions has not been determined.

Conclusions

From the data given we conclude:

1. Electroplated Ag can be used instead of evaporated Ag to reduce the use of expensive Ag.
2. Pd-Cu is not a suitable system since it cannot withstand sintering.
3. Ti-Pd electroplated Cu behaves essentially the same as the baseline system.
4. Ti and not Pd acts as a diffusion barrier.

Laser Interferometer Bevel Angle Measurement for Spreading Resistance Profiling

D. C. D'Avanzo,[1] C. Clare, and C. Dell'Oca*

Hewlett Packard Laboratories, Palo Alto, California 94304

ABSTRACT

A laser interferometer system is utilized to automatically measure bevel contours for spreading resistance profiling. Comparative results demonstrate the system's ability to measure angles between 0.2° and 2° with better than 10% consistency. The effects of bevel rounding are investigated by incorporating the complete bevel contour into a multilayer data analysis algorithm. Both rounding and three-dimensional effects are shown to contribute to the near-surface depletion of spreading resistance impurity profiles.

Spreading resistance measurements are widely used to determine the impurity profiles of diffused, implanted, and epitaxially grown layers (1). The method is capable of profiling an extensive range of resistivities and profile shapes and is relatively rapid and convenient. The procedure begins by beveling the sample at a shallow angle to achieve high spatial resolution. Spreading resistance is measured between two probes which are stepped along the beveled surface (Fig. 1). The impurity profile extracted from the measurement data is highly dependent on the bevel angle measurement which establishes the actual depth into the sample. As can be seen in Fig. 1, the perpendicular distance, y, from the original surface is the product of the sine of the bevel angle, θ, and the distance traveled in the x direction. An accurate bevel angle measurement is therefore essential for an accurate profile measurement.

Existing angle measurement techniques average the slope of the bevel over the entire beveled plane, resulting in significant error when the beveled surface is rounded. In order to minimize this error, considerable time and effort must be dedicated to sample preparation. In addition, these angle measurement techniques are usually made independent of the resistance measurement further increasing the total measurement time.

[1] Present address: Hewlett Packard, Santa Rosa, California 95404.

Key words: impurity profile measurement, two-point probes, multilayer analysis, bevel rounding, near-surface concentration.

In this work, a laser interferometer has been employed to measure the vertical displacement of one of the probes as it moves along the beveled surface. The probe serves as a profilometer so that the actual surface contour is measured. Furthermore, both the resistance measurement and the angle measurement are recorded simultaneously and automatically, reducing the measurement time and minimizing the need for operator interpretation. The laser system and optimization of the laser measurement are discussed in the next section. Comparative results are presented in the third section, and finally, bevel rounding and its effect on the corrected impurity profile are considered in the fourth section.

Laser Interferometer System

Figure 2 is a schematic of the laser interferometer system[2] (2) used in conjunction with the spreading resistance probe.[3] The helium-neon laser uses Zeeman splitting to produce a coherent beam composed of two slightly different optical frequencies of opposite circular polarization. The two components are split in an interferometer where one is reflected internally, while the other is reflected from a mirror mounted on the back of a probe arm. The two reflected beams interfere in the interferometer, producing a difference frequency. Relative motion of the probe arm results in a proportional Doppler shift in the difference frequency which is detected by the receiver and processed by the accompanying electronics. Displacements of approximately one-fortieth of the optical wavelength or 150Å can be detected.

Both the laser and spreading resistance systems are interfaced to a Hewlett-Packard Series 1000 21MX computer. The laser data is processed by the computer and a bevel contour is constructed. The raw spreading resistance data is combined with the contour information and analyzed by multilayer theory (3, 4) to produce a concentration profile for the sample.

Maximum laser resolution is difficult to obtain in practice due to the effects of mechanical vibrations, changes in air density, and thermal expansion of the supports. Vibrations are minimized by mounting the system on an isolation table while changes in air density introduced by turbulence are reduced by enclosing the beam in a protective column.

The third source of error, thermal expansion of the support structure, can lead to considerable inaccuracy if not compensated. The 10 in. aluminum structure supporting the interferometers expands at a rate of 7 microns per degree centigrade. The ambient temperature changes by approximately 0.1°C during a measurement resulting in a 6000Å expansion. Compensation has been achieved by measuring the path length between a reference mirror located near the sample and a reference interferometer mounted on the support structure close to the primary interferometer, Fig. 2. Changes in the reference path length are interpreted as displacement of the interferometer due to expansion of the supports. This displacement is substracted from the probe arm displacement. A typical result is reproduced in Fig. 3. In this experiment the probe arm was allowed to rest on the surface of a stationary sample. The change in path lengths to the probe arm and the reference mirror were measured every 30 sec for 15 min. Without compensation the probe appears to have moved over a micron. When compensation is included the apparent displacement is eliminated. The reduction in the noise level to a 300-400Å ripple is sufficient to accurately determine the bevel angles commonly used for spreading resistance profiling.

[2] The laser source, optics, and electronics, System 5501A, are commercially available from Hewlett Packard Company, Palo Alto, California.

[3] The spreading resistance system, the ASR 100, is produced by Solid State Measurements, Monroeville, Pennsylvania.

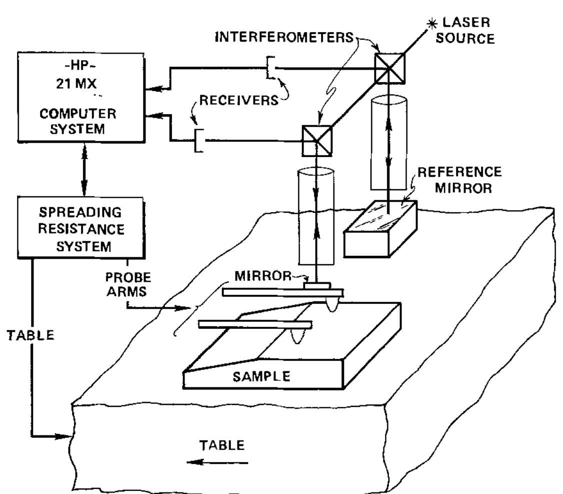

Fig. 2. Laser interferometer and spreading resistance system

Results

Bevel angle determination.—During each spreading resistance measurement cycle the probe is slowly lowered to the sample surface where it remains for several seconds while the resistance measurement is made, and then is lifted to allow the sample to be moved horizontally. Figure 4 shows the height of the probe throughout a measurement cycle. The local height of the sample surface is determined by averaging a burst of laser measurements while the probe is resting on the surface. The data selection interval is shown in Fig. 4. The standard deviation associated with the average value is usually less than 100Å. The averaging procedure is repeated each time the probe is lowered to the sample surface. The probe height is recorded as a

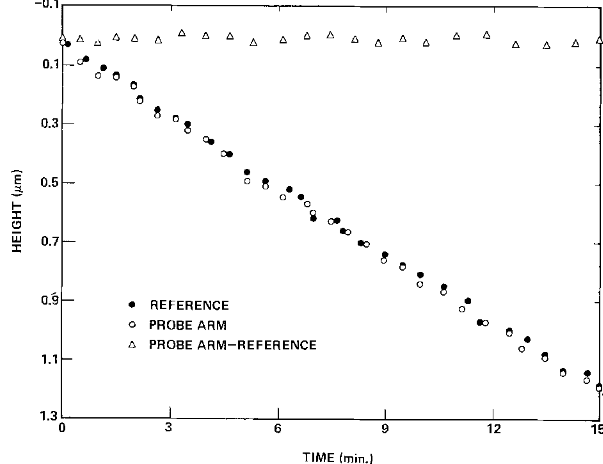

Fig. 3. Reference mirror compensation for thermal expansion

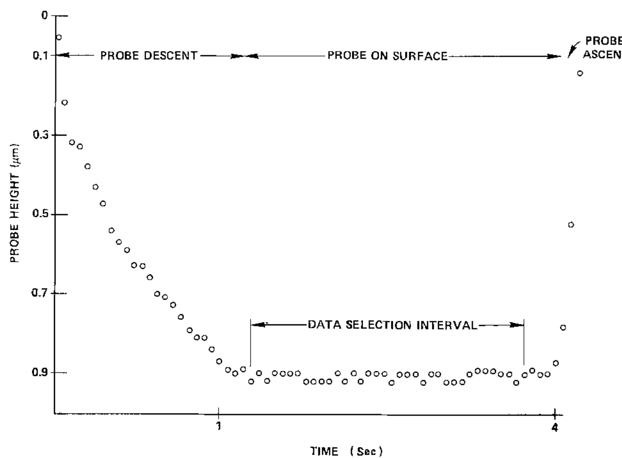

Fig. 4. Probe height during a measurement cycle

function of horizontal travel to recreate the bevel contour. Figure 5 shows a typical result for a nominal 1°9′ bevel block. The bevel angle is determined by fitting two lines to the measurement data; one on the beveled silicon surface and one on the original surface.

To evaluate the accuracy of the laser technique bevels between 0.15° and 2.8° were measured and the results were compared to the angles determined by multibeam interference using an interference attachment in an optical microscope. The bevel angle can be related to the angle formed by the interference fringes as they pass over the bevel edge. The absolute accuracy of the multibeam technique is difficult to evaluate since the fringe bending is measured manually. Repeatability of the method is typically between 5% and 10%.

The comparative results are shown in Fig. 6 where the ratio of the laser angle to the multibeam angle is plotted as a function of the laser angle. For angles over 0.2° (12 min) the agreement is always better than 10% and improves slightly as the angle increases. The apparent range over which reliable laser measurements can be made includes all the nominal bevel angles normally used for spreading resistance profiling which are between 16′ and 5°.

The ability of the laser technique to reproducibly measure junction depths is demonstrated in Fig. 7. The npn structure has junction depths of 0.5 and 2 μm. Each concentration profile was measured on a different chip taken from the same wafer. The triangles were extracted from a nominal 16′ bevel with 10 μm stepping, while the circles were measured on a 34′ bevel at 5 μm stepping to maintain the same approximate vertical resolution. (For comparison, the solid line in Fig. 7 was derived from a 34′ bevel at 5 μm steps and a multibeam angle measurement. The agreement in junction depths is within 500Å, which is the approximate spatial resolution for these particular angles and stepping distances.) The angles for both samples were determined by the laser interferometer and are shown in Fig. 8(a) and (b).

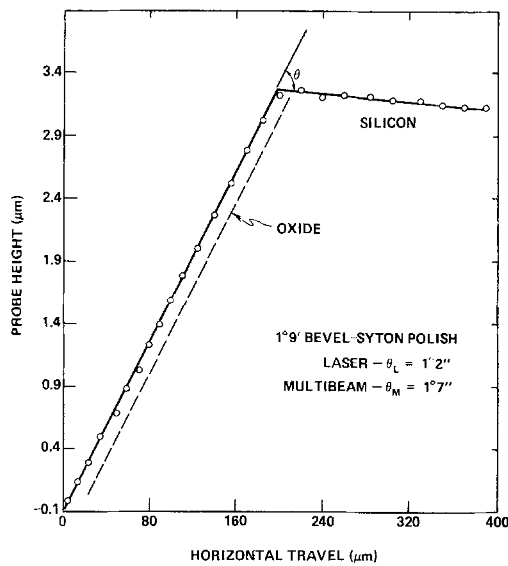

Fig. 5. Laser interferometer measurement of a beveled surface

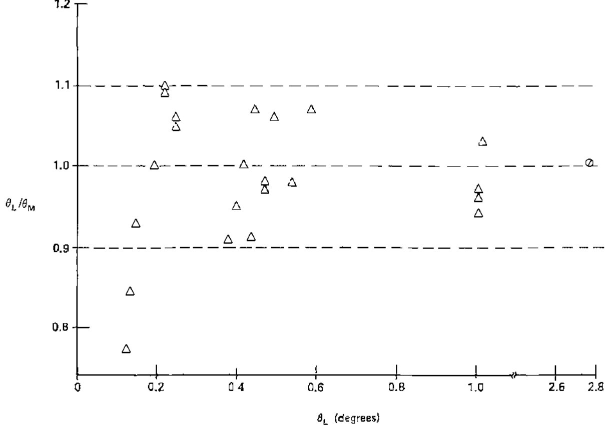

Fig. 6. Comparison of laser interferometer, Θ_L, and multibeam, Θ_M, angle measurement.

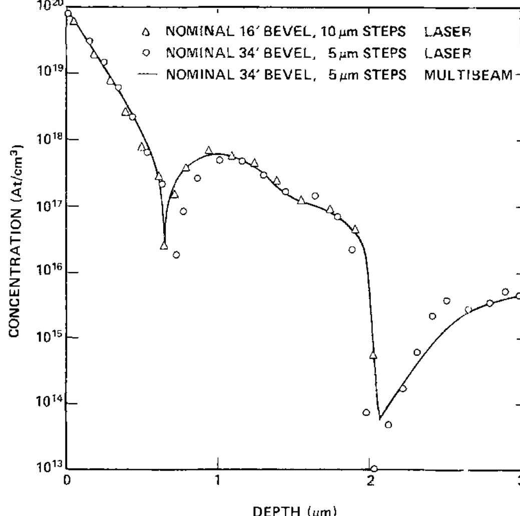

Fig. 7. Comparison of impurity profiles using laser angle measurements on 16′ and 34′ bevels and multibeam measurement on a 34′ bevel.

Up to this point the discussion has been limited to the ability of the laser interferometer to accurately and reproducibly measure bevel angles. The next section explores the potential of the laser technique to quantify the detailed contour of the beveled surface and demonstrate corresponding effects on corrected impurity profiles.

Bevel contour determination and effects.—For the analysis of spreading resistance data the beveled surface is usually assumed planar so that the distance between each measurement point is constant and equal to the product of the sine of the beveled angle and the stepping distance. In practice, the beveled surface can be rounded as has been shown qualitatively with surface profilometer measurements (4). Rounding will introduce nonuniformity in the actual distance between measurement points and may lead to erroneous concentration profiles if the effect is not included in the data analysis scheme. A rounded bevel is one possible cause for the previously reported (4, 5) anomalous depletion of impurities at the surface of diffused samples where none is expected. Since the laser interferometer technique measures the probe height at each point along the sample surface, the actual vertical distance between spreading resistance measurements can be determined and incorporated in the data analysis algorithm.

An example of a laser measurement on a rounded bevel is shown in Fig. 9. The rounded portion of the surface extends through the oxide and over 8000Å vertically into the silicon. The procedure for quantifying the contour measurement is schematically diagrammed in Fig. 10. A parabolic fit approximates the data in the rounded portion of the bevel while linear fits are sufficient outside the rounded area. The vertical distances between measurement points, the h_i, are calculated from the approximating functions. As can be seen in Fig. 10, rounding causes the vertical steps to increase with distance away from the original surface approaching a constant value equal to that derived from an angle measurement. The particular effect on the corrected impurity profile will depend on the data analysis algorithm but, in general, a decrease in h_i will result in an increased concentration, since the

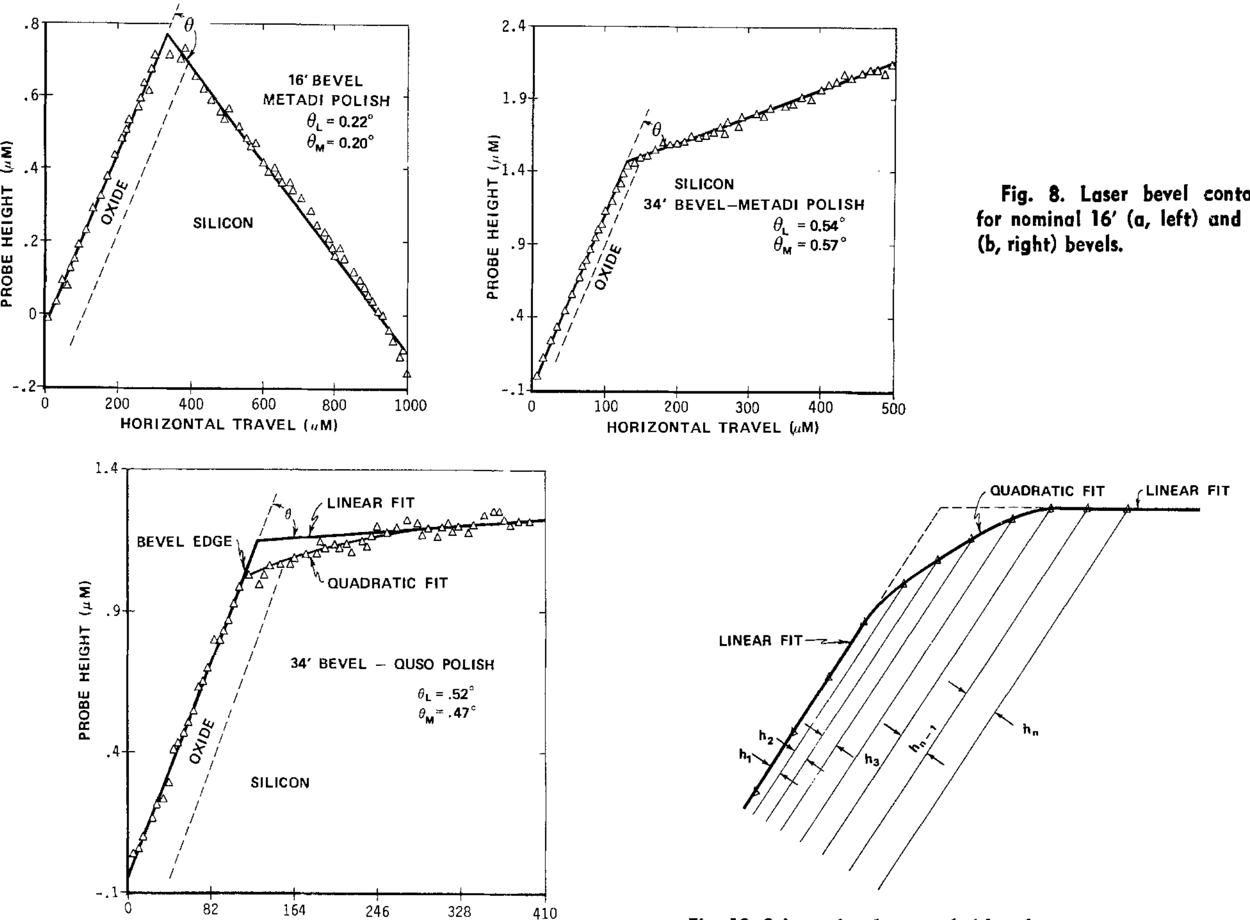

Fig. 8. Laser bevel contours for nominal 16' (a, left) and 34' (b, right) bevels.

Fig. 9. Laser contour measurement demonstrating bevel rounding

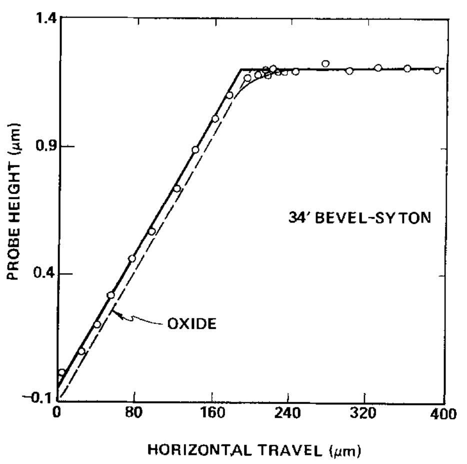
Fig. 10. Schematic of a rounded bevel contour and approximating functions.

concentration is roughly proportional to the local slope of the resistance data. Therefore, incorporation of the actual bevel contour will increase the near-surface concentration.

A typical result for a phosphorus predeposition is reproduced in Fig. 11. The laser data and corresponding linear and quadratic approximations to the bevel contour are shown in Fig. 11(a), and the resulting profiles determined by multilayer analysis are shown in Fig. 11(b). The circles are obtained when a planar bevel or uniform resolution is assumed while the triangles result when bevel rounding is included. Other measurement techniques and diffusion theory have confirmed that the solid solubility phosphorus redeposition should not deplete near the surface. The observed depletion of impurities is apparently an artifact introduced by the spreading resistance technique. Comparison of the two profiles indicates that the quantification and incorporation of bevel rounding improves the near-surface profile shape but fails to completely resolve the apparent anomaly.

To continue the investigation, the surface oxide was removed and both the spreading resistance and bevel contour were remeasured, Fig. 12. As expected, the spreading resistance (circles in Fig. 12) remained at a constant value far from the bevel edge in the original sample surface but begin to increase as the surface is approached. The accompanying surface contour clearly shows that the increase occurs before the bevel has penetrated the sample surface. It appears that the presence of the bevel influences the electric field distribution and hence the measured spreading resistance when the distance between the probes and bevel edge is approximately equal to the probe separation (100 μm for this measurement).

Exact analysis of the bevel influence on the measured resistance would require a three-dimensional solution



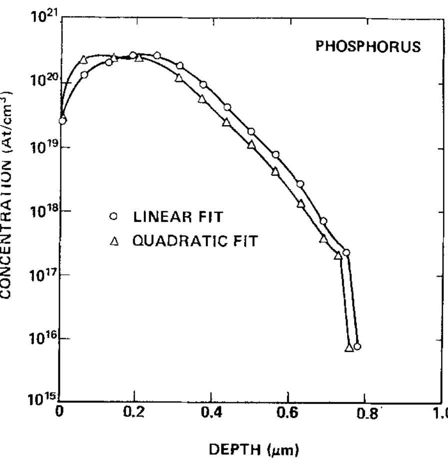


Fig. 11. Laser contour measurement (a, left) and resulting impurity profiles with and without bevel rounding (b, right).

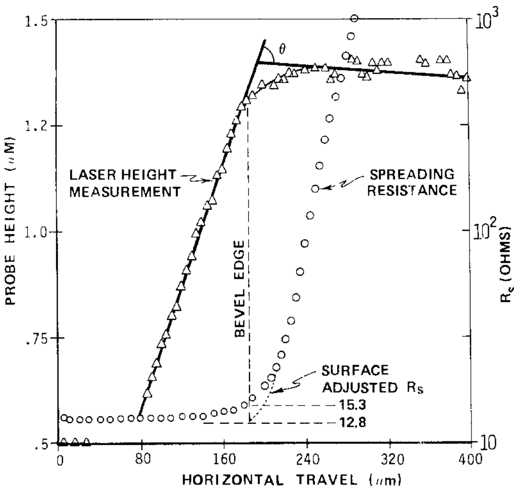

Fig. 12. Laser contour measurement and corresponding spreading resistance measurement after oxide removal.

of Laplace's equation. An empirical approach was adopted in order to estimate the relative effect of the three-dimensional geometry on the corrected impurity profile. This was accomplished by setting the spreading resistance at the bevel edge equal to the constant value measured on the original surface and adjusting the near-surface resistance values to obtain a smooth curve (the dashed line in Fig. 12). The adjusted spreading resistance values were analyzed first with uniform resolution, and then including the effect of bevel rounding. The results are compared in Fig. 13. Adjusting the surface resistance, assuming a planar bevel (the triangles), improves the surface concentration, but the most realistic profile is obtained when both the adjusted surface resistance and bevel rounding are included (the circles in Fig. 13). It appears that the anomalous depletion of impurities at the surfaces of spreading resistance profiles is influenced both by nonuniform spatial resolution due to bevel rounding and by the effect of the three-dimensional bevel geometry on the potential distribution.

The latter effect can be minimized by reducing the probe separation. Figure 14 compares spreading resistance measurements on a phosphorus diffusion with 100 and 25 μm probe separation. The difference between the resistance at the bevel edge and the constant value on the unbeveled surface decreases significantly with decreased probe separation.

Conclusion

A laser interferometer system has been successfully applied to the measurement of shallow bevel contours

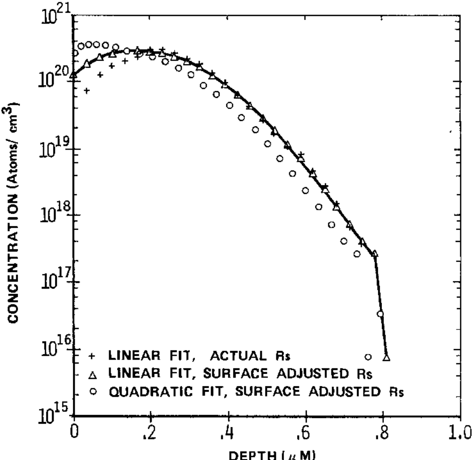

Fig. 13. Impurity profiles demonstrating the effects of bevel rounding and three-dimensional field distortion.

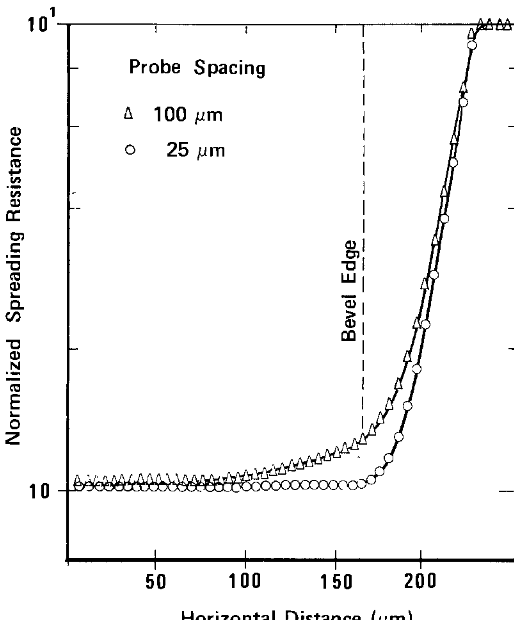

Fig. 14. Normalized spreading resistance measurements on a phosphorus diffusion with 25 and 100 μm probe separation.

for spreading resistance profiling. The new technique provides an automatic determination of bevel angles as well as a quantitative measure of the bevel contour. With adequate compensation for thermal expansion angles as small as 0.2° are accurately measured.

The quantitative contour information has been utilized to study the effects of bevel rounding on spreading resistance impurity profiles. The results imply that the apparent depletion of impurities at the sample surface is only partially caused by rounding. In addition, the three-dimensional bevel geometry tends to increase the spreading resistance near the bevel edge, resulting in lower impurity concentrations. Improved results are obtained when the quantitative bevel contour is taken into account and the near-surface spreading resistance is empirically adjusted.

Stabilization of n-CdSe Photoanodes in Nonaqueous $Fe(CN)_6^{3-/4-}$ Electrolytes

Rommel Noufi,* Dennis Tench,* and Leslie F. Warren

Rockwell International, Electronics Research Center, Thousand Oaks, California 91360

ABSTRACT

The systematic development of a nonaqueous ferro-ferricyanide electrolyte for stabilization of n-CdSe photoanodes is described. Selection of the solvent is discussed in terms of inherent stability provided, the rate of the redox reaction, the tendency toward specific adsorption of the redox species, and the equilibrium potential of the redox couple with respect to the flatband potential (attainable open-circuit voltage). Results are presented for cells of the type n-CdSe/methanol/$Fe(CN)_6^{3-/4-}$/Pt which have been operated for up to 700 hr at 6 mA/cm^2 with no detectable degradation in either the electrode surface or the photoresponse.

It is generally recognized that the key problem with electrochemical solar cells is photodissolution of the required narrow-bandgap semiconductor anode material. To date, the best stability in such cells has been attained with n-type cadmium chalcogenide (CdX, where X = S, Se, or Te) (1-5) and n-GaAs (6, 7) electrodes stabilized by chalcogenide/polychalcogenide redox couples (*e.g.*, Se^{2-}/Se_x^{2-}) in aqueous electrolytes. Photogenerated holes, which would otherwise lead to destruction of the semiconductor lattice, are preferentially consumed in the redox reaction. Unfortunately, the photocurrents in such systems, at least for CdX electrodes, still deteriorate slowly with time, especially at higher light intensities. In the case of CdX, this has been shown to involve chalcogenide exchange between the electrolyte and the electrode surface, possibly via photo-oxidation followed by reprecipitation (8-12).

Suppression of the photodissolution of n-CdX anodes in aqueous systems by X^{2-} ions appears to result primarily from specific adsorption of X^{2-} at the electrode surface and concomitant shielding of the lattice ions from the solvent molecules, rather than from rapid annihilation of photogenerated holes. This is apparent from the dramatic shift in the dissolution potentials for electrolytes containing sulfide[1] (4, 13), *i.e.*

$$CdS = Cd^{2+} + S + 2e^-, \quad E^\circ = 0.08V \qquad [1]$$

$$CdSe = Cd^{2+} + Se + 2e^-, \quad E^\circ = -0.12V \qquad [2]$$

compared with[2]

$$CdS + S^{2-} = Cd^{2+} + S_2^{2-} + 2e^-, \quad E^\circ = -0.72V \qquad [3]$$

$$CdSe + S^{2-} = Cd^{2+} + SeS^{2-} + 2e^-, \quad E^\circ = -0.78V \qquad [4]$$

Because of these shifts (which presumably also occur for Se^{2-} and Te^{2-}), X^{2-} oxidation has practically no energetic advantage compared to CdX dissolution in competing for photogenerated holes, *i.e.*

$$2S^{2-} = S_2^{2-} + 2e^-, \quad E^\circ = -0.71V \qquad [5]$$

$$2Se^{2-} = Se_2^{2-} + 2e^-, \quad E^\circ = -0.95V \qquad [6]$$

As a consequence of X^{2-} specific adsorption and the fact that the X^{2-}/X_n^{2-} couples involve a two-electron transfer, the overall redox process (adsorption/electron transfer/desorption) is also slow, which limits the degree of stabilization that can be attained in such systems. In addition, the type of interaction of the S^{2-} ions with the electrode surface which produces the shifts in the decomposition potentials also favors anion substitution in the lattice and the concomitant degradation of the photoresponse.

On the basis of these observations, fast one-electron redox couples which do not involve strong specific adsorption[3] on the electrode surface appear to be the best candidates for stabilization of n-CdX electrodes against photodissolution. The importance of kinetics in the competition for photogenerated holes is evident from the fact that the $Fe(CN)_6^{3-/4-}$ couple (E° = +0.12V *vs.* SCE) partially quenches the photodissolution of n-CdS in water (14, 15) even though its reaction is thermodynamically unfavorable compared to dissolution (E° = +0.08V). Of course, it is also evident from this example that fast electron transfer by itself is not sufficient to ensure stabilization. Added stability can be attained, however, through the use of nonaqueous solvents (16) which, in general, are inherently less ionizing than water, and also provide flexibility in gaining an energetic advantage for the redox reaction over photodegradation of the semiconductor.

In the present work, various nonaqueous ferro-ferricyanide electrolytes were evaluated for use in stabilizing n-CdSe photoanodes. This evaluation included determination of the inherent stability provided by each solvent, as well as the relevant kinetic and thermodynamic characteristics of the redox reaction in each system. The methanol/$Fe(CN)_6^{3-/4-}$ electrolyte chosen on the basis of these data was shown to completely stabilize n-CdSe photoanodes. This electrolyte also has the distinct advantage of being practically transparent to most of the solar spectrum, *i.e.*, light energies below 2.6 eV.

Experimental Details

Solvent purification.—Reagent grade solvents (Baker Analyzed) were further purified under inert atmosphere before use. Alcohols were refluxed over Mg, and then fractionally distilled. Acetonitrile was stirred over calcium hydride, refluxed over P_2O_5, distilled, and then stored over activated alumina. DMF (N,N-dimethylformamide) was stirred over activated alumina, then distilled under reduced pressure. Propylene carbonate was dehydrated over 4A molecular sieves.

Electrolyte preparation.—The tetraethylammonium cation was used as the counterion for the redox species

* Electrochemical Society Active Member.

Key words: electrochemical solar cells, stabilizing redox systems, methanol, ferro-ferricyanide.

[1] Note that a similar shift is expected for CdTe dissolution, but data do not appear to be available for this reaction.

[2] Note that these reactions are written as oxidations so that dissolution proceeds from left to right, but the E° values are reduction potentials (in agreement with accepted electrochemical practice). All voltages are referred to the saturated calomel electrode (SCE).

[3] It should be mentioned, however, that some interaction between the redox species and the electrode surface may be desirable if it results in a negative shift in the flatband potential so that the open-circuit voltage of the cell is increased.

and the supporting electrolyte. With the smaller tetramethylammonium cation, solubilities are inadequate, whereas the larger tetrabutylammonium cation produces a negative shift in the E° value of the redox reaction (17). The perchlorate supporting electrolyte used in acetonitrile, ethanol, and dimethylformamide was obtained from Southwestern Analytical Company (Austin, Texas). The tetraethylammonium fluoroborate used in the methanol and propylene carbonate solvents was precipitated from a solution of Et_4NBr and HBF_4 in ethanol by addition of isopropanol, and was then recrystallized twice from ethanol.

Tetraethylammonium ferrocyanide was prepared by *in situ* electrochemical reduction of the ferricyanide species using Pt electrodes (~10 cm^2 each) in individual compartments of a Pyrex glass cell separated by a medium glass frit. During the electrolysis, which was performed in an inert atmosphere dry box, the cathode potential remained constant at about −0.45V *vs.* SCE (saturated calomel electrode) and the current density was typically 3-5 mA/cm^2. The desired catholyte redox composition was attained by controlling the amount of charge passed. The tetraethylammonium ferricyanide starting material was prepared by a literature method (17).

Electrodes.—Reference electrodes were always isolated in a separate compartment which was connected to the main cell through a medium glass frit. Reference electrode potentials were checked periodically against that of the ferrocene-ferricenium rection on Pt, which was found to be independent of the solvent (0.40 ± 0.02V *vs.* SCE). The nonaqueous Ag/Ag^+ reference was used in acetonitrile. In the other solvents, both aqueous Ag/AgCl and saturated calomel reference electrodes were used with comparable results.

The Pt disk electrode (0.13 cm^2) used to study the kinetics of the $Fe(CN)_6^{3-/4-}$ reaction was mounted concentric and flush with the end of a 12 mm diam Kel-F cylinder by hot pressing. After mounting, the electrode was polished on successively finer aqueous alumina powder slurries to 1 μm particle size, and was then cleaned ultrasonically in water. Before each use, the electrode was further cleaned by immersion in boiling concentrated nitric acid.

The n-CdSe electrodes (0.18 cm^2 × 1 mm thick) were cut from rods supplied by Cleveland Crystals (Cleveland, Ohio) and had from 10^{17} to 10^{18} carriers/cm^3. Ohmic contacts were made with an In-Ga alloy. Before use, n-CdSe electrodes were polished to 0.05 μm particle size, then etched in 3*M* nitric acid or a 1:25 mixture of concentrated nitric and hydrochloric acids (with comparable results). For long-term studies, n-CdSe electrodes were mounted in Kel-F by hot-pressing. Results for electrodes mounted in silicone adhesive/sealant (Dow Corning Corporation, Midland, Michigan) were comparable.

Electrochemical measurements.—All electrochemical measurements were made in Pyrex glass cells inside an inert atmosphere dry box using a PAR Model 173 Potentiostat/Galvanostat in conjunction with a PAR Model 175 Universal Programmer. The effects of solution resistance were always eliminated by electronic *IR* compensation. The a-c impedance of n-CdSe electrodes was determined from the current response to a small a-c voltage (5 mV rms) measured by an Ithaco Dynatrac III Lock-In Analyzer. Electrodes were illuminated by a tungsten-halogen lamp through a quartz window. The illumination intensity was measured with a Pyroelectric Radiometer (Molectron, Sunnyvale, California).

Results and Discussion

Inherent electrode stability.—The inherent stability of n-CdSe electrodes in various solvents was investigated by following the photocurrent at the same degree of band bending as a function of time under illumination at constant intensity in the absence of redox species in the electrolyte. Data are shown in Fig. 1. Since in the absence of electrode photodegradation the rate of charge carrier recombination should be high, lower initial photocurrent and fast decay are taken as indications of intrinsic stability. Based on these criteria, Fig. 1 indicates that the resistance of CdSe to photodecomposition increases in the order: water << methanol ≅ ethanol < N,N-dimethylformamide < propylene carbonate ≅ acetonitrile.

Kinetic considerations.—The kinetics of the $Fe(CN)_6^{3-/4-}$ redox reaction in the various solvents were investigated using a rotating Pt disk electrode (18). Typical voltammograms obtained in methanol, ethanol, acetonitrile, and propylene carbonate are shown in Fig. 2. The plateau currents observed for both the anodic and cathodic branches were found to be diffusion limited in all cases. As shown in Table I, the equilibrium potential for the $Fe(CN)_6^{3-/4-}$ reaction correlates well with the solvent acceptor number (17), which reflects the stabilization of the iron(II) complex by outer-sphere solvent interactions. Note that there is no correlation with the dielectric constant. The equilibrium potential can be varied almost continuously through the use of mixed solvents. Because of the extremely negative E° value for the $Fe(CN)_6^{3-/4-}$ couple in dimethylformamide, which ensures a low open-circuit voltage, since based on the photocurrent onset the flatband potential is about −1.1V, this solvent was not considered further.

The $Fe(CN)_6^{3-/4-}$ reaction is generally reversible as indicated by the voltammograms in Fig. 2, and linear kinetic plots (19) of the type shown in Fig. 3 for the methanol electrolyte were generally obtained. The current function plotted in Fig. 3 includes corrections for the back reaction and mass transport for both the reactant and product; i = current, i_f and i_b = the diffusion-limiting currents for the forward and back reactions, respectively, E = electrode potential, and E_r = rest potential. When the redox reaction is reversible and specific adsorption does not occur, the slope of the kinetic plot ("Tafel" slope) should be 120

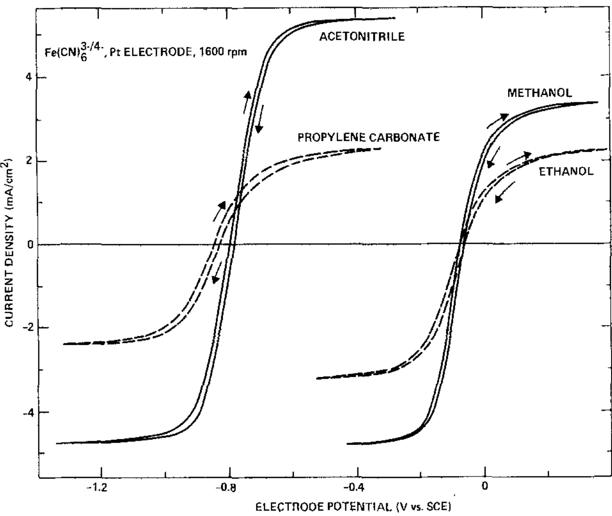

Fig. 2. Cyclic voltammograms at 100 mV/sec for a Pt disk electrode rotating at 1600 rpm in various solvents containing 0.01M tetraethylammonium ferro- and ferricyanide, and 0.1M tetraethylammonium supporting electrolyte (perchlorate in acetonitrile and ethanol, fluoroborate in methanol, and propylene carbonate).

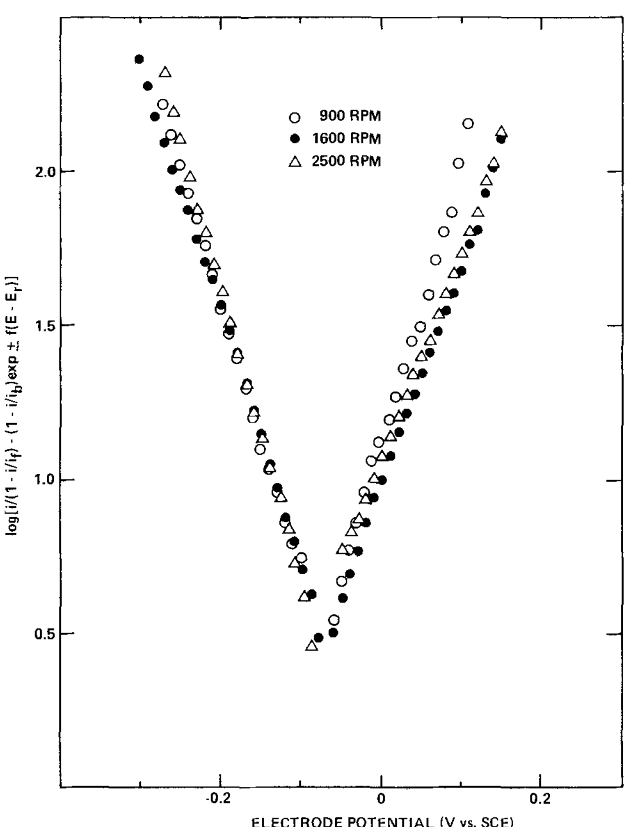

Fig. 3. Kinetic plots for the $Fe(CN)_6^{3-/4-}$ redox reaction on a rotating Pt disk electrode in a methanol electrolyte (conditions same as Fig. 2).

mV/decade (assuming that the symmetry factor, α, is 0.5) and extrapolation to the rest potential yields the apparent exchange current (and consequently the apparent rate constant). When specific adsorption occurs, the "Tafel" slope is generally higher.

Kinetic data for the $Fe(CN)_6^{3-/4-}$ couple on Pt are summarized in Table II. The electron transfer rate decreases with the solvent in the order methanol > ethanol > acetonitrile > propylene carbonate, by about a factor of 1/3 in each case. The Tafel slopes for ethanol and propylene carbonate of 130 mV/decade for the cathodic branch and 170-180 mV/decade for the

Table I. Correlation of the $Fe(CN)_6^{3-/4-}$ redox potential with the solvent acceptor number

Solvent	Dielectric constant	Acceptor number*	Equilibrium potential (V vs. SCE)
Methanol	32.7	41.3	−0.08
Ethanol	24.5	37.1	−0.10
Acetonitrile	38.8	18.9	−0.78
Acetonitrile-10% methanol	—	—	−0.50
Propylene carbonate	69.0	18.3	−0.82
Dimethylformamide	36.7	16.0	−1.08

After G. Gritzner et al. (17).

Table II. Kinetic data for the ferri-ferrocyanide couple at a rotating Pt disk electrode in nonaqueous solvents containing tetraethylammonium as the cation

Solvent	Anodic Tafel slope (mV/decade)	Cathodic Tafel slope (mV/decade)	Apparent rate constant (cm/sec)
Methanol	120	120	3.2×10^{-3}
Ethanol	170	130	1.3×10^{-3}
Acetonitrile	120	~120	0.4×10^{-3}
Propylene carbonate	180	130	0.1×10^{-3}

anodic branch suggest increasing specific adsorption at more anodic potentials in these solvents, which is reasonable for a highly charged anionic redox species.

These Pt data are indicative of the inherent kinetic limitations of the $Fe(CN)_6^{3-/4-}$ couple in each solvent, but caution must be exercised in extrapolating to n-CdSe electrodes. For example, it should be kept in mind that specific adsorption effects may vary with the electrode material. Nonetheless, the trends observed for Pt should also be valid for n-CdSe.

Thermodynamic considerations.—Flatband potentials were determined for n-CdSe in the various solvents [containing $Fe(CN)_6^{3-/4-}$] from a-c impedance measurements. A typical Mott-Schottky plot is shown in Fig. 4. The results are summarized in Table III.

System selection.—Although methanol provides the lowest inherent stability of the solvents investigated, this is more than compensated by fast electron transfer, no specific adsorption, and a favorable flatband potential, so that this solvent appears to be the most promising for stabilization of CdX photoanodes with the ferro-ferricyanide couple. If high inherent stability were weighted more heavily, acetonitrile would then appear most attractive. The choice of methanol seems to be vindicated by cyclic voltammetric data at 200 mV/sec for static n-CdSe electrodes under illumination at low light intensities in methanol and acetonitrile electrolytes containing 0.1M $Fe(CN)_6^{3-/4-}$ and 0.1M supporting electrolyte. For methanol, a stable anodic photocurrent plateau is observed from −0.7 to 0.1V *vs.* SCE, which indicates that photogenerated holes are collected at high efficiency over a wide potential range. For acetonitrile, the photocurrent begins to increase (above the plateau level) at about −0.5V, which indicates that some of the holes are not being collected by the redox couple. Furthermore, $Fe(CN)_6^{4-}$ is reported to be unstable in acetonitrile solution (17).

Table III. Solvent dependence of the flatband potential and photocurrent onset for n-CdSe

Solvent	Flatband potential (V vs. SCE)	Photocurrent onset (V vs. SCE)
Acetonitrile	−1.2	−1.1
Propylene carbonate	−1.1	−1.0
Acetonitrile/10% methanol	−1.0	−1.0
Methanol	−0.9	−0.8
Ethanol	−0.9	−0.8

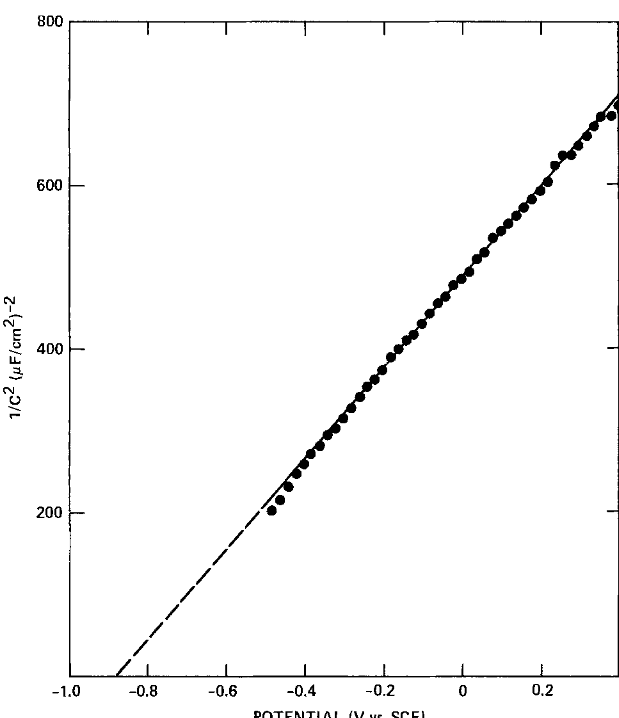

Fig. 4. Mott-Schottky plot for n-CdSe in methanol/0.01M $Fe(CN)_6^{3-/4-}$/0.1M Et_4NBF_4 solution.

Evaluation of the n-CdSe/methanol/$Fe(CN)_6^{3-/4-}$ system.—The long-term stability of n-CdSe photoanodes in the methanol/ferro-ferricyanide system was investigated using tungsten-halogen illumination of about 85 mW/cm² intensity. The current at single crystal n-CdSe photoanodes remained constant at 6 mA/cm² (conversion efficiency of ~3.5%) for as long as 700 hr in a stirred methanol electrolyte containing 0.4*M* each of tetraethylammonium $Fe(CN)_6^{3-/4-}$ plus 0.1*M* tetraethylammonium fluoroborate. No deterioration of the electrode surface or weight loss was detected although the charge passed was equivalent to 81 times the weight of the crystal. Since these studies were designed to demonstrate stability, no attempt was made to optimize the cell performance characteristics which were undoubtedly diminished because of the high carrier concentration of the n-CdSe electrodes (10^{17}-10^{18}/cm³). A current-cell voltage curve for this system with a Pt counterelectrode is given in Fig. 5. It was also demonstrated that the stability of n-CdSe photoanodes in methanol/ferro-ferricyanide is not sensitive to traces of water, as shown in Fig. 6.

Work is currently underway to optimize performance of the n-CdSe/methanol/$Fe(CN)_6^{3-/4-}$ system for both single crystal and polycrystalline electrodes. Considerable attention is focused on the electrolyte. At higher redox couple concentrations, ion pairing, specific adsorption, and impurity effects become more important. This necessitates development of better methods of preparing and purifying materials, and consideration of alternate counterions (*e.g.*, dications) and solvent mixtures. With redox electrolytes prepared by a new chemical method, sustained photocurrents at n-CdSe electrodes of about 17 mA/cm² have recently been attained. These results, which will be elaborated upon in a future publication, illustrate the potential of this system.

Conclusions

The thermodynamic and kinetic considerations outlined here seem to provide a rational basis for development and evaluation of new redox systems for stabilization of semiconductor anodes against photodegradation. These considerations include the inherent stability provided by the solvent, the rate of the redox reaction, the tendency of the redox species to specifically adsorb, and the equilibrium potential of the redox couple with respect to the flatband potential.

Band Bending and Passivation Studies of GaAs Grain Boundaries

J. W. McPherson, W. Collis, E. Stefanakos, A. Safavi, and A. Abul-Fadl

School of Engineering, North Carolina Agricultural and Technical State University, Greensboro, North Carolina 27411

ABSTRACT

The zero-bias band-bending properties of grain boundary (g-b) interfaces showing pronounced rectifying characteristics in polycrystalline GaAs were investigated both experimentally and theoretically. A strongly rectifying g-b presents a potential barrier to the majority carrier leading to a large g-b resistance R_B. R_B for individual g-b's was determined by passing a constant current normal to the g-b and monitoring the voltage drop, as a function of temperature, associated with the thermionic current. The band-bending $e\Phi_b$, as a function of donor density N_D, was obtained from a plot of the activation energy $k_B(TR_B)$ *vs.* $(1/T)$. A theoretical fit of the $e\Phi_b$ *vs.* N_D curve gave a dominant density of defect acceptor states at the g-b interface: $\sigma_1 = 5.2 \times 10^{11}/cm^2$ at 0.41 eV and $\sigma_2 = 9.0 \times 10^{11}/cm^2$ at 0.90 eV below E_c. These acceptor levels have been tentatively identified with the dangling bonds of A- and B-type dislocations which normally occur at III-V compound-semiconductor g-b's. In addition, the use of potassium as a grain boundary passivating dopant is discussed. After diffusing K into the g-b, a lower R_B and reduction in the g-b rectifying properties were noted.

The use of GaAs for large scale generation of electrical power depends on being able to grow thin layers ($\cong 1$ μm) of GaAs on a cheap foreign substrate. Without a recrystallization effort, present growth techniques (1, 2) have produced only fine grain polycrystalline films with an average grain size $d \leq 1$ μm, well below the required average grain size of 10 μm (3). The grain boundaries (g-b's) severely limit collection efficiency (best reported efficiency for polycrystalline GaAs is 6.3%) (4) for two reasons: (*i*) the g-b serves as a recombination region thereby reducing the short-circuit current and (*ii*) the high conductivity along the g-b can produce a shunting of the device with a reduction in open-circuit voltage. Since the g-b's so severely limit the collection efficiency, it was felt that a better understanding of GaAs g-b physics might lead to possible passivation ideas, and this was the impetus for the research.

Key words: GaAs grain boundary interface states.

Our experimental studies closely parallel the earlier works of Seto (5) and Seager and Castner (6) on the electronic properties of polycrystalline silicon films. We have chosen to use bicrystalline GaAs samples so that single g-b characterization could be facilitated. In the following section we describe sample preparation and characterization of the GaAs bicrystalline samples. There, we report the electrical resistance measurements conducted on the samples and

present the band bending *vs.* donor density data. Next, we discuss some of the underlying physics of g-b's in GaAs and present a g-b density of defect states calculation based on the band-bending data for strongly rectifying grain boundaries. G-B passivation efforts are reported. The article is concluded with a discussion of results.

Experimental Studies

Sample preparation and grain boundary characterization.—The large grain polycrystalline GaAs wafers used in the experiments were supplied by Morgan Semiconductors. The wafers (>10 cm^2) were cut from n-type, boat-grown, undoped and Si-doped crystals. The ingots were intended to be single crystals but a few independent nucleation centers in the boule produced a very large grain (some wafers contained only 5 or 6 grain boundaries) polycrystalline material. The use of large grain material allowed the carrier concentration to be determined by calculating the resistivity of single-grain filament sections and referring to published data on resistivity *vs.* carrier concentration for GaAs (14).

The samples used for g-b investigations were in the form of bars, approximately 0.1 × 0.05 cm^2 in cross-sectional area, cut with a wire saw from the large grain polycrystalline GaAs wafers. Included in the sample's length was a single g-b running transverse to the long dimension of the sample, as shown in Fig. 1. The sawed and lapped surfaces of the bar-like samples were degreased, then polished by etching in $5H_2SO_4{:}1H_2O_2{:}1H_2O$ for 2 min. Ohmic contacts were formed on the n-type GaAs by alloying Sn dots at 450°C for 1 min in a hydrogen atmosphere. As shown in Fig. 1, the two dots on the same single-grain region could be used to verify the ohmic nature of the contacts. To insure that the samples were bicrystals, both cathodoluminescence (CL) and electron beam induced current (EBIC) studies were performed using a scanning electron microscope (SEM).

Due to problems of poor contrast on a smoothly polished GaAs surface, g-b's can be difficult to detect in the normal secondary-electron mode of SEM operation and, if detected, give no information about the electrical characteristics of the g-b. However, by using a CL detector (8), regions of nonradiative recombination can be contrasted and resolved as is shown in the g-b micrograph of Fig. 2. The main advantage with CL is the fact that no electrical contacts to the sample are needed. The main problem encountered using CL microscopy is its dependence on surface morphology and electron beam penetration depth R ($R = 0.027E_b^{1.46}$ μm, where the electron beam energy is in kV) (9). Light emitted from a depth R can be absorbed before reaching the surface or, the light upon reaching a rough surface, can be scattered thus limiting resolution. These problems are avoided using EBIC. Here the electron beam is scanned over the sample generating electron-hole pairs up to a depth R. A space charge region in the crystal can serve to separate the pairs for collection. The resulting current can be amplified and used for imaging. Using the space charge region associated with a g-b to perform the separation, we show in Fig. 3 an EBIC micrograph taken of one of the bicrystals.

After the bicrystalline nature of the samples was established using CL and EBIC, preliminary characterization of the filamentary samples included the observation of the current (I)-voltage (V) characteristics of the g-b's. I-V curves for several bicrystalline samples taken from different regions of the same wafer showed a remarkable difference in rectifying characteristics. Figure 4 shows the I-V curves for three g-b's taken from the same wafer. Figure 4(a) indicates that this g-b has ohmic characteristics, indicative of scattering as the majority carriers traverse the g-b interface. Figure 4(b) shows a slight rectification indicating that a weak potential barrier must be negotiated by the majority carrier. Figure 4(c) shows that the rectification is large, indicating a significant g-b potential barrier.

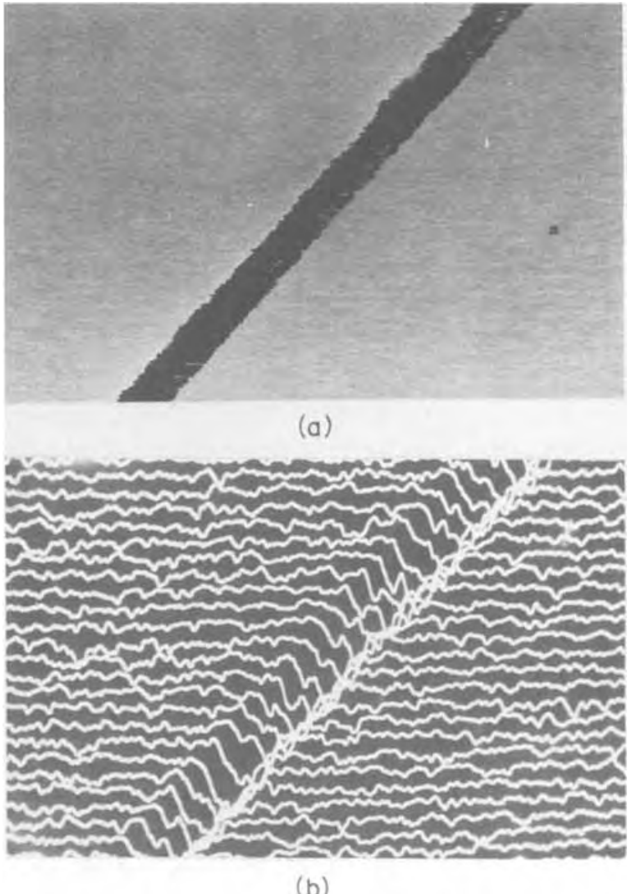

Fig. 2. CL and CL intensity line-scan micrographs of a single g-b (500×). (a) Shows CL imaging with the g-b appearing as a very dark diagonal line of nonradiative recombination. (b) Shows the reduction in intensity of the CL signal as the electron beam is rastered over the g-b region.

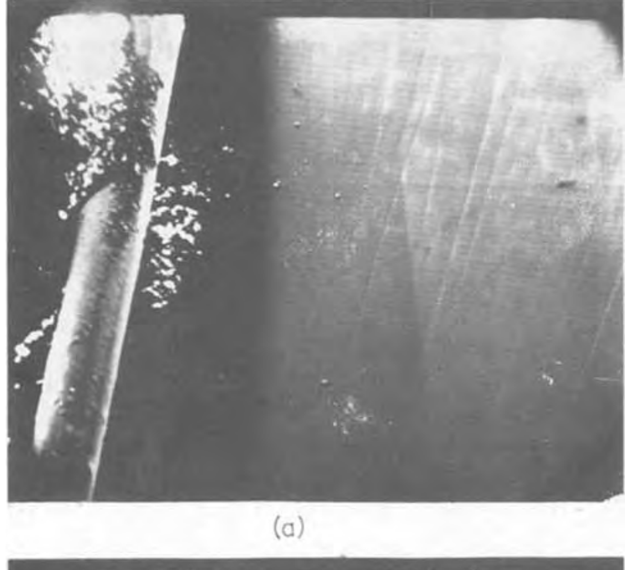
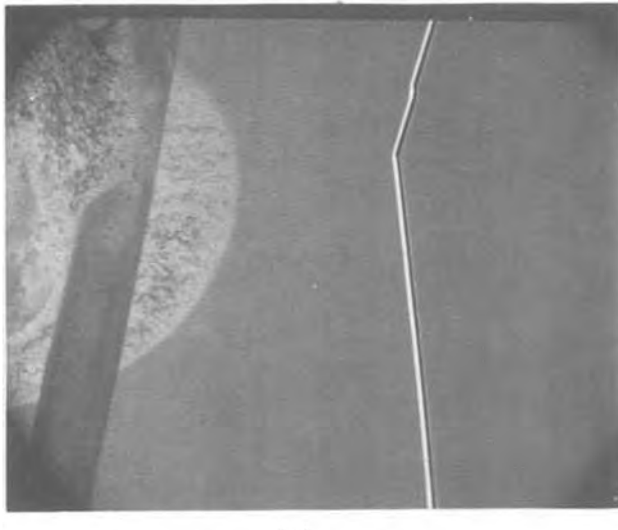
Some of the ohmic g-b's could be explained, at least qualitatively, in terms of an extended Read dislocation model for g-b's in GaAs as presented by McPherson *et al.* (10). According to dislocation theory, at donor levels $\cong 10^{16}/cm^3$ the space charge cylinder surrounding the dislocation core is expected to be of radius $R_o \cong 0.1$ μm. For low angle g-b's, the spacing between dislocations D is greater the $2R_o$. A carrier approaching such a g-b may traverse the interface by scattering, without having the required energy to go over the potential barrier. To substantiate the model, the dislocation spacing was observed experimentally.

A sample showing ohmic-like characteristics was etched with an inhibited Schell's reagent (200 HNO_3: 600 H_2O:1 butaylamine) (11) for 15 min at 80°C. An optical micrograph of the g-b (Fig. 5) after etching reveals a low angle g-b structure, *e.g.*, individual dislocation etch pits could be resolved with a spacing of $D \cong 1$ μm. This large value for D would indicate that the dislocation space charge cylinders do not overlap leading to a porosity in the g-b interface. Not all observed ohmic-like g-b's, with random grain



(a)



(b)

Fig. 3. SEM and EBIC-SEM micrographs of the same g-b (200×). (a) Shows an SEM micrograph of the g-b (to the right of contact and lead wire) and illustrates the problem of poor contrast on polished GaAs. (b) EBIC-SEM micrograph of the same area makes the g-b clearly discernible.

orientation, could be tested for their assumed low angle nature because of the reactive nature of the etchant, *i.e.*, the etchant reveals dislocations only on low index planes (12), in particular the (111) and $(\bar{1}\bar{1}\bar{1})$. The dislocation density determination could be made only on a few samples with proper orientation in an effort to extract a qualitative understanding of why at least some of g-b's have ohmic-like characteristics.

We expect that the slightly rectifying g-b's are of higher angle thus leading to a partial overlap of the space charge cylinders and that in the case of the highly rectifying g-b's the overlap is complete ($D << 2R_0$). However, this point could not be verified by a dislocation density determination because the etchant tended to etch the rectifying g-b's uniformly so that individual dislocation etch pits could not be resolved.

This research was focused on the highly rectifying g-b's. The quantitative analysis of our g-b band bending results relied on the theory as presented by Seager and Castner (15) for g-b band bending in polycrystalline silicon. Since this theory does not depend explicitly on dislocation densities and tilt angles, these parameters were not pursued further.

(a) Shows the *I-V* characteristics of an ohmic-like g-b (5 mA per vertical division, 50 mV per horizontal division). (b) Shows the I-V characteristics of a rectifying g-b (500 μA per vertical division, 1V per horizontal division). (c) Shows the *I-V* characteristics of strongly rectifying g-b (500 μA per vertical division, 10V per horizontal division).

Grain boundary band-bending studies.—Due to the disruption of the crystalline matrix, a g-b in an n-type semiconductor generally produces deep acceptor states associated with the distorted or broken bonds (13).

As the electrons leave the Fermi level to take up residence on the g-b, a space charge region develops in the grains adjacent to the g-b. This space charge separation produces a bending of the bands such as to make the addition of the next electron to the g-b more difficult. Electrons are added to the g-b until the work required, to add an additional one, produces a free energy change ≥ 0. The band bending produced by a g-b is schematically represented in Fig. 6.

The bent bands present a potential barrier to the majority carrier leading to a large g-b resistance R_B. R_B for individual g-b's was determined by passing a constant current (0.01 μA through the outer two contacts shown in Fig. 1) and monitoring (inner two contacts) the voltage drop associated with the thermionic current density J_{th} (14, 15)

$$J_{th} = A^* T^2 \exp\left(\frac{-e\Phi_b'}{k_B T}\right)\left[\exp\left(\frac{eV}{k_B T}\right) - 1\right] \quad [1]$$

with A^* the Richardson constant, T the temperature, $e\Phi_b'$ the barrier height, and V the applied voltage.

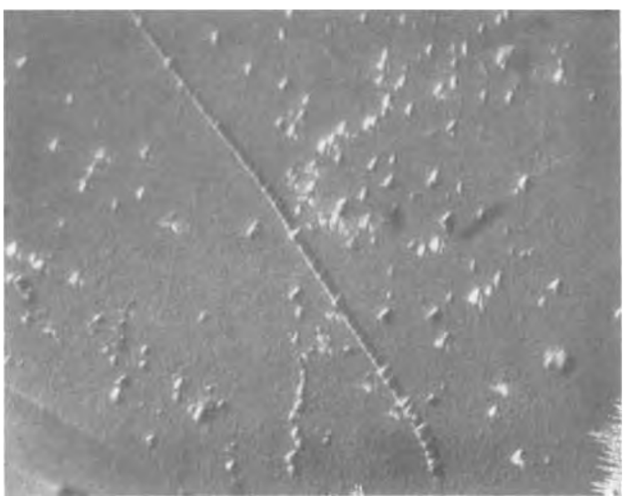

Fig. 5. Optical micrograph (400×) of an etched ohmic-like g-b. The micrograph reveals that the individual dislocation etch pits along the g-b are separated approximately 1 μm.

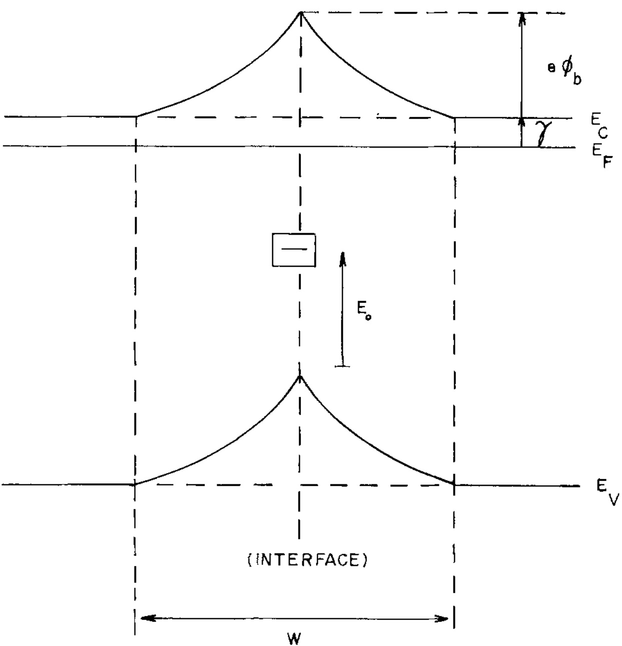

Fig. 6. Band bending $e\Phi_b$ which occurs at a g-b due negative charge accumulation at the interface.

Here it is assumed that only those carriers with sufficient thermal energy to surmount the potential barrier can contribute to the current. (Tunneling is expected to be negligible in the donor range ($<10^{18}$/cm^3) of samples investigated.) Expanding the last equation with $eV << k_B T$, we can write the g-b resistance as

$$R_B = \frac{V}{J} = \left(\frac{k_B}{eA^*}\right)[\exp(-e\Phi_b'/k_B T)/T] \quad (\Omega \cdot m^2) \quad [2]$$

Rewriting Eq. [2] in an activation energy form, we have

$$k_B \frac{\partial \ln (TR_B)}{\partial\left(\frac{1}{T}\right)} = e\left[\Phi_b' - T\frac{\partial \Phi_b'}{\partial T}\right] \quad [3]$$

The relationship between the barrier height Φ_b' and band bending Φ_b is given by

$$\Phi_b' = \Phi_b + \gamma = \Phi_b + k_b T \ln (N_c/N_D) \quad [4]$$

From this, we obtain

$$k_B \frac{\ln (TR_B)}{\partial\left(\frac{1}{T}\right)} = e\left[\Phi_b - T\frac{\partial \Phi_b}{\partial T}\right] \quad [5]$$

We note that the band bending is equal to the activation energy only at $T = 0$.

The data taken for two samples is shown in Fig. 7. From this data, we note that over the temperature range, kept small due to instrument limitations and the theoretical requirement that $eV << k_B T$, the experimental points are fit quite well by a straight line. Also, we note that the slope is a sensitive function of donor density N_D. The $T = 0$ band bending $e\Phi_b$ *vs.* the donor density N_D for the highly rectifying g-b's is shown in Fig. 8. $e\Phi_b$ decreases from 1.03 eV at $N_D = 4.5 \times 10^{15}$/cm^3 to 0.19 eV at 5.0×10^{17}/cm^3. The theoretical curve and the density of defect states calculation is presented in the next section.

Theoretical Studies

Physics and chemistry of GaAs grain boundaries.—When two separately nucleated grains are mated at the g-b, the lack of long-range order produces dangling (13) or severely stretched bonds at the g-b. These disturbed bonds are fairly well localized at the interface, *i.e.*, the disturbed bond region extends into the grains from the interface on the order of 10Å (16). These disrupted interfacial bonds generally lead to

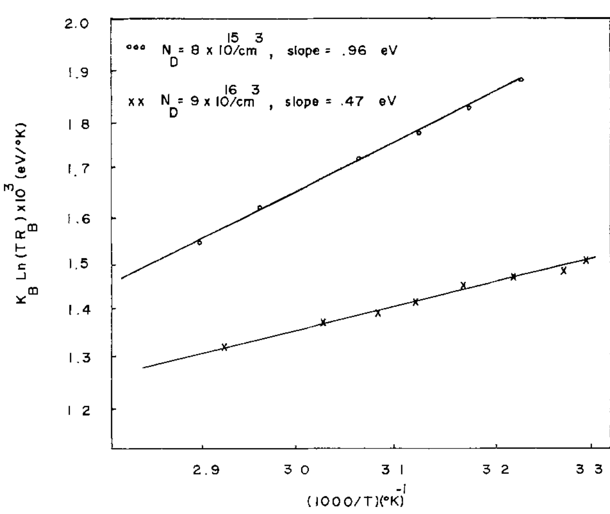

Fig. 7. G-B resistance R_B data taken for two strongly rectifying g-b's. It should be noted that the data is fit well by a straight line approximation.

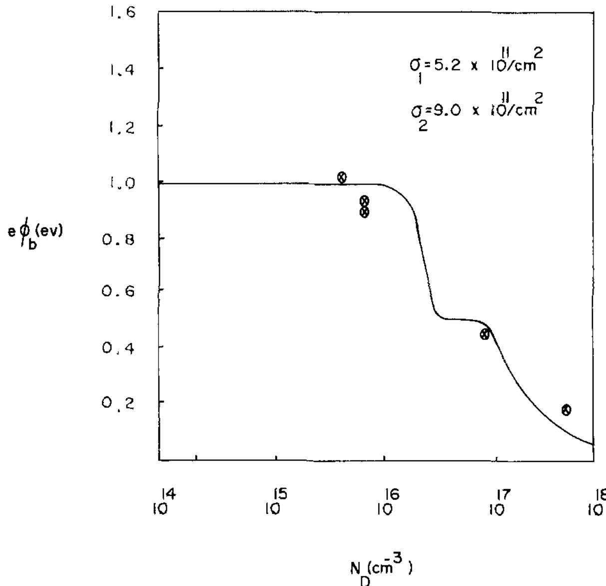

Fig. 8. $T = 0$ band bending $e\Phi_b$ vs. donor density N_D for strongly rectifying g-b's in GaAs. The experimental points were determined from the activation energy studies.

deep acceptor levels in semiconductors. The presence of deep levels at the g-b is manifested in the band bending and space charging associated with such an interface.

Models for g-b's have evolved from dislocation theory, *e.g.*, see McPherson *et al* (10). Evidence for a dislocation model of a g-b is extensive and has been accumulated for more than two decades [a review of the subject through 1970 can be found in Matare (17)]. Currently, the experimental evidence is still very supportive for such a model, *e.g.*, Syutkin *et al.* (16) reported from a field-ion microscopic study of the atomic structure of g-b's that the interface is dominated by the appearance of extra atomic rows which can be interpreted as the emergence of dislocations. This study also indicated the lack of evidence for an amorphous-like structure at g-b's. A g-b interface is thus substantially different from a free surface. The atoms will tend to restructure as one moves from the interior toward the free surface of a crystal. The restructuring of the atoms is associated with the crystal's effort to lower its high surface energy subject to the constraint that the crystal's total free energy be at a minimum. However, at a g-b, the grains are competing for periodicity in the lattice. This competition between grains freezes the extra atomic half-planes (dislocations) into metastable states at the interface.

The predominant slip system in GaAs (18, 19) is {111} with slip occurring in the <110> direction with Burger's vector $\vec{b} = a_o/2 <110>$ where $a_o = 5.65$Å is the lattice constant. With the dislocation core running at 60° to the slip vector, such dislocations are referred to as 60° dislocations. Due to its high mobility (20), 60° dislocation dominance (21) at the g-b is assumed. This places the dangling bonds along the core of the dislocation some 4Å apart.

Grain boundary modeling in GaAs is complicated by the fact that the dislocations may be formed either by terminating the extra atomic half-plane on a row of Ga atoms (A(s) $\equiv \alpha$ dislocation) (22) or on a row of As atoms (B(s) $\equiv \beta$ dislocation). Therefore, we can have A dislocations whose cores consist of a row of Ga dangling bonds and/or B dislocations whose cores consist of a row of As dangling bonds. The physics and chemistry of Ga and As dangling bonds are somewhat different, as evidenced by the different chemical properties of the (111) and $(\overline{111})$ surfaces (12).

A single dangling bond can accommodate up to two electrons. The first electron is added more easily than the second due to the electrostatic repulsion of two electrons in the same sp^3 orbital. Thus, as Mueller and Jacobson (23) assumed for InSb, two distinct energy levels are assumed for a single dangling bond, *i.e.*, separate one-electron and two-electron flaw levels are used. Since the dangling bonds are only 4Å apart on the 60° dislocation cores, some wavefunction overlap is expected leading to a broadening of these levels as depicted in Fig. 9. The one-electron flaw band for the A dislocation is shown 3/4 filled in the neutral state. This is dictated by the fact that Ga has three valence electrons which are spread over four sp^3 orbitals. However, the one-electron flaw band is filled and the second-electron flaw band is 1/4 filled for a B dislocation in the neutral state because As has 5 valence electrons which are spread over four sp^3 orbitals.

With the Fermi level above the neutrality level in n-type material, electrons will leave the Fermi level and take up a quasi-localized residence on the dislocation core. (Quasi-localized in a sense that while the electrons are confined to the g-b interface, some mobility along the dislocation cores at the interface is expected). This accumulation of excess negative charge at the g-b interface leads to a region of positive ionized donors (depletion width W) adjacent to the g-b and an electrostatic potential (band-bending $e\Phi_b$) associated with the space-charge distribution. The bands are bent such that they limit the amount of excess negative charge that can be placed on the g-b interface.

The exact energy level location of A and B neutrality levels are unknown. However, on the basis of results reported for InSb (24) and GaAs (25), selective dislocation production by four-point bending indicated that the A level is above midgap and the B level is below. Spencer *et al.* (26) report that two dominant g-b acceptor levels associated with atomic disorder were observed from deep level transient spectroscopy (DLTS) studies of GaAs bicrystals. These acceptor levels were located at 0.41 and 0.90 eV below the conduction band and were believed to be associated with atomic disorder.

Theory of GaAs grain boundary band bending.—As electrons leave the donors to take up residence on the g-b acceptor states, a region of positive donor ion density N_D develops in each grain adjacent to the

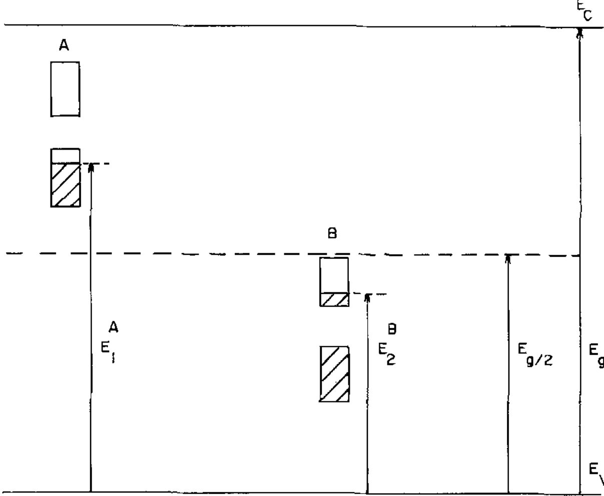

Fig. 9. Proposed flaw level diagram for A- and B-type dislocations in GaAs with neutrality levels indicated. The flaw band widths are exaggerated.

g-b. This positive space charge region is assumed to extend from the interface into each grain a distance L. To model the band bending, we assume that the excess negative charge added to the g-b is spread uniformly over an interface plane with a surface density of Q_s. Choosing the y, z axes in the plane and x normal to it, the one dimensional Poisson's equation to solve is of the form

$$\frac{d^2\Phi}{dx^2} = \frac{-\rho(x)}{\epsilon_s} \quad [6]$$

with

$$\rho(x) = eN_D - eQ_s\delta(x) \quad (-L \leq x \leq L)$$

The solution of Eq. [6] gives the depletion width $W(=2L)$ as a function of the band bending $e\Phi_b$ at the interface, as

$$W = \left(\frac{8\epsilon_s\Phi_b}{eN_D}\right)^{1/2} \quad [7]$$

A relationship between W and Q_s is obtained by invoking charge neutrality

$$WN_D = Q_s \quad [8]$$

which yields

$$Q_s = \left(\frac{8\epsilon_s N_D\Phi_b}{e}\right)^{1/2} \quad [9]$$

Another expression for Q_s can be obtained by integrating over the density of states times the probability of that state being occupied

$$Q_s = \int_0^{E_c} n(E)f(E, e\Phi_b, E_F)dE \quad [10]$$

where f is the occupational probability. f is a function of flaw level position E, band bending $e\Phi_b$, and Fermi level location E_F in the grains adjacent to the g-b. In Ref. (6), the g-b occupational probability is written as

$$f(E, e\Phi_b, E_F) = F(E + e\Phi_b, E_F) - \gamma \quad [11]$$

where

$$F(E + e\Phi_b, E_F) = \frac{1}{1 + \exp(E + e\Phi_b - E_F)} \quad [12]$$

and γ is the g-b occupational probability in the neutral condition. γ is given by $\gamma = F(E, E_{FB})$ with E_{FB} the neutral g-b Fermi level location.

DLTS measurements (26) indicate that the density of g-b interface states in GaAs is discrete, *i.e.*

$$n(E) = \sum_i \sigma_i\delta(E - E_i) \quad [13]$$

where σ_i is the number of flaw states per unit area of g-b interface with energy location E_i above the valence band. Substituting Eq. [11] and [13] into [10] gives

$$Q_s = \sum_i \sigma_i[F(E_i + e\Phi_b, E_F) - \gamma_i] \quad [14]$$

The self-consistent equation for band bending is obtained by equating Eq. [9] and [14], giving

$$\sum_i \sigma_i[F(E_i + e\Phi_b, E_F) - \gamma_i] = \left(\frac{8\epsilon_s N_D\Phi_b}{e}\right)^{1/2} \quad [15]$$

Equation [15] is a transcendental equation. Given the flaw level positions, flaw densities, and neutrality conditions, we can solve for the band bending as a function of donor density, or conversely, given the band bending *vs.* donor density we can elicit information about the flaw levels.

Theoretical analysis of experimental results.—For our numerical calculations, we wanted to solve Eq. [15] for the band bending in an effort to better understand its dependence on the g-b interface density of flaw levels σ, neutrality occupation γ, temperature T, and donor density N_D. We have used the following experimental data (26): two dominant discrete acceptor levels associated with atomic disorder at $E_1 = 1.01$ eV and $E_2 = 0.53$ eV (above the valence band) with respective equivalent volume densities of $N_1 > 1 \times 10^{16}/cm^3$ and $N_2 > 6 \times 10^{16}/cm^3$, and a high level of copper segregation with multivalent acceptor levels located at $E_3 = 0.15$ eV and $E_4 = 0.44$ eV with an equivalent volume density of $N_3 = N_4 > 8 \times 10^{15}/cm^3$. The copper contaminated g-b's are expected for the bulk grown polycrystalline samples.

The best-fit theoretical curve shown in Fig. 8 for the $T = 0$ band bending $e\Phi_b$ *vs.* donor density N_D was obtained using the two levels associated with atomic disorder, $\sigma_1 = 5.2 \times 10^{11}/cm^2$ at E_1 and $\sigma_2 = 9.0 \times 10^{11}/cm^2$ at E_2, and with an assumed g-b copper segregation of $\sigma_3 = 4.4 \times 10^{11}/cm^2$. The neutral g-b Fermi level E_{FB} was pinned at 0.46 eV above the valence band. This value of E_{FB} effectively excludes the importance of the copper segregation on the ($T = 0$) $e\Phi_b$ *vs.* N_D curve because the copper traps are filled even when the g-b is in a neutral condition. However, as discussed shortly, the values of E_{FB} and σ_3, used in the calculation, were necessary to produce a nearly temperature-independent activation energy which was experimentally observed.

The ($T = 0$) $e\Phi_b$ *vs.* N_D curve shown in Fig. 8 has two plateaus. The higher plateau at 0.99 eV occurs due to the filling of the E_2 trap as the donor density N_D increases. At $N_D \cong 10^{16}/cm^3$, the E_2 trap is filled and $e\Phi_b$ decreases as $(N_D)^{-1}$. At $e\Phi_b = 0.51$ eV the E_1 level, which had effectively been frozen out by the severe band bending at the lower donor levels, is now starting to be filled. The asymptotic behavior for $N_D > 10^{17}/cm^3$ occurs as N_D^{-1}.

The parameter values used to fit the ($T = 0$) $e\Phi_b$ *vs.* N_D data were tested to verify that this particular set of values could reproduce the nearly temperature-independent activation energy which was experimentally observed. First, using Eq. [15], we show in Fig. 10 the temperature dependence of the band bending as a function of N_D. It should be noted that a substantial temperature dependence exists, especially at the lower donor levels, and that the temperature dependence closely parallels the temperature dependence of E_F. However, for comparison, Fig. 11 shows the calculated activation energy, using Eq. [5] in conjunction with

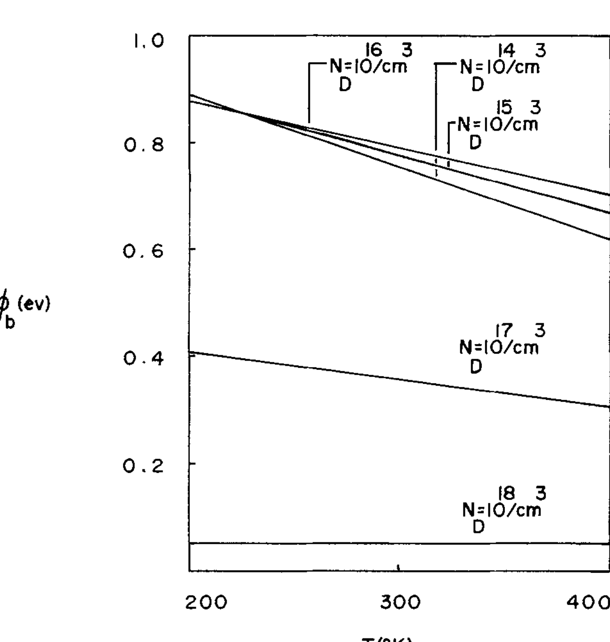

Fig. 10. Predicted temperature dependence of the band bending

Eq. [15]. We note that the activation energy is nearly temperature independent throughout the donor range for the set of parameter values used.

The number of flaw states per unit area ($\cong 10^{12}/cm^2$) presented here for g-b's in GaAs agree favorably with that reported by Seto (5) and Seager and Castner (6) for polycrystalline silicon grain boundaries.

GaAs G-B Passivation Efforts

Generally, the electronic properties of g-b's in photovoltaic devices are dominated by: (*i*) a tendency of the g-b to serve as a sink for the minority carrier leading to a high interfacial recombination velocity and (*ii*) a high sheet conductance along the g-b interface. While the high interfacial recombination velocity is a direct consequence of the band bending, the high sheet conductance may or may not depend on the band bending. For example, in n-type ($N_D = 10^{16}/cm^3$) bicrystalline samples of Ge and InSb the g-b sheet conductance is due to holes (27, 28). The hole conductivity in g-b's arises from the fact that the valence bands are bent above the Fermi level, *i.e.*, a degenerate inversion layer produces the observed high p-type sheet conductance.

In Si, the g-b band bending is only 0.4 eV at $N_D = 10^{16}/cm^3$ and one might expect conductance is due to electrons. However, in GaAs, the band bending is more severe (0.99 eV at $N_D < 10^{16}/cm^3$) and one might expect the conduction along the g-b to be due to both electrons and holes in low donor material.

In contrast to single crystal behavior, the g-b hole mobility may be greater than the g-b electron mobility. The g-b electrons are assumed to move along the g-b interface via dislocations. The dangling bonds are located only 4Å apart on the dislocation core and some wavefunction overlap occurs. However, a low electron mobility is expected for two reasons. First, the dangling p-orbitals are dangling transverse to the dislocation core and a small wavefunction overlap is expected (30). Second, in a real g-b, the one dimensional periodicity of the dislocation core is disrupted by jogs, kinks, impurity precipitation, and vacancy precipitation. A relatively high hole mobility is expected since the hole region is adjacent to the g-b interface (17) where lattice disruptions are expected to be minimal.

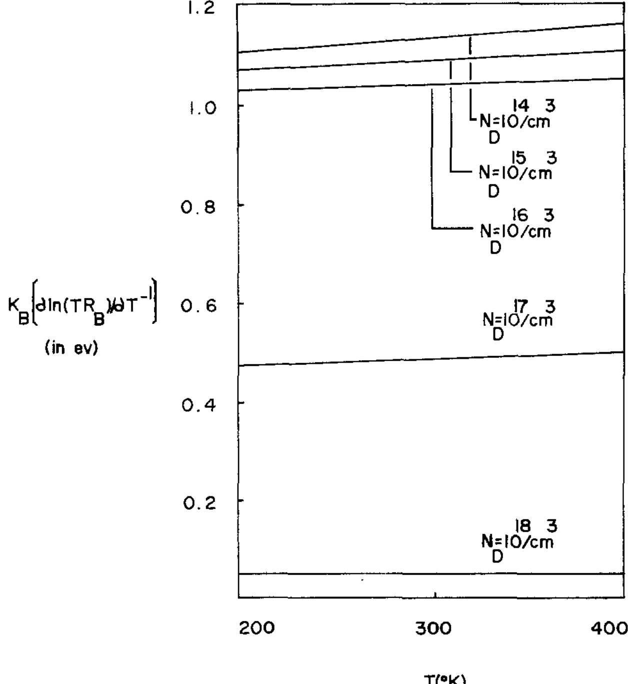

Fig. 11. Predicted weak temperature dependence of activation energy.

Since the g-b recombination is directly dependent on $e\Phi_b$ and the g-b sheet conductance may depend on $e\Phi_b$, it seems most natural to try to eliminate, or at least reduce, the band bending in order to improve photovoltaic efficiency. Approaches reported (31, 32) for Si g-b passivation have centered around hydrogenation. Monatomic hydrogen is introduced to the g-b via a plasma discharge. Located at the g-b, it is expected that the H covalently bonds to the dangling bond. Presumably, this lowers the dangling bond's energy and removes it from the bandgap. This eliminates many of the traps at the g-b and leads to a smaller band bending.

An approach, other than hydrogenation, is to add simple donors to the g-b interface. This tends to fill up the traps locally without the space charging and associated band bending. This would dramatically improve the short-circuit current due to a smaller recombination velocity. In addition, if the sheet conductance is primarily p-type, due to the bending of the bands, the sheet conductance may also decrease leading to an improved open-circuit voltage.

In an effort to add donors to the interface, one might be tempted to heavily dope the polycrystalline film with donors and then anneal the sample thereby diffusing many of the donors to the g-b interface. However, whether an element serves as a donor or acceptor depends on the crystal-field environment in which the given element is placed, *e.g.*, an amphoteric dopant can serve as a donor or acceptor depending on the lattice position. Thus, if either a IV element donor (at a Ga site) or a VI element donor (at an As site) diffuses to the g-b, the donor properties may not be conserved. In fact, if either of the substitutional donor elements chemically combines with a dangling bond, the electronic octet configuration is not completed and acceptor-like properties may be expected from the impurity-dangling bond complex.

