ABSTRACT

Separation of components has been measured in binary molten salt mixtures, $AgNO_3$-KNO_3, subjected to electrolysis between silver electrodes. The analysis of thin slices of frozen mixture contained in silica frits gives qualitatively the composition changes between anode and cathode and shows the expected enrichment of potassium ions at the cathode. Changes in concentration at the electrodes are measured electrochemically in free electrolytes and in electrolytes contained in frits. The time dependence of concentration at the electrodes is obtained both during electrolysis and during relaxation following electrolyses of different durations. The experimental results confirm the predictions from a mass transport model proposed previously for systems analogous to mixed molten salt batteries operated at high current densities.

Electrolyte composition gradients in aqueous fuel cells and electrolyzers have been observed (2, 3) and explained in terms of electrode reactions, diffusion, and migration (4-6). Previously derived equations for (one dimensional) diffusion and migration in molten salt binary mixtures during current flow predicted the establishment of concentration gradients in the electrolytes of molten salt batteries and fuel cells (7). Such gradients have been reported, but not analyzed, in an Al/NaCl-KCl-$AlCl_3$/Cl_2 battery (8) and in the electrolysis of LiBr-KBr mixtures for isotope separation (9). [Isotope separation by electrolysis of "pure" molten salt ^{6}LiCl-^{7}LiCl is itself an example of the development of composition gradients by virtue of difference of mobility (of $^6Li^+$, $^7Li^+$)] (10). These gradients, although potentially of significant magnitude and consequence in actual batteries (or fuel cells), are difficult to observe. Rapid back-diffusion during cooling imposes severe constraints on the sampling of such gradients for chemical analysis. In molten salt batteries (11, 12), variations of the potential between LiAl and FeS_x electrodes for reasons other than changes of the Li/K ratio of the LiCl-KCl electrolyte tend to obscure *in situ* potentiometric measurement of the composition changes. Consequently, there is a need for suitable analog experiments to test the validity of the predictions.

This paper presents the results of an experimental test of the predictions of the previously derived one dimensional equation for a system in which the electrode reaction, ion flows, and conditions of operation are analogous to those in a molten salt battery, but which is more amenable to quantitative analysis. We describe measurements of the composition changes in molten $AgNO_3$-KNO_3 mixtures subjected to electrolysis between two silver electrodes. Since silver, one of the two like-charged ions in the binary mixture, reacts at both electrodes, the ion flows are analogous to those in the LiCl-KCl electrolyte of a Li/S battery, in which Li^+ ion enters the electrolyte at the anode and leaves at the cathode (11, 12). Experiments were done both with free electrolyte and with electrolyte contained in a coarse silica frit, the latter configuration resembling the containment of the electrolyte in a molten salt battery. Two kinds of measurements were made of composition changes: first, chemical analysis, following electrolyses for differing lengths of time and at differing current densities, in sections of rapidly cooled frits; second, *in situ* potentiometric analysis in cells with free and with frit-contained electrolytes. The results of both kinds of experiment and both kinds of analysis demonstrate the depletion of silver ions at the cathode, and confirm the predictions of our model under the conditions studied.

Ion Flows in $AgNO_3$-KNO_3

The ion flows considered in our previous analysis (7) of mass transport in electrolyzed molten salt mixtures were: (*i*) the faradaic flow across the electrode-electrolyte interface arising from the electrode reactions; (*ii*) the electromigrational flow of ions carrying the current through the electrolyte; and (*iii*) the diffusional flow driven by the concentration changes produced by the two preceding flows. In a constant volume system the diffusion-migration equation derived for the ion not reacting at the electrodes (cation K^+) was shown to be, neglecting convection

$$\frac{\partial C_K}{\partial t} = \frac{\partial}{\partial x}\left(D\frac{\partial C_K}{\partial x}\right) - \frac{I}{\mathbf{F}}\frac{dt_K^{NO_3}}{dC_K}\frac{\partial C_K}{\partial x} \quad [1]$$

C_K is the ionic concentration of K^+ in eq cm^{-3}, x is the distance from the anode ($x = d$ at cathode), I is the current density, D is the binary diffusion coefficient in the $AgNO_3$-KNO_3 mixture, and $t_K^{NO_3}$ is the transference number of the cation K^+ relative to the nitrate anion; the boundary conditions at both electrodes ($x = 0$, $x = d$) are

* Electrochemical Society Active Member.

Key words: molten salt, transport, battery.

$$\frac{\partial C_K}{\partial x} = \frac{It_K^{NO_3}}{FD} \quad [2]$$

Although convection terms and frit porosity may alter the predictions, and are being treated currently, our experimental results indicate that these effects are probably not large under the conditions studied here.

Equation [1] together with Eq. [2] can be numerically solved (13) for the cases where D and (or) $t_K^{NO_3}$ are composition dependent. The computation gives the entire composition profile between the two electrodes at any time and the time dependences of concentration at both electrodes. Figure 1 shows the analogy of the three ion flows considered in the model in a Li/S battery on charge or on discharge and in the KNO_3-$AgNO_3$ mixture during electrolysis with silver electrodes. Only the two like-charged cations are indicated, since the common anions (Cl^- or NO_3^-) are taken as reference frame.

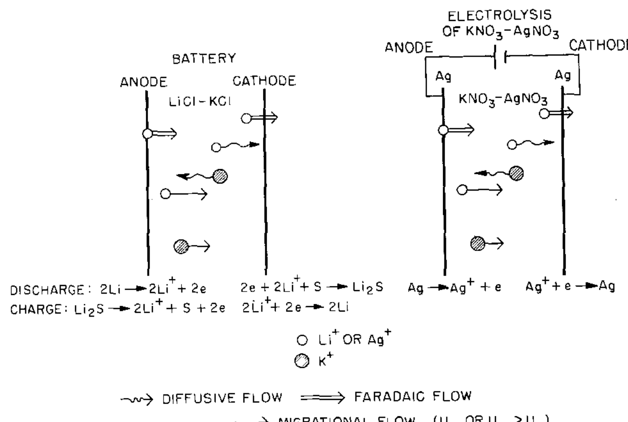

Fig. 1. Ion flow analogies in battery and in electrolysis cell

Experimental

Chemicals.—The silver nitrate was crystal certified A.C.S. from Fisher Scientific Company. The potassium nitrate was analytical reagent crystal from Mallinckrodt, Incorporated. It was dried in an oven at 300°C prior to weighing. The solutions were prepared by weighing the appropriate amounts of both components.

Electrolysis cells.—A typical silica cell for electrolysis of free electrolyte and electrochemical measurement of the concentration changes at both electrodes is shown in Fig. 2. The silver electrodes 1 and 2 are mounted in two pieces of Macor[1] (or of Teflon in experiments at temperature below 250°C) A and B in order to provide geometrically well-defined areas. The holders A and B are placed in the silica tube C, whose bore is machined to provide a tight fit to the bottom electrode support A. Two apertures, E and F, in the tube C, permit filling of all the space between the two electrodes with the molten salt when the tube C (maintained at the temperature of the melt) is inserted in the large tube D containing the binary nitrate melt. The silver electrode 3, dipping in the outer tube, is used as a reference electrode relative to the electrodes 1 and 2. The electrode separations were of the order of 1-2 cm and the electrode areas were of the order of 0.5 cm². The height of the melt in tube D was of the order of 4-5 cm. Uniformity of the temperature in the melt was obtained by inserting the assembly in an aluminum block G. A Leeds and Northrup Electromax Controller was used to maintain the furnace to within ±0.1°C of the desired temperature.

Figure 3 shows an electrolysis cell with the molten electrolyte contained in a coarse silica frit B. Silica frits 0.25-0.4 cm thick are sealed at one end of the silica tube A. Two planar silver electrodes 1 and 2, of 0.5 cm² area are placed against opposite faces of the frit. Electrode 2, introduced into tube A, has a known area in contact with the melt which impregnates the frit. Electrode 2 is used as anode or as cathode. The electrolyses are done between the electrodes 1 and 2. Silver electrode 3, dipping in the melt contained in the outer tube B, is used as a reference electrode. The level of the molten mixture in tube C is adjusted to touch the bottom of the upper electrode 2. This cell also is contained in an aluminum block for uniformity of the temperature.

Composition Changes

Measurements were made of the composition changes at the electrode surfaces and across the electrolyte between anode and cathode (concentration profiles) induced by electrolyses at 0.15 A-cm^{-2} of 1-2 min duration. Both kinds of measurements showed the trend towards separation of the mixture components predicted by the mass transfer analysis. The concentration profiles, which we discuss first, show this effect qualitatively, and higher analytical precision is needed for a more quantitative test of the model. The con-

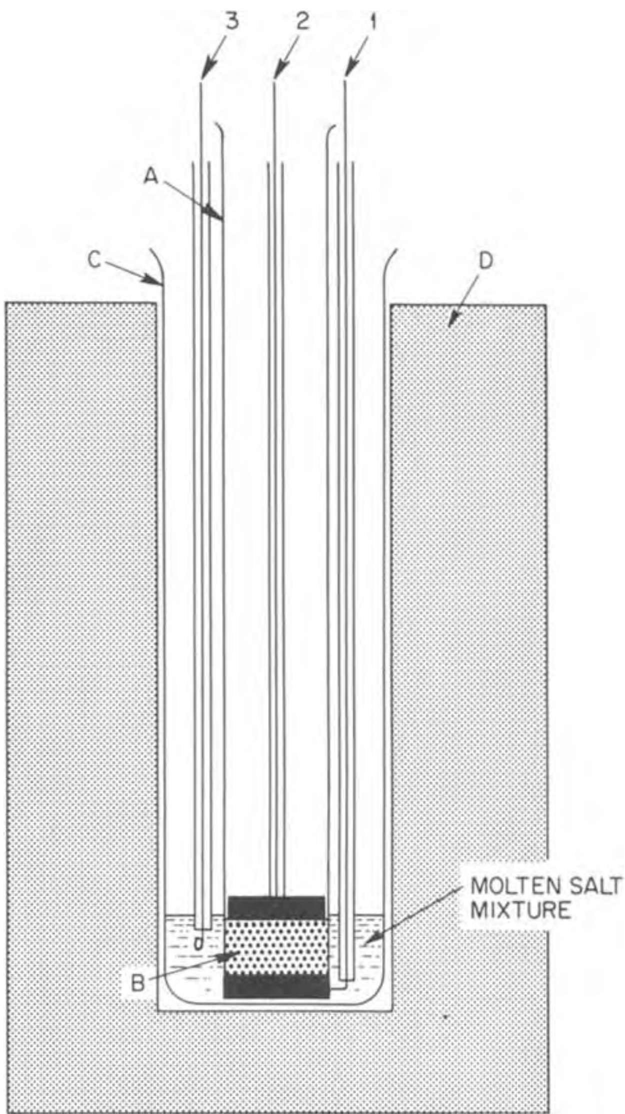

Fig. 3. Electrolysis cell with the electrolyte contained in a silica frit. A, Inner silica tubing; B, coarse silica frit sealed at the end of A; C, outer silica tubing; D, aluminum block; 1, 2, silver electrodes for electrolysis; 3, silver reference electrode.

centrations at the electrode surfaces and their change with time, however, are very well explained by the predictions of the mass transport model.

Experimental procedure.—A direct determination of the composition changes across the electrolyte was attempted after electrolyzing the $AgNO_3$-KNO_3 mixture, contained in the porous matrix in the cell shown in Fig. 3, at constant current for differing times. As soon as the current is cut off, the tube A (Fig. 3) is removed from the melt and rapidly cooled in a cold helium flow. The frit, B, is then sectioned into slices 15-20 thousandths of an inch thick using a Buehler low speed saw equipped with a diamond-faced blade 15 thousandths of an inch thick. A silicone cutting oil is used to increase the cutting speed. The slices are washed with cold benzene to remove the silicone cutting oil. The nitrate mixture is extracted from the frit slices by a hot (90°C) 0.01*N* HNO_3 solution. The hot solution is dropped onto the slice in a Buchner funnel as vacuum is applied to the collecting flask. The frit slices, dried in an oven, were weighed, and then reweighed after each washing. Table I gives typical weight losses (in mg) observed for four slices. Usually three washings are sufficient to reach a steady weight. The total weight loss of the slice is identified with the total weight of $AgNO_3$-KNO_3 mixture contained in the slice. The water solutions, which typically contained 1×10^{-3}g of salt per cm^3, are analyzed both for potassium and for silver. The potassium analysis is done by flame spectroscopy, silver by spark source spectroscopy. The accuracy of these methods is usually estimated to be ±5%. In order to test the analytical results and the extraction procedure from the frit, standard samples were prepared for analysis by diluting in 0.01*N* HNO_3 solution either a previously molten mixture of known composition or the mixture extracted from a quartz frit impregnated with a molten mixture of known composition. In most of the cases, both Ag and K analyses indicate a lower concentration of potassium. The results from silver analysis are found to be within 6% of the known compositions. Results from potassium analysis are within 10% of the known compositions. The extraction of the salt from the frit does not increase significantly the discrepancy between the results of the analysis and the known composition of the melt.

Composition profiles in $AgNO_3$-KNO_3.—A 0.2 $AgNO_3$-0.8 KNO_3 mixture at 310°C was electrolyzed at 0.15 A-cm^{-2} during 40 sec. The upper part of Table II gives the results of the analysis of the salt in five slices of the 0.5 cm-thick frit. Slice 1 was adjacent to the anode and slice 5 was closest to the cathode. The thickness of frit lost from each cut has been estimated to be about 0.05 cm, and the subsequent positions (relative to the anode) of the midpoints of the slices are reported in the third column. The lower part of Table II gives the results of the analysis of potassium and of silver in four slices of a 0.378 cm-thick frit in which a 0.5 KNO_3-0.5 $AgNO_3$ mixture has been electrolyzed for 90 sec at 0.15 A-cm^{-2}. The results in Table II for both initial compositions show a clear trend of increasing Ag/K ratio from cathode to anode. This is strengthened by a comparison of standard deviations of fit calculated for two models: (a) no effect of electrolysis, *i.e.*, the analytical results for

sections at differing positions are randomly distributed about the mean value, and (b) a systematic change of composition with position; for this, a least squares fit with a linear dependence on distance was assumed, although the solution of the diffusion-migration equation is not linear, since uncertainties in the data did not warrant a more complex function. Table III summarizes the standard deviation, σ_{N-1}, about the mean composition $<X_K>$ of the different sections, and the standard deviation of fit, σ_{N-2}, based on the linear least squares fit. Table III also lists the difference, ΔX_K, between the values of X_K at the cathode and at the anode as calculated from the linear regression. In all the cases the standard deviation of fit of a linear dependence on distance are smaller than the standard deviation about an assumed constant value. For 0.8 KNO_3-0.2 $AgNO_3$, σ_{N-2} is sixfold smaller for the silver analysis and twentyfold smaller for the potassium analysis than σ_{N-1}. For 0.5 KNO_3-0.5 $AgNO_3$, σ_{N-2} is about half σ_{N-1}. Figure 4 shows the least squares fits to both K and Ag analyses in the two melts together with the experimental results reported for the midpoint of each slice. (The middle lines are the fits to the average of the data from both analyses.) The differences in composition at the cathode and at the anode calculated from the linear regression are larger than twice the standard deviations of fit (σ_{N-2}), the electrolyte near the cathode being richer in KNO_3.

The results thus show that the direction and magnitude of the composition changes at the two electrodes are consistent with those predicted (7) from solution of the diffusion migration equation in a binary melt with electrode reactions involving one of the like-charged ions. A more accurate measurement of the composition profile, requiring both better resolution of the distance and improved analytical accuracy, is under way.

Concentration changes at electrode surfaces.—The most striking evidence for the predicted gradients is obtained from measurements of the composition changes at the electrodes during electrolysis, and of their rates of decay after electrolysis.

In this second kind of experiment, the concentrations at the electrode surfaces and their time dependence were measured potentiometrically. The composition (X_{Ag}) at the silver cathode (or anode) of the concentration cell with transference containing molten $AgNO_3$-KNO_3 mixtures, Ag/$AgNO_3$-KNO_3 ($X°_{Ag}$): $AgNO_3$-KNO_3(X_{Ag})/Ag, is related to the open-circuit potential difference between the cathode (or anode) and a reference electrode dipped in a mixture of known composition ($X°_{Ag}$) by (14)

$$E = \frac{1}{\mathbf{F}} \int_{X°_{Ag}}^{X_{Ag}} \frac{t_K^{NO_3}}{1 - X'_{Ag}} \frac{d\mu_{AgNO_3}}{dX'_{Ag}} dX'_{Ag} \quad [3]$$

where X'_{Ag} is the mole fraction of $AgNO_3$ in the melt and μ_{AgNO_3} the chemical potential of $AgNO_3$. The needed internal transference number may be calculated from the external mobilities of the Ag^+, K^+, and NO_3^- ions which have been determined by Duke and Owens (15) at 350°C. They report that the external mobility of nitrate ion is composition-independent, with absolute value 1.55×10^{-4} cm^2 sec^{-1} V^{-1}, and that the mobilities of all the three ions are

Table III. Standard deviation about the average value $<X_K>$, and of the linear regression

temperature-independent (15). A least squares fit of a second-order polynomial that represents the absolute values of the K^+ and Ag^+ mobilities, in cm^2 sec^{-1} V^{-1}, was reported (16) as

$$u_K = (4.83\, X_K^2 - 6.86\, X_K + 4.49) \times 10^{-4} \quad [4a]$$

$$u_{Ag} = (-3.87\, X_K^2 + 2.73\, X_K + 3.71) \times 10^{-4}$$

The transference number of the potassium cation relative to nitrate ions is

$$t_K^{NO_3} = \frac{C_K(u_K + u_{NO_3})}{C_K(u_K + u_{NO_3}) + C_{Ag}(u_{Ag} + u_{NO_3})} \quad [4b]$$

Figure 5 shows, in curve 1, the transference number $t_K^{NO_3}$ calculated from Eq. [4]. These values are confirmed by more recent measurements (17) of concentration cells with transference. The transference number of potassium relative to nitrate anions differs slightly from the KNO_3 mole fraction, ~20% at X_K = 0.5, and ~10% at X_K = 0.7. Its composition dependence is well represented in the composition range $0 < X_K < 0.55$ by a second degree polynomial

$$t_K^{NO_3} = 0.6\, X_K + 0.4\, X_K^2 \quad [5]$$

or by the assumption of a constant mobility ratio (18) $u_{Ag}/u_K = 1.5$, as shown in curve 2 of Fig. 5.

The activity coefficients of KNO_3 and $AgNO_3$ have been found (19) to be larger than 0.8 at all concentrations. They are virtually unity around $X_K = 0.8$, the composition studied here. Therefore, in our calculations of the emf of the concentration cells (with $X°_{Ag} = 0.2$) we may assume with very little error that the mixture is ideal. The emf of the concentration cell with transference becomes

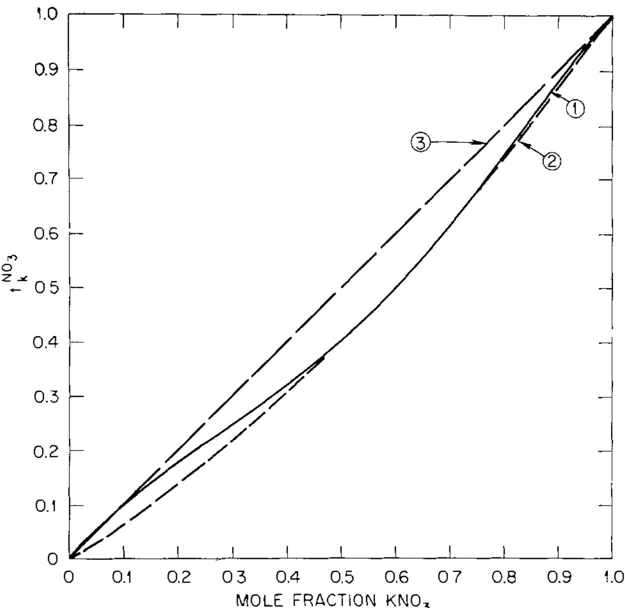

Fig. 5. Composition dependence of transference number of potassium relative to nitrate in $AgNO_3$-KNO_3. Curve 1, calculated from the external mobilities of Ref. (15); curve 2, fit assuming a constant mobility ratio $u_{Ag}/u_K = 1.5$; curve 3, transference number assumed equal to the mole fraction ($u_{Ag} = u_K$).

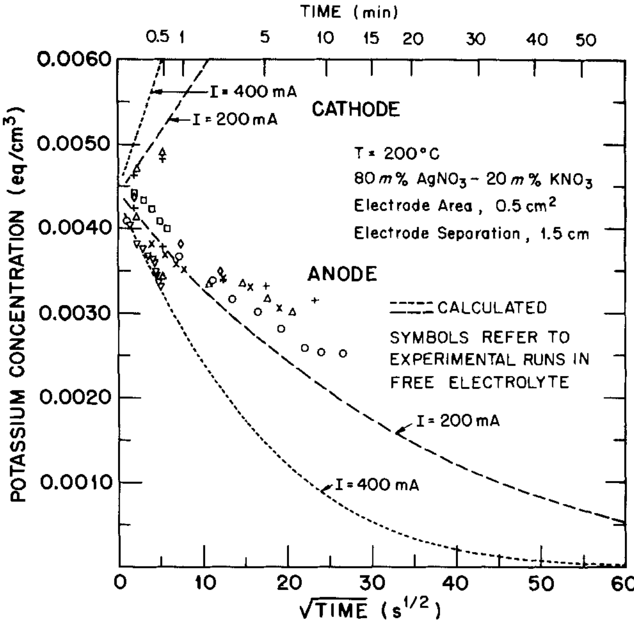

Fig. 6. Time dependence of concentration at electrodes during the electrolysis of 0.8 $AgNO_3$-0.2 KNO_3 free electrolyte, with constant current. +, △, ×, ○ current = 200 mA; ▽ current = 400 mA.

$$E' = \frac{RT}{\mathbf{F}} \ln \frac{X_{Ag}}{X^\circ_{Ag}} + 0.4 \frac{RT}{\mathbf{F}} (X^\circ_{Ag} - X_{Ag}) \qquad [6]$$

Note that the second term on the RHS results from the difference of the transference number from the mole fraction.

Time dependence of concentration in free electrolyte.—A 0.8 KNO_3-0.2 $AgNO_3$ mixture was electrolyzed at constant currents of 0.2 and 0.4A in the cell shown in Fig. 2. During electrolysis, the current was interrupted periodically for short periods of time in order to record the open-circuit potential of cathode and anode (electrodes 1 and 2) relative to the reference electrode, 3, in the melt of initial composition. The separation between the electrodes was 1.5 cm and the temperature 200°C. Figure 6 shows concentrations of potassium calculated with Eq. [6] from the measured potentials. As the electrolysis progresses, the concentration of potassium increases at the cathode and decreases at the anode. The dashed curves are the concentrations predicted by the model assuming an interdiffusion coefficient of 5×10^{-5} cm² sec^{-1} and the transference number $t_K^{NO_3}$ given in Eq. [4]. The experimental points fall on the predicted curves initially, but for times longer than 3 min the concentration at the anode is closer to the initial concentration than the predicted values. This may arise partly from cumulative errors introduced by the successive current interruptions, but is in the direction expected for convective mixing in the free electrolyte. Figure 7 is a recording of the potentials of the anode and of the cathode during the current interruptions shown in the upper part of the figure. After current interruption, the potential decreases rapidly with time, hence there is a very fast concentration change at the electrodes. At the end of a current interruption step the concentration profile between the two electrodes, consequently, is different from that at the beginning of the interruption, and leads to a different concentration at the electrodes at the time of the next current interruption. Few experimental points were obtained at the cathode because of silver dendrite formation. The initial portion of the curves yields a high value of the apparent interdiffusion coefficient (5×10^{-5} cm² sec^{-1}), which is in the direction expected for errors resulting from convection in the melt. Results from analogous experiments using silica frits (Fig. 3) to reduce convection yield a more reasonable,[2] lower, interdiffusion coefficient, $1.5\text{-}2 \times 10^{-5}$ cm² sec^{-1}.

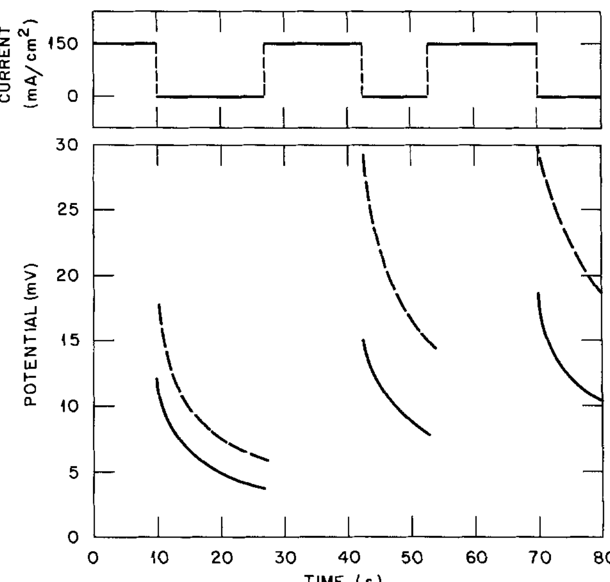

Fig. 7. Time dependence of potential of (+) anode (——) and of (—) cathode (– –) during interruptions of electrolysis with constant current in 0.2 $AgNO_3$-0.8 KNO_3 at 310°C.

Relaxation of the polarization emf in frits.—Since successive current interruptions disturb the development of concentration gradients in the electrolyte, another, related experiment was performed. The melt confined in a frit is electrolyzed at constant current for a known period of time, the current is cut off,

[2] At 300°C, the interdiffusion coefficient in $AgNO_3$-$NaNO_3$ mixtures has been reported as 2×10^{-5} cm² sec^{-1} (20).

and the relaxation to the uniform initial composition is followed by measuring the potentials of cathode and of anode (relative to a reference electrode in the melt of initial composition) as they decay back towards zero. The recording on a X-Y recorder starts a few seconds after the cutoff, allowing complete discharge of the double layer. Extrapolation of the recorded curves to zero time of relaxation, and the use of Eq. [6], gives the composition at both electrodes at the end of each electrolysis. Typical relaxations, at 320°C, are indicated by the emf measurements, shown as points in Fig. 8, of anode and cathode after 1 min of electrolysis of a 0.2 $AgNO_3$-0.8 KNO_3 melt at 0.15 A-cm^{-2}. The lines in Fig. 8 are the calculated diffusional relaxations (Fick's second law) from the concentration profiles at the end of electrolysis. These transient concentration profiles during electrolysis were calculated by numerical solution of Eq. [1] and [2], with Eq. [3] for the emf at the end of electrolysis and during the relaxation. A square root of time scale is used in order to separate the points in the fast initial portion of the relaxation curve. The solid line curves are predicted potentials, with Eq. [5] for the transference number, the dashed curves are the predictions with the assumption of a transference number equal to the mole fraction, which provides a simpler but slightly less accurate computation. In all the computations the interdiffusion coefficient is taken to be 1.5×10^{-5} cm^2 sec^{-1}. In the three experiments, shown in Fig. 8, the thickness of the frit was about 0.5 cm. Extrapolation of the experimental curves to zero relaxation time leads to a composition of $X_{Ag} = 0.30$ at the anode and of $X_{Ag} = 0.08$ at the cathode at the end of electrolysis. The experimental curves have the general shape of the predicted curves and the time scale of the predicted curves agrees with the time scale of the experimental curves. Neglecting the deviations of the transference number from the mole fraction (dashed line curves) gives predicted composition changes slightly larger than those observed. At short times of relaxation, the measured emf values at the cathode differ more from the predictions than those at the anode. The measured curves correspond to less negative potentials, *i.e.*, the composition change at the cathode seems to be smaller than predicted. Possible causes of the deviation may include convection, dendrite formation at the cathode reducing the real current density, formation of a saturated solution, or the onset of a mixed electrode reaction. At 320°C, the liquidus composition is $X_{Ag} = 0.08$ (21), corresponding to an emf of -44 mV. The extrapolated emf at zero time from the two sets of experimental points is close to the emf corresponding to saturation. In order to eliminate the possibility of saturation, similar experiments were carried out at a higher temperature, 350°C.

The experimental results obtained at 350°C after 5, 10, and 20 sec of electrolysis are presented in Fig. 9, together with the corresponding predicted emf curves calculated as above, with Eq. [5] for the transference number and $D = 2 \times 10^{-5}$ cm^2 sec^{-1}. The compositions corresponding to the emf's are shown on the right-hand ordinate. After 20 sec of electrolysis at 0.15 A-cm^{-2} with a 0.4 cm electrode separation, the measured silver nitrate concentration has increased by 60% at the anode and decreased by 42% at the cathode. Table IV compares the predicted compositions at anode and cathode at the end of electrolysis with the experimental compositions, the latter obtained by extrapolation to zero relaxation times. Experimental and predicted composition agree within 4-15%. As with the 320° results, the predicted anolyte composition changes at 350°C are smaller than those observed while the predicted catholyte changes are larger. This trend appears to increase with increasing electrolysis time, and cannot be attributed to saturation at the cathode (at 350°C) nor to convection or uncertainty in *D*, which would affect predicted cathode and anode composition changes in the same direction. The difference between predicted and observed composition changes is in a direction that could correspond to a higher current density at the anode than at the cathode.

which could result from dendrites at the cathode. Experiments are under way to determine the effects of frit porosity (*i.e.*, tortuosity, partial blocking of the electrode, etc.) and longer electrolysis times on the validity of the model predictions, in a system for which the interdiffusion coefficient (as well as the transference number) is better known.

Conclusions

Electrolysis of $AgNO_3$-KNO_3 mixtures between silver electrodes, under conditions similar to those in a molten salt battery (*e.g.*, Li(Al)/LiCl-KCl/FeS_x), demonstrates the development of significant current-induced composition gradients, as predicted from a consideration of the migrational, diffusional, and faradaic processes in binary molten salt mixtures. Chemical analysis of sections of salt quenched after electrolysis shows composition changes of direction and magnitude predicted, but with insufficient resolution for a rigorous test of the one dimensional model. Potentiometric analysis of compositions at the electrode surfaces after electrolysis and during diffusional relaxation are more precise than the chemical analysis; for short electrolysis times, they confirm strikingly the predicted end points of the composition profiles, but they cannot test the predicted shape of the profile in the bulk electrolyte. For longer electrolysis times, deviations occur between the predicted relaxations and the measurements, although the general features of the predicted gradients are observed. The deviations at long times are not attributable to convection alone, but probably also entail contributions from frit porosity, dendrite formation, and other effects. Work is in progress to resolve these contributions to the observed composition gradients and to incorporate them into the model, as well as to improve the analytical precision. The experimental demonstration of electrochemical composition changes in binary molten salt mixtures and the test of the model for predicting their extent are of importance because composition changes of the magnitude observed here may affect significantly the performance of fuel cells or batteries (8, 22).

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Oak Ridge National Laboratory.

LIST OF SYMBOLS

C_K	ionic concentration of K^+ (eq cm^{-3})
D	binary diffusion coefficient (cm^2 sec^{-1})
d	distance between cathode and anode (cm)
E	open-circuit potential difference (V)
$\mathbf{F}$	faraday (96,487C)
I	current density (A-cm^{-2})
R	gas constant
T	temperature (°K)
$t_K^{NO_3}$	transference number of K^+ relative to NO_3^-
u_i	absolute value of mobility of ion i
X°_{Ag}	mole fraction of $AgNO_3$ (reference)
X_{Ag}	mole fraction of $AgNO_3$ at anode (or cathode)
X'_{Ag}	mole fraction of $AgNO_3$ in the melt
X_K	mole fraction of KNO_3
$<X_K>$	mean composition (mole fraction of KNO_3)
$\overline{X}_K$	initial composition (mole fraction of KNO_3)
x	distance from electrodes
μ_{AgNO_3}	chemical potential of $AgNO_3$
σ_{N-1}	standard deviation about the mean composition
σ_{N-2}	standard deviation based on the linear least squares fit

The Kinetics and Mass Transfer of Zinc Electrode in Acidic Zinc-Chloride Solution

Jung Taek Kim*,[1] and Jacob Jorné*

Department of Chemical Engineering, Wayne State University, Detroit, Michigan 48202

ABSTRACT

The kinetics, mass transfer, and surface roughness of zinc electrode in acidic zinc chloride solutions have been investigated in order to understand and optimize its performance in the zinc-chlorine hydrate battery. Polarization and limiting currents were measured using a rotating hemispherical zinc electrode. Exchange current densities and Tafel slopes are reported and the cathodic zinc deposition is confirmed to be first order. A cathodic mechanism of two consecutive one-electron transfer steps are postulated where the first step is the rate-determining step. A diffusion coefficient of zinc ion in 0.05M $ZnCl_2$ + 1.0M KCl, $D_{Zn^{2+}} = 0.89 \times 10^{-5}$ cm²/sec, is obtained from the kinetics-diffusion mixed behavior. The surface roughness during the deposition depends strongly on the zinc-chloride concentration, the fraction of the limiting current i/i_l, and the deposition time. Two regions are observed: (*i*) at appreciable fraction of the limiting current where the roughness is determined by the hydrodynamic conditions, and (*ii*) at well below the limiting current where the roughness is governed by the microthrowing power of the zinc deposit. The growth of zinc dendrites at the edges of a rotating disk electrode was investigated potentiostatically. After an initiation period the current increased sharply and dendrites were detected. The growth direction of the dendrites is explained in terms of the hydrodynamic flow and the level of zinc ion concentration.

The zinc-chlorine hydrate battery is currently under development for utility peak-shaving and electric vehicle applications (1, 2). It is a flowing aqueous zinc chloride electrolyte battery which utilizes porous graphite flow-through chlorine electrode and dense graphite zinc-electrode substrate. The interelectrode gap is typically 2-4 mm and no separator is employed.

The individual overpotentials of the zinc and chlorine electrodes in the battery have been measured (3). The electrode kinetics and mass transfer effects have to be investigated in order to understand the source of the voltaic and coulombic inefficiencies in the battery. The kinetics of the chlorine electrode has been investigated in a previous paper by Kim and Jorné (4). The convective diffusion of the dissolved chlorine to the zinc surface which is responsible for the coulombic inefficiency has been investigated by Kim and Jorné (5), and by Kermani, Jorné, and Kodali (6). In this paper the kinetics, mass transfer, and the surface roughness of the zinc electrode are reported. Polarization measurements, limiting currents, coulombic efficiencies, and surface roughness effects were measured and the kinetics, transport parameters, and the reaction mechanism are discussed.

Although the deposition of zinc in aqueous solution has been extensively studied, most of the work dealt with its kinetics and postulated mechanisms. No general agreement has been reached pertaining to the kinetics, roughness of the deposition, and dendrite formation.

The kinetics of zinc deposition in acidic solution has been reported by a number of authors. Gaiser and Heusler (7) showed that zinc deposition is first order. Eriksurd (8) investigated the effect of halides and alkali cations on the Zn(Hg)/Zn(II) electrode reaction. Hulen and Eriksurd (9) studied the kinetics of the Zn(Hg)/Zn(II) electrode in acidic chloride solution. Sierra Alcazar and Harrison (10) suggested a cathodic reaction scheme in $ZnCl_2$ and KCl solution (pH = 3.0) of two consecutive one-electron transfer steps where the first one is the rate-determining step. Weber and Tomassi (11) investigated the mechanism of zinc electrodeposition from its sulfate and chloride solutions. In chloride solutions the proposed mechanism involves various zinc chloride complexes: $ZnCl_3^-$, $ZnCl_4^{2-}$, $(ZnCl_2)_{ads}$, and H^+_{ads}. Epelboin and his co-workers (12-16) suggested a more complex scheme in which adsorbed H atoms catalyze the zinc reduction. The model involves an autocatalytic step in which Zn^+_{ads} is being generated. The adsorption at the interface involves three species, hydrogen, an anion, and Zn^+ cation which may be complexed. Multiple steady states are predicted and verified based on an "S" shaped current-potential curve. Moreover, the presence of an autocatalytic step at the interface plays an important role in the appearance of spongy, compact or dendritic deposits which are successively obtained when the current density is increased. The spatial configuration of the deposit is explained in terms of a coupling between the interfacial reactions and the surface diffusion of the adsorbed Zn^+ species (13, 15, 16). Regular spatial structures are claimed to be observed and explained in terms of dissipative structures. The detailed mechanism of the electrodeposition process is rather complicated.

The quality of metal deposition generally depends on the intermediate reactions and on several process variables, such as current density, concentration, fluid velocity, temperature, additives, and hydrogen reaction.

Experimental

Cell arrangement, rotator, preparation of zinc hemispherical electrode, and graphite disk electrode were reported previously (4, 5). A constant current supply (Electronic Measurement Model 620) and a potentiostat (PAR Model 173) were used in the galvanostatic and the potentiostatic experiments, respectively. The potential and the current were measured with an electrometer (PAR Model 136).

Faradaic efficiency tests were performed galvanostatically in 37% $ZnCl_2$ solution. A rotating zinc hemispherical electrode (99.999% New Jersey Zinc) was used. The surface of the electrode was polished with waterproof Al_2O_3 paper (Grid No. 600) and de-

Key words: zinc-chlorine battery, battery, rotating hemisphere, roughness, diffusion, faradaic efficiency, dendrite.

greased with spectroscopic grade pentane. The zinc electrode was weighed on a Mettler balance (H80) and transferred into the cell. After the experiment, the deposited (or dissolved) zinc electrode was rinsed with double distilled water, washed with spectroscopic grade pentane, and weighed.

The measurements of the kinetic parameters were performed potentiostatically in various zinc chloride solutions. A universal programmer (PAR Model 175) was used in conjunction with the potentiostat in order to sweep the potential of the zinc hemispherical electrode anodically or cathodically. The sweep rate was 10 mV/sec. The potential-current data was recorded on a recorder (HP Model 7046A).

The experiments of zinc deposition on a zinc hemispherical electrode and the dendritic growth on nonporous graphite disk electrode (Union Carbide ATJ) were performed in various zinc chloride concentrations galvanostatically and potentiostatically, respectively. The current-time data were recorded on Honeywell recorder (Electronik 194).

Solutions were prepared by direct reaction of dissolved chlorine and pure zinc rods (99.999%, New Jersey Zinc) in triply distilled water. The desired concentrations were achieved by dilution. All experiments were performed in deaerated solutions. The electrolyte was deaerated by bubbling N_2 gas prior to the experiments. The pH of the solution was measured with Orion pH meter (Model 701A). Pure zinc rod (99.999% New Jersey Zinc) was used as a counterelectrode for all experiments. Conductivities of the solutions were measured at 25°C using an a-c bridge, Generator Detector, Model 861A, Electro Scientific Industries, Portland, Oregon. The cell resistance and capacitance were balanced with an Impedance Bridge, Model 290B, and variable Decade Capacitors, Model DC57, Electro Scientific Industries, Portland, Oregon. A "U" type conductance cell was used. It contained two parallel platinum disk electrodes and all electrical wires were shielded. The cell was filled with solution and then transferred into a constant temperature bath. The viscosity of the solution was measured with Ostward Viscometer in a constant temperature bath.

Results and Discussion

Faradaic efficiency of Zn electrode.—The faradaic efficiency and the number of electrons transferred were obtained galvanostatically by weight measurements. Faraday's law is given by

$$\frac{\Delta W}{M} = \frac{It}{n\mathbf{F}} \quad [1]$$

ΔW is the weight gained (or lost) by the electrode. M is the molecular weight of zinc, I is the current, t is the time, n is the number of electrons, and $\mathbf{F}$ is Faraday's constant.

The over-all cathodic reaction of the zinc ion is $Zn^{+2} + 2e \rightarrow Zn^\circ$. In order to verify the number of electrons transferred for the anodic dissolution or the cathodic deposition of zinc, weight loss or gain measurements were performed in 37% $ZnCl_2$ (pH = 1.0) solution. All variable factors, such as current, rotational speeds, time, concentration of solution, and pH were kept constant.

The number of electrons transferred was calculated from Eq. [1]. The obtained average values of the number of electrons transferred during the anodic and cathodic reactions are $n_a = 1.98$ and $n_c = 2.13$, respectively. These values represent an average of six experiments. The cathodic number of electrons transferred is slightly higher than the anodic number due to hydrogen evolution, although hydrogen overpotential is high on pure zinc surface. Sorensen, Davidson, and Klinberg (17) obtained the number of electrons for anodic zinc in various solutions at 30°C. The obtained values were $n_a = 1.77$ in 2.5M NaCl and 0.2M $NaNO_3$ solution, $n_a = 2.02$ in 2.5M NaCl and 0.2M $KClO_3$ solution. It was also observed that the number of electrons transferred decreased as the temperature increased and on addition of an oxidizing agent (*e.g.*, nitrate ion): in 0.2M $NaNO_3$ solution, $n_a = 1.90$ at $T = 30$°C and $n_a = 1.40$ at $T = 80$°C (17); $n_a = 2.0$ in 5M NaCl and in the absence of nitrate ion; $n_a = 1.72$ in 5M $NaNO_3$ and in the absence of the chloride ion; and $n_a = 1.62$ in 2.5M NaCl and 2.5M $NaNO_3$ at $T = 30$°C. The lower value of n_a in the 2.5M NaCl and 2.5M $NaNO_3$ solution was attributed by Sorensen *et al.* (17) to the oxidation of unipositive zinc ion by nitrate ion which is catalyzed by chloride ion. Libby (18) proposed a catalytic effect based on the formation of a complex ion containing chloride ion, and Taube *et al.* (19-21) proposed a bridge transfer mechanism wherein the added chloride ion is coordinated between oxidant and reductant to form a bridge which serves as a path for the electrons.

The present value $n_a = 1.98$ in 37% $ZnCl_2$ in the absence of an oxidant at $T = 22$°C is in general agreement with the results of Sorensen *et al.* (17). It might indicate that unipositive zinc ion is formed during anodic dissolution. The unipositive zinc ion (Zn^+) thus postulated is very reactive and readily forms the bipositive zinc ion (Zn^{+2}) in the absence of an oxidant.

The kinetics of Zn electrode.—The polarization measurements of zinc metal in zinc chloride solution were performed on a rotating hemispherical zinc electrode. In order to eliminate the concentration overpotential, the rotational speed of the electrode was sufficiently high, $\omega = 3000$ rpm. The results are plotted according to the Tafel equation and are shown in Fig. 1. The data was corrected for the ohmic drop using Newman's method (22) for the case where the reference electrode is located far away (3.50 cm)

$$R = \frac{1}{4\pi\kappa r} \quad [2]$$

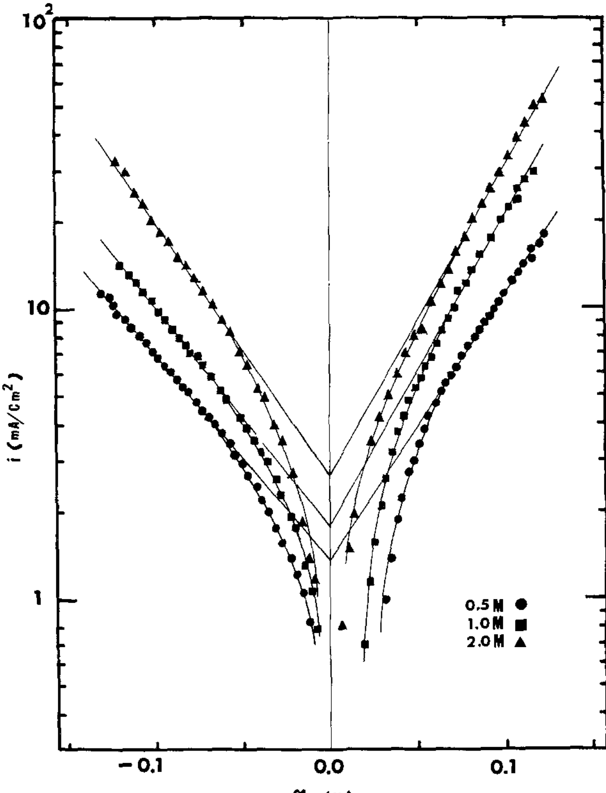

Fig. 1. Anodic and cathodic Tafel polarizations of zinc electrode in various $ZnCl_2$ and 1M KCl solutions. Electrode area: 0.752 cm². Rotational speed: 3000 rpm.

R is the resistance (Ω), κ is the conductivity (Ω^{-1} cm^{-1}) of the solution, and r is the radius of the electrode (cm). The conductivities of the various solutions are 0.0820, 0.0943, and 0.0980 Ω^{-1} cm^{-1} for 0.5, 1.0, and 2.0M $ZnCl_2$ solutions, respectively. The obtained exchange current densities and anodic and cathodic Tafel slopes are summarized in Table I. The theoretical cathodic Tafel slope is $b_c = -2.3RT/(1-\beta)n\mathbf{F}$. If a symmetric transfer coefficient $\beta = 0.5$ and one-electron transfer $n = 1.0$, are assumed, then the Tafel slope is $b_c = -120$ mV. The obtained experimental cathodic Tafel slopes (see Table I) are in agreement with the theoretical value. Sierra Alcazar and Harrison (10) measured Tafel slope of 120 mV using an a-c impedance technique.

The exchange current density (i_o) was calculated from the intercepts of the anodic and the cathodic branches in Fig. 1, and the obtained data are also summarized in Table I. An exchange current density of $Zn(Hg)/Zn^{+2}$ in KCl is reported by Sierra Alcazar and Harrison (10): $i_o = 2.0$ mA/cm² for 0.1M $ZnSO_4$ + 1.0M KCl (pH = 3.0). However, the exchange current also varies with the pH; in 3×10^{-3}M $ZnSO_4$ $i_o = 2.4 \times 10^{-2}$ mA/cm² for pH = 3.5 and $i_o = 1.8 \times 10^{-2}$ mA/cm² for pH = 2.5.

In general, the exchange current density depends on the concentration of reactants and products and can be written as (23)

$$i_o = n\mathbf{F}k_c^{(1-\beta)}\, k_a^{\beta}\, \pi C_i^{(Z_i+\beta S_i)} \quad [3]$$

S_i is the stoichiometric coefficient: $S_i > 0$ for anodic reaction and $S_i < 0$ for cathodic reaction. Clearly, the exchange current density increases if either the reactant's or product's concentration is increased. Figure 2 shows the log-log plot of the exchange current density *vs.* the zinc ion concentration. From the slope of the plot, the fractional power of the concentration in Eq. [3] is obtained, $Z + \beta S = 0.459$. If the reaction order $Z = 1.0$ and the stoichiometric coefficient $S_{Zn^{2+}} = 1.0$ are assumed, then the symmetric transfer coefficient β is 0.541 which is in agreement with the previous assumption $\beta = 0.5$ in the theoretical Tafel slope.

The reaction order of the zinc deposition process is obtained by

$$Z = \left[\frac{\partial(\log i_c)}{\partial(\log[Zn^{++}])}\right] \quad [4]$$

Figure 3 shows the cathodic current density *vs.* the zinc concentration at various fixed potentials ($E = -1.065$, -1.040, and -1.015V *vs.* SCE). The obtained reaction order is $Z = 0.75$. As shown previously, the reaction order is $Z = 1.0$ for $\beta = 0.5$. Thus, the zinc cathodic reaction order is believed to be first order.

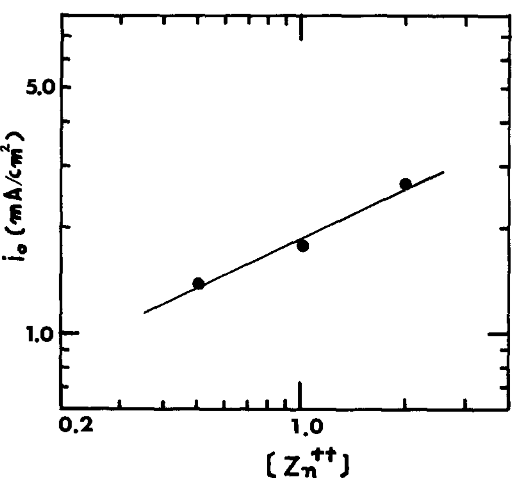

Fig. 2. The exchange current density vs. the molar concentration of zinc ion.

Table I. The kinetic Tafel parameters of zinc in zinc chloride solution (pH = 2.0)

$ZnCl_2$ (M)	i_o (mA/cm²)	b_a (mV)	$-b_c$ (mV)
0.5	1.36	108.5	139.5
1.0	1.75	94.4	131.3
2.0	2.65	90.6	113.7

The obtained kinetic parameters suggest the following kinetic mechanism of zinc deposition

$$Zn^{++} + e \xrightarrow{1} Zn^{+} \quad \text{(rate-determining step)} \quad [5]$$

$$Zn^{+} + e \underset{-2}{\overset{2}{\rightleftarrows}} Zn \quad [6]$$

If Eq. [5] is the rate-determining step, the rate expression for the above reaction is

$$i_c = n\mathbf{F}k_1 [Zn^{++}] \exp\left[\frac{-(1-\beta)\mathbf{F}E}{RT}\right] \quad [7]$$

Equation [7] yields a Tafel slope $b_c = -120$ mV (for $\beta = 0.5$) and a reaction order with respect to the concentration of the zinc ion $Z = 1.0$.

If Eq. [6] is the rate-determining step, the rate expression is

$$i_c = n\mathbf{F}k_2\theta \exp\left[\frac{-(1-\beta)\mathbf{F}E}{RT}\right] \quad [8]$$

$$\frac{d\theta}{dt} = k_1(1-\theta)[Zn^{++}]\exp\left[\frac{-(1-\beta)\mathbf{F}E}{RT}\right] - k_{-1}\theta\exp\left[\frac{\beta\mathbf{F}E}{RT}\right] - k_2\theta\exp\left[\frac{-(1-\beta)\mathbf{F}E}{RT}\right] \quad [9]$$

θ is the fractional coverage of Zn^{+} ion. At steady state and under the assumption of $k_{-1} >> k_2$, Eq. [9] reduces to

$$\frac{\theta}{1-\theta} = \left(\frac{k_1}{k_{-1}}\right)[Zn^{++}]\exp\left(\frac{-\mathbf{F}E}{RT}\right) \quad [10]$$

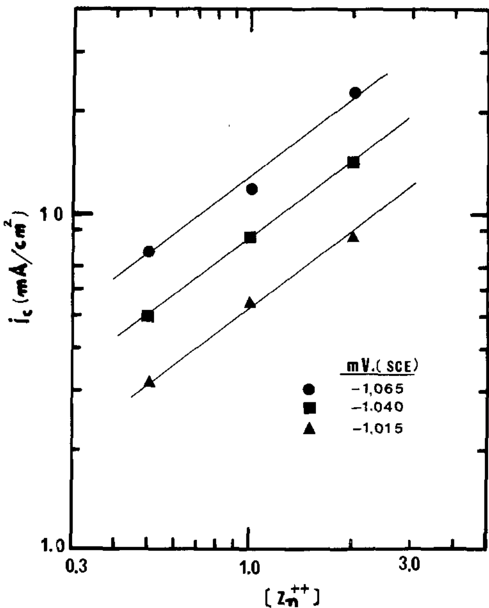

Fig. 3. The cathodic current density vs. the molar concentration of zinc ion at different fixed potentials.

θ is assumed to be very small $(1 - \theta) \cong 1$ and substituting Eq. [10] into Eq. [8], results

$$i_c = n\mathbf{F}\left(\frac{k_1k_2}{k_{-1}}\right)[\mathrm{Zn}^{++}]\exp\left[\frac{-(1-\beta)\mathbf{F}E}{RT}\right] \quad [11]$$

Equation [11] yields a Tafel slope $b_c = -40$ mV (for $\beta = 0.5$) and a reaction order $Z = 1.0$. If the fractional coverage is assumed to approach unity, then Eq. [8] yields a Tafel slope $b_c = -120$ mV and a reaction order $Z = 0$.

Thus, if Eq. [6] is the rate-determining step, the theoretical kinetic parameters contradict the experimental results. The present experimental results confirm that Eq. [5] is the rate-determining step.

The diffusion coefficient of zinc ion.—Cathodic polarization of zinc electrode in 0.05M $ZnCl_2$ and 1M KCl solution is shown in Fig. 4. Accurate zinc deposition limiting currents cannot be observed. The polarization shows a mixed kinetics behavior: partly controlled by mass transfer and partly controlled by kinetics. The steep rise in the current which appears at about −1.85V *vs.* SCE is due to hydrogen evolution. A similar result was reported by Justinijanovic and Despić (24) in 0.5M alkaline zincate solution. The zinc reaction is diffusion controlled and hydrogen evolves simultaneously, therefore, the effective limiting current for zinc deposition alone is lower than the experimental value.

Figure 5 shows the plot of the current *vs.* the square root of the rotational speed under a fixed potential ($E = -1.654$V *vs.* SCE). At low rotational speeds, the reaction is diffusion controlled and the current is proportional to the square root of the rotational speed, in agreement with the convective diffusion equation for a rotating hemispherical electrode

$$i_l = 0.451\, n\mathbf{F}D^{2/3}\nu^{-1/6}C_b\omega^{1/2} \quad [12]$$

At high rotational speeds, the reaction is kinetics controlled and the current becomes independent of the rotational speed

$$i_k = n\mathbf{F}kC_b{}^z \quad [13]$$

From Fig. 5 the true limiting current of zinc deposition is obtained from which the diffusion coefficient of zinc ion is calculated

$$D_{\mathrm{Zn}^{++}} = 0.89 \times 10^{-5}\ \mathrm{cm^2/sec}$$

The kinematic viscosity is $\nu = 0.935 \times 10^{-2}$ stokes. Diffusion coefficients of Zn(Hg) and Zn^{2+} were reported previously (8) using chronopotentiometric measurements: 1.5×10^{-5} and 0.7×10^{-5} cm²/sec, respectively, in general agreement with the present value.

Surface roughness during zinc electrodeposition.—It has been suggested that the surface roughness during metal electrodeposition is determined by the fraction of the limiting current at which the electrodeposition is performed, Landau (25).

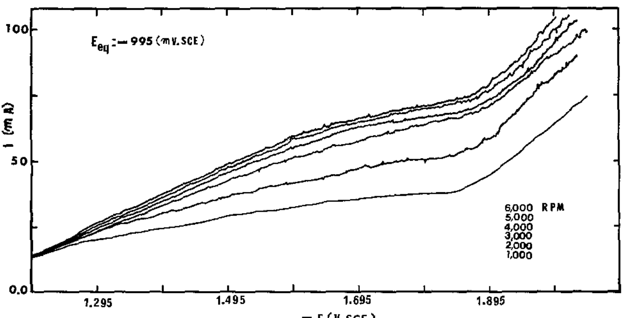

Fig. 4. Cathodic polarization of zinc hemispherical electrode in 0.05M $ZnCl_2$ + 1.0M KCl solution at various rotational speeds. Electrode diameter: 0.736 cm.

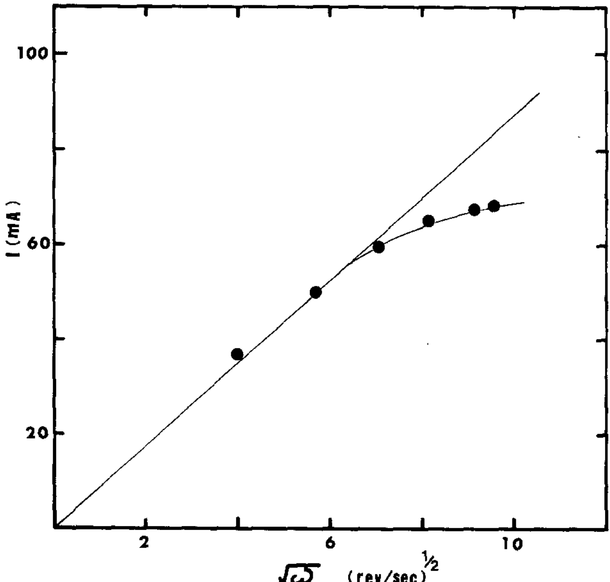

Fig. 5. Determination of the diffusion coefficient of zinc ion: the current *vs.* the square root of the rotational speed. Fixed potential $E = -1.654$V *vs.* SCE. 0.05M $ZnCl_2$ + 1.0M KCl. Electrode diameter: 0.736 cm.

In the present investigation the appearance of roughness during zinc electrodeposition in $ZnCl_2$ solution is investigated and correlated to factors such as the fraction of the limiting current I/I_l, the zinc ion concentration, and the deposition time. In order to investigate these effects, the current was fixed at various regions: above the limiting current, near the limiting current, and below the limiting current. Figure 6 shows zinc deposits on rotating hemispherical zinc electrodes at various rotational speeds in 0.5M $ZnCl_2$ and 1M KCl solution. The fixed current was 200 mA and the deposition time was 30 min for each electrode. The limiting current of zinc deposition in 0.5M $ZnCl_2$ solution can be estimated from the obtained limiting current in 0.05M $ZnCl_2$ (Fig. 5). The estimated limiting currents in 0.5M $ZnCl_2$ are 360, 620, and 800 mA for rotational speeds, ω = 1000, 3000, and 5000 rpm, respectively. The fraction of the limiting current (I/I_l) is 0.55 for 1000 rpm, 0.32 for 3000 rpm, and 0.25 for 5000 rpm. Clearly, at higher rotational speeds (or at small fractions of the limiting current), the surface of the deposit is smoother than at lower rotational speeds.

The roughness of the zinc deposit is influenced also by the deposition time as shown in Fig. 7. The fraction of the limiting current was $I/I_l = 0.44$ and the time varied from 3.44 to 45 min. Obviously, more roughness developed over the longer period of time. In Fig. 8, the current was fixed at the limiting current region (I = 62 mA) and at 50% of limiting current (I = 31 mA). As the fraction of the limiting current approaches unity, the surface becomes rougher. Also, above the limiting current region ($I/I_l = 1.53$), the zinc surface was rougher than under the limiting current (I/I_l = 0.65) as shown in Fig. 9, although the applied current was identical in both cases.

The mechanism of roughness formation can be separated into two regions: near the limiting current, and at well below the limiting current. The roughness is determined by the local current distribution. At well below the limiting current the current distribution is governed primarily by electrical, electrochemical, and crystallographical factors rather than by mass transfer processes. However, at the limiting current, the surface concentration is zero, and the current density is simply proportional to the mass transfer coefficient. The local current density depends on the initial surface profile. At peaks, the mass transfer coefficient is high and the local current density is high too. On

the contrary, since the mass transfer coefficient at recesses is smaller than at the peak, the deposition rate is slow. Thus, if a current is applied near the limiting current, roughness can be amplified due to varying local mass transfer rates.

The interesting phenomenon of spiral formation at a rotating disk and a rotating hemisphere has been observed elsewhere during the process of metal dissolution or deposition (5, 26-28, 30-31). Figure 10 shows zinc deposits on a rotating zinc hemisphere electrode in 0.05M $ZnCl_2$ and 1M KCl solution. The current was fixed well below the limiting current ($I/I_l = 0.16$) and the deposition process was examined at different times: $t = 20$ min and $t = 110$ min. After a short time of 20 min, a smooth deposit which contained many traces of hydrogen bubbles was observed. After a long period of 110 min, spiral tracings can be observed. At a higher current ($I = 20$ mA), less bubble tracing was observed. Since the rate of hydrogen evolution is higher at high currents, the residence time of the hydrogen bubbles on the surface is short. Kadija and Nakic (29) confirmed that the space between the bubbles on the surface decreases by increasing the current. The dark lines show probably trajectories of hydrogen bubbles and zinc deposition is not observed at these lines, because of the shielding effect of the bubbles and the low rate of deposition under the bubbles. The appearance of these spiral markings is discussed by Rogers and Taylor (30) and results from the appearance of tiny protrusions on the rotating electrode. These may be, for example, hydrogen bubbles or rough deposits at the electrode surface. Spiral markings are observed frequently at the transitional flow region, and it is quite possible that the bubbles follow the secondary flow and are carried outward in logarithmic spiral trajectories. Jaksic and Tobias (31) observed striated profiles during zinc electrodeposition from its chloride or bromide solutions. The grooves follow the direction of flow and on rotating disk elec-

trodes this resulted in spiral patterns. This phenomenon is explained by a secondary flow which results in alternating regions of higher and lower interfacial concentrations (31).

Dendritic growth.—Deposition and dendritic growth on a rotating graphite disk electrode were performed potentiostatically in zinc chloride solution. Figure 11 shows the current-time behavior of the zinc deposition on a rotating graphite disk electrode. During the first 10-15 min the current did not change with time. During this period the process involved zinc deposition far below the limiting current and the initiation of dendrites at the disk edges. After this initiation period the current increased with time and dendritic growth was observed simultaneously at the disk edges. The current increased faster in 0.4M $ZnCl_2$ than in 4.3M $ZnCl_2$ solution as shown in Fig. 11.

If the reaction is partially limited by mass transport, the surface concentration (C_o) is related to the bulk concentration (C_b) by

$$C_o = C_b\left(1 - \frac{i}{i_l}\right) \quad [14]$$

where i is the applied current density and i_l is the

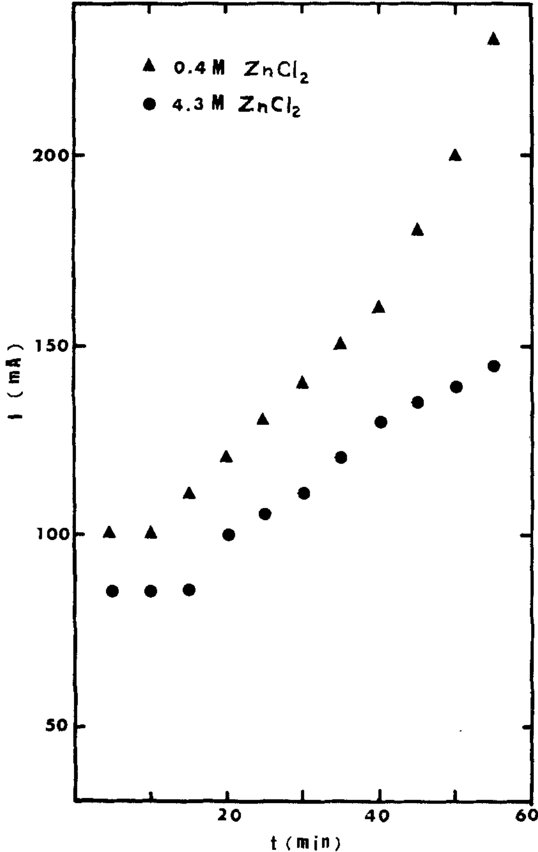

Fig. 11. The initiation and propagation of zinc dendrites at the edge of a rotating disk electrode under potentiostatic conditions. ▲ 0.4M $ZnCl_2$, E = −2.0V vs. SCE. ● 4.3M $ZnCl_2$, E = −1.4V vs. SCE. ω = 4000 rpm, area = 0.71 cm^2.

limiting current density. The limiting current was estimated from the plot of I vs. $\omega^{1/2}$ in Fig. 5. In 0.4 and 4.3M $ZnCl_2$ solutions the total currents during the initiation periods were 100 and 80 mA, respectively, and the estimated limiting currents at ω = 4000 rpm are 0.42 and 4.5A, respectively (Fig. 5). The average fractions of the limiting current are I/I_l = 0.24 and 0.018 and the surface concentrations during the initiation period are roughly 0.34 and 4.22M for the 0.4 and 4.4M $ZnCl_2$ solutions, respectively.

In both cases the currents were well below the limiting currents during the initiation period and as a result the initial current distributions were highly nonuniform. The local current densities at the edge of the disk electrode were much higher than in the center and dendrites initiated at the edges. The zinc deposition rate at the tips of the dendrites is very high and limited by mass transfer (spherical diffusion). Consequently, the surface concentration at the tip of the dendrite approaches zero. Since the deposition process is now diffusion limited the hydrodynamic condition becomes an important factor.

The effects of the hydrodynamic conditions and the concentration on the direction of the dendritic growth at the edge can be seen in Fig. 12 and 13. In the high zinc chloride concentration (4.3M) the dendrites grew in a vertical direction to the disk surface (Fig. 12). When the zinc chloride concentration was reduced by an order of magnitude (0.4M) the direction of dendritic growth changed drastically and the dendrites grew parallel to the Teflon disk and followed the flow direction (Fig. 13). The direction of the dendritic growth is an exact continuation of the spiral markings which have been observed before and can be seen also in Fig. 12 at the central region of the disk electrode.

The qualitative explanation to the change in direction of the dendritic growth is as follows: Initially,

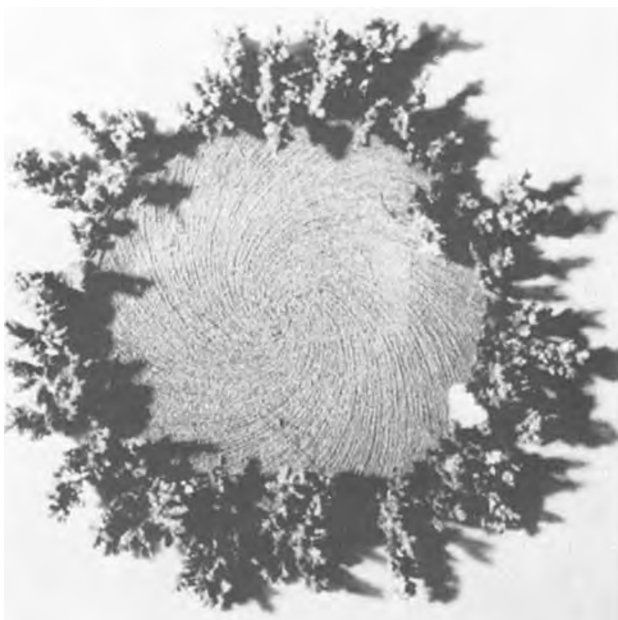

Fig. 12. Zinc dendrites on rotating disk graphite el-ctrode (note vertical direction of growth). 4.3M $ZnCl_2$. $E = -1.4V$ vs. SCE. $\omega = 4000$ rpm. Area $= 0.71$ cm^2.

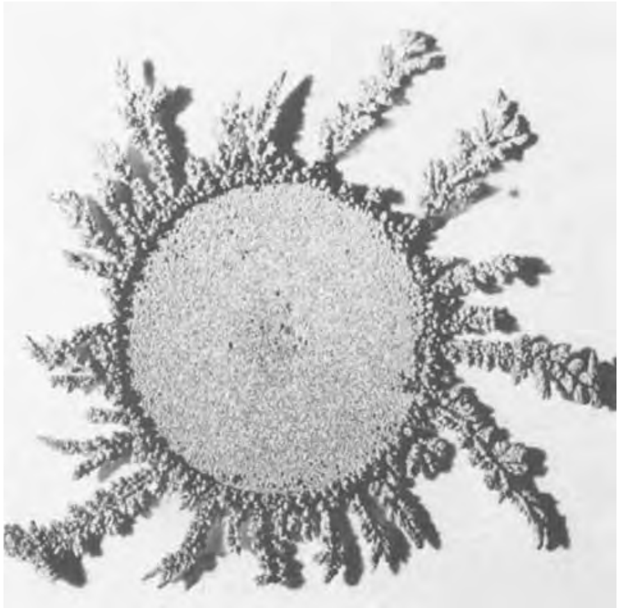

Fig. 13. Zinc dendrites on rotating disk graphite electrode (note horizontal direction of growth). 0.4M $ZnCl_2$. $E = -2.0V$ vs. SCE. $\omega = 4000$ rpm. Area $= 0.71$ cm^2.

zinc deposition is higher at the edge of the rotating disk electrode because of nonuniform current distribution. The zinc deposition reaction is fast and exhibits relatively high exchange current density which results in highly nonuniform current distribution below the limiting current. As a result, roughness develops at the edge and dendrites are initiated subsequently. The growth of the dendrites is mass transfer limited and the dendrites tend to grow toward a region of high zinc ion concentration. The dendrites also serve as large protrusions which interfere with the flow near the disk. The flow interaction reaches its full extent when the dendrites are about equal or slightly exceed the thickness of the hydrodynamic boundary layer. This effect results from flow separation at the tips of the dendrites and produces local eddies which transport small volumes of bulk liquid to the vicinity of the solid surface. Consequently, a narrow region behind the dendrites near the insulator surface of the disk has a higher concentration of zinc ions which is quite close to the bulk concentration. Similar observations and explanation are given by Jaksic and Tobias (31). In the case of the low $ZnCl_2$ concentration (0.4M) the dendrites grew in the direction of the wakes behind the dendrites because the zinc concentration there was significantly higher than elsewhere on the disk surface. However, when the zinc bulk concentration was ten-fold higher, the effect became negligible and the dendrites grew vertically toward the bulk solution.

Summary

The kinetics of a zinc electrode in acidic zinc chloride solution was investigated. The postulated mechanism for the cathodic reaction indicates two consecutive one-electron transfer steps where the first one is the rate-determining step. The reaction is quite fast as indicated from its high exchange current densities. The morphology of the zinc deposit depends on the current density, the deposition time, and the hydrodynamic conditions (through the fraction of the limiting current). At low zinc ion concentration the deposit is generally smoother. At well below the limiting current the surface roughness depends on the microthrowing power. At appreciable fraction of the limiting current, the roughness is proportional to the fraction of the limiting current, and the surface becomes very rough at or above the limiting current. Zinc dendrites initiate at the edges of a rotating disk where the local current density is high. The dendritic growth is diffusion limited and is influenced by the flow especially at lower concentrations. The dendrites interact with the flow because they serve as protrusions and generate wakes behind them.

Influence of Accelerated Weathering on the Corrosion of Low-Alloy Steels

H. Schwitter and H. Böhni

Swiss Federal Institute of Technology, Institute of Materials Chemistry and Corrosion, 8093 Zürich, Switzerland

ABSTRACT

In low-alloy steels under accelerated atmospheric corrosion conditions the type of weathering, particularly the ratio of the time of wetness to the drying time, has a greater influence on the corrosion behavior than does the composition of the alloys. Electrochemical measurements show that the rust protection is not only due to the formation of compact macroscopic protective layers, but also to passivation effects. Passivation occurs for a prolonged period only at favorable accelerated weathering conditions. We propose a model for the interpretation of the corrosion behavior of low-alloy steels.

Weathering steels exposed to the atmosphere form, as is well known, compact and well-adhering protective layers which inhibit a further attack by corrosion. Depending on the composition of the alloy a more or less decreasing corrosion rate can be observed. Numerous papers have been published which support this observation (1-3).

Although these steels have been used throughout the world for a long period of time, the corrosion protective properties of the formed rust layers are not well enough understood. Most of the atmospheric corrosion tests performed until today do not allow any conclusions in this direction, because the different parameters, which are important for the corrosion behavior, have not been varied systematically in these tests.

The practical experiences with this material as well as the results of long-time tests obtained by Larrabee and Coburn (4) in the USA and Eduards (5) in England show, however, that considerable differences can occur between the different test sites. In England comparable steels corroded 5-10 times faster than in the USA, suggesting that the type of weathering is at least as important as the alloy composition.

It was therefore the aim of this study to examine the influence of weathering as well as the importance of the alloying elements on the corrosion behavior of low-alloy steels by means of appropriate accelerated weathering tests. Additionally, natural exposure tests, light and electron-optical studies, x-ray diffraction, and electrochemical measurements were carried out.

Experimental

Materials.—Materials examined were plain carbon steel and low-alloy steels with variable composition. Table I shows the analysis of these steels.

All low-alloy steels tested have the same basic composition. In three different groups, however, the alloying elements copper, chromium, and phosphorus were systematically varied.

Key words: accelerated weathering tests, weathering steel, atmospheric corrosion, wet/dry cycles, rust layers.

Before exposure the steels were sandblasted and degreased in benzene.

Weathering.—The samples were exposed to three different types of accelerated weathering tests. Figure 1 gives a schematic survey of these weathering conditions. In the first weathering (3x) the samples were wetted and dried three times within 12 hr. In one week the samples were exposed 12 times to these 3x cycles and twice in 12 hr to a SO_2-containing atmosphere. In the weathering type 2x the specimens were exposed to two dry/wet cycles within 12 hr, in weathering type 1x they were wetted and dried only once in the same time. The average total time of wetness increased from 46% in the 3x cycle to 77% in the 1x cycle.

The specimens were wetted by means of aerosol spraying and sprinkling, dried at 42°C and at a relative humidity of 55%. During the SO_2-exposure the SO_2-concentration was 20 ppm and the relative humidity 85%. Before each SO_2-exposure the samples were also dried. For the natural exposure test in a suburban area near Zurich the samples were oriented towards the south at an angle of 45°.

Electrochemical experiments.—The electrochemical experiments were carried out in an air saturated 0.1M Na_2SO_4 solution. The current-potential curves were obtained potentiostatically by the usual electronic devices (potentiostat, function generator, potentialmeter). The sweep rate was 15 mV/min. As reference electrode a saturated calomel electrode was used. The surface of the sample examined was 4 cm^2.

Results

Weight losses.—Figure 2 gives a survey of the results obtained by the accelerated weathering tests. The copper as well as the chromium series clearly show the influence of weathering. The samples weathered with

	N	0.11	0.012	0.38	0.50	0.51	0.101	0.47	0.30

the 3x cycle have smaller weight losses than those with 2x and 1x cycle. The difference in the 2x and 1x type weathering, however, is not very pronounced. In the weathering 3x the influence of the alloying elements is weak. In addition, the unalloyed steel S shows only a very small corrosion rate after 9 weeks. The influence of the alloying elements in the weathering types 2x and 1x is slightly greater. In Fig. 2 the results of the most highly alloyed steels are at the lower limit, the ones of the less alloyed steels at the upper limit of the value band.

Figure 3 shows additionally the weight loss of the S and M-type steels as a function of total time-of-wetness t^* instead of exposure time. The results indicate that the lower weight losses of the 3x-type weathering are not only due to the shorter time-of-wetness during these weathering conditions but also due to the more protective properties of the rust layer.