In searching for donor candidates for g-b diffusion, the following requirements seem necessary: (*i*) the impurity must serve as a donor at the interface, (*ii*) the impurity must diffuse rapidly into the g-b's but not into the grains during diffusion cycle, and (*iii*) the passivating impurity must remain localized at the interface for long-time stability requirements. The alkaline metals seem to be excellent candidates for g-b diffusion.

Due to their compensating properties, every effort is made to eliminate the alkaline metals from single crystal growths. An element such as Li sits interstitially in the lattice at low concentrations and serves as a simple donor (35). However, as the concentration of the Li increases, the lattice energy associated with this interstitial impurity rises. To relieve the stress, a Ga atom (of smaller radius than Li) will hop out of its lattice site. The Li then proceeds to complex with the Ga vacancy (short three electrons). The Li will donate its electron, but to the complex not to the conduction band. Since the complex is still short some two electrons, the complex will serve as a deep acceptor in GaAs. It is this tendency of the alkaline metals to always donate their weakly bound s^1 electron, independent of crystal-field environment, which make them attractive candidates for g-b diffusion.

For our diffusion experiments we have used potassium (K). K has a larger radius than Li and this is expected to minimize intragrain diffusion during the diffusion process. However, the impurity is still expected to diffuse freely into the g-b due to the much higher diffusion constant associated with a g-b. To separate the effects of K diffusion from the thermal anneal, two bicrystalline samples (as described above) were cut from adjacent regions of the same g-b with one serving as a control sample.

In the diffusion process, a small amount of K was transferred in a nitrogen purged glove bag into one of the two Pyrex ampuls containing the GaAs bi-

crystalline samples. The ampuls were then evacuated, sealed, and heated in an oven for 75 min at 140°C. The samples were then removed, cleaned in HCl, and tin contacts are alloyed as described above.

The *I-V* characteristics of a bicrystalline sample (a) before diffusion and (b) after diffusion are shown in Fig. 12. We notice that to produce 500 μA of current in the virgin sample, 32V were required. However, to produce 500 μA in the sample after diffusion, only 26V were needed. To insure that the increased conductivity was due to g-b passivation and not due to improved intragrain conduction, intragrain resistivity measurements were conducted before and after diffusion with no appreciable change noted. This would indicate that the large radius of K prevents intragrain diffusion during the cycle. When the control sample was investigated, no changes were detected in either the rectifying properties of the grain boundary or the g-b resistance. This is somewhat expected for a low temperature (140°C) quick (75 min) anneal of the bulk-grown material.

A plot of the g-b resistance $k_B \ln (R_B T)$ *vs.* $(1/T)$ before and after diffusion (Fig. 13) reveals a reduction in grain boundary resistance. We also note that before diffusion the points are fitted quite well by a straight line. However, after the diffusion, the behavior is non-Arrhenius and the data could not be fitted with a straight line.

To ascertain the extent of passivation, Fig. 14 shows, using a set of common axes, the *I-V* curves for another sample before diffusion, after diffusion, after diffusion and after etching. Before diffusion the g-b shows strong rectifying properties due to a large band bending (experimentally we obtain $\Phi_b = 0.87$V). After diffusion, the strong blocking property of the g-b has diminished. Even after etching away some 20 μm of the surface, we still find evidence of partial passivation. The fact that the passivation may extend at least 20 μm is very important with respect to thin film passivation.

Discussion of Results

On the basis of our measurements on bulk grown GaAs polycrystalline material, it appears that the highly rectifying (bad) g-b's have an interface density of trapping states on the order of 10^{12}/cm^2. This interface density agrees well with that reported for bulk and vapor phase grown, polycrystalline Si. An interface density of 10^{12}/cm^2 would correspond to intrinsic (free from impurity precipitation) g-b's with a rather low tilt angle of less than 1°. Why g-b's with larger angles were not observed is unclear. Perhaps in the higher angle g-b's, either the dangling bonds are partially compensated extrinsically (by impurity precipitation) or else the severe lattice strain leads to a very brittle interface which cannot withstand the sample preparation (a few of the samples were observed to break at the g-b during the cutting and handling).

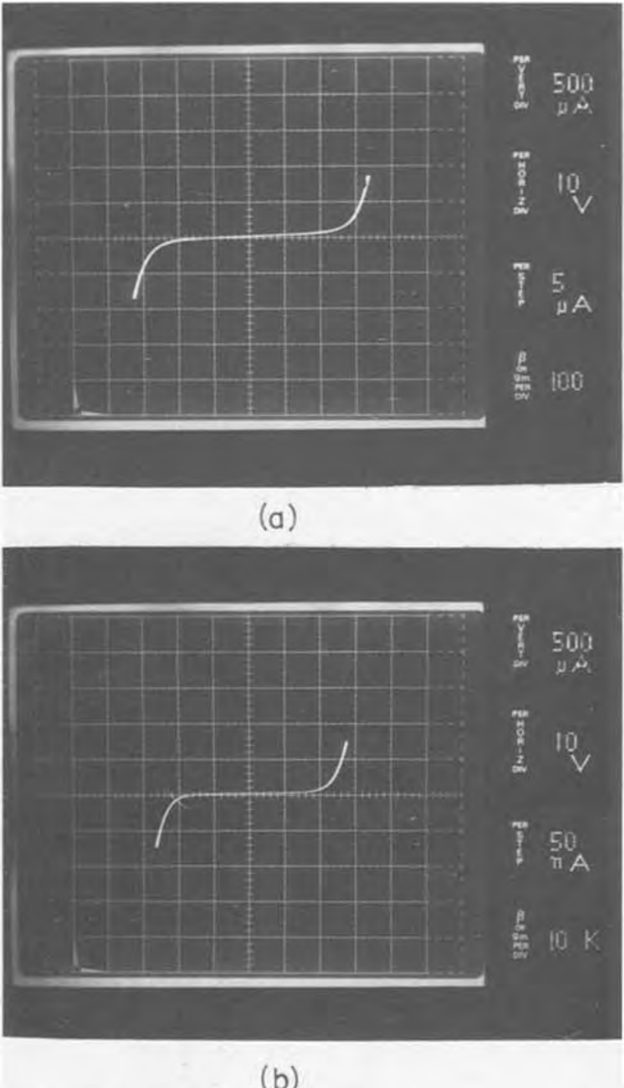

Fig. 12. *I-V* characteristics of a single g-b. (a) Before diffusion and (b) after diffusion (500 μA) per vertical division and 10V per horizontal division).

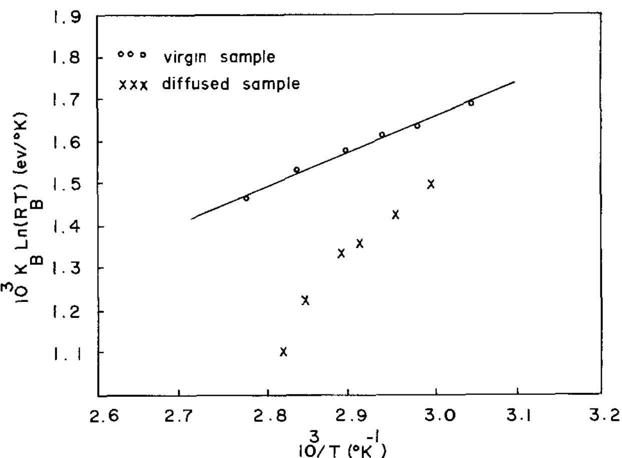

Fig. 13. Change in g-b resistance R_B of a single g-b after diffusion.

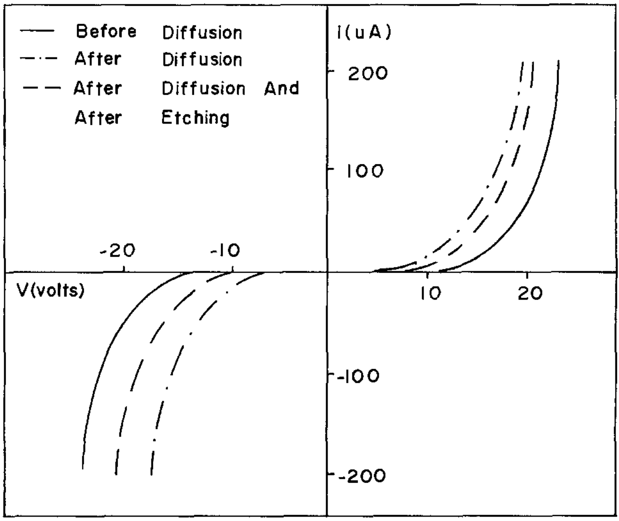

Fig. 14. *I-V* characteristics of a single g-b before diffusion, after diffusion, after diffusion and after etching.

Also, we found that the g-b resistance was lowered and the strong rectifying characteristics diminished after an introduction of K into the g-b via vapor phase diffusion. This is believed to be a result of a band-bending reduction due to the K ions serving as localized interfacial donors. However, while the g-b electrical characteristics changed after K diffusion, the intragrain properties were unchanged. This would indicate that intragrain diffusion of K during the diffusion cycle was not a problem.

With respect to polycrystalline solar cell applications, a reduction in the g-b band bending would improve the short-circuit current in the photovoltaic device due to a smaller g-b recombination velocity. Whether the K will lead to a higher sheet conductance (resulting in a smaller open-circuit voltage) depends on the conduction mechanism (holes or electrons) along the interface.

Direct Evidence for 1 nm Pores in "Dry" Thermal SiO_2 from High Resolution Transmission Electron Microscopy

J. M. Gibson[1] and D. W. Dong

IBM Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Thin films of thermally grown SiO_2 have been studied by high resolution bright-field electron microscopy. Contrast phenomena observed in images from 9 nm thick "dry" films are consistent with the existence of 1 nm pores, typically 10 nm apart. Similar films grown in a wet oxidizing ambient do not display this contrast. A pore structure had previously been suggested to explain differences in growth behavior and electrical properties between "wet" and "dry" SiO_2. The reliable detection of such pores or voids in electron micrographs from amorphous materials is not straightforward and a novel approach which has been successfully applied to these films is described. A simple model which explains the appearance of pores only in "dry" films is proposed and is related to the trapping behavior of thicker films.

Some properties of thermally grown SiO_2 are substantially affected by the presence of water in the oxidizing atmosphere (1). Incorporation of 2000 ppm H_2O into an oxidizing ambient of N_2 and O_2 has been shown to increase the mean dielectric breakdown voltage of 15 nm thick thermal SiO_2 layers by 30% (1). Furthermore, the value of film thickness at which the growth *vs.* time behavior starts to follow the linear-parabolic law (2) [typically several tens of nm for "dry" films (3)] decreases almost to zero (4).

The parabolic nature of the growth kinetics arises from a reduction in free oxygen concentration at the oxide-Si interface as the thickness through which O_2 must diffuse increases. On the other hand, the linear nature is characteristic of a thickness independent growth, *i.e.,* a free surface effect. The above observation that diffusion is almost immediately a limitation for the "wet" films has been interpreted by Irene (1) as evidence for pores or voids in "dry" films which are not present in "wet" films. Thus the "dry" film growth follows a linear law up to several tens of nm because O_2 has rapid access to the oxidizing interface through such pores. "Wet" films, which are more uniform, rapidly protect the virgin Si from further oxidation.

Irene's first observation, concerning dielectric breakdown, is also consistent with this hypothesis. He noted that while "dry" films follow a broad statistical distribution of number of breakdown events *vs.* applied field, the "wet" films follow much more closely the behavior expected from uniform dielectric layers, *i.e.,* a delta function at the field strength E_o which pulls the valence electrons from the Si-O bond. He proposed that the spread in breakdown field (always less than E_o) found for "dry" films occurs because the pores lead to fluctuations in the internal field which in some places can sufficiently exceed the applied field E_a to cause breakdown, even though $E_a < E_o$.

Current measurements through SiO_2 made while ramping an applied voltage are known to exhibit a linear Fowler-Nordheim regime which is displaced on retracing after a short time (5). This displacement is caused by a reverse field from charged traps. The magnitude of this shift was measured by Irene for both types of film. It is too small to explain the dielectric breakdown differences and is in any case similar for both "wet" and "dry" oxides.

Thus it was concluded that the significant difference between "wet" and "dry" films, when less than 20 nm thick, lies in the density of electrically inactive defects such as pores. Other workers (6, 7) have observed that "wet" SiO_2 contains many more electrically-active traps than "dry" SiO_2 at thicknesses greater than 20 nm, which would suggest that any pores must be in general electrically inactive. This point will be commented on in more detail later.

Irene made various transmission electron microscope (TEM) studies of these films in an attempt to find direct evidence for such pores. However, the resolution of his instrument and the conventional imaging methods he was obliged to use were not able to distinguish directly between the films or to resolve any defects down to 5 nm in size. By decoration and etching experiments he concluded that defects smaller than 5 nm may exist in either type of film.

In the present paper direct high resolution TEM evidence for 1 nm scale pores or voids in the "dry" films is presented. These have not been seen in images from "wet" films. The interpretation of high resolution TEM images from amorphous samples is complicated and one of the authors (JMG) has developed a new approach for the very purpose of locating very small voids in such specimens. This method has previously been described rather briefly (8, 9) and a more detailed account will be published separately. In this paper, the main aim of which is to present the results for the SiO_2 system, the technique will be elaborated only in necessary but sufficient detail. The provision of some background information about high resolution TEM of amorphous materials was also felt to be valuable as an aid to understanding the approach taken by the authors of this paper.

High Resolution TEM of Amorphous Materials

A good recent review of this subject is given by Howie (10). The principal points which we wish to emphasize here are: images are not simply related to the object (although they can appear deceptively so such as "lattice plane" images from crystals) because image contrast arises from complex electron wave interference; also the imaging mode to be used in any study of amorphous materials should be carefully considered to suit the information which is required. It is not always sensible to form an image utilizing the highest resolution of the microscope and containing the maximum information. This is because there is a considerable amount of meaningless signal which comes from random effects in a disordered sample and which can drown out nonrandom effects of interest. If one has a firm idea of what one is looking for one can

[1] Present address: Bell Laboratories, Murray Hill, New Jersey 07974.

Key words: voids, thin films, oxidation, silicon, electrical breakdown.

use an imaging mode which "homes in" on the meaningful information at the expense of random signal (which could be labelled "noise").

Not only will it be shown in this paper that such consideration is essential for the detection of small voids but it has previously been demonstrated to be very useful in locating small regions of long-range order in amorphous samples (11). These two types of "defect" encompass all the high resolution information which one could expect to obtain from TEM images of amorphous materials at present, *i.e.*, from the projected atomic density (on which images depend) one can only pick up either intense features (characteristic of voids) or weaker periodicities arising from atomic ordering. Therefore the approach to high resolution TEM imaging of which this paper is representative is felt by the authors [and for example, Howie (10)] to be the most fruitful one for high resolution real-space imaging of disordered materials.

Neglecting multiple scattering and assuming the independence of instrumental effects from scattering within the specimen, the emergent electron wave which results from plane-wave illumination (wavevector $\mathbf{k}$) of a thin sample is

$$\psi_0(\mathbf{r}) = (1 + i\phi(\mathbf{r}))\exp(i\mathbf{k}.\mathbf{r}) \quad [1]$$

where $\phi(\mathbf{r})$ is proportional to the projected atomic potential in the $\mathbf{k}$ direction (12). It can be seen from [1] that to a first approximation the incident-wave is simply phase-shifted by an amount proportional to ϕ and is therefore refracted. [These approximations are valid for weakly-scattering amorphous specimens < 20 nm thick, particularly in view of the qualitative nature of the conclusions to be made, but not for strongly scattering crystalline samples (13).]

A perfect microscope imaging system would display no contrast in the image plane, since all electron detectors are phase-insensitive. To obtain phase-contrast one must introduce a defect-of-focus (defocus) which causes a scattering-angle dependent phase-shift. Such a phase-shift gives rise to amplitude variations in the image plane (much like a hologram) where the scattered beams interfere with the unscattered reference beam. In the axial-bright-field (ABF) mode this leads to an image plane intensity given by

$$I(\mathbf{r}) = 1 + \phi(\mathbf{r}) \circ t(\mathbf{r}) \quad [2]$$

where o denotes convolution and

$$t(\mathbf{r}) = \text{Fourier Transform}\{\exp[-i\gamma(s)]a(s)E(s)\}$$

$\gamma(s)$ is the Scherzer aberration function (14) which takes account not only of defocus z but also of spherical aberration C_s which is present in all electron lenses

$$\gamma(s) = -\pi\lambda(zs^2 + C_s\lambda^2 s^4) \quad [3]$$

λ is the electron wavelength and s is the Fourier coordinate (spatial frequency) $= 1/d$, where d is a spatial period in the object. $a(s)$ allows for the presence of a microscope objective aperture of radius s_{ap} such that $a(s < s_{ap}) = 1$ and $a(s > s_{ap}) = 0$. $E(s)$ is an envelope function which takes account of limited spatial and temporal coherence in the illuminating wave (15).

One can see that $t(\mathbf{r})$ describes the response of the instrument to a point object and is consequently known as the "point-spread" function. The relation between ABF images and the object is more obviously revealed by Fourier transforming $I(\mathbf{r})$ to give the image power spectrum

$$P(\mathbf{s}) = \delta(s) + \tilde{\phi}(\mathbf{s})\sin[\gamma(s)]\,E(s)\,a(s) \quad [4]$$

It can thus be seen that the object's Fourier transform $\tilde{\phi}(s)$ is simply filtered by the function $\sin\gamma\, E(s)\, a(s)$ which is known as the contrast transfer function (CTF). This function determines how strongly and with which sign a given object spatial frequency is reproduced in the image. Figure 1 displays plots of

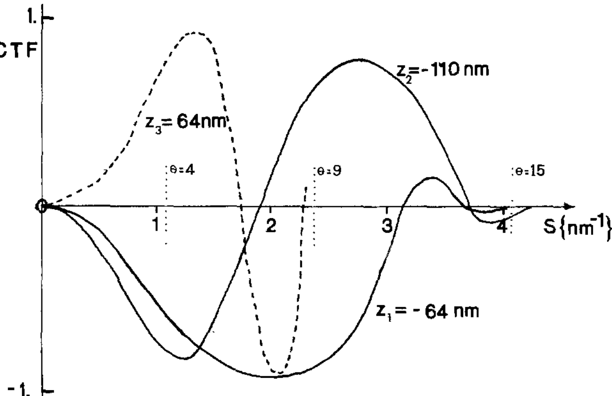

Fig. 1. The contrast transfer function (CTF) for three values of the defocus z. Microscope parameters are C_s = 1.1 mm, angular illumination spread 1.2 mrad, and source energy spread 0.9 eV. These are values appropriate to the Philips 301 TEM with biological pole piece which was used in this study. z_1 is known as the Scherzer defocus at which the point-to-point resolution of the instrument is at its highest value (0.31 nm). The effect of an objective aperture is to cut this function abruptly off at $s_{ap} = \theta/\lambda$ where θ is the half-angle subtended by the aperture. Three values of θ (in mrads) are marked on the s-axis.

the CTF for typical instrumental parameters which are appropriate to the Philips 301 TEM used in this study. At the Scherzer defocus there is a broad bandpass out to approximately 3.2 nm^{-1} (the reciprocal of which is the point-to-point resolution of the instrument: 0.31 nm). By increasing the defocus one can image higher spatial frequencies (higher spatial resolution) but now with reversed contrast beyond 1.9 nm^{-1}. Obviously image interpretation is not simple when the object's power spectrum extends over oscillations in the CTF (such as the diffraction from amorphous materials).

The other imaging mode of relevance to this discussion is tilted-illumination dark-field (TIDF). In this mode the reference or main beam is excluded from the image by an objective aperture ($a(0) = 0$). The image intensity is no longer linear in $\phi(\mathbf{r})$ but depends on ϕ^2. Therefore this mode particularly emphasizes atomic superpositions in projection against the background. In consequence TIDF is well suited for detecting ordered regions (16). However random superpositions yield a speckle pattern which can be misleading (17). It has been shown that spatial incoherence in the illumination can reduce the random contribution to the speckle, thus enhancing the visibility of small crystals (11). Incoherent dark field may also have application to the imaging of small voids due to its direct representation of projected thickness fluctuations with reduced confusion from interference effects, but this has so far been unexplored.

The above was a brief outline of the standard theory of high resolution TEM imaging of thin specimens, which originates from Born and Wolf's treatise on optics (18). Now we can go on to consider the specific problem of observing voids or pores in amorphous materials.

Detection of Small Voids

The following discussion of image contrast from small voids in amorphous materials applies equally well to any defect which gives rise to a variation in the projected potential, *e.g.*, an interstitial or vacancy cluster. The normal method for imaging such defects in crystalline materials (19), which utilizes the bending of lattice planes from long-range stress fields, is not appropriate to amorphous materials because of the lack of long-range order and the associated high oscillating strain field. Small voids in crystalline materials, which exhibit very little strain contrast, have often been detected by the ABF phase-contrast method,

described above and pioneered in this context by Rhule (20). They produce a fluctuation in the projected potential which can be imaged out-of-focus. One can see from Eq. [3] and [4] that the CTF for small s and large z has the same sign as z. So with a small objective aperture which excludes high spatial frequencies (reduced resolution), spherical aberration has negligible effect and a void will reverse its image contrast when the defocus is changed in sign (with no contrast in focus). This is often called, rather misleadingly, Fresnel contrast because large voids exhibit Fresnel fringes around their edges. For small voids at low defocus the fringes degenerate to a simple white or black spot (21). This method (or perhaps more accurately, concept) can be simply extended to large voids in thick amorphous specimens where the projected potential from the amorphous sample is effectively constant compared with the fluctuation due to the void. However, as the void size decreases to less than (say) 2 nm in a 10 nm thick film, the statistical fluctuations in projection of a random network become comparable in size to the effect from the void. When these two are of the same order it is impossible from one 2-D projection to sensibly identify the void.

One can estimate this absolute limit rather simply. Let the smallest resolvable feature in the image be of dimension R. Then in the film it defines a column of volume $\pi R^2 T$ in which there are $N = \pi R^2 T/\Omega$ atoms. (T is the film thickness and Ω its atomic volume.) For $N >> 1$ in a random film this number exhibits gaussian fluctuations with standard deviation $\sqrt{N}$. This is a simple estimate of the magnitude of the random fluctuation in an image with resolution R and with unit CTF out to $s_{ap} = 1/R$. For the void to be statistically distinguishable it must produce a decrease in N which is of magnitude at least $2\sqrt{N}$ (say). In the optimal condition that $R = d_{min}$, the diameter of the smallest detectable spherical void, one obtains the condition that

$$d_{min} > 1.8\ (\Omega T)^{1/4} \qquad [5]$$

which for SiO_2 of 9 nm thickness (as examined in this study) gives $d_{min} \cong 1$ nm. Given this fundamental limit it is still no simple task to identify such small features in an image, without perhaps a sophisticated statistical analysis of image intensity/area.

It should be noted that specimen tilting is one way of improving on this fundamental limit, which applies only to one 2-D projection. In an analogous way it has been pointed out that specimen (16) or beam (11) tilting differentiates between localized order and random superpositions which arise from typically larger volumes. Thus a fluctuation which is visible in two independent projections can be more clearly identified as nonrandom. At present this type of analysis has not been achieved due to the difficulty of identifying the same area on a featureless sample after tilting and specimen-stage stability problems.

The better imaging mode for the detection of voids in amorphous materials is ABF. This is because the nonlinear nature of TIDF emphasizes atomic superpositions very strongly. Thus M atoms in the film which happen to line up appropriately in projection can yield M^2 times the contribution from one atom in a TIDF image. On the other hand M atoms missing from the film can on average only change the mean intensity by M times one atomic contribution (neglecting effects from reconstruction of the surrounding atoms). Since the TIDF image from a disordered material is dominated by the "speckle" produced by many atoms superimposing constructively, a small unreconstructed void would be invisible in comparison. Even though interesting features have been seen in TIDF images from amorphous specimens which have the shape one might expect from voids (22), these are unlikely to originate from unreconstructed voids because of their high intensity. So it is better to use the linear ABF imaging mode where objects that do not exist give comparable intensity to those which do. This rule-of-thumb does not apply to crystals, however, where in TIDF atoms may be arranged to scatter very weakly into the aperture because of their long-range periodicity. Then a defect which destroys or removes this order can yield a much greater intensity than the background. This is the basis of the so-called elastic-diffuse-scattering imaging method (23).

The ABF conditions which lead to maximum signal-to-noise ratio from voids in amorphous samples are not in fact the best with which to detect them visually. In the Rhule technique for crystalline specimens and from the above discussion one would expect to use the smallest possible objective aperture to reduce unwanted high-frequency "noise." Thus the objective aperture size $s_{ap} = 1/d$. Under these circumstances it will be found that in order to observe the contrast reversal with focus from a void it is necessary to have

$$|z| > C_s \lambda^2 s_{ap}^2$$

from Eq. [3] and [4]. Then it is obvious that the whole image will reverse in contrast identically, since the only difference between the contrast from the void and the random effects is in intensity. This regime of aperture size and defocus is known as the projected-charge-density (PCD) approximation because it is to this which the image intensity is proportional (24).

Contrast reversal arises in PCD because the transfer function ($\sin(\gamma(s))a(s)$) is cut off at a low value of s and exhibits approximate mirror symmetry in the s-axis when the sizn of z is flipped. This can be seen in Fig. 1 for $z = \pm 64$ nm (z_1 and z_3) if $\theta = 4$ mrad. However, with θ much greater than this the mirror symmetry breaks down and image behavior when the sign of z is changed becomes less obvious. Low spatial frequencies will still reverse contrast, of course, but some higher frequencies will remain with the same sign of contrast or may even be extinguished on reversal of z, depending on their magnitude. Image features with a "white noise" (uniform) power spectrum will then look increasingly unrelated on either side of $z = 0$ as the objective aperture is increased in size. The exact values of aperture size and defocus at which an image appears to behave unpredictably like this cannot be analytically determined. Numerical simulations from thin amorphous specimens, generated from Eq. [2] using two fast Fourier transforms for the convolution integral, are very useful in this context.

Figure 2 shows computed images of this type. A totally random distribution of atoms corresponding to a 9 nm thick amorphous SiO_2 film was used as the object in the calculation. For this discussion of contrast from voids and pores, interatomic correlations are not significant, except perhaps to enhance the scattered intensity due to reconstruction on the void surface [an effect which would be much more important in TIDF (21) where atomic superpositions are nonlinear]. If the local power spectrum in image 2(b) were sufficiently distorted by the presence of (say) a void then the transfer function would be principally sampled in its "symmetrical" region yielding cross-correlation, untypical of the rest of the image. This will be seen in the next set of computations.

Figure 3(a) shows the same image pair as in 2(a) but with a 0.8 nm diam spherical void cut from the middle of the object. Although the void produces a slightly more intense image than the background, its contrast reversal does not uniquely identify it. One can see from these images that it is hopeless to try to identify the exact shape and size of a void from high resolution TEM micrographs and statements about these properties must be rather qualitative in comparison to the information that could be determined if the atomic-structure around the defect were exactly known (as in a crystal).

Figure 3(b) shows the same image pair with an intermediate-sized objective aperture. Now the void is identifiable qualitatively as the only reverse-

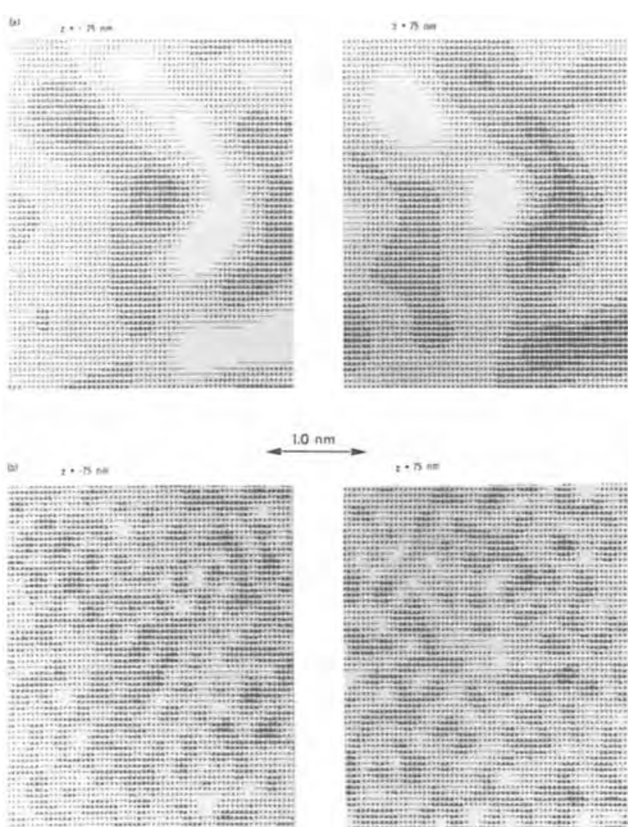

Fig. 2. Computed ABF images from a random distribution of atoms equivalent in projection to a 9 nm thick amorphous SiO_2 film. Complete reversal of image contrast with the sign of defocus (*z*) can be seen for a 4 mrad objective aperture (a) which limits the resolution to 0.6 mrad. With a 15 mrad objective aperture (b), the images display higher resolution and no simple behavior with the sign of *z*. (Seven gray levels were generated by overprinting. The intensity scale is arbitrarily adjusted to make all images of similar appearance, as one usually does in photographic printing.)

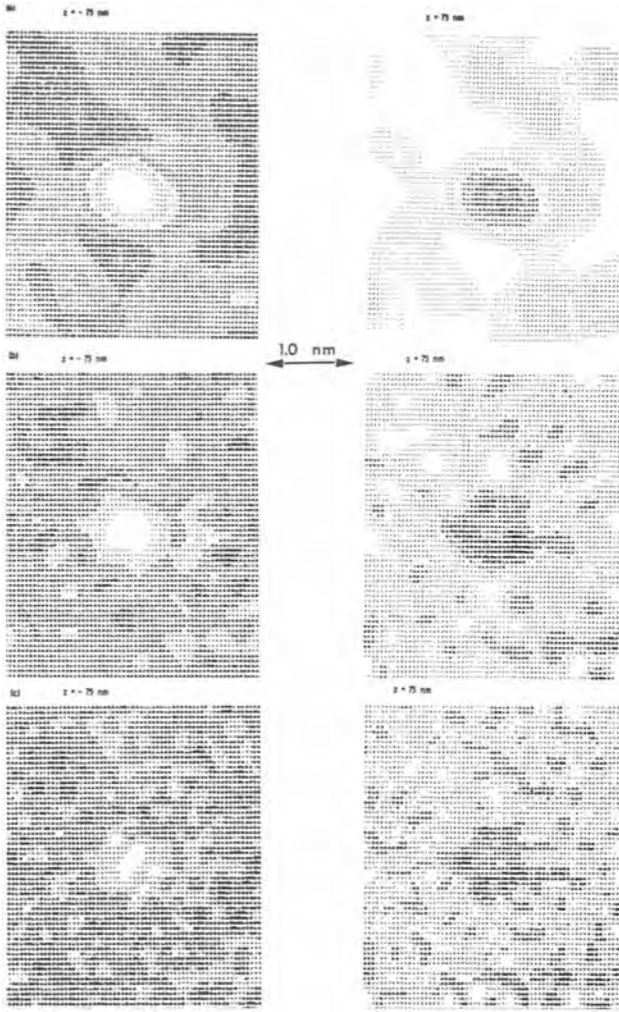

Fig. 3. (a) Same image pair as Fig. 2(a) but with a 0.4 nm radius spherical void cut from the center of the object. The void produces a slightly more intense fluctuation than the random effects but its image contrast behaves identically with reversal of *z*. (b) With a 9 mrad objective aperture the void is now qualitatively distinguishable in the images as the only feature which reverses contrast with *z*. (c) With a 15 mrad objective aperture the void is beginning to disappear. The void size was chosen by inspection as the smallest detectable by this method.

correlating object in a randomly-behaving background. If one increases the objective aperture size too much as in 3(c) [same size as in 2(b)], then the void itself becomes less distinct. In these computations the microscope parameters (including partial coherence) were the same as those used to compute the CTF's of Fig. 1. The critical objective aperture size will depend on the coherence. Some random cross-correlation will always be noticed but in this study, which involves comparison of two films, striking differences in the density of cross-correlating areas are seen which can be reliably attributed to nonrandom effects.

Note that it is not spatial extent in the image plane but the intensity (which comes from spatial extent in the beam direction) which this method is designed to reveal. Thus a column-shaped void in the beam direction may be clearly seen but could be invisible if its long axis were parallel to the image plane.

Of course this method, since it relies only on image projection, is unable to distinguish between a void and a surface pit. We emphasize that it shows up statistically unlikely fluctuations in the projected potential. Having said this, one can certainly identify the absence of voids or pores on the 1 nm scale with this technique. Furthermore it can give corroborative evidence when the presence of pores is suspected. For maximum information one should compare two films of identical thickness and structure using identical imaging conditions where the only suspected difference is the presence of voids or pores in one of the films. Thermal SiO_2 is thus an ideal system to examine, as we shall see. One simply compares image pairs while increasing the objective aperture size and looks for the onset of random image behavior with reversal of defocus. This identifies the critical aperture size at which the films should be compared for the presence of nonrandom fluctuations in projected potential. One practical point concerning the optimum objective aperture size: the coherence envelope function $E(s)$ effectively acts as an aperture in that it can prevent high spatial frequencies s from reaching the image. For this reason it will often suffice, depending on the electron-source coherence, to use no aperture at all for the optimal void imaging condition. The 15 mrad aperture used in these experiments was similar in effect to the 9 mrad aperture in the simulations because the real coherence was a little poorer than the values used in computation. Accurate figures for the microscope coherence parameters are not known and depend critically on condenser lens settings.

Experimental Details

All substrates were (100) oriented 10 Ω cm^{-1} p-type Si wafers. Irene has shown (4) that resistivity type and value in the range 2-10 Ω cm^{-1} has negligible effect on the oxidation process. Dry oxidations were carried out in O_2 containing less than 1 ppm water. For wet oxidation, H_2O was added to N_2 by passing the gas through a clean silica vessel containing deionized water.

The H_2O vapor pressure was approximately 10^4 ppm. Oxide thickness was measured with an automated optical ellipsometer system (25) which gives better than 0.3 nm accuracy averaged over 2 mm^2. The films described in this TEM study were both 9 ± 0.3 nm thick deduced from ellipsometric measurements.

Samples were prepared for TEM observation by jet etching from the back side of the wafer, the oxide surface being protected by beeswax. The acid mixture was 3 HF:5 HNO_3:3 CH_3COOH. Specimens were etched just until the formation of a tiny hole at which point several thin areas where the SiO_2 film was exposed were usually found. Although thinning with this acid mixture is a little more fortuitous than using an Si-preferential etch [such as pyrocatechol (26)] for the last few μm's, it is less likely to accentuate Si/SiO_2 interface roughness which could be confused with a pore structure in projection. Since the ellipsometric technique measures only average film thickness and acid attack may also change local SiO_2 layer thickness, another method was used to check the actual film thickness in the areas studied with TEM. With a small objective aperture in place in the TEM, there is a decrease in the average intensity due to scattering out of the aperture, which can be readily measured from a photographic plate. From knowledge of the scattering properties of the film, thickness can be deduced (27). In this case no absolute measurements of thickness were made, but the wet and dry films were found to be within 10% of the same thickness in the areas examined.

High resolution TEM images were taken with a Philips EM 301 electron microscope which was fitted with a biological high resolution fixed pole piece for this study. The pole piece has a spherical aberration of 1.1 mm at 100 kV operating voltage which gives a maximum point-to-point resolution (inverse of cutoff frequency at the Scherzer defocus) of 0.31 nm. Cross-correlation of defocal series was carried out very primitively using transparent tracing paper. An edge or some similar feature was always used to aid exact location of the same area on different plates. A more sophisticated but still relatively simple method would be to make positive and negative transparent prints from each member of the series. A positive taken at $z = -x$ nm when superimposed on a negative at $z = +x$ nm would show up reverse correlating features as bright dots when held up to a strong light source. However this is not really necessary except as a neat demonstration of the results. One of the main advantages of this TEM imaging technique is that it allows easy visual identification of voids without image processing. This can be achieved while viewing the image on the microscope screen by simply reversing the sign of the defocus under the conditions described above. Then any voids should catch the eye because of their simple contrast reversal behavior.

Results

Figure 4 shows ABF images from a "dry" film at ± 75 nm defocus with a 5 mrad semi-angle objective aperture in place. This small aperture restricts the point-to-point resolution to 0.7 nm and puts these images in the PCD regime. Thus exact contrast reversal with defocus can be seen. Nothing can be qualitatively deduced from these images because of this restricted regime. Similarly a "wet" film displays this effect in Fig. 5. These are the imaging conditions which would be recommended for imaging small voids in crystals and as discussed above they are obviously inappropriate for amorphous materials. (It should be noted that most crystals have amorphous oxide or contamination layers on their surface and the detection of the tiniest voids or point-defect clusters reverts to this same problem.) The images in Fig. 4 and 5 are analogous to the numerical simulations of Fig. 2(a) and 3(a). Any voids present in either film are not readily visible under these imaging conditions.

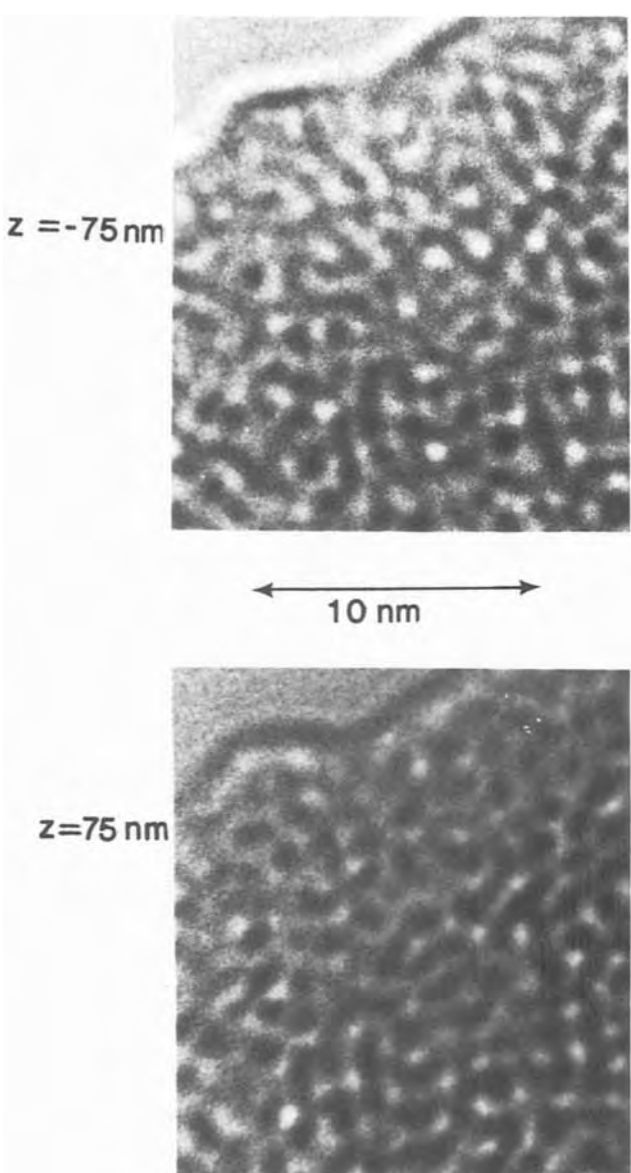

Fig. 4. ABF images from a 9 nm thick "dry" SiO_2 film with a 5 mrad objective aperture. Image reversal with sign of z is observed everywhere under these conditions. The defoci quoted in all experimental figures are accurate to ± 25 nm.

The images in Fig. 6 were formed with a 15 mrad semi-angle objective aperture from the "wet" film. Now there is no extensive correlation found on reversal of defocus from +75 to −75 nm. This is as predicted from the simulation in Fig. 2(b) where only random effects predominate. However, the "dry" film although generally exhibiting no simple behavior with reversal of z, does show isolated features which reverse correlate, some of which are indicated in Fig. 7. From our previous discussion these can be interpreted as arising from large nonrandom fluctuations in the projected potential. Furthermore the sign of these fluctuations can be inferred from the sign of the contrast at negative defocus—they are generally reductions in the projected potential. These observations are commensurate with voids or pores in the "dry" film of typical size 1 nm and typical separation 10 nm. This yields a density of 10^{12} cm^{-2}.

Krivanek and co-workers have looked at the interface between Si and "dry" SiO_2 at high resolution using samples prepared in cross section (28). They saw no surface roughness on a scale which would yield the fluctuations which we see in the projected potential, so that this effect can be ruled out.

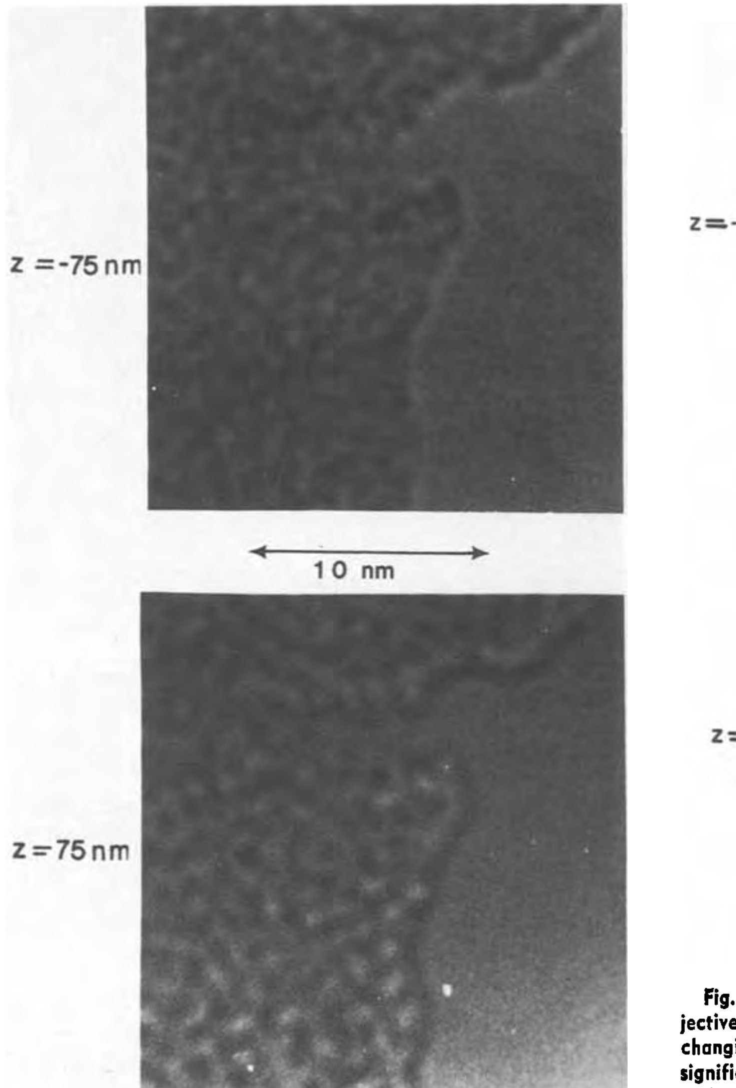

Fig. 5. ABF images from a 9 nm thick "wet" SiO_2 film which similarly show total reversal of contrast with sign of z because the objective aperture half-angle is only 5 mrad.

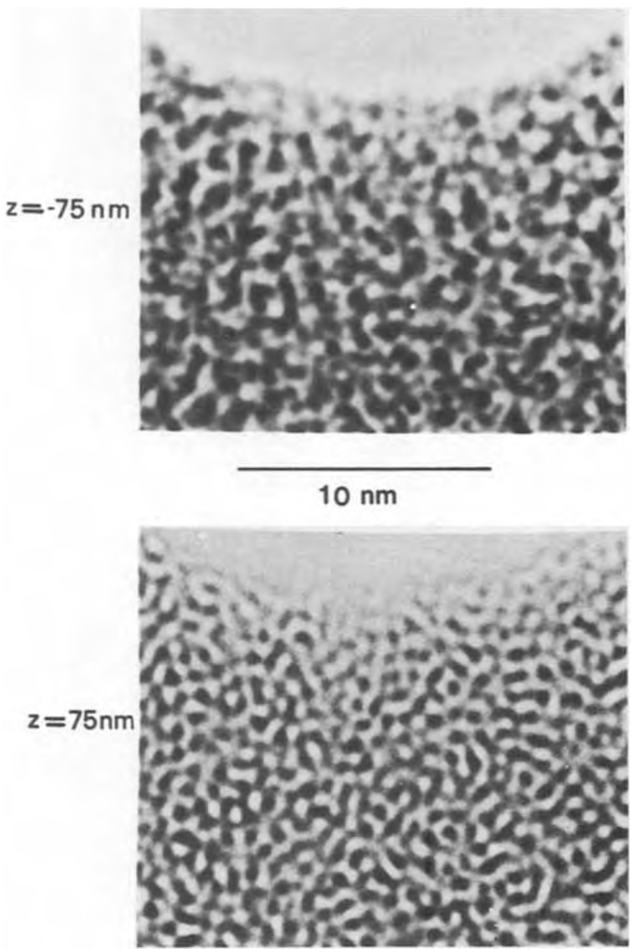

Fig. 6. ABF images from the "wet" film with a 15 mrad objective aperture. In general no simple contrast reversal is seen on changing the sign of z. This tells us that there are no statistically significant fluctuations in the projected potential on the 1 nm scale.

It has also been checked that in focus ($z = 0$) the image contrast in both films is very much less than out-of-focus. This confirms that the contrast phenomena observed with nonzero defoci are indeed of the phase-type discussed above. Amplitude effects, which could for example arise from heavy atom contaminants on the film surfaces, can be dismissed as they would show up just as prominently in focus.

Discussion

The contrast phenomena observed in high resolution images from the "dry" film agree well with the previous data and hypothesis of Irene (1). We have estimated that these defects have a density of about 10^{12} cm^{-2}. From Irene's I-V measurements it is clear that the trapping behavior does not explain the breakdown effect, which is no doubt caused by the nonuniformity of the potential introduced by these pores. Although the contrast features observed could conceivably arise from other effects such as surface roughness caused by the thinning process, they are very consistent with Irene's previous data and obviously add considerable weight to the pore hypothesis.

Unfortunately, one cannot conclude directly that the voids which are observed here in high resolution TEM images are interconnected or shaped in such a way as to form pores through the whole thickness of the film. However, considering the limited image-plane spatial extent of the voids and the fact that they must arise from density fluctuations of at least 25% of the film thickness (from Eq. [5]), one can conclude that they are in general elongated in the substrate (100) direction. Although the electrical data would be explained by the presence of unconnected voids, the growth behavior suggests that they are connected to form pores. High resolution images, of the type we have described, from samples prepared in cross section may help to resolve this question. If the voids are columnar in shape, as seems most likely, when viewed side-on they will probably not produce significant contrast to be detectable. Thus a null result in the cross-section samples from "dry" SiO_2 would actually confirm the pore hypothesis. Of course, if the voids are in general spherical-like, they would be just as visible in any direction.

Why should pores form in the growing "dry" films? The observation could be simply explained, in our view, if the structure of the films is not a true continuous random network (CRN) as is the case for vitreous silica (29). Let us suppose that the structure, although basically similar to the CRN, actually nucleates at first in a slightly different configuration from the bulk-metastable CRN structure. This sort of idea has been proposed by Gaskell (30), among others, for tetrahedrally-bonded amorphous materials and leads to a cluster-radius dependent strain field. As the radius reaches a critical size the introduction of breaks or pores is inevitable. The critical size estimated from the pore spacing would be about 10 nm, which is of the same order as the size of Gaskell-type cluster which

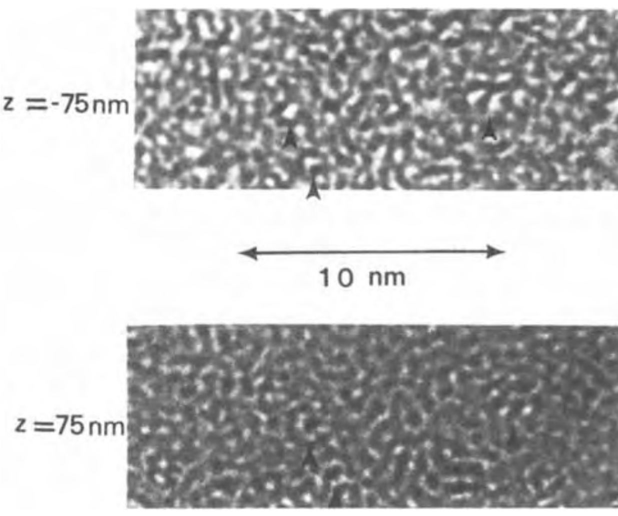

Fig. 7. ABF images from the "dry" film with a 15 mrad objective aperture. Although reverse correlation is not g⁻nerally observed between the image pair, there are several arrowed features which do exhibit this behavior. These correspond to large nonrandom fluctuations in the projected potential which probably arise from pores or voids. Their size or shape cannot be accurately estimated but the typical image plane dimension is in the region of 1 nm or less.

was calculated to be necessary to fit radial-distribution-function and elastic-strain energy-density measurements for amorphous Si (31).

Why then do the wet films not exhibit this pore structure? There are two possibilities consistent with the above hypothesis. The first is that the OH (or another water-related) radical in some way reduces the strain in the random network as it is growing, leading to a much less prominent void structure (perhaps just at a much lower density because the "critical radius" becomes greater). Hetherington *et al.* (32) have shown that the viscosity of SiO_2 films decreases as the water content goes up, which is consistent with this suggestion. Alternatively, the pores may still exist at the same density but may be "plugged" by OH-type bonding. [It is known that micropores exhibit large capture cross sections and form strong bonds with foreign atoms (33).] This would essentially block them as pipes for rapid oxygen diffusion to the oxidizing interface and would explain the growth-kinetic phenomena. It may also explain the breakdown phenomena because the potential fluctuation from water-filled pores would be less than from empty ones. The induced charge density would then be similar for both "wet" and "dry" films when very thin, and that density is close to the measured pore density in the "dry" films. As the film thickness increases the pores may be annihilated (they tend to be near the interface) in the "dry" films but the water may stabilize them in the "wet" films, explaining the observed (ref) higher trapping density in thick "wet" films. Finally, the TEM results would still be consistent because the fluctuations in projected potential from the filled pores in the "wet" oxide would be of much smaller magnitude than from the unplugged pores in the dry films.

The authors are in the process of attempting to differentiate between these last two hypotheses by using microdiffraction in a scanning TEM. This facility allows diffraction patterns to be obtained from 1 nm^2 areas on a thin specimen, and so any radius-dependent structural effects on the 10 nm scale should be detectable. Samples of thermal SiO_2 are also being thinned using other preparation techniques to identify any artifacts (which in any case must arise from genuine differences between the "wet" and "dry" oxide) introduced by this processing step.

Acknowledgments

The authors would like to thank E. A. Irene and D. R. Young for useful discussions and critical reading of the manuscript. One of us (JMG) would also like to gratefully acknowledge many past discussions with A. Howie, W. M. Stobbs, and A. B. Mistry from the University of Cambridge on the subject of imaging voids in amorphous thin specimens.

Manuscript submitted May 2, 1980; revised manuscript received June 12, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by IBM Corporation.

Molecular Beam Epitaxy of GaAs and InP with Gas Sources for As and P

M. B. Panish*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Arsine and phosphine were decomposed in a high temperature leak-source to provide As_2 and P_2 molecular beams for molecular beam epitaxy of GaAs and InP. Reasonable growth rates (0.5-1.5 μm/hr) were achieved for both semiconductors. The studies demonstrated that with this method, MBE of GaAs can be done with the substrate temperature as high as 700°C. The maximum growth temperature obtained for InP was approximately 600°C. A reasonable increase in leak rate at the source should permit GaAs-MBE at 750°C and InP-MBE at 650°C.

Conventional molecular beam epitaxy of III-V compounds is usually done with a source for the group V element that consists of a condensed phase in an effusion oven (1). Usually the condensed phase is the solid element itself, although many studies have been done in which it is a solution of the group V elements in liquid group III element. Effusion sources utilizing the solid group V elements have several disadvantages. They are rapidly depleted and the surface area of the condensed phase may change. Thus beam flux varies with time, in the nonideal effusion ovens used for MBE. Solid phosphorus may cause beam intensity control problems because the solid red phosphorus source generally consists of an ill-defined mixture of allotropic phases having different vapor pressures (2). When the liquid solution of group V in group III element is used the source is initially the III-V compound in contact with the liquid as the result of preferential loss of group V element at the source temperature. At a given temperature these sources will provide a constant flux of As_2 or P_2 as long as solid III-V compound remains. Such sources are usually exhausted quickly because it is inconvenient and expensive to maintain a large volume of source III-V compound at the high temperatures required. Furthermore, for such sources, the group V element beam intensity cannot be varied independently of the group III element beam intensity.

Several studies (3, 4) have demonstrated that the quality of MBE material, at least for GaAs and $Al_xGa_{1-x}As$, improves with increasing substrate temperature during growth. Furthermore there is an increasing interest in III-V solid solutions containing both As and P. At higher substrate temperatures the efficiency with which the group V element is used decreases rapidly as the result primarily of its rapidly increasing partial pressure over the III-V compound. A source is needed that does not require frequent replenishment. For MBE of the III-V solid solutions containing As and P, a source that provides precise control over the group V element beam intensities is needed.

In this work, AsH_3 and PH_3 were thermally decomposed in a "leak-source" at sufficiently high temperatures for the reaction

$$4MH_3 \xrightarrow{\Delta} M_4 + 6H_2 \quad [1]$$

to go to completion in a "high pressure" section at approximately 1/2 to 3 atm. An "effusion section" of the source is intended to thermalize the beam to yield a cosine distribution and cause the reaction

$$M_4 \rightarrow 2M_2 \quad [2]$$

to occur. This gas source for the group V elements does not require replenishment inside the vacuum system. The group V element beam intensity can be precisely controlled simply by exercising control over gas pressures at about 1 atm in a simple gas handling system; and, if necessary, mixed sources can be used to provide constant group V element ratios in the molecular beam.

Experimental

The MBE system used to demonstrate gas-source MBE is a modified vacuum system that was used for early MBE studies in 1970. Because of the necessity to pump rather large volumes of hydrogen, the original ion pumping system was replaced with a 6 in. oil diffusion pumping stack consisting of a 6 in. gate valve, an efficient liquid nitrogen cooled trap, and then the diffusion pump. The lowest pressure the system could achieve was about 5×10^{-9} Torr. The arrangement of the group III and group V element sources is illustrated in Fig. 1. Minimal cryopanneling was provided and the system was clearly not suitable for growth of extremely high purity material (even without oil diffusion pumping). However, it was adequate to permit definition of conditions under which GaAs and InP can be grown with gas source MBE.

The effusion sources for the group III elements were of conventional construction (1) with a pyrolytic boron nitride crucible to contain the group III element and most heated metal parts of molybdenum to preclude

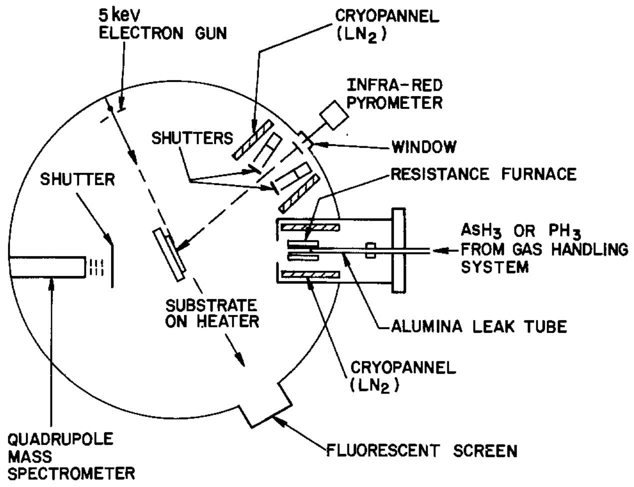

Fig. 1. Schematic representation of the MBE apparatus used for this work.

* Electrochemical Society Active Member.

Key words: semiconductor, arsine, phosphine, crystal growth.

their reaction with H_2. The source for the group V elements (Fig. 2) consisted of an alumina tube with a leaky end seal having a leak rate such that with the pumping stack used, and with the pressure in the gas handling system at about 3 atm, the vacuum system pressure did not exceed $\sim 5 \times 10^{-5}$ Torr during a run. Several centimeters of the end of the alumina tube were heated by a resistance furnace that was maintained at 800°-900°C during a run. As illustrated in Fig. 2, the alumina furnace tube protruded about 2 cm beyond the alumina tube seal to provide an effusion section for the source.

For the studies reported in this paper only one leak-source-furnace combination was used. This source was calibrated for As_2 and P_2 beam flux distribution at the substrate by having the beam impinge on a liquid nitrogen cooled Si wafer masked with a wire grid. The deposited arsenic layer was dense and metallic in appearance, with a surface that mirrored the surface of the Si substrate. Layer thickness was determined with profilometer scans across the masked and unmasked regions of the surface. For the determination of P_2 beam flux distributions, a similar procedure was followed. The only modification to the procedure was that a thin protective layer of As was deposited immediately following the phosphorus deposition. The thickness of the As layer was determined from the previous As runs, and the profilometer thickness measurement for the composite structure then yielded the phosphorus layer thickness.

Epitaxial layers of GaAs were grown on (100) GaAs substrate surfaces that were chemically polished with a Br_2-methanol solution and then briefly etched with a peroxide-H_2SO_4 solution. The InP epitaxial layers were grown on (100) InP substrates that were chemically polished only with a Br_2-methanol solution. During growth the substrate wafers were "glued" to the Mo heating block with indium. The oven orifice of the leak source was 9 cm from the substrate and the group III element source-to-substrate distances were about 12 cm. The group III beam intensities were regulated by monitoring and varying the effusion cell temperature with conventional thermocouple controlled regulators. Nominal effusion cell temperatures ranged from 900° to 1000°C for Ga and 800° to 840°C for In.

For both GaAs and InP epitaxy, the growing crystal surface was monitored by observing the reflection-high energy electron diffraction (RHEED) pattern for electrons diffracted at a glancing angle (1, 5) as illustrated in Fig. 1. In addition, the condition of the crystal surface was monitored visually and the temperature of the wafer surface was monitored with an infrared pyrometer. Calibration for the pyrometer was obtained for GaAs surfaces by observing the Si-Al eutectic transition at 577°C (6) for a partially Al-coated silicon wafer mounted on the heater block with the GaAs wafer. Similarly for InP, the Ge-Al eutectic temperature at 424°C (6) was used for calibration. It was assumed that the calibration corrections were constant over the temperature ranges studied.

Results and Discussion

The leak-effusion source.—The use of AsH_3 and PH_3 as sources for As_2 and P_2 beams requires that the hydrides be thermally decomposed before introduction into the vacuum system. This was done at 800°-900°C with pressures in the range 1/2 to 3 atm on the high pressure side of the leak. Virtually complete decomposition of the hydrides occurred. In the leak-source As_4 or P_4 plus H_2 molecules leak from the high pressure region at about 1 atm into the effusion section of the leak-source heater where the pressure is in the milliTorr range. Within the leak path there should be a transition from hydrodynamic to molecular flow. The leak is essentially a free jet (7), and in the ideal case, would produce a shock wave in the low pressure region. The shock wave is expected to rethermalize the velocity distribution so that the species emitted from tho effusion section would have the cosine distribution expected from an effusive source. Since the walls of the effusion section are at 800°-900°C, decomposition to the binary species (Eq. [2]) is also expected.

The measurements of the beam distribution suggest that for the very simple arrangement of Fig. 2, the jet is only partly rethermalized. In Fig. 3 a typical relative distribution for As actually measured at the substrate location is compared to the intensity curve expected for a cosine distribution from the source. Clearly the beam is much more sharply peaked than the cosine distribution and thus still retains some of the character imposed by hydrodynamic flow. This will be corrected in future experiments. However, the source was adequate for delineating the MBE conditions with small ($\sim$1 cm^2) substrate crystals used in this work.

The actual As_2 flux at the target under various AsH_3 input pressures was determined from the thickness of the As layers on the Si calibration targets. Similar experiments were done with the P_2 beams. However, while the As appeared metallic and fully dense, the thin P layers protected by As were less readily observed. The usual α (white) phosphorus that is found when P_4 vapor condenses is a lattice of P_4 molecules (2). It is unlikely that solid would result from the condensation of P_2 molecules on a cold surface. It is more probable that the condensed phosphorus phase is amorphous with a less open structure and a higher density than the P_4 based α phosphorus. The densities of the various allotropic forms of phosphorus range from 1.83 g/cm^{-3} for white phosphorus to 2.7 g/cm^{-3} for the high pressure induced black crystalline modification. The amorphous black and red, and crystalline red forms have densities from 2.2 to 2.5 g/cm^{-3}. Not knowing the density of the solid it is necessary to resort to our knowledge of the As_2 beam flux to determine that for P_2.

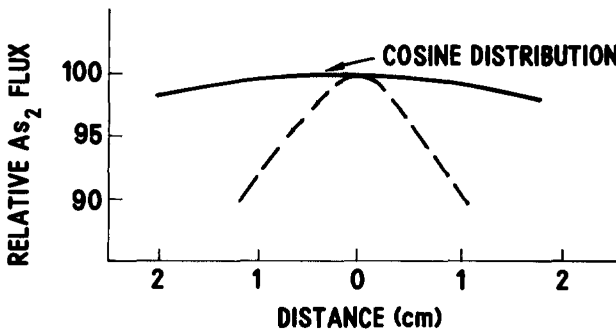

Fig. 3. Approximate relative As_2 flux distribution across the center of the substrate. Pressure on the high pressure side of the source was at about 1 atm. The curve is normalized to unity at the target center. Also illustrated is a cosine distribution.

The leak source under the pressure conditions of this experiment is, in the ideal case, expected to behave like a free jet that is formed by the expansion of a gas through a nozzle into a zero pressure region. For such a source the total flow rate will be linear with pressure and inversely proportional to the half power of the average molecular weight of the gas mixture on the high pressure side (7). In Fig. 4 the dependence of the As_2 beam flux on source input pressure is linear as expected. The dashed curve shows the P_2 flux calculated from the As_2 flux assuming free jet conditions at the leak. The rectangular data points show measured P_2 flux on the assumption that the density of the solid P is 2.7 g/cm^{-3}, the same as the most dense crystalline form. While these ways of arriving at the P_2 flux are certainly very approximate, the agreement in Fig. 4 suggests that the plotted curve is probably correct to within ±25%. That curve is used in the balance of this work.

Gas source MBE of GaAs.—Cho (5) has shown that, depending upon the As_2/Ga flux ratio in the impinging molecular beam, a number of RHEED patterns may be observed during MBE. The easiest to study are those obtained on the (100) surface with the electron beam along the $[\bar{1}\bar{1}0]$ azimuth. Summarizing much previous work, at the start of MBE, surface smoothing accompanied by the appearance of diffraction patterns characteristic of the growth conditions is observed (5, 8). These patterns result from diffraction by several different two-dimensional surface structures for the atoms constituting the crystal surface. These patterns, obtained when the diffracted electron beam strikes a phosphorescent screen, are a series of streaks with characteristic spacing. At relatively high As_2/Ga flux ratios a pattern with streak spacing one-half that of the bulk (1 × 1) crystal structure is observed. This is the one-half order or As-stabilized C (2 × 8) structure (1). With very clean substrates and vacuum systems extremely smooth layers of GaAs have been grown in the As-stabilized regime.

At relatively low As_2/Ga flux ratios a diffraction pattern having three equally spaced streaks between the bulk (1 × 1) streaks is obtained. This is the 1/4 order or Ga-stabilized C (8 × 2) structure. In the Ga-stabilized regime the crystal surface and diffraction pattern gradually degrade as the result of Ga droplet formation on the growing surface. Cho (5, 8) has also observed that in a plot of As_2/Ga flux ratio against $1/T$ the Ga and As stabilized growth regimes are separated by a transition region in which the (1 × 1) or faint transitional diffraction patterns exist. The boundaries of the different regions shifted, depending upon whether the transition was induced by heating or cooling. In this work the Ga and As-stabilized regimes were readily observed. However, they occur without hysteresis and, as shown in Fig. 5, at appreciably higher temperatures.

In experiments with much lower (but unspecified) Ga beam flux, Chang *et al.* (9) observed transitions between the Ga-stabilized, the transitional (3 × 1), and the As-stabilized structures at temperatures intermediate between those reported by Cho (8) and those reported here for As_2/Ga flux ratios in the same range. With comparable Ga beam intensities, but very low As_2/Ga flux ratios that overlap those reported here only at As_2/Ga = 1, the data of Chang *et al.* for the transition from the As-stabilized to the (3 × 1) or 1/3 order transitional structure are at slightly higher temperature. They also report a significant variation of surface transition temperature with absolute beam intensity.

The data of Fig. 5 cover a growth range of 0.45-1.5 μm GaAs/hr, corresponding to an absolute Ga beam flux at the sample ranging from 2.75 to 9.15 × 10^{14} Ga/cm^2 sec. Transitions from the 1/3 to 1/2 order pattern were gradual, over about a 10° temperature range, without a very precise transition temperature. Transitions to and from the 1/4 order structure were rapid. There seemed to be a region between the 1/3 order and 1/4 order regimes where only the (1 × 1) pattern could be observed. It should be pointed out that with the 5 kV electron gun used in this work the transition (3 × 1) pattern could only be observed under ideal conditions and actually may extend further toward the other regimes. The scatter in the data does not seem to depend upon Ga flux, but is probably related to the As_2 beam nonuniformity. In fact, the slope of the curves appear to become much shallower at As_2/Ga < 1 so that because of the beam nonuniformity shown in Fig. 3 different portions of the crystal surface were in different surface structural regimes. For that reason no attempt was made to study growth for As_2/Ga < 1 in this work.

At the highest As_2/Ga ratio studied, ~10.2, smooth GaAs epitaxy without surface defects was obtained with the substrate temperature as high as 700°C. The transition to nonsmooth (*i.e.*, Ga-droplet coated) surfaces occurred slowly within the transition region and rapidly as soon as the diffraction pattern characteristic of the Ga-stabilized structure appeared. A

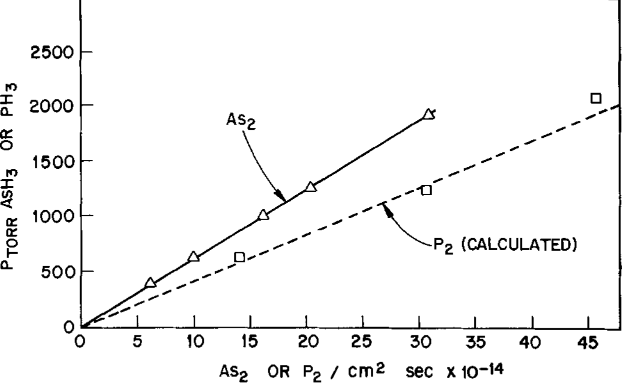

Fig. 4. Flux of As_2 (measured) and P_2 (estimated) at the target center as a function of P_{AsH_4} or P_{PH_3} on the high pressure side of the leak source. The square points were obtained upon the assumption that the density of the deposited phosphorus layer was 2.7 g/cm^{-3}.

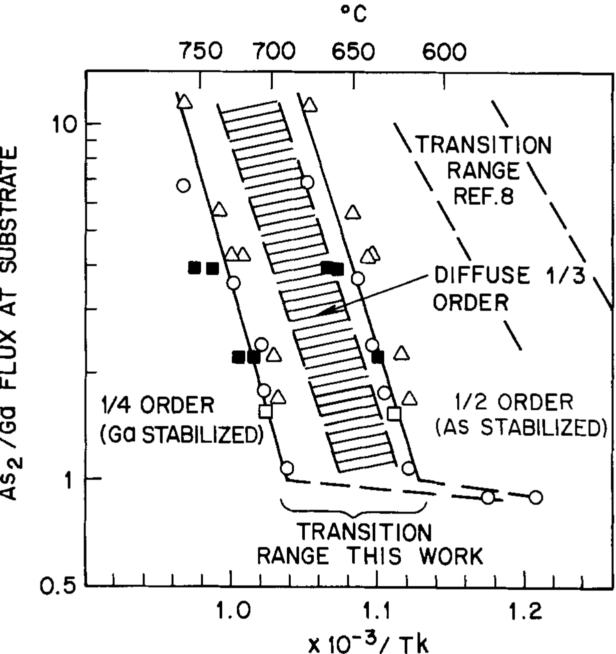

Fig. 5. As_2/Ga molecular beam flux ratio as a function of temperature for transitions between surface structures during MBE of GaAs. The growth rates were: △, 0.45 μm/hr; ○, 0.8 μm/hr; ■, 1.25 μm/hr; and □, 1.5 μm/hr.

clear demarcation from smooth to matte growth was not observed in the transition region. However, the way the experiments were done, changing temperature at a given As_2/Ga flux ratio and then repeating the experiment at different ratios after resmoothing the surface with As-rich growth, made it inconvenient to attempt to observe slow or very subtle surface appearance changes.

Since the apparatus was not designed to give high purity growth, little attempt was made to electrically characterize the grown layers. Several layers were grown on Cr-doped semi-insulating substrates. These samples were deliberately doped with Sn from a separate Sn-containing effusion oven. Hall and several photoluminescence measurements were made. For most of the samples studied ($N_D - N_A$) was in the range 2-4 $\times 10^{17}$ cm^{-3} and Hall mobilities were about 3000 cm^2 V^{-1} sec^{-1} at room temperature. This is about 15% lower than would be expected for the best mobilities for GaAs at that electron concentration. A few samples had mobilities as good as the best reported [*e.g.*, 4200 cm^2 V^{-1} sec^{-1} at ($N_D - N_A$) $= 1.5 \times 10^{17}$ cm^{-3}]. For these the room temperature photoluminescence peak intensity was as high as that obtained here for equivalently doped liquid epitaxy layers.

Gas source MBE of InP.—Indium phosphide layers were grown on (100) InP surfaces with the same leak source that was used for GaAs growth. During growth RHEED patterns were observed with the electron beam along the $[\bar{1}\bar{1}0]$ azimuth. The 1/2 order C (2×8) pattern could readily be observed on the surface after heating to 550°C with a P_2 flux of $\sim 5 \times 10^{15}$ P_2/cm^2 sec to remove oxide. Opening the shutter to the In oven started growth and the diffraction pattern usually became sharper and completely streaked. The sample surface during growth was visually observed while temperature was increased at a given P_2 and In beam intensity.

Usually a rapid change in gross surface morphology from smooth to matte could be observed with no change in diffraction pattern. The change in the temperature for this smooth-to-matte surface transition as a function of P_2/In flux ratio is given in Fig. 6 for InP growth rates ranging from 0.7 to 1.3 μm/hr (3.75-7.3 $\times 10^{14}$ In/cm^2 sec). With no In beam and a P_2 beam at 7.5 $\times$ 10^{15} P_2 cm^{-2} sec, the smooth-to-matte transition occurred at 600° ± 10°C. The 1/4 order, C(8×2) pattern could only occasionally be observed when the wafer was rapidly heated to a regime where liquid In was generated on the crystal surface.

In all cases studied the smooth-to-matte transition represented the formation of In droplets on the crystal surface. The surfaces of several InP crystals are shown with phase contrast microscopy in Fig. 7. Figure 7(a) shows the surface of an InP sample heated to 605°C with the P_2 flux at 5×10^{15} P_2 cm^{-2} sec^{-1} for several minutes. Etching of the surface and In droplet formation are clearly visible. The crystal shown in Fig. 7(b) is that used for the experimental point at the molecular beam flux ratio P_2/In $= 4.6$ in Fig. 6. The run was ended immediately after the smooth-to-matte transition. Figure 7(c) and (d) are micrographs of two locations at opposite ends of the $\sim$1.5 cm wide crystal used for the experimental point at P_2/In $= 1.0$ in Fig. 6. The 10-20% variation in the P_2/In flux ratio across the crystal as the result of P_2 beam inhomogeneity (Fig. 3) and tilting of the sample relative to the In oven (Fig. 1) yield the differences in morphology at the relatively P_2-rich end [Fig. 7(d)] and the relatively In-rich end, Fig. 7(c). Figures 7(c) and (d) show the great sensitivity of the surface morphology to flux ratio near the smooth-to-matte transition. For several layers grown on the right side of the curve on Fig. 6, surfaces were extremely smooth with some structure barely visible with phase contrast microscopy but at too low a contrast to be photographed. No electrical or optical characterization of the InP layers was done.

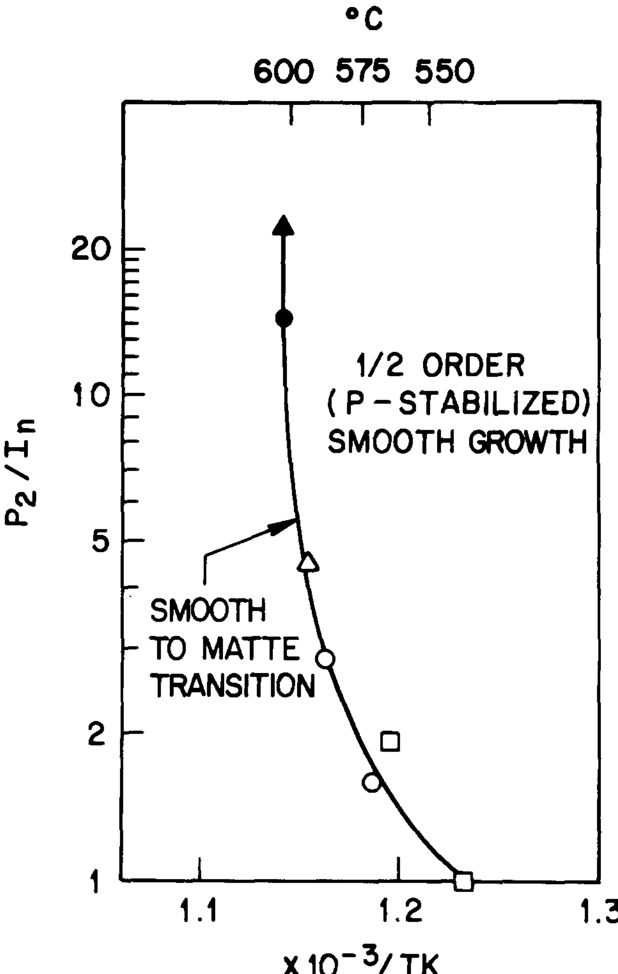

Fig. 6. P_2/In molecular beam flux ratio as a function of temperature for the observed transition from growth of InP with a smooth to growth with a matte surface.

The data of Fig. 6 and the morphological studies represented by Fig. 7 suggest that the limitation represented by the smooth-to-matte transition is simply the more rapid loss of P than In from the crystal lattice at the surface. In other words, the data of Fig. 6 represent the liquidus curve for the In plus P liquid in contact with the InP solid under the P_2 and In flux conditions of the experiment. Since each two impinging In atoms consume one P_2 molecule, the P_2 flux, less half of the In flux, represents the excess flux of P_2 molecules that are equivalent to a partial pressure of P_2 over the InP. The flux F of a vaporizing species can be related to its equilibrium partial pressure P by means of the Langmuir relation

$$F = \frac{P\alpha}{(2\pi mkT)^{1/2}} \quad [3]$$

where α is the accommodation coefficient. If α is taken as constant with T, a plot of log $[(F_{P_2} - 1/2\, F_{In})T^{1/2}]$ against $1/T$ should be equivalent to a plot of log P_{P_2} against $1/T$ and should be linear. The data of Fig. 6 are replotted in Fig. 8. The factor of $T^{1/2}$ is almost constant over the temperature range under consideration and has been omitted. For comparison, the partial pressure of P_2 in equilibrium with the In-P liquidus (10) against $1/T$ is also given in Fig. 8. The two curves appear to be equivalent.

Since the smooth-to-matte transition is actually the liquidus-partial pressure boundary, Fig. 8 represents the maximum InP-MBE growth temperature at any P_2 flux. A leak source with a flux ten times that of the source used in this work is feasible and from Fig. 8 would have an upper InP growth temperature limit of

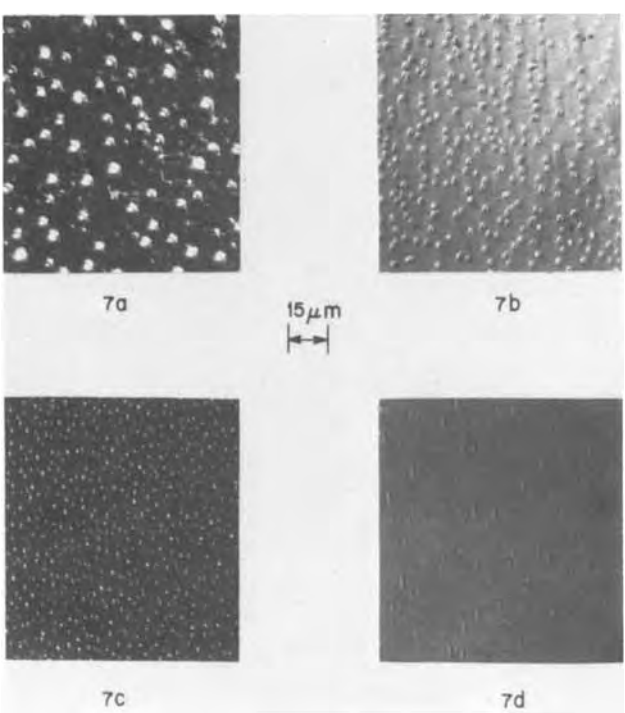

Fig. 7. (a) InP surface after several minutes at 605°C with a P_2 molecular beam flux of 5×10^{15} P_2/cm^2 sec. The smooth-to-matte transition occurred between 600° and 605°C. (b) InP surface after the smooth-to-matte transition during MBE at a P_2/In molecular beam flux ratio of 4.6. (c) and (d) InP surface at two different locations after the smooth-to-matte transition during MBE at a P_2/In flux ratio of 1.0.

650°C at infinitely small growth rate. A small additional P_2 flux with the appropriate In flux would then yield InP growth.

Conclusion

A series of experiments have demonstrated that with an appropriate input device and vacuum system, AsH_3 and PH_3 could be used to generate As_2 and P_2 beams for molecular beam epitaxy of GaAs, InP, and by extension, crystalline solid solutions of GaAs and InP. The leak source devised for this work permitted sufficiently intense beams that GaAs and InP could be grown at temperatures as high as 700°and 600°C, respectively. For InP this is higher than previously reported for MBE of these semiconductors. For GaAs, Gossard and Wiegmann (11) have obtained growth to approximately 750°C by generating an As_2 beam with an auxiliary heater on the end of a solid As source effusion cell. The limitation on the growth temperature of InP, and probably also GaAs by this technique appears only to be the formation of the liquidus as the result of a higher vaporization than flux rate of the group V element at the crystal surface. With modified sources to yield a factor of ten greater flux it is expected that growth at 750°C for GaAs and 650°C for InP could be achieved. Probably more important is the ease of control over beam flux that can be achieved with the gas source. Such a source will be useful for the growth of mixed crystals containing both As and P.

Acknowledgments

The author would like to thank G. Kubiak, J. Robinson, and S. Sumski for their help in building and running the MBE apparatus, and M. Cardillo, A. Y. Cho, and J. C. Bean for their advice and discussions during the course of this work.

Manuscript received May 5, 1980.

Phosphorus Silica Glass as Dopant Source

M. L. Polignano, P. Picco, and G. F. Cerofolini

Divisione MOS, SGS-ATES, 20041 Agrate, Milano, Italy

ABSTRACT

The behavior of phosphorus silica-glass (PSG) as a silicon dopant source has been studied by measuring PSG etch rate, depth, and resistivity of the junction formed after diffusion. Our results are in agreement with known data concerning phosphorus diffusion in a flat region.

The system formed by a silicon surface covered by a layer of doped oxide is not yet well characterized. This is due both to an insufficient knowledge of the properties of the oxide and to the difficulties of a mathematical description of the diffusion from one phase to another. In the past ten years we have seen several efforts to set up reliable systems for measuring the dopant (phosphorus and boron) level in the oxide (1-4) as well as to solve the diffusion problem (5-8). However, the diffusion problem has satisfactorily been solved only for phosphorus concentrations below 5% (5, 7, 8), when the high-concentration-PSG/silicon system was considered, only under 5% concentration in PSG agreement between the model and experimental results is obtained.

Barry, for instance, presented conclusions which though they claim to show linearity, actually evidence high concentration effects (7). He found [Fig. 5 of Ref. (7)] that the linearity predicted by his model between surface concentration C_o and phosphorus concentration in the oxide holds true only for $C \lesssim 4 \times 10^{20}$ P atoms/cm^3 ($\simeq$1 m/o).

In this work, we have undertaken the study of diffusion from high concentration ($\simeq$10 m/o) PSG, in order to verify whether the oxide characteristic induces a phosphorus profile in silicon as complex as the one described by Fair and Tsai [kink effect (10)], and in view of a possible use of this phosphorus source to form source and drain regions of n-channel MOS transistors.

Key words: diffusion, junction, resistivity.

The techniques used in this work are conventional V/I and x_j measurements of the layers formed after diffusion on p-type samples, and etch-rate measurement of the oxide, in order to characterize diffusion within it.

Experimental and Results

P-type, 3 in., (100) oriented, 1.7-2.6 Ω-cm (corresponding to a substrate concentration 8×10^{15} B atoms/cm^2) Si slices were used in this work.

PSG was deposited in an open-tube reactor at 420°C by simultaneous oxidation of silane and phosphine

$$SiH_4 + 2O_2 \rightarrow SiO_2 + 2H_2O$$

$$2PH_3 + 4\,O_2 \rightarrow P_2O_5 + 3H_2O$$

in the proportion required to have a P_2O_5 molar concentration of about 10% ($\simeq 3.9 \times 10^{21}$ P atoms/cm^3) and for a time sufficient to grow a thickness of about 5000Å.

After a moderate annealing (N_2, 800°C, 30 min), the wafers were partitioned in several groups and were treated at three different temperatures (940°, 1000°, 1050°C) for three lapses of time (0.25, 1, 2.25 hr) in a combined way. Measurements of V/I and junction depth x_j were carried out on all samples.

The etch rate profile was determined at 15°C only on the samples treated for 2.25 hr by using a P-etch solution (17 cm^3 49% HF, 10 cm^3 70% HNO_3, 300 cm^3 H_2O) diluted in five parts of H_2O to increase sensitivity and accuracy.

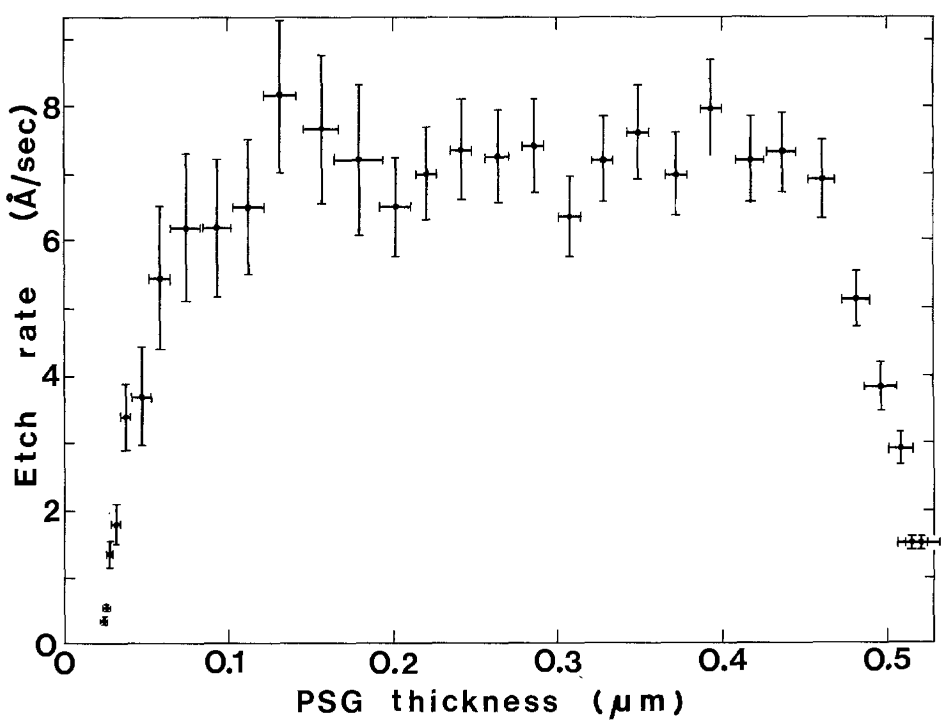

Fig. 1. Etch-rate profile for PSG after 2.25 hr annealing at 940°C. The shape is qualitatively the same for all the considered temperatures. Profiles obtained by successive etching of the doped oxide film. Etch rate is defined as $v(x_i) = (x_i - x_{i+1})/\Delta t_i$ (x_i, film thickness before the single etching; x_{i+1}, film thickness after the single etching; Δt_i, etching time). The last point is chosen as the last point keeping a physical meaning (*i.e.*, satisfying the condition $v \geqq v_0$). This point corresponds to a total asportation of the oxide on about 25% of the wafer surface, owing to lack in uniformity of the PSG film: for this it does not coincide with the origin.