From these results the following statement can be made: Frequent drying/wetting changes in the 3x weathering have a favorable influence on the corrosion behavior. After a large corrosion rate at the beginning of the exposure the samples corrode only slightly. This behavior is almost independent of the concentration of the alloying elements. For the unalloyed steel S the corrosion rate decreases significantly also.

When the samples are weathered with longer wetting periods (2x, 1x), the corrosion rate does not decrease so much. Moreover, the total metal loss is two to three times as high compared to weathering 3x. During these

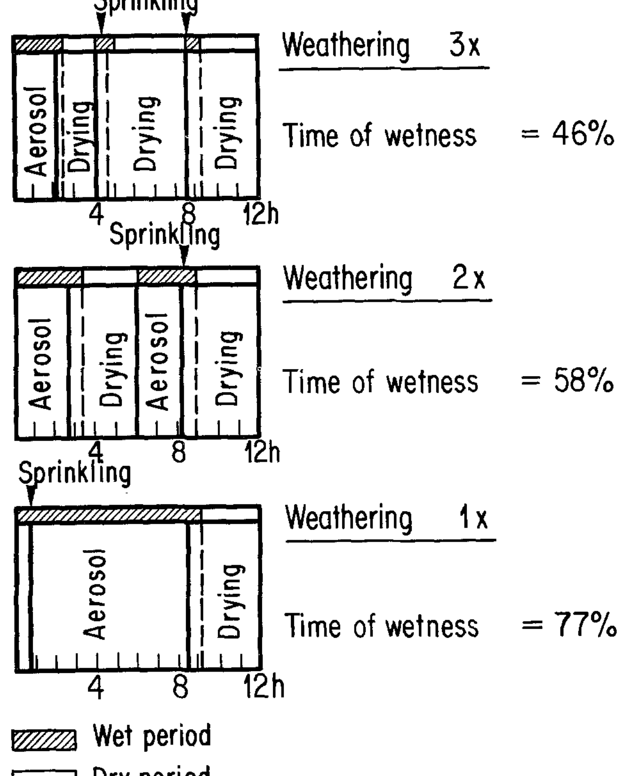

Fig. 1. Schematic survey of the types of accelerated weathering

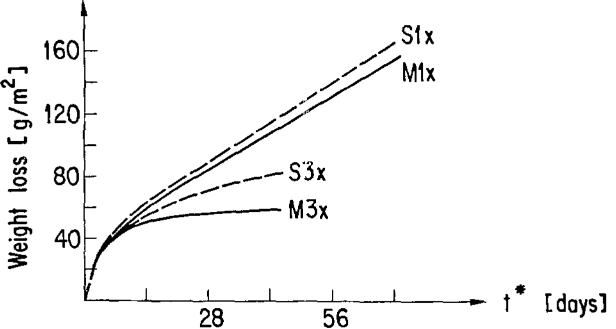

Fig. 3. Weight loss, x-axis reduced to time of wetness t^*

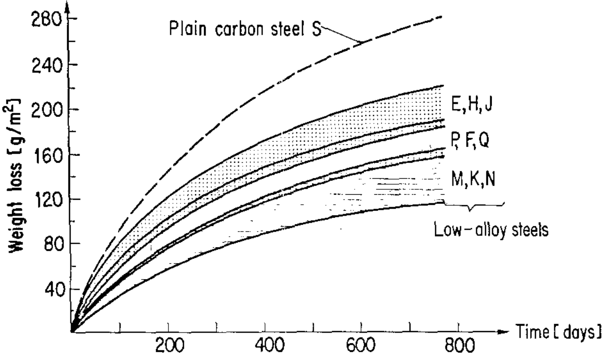

Fig. 4. Results of the natural weathering in suburban area

weathering conditions a beneficial influence of the alloying elements is observed.

Figure 4 shows the results of the natural exposure tests. In spite of the large scatter a similar influence of the alloying elements is obtained as in the case of the accelerated weathering 1x and 2x. Generally, the most alloyed steels have the lowest and the unalloyed carbon steels have the highest weight losses. Moreover, after two years exposure none of the steels tested formed the completely protective rust layers observed during 3x-type accelerated weathering.

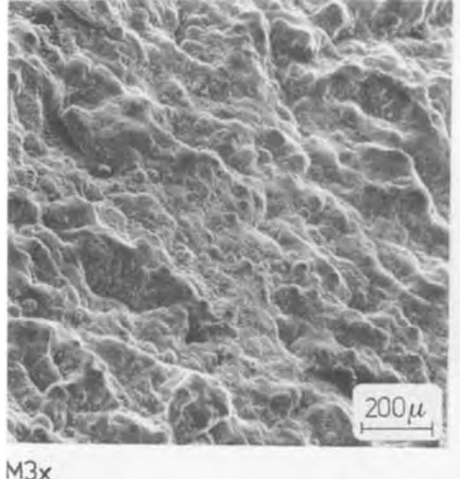
Metallographic tests.—For the description of the further tests only the results of the carbon steel S and the copper containing steel M are used. Also, the 2x weathering is not mentioned any more because the results are similar to those in 1x weathering.

Examined macroscopically, the samples of the 3x-type weathering have a relatively dark, homogeneous-looking surface. No real rust blisters are visible. On the other hand, the rust layers formed on the 1x-type samples have a lighter color. Moreover the surface is covered with numerous big blisters.

Scanning electron microscopy (SEM).—Figure 5 shows the surface of the samples M3x and S3x taken with SEM. Here the rust layer is very homogeneous and compact. The single blisters are very small and of about the same size. The surface of the M3x sample has no visible cracks and on the S3x sample only few thin cracks can be seen.

On the other hand, the pictures of the M1x and S1x samples show a rather inhomogeneous rust surface, as may be seen in Fig. 6. Beside numerous small rust blisters there are also big ones covered with relatively large cracks.

Light microscope tests.—Microscopic observations show the structure of the rust layer. Figure 7 illustrates the metallographic micrographs of samples M3x and S3x. Figure 7a is taken by means of a light microscope, Fig. 7b under polarized light and crossed nicols. The rust layer of the M3x sample consists of two layers: the dark one covering the metal surface and the light one above it. The optical behavior of the dark layer is isotropic. The other layer shows an anisotropic behavior caused by double refraction and is bright orange-colored in the microscope. Electron probe microanalysis showed that in the dark layer the alloying elements and sulfur are accumulated. X-ray diffraction analysis indicated that a large amount of rust has an x-ray amorphous structure. From these results can be con-



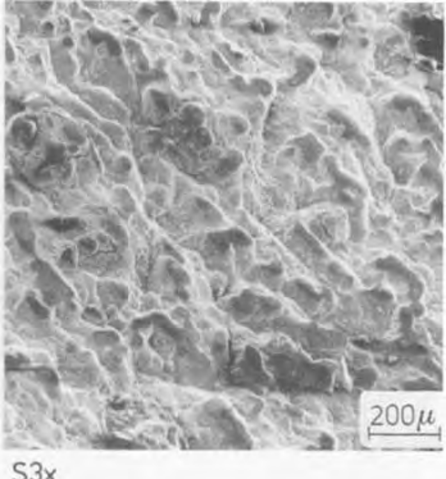


Fig. 5. Rust surface, weathering type 3x, scanning electron microscope.

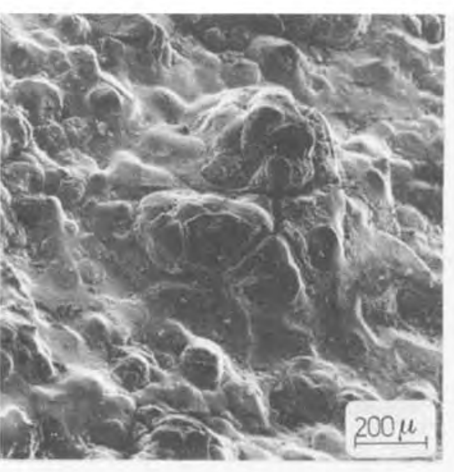

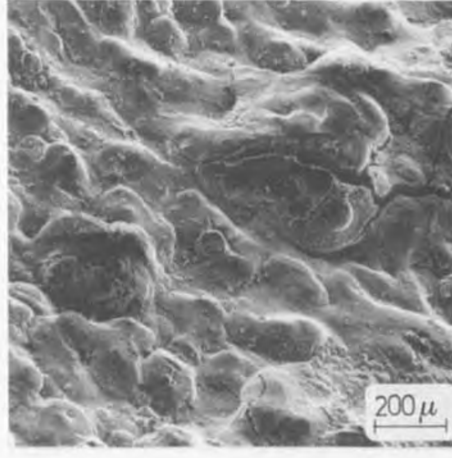

Fig. 6. Rust surface, weathering type 1x, scanning electron microscope.

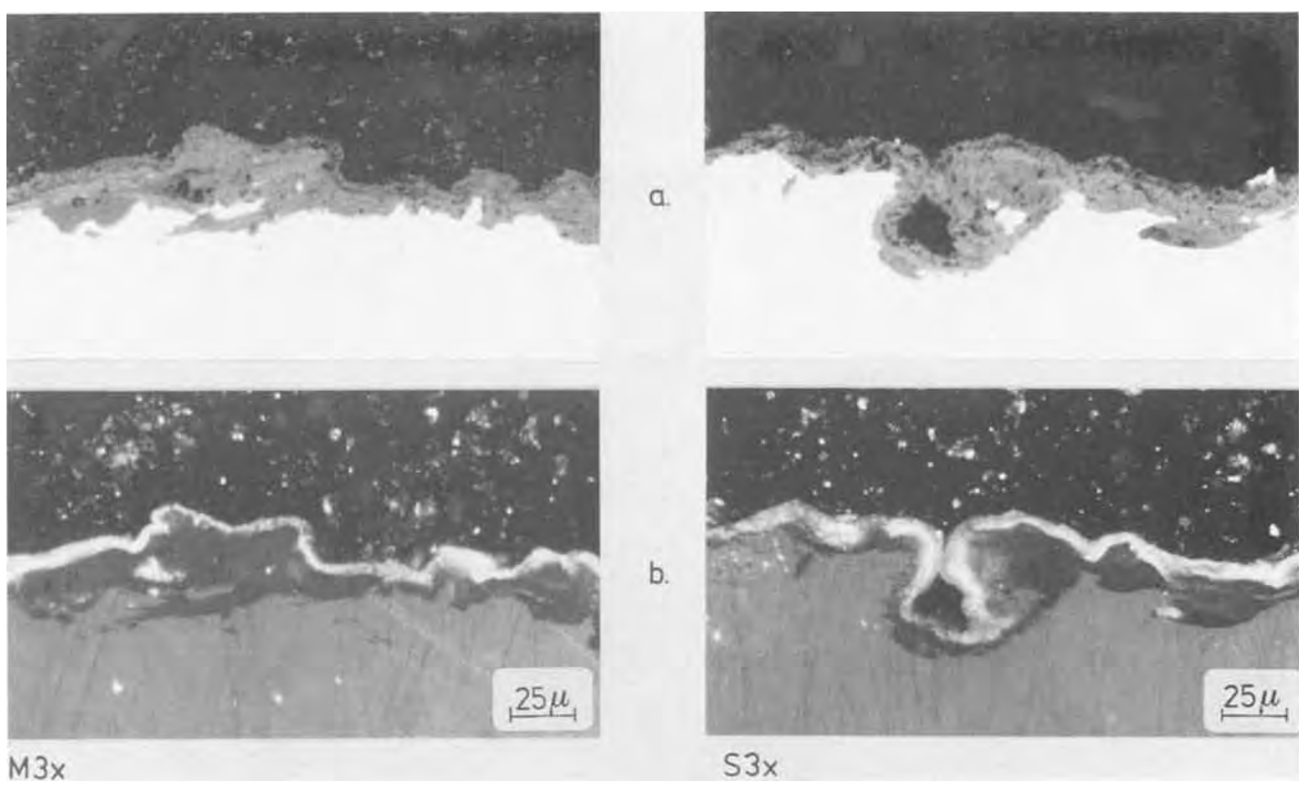

Fig. 7. Cross sections of the rust layers, weathering type 3x: a) light microscope; b) polarized light and crossed nicols

cluded that the dark parts in the cross sections consist of the amorphous $FeO_x(OH)_{3-2x}$ as was already described by Misawa (6).

The surface of the M3x sample is covered at 80-90% with the dark, amorphous layer. The cross section through the rust layer of sample S3x shows a slightly less ordered structure. The light anisotropic layer is a little thicker compared with the dark layer. Yet, the metal surface is largely covered with the gray rust phase.

Figure 8 shows cross sections of the rust layer of the samples M1x and S1x. In the case of 1x-type weathering, the rust layer does not have the same ordered structure as with the 3x-type weathering. The light rust phases also appear directly on the metal surface. The dark rust layer covers here only 50-60% of the whole metal surface. Furthermore, the thickness of the rust layer is not uniform. The rust layer beside the big blisters is usually very thin and consists mainly of the light-colored anisotropic rust phase. Additionally, sul-

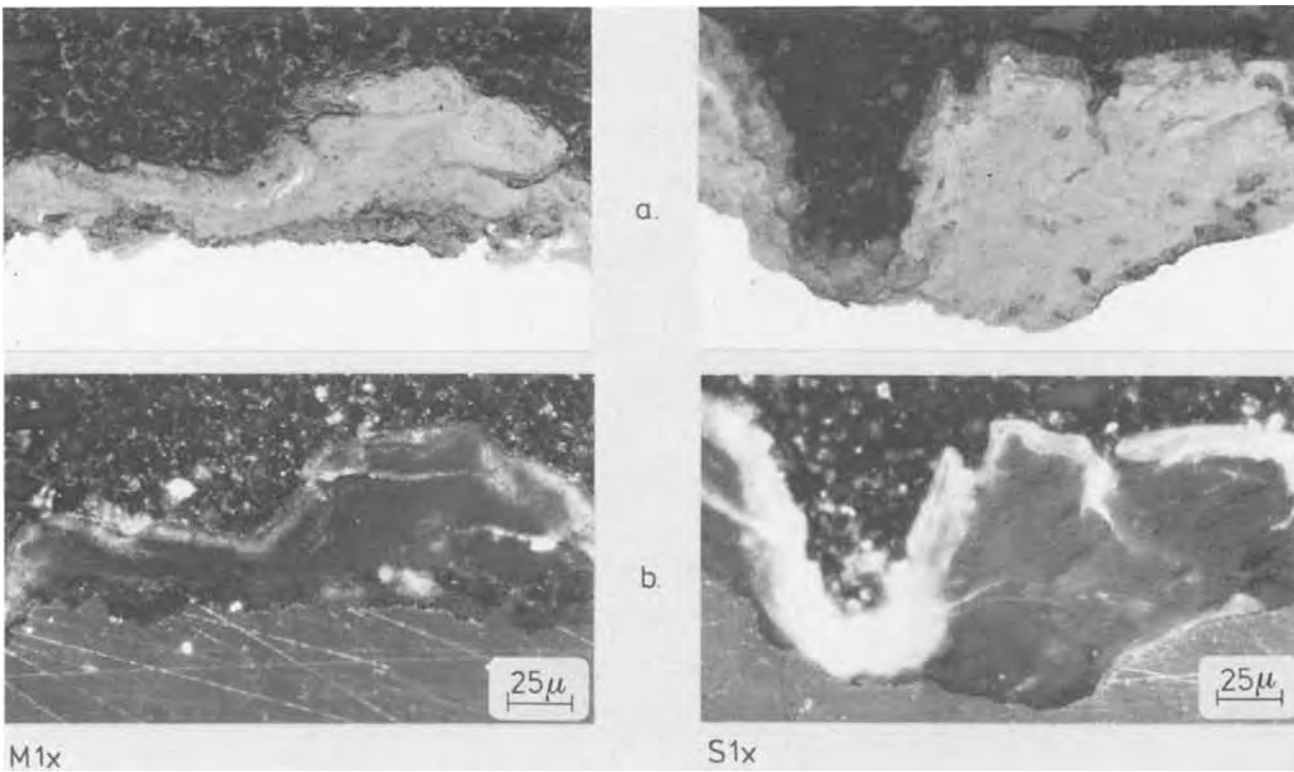

Fig. 8. Cross sections of the rust layers, weathering type 1x: a) light microscope; b) polarized light and crossed nicols

fate pockets are formed as can be seen in Fig. 8 (S1x) right underneath the big rust blister.

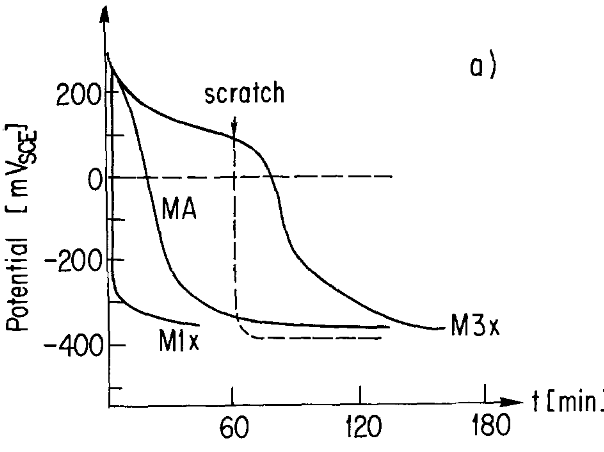
When preparing the metallographic cross sections, the light phases proved to be very brittle and tended to break out easily. The dark layers on the other hand are very compact and can easily be handled. This difference in the mechanical properties is very evident and points to the protective effect of the gray isotropic layer.

Electrochemical measurements.—Potential decay during immersion.—The dry samples were immersed in the electrolyte and the potential was continuously recorded.

Figure 9 shows the potential-time curves of the differently weathered alloyed and unalloyed samples after immersion. The potentials of the 1x-type weathered samples decrease in both cases within a few minutes by 300-400 mV and quickly reach a constant value. In the well-weathered samples this value is reached only after several hours. The constant potential value is nevertheless approximately the same in all the experiments. A rapid potential decay is also achieved by scratching the surface of the well-weathered sample (3x) with a needle (dotted line in Fig. 9).

Furthermore, the low-alloy steel M as well as the unalloyed steel S exposed to natural weathering conditions show quite similar potential-time curves as the 1x weathered samples (curves MA and SA in Fig. 9). This confirms the results already obtained by weight loss measurements where the natural exposure tests were also comparable with the 1x and 2x-type accelerated weathering.

Anodic polarization.—After having been immersed in the electrolyte for 20 min, the samples were anodically polarized.



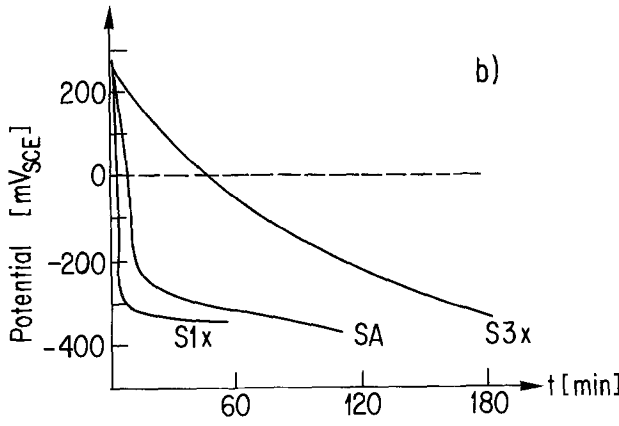


Fig. 9. Potential decay during immersion: a) weathering steel M; b) plain carbon steel S.

Figure 10 shows such polarization curves which are similar to current-potential curves of passive metals. It can be demonstrated that the more the potential decreases during immersion, the larger is the value of the peak current in the anodic polarization curve. Poorly weathered samples always show accordingly high peak-current densities, whereas in well-weathered samples they are extremely small or do not exist at all.

Figure 11 shows the anodic polarization curve of the sample M3x which was scratched during immersion. The peak current density for the passivation of the samples is remarkably higher than in the sample which was only immersed. The passivation potential ϵ_p however has the same value.

The reduction curves, starting in the passive state, also show an activation process in the same potential range, as is shown in Fig. 12. As is expected from the anodic polarization curves, this phenomenon appears more clearly in poorly weathered samples than in well-weathered ones.

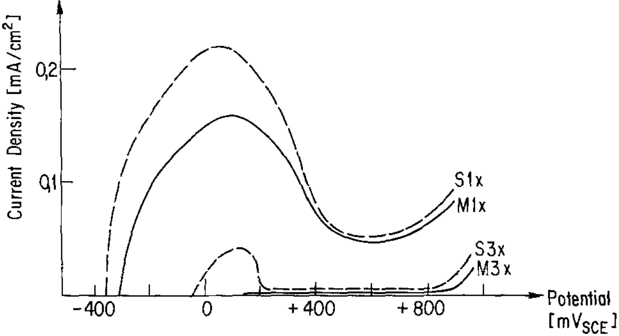

Fig. 10. Anodic current density-potential-curve after 20 min of immersion in 0.1M Na_2SO_4, sweep rate 15 mV/min.

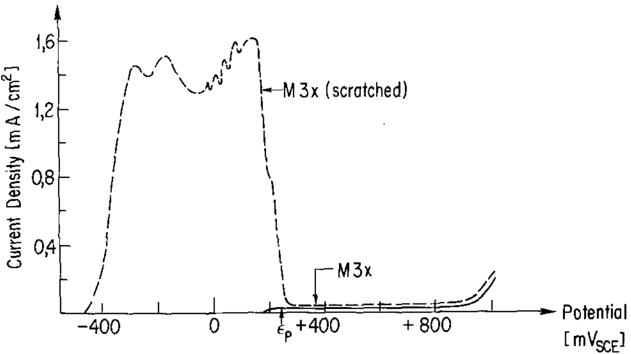

Fig. 11. Anodic current density-potential-curve of a scratched and an undamaged sample, 3x type weathering.

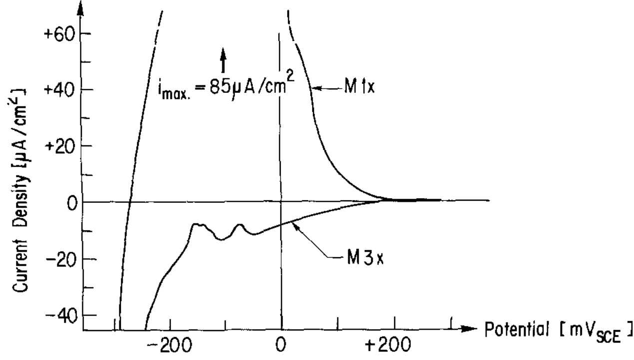

Fig. 12. Cathodic current density-potential-curve of different weathered (1x, 3x) steels immediately after immersion in 0.1M Na_2SO_4, sweep rate 15 mV/min., start at +400 mV.

Discussion

From the results of the electrochemical experiments one can conclude that the weathered samples are in a true passive state at the beginning of the immersion period. But with time the potential decreases to lower values and reactivation of the passive surface occurs. In order to maintain passivity, an easily reducible oxidizing agent has to be present in the rust of the weathered samples. This oxidizing agent keeps the potential of the system in the passive range until it is used up. Nothing can be said from this experiment concerning the quantity and the type of this oxidizing agent. As the different alloying elements do not influence the passivation within the different types of weathering, it may be concluded that an easily reducible part of the ordinary rust is responsible for maintaining passivity. In this experiment such a rust phase could be determined neither by cathodic reduction curves nor by x-ray diffraction analysis. This indicates that the amount is either very small and/or that the structure of the oxidizing agent is not much different from the structure of the ordinary rust.

The test with scratched samples showed that by increasing the active surface the anodic current increases as well. Therefore it can be supposed that the active surface of the poorly weathered samples 1x is much larger compared to the well-weathered ones. This fact explains also why the potential of the samples 1x decayed so much faster to lower values. Passivity is maintained here only until the oxidizing agent is used up.

Moreover the metallographic examinations show that the rust layer of the 1x weathered samples is covered by numerous cracks, in contrary to the rust obtained by 3x-type weathering which is almost free from cracks. In this case the metal surface is mostly covered with the dark compact rust phase. The cracks in the rust layer are supposed to be the sites of active corrosion on the metal surface. The better the steel is weathered, the more it is covered with the protective layer, *i.e.*, the longer the oxidizing agent lasts to maintain passivity. Thus the potential decreases slower. During the drying periods reduced rust is reoxidized again by the atmospheric oxygen, so that the samples are passive again.

With the results obtained so far the following model for the formation of corrosion protective layers on low-alloy steels can be proposed: When the metal surface is exposed to frequent dry/wet cycles, the whole surface corrodes rather evenly. In case of short wet periods no large sulfate pockets are formed. Due to precipitation of insoluble corrosion products and aging the metal surface is gradually covered by a rather compact and mainly amorphous rust layer which protects most of the surface from further attack. Finally the reduction current maintained by reducible rust components is sufficiently large to passivate the residual active areas during the wet periods. The growth of large rust blisters is therefore inhibited and the over-all corrosion rate decreases continuously. This process occurs not only on low-alloy but also on unalloyed steels.

When the metal surface is exposed to long wet periods, the corrosion rate increases and large sulfate pockets are formed. The surface is only partially covered by the corrosion inhibiting amorphous rust layer. In this case the residual active surface areas are considerably larger and can be passivated in the long wet period only for a short period of time. In this way localized corrosion processes are stimulated and due to the formation of voluminous corrosion products large cracks are formed. Finally the whole rust layer is peeled off. The corrosion inhibiting effect of these layers is therefore small.

Reaction of Copper and Copper Oxide with H_2S

S. P. Sharma*

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

The lack of sulfidation of copper in indoor atmospheric corrosion has been attributed to the formation of copper oxide on copper, *i.e.*, the oxide which forms on the copper surface initially inhibits the growth of corrosion (sulfide films) on the surface. A permeation tube apparatus has been constructed with a quartz crystal microbalance (sensitivity $\sim 10^{-8}$g) to elucidate the reaction of copper and copper oxide with H_2S. The film composition was measured with ESCA and Auger spectroscopy and the film thickness was measured with the quartz crystal microbalance to avoid the ambiguity of thickness estimation from sputter rate measurements in depth profiling. Results indicate that copper oxides grown in air (several hundred Å thick) provide good protection against H_2S at low relative humidities, but little protection at high relative humidities. Oxides grown in pure oxygen provide more protection, but still tarnish rapidly at higher relative humidities.

The atmospheric corrosion of copper is of significant interest to the electronic industry. Copper and its alloys are used as substrate materials for gold plated contacts. Porosity and wear processes may expose base metal, and in addition, diffusion of copper to the gold surface may take place. The tarnishing of the exposed copper may cause contact resistance increase and device failure.

Vernon (1, 2) has shown that a thin oxide film on Cu protects the metal from further attack by H_2S in air at room temperature but a sulfide film offers no protection. Baker (3) has studied the migration of corrosion products (sometimes referred to as creep) over the gold surface when copper and gold are in lateral contact and showed that the rate of migration increases with relative humidity. Tierney (4) showed recently that high relative humidity lessens the protective effect of oxide films towards sulfidation in the flowers of sulfur test. Frankenthal (5) has studied the tarnishing of copper in air with sulfur vapors at various humidities using Auger electron spectroscopy. It has been shown that in dry atmospheres the oxide films on copper protect the copper from sulfidation in flowers of sulfur environments (5). However, at higher relative humidities (>70%), the oxide films break down and the sulfide films keep on growing over the oxide.

The concentration of sulfur in the atmosphere generated from flowers of sulfur is much higher than that observed in the field. Also, gaseous pollutants in air normally include more H_2S and SO_2 than free sulfur. In order to understand the behavior of copper oxide films when exposed to gaseous pollutants, a study was conducted to determine the composition and the thickness of the tarnish films developed in an H_2S environment at $\sim$5 ppm level. The effect of relative humidity and H_2S was observed on the tarnishing of Cu metal and Cu covered with oxides of various thicknesses and prepared by two different modes (air and oxygen environment). The exposure of material systems was done in a permeation tube apparatus. The film analyses were made by electron spectroscopy for chemical analysis (ESCA) and Auger electron spectroscopy (AES) in conjunction with argon ion sputtering. The film thicknesses were measured by quartz crystal oscillators (6) and by sputter-back profiling in AES and ESCA. Results indicate that copper oxides grown in air (several hundred Å thick) provide a good protection against H_2S at low relative humidities but provide little protection against H_2S at high relative humidities. Oxides grown in pure oxygen environments provide more protection than air grown oxides.

Experimental

Coupons 15 mm square were cut from a 2.5 mm thick OFHC copper sheet. The coupons were degreased, finished to 600 grit and ultrasonically cleaned in distilled water and dried in air. In addition, 5 MHz AT-cut quartz crystals were coated with an electron beam evaporated Cu 1 μm thick, and were also used as samples. Some coupons and Cu-evaporated quartz crystals were preoxidized in air at 125°C for 18 hr to give an oxide film of $\sim$250Å in thickness. At this oxide thickness, SEM analysis shows that the original surface features are closely reproduced, *i.e.*, the morphology of the films is similar (7). There may, however, be some difference in the structure and composition. Another set of coupons and quartz crystal samples were preoxidized in oxygen for one hour at 150°C to give an oxide film $\sim$300Å in thickness. A third set of coupons and quartz crystal samples were not preoxidized. All samples were exposed to air containing H_2S at various relative humidities.

The exposure was done in a permeation tube apparatus schematically shown in Fig. 1. An FEP (fluorinated ethylene propylene) Teflon tube is filled with H_2S in the liquid state and sealed. After an initial induction period, permeation of the chemical through the tube proceeds at a very constant rate (8). Dry air containing low levels of impurities is obtained from a commercial supplier. All traces of grease, water, and sulfur compounds are removed by filtering the air through activated charcoal and phosphorous pentoxide. The pressure in the incoming air line is maintained at $\sim$5 psig. A double pressure regulator minimizes the pressure fluctuations in the incoming air line. Part of the dry air flows over a permeation tube which is maintained at a constant temperature of 30°C. A measured amount of this air containing H_2S enters the reaction chamber. Another part of the air from the incoming air line flows through a bubbler and is mixed with dry air in a mixing chamber. The amount of the wet air is measured with an electronic mass flowmeter and also enters the reaction chamber. The relative humidity in the reaction chamber can be varied by altering the humidity and the flow rate of wet air. The system flow rates were adjusted so that the H_2S concentration in the chamber was $\sim$5 ppm and the relative humidity was zero or 80%. All measurements were made at room temperature and the flow rate was maintained at 75 ml/min.

The sample coupons were mounted in a rack suspended from the top of the reaction chamber. Quartz crystals 5 MHz, AT-cut, were also suspended from the top. The frequency was measured with an HP-5325A frequency counter. The decrease in the frequency of

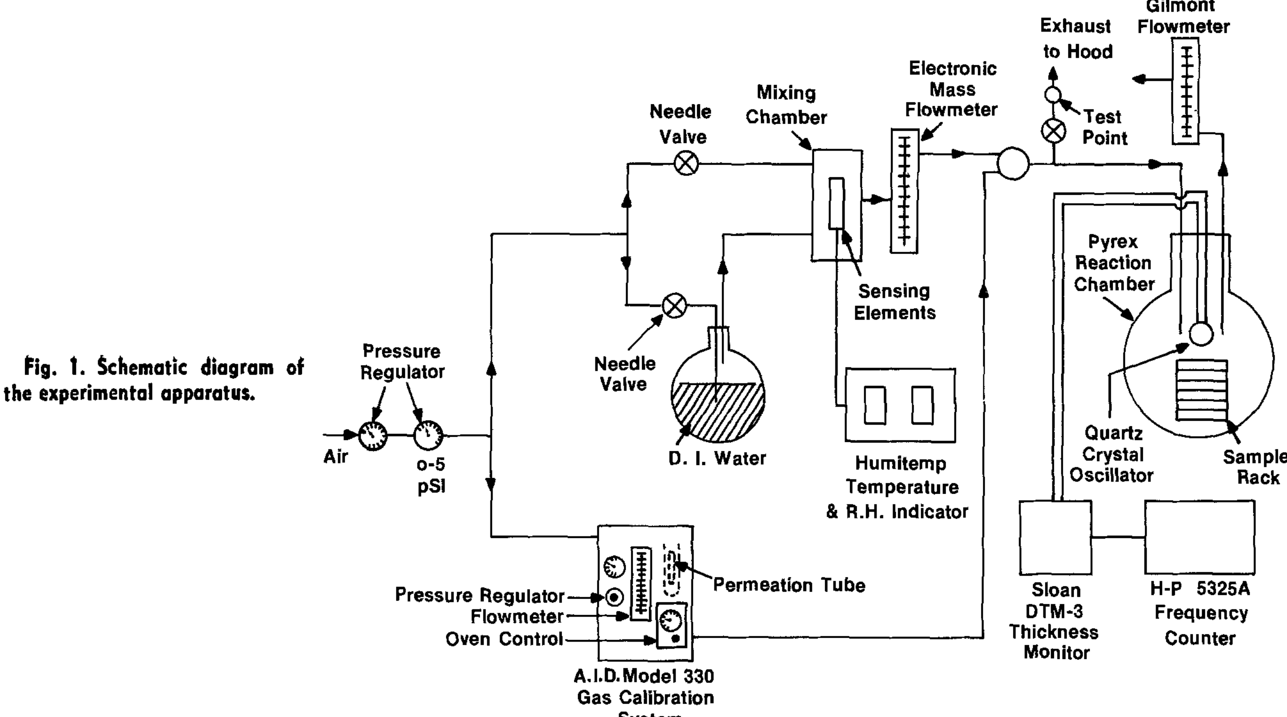

Fig. 1. Schematic diagram of the experimental apparatus.

the quartz crystal is related to the weight gain due to copper corrosion. Weight gain for a given frequency shift is obtained from the crystal constant (6) (1.77×10^{-8}g cm^{-2} Hz^{-1}). This technique provides a sensitivity of $\sim 10^{-8}$ g/cm^2.

The corrosion films were analyzed for the elements present on a Physical Electronics scanning Auger system (AES) and ESCA system. ESCA measurements were made using Mg K_α radiation at 400W input power as described earlier (9). In order to correct for instrumental drift and to obtain an accurate energy calibration, data were referenced to the Au $4f_{7/2}$ line at 84.0 eV using a gold standard. Normal operating conditions for Auger analysis were 3 kV electron gun voltage, 1200V electron multiplier voltage, 1 eV/sec sweep rate, 0.3 sec time constant on the lock-in amplifier, 3 eV modulation amplitude and 1.6 mA emission current. For sputtering, the argon pressure was 5×10^{-5} Torr. Film thickness can also be determined by knowing the sputter rate and the time to sputter through the film. Since the sputter rates of various oxides and sulfides of copper are not known accurately, this process does not yield unambiguous absolute thickness. Thicknesses measured by the quartz crystal oscillator method were therefore employed in this study. The sputter rates were calculated by knowing measured thicknesses (by the quartz crystal microbalance) and sputter times. Some films on quartz crystals were sputtered back and their frequency change was continuously monitored to further check the sputter rates. In addition, the films on the copper coupons exposed for the same amount of time as the quartz crystals were sputtered back. These films on the coupons took the same time to sputter completely at the equivalent settings on the ion gun as the films on the quartz crystals, further supporting the conclusion that the film thicknesses on the coupons and the crystals are the same.

Results

The specimens that were not preoxidized had a measured oxide film <60Å thick. This is the film which rapidly grows on copper at room temperature and is always present on copper surfaces. The rate of further growth of copper oxide (Cu_2O) at room temperature is very slow and during the time of our experiment very little film growth beyond this value will take place. Preoxidized copper samples in air at 125°C for 18 hr were measured to have ~250Å thick film, while Cu_2O films grown on copper in a flowing oxygen environment at 150°C for one hour were measured to have ~300-400Å thick film. The preoxidized or unoxidized copper samples when exposed to sulfur-free air at various RH showed no further film growth. Preoxidized samples exposed to air containing 5 ppm H_2S at 0% RH also showed no further film growth and AES and ESCA analysis showed that the sulfur is present only as an adsorbed species. Figure 2 shows the Auger depth profile of a film on an air oxidized sample exposed to 5 ppm H_2S at 0% RH for 24 hr. By quantitative Auger analysis, it can be shown that most of the film is Cu_2O. It is also seen from this figure that the sulfur is present only as an adsorbed surface

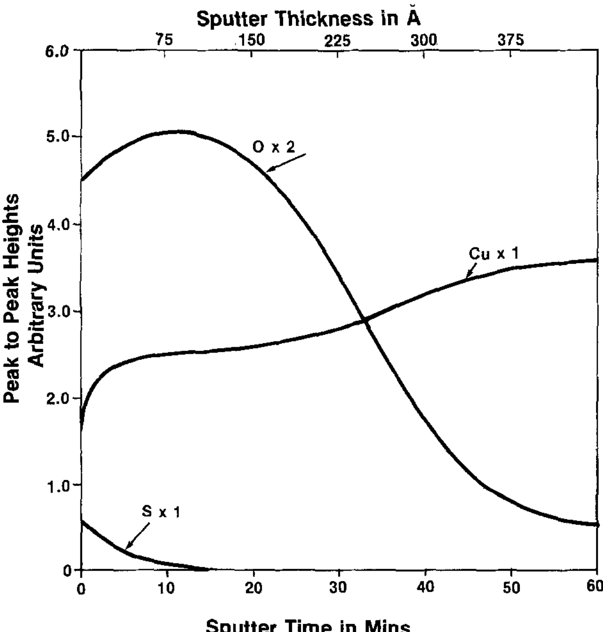

Fig. 2. Auger depth profile of the sulfided sample preoxidized in air and then exposed for 24 hr to H_2S at 0% RH ~5 ppm.

species. A similar kind of depth profile is obtained from O_2-oxidized sample. The situation is quite different on an unoxidized sample. Figure 3 shows the depth profile of a film grown on an unoxidized copper sample exposed to ~5 ppm H_2S, 0% RH for 8 hr. It is obvious that the sulfide film grows on copper and no inhibition of tarnish films occurs in this case.