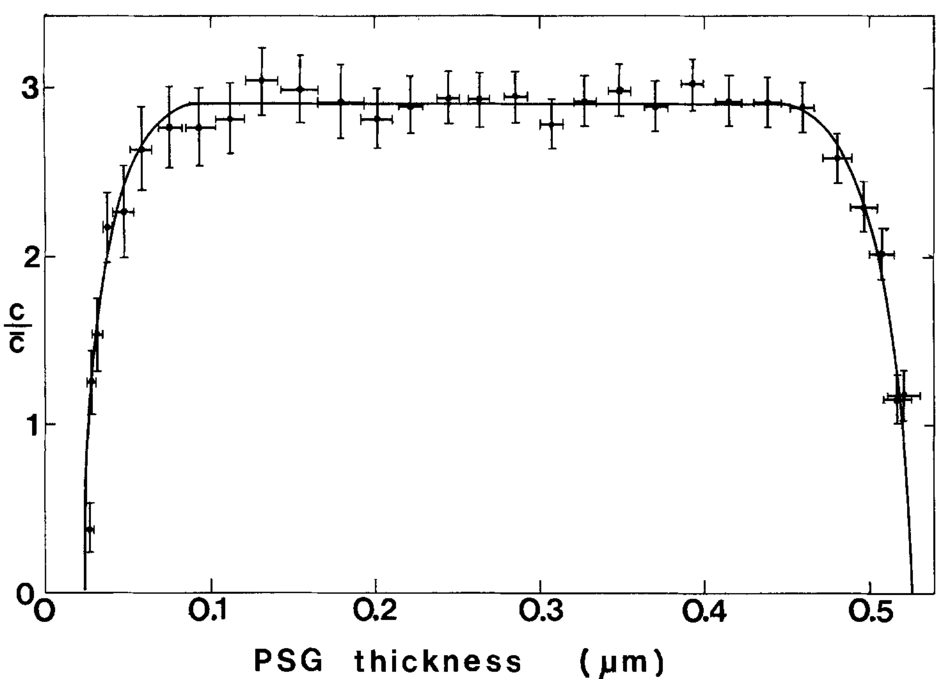

Fig. 2. Phosphorus concentration profile in PSG after 2.25 hr annealing at 940°C. The profile does not extrapolate to the origin for what was reported in Fig. 1. The estimated extrapolation to $C = 0$ is used for Q^{Si} calculations.

All our etch rate profiles have the same qualitative shape: the one annealed at 940°C for 2.25 hr is shown in Fig. 1. It is known (1, 2), and we have verified by measuring the etch rate of nondensified samples of calibrated concentration (measured by neutron activation analysis) that the etch rate of PSG in P-etch v depends upon phosphorus concentration c according to

$$v(c) = v_0 \exp(c/\bar{c}) \quad [1]$$

where $v_0 = v(0)$ and $\bar{c}$ is a suitable concentration. Because of its physical meaning v_0 can be measured on "undoped PSG" (our readers will excuse this contradiction) and has been found to depend upon thermal treatment; on the contrary, $\bar{c}$ has been found to be a constant. Table I confirms this statement.

Equation [1] allows us to transform kinetic profiles into concentration profiles: one of them is shown in Fig. 2. These profiles allow the estimate of the thickness x_d of the two phosphorus-depleted PSG layers, both next to silicon (x_d^{Si}) and facing vacuum (x_d^v); moreover, via a numerical integration, the total amount of phosphorus diffused into silicon (Q^{Si}) or toward vacuum (Q^v) are easily computed.

Table II reports these quantities and shows that $x_d^{Si} \simeq x_d^v$, $Q^{Si} \simeq Q^v$; this is an evidence that in the considered system the rate-determining step is the diffusion process in the oxide.

Figures 3 and 4 show the results of V/I and x_j measurements. All the presented data can be used to test different hypotheses on concentration profile of phosphorus in silicon. To this aim, a choice of diffusion coefficient D, which depends on concentration, and/or a determination of surface concentration C_0 are implied ($Q \propto C_0\sqrt{Dt}$).

Table I. Etch rate parameters in diluted P-etch after 2.25 hr annealing (V_{max} determined from the flat zone of the etch rate profile; v_0 measured on samples of undoped oxide; $\bar{c}$ follows from Eq. [1]

Temperature (°C)	V_{max} (A/sec)	V_0 (A/sec)	$\bar{c}$ (10^{21} cm^{-3})
940	7.1 ± 0.3	0.38 ± 0.02	1.33 ± 0.05
1000	6.2 ± 0.2	0.33 ± 0.03	1.32 ± 0.05
1050	5 ± 0.3	0.28 ± 0.02	1.36 ± 0.07

Let us consider the hypothesis of erfc or gaussian profile. The surface concentration C_0 can be determined with the aid of Irvin curves (9).

With such C_0, using the value for D given by Fair and Tsai (10), relative to the flat region, and considering it valid for the whole diffusing phosphorus, much higher Q with respect to the measured ones (Q_{Si}) are obtained (see Q_e and Q_G in Table III) (here and in the following, Q will indicate the generical phosphorus dose injected in silicon, Q^{Si} our experimental value of it, Q_e, Q_G, and Q_b the doses compatible with V/I and x_j measurements, relative to erfc, gaussian or box profile, respectively).

Trying to avoid this disagreement, a lower diffusion coefficient must be chosen. The intrinsic value for D can be considered (10, 11) but unreasonably high C_0 results, calculated from x_j values. The intermediate (and correct) possibility to test the erfc or gaussian profile hypothesis is to use the diffusion coefficient which fits Q^{Si} values, assuming again C_0 is known (from V/I and x_j). The result is a diffusion coefficient decreasing with increasing temperature.

In scheme 1 this whole discussion is summarized. The hypothesis of erfc or gaussian profile must then

be ruled out. The same holds true for any other profile for which $Q > Q^{Si}$.

The problem, "Does a profile exist for which $Q \leq Q^{Si}$, for the given V/I and x_j ?" arises. An affirmative answer is vital for the consistency of our data. Formally stated, this means we must first look for the profile $C(x)$ that, for given V/I and x_j, minimizes Q, which is then to be compared to Q^{Si}.

The variational calculus shows that such a profile is the box-function one, corresponding to the minimum dose Q_b. If Q_b were higher than our measured value Q^{Si}, an unresolvable contradiction would result. If it were lower, it would mean we are in presence of electrically nonactive phosphorus in our system, but no indication would arise about concentration profile.

But in this case good agreement results between the box-type value Q_b and Q^{Si} (see Table III): this is a strong indication for the existence of a flat region in phosphorus profile, since a box-type profile is the one which has a zone, near the surface, where $C(x)$ ranges in a region of nearly constant mobility (12), and in which the most part of the dopant is contained.

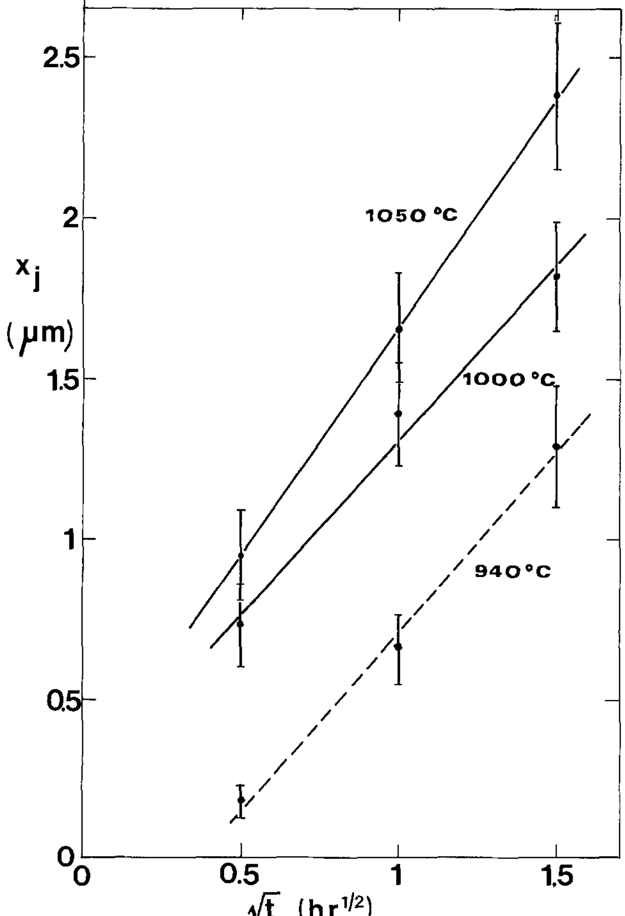

Fig. 4. Junction depth x_j vs. time

Discussion

At the first sight the results of our work seem to be in such a striking disagreement with previous observation to deserve a more accurate analysis. This seeming disagreement can be removed by invoking the diffusion properties of phosphorus at high concentration, *i.e.*, the profile of phosphorus in silicon [flat region near the surface, then a sudden decrease (kink), followed by a typical complementary error function behavior (tail)] are to be ascribed to the sufficiently high surface concentration of phosphorus, independently of the type of phosphorus source.

It is well known that conductivity and phosphorus amount of the whole diffused region are almost exclusively given by the flat region (plateau), while kink and tail position determine the junction depth.

According then to Fair and Tsai formulas (10), the total amount of phosphorus diffused into silicon after a time t is given by

$$Q = \tfrac{1}{2} C_o x_o \quad [2]$$

where

$$C_o = \tfrac{1}{2} n_s (1 + 2.04 \times 10^{-41} n_s^2) \quad [3]$$

$$x_o = 2(D_i^{=} (n_s/n_i)^2 h t)^{1/2} \quad [4]$$

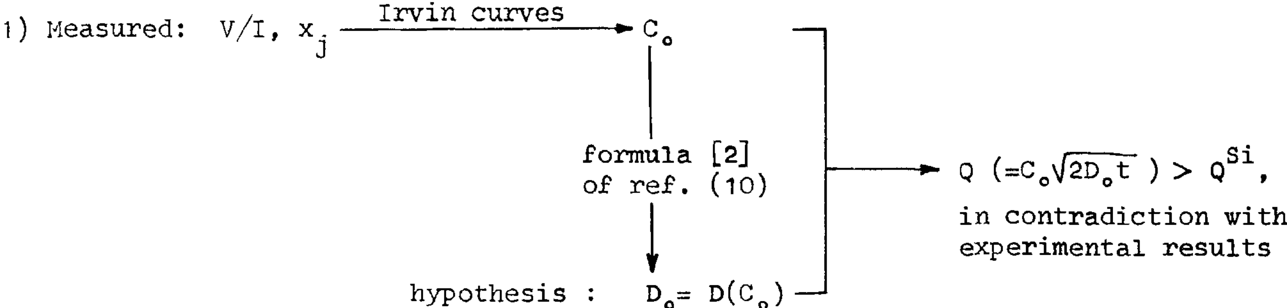
n_s being the electrically active surface concentration, n_i the intrinsic electron concentration, $D_i^{=}$ the intrinsic diffusion coefficient of the E-center with doubly ionized vacancy, h ($\simeq 2$) the electric field enhancement factor. Inserting Eq. [3] and [4] in Eq. [2] and solving for n_s allows determination of x_o and C_o.

The results are reported in Table IV and show that C_o decreases as diffusion temperature increases; this because the rate-determining step is the diffusion process in the oxide. Since x_o/x_j ranges from 0.36 to 0.50 (see Table IV) the concentration profile approaches the box-type one as temperature increases.

This fact may be the cause of the large disagreement between Q_e^{Si} (or Q_G^{Si}) and the experimental data at high temperature. The following conclusion may be

Table IV. Surface concentration and depth of the flat region as follows from (10, 11) for the measured Q^{Si}

Temperature (°C)	Q^{Si} (10^{16} cm^{-2})	C_o (10^{20} cm^{-3})	x_o (μm)	x_o/x_j
940	0.51	2.2	0.46	0.36
1000	0.79	1.9	0.83	0.46
1050	1.0	1.7	1.18	0.50



Scheme 1. Why gaussian (and erfc) profiles have been rejected.

drawn. The PSG etch rate in P-etch has been characterized as a function of the annealing temperature; measurements of the parameters v_o and $\bar{c}$ in formula [1] clearly showed that only v_o depends on annealing temperature, while $\bar{c}$ is constant in the considered temperature interval.

The behavior of high concentration (10%) PSG films also as dopant sources has been studied. It has been confirmed that this behavior is determined by diffusion in oxide. Moreover, for the first time consistency tests between the measured quantities (Q^{Si}, x_j, V/I) and different possible phosphorus concentration profiles have been performed. It has been found that at the considered PSG concentrations kink effect takes place.

Addendum

After the first submission of this paper, a referee put forward a criticism to value and limit of our experimental data in interpreting the diffusion mechanism. In particular, he showed that "the method used to reach the conclusions is . . . an indirect one, and the results, although self-consistent with the experimental data, must be considered speculative in nature."

The criticism is sound and so we have modified the text to present our conclusions according to their speculative character, but we have also measured a profile to verify the conclusions. This profile has been measured by determining x_j after annealing at 1050°C for 2.25 hr on substrates of different resistivities.

The profile is shown in Fig. 5. Although the experimental points do not directly give information about the flat region, however they support our conclusion mentioned earlier and agree with Fair and Tsai results.

Indeed, the three experimental points at lowest concentrations align along an erfc type profile with $D = 8.6 \times 10^{-14}$ cm²/sec. The extrapolation to the surface (dashed line) gives as previously said, unreasonably high C_o value.

The experimental point F fortuitously corresponds to the x_o value; at the point K, according to Eq. [2], [3], and [4] of Ref. (11), with our C_o (see Table IV), phosphorus concentration deviates from the erfc-type profile.

These considerations are supported by the following consistency test between our results and Fair and

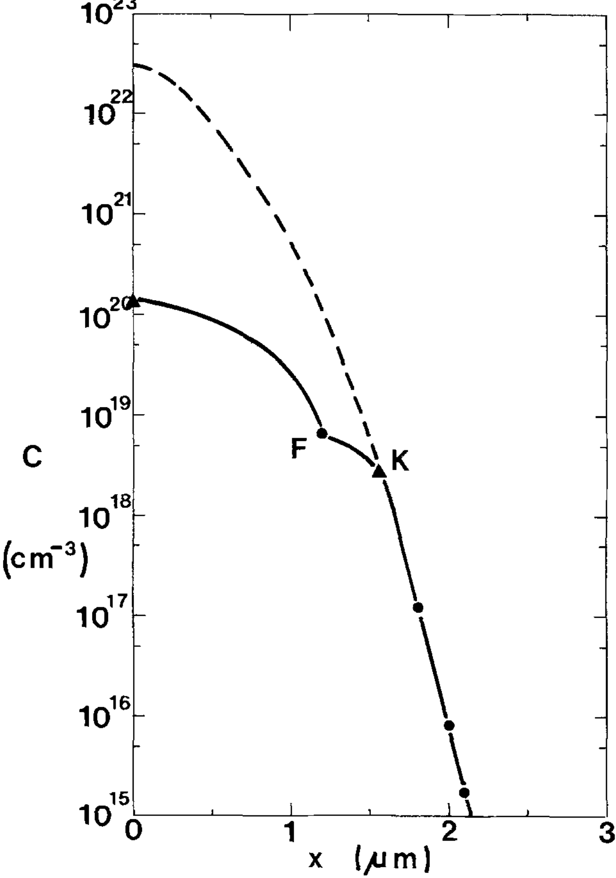


Fig. 5. Phosphorus concentration profile in silicon, after 2.25 hr annealing at 1050°C. Dashed line, extrapolation to the surface of the erfc-type part of the profile.

Tsai model. This model establishes a relation between diffusion coefficient in tail region, D_{TAIL}, and phosphorus surface concentrations C_o. Then a measure of D_{TAIL} is an independent, though indirect, measure of C_o.

We have measured diffusion coefficient in the tail region, and we then can compute C_o: $C_o = 1.2 \times 10^{20}$ cm^{-3} results, consistent with the value $C_o = 1.7 \times 10^{20}$ cm^{-3} (see Table IV) obtained in the last section of the paper.

Auger Electron Spectroscopy Study of the Chemisorption of Iodine on Zirconium

Gopala N. Krishnan, Bernard J. Wood, and Daniel Cubicciotti*

SRI International, Menlo Park, California 94025

ABSTRACT

Auger electron spectroscopy was used to observe the relative coverage of iodine on the surface of a zirconium crystal exposed to a flux of iodine gas molecules. The zirconium was heated to temperatures of 1000-1300 K, and the iodine pressures corresponded to 10^{-4}-10^{-6} Pa (10^{-9}-10^{-11} atm). Iodine was found to chemisorb on the surface; the isotherms corresponded to the Temkin model. Isoteres derived from these isotherms showed a logarithmic dependence of pressure on reciprocal temperature. The slopes of the isoteres indicated an enthalpy of formation of the surface layer of about 60 kcal/mole. The thermodynamics of formation of an iodine adspecies on a zirconium surface were compared with the thermodynamics of formation of zirconium monoiodide, the lowest solid iodide of zirconium.

The iodine-induced stress corrosion cracking (SCC) of zirconium involves chemical reactions between clean zirconium surface and iodine-containing species (1). That is, in the SCC process, fresh metal surface is created as cracks grow. The freshly formed surface apparently reacts with iodine-containing species in the system as evidenced by the fact that the topography of the cracks formed in the metal and the stresses required to form and extend the cracks are different in an iodine-containing environment than in a noniodine-containing environment. Consequently adsorption of iodine-containing species at the crack tip is likely to be the critical chemical reaction in the SCC process. Such a surface reaction would weaken the Zr-Zr bonds in certain crystallographic planes in the metal, leading to the observed effects of iodine on the failure process.

The reaction of iodine-containing species with clean zirconium surfaces is therefore central to the mechanism of iodine-induced SCC of zirconium alloys; however, no studies have been made of this reaction. The rates of reaction of iodine with zirconium have been studied but only under conditions in which the metal was covered by surface layers of zirconium iodides (1-3).

* Electrochemical Society Active Member.

Key words: surfaces, adsorption, stress corrosion.

In the present study, Auger electron spectroscopy (AES) was used to monitor the surface of a clean zirconium foil exposed to a flux of iodine vapor. The AES technique provided a quantitative measurement of the concentration of iodine chemisorbed on the surface as a function of zirconium temperature and iodine flux. The conditions of this AES study are different from those present in an SCC crack during formation and propagation; however the pertinent results are the demonstration of chemisorption of iodine on clean zirconium and the thermodynamic stability of the chemisorbed state.

Experimental Program

AES is a surface-sensitive analytical technique that has been used extensively to study gas-metal interactions at the monolayer levels (4). During AES analysis, the specimen is bombarded with a medium energy (~3 keV) electron beam, which causes secondary electron emission from the specimen. Some of these secondary electrons consist of Auger electrons arising from electronic transitions in the atoms present in the specimen. The technique is surface sensitive because of the limited escape depth of the Auger electrons. For electron energies from 50 to 500 eV, the range of interest in this study, the analysis depth varies from 0.5 to 1 nm.

The concentration of a particular elemental component in the near-surface atomic layer of a specimen determines the amplitudes of the peaks in its Auger spectrum. But the proportionality factor relating concentration to peak amplitude, frequently referred to as the Auger yield, is a complex quantity that cannot be precisely evaluated from first principles (4). However, changes in concentration of a component can be followed with good precision by measuring the growth or decay of an Auger peak.

Apparatus and materials.—All experiments were conducted in an ultrahigh vacuum system capable of attaining 10^{-8} Pa base pressure. The AES analyses were performed with a Varian cylindrical mirror analyzer with an integral electron gun. The incident electron beam was ~100 μm in diameter at the specimen and was normally operated at 3000 eV and 5 μA. The total pressure in the system was measured with an ionization gauge, and the partial pressures of gas components were determined with a quadrupole mass spectrometer. A rastered, 3-keV argon ion beam was used to clean the specimen surface. The arrangement of the various components with respect to the specimen in shown in Fig. 1.

The specimen used in this study was a high purity zirconium foil 0.0127 cm thick and ~0.3 cm wide. The strip was resistively heated, and its temperature was monitored by a Chromel-Alumel thermocouple spot-welded to the back of the specimen at its midpoint. A 0.01 cm diam area in the center of the specimen was analyzed by the Auger electron spectrometer.

Iodine was introduced into the vacuum chamber through a glass-lined stainless steel capillary tube[1] (~0.4 mm ID × 90 cm long). The upstream end of the capillary tube was attached to a Pyrex glass manifold by means of a Cajon ultra-Torr stainless steel vacuum connector. This small connector was the only metal surface in contact with the iodine vapor. The iodine reservoir could be isolated from the capillary by means of a Viton sealed glass valve. The iodine manifold was heated when necessary by a heating tape and could be evacuated through a liquid nitrogen-cooled, molecular sieve trap into a mechanical pump. Before the experiment began, the iodine reservoir was filled with resublimed iodine by vacuum distillation through a molecular sieve trap to remove traces of water. The reservoir, equipped with a break-seal tubulation, was pulled off from the distillation manifold and subsequently attached to the capillary inlet manifold. Immediately before the experiment began, the break seal was fractured to admit iodine into the manifold.

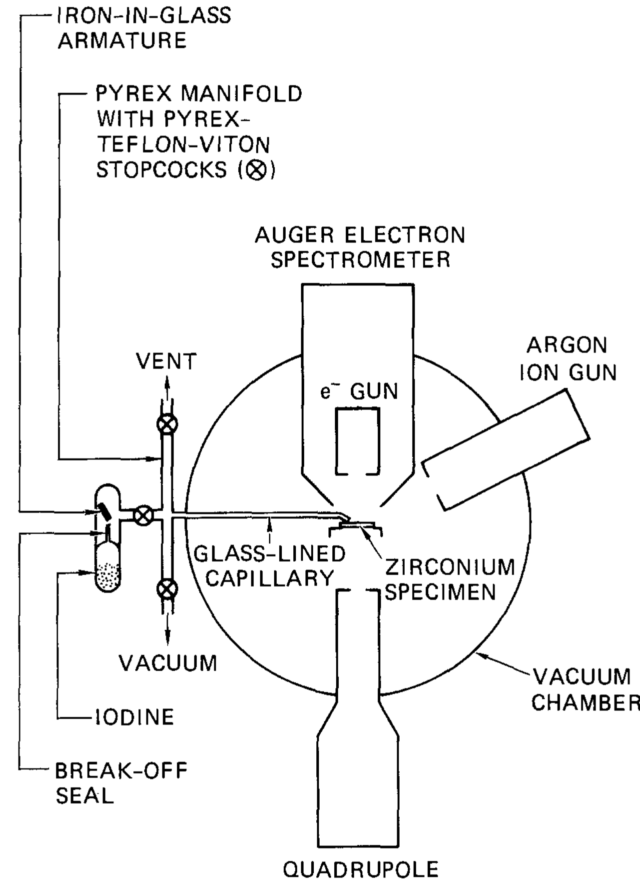

Fig. 1. Schematic diagram of apparatus

The outlet end of the capillary tube was pointed at the specimen and situated about 0.2 cm from its surface. On the basis of our measurements with oxygen with a similar arrangement (5), we estimate that 70% of the gas molecules leaving the capillary tube strike the specimen

Procedure.—The mass flow rate of iodine through the capillary tube was determined by the pressure of iodine in the manifold and by the conductance of the capillary tube. The pressure of iodine in the manifold was controlled by immersing the reservoir in various freezing bath mixtures designed to maintain constant subambient temperatures. The baths used and the attained temperatures are listed in Table I. The iodine manifold and the capillary tube were initially degassed at 400 K overnight. The iodine reservoir was kept at the bath temperature for 2 hr before the iodine valve was opened to admit iodine to the manifold and to the vacuum chamber.

The zirconium specimen surface was cleaned by a combination of argon ion sputtering and high temperature treatment. After initial sputtering, we found that holding the specimen at 1200 K was sufficient to maintain a relatively clean surface as observed from AES spectra. During the start of the experiment, the specimen was cooled or heated from 1200 K to the selected reaction temperature, and the capillary inlet valve was opened to admit iodine to the specimen surface. After a steady-state coverage was attained, the temperature of the specimen was increased to a higher temperature while a constant iodine reservoir temperature was maintained.

The iodine pressure near the specimen can be computed from the mass flow rate, $\dot{m}$, of iodine passing through the capillary tube by the following equation derived from kinetic theory of gases

$$\overline{P} = \frac{4k\dot{m}RT}{a\overline{c}} \quad [1]$$

where a = area of the specimen, $\dot{m}$ = mass flow rate, $\overline{P}$ = equivalent pressure, $\overline{c}$ = mean molecular velocity, T = gas temperature, and k = fraction of molecules leaving the capillary that strike the specimen surfaces.

Table I. Temperature of iodine bath and equivalent iodine pressure near the specimen

Bath	Bath temperature (K)	Iodine vapor pressure (Pa)	Mass flow rate through capillary Pa · liter sec⁻¹	Iodine pressure at the specimen[a] (Pa)
CCl_4 solid-liquid	252.7	4.34	3.04×10^{-5}	5.9×10^{-6}
Saturated KCl-ice	263.7	11.9	8.31×10^{-5}	1.6×10^{-5}
Ice-water	273.2	26.9	1.83×10^{-4}	3.6×10^{-5}
p-dioxane solid-liquid	281.2	48.4	3.39×10^{-4}	6.6×10^{-5}

[a] Pressure equivalent of collision rate averaged over area of specimen that intercepts 70% of iodine molecules leaving the capillary.

The mass flow rate of iodine through the capillary tube is proportional to its conductance and to the pressure at the inlet end

$$\dot{m} = P \cdot c \quad [2]$$

where P = manifold pressure and c = capillary conductance.

The iodine pressure in the manifold is equal to the vapor pressure of iodine at the reservoir bath temperature. The conductance of the capillary was determined in a separate experiment in which the manifold was connected to a Validyne stainless steel diaphragm pressure gauge. Iodine was introduced from the reservoir into the manifold of calibrated volume, V, up to a chosen pressure, P, and then the reservoir valve was shut off. From the observed rate of pressure decrease, dP/dt, due to iodine flowing through the capillary tube, the conductance, c, of the capillary was calculated from the following relation

$$c = \frac{V}{P}\frac{dP}{dt} \quad [3]$$

the conductance of the capillary tube was found to have a constant value of 6.4×10^{-6} liters sec^{-1} over an iodine pressure range of 13.3-66.7 Pa.

Results and Discussion

Auger electron spectra in the range of 70-570 eV were recorded at suitable intervals at various specimen temperatures and iodine pressures. Table II summarizes the Auger peaks and transitions of interest (6). Figure 2 shows representative Auger spectra at different specimen temperatures. The major peaks of iodine at 504 and 515 eV closely bracket the major oxygen peak at 510 eV. Hence, if oxygen is a significant component on the specimen surface, overlap would occur between the oxygen peak and these iodine peaks. To eliminate oxygen interference, we used high specimen temperatures at which oxygen accumulation on the surface was minimal (5), as confirmed by the absence of the AES oxygen peak under these conditions. Examining the ratios of the iodine peak heights provided further evidence. (Peak heights are represented by the symbol: A element, energy.) We found that values of the ratios $A_{I\,504}/A_{I\,515}$ did not change significantly with variations in the iodine pressure and the specimen temperature. Thus, any contribution of oxygen to the iodine 504-eV peak was negligible under our experimental conditions.

The zirconium and iodine Auger peaks do not appear to shift in energy with iodine coverage on the surface (Fig. 2). The absence of any energy shifts suggests that the iodine observed on the zirconium surface, at the high temperatures and the low iodine pressures used, is present in a chemisorbed state, in contrast to being combined in a surface or bulk compound.

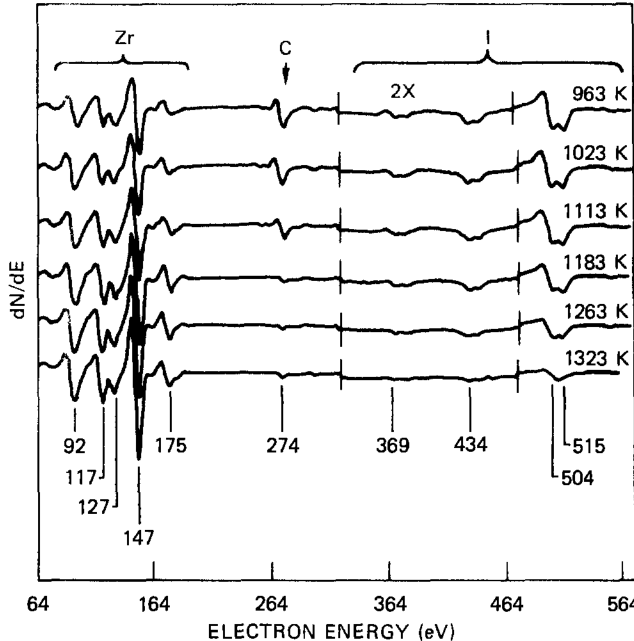

Fig. 2. Typical Auger electron spectra of zirconium foil exposed to iodine vapor at various temperatures.

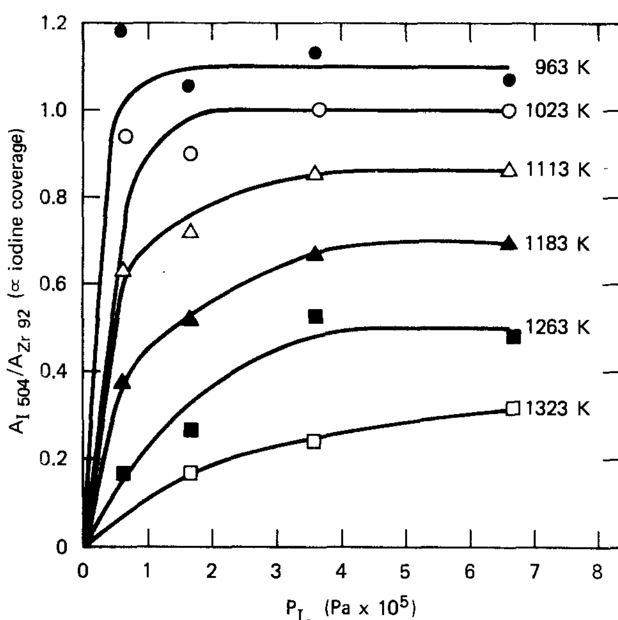

Fig. 3. Adsorption isotherms for iodine on zirconium

Figure 3 illustrates the change in the ratio $A_{I\,504}/A_{Zr\,92}$ as a function of iodine pressure at different specimen temperatures. This ratio of iodine to zirconium peak heights is a relative measure of the coverage of iodine on the surface. Normalization of the iodine peak to this stable core-level zirconium peak compensates for random variations in instrumental parameters such as incident electron beam current, electron multiplier gain, and the position of the specimen with respect to the focal point of the electron energy analyzer. As the temperature was decreased, the normalized iodine signal appeared to approach an asymptote with a value of $A_{I\,504}/A_{Zr\,49} \approx 1.2$, suggesting an upper limit in coverage. Under the high temperatures and low iodine pressures used in these experiments, such a coverage limit is likely to be less than a monolayer of the adspecies.

We attempted to establish unequivocally an iodine signal intensity that corresponded to monolayer coverage by taking the Zr crystal to much lower temperatures while exposing it to a high iodine flux. Our

effort was thwarted by the appearance of a significant oxygen signal at temperatures below 960 K. Carbon also appeared on the surface and increased significantly at lower temperatures. We concluded that these impurities originated in the bulk of the specimen because the background pressure in the vacuum chamber was too low ($\sim 10^{-8}$ Pa) to populate the surface to the observed impurity levels within the duration of the experiments. Although the general appearance of the curves in Fig. 3 is similar to the Langmuir isotherm, a critical plot of the data showed they deviated significantly from the Langmuir equation. That is, a plot of $A_{I\,504}/A_{Zr\,92}$ divided by pressure of iodine *vs.* pressure of iodine was not linear as it would be for the Langmuir form of isotherm (7). The results in the temperature range 1023-1323 K, however, were equally well fit by the Freundich equation (7) [proportionality of log ($A_{I\,504}/A_{Zr\,92}$) *vs.* log $P(I_2)$] and by the Temkin equation [proportionality of ($A_{I\,504}/A_{Zr\,92}$) *vs.* log $P(I_2)$]. Figure 4 shows the results of the Temkin plot.

The smooth isotherms of Fig. 4 were used to obtain the pressures of iodine in equilibrium with three different surface coverages, corresponding to ($A_{I\,504}/A_{Zr\,92}$) of 0.2, 0.4, and 0.8. Graphs of the log of iodine pressure *vs.* reciprocal of absolute temperature for these isosteres are shown in Fig. 5 to be straight lines.

On the basis of the experimental results, we postulate that the interaction between gaseous molecular iodine and metallic zirconium involves the following mechanistic model. At the gas pressures (10^{-4} Pa or less) and surface temperatures (1000-1300 K) used, thermodynamic data (8) predict that monatomic iodine will be several orders of magnitude more abundant than molecular iodine. Hence the iodine molecules that strike the metal surface and become thermalized will dissociate; therefore the iodine can be assumed to be monatomic in its interaction with the zirconium. The iodine striking the surface either adheres to form an adsorbed layer on the metal or is evaporated into the gas. The iodine that adheres to the surface forms a chemisorbed layer from which volatile species can then evaporate. Such a model is consistent with the results of studies of the evaporation of halides from metal surfaces exposed to halogen gases (9, 10). It has been shown that the processes can be represented by the following steps: (*i*) the incident molecules adsorb dissociatively, (*ii*) surface reactions occur between the adsorbed species and surface metal, and (*iii*) the reaction products evaporate. The atom ratios of the species that evaporate were found to be in good accord with values calculated from equilibrium thermodynamics for several transition metal-halide systems (9-12).

To apply this model to the present system requires an evaluation of the equilibrium partial pressures of the gaseous species. The thermodynamic information required (13-16) to evaluate the partial pressures in equilibrium with zirconium metal are available (9). The calculation shows that the predominant species is monatomic iodine. At the lowest temperature (1000 K) and highest pressure (10^{-4} Pa) considered, there was a small contribution by ZrI_4 gas, which amounted to about 0.1% of the iodine atom pressure. The pressures of all other species were smaller.

The interaction model and the equilibrium gas pressures calculation show that it is now reasonable to treat the system in terms of the equilibrium between monatomic iodine gas and a chemisorbed layer of iodine on the zirconium surface. Thus, the data presented in Fig. 5 relate to the equation

$$Zr(c) + I(g) = ZrI\ (\text{adsorbed};\ \theta) \qquad [4]$$

in which θ represents surface coverage and is proportional to $A_{I\,504}/A_{Zr\,92}$, referred to below as θ'.

The solid zirconium iodide in equilibrium with zirconium metal has the composition $ZrI_{1.05}$, which can be considered to be the monoiodide (ZrI) (17). Its enthalpy of formation has been evaluated, and its absolute entropy has been estimated so that for equilibrium

$$Zr(c) + I(g) = ZrI(c) \qquad [5]$$

the standard free energy change $\Delta G°$ is

$$\Delta G° = -59{,}500 + 30.5T\ (\text{kcal/mole}) \qquad [6]$$

Thus the equilibrium partial pressure of monatomic iodine is

$$\log P(I, \text{atm}) = -13{,}000/T + 6.67 \qquad [7]$$

Interestingly, the coefficient of the reciprocal temperature term (proportional to the enthalpy change for the reaction) is the same as the slope of the lines drawn through the data points in Fig. 5. Thus the enthalpy change for reaction [4] is the same as that for reaction [5] and we write the following equations from the data in Fig. 5

$$\log P(I, \text{atm}) = -13{,}000/T + 2.44 \quad (\text{for } \theta' = 0.8) \qquad [8]$$

$$\log P(I, \text{atm}) = -13{,}000/T + 1.20 \quad (\text{for } \theta' = 0.4) \qquad [9]$$

$$\log P(I, \text{atm}) = -13{,}000/T + 0.51 \quad (\text{for } \theta' = 0.2) \qquad [10]$$

Thus, for the three levels of iodine coverage, the enthalpy change for chemisorption, considered in terms of formation of surface ZrI, is the same as the enthalpy of formation of solid ZrI. The differences in the thermodynamics of formation of the solid and the chemisorbed state lie in the entropies of the reactions and indicate that the chemisorbed ZrI species have substantially larger absolute entropies than the crystalline solid.

These results show that iodine chemisorbed on zirconium is thermodynamically more stable than combined in the zirconium iodides. The free energy of transfer of a gram atom of iodine from the lowest solid iodide (namely ZrI) to a partially covered zirconium surface can be evaluated from Eq. [7] and [10] to be

$$\Delta G(\text{iodine transfer}) = (6.67\text{-}0.51) \times 4.57 \times T = 28T \text{ cal/mole}$$

Thus there can be a significant thermodynamic driving force for such a transfer. In the overall process of iodine-induced SCC of zirconium alloys this has the following significance. Iodine can initially react with exposed zirconium surface and the solid iodides formed can act as a source of iodine available to be transferred at a later time to fresh zirconium surface that might be formed when the metal is strained. The mechanism by which iodine can be transferred is not elucidated by these thermodynamic considerations, but surface diffusion of iodide species or vapor transport as ZrI_4 gas are possibilities.

Conclusions

We have shown from Auger electron spectroscopy measurements that a heated zirconium surface exposed to iodine vapor acquires a chemisorbed layer of iodine. The variation with iodine pressure of fractional coverage of the zirconium surface can be fitted to a Temkin model. Interpreted in terms of an equilibrium thermodynamic model, the results suggest that chemisorption of iodine on zirconium at high temperatures involves the formation of a ZrI surface compound.

Rapidly Quenched Tungstate and Molybdate Composition Containing Lithium: Glass Formation and Ionic Conductivity

K. Nassau, A. M. Glass, M. Grasso, and D. H. Olson

Bell Laboratories, Murray Hill and Holmdel, New Jersey 07974

ABSTRACT

Extended glass-forming regions were found by twin-roller quenching in the systems of Li_2O with WO_3 and/or MoO_3. The crystallization of the glasses was studied by DTA and x-ray analysis; a new metastable crystalline phase was observed for $Li_2W_2O_7$. The glasses exhibited lithium ion conductivities in the 10^{-5}-10^{-6} $(\Omega\text{-cm})^{-1}$ range at room temperature which were in all cases much greater than the conductivity of the polycrystalline phases after crystallization. The corresponding Li^+ diffusion coefficients in the low lithium content tungstates in the glassy and crystallized phases are comparable to the values reported for the grain boundaries and grains of fine grained polycrystalline WO_3 electrochromic films.

The formation of oxide glasses by twin-roller quenching (1, 2) has permitted the preparation of a wide variety of new glasses and metastable crystalline phases. Of particular interest to us is the observation that many of the glasses prepared with alkali oxides exhibit reasonably high alkali ion conductivities (3-5), a characteristic which makes these materials of possible interest as battery cathodes or solid electrolytes. Our previous studies have dealt with the preparation (2, 6) and properties of niobate and tantalate glasses (2, 3), as well as systems of Li_2O with Al_2O_3, Ga_2O_3, and Bi_2O_3 (4, 7). In this paper we continue our survey of glass formation and alkali ion conductivity in oxide system formed by rapid quenching of Li_2O with the oxides of tungsten and molybdenum. In both of these systems extended glass forming regions were determined by differential thermal analysis (DTA) and x-ray diffraction studies. Previous work on glasses in limited parts of the alkali molybdate and tungstate systems has been summarized by Gossink (8).

We find that all the glasses within these systems exhibit lithium ion conductivities considerably greater than do the polycrystalline phases which are produced by heating the glass through the crystallization temperature, a result which could have practical implications if tungstates are to be used as cathodes in lithium batteries (9).

Lithium ion transport in WO_3 has already attracted considerable attention in connection with electrochromic devices (10). In this case the lithium is introduced by insertion into evaporated or sputtered WO_3 films. The results reported here may shed light on the nature of the diffusion mechanism in these materials.

Experimental

The twin-roller quenching technique (2), giving quenching rates of about 10^7 deg/sec (6), the identification of glass in the product (2, 6), and the a-c conductivity measurement technique using blocking electrodes (3) have been described previously in detail. The preparation and quenching parameters are given in Tables I and II. Reagents used were Apache Chemicals Incorporated 5*N* Li_2CO_3, J. T. Baker Chemical Company reagent grade tungstic acid, and Fisher Scientific Company, reagent grade MoO_3. Throughout this work the lithium content of the material is expressed as the Li cation fraction in the starting material, *i.e.*

$$Li = [Li]/([Li] + \Sigma[M])$$

where M represents all other cations present. Chemical analyses have shown that there is no significant change in composition on melting or quenching. Many of the glasses, particularly the high Li-content ones, were quite hygroscopic, so all specimens were stored in a dessicator. Although significant ionic conductivity can derive from moisture present (11), optical absorption and thermal annealing experiments showed that this did not contribute significantly to the measured ionic conductivities.

Key words: quenched glasses, ionic conductivity, lithium tungstate glasses, lithium molybdate glasses, lithium tungstate, metastable.

Glass Formation and Metastable Phases

Six tungstate, one mixed tungstate-molybdate and five molybdate compositions were quenched as outlined in Tables I and II. Essentially pure glass was obtained with a lithium content of 0.6 or less except for the two lowest tungstate compositions, where mixed glass and crystals occurred. Above 0.667 only crystalline material was observed. At an Li content of 0.667 no glass was detected by DTA but a small peak observed in the ionic conductivity measurements indicated traces of glass. Trace amounts of glass can sometimes be observed in conductivity measurements by studies of selected flakes of material since the glass occurs as a continuous phase in the spaces between crystallites. Since the glass phase usually has a higher conductivity than the crystal, a decrease of conductivity is observed at the crystallization temperature. In the tungstate system the crystallization paths on heating the glass were worked out in full detail and are given in the last column of Table I.

Li_2O-WO_3 compositions.—Parts of the Li_2O-WO_3 phase diagram have been studied by various workers (12-18). There is almost unanimous agreement that Li_2WO_4 (Li = 0.667) and $Li_2W_2O_7$ (Li = 0.50) melt congruently. A noncongruent melting WO_3-rich compound is either $Li_2W_4O_{13}$ (12, 13, 17) (Li = 0.333), $Li_2W_5O_{16}$ (14, 15) (Li = 0.285), or LiW_4O_{13} (18) (Li = 0.20). Additional compounds reported include nongruent $Li_6W_2O_9$ (15, 16) and also Li_4WO_5 and Li_6WO_6 (13, 15, 17) (Li = 0.75, 0.80, and 0.857, respectively). The existence of a metastable crystalline compound in the Li_2O-WO_3 system during low temperature reaction has been mentioned without any detail (19).

The compositions quenched were chosen so that some corresponded to congruent melting compounds (Li = 0.50 and 0.667), some to possible incongruent compounds (Li = 0.333 and 0.75), and two near probable eutectics (Li = 0.25 and 0.60). The occurrence of

glass does not appear to be related to any of these characteristics.

In the WO_3-rich compositions some WO_3 [the powder x-ray diffraction pattern matched JCPDS Card No. 20-1324 (20) or $WO_{2.9}$ (JCPDS 18-1417)] was present together with the glass formed. In the Li = 0.25 composition, the first exotherm at 340°C appears to correspond to the crystallization from the glass of additional WO_3 and the second at 430°C to the formation of $Li_2W_2O_7$ (JCPDS 24-664) as shown in Table I. In the case of Li = 0.333, the $WO_{2.9}$ formed converted to WO_3 (possibly simultaneously with some WO_3 crystallizing from the glass) and $Li_2W_2O_7$ again formed subsequently. In neither case was pure glass obtained, nor were any of the other expected compounds, particularly the Li = 0.333 one, observed.

Essentially pure glass was obtained at Li = 0.5 and 0.6, with glass transitions at 340°C and 325°C, respectively, as shown in Fig. 1. In the first of these compositions, a metastable phase was observed on crystallization at 370°C; this subsequently transformed to the expected stable $Li_2W_2O_7$ at 430°C. The x-ray diffraction patterns for this transformation sequence are shown in Fig. 2. The x-ray diffraction peaks of the metastable $Li_2W_2O_7$ formed by heating the glass to 420°C are given in Table III; indexing was not possible in the absence of single crystals. At Li = 0.60, however, there was an exotherm at 340°C above which no crystalline phase could be observed by x-ray diffraction. Subsequently, the expected mixture of Li_2WO_4 (JCPDS 12-760) plus stable $Li_2W_2O_7$ formed at 430°C, with a possible minor phase change at 470°C.

At Li = 0.667 and 0.75 only the expected Li_2WO_4 and $Li_6W_2O_9$ (JCPDS 25-503) crystalline phases were observed by x-ray diffraction and no glass crystallization exotherm by DTA, although the conductivity measurements indicated a trace of glass at Li = 0.667.

Li_2O-MoO_3 and mixed compositions.—Parts of the Li_2O-MoO_3 phase diagram have been studied by various workers (12-15, 21-22). There is only agreement on the congruently melting Li_2MoO_4 (Li = 0.667) and noncongruent $Li_2Mo_4O_{13}$ (Li = 0.333). There are also

possible noncongruent $Li_2Mo_4O_{13}$ (21), noncongruent $Li_2Mo_3O_{10}$ (12, 21), congruent $Li_4Mo_5O_{17}$ (22), and congruent $Li_2Mo_2O_7$ (12-14, 21); an Li_4MoO_5 has also been mentioned (15) (Li = 0.333, 0.40, 0.444, 0.50, and 0.80, respectively). Here too a metastable crystalline phase occurring during low temperature reaction has been mentioned without any detail (19).

In this system, glass was obtained at four compositions ranging from Li = 0.333 to 0.50 as shown in Table II. The intermediate crystalline phases produced on heating gave complex diffraction patterns and no extended effort was made to interpret these; they are designated "a" to "f" in Table II. At Li = 0.667 the conductivity measurement indicated a trace of glass.

One composition, Li_2MoWO_4 (Li = 0.50) was quenched in the mixed tungstate molybdate system and essentially pure glass was obtained. The final crystalline phase formed on heating had an x-ray diffraction pattern very similar to that of $Li_2W_2O_7$ (JCPDS 24-664), although one report (15) had indicated that solid solution probably did not extend to the center of the $Li_2Mo_2O_7$-$Li_2W_2O_7$ pseudobinary.

Baynton *et al.* (23) prepared a glass near $LiMoO_4$ by cooling milligram-size samples on platinum foil.

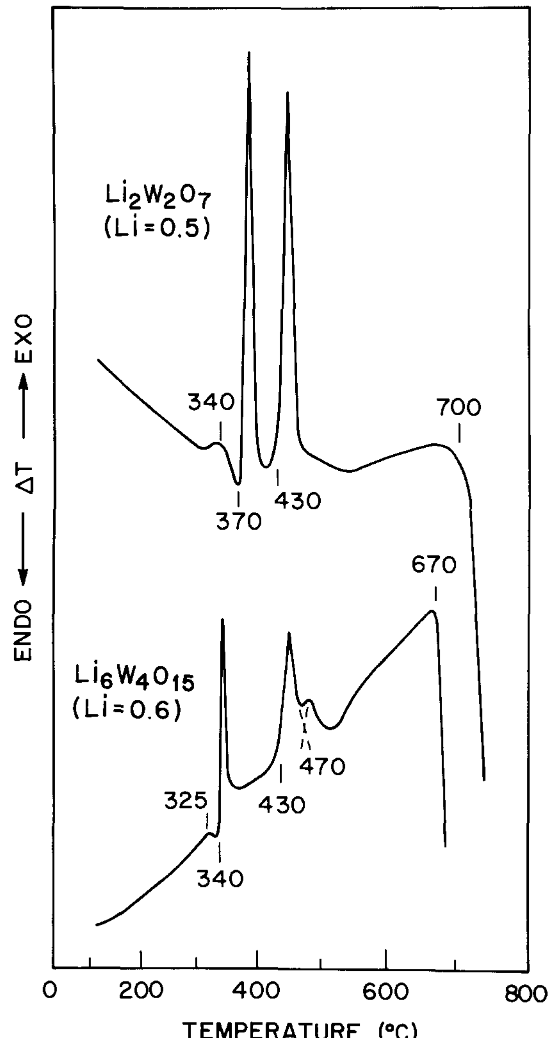

Fig. 1. DTA of quenched $Li_2W_2O_7$ (Li = 0.50) and $Li_6W_4O_{15}$ (Li = 0.60) in flowing N_2 at 20°C/min.

Stevels and co-workers used the same system to study parts of the alkali tungstate (24) and molybdate systems (21), including determination of the critical cooling rate (ccr) for glass formation to occur. The lowest ccr in the Li_2O-WO_3 system (24) was found near Li = 0.53 as about 2000 deg/sec with only a very small range of glass formation from Li = 0.51 to 0.54, extended by Gossink (8) down to 0.47. For the Li_2O-MoO_3 system (21) the minimum was near the same composition but at a ccr of about 25 deg/sec; glasses were obtained from about Li = 0.33 to 0.62, extended by Gossink (8) down to 0.17. Pure glassy MoO_3 had been previously reported by Sarjeant and Roy (25). The early workers (21, 24) appear to have been limited in their ccr to less than 10^4 deg/sec, while Gossink used splat cooling at about 10^6 deg/sec. Gossink measured a ccr of about 250 deg/sec in the mixed Li_2MoWO_7 composition.

The crystallization temperature was determined by Gossink (8) as the visual onset of crystallization, and his values were generally much higher than those in Tables I and II, indicating that he probably did not detect the initial crystallization but some later, advanced stage in the crystallizing process. These workers (8, 21, 24) also reported infrared spectra and discussed the possible structural aspects of glass formation in these systems.

The range of glass-formation in the Li_2O-MoO_3 system obtained in this report is consistent with these previous studies, but we have extended the range from the previous Li = 0.47-0.54 to 0.25-0.60 for the Li_2O-WO_3 system, this being consistent with our higher cooling rate of about 10^7 deg/sec.

Conductivity Measurements

The electronic conductivity, measured at d.c. with ionically blocking gold electrodes varied considerably from one flake to another, from values as high as 10^{-4} $(\Omega\text{-cm})^{-1}$ down to 10^{-10} $(\Omega\text{-cm})^{-1}$. Conductivities as high as 10^{-2} $(\Omega\text{-cm})^{-1}$ could be achieved by heating the flakes in hydrogen at temperature over 300°C, well below the crystallization temperature. Flakes with higher conductivities had a blue color due presumably to reduced tungsten or molybdenum ions. Only flakes having electronic conductivities below 1% of the total a-c conductivity were selected for ionic conductivity measurements with gold blocking electrodes.

Results, taken as a continuous function of temperature at 1 kHz, are plotted in Fig. 3 as log σ *vs.* $1/T$. In all cases the results fall on straight lines up to a temperature about 50° below the crystallization temperature. At the crystallization temperature T_{cryst} all compositions showed a maximum in the ionic conductivity indicating that the glass phase was more conductive than the polycrystalline phase. Typical data recorded by heating the sample through T_{cryst} followed by slow cooling in the crystalline phase is shown in Fig. 4. The peak in conductivity is much broader than the exotherm seen in Fig. 1 for the same material and no distinctive feature is observed at the temperature corresponding to the second exotherm. At room temperature the conductivity of the glass phase is some five

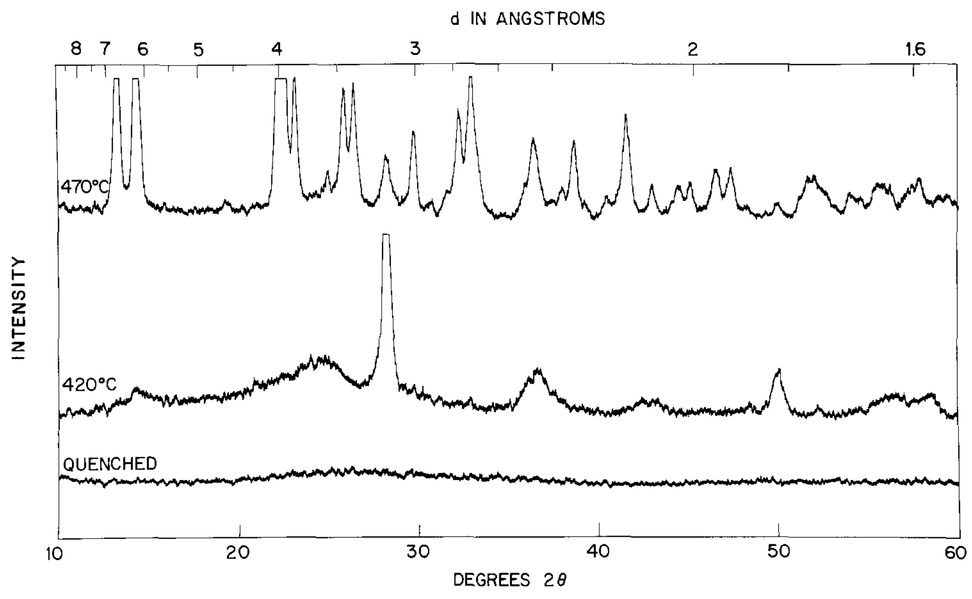

Fig. 2. Powder x-ray diffraction patterns of $Li_2W_2O_7$ as quenched, metastable crystalline phase after heating to 420°C, and as the stable crystalline phase after heating to 470°C.

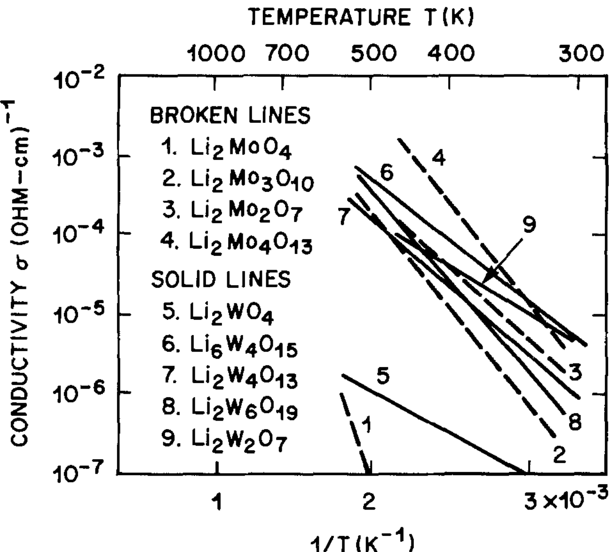

Fig. 3. Ionic conductivity of quenched lithium molybdates and tungstate glasses. Samples were pure glass except for 1 and 5, which were primarily crystalline. (In Ref. (4), line 6 was inadvertently drawn 10× too low). Also see note added in proof.

orders of magnitude greater than that of the same material after crystallization (extrapolated to room temperature).

The data in Fig. 3 show remarkably little variation of ionic conductivity with fractional Li ion content between 0.25 and 0.6. This is emphasized in Fig. 5 where conductivity is plotted as a function of Li ion content at two different temperatures. (The points at 0.667 cation percent are omitted since they were taken on primarily crystalline material so these values cannot be compared with the pure glass values.) These results are in marked contrast with the results for Li_2O-Al_2O_3, Li_2O-Ga_2O_3, and Li_2O-Bi_2O_3 glasses (4) in which the conductivity changed by several orders of magnitude over the same composition range. Furthermore, there does not seem to be any systematic varia-

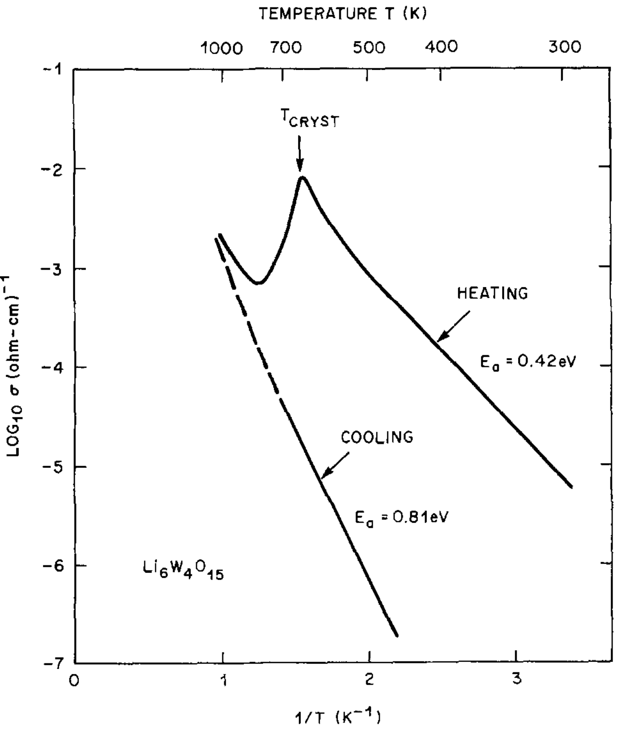

Fig. 4. Temperature dependence of the ionic conductivity of $Li_6W_4O_9$, measured at 1 kHz, upon heating through the crystallization temperature followed by slow cooling of the crystallized material.

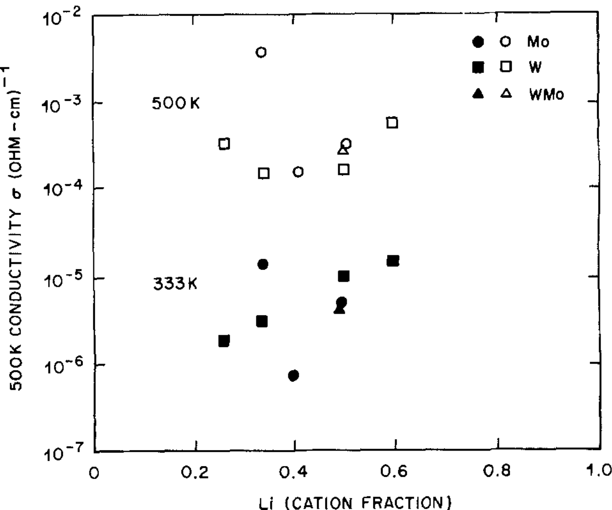

Fig. 5. Variation of the ionic conductivity at 500 K with the lithium content of quenched molybdate and tungstate glasses.

tion of the activation energy with Li ion content. Since the measured conductivity is just the product of the total concentration of Li ions, the ionic charge, and the average ionic mobility (averaged over all Li ions in the disordered structure), this result shows that the average mobility of the ions is not greatly affected by their concentration.

It is interesting to compare the diffusion coefficient of Li ions obtained from these conductivity measurements with apparent values in dry WO_3 films prepared by evaporation or sputtering (26). Films prepared in this way were found to be microcrystalline (26, 27) with up to 25% by volume of disordered material in grain boundary regions (10). There is some indication from the electrochromic behavior of the films that Li insertion proceeds by rapid diffusion along grain boundaries followed by slower diffusion into the crystallites. Using this model and the measured total diffusion coefficient, the estimated diffusion coefficient within the grain boundaries is (10, 26)

$$D \sim 10^{-11} \text{ to } 10^{-12} \text{ cm}^2/\text{sec}$$

and in the bulk (27)

$$D \sim 10^{-15} \text{ to } 10^{-16} \text{ cm}^2/\text{sec}$$

The diffusion coefficient obtained from conductivity measurement on bulk stoichiometric, electronically insulating lithium tungstate glasses may not be equivalent to lithium ion insertion into WO_3 where charge compensation occurs by simultaneous electron injection, in view of the differing oxygen content and higher electronic conductivity. The comparison is nevertheless interesting in view of the insensitivity of the ionic mobility to composition. Using the Nernst relation and the data of Fig. 4

$$\sigma = \frac{Ne^2D}{fkT}$$

where N is the concentration of lithium ions of charge e, we find that, if we take the correlation factor f for the glass phase at room temperature to be (28) 0.5, then

$$D \sim 10^{-11} \text{ cm}^2/\text{sec}$$

and after crystallization

$$D \sim 10^{-16} \text{ cm}^2/\text{sec}$$

Both these values are remarkably similar to those quoted above and are clearly in support of the two phase model for electrochromic films.

The conductivity data for the lithium molybdate glasses also shown in Fig. 3 and 5 are quite similar to those of the tungstate. The mixed composition Li_2MoWO_7 exhibited essentially the same conductivity

as the $Li_2Mo_2O_7$ composition. There was some variation of the ionic conductivity between glass samples quenched from the same melt (up to a factor of four) so that small differences in conductivity cannot be considered too significant.

To determine the effect of network forming additives to Li_2O-WO_3 glasses, 20 mole percent SiO_2, GeO_2 or B_2O_3 were added to the $Li_2O:2WO_3$ and the $5Li_2O:8WO_3$ compositions. In all cases pure glass was obtained, but no measureable difference of the ionic conductivity, within the experimental errors, due to the network forming additive could be detected.

Conclusions

Extended glass forming regions of the Li_2O-WO_3 and Li_2O-MoO_3 system have been found by using cooling rates of about 10^7 deg/sec. A new metastable phase which follows crystallization of the $Li_2W_2O_7$ composition is reported.

Lithium ion conductivities of all the molybdate and tungstate glasses studied are reasonably high, falling in the 10^{-5}-10^{-6} $(\Omega\text{-cm})^{-1}$ range at room temperature. Since the glasses can be made electronically conducting by suitable reduction of the material, these materials may be of interest as cathodes in lithium batteries. The measured conductivities yield lithium ion diffusion coefficients about 10^{-11} cm^2/sec in the glass phase and 10^{-16} cm^2/sec in the crystallized material which lends support to the grain boundary diffusion model for electrochromic WO_3 films.

Acknowledgments

We are grateful to W. C. Dautremont-Smith for valuable discussions concerning WO_3 electrochromic films.

Note Added in Proof: Measurements of the ionic conductivity as a function of frequency similar to those of Fig. 2 of Ref. (3), indicate that some blocking effects are already present at 1 kHz in the higher temperature regime (> 200°C). Data taken at 1 MHz suggest that the true ionic conductivities may be up to one order of magnitude greater than those shown in Fig. 3. The relative behavior of different compositions remains unchanged.

Technical Notes

The Chemical Vapor Deposition of Polycrystalline InP

Masahide Inuishi and Bruce W. Wessels*

Materials Research Center and Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois 60201

Heterojunctions involving indium phosphide have been suggested as possible candidates for solar cells because of the optimal match of the bandgap of indium phosphide with the solar spectrum (1). Moreover, since indium phosphide has a direct bandgap and a large absorption coefficient, it appears feasible to

* Electrochemical Society Active Member.

Key words: thin films, polycrystalline semiconductors.

prepare indium phosphide photovoltaics in thin film form.

Recently, the preparation of thin films of indium phosphide for use in polycrystalline solar cells has been investigated. Deposition techniques that have been studied include planar reactive deposition (2), chemical vapor deposition (CVD) from organometallics (3), and phosphorus trichloride (4, 5). In this paper experiments on the chemical vapor deposition of polycrystalline indium phosphide onto molybdenum substrates using an alternative method are examined. It is shown that using $In/HCl/PH_3/H_2$ system homogeneous thin films of InP can be deposited at temperatures as low as 410°C.

Experimental Conditions

The system used for the preparation of InP was similar to that described previously for the deposition of other III-V compounds from hydrides (6, 7). Reactant gases included electronic grade HCl, a 5% mixture of electronic grade phosphine in ultrahigh purity hydrogen, and palladium-diffused hydrogen as the carrier gas. Elemental indium of 5 nines' purity was the metallic source. Thin films of indium phosphide were deposited onto molybdenum substrates which were 0.1 mm × 100 mm^2 in size and had a (100) preferred orientation. Before deposition the substrates were ultrasonically cleaned in trichloroethylene and methanol, subsequently etched in a $1H_2SO_4$-$1HNO_3$-$3H_2O$ solution. In some experiments the Mo substrates were mechanically abraded in order to improve film nucleation (8).

Typical growth conditions consisted of an indium source temperature of 750°C and substrate temperatures of 410°-620°C. The phosphine and hydrogen chloride flow rates were 3.5 and 3.0-7.5 cm^3/min, respectively. The hydrogen flow rate over the In source was 180 cm^3/min, with a total hydrogen flow rate through the system of 280 cm^3/min.

The thickness of the deposited layers was obtained from the weight gain of the substrate and by optically measuring the cross sections for films with thicknesses of greater than 2 μm. In order to determine the degree of preferred orientation of the as-deposited films, relative x-ray intensity was measured with an x-ray diffractometer and subsequently compared to an ASTM standard. Correction for film thickness on the x-ray intensities was neglected as it was observed to have a negligible contribution.

Results

Growth kinetics.—Homogeneous growth of InP on molybdenum substrates was obtained only with careful control of the indium transport efficiency. Previous studies have shown that indium transport is extremely sensitive to gas flow conditions (9). The theoretical transport efficiency can be obtained by considering the source reaction

$$x\mathrm{In}_{(l)} + \mathrm{HCl}_{(g)} \rightarrow x\mathrm{InCl}_{(g)} + (1-x)\mathrm{HCl}_{(g)} + \frac{x}{2}\mathrm{H}_{2(g)}$$

where x the transport efficiency is defined as

$$x = \frac{n_{\mathrm{InCl}}}{n_{\mathrm{HCl}}}$$

the mole fraction of HCl converted to InCl.

Theoretically predicted conversion efficiency was obtained by adjusting flow conditions by the addition of baffles into the gas stream between the source and the substrate. For a source temperature of 750°C, the indium transport rate was linear with HCl input pressure as shown in Fig. 1. At total linear gas flow rates of 1 cm/sec the transport efficiency observed was 0.98, which is a good agreement with theoretical analyses (9).

The temperature dependence of the growth rate of polycrystalline indium phosphide was found to decrease exponentially with decreasing temperature

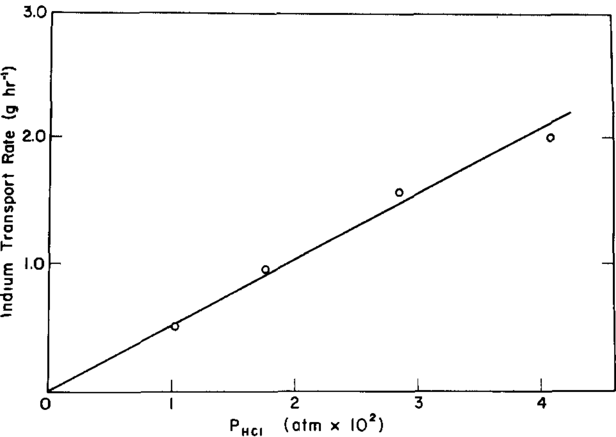

Fig. 1. Indium transport rate as a function of HCl input pressure. The source temperature is 750°C. Solid line indicates theoretically predicted rate.

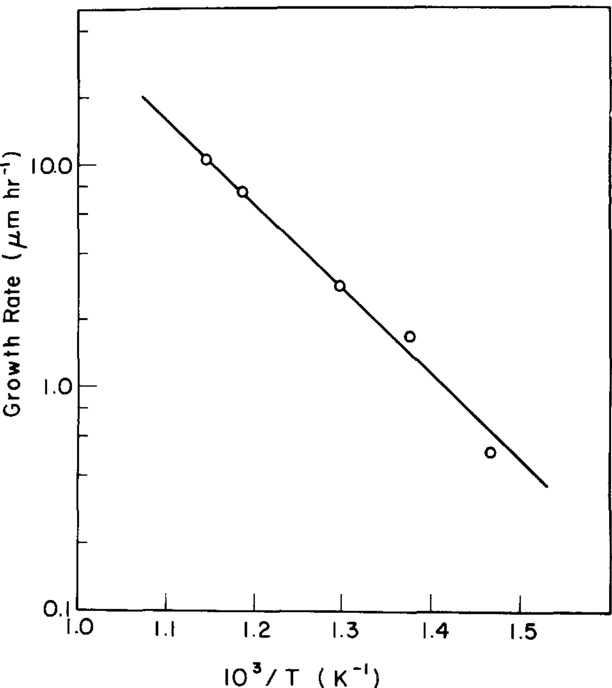

Fig. 2. Temperature dependence of growth rate for InP deposition. The HCl and PH_3 partial pressures were 1.6 × 10^{-2} and 1.0 × 10^{-2} atm, respectively.

(Fig. 2). Thus the growth of the InP films by CVD is an activated process. An Arrhenius plot of the deposition rate indicates an activation energy of 17.7 kcal $mole^{-1}$. This agrees well with the 15 kcal/mole observed by Saitoh *et al.* (4) for InP deposition using the $PCl_3/In/H_2$ reactant system. It should be noted that in the present study films were deposited at temperatures as low as 410°C, 250°C lower than that normally used in InP chemical vapor deposition. Low substrate temperatures are of course desirable to minimize film contamination by the substrate as a result of interdiffusion.

The kinetic model for the activated deposition process was established from the effect of PH_3/HCl reactant ratio on growth rate. For PH_3/HCl reactant ratios of less than 0.33 it was observed that the growth rate was strongly dependent upon the partial pressure of phosphine. For higher PH_3 pressures the growth rate saturated to a limiting value of 15 μm/hr as shown in Fig. 3. This dependence of film growth rate on phosphine pressure suggests that adsorption of phosphorus or a phosphorus-containing species by a Langmuir-

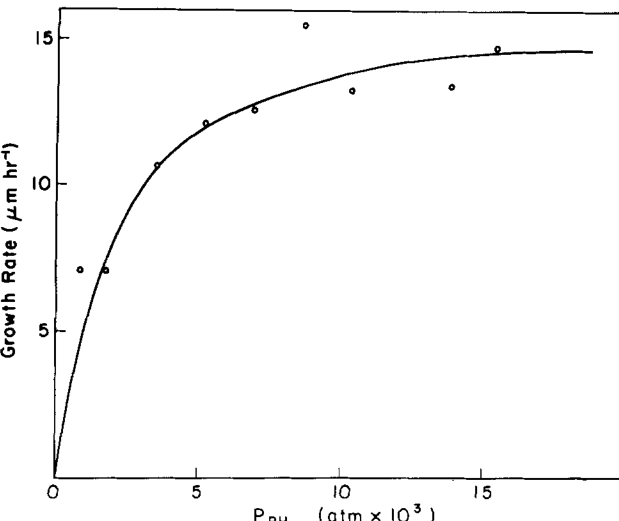

Fig. 3. The effect of PH_3 partial pressure on growth rate. The substrate temperature is 620°C and the partial pressure of HCl is 2×10^{-2} atm.

type mechanism is the rate-limiting step for indium phosphide film growth.

The proposed kinetic model was confirmed by plotting the data on the indium phosphide growth rate *vs.* phosphine pressure in an alternate form. If the InP growth rate G depends on the adsorption of a monolayer of phosphorus, then G should follow the Langmuir adsorption equation

$$y = K\theta = \frac{aP}{1 + bP} \quad [1]$$

where y is the amount of phosphorus adsorbed per unit area and is proportional to the surface coverage θ in Eq. [1]. The quantity P is the pressure, a and b are constants. By equating G to y and rearranging Eq. [1] we obtain

$$\frac{P}{y} = \frac{1}{a} + \frac{bP}{a} \quad [2]$$

or

$$\frac{P_{PH_3}}{G} = \frac{1}{a'} + \frac{b'P_{PH_3}}{a'} \quad [3]$$

Since a' and b' are constants, plotting P_{PH_3}/G *vs.* P_{PH_3} should yield a straight line as shown in Fig. 4. Good agreement between Eq. [3] and experimental observations over an order of magnitude of phosphine pressure variation is noted, supporting the conclusion that adsorption of phosphorus plays a key role in the growth of InP films by chemical vapor deposition.

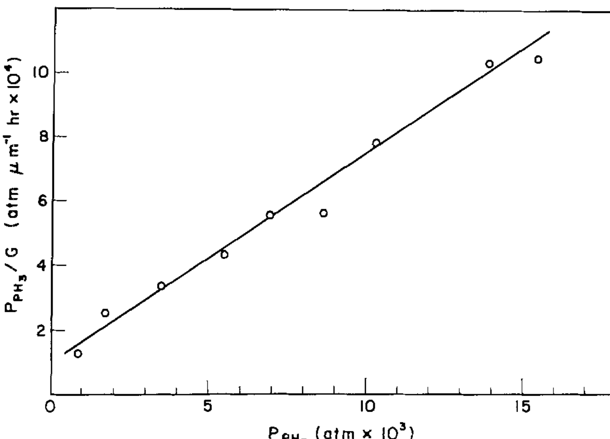

Fig. 4. Application of Langmuir equation to the growth of InP on Mo at 620°C.

Adsorption of phosphorus was also found to be important in the planar reactive deposition of InP at the sub-atmospheric pressures (10^{-4} Torr), Fraas *et al.* (2) observed that in order to obtain stoichiometric films, it was necessary to prepare the films under excess phosphorus conditions. Thus vapor deposition of indium phosphide is apparently controlled by the same type of surface reaction mechanisms at both high and low pressures.

Film structure.—Using x-ray diffractometer techniques the phases and the preferred orientation of the as-grown InP were analyzed. Films grown under stoichiometric as well as phosphorus-rich conditions are single phase and have diffraction lines characteristic of cubic indium phosphide. As shown in Fig. 5, at substrate temperatures below 500°C the films had predominantly a {111} texture, though as the substrate temperature was increased other orientations appeared including the {200} {220} {331} {311} planes. Nevertheless, the {111} remained the dominant orientation. Even for films as thin as 1 μm, preferred orientation was still prevalent.

The indium phosphide film morphology was observed by using optical and scanning electron microscopy. Films were found to be continuous over the entire 100 mm² area. The grain size of the as-deposited films also depended on temperature. For material grown at 620°C, the average grain size was 6 μm; whereas for films grown at temperatures of less than 500°C, the grain size was less than 1 μm (Fig. 6). Increased surface roughness coincided with the decrease in the preferred orientation.

Conclusions

These studies demonstrate that homogeneous InP polycrystalline thin films can be grown at temperatures as low as 410°C, using the hydride deposition technique. Films prepared at temperatures below 500°C have a preferred {111} orientation. Grain size of the films varied from 6 μm to less than a micron

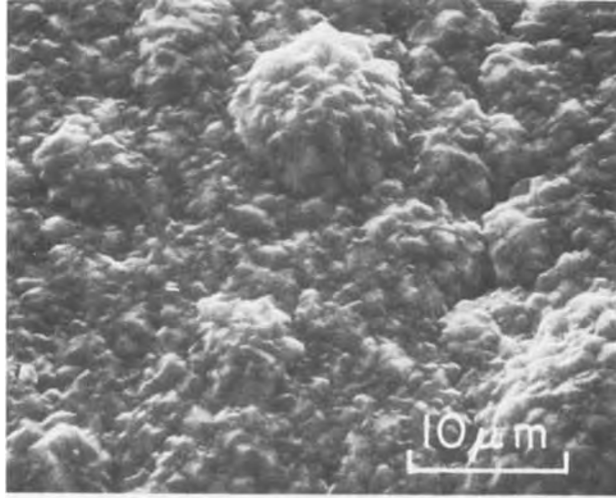

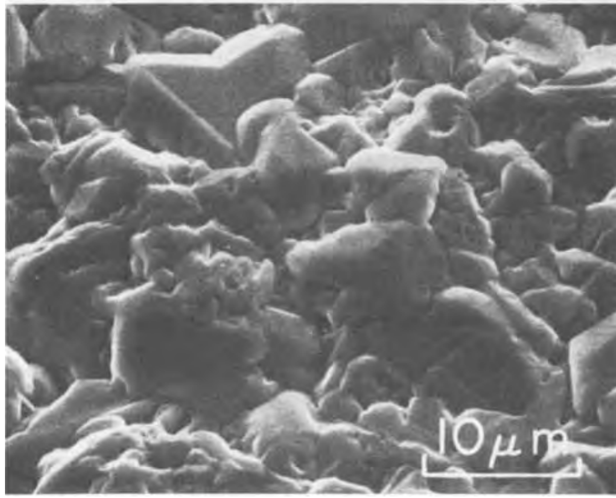

Fig. 6. Scanning electron micrographs of as-deposited InP films: (a, top) $T_{substrate} = 500°C$; (b, bottom) $T_{substrate} = 620°C$.

depending on the deposition temperature. Kinetic studies support that adsorption of phosphorus via the Langmuir mechanism controls the growth rate of the polycrystalline InP films over the temperature range studied.

Miniature Cantilever Beams Fabricated by Anisotropic Etching of Silicon

Richard D. Jolly[1] and Richard S. Muller

Department of Electrical Engineering and Computer Sciences and the Electronics Research Laboratory, University of California, Berkeley, California 94720

Anisotropic etching of single crystal silicon was shown to be capable of producing ultrasmall three-dimensional micromechanical devices (1). Petersen has used thin, metal-coated, SiO_2 cantilever beams made by this technique in light-modulator arrays (2), and for miniature switches (3). Roylance (4) and Rossvold (5) etched cantilever beams in silicon diaphragms to construct piezoresistive accelerometers.

Different beam structures are required for the most effective use of micromechanics with piezoelectric field-effect transducers (PI-FET's) (6). Preferred for this purpose is a beam in which thermal oxide separates one conducting electrode from another. Strain-induced charge in a piezoelectric can then be inhibited from relaxation so that a response to a d-c-applied strain is possible.

[1] Present address: Hewlett-Packard Laboratories, Palo Alto, California 94304.

Key words: mechanics, membrane, capacitance, composites.

This paper describes the construction of such beams as well as other beams with useful cross sections. The fabrication process is compatible with ion-implanted MOS planar technology.

Fabrication

The anisotropic etching of silicon makes use of ethylenediamine, pyrocatechol, and water (EDP) (7). The etchant can remove the silicon from below a layered structure consisting of SiO_2 and heavily-doped p-type silicon. We have used this process to construct four types of miniature cantilever beams having the cross sections sketched in Fig. 1. The beams consist of cantilevers: (*i*) with thin (100 nm) SiO_2 layers covering 200 nm of bulk p^+ silicon; (*ii*) with thin SiO_2 on bulk p+ silicon isolated from the substrate by a thick oxide beam (800 nm); (*iii*) formed of 200 nm thick p+ silicon; (*iv*) formed of 800 nm thick SiO_2.

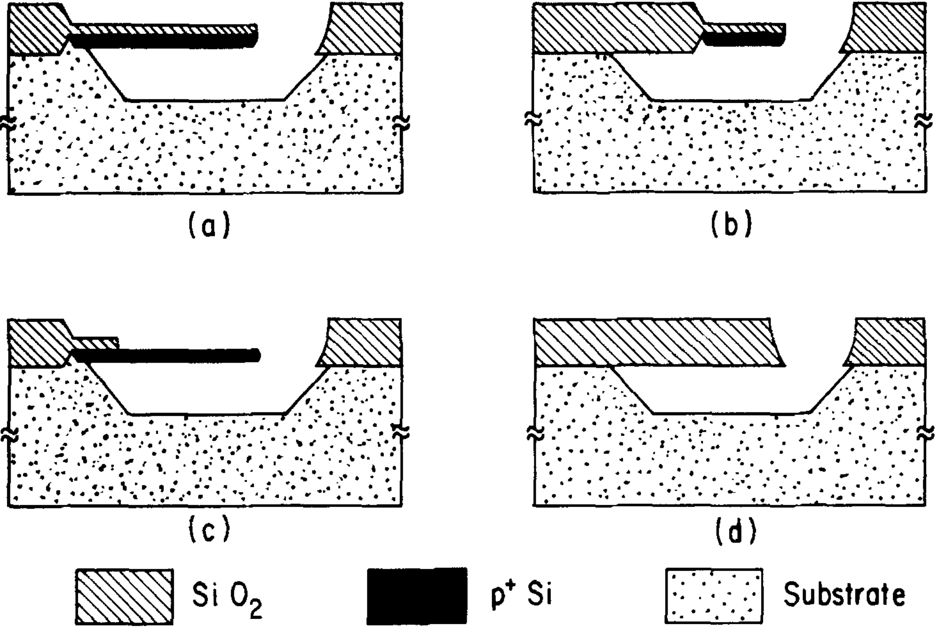

Fig. 1. Cross sections of the four types of miniature cantilever beams.

Each of the four types of beams were processed in widths varying from 5 to 40 μm, at lengths varying from 15 to 160 μm. The size of the cavity under the cantilevers is a function of the etch time—it is typically between 15 and 50 μm in depth.

All beams were fabricated on both p- and n-type substrate material. The starting wafers were B-doped, 4 Ω-cm <100>-oriented Si for the p-substrate and P-doped, 6 Ω-cm <100>-oriented Si for the n-substrate. To process the wafers, first a thick (800 nm) oxide is grown in a steam atmosphere at 1100°C followed by a 20 min anneal at the same temperature in N_2. Next, the oxide is patterned with buffered HF, and 100 nm of oxide is grown in a dry O_2-TCE ambient for 32 min at 1100°C. This step is also followed by a 20-min anneal at 1100°C in N_2. The p+ region is formed using an ion implant of BF_2^+ at 180 keV with a dose of 10^{16} cm^{-2}. An anneal at 600°C in N_2 and O_2 for 6 hr follows, after which the dopants are activated at 950°C in N_2 for 40 min. A computer simulation [using SUPREM (8)] predicts that this process results in a B concentration greater than roughly 10^{20} cm^{-3} in a layer extending about 0.4 μm downward from the Si-SiO_2 interface. Below this, the B concentration drops very steeply.

The beams are formed using EDP anisotropic etchant (8 ml water: 17 ml ethylenediamine: 3g pyrocatechol) at a temperature of 110°C using a glass refluxing system. The etch rate for the (100) plane is approximately 50 μm/hr.

Discussion

Figure 2 collects data about the micro-beams on a map with coordinates equal to the beam thickness t and the beam width w. The data points marked with an x represent beams which were broken or else so severely bent as to be useless as mechanical cantilevers. These failures in fabrication may result from the excessive stress present because of mismatched mechanical properties at the Si-SiO_2 interface.

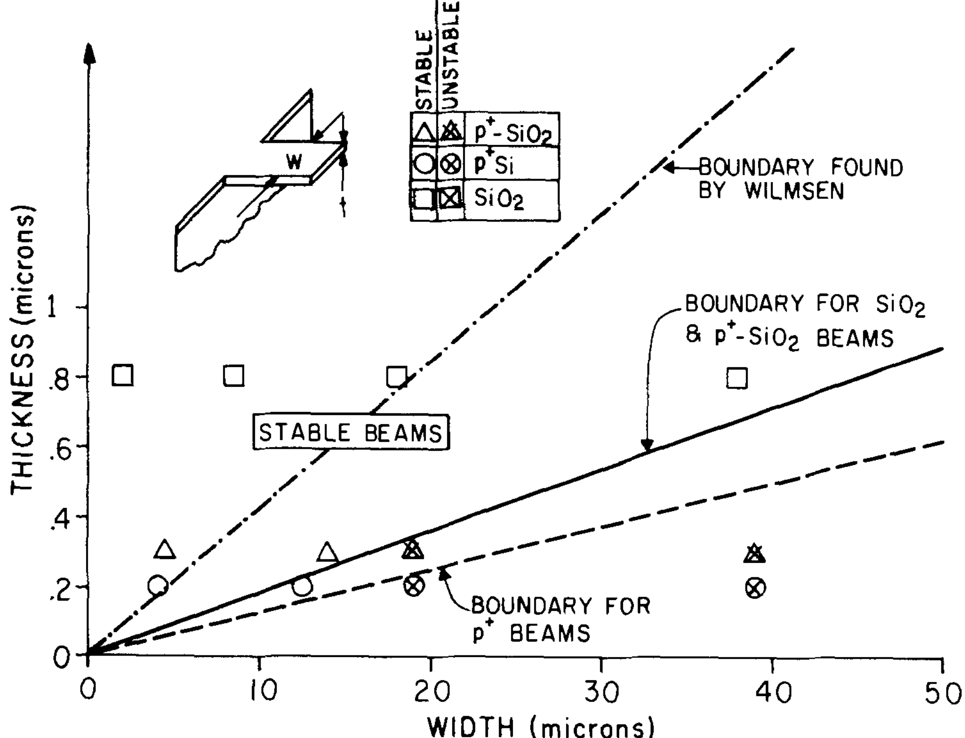

Fig. 2. "Map" of thickness vs. width of successful beam fabrications. The sloped lines indicate the lower bounds for t/w ratios that were produced: *(i)* solid line for oxide and composite Si-oxide beams, *(ii)* double dashed line for pure Si beams, and *(iii)* dot-dash line for unsupported SiO_2 windows as found by Wilmsen et al. (9).

Because the coefficient of thermal expansion for Si is greater than that for SiO_2, films formed by thermal oxidation are compressed when the processed wafer is cooled after oxidation. Wilmsen, Thompson, and Meissner (9) have discussed the effect of this energy on the buckling and fracture of unsupported SiO_2 windows. By applying elasticity theory, they show that it is not possible to obtain a stable oxide film if the ratio of its thickness to the window dimension t/w is made too small. The lower permissible limit for the t/w ratio is related to the difference in the coefficients of thermal expansion for Si and SiO_2 and to the change in temperature. By considering most and least restrictive boundary conditions, Wilmsen was able to show that the lower limit on t/w should be bounded according to Eq. [1]

$$0.52 \sqrt{\Delta\alpha\Delta T} < t/w < 1.2 \sqrt{\Delta\alpha\Delta T} \quad [1]$$

where $\Delta\alpha$ is the difference between the coefficients of thermal expansion for the SiO_2, and ΔT is the change in temperature. Wilmsen *et al.* fabricated stable windowed structures for $t/w > 0.7 \sqrt{\Delta\alpha\Delta T}$. This boundary is indicated by the dot-dash line on Fig. 2.

The cantilevered structures we studied are freed of stress on three sides and therefore not strictly comparable to the SiO_2 windows examined in Ref. (9). However, qualitatively similar results on SiO_2 film stability were obtained in this study. As seen in Fig. 2, the apparent lower bound for t/w for these cantilever beams is $0.4 \sqrt{\Delta\alpha\Delta T}$ for stable SiO_2 beams [Fig. 1(d)] and stable SiO_2 on p^+ Si beams [Fig. 1(a)]. Stable p^+ Si beams were obtained for $t/w > 0.27 \sqrt{\Delta\alpha\Delta T}$. These boundaries are also shown on Fig. 2. For our process, the oxide growth was carried out at 1100°C so ΔT is roughly 1075°C. For Si and SiO_2, $\Delta\alpha$ is 2×10^{-6}, so that $\sqrt{\Delta\alpha\Delta T} = 0.046$.

The differing thermal expansions for Si and SiO_2 are also responsible for bending observed in composite beams. When a cantilever of Si and SiO_2 is formed, it can be expected to bend downward as the tension in the Si and the compression in its oxide seek accommodation. However, cantilevers formed of one homogeneous material should not be bent in either direction unless there is some reconfiguration caused by the release of stored strain energy.

Figures 3 through 7 are SEM photographs of the cantilever beams. The beams were coated with roughly 20 nm of gold to avoid charging by the SEM electron beam. This coating had no appreciable effect on the mechanical loading of the structures. Figure 3 shows examples of three types of beams, all constructed with a mask dimension for the width of 10 μm and for the length of 30 μm. Bending in two of the beams may have resulted from the thermal-mismatch stress. As expected, the oxide-silicon beam bends downward. The bending in the thin Si beam may have resulted from plastic deformation of one surface or from inhomogenity of mechanical properties due to processing. Petersen (1) observed similar effects on some beams.

Figure 4 shows an 800 nm SiO_2 beam (lower structure), as shown in Fig. 1(d), adjacent to a beam composed of 100 nm of SiO_2 overlaying roughly 200 nm of p^+ silicon. This two-layer beam has the p^+ silicon underneath the oxide extending beyond the SiO_2 edge to facilitate inspection. The thickness of the p^+ layer has been estimated using these photographs and the known magnification of the SEM. When inspected with an optical microscope, the p^+ layer causes characteristic color fringes below the SiO_2 film.

Figure 5(a) shows a Fig. 1(b)-type beam (lower cantilever) next to an 800 nm thick oxide beam [Fig. 1(d)]. In Fig. 5(b), the tip of the lower beam of Fig. 5(a) has been magnified to show the p^+ Si projecting from beneath the 100 nm oxide. Figure 6 is an SEM photograph of a cantilever of thin p^+ Si [similar to Fig. 1(c)] below a beam of thick oxide [Fig. 1(d)].

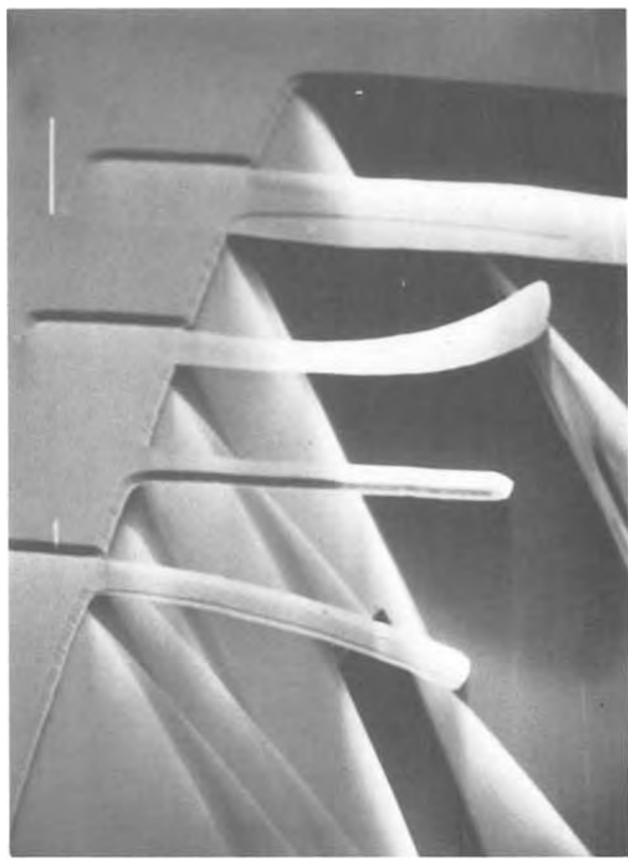

Fig. 3. SEM photograph of 3 types of miniature cantilever beams. From bottom to top: thin SiO_2 on p^+ Si [as in Fig. 1(a)], thick SiO_2 [as in 1(d)], thin p^+ Si [as in 1(c)], SiO_2 on p^+ Si (magnification 2000×, specimen angle 72°). The uppermost beam has 7 μm of extended p^+ Si and is incompletely etched.

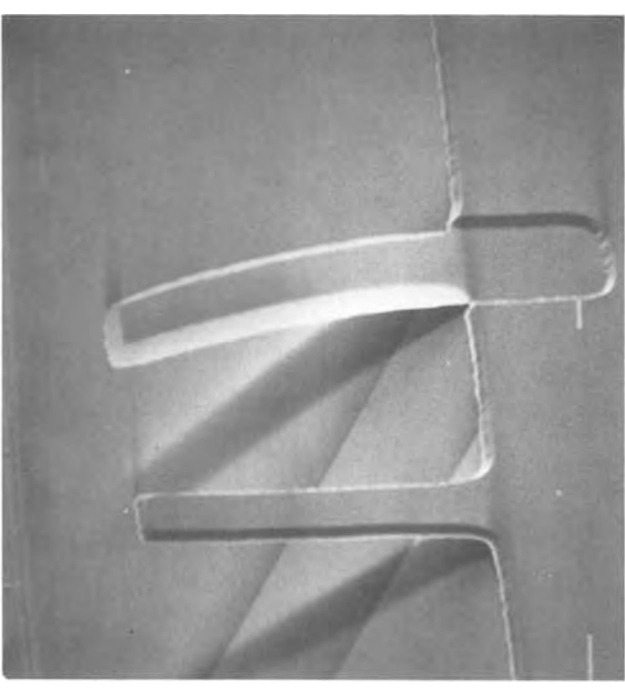

Fig. 4. SEM photograph of an SiO_2 beam (lower structure) and an SiO_2 on p^+ Si beam [Fig. 1(a)] (2000×, 50°).

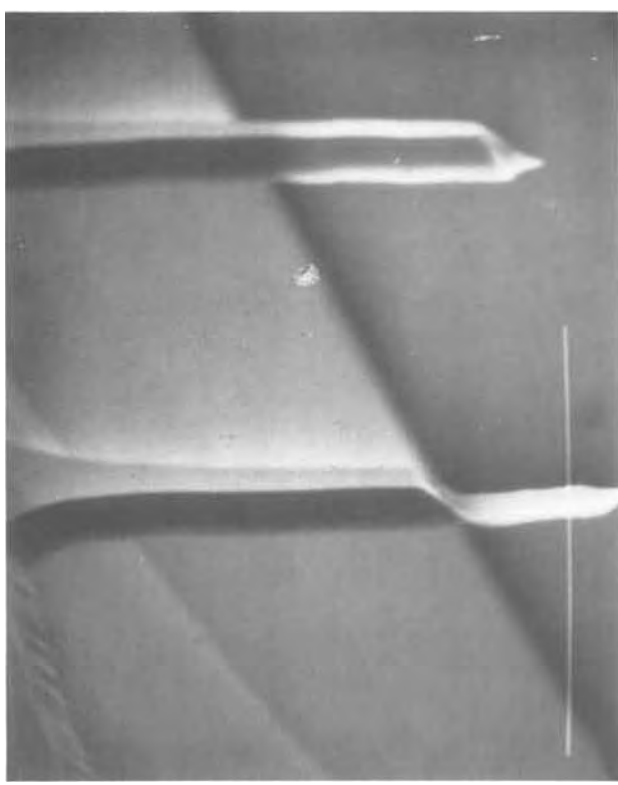

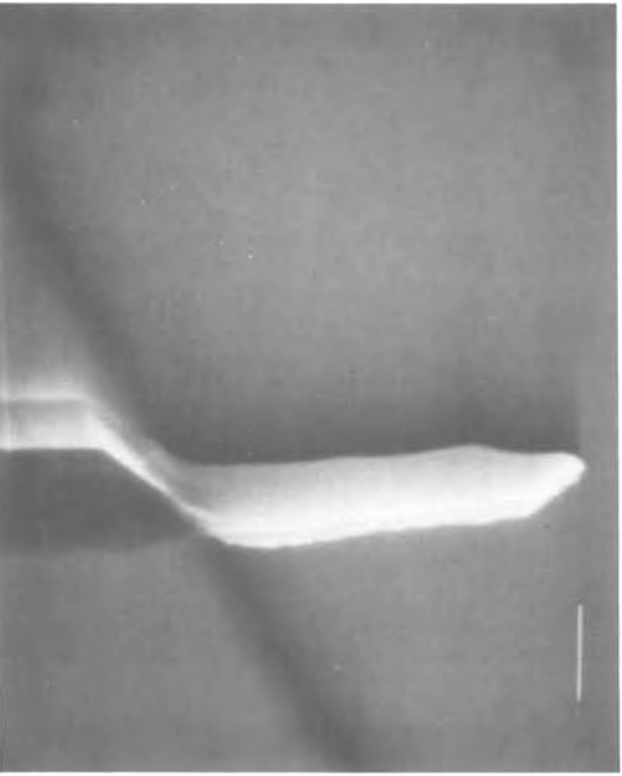

Fig. 5. (a, left) SEM photograph of a beam of SiO_2 on p^+ Si isolated by a beam of thick SiO_2 [Fig. 1(b)] (7500×, 75°), (b, right) an enlargement of the tip of the beam shown in (a) (20,000×, 75°).

Samples of all types of beams were fabricated without mechanical damage in widths ranging from 4 to 12 μm at lengths of 15-40 μm. Widths greater than 12 μm were only successfully constructed with the 800 nm SiO_2 films unless a stiffening technique was employed as in the cantilever shown in Fig. 7. A thicker oxide ridge (800 nm) has been left on the periphery of the cantilever to form a stiffer and more rugged beam.

Fig. 6. SEM photograph of a beam of thin p^+ Si (lower beam) (5000×, 30°), the upward-bending of this cantilever is unexpected, but observed on some beams.

Conclusions

The methods demonstrated in this work may apply to a number of electronic systems. Of particular importance is the fabrication of conducting layers underneath thermally-grown SiO_2. With this construction, the beam itself can be an electrical capacitor with very low leakage. It might be used to isolate a piezoelectric thin film on top of the beam, allowing direct reading of the surface charge on the piezoelectric. Other applications in the transducing area are also of interest

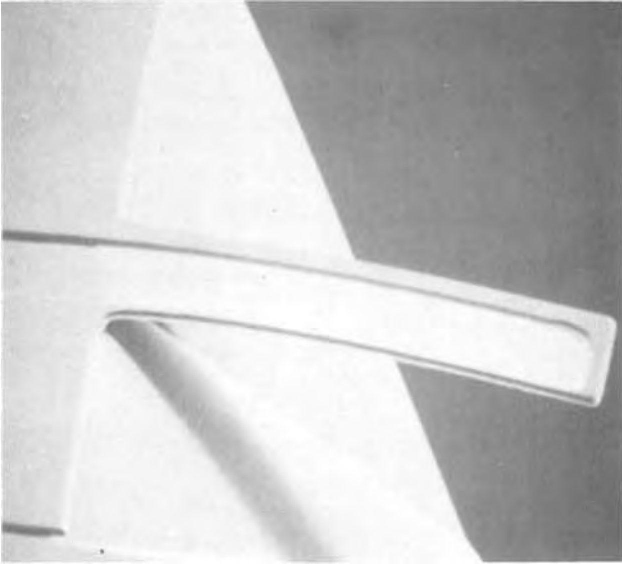

Fig. 7. SEM photograph of a thin SiO_2 on p^+ Si beam [Fig. 1(b)]. The beam is 20 μm in width and has been reinforced by a thick rib of SiO_2.

wherever the electrical isolation of one material from another is desired.

Although we studied only cantilever structures, doubly-supported beams consisting of SiO_2 supporting thin p^+ silicon could be built. Such beams could have applications to silicon integrated circuits in the production of transmission lines with very low capacitance per unit length. The transmission lines would be composed of the p^+ silicon layers overlain with insulating oxide suspended above cavities etched from the silicon by EDP.

Observation and Analysis of Surface States on TiO_2 Electrodes in Aqueous Electrolytes

R. H. Wilson (pp. 228-234, Vol. 127, No. 1)

J. F. Julião,[1] Franco Decker,[2] and M. Abramovich:[2] In a paper recently published[3] and coauthored by B. A. Parkinson, H. C. Chagas, and ourselves, a very similar effect on TiO_2 electrodes was reported and discussed on the basis of different electrochemical techniques. The potential of the peak observed by Wilson, the dependence of the peak height on the scan rate, and the effect of alkaline solutions on the phenomenon are very similar to that observed in our work. Our reduction peak, however, was observed in the dark, without previous u.v. illumination (therefore with no oxygen in the cell) and was reversible under cyclic voltammetry. No peak was seen unless the sample was previously held in contact with concentrated KOH or NaOH solutions for a few hours.

The presence of surface states is a reasonable explanation for such phenomena. However, it has been shown by Tomkiewicz[4] that with a proper surface treatment such states can be avoided on TiO_2, and straight $1/C^2$ *vs.* voltage plots result as a consequence. We have recently observed a correlation between the reduction peak, straight $1/C^2$ *vs.* voltage plots and surface treatment.

TiO_2 samples (001 surfaces) freshly polished with 0.25 μm diamond paste or polished and subsequently etched at 240°C for 30 min in a concentrated solution of sulfuric acid and ammonia sulfate (1:1) did not show the reduction peak in the cathodic region of the *i vs. V* curves, when phosphate buffer, 1M Na_2SO_4, or 1M H_2SO_4 were used as electrolytes. The $1/C^2$ *vs.* voltage plots for the same samples were linear for potentials up to 1.5V positive of the flatband potential (Fig. 1 of this discussion).

After these samples were immersed for 16 hr in 5M KOH two behaviors were observed: the etched samples showed the same behavior as before, while the polished ones showed now the reduction peak and nonlinear $1/C^2$ *vs.* voltage plots. A mechanical polishing, however, restored the same characteristics as prior the KOH treatment. The flatband potential as measured from capacitance plots had a Nerstian dependence on pH for the freshly prepared or repolished samples, while the samples aged in KOH had a much steeper slope (see Fig. 2 of this discussion), a behavior also observed by Wilson on page 232 for his samples.

Our experiments show that surface states are easily created on TiO_2, but can also be removed by proper treatments. Therefore, we believe it is very important to characterize the surface preparation of TiO_2 electrodes, due to its influence on the results. The relevance of surface states for photoelectrolysis, however,

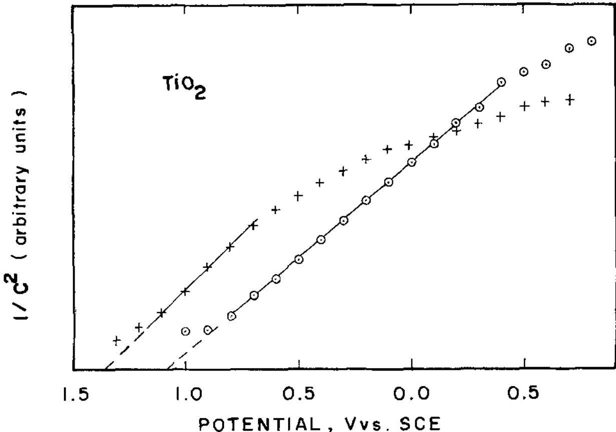

Fig. 1. $1/C^2 \times V$ plots of TiO_2 electrodes in a phosphate buffer solution, pH = 11. The circles are for a freshly polished sample. The crosses are for a KOH-aged sample.

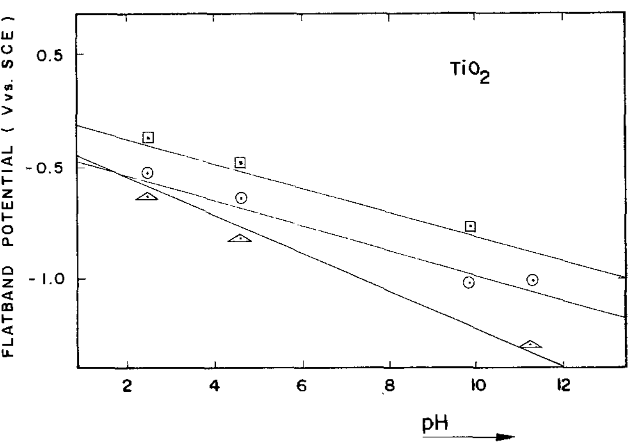

Fig. 2. Flatband potential as a function of pH for a TiO_2 sample after three different surface treatments: circles: freshly polished; triangles: aged in KOH; squares: repolished.

is still a big question. Actually, there is probably no relationship between the kind of surface states we observed and photoelectrolysis, since the photo-current-potential curves we measured (*i vs. V* plots in the anodic region, with illuminated electrode) were very much the same both for the fresh and for the KOH-aged samples.

R. H. Wilson:[5] The comments by Julião *et al.* are interesting but have very little to say about the principal observations and conclusions in the paper under discussion. The potential of the reduction peak described in my paper and its dependence on illumination demonstrate that it is not the same peak discussed by Julião *et al.*

While the observations reported by Julião *et al.* are interesting, they must be interpreted with care. The near surface bulk properties of TiO_2 can be affected by electrochemical exposure and by mechanical polishing.[6,7] These can change the capacitance-voltage behavior as observed in differential capacitance measurements as well as in capacitive currents observed during a voltage sweep. These possible changes in bulk properties have not been considered by Julião *et al.* in interpreting their observations.

Silicon Deposition on a Rotating Disk

R. Pollard and J. Newman (pp. 744-752, Vol. 127, No. 3)

Michael L. Hitchman:[8] In deriving theoretical transport-controlled growth rates for CVD processes the effect of the temperature gradient close to the reaction surface is usually neglected in order to obtain a simple analytical treatment, and values of gas properties corresponding to some average temperature are taken. A simple consideration of the differential equations for fluid flow and heat and mass transfer shows[9] that one might expect the steep temperature profile commonly encountered at a susceptor surface to lead to a considerable distortion of the diffusion boundary layer and hence of the growth rate. Nevertheless, the agreement between theory based on constant gas property conditions and experiment for various reactor geometries is usually reasonable.[9] However, in order to make use of this approximate approach one still has to obtain an exact solution to the constant property problem, and although this is simpler than for the variable property case it is not always easy, especially for those instances where there is distortion of boundary layers by, for example, reactor walls. Therefore the one-dimensional rotating disk system which has been such a powerful tool for studies with solutions could be expected to be equally valuable for the investigation of CVD processes. The paper under discussion extends the theory of fluid dynamics and transport of a disk rotating in an isothermal medium to one in nonisothermal medium. The analysis should allow one to take account of the variation with distance from the surface of a heated disk of the physical properties of the medium and of the change of equilibria and kinetic rates for homogeneous processes. A more exact comparison between theory and experiment than the approximate approach allows should then be possible for CVD processes, such as the epitaxial deposition of silicon quoted in the paper

$$SiCl_4 + 2H_2 \rightarrow Si + 4HCl \quad [1]$$

However, there is a fundamentally important difference between the more usual case of a disk electrode, for example, rotating in a liquid and a heated disk rotating in a gas mixture for a CVD process. This difference is that whereas in the first case the solution is essentially stationary and the hydrodynamic flow pattern, and hence the mass transport, are imposed by the disk rotating, in the second case one has a gas mixture being continuously fed to the reactor with the result that the fluid dynamics and heat and mass transport can be determined not just by the rotating disk but by the inlet gas flow as well. This distinction does not seem to have been appreciated either by Pollard and Newman, or by Sugawara[10] in the paper from which the authors have taken results in order to test their theoretical analysis. Unfortunately, Sagawara does not explicitly state what gas flow was used during the silicon deposition, but a flow of 40 liter/min^{-1} is implied since he says "the quartz tube was fixed, 40 liters/min of H_2 was inserted, and rf heating was effected. After reaching the set temperature for the epitaxial reaction, a 5 min interval was taken before feeding $SiCl_4$ together with H_2." If such a high flow rate was employed during the deposition then it is very probable that the flow characteristics would have been largely determined by the inlet gas flow rather than the disk rotating. The reported weak dependence of growth rate on rotation speed would then simply be a reflection of this and not of rate control by homogeneous gas phase kinetics. Strong evidence in support of this conclusion is given by results we have obtained from studies of the rotating disk system for CVD processes in general and, with a reactor very similar to that described by Sugawara, for the deposition of silicon by reduction of $SiCl_4$ in particular.[11,12] Detailed results will be published shortly,[13,14] but we can briefly summarize the main findings here.

We have monitored the temperature profile with a small thermocouple probe on the axis of a rotating disk heated to 1200°C in a hydrogen gas flow. These measurements clearly show that the thickness of the thermal boundary layer is very sensitive to the inlet gas flow. For example, with a rotation speed of 500 rpm and a gas flow of 1.9 liter/min^{-1} the thermal boundary layer thickness (obtained by extrapolation of the linear portion of the temperature profile at the surface to intercept the horizontal portion corresponding to the bulk temperature) is $\sim$ 20 mm, while

with a gas flow of 6 liters/min^{-1} it is $\sim$ 12 mm. Also with a rotation speed of 1000 rpm and 1.9 liters/min^{-1} of hydrogen the boundary layer thickness of $\sim$ 18 mm is not significantly different from that at 500 rpm under the same conditions. It is evident, therefore, that before one can use the rotating disk for studies of CVD processes analogous to those made with isothermal disks in solution, the effect of the gas flow on the mass transport must be compensated for. We have done this by setting up, at a given disk temperature, conditions with the carrier gas alone which give experimental temperature profiles in accordance with those expected on the basis of theory;[15] this theory is, admittedly, only approximate and does not take account of the physical property variations with distance from the disk surface, but the indications are that this does not lead to errors which are too serious.[16] Then we have carried out epitaxial deposition of silicon under the same conditions and measured the growth rate. If the growth rate is truly transport controlled one would expect a dependence on the square root of the rotation speed (Ω), whereas for kinetic control a smaller dependence would be expected, as pointed out by Pollard and Newman. We find at 1200°C, for example, a linear dependence of growth rate on $\Omega^{1/2}$ at low rotation speeds ($<$ 300 rpm) with a lower dependence at higher speeds ($>$ 300 rpm), thus indicating a transition from mass transfer control to reaction rate control. A complete analysis of the results for growth rate against temperature over the range 900°-1300°C with a two parameter fit to an expression for combined kinetics and transport allows the activation energy and pre-exponential term for the kinetic rate constant of the rate-determining step to be obtained. An activation energy of $\sim$240 kJ mole^{-1} is required to fit the experimental points and this is considerably higher than the values in the range 120-170 kJ mole^{-1} commonly reported in the literature for the reaction [1]; the low literature values are obtained from the linear portion of an Arrhenius type plot at temperatures below $\sim$1100°C, and it can be shown[11] that transport has a significant effect on the overall growth at temperatures down to 1000°C or less. The pre-exponential term needed to fit the data is $\sim 10^{10}$ cm sec^{-1} which, when due allowance is made for surface concentrations, can be converted to an equivalent homogeneous first-order rate constant of $\sim 10^{10}$ sec^{-1}. Both the kinetic parameters determined from fitting the data are in reasonable agreement with those found experimentally for the reaction[17]

$$SiCl_4 + H_2 \rightarrow SiHCl_3 + HCl \quad [2]$$

which is described by

$$d[SiHCl_3]/dt = 7 \times 10^9\ [SiCl_4]\ \exp\ (-230 \times 10^3/RT)$$

for a hydrogen pressure of 1 atm. Thus the rate-determining step in the silicon deposition would appear to be reaction [2] which is, in fact, the same process postulated by Pollard and Newman, albeit on the erroneous basis of earlier published results.

In conclusion, it may be said that the rotating disk is as potentially useful a tool for the study of CVD reactions as it has been for reactions at an interface in contact with a liquid, and the analysis of Pollard and Newman should allow a more exact comparison between theory and experiment than is possible with less rigorous approaches. However, as our results clearly show, whether one uses an exact or approximate analysis of the mass transport problem it is essential to ensure that due consideration is given to the effect of inlet gas flow on the mass transfer.

[17] D. J. Ashen, G. C. Bromberger, and T. J. Lewis, *J. Appl. Chem.*, 18, 348 (1968).

R. Pollard[18] and J. Newman:[19] Hitchman suggests that the weak dependence of growth rate on rotation speed reported by Sugawara[20] is caused by high inlet gas flow rates. However, if bulk gas flow increases the mass transfer rate, the observation of deposition rates below the mass transfer limit at high rotation speeds can only be explained by a transition to reaction rate control, as Hitchman's own data indicate. Certainly, distortion of the velocity profile by passage of gas through the reactor could be an additional reason for discrepancies between experimental results and theoretical predictions, but this only emphasizes the need for careful experimental procedure.

The influence of bulk gas velocity cannot be properly accounted for by simply "adding on" the effect of carrier gas as Hitchman proposes. A rigorous treatment would necessitate a complete solution of the partial differential equations of motion, subject to the appropriate boundary conditions. The von Kármán transformation would no longer apply, even with the assumption of constant physical properties, and the attractiveness of the rotating disk, as a system with mass transfer and fluid flow characteristics that can be predicted accurately, would be lost. Similarly, attempts to account properly for natural convection and radial diffusion would make the mathematical formulation far less tractable and would introduce radial dependences that could cloud the interpretation of experimental data.

Application of the present analysis to chemical vapor deposition of silicon shows that the large physical property variations across the boundary layer can significantly affect the predicted behavior. Simplifications to the model (that Hitchman needs to account for large inlet gas velocities in a simple manner) immediately raise questions concerning the choice of the most appropriate diffusion coefficient, density, viscosity, and other physical properties. Naturally, values can be chosen to give the best fit between experiment and theory, but this has no theoretical basis and makes the predicative capability of the model questionable. The need to resort to analyses of this type can only be regarded as a retrograde step.

Alternatively, the use of large, downward-facing disks and long gas residence times could minimize the uncertainties associated with radial diffusion, natural convection, and inlet gas flow rates, in a quantitative manner. With carefully chosen experimental conditions, the rigorous model presented for the rotating disk may be used with confidence to predict reaction mechanisms and fundamental kinetic parameters for chemical vapor deposition processes.

If external factors dictate the need for large inlet gas velocities, it may be more appropriate to use an alternative to the rotating disk, such as the impinging jet system, in the laboratory.

Universal Ending of a Technological Quartz Furnace Tube

Andrzej Hejduk

Instytut Technologii Elektronowej Politechniki Wrocławskiej, Wybrzeze St. Wyspiańskiego 27, 50-370, Wroclaw, Poland

Basic high - temperature processes of planar silicon technology /i.e. semiconductor doping, making of SiO_2 films, heating in various technological stages/ are performed mainly in large diameter quartz tubes. Necessary components of the working atmosphere are supplied to the tube in the gaseous phase through a tube ending. Such an ending is a section of a quartz tube closed at one end, with short, thin quartz pipes soldered in /gas line supplies are installed to them/.

The ending is connected to the main tube through a conic, quartz, ground tube [1] ; in particular cases the ending is formed on the main tube itself.

The construction of the whole-glass ending described here has some basic disadvantages:

- the ending is hard to make, what makes it expensive,
- due to the brittleness of quartz, the ending is easy to damage, especially during gas line supplies installing,
- the quantity of the gas line supplies is determined by a particular technological process being performed in the tube,therefore adaptation of such an ending to the requirements of another process cannot be made easy.
- exchange of a damaged tube or ending often requires grinding of newly selected set of connection tubes.

The disadvantages described above make exploitation of the whole-glass ending a difficult task, especially when it is used in the research work.

Therefore a new construction of the ending is developed [2] .

The ending is made from acid-resistant steel and polytetrafluoroethylene, securing the high purity of the working atmosphere in the tube.

The scheme of the design is shown in figure 1.

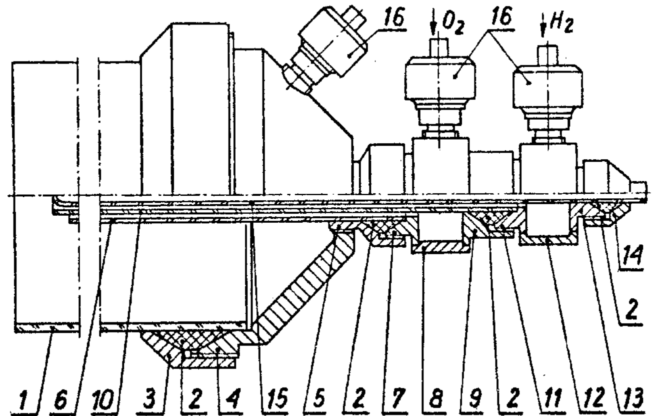

Fig. 1. Schematic section of a quartz tube end with fastened ending, and with an oxygen-hydrogen blowpipe producing steam.

Easiness of the fastening of the ending to the tube 1, which is cut straight, is being the greatest advantage of this construction.

Connection of the ending to the pipe 1, which is both mechanically resistant and very tight, is obtained due to the mating of an elastic annular connector 2 made from polytetrafluoroethylene with correspondent seats in the nut 3 and in the ending body 4. Holes, in which the gas line supplies are screwed, are situated in a way as to make the gas stream coming into the tube move along a screw line. Such a shape of the stream improves the homogenity of the working atmosphere. The ending may be easily adapted to the requirements of a specific technological process by screwing a proper amount of gas lines 16 into the body 4 /holes not used are to be closed by proper pins/.

An idea of an oxygen-hydrogen blowpipe [3] is also shown in figure 1.

Key word: semiconductors technology

Two basic disadvantages of a whole-glass quartz blowpipe[4] are avoided in this construction: high price and vulnureability.
In the new construction, principe of quartz pipe fastening is the same as in the construction of an ending described above. Working gases are supplied to the tube 1 through two nozzles: 6 /oxygen/ and 10 /hydrogen/. The temperature is controlled by means of a thermocouple secured by pipe 15. Concentric setting of pipes 6, 10, and 15 is made due to the mating particular pipes with annular connectors 2 compressed by elements 5, 7 /oxygen nozzle/, elements 9, 11 /hydrogen nozzle/, and in the case of thermocouple pipe 15, by elements 13 and 14. Supply of the working gases to the blowpipe is made through deliveries 16 screwed into the oxygen chamber /composed of elements 7, 8, 9, 10/ and into the hydrogen chamber /composed of elements 11, 12, 13, and 14/.
Process of oxidation of silicon substrates can be made with the use of the oxygen-hydrogen blowpipe in the atmosphere of both dry oxygen and steam; humidity of the oxidating medium can be regulated by changing the proportion of hydrogen to oxygen. It is to be underlined that the steam produced by the blowpipe is of the highest purity, and is being mainly determined by the quality of supplied gases.

SUMMARY Designs of the technological tube ending and of the oxygen-hydrogen blowpipe producing steam of the highest purity, are described in this paper. In the construction shown here, disadvantages of well-known whole-glass quartz designs are eliminated. The basic advantages of a new designs are: easy adaptation of the ending to the requirements of different high-temperature processes and its resistance to mechanical damage. These advantages make the research work easier, especially in the field of semiconductor devices and integrated circuits technology.

Azide Photoresists for Deep U.V. Lithography

T. Iwayanagi, T. Kohashi, and S. Nonogaki

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo, Japan

Deep UV lithography utilizing wavelengths in the 200-300 nm region has become of interest in recent years, since it provides a means of defining 1-2 μm patterns in the microfabrication of solid-state devices (1,2). A reflecting 1:1 projection printer, VL-MR1, was recently developed for a deep UV exposure system (3). One problem with deep UV lithography is the lack of high power light sources, which places the requirement of high sensitivity on deep UV resists (4). Methacrylate resists such as PMMA (polymethyl methacrylate) (1,5) and sensitized PMIPK (polymethyl isopropenyl ketone) resists (6) have so far been used for deep UV applications. However, the sensitivity of these resists is not sufficient to achieve practical exposure times for scanning type deep UV projection printers such as VL-MR1 (3). In this paper, we report highly sensitive azide photoresists suitable for deep UV lithography.

Current negative resists in conventional photolithography consist of cyclized polyisoprene and photosensitive diazide compounds. The most commonly used diazide is 2,6-di(4'-azidobenzal)-4-methylcyclohexanone (7), with an absorption maximum at 355 nm. Therefore, resist composed of this diazide and cyclized polyisoprene has maximum sensitivity at about 360 nm (8) and is not well suited for deep UV applications. Diazides for deep UV resists should possess the following absorption properties: (I) wavelength of absorption maximum lying between 200 and 300 nm to give high sensitivity to deep UV radiation; and (II) sharp cut-off in the longer wavelength region. Aromatic diazides without conjugation between the two benzene rings would satisfy the above requirements. Such diazides were synthesized from parent diamines by the established method (Table I). Resists consisting of the diazides and cyclized polyisoprene were evaluated as negative deep UV resists. These resists are insensitive to ordinary white fluorescent lamps and are hence abbreviated as WR (White Resist).

Cyclized cis-1,4-polyisoprene was obtained from Tokyo Ohka Kogyo Co. (OBC-83, Mw 150,000, degree of cyclization 70%). Cyclized polyisoprene was dissolved to 10 weight percent (wt.%) in xylene and then 0.2 -10 wt.% of diazide based on the polymer was added to the solution. The resist films were spin coated on silicon wafers with thicknesses of 0.7-1.2 μm and prebaked at 60°C for 20 min. All exposures were carried out in air with Xe-Hg lamps. After exposure, the films were developed by dipping in a 70 vol.% n-heptane/30 vol.% xylene mixture for 2 min at 25°C and then rinsed in n-butyl acetate for 1 min.

Table I Melting Points and Wavelengths of Absorption Maximum for Diazides and Exposure Times for Cyclized Polyisoprene-Diazide Resists

	Diazide	m.p. (°C)	λ_{max} (nm)	Expoure Time*(sec)
A	$N_3C_6H_4$-SO_2-$C_6H_4N_3$ (N_3 groups at the upper ring positions)	116	240	0.6
B	N_3-C_6H_4-CH_2CH_2-C_6H_4-N_3	80	254	0.3
C	N_3-C_6H_4-CH_2-C_6H_4-N_3	44	256	0.5
D	N_3-C_6H_3Cl-CH_2-C_6H_3Cl-N_3	128	258	0.5
E	N_3-C_6H_4-O-C_6H_4-N_3	77	264	0.2
F	N_3-C_6H_4-S-S-C_6H_4-N_3	37	266	0.7
G	N_3-C_6H_4-S-C_6H_4-N_3	90	273	0.1
H	N_3-C_6H_4-SO_2-C_6H_4-N_3	163	284	0.3

* Exposure time required for 50% remaining film thickness for resist consisting of cyclized polyisoprene and diazide (1.0 wt.% based on polymer).

Key words: Negative photoresist, Deep UV resist, Deep UV lithography

The sensitivity of WR containing 1.0 wt.% diazide (based on polymer weight) was measured. The resist films were exposed at a fixed light intensity (120 mW/cm^2) for various exposure times using a 600 W Xe-Hg lamp (Canard Hanovia Inc.) in conjunction with quartz optics and a 4 cm water filter. The exposure times for WR required to give a 50% remaining film thickness after development are given in Table I. An exposure time of 45 sec is required for PMMA under the same exposure conditions; hence WR is approximately 60-450 times more sensitive than PMMA. The use of diazide G (4,4'-diazidodiphenyl sulfide) for WR resulted in the highest sensitivity, as shown in Table I. Therefore, it was decided to select diazide G from the various diazides listed in Table I.

The sensitivity of WR with diazide G (WR-G) was measured with the deep UV projection printer VL-MR1, equipped with a 2 kW Xe-Hg lamp (Ushio Electric Inc.) and a cold mirror CM-290 (Canon Inc.) (3). The exposure characteristics of WR-G resists were examined with varied concentrations of diazide G. The sensitivity increased by a factor of three as the diazide G content increased from 0.5 to 3.0 wt.%, while concentrations above 3 wt.% did not enhance the sensitivity any further. With concentrations of 2.0 wt.% or above, the resist patterns were found to be subject to swelling and deformation during development unless the resists were overexposed. On the other hand, with concentrations of 0.5 wt.% or below, a marked decrease in film thickness after development was observed upon projection exposure in air. This is due to the oxygen effect often encountered in diazide photoresists (8-10). From these results, it was concluded that WR-G 1.0 which contains 1.0 wt.% diazide G based on cyclized polyisoprene would be most suited for deep UV projection printing. Exposure characteristics for WR-G 1.0 are compared with those for a sensitized PMIPK (ODUR-1013 of Tokyo Ohka Kogyo Co.) and a current negative photoresist OMR-83 (Tokyo Ohka Kogyo Co.) in Figure I. A practical scanning exposure time of about 20 sec can be achieved for WR-G 1.0. OMR-83 is slightly more sensitive than WR-G 1.0 under the stated exposure conditions. The cold mirror used for these exposures is known to permit the transmission of some light with wavelengths above 300 nm (3). If the OMR-83 resist were evaluated in a system which eliminated the light with wavelengths longer than 300 nm, then its sensitivity would be reduced.

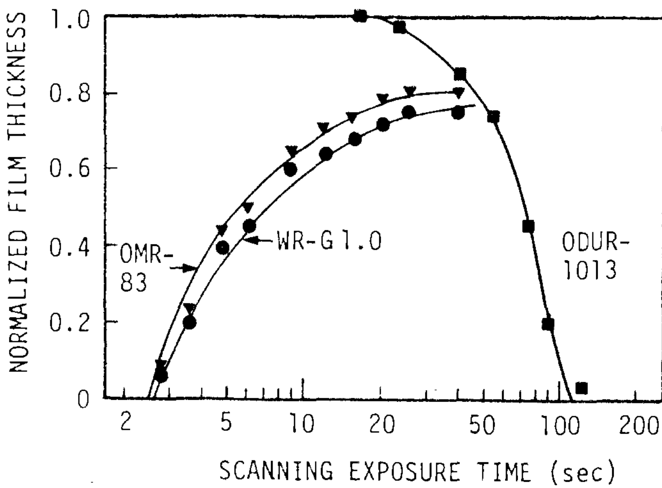

Figure I Exposure Characteristics for Deep UV Resists (1:1 projection printer VL-MR1 with 2 kW Xe-Hg lamp and cold mirror CM-290).

Pulication costs of this article were assisted by Hitachi Limited.

The resolution and lithographic performance of WR-G 1.0 will be described in a subsequent paper.

ACKNOWLEDGMENT

The authors are grateful to Y. Hatano for his preliminary study of this work. They would like to thank S. Iwamatsu and K. Asanami for deep UV exposure by VL-MR1.

A Reversible Redox Couple in Quinone-Hydroquinone System in Nonaqueous Medium

V. J. Koshy, V. Swayambunathan, and N. Periasamy
Chemical Physics Group, Tata Institute of Fundamental Research, Bombay 400 005 India

In aqueous acidic solutions an equimolar mixture of a quinone and the corresponding hydroquinone forms the well-known quinhydrone reversible redox couple (1). In nonaqueous

$$Q + 2H^+ + 2e \rightleftharpoons QH_2 \qquad [1]$$

solvents quinone and hydroquinone are not electrochemically coupled as the reduction potential of the quinone and the oxidation potential of the hydroquinone occur at potentials separated by more than one volt (1, 2). It is reported (3) that in pyridine the electrochemical reduction of p-benzoquinone (BQ) is not affected by the presence of p-benzohydroquinone (BQH_2). In acetonitrile, however, it is observed (4) that BQH_2 acts as a proton donor affecting the electrochemical reduction of BQ. Complexities in the chemical and electrochemical reactions of 'quinhydrone' solutions have been observed (4) and the mechanism has not been understood. We report here our preliminary results on the study of quinone-hydroquinone systems in a nonaqueous solvent. Our results suggest the existence of the following quasi-reversible redox couple:

$$Q + QH_2 + 2e \rightleftharpoons 2QH^- \qquad [2]$$

Such a redox couple has not been previously reported for a quinone-hydroquinone system in nonaqueous solvents.

The cyclic voltammogram of anthraquinone (AQ) (1.7×10^{-3} M) in 1,2-dimethoxyethane (DME) containing the supporting electrolyte, tetra-n-butyl ammonium perchlorate (TBAP) is shown in Fig. 1A. The vacuum electrolysis cell used in the experiment consists of a Pt wire (test electrode), a Pt mesh (counter electrode) and a silver wire (quasi reference electrode). The solution was degassed on a vacuum line ($< 10^{-4}$ Torr) by freeze-pump-thaw cycle method. As shown in Fig. 1A, AQ is reduced in two steps, $AQ + e \rightleftharpoons AQ^{\cdot}$ and $AQ^{\cdot} + e \rightleftharpoons AQ^{2-}$, and the reduction peak potentials (waves I and II) of the two redox reactions in DME are -0.97 and -1.62 V vs SCE, respectively.

Anthrahydroquinone (AQH_2) is an oxygen (air) sensitive substance and the following method was adopted to prepare a solution of AQ and AQH_2 in DME for the cyclic voltammetric experiment. A solution of AQ (2.1×10^{-3} M) and TBAP (0.2 M) in isopropyl alcohol (IPA) was taken in the vacuum electrolysis cell and degassed on a vacuum line. The solution was transferred to a side arm of quartz tube and UV (300 - 400 nm) photolysed for one minute. Facile photoreduction of AQ to AQH_2 occurs in IPA (5) as indicated by the strong green fluorescence of AQH_2. Approximately 80% of AQ was converted to AQH_2 after the photolysis for one minute. IPA was expelled from the electrolysis cell and DME was distilled into

Key words: Quinone, Hydroquinone, Redox couple, Nonaqueous medium, Cyclic voltammetry

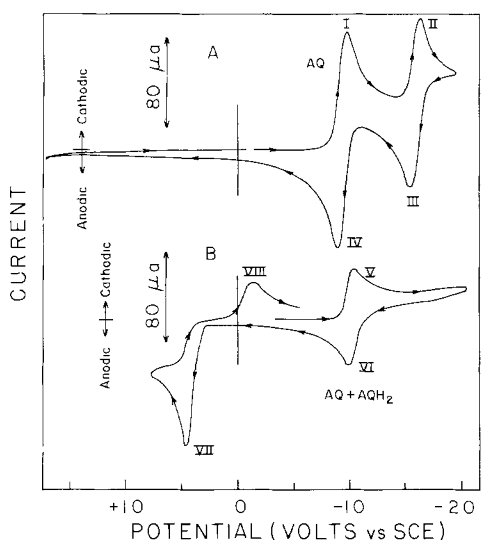

Fig.1 Cyclic voltammograms in DME: (A) AQ (1.7×10^{-3}M), (B) AQ and AQH_2 ($[AQH_2] > [AQ]$, $[AQ] + [AQH_2] = 2.1 \times 10^{-3}$M). [TBAP] = 0.2 M. Sweep rate = 145 mV/sec. iR compensation has been given.

the cell on a vacuum line to make a solution of AQ and AQH_2 whose total concentration is 2.1×10^{-3} M.

The cyclic voltammogram of AQ and AQH_2 in DME is shown in Fig.1B. It is significant to note that the waves II and III which correspond to the second electron redox reaction, $AQ^{\cdot} + e \rightleftharpoons AQ^{2-}$, are absent showing that $AQ^{\cdot}$ is consumed in a chemical reaction. And more importantly, an oxidation wave VI ($E_p = -0.96V$) appears in the reverse anodic scan which cannot be attributed to $AQ^{\cdot} \rightleftharpoons AQ + e$, as one would interpret the wave IV to be in Fig.1A. Wave VII ($E_p = 0.48V$) is attributed to the oxidation of AQH_2 and wave VIII ($E_p = -0.12V$) may be attributed to the reduction of AQH^+ or AQ/H^+ (4). AQH_2 was oxidised to AQ by admitting air (oxygen) into the vacuum cell. The solution was then degassed and the cyclic voltammogram of this solution was identical to that shown in Fig.1A.

These results are interpreted as follows. The electrogenerated $AQ^{\cdot}$ undergoes proton transfer reaction with AQH_2 and wave V ($E_p = -1.02V$) in Fig.1B is interpreted to be the result of the following electrode and chemical reactions:

$$AQ + e \longrightarrow AQ^{\dot{-}} \quad [3]$$

$$AQ^{\dot{-}} + AQH_2 \longrightarrow AQH^{\cdot} + AQH^{-} \quad [4]$$

$$2AQH^{\cdot} \longrightarrow AQ + AQH_2 \quad [5]$$

$$AQH^{\cdot} + e \longrightarrow AQH^{-} \quad [6]$$

The semiquinone radical, $AQH^{\cdot}$ is known to disproportionate fast (6, 7) and AQH^- is the only stable species formed in the reactions (3) - (6). Spectroelectrochemical investigation of this system using Pt OTE confirms the formation of AQH^- (8). The absence of the second electron reduction wave of $AQ^{\cdot}$ in Fig.1B indicates that the reaction (4) is sufficiently fast in the time scale of the experiment. The appearance of wave VI in the reverse anodic scan is attributed to the oxidation of AQH^-, followed by the disproportionation of $AQH^{\cdot}$.

$$AQH^{-} \longrightarrow AQH^{\cdot} + e \quad [7]$$

$$2AQH^{\cdot} \longrightarrow AQ + AQH_2 \quad [8]$$

The appearance of the reduction wave V and the oxidation wave VI with a peak potential separation of 50 mV and less suggests the possible existence of the following redox couple:

$$AQ + AQH_2 + 2e \rightleftharpoons 2AQH^{-} \quad [9]$$

Such a thermodynamic quasi-reversible redox couple is possible if the reactions (3) - (8) are sufficiently fast. It is observed that an increase in the concentration of AQH_2 relative to that of AQ decreases the peak separation of waves V and VI approaching the theoretical value of 29 mV for the reversible 2e redox couple.

The electrochemical behaviour of BQ - BQH_2 system in DME is found to be identical to that of AQ - AQH_2 system when the concentration of BQ is low. The cyclic voltammogram of BQ (1.2×10^{-4} M) in DME is shown in Fig. 2A. The reduction waves I and II are attributed to the 1e reduction of BQ and $BQ^{\cdot}$. Addition of BQH_2 (1×10^{-2} M) (Fig.2B) to this solution completely suppresses the second electron reduction wave II and the reduction peak current of wave V is nearly twice that of wave I. The appearance of the oxidation wave VI in the reverse anodic scan is attributed to the oxidation of BQH^-. The peak separation of waves V and VI is 50 mV or less. The following quasi reversible redox couple is suggested in this system also:

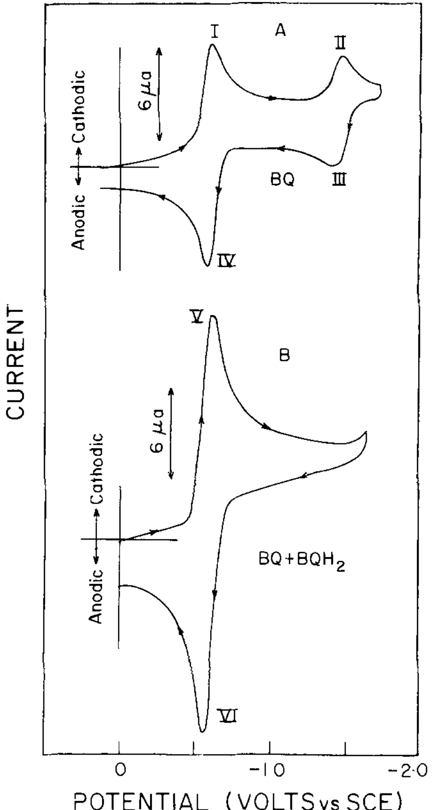

Fig.2 Cyclic voltammograms in DME: (A) BQ (1.2×10^{-4}M), (B) BQ (1.2×10^{-4}M) and BQH_2 (1×10^{-2}M). [TBAP] = 0.2M Sweep rate = 145 mV/sec. iR compensation has been given.

$$BQ + BQH_2 + 2e \rightleftharpoons 2BQH^- \quad [10]$$

The complexities in the electrochemical reduction of BQ in the presence of BQH_2 in acetonitrile, observed by Eggins and Chambers (4) is also observed in DMF when the concentration of BQ is increased to 1×10^{-3}M or more. These complexities are explained (8) to be due to the electrode deposition of BQH^- (as salt), presumably due to the low solubility of BQH^- in nonaqeous solvents (4, 9).

Microlithography—Key to Solid-State Device Fabrication

C. A. Deckert* and D. L. Ross

RCA, David Sarnoff Research Center, Princeton, New Jersey 08540

Over the past twenty years or so, expressions such as "solid-state circuitry" and "electronics revolution" have become increasingly familiar to the American consumer. The birth and growth of the solid-state industry has been responsible for increased reliability, availability, miniaturization, complexity, and cost reduction of consumer electronics items (1).

The solid-state device, or chip, consists of patterned thin films of one or more metals, dielectrics, and semiconductors on a monolithic substrate, usually a silicon or sapphire wafer as large as 100 mm in diameter. An individual chip varies from about 4 to 15 mm on a side, and may contain from one to 250,000 discrete components (usually transistors).

The fabrication of these devices depends on controlled deposition and removal of the various thin film and substrate materials (2). In order to produce the desired patterns in the solid-state device, a process called microlithography is employed. At various stages in the fabrication process, whenever a new pattern must be defined in the device, a temporary, stencil-like pattern in a thin film covering the surface is defined by techniques related to photography, and selective etching (or, in some cases, deposition) takes place in the unprotected areas. The temporary film known as a "resist" material is then removed and processing continues (3).

This image-forming process is clearly the key to producing complex, patterned, multilayer solid-state devices. Because of its functional similarity to photolithographic operations used in graphic arts, and because of the fine patterns involved, the overall process is known as photolithography, or, more generally, microlithography.

The Historical Development of Modern Microfabrication Techniques (4, 5)

Techniques directly related to microlithography have been widely used in the graphic arts industry for over 100 years. The term "lithography" (literally, writing on stone) is actually a misnomer as applied to the process described here. Lithography is a printing method that utilizes a flat-surfaced, normally water-receptive, plate or stone on which the image areas have been made water-repellant and ink-receptive by photochemical or other means. The surface is wet with water and a greasy ink is applied which adheres only to the image areas. The ink is transferred from the surface to the paper (sometimes via an intermediate rubber surface) by pressure. The procedures developed by the printing trade that are the true antecedents for today's electronics microfabrication industry relate to the manufacture of printing plates, usually of metal, on which a surface relief pattern is produced by removal of material through chemical etching.[1] In the process called gravure printing, ink is transferred to paper from small "wells" that have been etched into the surface of a plate. Photogravure processes are well established in graphic arts. Thus, "microgravure" might be a more accurate term to apply to the subject of this article.

The development of photoetching techniques represents an example of the impact of the Industrial Revolution on fields that had traditionally been the province of artisans. Chemical technology was substituted for the meticulous hand labor involved in the cutting away of portions of the surfaces of plates (woodcuts, engravings) used to print pictorial images. The invention of lithography in the last decade of the 18th century by the Bavarian, Alois Senefelder, was perhaps the first step in this process. The key events leading to the discovery of an integrated process for chemically etching a relief printing plate with the use of a photoresist have been well documented and can be outlined as follows:

1782: Jean Senebier, a Swiss, studied the influence of light on a variety of materials (including silver compounds) and found that certain naturally occurring resins change color on exposure to sunlight.

ca. 1814: Joseph Nicéphore Niépce (French) wished to capture the images produced by the *camera obscura* without the labor involved in tracing them on paper. He began experiments on light-sensitive materials. By about 1824, he had found that a natural asphalt, "bitumen of Judea," when exposed to light, became less soluble in certain organic solvents. Niépce made the first photograph by coating a polished pewter plate with a thin layer of the asphalt, exposing it (for 8 hours!) in a camera, and developing the image. Within the next several years (*ca.* 1826), he had used the insolubilized asphalt pattern as a resist and etched the metal (pewter, copper) with acid to produce a relief plate. [Niépce went on to collaborate with Louis Jacques Mandé Daguerre who discovered (*ca.* 1837) how to make permanent images on the surfaces of silvered copper plates which had been sensitized with iodine vapors (the daguerreotype).]

1832: Gustav Suckow (German) published his observations that mixtures of organic substances with potassium dichromate change color on exposure to light.

1839: Alfred Donné (French) etched daguerreotypes with acid, producing relief printing plates.

1839: Mungo Ponton, a Scot, found that paper soaked in potassium dichromate was light sensitive. When the paper was washed in water following exposure, the unexposed regions washed clean while the exposed pattern remained orange-brown.

* Electrochemical Society Active Member.

[1] In the graphics arts, a distinction is made between relief plates, from which the ink is transferred to the paper from the raised portions of the surface (examples: letterpress, woodcuts), and intaglio plates, from which the ink is transferred from those portions cut below the surface (engravings, etchings, gravure plates).

1840: Edmund Becquerel (French) investigated Ponton's findings and determined that the starch sizing in the paper played an important role in the image formation.

1841: Joseph Dixon (American) employed the fact that a mixture of dichromate and natural gum, on exposure to light, changed its surface properties (the exposed areas become ink-receptive while the unexposed areas remain water-receptive) to produce lithographic printing plates. He used such plates to counterfeit bank notes.

1852: W. H. Fox Talbot (English) discovered that exposing films of dichromated natural colloids (*e.g.*, gelatin) to light produced sufficient solubility reduction to permit the unexposed regions to be selectively washed away with water. He patented the use of these materials in photoengraving. This was the first use of a synthetic (man-made) photoresist.

Thus, by the mid-1800's, the groundwork had been laid for today's sophisticated microelectronics fabrication techniques.[2] It is interesting to note that, with the exception of Suckow and Becquerel, who were university professors, all of the above investigators were amateur inventors.

Dichromated colloid resists suffer from a number of practical shortcomings including a relatively short "pot life," "dark-hardening" (the unexposed coating gradually loses its solubility on storage), excessive dependence of solubility (developability) properties on environmental factors such as ambient humidity, and poor resistance against the strong etchants used for microelectronics materials. In spite of this, dichromated colloids remained the workhorse photoresists of the printing industry until after World War II. Even today, the television industry uses substantial quantities of these materials for the printing of phosphor screens in kinescopes and for the etching of shadow masks for color picture tubes.

Photoengraving techniques were first employed by the electronics industry in the fabrication of copper printed circuits shortly after the war. The application of this technology to transistor fabrication in the early 1950's depended on the development of new classes of entirely synthetic photoresists.

Resists: Chemical Principles (3, 6)

All the resist materials used for microelectronics depend on radiation-induced changes in the solubility of a synthetic organic polymer in some selected developer solvent. Resist materials are classified as either positive-working or negative-working, depending on whether solubility in the developer increases (positive) or decreases (negative) upon exposure to irradiation (Fig. 1). Polymers are universally used for preparing resists because of their excellent film-forming and coating properties and the ease with which such properties can be influenced by synthetic techniques. The polymers usually employed are linear and have molecular weights ranging from a few thousand to several hundred thousand. When dissolved in easily evaporated solvents, the viscosity of their solutions are such that films of useful thickness can be obtained by spin-coating. The molecular structures of the polymers are chosen to permit good spreading and wetting behavior on metal and oxide surfaces. Polymers used to prepare positive resists, where the "stencil" is comprised of unexposed (and, therefore, chemically unchanged) material, must possess the physical and chemical robustness and adhesion to the substrate necessary to withstand subsequent processing steps (or be capable of having these properties imparted to it by a simple post-development step, such as baking).

[2] In fact, by about 1870, optical equipment had been developed that permitted photoreduction of images by a factor of 1/300 to produce pellicles in silver halide emulsions. These precursors of microfilm and photoreticles were used by the French with the help of pigeons, to communicate with the outside world during the siege of Paris.

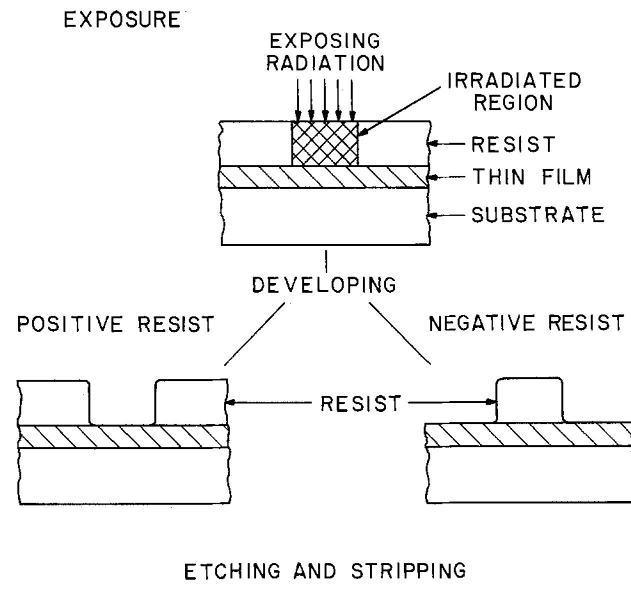

Fig. 1. Schematic diagram of the microlithographic process

To act as a resist, the polymer must be capable of absorbing the radiation used to expose it, and it must contain, either as components of its molecular composition, or as a second constituent mixed with it, species that will chemically react in carefully selected ways when excited by the absorbed radiant energy. These chemical reactions bring about the desired changes in solubility.

Photoresists must absorb light in order to react. It usually is necessary for the light to be absorbed directly by the molecular species that are to undergo the desired chemical reactions. This is accomplished by choosing conjugated unsaturated systems as the reactive species so as to provide molecular energy levels capable of undergoing electronic transitions corresponding to optical wavelengths in the near ultraviolet (350-450 nm).

The applications of these principles to modern resist technology are outlined below.

Photoresists

Negative-working.—There is only one general type of negative photoresist presently of significance to microelectronics fabrication. Exposure to light causes cross-linking of the polymer molecules. This cross-linking produces an increase in molecular weight, reducing the solubility. Eventually, a three-dimensional network of interconnected polymer molecules (a gel) forms that is totally insoluble. The resist is prepared by mixing with a suitable polymer a polyfunctional, light-sensitive additive that, when excited by the absorption of light, can attach itself to at least two sites on the polymer molecule. Modern negative resists of this class use difunctional azides, N_3-X-N_3, in which X contains aromatic groups as part of a conjugated system so as to place the optical absorption band in a useful region of the spectrum. On excitation, these compounds lose two molecules of nitrogen and form species known as nitrenes :N-X-N:. These highly reactive, short-lived intermediates can react with the C-H bonds (Fig. 2) of a polymer to form the desired cross-links

$$\begin{array}{c} \quad\ \ H \qquad\quad H \\ \diagdown\ \ |\qquad\quad |\ \ \diagup \\ C—N—X—N—C \\ \diagup\qquad\qquad\qquad\diagdown \end{array}$$

Fig. 2. A typical negative-working photoresist is a mixture of polymer molecules (represented by the wavy lines) and molecules of a light-sensitive, polyfunctional additive (symbolized by the P's). When excited by the absorption of light, the additive reacts with several sites on the polymer chains, causing the polymer to cross-link and, thus, decrease in solubility in the developer solvent.

The polymers used for azide-based resists are usually aliphatic, rubber-like materials based on poly(isoprene). Some closely related resists have been described in which monofunctional aromatic azides are attached to the polymer chains. The patent literature suggests that certain organic compounds act as photochemical sensitizers for azide systems. These compounds absorb some of the incident light and are raised to electronically excited states from which energy can be transferred to the azide molecules which then react as though they had been directly excited. By this means, the sensitivity of these systems can be extended to wavelengths beyond those at which the reactive sites themselves absorb.

While their solutions, and coatings made from them, have considerably better stability and life than dichromated colloids, and their processing is relatively insensitive to environmental factors, all of the negative photoresists currently used for microelectronics suffer from several shortcomings. Two are inherent to all conventional negative resists: (*i*) Because adhesion of the image areas to the substrate depends on the photo-crosslinking reaction, the exposure required must be adequate to penetrate to and produce some minimum amount of cross-linking at the substrate-resist interface. This sometimes makes it difficult to achieve adequate adhesion without overexposure of the resist (line broadening); (*ii*) Although the cross-linking reactions render the polymer insoluble in the developer, they cannot completely prevent the exposed resist from solvent-induced swelling. This causes very fine patterns ($\sim<2$ μm) to distort in size and shape and, in extreme cases, to lift from the substrate. Defects known as "stringers" and bridging can be produced by such processes.

In addition, the azide-based resists are sensitive to oxygen which can compete with the desired photocrosslinking reaction by reacting with the nitrene intermediates. This can lead to "reciprocity law failure": the amount of insolubilization produced by a given total exposure is dependent on the rate at which the exposure is delivered, since the kinetics of the oxygen-based reactions depend on the rate with which oxygen molecules can diffuse in the resist film. When exposure and pattern definition are very critical, films of these resists are generally purged of oxygen prior to exposure by flooding with an inert gas (nitrogen, CO_2).

Positive-working.—All positive photoresists in current use are based on the photochemical conversion of an ortho-diazoketone to a carboxylic acid (Fig. 3). This reaction converts a neutral, organic-soluble molecule to one that is readily soluble in weakly alkaline aqueous developer solvents. These resists are usually formulated from a mixture of a relatively low-molecular weight, hydrophobic, phenolic polymer (which, itself, has some alkali solubility) and a diazoketone (about 15% by weight) derived from an aminonaphthol sulfonic acid, such as is illustrated in Fig. 3. In other closely related systems, the diazoketone is attached directly to the polymer molecules. As a result of association between the polymer and the diazoketone, the solubility of the mixture in the alkaline developer is inhibited. The hydrophobic nature of the polymer further inhibits attack by the developer. On exposure to light, the diazoketone liberates a molecule of nitrogen and undergoes a molecular rearrangement to the alkali-soluble acid. The formation of the polar carboxyl groups in the exposed areas also renders the film less hydrophobic and, thus, more easily attacked by the aqueous developer (7).

One of the most significant advantages of this family of resists is the fact that, instead of swelling the film and leaching out the solubilized materials, the developer removes the exposed areas by an etching process. As a result, no swelling-induced pattern deformation occurs, and images of extremely high resolution (<0.25 μm) can be formed. Because the adhesion to the substrate is not influenced by the photochemistry, the exposure and development conditions can be adjusted strictly in terms of the relief pattern geometry desired.

The diazoketone resists do not respond to photochemical sensitizers and are not affected by the presence of oxygen.

"Deep-U.V." resists.—The pattern resolution achievable by photoresists is ultimately limited by the wavelengths of the light used to expose them. During the last several years, in attempts to define patterns 1.0-1.5 μm in size, work has been carried out with new light sources and special (quartz) optics to permit exposure systems to utilize wavelengths in the 200-250 nm region. While some conventional photoresists respond adequately to these wavelengths, many do not because the polymers from which they are derived absorb strongly enough to block the transmission of the exciting radiation. The use of these shorter wavelengths makes the task of designing the reactive sites somewhat easier because simpler systems can be used (long conjugated systems are unnecessary). Because of the limitations of negative resists discussed above, most of the new resists being developed for deep-u.v. applications are positive-working and are based on polymers that will undergo a reduction in molecular weight (and, thus, an increase in solubility)

Fig. 3. The molecular structure of a 2-diazo-1-naphthol-5-sulfonic acid ester. Compounds of this type are mixed with phenolic polymers to prepare positive-working resists. When excited by the absorption of light, the normally alkali-insoluble compound loses a molecule of nitrogen and is converted to a carboxylic acid. This causes an increase of the solubility of the mixture in the aqueous alkaline developer.

as a result of photo-induced main-chain scission. Work in this field is in its infancy. The degree to which it flourishes will depend on systems evaluations comparing this approach to higher resolution with those involving electron beam and x-ray exposure schemes.

Electron Beam and X-Ray Resists

With the ability to focus electron beams to very small diameters (below 1000Å), and the very short wavelengths of soft x-rays (5-50Å), the pattern resolution obtainable when resists are exposed to this kind of radiation is no longer primarily dependent on the exposure means. The fundamental limitations are now a function of the scattering of electrons (or, in the case of x-rays, the range of the photoelectrons produced on absorption of the radiation) in the resist material, or the scattering of electrons reflected from the substrate. During the last 10-15 years, electron beam exposure schemes for the defining of sub-μm patterns in resist materials have been examined at several electronics companies (8). At RCA, the impetus was the mastering of the VideoDisc for which it was desired to record relief patterns having wavelengths of *ca.* 0.5 μm (9). At Bell Laboratories and IBM, the application was the fabrication of chrome master masks and direct exposure of IC wafers. More recently, research done at MIT Lincoln Laboratories demonstrated that soft x-rays could also be used to expose appropriate resist materials. The electron beam techniques employ a scanned, sharply focused beam as a "pencil" to delineate the desired patterns while the x-ray scheme uses a flood exposure through a patterned mask. In both cases, the interaction of energetic electrons with the resist material brings about the solubility-altering chemical reactions.

The principal difference between these materials and photoresists lies in the fact that, here, the incident energy is absorbed more or less indiscriminately by all functional groups in organic polymer molecules rather than being selectively absorbed at specific reactive sites. The primary chemical event induced by exposure is the breaking of covalent bonds to produce free radicals or ions. As a consequence, the chemical changes brought about are more analogous to those produced by heat than by light. The fate of the ions or radicals determines whether the resist is negative- or positive-working: if these species react with one another to form new covalent bonds, the polymer can increase in molecular weight and/or cross-link; while, if the fragmentation leads to backbone scission, the molecular weight will decrease.

The major emphasis in the search for negative resists is the identification of materials that have the highest practical sensitivity and the best edge definition in the face of the usual swelling problems. Of course, the usual requirements, outlined above, of good adhesion, etch resistance, etc., must be met. Currently, the most widely used negative electron beam resist is a copolymer of ethyl acrylate and glycidyl methacrylate ("COP") developed at Bell Laboratories. The epoxy groups provide a highly sensitive route for cross-linking. It is interesting to note that the cross-linking reactions in this material proceed for a time following the electron exposure. Thus, exposed substrates must be kept in the vacuum chamber of the exposure apparatus for some 20-40 min after exposure is completed to obtain uniform results.

The most useful classes of polymers for positive resists are those known to degrade in molecular weight by thermal processes. The first, and still widely used, positive electron beam resist is poly(methyl methacrylate), long known to be capable of "cracking" back to monomer by destructive distillation. Although a factor of 10-50 lower in sensitivity than is required by today's electron beam exposure systems, it has very high resolution and good etch resistance. Another class of polymers known to undergo efficient thermal degradation is the poly(olefin sulfones) (10). These materials are synthesized by the copolymerization of SO_2 and unsaturated monomers

$$SO_2 + \overset{|}{\underset{|}{C}}=\overset{|}{\underset{|}{C}} \rightarrow \left[-SO_2-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}- \right]_n$$

A wide variety of these has been examined at RCA and Bell Laboratories. One, the copolymer of butene (polybutene sulfone, "PBS"), is currently used in the production of chrome masters in MEBES (11). With these polymers, cleavage of the backbone can lead to a chain depolymerization reaction from which the comonomers are regenerated. This introduces considerable "gain" into the exposure process and can produce excellent separation of molecular weight (and, thus, good differential solubility in developers) between exposed and unexposed regions of the resist film. In some materials, the depolymerization process is so efficient that relief patterns are produced directly by evaporation of the reaction products in the vacuum chamber of the exposure apparatus without the need for a separate development step. PBS suffers from several shortcomings: its development characteristics are very dependent on the effects of moisture and ambient humidity; it cannot be used in coatings that are as thick as are needed for step coverage in wafer fabrication; and it has poor resistance against the "dry etching" procedures to be discussed below.

Because the phenolic polymers have low sensitivity to electron-beam-induced cross-linking and because the diazoketones can also undergo heat-induced molecular rearrangement, certain formulations related to typical positive photoresists can function usefully as electron beam resists. At RCA, over a thousand VideoDisc masters were fabricated by electron beam recording using "Mark II" resist, a proprietary material of this type.

While the field of x-ray resists is quite new, it can be predicted that most of the findings relevant to electron beam sensitive materials will apply here. Many of the materials that function well as electron beam resists show similar behavior on x-ray exposure. Considerable emphasis is placed on the incorporation of high Z-value elements in the polymer structure so as to increase the absorption of incident soft x-ray energy.

Microlithographic Processing—Overview

In the fabrication of solid-state devices, the photolithographic process is constantly pushing the limits of the state of the art. Many of the requirements for producing today's complex chips would have been considered impossible just a few years ago, and this trend appears to be continuing unabated (1, 12, 13), as shown in Fig. 4.

The most important resist properties required for producing a microlithographic pattern are resolution, contrast, freedom from defects, uniformity, high sensitivity to the exposing radiation, ease of processing, adhesion to the substrate, resistance to degradation by the etchant, and subsequent ease of removal (3).

The resolution requirement in particular has increased rapidly over recent years. It is important to distinguish between best possible resolution achievable over a small-area unpatterned substrate under carefully controlled laboratory conditions, and best resolution achievable at reasonable yields over large areas in a production environment when various levels must be accurately aligned and precise dimensions maintained. In this paper, unless otherwise stated, the term "resolution" will be taken to mean the smallest feature on a chip that can be imaged economically on 3 in. wafers under production conditions. For example, RCA's 16K RAM SOS devices, the MWS-5114, requires four-micrometer resolution. This chip

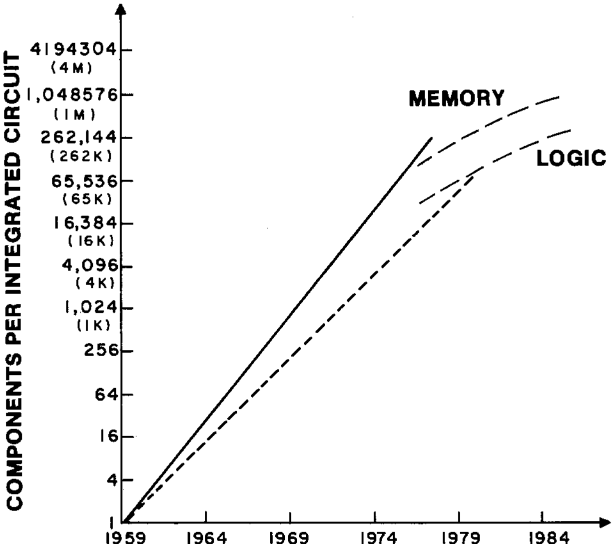

Fig. 4. Number of components per chip has been increasing at a geometric rate since 1959, when the planar transistor was developed. Solid line Ref. (1); short dashes, Ref. (12); long dashes, Ref. (13) (prediction).

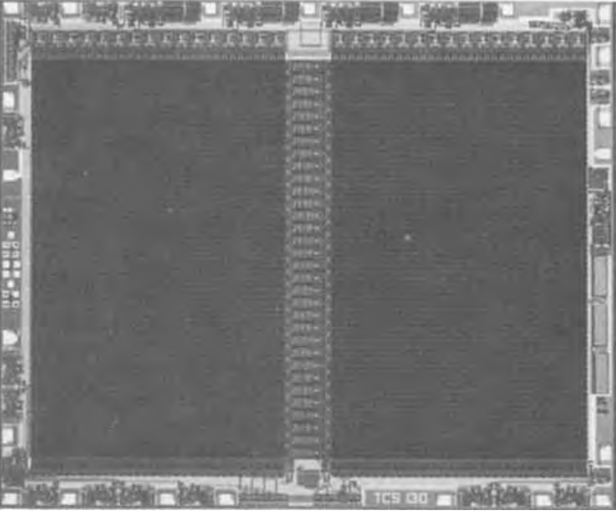

Fig. 5. A complex chip, RCA's 16K RAM SOS device illustrated here, requires four-μm resolution. Even finer dimensions will be required on next-generation circuits.

is illustrated in Fig. 5. It is thought that the current practical limit for production using conventional photolithographic methods is no better than 3 μm (14). On the other hand, surface structures as small as 80Å have reportedly been defined in the laboratory (15). Some examples of the recording of high resolution on resists, not from the solid-state industry, include RCA's VideoDisc masters (9), which were formerly fabricated using electron beam recording, and Holotape® (16), relief-phase holograms which were recorded using an He-Ne laser. In both these cases, illustrated in Fig. 6 and 7, resolution of 0.25 μm was routinely achieved over a large-area substrate.

In order to fulfill the requirements of microlithography, some steps of the process have become more or less standardized (3), while at most steps, a compromise between high performance and cost is reached. Control of the environment and the choice of resist material itself are other factors where choice is dependent on process requirements.

"Microlithography," as used in electronic device fabrication, designates the successive steps of: preparing the substrate, (*e.g.*, a silicon wafer); applying a thin (usually less than 5 μm) film of radiation-sensitive polymeric composition (the "resist") to the surface of the substrate; prebaking the resist coating; exposing the film to a pattern of electromagnetic radiation (light, electron beams, x-rays) so that chemical reactions take place in the film that change its solubility in certain solvents ("developers"); bathing the film in a developer solvent that selectively removes either the exposed ("positive-working") or unexposed ("negative-working") areas thereby creating a patterned stencil in the resist film; postbaking the resist; selectively removing material from or depositing material on those areas of the substrate which have been uncovered by the development step;

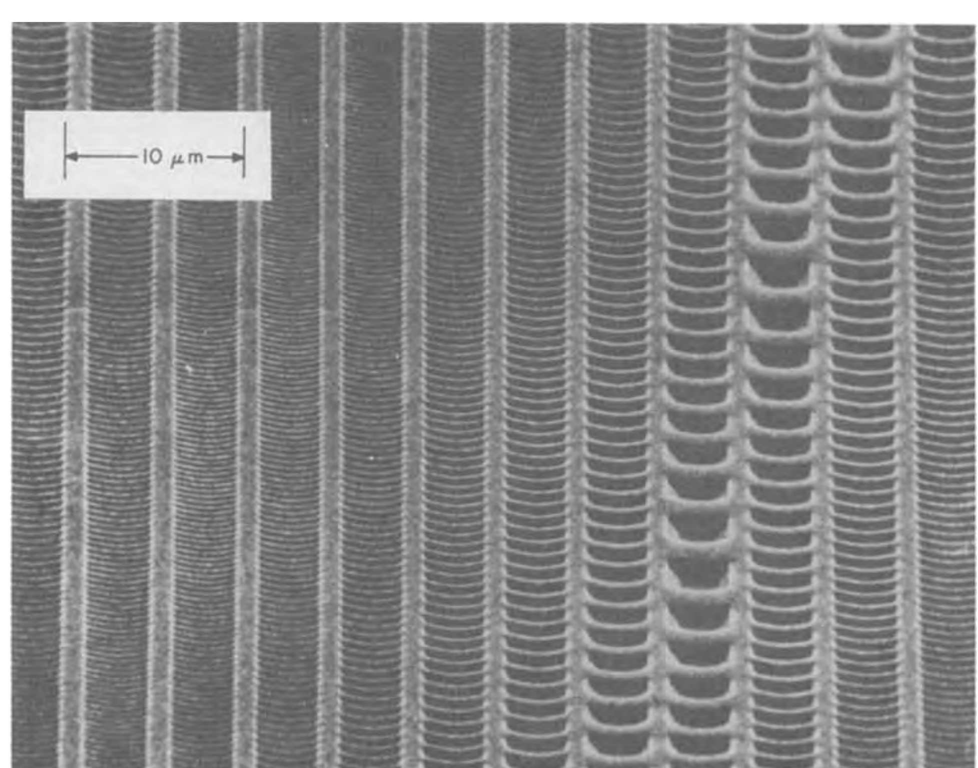

Fig. 6. The masters for RCA's VideoDisc were formerly recorded in a resist material using electron beam exposure.

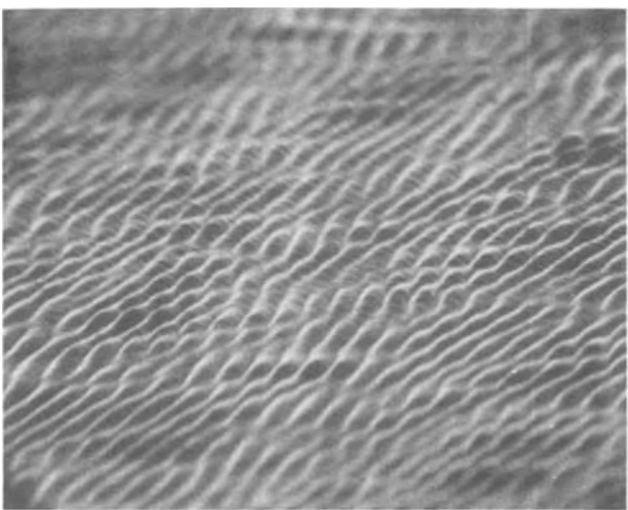

Fig. 7. This Fraunhofer hologram was recorded in a resist material using an He-Ne laser. The pattern exhibits 1 μm periodicity.

and finally removing the remaining resist pattern ("stripping").

Substrate Preparation

Preparation of the substrate may involve film growth or deposition, diffusion or implantation of impurities, or cleaning procedures. If the wafers have been exposed to the ambient for more than a few minutes, contamination is probable (3), and a high temperature bake (~200°C) and/or application of an adhesion promoter are employed. In many wafer processing areas, these steps are routinely used regardless of the time lapse. The importance of cleanliness in solid-state processing cannot be overemphasized. Surfaces must be scrupulously cleaned and kept clean. Contamination, in some form or another, is probably the principal cause of day-to-day processing problems in fabrication areas. For this reason, environmental control (particle count, air flow and quality, clothing, humidity level) is a major factor in determining yields of good chips. A defect which can be traced to surface contamination is shown in Fig. 8.

Coating and Prebaking

Microlithographic processes usually employ liquid resist materials rather than dry film resists[3] because of the higher resolving power of the former. The method of application is nearly always a spin-on technique, which offers very good uniformity at a low processing cost. Resist solutions are formulated so that during the application and spinning process, the solvent(s) evaporate at a rate optimum for producing a non-"skinned" coating of uniform thickness (17). In order to remove the last traces of solvent from the resist film and to promote adhesion to the substrate, a prebake step is next carried out, usually at a moderate temperature (70°-90°C).

Exposure

Exposure is probably the single most important step in the microlithographic process. Resolution and pattern uniformity are determined at this step, and the exposure equipment and operation must be maintained at the precise optimum level to ensure good image production.

The most common type of exposure system involves near-u.v. exposure of the resist-coated wafer through a patterned (photographic emulsion, chrome, iron oxide) glass mask with which it is in contact; however, several other types of exposure systems are now available or under development. These various systems,

[3] Dry film resists are nonsolvent-containing photoresist films, as thin as 25 μm (one mil), supplied in a laminated form, and used primarily in the printed circuit board industry.

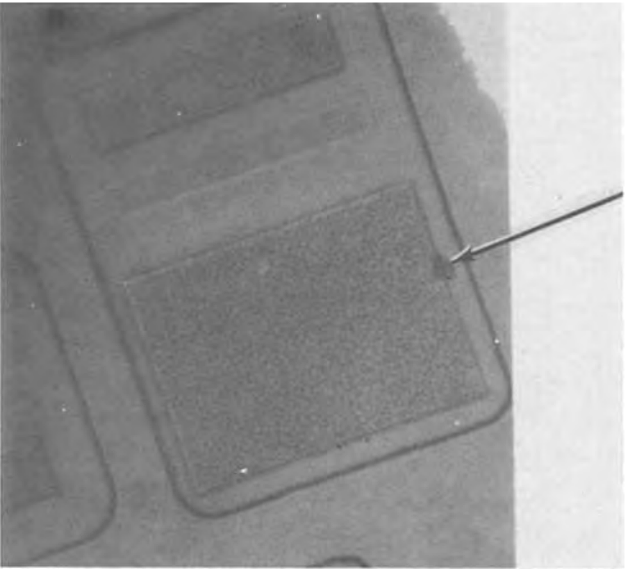

Fig. 8. A foreign particle, either on the surface or in the resist, produced the defect seen in this photoresist pattern. (Light gray areas bear resist material.)

as well as their respective advantages and disadvantages, will be discussed below.

Development

Following exposure, the resist film is developed, *i.e.*, treated by a solvent in which either the unexposed (negative resist) or exposed (positive resist) areas are soluble. Development is carried out either by a spray or immersion technique. As discussed previously, certain types of resists are treated in a rinse solvent to remove residual developer and to reduce any swelling. Some types of resist pattern defects can be detected by inspection at this point, as illustrated in Fig. 9.

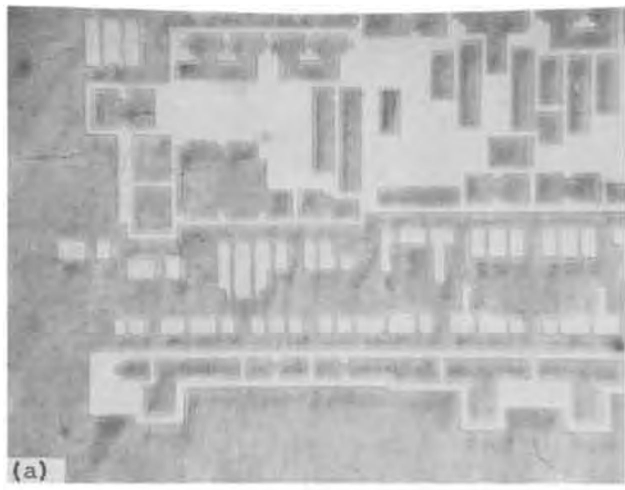
Recently, a "dry-developable" negative resist has been prepared (Motorola), thus permitting use of an entirely dry photolithographic process (18).

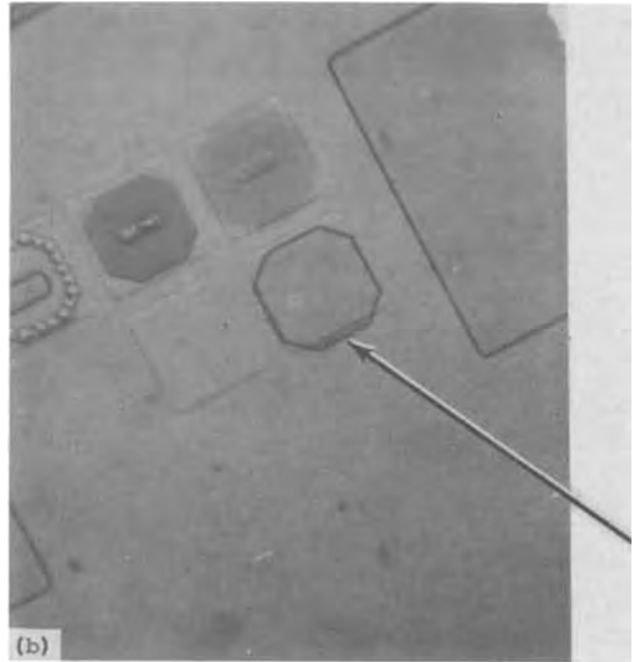
Postbake

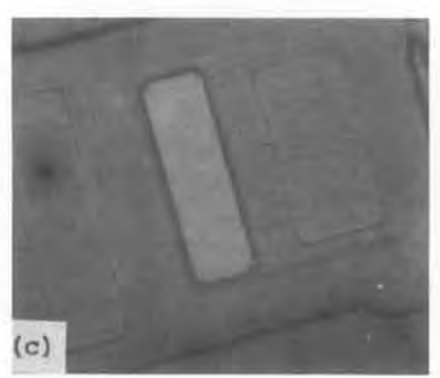
After developing, the patterned resist films are postbaked to drive off any remaining developer or rinse solutions and to maximize the film/substrate adhesion. Typical postbake temperatures are 120°-135°C. It is thought that best adhesion is obtained by baking at as high a temperature as possible just below the softening point of the resist.

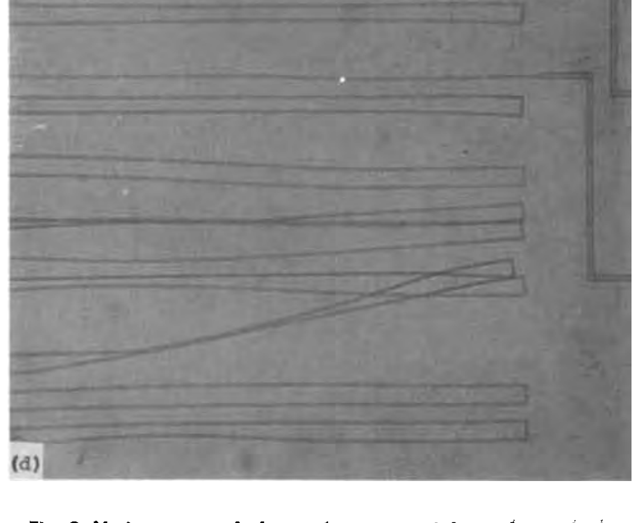
Etching

In most cases, the photolithographic process is subtractive, and the next step involves etching the unprotected areas of the wafer. Either wet or dry etching processes may be used. Wet, or chemical, etching is the traditionally used method, in which the wafers are immersed in liquid etchant (gas phase etching is also included in this category) (19). Wet etching is simple and inexpensive, and this method was used almost exclusively until the past few years, when it became evident that the sloped edges inherent in isotropic wet-etching processes would limit control of the feature size. In addition, the lack of perfect adhesion of photoresist film to the substrate during wet etching leads to "undercutting," a failure mechanism in which very highly sloped edges occur (19, 20) (Fig. 10). In certain instances, a sloped edge is preferred so that the material to be subsequently deposited will cover the edge uniformly and completely. In order to achieve controlled undercutting, a very thin layer of material which dissolves in the etchant more rapidly than does the substrate film may be deposited prior to resist application. Equipment is now available for "dry etching"









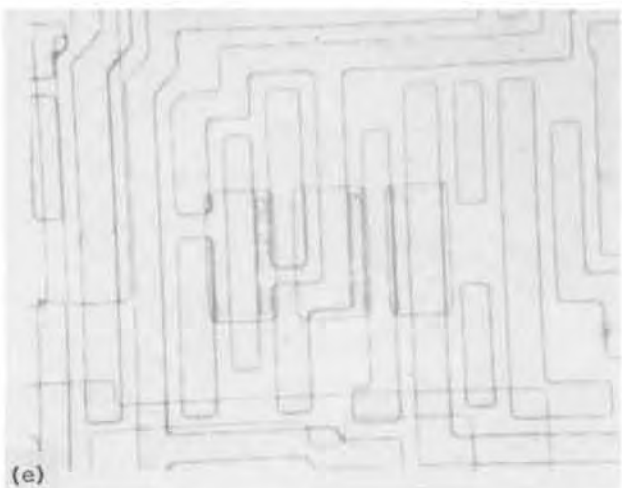


Fig. 9. Various types of photoresist pattern defects observed after development. (a) "Orange peel" is a common occurrence when negative resists are underexposed; (b) the photoresist pattern is slightly misaligned in this pattern test key, since the octagon-shaped resist image does not coincide perfectly with the underlying substrate image; (c) imperfect contact between mask and wafer caused the inward notching at the corners of this photoresist pattern (gray areas are covered with resist); (d) poor adhesion of the photoresist to the substrate can lead to lifting of the resist image during development; (e) Bridging of the resist across open areas can be due to either substrate contamination, poor contact during exposure, or underdevelopment.

(plasma etching) (21) of wafers reproducibly, at high resolution, and in production volumes. Photoresist adhesion is much less critical in dry etching processes, and very high aspect ratios can be achieved in planar systems (22) as illustrated in Fig. 11.