Figure 4 shows the Auger depth profile obtained from an air-oxidized sample exposed to ~5 ppm H_2S at 80% RH for 20 hr. As seen from this figure, the sulfide film grows over the oxide film. Initially, the surface film is a mixture of oxide and sulfide, for example, at 3 hr exposure (not shown) the elemental composition of the surface film is $Cu_{0.63}O_{0.12}S_{0.25}$. As the exposure increases (>8 hr), the film becomes a layered structure, the top film being the sulfide film. The composition of the surface film is $Cu_{0.65}S_{0.35}$. The surface composition does not change with the exposure time. This kind of layered structure with oxide sandwiched between a mixed sulfide layer and the metal is seen at almost all exposures (>8 hr). Interestingly enough, apart from the sulfide layer growth, the sandwiched oxide layer also increases in thickness with the exposure time. The compositional analysis of the sandwiched oxide layer reveals that this film becomes richer in Cu, *i.e.*, this composition no longer corresponds to Cu_2O, instead it becomes $Cu_{0.82}O_{0.18}$. This suggests that the Cu_2O at higher relative humidities is no longer completely protective when exposed to H_2S.

Figure 5 shows a typical depth profile of a film which grew on a copper sample that has not been preoxidized (exposure time to H_2S—50 hr, 5 ppm, 80% RH). If this film is compared to the film which grows on air-oxidized copper in the same time period (not shown), the film which grows on bare Cu is thicker than the film on air-oxidized samples.

Another set of samples that were preoxidized in an oxygen environment (150°C, 1 hr), were also exposed to 5 ppm H_2S for 8 hr at 80% RH. These samples show less sulfiding than air-oxidized or unoxidized copper (Fig. 6). The composition of the sulfide film is $Cu_{0.66}S_{0.34}$ and the sandwiched oxide composition remains at $Cu_{0.68}O_{0.32}$ (Cu_2O). This suggests that the oxide film grown in oxygen is more protective to H_2S exposure than air-oxidized copper samples.

The kinetic film growth rate data from the quartz crystal microbalance have been plotted in Fig. 7. The x-axis shows the time of exposure in hours and the y-axis is the frequency shift in Hz. The frequency shift can be converted to the total weight of the corrosion product by knowing the crystal constant. The thickness of the sulfide film can be calculated by knowing the density of Cu_2S (from the CRC Handbook), the area of the exposed material on the quartz crystal, and the total weight gain. We can also calculate the rate of film growth for various samples at different relative humidities. It is seen that at 0% RH, the sulfide film growth on copper follows a linear law, while air-oxidized samples show very little corrosion (the linear law may change as the film thickens). At 80% RH, the growth rate is initially linear but becomes parabolic as the thickness increases for both kind of samples, oxidized and unoxidized. This figure can also be utilized

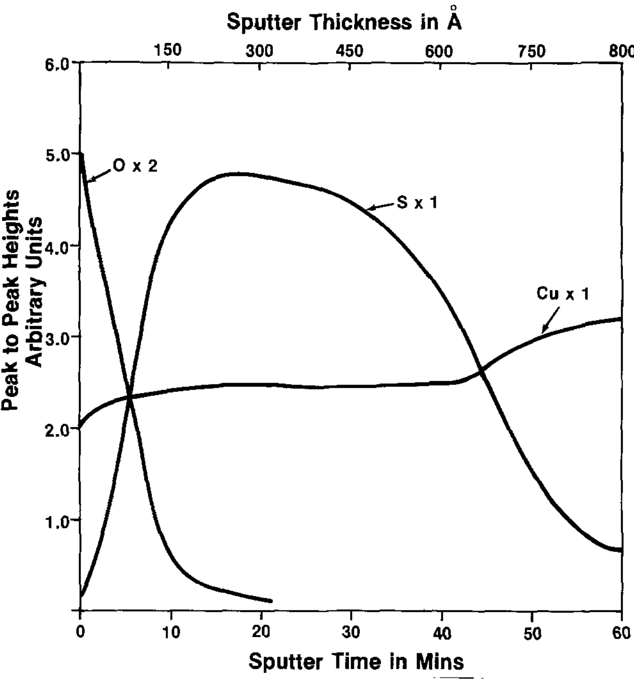

Fig. 3. Auger depth profile from the unoxidized Cu sample exposed for 8 hr to 5 ppm H_2S at 0% RH.

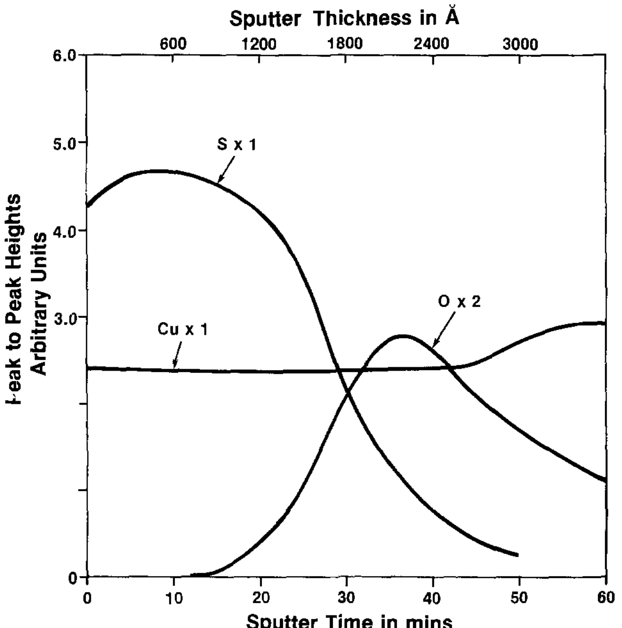

Fig. 4. Auger depth profile from an air-oxidized Cu exposed for 20 hr to 5 ppm H_2S at 80% RH.

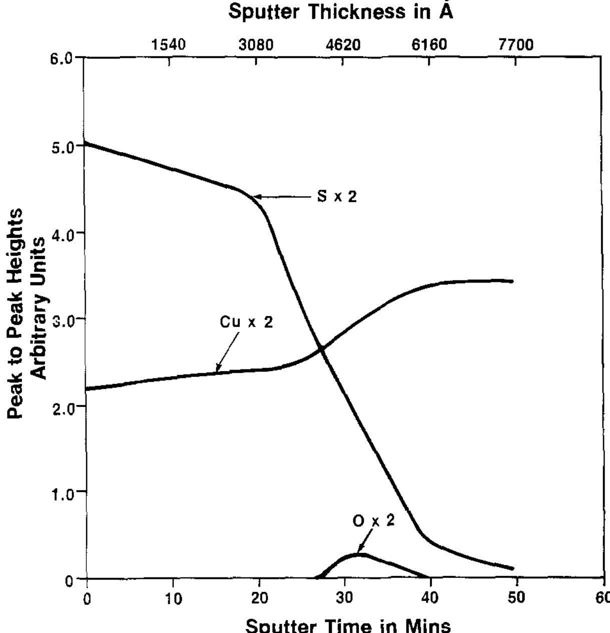

Fig. 5. Auger depth profile from the unoxidized Cu exposed for 50 hr to 5 ppm H_2S at 80% RH.

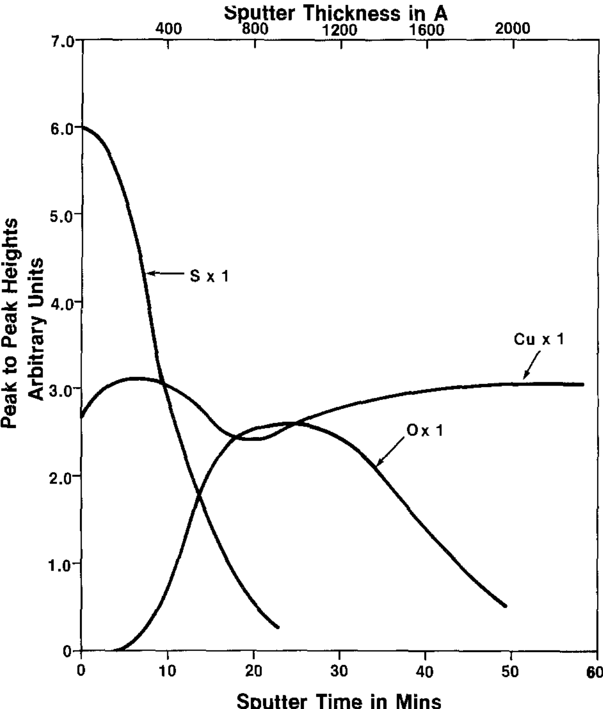

Fig. 6. Auger depth profile from the O_2-oxidized sample exposed for 8 hr to 5 ppm H_2S at 80% RH.

as a quantitative measure of amount of protection offered against sulfidation by various oxidized samples (the density difference between Cu_2S and Cu_2O is not appreciable and the density of the film can be assumed in between Cu_2S and Cu_2O). Figure 7 shows as an inset the film growth rates in the linear region for various samples. In the linear range the film growth on bare copper at 80% RH, is four times the rate of growth at 0% RH. The O_2-oxidized samples offer more protection against sulfidation than air-oxidized samples. Thus, in the linear region at 80% RH, the film thickness on air-oxidized copper is 75% of the film on bare copper, while the film thickness on O_2-oxidized copper is 47% of the film on copper. The film thickness determined from depth profiling will be the total film which has grown on the sample (oxide and sulfide) and can be compared to thicknesses from Fig. 7.

Interestingly, the sulfur Auger peak on bare Cu samples shows a fine structure (at 0% and 80% RH). There are three distinct peaks in the sulfur spectrum at 146, 151, and 156 eV as shown in Fig. 8. The air-oxidized Cu shows the same sulfur peak structure at 80% RH but the 146 eV peak is much less pronounced at 0% RH. Oxygen-oxidized Cu shows the sulfur peak at 146 but it is not very pronounced at either relative humidity. Finally, Fig. 9 shows an ESCA spectra from a typical sulfided Cu sample at 80% RH with insets showing the Cu and S peak structure. The binding energy peak for Cu occurs at 932.5 eV and the sulfur peak structure has been deconvoluted to yield two peaks, one at 161.7 eV and the other at 162.5 eV. ESCA spectra showed no difference in the sulfur peak structure on air-oxidized or bare copper samples at 80% RH. The ESCA analysis confirms the composition to be primarily Cu_2S (Cu at 932.5 eV and S at 161.7 eV). The peak at 162.5 eV in ESCA spectrum suggests

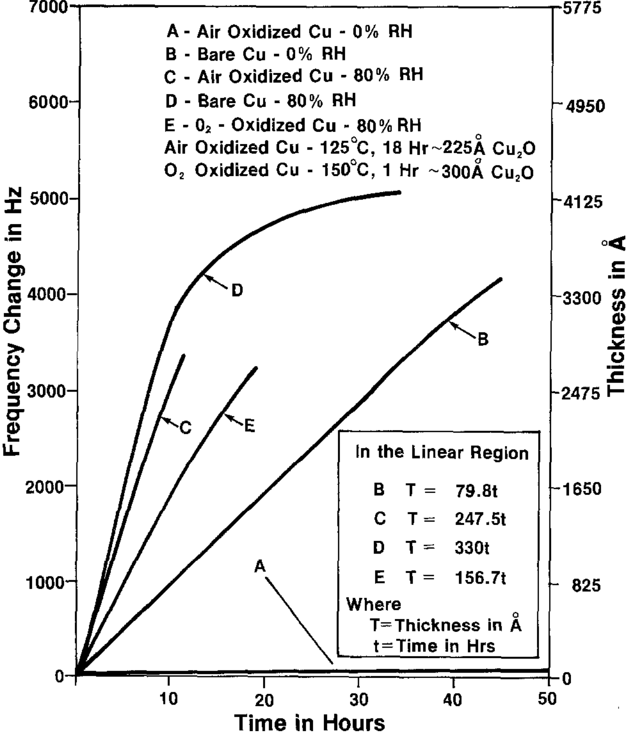

Fig. 7. Kinetic growth rate data obtained from quartz crystal microbalance is shown for various samples.

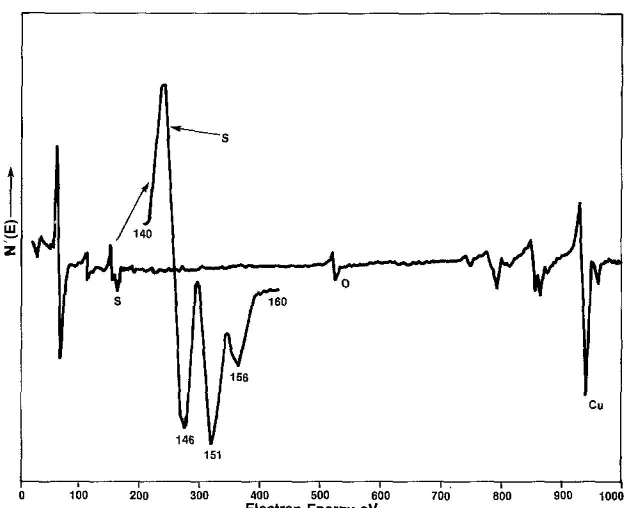

Fig. 8. A typical Auger spectra obtained from bare copper is shown. The three peak structure in the sulfur spectra is clearly visible.

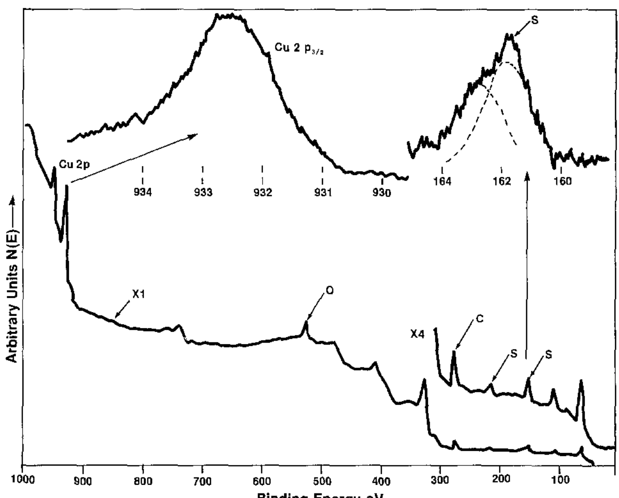

Fig. 9. ESCA spectra from a typical sulfided Cu sample is shown

the presence of free sulfur. At 0% RH, the 161.7 eV peak is not very pronounced on oxidized (air and O_2) samples.

Discussion

Low relative humidity.—In the absence of high relative humidity, the H_2S reaction with bare copper proceeds at a slower rate and the rate is observed to be linear. On preoxidized samples, no significant growth of tarnish films occurs at low RH. This can be explained as follows. Since the oxide thickness on preoxidized samples is considerably greater than the thickness (~60Å) of the oxide present at room temperature (10, 11), and Cu_2O is thermodynamically more stable than Cu_2S or CuS [standard free energy of formation at room temperature for Cu_2O, Cu_2S, and CuS are −34.98, −20.6, and −11.7 kcal/mole respectively (12)], oxide films are protective against further attack at low relative humidities.

Bare copper reacts with dry H_2S (0% RH) as well as with H_2S at a high relative humidity. The reaction rate of H_2S with bare copper at 0% RH is smaller (Fig. 7) than at high RH. Other investigators have observed this before (13, 14). Cu can react with H_2S according to one of the following schemes

	($\Delta G°$ Estimated (15), cal/mole)	
a) $2Cu + H_2S = Cu_2S + H_2$	$-10{,}900 - 1.72T$ (298°-376°K)	[1]
b) $Cu + H_2S = CuS + H_2$	$-5400 + 5.35T$ (298°-376°K)	[2]
c) $Cu_2S + H_2S = 2CuS + H_2$	$150 + 12.43T$ (298°-376°K)	[3]

The first reaction has a lower standard free energy of reaction and is thermodynamically more favorable. In actual experiments, the sulfide on copper is found to be Cu_2S with some free sulfur (16). The activation energy of sulfidation (for Cu_2S) has been measured to be between 17.6 kcal/mole (13) to 21.3 kcal/mole (17). Our experiment and the experiments of others (13, 17) (at higher temperatures) revealed that the rate of tarnishing follows a linear rate law. Earlier authors (13, 17) have also observed that the sulfidation rate (or more specifically, the linear rate constant) increases with increasing concentration of H_2S. From this it can be argued that on bare copper, the rate-determining process is most likely to involve a phase boundary reaction at the gas/film interface (18). At this interface, the following reaction is most probable (13, 17)

1) adsorption of H_2S on the sulfide film

$$H_2S(g) \rightarrow H_2S\ (ads) \quad [4]$$

and

2) dissociation of adsorbed H_2S

$$H_2S\ (ads) \rightarrow H_2 + S^{2-} + 2\oplus \quad [5]$$

where $\oplus$ represents a positive hole in the sulfide. This dissociative adsorption reaction has been observed on nickel, tungsten, and iron at low temperatures (19). The activation energy of H_2S adsorption is very low for these materials (<1 kcal/mole). On other metals such as Ag and Pb, adsorption of H_2S also occurs but is reversible and nondissociative. This may explain why silver does not react with dry H_2S while Cu and Ni do. Since the process of dissociation is more difficult than adsorption, step 2 is likely to be rate-determining. Formation of S^{2-} ion at the gas/sulfide interface results in the depletion of cuprous ions. The usual defect equilibrium for Cu_2S at the gas/sulfide interface can be written as

$$S \rightleftarrows Cu_2S + 2Cu\square' + 2\oplus \quad [6]$$

The cation vacancies ($Cu\square'$) and positive holes $\oplus$ will diffuse inward to the metal/sulfide interface where they will be annihilated as

$$Cu + Cu\square' + \oplus \rightleftarrows Cu^+ + e \quad [7]$$

forming cuprous ion Cu^+ and electron (e) which will diffuse outward to the gas/sulfide interface.

The copper sulfide which grows on copper is much more porous than Cu_2O. This is related to the fact that the volume quotient (that is, the ratio of the volume of the sulfide divided by the volume of the equivalent quantity of metal), which should always be larger than unity, assumes a very high value of 1.95 (18). This leads to high stresses at the metal/sulfide boundary resulting in cracks and fractures in the sulfide layer. Through the appearance of porous layers, the free sulfur may also migrate into the sulfide and come in direct contact with the metal. The three peak structure of sulfur on bare Cu observed in Auger spectra can be interpreted in the light of the above discussion. The most probable explanation is that the peak at 146 eV is due to Cu_2S while the peaks at 151 and 156 eV are due to adsorbed or free sulfur (20). More kinetic energy will be lost for sulfur in a bound chemical state and therefore a chemical shift towards lower kinetic energy might occur for Cu_2S resulting in a peak at 146 eV. The peaks at 151 and 156 eV arise from Auger transitions involving electrons in surface molecular orbitals formed by chemisorption of sulfur or free sulfur not strongly bound to copper (21). The above explanation is only suggestive and needs to be confirmed by further experimentation. In the case of oxidized copper exposed to H_2S at low relative humidity, the peak at 146 eV is not pronounced, confirming the depth profile analysis that sulfur does not react with Cu_2O. ESCA analysis in conjunction with ion sputtering also confirms that free sulfur is present in the entire Cu_2S film on bare copper. The peak at 161.7 eV is due to Cu_2S and at 162.5 eV is due to free sulfur.

Cu_2O does not react with H_2S at low RH because Cu_2O is thermodynamically more stable than Cu_2S as explained earlier and because the oxide thickness hinders the cation migration. In addition the rate of dissociative adsorption of H_2S on Cu_2O may be very small.

High relative humidity.—At high relative humidities Cu_2O reacts with H_2S. The rate of reaction with bare Cu is also much greater. The kinetic growth law starts as a linear law but becomes parabolic as the film thickness increases. This suggests that a different kind of reaction involving H_2S and Cu occurs at high relative humidities, *i.e.*, a reaction involving the aqueous solution at the gas/sulfide interface is important in understanding the kinetics in this case. It is known that H_2S easily dissolves in water. The H_2S therefore goes into aqueous phase in adsorbed water layers on Cu and Cu_2O. From measurements of water adsorption by the author (22), it was found that several monolayers of water are adsorbed on Cu and Cu_2O at 80% RH. For a given relative humidity the amount of $[H_2O]$ adsorbed is greater on Cu_2O than on Cu (22). The oxidation of H_2S to sulfur in aqueous solution takes place with dissolved oxygen according to the following reaction

$$[H_2S]_{aq} + [O_2]_{aq} \rightarrow S + H_2O \quad [8]$$

as suggested by Lilienfield and White (23), Campbell and Thomas (14), and Sneed *et al.* (24).

The composition of the sulfide film at the surface in all exposed samples is $Cu_{0.65}S_{0.35}$ (after an exposure of 8 hr). For air-oxidized Cu, it is also seen that the sandwiched oxide layer increases in thickness with the exposure time and the composition of the oxide film becomes $Cu_{0.82}O_{0.18}$ instead of Cu_2O. A model of

fim growth can be proposed to account for these observations. The growth occurs at the sulfide/oxide interface but not at the oxide/metal interface. Copper ions migrate from the metal/oxide interface through the oxide and this accounts for increasing the ratio of Cu to O_2 in the oxide layer. This may also account for the increase in the thickness of the oxide layer, *i.e.*, some migrating Cu ions may interact with O_2 ions and increase the thickness of oxide layer while increasing the ratio of Cu to O_2. Sulfur ions migrate inwards to the sulfide/oxide interface and it appears that the reaction occurs at the sulfide/oxide boundary.

The copper which has been preoxidized in oxygen offers slightly more protection against sulfidation than air-oxidized copper (Fig. 7). This may partly be due to the fact that the oxide thickness of the O_2-oxidized sample is greater than an air-oxidized sample. In addition, the oxide grown in the oxygen environment is expected to be more compact, *i.e.*, structurally less porous. Cation migration through this oxide may be hindered and the rate of sulfidation will therefore be less. The above argument is strengthened by the fact that most of the sandwiched oxide layer after sulfidation in this case corresponds to Cu_2O, *i.e.*, the rate of oxide breakdown is less.

Conclusions

An experimental permeation tube apparatus has been constructed. By utilizing the quartz crystal microbalance with a sensitivity of 10^{-8} g/cm^2/Hz, ESCA and Auger spectroscopy, the reaction of copper and its oxides with H_2S, has been investigated at various relative humidities. The kinetic growth rate laws have been derived from the thickness measurements. It is concluded that cuprous oxide protects copper against further oxidation or sulfidation in H_2S environment in dry air. Dry H_2S attacks copper and the rate of reaction is linear. The film composition in this case is Cu_2S. At higher relative humidities the rate of reaction with bare copper starts as linear but becomes parabolic as the film thickness increases. In the linear range, the rate of reaction with bare copper at 80% RH is four times the rate of 0% RH. At higher RH, the oxide film breaks down and is attacked by H_2S. The films grown in oxygen offer slightly more protection than those grown in air. Thus in the linear region at high RH, the air-grown and oxygen-grown films have 75% and 47% of the film tarnish rates of bare copper. This difference may partly be due to thicker oxide on the oxygen-grown sample but is most probably due to the fact that these films are structurally less porous. In general, a layered tarnish film structure with an oxide film sandwiched between the metal and the sulfide film (Cu_2S) grows on preoxidized coupons.

Electrochemical Formation of Sulfur at Stainless Steel Surfaces

D. W. Shoesmith, T. E. Rummery, M. G. Bailey, and D. G. Owen

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba, R0E 1L0, Canada

ABSTRACT

The electrochemical formation of elemental sulfur at stainless steel electrodes has been studied in aqueous H_2S solutions at temperatures between 298° and 373°K and a total pressure (with H_2S) of 1.4 MPa. A deposit of sulfur was found only in solutions containing a low concentration of soluble iron ($\lesssim 10^{-6}$ mole dm^{-3}); at higher iron concentrations, pyrite and marcasite formation occurred. All three deposits formed from a common polysulfide intermediate, the nature of the deposit depending on the relative concentrations of soluble iron and polysulfide at the surface of the stainless steel.

In a previous paper (1), formation of iron disulfides, pyrite, and marcasite, on stainless steel surfaces from aqueous H_2S solutions at a total pressure of 1.4 MPa, was shown to occur via an electrocrystallization mechanism. Oxidation of H_2S to polysulfide species occurred as an anodic reaction at the stainless steel, followed by deposition of ferrous ion (as FeS_2) transported from a corroding carbon steel surface. Marcasite was formed only when the concentration of S_2^{2-} was increased by applying an anodic current to the stainless steel. From these results, it was concluded that marcasite can form when the concentration of S_2^{2-} is high relative to the concentration of Fe^{2+}.

This mechanism offers an explanation for the observation of pyrite and marcasite deposits on stainless steel surfaces at temperatures $\gtrsim$ 353°K in heavy water (D_2O) production plants utilizing the Girdler sulfide process (2, 3). However, small quantities of elemental sulfur can also form on the stainless steel sieve trays in the Girdler sulfide process and the purpose of this communication is to show that a similar mechanism to that previously described (1) could be, at least in part, responsible for these sulfur deposits.

Experimental

Experiments were performed in a thermostatted titanium autoclave containing aqueous solution pressurized with H_2S. The details have been discussed previously (1). To prevent charging and poor resolution during scanning electron microscopic examination, the sulfur deposits were coated with a thin gold film. Unless otherwise stated, all experiments were carried out for 160-170 hr at a total pressure (with H_2S) of 1.4 MPa. A temperature of 373°K or lower was used to avoid significant thermal cracking of the H_2S on the autoclave walls in the vapor space above the aqueous solution.

Results

The potential of the stainless steel electrode varied with the Fe^{2+} concentration as shown in Fig. 1. The datum for the intermediate soluble iron concentration (open circle in Fig. 1) was obtained using a small carbon steel electrode (5 cm^2) to supply soluble iron; data at higher iron concentrations (solid circles in Fig. 1) were obtained using a larger electrode (32 cm^2). The most anodic point (x in Fig. 1) was measured in an "iron-free" system. In this experiment no carbon steel electrode was included in the autoclave. The residual iron in solution resulted from dissolution from the autoclave walls of traces of iron disulfides deposited during previous experiments. The vertical dashed line in Fig. 1 represents the equilibrium potential for the reaction

$$H_2S \rightleftharpoons S_\alpha + 2H^+ + 2e \quad [1]$$

under the conditions used. This value was taken from the calculations of MacDonald and Hyne (4).

In Fig. 2, the potential of the stainless steel electrode in "iron-free" solution is plotted as a function of applied anodic current and compared to the data previously recorded for pyrite and marcasite deposition (1). The dashed lines in Fig. 2 represent the equilibrium potentials for reaction [1] and for the further oxidation of sulfur to sulfate via reaction [2]

$$S_\alpha + 4H_2O \rightleftharpoons SO_4^{2-} + 8H^+ + 6e \quad [2]$$

Table I summarizes the nature and location of the deposits found in the autoclave. At 373°K and with zero applied current (experiment 1), no sulfur was detected in the autoclave. At an anodic current of

ND Nothing detected.

100 μA (experiment 2), a deposit of sulfur[1] was obtained around the upper rim of the autoclave. A trace deposit of what was probably sulfur also formed on the stainless steel electrode. When the 100 μA experiment was repeated and the autoclave periodically vented and recharged with H_2S (experiment 3), no sulfur deposit was obtained. This indicated that the deposit on the upper rim of the autoclave in experiment 2 was formed from sulfur in the H_2S vapor when the autoclave was cooled prior to opening. The periodic venting in experiment 3 removed this sulfur vapor and consequently no deposit was formed. Its formation by reaction of H_2S with O_2 can be ruled out since O_2 was carefully excluded from the autoclave (1). When the current was increased to 250 μA, no sulfur deposit was obtained (experiment 4).

When both the current and the temperature were reduced (experiment 5), a large deposit of elemental sulfur was obtained on the stainless steel electrode. The morphology of this deposit is shown in Fig. 3. X-ray spectroscopy showed that both the upper layer chain-like deposit [Fig. 3(b)] and the nodular base layer [Fig. 3(c)] were sulfur. No deposit was obtained on the autoclave walls at this temperature. An unpolarized stainless steel electrode situated close to the anodically polarized electrode in the autoclave showed only faint traces of a sulfur deposit. A further reduction in temperature to ≈298°K (experiment 6, Table I) resulted in the formation of substantial deposits of sulfur on all surfaces throughout the autoclave, including those above the surface of the liquid. In this case the potential of the stainless steel electrode rose to greater than 2.0V and became erratic. Figure 4 shows a photomicrograph of the stainless steel surface. The x-ray energy spectrum of the surface indicated that the deposit was essentially all sulfur.

[1] Only S_α, the low temperature, orthorhombic form, was observed. Any sulfur deposited at > 96°C would probably be monoclinic, but unless very careful annealing or rapid quenching is performed, this transforms rapidly to α-S_8.

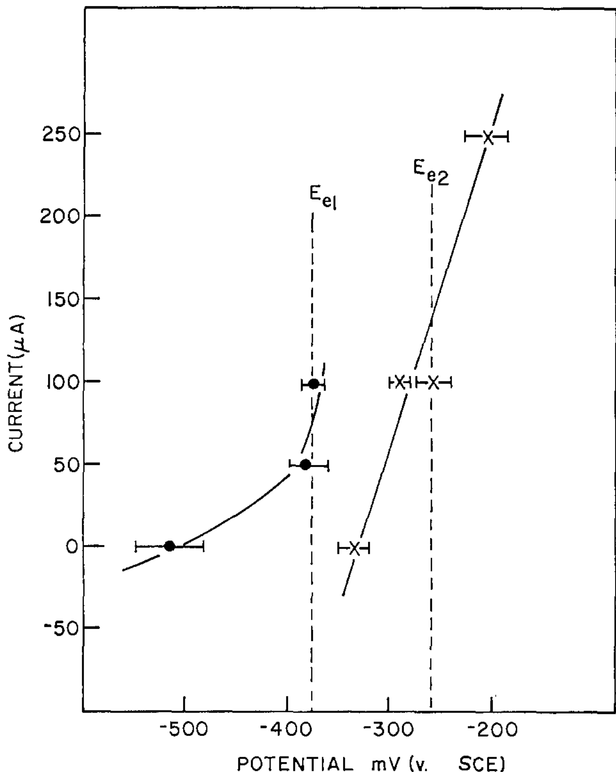

Fig. 2. Potential of stainless steel electrode as a function of applied current at 373°K and 1.4 MPa total pressure (with H_2S); —X— data recorded in "iron-free" solutions; —●— previously published data from Ref. (1); ---- equilibrium potentials for reaction [1] (E_{e1}) and reaction [2] (E_{e2}).

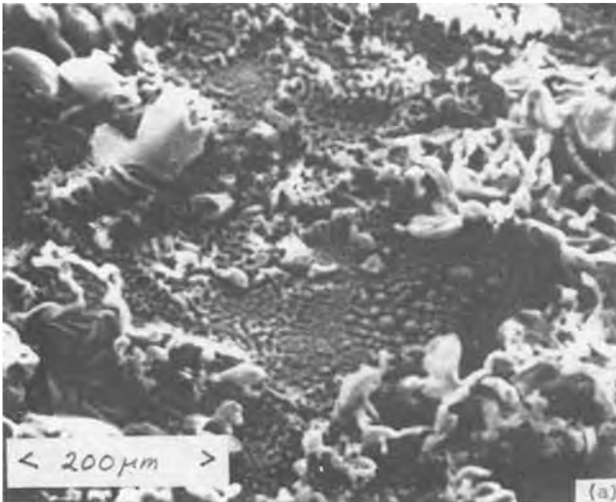
Discussion

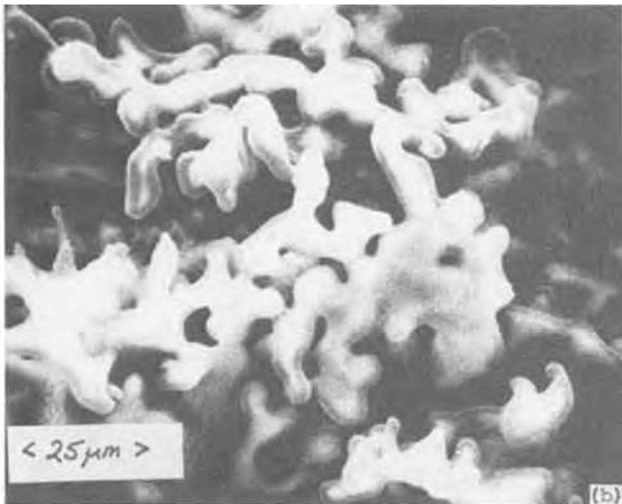
The data of Fig. 1 show that as the soluble Fe^{2+} concentration was decreased the potential of the unpolarized stainless steel shifted to more anodic values. This is as expected from the potential-pH diagram for the Fe-H_2S-H_2O system (1, 4) if the potential of the stainless steel is governed by the reaction

$$Fe^{2+} + 2H_2S \rightleftharpoons FeS_2 + 2H^+ + 2e \quad [3]$$

as previously demonstrated (1). For potentials greater than the equilibrium potential for reaction [1], the formation of elemental sulfur becomes thermodynamically possible. This condition was achieved in the "iron-free" solution (point x in Fig. 1). The fact that no elemental sulfur, or at the most only traces, were found (experimental, Table I) showed that the reaction was very slow at 373°K in the absence of an applied current.

The application of an anodic current (cf. experiments 1 and 2 in Table I) accelerated the formation of sulfur. However at 373°K transfer of sulfur from the liquid to the vapor phase occurred, sulfur being deposited on the autoclave walls. The mechanism of this transfer has not been studied but one possibility is that the sulfur deposit on the electrode [or a polysulfide intermediate (1)] dissolved to give aqueous polysulfide species and, subsequently, gas phase sulfanes (H_2S_x). Entrainment of sulfur in H_2S gas streams has been shown to occur for temperatures above the melting point of sulfur (5, 6), but not at the temperatures used in the present work. However there will be a finite concentration of polysulfide in solution [$\approx 10^{-8}$ mole dm^{-3} under the conditions used (7)] and the sulfane H_2S_2 has a high vapor pressure, boiling at 343°K at normal pressure (8). Consequently the proposed pathway for the transfer of sulfur from liquid to vapor is not unreasonable. The fact that the transfer occurred suggested that the rate of such a process was significant at 373°K.





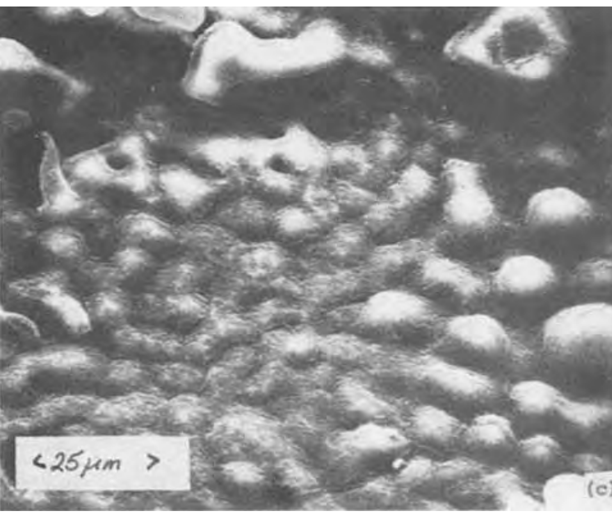


Fig. 3. Scanning electron photomicrographs of the elemental sulfur deposit on the stainless steel electrode after experiment 5 of Table I; (a) general surface, (b) upper layer deposit, (c) base layer deposit.

Dissolution and transfer of sulfur to the vapor was negligible at 323°K as shown by experiment 5 in Table I. The deposit remained localized on the stainless steel surface. The reason for the variations in morphology of the sulfur deposit is not known. One possibility was that the upper layer deposit [Fig. 3(b)] resulted from a precipitation reaction due to the finite solubility of the sulfur under these conditions.

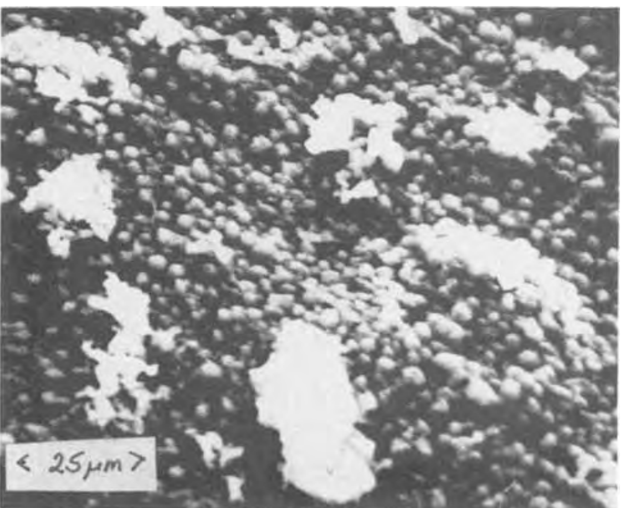

Fig. 4. Scanning electron photomicrograph of the elemental sulfur deposit on the stainless steel electrode after experiment 6 of Table I.

If the current was increased to 250 μA at 373°K (experiment 4, Table I) no elemental sulfur was formed in the autoclave. Under these conditions the potential at the stainless steel electrode was more positive than the equilibrium potential for reaction [2] (Fig. 2) and it is likely that further oxidation of the sulfur to sulfate (or some intermediate oxidized state) occurred.

No attempt was made, in the present work, to characterize the nature of the corrosion film occurring on the stainless steel. However the current-potential data of Fig. 2 suggest that for the major part, the electrode potential was set by reactions 1 or 3. The one obvious exception is experiment 6 (Table I) where the potential of the stainless steel was $>$2.0V and all surfaces in the autoclave were covered with elemental sulfur. In this case the stainless steel was passivated either by the deposit of spherical sulfur particles (Fig. 4) or by an underlying film of iron and chromium oxides or sulfides. The potential of the stainless steel was sufficiently positive to cause the decomposition of water to O_2, which leads to the oxidation of H_2S via the reaction

$$2H_2S + O_2 \rightarrow 2S + 2H_2O \quad [4]$$

both in solution and in the gas phase (9, 10). The elemental sulfur so formed settled on any convenient surface. The ill-formed, larger particles shown in Fig. 4 were probably sulfur particles formed in aqueous solution, via reaction 4, which subsequently settled on the stainless steel surface.

The formation of elemental sulfur on anodically polarized metal surfaces in sulfide solutions has been

observed in a number of situations. Thus sulfur can be deposited on platinum from aqueous sulfide solutions (11, 12) and from polysulfide solutions in potassium thiocyanate melts (13). It has also been deposited on vitreous carbon and pyrolytic graphite electrodes from polysulfide melts (14). Little information is available on the mechanism of formation of elemental sulfur. The nodular nature of the base layer deposit [Fig. 3(c)] suggested the nucleation and growth of individual centers. A mechanism consistent with the present observations, and with the previously observed formation of iron disulfides in the presence of soluble iron, involves a polysulfide intermediate (1)

$$H_2S_{ads} \rightarrow SH_{ads} + H^+ + e \quad [5]$$

$$SH_{ads} + H_2S_{ads} \rightarrow H_2S_{2ads} + H^+ + e \quad [6]$$

The further oxidation of this intermediate would lead to the formation of sulfur

$$4H_2S_{2ads} \rightarrow S_8 + 8H^+ + 8e \quad [7]$$

As shown in the previous paper (1) the presence of soluble iron leads to the formation of pyrite and marcasite and the prevention of further oxidation via reaction [7]. The alternate processes can be summarized in the following reaction scheme

$$2S^{2-} \xrightarrow{-2e} S_2^{2-} \begin{cases} \xrightarrow{Fe^{2+}} \text{Pyrite } (FeS_2) & \{[Fe^{2+}] > [S_2^{2-}]\} \\ \xrightarrow{Fe^{2+}} \text{Marcasite } (FeS_2) & \{[Fe^{2+}] < [S_2^{2-}]\} \\ \xrightarrow{\text{reaction [7]}} S_8 & \{[Fe^{2+}] \rightarrow 0\} \end{cases}$$

Protons have not been included in this reaction scheme although they are probably involved. Their production during the anodic reactions [5] to [7] will not lead to pH variations since an equivalent number will be consumed in the cathodic reaction.

Thus in the absence of soluble iron, the formation of elemental sulfur could occur via an electrochemical mechanism in heavy water production plants using the Girdler sulfide process. However at 373°K the rate of sulfur production would be very slow. Finally both disulfide and elemental sulfur formation appear to proceed through the same polysulfide intermediate.

Stress Corrosion Cracking and Electrochemical Behavior of AISI 304 Stainless Steel in Chloride-Containing Sulfate Solutions

H. S. Tong and D. J. Swartz

Allied Chemical Corporation, Morristown, New Jersey 07960

ABSTRACT

The slow strain rate testing technique was used to study the stress corrosion cracking (SCC) susceptibility of AISI 304 stainless steel in chloride-containing 35% $(NH_4)_2SO_4$ solutions at 104°C. The SCC susceptibility was evaluated from experimentally obtained quantitative expressions for the decreases of ultimate tensile strength and reduction of area in these solutions compared to inert conditions. The inhibiting effect of nitrates was also studied. Electrochemistry of the alloy-environment system is presented, and correlation between SCC susceptibility and the electrochemical parameters was established. Results are summarized as follows: (*i*) SCC of 304 SS may occur in the chloride-containing sulfate solutions at 104°C, (*ii*) the critical chloride concentration is 2000 ppm or less, above which SCC will occur, (*iii*) the threshold nitrate concentration is 1000 ppm or less, above which SCC can be inhibited, and (*iv*) the results are consistent with the view that SCC and pitting initiate in the same way.

The austenitic stainless steels are extensively used in chemical plant construction because of their general resistance to many common corrodents. They are used in the area of vessels, piping, valves, heat exchangers, and supporting hardware. Type 304 has been extensively used because of its economy and relative ease of fabrication, taking proper precautions to minimize the deleterious precipitation of carbides in the heat affected zone. A continuing problem with the use of the austenitic alloys has been the danger of stress corrosion cracking (SCC) in certain environments and stress situations. One of the well-known and probably most widely encountered form of SCC is that caused by the presence of chloride ion (1-5). Consequently many studies have been performed to determine mechanisms (6, 7), and to obtain data in specific systems on concentration and temperature (8, 9) bounds below which these alloys could be confidently applied. Considerable efforts have also been expended to determine the inhibiting effect of anions on the SCC of stainless steels in the chloride-containing media. For example, Uhlig and Cook (10) have shown that the addition of small amounts of nitrate, acetate, iodide, and benzoate inhibit SCC in $MgCl_2$ at 130°C. Okada (11) also reported that SCC propagation in the $MgCl_2$ solution may be halted by the presence of sodium nitrate.

The present paper presents data on a specific system which has been known to exhibit SCC in an operating chemical plant. The inhibiting effect of nitrate was also studied. Several observations were made which support empirical knowledge obtained in large scale use and the electrochemical characteristics of the system was examined.

Experimental Procedure

The test alloy was prepared in a form of 0.635 cm (¼ in.) diam rods. The rods were quench annealed. Chemical analysis [weight percent (w/o)] of the steel was Ni-8.9, Cr-18.3, C-0.04, Si-0.02, Mo-0.2, and Cu-0.4. Specimens were pickled in 10% oxalic acid and cleaned with acetone and deionized water prior to testing. Round specimens with a reduced testing gauge of approximately 3 mm diam were used to facilitate uniform deformation and allow complete immersion, which negates problems associated with the liquid-vapor interface and cell seals. The test solution was 35% w/o $(NH_4)_2SO_4$ with various chloride and nitrate concentrations, to which chloride was added as NaCl and nitrate was added as NH_4NO_3.

The constant strain rate tensile testing technique was used in this test and the assembly is shown in Fig. 1, which is similar to that used elsewhere (12). The specimen is threaded at both ends to connect both supporting rods. The lower supporting rod is fixed to the lower plate of the metal frame by two stainless nuts to provide firm support during the specimen

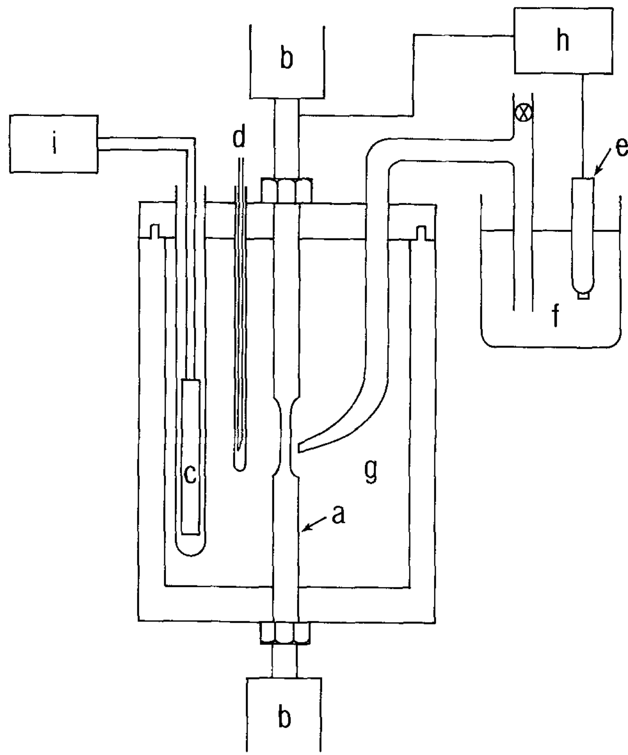

Fig. 1. Schematic assembly for SCC test: (a) specimen, (b) slow strain rate test machine, (c) heating rod, (d) thermocouple, (e) calomel electrode, (f) saturated KCl solution, (g) test solution, (h) potentiostat, and (i) heat control system.

straining experiment. A Teflon corrosion cell of 500 ml capacity is used with the specimen sealed at the point of entry into the cell by passing it through a Teflon fitting. The top of the cell was sealed by a removable Teflon cover with a loosely fitted Teflon fitting through which the specimen emerged from the cell. A salt bridge capillary was located near the surface of the test specimen, leading to a saturated calomel electrode. A heating rod and a thermocouple were inserted into the cell to heat the solution and monitor the temperature of the solution, respectively. Air at about 7.0×10^4 Pa (10 psi) was bubbled through the solution during the test.

After the specimen was mounted inside the test cell, the test cell was heated to the desired temperature, *i.e.*, 104°C. The specimens were not strained until a stable equilibrium testing temperature was reached. It was gradually pulled until the load cell on the strain ing machine registered a slight load, indicating the absence of slack between the pull rod, universal joint, and the specimen. Straining was then continued at a crosshead speed of 7.00×10^{-5} min^{-1}. The load, elongation, and open-circuit potential (OCP) being monitored continuously until fracture occurred. The reduction of area (ROA) of the fractured specimen was then measured, and the fracture morphology was studied by means of scanning electron microscopy (SEM).

Anodic polarization was also studied on each alloy/environment system at a scan rate of 6 mV/min. The solution was saturated with air. The anodic polarization curves were obtained starting from the corrosion potential. Potentials were measured against a saturated calomel electrode, as were all potentials in this investigation. The ASTM recommended (13, 14) practice was taken into account in making the electrochemical measurements.

Results

Stress-elongation curves.—Stress-elongation curves obtained in various environments at a strain rate of 7.00×10^{-5} min^{-1} are shown in Fig. 2. The constant strain rate tensile test was initiated when the temperature reached a constant value, *i.e.*, 104° ± 1°C. A little variation was observed at the initial stage because of the sliding resistance of the pull rod. From the results, it can be seen that there was relatively little difference between stress-elongation curves in controlled 35% $(NH_4)_2SO_4$ solution (no chloride) and those in the solution containing 1000 ppm chloride. However, relatively severe decreases in elongation were observed in the solutions containing 2000 ppm Cl^- and above.

The crack velocity was estimated from the measured crack depth and the time to failure. Cracking was assumed to have initiated when the load exceeded the yield strength of the material. It is interesting to note that the crack velocity increases slightly with increasing chloride concentration (for example, see Table I).

It is known that the SCC severity can be evaluated from the decrease in the ultimate tensile strength (UTS) and the decrease in the reduction of area

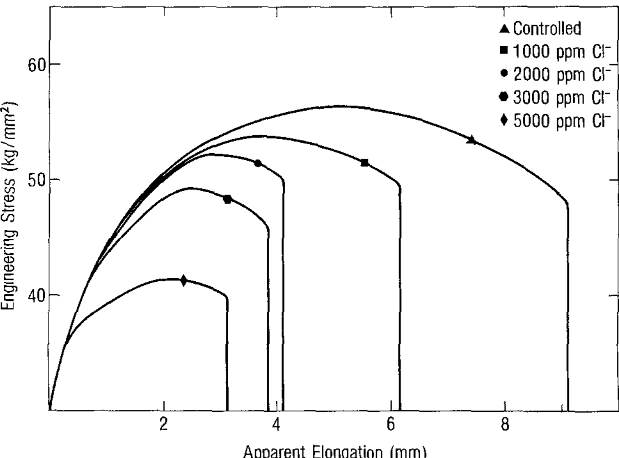

Fig. 2. Engineering stress-apparent elongation curves obtained in 35% $(NH_4)_2SO_4$ solutions with different Cl^- concentration at 104°C.

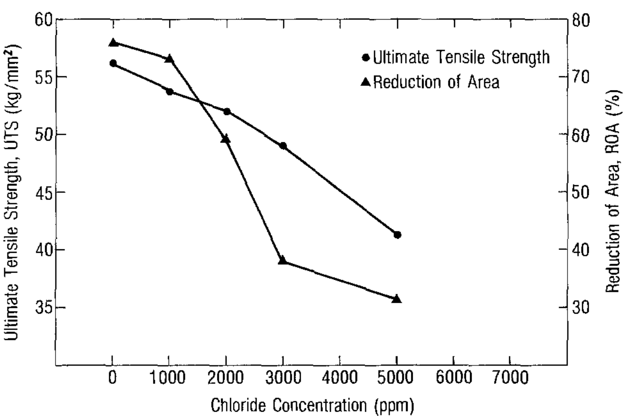

Fig. 3. Effect of Cl^- concentration on reduction of area (ROA) and ultimate tensile strength (UTS) in 35% $(NH_4)_2SO_4$ solutions at 104°C.

(ROA) in these solutions compared to the controlled conditions. The effect of chloride concentration on UTS and ROA is shown in Fig. 3. Results indicated that significant decreases in UTS and ROA occur in the solutions containing 2000 ppm Cl^- or above, which suggests that SCC may occur in those solutions. Visual examination of specimen surfaces confirmed the presence of rapid stress corrosion cracking at 2000 ppm Cl^- and the absence of cracking in the controlled condition. Cracks are clearly visible in the specimen side faces exposed to the sulfate solution containing 2000 ppm Cl^- (Fig. 4).

Scanning electron microscopic (SEM) studies have been carried out to examine the fracture morphology after each test, and the results are consistent with the slow strain rate test results. A typical transgranular

Solution	Total time to failure (hr)	Time for crack propagation (hr)	Average crack velocity (cm/sec)	Remarks
35% $(NH_4)_2SO_4$	86.4	42.4	4.1×10^{-7}	Ductile
35% $(NH_4)_2SO_4$ + 1000 ppm Cl^-	57.1	27.0	6.8×10^{-7}	Ductile
35% $(NH_4)_2SO_4$ + 2000 ppm Cl^-	37.0	13.3	1.7×10^{-6}	TGSCC
35% $(NH_4)_2SO_4$ + 3000 ppm Cl^-	36.2	14.8	1.9×10^{-6}	TGSCC
35% $(NH_4)_2SO_4$ + 5000 ppm Cl^-	28.5	8.7	3.4×10^{-6}	TGSCC
35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- + 100 ppm NO_3^-	32.1	15.4	1.3×10^{-7}	TGSCC
35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- + 1000 ppm NO_3^-	63.8	33.7	2.3×10^{-7}	Ductile
35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- + 8000 ppm NO_3^-	65.1	37.2	1.8×10^{-7}	Ductile

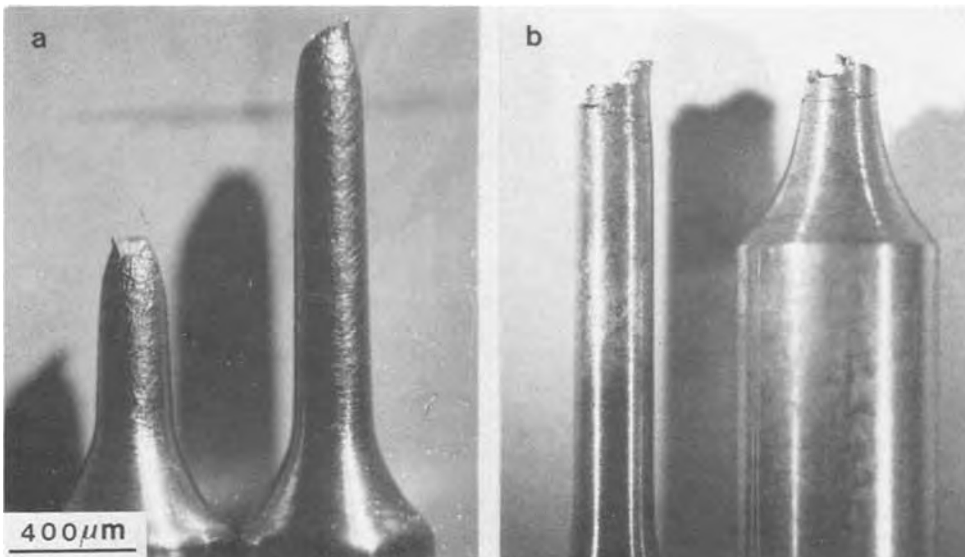

Fig. 4. Photomacrographs of specimens after slow strain rate experiment: (a) ductile failure in 35% $(NH_4)_2SO_4$ solution, and (b) SCC in 35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- (original diam 2.54 mm).

cleavage-like fracture surface was observed in the specimens tested in the solution containing 2000 ppm Cl^- or above (see Fig. 5c-5e), while only dimple-like fracture structure was evident throughout the fracture surfaces in those solutions containing lower chloride concentrations (see Fig. 5a and 5b). In the case of the transgranular-type morphology multiple cracks were commonly observed. Figure 6 shows the typical multiple branching associated with SCC. Combining the above results suggests that SCC in this alloy/environment system will occur in the solution containing Cl^- somewhere in the range of 1000-2000 ppm.

Fig. 5. SEM fractographs of specimens after a slow strain rate experiment in 35% $(NH_4)_2SO_4$ solution containing (a) 0 ppm Cl^-, (b) 1000 ppm Cl^-, (c) 2000 ppm Cl^-, (d) 3000 ppm Cl^-, and (e) 5000 ppm Cl^- at 104°C.

Since it has been reported (10) that the presence of nitrate may have a beneficial effect on the resistance to SCC, nitrate was added to the 35% ammonium sulfate solution containing 3000 ppm Cl^- in order to determine the approximate threshold nitrate concentration above which SCC can be inhibited at 104°C. In the absence of nitrate, this environment, as indicated above, had caused the onset of SCC in the alloy tested. Figure 7 shows the stress-elongation curves in the solutions with various nitrate concentrations. The addition of nitrate caused an increase in elongation, as expected, and the UTS and ROA increased significantly above 1000 ppm nitrate (see Fig. 8). ROA increased significantly even at 100 ppm nitrate. SEM studies showed that the presence of 1000 ppm nitrate or above inhibited SCC (see Fig. 9). In the case where 100 ppm nitrate was added to the solution, the crack mode was predominantly ductile (see Fig. 9a). However, at higher magnification, a transgranular and cleavage-like fracture morphology was evident in some limited regions, see Fig. 10. The crack velocity was found to decrease with increased nitrate concentration (see Table I).

Anodic polarization curves.—It is accepted that the SCC of a metal is governed, at least to some extent, by electrochemical reactions. Therefore, the electrochem-

istry of the system has been studied to determine if any correlation can be established between SCC susceptibility and its electrochemical characteristics. Polarization curves were determined on unstressed specimens in each solution at 104°C, and the results are illustrated in Fig. 11. These figures illustrate the effect of chloride concentration in the sulfate solution on the electrochemical behavior of the metal. Some electrochemical parameters such as open-circuit potential (OCP), active-passive transition potential (E_{pp}), pitting initiation potential (E_b), are of great interest.

The current responses in Fig. 11 are typical for polarization runs in the various Cl^- solutions. In the solutions containing 0 ppm Cl^- and 1000 ppm Cl^-, an anodic current maximum was observed at ~ + 700 mV, which is probably due to the compositional change of the oxide film on the specimen's surface. A transpassive potential was obtained at even more noble region. Results indicate that the potential differences between the metastable OCP and E_b, above which pitting corrosion is initiated, decreases with increasing Cl^- content of the solution. Most significantly, a dramatic decrease of the potential difference occurs in the solution containing 2000 ppm Cl^- or above. These electrochemical results are consistent with the results obtained above that SCC will occur in the solution containing approximately 2000 ppm Cl^- or above. Furthermore, the results are consistent with the view (1) that pitting may be responsible for the initiation of SCC in this alloy/environment system.

The effect of nitrate in the chloride-containing sulfate solutions was also investigated, and the results are shown in Fig. 12. The anodic polarization curves were determined in the solution containing 3000 ppm

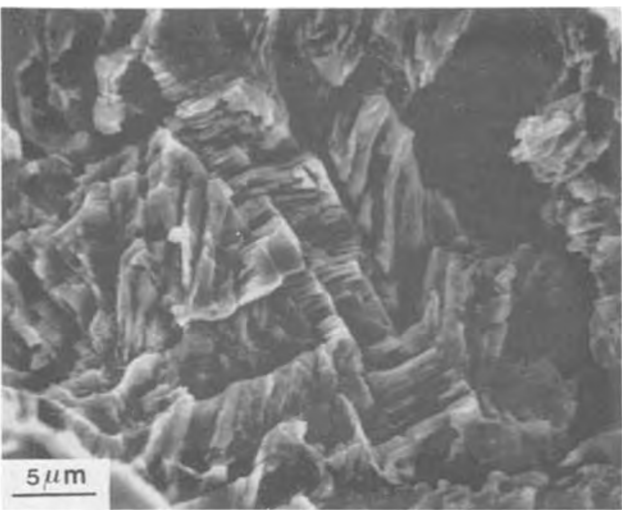

Fig. 10. The enlargements of region A of Fig. 9 (a)

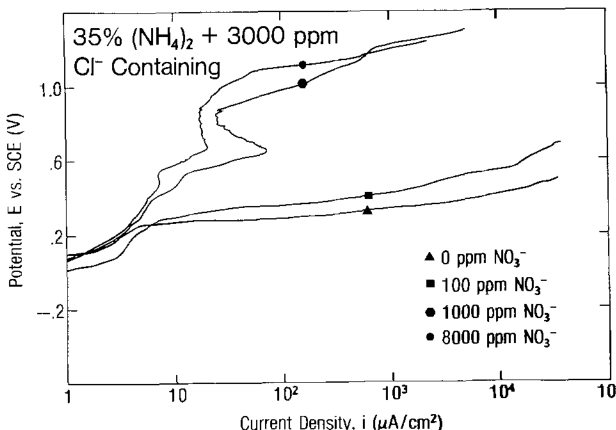

Fig. 12. The anodic polarization behavior of Type 304 stainless steel in 35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- solution containing different NO_3 concentration at 104°C.

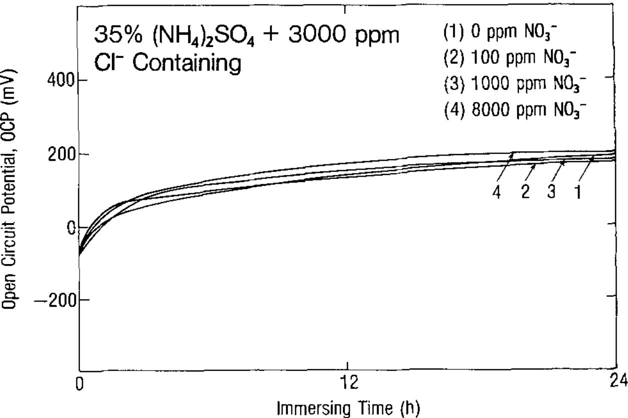

Fig. 14. The change in open-circuit potential (OCP) of Type 304 stainless steel in 35% $(NH_4)_2SO_4$ + 3000 ppm Cl^- solution with different NO_3^- concentration as a function of immersing time.

chloride with various nitrate concentrations. From the results, it is obvious that nitrate has a beneficial effect on the noble shift of pitting potentials in the chloride-containing sulfate solution. Significantly, the addition of 1000 ppm nitrate or above results in a dramatic increase in the potential difference. This result correlates well with the constant strain rate results that the presence of approximately 1000 ppm nitrate or above may inhibit SCC.

Open-circuit potential-time curves.—The open-circuit potential (OCP) of the alloy was monitored as a function of immersion time at 104°C, and the resulting curves are illustrated in Fig. 13. The curves were obtained from tests in 35% $(NH_4)_2SO_4$ solutions containing various chloride concentrations. Note that, in general, OCP of the specimen shifts to a more noble direction as a function of immersion time. Comparing the results with the anodic polarization curves, Fig. 11, indicates that, in the solution containing 3000 ppm chloride or above, relatively long time immersion of the specimen results in a noble shift of OCP, which is eventually close to or more noble than the E_b, and pits formed subsequently.

Figure 14 shows the effect of nitrate in the sulfate solutions containing approximately 3000 ppm chloride. It can be seen from the figure that in the solution containing 1000 ppm NO_3^- or above, the OCP after 48 hr immersion is still much more active than the E_b (see Fig. 12).

Discussion

The results given above clearly demonstrate that Type 304 stainless steel may experience SCC in an ammonium sulfate solution containing chloride ion at 104°C. Evidently, the electrochemistry of the alloy/environment plays an important role in determining the SCC behavior.

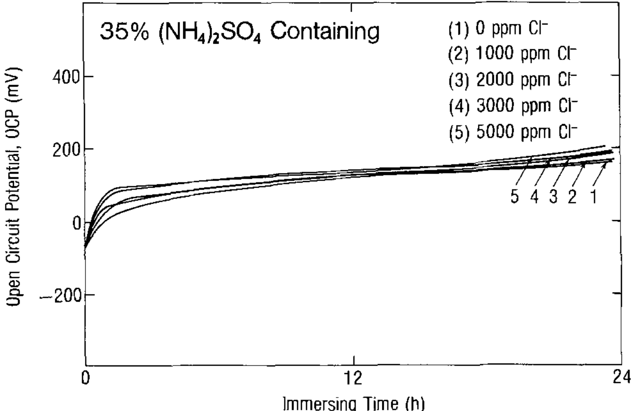

Fig. 13. The change in open-circuit potential (OCP) of Type 304 stainless steel in 35% $(NH_4)_2SO_4$ solution with different Cl^- concentration as a function of immersing time.

Anodic polarization curves suggest that the metal is essentially passive in all the solutions tested, and the OCP shifts to a more noble direction with increasing chloride concentration. An interesting point with respect to SCC is that, as was shown in the anodic polarization curves, the potential difference between OCP and E_b decreases substantially in the solution containing 2000 ppm chloride or more. Monitoring the OCP against the immersion time further indicated that in the solution containing 2000 ppm chloride or more, the OCP after 48 hr immersion became close to or more noble than E_b. This result is consistent with the suggestion that the pitting is responsible for the initiation of SCC, where the effect of chloride is to destroy the protectiveness of the surface film through the formation of active pits, which subsequently act as initiation sites of SCC.

Several authors have suggested that the critical factor in SCC is the rate at which a metal surface repassivates after the original passive film has been ruptured by slip-step emergence, etc., and therefore metals in the potential regions near the active-passive (17) and passive-transpassive transitions (17, 18), where the surface is still filmed but the impetus for passive film renewal is somewhat slow, should be more susceptible to SCC. The present results from fractographic and anodic polarization studies may represent another instance where SCC occurs near the passive-transpassive transition regions. This will, however, reemphasize the importance of the passive film and repenetration process SCC.

It has been reported that the SCC morphology in strongly acidic solutions is dependent on the $SO_4^{=}/Cl^-$ ratio (19); the higher ratios favoring intergranular cracking and the lower ratios producing a mixture of transgranular and intergranular cracking. In the weakly acidic solutions of the present study, however, the fractures were always transgranular. The mechanism of the SCC propagation is not understood nor is such investigation the intent of this study. However, based on the fractographic observation that the river patterns, which are often thought to be associated with cleavage, were commonly seen on the fracture surfaces, it can be suggested that the SCC propagation is mechanical in nature.

The inhibiting effect of nitrate was clearly demonstrated by the slow strain rate testing and anodic polarization results. Similar results have been reported by Uhlig and Cook (10) in boiling $MgCl_2$ solution. They suggested that the addition of nitrate shifted the critical potential, above which cracking occurs, in a noble direction, and when the shift exceeds the corro-

sion potential for the alloy in the same solution, cracking is apparently inhibited. The present results indicated that the addition of nitrate essentially shifted the E_b value in a noble direction, and consequently widened the potential difference between OCP and E_b. In other words, the nitrate plays a role to prevent pitting initiation of the alloy in the solution. These results are consistent with the view that pitting may be responsible for the initiation of SCC. However, since no correlation between the critical SCC potential and other electrochemical parameters, such as pitting potential, were made, further experiments are essential to pursue this goal.

Another significant feature of this study is that a good correlation between SCC susceptibility and the electrochemical behavior of the alloy/environment system has been developed from which a better understanding of the mechanism of SCC can be obtained. Similar experiments are in progress (20) in our laboratory for Type 316 stainless steel. However, it should be emphasized that the theory derived from our present observations has only been explored for the ammonium sulfate system, as it exists in our production operation at 104°C, and the applicability of the conclusions from this study to other systems remains to be demonstrated.

Conclusions

The test results presented above may be summarized as follows:

1. AISI 304 stainless steel is susceptible to SCC at 104°C in the 35% $(NH_4)_2SO_4$ solution with the critical chloride concentration of approximately 2000 ppm or above.

2. Addition of 1000 ppm nitrate or above to the 35% $(NH_4)_2SO_4$ +3000 ppm Cl^- solution inhibited SCC of the test steel at 104°C.

3. Results are consistent with the view that pitting may be responsible for the initiation of SCC.

ABSTRACT

The use of Raman and infrared spectroscopy to analyze surface films on metals is described. Surface films formed on lead by reaction with aqueous buffer solutions were examined. The composition of each film was determined by Raman spectroscopy while the sample was in the solution. Multiple reflection infrared spectra of dry samples confirmed the Raman results. The Pourbaix diagram for lead in water was calculated, and potentiostatic exposures were conducted to see if the compounds corresponded to those predicted in the diagram. Tetragonal PbO was found to occur over a much greater range of potentials than thermodynamic stability would indicate.

Passive films play an important role in corrosion and other electrochemical phenomena. Passive film studies frequently emphasize either the kinetics of film growth, breakdown, and repair or else they emphasize the structure and composition of the film. A number of techniques have been developed for both purposes.

This investigation was aimed at demonstrating the use of infrared (IR) and Raman spectroscopy for studying passive films formed on lead. The advantages of these techniques for passivation film studies are also discussed.

Surface analysis techniques.—A number of techniques are available for the study of passive film composition and structure. Recent reviews by Vermilyea (1) and Leidheiser (2) discuss most of the important surface analysis techniques available for use in studying passive films. Table I summarizes the techniques used in corrosion studies.

The ideal surface analysis technique would be able to provide structural information, *in situ,* on a variety of substrates. It should require no vacuum, work on amorphous as well as crystalline films, and be confirmable by other techniques. It should cover the entire atomic spectrum and not be limited, as is the case with Mössbauer spectroscopy, to certain elements (3-4). It is clear that Raman spectroscopy, with its capability for *in situ* analysis of passive films as they form in aqueous media, has several important advantages over other surface analysis techniques. The combination of infrared and Raman spectroscopy offers structural analysis possibilities which cannot be met by other surface analysis techniques with the possible exception of differential reflectometry (5).

Vibrational Spectroscopy

Infrared and Raman spectroscopy.—Infrared and Raman spectroscopy are two similar structural analysis techniques. They are complementary in that one technique will often be highly sensitive to certain structures at the same time that the other technique will provide little, or no, information. For this reason they are usually used together, and the term vibrational spectroscopy is used to cover both techniques.

The optical schematic of a typical infrared spectrometer used for surface studies is shown in Fig. 1. Instruments of this type for use in corrosion studies were first described by Hannah (6), and subsequently have been used by Poling (7, 8), Mertens (9, 10), and others. Light from a single infrared source is split and directed along two parallel light paths. The sample(s) of interest are inserted into one light path (m_3 in Fig. 1), and the combination infrared reflection-absorption spectrum obtained from the sample is compared with the spectrum obtained in the reference beam, which is identical to the sample path in all aspects except the identity of the sample mirror. Comparison of the sample and reference beams eliminates source and light path artifacts from the spec-

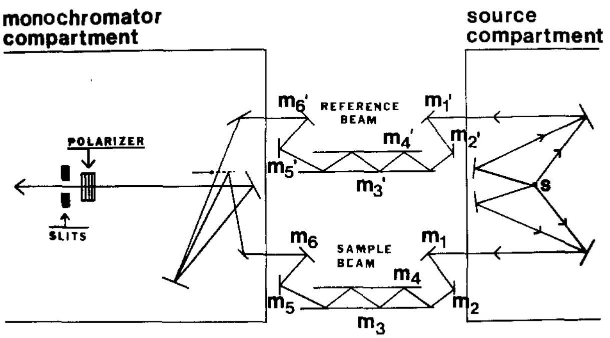

Fig. 1. Optical schematic of the infrared reflection-absorption setup used. S is the infrared source, reflecting surfaces are labelled m, and the sample is at position m_3.

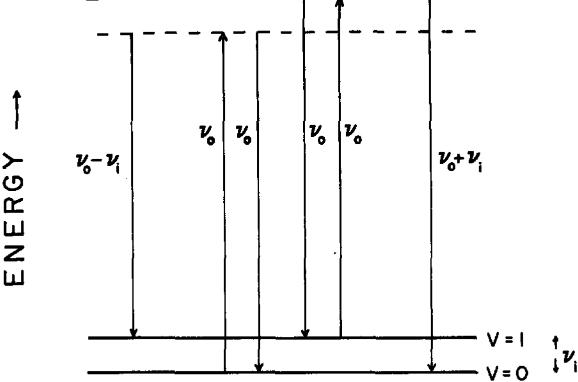
trum (11). It is beyond the purposes of this paper to discuss the reflection-absorption nature of the infrared spectra obtained using this technique. Detailed discussions of this are available (12-15).

Infrared spectra of liquids and solids are due to transitions between vibrational energy levels of the compound under investigation. Absorption bands are associated with the resonant energies of the chemical bonds in the material (11).

The optical schematic of a modern Raman spectrometer is shown in Fig. 2. The spectrometer consists of a laser, a sample compartment, an optical monochromator, and a detection system. The laser acts as a source of monochromatic light which strikes the sample. Most of the incident light is reflected from the sample surface and undergoes no change in wavelength. However, some of the incident light interacts with the surface, loses some of its energy, and causes scattering of light at wavelengths different than the incident radiation. It is this scattered light which is measured in Raman spectroscopy.

The transitions responsible for Raman scattering are shown in Fig. 3. Consider a molecule in the ground ($v = 0$) vibrational state. The incident radiation in the visible range (*e.g.*, $\nu_0 = 20{,}000$ cm^{-1}) excites the molecule to a pseudoenergy level by inducing a temporary dipole in the molecule. In a short time period ($\sim 10^{-14}$ sec) the molecule emits a photon at the same frequency (Rayleigh scattering) and returns to the ground state, or it emits a photon at a lower frequency and returns to a higher vibrational level, *e.g.*, $v = 1$. In the latter case, the energy of the photon will correspond to a frequency $\nu_0 - \nu_i$; this type of transition is referred to as Stokes Raman scattering.

There is a Boltzmann distribution of molecules at all possible vibrational energy levels. Thus, even at room temperature there are molecules in the $v = 1$



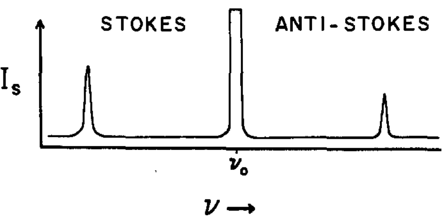


Fig. 3. Energy level diagram for a typical vibrational Raman transition and the Raman spectrum resulting from such a transition.