Deposition

In those cases where an additive photolithographic process is employed, the substrate is not etched, but rather, an evaporation, ion implantation, or plating step is carried out at this point. In the trimetal (Ti-

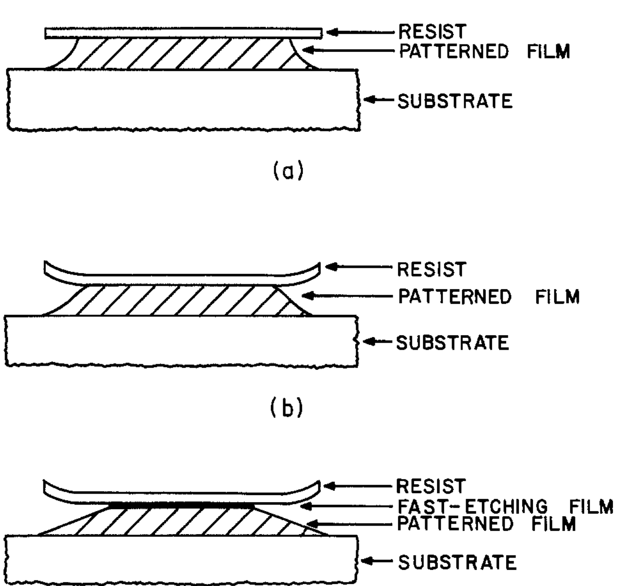

Fig. 10. Different edge profiles produced from various degrees of undercutting (a) good resist-to-film adhesion produces this type of edge; (b) undercutting has occurred at resist-film interface; (c) use of a fast-etching film to achieve controlled undercutting.

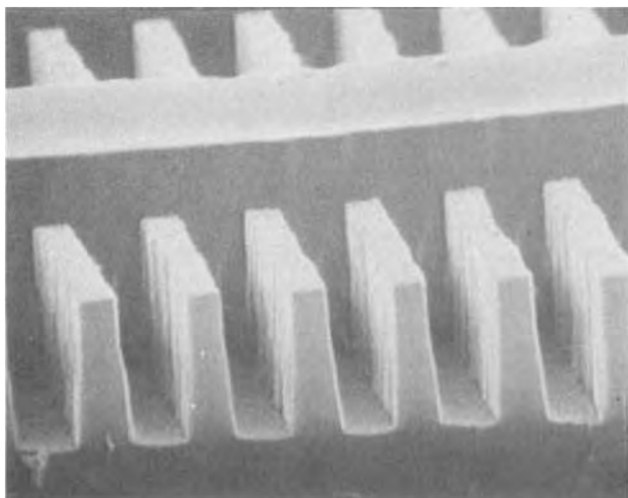

Fig. 11. Photoresist pattern over grating in fused quartz. Thickness of resist layer from top of lines = 1 μm. Periodicity of grating in SiO_2 = 1.4 μm; periodicity of grating in photoresist = 10 μm (5 μm line width). A reactive sputter etching procedure in a fluorocarbon gas was used to etch the SiO_2.

Pt-Au or Ti-Pd-Au) process (23), for example, the gold layer is electroplated through openings in the photoresist onto the Pt or Pd layer on the substrate. In this case, poor resist adhesion leads to "underplating," an example of which is shown in Fig. 12.

Resist Removal

Finally, the resist material must be stripped before the next level of the device can be defined. A variety of acids, bases, and solvents are used for stripping, as is a plasma stripping procedure. Removal of the last traces of resist residue, however, can be rather difficult to achieve (24). An example of incomplete resist removal is shown in Fig. 13.

Quite relevant to a discussion of processing is the procedure of inspecting wafers and masks. Operator inspection using an optical microscope is the traditional inspection method, but for masks, in particular, several types of highly sensitive and accurate, automatic inspection instruments have recently been developed (25, 26). Some very simple mask inspection techniques, such as optical examination using a collimated light

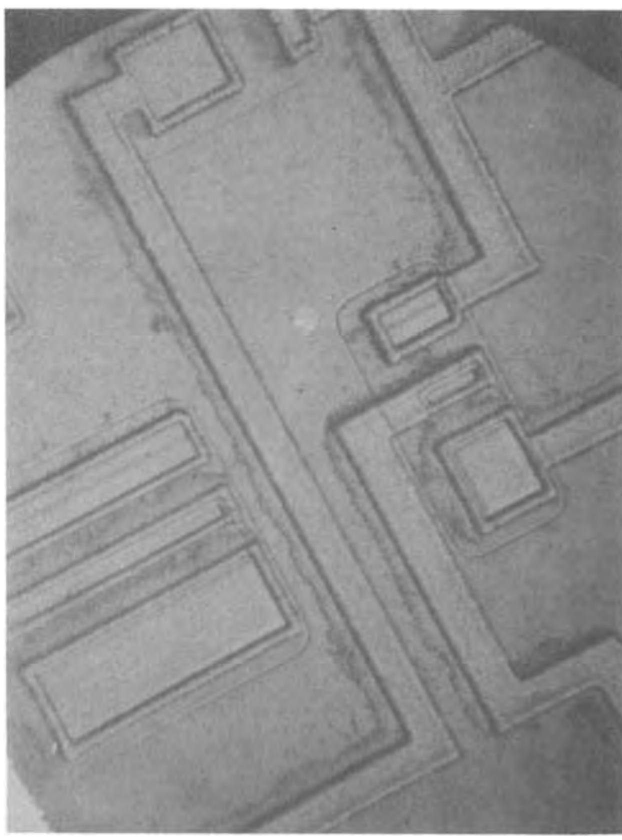

Fig. 12. Gold has been electroplated into the open (interconnect) areas of the photoresist pattern. Poor photoresist adhesion has led to plating under the resist film pattern edges.

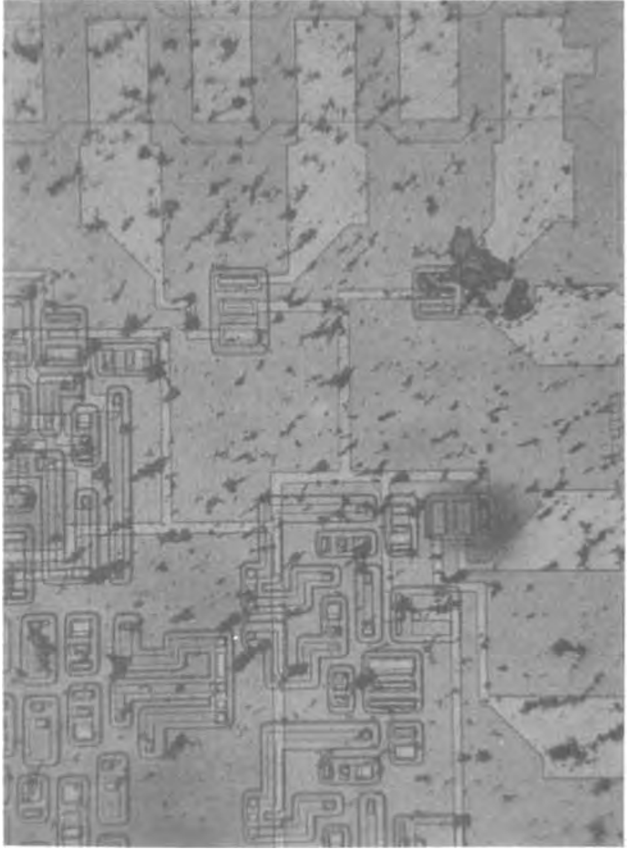

Fig. 13. An extreme case of incomplete photoresist removal

beam, either at a glancing angle or from behind the substrate, can also be very sensitive to defects.

Exposure Techniques are Crucial to the Microlithographic Process

As discussed above, exposure is often considered the most crucial step in the photolithographic process. It is at this point that the resolution, uniformity, and image fidelity of the device are determined. Because of the interaction of the mask, the exposure equipment, and the resist material, the choice of an exposure system must consider all these elements. Trade-offs in terms of resolution, cost, and throughput will determine which system is chosen.

Masks

Masks which are either in current use or will be used in developmental systems include photomasks, electron-beam masks, photo-reticles, and electron-beam reticles. [Photomasks and electron-beam masks bear an array of patterns whose magnification is the same as the pattern to be defined on the device wafer; a reticle, on the other hand, bears a single pattern whose magnification is larger (usually 5 or 10 times) than that to be defined on the wafer.] In addition, applications not requiring a mask, for example, the use of direct E-beam writing on a wafer, are under consideration. Masks are typically fabricated of silver halide emulsions, chromium (reflective or nonreflective), or iron oxide patterned onto a glass substrate. Emulsion masks are lowest in cost, but resolution and durability are limited. Iron oxide masks offer the advantage that the operator can see through them for easy pattern alignment. However, most high quality masks are now fabricated of chromium with a thin surface layer of oxide which makes the metal film nonreflective. Exceedingly complex and/or large masks, such as a CCD mask [Fig. 14(a)], and masks to be used in noncontact exposure systems may be generated by contact printing from an electron-beam master (11), or an optically generated step-and-repeat (S&R) master may be used directly. Very fine geometry (<2 μm) masks can be fabricated directly by electron-beam recording. Masks which are to be used with deep (far) u.v. exposure systems require quartz substrates, and x-ray exposure systems utilize a heavy metal (*e.g.*, gold) pattern on a thin substrate such as beryllium, silicon, silicon carbide, or an organic polymer (27).

Systems and Equipment

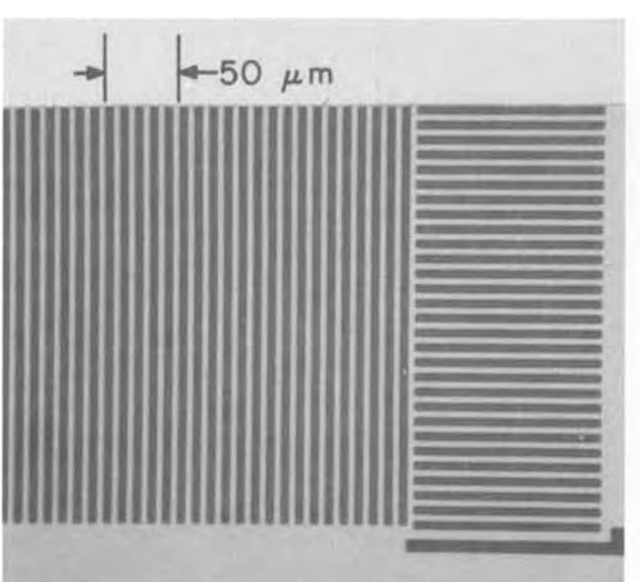
Various types of wafer exposure systems may be used. These include u.v. flood exposure (contact or proximity), u.v. exposure (projection), u.v. S&R reduction exposure (projection), x-ray flood exposure (proximity), or electron-beam scan exposure (direct writing). The various combinations of mask types and wafer exposure systems which are in use or are being developed are shown in Fig. 15, along with a summary of some features of each type.

Near u.v. flood exposure (contact mode) is the traditional method of photolithographic exposure. This method affords very good resolution; in production, about 3 μm can be achieved on the newest instruments (14), and throughput is usually high. On a laboratory scale, square wave gratings with micron and submicron periodicities and etch depths up to 3 μm have been achieved (21) (Fig. 11 and 16). Hard contact (thousands of grams force between mask and wafer) causes short mask life, however; as a result, very expensive masks, such as electron-beam generated masters, or very complex masks where very low defect levels are required, cannot be used economically.

Near-u.v. flood exposure using soft contact (only a few grams force between mask and wafer) or proximity (wafer separated from mask by tens of micrometers) is another exposure scheme. The resolution capability is somewhat lower than for hard contact, but improved mask life can make this a feasible process in certain cases. Power transistors, for example, use relatively coarse geometries and often have mask-damaging "bumps" on the wafer surface.

Projection near-u.v. exposure has become quite popular in the microelectronics industry over the past 3-4 years because of the advent of accurate, relatively high resolution 1:1 projection alignment instruments (Perkin-Elmer Corporation). These instruments are highly cost effective because they afford essentially infinite mask life and can achieve resolution down to about 2.5 μm. Because of the long mask life, expensive masks, such as electron-beam generated masters, can be used.

Under typical factory conditions, existing near-u.v. exposure systems are limited in resolution by factors such as photomask accuracy and dimensional stability, runout, and wafer flatness (28). The advent of commercial S&R reduction u.v. exposure systems (14, 29), using a single 5 or 10× photo- or E-beam-generated reticle as the photomask, is of considerable interest at



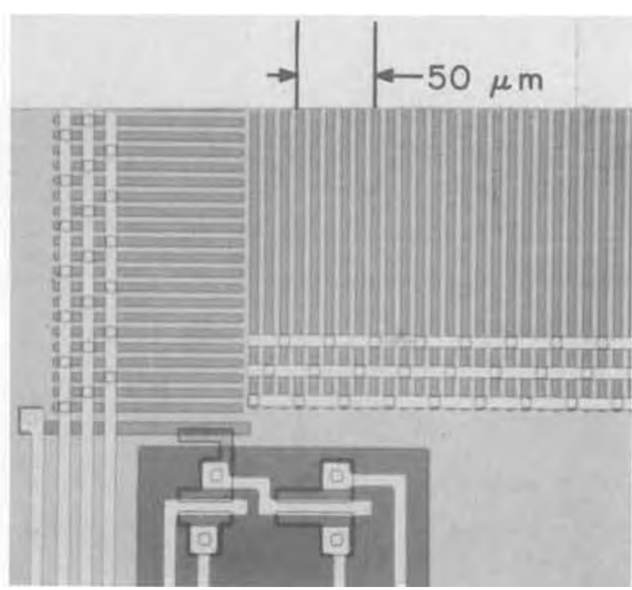


Fig. 14. RCA's CCD requires essentially perfect photolithographic patterning over a large area (10 mm × 15 mm). A small portion of the pattern is shown here. (a, left) E-beam generated chrome master for the polysilicon gate level; (b, right) completed CCD.

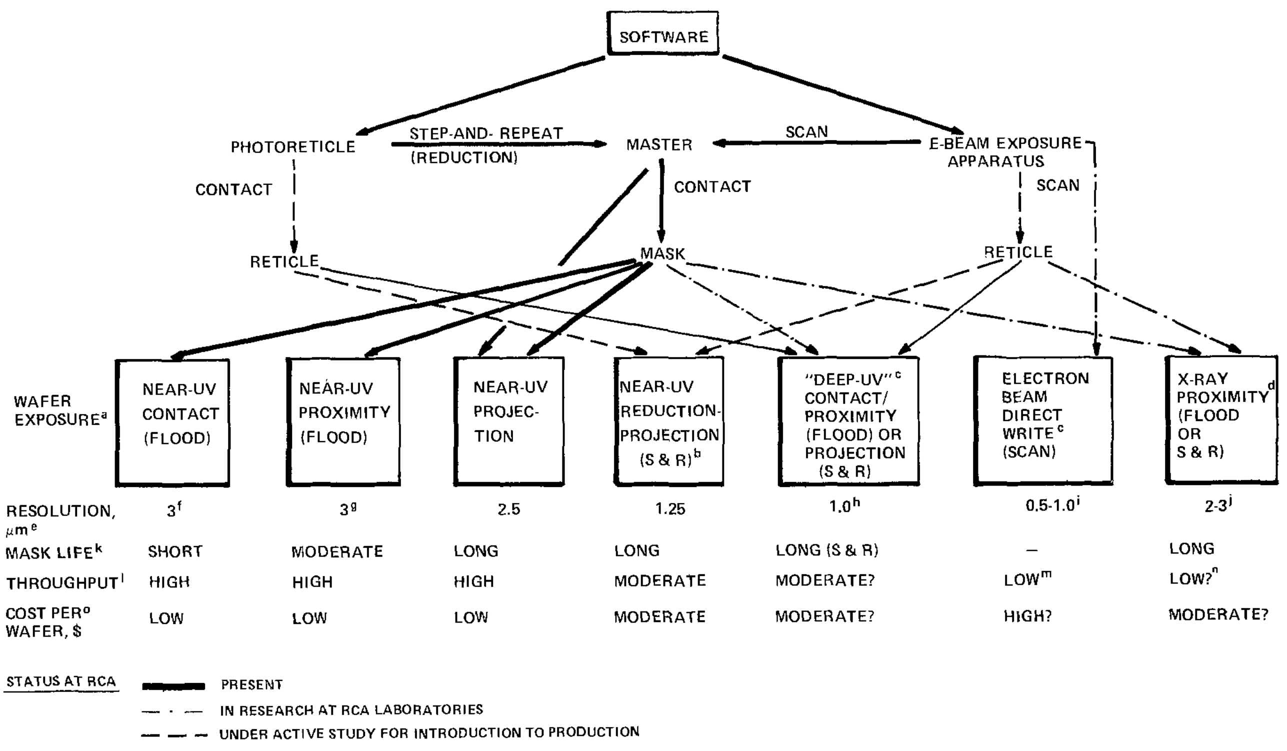

Fig. 15. Wafer exposure processes and parameters. Notes: (a) much of the data in this chart was updated by us from information assembled by R. Epifano of Central Engineering, RCA Solid State Division, in mid-1978; (b) using 10× reticle; (c) only a few prototype systems available; (d) first commercial system prototype (Cobilt) using proximity flood exposure now being tested. S&R systems not commercially available; (e) factory conditions, 3 in. wafers assumed. For near-u.v. exposure, resolution quoted is for positive photoresist. Near-u.v. exposed negative resist resolution about 30% larger; (f) one μm resolution possible on small flat substrates; (g) at 20 μm mask-to-wafer spacing, the minimum acceptable to avoid frequent mask-to-wafer contact; (h) estimate for a projection S&R system; (i) using MEBES (Manufacturing Electron-Beam Exposure System, ETEC Corporation), raster scan. Vector scan can resolve 0.1 μm; (j) resolution limit on prototype system, limited by manual alignment accuracy. Bell Labs proprietary resist and equipment can resolve 0.5 μm; (k) short, 100-150 exposures; moderate, 150-1500; long, 1500-5000 or more; (l) low, <25 3 in. wafers per hour; moderate, 25-50; high, 50-100; (m) MEBES could print <2 3 in. wafers per hour. IBM EL-1 can do 22 2¼ in. (or 12 3 in.) wafers per hour; (n) Bell Labs resist and equipment can do 15 3 in. wafers per hour. Information not available for Cobilt system; (o) based on ratio of capital equipment cost to wafer throughput only.

present (GCA Mann, Electromask Corporation). Some features of these systems are high resolution (1.25 μm), virtually no runout over the wafer, automatic focusing at each step, long mask life, and relative insensitivity to dust on the mask (because of the reduced image size).

The eventual use of deep u.v. exposure may extend the useful wavelength range of conventional photolithography and thus allow somewhat higher resolution (30). A few domestic commercial deep u.v. systems are now reportedly being tested.

No x-ray exposure systems are commercially available as yet, but an experimental model (Cobilt), offering 2-3 μm resolution capability, is reportedly now being tested. This method, using flood exposure in a proximity mode (Fig. 17), appears quite promising in terms of resolution (limited by alignment, by dimensional stability of mask and wafer, by the resolving power of the resist, and by accuracy of defining the mask pattern) and anticipated moderate cost per wafer (14, 27, 29).

Use of an electron beam for wafer fabrication appears to be limited to direct writing by a computer-

Fig. 16. Photoresist pattern on (111)-Si, thickness of resist layer, 1.5 μm; 1.4 μm periodicity grating.

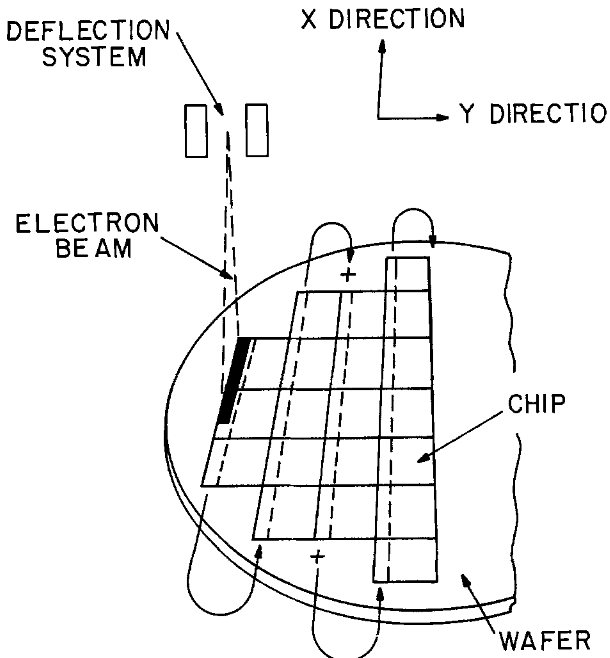

Fig. 18. A raster scan technique may be used for wafer fabrication by direct electron beam exposure.

controlled scanning method (29, 31) (Fig. 18). At present, this procedure is not commercially feasible because of low throughput, but improved system design and the advent of very large scale integrated (VLSI) circuits may bring the method into use in the 1980's (14).

An alternative method for fabricating devices by an electron beam is E-beam projection (29, 32), whereby a special thin film photomask is bombarded with electrons, and resultant emission of electrons from the mask projects the mask image onto the wafer. However, because of numerous problems, this approach will require considerable improvement before commercial application is practical.

Resist Material

The type of resist material chosen depends on the type of exposure system used. In general, photoresists cannot be used in electron-beam or x-ray exposure systems, but there are exceptions. For example, certain of the diazoquinone-type positive resist materials can be used in either deep u.v. or E-beam systems as well. In all areas of microlithography, more sensitive resist materials are constantly being sought, particularly in x-ray lithography, where low source intensity is a particular problem.

As mentioned previously, liquid resists are used almost exclusively, even in relatively low resolution applications. Conventional u.v./contact exposure processes have traditionally used negative photoresists, both for historical reasons and because of their greater process latitude (33), better adhesion, and lower costs relative to positive photoresists. Proper exposure and use of nonxylene developers can permit definition of dimensions down to ~2 μm with negative resists, but the relative ease of achieving very fine resolution with positive photoresist materials has led to a shift throughout the microelectronics industry over the past several years, as more and more highly complex chips are designed.

Conclusion and a Look Ahead

The field of microlithographic processing for producing integrated circuit devices has evolved so far from classical lithographic procedures that a comparison is hardly possible. Requirements for producing the next generations of devices, such as 1M RAM's, will surely bring about more developments of high sophistication and capability. Minimum geometries of 2 μm by 1980 and 1.3-1.5 μm by 1982 are estimated (14, 34), and thus future trends in the solid-state industry will include such processes as x-ray and electron-beam exposure of wafers, and increased use of dry etching processes. However, the wide range of device requirements will surely ensure continued use of conventional photolithographic processes in many areas as well.

Acknowledgments

The authors are very grateful to various individuals within RCA who have assisted in preparing this article, either by consultation, by critical review of the manuscript, or by assistance in gathering the illustrations. These individuals include R. A. Bartolini, W. Bösenberg, D. A. Doane, R. Epifano, R. Geshner, N. Goldsmith, W. Henry, W. Hobson, R. Hollingsworth, H. Lehmann, D. L. Matthies, M. S. Miller, C. Musser, D. A. Peters, J. H. Reisner, G. L. Schnable, and J. L. Vossen.

Manuscript submitted July 23, 1979; revised manuscript received Oct. 15, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by RCA, David Sarnoff Research Center.

Interfaces in Electrochemistry

Roger Parsons[2]

The news of the award of the Olin Palladium medal was a great surprise to me and I am very conscious of the honor which represents the regard of my friends and colleagues in electrochemistry. It is an unexpected honor in view of the eminence of the previous holders of the medal as well as of the many distinguished electrochemists who deserve it, but have not yet had the good fortune to be honored in this way. For this I would like to thank the members of the Selection Committee. I am also very grateful to Fred Anson for his kind introduction. I spent an enjoyable year in his laboratory twelve years ago, where I was able to confirm my belief that what people called "electroanalytical chemistry" was just as interesting and exciting as what people call "electrochemistry."

It is true of practically every research worker in the modern world that he works as part of a team. My own work could not have been done without the help and stimulation of my friends. Almost all my career has been spent in universities, the largest part in Bristol, and I am a firm believer in the informal collaboration of the small university research group as an efficient generator of new science. My co-workers have been mostly undergraduates, graduate students, post-doctoral fellows, and visitors from a wide variety of countries. I am glad to say that without exception they worked together harmoniously and I am glad to acknowledge the major part which they have played in my work. I have learned in this sort of environment that illumination may come from unexpected places and that the fresh approach of a beginner may be as helpful as the insight of a savant.

The title of my lecture could be taken in several ways. Electrochemistry has important interfaces with many other subjects, such as engineering, biology, physics, etc. . . Nowadays the properties of the interface between our experimental systems, their electronic controls, and computers play an increasingly important part in our research lives. However I propose to use the term in its original sense and to describe some of the progress made in the study of junctions between chemical phases, mainly between a metal and an electrolyte and to talk about structure and kinetics.

I began my research career 33 years ago in just such a university group which John Bockris started at Imperial College. It was his undergraduate lectures which stimulated my interest in electrochemistry and his energy which kept me in the subject. I was in fact the first of a very long line of Ph.D's who graduated under his detailed supervision. Only those who had contact with the earlier atmosphere of physical chemistry at Imperial College (1) can fully appreciate the impact of John Bockris on the research there. I shall always be grateful to him for starting me off so well in electrochemistry, with the classical problem of hydrogen overpotential which still plays an important part in electrochemistry even if it is far from being as dominant as it was then. The flavor of electrochemical research at that time can be judged very well by looking at the reports of the Faraday Society Discussion on Electrode Processes (2) held in Manchester in April 1947 which my friend and contemporary Brian Conway recalled in his excellent profile on electrode kinetics recently (3). As he implies, this discussion marked a watershed in the subject. One can see, side by side, work pointing towards the future and work which nowadays seems to be part of the dark ages. It was unfortunate that some of the most stimulating papers, those by Frumkin, Levich, and Ershler could not be presented by the authors and so played much less part in the actual meeting than they deserved. The work of Frumkin and his colleagues had already been brought to the attention of our group by Bockris and it has played an important part in my scientific development as it must for any electrochemist of my generation.

After my Ph.D. I began to work on interfacial structure because it seemed essential to know more about this in order to understand the kinetics of processes which occur in the interphase. The power of methods developed in the nineteenth century to solve these problems still fascinates me and although remarkable techniques have been developed to apply these methods, the basic principles are still yielding useful results in competition with those based on more recently developed ideas.

For example the Lippmann electrometer which is 104 years old is still yielding useful results of high precision which are analyzed by the powerful thermodynamic methods developed by Willard Gibbs shortly afterwards. (It is perhaps surprising to remember that one of the first to recognize the power of Gibbs' work and to publicize it was James Clerk Maxwell who died a century ago this year. Of course his other contributions have overshadowed his role as Gibbs' advocate.) I remain astonished that classical thermodynamics (which is, after all, a rigorous method of rearranging experimental information in a perhaps more comprehensible form) can give use so much insight into the minute regions of space occupied by electrochemical and other interfaces.

The concept of the electrical double layer in such systems was first clearly expressed by Helmholtz (4) also a century ago. Although the essential principles were laid down so long ago and much important application of them was made by Gouy and by Frumkin, systematic study of the metal/electrolyte interface really began in the nineteen forties when David Grahame (5) showed how precision measurements of the capacity of the double layer could be made using the dropping mercury electrode. I have no doubt that if it had not been for his early death, he would have been a Palladium medallist and would have continued to make important contributions to electrochemistry. The whole modern picture of the electrical double layer is founded on the work of Frumkin, Stern, and Grahame, and largely on the detailed study of the mercury electrode. Using essentially classical thermodynamics one can build up a reliable picture of the composition, and to some extent deduce information about the orientation of molecules, in the interface. Figure 1 shows a sketch of the probable molecular arrangement at a structureless metal surface.

I would like to recall a few simple examples of this type of approach. The fact that one can measure only surface excesses leads to a method of estimating the thickness of the inner part of the double layer, that is the distance of closest approach of solvated ions to the metal surface (6-8).

We consider a perfectly polarized electrode and assume that the adsorption of ions from a binary 1:1-electrolyte is due entirely to electrostatic forces. The adsorbed ions then populate the diffuse layer described by Gouy-Chapman theory (9, 10). Owing to the finite size of the ions and possibly to a difference in the solvent structure near the electrode there is

[2] Olin Palladium Medal Address delivered October 16, 1979 at the Los Angeles, California Meeting of The Electrochemical Society. The medal was struck from palladium supplied by the International Nickel Company, 67 Wall Street, New York, New York 10005.

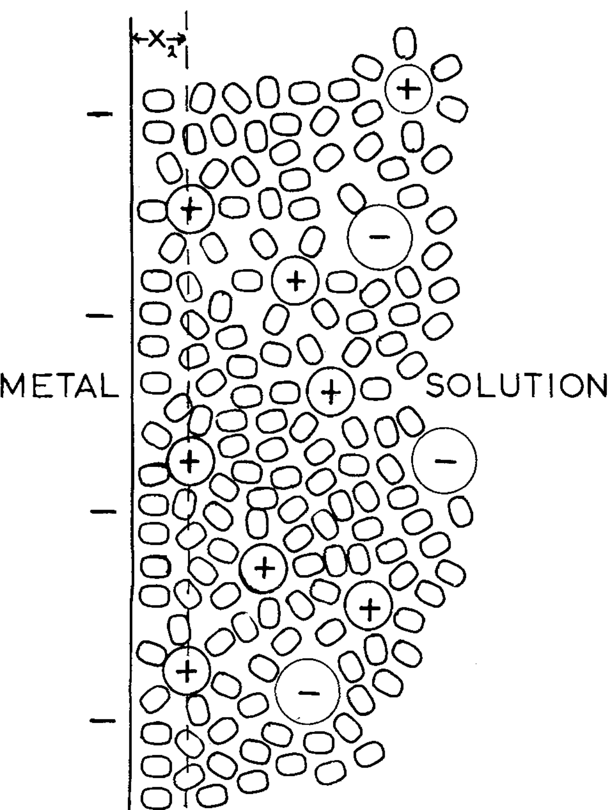

Fig. 1. Schematic picture of the structure of the electrical double layer at a uniform metal surface.

a region between the metal and the diffuse layer in which there are no ions (8). Thus the distribution of ions is similar to that shown in Fig. 2.

If we assume that the system consists of an aqueous solution of MX in contact with a mercury electrode then we may obtain the quantity $\Gamma_{M^+(H_2O)}$ from experiment

$$\Gamma_{M^+(H_2O)} = \Gamma_{M^+} - (x_{MX}/x_{H_2O})\Gamma_{H_2O} = \Gamma_{M^+} - (n^b{}_{MX}/n^b{}_{H_2O})\Gamma_{H_2O} \quad [1]$$

where $n^b{}_i$ denotes the concentration of species i in the bulk of the solution.

If the local concentrations of M^+ and of H_2O are n_{M^+} and n_{H_2O}, respectively, then the surface excess can be expressed as

$$\Gamma_{M^+(H_2O)} = \int_0^\infty \{n_{M^+} - (n^b{}_{M^+}/n^b{}_{H_2O})n_{H_2O}\}dx \quad [2]$$

where $x = 0$ corresponds to the physical interface and positive x is towards the solution. The integral should more accurately have a lower limit of $-\infty$ but if we can assume that neither component is present in the metal phase the contribution from $-\infty$ to 0 is zero. If the distance of closest approach of the ions is x_2, then we may split the integral into two parts

$$\Gamma_{M^+(H_2O)} = \int_0^{x_2} \{-(n^b{}_{M^+}/n^b{}_{H_2O})n_{H_2O}\}dx + \int_{x_2}^\infty \{n_{M^+} - (n^b{}_{M^+}/n^b{}_{H_2O})n_{H_2O}\}dx \quad [3]$$

The second term on the right-hand side of [3] can be evaluated from Gouy-Chapman theory if it is assumed (as it is in G-C theory) that the solvent concentration is independent of x, *i.e.*, $n_{H_2O} = n^b{}_{H_2O}$. This term then becomes

$$\Gamma^{2-s}{}_{M^+(H_2O)} = \int_{x_2}^\infty (n_{M^+} - n^b{}_{M^+})dx \quad [4]$$

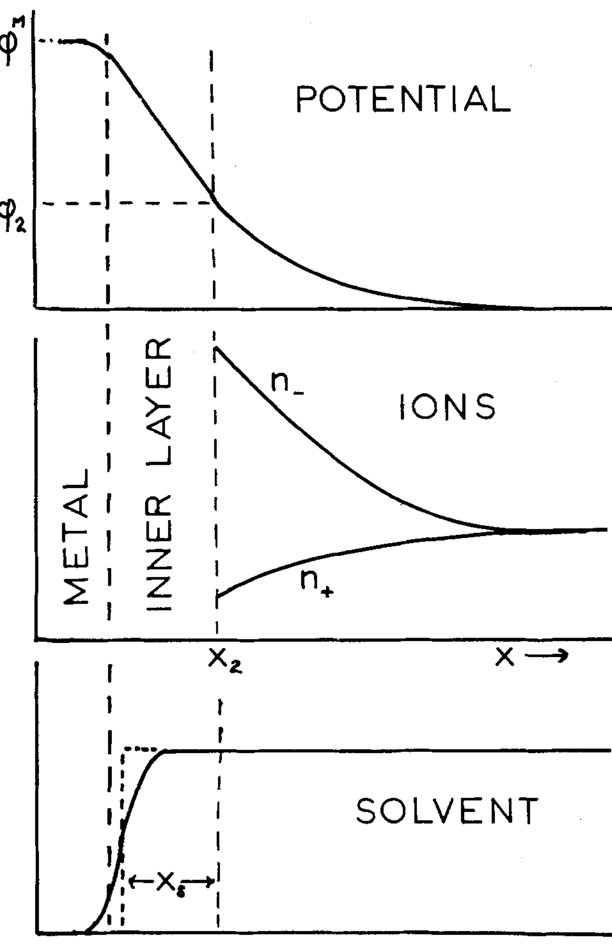

Fig. 2. Schematic diagram of potential and concentration distribution in the electrolyte near the electrode. The x coordinate is perpendicular to the interface and positive in the direction of the solution. The physical interface is assumed to be at the origin. x_2 is the distance of closest approach of the ionic species in solution; at this distance and at $x > x_2$ the only interaction between the ions and the electrode is assumed to be the simple electrostatic force due to their charges. (a, top) shows the distribution of potential Φ averaged in planes parallel to the interface. Φ^M is the potential at the metal surface due to free charges; Φ_2 that at x_2. The potential in the bulk of the solution as $x \rightarrow \infty$ is taken as zero. The charge on the metal is assumed to be positive. (b, middle) shows the distribution of cations corresponding to the situation described above. n_- is the local concentration of anions, n_+ that of cations averaged in planes parallel to the interface. (c, bottom) shows the supposed distribution of the concentration of water (solvent) molecules. The real concentration (full line) can be replaced by an equivalent rectangular distribution (dotted line) as described in the text leading to Eq. [6].

and this can be evaluated using the G-C theory (5) to obtain

$$\Gamma^{2-s}{}_{M^+(H_2O)} = (2n^b{}_{M^+}/\kappa)\{\exp(-e\Phi_2/2kT) - 1\} \quad [5]$$

This quantity can be evaluated since Φ_2 is obtained from σ^s, the charge on the solution given by the Lippmann equation $\sigma^s = (\partial\gamma/\partial E)_{\mu_{MX}}$ again using G-C theory.

The other part of the integral can be evaluated if we assume that the actual distribution of water in the inner layer can be replaced by a distribution consisting of a constant concentration up to a plane at x_w and a zero concentration at $x < x_w$ (Fig. 2c). Then

$$-\int_0^{x_2} (n^b{}_{M^+}/n^b{}_{H_2O})n_{H_2O}dx = -\int_{x_w}^{x_2} n^b{}_{M^+}dx = -n^b{}_{M^+}(x_2 - x_w) \quad [6]$$

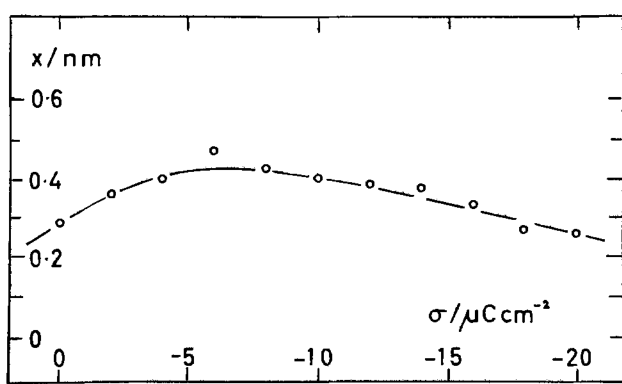

Fig. 3. Experimental determination of the thickness of the inner layer ($x_2 - x_w$) as a function of charge on the electrode.

Thus the experimental surface excess is given by

$$\Gamma_{M^+(H_2O)} = -n^b{}_{M^+}(x_2 - x_w) + 2(n^b{}_{M^+}/\kappa)\{\exp(-e\Phi_2/2kT) - 1\} \quad [7]$$

The first term on the right-hand side can be found by finding the difference between the experimental surface excess and that calculated from G-C theory (second term on the right-hand side). If it is verified that it is linear in the ionic concentration the value of $x_2 - x_w$ may be obtained. This result depends on a model, that of Gouy and Chapman, which is stretched to its limits, but we have other evidence which suggests that in this type of use the result is not very model-sensitive. The result obtained (8, 11) (Fig. 3) is in the region of 0.3 nm, which corresponds to the thickness of one water molecule and so seems reasonable. It is remarkably close to a very early estimate of the double layer thickness given by William Thomson (Lord Kelvin) and quoted in Helmholtz's 1879 paper (4).

An alternative route to the dimensions of the inner layer come from the use of a parallel plate condenser model with an approximate measure of the effective permittivity (ϵ). This can be done by measuring the potential shift (ΔE) produced by a small molecule (thiourea) adsorbed in this layer if the perpendicular component of its dipole moment (p) is assumed to be known (12, 13). Use of the Helmholtz equation

$$\Delta E = -p\Gamma/\epsilon$$

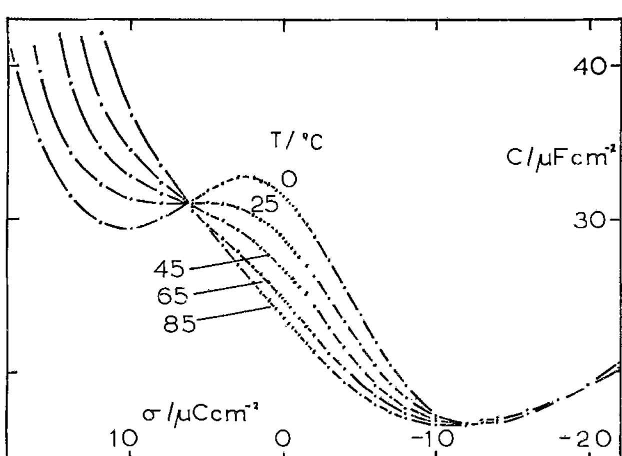
leads to values of ϵ in the region of 8 ϵ_0 to 10 ϵ_0, where ϵ_0 is the permittivity of free space, and hence again a thickness of about the same magnitude as the diameter of a water molecule.

The low value of the permittivity in the inner layer, compared with that in the bulk solvent, had been foreshadowed by Frumkin from a comparison of results in several solvents (14), and it enabled an explanation (15) of the remarkable independence of the capacity of negatively charged mercury of the nature of the cation in solution discovered in Grahame's work. In a system with a rather sharp change in permittivity, almost all the potential drop occurs in the region of low permittivity (the inner layer) and the capacity is insensitive to the precise position of the counter charge provided it is present in the high permittivity region.

More detailed models of the solvent in the inner layer were developed by Macdonald (16), Watts-Tobin (17), Bockris, Devanathan, and Muller (18), Levine (19), Frumkin and Damaskin (20) and this led to a semi-quantitative explanation (21) of the temperature dependence observed by Grahame (Fig. 4) as well as of the shapes of the capacity curves in nonaqueous solutions (22). More recent work by Fawcett (a former post-doc. at Bristol) and Levine has refined this model and removed some of its inconsistencies.

Although these classical methods remain useful, it is, naturally, important to use other independent methods to examine the interface. One of the most promising is the group which includes reflection spectroscopy and ellipsometry, because the possibility of measuring very precisely the state of polarization of visible light allows the small changes due to a monolayer or less to be detected and their refractive index and mean thickness to be determined. In a complicated adsorption system such as that of β-quinoline (23) this allows the orientation of molecules to be followed in close comparison with the amount adsorbed (Fig. 5).

Unfortunately so far we have not succeeded in following the orientation of solvent molecules which would be so desirable for comparison with the models. However, Bewick and Robinson (24) showed that reflection spectroscopy can reveal a change in the density of water in the inner layer which can amount to about 5%. This has recently been extended at Meudon to gold, both polycrystalline (25) and single crystals (26). The results for polycrystalline gold are similar to those for lead and mercury although it is possible in this case to see effects at both charge extremities (Fig. 6). The results at single crystal surfaces are particularly interesting (Fig. 7) because they show the effect of surface structure. In particular the (110) surface which has an asymmetric structure of "rails"; parallel to these "rails" the apparent change is similar to that on the "smooth" (111) surface indicating that the molecules can move equally freely along the rails as on a smooth surface. On the other hand if the electric vector is perpendicular to the "rails" the apparent change in concentration is very much less, indicating that the movement of molecules is more restricted in this direction.



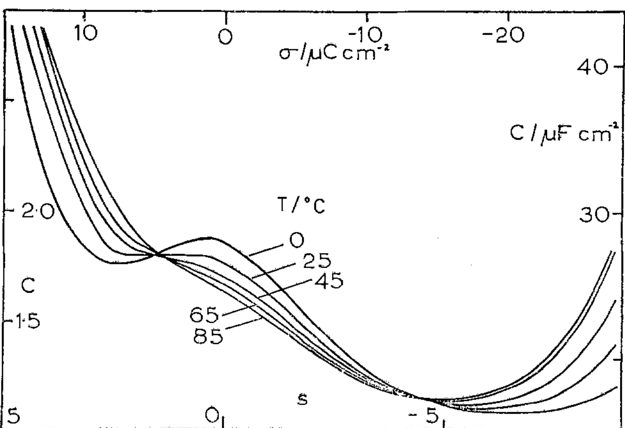


Fig. 4. (a, left) Capacity of the inner layer as a function of temperature measured by D. C. Grahame. (b, right) Curves calculated using the simple four position model.

Fig. 5. (a, left) Adsorption of β-quinoline at the mercury-aqueous 0.5M NaOH interface. The charge of the ellipsometric parameters $\Delta\Psi$ and $\delta\Delta$ is shown as a function of electrode potential E (vs. SCE) for several adsorbate concentrations (a) 0.3 mM, (b) 1.5 mM, (c) 3.0 mM, (d) 6.0 mM, (e) 15 mM, (f) saturated solution (~30 mM). Angle of incidence 70°, wavelength 546.1 nm, temperature 25° ± 1°C except curve (b) 22°C. (b, right) Surface excess of β-quinoline at a mercury electrode 0.5M Na_2SO_4 (data of N. Van Laethem, C. Herman, and L. Gierst).

We hope soon to extend this type of approach to silver electrodes to help to explain the spectacular capacity peak which has been observed with single crystals (27). It seems to be due to reorientation of individual water molecules but is structure-sensitive at positive charges which suggests strong silver-water interactions.

The electroreflectance spectrum of the metal itself shows remarkable features. On gold (28) it is strongly dependent on the structure of the face being observed. Present models of surface electronic structure do not seem to be able to account for this, but theoretical developments seem imminent. Such experiments show promise for the *in situ* study of solid surfaces. We have a great deal to learn about the behavior of solid surfaces in contact with liquids and the prospects for the immediate future are exciting.

I want now to turn to the problems of the kinetics of electrode reactions. As I mentioned earlier, my Ph.D. work with John Bockris was mainly on hydrogen overpotential. In a written comment to the 1947 Faraday Discussion, Frumkin remarked, "It is noteworthy that in the case of a mercury electrode, the value of the coefficient $b = RT/\alpha\mathbf{F}$ in the term containing log i in Tafel's equation, corrected for the influence of the ψ_1 term, gives for α the value ½ with an accuracy up to 0.01. It must be conceded that, up to date, no one has

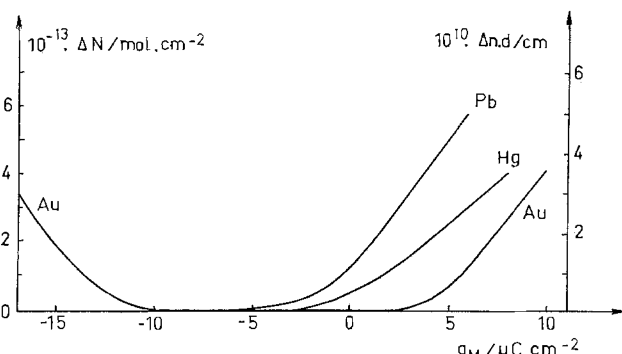

Fig. 6. Change of concentration of water in the inner layer of mercury and polycrystalline lead [data from Bewick and Robinson, Ref. (24)] and also for polycrystalline gold [data from Hinnen *et al.*, Ref. (25)].

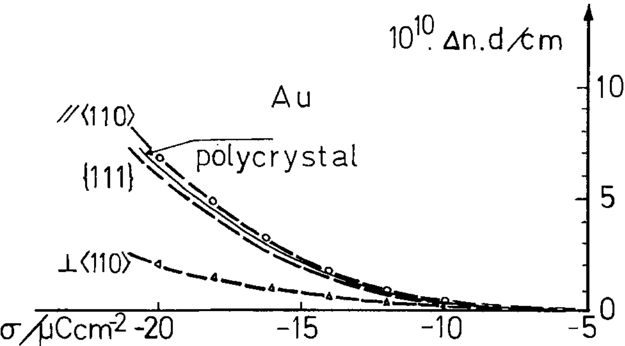

Fig. 7. Change concentration of water in the inner layer of single crystal gold [data from Hinnen *et al.*, Ref. (26)].

been able to explain why α, in this case at least, is so close to ½ and remains constant over such a wide range of potentials. It appears to the author that since the paper by Horiuti and Polanyi, no considerable progress has been made in the interpretation of the coefficient α". Not being so conscious of my limitations as I am now, I rushed in to solve this problem. I took what was essentially Butler's theory (29) and worked it out quantitatively using Morse curves and showed (in my thesis) that this gave not only about the right rate for the process but also a reasonably constant value of α over the range of potential which was used experimentally. Unfortunately this was not the final answer; the problem of α is still with us. Most people know that the models of simpler electrode processes involving only electron transfer yield in the first approximation a linear dependence of α on potential. Rudy Marcus mentioned in his opening lecture that we attempted to verify this model using the slow Cr^{3+}/Cr^{2+} reaction (30). We appeared to have good success but the accuracy of the fit was rightly criticized by Fred Anson (31) although the theory has been largely vindicated by later work in respect of the potential dependence of α (32).

Work on the hydrogen reaction led first to an attempt to construct a general framework for electrode reactions so that it was possible to see more clearly what was useful to measure and how the purely kinetic problems might be disentangled from the changes in the double layer structure. This was originally written as a large single paper but was split into two for publication. The first considered the situation when a single elementary step is rate-determining (33) while the second considered the possibility of simultaneous control of the rate by two elementary steps and suggested that this could occur only over rather narrow regions of potential (34). It is interesting that the separation of this work has resulted in the first part being much better known than the second and illustrates the necessity for publishing in the right place.

After this rather formal approach a somewhat more practical kinetic problem was presented. How can one predict the optimum catalyst for a given reaction? Of course the answer to this problem depends on a number of factors but since heterogeneous catalysis depends on the bonding of the reactant to the catalyst, it seems that the most important factor is likely to be the energy of this bond. The consequences of this simplification were worked out for the hydrogen reaction (35) and led to the "volcano" curve previously predicted by Balandin for gas phase catalytic reactions, using a thermochemical argument. The same simple kinetic argument is applicable in principle for both gas phase and electrochemical catalysis (36) and the general predictions are borne out for many of the former (37) and a few of the latter notably of course the hydrogen reaction (38).

Nevertheless this model is at best a first approximation, and, in an attempt to find the way in which it might be extended under more complicated conditions, we made a study of the oxidation of formic acid on a series of metals (39). Here it seems appropriate to show the result on palladium electrodes, which, as it happens, is the simplest type of behavior found for this reaction. That is, the oxidation current observed (Fig. 8) in a cyclic voltammogram is independent of the direction of the sweep. This indicates that the oxidation of formic acid on Pd is an irreversible surface reaction, occurring with the absence of any substantial concentration of blocking intermediates. Nevertheless, the presence of a maximum in the current-voltage curve is remarkable. It appears that the simplest mechanism which can account for this type of behavior is one involving three partial reactions and two transient adsorbed intermediates, the second occupying more sites than the first (40). These may be present at rather low concentrations and they have not yet been detected

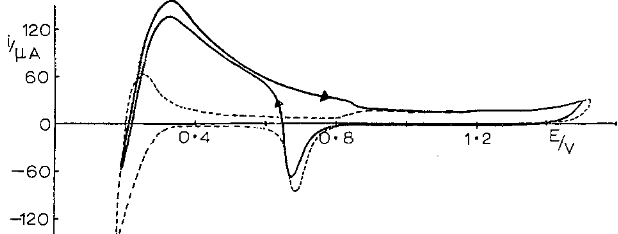

Fig. 8. Cyclic voltammogram for palladium electrode in (·····) 0.5M H_2SO_4, (———) 0.5M H_2SO_4 + 0.1M HCOOH. Sweep speed 70 mV sec^{-1}. Potential E on the hydrogen scale. Temperature 25°C.

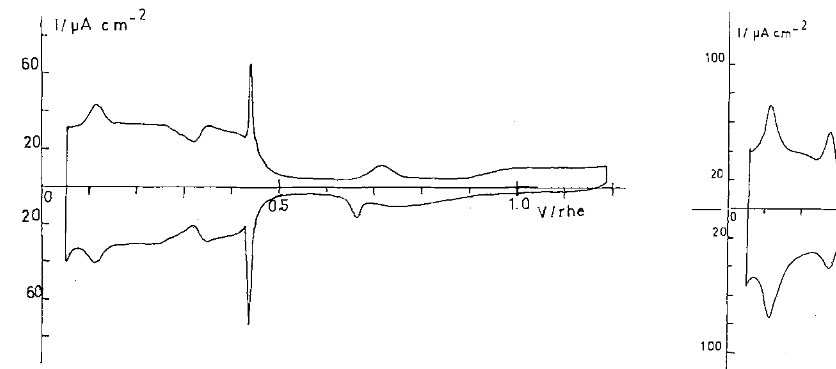
so that the mechanism remains hypothetical. Even with such a simple mechanism the prediction of the effect of the nature of the metal on the binding of the two species and hence on the kinetics takes us beyond present knowledge. If the interactions between adsorbed species and the heterogeneity of the surface are to be considered then at best only rather formal solutions can be found.

There is now some sign that the problem of preparing clean well-defined surfaces for electrochemical studies is approaching a reasonable solution at least for some surfaces. To show that work on this type of fundamental problem can still produce exciting results on systems thought to be simple and relatively well understood, I should like to finish by showing some very recent work on platinum single crystals done in my laboratory at Meudon by Clavilier together with some research workers in another C.N.R.S. laboratory at Grenoble (41). Clavilier has developed a simple and effective method of preparing clean metal surfaces and putting them into an electrolytic cell. Their cleanliness is verified by parallel Auger experiments and by the fact that the cyclic voltammogram is stable from the first cycle. Most striking results are obtained on the (111) surface which in sulfuric acid gives the curve a of Fig. 9 which is stable, provided that the positive potential limit is kept below 1.2V (no formation of oxide layer). However extension of the potential limit to 1.5V yields a remarkable change in the hydrogen adsorption region indicating loss of the high energy hydrogen adsorption sites presumably by a reconstruction of the surface. If the surface is deliberately slightly contaminated the voltammogram a of Fig. 10 is obtained. Up to 20 cycles are required to decontaminate the surface but at the same time it is reconstructed to yield curve b which is essentially the same as curve b in Fig. 9. Thus, with a contaminated surface the high energy adsorption of Fig. 9a is never seen. This high energy adsorption is very sensitive to the nature of the anions in solution and curves obtained in the presence of $HClO_4$ (Fig. 11) which is less strongly adsorbed show this hydrogen adsorbing at even more positive potentials. Addition of increasing amounts of SO_4^{2-} causes the high energy adsorption region to shift towards more negative potentials until the curve of Fig. 9a is reached. Results on the (110) plane are notably less sensitive and are in good agreement with those found in other laboratories. One important conclusion from this work is that electrochemistry can provide results which are extremely sensitive to surface structure and conversely this underlines the importance of surface structure in electrochemical reaction.

The work I have just described is an illustration of the development of electrochemistry in that it depends on an essentially modern way of thinking about surfaces and surface structure as well as modern techniques while using a basically simple technique of the measurement of current and voltage.

The increasing interest in the molecular and atomic structure of the interface in electrochemistry parallels the similar development in physical chemistry in general and in solid-state physics notably, of course, in the



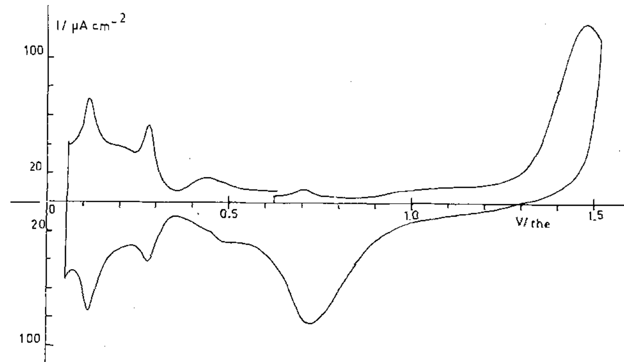


Fig. 9. (a, left) Voltammogram for Pt (111) in 0.5M H_2SO_4 after annealing. Sweep rate 50 mV sec^{-1}. Potential on the hydrogen scale. (b, right) The same but first cycle in which the limit at positive potentials was 1.5V (RHE).

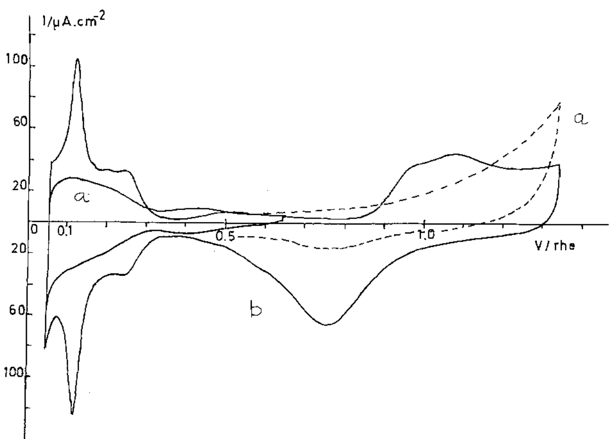

Fig. 10. (a) Voltammogram for Pt (111) in 0.5M H_2SO_4 annealed and then contacted with laboratory atmosphere for a few minutes. (b) The same after 20 cycles.

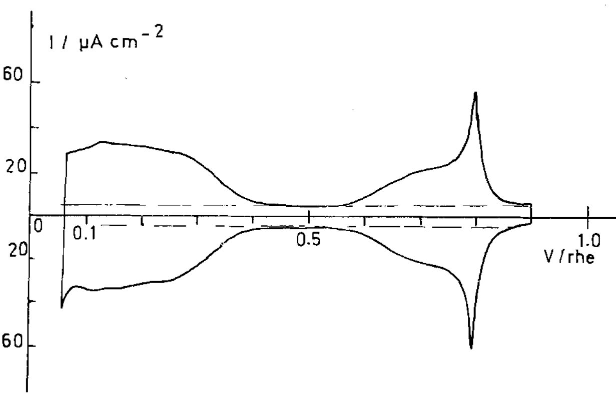

Fig. 11. Voltammogram for Pt (111) in 1M $HClO_4$ after annealing. Sweep rate 50 mV sec^{-1}.

shift of interest from bulk properties to surface properties which has accelerated in the past few years. The tendency in the past has been to attempt a molecular-quantum interpretation of experiments which were still based on averaged properties whether thermodynamic or kinetic. Too often the comparison between theory and experiment of this type is unspecific and cannot reveal much about the true nature of the system. Experiments which are themselves more directly based on molecular properties are now being done, notably in the study of the interaction of light wit. electrodes as so brilliantly described by Heinz Gerischer in his Palladium medal lecture. I believe that we are on the threshold of the transformation to a real molecular understanding of electrified interphases and consequently that we are now at an exciting interface in electrochemistry.

Diamond Shamrock Corporation, T. R. Evans Research Center, Painesville, Ohio 44077

Chlorine-Caustic Soda

Production and capacity.—U.S. production of chlorine in 1979 rose 11% to 12,271,519 tons. Industry capacity increased less than 1%, from 39,165 tons/day to 39,279 tons/day, during the year. Production rates exceeded 90% of capacity at the end of the year, up significantly from the beginning of the year (1-3).

Estimates of the production capacity of individual U.S. producers are shown in Table I (4).

Expansions completed in early 1979 by BASF Wyandotte and Georgia Pacific are included in Table I.

Pennwalt completed two expansions during 1979, raising its capacity to 464,000 tons/year of chlorine.

During 1979 several acquisitions occurred: Linden Chemicals and Plastics acquired three chlor alkali plants from Allied Chemical, raising their capacity from 450 tons/day to 1150 tons/day (5, 6). Vulcan Materials Company purchased a chlor alkali plant located at Port Edwards, Wisconsin from BASF Wyandotte Corporation, increasing their capacity 200 tons/day to 1340 tons/day (8-10).

New plant expansions and modernizations are shown in Table II (11).

During 1980, PPG plans to complete the 750 tons/day second phase of its Lake Charles, Louisiana, plant doubling capacity. Hooker will increase the capacity of its Tacoma, Washington, plant to 675 tons/day. Fort Howard Pulp and Paper will start up a 12.5 tons/day membrane cell plant in Muskogee, Oklahoma. In early 1981 Convent Chemical will start up its 800 tons/day unit in Convent, Louisiana. Dow will add an increment to its Freeport, Texas, plant in 1980 or 1981 (4, 12).

Average annual chlorine capacity is estimated to be 16,435,000 tons/year and consumption is estimated to be 12,820,000 tons in 1982 (13).

Caustic soda production was 12,313,848 tons, up 14.6% from 1978. Production of caustic soda may increase to 13,000,000 tons in 1980. Plant capacity for caustic soda was 15.5 million tons/year in the first quarter of 1980 (14, 15).

Canadian production capacity increased 650,000 tons/year in 1979, to 1,650,000 tons/year. Canadian Industries increased the capacity of their Becancour, Quebec, facility 150,000 tons/year.

Dow Chemical of Canada increased the capacity of their Fort Saskatchewan, Alberta, facility 500,000 tons/year. Production nameplate capacity of the Canadian producers is shown in Table III (16-26).

Total Canadian chlorine production is forecast to be 1220.5 kilotons by 1983 (16).

The amount of salt used to manufacture chlorine and caustic soda increased as the chlorine production increased. Chlorine and caustic soda production is the largest single salt consumer, comprising 41% in 1978. Some supply problems were encountered during 1979 as a result of hurricane David "melting" solar salt crops, and production problems encountered in the Louisiana rock salt mines. Expansion of salt production was announced by Cargill, Incorporated and Great Lake Minerals and Chemicals Corporation (27-31).

Markets and prices.—World demand for chlorine from the U.S. increased during 1979. Energy prices helped exports of energy intensive chlorine derivatives. Chlorine prices gained strength on the booming market for ethylene dichloride export. Price increases during the year resulted in $10-20 increase in chlorine, up to $135 to 150, and caustic soda up to $160 to 175/ton (32).

Reduced world wide demand for chlorine has lead to a tightening in the caustic soda market. Price increases in early 1980 increased prices for caustic soda up to $25/ton (33-44).

Table I. U.S. chlorine producers 1000 tons/year of chlorine

Producer	
Allied Chemical	350

The Industrial Electrolytic Division is grateful for the support received from the Vittorio de Nora-Diamond Shamrock Fund in assisting with the publication costs of this report.

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. It represents a summary of the published information on production, plant capacities, consumption, markets and trends, prices, raw materials, new developments, health and environmental aspects in the electrolytic and related industries.

The material presented herein has been obtained from many sources, as noted in the reference list, and does not necessarily represent the opinions of the authors.

Table II. New plant expansions and modernizations in the United States

Location	Producer	Project	Status	Projected completion	Notes
Louisiana					
Convent	Convent Chemical Co.	800 tons/day Diamond MDC 55	Building	1st Quarter 1981	1
Lake Charles	PPG Industries, Inc.	Phase 2, 750 tons/day, (bipolar)	Building	2nd Quarter 1980	1
Oklahoma					
Muskogee	Fort Howard Paper Co.	12.5 tons/day Hooker MX (membrane)	Building	2nd Quarter 1980	1
Oregon					
Portland	Pennwalt Corp.	Expansion 310-410 tons/day	Building	1st Quarter 1980	1
		Expansion 410-570 tons/day (diaphragm)	Engineering	1981	
Texas					
Freeport	Dow Chemical USA	Expansion, Dow (diaphragm)	Continuing	1980-1981	1
Washington					
Tacoma	Hooker Chems. & Plastics Corp.	Expansion 400-675 tons/day	Engineering	3rd Quarter 1980	1
		Hooker H-4			
		Expansion 200-250 tons/day	Building	1st Quarter 1980	1

Note: All Dow USA locations—conversion to metal anodes scheduled to have started in late 1979.
[1] Electrolytic plant producing caustic soda, chlorine, and hydrogen from brine.

U.S. producers claimed chlorine was still under priced, despite price hikes (45).

Chlorine burning to produce HCl is forecast to increase at 10% annual growth rate in the early 1980's (46).

Ethylene dichloride had a good year in 1979 but will probably not have as good a year in 1980 (47).

Chlorinated solvents remain under the pollution gun. Demand for these chlorine derivates appears likely to have little growth prospect (47).

The pattern of chlorine and caustic end use is shown in Table IV, and Table V (48).

Membrane cells.—Akzo Zout Chemie Netherland BV announced plans to build the first world scale membrane cell chlor alkali plant, 250,000 tons/year chlorine, in June 1979. Akzo chose Asahi Chemicals membrane technology because of the performance of the Asahi cells and the fact that the technology is more advanced than any other in the field. The plant is due on stream in 1982 (49-60).

Table III. Canadian chlorine producers (16) (kilotons/year of chlorine)

	Capacity
Canadian Industries (CIL)	388

Exports	17

Sweden's A.B. Celleco (Stockholm), established to sell membrane cell technology developed by Ionics using duPont Nafion membranes, is supplying Celleco's process package to Elkem Spigeverk. The 25 tons/day chlorine plant will cost $4.5 million and is due on stream in mid 1980 (61-63).

Uhde GmbH will supply the Hooker MX type electrolysis cells to Tofte Cellulose Fabrikk of Hurum, Norway. The 14,000 tons/year plant is scheduled to be on stream in July 1980, at Tofte on the Oslo Fjord. Caustic soda will be a 15% solution, virtually salt free (63-67).

Diamond Shamrock Corporation licensed its diaphragm cell chlor alkali technology to the Peoples Republic of China. A 625 tons/day plant will be built at Shengli in Shantung Province (68-71).

Diamond Shamrock Corporation licensed a 22 metric tons/day caustic membrane cell plant to Nigerian National Paper using its bipolar membrane cells, and a 24.5 metric tons/day membrane cell plant using its new DM-14 monopolar membrane cells to Paek Kwang in South Korea (72).

Asahi Glass Company has constructed a pilot plant at its Chiba factory for the production of ion exchange membranes. The company has decided to construct a full-fledged plant for the production of ion exchange membranes. Construction time, startup, and capacity have not been disclosed (73).

During 1979 Asahi Glass Company has continued to sell its membrane technology: Imperial Chemical Industries, ICI, concluded an agreement for the evaluation of Asahi Glass' membrane technology. The agreement cost ICI $500,000 (74, 75). Uhde GmbH reached an agreement for full disclosure of Asahi's ion exchange membranes and electrolytic cells and appointed Udhe sole agent for their manufacturing and sales. A demonstration plant of 3,000 tons/year will be constructed. Asahi Glass will also supply ion exchange membranes to Bayer & Hoechst (76, 77). Nippon Carbide Industries will switch its (1,450 tons/year) mercury process to an ion exchange membrane process plant using Asahi Glass Company's membrane technology by November 1980. Nippon Carbide is the first to announce the switch over (80). P. N. Soda Waru in Indonesia and the Paper Industries Corporation of the Phillippines have also licensed plants of undisclosed capacity from Asahi Glass Company (81).

Asahi Chemical Company has licensed its ion exchange membrane cell technology to N. Z. Forest products of New Zealand. The plant will produce 10.000 tons/year caustic soda (78, 82).

The world membrane cell plants are listed by technology utilized in Table VI.

Performance of the leading Japanese membrane cell technology is detailed in Table VII (83).

Tokuyama Soda has increased the caustic concentration from its process from 20 to 27% without

Table VI. Membrane cell plants

Plant	Capacity
I. Asahi Chemical Company Technology	
1. Asahi Chemical Company 1975 Nobeoka, Japan	80,000 Mtons/ year
2. Prince Albert Pulp Company 1978 Saskatoon, Sask., Canada	30,000 Mtons/ year
3. St. Anne-Nackawic Pulp & Paper 1979 Nackawic, New Brunswick	10,000 Mtons/ year
4. Denki Kagaku Company 1976 Ohmi, Japan	60,000 Mtons/ year
5. Akzo Zout Chemie Netherland BV 1982 Hengelo	280,000 Mtons/ year
6. N.Z. Forest Product Ltd. 1981 New Zealand	10,000 tons/year NaOH
II. Hooker & Uhde Technology	
1. Reed Paper 1975 Dryden, Ontario	13,000 Mtons/ year
2. Ft. Howard Pulp & Paper 1980 Ft. Howard, Arkansas	4,500 Mtons/ year
to be expanded	9,000
3. Tofte Cellulose Fabrikk 1980 (Hurum) Norway	16,500 Mtons/ year
III. Diamond Shamrock Technology	
1. Muscle Shoals 1975	3,000 tons/year
2. Uddeholms AB 1978 Skoghall, Sweden	20,000 tons/year
3. Aracruz Cellulose 1980 Victoria, Brazil	13,000 tons/year
to be expanded	38,000 tons/year
4. Nigerian National Paper	8,000 Mtons/ year
5. Paek Kwang South Korea	9,000 Mtons/ year
6. Korea Potassium South Korea	12,000 Mtons/ year KOH
IV. Ionics & Celleco Technology	
1. Elkem Spigeverk 1980 Bremanger, Norway	10,000 tons/year
2. ROT Chimica Monterey, Mexico	72 Mtons/ day KOH 2,600 Mtons/ year
V. Asahi Glass Company Technology	
1. Asahi Glass Company 1978 Kansai, Japan	10,000 tons/year
2. P.N. Soda Waru Indonesia	Undisclosed
3. Paper Industries Corp. of Phillippines	Undisclosed
4. Uhde GmbH West Germany	3,000 tons/year
5. Nippon Carbide Industries, Inc. Japan	1,450 tons/year
VI. Tokuyama Soda Company Technology	
1. Tokuyama Soda 1977 Yamaguchi, Japan	10,000 tons/year
VII. Allied Chemical Corp.	
1. Allied Chemical 1976 Syracuse Pilot Plant	2,000 tons/year

increasing its power consumption. Tokuyama Soda plans to begin construction of a commercial plant in fiscal year 1981 (79).

Allied's technology utilizes a patented series catholyte flow for optimized production of low strength 10-20% NaOH. Power consumption is 10% below a parallel flow unit when producing 16.5% NaOH. A six tons/day commercial prototype has been in operation since early 1978 (84).

Developments.—A nonelectrolytic chlorine process has been patented by Battelle Memorial Institute. The process recovers chlorine from hydrochloric acid by oxidation in a molten salt containing vanadium oxide and alkali metal sulfates and pyrosulfates. The work is reportedly still at the laboratory stage, and further development would require an industrial sponsor (85-87).

Conradty GmbH and Great Lakes Carbon have formed a joint venture company called Grelcon to market electrodes. Conradty's subsidiary Metallelektroden developed technology for coating electrodes which have been sold in Europe for many years (88).

Asahi Glass, PPG, and De Nora have agreed to the joint development of a new caustic soda manufacturing process called SPE, Solid Polymer Electrolyte. The process features 20% lower electric power consumption than the latest ion exchange membrane processes. Asahi Glass Company has recently launched its own R&D program on the SPE separately from the joint undertaking with PPG and De Nora (89-91).

New energy saving cathodes are being developed for diaphragm and membrane chlor alkali cells. Tokuyama Soda has announced that its new cathode is being applied successfully in its 10,000 tons/year membrane cell plant, reducing cell voltage from 3.5 to 3.3V (92).

Diamond Shamrock expects to save $2 million/year at its Houston plant where high surface area nickel cathode coatings on its steel diaphragm cell cathodes reduces hydrogen overvoltage 120-140 mV. A commercial facility to produce coated cathodes for other chlor alkali producers has been constructed (93, 94).

Hooker Chemicals and Plastics Company and Lurgi discussed cathode coatings at the Society of the Chemical Industry Conference on the Advances in Chlor Alkali Technology, which should be commercially available in 1980 for diaphragm cells (95).

D. H. Porter of Hooker Chemicals and Plastics Company discussed the reduction in energy consumption of the Hooker diaphragm cells at the Society of the Chemical Industry Symposium on Advances in Chlor Alkali Technology. Power consumption reduction of 20% using a new microporous diaphragm, a lower brine gap, and new electrode coatings, along with greatly increased surface area in the same basic cell design, was discussed. Power consumption was reduced from 2900 kW-hr/ton chlorine to 2300 kW-hr/ton chlorine (95).

General Electric has developed and commercially operates a catalytic system to remove 85-97% of the sodium chlorate from its diaphragm cell caustic soda. Product quality of less than 30 ppm sodium chlorate can be obtained (96).

Mercury cells.—The Japanese mercury cell plants must discontinue operations by the end of 1984. MITI has proposed a plan to divide the 21 mercury process companies into two groups. MITI will urge the first group of three companies, Asahi Chemical Industry Company, Asahi Glass Company, and Tokuyama Soda Company to complete the switch to ion exchange membrane technology within 2 years. Each company has developed its own technology. The remaining medium and small scale producers will be required to convert the technology within 5 years. The program also calls for a closure of 423,000 tons/year of capacity, 290,000 tons/year mercury and the remainder in diaphragm production capacity. A total of 1,360,000 tons

Table VII. Performance parameters Japanese membrane cell technology

	Current efficiency	Voltage	Current density	Power consumption	HCl consumption	Caustic concentration	Cell temperature
Asahi Chemical Co.	93.4-94.8	3.81-3.90	4 kA/m²	2698 to 2776 kW-hr/MT NaOH	132 to 146 kg/MT NaOH	40%	90°C
Asahi Glass Co.	92.0-95.5	3.80-3.87	2 kA/m²	2667 to 2781 kW-hr/MT NaOH	None	38.5-40.8%	85°-90°C
Tokuyama Soda	94	3.50	2 kA/m²	2496 kW-hr/MT NaOH	40 kg/MT NaOH	20%	85°C

	NaCl depletion	Cell type	Size of membrane	Source of membrane	Source of anode
Asahi Chemical Co.	70%	Bipolar	1.2m × 2.4m	Self supply	Self supply
Asahi Glass Co.	46-56%	Monopolar	1m × 2m	Self produced	Purchase
Tokuyama Soda Co.	40-50%	Bipolar	270 dm²	Self supply	Purchase

of capacity will be converted to ion exchange membrane technology (97-99).

The EEC Commission has made two proposals to limit the mercury content of effluent from mercury cell chlor alkali plants. The first proposed directive limits the mercury content of the effluent from chlor alkali plants:

Mercury in effluent g/ton of chlorine capacity

	Recycle brine process	Brine discharge process
July 1, 1983	1.5	8
July 1, 1986	1.0	5
July 1, 1989	0.5	2.5

The second directive covers fresh water after receiving the effluents:

Fresh water	0.5 mg/m^3
Seawater	0.05 mg/m^3

Mercury concentration in fish cannot exceed 0.3 mg/m^3. Industry is dissatisfied with the proposals, particularly the water quality and imposition only to the chlor alkali industry (100, 101).

Health and environment.—Dow is planning to build a 30 million pound a year bromine-chloride plant for use in disinfecting municipal and industrial waste water. Bromine-chloride is considered environmentally safer and as effective as chlorine (102).

OSHA has set a ceiling limit of 1 ppm for the workplace exposure to chlorine. NIOSH has developed a criteria document calling for 0.5 ppm ceiling limit to protect the worker from acute eye and respiratory irritation. The stay by OSHA in February 1979 was lifted on July 17, 1979, resulting in the Chlorine Industry's petition of the Court of Appeals. On March 7, 1980, the Fifth Circuit Court of Appeals affirmed OSHA's position relative to the chlorine standard (103-111).

Studies by an Italian research team have concluded that trichloroethylene is not carcinogenic, a direct contradiction of the U.S. National Cancer Institute findings issued in a 1976 report. The research team says the epichlorohydrin used as a stabilizer was responsible for the NCI findings and that Montedison trichloroethylene is free of any epichlorohydrin (112, 113).

Asbestos regulations are being considered by the U.S. EPA and Consumer Product Safety Commission. EPA advanced Notice of Proposed Rulemaking for Asbestos Regulation under TSCA. Its entire asbestos control program is expected to become effective between 1985-95, but commercial and industrial uses are targeted for ruling in the fall of 1980, and promulgation in the summer of 1981 (111, 114, 115).

Derailment of a 106-car Canadian Pacific freight train in Mississauga, Ontario, 20 miles southwest of Toronto, resulted in evacuation of 220,000 people due to a leaking chlorine car. Evacuation occurred because it was feared additional explosions of propane cars could cause dangerous concentrations of chlorine in the surrounding area. The largest evacuation in North American history turned out to be a valuable opportunity to test a theoretical disaster plan. Emergency planners, civil defense people and government representatives from all over the world have asked Mississauga for their plan. A seminar package, including eight hours of color videotape is in the process of being developed (111, 116).

Other Alkaline or Chlorine Compounds

Caustic potash.—Domestic caustic potash production totaled 284,258 short tons in 1979, an increase of 18.1% over 1978. Production during the 4th quarter of 1979 exceeded the 4th quarter of 1978 by over 72% (117).

The domestic price of liquid caustic potash, 45% solution, increased $15/ton (in September 1979) to $200/short ton for standard grade and to $205/short ton for low chloride grade (118).

The sole Canadian supplier of 45% KOH solution, Canadian Industries, announced expansion of the output of caustic potash at Cornwall, Ontario, by 50% before the end of 1979 (119, 120).

The first North American membrane cell plant to produce potassium hydroxide started production at ROT Quimica Monterey, Mexico. Ionics "Cloromat" membrane cell technology is used in the 2000 tons/year plant (121).

Diamond Shamrock has confirmed the licensing of its monopolar membrane cell technology for production of potassium hydroxide to Korea Potassium Chemical Company, South Korea. The plant will initially produce 32 metric tons/day of KOH (122, 123).

Domestic production of potash increased 1% in 1979 to about 2.24 million metric tons (K_2O content). U.S. demand increased 6% to about 6.6 million tons (124).

The world potash supply is estimated to be 32.3 million short tons K_2O in 1979. World demand for potash is at record levels. Production capacity increases are expected to increase the world supply to 43.2 million tons by 1985 (125).

The average domestic price of muriate of potash, excluding soluble and chemical grades, increased from $76 to $96/metric ton during the year (124).

Soda ash.—Early projections predicted a modest increase of perhaps 3% in the production of soda ash in the United States in 1979, but the estimated total of 8.17 million short tons represented a decrease of over 1%. This decline has been largely attributed to the closing in 1978 of two plants, one in Corpus Christi, Texas (PPG Industries, Incorporated) and the other the facilities of BASF Wyandotte Corporation in Michigan, which effected a loss in production of synthetic soda ash of over one million short tons (126-128).

Continued growth in the production of natural soda ash in the United States is forecast through 1985. Confidence in the availability of markets, both at home and abroad, is mirrored in the announced expansions to existing facilities and construction of new plants. It is interesting to note that the replacement of synthetic soda ash with the natural product has in fact been a major change in the industry. This change is almost complete in the United States, where synthetic soda ash is produced only by Allied Chemicals in Syracuse, New York (127, 129-136).

The United States is the principal source of natural soda ash, with a total output of approximately 7.3 million short tons in 1979, from: (*i*) trona ore deposits (a sodium sesquicarbonate), located in Green River, Wyoming; and (*ii*) brine, *e.g.*, Searles Lake, California.

In the free world today, there are only two other sources of natural soda ash capable of supporting commercial production. At one of these locations, in Kenya, the Magadi Soda Company (a subsidiary of ICI) is both expanding and upgrading its existing facility and building a new plant, to thereby essentially double its output by 1983 (137).

A multimillion dollar development program to commercialize new solution mining and processing techniques for natural soda ash has been undertaken by FMC Corporation in the Green River Basin in Wyoming. The company has stated that the new technology substantially reduces costs and improves the basic economics of soda ash production relative to conventional dry mining techniques (135, 136, 138).

PQ, a privately-owned U.S. company, is seeking participants in the joint development of its deposits of trona ore in Wyoming. Itself a major use of soda ash, PQ estimates that approximately 100 million short tons of natural soda ash could be produced from its lease holdings. The cost of the overall venture is predicted to be approximately $300 MM and it may be 7-8 years before the project is "off the ground" (136).

Texasgulf Chemicals Company is planning a major expansion of its natural soda ash plant also in Green River, Wyoming, thereby increasing the company's output to approximately two million short tons per year. Permission for the expansion, to be granted by the American EPA and Wyoming authorities, will depend upon the results of environmental and socio-economic studies undertaken this year (130).

Tenneco Oil Processing and Marketing Company announced that construction of a plant for the mining and processing of trona ore had begun. Scheduled for completion in mid-1982, the facility is designed to produce one million short tons of high purity soda ash per year (134).

Exports of soda ash from the United States had shown steady overall growth since 1975, but decreased approximately 6% to 730,000 short tons this year (127, 129).

Year	Total exports (1000 short tons/year)
1975	530
1976	645
1977	760
1978	780

A factor in this unexpected reversal is that the major manufacturers of soda ash in Europe appear to have succeeded in securing their market shares in the face of the U.S. imports. Early in 1979, the European soda ash industry was closely scrutinized on two counts: (*i*) the proposed importation into Belgium of natural soda ash from the United States, a situation that was resolved in favor of Solvay, and (*ii*) the inquiry into the pricing policies of ICI, which again was resolved in favor of the European Company (139).

Furthermore, imports of low-priced light soda ash from the Soviet Union into Europe were curbed by the imposition of a provisional antidumping duty, effective November 24, 1979 (140).

However, it is anticipated that the demand for American natural soda ash will climb rapidly in the export market in the next few years, particularly as the old European plants (producing synthetic soda ash) become economically unattractive and environmentally unacceptable (132).

Late in the year, Stauffer Chemical Company, Allied Chemical Company, and Kerr-McGee Chemical Company raised the price of soda ash, following the initiative of Texasgulf. The year-end price for bulk dense soda ash varied from $66 per ton (FMC) to $76 per ton. Kerr-McGee raised its price for the product to $90 per ton (141).

The average price for synthetic soda ash at the end of 1979 was $111-112/ton (141).

Sodium chlorate.—Domestic production of sodium chlorate decreased 3.2%, down to 248,073 tons, from the 1978 level of 256,320 tons (142).

There are now ten sodium chlorate producers in the U.S. Production capacity is estimated in Table VIII (143).

Four U.S. sodium chlorate plants started up: Erco 25,000 tons/year plant in Monroe, La; IMC's 40,000 tons/year plant in Orrington, Me; Georgia Pacific Corporation's 27,000 tons/year plant in Plaquemine, La; and Olin's 20,000 tons/year plant in McIntosh, Alabama (144-148).

Table VIII. Sodium chlorate 1979 estimated annual capacity Thousands short tons

Company	Capacity
Brunswick Chemical	8
Erco	25
Georgia Pacific	31
Hooker Chemicals	149
Huron Chemicals	11
IMC	40
Kerr-McGee	67
Olin	26
Pacific Engineering	6
Pennwalt	80
Total	443

Brunswick Pulp and Paper has announced it will build a 25,000 tons/year crystal and solution sodium chlorate plant at Brunswick, Georgia, replacing the old 8,000 tons/year plant. Krebbs NC electrolytic cell process will be used. The plant is estimated to cost $12-15 million, with completion in late 1980 (149-151).

Domestic sodium chlorate prices firmed up to $345/ton during the year (152-157).

Canadian production capacity is expected to increase 30% to 303,000 tons/year during the 1979-1980 period. Canadian manufacturers' production capacities are detailed in Table IX.

QueNord Incorporated opened its $17 million 25,000 tons/year plant at Magog, Quebec (159-161).

St. Anne Chemical began operations, while Tidal ceased operations (162).

The $8.5 million 15,000 tons/year plant to be built by Saskatoon Chemicals has an expected completion date of mid 1980. Start-up of the Saskatoon Chemicals plant could concide with yet another shutdown of Canadian Oxy's Brandon Manitoba facility (163-166).

Erco will become the world's largest producer of sodium chlorate, 172,000 tons/year once the Thunder Bay expansion is completed (167-174).

New Canadian producer price schedules effective January 1, 1980 increased the cost of solution chlorate to $353/ton, up 17.7%, and crystal grade chlorate to $408/ton, up 16.6% (175, 176).

Metals

Aluminum.—Domestic production of primary aluminum rose an estimated 4% to 5 million short tons. Domestic consumption increased to 6.2 million tons. Imports decreased to 0.9 million tons (177).

At the beginning of 1979 all the aluminum potlines in the Pacific Northwest were operating, but by the

* Scheduled to close September 1, 1979.

end of the year 162,500 tons, 3.1% of the total U.S. capacity, had been idled due to power cutbacks. Potlines in Texas that were idle at the beginning of the year had been restarted by the end of the year. Kaiser restored 20,000 tons/year of idled capacity in January 1980 in anticipation of improved power production (178, 194).

Uncertain power situations face the six U.S. aluminum producers in the Pacific Northwest where 31% of the U.S. primary aluminum capacity is located. Power cost increases of 95% occurred on December 20, 1979, increasing from 3.12 to 6.095 mills/kW-hr, adding approximately 2.4¢/lb to the cost of producing aluminum (195).

Power contracts also expire in the 1984 to 1988 time frame when the Bonneville Power Administration is expected to be deficient in meeting power obligations.

Some of the northwest producers are converting production to new energy saving technology that can reduce energy consumption by an estimated 20% (195).

Martin Marietta plans to expand its primary aluminum production from 65,000 tons/year to 185,000 tons/year by the end of 1981. The project will utilize the energy saving Sumitomo technology and is expected to cost $125 million. Energy consumption could be 25% less than the old potlines (196-199).

Kaiser Aluminum and Chemical Corporation cancelled its $66 million program to revamp the Baton Rouge, Louisiana, aluminum refinery, due to uncertainties over construction costs and energy prices (200, 201).

Kaiser Aluminum and Chemical Corporation will spend $30 million plus as the initial phase to upgrade its primary aluminum plants at Tacoma, Washington, and Chalmette, Louisiana (202).

Alumax may still build a 186,300 tons/year smelter at Umatilla, Oregon, despite environmental and energy costs (195).

A 200,000 tons/year primary aluminum smelter may be built at Clarendon, North Carolina, by a Middle East consortium of metal users and investors. The project is estimated to cost $400 million and be on stream by the end of 1982. Much of the smelter's production will be exported (203, 204).

The Alumax 197,000 tons/year 400 million dollar primary smelter at Berkley, South Carolina, is expected to start pots late in the summer of 1980. Reports of a new primary smelter being constructed by Alcoa in Kentucky have not been confirmed by the company (204).

U.S. prices for 99.5% aluminum ingot ranged from 55 to 57.5 cents/pound. Price increases by the producers at various times during the year advanced prices to 66 to 66.5 cents/pound. Merchant spot prices exceeded published prices all year long and reached nearly 80 cents/pound at year end (205).

Total domestic aluminum demand had begun to fall in the last half of 1979 and is projected to become weaker in 1980. Some forecasters predict at least a 2% decline of 144,000 tons, others predict 5.6-15% decline in U.S. consumption (206-208).

Table X. Northwest aluminum producer power contract expiration dates (195)

	Smelter capacity (tons/year)	Expiration date
Alcoa, Vancouver, Washington	115,000	June 1978
Wenatchee, Washington	205,000	June 1987
Anaconda, Columbia Falls, Montana	180,000	Dec. 1986
Intalco, Ferndale, Washington	265,000	Oct. 1984
Kaiser, Mead, Washington	220,000	Oct. 1986
Tacoma, Washington	81,000	Oct. 1986
Martin Marietta, The Dalles, Oregon	90,000	Feb. 1988
Goldendale, Oregon	120,000	Feb. 1988
Reynolds, Troutdale, Oregon	210,000	Dec. 1986
Longview, Washington	130,000	Dec. 1986
Total	1,616,000	

Reynolds Aluminum Recycling Company announced a record 75 million pounds of aluminum recycled during the first six months of 1979, an increase of 7%. Payment for recycle aluminum beverage cans was increased to 23 cents/pound, an increase of 3 cents (209, 210).

Reynolds Metals Company's Recycling and Reclamation Division plans to build a scrap metal separations plant to separate aluminum and other nonferrous metals from automotive shredder residues. The facility located in Sheffield, Alabama, is expected to recover more than 10 million pounds of aluminum during its first year of operation (179, 181).

Recycling aluminum requires only 5% of the energy needed to produce aluminum from ore. In November 1979 Howmet Aluminum in Rockwall, Texas, completed a 75 million pounds/year plant that will produce high quality aluminum from 100% recycled material. Martin Marietta Aluminum is building a scrap recycling processing plant that can produce up to 240 million pounds of sheet ingot for their steel mill. "A Way of Life," a color film on aluminum recycling and energy is available on free loan from Modern Talking Picture Service, 1901 L Street NW, Washington, DC 20036 (212).