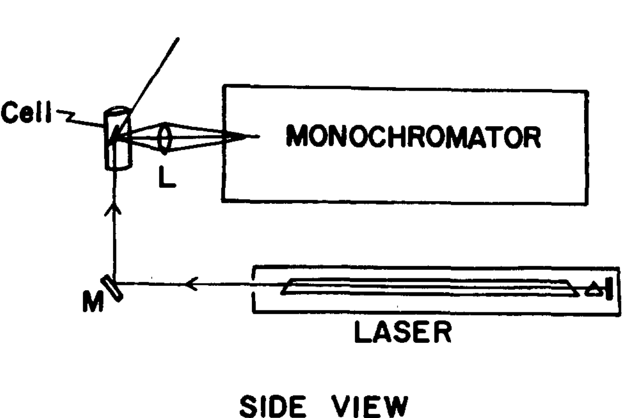
level. These can also be excited by the incident radiation to a pseudolevel. These molecules can then return to the same level and emit a photon of ν_0, or they can return to $v = 0$ and emit a photon of $\nu_0 + \nu_i$. These latter transitions are also Raman, and are referred to as anti-Stokes Raman scattering.

A typical Raman spectrum of a diatomic molecule is shown in the bottom of Fig. 3. The intensity of the anti-Stokes Raman bands depends upon the magnitude of ν_i, *i.e.*, the greater ν_i, the smaller the number of molecules in the level (Boltzmann distribution) and the smaller the intensity of the transition. Thus, in conventional Raman spectroscopy only the Stokes transitions are measured, and only the left half of the spectrum is used. Furthermore, it is conventional to plot the frequency difference, *i.e.*, $\nu_0 - (\nu_0 - \nu_i) = \nu_i$, or the frequency corresponding to the differences between vibrational levels. For polyatomic molecules, Raman transitions to some or all of the possible vibrational levels can take place.

For a Raman transition to occur, the geometry of the molecule in the excited state must be such that a change in polarizability has taken place, *i.e.*, the electron density about the molecule must be distorted



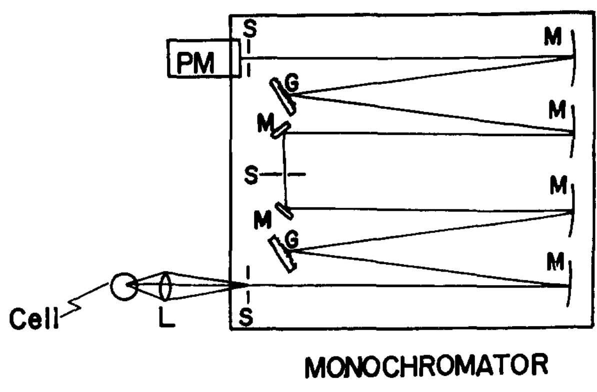


Fig. 2. Schematic drawing of a laser Raman spectrometer. Mirrors are labelled M, gratings, G, and slits, S

by the transition. For an absorption of infrared radiation to occur, the geometry of the molecule in the excited state must be such that a change in the dipole moment has taken place. Thus, both Raman and infrared absorption spectra provide data on vibrational transitions which in turn provide information on the bonding and the structure of the molecule. However, the two processes are entirely different, and one may occur without the other. Generally they provide complementary information, and both spectra are needed to completely understand the vibrational properties of the chemical species in the material.

Every molecule has its own characteristic infrared and Raman spectrum which can be used to identify the molecule (exceptions are homonuclear diatomic molecules which do not absorb infrared radiation). The primary use of these techniques has been in identification. The spectrum of an unknown chemical can be identified by comparing its infrared or Raman spectral "fingerprint" to those of known chemicals. It is this method that we have used to identify the composition of films on the surface of metals, *i.e.*, we compare spectra from surface films with spectra of known chemicals.

Pourbaix diagrams.—Potential-pH diagrams (Pourbaix diagrams) are available for a wide variety of metals (16), and they have found wide application in corrosion research (17, 18). The Pourbaix diagram of lead (16) was used as a basis for choosing exposure conditions for forming passive films on lead surfaces which were subsequently analyzed by Raman and infrared spectroscopy in this study. The lead diagram also contains a number of different insoluble species and is similar in many respects to the diagram for iron, the most important structural metal (16).

Experimental

Raman spectra were recorded with a Spex Industries Model 1401 double monochromator using a photon counting detection system. A simplified optical schematic of a spectrometer of this type is shown in Fig. 2. A Coherent Radiation Laboratories Model CR-3 argon ion laser is located beneath the monochromator, and the laser beam is directed by a mirror to the bottom of the sample cell. Some of the light scattered by the sample is collected by the lens (L), positioned 90° from the vertical laser beam, and is focused onto the entrance slits of the monochromator. Light passing through the slits is collimated by a mirror and dispersed by the first grating. The light, spread out according to frequency, is then directed by a second collimating mirror and a plane mirror to the intermediate slits. The narrow frequency band of light which has passed through the first monochromator then passes through a second identical monochromator, to maximize rejection of stray light, and reaches the detector, a photomultiplier tube. Each photon reaching the photomultiplier is converted to an electrical pulse which is amplified and counted. The number of counts (number of photons) per selected time interval is converted to an analog signal which drives the pen on a strip chart recorder. A frequency range is scanned by turning the two gratings in the monochromator simultaneously so the frequency of light reaching the detector is changed. The Raman spectrum recorded is thus a plot of light intensity *vs.* frequency difference from the excitation frequency.

The electrochemical cell shown in Fig. 4 is used in the sample compartment of the spectrometer to allow Raman spectra to be recorded while the sample is undergoing oxidation in an aqueous solution. The cell is designed for potentiostatic exposures of fairly large samples. The working electrode is a flat 2.8 × 5.7 cm rectangular sample held in a Teflon sample holder. The auxiliary electrode is platinum mesh, and the potential is maintained relative to a saturated calomel electrode by a potentiostat. The sample is held close

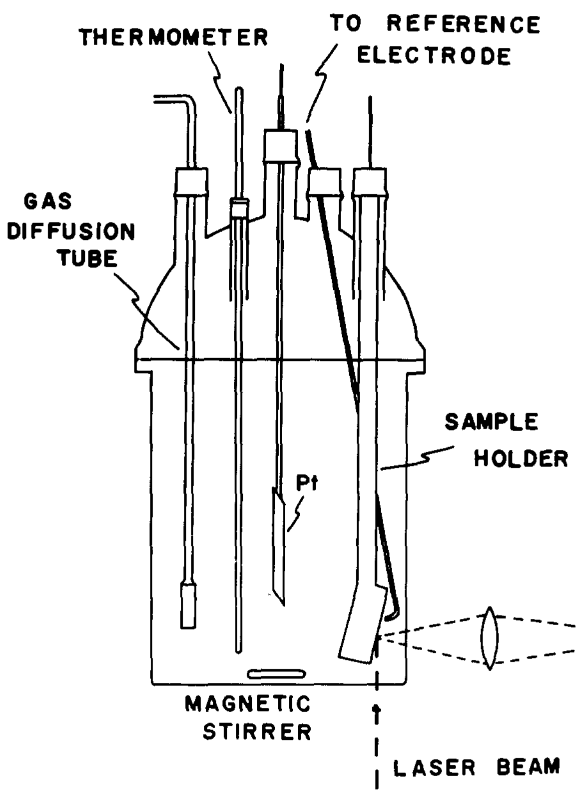

Fig. 4. Drawing of the electrochemical cell used for *in situ* Raman spectroscopy.

to the bottom and side of the cylindrical glass cell and at an angle of 20° from vertical so that it is in the optimum position for observation of Raman spectra. The angles between the sample surface and the incident beam, and between the surface and the axis of the collection optics are important in optimizing the efficiency of collecting Raman scattered light (19). The angles are chosen so that the electric vector of the incident beam may interact most strongly with the film and produce the maximum Raman scattering.

The sample size (2.8 × 5.7 cm) was selected so that the sample, after *in situ* examination by Raman spectroscopy, can be placed in the holder of a Wilks Scientific Corporation Model 9 multiple specular reflection attachment for infrared reflection-absorption analysis. An optical schematic of the reflection attachments in the Perkin-Elmer Model 521 infrared spectrophotometer is shown in Fig. 1. Two multiple reflection attachments are used in the spectrophotometer, one in the sample beam holding the oxidized metal sample and one in the reference beam holding an aluminum mirror.

Each time the infrared beam reflects off of the sample surface some radiation is absorbed by the surface film at frequencies of infrared absorption bands. Some light is also lost at all frequencies with each reflection so the mirrors are adjusted to provide the optimum angle of incidence (65°-88°, depending on film thickness) and the optimum number of reflections (1-3) for recording the spectrum of a film on a lead substrate. After the sample and reference beams are combined in the monochromator portion of the instrument, the light must pass through a polarizer which transmits only that light with its electric vector in the plane parallel to the plane of incidence with the sample surface. Only the parallel polarized light will interact with a thin film (13) so the extra light not in this plane, and containing no information, is filtered out to increase the sensitivity of the instrument.

Lead foil (Alfa Products, Incorporated, Danvers, Massachusetts), 1 mm thick and 99.9995% pure, was

cleaned by immersion in warm, concentrated ammonium acetate solution for 5 min and rinsed with distilled water before being placed in solution in the electrochemical cell. The solution was purged of reactive dissolved gases by bubbling dry nitrogen through it for an hour before and throughout the period of sample exposure. For a few exposures, the lead sample was not connected to the potentiostat but was allowed to react at its equilibrium potential. For other exposures, the potentiostat was turned on immediately after placing the sample in solution, and it maintained the potential at a constant value throughout periods of exposure ranging from 6 min to 24 hr.

Some exposures were conducted on lead films which were vapor deposited onto gold substrates on glass microscope slides. These samples, similar to those used by Poling in his infrared studies of high temperature oxidation of iron and copper (7), allowed the lead to be completely oxidized leaving a nonreacted gold mirror substrate.

Table II lists the electrolytes used in this investigation. They are similar to those used by Pourbaix, Verink, and co-workers at the University of Florida (20) and have been used in other electrochemical studies in these laboratories (21). The exposures performed in this investigation are summarized in Table III.

Results and Discussion

Spectra.—A lead sample was immersed in 2.3m hydrobromic acid and allowed to corrode freely (no connection to the potentiostat). After 8 days the *in situ* Raman spectrum of the surface shown in Fig. 5a was recorded. The spectrum of the gray surface layer clearly indicates that it consists of $PbBr_2$. The six strongest bands in the spectrum of pure $PbBr_2$ (Fig. 5c) are present in the spectrum of the film. Furthermore, the band shapes and frequencies in the spectra of the film and the powder are identical.

[b] Current flow in reducing direction.

tals formed on the surface. After immersion for 34 days, the sample was removed and dried. The white crystals were scraped off and ground into powder. The Raman spectrum of the resulting powder was identical to that of the surface film. It is clear that the Raman spectrum of a thick film is identical to that of a bulk sample. Possibly a spectrum of an extremely thin film might differ due to changes in the bonds because the surface compound is bound to the underlying metal, but for relatively thick films (hundreds or thousands of angstroms) the spectra are the same as that of a powder.

At this point it should also be pointed out that the films analyzed in this investigation were surface reaction products. No attempt was made to separate precipitated deposits, such as those discussed above, from adherent conversion products which may have acted as passive films and altered metal-environment reaction kinetics.

Analysis of surface films by infrared spectroscopy gives somewhat different results. While the entire range of vibrational bands, from lattice modes at 20 cm^{-1} to overtones beyond 6000 cm^{-1}, are easily observed with a Raman spectrometer, normally two different instruments are required to scan that range in the infrared. For this study, infrared spectra were obtained in the region 1500-250 cm^{-1}. The low frequency bands of a compound like lead bromide could not be observed. Nearly all infrared spectra found in the literature are transmission spectra, observations of the amount of light passing through a partially absorbing sample. By combining absorption with reflection at the surface film-metal interface, the resulting absorption spectrum from the multiple reflections has a different appearance from a pure absorption spectrum. An infrared reflection-absorption spectrum results from changes in the extinction coefficient and the index of refraction, both of which can change radically in the vicinity of an absorption frequency, whereas a transmission spectrum is due to changes in extinction coefficient alone (11, 15). The result, as demonstrated in Fig. 6, is that a reflection-absorption spectrum usually has bands of slightly different shape and frequency from a transmission spectrum (13, 14). The magnitude of the differences depends on such variables as angle of incidence of the infrared beam, film thickness, and number of reflections used. Since the spectra are sensitive to instrumental conditions, identification of compounds with infrared reflection-absorption alone is sometimes difficult. Infrared reflection-absorption, combined with Raman spectroscopy, permits much more accurate identification of the species present.

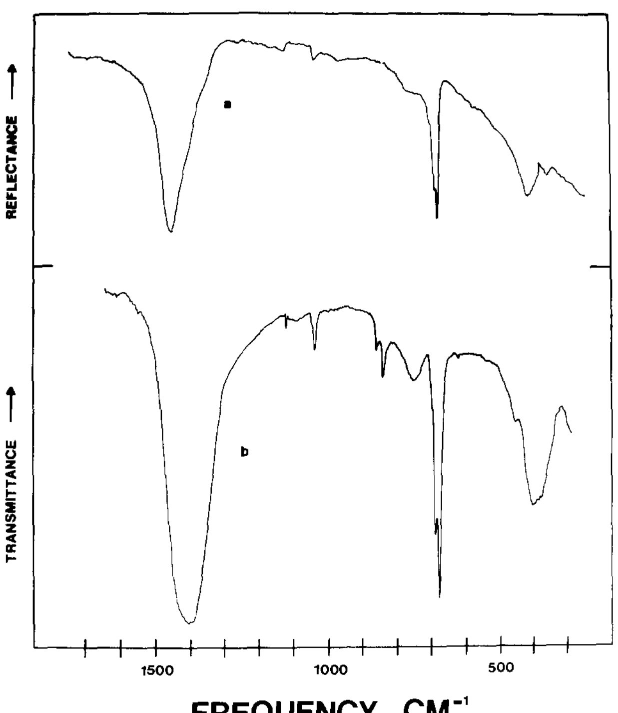

Fig. 6. (a) Infrared reflection-absorption spectrum of a lead sample after exposure in pH 10 solution at —0.42V *vs.* NHE for 24 hr, (b) transmission infrared spectrum of $(PbCO_3)_2 \cdot Pb(OH)_2$ in a KBr pellet.

Some compounds have vibrational transitions which are much stronger in the infrared than in Raman, and some have vibrations which are much stronger in Raman spectra. Such is the case for the conditions in Fig. 6. The basic lead carbonate, $(PbCO_3)_2 \cdot Pb(OH)_2$, on the lead surface that produced the strong infrared spectrum of Fig. 6 produced only a weak Raman band at 1050 cm^{-1} to indicate the presence of carbonate. Although $(PbCO_3)_2 \cdot Pb(OH)_2$ can give the Raman spectrum shown in Fig. 7, it was necessary to use the complementary technique, infrared absorption, to specify which carbonate compound was present.

Water is a strong infrared absorber so samples must be dried before a spectrum can be observed. This is not the case with Raman spectroscopy; water poses little problem in obtaining a Raman spectrum. For potentiostatically exposed samples, Raman spectra were recorded with the sample in the solution with a potential applied. After obtaining a spectrum the sample was removed from the electrochemical cell, washed with distilled water, and dried at room temperature. The dry sample was then returned to the spectrometer sample compartment and another Raman spectrum recorded. This was done to identify any changes that might occur in the surface film upon drying. In the present investigation no significant differences between *in situ* and dry sample Raman spectra were found. Spectra obtained under both conditions are very similar as demonstrated in Fig. 8. Both spectra contain the three strongest bands of tetragonal PbO, enough to conclusively identify the compound as the surface species present. After removal from the cell and drying of the sample, the spectrum is slightly stronger. In this investigation the intensity of the Raman spectra recorded with samples in solution in the electrochemical cell was approximately half the spectral intensity of dry samples. The reasons for the decrease in intensity are scattering and reflection from the solution and sides of the cell and the difficulty of focusing light scattered in the cell onto the monochromator entrance.

Figure 9 shows the Raman spectrum of orthorhombic PbO (12). The thickness of the film that produced the spectrum was measured at 1600Å using a Taylstep-1 stylus instrument. From the PbO spectra ob-

tained in this investigation for vapor-deposited samples, it is estimated that a minimum film thickness of approximately 200Å is necessary to obtain usable spectra using the infrared and Raman instruments employed. Other oxides should have different minimum detectable thicknesses. Other researchers have reported infrared spectra from thinner films formed on nonlead substrates (6-10).

Single spectrometer scans were used to record the spectra recorded in this investigation. Signal averaging of multiple scans should increase the signal to noise ratio and reduce the minimum detectable thicknesses (22).

The lead-water Pourbaix diagram.—Most available potential-pH (Pourbaix) diagrams are based on the same type of thermodynamic calculations employed by Pourbaix in compiling his original atlas (16). Several experimental Pourbaix diagrams have appeared (17, 18, 20-26), and these are normally based on electrochemical polarization techniques which emphasize electrode kinetics.

Vibrational spectroscopy seems especially suited to analyze, *in situ*, films formed on metals under passivating conditions as predicted by Pourbaix diagrams. In this manner, experimental determinations of the composition of films formed in the passive region of a Pourbaix diagram should be possible.

The Pourbaix diagram of lead was chosen to test this hypothesis. Lead was chosen because its high atomic weight means that lead compounds should be relatively strong Raman scatterers (27). The lead diagram also contains a number of different insoluble species and is similar in many respects to iron, the most important structural metal (16). A report of similar attempts to verify some portions of the lead Pourbaix diagram using Raman spectroscopy was published during the course of this investigation (28). Hendra and co-workers used chloride-containing electrolytes in their investigation. Thus, a comparison with their results is beyond the scope of this paper. Studies of the effects of anions on the corrosion films formed on lead have been conducted (12, 29) and will be summarized in subsequent papers (30).

The lead-water equilibrium diagram published by Pourbaix is shown in Fig. 10. Initial attempts to verify this diagram using infrared and Raman spectroscopy led to a number of discrepancies between predicted and experimentally determined passive species. Recalculation of the Pb-H_2O equilibria using the most recent thermodynamic data from the National Bureau of Standards (31) resulted in the diagram of Fig. 11. It was hoped that fewer differences between predicted and observed species would be noted when this new data was used. The free energies of formation for the species in question in Fig. 10 and 11 are listed in Table IV. Figure 11 was used, in conjunction with potentiodynamic polarization curves run in the solutions of interest, to identify potential-pH combinations to be used to form passive films for spectroscopic investigation.

The results of the immunity (low potential) region of the Pourbaix diagram agree with the thermodynamic predictions summarized in Fig. 11 except for the appearance of basic lead carbonate for some potentials at pH 10. Spectra of tetragonal PbO were observed in regions where PbO, Pb_3O_4, Pb_2O_3, and PbO_2 were predicted by thermodynamics. At lower potentials the sample surfaces remained shiny, oxidation was relatively slow, and the oxide films were apparently thin. At higher potentials the metallic

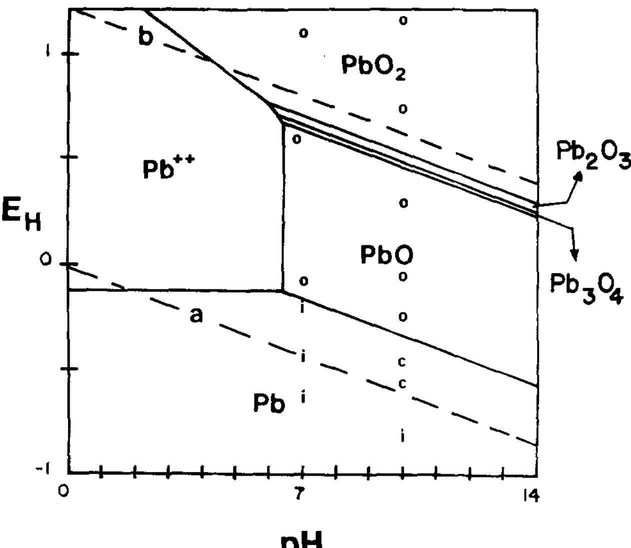

Fig. 11. Calculated Pb-H_2O Pourbaix diagram using the most recent NBS data (31). Experimental results, 0 = tetragonal PbO, i = apparent immunity, no spectrum observed, C = basic lead carbonate.

surface quickly became black. The black lead oxide has been previously described as PbO with a thin outer surface film of elemental lead (32). At the slower rates of oxidation occurring at lower potentials, the film did not become black.

The formation of tetragonal PbO under conditions where other oxides are predicted to be stable cannot be adequately explained. It must be noted, however, that, if PbO_2 were formed, it could probably not be detected using infrared and Raman spectroscopy. Lead dioxide has been reported to have no infrared absorption bands in the region 1500-250 cm^{-1} (33), and no Raman spectra were observed from bulk samples of reagent grade PbO_2 (29).

Spectra have been obtained for orthorhombic PbO and Pb_3O_4 and are reported elsewhere (30, 32-35). The lack of observation of these species during the electrochemical exposures of the investigation may be due to errors in the theoretical Pourbaix diagram (Fig. 10 and 11). Another possibility is the presence of insufficient amounts of these compounds to be detectable by the instrumentation used. The possibility of a multilayered film with an outer layer, which is detectable spectroscopically, masking an inner film must also be considered (12).

Conclusions

Infrared and Raman spectroscopy can be used to identify surface films formed on electrodes in corrosive environments. Raman spectra can be obtained *in situ* in aqueous environments. There are only slight differences in intensity between *in situ* Raman spectra and those recorded on dry samples. Multiple reflection infrared spectroscopy complements *in situ* Raman spectroscopy.

Surface films identified on lead samples using infrared and Raman spectroscopy differed from those predicted by thermodynamics. Differences may be due to experimental limitations or may indicate deficiencies in thermodynamic prediction techniques such as anion effects which are not considered in the calculations for Fig. 10 and 11.

Effects of Target Materials on the Structural Properties of Sputtered SiC Films

Takao Tohda, Kiyotaka Wasa, and Shigeru Hayakawa

Materials Research Laboratory, Matsushita Electric Industrial Company, Limited, Kadoma, Osaka 571, Japan

ABSTRACT

SiC films were prepared either by direct sputtering of a SiC target in Ar or by reactive sputtering of a Si target in a mixture of Ar and hydrocarbon. Their chemical composition and structural properties were examined by Auger electron spectroscopy, infrared transmission, and reflection electron diffraction. It is seen that the chemical composition of the films sputtered from the Si target is strongly dependent on the deposition rate and the partial pressure of hydrocarbon. The sputtered films from the SiC target crystallize at lower deposition temperature than those from the Si target.

Silicon carbide, SiC, films have very promising electrical and chemical properties in high ambient temperature. For example, SiC thin films are found to be useful for making high temperature sensors (1). Reactive deposition of Si in hydrocarbon or direct sputtering of SiC is widely used for preparing SiC films. Learn and Haq prepared epitaxial β-SiC films by reactive evaporation of Si at 1100°C in a reactive gas of C_2H_2. They found that the ratio of the arrival rate of C_2H_2 to the arrival rate of Si at substrates should be more than 30 (2). Haq has studied reactive sputtering of Si in a mixture of Ar and C_2H_2 at a substrate temperature of 1150°C and suggests that there exists an optimum range in the partial pressure of the reactive C_2H_2 gas (3). Murayama and Takao have proposed an rf-ion plating method in C_2H_2 at 1000°C and concluded that the C_2H_2 pressure should be lower than 1.3×10^{-2} Pa and the deposition rate of Si should be higher than 200 Å min^{-1} (4). Wasa, Nagai, and Hayakawa prepared polycrystalline SiC films by rf-sputtering of SiC in Ar and investigated the structural and mechanical properties (5). Nishino, Matsunami, Odaka, and Tanaka prepared epitaxial β-SiC films by rf-sputtering of β-SiC at 1200°C (6).

Recently we have studied the structural properties of rf-sputtered SiC films and found that the target materials used strongly affected the structural properties of the resultant SiC films. This paper describes the chemical composition and crystalline structure of rf-sputtered SiC films prepared from two different sputtering targets, SiC and Si.

Film Preparation

A conventional rf diode sputtering system was employed for the film deposition. Two different materials were used as a target: one was sintered 6H-SiC (diameter 100 mm, thickness 5 mm, purity 99.5%) and the other was single crystal Si (diameter 50 mm, thickness 0.25 mm, purity 99.9999%). Silicon (111) wafers were used for substrates. The substrates were etched in HF prior to sputtering deposition. The distance from the target to the substrates was 25 mm. The substrate temperature was controlled between 200°-740°C during film deposition.

For the SiC target, sputtering was done in Ar at a pressure of 2.7 Pa. A typical deposition rate was 0.3 μm/hr with an rf power density of 2 W/cm^2. In this case the deposition rate increased linearly with the rf power. The substrate temperature had little effect on the deposition rate.

For the Si target, sputtering was done in a mixture of Ar and hydrocarbon (CH_4 or C_2H_2) at a pressure of 2.7 Pa. The partial pressure of CH_4 and C_2H_2 was varied from 4.1×10^{-2} to 1.3 Pa and from 9.2×10^{-3} to 5.9×10^{-2} Pa, respectively. In these cases the deposition rate varied with the partial pressure even at a constant rf power. A typical result for CH_4 at an rf power density of 3 W/cm^2 is shown in Fig. 1. At low CH_4 partial pressures, the deposition rate is independent of the partial pressure. At partial pressures above a critical pressure, 1.5×10^{-1} Pa, the

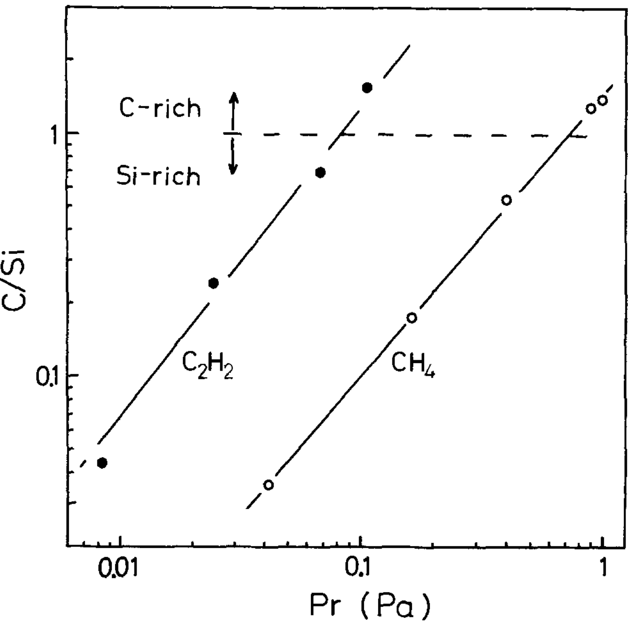

Fig. 2. Plots of C/Si vs. Pr ($\equiv P \times R_0/R$) for $R_0 = 0.5$ μm/hr

rate decreases with increasing partial pressure. The deposition rate for C_2H_2 showed a similar variation to that for CH_4, although the critical pressure was much lower than for CH_4 being 1.6×10^{-2} Pa.

Results and Discussion

Auger electron spectroscopy (AES).—AES measurements were used to examine the chemical composition of the resultant films. A SiC bulk single crystal and the films sputtered from the SiC and Si targets were used for samples in the measurements. The ratio of the 272 eV C line intensity to the 92 eV Si line intensity of the samples, I_C/I_{Si}, was measured for all the samples after removal of surface layers of the samples by means of ion sputter-etching. The chemical composition ratio C/Si was estimated from I_C/I_{Si} assuming that C/Si is proportional to I_C/I_{Si} and C/Si is equal to unity for the bulk single crystal. I_C/I_{Si} and C/Si are listed in Table I for films together with their growth conditions and for the bulk single crystal. It is seen that the ratio C/Si of the films sputtered from the SiC target (samples 1-3) is not significantly affected either by the deposition rate or by the substrate temperature and is slightly larger than unity.

The ratio C/Si of the films sputtered from the Si target varies with the hydrocarbon partial pressure P and the deposition rate R. To examine the variation of C/Si with P and R, C/Si is plotted against Pr, which is defined by the relation

$$\mathrm{Pr} \equiv P \times R_0/R$$

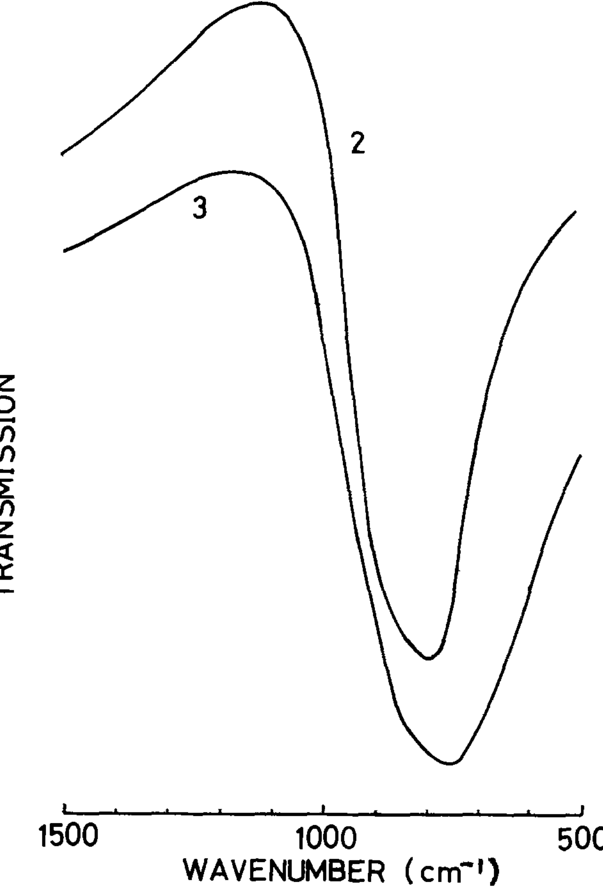

Fig. 3. Infrared transmission spectra of SiC films sputtered from a SiC target at 740°C (2) and at 200°C (3). Numbers in the figure indicate the sample number in Table I.

where R_0 is a normalization factor for the deposition rate. Figure 2 shows typical plots of C/Si *vs.* Pr for R_0 of 0.5 μm/hr. It is found from the figure that stoichiometric SiC films are obtained at 8.0×10^{-2} Pa for C_2H_2 and 7.3×10^{-1} Pa for CH_4 when the films are prepared at a deposition rate of 0.5 μm/hr. The straight lines with slope of unity imply that the ratio of the arrival rate of hydrocarbon molecules ($\propto P$) to the arrival rate of Si atoms ($\propto R$) at the substrate is proportional to C/Si. The fact that the CH_4 partial pressure to obtain stoichiometric SiC films is higher than the C_2H_2 partial pressure suggests that C_2H_2 has higher chemical reactivity with Si than does CH_4.

Infrared transmission spectra.—Infrared transmission measurements were used to examine the formation of SiC. The films listed in Table I were used for the samples in the measurements. The spectra of the

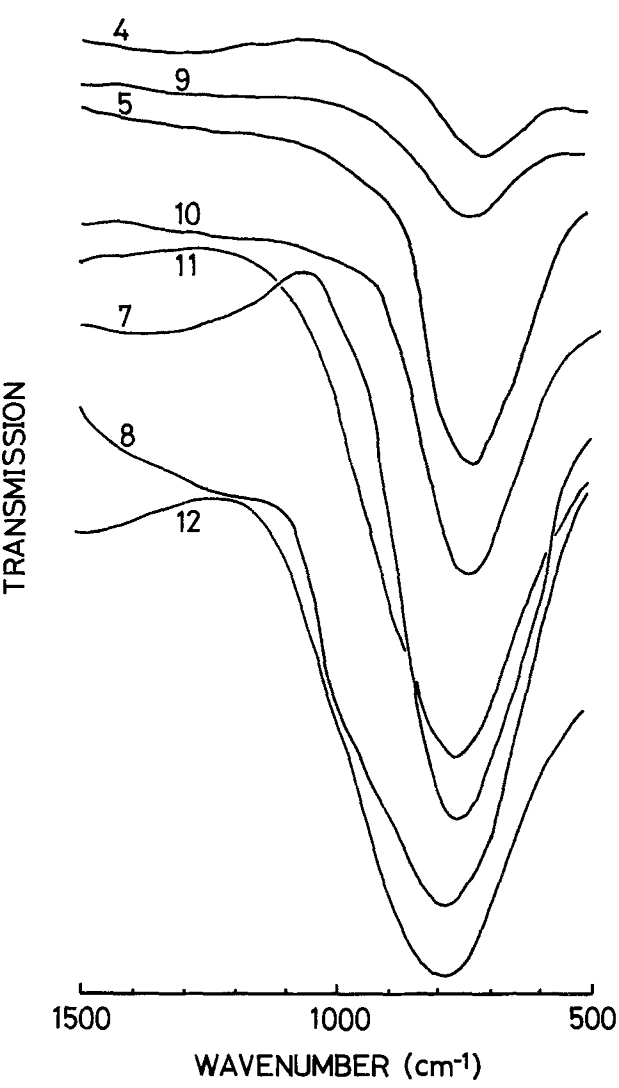

Fig. 4. Infrared transmission spectra of SiC films sputtered from a Si target at various partial pressures of CH_4 and C_2H_2. Numbers in the figure indicate the sample number in Table I.

films sputtered from the SiC target (samples 2 and 3) at different deposition temperature are shown in Fig. 3. A large absorption band at about 800 cm^{-1} is due to the fundamental lattice vibration of SiC (7). The absorption band of sample 3 is broader than that of sample 2 and is shifted to lower frequency, *i.e.*, about 770 cm^{-1}. This is due to the amorphous nature of the films prepared at low temperature (8).

The spectra of the films sputtered from the Si target in various partial pressures of CH_4 (samples 4, 5, 7, 8) and C_2H_2 (samples 9-12) are shown in Fig. 4. The position and the strength of the absorption band vary with the hydrocarbon partial pressure. The position shifts to higher frequency with increase of the ratio, C/Si. This may be caused by the difference in specific gravity between C-rich films and Si-rich films. The strength of the absorption band increases with the number of Si-C bonds. The largest absorption band at the same frequency as sample 2 is obtained in samples 7 and 11 for CH_4 and C_2H_2, respectively. This fact agrees with the results obtained from the AES measurements, *i.e.*, these samples are most stoichiometric among the samples listed in Table I.

Scanning electron microscopy (SEM) and reflection electron diffraction (RED).—SEM images and RED patterns of films of 0.6 μm thickness sputtered from the SiC target at a deposition rate of 0.3 μm/hr for various substrate temperatures are shown in Fig. 5. Epitaxial β-SiC films on Si (111) substrates were

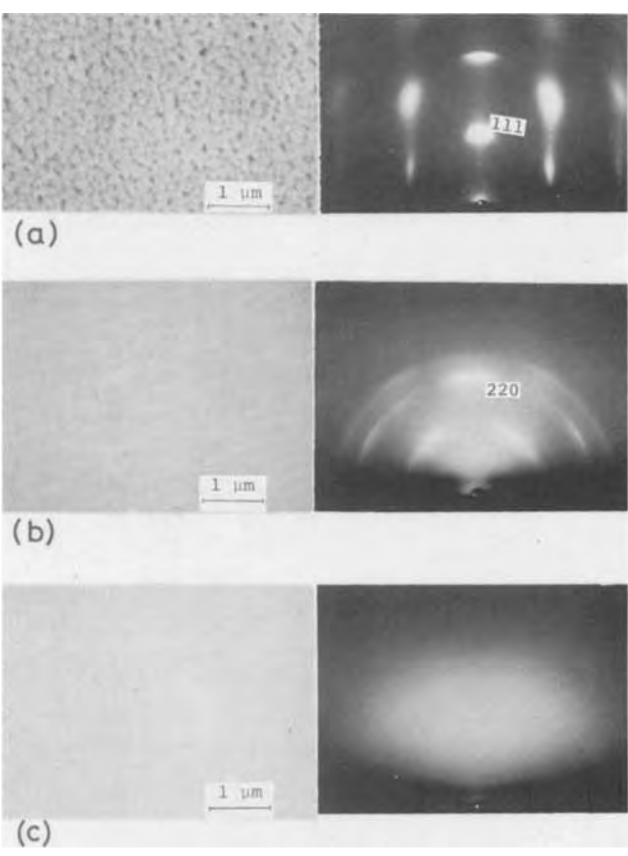

Fig. 5. SEM images and RED patterns of SiC films of 0.3 μm thickness on Si (111) substrates. The films were sputtered from a SiC target at a deposition rate of 0.3 μm/hr for substrate temperatures: (a) 740°C, (b) 600°C, (c) 200°C.

obtained at a substrate temperature of 740°C as shown in Fig. 5(a). The epitaxial relation is SiC(111) // Si(111). Polycrystalline β-SiC films with the (220) plane parallel to the substrate surface were obtained for substrate temperatures higher than 550°C. A typical result is shown in Fig. 5(b). Amorphous SiC films with a specular surface were obtained below 500°C as shown in Fig. 5(c).

When SiC films were prepared by reactive sputtering from the Si target, the films showed halo RED patterns and specular surfaces even at a high substrate temperature of 650°C. These results indicate that the SiC films sputtered from the SiC target crystallize more easily than those sputtered from the Si target.