Ford Motor expects to increase aluminum usage in its cars from its 1980 model year content of 140 pounds/car to 190-200 pounds by 1985. Other auto producers also expect to achieve 190-200 pounds/car. Aluminum castings are expected to be the major portion of the growth (213, 214).

The aluminum industry succeeded in 1978 in achieving the U.S. Department of Energy goal of 10% reduction in energy by 1980. Additional new ideas in processing and materials promise significant energy savings in the next decade. (215-218).

A study of aluminum smelting processes carried out by Arthur D. Little, Incorporated for the Department of Energy through Argonne National Laboratory, reached a major conclusion that the only alternative technology at present to the Hall Heroult cell for the production of primary aluminum is the Alcoa chloride electrolysis process, with the sulfide and nitride electrolytic processes offering potential advantages in the future. Titanium diboride cathodes may achieve significant energy consumption reductions in the Hall Heroult cell (179, 180).

Alcoa continues the development of its low energy process, called the Alcoa smelting process (ASP), that began in 1973. Redesign, construction, and testing of a new segment of the chemical plant is expected to take 3-4 years additional development. The ASP system is viewed as holding promise for a 30% reduction in the smelting energy perhaps, to 4.5 kW-hr/pound, down from 6 kW-hr/pound in the most efficient Hall's cells (220-224).

Direct reduction (DR) that produces an aluminum and silicon alloy is being studied by Alcoa in a small pilot reactor with partial funding by the U.S. Department of Energy. Commercial scale demonstration may occur in 1990 after formidable technical obstacles are overcome (224).

Technology to produce aluminum metal and chemicals from kaolin via alumina and aluminum chloride will be the joint development of Pullman Kellogg and Toth Aluminum Corporation. Success could lessen U.S. dependence on imported bauxite (225, 226).

Kaiser Aluminum will install 10 prototype aluminum reduction cells that will use in-house "prebake" technology to effect significant improvements in the plants energy efficiency and work environment (215).

Oak Ridge National Laboratory is evaluating a commercial sized plant to process 1 million tons/year of fly ash to recover 98% of the aluminum and over 90% of the other metals. This plant is based on the

process called Calsinter that Oak Ridge National Laboratory developed (227-229).

New aluminum structural materials made from aluminum and silicon carbide whiskers are being tested by Lockheed Georgia Company for application in aircraft structures.

Alcan Aluminum Corporation's new super plastic aluminum alloy, containing zinc and calcium, offers lightness, strength, and corrosion resistance and has potential in limited production vehicles. A thermoforming process using compressed air can be used to form complex shapes, allowing more economical production than traditional stamping techniques (231, 232).

Free world primary aluminum production increased to 13.2 million short tons in 1979, an increase of 409,000 short tons. Changes in the free world primary aluminum capacity in 1979 are shown in Table XI.

Australia plans to become a major aluminum exporter by the mid '80's. Five projects are expected to add 585,500 metric tons/year to the existing 280,000 metric tons/year.

Domestic production of bauxite was estimated at 1.7 million metric tons in 1979, the same level as 1978. Jamaica, Guinea, and Surinam remain the principal sources of bauxite. Imports of dried and calciumed bauxite declined slightly in 1979, totaling approximately 14 million tons. Imports of alumina increased, reaching a record level of 4.1 million metric tons of which three fourths came from Australia (177).

Alumina capacity of the free world rose to 34,436,000 short tons/year, up 1.9%. Alumina production rose 4.1% to 29.4 million short tons in 1979. Free world production of bauxite was 89.9 million short tons, an increase of approximately 10 million short tons (233).

Development of non-bauxite routes to aluminum originally designed to reduce the U.S. dependence on imported bauxite have stalled, due to changes in the IBA, International Bauxite Association, that has resulted in a brighter future for the bauxite supply picture. The U.S. produces about one-third of the world's aluminum but imports more than 90% of the raw materials. Originally, ten domestic alumina consumers and the U.S. Bureau of Mines funded a program to evaluate a hydrochloric acid/clay process. Now participation has dwindled to four producers and the pilot plant costing 52 million cannot be built due to the level of cost participation necessary by the remaining few producers (234, 235).

Beryllium.—Production and consumption of beryllium ores in the United States in 1979 were essentially unchanged from that in 1978. In fact, there has been no significant growth in this industry over the last several years. There are two major beryllium ores. *(i)* Bertrandite, which is produced in Mallard County, Utah by Brush-Wellmann, Incorporated. Future demand for this ore is expected to increase in light of the announced expansion in the extraction of beryllium from bertrandite by a major U.S. consumer of beryllium metal. *(ii)* Beryl, approximately 80% of which was imported from Brazil and Argentina. The average value of the imported beryl in 1979 was $574/ton (236).

Table XI. Additions to free world primary aluminum reduction capacity in 1979 (233)

Country	Company	Amount (short tons/year)
U.S.	Anaconda	60,000
Brazil	Pocos de Caldos	33,000
	Aluminas	16,000
Brazil	Cia Brasileira de Aluminio (CBA)	30,000
Venezuela	Industria Venezolana de Aluminio SA	235,000
France	Pechiney Ugine Kuhlmann	25,000
Spain	Aluminio Espanol	150,000
South Africa	Alusaf	6,000
Japan	Closed a total of	75,000
Bahrain	Alba	5,000
Dubai	—	15,000
India	Bharat Aluminum (Balco)	25,000
Australia	Alcan Australia	50,000
	Total	725,000

Beryllium metal is used in the aerospace industry because of its high strength and rigidity yet light weight, and in the nuclear industry, where both low thermal-neutron absorption and high neutron-scatter cross section are required. However, in the free world, a more important end-use for this metal is in the production of beryllium-copper alloys; the addition of approximately 4% beryllium significantly improving the strength, as well as the fatigue and corrosion resistance of the copper. The volatility of the copper market in 1979 led to a new pricing system for beryllium-copper alloys being introduced by Kawecki Berylco Industries during the fourth quarter. This company also increased the base price of beryllium-copper products in the fourth quarter, so that, effective January 1980 the price of strip (number 25) will be $5.54/lb; of bar, rod and wire (number 25) will be $5.80/lb; and the master alloy will be $90/lb. It was also stated that size extras and "adders" for special treatment, such as mill hardening and cadmium plating, have been adjusted in accordance with the cost content of specific operations (237).

The carcinogenic properties of beryllium and beryllium compounds led to the introduction of standards by OSHA that the industry maintained were impossible to achieve economically. Additional studies and commentary were initiated during 1977-1978, the results of which were expected to support the Government's position, but no reports have been published in 1979 (238).

Although not necessarily related to the environmental regulations, Kawecki Berylco Industries (a wholly owned subsidiary of Cabot Corporation and one of only two producers of beryllium in the free world) announced that it will phase out production of the metal. It was stressed that the change in business direction is not expected to affect the production of beryllium ores (239).

As of November 30, 1979, the Government stockpile inventories were as follows:

Beryl (11% BeO equivalent)	17,987 short tons
Be/Cu master alloy (~4% Be)	7,387 short tons
Beryllium metal	229 short tons

Chromium.—Domestic demand for chromium was strong in 1979, primarily due to a high level of stainless steel output. Domestic consumption of chromite increased 19%, totaling 1.2 million tons, with the major increase occurring in the metallurgical industry:

	1978	1979
Metallurgical	53%	61%
Refractory	23%	18%
Chemical	24%	21%

Consumption of chromium alloys increased almost 5% to nearly 526,000 tons (240, 241).

Domestic producers of chromium alloys exceeded the record year of 1974, producing about 280,000 tons of chromium alloys. Chromium alloy imports were expected to substantially decrease from 1978 levels. The Republic of South Africa continued to be the leading supplier, accounting for 66% of the imports. (240).

Published year-end chromite prices were close to year-end 1978. South African high-iron chromite remained at $54-58/metric ton, high chromium. Turkish chromite increased $5 to $110 per long ton, and the price of Russian chromite was suspended. Prices for chromium alloys fluctuated as shown in Table XII.

Table XII. Chromium alloy pricing during 1979 (Cents per pound of chromium)

	Beginning	End
Ferrochromium silicon,	29.3-29.5*	43-44.5*
Low Carbon ferrochromium	74	95
Imported 50-55% charge chromium	40-44	43-44.5
Producer 50-55% charge chromium	43-44	46-49
Electrolytic chromium metal	299	350

* Units—cents/pound of alloy.

The United States removed economic sanctions against Southern Rhodesia in mid-December 1979, allowing resumption of the import of chromium materials (240).

Boycott action by the International Longshoremans Association against USSR vessels, in protest of the Afghanistan invasion by the Soviets, could affect the U.S. ferrochrome industry in the second half of 1980. Inventories of chromite, estimated to be 500,000 tons, potentially a years supply, are held by U.S. ferroalloyers. This situation could shift the use of chromite ore from high grade to low grade, increasing the imports from South Africa. A total and sustained curtailment of Soviet chrome imports will almost certainly be translated into higher prices. U.S. companies produce about one-half of the U.S. stainless steel industry requirements (242).

PPG and Harrison & Cranfield, a United Kingdom based company, agreed in principle for the sale of PPG's chrome chemicals business for around $15-20 million (243, 244).

Airco sold its ferroalloy operations in Niagara Falls, New York, and Calvert City, New York, to Satra Corporation; its operations in Charleston, South Carolina, to Macalloy Corporation; and its operations in Sweden to Vargon Alloy AB (245, 246).

A platinum-chrome mine may be developed by Texasgulf Incorporated, based on a new process developed for Foster Wheeler Corporation by Tetronics Research and Development in the United Kingdom. The plasma process produces a temperature of 2000°C, achieving a fine melt and facilitates recovery (247).

A process for regeneration and recycle of spent chromium solutions produced from plating and finishing printed circuit boards, and other surface treatment operations, has been developed by scientists at the Bureau of Mines, Rolla Metallurgy Research Center. The process utilizes an electrolytic cell with Nafion® 427 membrane to oxidize the chromium in the anode compartment, while other metal ions migrate to the cathode compartment. Energy use is 3-4 kW-hr/pound of regenerated etchant (248).

Copper.—The major copper producing and consuming countries, including the United States, held three meetings in 1979 under the auspices of the United Nations Conference on Trade and Development (UNCTAD). The primary objectives of the conference were to continue to examine the causes of market instability and to consider possible solutions to the problem. Special attention was directed to the feasibility and desirability of using buffer stocks to stabilize prices. Further meetings are expected in 1980 (249).

The significant improvement in the copper industry shown in 1977 and 1978, after several years of a depressed market and oversupply of the metal, was maintained in 1979. The consumption of refined copper in the United States increased again (~1%) to 2.2 million tons, approximately equal to the record high level realized in 1973 (249).

Production of copper from mines in the United States was estimated to be 1.57 million short tons, showing an increase of 5% over 1978 production. The rapid escalation in the price of copper in the market place during 1979, resulted in a substantial increase (~45%) in the value of the copper produced, its being estimated at $2.9 billion. This improved outlook for marketing copper and the increased value of the metal prompted the reopening of several mines that were closed following the slump in demand in 1975. Principal states for the production of copper were Arizona (65%), Utah (13%) and New Mexico (12%).

The average estimated price for refined copper in 1979 on the London Metal Exchange (LME) was 92 cents/pound, showing approximately a 50% increase relative to 1978 prices. Producer prices in the United States for refined copper increased similarly; the average price in 1979 being 93 cents/pound (249).

A comprehensive study, sponsored by the United Nations, has concluded that the free world countries must increase their capacity to produce copper metal to meet the demand projected through 1990. The analysis predicted that the consumption of refined copper will grow at approximately 4% per year over the fifteen year period 1977-1992. (Although the increase in consumption was only approximately 1% in 1979, the combined increase over 1978 and 1979 agrees with this prediction.) This forecast, when translated into the required mine capacity, projected a cost of $46.5 billion (1977 prices) to expand the copper capacity in the free world (249-251).

Kennecott Copper Corporation has announced plans to expand and upgrade its mining properties over the next five years at an estimated cost of approximately $700 million. In particular, Kennecott intends to extensively improve the Chino Mines Division in New Mexico, to make the mine "one of the lowest-cost copper properties in the United States." The introduction of new concentrator facilities at the Utah Copper Division will cost about $300 million, and a project for low-cost recovery of copper concentrates from existing tailings ponds is also planned at the Nevada Mines Division (252).

Kaiser Engineers Incorporated has been awarded a contract by Asarco Incorporated (New York) to provide engineering and procurement services for a $50 million plant to concentrate copper to be built near Troy, Montana. This unit will be adjacent to a new underground mine being developed by Asarco and will produce approximately 60,000 tons of copper per year from copper sulfide ore. Production is scheduled to begin in mid-1981 (253).

Texasgulf plans to construct a copper smelter and refinery in Kidd Creek, Ontario. The production of copper at the new plant is estimated to be 65,000 tons/year and the projected cost of construction is $200 million (254).

It has been reported that Israel Chemicals will reactivate the Timna Copper mines near Eilat and build a plant to produce copper salts and manganese metal on-site. The mines were closed about three years ago following the decline in the world markets for copper (255).

Acceleration of the development of the vast Duluth Gabbro mineral lode in Minnesota is being seriously considered by several of the mining companies, in particular Amax Incorporated, the world's largest producer of nonferrous metals. The mineral lode is regarded as a future source of copper, cobalt, and nickel, which will become economic when richer ores worldwide have been exhausted. Amax Incorporated estimates that the vein of copper-nickel sulfides is worth $50 billion (1979 prices) and would support mining for 50 years, increasing the U.S. copper reserves by 25%. However, the deposits lie in a region that is today perhaps the most actively protected environmentally. The chief concerns of the environmental lobby are: *(i)* that toxic metals from mine waste will be leached into the water table and the lakes of the Boundary Waters Canoe Area, and; *(ii)* the pollution associated with smelting. *i.e.*, the production of sulfur gases and, therefore, "acid rain." An extensive study of the en-

vironmental and economic impacts of mining the Duluth Gabbro mineral lode was completed in September 1979 and the State legislature is presently conducting hearings upon the results (256).

Total spending by the U.S. copper industry in order to meet environmental, safety, and health regulations by 1987 will be $3.5 billion (1974 dollars) according to a comprehensive survey released by the Commerce Department in April. The report also highlighted several "probable shutdowns" of copper smelting facilities as a result of the inability of the plants to economically meet future environmental standards. In this respect, the copper industry appears to be one of the hardest-hit of the mineral industries. It is evident that the application of new technology and large capital investments will be required to either modify existing pyrometallurgical practices or adopt new chemical processing techniques (257, 258).

On October 30, the Federal Trade Commission amended the consent order negotiated with Atlantic Richfield Company (ARCO) in February, deleting provisions that brought sharp protests from leading U.S. copper producers, especially Asarco Inc. The consent order requires ARCO to divest itself of certain copper properties acquired in 1976 in a merger with Anaconda Company, but: *(i)* prohibits purchase by any company with more than 10% of U.S. copper mine production (eliminating Kennecott, Phelps Dodge, and Newmont Mining); *(ii)* stipulates that companies with 5-10% of the market must seek FTC approval before bidding on any Anaconda properties (which applies to Asarco, Duval, and Cyprus Mines); *(iii)* requires that the four biggest integrated copper producers seek prior FTC approval of any joint ventures (which affects Asarco, Kennecott, Phelps Dodge, and Newmont Mining (256).

An electrolytic process utilizing a fluidized particle-bed has been developed by Akzo Zout Chemie (Netherlands) and is applicable to the removal of copper from the waste streams from vinyl chloride monomer plants. The metal is deposited onto cathodically charged particles, which then sink and are discharged from the cell. Concentrations of metal particles in wastewater streams can be reduced from 100 to 0.1 ppm. The first commercial unit using this process has been in operation for several months at an Enka plant in Wuppertal, West Germany (259, 260).

The recovery of copper metal from industrial waste streams has been the subject of considerable research and development. Several new processes are claimed to show promise in both laboratory and pilot-plant trials, *e.g.*, the use of ion exchange resins and leaching with solutions containing chloride ions (261-263).

A new metal electrowinning process, involving the oxidation of a slurry of coal rather than water as the anodic process, is claimed to significantly reduce the power consumption for the recovery process. Electrowinning is presently an important source of chromium, cobalt, nickel, copper, zinc, and cadmium in the United States. In laboratory experiments the electrodeposition of copper in this new cell required approximately 66% less electrical power than the conventional electrodeposition process (264).

Lithium.—World wide lithium chemical consumption increased 6% over that of 1978, with the largest increases occurring in Western Europe and South America.

No new producers of lithium chemicals or ores emerged in 1979 (265).

Lithium Corporation of America, a subsidiary of Gulf Resources and Chemical Corporation, began construction of a new plant in the United Kingdom, near Liverpool, to produce an alkyl lithium catalyst, important in production of high performance synthetic rubber products for European markets. Initial capacity of 200.000 pounds/year is expected to start up in late 1980 (265-267).

Estimated 1979 world consumption of lithium metal and chemicals (Tons Li_2CO_3 equivalent)

North America	12,500
Western Europe	5,500
Japan	2,350
South America	1,900
Other Countries	3,000
TOTAL	25,250
USSR (est.)	4,000-6,000

The production capacity of the domestic producers is estimated to be (265):

	Tons $LiCO_3$ equivalent		
	1979	1980	1981
Lithium Corp. of America Bessemer City, North Carolina	14,000	18,000	22,500
Foote Mineral Company Silver Peak, Nev.	8,000	8,000	8,000
Kings Mtn., North Carolina	7,000	7,000	7,000
	15,000	15,000	15,000
Estimated total U.S. capacity	29,000	33,000	37,500

World production capacity of lithium mineral is estimated to be 10,200 short tons of contained lithium in 1979 and is forecast to be 17,400 short tons by 1985 (268).

Foote Mineral Company has completed the feasibility study for a 6000 tons/year lithium carbonate plant from brine in Northern Chile (265).

Tantalum Mining Corporation jointly owned by the Manitoba government, 25%, Hudson Bay Mining Company, 37.5%, and Kawecki Berylco Industries, 37.5%, is conducting a feasibility study for a 7,500 to 10,000 tons/year lithium carbonate plant at Bernic Lake, Manitoba (265).

Lithium chemical prices increased approximately 11% on October 1, 1979. New schedule prices are:

Technical grade lithium carbonate	$1.15 per/pound
Lithium carbonate pellets	$1.19
Lithium hydroxide monohydrate	$1.53
Anhydrous technical lithium chloride	$1.85 (269, 270)

Lithium metal prices were $15.20-$15.65/pound for ingot, and $24.80-$25.25/pound for rod (271).

Demand for lithium chemicals and metal is forecast to have a probable average annual world growth rate of 6.2% through the year 2000. New uses not yet commercialized or not yet discovered are expected to approximate one quarter of the total end use of lithium by the year 2000. Probable demand for lithium chemicals and metal in the U.S. is estimated to be 13,600 short tons of contained lithium by the year 2000. End uses are projected to be

Aluminum production	37%
Ceramics and glass	11
Lubricants	7
Other	15
New uses	30 (272)

Lithium batteries can deliver 1.5-10 times the power of conventional batteries of the same volume, and 3-5 times those of the same weight. Virtually all pacemakers, over 250,000 installed in the last 7 years, are powered by lithium batteries (273).

Magnesium.—Based upon data collected by the International Magnesium Association, the domestic production of primary magnesium metal was estimated to be 160,000 short tons for the period from January to September in 1979. Although data for the total production of magnesium metal are not yet available, it is clear that it will substantially exceed that produced in 1977 and 1978. Exports of the primary metal, valued at $98.9 million, were actually more than ten times the amount imported, which also represents a significant increase to the metal industry (274, 275).

Consumption of the metal in North America is estimated to be 115,000 short tons for the year. At the end of 1979, the quoted prices were as follows.

Magnesium ingots	$1.09/pound	
Magnesium die-casting alloy	$1.07/pound	(274)

In contrast to the mediocre performance from 1973 to 1977, when the annual consumption of magnesium appeared to reflect the worldwide economic slowdown, there has been a sharp increase in the use of magnesium in 1978 and 1979. It has been projected that by 1985 an annual growth rate of approximately 5% will be achieved by the industry. Furthermore, with the continued increase in the production of magnesium in North America through 1985, the industry is confident that supply will continue to significantly exceed this increased demand (276-278).

The major producers of magnesium metal in the United States are: NL Industries, Incorporated (Rowley, Utah), Dow Chemical Company (Freeport, Texas); and Northwest Alloys, Incorporated (Addy, Washington). Despite the optimistic forecast for magnesium, NL Industries announced plans to sell a magnesium facility at Salt Lake City. This plant, which produces approximately 15% of the total U.S. magnesium, has operated at a loss since it was opened in 1972. It is expected that the plant will continue to operate at least until the end of 1980 (279).

The largest single application for magnesium is in the production of an aluminum-magnesium alloy, essentially half of the total production being used in this way. Other important markets for the metal are die-casting (~16% of production) and chemical uses, such as Grignard reagents, production of pyrotechnics and antiknock additives for leaded gasoline (~15% of production).

It is projected that a major increase in the use of magnesium will be for the desulfurization of iron. Apparently anticipating this, Dow Chemical Company has authorized the construction of a 20 million pounds/year plant for the production of magnesium metallurgical granules, due to be "on-stream" in mid-1980 at Freeport, Texas. The product is specifically for use in the blast furnaces, offering several advantages over calcium carbide or other forms of magnesium in terms of energy savings, improved productivity and better control of sulfur (278-280).

du Pont has recently announced the development of an aluminum-magnesium composite, incorporating 55% alumina fiber, which has structural properties superior to steel. The reinforcement is a continuous web of polycrystalline α-alumina fiber and outlets in both the aerospace and automobile industries are foreseen (281).

Certainly the demand for fuel-efficient automobiles is likely to be an important factor in the growth of the magnesium industry. Until recently the high price of magnesium relative to aluminum, has excluded it from being considered as a replacement for zinc and iron in automobile castings. However, recent projections indicate that the price of aluminum will approach that of magnesium, making the latter metal economically attractive to the auto industry (276, 277, 282).

Ford Motor Company has pioneered the use of magnesium in automobiles, already having used the metal to cover side-mirrors for some 1980 models. Two additional components fabricated from magnesium will be introduced later this year (1980). Larger components are presently being considered, since the auto industry has now gained experience with this highly flammable metal.

In order to gain full advantage of any competitive edge it is essential that the cost of production of magnesium be reduced. Thus, Dow Chemical Company is developing a new process that is claimed to reduce overall energy consumption by 35%. More economical methods of fabrication are being explored by the various companies, *e.g.*, Black and Decker Manufacturing Company. It is also recognized that safe working practices, particularly in any large scale manufacturing process, are of primary importance (282).

Manganese.—No production or shipment of manganese ore containing 35% or more manganese occurred in the U.S. during 1979. Lower grade maganiferous ores continue to be produced in Minnesota, New Mexico, and South Carolina (283).

Manganese ore consumption increased but was less than one quarter of that imported in 1970. Imported ferromanganese was brought in to make up the deficit. Domestic production of ferromanganese increased in 1979. Major shifts in ownership of U.S. ferromanganese production occurred in 1979 as a result of sale of the 40,000 metric tons/year plant of Circo, Incorporated at Mobile, Alabama, to Mexico's Cia. Mineia Autlan. Airco's Calvert City, Kentucky manganese ferroalloy plant was sold to Germany's SKW Alloys, Incorporated, a wholly owned subsidiary of SKW Trostberg, AG. Roane Limited, a subsidiary of South African Manganese Amcor Limited, (SAMANCOR) purchased Engelhard Mineral and Chemicals Roane Electric Furnace Company at Rockwood, Tennessee, which produces ferromanganese and silicomanganese. Preliminary ruling by the U.S. Treasury Department against Brazil and Spain for subsidizing ferromanganese and silicomanganese exports to the U.S. would allow countervailing duties to be imposed (283, 284).

Prices for metallurgical ore containing a minimum of 48% manganese were $1.36 to 1.42/long ton unit (ltu) on contract during 1979. Annual contract negotiations for 1980 have suppliers asking $1.80 to $1.83/ltu, an increase of 29 to 33%, primarily due to rapidly escalating ocean freight costs (284, 285).

Union Carbide Corporation expanded and modernized its Marrietta, Ohio, electrolytic manganese metal facility, increasing capacity approximately 10-15% to 10,000 tons/year (286).

Electrolytic manganese metal prices were increased 4 cents/pound to 62¢, up 7% during the last quarter of 1979 by U.S. producers, Union Carbide, Foote Mineral, and Newmont. The increases were expected by the industry due to rising energy costs (284, 287-289).

U.S. produced high carbon ferromanganese (78% Mn) were $440/long ton (lt) in early 1979, moving upward in stages to $490/lt by May. Union Carbide increased prices to $530/lt on November 1. Imported alloys of the same grade were quoted at $375-420 at the beginning of the year and went through a high of $450-490 in the summer and declined to $440 to $450 during November. LeNickel Incorporated, sales agent for SAMANCOR, announced effective December 31, a price of $485/long ton (283,290).

World manganese production is steady at 23-25 million metric tons/year. The USSR accounts for about 40% of the world total. Eight countries supply 95% of the world total (284).

Total dependence of the U.S. on imported ore and ferromanganese have lead to controversy over world manganese ore reserves. Fran R. Dykstra, who testified before a Senate subcommittee, projected supply

and demand crossover in manganese resulting in a world pinch on manganese in the late 80's. He disagrees with the Bureau of Mines estimation of Russian reserves. He urged passage of legislation to enable the U.S. to begin harvesting sea floor manganese nodules (291).

Manganese ore reserves are estimated to be:

Manganese ore reserves

	(million short tons contained Mn)
USSR	1,350
South Africa	1,680
Australia	175
Gabon	100
Mexico	15
Brazil	70
China	34
Other	176
Total	3,600 (284)

The Bureau of Mines issued Report of Investigations No. 8330, "Catalytic Properties of Natural and Rare-Earth-Promoted Manganese Nodules." After study of small samples from both the Atlantic and Pacific Oceans, it was concluded that the deep-sea nodules have sufficient potential as oxidation catalysts for control of air pollution to warrant more extensive investigation after commercial production of the nodules has begun. Report of Investigations No. 8383, "Properties of Manganese-Copper Alloys Prepared From Metal Powders," reported on Bureau research, demonstrating that high-damping manganese-copper alloys can be made by powder metallurgy techniques (286).

The U.N. Law of the Sea conference is still stumbling over taxation questions related to mining manganese nodules. Mining tests conducted by Ocean Minerals Company (OM Co.) which used the Glomar Explorer have, it is believed, gone to lesser scale efforts to mine these nickel cobalt manganese nodules from the ocean floor. The other four consortiums have maintained a low level of activity in 1979. Expectations of 1990 nodule mining operations are fading. Japan has launched a new $19 million nodule exploration vessel and the 35 company Deep Ocean Mining Associate expects nodule mining by 1990 (284).

The USEPA lifted its ban temporarily on manganese gasoline additive, MMT, to stretch gasoline supplies (284).

Nickel.—Production of the only domestic nickel mine was about 14,000 tons, a slight decline from 1978, while primary nickel consumption was 201,000 tons, an increase of 11%. Total nickel demand was 271,000 tons, the third highest year on record. Labor strikes in Canada and curtailed production caused producer stocks to decline during the first half of the year (292).

Smelter production, with the ore supplied by the single domestic mine in Oregon, totaled 11,000 tons of nickel in ferronickel, and about 1,000 tons were recovered as by-product from primary copper operations (292).

AMAX Nickel, Incorporated's facility at Port Nickel, Louisiana, produced 25,000 tons of nickel. An hourly work stoppage which continued for four months impaired production (292-294).

Nickel was consumed in three principal primary forms showing minor change from 1978:

Unwrought	68%
Ferronickel	21%
Nickel oxide	8%

Product line consumption of nickel varied slightly:

	1978	1979
Stainless and alloy steel	44%	47%
Nickel and copper base alloys	33	33
Electroplating	17	16
		(292, 295)

Nickel recovered from scrap increased in total tonnage in 1979 but remained at 17% of total demand (292).

Nickel inventories declined significantly below normal levels as revealed by Inco, the world's largest nickel producer:

	Year end
1977	89 million pounds
1978	141 million pounds
1979	341 million pounds
Normal level	120 million pounds

Most producers are operating at 60-70% of capacity and share Inco's light inventory situation.

List prices of $2/pound for melting nickel were regained in February 1979 and successive, almost monthly, increases raised the price $3.20 by years end. Producer nickel price profile is shown in Table XIII.

OPEC oil price hikes of $8 per barrel may further increase producer prices 15-50 cents/pound, especially for energy intensive lateritic nickel which makes up half the world supply (298).

World nickel production rose 12% above 1978 levels to 1.04 billion pounds. Inventories dropped with finished nickel production for 1979 corresponding to approximately 70% of capacity utilization. 1980 nickel production is expected to increase to about 1.2 billion pounds with an increase in producer inventories. Over the long term, through 1985, production is expected to rise to about 80% capacity utilization (299).

Current free world nickel industry capacity is estimated to be 1.6 billion pounds per year, growing to 2 billion pounds by 1985. Free world consumption of 1.3 billion pounds in 1979 is expected to reach 1.58-1.65 billion pounds in 1985. Costs of adding nickel capacity have tripled since 1970, from $3.00 to $11.00/pound. Increased oil prices have added a $1/pound to the cost of producing nickel from lateritic ores since 1973. These escalating costs will put upward pressure on nickel prices over the next decade (300).

Table XIII. Producer nickel price profile (297)

Inco (eff. Dec. 4)	
Cathode (1x1, 2x2), S-rounds	$3.25
Cathode (4x4, up), pellets, 123 powder	$3.20
Sinter 75, Incomet, utility shot/pig	$3.11
(Europe)	$3.08
Falconbridge (eff. Dec. 10)	
Cathode (1x1, 2x2), crowns	$3.25
Cathode (4x4, up)	$3.20
Ferronickel (37% nickel)	$2.19
SLN (eff. Dec. 3)	
Electroplating cathode	$3.25
HP cathode	$3.20
FN-1 ferronickel	$3.29
FN-3 ferronickel	$3.26
FN-C ferronickel	$3.24
SLN 25 granules	$3.23
FN-4 ferronickel	$3.22
Western Mining (eff. Dec. 6)	
Briquettes	$3.20
Steelmaking briquettes, steelmaking powder	$3.11
Hanna (eff. Dec. 11)	
Ferronickel (50% nickel)	$3.15
Sherritt Gordon (eff. Dec. 5)	
Briquettes, S-grade powder	$3.20
Larco (eff. Dec. 12)	
Ferronickel (25% nickel)	$3.22
Amax (eff. June 11)	
Briquettes	$3.00
Nickel corrugates	$2.97
Steelmaking powder	$2.93

The London Metal Exchange began trading pure nickel class I material on contracts for six (6) metric tons, 13,228 pounds, in April. During the last half of the year 2,500 tons of nickel reached consumers at 25-45 cents/pound below producer prices (292, 301).

General Motors claims to have cleared a major technological obstacle to the introduction of electric powered vehicles in the mid-1980's with its zinc-nickel oxide battery developments. Energy storage of 2-2.5 times the level of lead acid batteries is claimed. Production of 100,000 Electrovettes (converted Chevrolet Chevette) would consume 1.5% of the nickel industries current annual production (302-304).

The Department of Energy has said that at least 200 of the 700 demonstration vehicles to be purchased in 1980 will be powered by nickel-zinc or nickel-iron batteries (305).

AMAX continues with the evaluation of the Duluth gabbro copper-nickel deposits. A multiagency report concluded that the large resource could be mined with proper precautions to protect the environment (292).

Work continues on a demonstration plant evaluation to extract cobalt and nickel from western laterites using a new hydrometallurgical process (292).

A Japanese consortium announced construction of an ocean survey vessel, scheduled for operation in July 1980, which is specifically equipped to survey for manganese nodules in the promising area southeast of Hawaii (292).

Sodium.—No references to metallic sodium were found for the year 1979.

Titanium.—With respect to both production and consumption of titanium, 1979 was a strong year and the trends established in 1977 and 1978 were maintained (306-308).

The strong market for titanium metal results primarily from the demands of the aircraft industry and the purchase of airplanes, such as the Boeing 747 and 767, Lockheed L1011, and McDonnell-Douglas DC10, with relatively high titanium content. It is predicted that the market for titanium will continue to grow, since aging fleets of jetliners need to be replaced by planes having lower fuel consumption, smaller engines, and lower noise levels (307).

Boeing Commercial Airplane Company is considering the use of trans-beta-titanium alloy in the construction of new 767 airliners. Studies carried out at the Boeing Central Technical Center indicate that the alloy is superior to other titanium alloys, offering significant weight savings and therefore reduced costs. The alloy is a proprietary interest of Timet Incorporated, one of four companies engaged to fabricate parts from the material. Other companies involved are Alcoa, Ladish Company, and Wyman-Gordon (309).

The new Pratt and Whitney jet engine JT8D-209, utilizing titanium "in new ways." will be incorporated in the McDonnell-Douglas DC-9 Super 80 twin jet. The engine is claimed to use approximately 10% less fuel than the older JT8D engines. Furthermore, noise levels are significantly reduced as a consequence of the use of an alloy, Ti-6Al-2Sn-4Zr-Mo-Si, developed by Timet Incorporated and Pratt and Whitney specifically to withstand the high temperatures of the jet exhaust (310).

According to the Bureau of Mines the production of titanium ingots remained stable over the four quarters of 1979 and totaled 37,000 short tons, an increase of 18% over 1978 production levels. Although the total production of titanium ingot (plus approximately 400 short tons that were imported) was sufficient to meet the market demand both at home and abroad, there was a small decrease in the industry's stockpile. Similar trends were shown in the production and consumption of titanium sponge. Domestic production increased 22% relative to that in 1978 and there was a significant increase in imports (from 1500 short tons in 1978 to 2500 short tons), primarily from Japan (306, 311).

The limited supplies of titanium throughout 1979 led to controversy between purchasers (primarily the aircraft industry) and the mill suppliers over conditions of long term contracts. Titanium Metals Corporation of America (TIMET) and RMI Company of Niles, Ohio, began to demand contracts for supply of titanium over the next three years with substantial penalties for cancellation (312).

This continuing shortage of titanium has led producers, both in the United States and abroad, to increase production capacity. For example, Howmet Turbine Components Corporation announced the purchase of a titanium ingot plant at Reno, formerly operated by a division of Whittaker Corporation, but idle since 1976. The facility contains three vacuum arc melting furnaces, with an annual capacity of approximately 2000 short tons of ingot, according to Howmet. The Reno plant, which is the second ingot facility for the company, is expected to begin production early in 1980 (313).

Shotton, Wales, has been selected as the site for the construction of a $55 million plant to produce approximately 5500 tons of titanium metal granules per year. The plant will be operated as a joint venture of Britain's National Enterprise Board, IMI Limited and government-owned Rolls-Royce Limited (314, 315).

Considerable emphasis is also being placed on increased production of titanium sponge. New technology and expansion plans already underway, announced or under consideration, could raise the total annual capacity in the United States to 34,000 short tons by 1985. The current U.S. capacity for the production of titanium sponge is shown below, together with the process and producer (306, 307).

Company	Current capacity	Process
Timet Incorporated	14,000 short tons	Kroll
RMI Company	7,500 short tons	Hunter
Oregon Metallurgical Corporation	2,500 short tons	Kroll
Totals	24,000 short tons	

Dow Chemical Company and Howmet Turbine Components Corporation (a subsidiary of Pechiney Ugine Kuhlmann Incorporated) have announced a joint venture agreement to commercialize an electrolytic process for the production of titanium sponge. The process is based upon work by the Bureau of Mines in the mid-1960's, which has been subsequently developed by Dow and by Homet. Electrolytic reduction of titanium tetrachloride yields a titanium sponge which can be melted to give the pure metal or used to make titanium alloys. If successful, it is anticipated that a production-scale operation will be "on-stream" by the mid 1980's. At present, virtually all titanium is produced by either the Kroll process (reduction of $TiCl_4$ using magnesium) or the Hunter process (the reducing agent being sodium metal). According to Dow, the energy requirements for the electrolytic process are approximately one-half those of the conventional processes. Furthermore, the titanium product is of a higher quality with respect to consistency of both size and purity (316-318).

RMI Company is expanding its main plant in Niles, Ohio, to increase the output of mill products approximately 25%. Earlier in the year RMI had announced a $3.5 million expansion of the company's sponge facility at Ashtabula, Ohio. Both expansions are scheduled for completion by the third quarter of 1980 (318, 319).

Cometals Incorporated, has agreed to import titanium sponge from China in amount described as "significant" relative to that imported from Japan, the Soviet Union and the United Kingdom (320).

Production of titanium ores in the United States is summarized in tabular form below (306):

Ore	Production (short tons/year)
Ilmenite	550,000, a decrease of 7% from 1978 production levels
Rutile	No domestic production

The heavy minerals operation at Boulougne in Florida, which produced a bulk titanium concentrate containing rutile, was closed down in November because of depleted reserves. The only U.S. plant producing synthetic rutile, located in Alabama, is expected to resume production early in 1980 (306).

Imports of ilmenite, essentially all from Australia, was estimated to be 280,000 short tons, a decrease of approximately 9% from 1978. There was a substantial decrease (approximately 37%) in the amount of natural rutile imported in 1979, but in sharp contrast, a fourfold increase in the imports of the synthetic rutile. The major sources of the synthetic ore were Australia (69%) and Taiwan (21%) (306).

Sierra Rutile Limited, owned by subsidiaries of Bethlehem Steel Corporation (85%) and Nord Resources Corporation (15%), began to mine rutile in Sierra Leone from the Mogbwemo deposit, about 80 miles from Freetown. It is anticipated that in 1980 Sierra Rutile will ship 110,000 short tons of the ore (318).

Associated Minerals Consolidated, a subsidiary of Consolidate Goldfields of Australia, announced that it will expand the capacity of the plant at Capel (producing synthetic rutile) to 60,000 tons/year. It was also reported that the company, the world's largest producer of rutile, plans an eventual increase in total capacity to 120.000 tons/year (321).

Reports indicate that NL Industries will sell its subsidiary, Titanium Alloy Manufacturing Company Pty. Limited (Tamco) to Utah Mining Australia, Limited (321, 322).

The spot price of rutile at the year end was $375-400 per short ton f.o.b. Atlantic and Great Lakes ports; the price f.o.b. Australia increased approximately 40% during the year to $348-369 per short ton (306).

Zinc.—According to the Bureau of Mines, U.S. Department of the Interior, in 1979 the mine production of zinc in the United States was only 286,000 short tons, the lowest level since 1932 and a decrease of 14% from the production in 1978. Several prolonged strikes were largely responsible for the observed decrease in production. The year long strike at the Balmat-Edwards mine (St. Joe Zinc Company) was settled in July, but production for the remainder of the year was only 50% of capacity. Production at both the Azark Lead Company mine in Missouri and the New Market Mine (Asarco Incorporated) was interrupted by strikes, the latter mine having been reopened in January 1979. Workers at the Young mine in Tennessee struck in September and the mine has remained idle through the remainder of the year (323-325).

The Shullsburg mine in Wisconsin closed indefinitely due to problems meeting environmental regulations and the unfavorable conditions of the zinc market (326).

The production of approximately 540,000 tons of zinc metal in 1979 by U.S. primary and secondary smelters represents an increase of 22% over that of 1978. The new electrolytic plant in Tennessee, owned by Jersey Miniere Zinc Company, operated almost at capacity for the whole year, producing approximately 82,000 tons of zinc metal (323).

In November, St. Joe Zinc Company announced the closing of its electrothermic zinc smelting facilities in Monaca, Pennsylvania (capacity 200,000 tons/year). The increasing cost of energy, labor demands, and the large capital investments required to meet the environmental regulations, were cited as the primary reasons for the shutdown. It was stated that the joint venture of SNC/Dravo had been engaged by St. Joe Zinc Company to design a new electrolytic refinery to be built at one of several possible locations. In the meantime, St. Joe will meet customer demand for zinc slab with tolled metal produced from its zinc concentrates and with purchased metal (323, 327, 328).

Exxon Minerals Company, U.S.A. continued to explore the zinc-copper deposit at Crandon, Wisconsin. Furthermore, the company anticipated the start of an underground sampling program in 1980 at the properties in New Mexico, properties which have been estimated as a deposit of 7 million tons, grading 2% copper, 3% zinc, and recoverable quantities of silver and gold (323).

Cominco Limited announced plans for the immediate development of the "Polaris" zinc-lead ore deposit of Arvik Mines Limited. The cost of the development program is estimated at approximately $150 million and the mine is expected to produce almost 190,000 short tons of zinc concentrate annually. Agreement has been reached with the Government of Canada with respect to the conditions under which the Polaris mine can be developed and production of the zinc concentrate (and lead concentrate) should begin early in 1982 (329).

A joint venture of Louisiana Land and Exploration Company and Superior Oil Company have reported that if technical and environmental studies are favorable the development of the Bald Mountain property in Maine could begin in 1984 (323).

A new study conducted by the Commerce Department has concluded that by the year 2000 minerals found in the deep ocean floor, including copper, cobalt, manganese, and zinc, will be critical not only to the industrial and economic strength of the United States, but also to its national security. This is perhaps made more significant by the recent discovery of massive deep-sea deposits of ore-grade zinc, copper, and iron sulfides by a team of French, American, and Mexican geologists. The discovery also confirms a geochemical theory that such deposits were formed when seawater rapidly cooled the lava (330-332).

Noranda Exploration Incorporated exercised its option to acquire an interest in the Ontario mine of Park City Ventures in Utah. The company announced plans to reopen this mine in 1980 (323).

The consumption of slab zinc in 1979 decreased 3% (relative to 1978) to approximately 1 million tons, apparently due to significantly decreased demand for zinc in die-casting, rolled zinc, and zinc oxide (323, 333).

Use	Consumption (tons/year)	% of total consumption
Galvanizing	411,000	45
Zinc-base alloys	282,000	31
Brass and bronze	139,000	15
Rolled zinc	22,000	2
Zinc oxide	36,000	4
Miscellaneous (includes batteries, zinc dust)	30,000	3

The demand for zinc in 1980 is expected to continue to decrease, particularly that for die-cast metal. However after 1980 the market is expected to strengthen the demand increasing at probably 2-3% per year for several years (334).

A new zinc alloy, ZA-12 (containing 12% aluminum) is claimed to have improved casting properties and can be used to replace bronze, cast-iron, and heat-treated aluminum. The alloy, developed by Pittsburgh Cast Products Incorporated, is approximately 30% lighter and stronger than either cast iron or bronze and offers significant savings in both materials and machine costs (335).

The average price of prime western grade zinc in 1979 was 37.4 cents/pound, an increase of approximately 20% relative to 1978 prices. On the Long Metal Exchange the average price was 33.2 cents/pound, maintaining the smaller difference between the European and U.S. prices observed late in 1978 (323, 336).

Imports of zinc in ore and concentrates were essentially unchanged from 1978 and major sources were again Peru, Bolivia, Mexico, and Honduras. It was noted that several of the countries supplying zinc to the United States are politically unstable and may pose a threat to future supply of the metal (323, 337).

In contrast, the major supplier of zinc metal to the United States is Canada, total imports in 1979 decreasing to 510,000 tons, 18% lower than in 1978 (323).

Confrontation between several U.S. producers of lead and zinc (St. Joe Minerals Corporation, New Jersey Zinc, Anaconda, Asarco Incorporated) and the Council on Wage and Price Stability (COWPS) occurred throughout 1979, following the announcement by the Council that unlike copper these metals were not exempt from the voluntary guidelines. Discussions led to the Council agreeing to consider special guidelines in which the U.S. prices for zinc and lead would be related to the world market prices on the London Metal Exchange (338, 339).

The Electrical Industry

The once-placid, investor-owned electric utility which produces 77% of all electrical power in the United States, finds itself caught in a spiral of uncertainties: the energy crisis, regulation, and inflation (340).

The slower growth in energy sales in recent years was initially regarded as a "short-term aberration" by executives of the utility companies and it is, of course, well known that the industry responds slowly to changes. Furthermore, stringent environmental regulations and inflation have made new construction appear prohibitively expensive. It was recently reported by the Edison Electric Institute that the average capital cost of a coal-fired plant has increased from $144 per kilowatt hour (kW-hr) in 1970 to $1096 kW-hr for a plant to come "on-stream" in 1987. For a nuclear power plant the comparable costs are $165 and $1861. Of necessity then many utilities are delaying and/or canceling new construction (340).

The cumulative woes of the electrical industry are exemplified by the present position of San Diego Gas and Electric Company. Faced with a projected growth of 5% per year in customer demand for electricity, the utility cannot afford to build any new capability. A major problem has been the rapid escalation in the cost of producing power, costs that have increased approximately 250% in the last five years, while increases in customer rates have been limited to only approximately 140% over the same time period. This has resulted in lower bond ratings, restrictions on the utilization of current debentures, and the inability to sell new stock. San Diego Gas and Electric Company has cancelled plans to upgrade a fossil-fired unit (projected cost $60 million) and to construct a $50 million 45 MW geothermal plant in Imperial Valley in California (340).

The Energy Crisis.—In a recent review of sources of energy available to the United States in the near term (1985-2000), it was pointed out that the growth in production and sales of energy has diminished and will probably level off in the 1990's. The production of oil and gas in the U.S. peaked approximately seven years ago and it is claimed that there is no reasonable basis to justify predictions of increased yields. Estimates of undiscovered petroleum liquid resources in this country are presently placed at 100 billion barrels, and it is evident that the U.S. resources of conventional oil will be seriously depleted within 20-25 years (341-343).

Since the early predictions of expansion and growth the development of nuclear energy has suffered a series of setbacks and consequently diminished expectations. This has in part been due to environmental and sociological constraints, and it has become evident that nuclear power may not be regarded as the major future source of energy in the United States (341, 344).

According to the Bureau of Mines, recent estimates indicate that there are 437 billion tons of coal in deposits in the United States that can be mined under present economic conditions and using current technology. Furthermore, it is projected that coal will be available in increasing quantities, sufficient to meet increased demand for energy and allow transition to a society that is able to use energy more efficiently and/or alternative abundant sources such as solar and geothermal energy. Thus despite the present environmental and sociological constraints, coal is the only domestic energy resource capable of substantial expansion (341, 345).

Environmental regulations, health, and safety.—It has been estimated that in 1990 additional revenues amounting to 16% of the electric plant base costs would be required to meet federal air, water, and nuclear regulations. This is an indication that federal regulation itself represents "a massive industry" and that the cost of compliance is rapidly becoming prohibitively expensive (346).

To bring existing facilities up to the pollution control standards (effective January 1979), it was estimated that the total cost to the U.S. business was $27.2 billion. The expenditures of two industries, the electric utilities and the petroleum industry, account for 44% of the cost of all planned pollution-control modifications. Also for most industries and businesses, modest increases are forecast in planned spending for antipollution measures over the next 3-5 years whereas for the electric utilities expenditures of $4 billion have been projected (see Table XIV) (347).

According to the method chosen by Department of Energy for classification of power plants as "new" or "existing" under the Fuel Use Act (FUA), as of May 8, 1979 a new power plant was prohibited from burning oil or gas. An existing plant may continue to burn oil although conversion may be ordered in certain cases. In order to be classified as an "existing" plant a utility must indicate that it will suffer a "substantial financial penalty" or impairment of reliability if it is not. In response to many objections, the act was revised and the Economic Regulatory Administration

Table XIV. Expenditures for pollution control 1978, 1979 and 1982 (347)

Industry	Air pollution 1978	Air pollution 1979	Air pollution 1982	Water pollution 1978	Water pollution 1979	Water pollution 1982
Gas utilities	21	31	76	31	18	54
Aerospace	26	38	20	11	15	21
Rubber	76	50	69	9	10	16
Paper	135	249	211	136	184	164
Mining	231	231	243	113	171	97
Chemicals	211	287	280	281	292	458
Iron and steel	278	395	254	144	264	138
Petroleum	354	808	442	377	291	277
Electric utilities	1785	1883	1542	935	1032	2311

of the Department of Energy will now "take into consideration any financially related factor that is considered appropriate" (348).

The Tennessee Valley Authority (TVA) is now implementing a $1 billion program to reduce air pollution at its coal-fired power plants. Thus TVA emerges as the costly pacesetter for many of the nation's utilities, and it is clear that the Environmental Protection Agency (EPA) intends to use the performance of TVA to push into line utilities that are not presently in compliance with the clean-air regulations. In a series of modifications that will be fully implemented by 1982 it is predicted that sulfur dioxide emission will be reduced 42% at ten TVA plants. It is also predicted that particulate emission at ten TVA plants will be reduced 22% (349).

A controversy involving Dow Chemical Company, the EPA, and the State of Michigan concerned the chemical company's innovative pollution control system at its Midland plant. The EPA has yet to approve the amendments introduced by the state of Michigan and is charging Dow with violation of the standards outlined in the Clean Air Act. Although some agreements were recently reached several major issues remain:

1. Can a company be forced to spend $22 MM to switch fuels for boilers that will be obsolete in 3-4 years?

2. Can the EPA deny the State's amendments to the state implementation plan?

3. Is there sufficient flexibility in the Clean Air Act for the EPA to allow controls that meet the spirit, if not the letter, of the law?

Dow Chemical Company has also argued that conversion to total oil would consume an additional 7000 barrels/day and result in an additional $22-25 MM outlay for fuel. (350).

For several years, officials of the State of Ohio have struggled to prevent imposition of sulfur dioxide emission standards on the electric utilities in their state. Recent air control plans outlined by the State were rejected in October of 1979, but at the same time the EPA has eased the requirements for the major utilities in Ohio. As a result many of the power plants will continue to burn high-sulfur coal without the addition of costly pollution-control equipment. A major winner in the confrontation was Cleveland Electric Illuminating Company, since the EPA agreed to fourfold relaxation in the emission limits for two large plants at Avon Lake and Eastlake. It was estimated that installation of scrubbers to meet the original standards would have cost approximately $524 MM (351, 352).

The moratorium on new construction permits and operating licenses for nuclear plants imposed by the Nuclear Regulatory Commission has created considerable unhappiness in the electrical industry. It was pointed out that with today's high rates of inflation any delays were extremely costly. The announcement of the indefinite delay in licensing surprised TVA, which had planned to begin fuel loading at Sequoyah unit 1 in mid-November. Financial officials of the company estimated that the delay will cost $10 MM per month and would cost residential customers an additional $1.20 per month. Southern California Edison Company is also concerned, pointing out that within the next 12 months 15 nuclear units, representing an aggregate capacity of 15,450 MW, will require operating licenses. Extended delays would be costly and would strain the summer capacity reserves, particularly in the southeast (353).

The chemical affinity of neoprene for PCB's, which has previously been a definite drawback, has been adapted to provide a system to remove PCB's from oil insulating fluids. Introduced by RTE Corporation as a disposable filter the neoprene "gravel" effectively reduces the levels of PCB in transformer fluids to less than 50 ppm (354).

It is reported that the investor-owned electrical utilities in the United States plan to spend $413 MM on health and safety of employees, placing the utilities third among all U.S. industries surveyed by the McGraw-Hill Department of Economics. These expenditures represent 1.4% of total capital spending by the electric industry, slightly lower than the 1978 level of 1.8% (355).

The electrical industry has shown that significant effort is expended to make transmission rights-of-way (ROW) esthetically pleasing. A utility's vegetation manager plays a major role in developing ROW's that will be assets physically to the general public as well as functionally to the industry. In general, three distinct components contribute to the structural makeup of the vegetation. By evaluating these components on a variety of ROW's, sites can be created that blend harmoniously with their surroundings (356).

Power generation in the United States.—Sales of electrical energy increased only 2.85% in 1979, to a total of 2075 billion kilowatt-hours (kW-hr), significantly lower than forecast. A sharp decrease in the *growth* of sales of electrical power to residential users (see Table XV) probably reflects the surging inflation rate and the demand for national energy conservation. This is certainly supported by the decrease in the average use for residential power (Table XVI) from 8849 to 8820 kW-hr, only the second decrease in a decade. However, with the average rate for electrical power for the residential user escalating to 4.32 cents/kW-hr the average annual bill actually increased approximately $25 in 1979. Data for commercial and industrial power are also shown in Table XVI (357, 358).

A survey released by the National Utilities Service Incorporated (New York) showed that over a period of fifteen months (January 1978 to March 1979) rate increases were moderate. The average rate increase for the nation's 24 largest utilities was 7.5%. It is of interest to note that for utilities heavily dependent upon nuclear energy, *e.g.*, Connecticut Light and Power

Table XV. Electric utility sales, 1977, 1978, and 1979 (357)
(Billions of kW-hr)

	Residential	Industrial	Commercial	Other	Total
1977	652.3	757.2	469.2	72.1	1950.8
1978	679.2	782.1	480.7	75.8	2017.8
1979	693.4	812.5	493.6	75.9	2075.4
% Change 1977-1978	4.1	3.3	2.3	1.3	3.5
% Change 1978-1979	2.1	3.8	2.7	—	2.85

Table XVI. Average annual use, electric rate, and utility bill 1977, 1978, and 1979 (357)

	Residential			Commercial			Industrial		
	Average use, kW-hr	Average bill		Average use, kW-hr	Average bill		Average use, kW-hr	Average bill	
		Per kW-hr	Annual		Per kW-hr	Annual		Per kW-hr	Annual
1977	8693	3.78¢	$328.6	52,892	3.84¢	$2031	1,722,567	2.33¢	$40,105
1978	8849	4.03¢	$356.6	53,085	4.10¢	$2176	1,702,939	2.59¢	$44,156
1979	8820	4.32¢	$381.5	53,184	4.38¢	$2332	1,707,768	2.85¢	$48,614

Company, rate increases were unusually moderate (359).

The capability of the electrical industry to generate power grew modestly (approximately 4%) in 1979, increasing to 597,523 MW, vis-a-vis a capability of 574,365 MW as of November 30, 1978. As can be seen in Table XVII the dependence upon fossil fuels has strengthened, with the use of coal dominant (in terms of kW-hr of generated power) (357).

Perhaps as a consequence of the limited U.S. reserves and the inflated world market prices, the electrical industry consumed significantly less oil in 1979 (see Table XVIII), the preliminary estimates showing a decrease of 17.6% from 635.8 to 523.5 millions of barrels (357).

The present and projected generating capability for the industry is shown as Table XIX. Although the planned capability includes a substantial amount (108,491 MW) from nuclear power-plants, it can be seen that the strong dependence upon fossil fuels will be maintained (357).

Total revenues for the investor-owned electric utility industry were $68 billion in 1979, which represents a record high for the industry. Although total expenses have increased, the overall performance closely matches that achieved by the industry in 1978. It was reported that 88 electric utilities announced increased dividends in 1979, the net increase for the industry being 6.2% (357).

According to data compiled by the Ebasco Business Consulting Company, electricity rates were increased by 80 utilities, amounting to an increase in revenues of $4.57 billion, which is substantially larger than that obtained in 1977 or 1978 (see Table XX) (357).

Table XVII. Energy generated and source, 1977, 1978, and 1979 (357)

	(Billions of kW-hr)				
	Coal	Oil	Gas	Nuclear	Total

Table XX. Electric rate increases in 1977, 1978, and 1979 (357)

	Increases granted		Applications pending	
	Number	Revenue ($)	Number	Revenue ($)
1977	88	2636.8 MM	61	2518.0 MM
1978	73	2362.7 MM	59	3458.9 MM
1979	80	4567.0 MM	70	4715.4 MM

Capital expenditures primarily for generation, transmission, and distribution of electricity in the United States were $35.2 billion in 1979, and forecasts again indicate increased capital outlay in 1980. In particular, the capital required for nuclear power plants is expected to amount to $13.7 billion, an increase of approximately 11% from the level of expenditure in 1979. Comparable outlay is anticipated for fossil-fuel plants. It is of interest that because of several factors, including a higher forced-outage rate, long-range load-forecasting difficulties financing, land-use and the selection of suitable sites, construction of large power plants (approximately 3000 MW capacity) is being reexamined and reevaluated. The sequential construction of smaller plants allows much shorter lead-times for design and construction (357, 358, 360).

Energy from fossil fuels.—The amount of power generated in the United States utilizing fossil fuels has varied only slightly over the last three years, being 86.8% in 1977, 85.6% in 1978, and 87% in 1979 (see Table XVII). On the other hand, there has been a significant change in the consumption of particular fossil fuels, especially in 1979 when there was a substantial decrease in the consumption of oil (see Table XVIII). As has been mentioned previously, coal continued to strengthen its position in the national energy picture.

With respect to capability beyond 1980, planned additions would utilize fossil fuels to generate 47.5% of the electrical power, which is now slightly higher than that forecast earlier (361).

Oil shale.—A new oil shale extraction process, using radio-frequency electric fields to heat the deposits, is being jointly developed by Texaco, Raytheon, and Badger. In this process both liquid and gaseous hydrocarbons are produced *in situ*, eliminating the need for mining, retorting, and waste disposal. At this time, no economic assessment of the process has been carried out, and it is believed that by the end of 1980 only feasibility will have been demonstrated (362, 363).

A cost-sharing agreement also to produce oil-shale *in situ* is being considered by Occidental Petroleum and the Department of Energy. It is planned to construct two retorts at the Loga-Walsh test site near Debeque, Colorado, at a cost of approximately $24 MM. The expected agreement represents the second phase of a $45 MM pact between the two organizations signed in 1977 (363).

Under an agreement with the Aero-Propulsion Laboratory of the U.S. Air Force, the Process Division of UOP, Incorporated, will evaluate a new technique for the conversion of shale-oil to transportation fuels, primarily jet fuel. The contract with UOP covers a four-phase effort for a total of $1.87 MM, the whole program extending over two and one-half years (364).

Coal gasification and coal liquefaction.—Two projects to liquefy coal, one a joint venture between Air Products and Chemicals and Wheelabrator-Frye and the other a U.S./West German/Japanese plant, will be supported by the U.S. Government, Department of Energy. The former venture, projected to cost $625 MM and to be located in Kentucky, is expected to be operating in 1984, converting 6000 tons of coal/day into 20,000 barrels/day of oil. The plant will use a combination of a solvent refining process (SRC-1) and a catalyst hydrocracking process. The other project involves a plant to be located in Morgantown, West Virginia, and uses the SRC-II process developed by Gulf Mineral Resources. Initial plans are also to process 6000 tons/day of coal (365).

The first commercial coal-gasification project in the United States has been given approval by the Federal Energy Regulatory Commission. The $1.2 billion project, to be located in Beulah, North Dakota, will convert 4.5 MM tons/year of lignite into high-Btu pipeline gas,

using the Lurgi gasification process. Called the Great Plains Coal Gasification Project, the undertaking is owned by a consortium of American Natural Resources Company and four other firms (366).

In October 1979, the Department of Energy and Gulf Science and Technology (the research arm of Gulf Oil) began a test-burn in Rawlins, Wyoming, as part of the first demonstration of coal gasification in a steeply slanted coal seam. This phase is part of the agreement established between Gulf Oil and the Department of Energy in 1976 (363).

Fluor Engineers and Constructors (Irvine, California), a subsidiary of U.S. Fluor Corporation, and Sasol (Johannesburg, South Africa) have agreed to market coal-conversion technology (developed by Sasol) in the United States. Sasol has been using the Fischer-Tropsch process to make a range of fuels and chemicals from coal since 1955. Fluor Engineers and Constructors have completed Sasol-2, a $2.8 billion complex with an estimated capacity of 1.7 million short tons/year of fuel products, 170,000 short tons/year of ethylene, 110,000 short tons of ammonia and 220,000 short tons/year of coal-tar derivatives. The complex plant incorporates thirty six gasifiers that consume 30,000 tons/day of coal (367).

Texaco and Southern California Edison announced plans to construct a coal gasification unit capable of treating 1000 tons/day of coal. The products will feed gas and steam turbines to generate 90-95 MW of electric power. The new unit is to be located northeast of Los Angeles and the joint project will be supported by the Electric Power Research Institute (Palo Alto, California) (368).

A demonstration plant, utilizing a chemically activated fluidized-bed process for producing low-sulfur, low Btu gas from high-sulfur coal or lignite, came online mid-year. This plant, located at San Benito, Texas, is the culmination of gasification research project jointly undertaken by Central and Southwest Corporation (Dallas), Foster Wheeler Energy Corporation (New Jersey), and the federal EPA (369).

Exxon has developed a catalytic process for coal gasification that is claimed to overcome many of the problems associated with the fluidized-bed process. The use of alkali metal compounds enables the gasification reactions to occur at significantly lower temperatures than in the normal process. The predevelopment phase has been completed and Exxon is preparing to start up a 1 ton/day development unit in Baytown, Texas (368).

Coal.—The demonstrated annual production capacity from coal-mining operations in the United States is approximately 900 MM tons and of this the electric utilities burned 529 MM tons to produce electricity (see Table XVIII). The characteristics of specific classifications of available coal shows: *(i)* The Eastern and mid-Western coals, which represent 70% of the total U.S. recoverable reserves, are mostly high sulfur (2.8% and above) and high Btu (12,600-14,000 Btu/lb) coals and the majority is deep-mined. *(ii)* The Western coals, which represent only 20% of the total U.S. recoverable reserves, are low sulfur (0.8% and less) but low Btu coals.

The demand for the low-sulfur Western coal has recently increased substantially, probably as a consequence of the Amendments to the Clean Air Act in 1977. Blending of the low-sulfur coals with the high-sulfur, high Btu coals from the East and mid-West has been effective in meeting pollution standards in many states. Alternatively, coal-washing processes or flue-gas desulfurization techniques allow use of the Eastern coals. As discussed earlier (see the section on Environmental Regulations, Health, and Safety), Ohio faced a serious problem with respect to the air pollution standards imposed on its electric utilities, *e.g.*, Cleveland Electric Illuminating, Toledo Edison, Ohio Edison, and Dayton Power and Light, and anticipated purchase of significant quantities of out-of-state coal. Such action could have resulted in a depression in the coal industry in eastern Ohio but relaxations in the EPA regulations late in 1979 allowed the utilities to continue to burn the high-sulfur coal (370-372).

To meet the goal of the production of 1.1 billion tons/year of coal by 1985, the goal announced by President Carter in 1977, the railroads have embarked on programs to increase and improve their coal-hauling capabilities. The Chessie System, the largest coal-hauling system in the United States, is presently installing 16,000 new open-top hopper coal cars and has increased the number of available locomotives. Conrail is involved in an extensive long-term rehabilitation program estimated to cost $6 billion. In the West, the Burlington Northern has undertaken a program of coal-related expenditures that may exceed $1.5 billion between 1979 and 1983. This program calls for the relaying or replacing of 2300 miles of track and the construction of over 400 miles of new track and siding (371).

The cost of coal shipments by rail is presently a subject of concern to the electric utilities. Present controversies include (372): *(i)* the railroad deregulation bill pending in the Senate; *(ii)* a house committee investigation of freight-rate increases for the Tennessee Valley Authority; *(iii)* an alleged restraint-of-trade suit in Montana involving two railroads and a mining company.

The Edison Electric Institute favors deregulation for competitive rail traffic, but opposes it for captive-coal traffic. The Potomac Electric Power Company are concerned that full deregulation would lead to substantial increases in railroad rates and, therefore, increases in consumer electric rates.

The Tennessee Valley Authority is so concerned with the recent increases in freight-rates imposed by Louisville and Nashville Railroad that it is "seriously considering" joining utilities studying the construction of a pipeline for coal-slurry, running from eastern Kentucky through Tennessee and Georgia into Florida (372).

Poland is eastern Europe's major producer of anthracite coal. Although it is within the Soviet block, Poland does enjoy relative independence in the technological development, use, and export of this coal, even to the United States. Tampa Electric Company is currently importing Polish coal, the utility receiving 700,000 short tons of coal in 1978. New England Electric Power Company and Baltimore Gas and Electric Company have also utilized coal from Poland (373).

Energy from Nuclear Fuels.—The accident at Unit 2 of Metropolitan Edison Company's Three Mile Island Nuclear Plant on March 28, was caused by a combination of human and design errors and equipment failure. In a preliminary report, staff on the Nuclear Regulatory Commission listed several major errors that contributed to the accident (374, 375).

1. The failure to keep spare auxiliary feedwater pumps on-line. Only one of four was operational on March 28, leaving no margin for safety when the accident began.

2. A relief valve in the primary coolant loop opened during the accident, as it should have, to release overheated water. Then it failed to close, causing a dangerous drop in pressure.

3. At least one water level indicator on the pressurizing system appears to have given a faulty reading, causing a technician to think the system was full of water when it was not.

4. When the emergency core cooling system came on automatically, which only happens under serious circumstances, another automatic system designed to contain radioactive leaks failed to operate.

5. Technicians in the control room turned off the

emergency and primary cooling pumps. No one knows why they were stopped.

The results of what is the worst commercial nuclear power plant accident in U.S. history were the discharge of radioactive gases into the air and substantial damage to the plant and nuclear core. No one was injured or killed by the accident (374).

For Metropolitan Edison and General Public Utilities, the costs associated with the accident are large. In an effort to conserve resources to meet the total costs that will be incurred, General Public Utilities has announced suspension of all construction projects involving additional generating and transmission facilities. It has also stopped all, except the most critical, construction programs on existing stations and postponing all nonessential maintenance activities (374).

The three owners of Unit 2, Metropolitan Edison (50%), Jersey Central Power and Light (25%), and Pennsylvania Electric (25%), have an investment of $780 million in the plant, including the nuclear core. It is believed that the major part of the cost of cleanup and repair will be covered by insurance. The cost of replacement power is obviously not (374).

Radiation dosage claimed much of the attention of the media. It has been shown that for the fifteen days following the accident no one in the vicinity of the nuclear plant received any unusual radiation. Very little radioactive iodine was found in the milk in the area (that found being well below allowable limits), and none was detected in the vegetation or in the soil (374, 375).

The antinuclear demonstration in Washington on May 6, provided a strong message to members of Congress and increased the pressure for a nuclear moratorium (imposed later in the year as is discussed in a section on Environmental Regulations, Health, and Safety). For the nuclear industry and the electric utilities the demontration heralded future uncertainty, particularly with respect to the regulatory issues. Despite significant review and investigation, the risks associated with nuclear technology are still uncertain. A recent report written by radiological experts from the National Academy of Sciences appeared to make nuclear power an attractive source, but did not adequately consider the hazards posed by terrorism, leaks from waste storage areas, and obviously leaks from a major nuclear power plant (376, 377).

In mid-1979, the General Accounting Office issued a report examining the implications and trade-offs should the growth of nuclear power be limited. The report concluded that without severe reductions in the total demand or increased use of coal, the generation of electricity by nuclear technology would be essential to avoid power shortages in the 1980's. The report further indicated that, even with steady growth in coal production in the United States to 2 billion tons/year by the year 2000, over the mid-term (1985-2000) the combined demands on coal to: *(i)* displace oil and gas from electricity generation and *(ii)* meet the growth in demand for energy would seriously constrain expansion of nonelectrical uses for coal, *e.g.,* coal gasification, synthetic fuels, chemicals (378).

Officials of the Arizona Public Service Company stated that without nuclear power the company could not possibly meet the energy needs of the state in the mid-1980's and beyond. Unlike the Northeastern United States, electricity shortfalls in the West cannot be supplemented by surpluses from neighboring states. In the long-term, the utilities believe that extensive coal-fired generation and possibly solar power systems will adequately provide electrical power (379).

Energy from other sources.—Seattle City Light and Tacoma City Light, in order to protect future generating capability, are jointly going to develop six low head hydro plants along approximately 1000 miles of irrigation canals in the eastern part of the state of Washington. The six plants are expected to produce 100 MW of electricity at an estimated cost of only 1.5¢/kW-hr, which is substantially lower than power produced by either coal-fired plants or nuclear plants (382).

Most development effort being expended on ocean thermal energy conversion (OTEC) is concerned with closed-cycle systems. The most common working fluid in these systems is ammonia and there is little doubt that the first generation of OTEC plants will be closed-cycle systems. However, there are indications that significant improvements are possible with open cycles based on water. In one of the new approaches, a research group at Carnegie-Mellon University has made use of the thermodynamic properties of foams generated from water and a surfactant. A variation of the foam system has been proposed by engineers at the University of California (Los Angeles), this being a "mist-lift" system involving a vertical concentric pipe riding in the ocean (383).

The first demonstration plant to utilize heat energy from the ocean has been put into operation in Hawaii. This is a closed-cycle system, using ammonia as the working fluid, and has an output of 50 kW. One of the sponsors of the project, Lockheed Missiles and Space Company, is confident that this small demonstration unit will point the way to much larger OTEC plants (384).

Malfunctions delayed the start-up of Magma Power Company's 11 MW demonstration binary-cycle geothermal unit at East Mesa in California. It is expected that the unit will use geothermal heat to power a gas-expansion turbine generator and the $15 MM installation is wholly financed by Magma. The company has a two year contract to sell the power to the San Diego Gas and Electric Company for 25 mills/kW-hr (385).

It is reported that San Diego Gas and Electric Company may resurrect plans for a 50 MW, $50 MM geothermal binary-cycle unit if the Department of Energy is able to provide financial support. The utility shelved the project in July 1978 when the DOE selected Public Service Company of New Mexico for demonstration funding for a similar project (385).

Southern California Edison Company and San Diego Gas and Electric Company have completed initial discussions with the Mexican government-owned utility Commission Federal de Electricidad for the purchase of 600 MW of surplus geothermal power from Mexico's Baja California region. To furnish the power Mexico will have to expand its 150 MW flash process geothermal generating facility at Cerro Prieto at an estimated cost of approximately $480 MM. The American utilities will build 28 miles of 230 kV transmission lines with the first interconnection to be completed in 1981 (386).

Working in cooperation with Pacific Gas and Electric Company at the Geysers in California, EIC (Newton, Massachusetts) has recently demonstrated the feasibility of a new process for effectively removing approximately 95% of the hydrogen sulfide from the geothermal steam. It is predicted that the new process will allow substantial expansion in the electrical output from the Geysers (387).

Magnetohydrodynamics (MHD) is an alternative way to produce electric power that promises dividends in energy efficiency and environmental protection. MHD has remained a laboratory curiosity since the first generator was built by Avco Corporation in 1958, but present economic conditions have led to significant government support for its development. The University of Tennessee received a five-year, $37 MM contract to continue development of a coal-fired flow concept for a magnetohydrodynamic system. Independent of government funding, a small company in Pittsburgh, Roldiva Incorporated, has acquired the backing of Southern California Edison Company to

build a commercially operating MHD facility. The unit, scheduled for completion in 1985, will be attached to a conventional, 125 MW steam turbine generator at Fontana (California) and will produce an additional 60 MW of power (388, 389).

Engineers at General Electric's research and development center in Schenectady (New York) have successfully tested the key component of an advanced superconducting generator. Fabricated from thousands of niobium-tantalum filaments, bound into a copper matrix by a special vacuum epoxy-impregnation process, the superconductor spins a 13 foot long, 1.5 ton rotor at 3600 rpm in liquid helium at 4°K. When completed in 1981, it is estimated that the experimental generator will produce 18 MM watts of alternating current (390).

A commercial superconducting generator will be designed and built by Westinghouse Electric Company under a $19 MM, five-year contract awarded by the Electric Power Research Institute, Palo Alto (California). The generator will be rated at 300 MW and once in commercial operation will supply enough electricity for some 90,000 homes (391).

Wind turbine generators are increasing in importance in the production of electricity. Southern California Edison is a leader in the development and commercialization of this technology. A three-bladed unit, called a Schachle, is currently under construction at SoCal Edison's Wind Turbine Test site. Other designs of wind turbines are also being developed by General Electric Company for the Department of Energy (392).

Industrial applications for solar energy systems are becoming more attractive. In 1978 an industrial solar process for generation of hot water, developed by General Electric Company was installed to heat water for an open fabric-dyeing vat at a textile plant in La France, South Carolina. The energy savings are estimated to be approximately 8 MM equivalent barrels of oil per year. A second system will provide high temperature steam to a pasteurizing unit in an orange-juice processing plant (Tropicana Products) in Florida. General Electric, under a $235,000 contract from the Department of Energy, will design this system (393).

PFR Engineering Systems Incorporated are designing a $13.5 MM solar-powered primary reformer for a 600 tons/day ammonia plant operated by Valley Nitrogen Producers Incorporated (394, 395).

Florida Power is joining Sea World Incorporated and General Electric Company in the design of a 300 kW photovoltaic concentrator solar plant to be located adjacent to Sea World. The federal government is participating on a cost-share basis in the nine-month study (396).

A low cost route to high purity silicon has been developed at SRI International (Menlo Park, California). If commercialized, SRI claims that it would reduce the cost of silicon for solar cells to about $5/kg, more than meeting the goals set by the Department of Energy. The new process involves the heating of sodium metal and sodium fluorosilicate in the presence of a catalyst (394).

Instrument maker Ametek, Incorporated (Paoli, Pennsylvania) has filed for several patents on thin-film semiconductor materials that the company thinks can be used to make low-cost photovoltaic solar cells. The new cells are claimed to be close to realizing the DOE price goal (1986) of 70¢/peak watt of generated power. Ametek credits its lower costs to two factors: material cost is low because the film is only 1-2 micrometers thick and the coating is produced at essentially ambient temperatures (397).

The probability that a commercially successful electric vehicle will be developed by 1990 is claimed to be greater than 75%. The leading battery contenders for electric cars remain those that have shown promise for the past several years, *i.e.*, lead-acid, nickel-iron, and nickel-zinc batteries for development by 1985, and the zinc-chlorine, lithium-metal sulfide and sodium-sulfur batteries by the year 2000. Few other candidates are likely to be successfully commercialized by the end of the century without major technical breakthrough (398).

In this light, General Motors Corporation claimed to have achieved a "long-elusive breakthrough" in the development of a zinc-nickel oxide battery for vehicle propulsion. The energy density of the new GM battery is stated to be 27 W-hr/pound (cf. lead acid batteries have an energy density of 12 W-hr/pound) and further development is expected to increase that to 32 W-hr/pound. The R&D programs supported by GM during fifteen years has cost approximately $33 MM (399, 400).

Gulf and Western Industries (New York) claims to have progressed significantly in the development of a zinc-chlorine battery for off-peak power storage. Limited production is expected to begin in 1980. The company has also been developing a similar battery system for vehicle propulsion but commercial application is stated to be "a few years away" (401).

General Electric Company and EPRI will jointly develop an advanced storage-battery system to help the utilities to conserve oil and natural gas and to manage peak energy demands. GE will design, fabricate, and test 2000 cells (sodium-sulfur system) and will assemble four 100 kW-hr capacity modules (402).

Fume-free nickel/cadmium batteries are presently being used as a source of reserve power in the Bureau of Reclamation's Central Valley hydroproject computer-control system. The use of these batteries (as opposed to lead-acid batteries) eliminates the need for extensive ventilating systems, fluid drains and safety equipment (403).

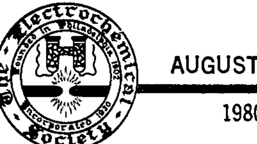
JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS



AUGUST 1980

The Invention and Industrial Development of Metal Anodes[1]

Henri Bernard Beer

Scientific Research Society, NV, 2190 Essen, Belgium

Madame President, ladies and gentlemen, I should like to begin by expressing my gratitude to the Board of Directors of The Electrochemical Society for the honor of having been elected to receive the Vittorio de Nora-Diamond Shamrock medal and prize for 1980. I could never have dreamed that such an award would be bestowed on me when I first began to attend your meetings. It is indeed a great honor and pleasure for me to speak here today about the inventions and the industrial development of the activated metal anodes, or "DSA"R as they are usually called nowadays.

Let me start by telling you how the invention of these anodes was brought about and accomplished.

I had already been searching for a better anode material to replace the customary graphite, magnetite etc. for about 20 years, without success, when between the years 1954 and 1957 it happened that I was experimenting with a new method to manufacture magnetic oxide materials as, *e.g.*, ferrites by means of an electrolytic process. For this purpose I used metals like iron, nickel, cobalt, etc. which were anodically dissolved and then chemically coprecipitated without causing any changes in the electrolyte. Then on a certain day in 1956 someone asked me to preapre ferrotitanate according to this method. I did not expect difficulties in doing this by means of an iron and a titanium anode, but I soon found out that I could not dissolve the titanium anodically in my usual chloride containing electrolyte, because the titanium became inert by the formation of a unique oxide layer, which prevented completely the passage of the electric current to the electrolyte. I then tried out various other electrolytes with more or less the same result. It was this phenomenon that brought me to the idea that this titanium might be an ideal and economical base metal for among other things, anodes to be used in the chlorine-alkali electrolysis, if it could be coated with an electrical conducting and electrocatalytic active, chemically inert material which itself would not become nonconductive under anodic conditions. The oxide layer which is formed anodically on the titanium prevents the current to flow to the electrolyte, but is conductive to another electrical conductive material as for instance the platinum metals etc. On those spots where the platinum metals might be porous or where they had been worn off, the titanium substrate will anodically protect itself against further corrosion by forming an oxide layer. In this way the substrate of the titanium anode is "self-healing."

It was therefore between 1956 and 1957 that I became aware that on account of its special properties, titanium was exceptionally suitable for use as a base metal for the manufacture of anodes to be used, *e.g.*, in the chlorine-alkali electrolysis.

After that a long searching activity began, to find an appropriate and reliable electrocatalyst for the production of chlorine. The reason why the production of chlorine was chosen, was that this product is being produced on a large scale by means of an electrochemical process and that consequently a new and better type of anode might be of great technical and economical importance. The first coatings I was experimenting with were made of metals of the platinum group which were galvanically deposited on the titanium. Most of these coatings were subject to too great a loss of platinum metals and especially of platinum per se per ton chlorine produced. Besides, on account of an excessive overvoltage of these coatings during the electrolysis of brine, the energy consumption was too high so that in this respect there was no real saving in comparison with the existing graphite anodes. On top of this, the platinum coating had the tendency to become passive during operation.

I also found out then that the pretreatment of the titanium was very important if one wished to apply on it an active layer with good adhesive properties. Therefore the titanium was first thoroughly degreased chemically and electrolytically and all other products like oxides etc. removed.

After this the titanium was etched in such a way that the total surface area of the anode had at least trebled, while after the etching and even after rinsing following the etching bath, preferable a titaniumhydride remained on the surface which protected the underlying titanium metal during a few hours against air oxidation. Upon this surface the active layers were applied. According to the type of coating to be used, the enlargement of the surface area of the titanium can in some cases be increased by mechanical treatment, such as sand-blasting whereafter the titanium may be treated by a short acid-etch. I also found out that the crystal structure of the titanium is of importance, because this has a great influence on the passivation of this metal when used under anodic conditions in chloride-containing solutions. Both problems, the passivation and the excessive loss of platinum metal were solved by the addition of iridium to the platinum in a ratio of about 20 to 30 weight percent.

Instead of applying these layers galvanically, a thermochemical process was developed by dissolving the desired metals as their salts in an organic liquid which solution was then applied to the etched titanium, either by immersion or by painting with a brush, after which the solvent was evaporated. By increasing the temperature under alkaline reducing conditions the platinum metal salts were then decomposed and

[1] The Vittorio de Nora-Diamond Shamrock Award Address delivered May 13, 1980 at the St. Louis, Missouri, Meeting of the Society.

thus a metal deposit was formed on the titanium with good adhesion and electrocatalytic properties.

In practice it became evident, however, that the use of platinum, either alone or in combination with other platinum metals, as an active layer on titanium for the production of chlorine in mercury cells was not economical. The main reason is that in mercury cells it is practically impossible to prevent the formation of the so-called mercury-butter in the mercury amalgam on account of impurities in the mercury.

This mercury-butter keeps on growing until it reaches the anode surface and through contact with it, the electrocatalytic layer of platinum metals on the titanium is damaged and partly or totally removed. As the formation of this mercury-butter and the unavoidable contact with the anode will inevitably occur several times when the cell is in operation, it became obvious that metal anodes, that is to say those made of titanium coated with platinum metals, would never give a satisfactory performance in mercury cell operation.

For those amongst you who are not familiar with the mode of operation of the chlorine-alkali electrolysis, it may be useful to explain briefly the basic principles of this process.

Chlorine is being produced mainly by an electrochemical process, in cells through which an aqueous solution circulates of about 30% sodium chloride, called brine, having a *p*H of 2-4 and a temperature of 75°-90°C. By conducting through this brine a direct electrical current chlorine is generated at the anode.

In principle there exist three main cell types for the electrolysis of brine: (*i*) the mercury cell, (*ii*) the diaphragm cell, and (*iii*) the membrane cell, which is the latest development.

In the modern mercury cell, anodes are used made of titanium rods or mesh coated with stabilized oxides of ruthenium and titanium as the active catalytic coating. The cathode consists of liquid mercury in which the sodium ions are reduced to sodium. This sodium is dissolved into the mercury and forms with it an amalgam. The amalgam is transported outside the cell to the decomposer or denuder, where the sodium-amalgam is decomposed into sodium-ions and hydrogen-gas through contact with water and pieces of carbon. The result is a very pure and highly concentrated aqueous sodium hydroxide solution. The mercury, now free from sodium, is recirculated through the cell and is used again.

In the diaphragm and membrane cells the cathode and anode are placed vertically in 2 compartments, separated one from the other by a diaphragm or by a membrane. The diaphragm, which consists generally of asbestos and additives, is a separator through which ion transport and electrolyte flow from the anodic compartment to the cathodic compartment is possible, on account of hydrostatic pressure. The diaphragm cell produces therefore a caustic of lesser quality, because it always contains some sodium chloride. Contrary to this a membrane only allows ions to pass, so that the catholyte and the anolyte are completely separated. During the reaction, the anolyte is diluted, but is continuously replenished with sodium chloride. At the anode chlorine is evolved.

In general, plain steel cathodes are used in these cells, or else steel cathodes with for instance a nickel coating, in order to obtain a lower hydrogen overvoltage and all through the reaction the aqueous catholyte is enriched with sodium hydroxide. This solution is called "lye" or caustic.

In membrane cells, lye of a high purity grade is formed, but at the moment the concentration cannot be so high as for instance in mercury cells, because back-diffusion might occur through the membrane from the cathode to the anode compartment by the osmotic pressure. Therefore, unlike the mercury cells, which produce a concentrated product directly, the membrane cells need extra energy to obtain the desired concentration of the lye, which naturally increases the general costs. The first chlorine plants which were equipped with membrane cells have been installed during the last two years.

In membrane cells the use of graphite anodes would have been practically impossible as the membranes get clogged entirely by the loose graphite particles which drift about in the electrolyte as a result of the oxidation and disintegration of the graphite anodes. The industrial development of the membrane cells can therefore be mainly attributed to the invention of the DSA[R] anodes.

For the sake of completeness I should like to say something about the commercial experience I gained in the beginning and also later on with these anodes in my contacts with the industry. Though I knew a good deal about electrochemistry in general, my knowledge about the chlorine-alkali industry was limited. My visits to various industrial firms, were therefore of an exploring nature. I wanted to find out what the producers would expect and require from a new type of anode. Any alterations to the existing graphite anodes had hardly ever been considered during the last 50 years as their deficiencies had simply been accepted and the industry had learned to live with them.

It is true, of course, that changing over to a new type of anode was not easy for the chlorine manufacturers, as the consequences which would be attached to it were great. In the event of a failure, the consequences would be considerable. Most industries in Europe which manufactured chlorine, did so for their own captive use in the production of all kinds of chemical products. Hence, a possible even short stagnation of the chlorine production, might paralyze the whole line with serious economic losses.

For the relatively few factories supplying merchant chlorine to third parties, a stagnation was just as inconvenient as they generally had contractual obligations.

Moreover, a change from graphite anodes to metal anodes was extremely costly for some producers, when not only the anodes had to be replaced, but also because the old cells for which a switch to metal anodes would be made, had to be partly rebuilt in order to obtain the best possible results. For some mercury cells the current density could be increased considerably in order to justify the new anodes.

It was further necessary that the gap between the anode and cathode be as small as possible, without increasing the chance of a short circuit. The assessment of this gap could not be made any more in the usual manner as with the graphite anodes, by provoking a slight short circuit, but had to be made in a different way. For the mercury cells there were some reasons to object against these new anodes and understandably the objections were mostly of an economical nature.

For the diaphragm cells some constructional readjustments were necessary as well, to adapt them to the use of metal anodes, such as the purchase of copper bases.

In any case it can be said that the opposition lay sometimes in the difficulty to accept that an outsider should be able to bring about such a substantial innovation in so exclusive and secret an industry as the chlorine manufacture. I often felt that the "not invented here" syndrome may have played a prominent part in this too.

Reverting to the technical development of the anodes, some of the problems which arose in connection with the mercury cells could be solved towards the end of 1965 through the development of my new generation of titanium anodes in which oxides of the metals of the platinum group were used, either alone or with oxides of nonprecious metals.

In these anodes the overpotential for the chlorine process is reduced to practically its theoretical value even at very high current densities, on account of which a considerable saving in energy per ton chlorine produced, can be obtained and at the same time a near-doubling of the chlorine production capacity can be achieved with practically no increase in unit power consumption.

Moreover, I had found out in the meantime that it was possible to use also the cheapest of the platinum metal oxides for the coating, namely ruthenium oxide. This too accounted for an important reduction of the cost of the anodes, as ruthenium costs only a fraction of the price of platinum or iridium.

Nevertheless, there were still a few problems left for the use of these oxide anodes in mercury and other cells and that because of the following:

1. The sodium-amalgam as well as the mercury-butter which are formed in mercury cells during the electrolysis are strong reducing agents and a direct contact with one or both, reduces again the platinum oxides (or the mixture of these with some oxides of other metals) to their metallic state. As a result the oxide coating is lost through further contact with the amalgam or mercury-butter, just as it happens with the original metal coatings.

2. The anodes coated with the oxides of platinum metals were rather sensitive to the current reversal occurring whenever the cell is short-circuited, which happens from time to time when cleaning the cell or doing other maintenance work. This also causes losses of platinum oxides which are considered to be too high.

When I speak of platinum oxides, this means the oxides of all the platinum metals like rhodium, palladium, ruthenium, and iridium.