In sputtering processes, sputtered species are ejected from targets as atomic particles. The SiC films may be synthesized according to the following reactions

Direct sputtering of SiC: $Si + C \rightarrow SiC$

Reactive sputtering of Si:

$$Si + CH_4(\frac{1}{2}C_2H_2) \rightarrow SiC + 2H_2(\frac{1}{2}H_2)$$

The Si atoms react with the C atoms or the hydrocarbon molecules primarily on the substrate surface, since collisions between Si atoms and C atoms or hydrocarbon molecules in the space between target and substrate is less probable. Silicon atoms may react more easily with C atoms than hydrocarbon molecules because the C atoms sputtered from the SiC target have higher chemical activity and kinetic energy in comparison with the hydrocarbon molecules. In reactive sputtering, the higher chemical activity of C_2H_2 compared with CH_4 may not be inconsistent with the fact that CH_4 is more stable than C_2H_2 since CH_4

shows a negative Gibbs free energy (−51 kJ mole^{-1}) and C_2H_2 shows a positive one (209 kJ mole^{-1}).

Conclusions

Stoichiometric SiC films are obtained by reactive sputtering of a Si target under a suitable choice of hydrocarbon pressure and deposition rate, because the chemical composition ratio C/Si is proportional to the ratio of hydrocarbon pressure to deposition rate (P/R).

Although the chemical composition ratio C/Si is slightly larger than unity in the films sputtered from the SiC target, it is little affected either by deposition rate or by substrate temperature.

The crystallization temperature during film deposition differs for the target materials used. The SiC target gives lower crystallization temperature than the Si target: 550°C for the SiC target and above 650°C for the Si target.

Electrode Kinetics of Copper Deposition from Copper Cyanide Solution

R. E. Sinitski, V. Srinivasan,[1] and R. Haynes*

Western Electric, Princeton, New Jersey 08540

ABSTRACT

Distinct limiting current densities can be observed in dilute acid copper cyanide solutions on both platinum and copper electrodes. The Levich equation is obeyed. Diffusion coefficients range (calculated from plots of limiting current densities *vs.* concentration and disk rotational speed) from 0.79 to 0.85×10^{-6} cm^2/sec. These apparent diffusion coefficients are considered the lower limit due to an uncorrected concentration term. Tafel slopes range from 0.130 to 0.165V with a mean value of 0.144 ± 0.016V and $\alpha = 0.40 \pm 0.03$. The exchange current density is $8 \pm 1 \times 10^{-5}$ A/cm^2. The copper deposition reaction is first order with respect to the copper-containing species. The decomposition of the copper-containing species responsible for the limiting current density is first order with a rate constant equal to $3.35 \pm 0.03 \times 10^{-6}$ sec^{-1}.

Fundamental electrokinetic studies of copper deposition from electrolytes containing cyanide are few in numbers (1-3). There is difficulty in identifying the discharging species among many possible complexes, such as $Cu(CN)_2^-$, $Cu(CN)_3^{-2}$, and assuring a unique separation between the hydrogen evolution reaction and copper deposition. No measurement of the diffusion coefficients of any of the copper cyanide complexes exists to date. Such a lack of emphasis is surprising since the copper cyanide plating system is of industrial importance and the copper cyanide complex may be significant in the electroless plating systems. The purpose of this study was to investigate electrode kinetics of copper deposition and to determine decomposition rates of the copper complex in acid copper cyanide solutions. Potentiodynamic sweeps were obtained using a Beckman Electroscan 30. An E.S.B. Model XLR-3A rotating assembly was used with a platinum rotating disk electrode. An electrolytic cell with a circular platinum mesh anode 3 cm in diam was used. The area of the platinum cathode was 0.3 cm^2.

The stock solution was made of the following components at 160°F

CuCN	82.17 g/liter
NaCN	101.1 g/liter
KOH	32.8 g/liter

All test solutions were made by diluting with water, adding 7.8 g/liter of KCl and adjusting the pH by adding dilute nitric acid. pH valves were determined within ± 0.05 pH units.

The platinum rotating disk electrode was prepared by immersion in concentrated nitric acid for 5 min after each experiment to remove the deposited copper and activate the platinum.

The i-V curves were determined at a sweep rate of 50 mV/sec starting at the most anodic currents and sweeping cathodically.

Results and Discussion

Steady-state distinct limiting current densities are not observed in alkaline copper cyanide solutions. Figure 1 shows the effects on the current potential curves when the pH is changed from alkaline to acid. Changing the pH from 11.35 to 9.05 causes the current-voltage curve to shift uniformly to more anodic poten-

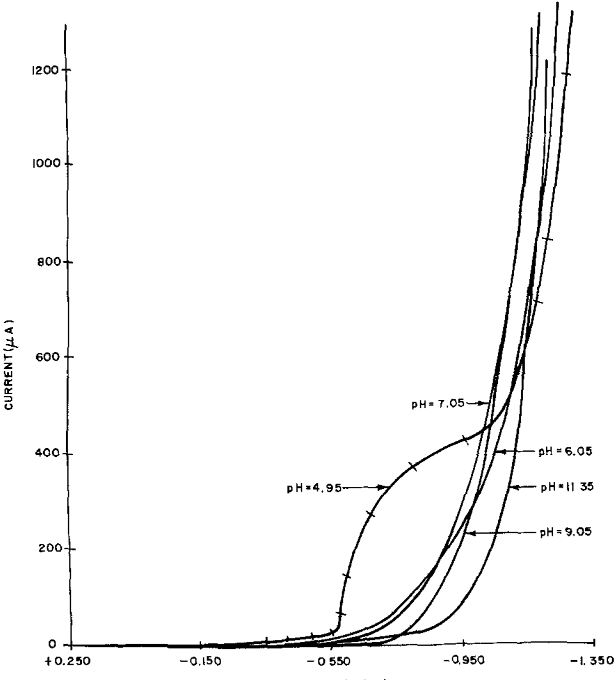

Fig. 1. Potential sweep: pH variation

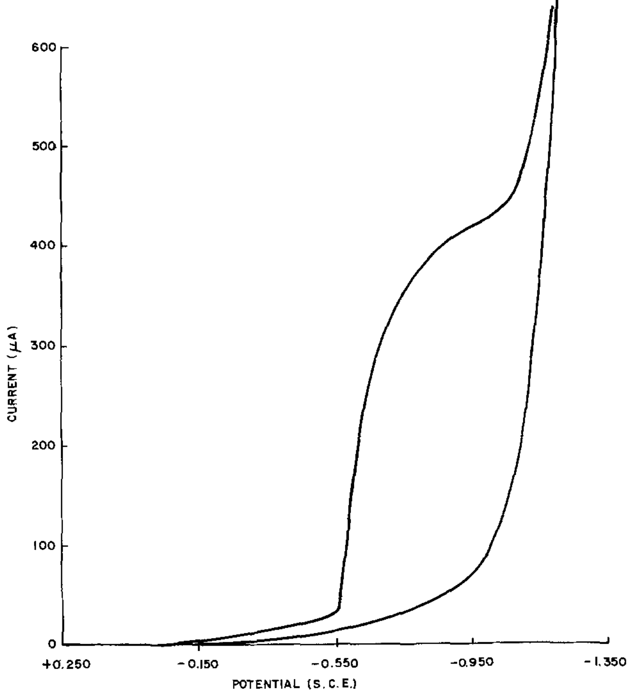

Fig. 2. Potential sweep: comparison with residual current

tials. On decreasing the pH further the lower current densities begin to increase rapidly at a given potential. At the higher current densities the curve is shifted to more cathodic potentials. By decreasing the pH to 4.95 a distinct limiting current density is observed. The initial decrease in pH from 11.35 to 9.05 causes the free cyanide ion concentration to decrease from approximately 98% to 30% through an increase in the ion pair formation producing hydrocyanic acid (4). Further decreases in pH to 7.05 cause the fraction of ion pairs to approach 99%. Decreasing the cyanide ion concentration causes the concentration of the species $Cu(CN)_3^{-2}$ to increase at the expense of $Cu(CN)_4^{-3}$. The equilibrium potential for $Cu(CN)_4^{-3}$ is −0.75V and $Cu(CN)_3^{-2}$ is −0.40V (NHE). Decreasing the pH to 4.95 shifts both the concentration of copper to a higher fraction of $Cu(CN)_3^{-2}$ and the equilibrium potential closer to −0.40[2]. At this lower pH the deposition can occur at a higher rate from the $Cu(CN)_3^{-2}$ species and thus be separable from the hydrogen evolution reaction. At pHs less than about 3.0 CuCN begins to precipitate. Figure 2 shows current-voltage curve where a distinct limiting current density is observed. The residual current-voltage curve for the supporting electrolyte is also included in Fig. 2. Potentiodynamic sweeps starting at +0.250 and stopping at −1.350 were repeated on the same electrode three times. The results are shown in Fig. 3. The magnitude of the limiting current density is equal for the three repetitive sweeps. The peak at −0.560V that appears on the second sweep and whose amplitude increases on the third sweep is due to reduction of the copper oxide formed at potentials anodic to −0.150. The limiting current density is diffusion-limited with respect to diffusion of ions to the electrodes from the solution. The limiting current occurs on platinum, copper, and copper electrodes partially covered with copper oxides. Figures 4-7 give data showing adherence to the Levich equation where either the concentration of the discharging species is varied or the rotational speed of the electrode is changed.

The plot of limiting current density *vs.* concentration of discharging species is linear up to 6×10^{-3} M/liter (see Fig. 7). The limiting current density plateau above this concentration at this rotational speed becomes of questionable usage for analytical purposes. The plot of limiting current density *vs.* the square root

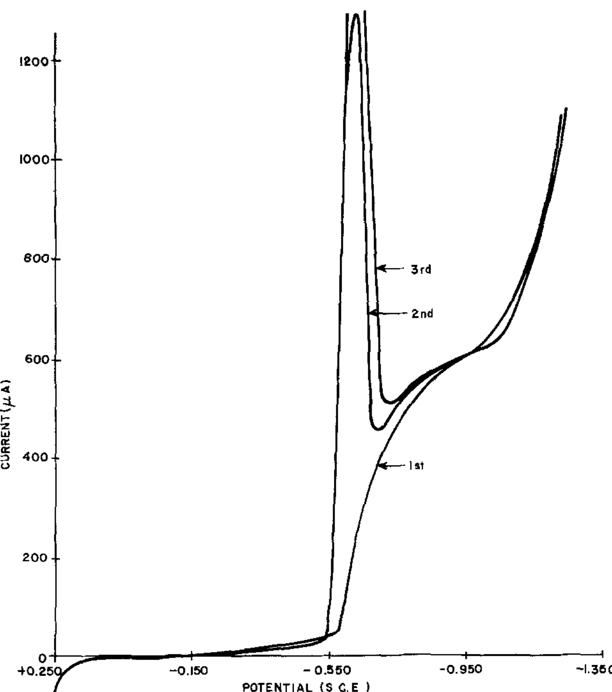

Fig. 3. Potential sweep: copper and platinum

of the rotational speed, given in Fig. 5 is valid up to 20 rps which is the limit of this study. Apparent diffusion coefficients calculated from the plots i_L *vs.* concentration are $0.85 \pm 0.09 \times 10^{-6}$ cm²/sec (95% confidence limits). Apparent diffusion coefficients from plots of i_L *vs.* $w^{1/2}$ are $0.79 \pm 0.08 \times 10^{-6}$ cm²/sec (95% confidence limits). The discharging species in these systems (1) is usually considered to be $Cu(CN)_2^-$. Diffusion coefficients for $Au(CN)_2^-$ in similar systems (5) range from 1.63×10^{-5} cm²/sec to 1.68×10^{-5} cm²/sec. These diffusion coefficients are calculated on the basis of the total copper metal content and are to be considered a lower limit. To calculate Tafel slopes current-voltage curves have been obtained over a wide range of concentrations of cop-

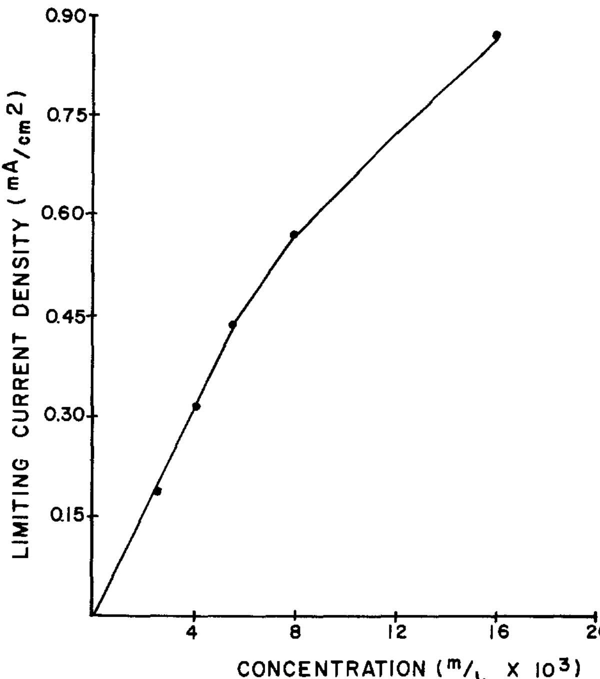

Fig. 7. Limiting current density vs. concentration

per cyanide with additional free cyanide yielding a constant ratio of copper cyanide to free cyanide and several diffusion layer thicknesses. Figure 8 shows a Tafel plot corrected for the effects of mass transfer for several different diffusion layer thicknesses corresponding to rotational speeds varying from 2.5 to 20 rps. Figure 9 gives data for Tafel plots corrected for effects of mass transfer for several concentrations of copper cyanide with added free cyanide. The ratio of copper cyanide to free cyanide is kept constant. Tafel slopes calculated from data in Fig. 8 and 9 yield an average value of the Tafel slope equal to 0.144V with a sample standard deviation of 0.016V. The transfer coefficient is equal to 0.40 ± 0.03 for 95% confidence limits. This value of the transfer coefficient is essentially equal to that reported in the literature $\alpha = 0.38 \pm 0.04$ (1).

An approximate exchange current density can be obtained from the linear polarization curve. For a concentration of copper cyanide equal to 8×10^{-3} M/liter (with CuCN/CN = 2.5) $i_o = 8 \pm 1 \times 10^{-5}$ A/cm². The equilibrium potential measured for the solution of copper cyanide concentration equal to 8×10^{-3} m/liter (with CuCN/CN = 2.5) at pH = 4.75 is equal to −0.430V (SCE). The order of the deposition reaction with respect to the copper-containing species is obtained (6) from the transfer coefficient and the slope of the log-log plot of the current-copper concentration at a constant potential. The order of the deposition reaction with respect to copper is 1.12 ± 0.05.

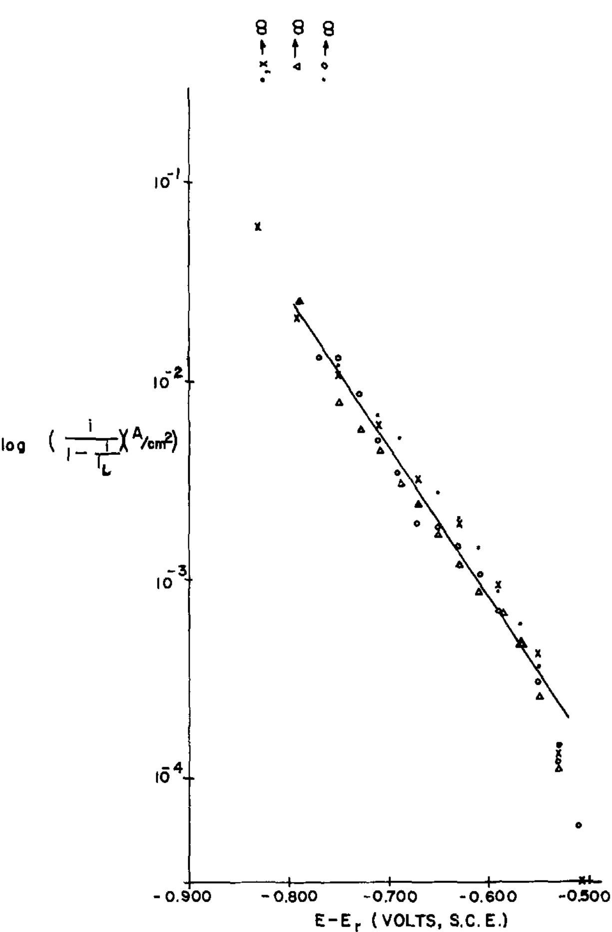

Fig. 8. $E - E_r$ vs. log (1/1 — i/i) for rotational speed dependence;

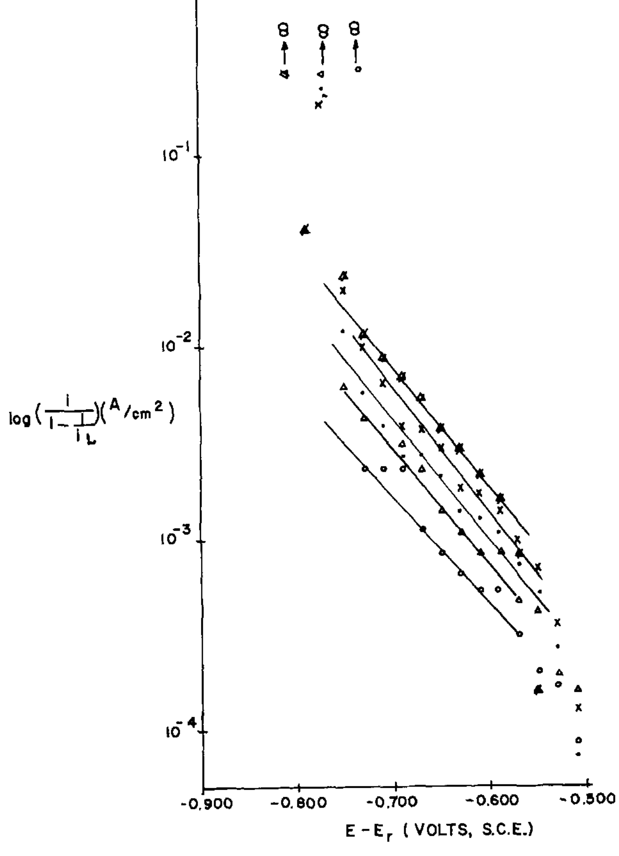

Fig. 9. $E - E_r$ vs. log $(i/1 - i/i_L)$ for concentration dependence

concentration × 10^3 m/g	16	8	5.6	4	2.4
	△	×	·	△	○

Dilute solutions of copper cyanide at pH equal to 4.75 decompose on standing. Figure 10 shows the current-potential curves of a solution containing 8×10^{-3} M/liter (with CuCN/CN = 2.5). The decomposition of the copper cyanide complex follows first order kinetics with a rate constant equal to $3.35 \pm 0.03 \times 10^{-6}$ sec^{-1}. During the period that decomposition takes place an increase in the turbidity takes place with an increase in hydrocyanic acid above the solution.

Conclusions

1. A distinct limiting current density can be observed in dilute acid copper cyanide solutions on both platinum and copper electrodes. The Levich equation is obeyed for copper deposition from dilute acid copper cyanide solutions. The limiting current density is proportional to the concentration and to the square root of the rotational speed of the disk electrode.

2. Electrode kinetic parameters have been determined for copper deposition from dilute acid copper cyanide solutions. Apparent diffusion coefficients considered to be a lower limit range from 0.79×10^{-6} cm^2/sec to 0.85×10^{-6} cm^2/sec. Tafel slopes range from 0.130 to 0.165V with a mean value of 0.144 ± 0.016V and $\alpha = 0.40 \pm 0.03$. The copper deposition reaction is first order with respect to the copper-containing species. The exchange current density determined for one concentration is $8 \pm 1 \times 10^{-5}$ A/cm^2 and the equilibrium potential for this condition is −0.430 (SCE).

3. The decomposition of the copper-containing species responsible for the limiting current density is first order with a rate constant of $k = 3.35 \pm 0.03 \times 10^{-6}$ sec^{-1}.

Kinetics of Electroless Copper Plating

III. Mass Transport Effects

Francis M. Donahue*

Department of Chemical Engineering, The University of Michigan, Ann Arbor, Michigan 48109

ABSTRACT

Gas bubble formation and evolution at the plating surface for electroless copper produces a microconvection condition which influences the mass transfer rate. The interfacial concentrations of the reactant species in the absence of forced convection are computed from this model and are found to be dependent on the plating rate and the bulk concentrations, diffusivities, and reaction stoichiometry. Analyses of published rate studies show that the interfacial concentrations of cupric ions were less than the bulk values and that the apparent reaction order based on the interfacial concentration was approximately constant. Two different correlations for superposed micro and macroconvection were found to be indistinguishable and consistent with the microconvection model when applied to published plating rate data at rotating cylinders.

Dumesic, Koutsky, and Chapman (1) have shown that the apparent reaction order of cupric ion in electroless copper plating solutions is dependent upon the rate of mass transport to rotating copper-plated cylinders. Since most technical practice and research studies operate at vertical surfaces in the virtual absence of forced convection, it is prudent to ascertain the nature of the transport process and to obtain a mathematical description of the mass transfer coefficient under these conditions. Further, the mechanism of the electroless copper plating reaction is accessible only if the interfacial concentrations of the species involved can be estimated.

This paper will discuss the nature of the transport process in the absence of forced convection and present the mathematical expressions describing the relationships among experimental conditions and mass transfer coefficients and interfacial concentrations. These results will be used to analyze the data from published kinetic studies. Finally, the effects of forced convection superimposed on the microconvection process will be analyzed.

General Remarks: Mass Transport

The flux of a transporting species, "j", in the absence of migration and bulk flow (conditions which prevail for the reactants in electroless copper plating) is

$$N_j = (10^{-3}\, D_{jm}/\delta)\,(c_{sj} - c_{bj}) \quad [1a]$$

or

$$N_j = 10^{-3}\, k_{cj}\,(c_{sj} - c_{bj}) \quad [1b]$$

where N_j is the flux of the transporting species "j" (mole/cm^2 sec), D_{jm} is the diffusivity of the species in the solution mixture (cm^2/sec), δ is the mass transfer boundary layer thickness (cm) and c_{sj} and c_{bj} are the interfacial and bulk concentrations of the transporting species, respectively, (M) and k_{cj} is the mass transfer coefficient of the species ($= D_{jm}/\delta$) (cm/sec). The diffusivity is a property of the transporting species-solution system and can be estimated (2-4) or measured. Mass transfer coefficients can be estimated from mass transfer correlations for particular system geometries and flow regimes (5-12). Similarly, boundary layer thicknesses for some system geometries and flow regimes are available (8, 10, 12).

If the flux of the transporting species is known along with its mass transfer coefficient or its diffusivity and boundary layer thickness, the interfacial concentration can be computed from

$$c_{sj} = c_{bj} + 10^3 N_j \delta / D_{jm} \quad [2a]$$

or

$$c_{sj} = c_{bj} + 10^3 N_j / k_{cj} \quad [2b]$$

General Remarks: Kinetics of Electroless Copper Plating

The over-all chemical reaction for the process is

$$Cu^{2+} + 2H_2CO + 4\,OH^- \rightarrow Cu + 2HCO_2^- + 2H_2O + H_2 \quad [3]$$

The relationships among the fluxes of the transporting reactant species and the measured plating rate based on this equation are

$$N_{Cu^{2+}} = \frac{N_{H_2CO}}{2} = \frac{N_{OH^-}}{4} = -\,3.9 \times 10^{-9}\, r_p \quad [4]$$

where r_p is the plating rate (μm/hr). Therefore, the fluxes of the reactant species can be computed from the measured plating rate(s) and used in Eq. [2a] or [2b] to estimate the interfacial concentrations.

Mass Transport in the Absence of Forced Convection

The evolution of hydrogen gas at the reaction surface (see Eq. [3]) provides a unique mass transfer

* Electrochemical Society Active Member.

Key words: electroless copper plating, gas evolution, kinetics, macroconvection, mass transport, microconvection.

condition in the absence of forced convection. Mass transfer coefficients and boundary layer thicknesses have been shown to be dependent on the volumetric flux of evolved gas (13-21). Although the bulk of the data presented in these publications is in the range of gas volumetric fluxes (current densities) of interest in industrial electrolytic cells (*i.e.*, one or more orders of magnitude greater than those for electroless copper plating), the lower end of the data of Ibl and Venczel (14, 16) is in the region of electroless copper plating. Therefore, a correlation obtained from their data for the diffusion boundary layer thickness will be used in this analysis, *i.e.*

$$\delta = 1.6 \times 10^{-3} v^{-0.53} \quad [5]$$

where v is the volumetric flux of hydrogen gas (cm³/cm² min). From Eq. [3] the gas volumetric flux is related to the plating rate by

$$v = 5.2 \times 10^{-3} r_p \quad [6]$$

Inserting Eq. [6] in [5]

$$\delta = 2.6 \times 10^{-2} r_p^{-0.53} \quad [7]$$

The interfacial concentrations of the respective reactant species can be estimated by inserting Eq. [7] and [4] in [2a] using estimates of the species diffusivities (*i.e.*, $Cu^{2+} = 9.3 \times 10^{-6}$ cm²/sec, $OH^- = 6.8 \times 10^{-5}$ cm²/sec and $H_2CO = 10^{-5}$ cm²/sec)

$$[Cu^{2+}]_s = [Cu^{2+}]_b - 1.1 \times 10^{-2} r_p^{0.47} \quad [8]$$

$$[OH^-]_s = [OH^-]_b - 5.8 \times 10^{-3} r_p^{0.47} \quad [9]$$

$$[H_2CO]_s = [H_2CO]_b - 2.0 \times 10^{-2} r_p^{0.47} \quad [10]$$

where the terms in brackets represent the concentrations of the species.

Plots of the absolute values of the differences between interfacial and bulk concentrations of the respective species with respect to the plating rate according to Eq. [8]-[10] are shown in Fig. 1. In addition, the plating rate range for published electroless copper plating rate studies (22-30) is shown. Inspection of Fig. 1 and the plating rates and compositions of plating baths found in the literature reveal that the concentration differences for formaldehyde and hydroxyl ion are less than ten percent of the bulk concentrations. Therefore, mass transport of these species cannot be expected to play a significant role in the control of the over-all process, as observed by Dumesic (1). On the other hand, the data indicate that for baths which are dilute in cupric ion (*i.e.*, $[Cu^{2+}]_b < 10^{-2}$M) with low plating rates (rates less than 0.5 μm/hr are characteristic of these copper-poor baths) the role of mass transport is decisive. Even in the more concentrated baths ($0.01M < [Cu^{2+}]_b < 0.2M$) the interfacial concentrations are between twenty and eighty percent of the bulk values—a region which is intermediate between mass transport and chemical or electrochemical control of the process.

Figure 2 shows plots of the plating rates as a function of bulk and interfacial cupric ion concentrations for five extensive rate studies (1, 22, 25, 27, 28). The lines through the data points (with the exception of the curved portion for the bulk concentration data of Molenaar (27)) are least squares fit of the respective data. Where data points are not shown for interfacial concentrations (open symbols), the estimated concentration differences were negative, zero, or smaller than the estimates of the bulk concentrations.[1]

[1] With the exceptions of Ref. (25) and (28), the data had to be estimated from published graphs.

(28)	0.43	0.27

* Partial analysis of Goldie's data for "strong" solutions by the author.
** "Final" deposition rate at 0 rpm.

Table I shows the apparent reaction orders for cupric ion in electroless copper plating solutions. When the bulk concentration is used as the basis for the reaction order computation, the reaction orders exhibit a range from 0.36 to 1.0. On the other hand, when the interfacial concentration is used, the range is substantially diminished and, considering that the interfacial concentrations are only estimates and the data are from four different laboratories, the agreement is good. This agreement for the cupric ion reaction order, after allowing for mass transport effects, strongly suggests a mechanistic role for cupric ion which is independent of the complexing agent.

One can intuit the effect of mass transport on the empirical rate law (25) by noting that the higher the "bulk" reaction order, the greater is the "correction" when mass transport is taken into account (see Table I). Thus, the data of Dumesic (1) and Molenaar (27) were taken under conditions which were substantially influenced by mass transport while Goldie (22) and El-Raghy (26) evidently were operating in a region where mass transfer effects were minimal.

According to the mixed potential theory of electroless copper plating (31), the limiting value[2] of the apparent reaction order for cupric ion is 0.26. Three of the "interfacial" reaction orders given in Table I are approximately equal to this value.

Traditionally, when forced convection is absent from a system, it is prudent to evaluate the possible role of natural convection as the mode of mass transport (9). To this end, mass transfer coefficients for cupric ion due to natural convection were estimated for the data of Wong and Bhalla (28). In all cases, the mass transfer coefficients were smaller than those estimated for gas evolution (see below). Therefore, it can be concluded that the mode of mass transport in electroless copper plating baths at vertical surfaces is that due to microconvection (gas bubble formation and evolution).

Mass Transport in the Presence of Forced Convection

Vogt (20) has proposed a method of estimating the mass transfer coefficient in the presence of superposed microconvection (gas bubble formation and evolution at low gassing rates) and macroconvection (forced convection or convection induced by high gassing rates). His correlation can be written

$$k_c = (k_{cg}^2 + k_{cf}^2)^{0.5} \qquad [11]$$

where k_c is the "net" mass transfer coefficient, k_{cg} is the microconvection coefficient, and k_{cf} is the macroconvection coefficient. Beck (13) has suggested a linear combination, *i.e.*

$$k_c = k_{cg} + k_{cf} \qquad [12]$$

for the same situation.

[2] This value is based on Paunovic's values of Tafel slopes (32) corrected for temperature, a reaction order of one for cupric ion in the cathodic partial process and no interaction by cupric ion in the anodic partial process.

Since electroless copper plating operates at relatively low gassing rates, it can be assumed that the conditions discussed above represent microconvection. Therefore, the microconvection mass transfer coefficient can be computed by substituting (in turn) Eq. [4], [8], [9], and [10] in [1b] and rearranging to obtain equations of the form

$$k_{cgj} = A_j\, r_p^{0.53} \qquad [13]$$

where k_{cgj} is the microconvection coefficient for species "j" and A_j is a constant for each "j". Figure 3 shows the dependence of microconvection mass transfer coefficients on plating rate for the reactant species.

The experiments of Dumesic (1) should provide a means of evaluating the relative merits of the correlations of Beck (13) and Vogt (20) since their experimental conditions with rotating cylinders represent a superposition of hydrodynamic flows. Unfortunately, their estimated mass transfer coefficients are too large due to an error in calculating the values of the Reynolds number. The Reynolds number should have been defined (10, 33)

$$Re = \Omega d^2/2\nu = 0.052\, \omega d^2/\nu \qquad [14]$$

where Ω is the cylinder angular velocity (rad/sec), d is the cylinder diameter (cm), ν is the kinematic viscosity (cm²/sec), and ω is the cylinder rotation rate (rpm). Using their values of physicochemical properties and the correct form of the Reynolds number, the computed values of the macroconvection mass transfer coefficients for cupric ion, k_{cf}, were 6.2×10^{-4} cm/sec at 150 rpm, 1.6×10^{-3} cm/sec at 600 rpm, and 2.5×10^{-3} cm/sec at 1100 rpm. Table II shows the computed "net" mass transfer coefficients for cupric ion, k_c, based on the respective correlations. For Vogt's correlation (20), the coupling of the flows produces a moderate enhancement of the mass transfer rate at the lowest rotation speed while at the other rotation speeds macroconvection predominates. The correlation of Beck (13), on the other hand, predicts enhancement due to the superposed flows for all experimental conditions.

The interfacial concentrations of cupric ion can be computed from (inserting Eq. [4] in [2b])

$$[Cu^{2+}]_s = [Cu^{2+}]_b - 3.9 \times 10^{-6}\, r_p/k_c \qquad [15]$$

Figure 4 represents the computed cupric ion interfacial concentrations for all of the data given in Dumesic's Fig. 8. The data for zero rpm were computed from Eq. [8] while the rotating cylinder data were computed from Eq. [15] using the "net" mass transfer coefficients from Table II. If the reaction mechanism does not change with rotation speed and cupric ion

concentration, the data should fall on a single line. The "filled" symbols represent computations based on Beck's correlation (13) while the "open" symbols are for the correlation of Vogt (20). The least squares lines for both correlations are virtually indistinguishable with identical correlation coefficients. Therefore, although the correlations give different values of "net" mass transfer coefficients (see Table II), one cannot discriminate between the two on the basis of interfacial concentration computations for this study.

Conclusions

In the absence of forced convection, the mode of mass transport of reactant species in electroless copper plating is microconvection induced by gas bubble formation and evolution from the reaction surface. Equations describing the interfacial concentrations of the reacting species and the microconvection mass transfer coefficients have been developed and have been shown to depend on the plating rate, reaction stoichiometry, and species diffusivity.

The dependence of the plating rate on the interfacial concentration of cupric ion, *i.e.*, the apparent cupric ion reaction order, has been found to be approximately constant for five electroless plating systems.

The interfacial concentration of cupric ion has been found to be smaller than the bulk concentration for all published electroless plating rate studies where sufficient information has been provided to effect an analysis. At low cupric ion concentrations and low plating rates (in the absence of forced convection) the effect of this concentration difference approaches mass transport control of the process.

No significant difference could be found between two correlations for mass transfer coefficients in superposed micro and macroconvection flows when data for electroless copper plating in a well-defined forced convection system were analyzed. Both correlations gave results which were consistent with the microconvective analysis presented here.

Investigation of Two- and Three-Phase Fields in the Ga-As-Sb System

Michel F. Gratton[1] **and John C. Woolley**

Physics Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5

ABSTRACT

The technique of annealing samples at a temperature at which both liquid and solid phases occur, followed by quenching to freeze-in the solid phase, has been used to investigate equilibrium conditions off the pseudobinary section. It has been found that large three-phase liquid-solid-solid fields occur corresponding to the two-phase solid-solid field of the pseudobinary section. The tie-lines of the various two-phase liquid-solid fields have been determined together with the boundaries of the three-phase fields at various temperatures in the range 600°-730°C. The locus of the cusp in the liquidus sheet corresponding to the liquidus point of the three-phase field has also been found. Finally, the two solid phases of the three-phase fields give the ranges of immiscibility in the pseudobinary section $GaAs_ySb_{1-y}$, and hence the variation of the miscibility gap with temperature has been determined. This gap is found to be very asymmetric even at temperatures a little below the peritectic horizontal, the solubility limits at 700°C being $y = 0.30$ and 0.95. The results are compared with the predictions of the simple solution model which give reasonable agreement with the liquidus data but poor agreement with the miscibility gap values.

The increased interest in ternary III-V alloys for various technological applications has resulted in considerable work being done on the form of the general ternary diagrams which contain these alloys in a pseudobinary section. Thus, experimental measurements have been made and calculations carried out to determine such quantities as liquidus and solidus isotherms and solidus isoconcentration lines [see, for example, Ref (1)]. The ternary system Ga-As-Sb is more complicated than some of the others because a miscibility gap occurs in the solid solution region of the section GaAs-GaSb and hence there must be three-phase, liquid-solid-solid, fields in the general diagram. Although some data are available concerning the liquidus sheet (2-7), little information has been obtained concerning the behavior of solid phases in the various isothermal sections (4, 7).

Here, experimental measurements have been made to determine as a function of temperature the boundaries of these three-phase fields, the position of tie-lines in the adjacent two-phase, liquid-solid, fields, and the position of the cusp in the liquidus sheet corresponding to the liquid vertex of the three-phase field. These results give immediately the variation with temperature of the solid-solid miscibility gap in the GaAs-GaSb pseudobinary section. These experimental data have then been compared with the predictions of the simple solution model (1).

Key words: ternary phase diagram, $GaAs_ySb_{1-y}$ alloys, miscibility gap.

Experimental Method and Results

The presence of peritectic form in the pseudobinary section $GaAs_ySb_{1-y}$ (4, 7) indicates that at temperatures below the peritectic horizontal, three-phase (liquid-solid-solid) fields must occur in the general ternary diagram in addition to the two-phase (liquid-solid) fields which terminate on the single-phase solid solution fields in the pseudobinary section. In order to investigate the boundaries of these fields and the tie-lines of the two-phase fields, it is necessary to investigate samples at various compositions well away from the pseudobinary section.

The samples used in the work were prepared from the required weights of GaAs, GaSb, and antimony or gallium as appropriate; this method being convenient and avoiding the necessity of dealing with elemental arsenic. The sample treatment was as de-

scribed previously (8) using the anneal and quench technique. Thus each sample was weighed, sealed in a quartz ampul under reduced argon pressure, and held for 1-2 hr at 1250°C while being agitated to give good mixing of the components. The sample was then cooled to the required annealing temperature where it was allowed to attain equilibrium. It was found that, for the range of composition used in the work, annealing times of 3 days were quite sufficient for the sample to reach an equilibrium condition. Tests showed that annealing times of up to 60 days did not change the conditions attained after 3 days. The samples were then quenched in order to freeze-in the equilibrium solid phase. This technique is well suited to the present work since, provided the composition of the samples is appropriately chosen, an appreciable part of the mixture is liquid during the annealing, thus allowing a reasonable speed of diffusion. However, during the quench, the diffusion rate in the solid is very low and hence the solid phase (or phases) at the annealing temperature is retained unchanged. This phase (or phases) can be identified from an x-ray powder photograph using the known lattice parameter *vs.* composition relation (4) for the $GaAs_ySb_{1-y}$ section. In the present work, the homogeneity of the required solid phase was clearly demonstrated by the sharpness of the high angle x-ray lines.