I succeeded in solving these problems also in my following generation of anodes in the year 1967. In that period the oxides of the platinum group could be stabilized by the addition of titanium oxide or one or more oxides of the other valve metals like tantalum, niobium, or zirconium to the coating mixture and by coprecipitating these oxides thermochemically on the titanium from a solvent. These are the anodes which have been registered by Diamond Shamrock under the trademark DSA[R].

The catalytically stabilized oxides of the metals of the platinum group like platinum, rhodium, iridium, ruthenium, and palladium with the oxides of valve metals like tantalum, zirconium, niobium, etc. can be used for other applications than for the production of chlorine.

It is, however, the ruthenium oxide plus titanium oxide stabilized coatings on titanium which presents such an extraordinary electrocatalytic activity for the production of chlorine, that this type of coating is generally used nowadays for the chlorine-alkali electrolysis in either mercury, diaphragm, or membrane cells.

Very large chlorine plants with a capacity of up to 1500 metric tons per day, using diaphragm cells provided with dimensionally stable anodes, have now been installed in the United States and elsewhere and are run by fewer operators than those needed with graphite anodes. DSA[R]-type anodes have been in use in diaphragm cells for more than 10 years and are still in good condition. They will certainly last another few years.

Graphite anodes even of improved quality have a life of only about 1-2 years according to the current density and other operating conditions. On account of the fact that the graphite is burned off constantly, the electrical resistance in the cell increases and causes the cell voltage to rise. The consequence is that the energy consumption of a cell with graphite anodes is gradually increasing.

Also the performance of diaphragms in cells is greatly improved by use of DSA[R] anodes on account of prolonging their life and making them more dimensionally stable. The use of the improved diaphragms became possible only after the introduction of the DSA[R].

The dimensionally stable anodes of the present day, by which about 60% of the chlorine output in the western part of the world is produced, are generally fabricated from titanium rods or from expanded metal, provided with an electrocatalytic coating of stabilized ruthenium oxides and titanium oxides. The rods are mounted on a titanium substructure to build a solid unit and also to provide good electrical conductivity.

These anodes are mounted in the cells in such a way that they are placed on a distance of only a few mm from the cathode. In mercury cells they are fixed in a horizontal position, in diaphragm and membrane cells in a vertical position. Especially at high current densities the geometric configuration of metal anodes favors the release of gas bubbles from the anode surface and prevents "gas bubble effect" which lowers the efficiency of the cell.

The replacement of graphite anodes by dimensionally stable anodes in the chlorine-alkali cells has brought about a considerable saving of energy since they were first introduced and applied in the United States in 1968. Since 1970 up to the end of 1979 the savings of electric energy in North America which can be attributed directly to the use of DSA[R], in 70 different plants, totals considerably over 19 billion kW-hr. The energy savings in North America for 1979 in these plants is estimated at about 3 billion kW-hr.

Whenever mercury cells might become forbidden on account of the mercury pollution, the switch from mercury cells to membrane cells might be a perfect alternative.

The massive change-over to metal anodes, called DSA[R], has opened the possibility to embark on a great volume of research and development work in various directions.

Another field where the DSA[R] is applied on a large scale and which is in full development is the production of sodiumhypochlorite solutions, used in great quantities for disinfection purposes. These hypochlorite solutions are employed as a means to prevent fouling of the cooling systems of power stations due to growth of aquatic organisms, by blocking the biological activity in the cooling water during supply and drainage.

Water, sterilized by hypochlorite solutions is also used to be injected into oil and gas-containing strata to compensate the decrease in pressure of the oil wells and to boost it up in order to raise the oil production.

Hypochlorite solutions are also applied for the destruction of the cyanide used in the galvanizing industry, for the disinfection of potable water from seawater, for bleaching paperpulp and textiles, for the sterilization of water in swimming pools, and for treating sewage.

Since hypochlorite solutions have the tendency to deteriorate with time and are also difficult to transport in large quantities, it is now becoming popular for users to produce their own hypochlorite solutions by means of small cells placed right at the point of use, by the direct electrolysis of brine or seawater. Many types of these cells are offered and are generally electrolyzers of bipolar design, available in different sizes ranging from an electrolyte-flow rate of 0.5-100 cubic meters per hour to produce a hypochlorite solution with a concentration from 1 to 8 g/liter.

The use of these hypochlorite generators, equipped with DSA[R], right on the point of use, avoids the problems arising when chlorine is used for the above purposes, since the storage of chlorine is dangerous and the dosage of chlorine to the liquid to be treated is not an easy matter, because it has to be carefully

controlled. Moreover, some countries have restricted the transportation of chlorine on public roads.

The most used electrocatalytic coating on titanium anodes for the preparation of hypochlorite solutions, consists of stabilized mixed oxides of ruthenium and titanium.

For all these and other purposes, the coatings can be modified by the addition of other metals or metal oxides such as tin, antimony, and noble metals to improve their catalytic activity and life. The field of application of these anodes, apart from the chlorine-alkali electrolysis, is constantly expanding. Such is the case for example in the electrowinning of metals from aqueous solutions of metal chlorides or metal sulfates, where the dimensionally stable anodes have met with great success, as they permitted a more economical winning of metals from ores having a low concentration of metals.

Here again the dimensionally stable anodes have brought considerable improvements to this field. They may be summarized as follows: (*i*) lower half-cell potential, (*ii*) use of higher current densities, (*iii*) lower gas bubble effect through special anode designs, (*iv*) no loss of anode material, keeping the electrolyte pure, (*v*) no contamination of the cathode deposits on the cathode, (*vi*) high current efficiency, and (*vii*) simple cell constructions. The electrowinning of cobalt on an industrial scale by means of dimensionally stable anodes has been initiated in Sweden a few months ago.

Since my invention of the dimensionally stable metal anodes with stabilized coatings of mixed oxides in 1967, these anodes have been widely accepted in the industrial world, for use in all kinds of electrolytic processes and has consequently spurred much research activity in the whole world.

Unquestionably the invention of the dimensionally stable anodes has stimulated the general interest for electrochemistry and has drawn the attention again on its importance for the industry in many different fields. Scientific reports and patents relating to electrochemistry have been increasing yearly.

A result of this is that recently much research is being done on cathodes, diaphragms, membranes, cell constructions etc. all of which have contributed to savings in energy and capital investments.

It was in April 1957 that I handed in my first patent application for the protection rights regarding titanium metal coated with one of the platinum metals for use as an anode, in the first place with a view to the electrolysis of brine. Towards the end of 1965 I claimed protective rights for titanium anodes coated with oxides of platinum metals alone or together with oxides of nonprecious metals such as lead oxide, iron oxide, copper oxide, etc.

In 1967 I sought protection regarding the use of electrocatalytic materials on titanium, tantalum, etc. which consisted of stabilized mixed oxides of platinum metals and the oxides of the so-called valve metals such as titanium, tantalum, zirconium, etc.

My patent application of 1965 was submitted in 26 countries, in all of which it was granted. The application of 1967 was presented in 44 countries and granted in all of them with the exception of one or two.

The patent priority of the anodes coated with simple oxides therefore dates back to 1965, while that of the stabilized mixed oxides as for example RuO_2/TiO_2 dates from 1967.

The fact that some of these patents, as, *e.g.*, in the United States, have only been granted in 1972 does not alter the fact that the inventions were made and claimed in 1965 and 1967, respectively, and have priority patent protection from that time on. In some countries, as for instance in the United States, supplementary patents of third parties have been granted earlier than these basic patents of the oxide anodes. This has to be attributed to the longer period needed for the examination of the original basic patent applications of 1965 and 1967 which therefore were granted on a later date. Since 1956, the beginning of the first generation of titanium anodes, until the year 1970, I have applied for more than 400 patents in this field, spread over various countries. Practically all of these have been granted.

I would like to add that the invention of stabilized electrocatalytic oxides on titanium for use in electrochemical reactions came just at the right time, but its success would not have been so great and its worldwide application not so rapid without the contribution of Vittorio de Nora. His profound knowledge of electrochemistry and his vision of the future revolutionary applications of DSA^R, particularly to the chlorine and electrometallurgical industry, made him sure (probably the only one at that time) that my electrodes, presently known as DSA^R, could work with great advantages in substitution of graphite anodes with enormous savings in energy and that they would permit the design of a new generation of cells. He was sure of the success and had the enthusiasm and perseverance to reach this success.

But in doing so he had the full support of his brother Oronzio and the backing of his company "Impiati Elettrochimici S.A." which for many years had supplied chlorine cells to the United States, Japan, France, and other countries, as well as that of Diamond Shamrock with its unique position of supplier of electrochemical technology and one of the world's biggest chlorine producers. Bill Bricker, chairman of Diamond Shamrock did understand the importance of this new technology and acquired the world rights for this technology, which is continuously being improved, thanks to the great research efforts for which he gives the financial support and personal encouragement of his company.

I remember that when I began to experiment with platinized titanium back in 1957 there was very little interest for metal coated anodes in the industry. Of course nobody could foresee the energy crisis and the costs of labor were no special difficulty at that time. Consequently there was in the first ten years hardly any interest on the part of, *e.g.*, the chlorine-alkali industry. Luckily it was different for the installations for cathodic protection systems, electroplating industries, and other minor industrial fields where these anodes could at once solve existing technical problems. This kept me going more or less financially through all those years.

The chlorine-alkali industry did not generally struggle with problems, which urgently needed a solution or with any major technical difficulty. In this particular branch the industry had learned to live with some inconveniences connected with the operation of their plants. But in 1967 the upcoming of DSA^R with its improved catalytic coatings of stabilized mixed oxides, at once filled a vacuum in the chlorine-alkali industry, created by the sharp rise in energy costs, labor, and because the experts began to believe in the advantages of DSA^R.

DSA^R should not be looked upon as an integral system of its own, the effect of which can be measured at a glance and therefore might be easily accepted. Rather it should be considered as one of the components in a very complicated system as for instance the chlorine-alkali process and the intricate function of the cells in which it takes place.

Vittorio de Nora has been successful in convincing the greatest chlorine producers of the enormous advantages which these new anodes would have for their industries and he persuaded them to try out these anodes in their plants. This was by no means an easy job, as industrial firms are often rather skeptical when it comes to the introduction of new technologies in their plants especially when it would require an in-

vestment of millions of dollars and might be a big failure.

Especially the idea not to sell but to lease the anodes to customers and guarantee their performance, has to a great extent, contributed to this successful enterprise, with the result that these anodes could be commercialized on a large scale and did not remain a laboratory curiosity.

As you have heard in the beginning of my paper, the invention of the metal anode has been made quite accidentally. I may say, by a lucky chance, but after that followed a long time of research, testing, negotiating, and commercializing. But many inventions have been made in this way in the past and many examples from earlier times can prove it. But even in our days it still happens rather often. A recent example is the award of the two Nobel prizes for organic chemistry last year to Herbert C. Brown and Georg Wittig. Their discovery also was made quite accidentally and it became their point of departure for their eventual successful results.

Professor Wittig himself said the following about this: "The paths of research rarely lead in straightforward fashion from starting point to desired goal. Although intention predisposes the route, chance or occurrences along the way often enforce a change of course. Just such an interplay of intent and chance has dominated my chemical career, begun approximately 50 years ago." (Chemical & Engineering News, Oct. 22, 1979.)

That is the reason why in research work, it is so important to give full attention to the smallest details especially the most unexpected ones, and to examine them thoroughly, because once fully developed, they may prove to be more important than the original target of the research program.

I should like to finish my paper by emphasizing the great importance of the savings in energy and the contribution of pollution control which are being obtained by the application of dimensionally stable anodes, especially in the chlorine-alkali electrolysis.

It has recently been calculated that all energy savings in this field in the United States of America, taken together, from the year 1973 until now, would make it possible to supply 2 million houses of middle-sized families with electricity for a whole year. Taking into account that in the States almost half of all the western-world production of chlorine is being manufactured, it would mean more than twice as much for the total western hemisphere and three times for the entire world. This is the contribution of the dimensionally stable anodes to the energy problem.

At the end of this paper I should like to express my gratitude to all those who have assisted me in the past morally, technically, commercially, and financially to bring this venture to a good end.

I thank you for your attention.

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1979 the following graduate students received $1,875, $1,575, and $1,050, respectively, representing the three Summer Fellowship Awards of The Electrochemical Society.

Mr. Lawrence A. Bottomley, The University of Houston, Houston, Texas, was awarded the Edward Weston Fellowship.

Mr. John D. Porter, Carleton University, Ottawa, Canada, was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. Bradley R. Karas, University of Wisconsin-Madison, Madison, Wisconsin, received the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his or her work.

The Edward Weston Summer Fellowship Report

Mr. Bottomley's report is given below.

An Electrochemical Investigation of Several μ-Nitrido Iron Porphyrin Dimers

To date, there are a limited number of complexes known in which two heme centers exist in close proximity. The most well characterized of these is the μ-oxo dimer (1) in which the Fe atoms of two porphyrin or Schiff base complexes are bound to a single O atom. Crystallographic evidence (2) has shown that the μ-oxo dimer of tetraphenylporphinatoiron, $(TPPFe)_2O$[1], has a nearly linear Fe-O-Fe bond. Theoretical work has predicted this bond to be bent, and such is the case for μ-oxo Schiff base complexes which do not have steric factors in opposition to the bending forces in the molecule (3). In the case of $(TPPFe)_2O$, both Fe atoms are antiferromagnetically coupled and are displaced from the porphyrin plane toward the O atom by 0.50Å. The distance between the two mean porphyrin planes is 4.40Å. This system has been the subject of detailed infrared, Mössbauer and NMR spectroscopic (1) investigations. Recent electrochemical studies (4) have shown that the parent [TPPFe(III)-O-Fe(III)TPP] complex can be oxidized to form the mixed valence $[TPPFe(IV)\text{-}O\text{-}Fe(III)TPP]^+$ dimer or reduced to form the mixed valence $[TPPFe(II)\text{-}O\text{-}Fe(III)TPP]^-$ complex. In all three complexes, the formal O^{2-} bridging moiety does not permit axial coordination of Fe atoms by any additional ligands.

Summerville and Cohen (5) have reported that the thermal decomposition of hemin azide produces a second type of hematin dimer, μ-nitrido-bis-[α,β,γ,δ-tetraphenylporphinatoiron], $(TPPFe)_2N$. This was the first complex reported in which two first row transition metal complexes were bridged by a single N atom. Crystallographic results (6) have shown that both Fe atoms are displaced from the porphyrin plane by 0.32Å toward the N atom. In addition, the distance between the two mean porphyrin planes is 4.15Å, 0.25Å shorter

[1] Abbreviations used in this report are as follows: μ-oxo-bis[α,β,γ,δ-tetraphenylporphinatoiron] $(TPPFe)_2O$; μ-nitrido-bis[α,β,γ,δ-tetraphenylporphinatoiron], $(TPPFe)_2N$; (chlorato) (meso-tetraphenylporphinato)iron, TPPFeCl; (perchlorato) (meso-tetraphenylporphinato)iron, $TPPFeClO_4$; tetrabutylammonium perchlorate, TBAP; 1,2-dichloroethane, $EtCl_2$; dichloromethane, CH_2Cl_2.

than the distance observed for the μ-oxo hematin dimer. Each Fe atom was formally assigned a +3½ valence state. This formalism was precedented by the earlier assignment of −3 for the bridging N atom from studies on second and third row transition metal systems (7).

A recent electrochemical investigation by Kadish and co-workers (8) has demonstrated that the neutral [TPPFe(III 1/2)-N-Fe(III 1/2)TPP] dimer can be oxidized to form the mixed valence $(TPPFe(III)-N-Fe(IV)TPP]^+$ dimer or reduced in a one electron transfer to form $[TPPFe(III)-N-Fe(III)TPP]^-$ complex, isoelectronic with the μ-oxo dimer. Both Fe atoms of the parent complex were shown to be equivalent on the XPS time scale (9). From this data, the electronic configuration about each Fe atom was unambiguously assigned as low spin. This was only the second case of a five coordinate Fe porphyrin complex designated as such (10): thus the uniqueness of this complex prompted the electrochemical investigation of possible ligand binding by nitrogenous bases to the μ-nitrido dimer.

Experimental Section

Materials.—$(TPPFe)_2N$ was the generous gift of Professor Irwin Cohen. The supporting electrolyte, TBAP, was purchased from Eastman Chemical and dried *in vacuo* prior to use. $EtCl_2$ was obtained from Mallinckrodt as reagent grade. Ethanol, added by the manufacturer as a stabilizing agent, was removed by extraction with an equal volume of concentrated H_2SO_4 followed by a distilled water wash and then extraction with an equal volume of 5% KOH solution. The solvent was then distilled from P_2O_5 and stored over 4Å molecular sieves prior to use. All ligands used were obtained from Aldrich Chemical. Pyridine, py, was distilled from CaO and stored over 4Å molecular sieves prior to use. 3-Pic and 4-Pic were distilled from KOH pellets and stored in the dark. 3-CN Py and 4-CN Py were recrystallized from benzene and dried *in vacuo* prior to electrochemical titrations. The remaining ligands listed in Table I were used as received.

Instrumentation.—Cyclic voltammetric measurements were made with an EG & G Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat driven by a PAR Model 175 universal programmer. Scans were recorded with a Houston Omnigraphic 2000 X-Y recorder or with a Tektronix Model 5111 storage oscilloscope. A conventional three-electrode system was utilized. A Pt button served as the working electrode and a Pt wire was used as the counterelectrode. A commercial saturated calomel electrode (SCE) was utilized as the reference electrode. Current-voltage curves were measured at 0.02-10 V/sec while all titrations were recorded either at 0.05 or 0.10 V/sec. At faster scan rates *IR* loss was held to a minimum by the use of a positive-feedback device built into the Model 176 current follower. All solutions were made 0.1M in TBAP and were deoxygenated by bubbling solvent-saturated N_2 through the solution for 10 min. For all electrochemical measurements the SCE was separated from the bulk of the solution with a fritted-glass bridge filled with solvent and supporting electrolyte. Stability constants were determined from the shifts of half-wave potentials as a function of ligand concentration. The method of calculation has been described in previous publications (12, 13). All potentials are reported in volts *vs.* the SCE. Half-wave potentials were measured as $E_{1/2} = ½(E_{pa} + E_{pc})$ as determined from cyclic voltammetric data.

Table I. Formation constants for the addition of selected ligands to $(TPPFe)_2N$

Ligands[a]	σ[b]	log β_2[c,d]
3,5-dichloropyridine	0.75	3.8 ± 0.2
3-cyanopyridine	0.56	4.35 ± 0.2
4-cyanopyridine	0.66	4.74 ± 0.15
3-chloropyridine	0.37	5.8 ± 0.2
3-bromopyridine	0.39	5.6 ± 0.1
3-acetylpyridine	0.38	6.90 ± 0.17
4-acetylpyridine	0.50	6.65 ± 0.25
Pyridine	0.00	7.62 ± 0.04
3-picoline	−0.07	7.8 ± 0.2
4-picoline	−0.17	8.10 ± 0.09
3,4-lutidine	−0.24	8.6 ± 0.2

[a] See footnote 1 for explanation of abbreviations.

[c] Measured in $EtCl_2$, 0.1M TBAP.
[d] Temperature = 23° ± 1°C.

Results

$(TPPFe)_2N$ was dissolved in $EtCl_2$, which was 0.1M in TBAP and its redox behavior studied by cyclic voltammetric methods at a Pt button. The redox mechanism previously reported (8) for electrooxidation reduction in CH_2Cl_2 was identical to that observed in $EtCl_2$. In the absence of any nitrogenous base, $(TPPFe)_2N$ was reduced at +0.17 and −1.19V *vs.* SCE to form $[(TPPFe)_2N]^-$ and $[(TPPFe)_2N]^{-2}$, respectively. Additions of aliquots of substituted pyridines produced negative shifts in potential for the first reduction of $(TPPFe)_2N$. A typical plot of $E_{1/2}$ for the reduction of $(TPPFe)_2N$ *vs.* the bulk concentration of added ligand is presented in Fig. 1. Similar potential dependences on added ligand concentration were observed for all ligands investigated. In contrast, potentials for the second reduction of $(TPPFe)_2N$ were invariant over the ligand concentration ranges studied. The potential shifts observed were consistent with complexation of the starting material, $(TPPFe)_2N$, by two ligand molecules, but not of the reduced species, $[(TPPFe)_2N]^-$. From the shifts in $E_{1/2}$ stability constants were calculated and are listed in Table I.

Discussion

The complexation of the μ-nitrido dimer reported herein is the first evidence of six coordinate dimeric

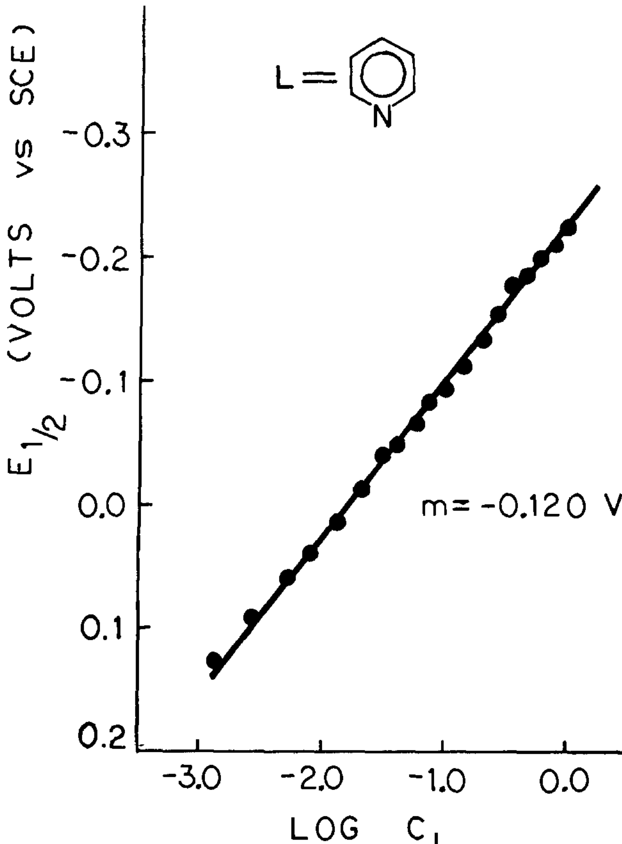

Fig. 1. Half-wave potential dependence upon the bulk concentration of pyridine.

Fe porphyrin species. The coordination of the dimer is intriguing when compared to the behavior of the μ-oxo dimer in the presence of similar complexing agents. There is currently no evidence of any axial coordination of the μ-oxo dimer by substituted pyridines. Ostfeld (14), however, has reported that the μ-oxo dimer is cleaved by the addition of imidazole in nonaqueous media to form the bis imidazole complex of $TPPFe^+$. The stability of the μ-nitrido dimer adducts may be attributed, in part, to the increased charge on the bridging N^{3-} atom when compared to O^{2-}. However, a knowledge of the factors responsible for this increased stability is unknown at the present time. Theoretical modeling studies are currently underway in an attempt to explain the observed chemistry (15).

Of special note is the magnitude of β_2 (see Table I). Previous measurements of the affinity of TPPFeCl (16) and $TPPFeN_3$ (17) for pyridine have yielded values of $\beta_1 = 0.2$ and $1.75M^{-1}$, respectively. It is tempting to consider the complexation of each Fe atom in the dimer as a monomeric species with $(N\text{-}FeTPP)^-$ as the counterion, in an analogous fashion to Cl^- or N_3^-. However, stepwise addition of the ligands to the μ-nitrido dimer is not observed. Secondly, comparison of the formation constant magnitudes makes any attempts at such a formulation fortuitous.

A linear free energy relationship has been constructed in Fig. 2 comparing the formation constant magnitudes with the respective electron donating or withdrawing substituents on the coordinating ligand. From the slope of log β_2 *vs.* 2σ, a $\rho = -2.38$ was computed. This value is similar to that observed for monomeric iron porphyrin complexes and implies that electron donating substituents on the pyridine facilitate the formation of the complex (see Table II).

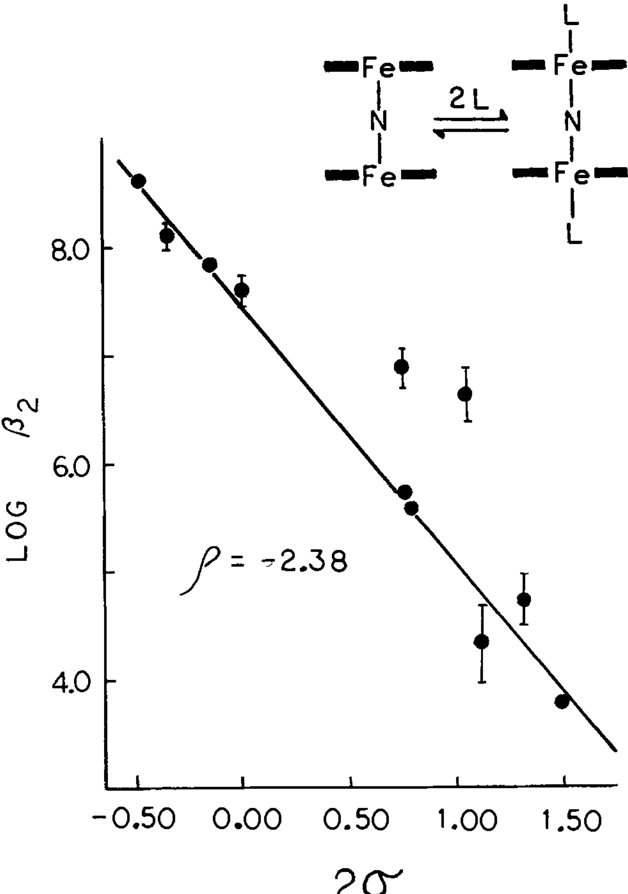

Fig. 2. Linear free energy relationship for addition of two substituted pyridine molecules to $(TPPFe)_2N$ in $EtCl_2$.

Complex	Formal oxidation state	Solvent	ρ[a]
$TPPFeL_2$	II	CH_2Cl_2	−1.25[b]
$[TPPFeL_2]^+ClO_4^-$	III	CH_2Cl_2	−4.19[b]
$(TPPFeL)_2N$	III½	$EtCl_2$	−2.38

[a] Calculated from plots of log β_2 *vs.* 2σ.
[b] Calculated from data in Ref. (11).

The reactivity of the μ-nitrido dimer towards imidazole and substituted imidazoles is being studied and will be reported in a subsequent communication.

Acknowledgments

The support of The Electrochemical Society through the Edward Weston Fellowship is gratefully acknowledged. In addition, the author wishes to thank Professor Karl M. Kadish for his support and guidance and Professor Irwin A. Cohen for his gift of the μ-nitrido dimer. Partial support of this research from the National Institutes of Health (Grant GM 25172-02) is also acknowledged.

The Colin Garfield Fink Summer Fellowship Report

Mr. Porter's report is given below.

Two-Dimensional Electrocrystallization at Low Overpotentials

Detailed, quantitative studies of the potential dependences of two-dimensional electrocrystallization processes at low overpotentials are lacking. Frequently, experimental results are analyzed in terms of the Fleischmann-Thirsk (FT) geometric model of growth at constant potential (1), which states that the composite rate (k^2Z_n) is related to the transient maximum parameters t_m and i_m (see List of Symbols). Data are collected at individual potentials, and are routinely fit (sometimes implicitly) to empirical equations of the form

$$\left.\begin{array}{ll} \log t_m = a_t\eta + b_t & \text{[1a]} \\ \log i_m = a_i\eta + b_i & \text{[1b]} \end{array}\right\} \text{for } (t_m, i_m)_{\eta=\text{constant}}$$

The geometric FT model demands that $a_t \equiv -a_i$, and consequently the absolute value of either a_t or a_i is usually all that is reported, although the nucleation order n [$n \equiv 0$ for instantaneous nucleation and $n \equiv 1$ for progressive nucleation (2)] is sometimes given as well.

Equations [1a] and [1b] were critically tested in the present study, along with the ability of the FT geometric model to quantitatively describe experimental responses to both potential step and (in an extended form) linear potential ramp perturbations. A self-consistent analysis of transient responses to these perturbations as well as to galvanostatic perturbations was developed for that purpose, and in this scheme experimental results are analyzed in terms of surface coverage. The details of the surface coverage analysis are presented elsewhere (2).

Experimental investigations were performed on the formation of calomel at 22° and −5°C on mercury (2, 3), the formation of thallous chloride at −6.3°C (2, 4), and the formation of thallous bromide at −3.0°C (4), both on thallium amalgam. For reasons of brevity, only the results concerning the formation of thallous chloride will be presented here in any detail.

Experimental

Thallium shot (m6N, Alfa Inorganics) was combined directly with electronic instrument grade mercury (m5N8, Alfa Inorganics) under dry nitrogen to form the 2.1 atom percent (a/o) amalgam used in the present study. The base electrolyte was 0.1M HCl (AristaR, B.D.H.) and oxygen was purged using purified nitrogen. The reference half-cell was the 2.1 a/o Tl(Hg)/TlCl couple in the same base electrolyte and maintained at the same temperature as the working electrode compartment (−6.3° ± 0.1°C). Potentials are quoted either with respect to the reversible potential of the bulk couple or with respect to the reversible potential of the monolayer phase, whichever is appropriate. Careful attention was paid to cell design in order to minimize instrumental limitations to a negligible level. The entire cell assembly was enclosed in a light-tight Faraday cage, which was mounted on a vibration-damped platform.

The potentiostat used in the experiments reported here was a Wenking Model 70 HP 10, and potential perturbations were supplied by a PAR 175 Universal Programmer through a wideband 10:1 divider. Responses to potential perturbations were recorded on a Tektronix 503 x-y/y-t oscilloscope and a Biomation 805 transient recorder, which allowed data to be obtained in a digital format.

Results

General features of the Tl(Hg)/TlCl system.—The anodic electrocrystallization of thallous chloride on thallium amalgam was found to follow the general scheme: (*i*) simultaneous dissolution and specific adsorption of chloro-thallous complexes, (*ii*) formation of the first crystalline monolayer of thallous chloride, probably of (110) orientation, (*iii*) formation of the second crystalline monolayer, probably of (100) orientation, (*iv*) formation of the third monolayer, (*v*) formation of the thick layer of bulk thallous chloride. This sequence of events can be seen in Fig. 1, which presents an illustrative current transient recorded in response to a potential step to a high overpotential with respect to the bulk couple. Completely analogous responses were observed to linear potential ramp perturbations. The same pattern was recorded for the formation of thallous bromide (4).

Previous studies performed using thallium amalgam electrodes failed to report the formation of three distinct monolayer phases (5-7), although indications of a third peak in triangular sweep experiments were reported for the case of TlCl formation on solid thallium (6). The reversible potential for the first monolayer has been reported to be at −38 mV with respect to the reversible potential of the bulk couple at 25°C (8), *i.e.*, at underpotential with respect to the bulk phase. This result was confirmed in the present work, a value of (−31 ± 1) mV being routinely observed at −6.3°C.

The experimental procedures reported in a widely quoted early study (5) involved the application of a double potential step, where the intermediate potential was the "rest potential" with respect to the bulk Tl(Hg)/TlCl couple. It is clear that the formation of the first layer could not have been observed in this study under the reported experimental conditions; consequently, the reported formation (5) of two monolayers prior to the formation of the bulk phase, at posi-

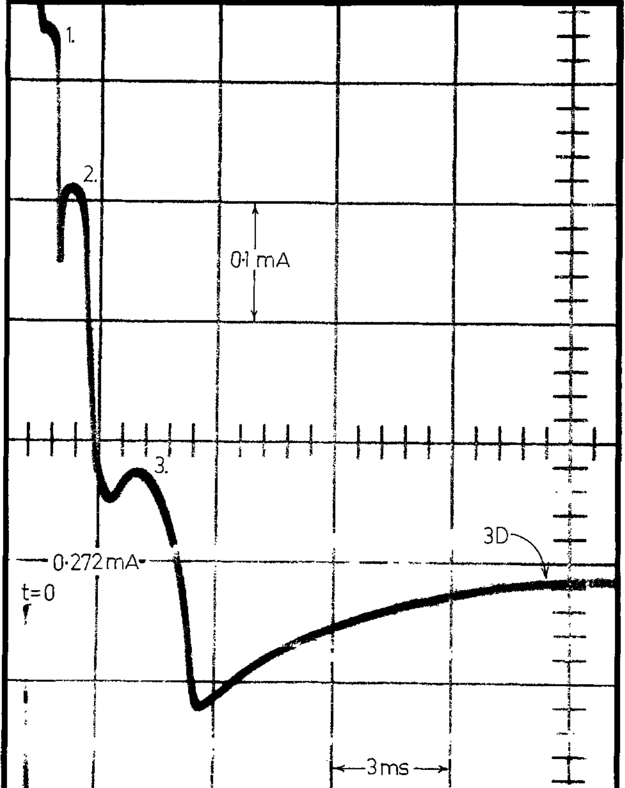

Fig. 1. Representative current transient obtained in response to a potential step to high overpotentials with respect to the bulk phase Tl(Hg)/TlCl couple. The successive formation of three monolayers prior to thick film formation can be seen. η = 143.7 mV, T = −6.3°C, electrode area = 9.13 × 10^{-3} cm^2.

tive overpotentials with respect to the bulk phase, must represent the formation of the second and third monolayers. The crystallographic assignment of (100) orientation for the first of these (5) is consistent with the results obtained for the second monolayer as it is defined in the present study. The crystallographic assignments made here are based upon precise determinations of monolayer charges at their reversible potentials (see Table I), experimental data being compared with crystallographic values (9). Crystalline monolayers of TlBr formed on mercury from aqueous Tl^+, Br^- solutions have been assigned (110) orientations based upon monolayer charges (10, 11).

The first monolayer was observed to remain both kinetically and thermodynamically distinguishable from bulk phase thallous chloride (and bromide) at all times, even in the presence of a thick film. A separate and distinctive peak was observed for the reduction of the first monolayer subsequent to the reduction of the bulk phase during triangular linear potential ramp perturbations. The unusual property of "underpotential electrocrystallization" observed for the first monolayer of thallous bromide (4) and thallous chloride (8) allowed the formation of the monolayer to be studied in detail, completely separate from the formation of subsequent layers, over a wide potential range. The results of such a kinetic investigation for the case of the formation of the first monolayer of thallous chloride on thallium amalgam are reported below.

Potential step perturbation.—Transient responses were obtained at a series of low overpotentials with respect to the reversible potential of the first monolayer. For reasons of clarity, individual transients were analyzed in terms of surface coverage and quantitatively compared with model curves of $i_r(S)$ (2). Surface coverages were obtained by the numerical integration of current transients using the relationship

$$S(t) = \frac{\int_0^t i \cdot dt}{\int_0^{t_x} i \cdot dt} = \frac{q(t)}{q_x} \qquad [2]$$

where $q_x \rightarrow q_{tot}$ as $t_x \rightarrow \infty$. Quantitative agreement between individual experimental transients and model curves was observed regardless of overpotential, provided that the transients were recorded under conditions of low instrumental distortion. A nucleation order $n = 0$, corresponding to instantaneous nucleation of N_o nuclei, was observed to be in force. The FT geometric model of two-dimensional electrocrystallization appeared to be a quantitatively useful one, therefore, and a more detailed analysis of experimental data based upon the application of this model seemed to be justified. The same conclusion was drawn in the case of the other systems investigated.

However, the parameter q_{tot} was found to be a uniform function of overpotential, again in every case investigated (*i.e.*, for the first monolayers of Hg_2Cl_2, TlCl, and TlBr), in direct violation of one of the fundamental assumptions of the FT geometric model. For the case of the first monolayer of TlCl, q_{tot} was observed to closely obey an empirical equation of the form

Table I. Integrated monolayer charges† at the monolayer reversible potentials

Salt	Crystallographic*			Experimental	
	$q(100)$	$q(110)$	$q(111)$	q_1	q_2
TlCl	108.99	77.07	125.85	76	103
TlBr	101.65	71.88	117.38	77	102

† In $\mu C\ cm^{-2}$.
* Ref. (9).

$$\log q_{tot} = \log q_1 - a_q \eta \qquad [3]$$

where a_q was determined to be $(10.8\ mV)^{-1}$. This dependence is too high to be due to a potential dependent variation of the crystallographic lattice parameters, despite the excellent agreement between the model and experimental reduced variable curves. A more likely explanation in this case is that the apparent variation in layer charge is due to the potential dependence of $\theta_{Tl(I)}$, where Tl(I) represents specifically, randomly adsorbed thallium (I) species [likely neutral TlCl units (7, 10, 11)]. The "equilibrium" value of $\theta_{Tl(I)}$ is likely to be rapidly established at short times during the falling "dissolution" component of the current transient. Electrocrystallization would then occur, drawing proportionally from the adsorbed reservoir of Tl(I) species and from the Tl°(Hg) species through further charge transfer; only the latter process contributes to the value of q_{tot} as it was determined in the present study.

This is apparently the first time that uniform variations in the observed "electrocrystallization charges" of two-dimensional layers have been reported. The vital consequence of this observation is that experimental transient maximum parameters may not be converted directly to fundamental kinetic parameters in these cases. Hence, kinetic analyses of systems which exhibit this apparent charge variation, based upon the direct application of the geometric FT model to experimental transient maximum parameters, are invalid unless the effects of the apparent charge variation are eliminated.

The potential dependences of the transient maximum parameters t_m and i_m were investigated carefully in the light of this observation. Both parameters were observed to be extremely potential dependent at "low" overpotentials. Equations [1a] and [1b] were found to be excellent representations of both t_m and i_m, respectively, down to overpotentials as low as 0.2 mV. Least squares values of the empirical constants of Eq. [1a] and [1b] are presented in Table II. One incidental side effect of these extreme, but uniform and well-characterizable potential dependences, was to force an alteration of traditional concepts of overpotential "magnitude" in the author, when electrocrystallization process was being considered. It was often found to be useful to think of potentials in terms of units of a_t or a_i, *i.e.*, to translate potential differences into orders-of-magnitude of observed rate differences.

When plotted in logarithmic form, both $\log t_m(\eta)$ and $\log i_m(\eta)$ were observed to exhibit curvature beginning abruptly at overpotentials "moderately" removed from zero ($\eta \gtrsim 1.5$ mV). A quantitative analysis of this curvature will be presented in a section below.

Consistent with the observation of q_{tot} being a function of potential, the parameters a_t and a_i were not observed to be equal and opposite. For those values of overpotential where [1a] and [1b] represent the data well, $(d \log q_{tot}/d\eta) = a_t + a_i$ (2); the least squares data yield a value of $-0.097\ mV^{-1} = (-10.3\ mV)^{-1}$. This agrees well with the empirical value of a_q, which is valid as well for overpotentials where [1a] and [1b] do not hold. A model-based value for q_1 may be calculated from the empirical b parameters (2), and they give a value of 79.6 $\mu C\ cm^{-2}$ which agrees well with the experimental and crystallographic values presented in Table I.

Because of experimental limitations, reliably precise measurements were difficult to make at overpotentials less than about 0.2 mV. Down to that limit, however, there was no evidence of a "linear" region where t_m and/or i_m were proportional to η^1. Strictly expo-

Table II. Least squares derived constants for Eq. [1a] and [1b], TlCl

$a_t = -1.110\ mV^{-1} = (-0.901\ mV)^{-1}$	$b_t = -0.130$
$a_i = 1.013\ mV^{-1} = (0.987\ mV)^{-1}$	$b_i = -1.186$

nential behavior of those parameters with overpotential was universally observed at the lowest limits of overpotential experimentally accessible. In direct consequence, no nucleation-growth rates lower than the extrapolated values at $\eta = 0$ could be investigated using this technique at the time of the investigation.

Linear potential ramp perturbation.—The analysis of individual transient responses to linear potential ramp perturbations was performed in terms of surface coverage in an analogous manner to the analysis of potential step data, *i.e.*, in terms of $i_r(S)$. Experimental data were compared with model reduced variable curves generated using an extended form of the geometric FT model (2), which is based upon a strictly exponential potential dependence of the combined rate (k^2Z_n). The curves were observed to be encouragingly similar at low potential ramp gradients, but there were some significant differences between the experimental and model responses at surface coverages less than about ½ (2). These differences are reflected in the values of S_m:S_m $\sim$ 0.56 (observed) *cf.* $S_m = 0.63$ (model). It is postulated that the differences observed beween the extended model and experiment could be due to: (*i*) growth occurring, at least partly, in potential regions where equations [1a] and [1b] are poor representations of the potential step data, (*ii*) the presence of effects due to the form of $\theta_{Tl(I)}$ (E), *i.e.*, the phenomenon manifested as the apparent "electrocrystallization charge" variation in the potential step experiments.

The numerical simulations showed clearly that sets of $(\eta_m, i_m)_\nu$ data obtained in response to linear potential ramp perturbations at a variety of ν, could also be analyzed to yield kinetic information about the electrocrystallization processes, equivalent to that obtained through the analysis of sets of $(t_m, i_m)_\eta$ data obtained in response to potential step perturbations at a series of η values (2). That observation was tested experimentally in the present investigation, and was found to be valid. Kinetic data derived from transient data obtained in response to the two potential perturbation techniques are compared below.

Transient maximum currents were characterized in terms of linear potential ramp gradient as shown in Fig. 2. When plotted in log *vs.* log format, the data could be described best by a series of linear segments. Table III lists their gradients and intersection points. Two important observations can be made: (*i*) at no time is the observed gradient equal to one, the value demanded by theory and numerical simulation (2, 12), (*ii*) the gradients decrease as log ν increases, again in opposition to theory (12). Similar piecewise-linear behavior was observed both for TlBr formation (4, 12)

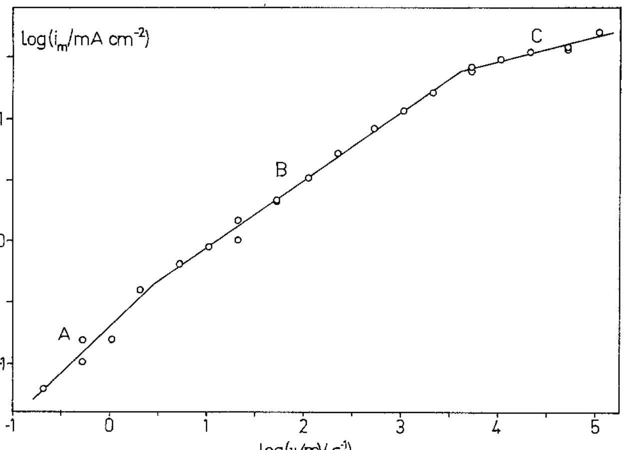

Fig. 2. The dependence of the current maximum observed for the formation of the first monolayer of TlCl on linear potential ramp gradient. The data are represented well by three linear segments (see Table III).

Table III. Analysis of linear potential ramp current maximum data

Section†	Gradient	log ν (low)	log ν (high)
A	0.758	(−1)*	0.47
B	0.550	0.47	3.62

* Experimental, not phenomenological limit.

and Hg_2Cl_2 formation (3, 12), and has been recorded for other 2D systems as well (12). In the case of TlBr formation the apparent charge variation effects are comparatively much smaller and the observed gradient was approximately equal to one in the limit of low ν. Correction of the data at low ν for apparent charge variation in the Hg_2Cl_2 data (directly) and the TlCl data (approximately, via Eq. [3]) gave gradients of 0.95 and 0.85, respectively. A value of $(d \log \nu/d\eta_m) = 1.007$ mV^{-1} was observed for TlCl at log ν values less than about 0.5. The gradient corresponds well with a_i, obtained from the potential step data.

Potential dependence of derived kinetic parameters.—The FT geometric model states that the transient maximum parameters t_m and i_m, observed in response to a potential step perturbation, are related to the more fundamental composite rate (k^2Z_n) in the following manner, regardless of the form of $(k^2Z_n) = f(\eta)$

$$t_m = ((n+1)^2\rho^2/2\pi M^2(k^2Z_n))^{1/(n+2)} \quad [4a]$$

$$i_m = (2\pi(z\mathbf{F}h)^{(n+2)}(\rho(n+1)/M)^n(k^2Z_n))^{1/(n+2)} \exp(-(n+1)/(n+2)) \quad [4b]$$

In regions of overpotential where Eq. [1a] and [1b] represent the potential step data well, then the following form of $(k^2Z_n) = f(\eta)$ is implied

$$(k^2Z_n) = K_n \exp(a'\eta) \quad [5]$$

where $K_n = (k^2Z_n)_{\eta=0}$ and a' is an empirical constant. It can be demonstrated that a' and K_n are related to the a and b parameters of Eq. [1a] and [1b] in a direct fashion (2). Using the data presented in Table II, standard values for physical constants (13) and correcting for the apparent charge variation when necessary, values for K_0 and $(a'/2.303)$ were calculated to be: (2.5×10^{-4}) mole^2 cm^{-6} sec^{-2} and 2.220 mV^{-1} from the t_m data, and (9.1×10^{-4}) mole^2 cm^{-6} sec^{-2} and 2.211 mV^{-1} from the i_m data, giving mean values of $\log K_0 = (-3.32 \pm 0.28)$ and $(a'/2.303) = (2.22 \pm 0.01)$ mV^{-1}. If an absolute upper bound for N_0 at $\eta = 0$ is assumed to be 6.8×10^{14} cm^{-2}, which corresponds to a critical nucleus size of one TlCl unit in a (110) plane, then an absolute lower bound for $k(\eta = 0)$ can be calculated to be $\sim 8.4 \times 10^{-10}$ mole cm^{-2} sec^{-1}. The corresponding linear potential ramp data yielded a value of $(a'/2.303) = 2.20$ mV^{-1}, in good agreement with the mean value given above. Two sets of data are given in Fig. 3, the least squares slope giving $(a'/2.303) = 2.21$ mV^{-1}.

Quantitative analysis of the data which occur in the curved region of $\log (k^2N_0)$ *vs.* η plots was also performed. The data derived from both perturbation techniques were found to be well described by an empirical equation of the form

$$(k^2N_0) = \dot{K}_0 \exp(\alpha'\eta^{1/2}) \quad [6]$$

This is shown in Fig. 4. The best-fit value of α' appeared to be dependent upon the perturbation technique used to obtain the data ($\alpha' = 5.64$ mV$^{-1/2}$ for the potential step data and $\alpha' = 4.70$ mV$^{-1/2}$ for the linear potential ramp data, their ratio being 0.83). It is possible that a more precise correction for apparent charge variation would yield better agreement of the linear potential ramp data with the potential step

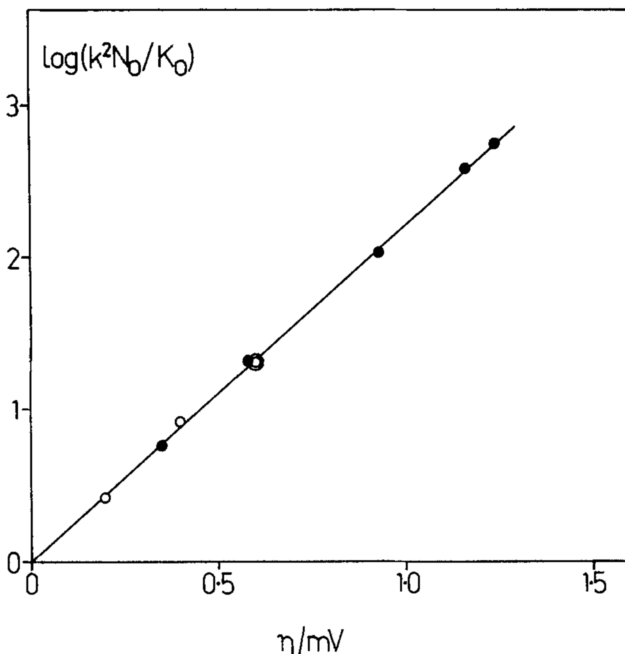

Fig. 3. The potential dependence of the composite rate (k^2N_0) for the formation of the first monolayer of TlCl is illustrated in the "exponential" region where the empirical equation (5) approximates the data well. Rates are derived from (●) potential step and (○) linear potential ramp perturbation responses.

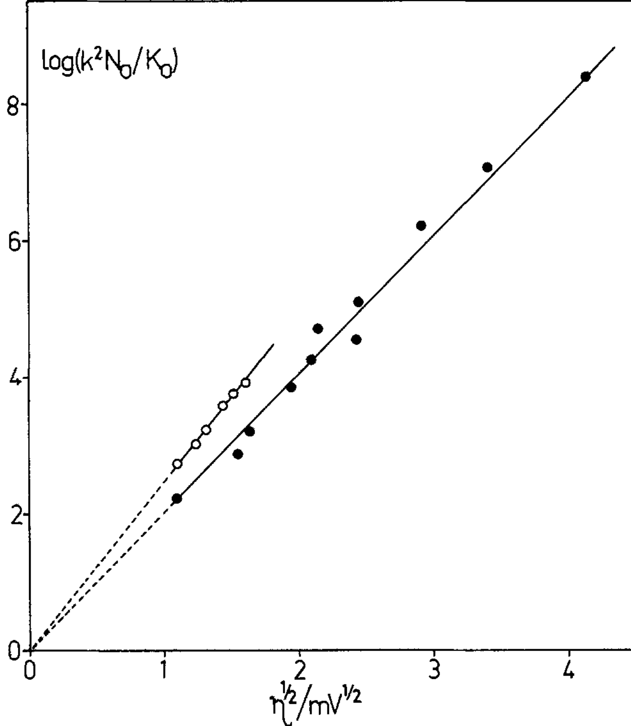

Fig. 4. The potential dependence of the composite rate (k^2N_0) for the formation of the first monolayer of TlCl is illustrated in the "parabolic exponential" region where the empirical equation (6) describes the data well. Rates are derived from (○) potential step and (●) linear potential ramp perturbation responses. The data of Fig. 3 occur in the region of the dotted lines.

data. Certainly the close correspondence observed between the two sets of data can be considered to be indicative of the quantitative usefulness of the linear potential ramp technique for investigating electrocrystallization processes.

Conclusions

The electrocrystallization of thallous chloride on thallium amalgam was found to follow the sequence: (*i*) simultaneous dissolution and specific adsorption of Tl(I) species, (*ii*) formation of the first monolayer of (110) orientation, (*iii*) formation of the second monolayer of (100) orientation, (*iv*) formation of the third monolayer, (*v*) formation of the thick three-dimensional film. The electrocrystallization of thallous bromide was found to follow the same scheme. The first monolayers of TlCl and TlBr are deposited at underpotential with respect to the reversible potential of the bulk phase, and hence their formation could be studied in detail, relatively free from interference. The results for TlCl are presented here.

The FT geometric model of two-dimensional nucleation-growth at constant potential was tested by experimental data analyzed in terms of surface coverage. It was found to be a quantitatively useful model with which to describe the formation of the first monolayers of TlCl, TlBr, and Hg_2Cl_2 using the potential step perturbation technique. An apparent variation in the electrocrystallization charge with overpotential was noted in all three cases. It was strictly necessary to correct characteristic transient parameters for the apparent charge variation before a meaningful kinetic analysis could be performed.

Transient responses to linear potential ramp perturbations proved amenable to quantitative analysis as well, yielding kinetic information which compared favorably with that obtained using the potential step technique. The functional form of the composite rate $(k^2N_0) = f(\eta)$ was determined empirically. At low overpotentials, log (k^2N_0) was found to be strictly linear with respect to η; at higher overpotentials log (k^2N_0) was found to be linear with respect to $\eta^{1/2}$, the transition being abrupt.

The unusual dependence of log i_m obtained in response to a linear potential ramp perturbation as a function of log ν may be rationalized as being due to a combination of factors. In potential regions where log $(k^2N_0) \propto \eta^1$, the gradient is approximately one as predicted by theory and simulation; where log $(k^2N_0) \propto \eta^{1/2}$, the gradient is strictly less than one. The effects of potential-dependent charge variation are complex in this case but, overall, this phenomenon serves to decrease the experimentally observed values of $(d \log i_m/d \log \nu)$.

Acknowledgments

The author would like to thank Miss Lilah Moore for her invaluable assistance in obtaining the experimental data presented in this paper. He would also like to thank Professor R. G. Barradas for providing the facilities of his laboratory and for his continuing supervision and encouragement. The receipt of the Colin Garfield Fink Summer Fellowship (1979) of The Electrochemical Society is also most gratefully acknowledged.

LIST OF SYMBOLS

a_t, a_i, a_q, a'	empirical constants, mV^{-1}
A	normalized limiting nucleation rate, $cm^{-2} sec^{-1}$
b_t, b_i	empirical constants
h	monolayer height, cm
i_r	reduced current, $i_r = i/i_m$
k	lateral spreading rate, mole $cm^{-2} sec^{-1}$
m	refers to transient maximum
M	gram formula weight, g $mole^{-1}$
n	nucleation order, $n = 0$ instantaneous, $n = 1$ progressive
N_0	number of nucleation sites per cm^2
q_j	charge density of jth monolayer at its reversible potential, $\mu C\ cm^{-2}$
q_{tot}	integrated monolayer charge density, $\mu C\ cm^{-2}$
S	surface coverage
z	number of electrons
Z_n	nucleation parameter, $Z_0 = N_0$, $Z_1 = A$
α'	empirical constant, $mV^{-1/2}$
η	overpotential, mV

$\theta_{Tl(I)}$ fractional surface coverage of adsorbed Tl(I) species
ν linear potential ramp gradient, mV sec^{-1}
ρ density, g cm^{-3}

The Joseph W. Richards Summer Fellowship Report

Mr. Karas' report is given below.

Temperature Effects on Excited-State Deactivation in Luminescent Photoelectrochemical Cells Employing Tellurium-Doped Cadmium Sulfide Electrodes

Photoelectrochemical cells (PEC's) have received widespread attention recently, owing to their ability to convert optical energy directly into electricity (1). A typical PEC consists of an n-type semiconductor, a counterelectrode, and an electrolyte. The key element of the PEC is the semiconductor, which serves as both photoreceptor and electrode.

The excited state is efficiently formed by the semiconductor's absorption of an ultrabandgap energy photon to generate a conduction band electron and valence band hole ($e^- - h^+$ pair) (2). We consider deactivation of the semiconductor excited state by three routes: $e^- - h^+$ separation leading to photocurrent, radiative $e^- - h^+$ recombination, and nonradiative $e^- - h^+$ recombination (heat). Thus far, only a few studies have dealt with radiative recombination in PEC's (3-5).

To date, we have determined the general characteristics of Te- and Ag-doped CdS-based PEC's (6-8). The stability of Te- and Ag-doped CdS (CdS:Te, CdS:Ag) photoelectrodes was demonstrated by lack of weight loss and surface damage after prolonged PEC operation. Both CdS:Te and CdS:Ag resemble undoped CdS in their ability to sustain the conversion of ultrabandgap ($\gtrsim$ 2.4 eV; $\lambda \lesssim$ 500 nm) light into electricity. The novel feature of these doped electrodes is the luminescence observed while they function in an operating PEC. Luminescence in this context signifies that radiative recombination of $e^- - h^+$ pairs occurs in direct competition with $e^- - h^+$ separation leading to photocurrent.

Emission from CdS:Te and CdS:Ag involves intrabandgap states. Tellurium is thought to substitute for S to yield states ~0.2 eV above the valence bandedge (9-11). Because of its smaller electron affinity, Te can trap a hole which can then coulombically bind an electron to form an exciton. Radiative collapse of the exciton is the source of luminescence ($\lambda_{max} \sim$ 600 nm for 100 ppm CdS:Te). The mechanism by which CdS:Ag emits is more complex and depends on the presence of additional impurities and on whether Ag substitutes at Cd sites or interstitially (15-17).

The emissive properties of CdS:Te- and CdS:Ag-based PEC's were exploited by assembling the cell in the emission compartment of a spectrophotofluorometer. Inclining the semiconductor photoelectrode at ~45° to both the Ar ion laser excitation source and the emission detection optics allows for sampling of front-surface emission during PEC operation. PEC parameters such as excitation wavelength (457.9-514.5 nm) and intensity ($\lesssim$ 30 mW/cm^2), the presence of composition of (poly)chalcogenide electrolytes, and applied potential (−0.3V *vs.* SCE to the onset of cathodic current) only perturb the emission intensity, not its spectral distribution. For ultrabandgap excitation ($\lambda \lesssim$ 500 nm), increasingly negative bias decreases the driving force for $e^- - h^+$ separation and increases the luminescence intensity by ~15-1400% in passing from −0.3V *vs.* SCE to open circuit. Over this same potential range the photocurrent progressively declines to zero. With bandgap edge illumination (514.5 nm) the luminescence intensity is almost independent of electrode potential (6-8). These observations are likely due to the difference in penetration depth between ultrabandgap and bandgap edge photons.

The temperature coefficient for the CdS bandgap edge is $\sim -5 \times 10^{-4}$ eV/°K (12). As the temperature is raised, the absorption onset should red shift, and a marked change in penetration depth for 514.5 nm excitation should occur. Our goal was to investigate the effect of elevated temperature on the emission intensity, spectral distribution, and photocurrent as a function of voltage, excitation wavelength, and electrolyte composition.

Experimental

Single crystal plates of vapor-grown 100 ppm CdS:Te and undoped CdS were obtained from Cleveland Crystals, Incorporated, Cleveland, Ohio. The ~5 × 5 × 1 mm samples were oriented with their 5 × 5 mm face perpendicular to the c-axis. Electrode and electrolyte preparation as well as electrochemical and optical instrumentation have been described previously (8, 13).

Results and Discussion

As stated above, a diminution of the CdS:Te bandgap is expected with increasing temperature; however, the effect on the CdS:Te emission spectral distribution will depend on the relative positions of the valence band, conduction band, and the intrabandgap tellurium states. In (di)selenide electrolyte between 20° and 100°C, little or no change in the emission spectrum occurs. The emission spectrum is also independent of whether 501.7 or 514.5 nm excitation is used and independent of electrode potential between +0.7V *vs.* Ag (pseudoreference electrode, PRE) and the onset of cathodic current (13). To facilitate emission intensity measurements a single wavelength was monitored, generally λ_{max}.

A decrease in emission intensity obtains with increasing temperature over the range 20°-100°C. Figure 1(a) displays the open-circuit emission intensity monitored at 600 nm for 501.7 and 514.5 nm excitation. It is apparent that the rates of decline (a factor of ~10-20) are comparable for both excitation wavelengths. In addition, the effect of potential on the emission intensity is shown in Fig. 1(b) and (c) which present emission-temperature plots for 514.5 and 501.7 nm ex-

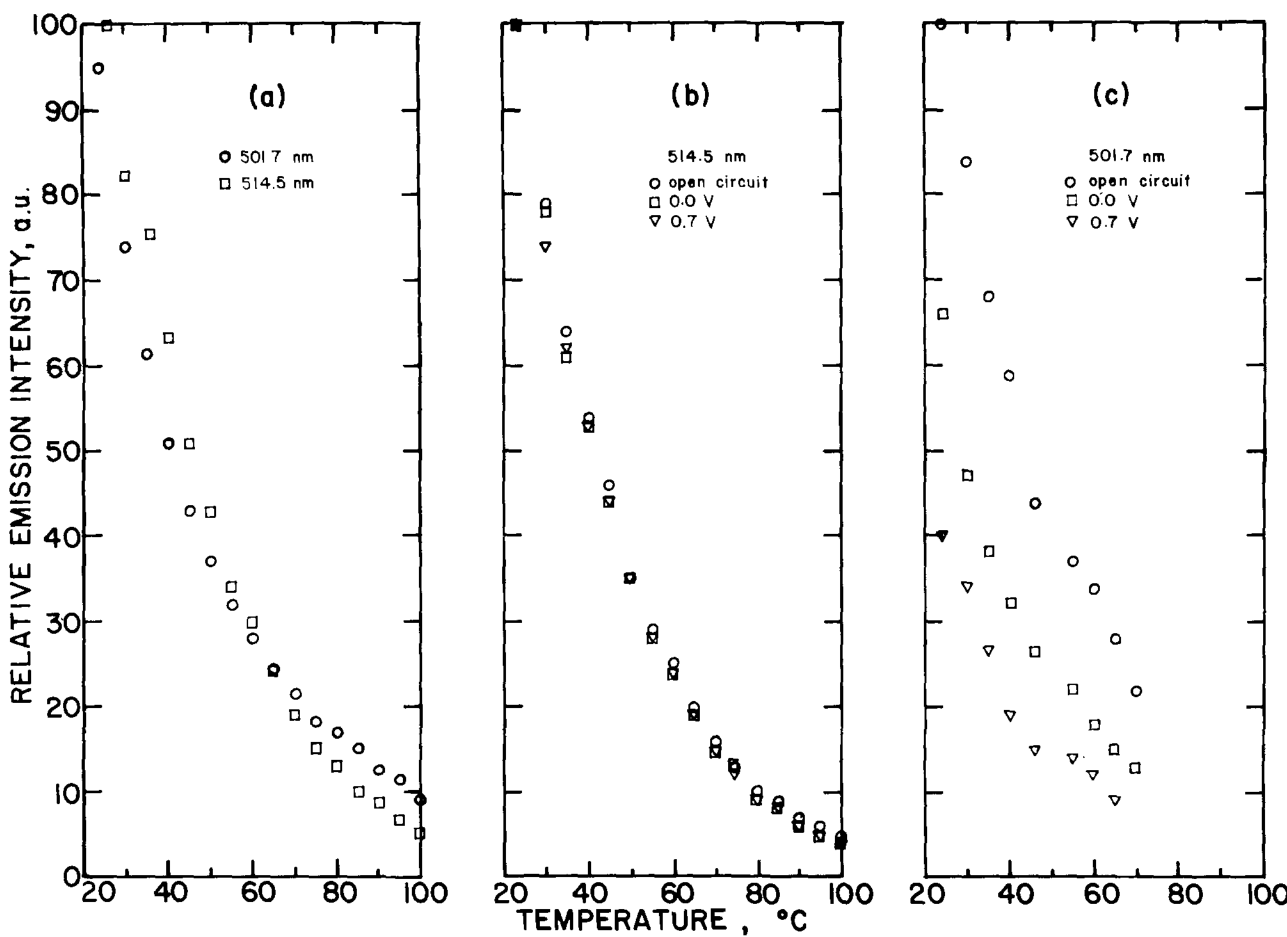

Fig. 1. (a) Relative emission intensity monitored at 600 nm vs. temperature in polyselenide electrolyte (5M OH^-/0.09M Se^{2-}/0.001M Se_2^{2-}) of CdS:Te excited at open circuit with 501.7 nm (circles) and 514.5 nm (squares) light. The excitation intensity at 501.7 nm is 6× that at 514.5 nm in order to approximately match emission intensity at room temperature; (b) relative emission intensity vs. temperature for 514.5 nm excitation of a CdS:Te electrode [different sample than in (a)] in polyselenide electrolyte (5M OH^-/0.02M Se^{2-}/0.001M Se_2^{2-}) at three potentials. Circles, squares, and triangles correspond to open circuit, 0.0V, and 0.7V vs. Ag (PRE), respectively; (c) relative emission intensity vs. temperature for the same electrode and geometric configuration as in (b), but now excited with an equivalent number of 501.7 nm photons as in (b). The point "100" on the emission scale is ~one-fifth the corresponding point in (b). The symbols in (c) have the same significance in terms of potential as in (b). Typical photocurrent behavior at 0.7V accompanying the emission changes shown in (b) and (c) is given in Fig. 2(a).

citation, respectively, at three potentials: open circuit, 0.0V, and 0.7V *vs.* Ag (PRE). The rate of decline in both figures is roughly independent of potential. This is most easily seen in Fig. 1(b) where little potential dependent emission occurs until high temperatures are reached. However, even with potential dependent emission (ultrabandgap 501.7 nm excitation) in Fig. 1(c), roughly parallel rates of decline are observed. These data demonstrate that the emission intensity declines at a rate which is basically independent of excitation wavelength (501.7 and 514.5 nm) and potential (0.7V *vs.* Ag (PRE) to open circuit).

The room temperature photocurrent for 501.7 nm excitation of a CdS:Te photoelectrode is ~15-20 times greater than for bandgap edge 514.5 nm light [Fig. 2(a)]. In (di)selenide electrolyte between 20° and 100°C, the 514.5 nm photocurrent increases by an order of magnitude, reaching 50-100% of the room temperature 501.7 nm value. Over the same temperature excursion 501.7 nm photocurrent increases modestly by ~20%. A similar photocurrent-temperature profile for undoped CdS is shown in Fig. 2(b).

Simultaneous measurement of current, luminescence, and voltage (*iLV* curve) as a function of temperature is shown in Fig. 3. Equivalent intensities (ein/sec) of 501.7 and 514.5 nm excitation were used at both room temperature and elevated temperatures (49°C for 501.7 nm, 86°C for 514.5 nm). The *iLV* curves may be summarized as follows: photocurrent at 23°C is ~18 times greater for 501.7 nm excitation (curve A *vs.* curve B) and emission intensity is ~5 times smaller (A′ *vs.* B′). The ratio of the open-circuit to the in-circuit [0.7V *vs.* Ag (PRE)] emissive quantum efficiencies (ϕ_{r_0}/ϕ_r) is 1.0 for 514.5 nm (B′) and 3.5 for 501.7 nm light (A′). Increasing the temperature to 49°C increases the 501.7 nm photocurrent by ~15% (C) and reduces the emission intensity by a factor of 2. However, a similar value of ϕ_{r_0}/ϕ_r of 3.4 obtains (C′). At 86°C the 514.5 nm photocurrent increases by a factor of almost 8 (D). For the first time with 514.5 nm excitation and despite its lower absolute intensity, potential dependent emission was observed and a ϕ_{r_0}/ϕ_r value of 1.27 recorded (D′, note 10× scale expansion). All of the aforementioned changes were reversible upon returning to lower temperature. Similar photocurrent and emissive trends are observable in OH^-/S^{2-} electrolyte.

Observation of an increased photocurrent quantum yield (ϕ_x) and a nonunity ϕ_{r_0}/ϕ_r value for 514.5 nm excitation provided insight into a correlation of ϕ_x with ϕ_{r_0}/ϕ_r. These relationships is described in detail elsewhere (13, 14).

Acknowledgment

I am grateful to The Electrochemical Society for its support through the Joseph W. Richards Summer Fellowship. In addition, the author wishes to thank Professor Arthur B. Ellis for his continued support and guidance; David J. Morano and Daniel K. Bilich are

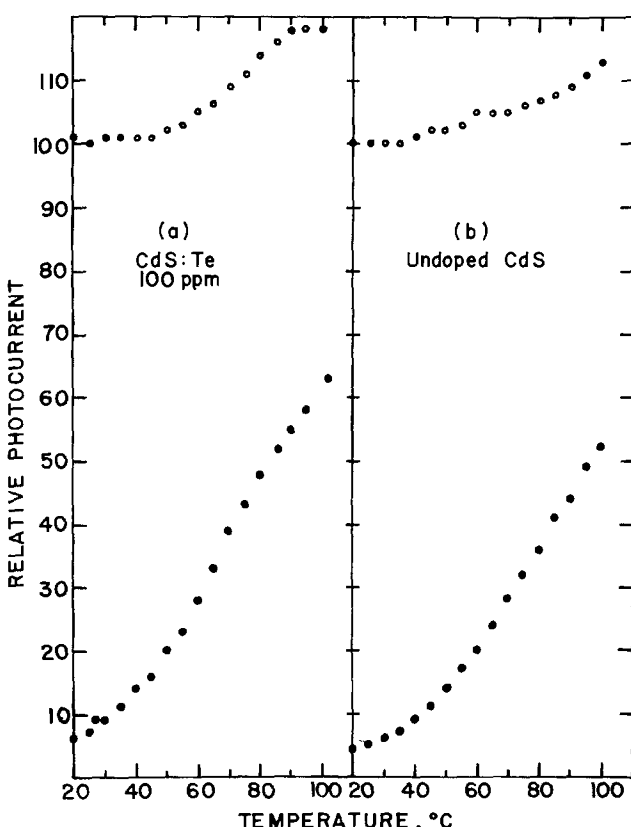

Fig. 2. (a) Relative photocurrent *vs.* temperature for a CdS:Te electrode in aqueous polyselenide electrolyte (5M OH^-/0.02M Se^{2-}/0.001M Se_2^{2-}) excited with equivalent photons of 514.5 nm (filled circles) and 501.7 nm (open circles) light at 0.7V *vs.* Ag (PRE). The scale is such that the photocurrent at 25°C from 501.7 nm excitation has been arbitrarily set at 100 and corresponds to a current density of ~0.36 mA/cm² and a quantum yield for electron flow, ϕ_x, of ~0.50; (b) relative photocurrent *vs.* temperature for an undoped CdS electrode in the same electrolyte as in (a), excited with an equivalent photon flux of 514.5 nm (filled circles) and 501.7 nm (open circles) light. Again, "100" has been arbitrarily set as the 25°C photocurrent from 501.7 nm excitation and represents a current density of ~0.44 mA/cm² and a ϕ_x of ~0.60.

acknowledged for their assistance with some of the measurements.

Photochemical Selective Activation for Electroless Metal Deposition on Nonconductors

Milan Paunovic*

Kollmorgen Corporation, PCK Technology Division, Glen Cove, New York 11542

ABSTRACT

The photochemical methods for selective activation of nonconductors for electroless metal deposition have been classified in this review on the basis of kinetic scheme involved. There are three general kinetic schemes for the formation of catalytic metallic nuclei on nonconductors: photoelectrochemical, photoelectron, and intramolecular photoreduction. Photoelectrochemical scheme involves a photochemical reaction which is followed by an electrochemical reaction. The photochemical reaction is used to produce or deactivate the reducing agent. Catalytic metallic nuclei are formed in the subsequent electrochemical reaction. In the photoelectron method, electrons necessary for the formation of catalytic metallic nuclei M from metallic cations M^{+n} are generated in the direct absorption process of a photon by a semiconductor crystal, which results in the generation of an electron and a hole. In the intramolecular photoreduction kinetic scheme catalytic metallic nuclei are formed in the intramolecular ligand to metal electron transfer process. This review surveys fundamental photochemical principles and discusses problems and prospects of the above processes.

Photochemical processes have been used to produce catalytic metallic nuclei in three ways, each characterized by a different kinetic scheme: photoelectrochemical, photoelectron, and intramolecular kinetic scheme.

Photoelectrochemical method.—In this method the catalytic metallic nuclei M are generated in an electrochemical oxidation reduction process

$$\text{Red} + M^{n+} \rightarrow M + \text{Ox} \quad [1]$$

where Red is the reduced and Ox the oxidized form of a substance and M^{n+} the metallic ion.

The reducing agent (Red) necessary for the reduction of M^{n+} into M according to reaction [1] can be generated in a photochemical process, *e.g.*, the Fe^{2+} (Red) reducing agent is generated in the photochemical process

$$Fe^{3+}\ (\text{Ox}) \xrightarrow{h\nu} Fe^{2+}\ (\text{Red}) \quad [2a]$$

or, in general

$$\text{Ox} \xrightarrow{h\nu} \text{Red} \quad [2]$$

Alternatively, the photochemical reaction

$$\text{Red} \xrightarrow{h\nu} \text{Ox} \quad [3]$$

can be used to deactivate Red in the area where reaction [1] is not desired (background area), *e.g.*, the Sn^{2+} (Red) reducing agent is deactivated in the photochemical reaction

$$Sn^{2+}\ (\text{Red}) \xrightarrow{h\nu} Sn^{4+}\ (\text{Ox}) \quad [3a]$$

Photoelectron method.—In the photoelectron method, electrons (e^-) necessary for the formation of the catalytic metallic nuclei M according to the reaction

$$M^{n+} + ne^- \rightarrow M \quad [4]$$

are generated in the direct absorption process of a photon by a semiconductor crystal which results in the generation of an electron and a hole p^+

$$\text{lattice} \xrightarrow{h\nu} e^- + p^+ \quad [5]$$

Intramolecular photoreduction method.—Catalytic metallic nuclei M can also be formed in the intramolecular ligand to metal charge transfer

$$\overset{\curvearrowleft}{ML} \xrightarrow{h\nu} M + L' \quad [6]$$

where $h\nu$ designates a quantum of absorbed energy (photon), L a ligand, L' the reaction products originating from L, and the arrow above the molecule ML the direction of the electron transfer. The term ligand is taken here in its most general definition: an atom, ion, or molecule capable of functioning as the donor in a coordinate bond.

This review will survey fundamental photochemical principles and basic steps of major processes for the photochemical selective activation of nonconductors for electroless metal deposition. Emphasis will be on the mechanism of image formation since understanding the mechanism of these processes may contribute to the solutions for remaining practical problems and the development of new processes.

Description of Kinetic Schemes

Photoelectrochemical Method

The photoelectrochemical method for the formation of catalytic metallic nuclei on nonconductors (1, 2) has three basic steps: (*i*) sensitization, (*ii*) latent image formation, and (*iii*) activation.

* Electrochemical Society Active Member.
Key words: absorption, catalysis, energy transfer, nucleation.

According to the redox theory: (1) the catalytic metallic nuclei M on a nonconductor are formed in the third step, activation, which is interpreted as the electrochemical process represented by the general equation

$$\text{Red} + M^{n+} \rightarrow M + \text{Ox} \quad [7]$$

where Red represents a reducing agent (*e.g.*, Fe^{2+}, Sn^{2+}, Ti^{3+}, Pb^{2+}) for the metallic cation M^{n+} (*e.g.*, Pd^{2+}) and Ox is the oxidation product of Red; (2) the function of the first and the second step is to produce a latent image that consists of the active sites of the reducing agent Red in the pattern area.

Sensitization.—In the first step a photosensitive salt is applied on the surface of the nonconductor. The photosensitive salt can be in its electrochemically active (with respect to reaction [7]), lower oxidation state, Red form, or it can be in its electrochemically inactive, higher oxidation state, Ox form.

An example for the sensitizer which is initially active in the electrochemical step is $SnCl_2$, Stannous ion Sn^{2+} can reduce Pd^{2+} ions into palladium metal. A typical sensitizer solution is 0.044M $SnCl_2$ in 0.1M HCl (3, 4).

An example for the sensitizer initially inactive in the electrochemical step is ferric oxalate, $Fe_2(C_2O_4)_3$. Ferric ion cannot act as a reducing agent, Red, in reaction [7]. However, the reducing agent Fe^{2+} (Red) can be formed from ferric oxalate, $Fe_2(C_2O_4)_3$, the Ox form, in the photoreduction reaction

$$\underset{(\text{Ox})}{Fe^{3+}} \xrightarrow{h\nu} \underset{(\text{Red})}{Fe^{2+}} \quad [8]$$

The photogenerated reducing agent Fe^{2+} can reduce Pd^{2+} ions into Pd metal. The two preferred sensitizer solutions (2) of this type are 0.1M to 0.5M $Fe_2(C_2O_4)_3$ or 0.1M to 0.5M $Hg_2C_2O_4$.

Thus, there are two types of sensitizers in the photoelectrochemical method of formation of catalytic metallic nuclei: (*i*) initially electrochemically active and (*ii*) initially electrochemically inactive sensitizers.

Sensitizers can be applied on the surface of a nonconductor selectively, the pattern sensitizing technique, or the entire surface can be covered by the sensitizer, the panel sensitizing technique. In the first case, the pattern printing technique (5), a rubber stamp having the desired pattern can be used to transfer sensitizer from the stamp pad to the nonconductor. The amount of stannous chloride applied to a surface by this technique is found to be in the order of $\mu g/cm^2$ (5).

In the second case, the panel sensitizing technique, the sensitizer is applied on the entire surface of the nonconductor using roller coating or immersion technique (2). The amount of the $SnCl_2$ sensitizer in the sensitized layer was determined by the x-ray fluorescence to be in the order of $\mu g/cm^2$ (5).

Thus, the result of the sensitization process is a nonconductor having a layer of a sensitizer in the pattern areas or on the entire surface. If the sensitizer is applied in the pattern areas only, and if the sensitizer is of the initially electrochemically active type (Sn^{2+}), the result of the sensitization process is a latent image of the pattern and the nonconductor is ready for the third, activation step. If the panel technique for sensitization is used, the latent image is formed in the second, photochemical step, which is followed by the third, activation step.

Image formation.—Positive version.—The starting material in this process (1) is a nonconductor covered with a layer of the electrochemically active sensitizer, $SnCl_2$. The pattern is formed by exposing the sensitized layer to the photochemically active radiation in the background areas leaving pattern areas not exposed. The photochemical reaction is

$$Sn^{2+} \xrightarrow[\lambda < 300\text{ nm}]{h\nu} Sn^{4+} \quad [9]$$

The result of this photochemical process is that only the pattern area contains Sn^{2+} and the background area Sn^{4+} ions. Since only Sn^{2+} ions can form catalytic active species with Pd^{2+} (*e.g.*, Pd metal, according to reaction [1]), only the pattern area can be subsequently activated to produce catalytic Pd nuclei.

Negative version.—The starting material in this process (2) is a nonconductor covered with the layer of an electrochemically inactive sensitizer, $Fe_2(C_2O_4)_3$. In this case the pattern is formed by exposing the pattern area to the photochemically active radiation leaving background areas unexposed. The photochemical reaction in the exposed area is

$$Fe^{3+} \xrightarrow[\lambda < 300\text{ nm}]{h\nu} Fe^{2+} \quad [10]$$

As the result of this process electrochemically active Fe^{2+} ion is generated in the pattern area only, while the background area contains inactive Fe^{3+} ions. Since only Fe^{2+} ions can reduce Pd^{2+} into catalytic Pd metal sites, only the pattern area can subsequently be provided with catalytic metallic nuclei.

Activation.—The activation step consists of exposing a nonconductor containing the latent image of a pattern to an activator solution in order to produce catalytic metallic nuclei according to the general equation

$$\text{Red} + M^{n+} \rightarrow M + \text{Ox} \quad [11]$$

where M represents catalytic metallic nuclei in the pattern area on the nonconductor surface. The activator usually contains salts of noble metals, $PdCl_2$, $PtCl_2$, or $AgNO_3$, that can be reduced in the pattern areas by the reducing species Red.

Specifically, for the positive process (1, 3, 6, 7) using Sn^{2+} as the sensitizer, the activation process is described by the equation[1]

$$Sn^{2+} + Pd^{2+} \rightarrow Pd + Sn^{4+} \quad [12]$$

and for the negative sensitizing process (2) using Fe^{3+} as a sensitizer, by the equation

$$2Fe^{2+} + Pd^{2+} \rightarrow Pd + 2Fe^{3+} \quad [13]$$

Ions present in the background areas, Sn^{4+} in the positive process and Fe^{3+} in the negative process, are inactive in the activator solution. However, Sn^{4+}, under certain conditions, can be chemically active in the activator solution (4, 8-13).

A solution can be prepared that contains both the sensitizer and the activator, for the negative process, in one and the same solution (2). The sensitizer and the activator components will react at the surface on the nonconductor when exposed to the photochemically active radiation in the pattern area. However, one-step tin-palladium solution cannot be used for the positive process (4).

Thus, at the end of the activation process the nonconductor surface contains catalytic metallic nuclei in the pattern area. These nuclei are capable of catalyzing electroless metal deposition.

Mechanism of image formation.—In this review only one mechanism of each kinetic scheme will be discussed.

Negative version. General: photochemistry of coordination compounds.—Understanding the mechanism of photochemical processes requires knowledge of the absorption spectrum of the molecule under consideration. A typical absorption spectrum of a coordination compound consists of several broad bands in the ultraviolet and visible spectrum, each of which is associated with one or more electronic transitions.

[1] In some cases this is a simplified presentation of a very complex system. Details are given by R. L. Cohen and K. W. West, *This Journal*, **120**, 502 (1973) and R. L. Meek, *ibid.*, **122**, 1478 (1975).

Spectra of coordination compounds can be interpreted on the basis of the molecular orbital (MO) theory (14, 15). The ligand-metal bonding system of a coordination compound is mutually interacting in such a degree that one cannot consider excited states of isolated bonds or groups but rather the excited states of the molecule.

Molecular orbitals for a metal complex can also be constructed by the LCAO (linear combination of atomic orbitals) method. These orbitals are given by the Ψ function

$$\Psi = a\,\Psi_M + b\,\Phi_{Lig} \qquad [14]$$

where Ψ_M is the metal ion orbital, Φ_{Lig} a normalized combination of ligand orbitals, and a and b are the coefficients that determine relative contribution of Ψ_M and Φ_{Lig} to Ψ.

In general, a molecular orbital Ψ formed from two component orbitals, Ψ_A and Ψ_B, includes a larger contribution from that component orbital which is closer to it in energy.

In the first approximation some molecular orbitals Ψ of a metal complex are predominantly metal Ψ_M orbitals, and some ligand orbitals Φ_{Lig}, in character. This localization of states on the central metal ion or on the ligand is only a very rough approximation. The degree of this delocalization of the electron is determined by the values of the coefficients a and b, Eq. [14]. When $a >> b$ the orbital Ψ is largely localized on the metal and the orbital is a metal-localized orbital. When $a << b$ the orbital Ψ is largely localized on the ligand and the orbital is a ligand-localized orbital. This description of the molecular orbitals should be taken as a first approximation only. The molecular orbital diagram for a hypothetical octahedral transition metal complex is shown in Fig. 1.

On the basis of the molecular orbital theory one can classify the electronic transitions in coordination compounds into three types.

Ligand field transition (or d → d transitions).—These are electronic transitions between MO's mainly localized on the central metal ion (d orbitals).

Intra-ligand transitions.—In the internal ligand transitions electronic transitions occur between MO's mainly localized on the ligand.

Charge transfer (CT) or electron transfer transitions.—In the charge transfer transitions the transfer of electronic charge occurs between MO's mainly localized around the ligand and MO's mainly localized on the central metal.

Depending on the origin of the excited electron one distinguishes two basic types of the charge transfer. (*i*) Excited electron originally localized on central metal. [Metal → Ligand (M → L) Charge Transfer (MLCT, or CTTL)] In this transition the electron transfer occurs from the metal to a ligand. MLCT can be schematically represented as

$$\overset{\curvearrowright\; h\nu}{ML \longrightarrow M^{+}L^{-}} \qquad [15]$$

where the arrow above the molecule ML shows the direction of the charge transfer.

(*ii*) Excited electron originally localized on ligand(s). [Ligand → Metal (L → M) Charge Transfer (LMCT or CTTM)] In this transition the electron moves from the ligand toward the central metal. LMCT can be schematically represented as

$$\overset{\curvearrowleft\; h\nu}{ML \longrightarrow M^{-}L^{+}} \qquad [16]$$

where the arrow above the molecule ML shows the direction of the charge transfer.

Thus, in both cases, MLCT and LMCT, the absorption of electromagnetic radiation results in an oxidation-reduction process. The ligand to metal charge transfer processes (L → M) are of central interest in our discussion of the formation of catalytic nuclei on nonconductors.

MLCT and LMCT can be classified as internal charge transfers, charge transfers within a molecule. Another type of charge transfer can occur which can be classified as intermolecular charge transfer. In this type of charge transfer the electron is transferred from either a ligand or the complex as a whole to the solvent, CTTS. In this case the electron is lost to the solvent.

Irradiation of different absorption bands produces different excited states which result in different reaction products and yields. Thus, an interpretation of the absorption spectrum of a photosensitive molecule is necessary in order to be able to conduct a photochemi-

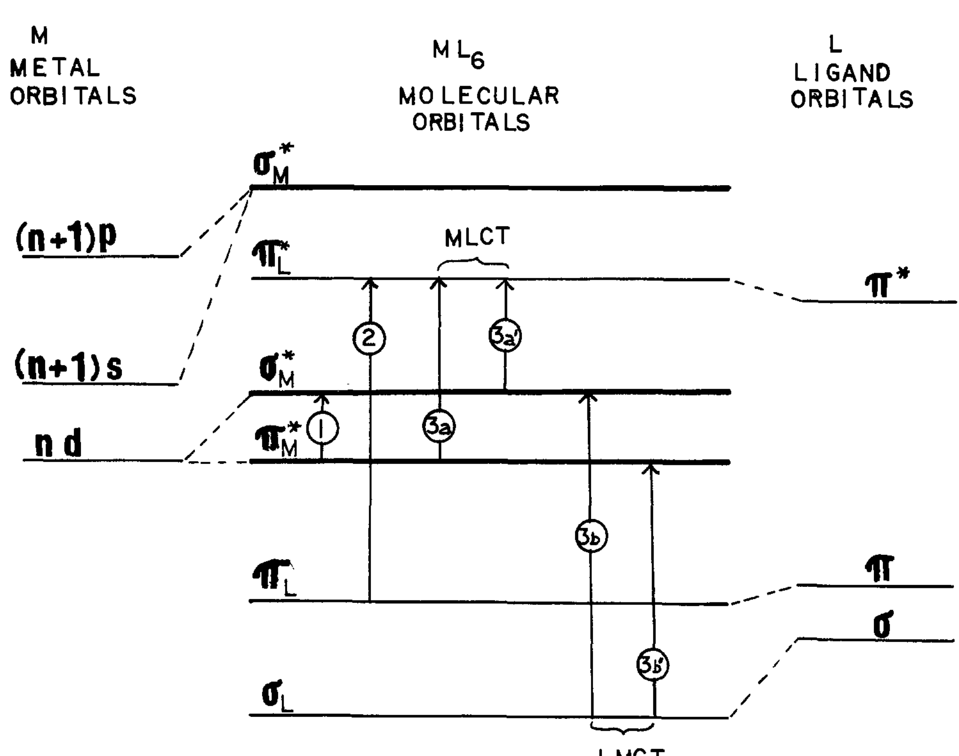

Fig. 1. The molecular orbital diagram for a hypothetical octahedral transition metal complex in which ligands have σ and π orbitals. A molecular orbital which is in the first approximation associated with a ligand orbital is shown in thin line and molecular orbital associated with the central metal is shown in thick line. Arrows: 1, ligand field transition; 2, intra-ligand transition, 3a, 3a', MLCT; 3b, 3b', LMCT transition.

cal reaction in a direction of production of specific, desired products.

Photochemical reduction of complexed ferric ions.—The redox photolysis of the trisoxalatoferrate(III) in the solid state and in the solution (16, 17) proceeds in such a way that the tripositive Fe^{3+} ion is reduced to the dipositive Fe^{2+} ion and oxalate is oxidized to carbon dioxide, according to the overall reaction

$$2Fe\,(C_2O_4)_3{}^{3-} \xrightarrow{h\nu} 2Fe^{II} + 5C_2O_4{}^{2-} + 2CO_2 \quad [17]$$

The net primary photochemical reduction reaction of monoxalatoiron(II) ion is, according to Cooper and De Graff (18), the ligand to metal charge transfer

$$Fe(C_2O_4)^+ \xrightarrow{h\nu} Fe^{2+} + \cdot C_2O_4{}^- \quad [18]$$

$$Fe^{3+} + e^- \rightarrow Fe^{2+} \quad [19]$$

where Fe^{3+} is reduced to Fe^{2+} and the oxalate ion is oxidized to the oxalate radical $\cdot C_2O_4{}^-$

$$C_2O_4{}^{2-} \rightarrow \cdot C_2O_4{}^- + e^- \quad [20]$$

The oxalate radical generated in the primary photochemical process reduces monoxalatoiron(III) ion in a secondary reduction reaction

$$\cdot C_2O_4{}^- + Fe\,(C_2O_4)^+ \rightarrow Fe\,(C_2O_4) + 2CO_2 \quad [21]$$

It was proposed (19) that the oxidized ligand, the oxalate radical, can dissociate to give the $\cdot CO_2{}^-$ radical and CO_2

$$\cdot C_2O_4{}^- \rightarrow \cdot CO_2{}^- + CO_2 \quad [22]$$

The radical $\cdot CO_2{}^-$ can react with the monoxalatoiron(III) ion in a reaction analogous to reaction [20].

In the presence of an excess of Fe^{3+} ions, the oxalate radical can reduce Fe^{3+} ions into Fe^{2+}

$$\cdot C_2O_4{}^- + Fe^{3+} \rightarrow Fe^{2+} + 2CO_2 \quad [23]$$

Thus, the overall reaction of oxidation of $C_2O_4{}^{2-}$ is

$$C_2O_4{}^{2-} \xrightarrow{h\nu} 2CO_2 + 2e^- \quad [24]$$

A similar mechanism was proposed for the photochemical reduction of dioxalate and tris-oxalato ferrate (20-23). In the primary photochemical process the electron transfer occurs, resulting in generation of either $\cdot C_2O_4{}^-$ or $\cdot CO_2{}^-$ followed by the secondary reactions of these radicals with ferrioxalate or itself, or both.

Positive version. Photochemistry of the Sn(II) sensitizer.—D'Amico, Litt, and DeAngelo (7) postulated that the role of the light is to generate electron hole pairs, in the SnO-SnO_2 sensitized layer, which can participate in the Sn(II) oxidation into Sn(IV). The side reaction in the oxidation of Sn(II) is the reduction (3) of Sn(II) to Sn.

This photochemical reaction needs more study.

Photoelectron Method

In the photoelectron method the catalytic nuclei on nonconductors are formed in two basic steps: (*i*) sensitization and (*ii*) image formation. A latent image in this process consists of metallic nuclei M, where M can be Pd, Pt, Au, Ag, or Cu.

Sensitization.—The sensitized nonconductor contains in the surface a pair of substances: a photosensitive substance reacting according to reaction [5] and a reducible metal ion salt reacting according to reaction [4]. These substances are usually (24, 25) applied in two separate steps.

Application of a photosensitive layer.—Titanium dioxide is applied to the surface of a nonconductor in the form of a homogeneous dispersion of fine solid particles ranging in size from 0.02 to 0.2 μm in an adhesive (25). The adhesive serves as the medium in which the photosensitive compound is dispersed. In this photosensitive layer the TiO_2 particles are completely enveloped with a thin layer of adhesive.

The encapsulation of TiO_2 particles by adhesive ensures the adhesion between photosensitive layer and substrate. However, the encapsulation makes TiO_2 particles inaccessible to the second compound of the sensitizer, the aqueous solution of salts of metal ions such as Pd^{2+}, Pt^{2+}, Au^+, Ag^+, and Cu^{2+}, which are necessary for the formation of a metallic, latent image according to reaction [4]. TiO_2 particles are therefore made accessible by etching the surface of the adhesive layer thus partially uncovering the upper layer of TiO_2 particles and rendering them accessible to the aqueous metal ion solution. In order to ensure good adhesion the thickness of the adhesive layer after etching should be at least 5 μm.

In a modification of this procedure (25) TiO_2 particles are incorporated into the substrate during its fabrication. For a glass-epoxy-based material, TiO_2 particles are intermixed with the epoxy-resin before impregnating the glass-cloth. The impregnation and the lamination of the glass-epoxy based substrate are performed in such a way that the final laminate has a glassless top layer (> 40 μm) of epoxy-resin.

Application of metal ion salts.—The sensitization process is completed by treatment of the TiO_2-adhesive-coated substrate having exposed TiO_2 particles with a dilute aqueous solution of a metal ion salt. Salts of Pd^{2+}, Pt^{2+}, or Au^+ are used when the electroless plating of Cu, Ni, or Co is desired. Cu^{2+} salts may be used when the electroless plating is restricted to copper.

Image formation.—The latent (or printout) image of the desired pattern on a sensitized nonconductor is formed in the following sequence of reactions

$$TiO_2 \xrightarrow[\lambda < 410\text{ nm}]{h\nu} e^- + p^+\,(TiO_2)$$
$$2e^- + Pd_{ads}{}^{2+} \rightarrow Pd \quad [25]$$

where $Pd_{ads}{}^{2+}$ designates the Pd^{2+} ions adsorbed on TiO_2 (24-26). In the exposed areas Pd^{2+} ions are converted into Pd metallic nuclei in the activation step. Nonexposed areas contain Pd^{2+} ions. When the substrate is sensitized with Pt^{2+}, Au^+, Ag^+, or Cu^{2+} salts, metallic nuclei of Pt, Au, Ag, or Cu are formed, respectively.

Mechanism of image formation.—Photoelectron processes are based on the photophysical properties of titanium dioxide (26). Absorption of a photon by a solid TiO_2 promotes an electron e^- from the filled (2p) valence band to the vacant (3d) conduction band, when the energy of the photon is equal to or greater than the bandgap energy (27, 28). Result of this absorption is generation of a free electron in the conduction band and a free hole p^+ in the valence band. This process can be represented by the simplified kinetic scheme

$$TiO_2 \xrightarrow{h\nu} e^- + p^+\,(TiO_2) \quad [26]$$

resulting in the formation of a hole-electron pair.

Mobile electrons, e^-, generated in the process [26] can be captured by a species adsorbed on TiO_2, *e.g.*, a metal ion M^{n+}, which is thus reduced into metal M

$$ne^- + M_{ads}{}^{n+} \rightarrow M_s \quad [27]$$

where n is the number of electrons, and subscripts s and ads designate surface and adsorbed species, respectively.

Metallic nuclei M formed in the reduction step [27] can catalyze electroless metal deposition. M may be Pd, Pt, Au, Ag, or Cu (24, 25).

Photoholes p^+, generated in the process [26], can be trapped (26) by the surface O^- ions and form O_2, recombined with electrons, or participate in the destruction of the metallic phase (M) to form metal ions (M^{n+}).

For the case when M is Ag and Pd it was found that quantum yield for Ag formation is dependent on the silver ion concentration in the solution and independent of light intensity (26, 29, 30). Kinetic data for TiO_2 in solutions of different $AgNO_3$ concentrations obey the Stern-Volmer mechanism

$$\Phi = \Phi_{lim} C_{Ag^+}/(k + C_{Ag^+}) \quad [28]$$

where Φ is the yield at silver concentration C_{Ag^+}, Φ_{lim} is the limiting yield at high C_{Ag^+}, and k is a constant.

Quantum yield for reaction [26], and thus Φ_{lim} in reaction [28], can be increased by the use of photosensitizers. In this case TiO_2 is excited by the sensitizer (30).

Reaction [27] can be catalyzed by multiequivalent reducing agents (31-36). If a two equivalent reducing agent R is adsorbed on TiO_2 a two-step sequence occurs upon irradiation

$$\underset{}{R} \rightarrow \underset{\text{Intermediate}}{R^+} \rightarrow \underset{\text{Stable product}}{R^{2+}} \quad [29]$$

In the first step the reducing agent R is oxidized by a photogenerated hole p^+

$$R + p^+ \rightarrow R^+ \quad [30]$$

producing the intermediate R^+. The intermediate R^+ can be oxidized into the stable species R^{2+} in two alternative pathways

$$R^+ \text{ (Intermediate)} \xrightarrow{1} R^+ \longrightarrow R^{2+} + e^- \quad [31]$$

$$R^+ \text{ (Intermediate)} \xrightarrow{2} R^+ + p^+ \longrightarrow R^{2+} \quad [32]$$

In the pathway 1, reaction [31], R^+ is oxidized by the release (injection) of an electron to the conduction band while in the pathway 2, reaction [32], R^+ is oxidized by a hole. The pathway 1 is the preferred one.

In the case when M^{n+} is present on the surface of TiO_2, simultaneously with R, the pathway 1 consists of the electron transfer from R^+ to M^{n+} resulting in the reduction of M^{n+}, *i.e.*, catalysis of reaction [27].

Catalyzed reduction of Pd^{2+} on TiO_2 can be achieved by R = methanol, ethanol, and 1-propanol (35).

Intramolecular Photoreduction Method

Intramolecular photoreduction method has two basic steps: (*i*) sensitization and, (*ii*) image formation.

Sensitization.—The sensitizer layer applied on a nonconductor in the intramolecular photoreduction method contains three principal components: cupric acetate, cupric bromide, and anthraquinone-2,6-disulfonic acid, disodium salt (37, 38). In the panel sensitizing technique the sensitizer is applied using roller coating.

Image formation.—The latent, or printout, image is formed in the photochemical reaction

$$CuAc \xrightarrow[\lambda < 350 \text{ nm}]{h\nu} Cu + Ac' \quad [33]$$

where Ac' stands for the oxidation products of acetate ion Ac. Thus, the pattern area in this process is composed of catalytic copper nuclei. Images containing Pd, Pt, Au, or Ag can be made using this method.

Mechanism of image formation.—As far as we know there is no published study on the mechanism of photoreduction of cupric ions in the system of cupric acetate, cupric bromide, and anthraquinone-2,6-disulfonic acid, disodium salt. The following mechanisms are suggested for the formation of catalytic metallic nuclei in the intramolecular photoreduction method.

Mechanism of photoreduction of cupric acetate.—On the basis of mechanistic studies (39) on photoreduction of acetatopentaamminecobalt (III) the following mechanism is proposed for the photoreduction of cupric acetate. In the case of cupric acetate, ($[Cu_2(OCOCH_3)_4] \cdot 2H_2O$), a dimer in the crystalline state (40, 41), irradiation of the charge transfer band results in the electron transfer from the acetato ligand to the copper ion center. The excited electron, originally localized on the ligand, is predominantly on the central copper ion. The result of this charge-transfer process is the oxidation of the acetato ligand (39) to an oxidized ligand free radical and the reduction of Cu^{2+} ions to Cu^+ or Cu.

Mechanism of photoreduction of cupric bromide.—The mechanism of photolysis of cupric bromide can be discussed on the basis of the band theory of the solid state or on the basis of theories of photochemical reactions in solution. Since the sensitizer layer in this process contains a considerable amount of water molecules we feel that the interpretation in terms of photochemistry of solutions can provide useful insights (42-46). In this case, in the primary photochemical process of photolysis of cupric bromide, the light is absorbed by the hydrated bromide ion resulting in the formation of solvated electron, e_{aq}^-. The solvated electron then reacts with Cu^{2+} to produce the copper nuclei. Reduction of Cu^{2+} ion in cupric bromide can occur also in a direct "intramolecular," ion pair process.

Mechanism of photosensitized reduction of copper ions.—So far we have considered interaction of electromagnetic radiation with a single molecule or a collection of molecules of one type. In this section we will consider interaction of electromagnetic radiation with a system of two distinct molecules separated in space, or a collection of molecules of two distinct types. In this system a photosensitized reaction can occur (47, 48).

A photosensitized reaction proceeds in three basic steps

$$S + h\nu \longrightarrow S^* \quad [34]$$

$$S^* + A \longrightarrow A^* + S \quad [35]$$

$$A^* \rightarrow \text{primary product} \rightarrow \text{final products} \quad [36]$$

In the first step photons are absorbed by the sensitizer molecule S resulting in the production of the electronically excited molecule S*. The second step is the energy transfer step in which the energy is transferred from the excited sensitizer molecule S* to molecule A with production of the excited molecule A* and the ground state of the sensitizer molecule, S. In the third step the electronically excited molecule A* is deactivated in a photochemical reaction. It is proposed that for the discussed process the antraquinone-2,6-disulfonic acid, disodium salt is the sensitizer S (the energy donor) and the copper acetate molecule the energy acceptor A (the quencher).

Energy transfer from S* to A may occur by two mechanisms: resonance transfer and electron transfer mechanism (20, 49-53).

Image Development

In all three kinetic schemes the catalytic metallic nuclei are used to initiate electroless metal deposition in the image development process. Prior to development the background is desensitized by removing the components of the sensitizing solution. Background desensitization is achieved by rinsing with water (54) or other solvents, or with solutions of complexing agents suitable to remove metallic cations (55, 56). Developers used in the electroless (physical) development contain a developing (reducing) agent, a metal

salt, and usually a complexing agent for metal ions. in a water solution at a pH depending on the developing and the complexing agent (20, 37, 38, 57, 58).

The general reaction of development or amplification of the latent and printout images of copper can be expressed by

$$\text{Red} + Cu^{2+} \xrightarrow[\text{catalytic nuclei in the pattern area}]{\text{M } (e.g., \text{ Pd or Cu})} Cu + \text{Ox} \quad [37]$$

where Red and Ox are the reduced and oxidized form of the developer, respectively.

Processes of electroless copper deposition are well known and will therefore not be discussed here (59, 60). Image composed of Pd nuclei can be developed in the electroless Cu, Ni, Pd, or Co bath. Electroless metal deposition bath used as a developer should be formulated in such a way that it deposits only on the photoimage areas and not on the background. Background areas can be catalytic for processes in a developer, due to incomplete removal of sensitizer.

Discussion

We will discuss characteristic problems of individual processes and prospects for the photochemical selective activation of nonconductors, in general.

Photoelectrochemical Method

Positive version.—Characteristic problems of this method are: (*i*) stability of the Sn^{2+} sensitizer solution, and (*ii*) the short u.v. radiation (220-300 nm) in the image formation step.

The most important characteristic of aqueous $SnCl_2$ solutions relevant to the process of sensitizing is "aging." Freshly made $SnCl_2$ sensitizing solution consists of about 95% Sn^{2+} ions complexed with Cl^- ions and 5% Sn^{4+} ions complexed with OH^- and Cl^- ions (61). The "aging" of the stannous chloride sensitizing solution can be described as a two-step process. In the first step Sn^{4+} ions are produced in the solution as a result of exposure of Sn^{2+} ions to the atmospheric oxygen. In the second step the produced Sn^{4+} ions (*i*) precipitate on the existing colloid particles, or (*ii*) nucleate new colloidal particles (62, 63). This instability of the sensitizer is certainly a drawback in the positive version of the photoelectrochemical method.

The short u.v. radiation (220-300 nm) used in the image formation step can be hazardous and requires special shielding for the protection of production personnel.

Negative version.—The latent image in the pattern area in this process is composed of Fe^{2+} ions. The Fe^{2+} latent image is unstable since Fe^{2+} ions are easily oxidized into Fe^{3+} ions. This instability of image is a problem in the negative version of the process.

Photoelectron Method

The background is the major problem in this method. It was found (35) that in the $TiO_2/PdCl_2$ system Pd^{2+} ions remain in nonexposed areas of the surface even after thorough rinsing with water. The remaining Pd^{2+} ions in the background areas cause fogging during the development, since Pd^{2+} can be reduced to Pd by the reducing agent present in electroless plating solution, giving rise to catalytic Pd nuclei and thus the extraneous deposition of metal present in the developer as metal ions (*e.g.,* Cu, Ni, Co). The amount of palladium salt adsorbed on TiO_2, or the surface in general, in the nonexposed areas, can be considerably reduced if the rinsing is assisted by treating with an aqueous solution of a strong complexing agent for Pd^{2+} ions. Effective complexing agents are, *e.g.,* aminoacetic acid and triethanolamine (35).

An advantage of the photoelectron method over other photochemical methods is the long u.v. (410 nm) radiation.

Intramolecular Photoreduction Method

The background desensitization, after image development, is the major problem in this process. The compounds present in the background are: cupric acetate, cupric bromide, and anthraquinone-2,6-disulfonic acid, disodium salt. If not removed, the compounds present in the background may react with components of the developing solution, thus causing nonselective deposition of electroless metal over the entire surface.

An advantage of this method is that it involves the nonnoble metal nuclei (Cu).

Photochemical Selective Activation: Prospects

Major activities in the field are related to the two common problems in the development step: (*i*) the nonselective, extraneous deposition of electroless metal over the background, and (*ii*) the lateral growth of the pattern (the vertical/horizontal growth ratio).

The extraneous deposition in the background area can be hindered by specific additives in the image development solution. This type of additive should preferentially adsorb on the background, the adhesive layer of the surface, but not on the metallic nuclei in the pattern area. Search for additives of these properties is a very active area of research, see, for example, Ref. (64).

The problem of hindering the horizontal (lateral) growth is approached in the same way. Specific additives can block the lateral growth (65), causing the development of the photo image to proceed in the vertical direction only. The ratio between the vertical and the lateral growth rate is the determining factor for line resolution in the printed circuit boards production.

Resolution for the photochemical selective activation methods depends on the wavelength of the electromagnetic radiation used and the particle size of sensitizer on the surface of the nonconductor. Since the wavelengths are of the order of 350 nm and less (u.v. range), and since the particle size is of the order of 100 nm and less (1, 25), the expected resolution is about 1 μm. In practice, pattern lines with width of 3-4 μm have been made (1, 24).

Production resolution limits, with good yield, for the manufacture of printed circuit boards are: linewidth and spacing 175, 125, and 75 μm for the copper thickness of 35, 25, and 20 μm, respectively.

Solutions to the background and the lateral growth problems are essential for the successful application of the discussed kinetic schemes in the selective activation of nonconductors for the production of printed circuit boards.

Summary

Fundamental aspects of photochemical selective activation can be summarized in three major points.

1. Three types of photochemical reactions can result in activation of nonconductors: (*i*) catalytic metallic nuclei can be generated in an intramolecular electron transfer resulting from photon absorption. In this case catalytic nuclei are of the same metal as the photosensitive compound. Intramolecular charge transfer can be a primary or a sensitized photochemical reaction. (*ii*) Catalytic metallic nuclei can be formed in an interaction of a metallic compound and photoelectrons generated in the absorption of photons by a semiconductor crystal. (*iii*) Catalytic metallic nuclei can be formed in the oxidation reduction process where the reducing agent is generated in a photochemical reaction.

2. Wavelengths of photochemically active electromagnetic radiations for the above reactions are in the range of 220-410 nm.

3. Nonconductors can be activated photochemically with Pd, Pt, Au, Ag, or Cu catalytic nuclei. These nuclei are catalytic for electroless metal deposition.

Technological aspects can be summarized as follows.

1. Pattern lines with a width of 3-4 μm have been made.

2. Production limits, with good yields, for the manufacture of printed circuit boards are: linewidth and spacing 175, 125, and 75 μm for the copper thickness of 35, 25, and 20 μm, respectively.

3. Catalytic nuclei of noble (Pd, Pt, Au, Ag) and nonnoble metals (Cu) can be photochemically generated in the pattern areas on a nonconductor.

Theory of Electrochemical Memory

Application to Short-Circuit Memory in Electrochromic Displays

G. Beni

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

We introduce the concept of electrochemical memory and discuss it in relation to electrochromism. We show that the electrochemical memory could be created by the dynamics of the ion-electrolyte interaction during the ion-insertion process. To calculate the electrochemical memory we introduce a small-polaron model of ion transfer at the electrochemical interface and derive general, analytical expressions for the probability of transitions. We apply these expressions to a Langmuir-type macroscopic model of the electrochromic reaction. Under these assumptions, we establish lower limits of the breakdown voltage necessary for short-circuit memory with threshold in an electrochromic display cell. We also derive a simple expression for the maximum memory in terms of the intrinsic response time of the electrochromic cell. For response times ~10 msec and breakdown voltages ~2V, the maximum memory would be ~20 min at room temperature. Finally, we calculate the electrolyte reorganization energy required to achieve the maximum memory. Its value lies in the range 1.5 ↔ 2.0 eV. In applying these results to displays, we find that the number of lines which could be sequentially matrix addressed in an electrochromic display matrix spans the range 10 ↔ 10^5. In contrast to the current notion, this proves that direct matrix addressing of electrochromic displays is theoretically possible.

Electrochromics are promising display materials (1). Unlike liquid crystals, they have open-circuit memory and an unrestricted viewing angle. Although early electrochromics degraded rapidly (2), the recently discovered (3-8) anodic iridium oxide films (AIROF's) are highly stable. They have been tested for ~10^6 cycles with no detectable degradation. In addition, all-solid-state display cells have been demonstrated (9) and reactive-sputtering techniques (10) have simplified considerably the fabrication of practical devices. Thus, electrochromics promise to play a significant role in new passive-display technologies.

Even so, displays consisting of many electrochromic elements are considered impractical. When the number of display elements in a matrix exceeds ~100 it becomes essentially impossible to drive each element individually. Instead, rows and columns of the display matrix must simultaneously be driven according to a scheme known as "matrix-addressing" (11). But the possibility of direct (12) matrix-addressing of electrochromic displays has been ruled out. Indeed, electrochromics have been regarded as "fundamentally unsuited for matrix-addressing" (13) and, consequently, fundamentally unsuited for any but the simplest multielement displays. In contrast, this paper shows how, by appropriate choice of the electrolyte, electrochromic displays might be matrix-addressed. Large matrixes of electrochromic elements might then become a practical possibility.

The paper is organized as follows. The remaining part of this section is devoted to a more precise description of memory in electrochromic cells and of the problems of matrix-addressing. In particular, the concept of short-circuit memory is introduced and it is shown that matrix-addressing requires electrochromic cells with short-circuit memory. The following section discusses, in general, the concept of electrochemical memory: how it relates to the free energy of the electrochromic reaction and to the concepts of metastability, hysteresis, and relaxation. It is shown that the free energy barrier of the electrochromic reaction is the essential element for electrochemical memory. The physics of the free energy barrier is the subject of the section "Microscopic Model." A microscopic model for the charge transfer at the electrolyte-electrochromic interface is presented. Analytical results yield the probability of charge transfer as a function of the potential difference across the interface. The section "Macroscopic Model" is devoted to the macroscopic model of the electrochromic reaction. Using the microscopically calculated probability of transition, the macroscopic model yields general results (*e.g.*, upper limits) on the electrochemical memory. Specific numerical results are given in the Results section where the properties of the electrolyte are related to the size of the memory and to the maximum number of elements in an electrochromic display matrix. The last two sections discuss the approximations involved in the calculations, compare various types of electrochromic memories, and summarize the results.

Broadly defined, electrochromism is a persistent but reversible color change induced electrochemically. Although electrochromism is a widespread phenomenon, here we consider only electrochromism of ion-insertion materials. An ion-insertion material (14) is a mixed conductor (*i.e.*, electronic and ionic) in which ions can be rapidly and reversibly inserted. Of course, for charge neutrality, an electron

* Electrochemical Society Active Member.

Key words: displays, electrochemical kinetics, electrochromism.

is also inserted (extracted) whenever an anion is extracted (inserted) or whenever a cation is inserted (extracted). Examples of ion-insertion materials are Li_xTiS_2 and $Li_xV_2O_5$ which are used as electrodes in lithium-insertion batteries (15). Electrochromics are ion-insertion materials whose optical properties depend strongly on the number of inserted ions. Thus, they may be regarded also as storage batteries with a visible state of charge.

An important property of an ion-insertion material is its internal electromotive force (emf). In order to define it, consider first the "capacity" of the ion-insertion material. This is the maximum number N_{max} of ions that can be inserted in a unit volume. When N ions per unit volume are inserted in the material, the "relative ion-occupancy" $q = N/N_{max}$ determines the chemical potential $\mu(q)$ of an ion in the ion-insertion material. In turn, the chemical potential is related to the internal emf ϵ by $\epsilon(q) = -e\mu(q)$, where e is the electron charge. Obviously $\epsilon(q)$ varies with the temperature; at a given temperature the function $\epsilon(q)$ is usually referred to as an "isotherm" of the ion-insertion material. Isotherms of electrochromics are measurable and have been studied extensively (16-20). They are the most fundamental properties characterizing the ion-insertion material.

Let us consider now the symmetric cell shown in Fig. 1a. 1 and 5 are electronic conductors. 2 and 4 are ion-insertion mixed conductors. 3 is the electrolyte. For simplicity let 1,5 and 2,4 be identical. Let us assume also that the relative ion-occupancies q_4 of 4 and q_2 of 2 are such that $q_2 + q_4 = 1$. The potential difference between 1 and 5 is $\Delta\epsilon = e[\mu(q_4) - \mu(q_2)]$. Thus, if 1 and 5 are externally connected, and if $q_2 \neq q_4$, ions will be transferred between 4 and 2 across the electrolyte 3 until $q_2 = q_4 = 1/2$ and $\Delta\epsilon = 0$. The cell is in thermodynamic equilibrium. The cell can be displaced from equilibrium by applying an external voltage between 1 and 5. If, by application of the appropriate voltage, a configuration q_2, q_4 ($q_2 + q_4 = 1$) is obtained, this configuration persists after opening the external circuit since charge cannot be transferred unless 1 and 5 are connected. This property of the cell is referred to as open-circuit memory.

Open-circuit memory is a useful property of an "electrochromic" cell, *i.e.*, a cell where 2 and 4 are electrochromic materials. Typically in such a cell, 1 is a transparent conductor *e.g.*, SnO_2 and 3 a white-pigmented electrolyte. If 2 is transparent for $q_2 = 0$ and is blue for $q_2 = 1$ then, when viewed from above, the display cell appears either white or blue depending on the applied potential. The color persists even after disconnecting 1 and 5 from the applied voltage. This open-circuit memory is clearly useful in many applications, but it cannot be used for matrix-addressing.

Matrix-addressing is a technique used to drive a large number of display elements. Figure 2 shows schematically, for a 2×3 matrix, how this technique works. The top electrodes, 1, are connected in rows and the bottom electrodes, 5, are connected in columns. For illustration, assume the existence of a voltage V_A such that, [see Fig. 1(b)], for any elements: (a) $q_2 = 1 (q_4 = 0)$ if $V_1 - V_5 \geqq V_A$ where $V_1 - V_5$ is the potential difference between top and bottom electrodes; and (b) $q_2 = 0 (q_4 = 1)$ if $V_1 - V_5 \leqq -V_A$.

In an actual device, only the upper part, 1, 2, 3, of any display element is visible, whereas 4 and 5 are hidden from view. Thus, in (a), the display element appears colored and, in (b), it appears bleached.

The information to be displayed on the matrix is multiplexed onto the columns which are addressed with bias $+3V_A$ or $+V_A$. The rows, instead, are addressed sequentially (*i.e.*, only one row is selected in a given interval) by bias pulses of amplitude $+2V_A$ and duration Δt. This kind of addressing colors the ij display element if, and only if, the jth column is biased at $+V_A$ during the ith row selection interval. Thus, for the particular addressing example shown on the right-hand side of Fig. 2, the display elements 12, 13, and 21 become colored whereas 11, 22, and 23 remain bleached.

This example is easily generalized to an nxm matrix. For an nxm matrix, driving each display element individually requires nxm inputs whereas matrix-addressing requires only $n + m$ inputs. Thus, matrix-addressing greatly simplifies the circuitry of multielement displays.

Many variations of the basic matrix-addressing scheme exemplified in Fig. 2 are possible. But every scheme requires two essential properties of the display cell: (*i*) threshold response and (*ii*) short-circuit memory.

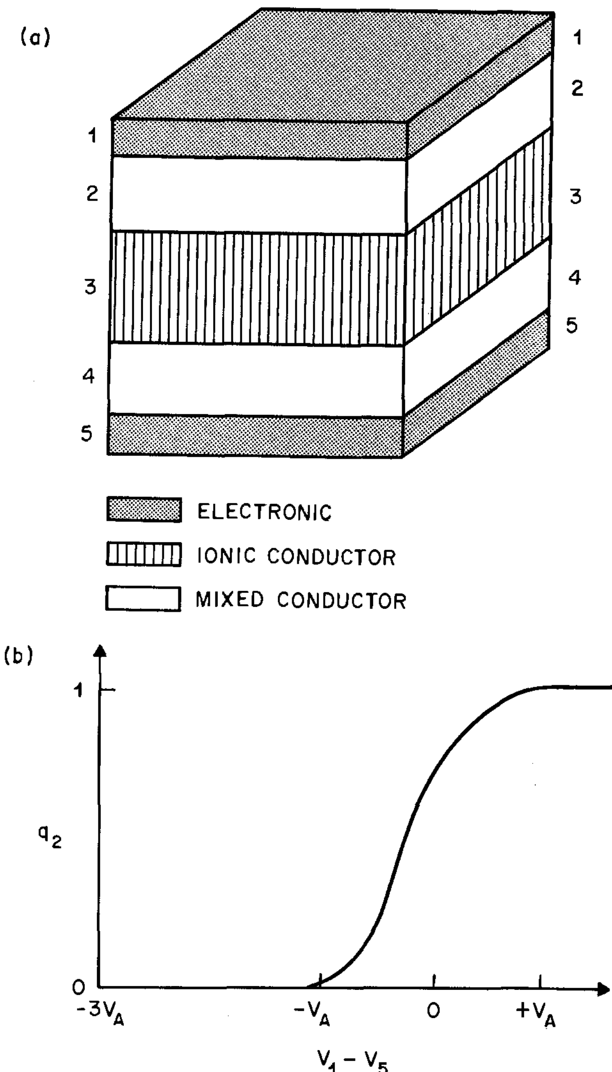

Fig. 1. (a) Schematic structure of an ion-insertion cell. 1 and 5 are electronic conductors. 2 and 4 are mixed conductors and, more specifically, ion-insertion materials. 3 is the electrolyte, *i.e.*, an ionic conductor. In a typical electrochromic cell, 1 is a transparent conductor such as SnO_2, 2 is the electrochromic material, and 3 is a white-pigmented electrolyte. 4 and 5 are hidden from view. (b) Example of relative ion-occupancy q_2 of the ion-insertion material 2 as a function of the voltage difference $V_1 - V_5$ applied between the electrodes 1 and 5. In this example, the relative ion occupancy is negligible for $-3V_A \leqq V_1 - V_5 \leqq -V_A$ and increases gradually to 1 at $V_1 - V_5 = +V_A$. Thus, $-V_A$ is the threshold voltage.

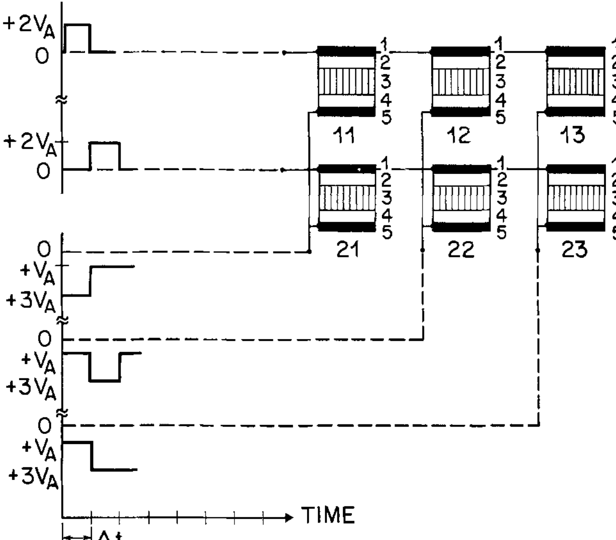

Fig. 2. Schematic matrix-addressing for a 2 × 3 array of electrochromic cells. The vertical numbers have the same meaning as in Fig. 1(a). The numbers underneath each cell are simply labels. Each cell is assumed to have threshhold at $-V_A$ [see Fig. 1(b)]. Rows are addressed one at a time with voltage pulses of amplitude $+2V_A$ and duration Δt. Columns are addressed with either $+3V_A$ or $+V_A$. The addressing voltages shown on the left-hand side give rise to "coloration" of cells 12, 13, and 21, whereas 11, 22, and 23 remain "bleached."

Threshold response.—In the example of Fig. 2, we assumed the existence of a voltage V_A satisfying the conditions (a) and (b). This is not a restrictive assumption for most electrochromics. The addressing voltages, however, impose strict requirements on the electrochromic cell. In the example, addressing voltages vary from $+3V_A$ to 0 corresponding to the potential differences $-3V_A \leq V_1 - V_5 \leq + V_A$. If, for any voltages in the interval $[-3V_A, -V_A]$, the electrochromic cell is unstable (*e.g.*, because of side reactions such as gas evolution, degradation etc.), then matrix-addressing is precluded. Thus, it is imperative that the electrochromic cell remains essentially inert during the scan $-3V \leq V_1 + V_5 \leq -V_A$. In general, regardless of the particular value of V_A, this threshold response of the electrochromic cell is necessary for any matrix-addressing scheme. A second essential requirement is short-circuit memory.

Short-circuit memory.—In Fig. 2, let us consider the closed circuit formed by cells 11, 12, 21, and 22. The voltage-scans in the example color 12 and 21. Thus, these four cells form a series with a total emf of $+4V_A$. Current will flow until the four cells are in equilibrium at $q_2 = 1/2$, all of them being half-colored. This example illustrates the general problem of "cross-talk" among the electrochromic cells in a matrix. Since colored electrochromic cells are basically charged batteries, they can discharge through the connecting circuits and thus partially color other cells. This happens essentially because the cells lack short-circuit memory. In fact, if in a cell $q_2 \neq 1/2$ and its electrodes 1, 5 are short-circuited, then q_2 quickly relaxes to $1/2$ while the cell loses any memory of the displayed information.

Thus, both threshold-response and short-circuit memory are essential for matrix-addressing. Early electrochromics lacked both (21). The recently discovered AIROF's have a fairly sharp threshold which is satisfactory for matrix-addressing. AIROF's in common aqueous electrolyte, however, have no intrinsic short-circuit memory. In the following sections we shall see how this problem can be overcome.

Electrochemical Memory

Strictly speaking, no electrochromic cell has zero short-circuit memory. When an electrochromic cell is short-circuited, it relaxes to equilibrium in a characteristic time t_M determined by its internal emf and its internal resistance. However, to avoid "flickers" in the display-matrix, t_M must satisfy the condition $t_M \geqq n\Delta t$ where $n\Delta t$ is the matrix total scanning time. An obvious way to increase t_M is to increase the resistivity of the electrolyte. This method, however, besides requiring high driving voltages, would correspondingly increase the response time t_R and thus, necessarily, Δt. The maximum number n_{max} of addressable rows would remain constant, since $n_{max} \sim t_M/t_R$. So, increasing the electrolyte resistivity does not solve the short-circuit memory problem. Similar considerations apply to any scheme based on increasing the circuit impedances within the display matrix.

We will investigate a different method by which a useful short-circuit memory might be built into the electrochromic cell. The method discussed in this paper takes advantage of the unique properties of electrochemical interfaces. Since the electrochemical interface is the physical basis for this type of short-circuit memory we shall refer to it as electrochemical memory. Let's now discuss its general character.

Figure 3(a) shows a schematic free energy diagram of a model system. Each curve refers to one particular value of the external variable x (*e.g.*, temperature, pressure, applied field etc.). Let $x_1 \leq x' \leq x'' \leq x''' \leq x_2$. The abscissa indicates the internal variable y (*e.g.*, volume, charge density, magnetization etc.). For a classical system at absolute zero, $y = y_1$ at $x = x_1$. As x increases, y does not change until $x = x_2$. At $x = x_2$, where no energy barrier separates $F(y_1)$ from $F(y_2)$, y switches from y_1 to y_2. Similarly, in reversing the path, $y = y_2$ for $x > x_1$. At $x = x_1$, y switches from y_2 to y_1. Thus, at x_1, $y = y_1$ and, at x_2, $y = y_2$, but, for $x_1 < x < x_2$, y is either y_1 or y_2 depending on the history of the system. This phenomenon is well known (23) and is usually referred to as supersaturation or metastability. In general, a system exhibits metastability if, by exchanging the external variable $x_1 \leftrightarrow x_2$, the corresponding change of the internal variable $y_1(x_1 \leftrightarrow y_2(x_2)$ occurs, for $x_1 \rightarrow x_2$, along a path A and, for $x_2 \rightarrow x_1$, along a path B $\neq$ A [see Fig. 3(b) upper graph].

Metastability is at the basis of hysteresis, relaxation, and memory. It is important, however, to distinguish carefully between these various concepts. Hysteresis is exhibited by a system composed of a large number of subsystems (domains) with metastability and with slightly differing switching points randomly distributed around their average values $\bar{x}_1$, $\bar{x}_2$. In the metastability "loop" [Fig. 3(b) upper graph], at least some of the states are metastable (dashed lines) and/or nonreproducible (dotted lines), whereas in the hysteresis loop [Fig. 3(b) middle graph] all points are stable and reproducible (solid lines). Thus, in a hysteretic loop (but not in a metastability loop), the internal variable is a genuine double-valued thermodynamic function of the external variable. And, therefore, a hysteretic system has infinite memory.

On the other hand, a metastable system may or may not have infinite memory. The classical system of Fig. 3(a) has infinite memory at absolute zero. Similarly, this system has infinite memory above zero temperature if the free energy barrier between y_1 and y_2 may be regarded as infinite for some values of x. Apart from these two special cases, however, a metastable system does not have infinite memory since its metastable states will eventually decay to lower energy states in a characteristic

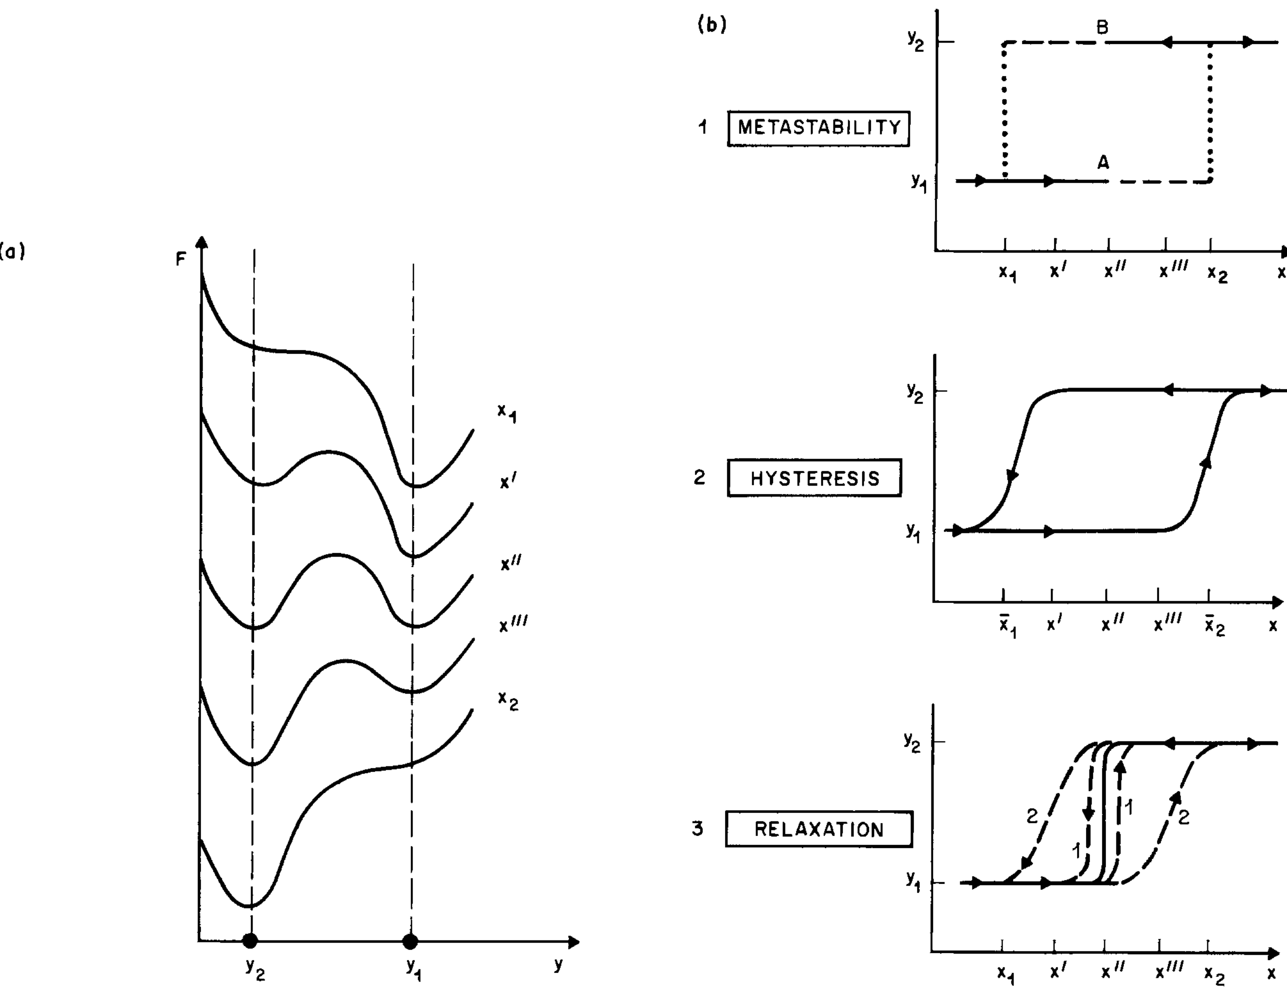

Fig. 3. (a) Schematic free energy diagram of a metastable system characterized by an internal variable *y*, for 5 different values ($x_1 < x' < x'' < x''' < x_2$) of the external variable *x*. (b) Internal variable *y* vs. external variable *x* for: 1. a metastable system with infinite equilibration time. Solid lines are metastable states and dotted lines are nonreproducible states. 2. A system composed of a large collection of metastable domains with switching points randomly distributed around their averages $\bar{x}_1$, $\bar{x}_2$. All states in the loop are stable and reproducible. In this case the system exhibits hysteresis. 3. A metastable system with finite equilibration time. This system exhibits relaxation. The size of the relaxation loop depends on the rate of change of *x*. Loop 1 corresponds to a lower rate than loop 2. The solid line refers to an infinitely slow change of *x*.

time t which depends on the temperature and on the free energy barrier height. Even so, such a system may have a large finite memory. If the rate of change of the external variable x is very small, then the states at y_1 and y_2 are always in equilibrium and thus there is no memory. [Fig. 3(b) lower graph, solid line.] But, as dx/dt increases, the states at y_1 and y_2 do not have time to equilibrate so that the system exhibits memory. In this case, the internal variable $y(x)$ becomes double-valued and so the $y(x)$ plot shows a loop. [Fig. 3(b) lower graph, dashed lines.] This phenomenon (24) is referred to as time-dependent hysteresis or simply relaxation. The size of the relaxation loop depends on t and on dx/dt. All points on the loop correspond to metastable states (except for $dx/dt \rightarrow 0$) but are all reproducible. To sum up, a metastable system may have infinite, finite, or zero memory depending on t and on the rate of change of the external variable. In any case, the required characteristic for metastability and, thus, memory is that the free energy diagram have 2 valleys in the direction of the internal variable and that each valley turn over to its neighbor at a point of inflection.

This characteristic is inherent in the most fundamental electrochemical reaction, *i.e.*, the charge transfer at the electrolyte-electrode interface. In fact, the schematic free energy diagram of the charge transfer reaction [Fig. 4(a)] has the same basic features as the free energy diagram of Fig. 3(a). According to Fig. 4(a), the ion is in the electrolyte when the electrode potential is at V_1 and in the electrode when the potential is at V_2. At the intermediate potentials, however, the ion is in the electrode or in the electrolyte depending on the history of the system. (For simplicity we assume that the energy level in the electrolyte does not change with the applied voltage.) Unlike other chemical reactions, an electrochemical reaction is ideal for inducing relaxation phenomena since the free energy level in the electrode can be easily changed by the applied voltage. The rate of change of the applied potential and the height of the free energy barrier determine the size of the relaxation loop [Fig. 4(b)]; and, correspondingly, the size of the electrochemical memory.

The same size of electrochemical memory can be obtained: (a) with a low free energy barrier and a high potential scanning rate or (b) with a high free energy barrier and a low potential scanning rate. To obtain a significant short-circuit memory in an elecchromic cell we must resort to case (b), since short circuit is equivalent to essentially zero scanning rate. Therefore, for short-circuit memory, it is necessary to have a high free energy barrier at the electrolyte-electrochromic interface.

It is important to note that the effect of a high free energy barrier at the electrochemical interface

is not equivalent to the effect of an electrolyte with high resistance. The electrochemical interface with a high free energy barrier is equivalent to a large resistance only when the free energy difference between electrode and electrolyte is zero. By changing the electrode potential, this resistance drops to zero at a given voltage which depends on the barrier height. At this voltage, the intrinsic response time is unaffected by the barrier. Thus, the electrochemical interface acts, in effect, as a voltage-controlled resistor. And this is precisely what is required to provide the cell with short-circuit memory without altering the intrinsic response time of the cell. There remains to see how a high free energy barrier can be built into an electrochemical interface, without altering the response time. This is discussed in the next section.

Microscopic Model

So far, we have considered only the macroscopic aspects of the electrochemical interface. Microscopically, the electrochemical interface has an extremely complicated structure which is very poorly understood (25). Even more complex is the dynamics of charge transfer across the interface. The free energy barrier of Fig. 4(a) is obviously an oversimplified way to characterize the probability of transition across the interface.

The probability of transition depends on many factors which can be classed into three groups: (*i*) nature of the transferred particle; (*ii*) nature of the electrode, and (*iii*) nature of the electrolyte. Here, we shall not be concerned with (*i*) and (*ii*). These factors should be taken into account in a general discussion of electrochemical memory, but, in this paper, we are basically trying to answer the question: "given an ion-insertion electrochromic material, how can we design an electrochromic cell with short-circuit memory?" Thus, the nature of the electrode and of the transferred ion are fixed at the outset. Therefore we restrict our attention to the dependence of the probability of transition from the electrolyte.

As in other fields of chemical kinetics, a satisfactory *a priori* theoretical evaluation of rate constants for electrochemical reactions is still an elusive goal. Many models have been proposed and the field is still controversial (26). However, in the early sixties, and continuing to the present, a major thrust in interpretation was made by Marcus (27) and by Levich, Dogonadze, and Kuznetzov (LDK) (28). Their theories contain the most widely accepted model of charge transfer at the electrochemical interface.

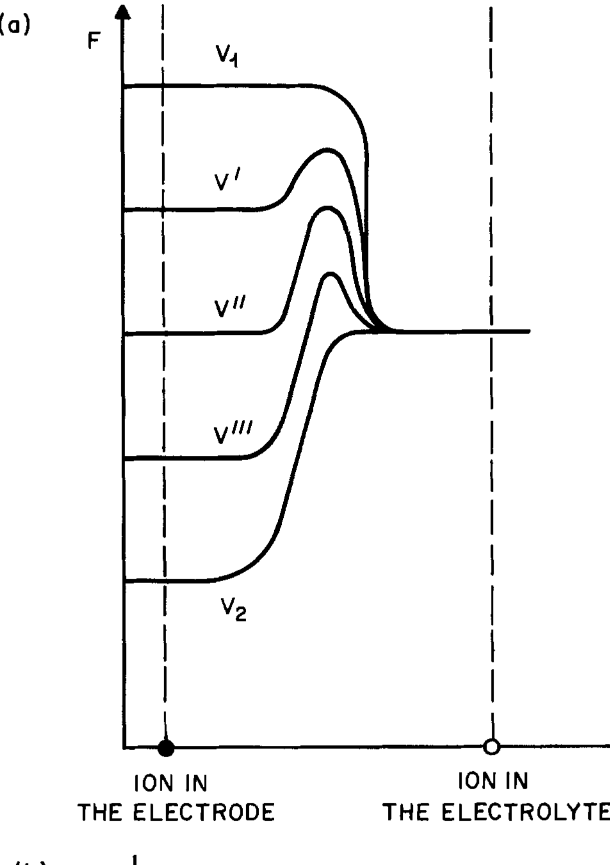
These theories are based on two main concepts.

1. The electrolyte is represented as a continuous polarizable medium characterized by a frequency ω and a "reorganization energy" E_R. The latter is a measure of the change in the solvation structure of the ions in the electrolyte when an electron, or ion, is transferred across the electrochemical interface. A detailed discussion of ω and E_R is given in Ref. (28).

2. The charge transfer across the interface is determined primarily by thermal fluctuations in the electrolyte.

In general, the problem of charge transfer at the electrochemical interface has much in common with the polaron (29) problem. In fact, it was pointed out (30) by the author that, for electron transfer, the results of the LDK theory could be easily derived from the small-polaron theory (31). Indeed, the small-polaron theory yields more general results than the LDK theory.

Less studied is the case of ion transfer across the electrochemical interface. The LDK theory, in this case, becomes quite complex and it has been worked out only for proton transfer. As for the small-polaron theory, very few extensions beyond electron transfer have been developed (32), even outside electrochemistry. Recently, however, Emin *et al.* (33) have applied successfully the small-polaron theory to the motion of interstitials in solids. In this section we extend the small-polaron theory to the transfer of ions across the electrochemical interface.



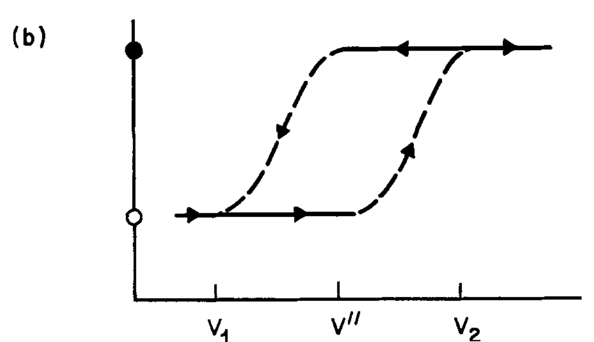


Fig. 4. (a) Schematic free energy diagram for charge transfer in an ion-insertion reaction. The five curves correspond to five different values of the electrode voltage. The open circle corresponds to a state of the ion in the electrolyte and the full circle to a state of the ion in the electrode. (b) Schematic relaxation loop for an ion-insertion reaction. The size of the loop depends on the voltage-scanning rate.

The small-polaron theory describes the motion of a particle between adjacent sites in response to fluctuations of the medium of propagation (characterized by a frequency ω). Since, in this work, we are mainly concerned with room temperature effects, we consider only the high temperature limit. For $k_B T \gtrsim \omega$ (T is the temperature; k_B the Boltzmann constant, and $\hbar = 1$ throughout the paper), the dynamics of transfer reduces to a two-site problem and the medium may be viewed as classical. The thermal fluctuations of the medium create temporary degeneracies between two adjacent energy levels (coincidence events). During each coincidence event,

the particle has a finite probability of transferring to the adjacent level. The probability depends on ν, the time derivative, evaluated at coincidence, of the energy difference between the two adjacent energy levels. The rate of transfer W is givn by

$$W = \int_0^{\infty} < P_c(\nu) > P_t(\nu) d\nu \qquad [1]$$

where $<\ldots>$ means thermal average, $P_c(\nu)$ is the probability of a coincidence event and $P_t(\nu)$ is the probability of transfer during the coincidence event. Holstein (31) has shown that

$$P_t = \frac{(1 - e^{-\alpha})}{(1 - (1/2)e^{-\alpha})} \qquad [2]$$

where $\alpha = 2\pi J^2/|\nu|$ and J is the transfer integral at coincidence.

Let us now extend this general approach to the electrochemical interface. Two main aspects distinguish this case from the classic small-polaron problem.

1. Only one of the two sites is inside the fluctuating medium, *i.e.*, the electrolyte. The other energy level (*i.e.*, the energy level of the ion in the electrode) is not affected by the fluctuations in the electrolyte.

2. The energy difference between the two levels, besides fluctuating thermally, can also be changed by the applied electrode potential. Taking these two features into account, let us calculate the probability of ion transfer using Eq. [1] and Eq. [2].

First, let us establish the basic parameters and the restrictions of the theory. Besides ω the electrolyte is characterized by the reorganization energy E_R. To define E_R and to illustrate its physical meaning, let us recall that, at $k_BT \gtrsim \omega$, we regard the electrolyte as a classical polarizable medium, *i.e.*, as a collection of classical oscillators. When an ion transfers from the electrode into the electrolyte, the potential energy of one of its oscillators changes from

$$E(X) = (1/2)kX^2 \qquad [3]$$

(X is a generalized coordinate; k the "spring constant") to

$$E(X) = (1/2)kX^2 - AX \qquad [4]$$

(assuming linear coupling with coupling constant A). Equation [4] can be rewritten as

$$E(X) = (1/2)k(X - X_0)^2 - E_R \qquad [4a]$$

($X_0 = A/k$; $E_R = A^2/2k$) which defines the reorganization energy E_R as the "polaron binding energy" of the ion in the electrolyte.

The validity of the small-polaron theory is restricted by the conditions $J/E_R << 1$ and $J^2/E_Rk_BT << 1$. These two conditions however are easily satisfied in the electrochemical case since, typically, $J < k_BT$ and $E_R > 1$ eV.

To calculate the rate of transfer from Eq. [1] and [2] we need to calculate $<P_c(\nu)>$. If no potential difference exists across the electrochemical interface, a coincidence event occurs when $X = 0$, in accordance with the Franck-Condon principle. The probability to satisfy this condition, for a given value of ν, *e.g.*, $\nu = \nu'$, is

$$P_c(\nu') = <\delta(X)><\delta(\nu - \nu')>\nu' \qquad [5]$$

where $\delta(\ )$ is the Dirac delta function. $<\delta(X)>$ and, thus, $P_c(\nu')$, depend on whether the ion is in the electrolyte or in the electrode. When the ion is in the electrolyte, *i.e.*, coupled to the oscillator

$$<\delta(X)> = \frac{\int_{-\infty}^{+\infty} dX e^{-[(1/2)kX^2 - AX]/k_BT}\delta(X)}{\int_{-\infty}^{+\infty} dX e^{-[(1/2)kX^2 - AX]/k_BT}} = \frac{Ae^{-E_R/k_BT}}{(4E_Rk_BT\pi)^{1/2}} \qquad [6a]$$

Whereas when the ion is in the electrolyte

$$<\delta(X)> = \frac{\int_{-\infty}^{+\infty} dX e^{-(1/2)kX^2/k_BT}\delta(X)}{\int_{-\infty}^{+\infty} dX e^{-(1/2)kX^2/k_BT}} = A/(4E_Rk_BT\pi)^{1/2} \qquad [6b]$$

On the other hand, $<\delta(\nu - \nu')>$ is, in either case, given by

$$<\delta(\nu - \nu')> = \frac{\int_{-\infty}^{+\infty} d\nu e^{-(1/2)k\nu^2\omega^{-2}/k_BT}\delta(\nu - \nu')}{\int_{-\infty}^{+\infty} d\nu e^{-(1/2)k_\nu{}^2\omega^{-2}/k_BT}} = \left(\frac{k}{2\pi k_BT\omega^2}\right)^{1/2} e^{-\frac{k\nu'^2}{2k_BT\omega^2}} \qquad [7]$$

Finally, from Eq. [1], [2], [5], [6a], [6b], and [7], we obtain the transition rates

$$W_{\vec{23}} = \frac{\omega}{2\pi} g(\gamma) \qquad [8a]$$

$$W_{\vec{32}} = \frac{\omega}{2\pi} g(\gamma)\, e^{-E_R/k_BT} \qquad [8b]$$

where, in conformity to the notation of Fig. 1(a), the subscripts 2 and 3 stand for electrode and electrolyte, respectively; and

$$\nu = \frac{J^2\pi}{\omega(2E_Rk_BT)^{1/2}} \qquad [9a]$$

and

$$g(\gamma) = 1 - \int_0^{\infty} dz \frac{ze^{-z^2}}{1 - (1/2)e^{-\gamma/z}} \qquad [9b]$$

The function $g(\gamma)$ is plotted in Fig. 5. For $\gamma << 1$ (nonadiabatic limit), $g(\gamma) \sim \gamma\pi^{1/2}$ and, for $\gamma >> 1$

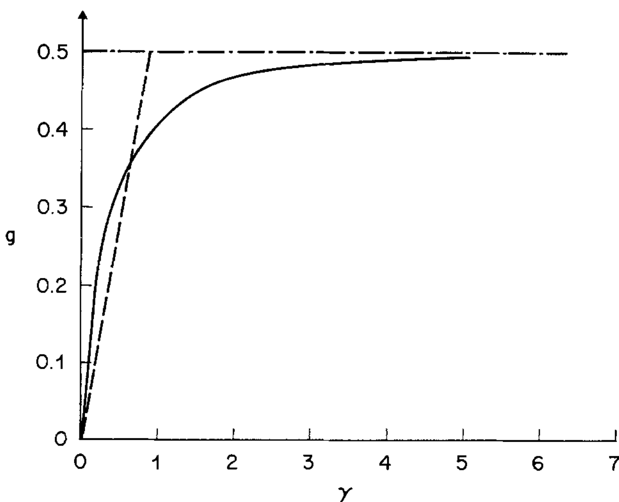

Fig. 5. Dependence of the function g (defined in Eq. [9b]), on the adiabaticity parameter ν (defined by Eq. [9a]). The dashed line refers to the nonadiabatic limit, whereas the dot-dashed line refers to the adiabatic limit.

(adiabatic limit), $g(\gamma) \sim 1/2$. When a potential difference V is applied across the interface, the Franck-Condon condition for coincidence becomes $AX = V$ and the probability of satisfying this condition for $\nu = \nu'$ is given by

$$P_c(\nu') = \left\langle \delta \left(X - \frac{V}{A} \right) \right\rangle <\delta(\nu - \nu')>_{\nu'} \quad [10]$$

Following a procedure analogous to the one followed from Eq. [5] to Eq. [8], we obtain

$$W_{23}^{\rightarrow}(V) = \frac{\omega}{2\pi} g(\gamma)\, e^{\frac{V}{2k_BT}\left(1 - \frac{V}{4E_R}\right)} \quad [11a]$$

$$W_{32}^{\rightarrow}(V) = \frac{\omega}{2\pi} g(\gamma)\, e^{-E_R/k_BT} e^{\frac{-V}{2k_BT}\left(1 + \frac{V}{4E_R}\right)} \quad [11b]$$

Equations [11a] and [11b] are the general expressions for the transfer rate across the interface and constitute the main result of this section. In order to apply them to our electrochromism problem, however, it is convenient to introduce a few simplifying approximations.

1. Since we are assuming $E_R > 1$ eV and $J \lesssim k_BT, \omega$, we have $\gamma << 1$ and thus we may use the nonadiabatic limit value of g, *i.e.*, $g(\gamma) = \gamma\pi^{1/2}$.

2. For $V \lesssim E_R$ we may simplify Eq. [11] by neglecting the $V/4E_R$ term in the exponential. Thus

$$W_{23}^{\rightarrow} \sim \frac{\omega}{2} \gamma\pi^{-1/2} e^{V/2k_BT} \quad [12a]$$

$$W_{32}^{\rightarrow} \sim \frac{\omega}{2} \gamma\pi^{-1/2} e^{-E_R/k_BT} e^{-V/2k_BT} \quad [12b]$$

3. The symmetric cell of Fig. 1(a) has two electrochemical interfaces: 2|3 and 3|4. Assuming that the applied voltage V_1-V_5 divides equally at the two interfaces, and assuming fast transport across the electrolyte, we obtain the effective probabilities of transition between 2 and 4

$$W_{42}^{\rightarrow} = (W_{43}^{\rightarrow} W_{32}^{\rightarrow})^{1/2} = \sqrt{\pi/8}\,\frac{J^2}{\sqrt{E_Rk_BT}} e^{-E_R/2k_BT} e^{\frac{V_1 - V_5}{2k_BT}} \quad [13a]$$

$$W_{24}^{\rightarrow} = W_{42}^{\rightarrow} e^{-\frac{V_1 - V_5}{k_BT}} \quad [13b]$$

Equations [11]-[13] establish that E_R determines the electrochemical memory. In fact, from Eq. [13], we see that, at short-circuit (*i.e.*, $V_1 = V_5$), the transfer rate is independent of ω and varies as $\sim \exp[-E_R/(2k_BT)]$, corresponding to an effective free energy barrier $\sim E_R/2$. An increase in the reorganization energy from an initial value E_{Ri} to a final value E_{Rf}, results in a decrease of the short-circuit transfer rate by a factor $(E_{Ri}/E_{Rf})^{1/2} \exp[(E_{Ri} - E_{Rf})/(2k_BT)]$, which is independent of J and, obviously, is very sensitive to $E_{Rf} - E_{Ri}$. So, to increase the electrochemical memory we need to choose an electrolyte with a larger reorganization energy. Reorganization energies of many different electrolytes have been calculated and measured (34). This makes it possible, in practice, to tailor the electrolyte in order to obtain the appropriate electrochemical memory. The quantitative relationships between reorganization energy, electrochemical memory, response time, and size of the electrochromic display matrix are established in the next two sections.

Macroscopic Model

So far, we have established that we can increase the electrochemical memory by increasing the reorganization energy of the electrolyte. There is a limit, however, to this process. The limit is set by the breakdown voltage of the electrolyte. In fact, the larger E_R (and, thus, the free energy barrier at the interface), the larger must be the applied voltage to lower the barrier to zero and thus allow charge transfer [*cf.* Fig. 4(a)]. Clearly, a high voltage is not desirable in the driving circuitry. But, more fundamentally, a high enough applied voltage eventually decomposes the electrolyte. Moreover, it is found frequently that it is impossible to drive the electrochromic cell even at voltages lower than the breakdown voltage because of side reactions such as gas evolution, electrode corrosion, and so on. Thus, for each electrochromic reaction there is a finite "window" that can be reversibly scanned by the applied voltage. The amplitude of the window, $2V_o$, limits the maximum value of E_R and, thus, the maximum value of the electrochemical memory.

To calculate the maximum electrochemical memory, let us consider the simplest model of electrochromic reaction in an electrolyte of scanning window $2V_o$. The simplest electrochromic reaction can be written as

$$A \leftrightarrow A^{\pm} \pm e^- \quad [14]$$

where the atom A resides in the electrode and the ion $A^{\pm}$ in the electrolyte. (+ and − refer to cation and anion electrochromism, respectively.)

The rate-determining step for most electrochromic reactions has not been established yet. Regardless of the initial rate-determining step, however, once the free energy barrier at the interface has been established by increasing E_R, the rate-determining step becomes the rate of charge transfer at the electrochemical interface. For a reaction of the type of Eq. [14], in its simplest case, the rate of charge transfer across the electrochemical interface [*e.g.*, 2/3 of Fig. 1(a)] is given by

$$\dot{q}_2 = W_{32}^{\rightarrow}(1 - q_2) - W_{23}^{\rightarrow} q_2 \quad [15]$$

where $W_{23}^{\rightarrow}$ and $W_{32}^{\rightarrow}$ are given by Eq. [11a] and [11b]. For a symmetric cell, using Eq. [13a] and [13b], with $V_1 - V_5 = V$, $W_{42}^{\rightarrow} = W \exp(V/2k_BT)$ and $q_2 = q$, $q_4 = 1 - q$ we get

$$\dot{q} = W[e^{V/2k_BT}(1 - q) - e^{-V/2k_BT} q] \quad [16]$$

which is of the Butler-Volmer type (25) with symmetric transfer coefficients.

The solution of Eq. [16] depends on the form of the scanning voltage. For triangular scanning, *i.e.*, for periodic scanning with waveform

$$V(t) = \mp V_o \pm st \quad [17]$$

(upper signs for $0 \leq t \leq 2V_o/s$; lower signs for $2V_o/s \leq t \leq 4V_o/s$) the equation can be easily solved. This choice of the voltage scanning wave form is used in cyclic voltammetry (35). An equation of the form [16] appears in the theory of electrochemical adsorption kinetics (36)—a process which has been studied extensively by cyclic voltammetry. In this context, Eq. [16] (with W as a free parameter) has been discussed first by Srinivasan and Gileadi (37). In our case we focus on the role of $2V_o$—the voltage scanning window—which, in Eq. [17], we have assumed to be symmetric around $V = 0$. This assumption, which is generally not satisfied by real systems, is introduced here for simplicity. It will be relaxed later, after we have obtained some general results qualitatively independent of this assumption.

From Eq. [17] and the initial condition $q(t = 0) = 0$, the solution of Eq. [16] can be written in terms of a simple one-dimensional integral as

$$q = fe^{-2f\sinh(V/2k_BT)} \int_{-V_o/2k_BT}^{V_o/2k_BT} dz e^{z + 2f\sinh z} \quad [18]$$

where $f = 2k_BTW/s$. It is important to note that: (*i*) q depends on the time only through V; and (*ii*) q depends on the scanning rate s and the probability of transition W only through f, *i.e.*, only through their ratio. Physically, this is consistent with the discussion about Fig. 4(a). Namely, the same amount of charge is transferred between the two levels either by a high scanning rate through a low barrier or by a low scanning rate through a higher barrier.

Analytical solutions of Eq. [18] are easily obtained in 2 special cases: (*i*) at quasi-equilibrium, *i.e.*, for $f \to \infty$. In this case

$$q = (1 + e^{-V/k_BT})^{-1} \quad [19]$$

(*ii*) Whenever the backward reaction can be neglected, *i.e.*, for $f \to 0$. In this case

$$q = 1 - e^{(e^{-V_o/2k_BT} - e^{V/2k_BT})f} \quad [20]$$

Clearly, for very small f, not all the charge can be transferred during a voltage scan, *i.e.*, $q(+V_o) < 1$. But full coloration in a practical electrochromic cell usually requires full ion-occupancy, *i.e.*, $q = 1$. From Eq. [18], we can easily determine the minimum value of f which satisfies this condition. Setting $q = 1$ and $V = V_o$ in Eq. [18] and solving numerically, we obtain

$$f_m \sim \pi[\sinh(V_o/2k_BT)]^{-1} \quad [21]$$

with an accuracy of $\sim 0.2\%$.

For $f = f_m$, the numerical solution of Eq. [18] yields the relaxation loops showed in Fig. 6 (dashed lines 2 and 3) for $V_o = 20k_BT$ and $V_o = 40k_BT$. At room temperature, these values of V_o correspond to 0.5 and 1.0 eV, respectively, which are realistic voltage limits for electrochromic cells.

Figure 6(b) shows the "pseudocapacitance" $q(2k_BT/s)$ corresponding to the ion-occupancy curves of Fig. 6(a). The pseudocapacitance is the quantity which is measured by cyclic voltammetry.

Two features of these figures are worth noting: (*i*) both curve 2 and 3 have excellent threshold. Even in the least favorable case, *i.e.*, for $V_o = 20k_BT$, the ion-occupancy at $V_o/2$ is only a few percent. (*ii*) The size of the loops is closely related to V_o and, thus, to f_m. Indeed it is easy to show that the inflection points in the $q(V)$ curves (*i.e.*, the maxima and minima of the pseudocapacitance) occur (if $V_o \gtrsim 20k_BT$) at

$$V_{Max} = \pm 2k_BT \log f_m \quad [22]$$

Thus, f_m is a measure of the maximum size of the relaxation loops.

Actually, f_m is basically a measure of the maximum free energy barrier that can be established at

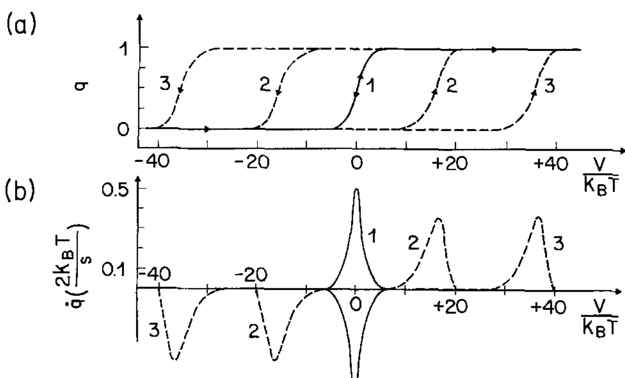

Fig. 6. Relative ion-occupancy (a) and pseudocapacitance (b) of the electrochromic electrode as a function of the applied voltage for no-memory conditions (solid lines 1) and for two different values of the memory parameter f_m. Loop 2: $f_m = \pi(\sinh 10)^{-1}$. Loop 3: $f_m = \pi(\sinh 20)^{-1}$.

the electrochemical interface, without altering the response time of the cell. In fact, let t_R be the cell intrinsic response time, *i.e.*, the response time at 0 free energy barrier. This time sets the minimum voltage scanning speed at

$$s_m \sim V_o/2t_R \quad [23]$$

Thus, the minimum probability of charge transfer W_m across the interface is

$$W_m = \frac{f_m s_m}{2k_BT} \sim \frac{f_m V_o}{4t_R k_BT} \quad [24]$$

and the maximum free energy barrier $\sim f_m^{-1}$.

Now, let us use as a practical definition of "maximum electrochemical memory" the time t_M necessary to reduce by 1% the relative ion occupancy, following a voltage excursion $0 \to +V_o \to 0$. With this definition, using Eq. [21] and [24], it is easy to obtain

$$t_M = \frac{2 \times 10^{-2}}{\pi} \left(\frac{k_BT}{V_o}\right) t_R e^{V_o/2k_BT} \quad [25]$$

Another way of looking at the memory time is as follows: Let us determine the maximum value f_M of f for which at $V = 0$, the ion occupancy is ~ 0. Numerically (0.3% accuracy), we find (for $V_o \gtrsim 20k_BT$)

$$f_M \sim \pi 10^{-2} \quad [26]$$

For $W = W_m$, this value of f corresponds to a scanning rate $s_M = f_m V_o/2f_M t_R$. Thus, if we define the memory time t_M as $t_M = k_BT/s_M$, we obtain

$$t_M \sim \frac{2f_M k_BT}{f_m V_o} t_R \sim 2 \times 10^{-2} e^{V_o/2k_BT} \frac{k_BT}{V_o} t_R$$

which is identical to Eq. [25]. This equation relates the maximum electrochemical memory to the intrinsic response time and to the electrolyte breakdown voltage. For example, for $V_o = 1.0V$ and $t_R = 10$ msec, the maximum memory at room temperature is $\sim$20 min.

In the opposite limit, *i.e.*, for large f at the same scanning rate, the memory is zero. Curves 1 of Fig. 6(a) and 6(b) are obtained for $f \gtrsim \pi$. This is the so-called reversible limit of cyclic voltammetry. In this limit, the pseudocapacitance is symmetric about V, the charge is a single-valued function of V, and the electrochromic cell has no memory.

In this section, then, we have seen that, starting from the reversible limit and decreasing W we can increase the electrochemical memory up to a maximum determined by f_m and, thus, by V_o. Since, as shown in the previous section, W is determined primarily by E_R, we have now all the elements to relate the performance of an electrochromic display matrix to the microscopic properties of the electrolyte. The results are presented in the next section.

Results

From the results of the two previous sections we can obtain a lower limit on the reorganization energy necessary to achieve the maximum electrochemical memory compatible with response time t_R and scanning voltage window $2V_o$. In fact, from Eq. [13], [21], and [23], with $J \lesssim k_BT$, we obtain

$$E_R \gtrsim V_o + 2k_BT \log \left[(k_BT/E_R)^{1/2}(k_BT/V_o) \frac{k_BTt_R}{\pi} \right] \quad [27]$$

From Eq. [27], the lower value of E_R is plotted in Fig. 7(a) as a function of V_o for $t_R = 10$ msec and for $t_R = 100$ msec. It is clear that E_R practically scales with V_o but is not too sensitive to t_R. The magnitude of E_R is approximately $2V_o$, which is the amplitude of the scanning window. The range of values of E_R,

i.e., 1.5-2.0 eV are realistic numbers for the reorganization energy of various electrolytes. And, from Fig. 6 (curves 2 and 3), it is clear that, within this range, the relaxation loops are large enough to exhibit a distinct threshold in $q(V)$.

Having established the range of E_R suitable for memory with threshold, it is possible to relate E_R to the maximum number of display elements that can be matrix addressed. As discussed in the introduction, the short-circuit memory t_M of the electrochromic cells in the matrix must be such that $t_M \gtrsim n\Delta t$, where n is the number of rows and Δt the duration of each biasing pulse. Since $\Delta t \gtrsim t_R$, we have, from Eq. [25], $n \leq t_M/t_R \sim 10^{-2}(k_BT/V_o)e^{V_o/2k_BT}$. In turn, V_o and E_R are related through Eq. [27], which establishes a relationship between the maximum number of addressable rows and the reorganization energy of the electrolyte. The relationship is shown graphically in Fig. 7(a) and 7(b). We see that, for 1.5 eV $\leq E_R \leq$ 2.0 eV, n spans the range $10 \leftrightarrow 10^5$, which encompasses any practical size of display matrices.

We remark that the results obtained so far, apply to: (*i*) a symmetric electrochromic cell and, (*ii*) to an electrochromic reaction occurring at the center of the scanning voltage window. Both restrictions were adopted for simplicity of exposition and can now be relaxed.

An electrochromic display needs only one electrochromic electrode [*e.g.*, 2 in Fig. 1(a)]; the counterelectrode (*e.g.*, 4 in Fig. 1(a)] needs simply be an ion-insertion material. Moreover, the ions inserted in 2 and 4 may be different. In fact, if the electrolyte conducts via both anions and cations, a frequent circumstance, then the electrode 2 could, *e.g.*, exchange anions with the electrolyte, while the counterelectrode 4 exchanges cations. In practice, it is convenient to have a counterelectrode with fast ion-exchange and with "flat" isotherms, *i.e.*, with $\epsilon(q)$ almost independent of q. In this case, the counterelectrode may essentially be ignored, and the memory of the cell depends only on the 2/3 electrochemical interface. This, in a sense. is the opposite limit of the symmetric cell considered previously.

In this asymmetric cell, the rate of charge transfer across the 2/3 interface can be calculated from Eq. [15] with $\overrightarrow{W_{32}}$ and $\overrightarrow{W_{23}}$ given by Eq. [12]. It is convenient to rewrite Eq. [15], for the asymmetric cell, in the symmetric form

$$\dot{q}_2 = W\left[e^{\frac{V - E_R}{2k_BT}}(1 - q_2) - e^{\frac{E_R - V}{2k_BT}}q_2\right] \quad [28]$$

By comparing Eq. [28] and [16] it is clear that the asymmetric case yields the same results as the symmetric case, but with V replaced by $V - E_R$. Actually, in Eq. [28], we have tacitly assumed that, by increasing the voltage, anions are inserted. If, instead, by increasing the voltage, cations are extracted, then it is easy to see that the transfer rate is the same as in the symmetric case, but with V replaced by $V + E_R$.

From the previous results, it is clear that, if the electrochromic reaction is not centered in the middle of the voltage window, it will be convenient to use an asymmetric cell, so that the center of the memory loop will be displaced by E_R or $-E_R$. Naturally, the actual amount of asymmetry to be built into the cell depends on the position of the electrochromic reaction in the voltage window.

There is, then, a substantial degree of flexibility in creating the short-circuit memory of electrochromic cells. The value of E_R necessary to create the memory does not have to be specified exactly, but only within a range of typical values; and if, in the electrolyte with the appropriate E_R, the electrochromic reaction does not occur at the center of the voltage window, then the counterelectrode can be modified to keep the relaxation loops within the window.

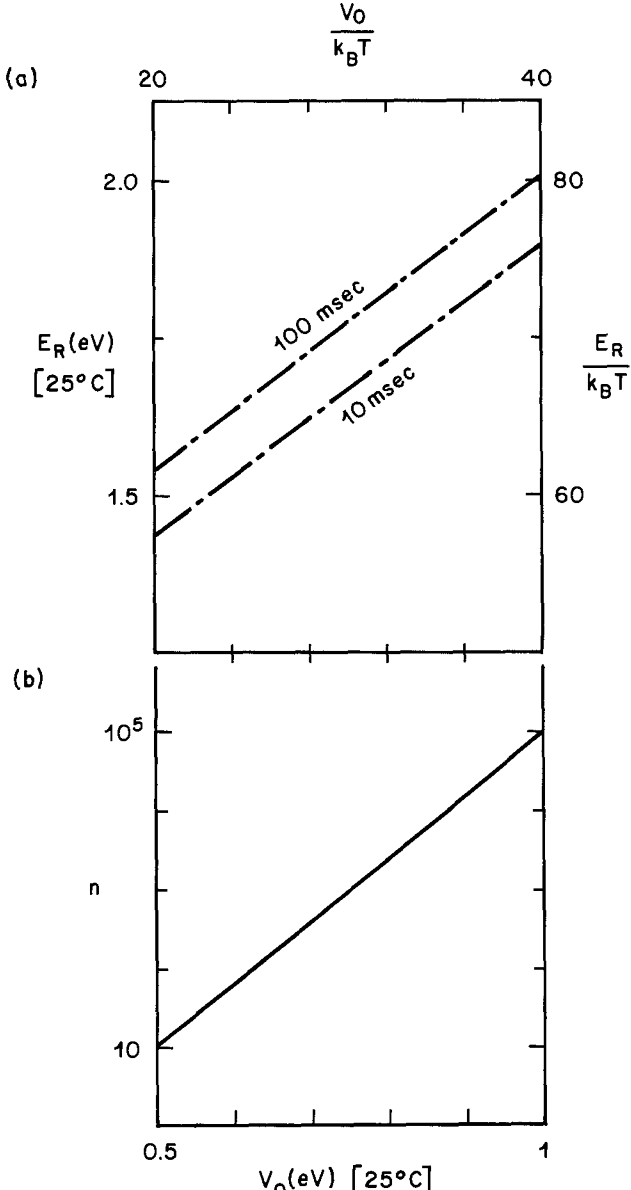

Fig. 7. (a) Reorganization energy E_R as a function of V_o for two different response times. (b) Maximum number of rows that can be matrix addressed in a display-matrix consisting of electrochromic cells with scanning window $2V_o$. By combining (a) and (b) n is related to the reorganization energy of the electrolyte.

Discussion

The main conclusions of this work rest on the physical basis of electrochemical memory and thus do not depend on the particular models chosen. We have in effect, introduced the simplest possible models and solved them in the simplest possible cases. These simplifications have facilitated the task of proving the main point of the paper, *i.e.*, that electrochromic display cells can have short-circuit memory. They have also allowed us to show a general method to design electrochromic cells suitable for matrix-addressing. The details of our results, however, depend on several assumptions and approximations.

The major assumption is the choice of the microscopic model. As already stressed in the section "Microscopic Model," the problem of ion transfer at the electrochemical interface has not been given a general quantitative solution yet. The small-polaron

approach is the simplest treatment of electron transfer at the electrochemical interface. In this paper we have extended this treatment, for the first time, to ion transfer. Thus, this theory is still experimentally untested. It is hoped that the results presented here may stimulate further work in this direction.

In addition, although we obtain general expressions, *i.e.*, Eq. [11], for the probability of ion transfer, we have subsequently introduced the simplifying assumption of large E_R, *i.e.*, $V/4E_R << 1$. This is not an unreasonable approximation. In fact its validity is confirmed, *a posteriori*, by the results presented in the Results section, *i.e.*, $E_R \sim 2V_o$, which is also consistent with the choice of the transfer probability.

The most restrictive assumption of the macroscopic model is the form of the equation describing the electrochromic reaction, *i.e.*, Eq. [15]. This equation leads to simple Langmuir (38) isotherms. In general, however, the electrochromic isotherms (18) are more complicated. In fact, an improved macroscopic model would use an equation leading to the experimentally observed electrochromic isotherms. It is interesting to note, however, that, for AIROF's, the electrochromic isotherms are indeed of a generalized Langmuir type. That is

$$\epsilon(q) = pk_BT \log (q/(1 - q)) \quad [29]$$

with $p = 2$ or 3, whereas, for Langmuir isotherms, $p = 1$. Thus, our choice of the electrochromic reaction equation is of the same general form as the experimentally observed ones.

Implicitly, we have also made two assumptions on the physical properties of the electrolyte. First, we have neglected its internal resistance. Clearly, if the electrolyte with the appropriate E_R has a high resistivity, it would slow down the response of the electrochromic cell. But a large E_R is not necessarily associated with a high resistivity of the electrolyte. In fact, E_R depends on the binding to the electrolyte of the ion involved in the electrochromic reaction, whereas the electrolyte conductivity depends either on the mobility of a different ionic species or on the mobility of the complex to which the ion is bound. An example of fast ion transport of a bound ion-complex is provided by proton-insertion electrochromics—here the transferred ion is H^+, but the mobility depends on H_3O^+. Tnus, it is not inconsistent with our model to neglect the electrolyte resistivity.

We have also implicitly assumed that the probability of charge transfer at zero free energy barrier, *i.e.*, J, is independent of E_R. In general, however, a different E_R is associated with different interfacial structures. Thus, J could depend on E_R. But how sensitive J is to E_R remains an open question since no experimental or theoretical study of this relation has been carried out yet.

Finally, for a symmetric cell, we have assumed that the applied voltage is divided equally between the two interfaces. This is generally not so since the impedance of the electrochromic material may depend on q. In such cases, it is straightforward to relax this assumption, the results remaining qualitatively unchanged.

Having discussed the approximations, let us now look at our results from a different perspective. It has recently been pointed out (39) that nickel hydroxide films are electrochromic and exhibit a hysteretic voltammogram. Obviously, an electrochromic with large hysteresis in $\epsilon(q)$ has short-circuit memory and thus could be suitable for matrix-addressing. There are, however, two major problems with nickel hydroxide films. First, the electrochromic reaction occurs in the region of oxygen gas evolution, so that the electrode is basically unstable. Second, although the isotherms are hysteretic, they have no threshold. Thus, nickel hydroxide cannot be used for matrix-addressing. Similar considerations apply to all the known group VIII oxide exhibiting hysteresis.

On the other hand, a hysteretic ion-insertion material could be used as a counterelectrode in an electrochromic cell to provide the necessary short-circuit memory. The counterelectrode should: (*i*) be compatible with the electrolyte; (*ii*) have fast kinetics; and (*iii*) exhibit hysteresis with threshold.

This approach to short-circuit memory may be advantageous, but it has not been explored yet. Obviously, the main difficulty is finding or designing a counterelectrode with the required characteristics. In contrast, our approach to short-circuit memory does not require modifications of the properties of the electrode or counterelectrode—the electrochromic memory being based primarily on the properties of the electrolyte.

In a sense, the concept of electrochemical memory may be regarded as the antithesis of the concept of electrocatalysis. The central problem of electrocatalysis is to lower the barrier at the interface in order to increase the exchange current and reaction rate. The opposite is true in the electrochemical memory problem. The barrier at the interface should be as high as possible to prevent charge transfer at short circuit. Ultimately, both electrocatalysis and electrochemical memory depend on the structure of the electrochemical interface and on the kinetics of the transfer across it. Thus, further study of the electrochemical memory may shed some light on the fundamental nature of electrochemical kinetics.

Summary

Electrochromics, although promising display materials, have been regarded as unsuitable for matrix addressing because of their lack of threshold and short-circuit memory. In this paper we have shown that threshold and short-circuit memory of an electrochromic display cell depend on the electrolyte. If an appropriate electrolyte can be found, the threshold and short-circuit memory of the electrochromic display cell might become sufficient to matrix-address multielement electrochromic displays of practically any size.

To reach this conclusion, first we have introduced the concept of electrochemical memory. In general, the memory of an ion-insertion electrode can be defined as the memory of its relative ion-occupancy following an excursion of its internal emf. In a hysteretic electrode, the memory has a thermodynamic origin. In a nonhysteretic electrode (such as AIROF) the memory has a kinetic origin, arising from the dynamics of charge transfer at the electrochemical interface. This type of memory we have referred to as electrochemical memory.

We have shown that the electrochemical memory is created by the interaction of the transferred ion with the electrolyte. This interaction is measured by the electrolyte reorganization energy E_R.

To calculate the electrochemical memory, we have introduced a small-polaron model of ion transfer at the electrochemical interface. We have obtained general expressions for the probability of transition in terms of the properties of the electrolyte. In the limits of interest, the probability of transition depends exponentially on E_R and on the cell potential (Eq. [13]).

Then, we have introduced a macroscopic model of the electrochromic reaction, based on Langmuir-type isotherms. Coupled with the transition probability expressions obtained from the microscopic model, the rate equation for the reaction turns out to be of the Butler-Volmer type with symmetric transfer coefficients (Eq. [16]). We have solved this equation as a function of the electrolyte breakdown

voltage, $2V_0$. From its solution, we have established the lower limit of the electrolyte breakdown voltage necessary for threshold and short-circuit memory.

Next, we have found a simple expression, Eq. [25], for the magnitude of the maximum short-circuit memory with threshold in terms of the breakdown voltage and the cell response time t_R. For $t_R \sim 10$ msec and for $V_0 \sim 1$ eV, the maximum memory is ~20 min.

Finally we have determined the value of the reorganization energy required to obtain the maximum short-circuit memory with threshold. The calculated values of E_R lie in the range 1.5 ↔ 2 eV, which are realistic numbers for many electrolytes. These values of E_R, in turn, correspond to a range of matrix addressable lines 10 ↔ 10^5 which encompasses all practical cases. Thus, there is no intrinsic theoretical limitation to matrix-addressing large matrixes of electrochromic display cells.

Naturally this conclusion has been reached by introducing assumptions and approximations. However we have seen that neither are very restrictive so that the main results are not qualitatively affected by them.

We have also remarked that, unlike the electrochemical memory discussed here, the hysteretic memory of the kind exhibited by, *e.g.*, nickel hydroxide, is unsuitable for matrix addressing because of its lack of threshold.

Finally, we have pointed out that electrochemical memory and electrocatalysis are opposite limits of the same general concept.

Acknowledgments

I am grateful to J. L. Shay for his valuable comments and his constant interest. I wish to thank also W. C. Dautremont-Smith, C. E. Rice, and L. M. Schiavone for many stimulating discussions.

Manuscript submitted Dec. 26, 1979; revised manuscript received April 7, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by Bell Laboratories.