Conditions for equilibrium were investigated at various temperatures and the choice of starting compositions was guided by a preliminary theoretical estimate of the boundaries of the three-phase fields as described below plus the requirement that sufficient liquid phase be present during annealing to allow equilibrium to be attained rapidly. Firstly, the GaSb-rich side of the diagram was investigated, specimen compositions being chosen so that they would cover both the two-phase field and the three-phase field at the particular temperature of anneal. For convenience, two series of compositions were chosen, each with a fixed value of gallium concentration (*i.e.*, $N_{Ga} = 0.65$ and $N_{Ga} = 0.40$) and the compositions investigated at 700°C are shown in Fig. 1. Thus, for example with the $N_{Ga} = 0.65$ series, three samples gave tie-lines in the two-phase field and four samples were in the three-phase field and, within the limits of experimental error, gave identical phases. For samples in both fields, the liquid phase on quenching gave almost pure GaSb plus some gallium-rich phase and the lines due to these phases could be easily observed in the x-ray photograph and discarded. The two-phase samples gave the required equilibrium solid while in the three-phase field two equilibrium solids, one GaSb-rich and one GaAs-rich, occurred. With the above choice of compositions, the GaSb-rich solid could be easily determined but the amount of the GaAs-rich phase was sufficiently small that only weak lines were obtained and these were not used in this section of the work. Similar results were obtained for the series with $N_{Ga} = 0.40$. The data obtained from these measurements plus those obtained similarly at other temperatures are given in Table I.

In order to determine the boundaries of the three-phase fields for any given temperature, graphs were plotted of the composition y of the equilibrium solid (determined from lattice parameter) against the arsenic content N_{As} of the annealed samples. The results for the cases of 700° and 675°C are shown in Fig. 2. For each temperature, the samples occurring in either three-phase field should all have the same value of y and a mean horizontal line has been drawn through these. It can be seen that in the two-phase field the variation of y with N_{As} can, within the limits of experimental error, be taken as a straight line, separate lines being drawn for the two sets of samples with different N_{Ga}. These lines will pass through the origin for temperatures below the melting point of GaSb. The point of intersection of each of these lines with the line from the three-phase field gives the parameters determining the three-phase boundary, *i.e.*, the y value gives a point on the pseudobinary section and the N_{As} value together with the appropriate N_{Ga} value gives a second point on the boundary. Lines showing the boundaries in the 700°C case are shown

in Fig. 1 and tie-lines for the two-phase fields are also shown. Similar results have been obtained for various temperatures in the range 600°-700°C.

While the pseudobinary section clearly defines one end of this three-phase boundary, the liquidus point is still undetermined. (These liquidus points will form a cusp across the liquidus sheet and so the point will, for convenience, be referred to as the cusp point.) It was hoped to determine the boundary on the GaAs side of the three-phase field by the same method, so that the two lines, together with the pseudobinary section, would completely define the three-phase triangle. However, it was found that a construction like that used in Fig. 2 was not possible in this case, since the range of solid solution of GaSb in GaAs was found to be very small for temperatures below 720°C. Thus the value of y for the equilibrium solid phase was in the range 0.95-1.00 for all annealed samples. Hence, although a figure could be obtained for the limiting y value, no N_{As} value could be found to give a second point on the limiting tie-line.

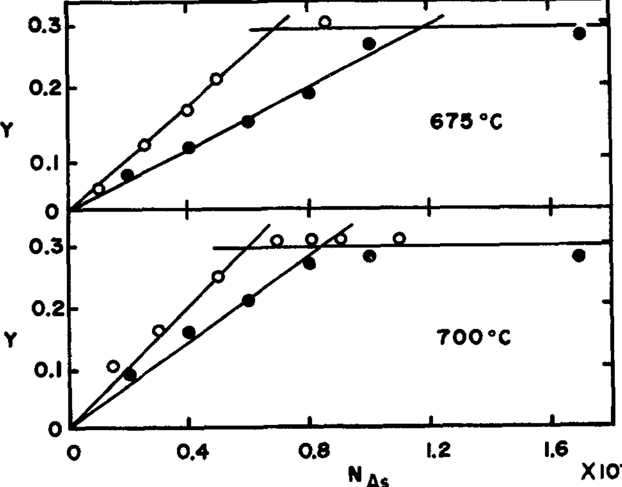

Fig. 2. Variation of composition y of equilibrum phase with arsenic concentration N_{As} of annealed sample. ●, N_{Ga} = 0.40 and ○, N_{Ga} = 0.65.

The cusp point has therefore been determined as the point of intersection of the GaSb-rich three-phase boundary and the appropriate liquidus isothermal curve. As was shown previously (1, 8), the simple solution model gives good agreement with experiment when used to calculate liquidus isotherms in these ternary systems. Thus, this model has been used here to calculate the appropriate liquidus isotherms, as is discussed further below. Figure 1 shows the calculated isotherm for 700°C, and it is seen that it lies very close to the Ga-Sb boundary of the diagram. For lower temperatures, the isotherms will be even closer to the boundary and, since the temperature gradient is relatively large in this range, little error should occur in the compositions of the points determined from these curves. However, problems occur for samples with N_{Ga} less than 0.5 at temperatures below about 650°C. In these cases, the cusp point is found to be close to the Sb apex of the main diagram. In this range, the calculated isotherms are not satisfactory as they do not indicate the position of the eutectic valley which must run out from the Ga-Sb eutectic [at N_{Ga} = 0.12 (9)] probably towards the minimum in the As-Sb liquidus curve [at N_{As} = 0.25 (10)]. Thus, the cusp point of the three-phase triangle has not been determined in this range.

As indicated above, the GaAs-rich sides of the three-phase triangles could not be determined by the same method as the GaSb-rich sides. However, annealing of samples in the GaAs-rich region of the three-phase fields gave the GaAs-rich equilibrium solid phase, and again, x-ray powder photographs gave the corresponding point of the pseudobinary section, thus completing the information needed to specify the three-phase fields. Figure 3 shows the three-phase fields for three different temperatures, 730°, 700°, and 600°C. It is seen that the position of the cusp point moves appreciably with temperature in the range 600°-745°C and Fig. 4 shows the variation of the values of N_{Ga} at the cusp point as a function of temperature. The N_{As} values at the cusp point were very much smaller, except in the Sb-rich region, as discussed above, and so could not be determined with any accuracy.

The other important information which is obtained immediately from the three-phase field data is the variation with temperature of the range of solid solution in the pseudobinary section. The experimental values are shown in Fig. 5. In the initial work on this question, samples with compositions on the pseudobinary section were annealed to equilibrium in the solid-solid two-phase field (7). The main difficulty

with this method is that the diffusion rates are so slow that very long annealing times are required. Figure 5 shows results obtained in this way for samples annealed for three months or longer. These results confirm the data obtained from the three-phase field work, giving good agreement at both ends of the miscibility gap. It is worth noting that samples in the three-phase fields needed less than three days annealing to attain equilibrium while samples in the solid-solid two-phase field required at least three months.

Theoretical Analysis and Discussion

Little work has been published on calculations for this system. Panish and Ilegems (1) and Stringfellow (11) have calculated the liquidus and solidus curves of the pseudobinary section, and Antypas and James (3) have used Darken's quadratic formalism for a

ternary liquid and assumed a regular solid solution to calculate liquidus data for compositions with $N_{Ga} > 0.5$. More recently, Nahory *et al.* (5) have made an analysis based on the simple solution model, but treating the $\alpha_{As\text{-}Sb}$ interaction parameter as composition dependent rather than making the usual assumption of linear temperature dependence. Here, the simple solution model has been used to predict values for comparison with the various data determined experimentally.

The theory used for the simple solution model was summarized in a previous work on the Ga-In-Sb diagram (8) and the final equations necessary for the calculations are repeated here.

$$\ln \gamma_{AC} = \ln \frac{\gamma_A \gamma_C}{\gamma_A{}^{s1} \gamma_C{}^{s1}} + \ln 4 \frac{N_A N_C}{x} + \frac{\Delta S^F{}_{AC}}{RT} (T^F{}_{AC} - T) \quad [1a]$$

$$\ln \gamma_{BC} = \ln \frac{\gamma_B \gamma_C}{\gamma_B{}^{s1} \gamma_C{}^{s1}} + \ln 4 \frac{N_B N_C}{1 - x} + \frac{\Delta S^F{}_{BC}}{RT} (T^F{}_{BC} - T) \quad [1b]$$

$$RT \ln \gamma_{AC} = \alpha_{AC\text{-}BC} (1 - x)^2 \quad [2a]$$

$$RT \ln \gamma_{BC} = \alpha_{AC\text{-}BC} x^2 \quad [2b]$$

$$RT \ln \gamma_A = \alpha_{AB} N_B{}^2 + \alpha_{AC} N_C{}^2 + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC}) N_B N_C \quad [3a]$$

$$RT \ln \gamma_B = \alpha_{AB} N_A{}^2 + \alpha_{BC} N_C{}^2 + (\alpha_{AB} + \alpha_{BC} - \alpha_{AC}) N_A N_C \quad [3b]$$

$$RT \ln \gamma_C = \alpha_{AC} N_A{}^2 + \alpha_{BC} N_B{}^2 + (\alpha_{AC} + \alpha_{BC} - \alpha_{AB}) N_A N_B \quad [3c]$$

where the γ's are activity coefficients, the α's interaction parameters, N_A, N_B, and N_C concentrations of the three elements, x the mole fraction of AC in the solid phase, and $\Delta S^F{}_j$ and $T^F{}_j$ the entropy of fusion and melting temperature of the compound j.

Vieland's equation [12] giving the relation for the liquidus curve of a binary system A-C with a line compound AC is

$$\alpha_{AC} = -\frac{RT}{2(0.5 - c)^2} \left[\ln 4c(1 - c) + \frac{\Delta S^F{}_{AC}}{RT} (T^F{}_{AC} - T) \right] \quad [4]$$

where c is the atomic fraction of C.

The binary phase diagram data for the Ga-Sb system of various workers (9, 12-15) have been used in Vieland's equation [16] (Eq. [4]) to give values of $\alpha_{Ga\text{-}Sb}$, the melting point and entropy of fusion of GaSb being taken as 712°C and 66.1 J mol^{-1} K^{-1}, respectively (17). The values were fitted to a linear temperature dependence and the resulting parameters are given in Table II. A similar least squares fit to the Ga-As data gave an expression for $\alpha_{Ga\text{-}As}$ slightly different from that of Thurmond (18) and the value of $\alpha_{Ga\text{-}As}$ used here is also given in Table II. Jordan and Weiner (19) have questioned the validity of Vieland's method, but their improved formulation reduces to that of Vieland when a linear dependence on temperature is obtained, as in this case.

The other interaction parameters required for the analysis are $\alpha_{As\text{-}Sb}$ and $\alpha_{GaAs\text{-}GaSb}$. As in the case of the Ga-In-Sb diagram (8), values of these parameters have been determined here as a function of temperature by simultaneous solution of the experimental values for points on the liquidus and solidus curves of the pseudobinary section. Again, these α values were least squares fitted to a linear temperature variation and the resulting forms for $\alpha_{As\text{-}Sb}$ and $\alpha_{GaAs\text{-}GaSb}$ are shown in Table II.

Equations [1]-[3] were then solved simultaneously for T and y for various combinations of N_{Ga}, N_{As}, and N_{Sb} covering the complete ternary diagram, and liquidus isotherms were determined by appropriate interpolation of the data. These isotherms are shown in Fig. 6, together with the values predicted previously by Antypas and James (3), and the pseudobinary experimental values. The present results differ somewhat from those of this earlier work, but give a better fit to the known values on the pseudobinary section, as is to be expected from the method of $\alpha_{GaAs\text{-}GaSb}$ determination.

The isotherms at temperatures below 800°C are crowded together at low arsenic concentrations and these are shown separately in Fig. 7 using an orthog-

onal plot rather than the conventional cne. The calculated isotherms of Nahory *et al.* (5) are also shown in Fig. 7 together with the experimental values obtained from liquid phase epitaxy work. In the calculations of Nahory *et al*, $\alpha_{As\text{-}Sb}$ was treated as linearly dependent on N_{Sb}, and $\alpha_{GaAs\text{-}GaSb}$ was adjusted to give the best fit to the experimental data. The present curves show reasonable agreement with those of Nahory *et al.* Here, a better fit to the experimental points in the range $N_{Ga} > 0.50$ could be obtained by changing the constants in the expression for $\alpha_{As\text{-}Sb}$ while still retaining a linear temperature variation. However, such an expression for $\alpha_{As\text{-}Sb}$ gave a considerably poorer fit to the pseudobinary data.

From the calculated liquidus curves, the position of the cusp associated with the three-phase field can be predicted. Figure 8 shows the variation of the liquidus temperature T as a function of N_{As} for constant values of N_{Ga} (with $N_{Ga} < 0.5$), the calculated cusp point being given by the cross. These results are compared with the experimental data in Fig. 4 where the calculated values of T *vs.* N_{Ga} and those of T *vs.* N_{As} are shown. For the range $0.3 < N_{Ga} < 1.0$, there is good agreement between the calculated and experimental values for T *vs.* N_{Ga}. As indicated above, in the range $0 < N_{Ga} < 0.3$, the problem is complicated by the presence of a eutectic valley and experimental points have not been obtained.

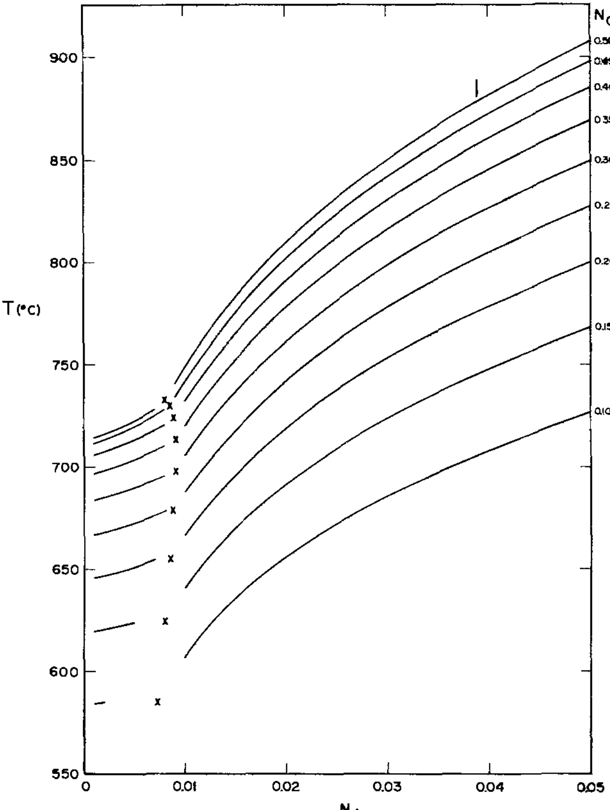

Fig. 8. Variation of temperature T with arsenic concentration N_{As} on liquidus sheet for various fixed values of gallium concentration N_{Ga}. ×, cusp point.

Other results obtained from the simple solution analysis are the form of the pseudobinary section shown in Fig. 8. As is to be expected from the method of determining the α parameters, the fit to the liquidus and solidus curves is good, although the predicted peritectic temperature is 732°C as compared with the experimental value of 745°C (7). However, the case of the boundary of the two-phase solid-solid field is very different. The agreement between experiment and predicted value is very good for the GaSb-rich side of the miscibility gap, but is very poor for the GaAs-rich alloys. Some disagreement in this range is to be expected since it can easily be shown that any solid-solid miscibility gap predicted by the simple solution model using α's, which are linear functions of T, will be symmetrical about $y = 0.5$. Since the experimental values show appreciable asymmetry, the simple solution model is bound to give poor agreement in this case.

The parameter of importance in the two-phase solid-solid field is $\alpha_{GaAs\text{-}GaSb}$. It is clear that to obtain an asymmetrical form for the miscibility gap, $\alpha_{GaAs\text{-}GaSb}$ must vary with y. It is of interest to check what form of expression is required for $\alpha_{GaAs\text{-}GaSb}$ to give the present experimental results. For two compounds, M and N, in equilibrium, the chemical potentials μ are given by

$$\mu_M = \mu_M{}^\circ + RT \ln \gamma_M y$$

$$\mu_N = \mu_N{}^\circ + RT \ln \gamma_N (1 - y)$$

where μ° is the chemical potential of the pure compound, γ the activity coefficient, and y the mole fraction of M. If the limits of solid solution occur at compositions y_1 and y_2, then

$$\mu_{M1} = \mu_{M2} \quad \text{and} \quad \mu_{N1} = \mu_{N2}$$

giving

$$\ln \gamma_{M1} y_1 = \ln \gamma_{M2} y_2$$

$$\ln \gamma_{N1} (1 - y_1) = \ln \gamma_{N2} (1 - y_2)$$

The relation between the activity coefficients and the interaction parameters is

$$RT \ln \gamma_M = \alpha (1 - y)^2$$

$$RT \ln \gamma_N = \alpha y^2$$

Hence, if α_1 and α_2 are the values of α at y_1 and y_2 it can be shown that

$$\alpha_1 = \frac{RT \left\{ y_2^2 \ln y_2/y_1 - (1 - y_2)^2 \ln \dfrac{(1 - y_2)}{(1 - y_1)} \right\}}{(y_2 - y_1)(y_2 + y_1 - 2y_1y_2)}$$

$$\alpha_2 = \frac{RT \left\{ y_1^2 \ln y_2/y_1 - (1 - y_1)^2 \ln \dfrac{(1 - y_2)}{(1 - y_1)} \right\}}{(y_2 - y_1)(y_2 + y_1 - 2y_1y_2)}$$

In the present case, for each value of T, α_1 and α_2 have been determined from the experimental values of y_1 and y_2, and the resulting variation of $\alpha_{GaAs\text{-}GaSb}$ is shown in Fig. 9. The values of α_1 and α_2 obtained are sensitive to the values of y_1 and y_2 used, and since the y_2 values are uncertain to a few percent, the resulting values of $\alpha_{GaAs\text{-}GaSb}$ are approximate only. In an attempt to fit these values to a relatively simple form, the relation $\alpha_{GaAs\text{-}GaSb} = 17{,}200 + 9000\, y^4$ J·mol^{-1} has been used, giving the curve shown in Fig. 9. This expression for $\alpha_{GaAs\text{-}GaSb}$ will, of course, give a good prediction of the solid miscibility gap but is inconsistent with that given in Table II from the pseudobinary liquidus-solidus data. It is clear that no simple form for $\alpha_{GaAs\text{-}GaSb}$ will allow the simple solution model to fit all of the experimental results.

Modifications to the simple solution model to include the effects of association of atoms in the liquid phase have been proposed by Jordan (20) and by Osamura and Murakami (21). As will be shown elsewhere, various possibilities of association in the liquid phase have been considered and none make any appreciable difference to the predicted values of the solid phase miscibility gap in this system. In no case can agreement with the experimental values be obtained without arbitrarily including an $\alpha_{GaAs\text{-}GaSb}$ variation of the form given above.

Conclusions

The work described here, together with that in a previous paper (7), indicates clearly that the pseudobinary section $GaAs_ySb_{1-y}$ of the Ga-As-Sb system shows peritectic behavior, and that no equilibrium solid phase occurs in the pseudobinary section in the range $0.38 < y < 0.68$. This explains the problems that various workers (5, 22) have encountered in attempting growth of the alloys by liquid phase epitaxy. Samples in the above range have been produced by molecular beam epitaxy (6, 23) and, as indicated previously (7), it is suggested that these must represent a metastable condition.

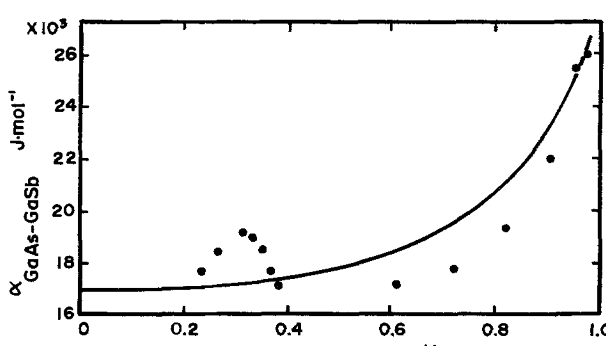

Fig. 9. Variation of interaction parameter $\alpha_{GaAs\text{-}GaSb}$ with composition y. ●, values determined from limits of pseudobinary miscibility gap; —— $\alpha_{GaAs\text{-}GaSb} = 17{,}200 + 9000\, y^4$ J·mole^{-1}.

The problems of liquid phase epitaxy are further illustrated by the diagrams in Fig. 3 and 5. For the composition range $0.67 < y < 1.00$, the temperature range in which certain alloys can be grown is very small, *e.g.*, for $y = 0.80$ growth is possible only in the temperature range 735°-785°C. As is also indicated in Fig. 3, the possible composition range of liquid solution from which alloys can be grown is very limited since compositions in the three-phase fields cannot be used for this purpose.

Acknowledgments

The authors wish to thank Dr. M. B. Panish and Dr. G. B. Stringfellow for useful discussions.

Differential Infrared (DIR) Studies of CVD Borosilicate Films

Joe Wong

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Room temperature infrared transmission spectra in the range 4000-250 cm^{-1} of binary borosilicate glass (BSG) films vapor-deposited by reacting nitrogen-diluted B_2H_6-SiH_4-O_2 mixtures on heated Si substrates at 350°C have been obtained across the whole composition range. A differential infrared (DIR) technique has been used to identify a new B-O-Si stretching mode at ~1130 cm^{-1}. The intensity variation of this mode with composition is very similar to the well-characterized B-O-Si mode at 930 cm^{-1}, and lends further support to the structural model proposed earlier for the B_2O_3-SiO_2 glass system in which the boron and silicon are three-fold and four-fold coordinated with oxygen, respectively, and each oxygen is bridging a pair of B and/or Si atoms to form a 3-dimensional random network. The effect of thermal history on the structure of CVD glasses deposited above the glass transition temperature, T_g, as in the case of B_2O_3 is contrasted with that of CVD SiO_2 deposition at temperatures far below the T_g of the bulk material. Furthermore, it is shown by annealing experiments that the B-O-Si mode at 930 cm^{-1} is a very sensitive probe for structural changes in the borosilicate system.

Glassy solids are commonly formed by continuous cooling from the liquid state. The procedure consists of quenching a normal liquid into the supercooled liquid range at such a rate so as to bypass its equilibrium crystallization point. Finally, at T_g, the glass transition temperature, the system falls out of its internal equilibrium. The supercooled liquid now transforms to a glass, carrying with it the structural configuration at T_g. However, the essential requirement for glass formation is that the thermal energy of an ensemble of particles, whether molecules, ions, atoms, etc., can be removed at a rate which for kinetic reasons precludes the organization of these particles into a crystal lattice. For this purpose an initially liquid state of the glassy system is by no means necessary. In fact a more efficient procedure for removing the molecular thermal energy is to deposit the molecules sequen-

Key words: infrared, CVD, films.

tially from a vapor onto a cold substrate (cold with respect to T_g of the deposited material).

Thus, the vapor-phase route provides not only another way of arriving at the glassy state of matter, but oftentimes allows preparation of novel amorphous materials unattainable by conventional techniques of quenching the liquid state. Binary B_2O_3-SiO_2 glasses of composition not readily obtained by melt-quenching can be prepared by chemical vapor deposition (CVD) techniques (1) from one end component to the other (2). In the CVD technique, a preset mixture of the desired gases and vapors containing constituents of the desired material is passed over and allowed to react at a heated substrate, thereby producing a solid-phase reaction product in the form of a thin film (3). These CVD materials in the form of thin film are ideal for transmission spectroscopy in the frequency region where the materials exhibit high absorption coefficient, *e.g.*, $\sim 10^4$ cm^{-1} in the infrared (4). Technologically, these binary glass films have wide applications as diffusion sources in the planar technology of microelectronic fabrication (2, 5) and, more recently, as cladding materials for low-loss SiO_2-core fibers in optical waveguides (6, 7).

In this paper the infrared transmission spectra of binary borosilicate glass films vapor-deposited at low temperatures (350°-600°C) from N_2-diluted reactive mixtures of B_2H_6, SiH_4, and O_2 are studied in some detail as a function of thermal history and composition. The spectra and structure of CVD B_2O_3 deposited above its T_g ($\sim$260°C) are contrasted with those of CVD SiO_2 deposited far below its T_g ($\sim$1159°C). In addition, taking advantage of the ease of control of film thickness during deposition, a differential technique has been used to elucidate some of the complex spectral features in the vibrational spectra of the binary glasses. The analysis and understanding of the infrared spectra of this simple binary borosilicate glass system form a basis of interpretation of the vibration spectra of other complex borosilicate glasses.

Experimental

The glass films studied were deposited on chemically polished 10 Ω-cm n-type (100)-oriented silicon wafers, 2.5 cm in diam and 0.05 cm thick. The technique of chemical vapor deposition was used for the pyrolytic oxidation of nitrogen-diluted mixtures of silane, diborane, and oxygen in the presence of excess oxygen such that the molar ratio of O_2 to total hydride in the reaction mixture was always greater than 10:1. The gas flow system and reactor used were identical to those employed by Brown and Kennicott (2) from this laboratory. The substrate temperature varied from 350° to 600°C. For example, with flow rates of 3800 cm^3 min^{-1} N_2, 20 cm^3 min^{-1} O_2; 320 cm^3 min^{-1} SiH_4 (1% in Ar); and 80 cm^3 min^{-1} B_2H_6 (1% in Ar), a 25 mole percent (m/o) B_2O_3 glass film can be deposited at a rate of 700 Å min^{-1} at a substrate temperature of 350°C.

Since the refractive indexes of vitreous SiO_2 and B_2O_3 are very similar ($\sim$1.46) (9), one can use the color-thickness of Plisken and Conrad (10) for thermal SiO_2 to monitor film thickness of the borosilicate films during deposition. Film thicknesses used in the present study vary from 4000 to 6000Å ± 200Å.

Films containing more than 20 m/o B_2O_3 are hygroscopic and are prevented from atmospheric moisture degradation during infrared measurement with a covering layer of pure SiO_2 ($\sim$400Å thick) deposited sequentially from a preset SiH_4-O_2 mixture. The covering layer of SiO_2 is compensated quantitatively in a Perkin-Elmer double-beam spectrophotometer (Model 457) with an identical SiO_2 layer deposited on a reference Si substrate. Film compositions were determined from the intensity ratio of the bands at $\sim$1300 cm^{-1} and $\sim$1000 cm^{-1} using a composition calibration curve of Tenney (9).

A differential infrared (DIR) technique applicable to transmission measurement of thin films has been described in some detail elsewhere (11). For clarity the essential steps will be outlined in the section on DIR data.

Films were heat-treated in the deposition reactor to a maximum temperature of 700°C for 10 min. Under this condition the free-carrier absorption arising from the diffusion of boron into the silicon substrate is negligible so that the infrared spectra below 1000 cm^{-1} are not obscured.

Results and Discussion

In this section the infrared data of as-deposited and heat-treated pure B_2O_3 and SiO_2 is first presented and discussed. This is followed by DIR data on the binary B_2O_3-SiO_2 films using B_2O_3 and SiO_2 separately as a reference. Finally, the effects of annealing at 700°C on the binary glass spectra will be discussed.

Pure components.—CVD B_2O_3.—The room temperature infrared transmission spectrum of pure B_2O_3 deposited at 350°C is shown in Fig. 1. Two prominent absorption bands at 1265 cm^{-1} and 715 cm^{-1} are evident. Using the relationship $A = \alpha t$ where A is the absorbance, α the absorption coefficient, and t film thickness, the absorption coefficients at these two frequencies are found to be $(2.1 \pm 0.1) \times 10^4$ cm^{-1} and $(0.32 \pm 0.02) \times 10^4$ cm^{-1}, respectively. With isotopic substitution of ^{10}B for ^{11}B the 1265 cm^{-1} band exhibits a 21 cm^{-1} upshift (12) and is associated with B-O bond stretching modes in the glassy lattice, while the lower frequency band exhibits only a 6 cm^{-1} upshift and is associated with bond bending modes.

When deposited above its equilibrium melting point in the range 450°-600°C (so that B_2O_3 is now deposited as liquid films) the resultant infrared spectra remain invariant and are directly superimposed onto that of the film of the same thickness deposited at 350°C shown in Fig. 1. However, when the as-deposited films are subsequently heat-treated at 700°C for 10 min in N_2, a large change in the shape of the B-O band at 1265 cm^{-1} is observed, as indicated by the dotted scan in Fig. 1. The absorbance at band maximum decreases from 0.90 to 0.66 while the bandwidth at half height increases from 65 cm^{-1} to 120 cm^{-1}. The integrated intensity (area under the band) remains constant indicating that the total number of oscillators responsible for this absorption remain unchanged after heat-treatment. The increase in bandwidth after annealing at 700°C is indicative of a quenching-in of high temperature liquid configurations which, in general, have a broader distribution.

CVD SiO_2.—The above observation in B_2O_3 is contrasted with that of CVD SiO_2 films deposited at tem-

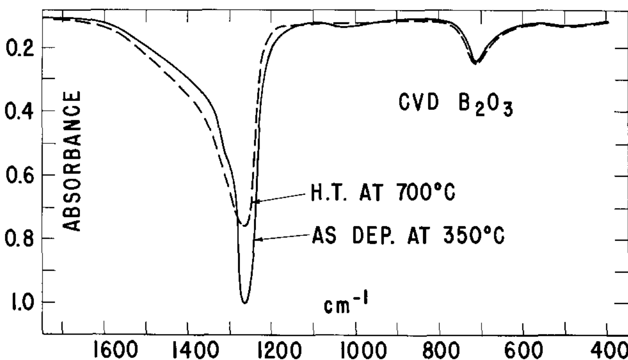

Fig. 1. Room temperature infrared transmission spectra of B_2O_3 vapor-deposited on Si. The solid curve denotes that of the as-deposited film deposited at 350°C while the dashed curve is that of the same film heat-treated at 700°C. The film was 4000Å thick and was covered with a 400Å thin layer of SiO_2 which was compensated in the reference beam with an identical SiO_2 film deposited on a bare Si wafer.

peratures much below its T_g (1159°C) (13). When heat-treated to 800°C and above, the infrared spectrum of SiO_2 deposited at 450°C from SiH_4-O_2 mixtures exhibits a progressive bandwidth narrowing (14) accompanied by an increase in both the absorbance and frequency at band maxima (Fig. 2) (15).

According to the dynamical calculation of Bell *et al.* (16) using a physically realistic random network model for vitreous SiO_2, the observed bands at ~1060, 800, and 450 cm^{-1} shown in Fig. 2 can be assigned to the Si-O bond stretching, O-Si-O bond bending, and Si-O-Si bond rocking modes in the glass structure. The integrated intensity of each band upon annealing remains invariant as in the case of the B-O absorption. The infrared data are correlated with a decrease in the root mean squared deviations of atomic distances in the radial distribution function (14). Together with the changes in other physical properties such as density, refractive index, etch rate, etc. (5) the combined vibrational and structural variations are indicative of a densification process brought about in as-deposited SiO_2 as a result of thermal annealing above its deposition temperature. Angular reorientation of the Si-O-Si centers (17) and/or further condensation of hydrogen-terminating Si-O chains (18) are possibilities of these structural changes.

Binary glasses.—The room temperature infrared spectra of as-deposited borosilicate glasses (BSG) have been studied systematically as a function of composition across the whole binary system (8). A distinct absorption at 930 cm^{-1} not present in either of the pure component spectra appears in the spectra of the binary gasses, and is associated with a vibration of the B-O-Si linkages in the borosilicate structure (19). The composition variation of the intensity of this band has been used quantitatively to construct a structural model of random networks of BO_3 triangles and SiO_4 tetrahedra bridged by oxygens. Above 1000 cm^{-1}, the absorptions are more complex and will be studied here with a DIR technique that has been proven useful in unraveling the vibrational spectra of CVD P_2O_5-SiO_2 glasses (11).

Differential Infrared Spectra

The vibrational spectra of impurities in a solid can often be masked and overshadowed by that of the host material. This is more so in the case of glassy solids which have broad absorption spectra of their own arising from structural disorder. The normal infrared spectra of binary and multicomponent glasses are usually more diffuse and sometimes featureless. Meaningful interpretations of these spectra are difficult if not impossible (20). Recently, a DIR technique has been applied by Smith (21) to study the vibrational modes arising from impurities such as C, B, Na, and Ti doped in bulk vitreous silica. The technique consists simply of measuring the transmission spectrum of a sample *vs.* that of a host "pure" sample having the same effective absorption thickness placed in the reference beam of a double-beam spectrophotometer. Provided that both the sample and pure reference are sufficiently thin so that total absorption does not occur in the frequency range scanned, differential vibrational absorptions characteristic of the impurities can be isolated from the host spectrum. The DIR method has frequently been employed to eliminate solvent interference in organic systems (22).

The thickness of vapor-deposited films can easily be controlled during the CVD process by simply monitoring the time of deposition so that zero transmission in the absorption region 1600-250 cm^{-1} is avoided. The results for an as-deposited BSG film containing 24 m/o B_2O_3 are shown in Fig. 3. The curve labeled "BSG" is the normal infrared spectrum taken *vs.* an identical covering layer of SiO_2 (~400Å thick) deposited on a bare Si in the reference beam. The curve labeled "SiO_2" corresponds to the normal infrared spectrum (compensated by the same reference) of a pure SiO_2 film deposited under the same conditions of temperature, time, and flow rate of SiH_4, O_2, and N_2 carrier gas as the BSG film. The curve labeled "DIR" was obtained by rescanning the BSG spectrum but now using the SiO_2 film in the reference beam. From the DIR spectrum, in addition to the B-O-Si mode at 930 cm^{-1}, a band at 1125 cm^{-1} can clearly be differentiated from the broad absorption at 1100 cm^{-1} in the BSG spectrum. The position and half-width (110 cm^{-1} ± 5 cm^{-1}) of this differential band remain constant with composition across the binary system, as shown in Fig. 4. The intensity of this band, measured as peak absorbance with respect to point X in the DIR spectrum, shown in Fig. 3, and normalized to a 1 micron film absorption exhibits a maximum in the vicinity of 40 m/o B_2O_3 as shown in Fig. 5. This variation is very similar to the behavior of the well-defined Si-O-B vibration at 930 cm^{-1} studied previously (8). The constancy in frequency and bandwidth suggests that this mode is intrinsic of the borosilicate structure and its intensity variation with composition in analog to that of the 930 cm^{-1} band strongly indicates that it is a bond-stretching vibration of the Si-O-B linkages in the borosilicate lattice. In addition, the broad absorption at 450 cm^{-1} in the BSG spectrum in Fig. 3 can be seen to consist of overlapping contributions of the Si-O-Si and B-O-B bending modes in the binary mixtures.

Similarly, DIR spectra have been recorded *vs.* pure B_2O_3. The results for the same 24 m/o B_2O_3 film discussed above is shown in Fig. 6. The curve labeled "B_2O_3" is that for a pure B_2O_3 film deposited under identical conditions of temperature and time flow rates of B_2H_6, O_2, and N_2 to those of the BSG film. The DIR spectrum in this case consists simply of a differential band at ~1360 cm^{-1}. The DIR spectra *vs.* pure B_2O_3 as a function of B_2O_3 content in the film are

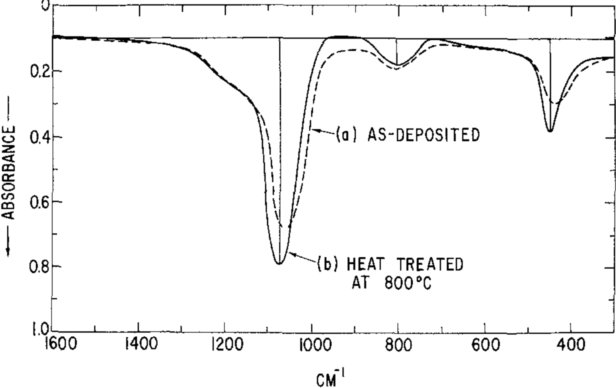

Fig. 2. Room temperature infrared transmission spectra of CVD SiO_2 film, 5200Å thick: (a) as-deposited at 450°C and (b) the same film heat-treated at 800°C for 15 min.

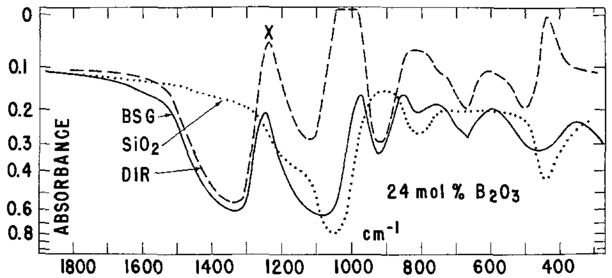

Fig. 3. DIR spectrum of an as-deposited borosilicate film containing 24 m/o B_2O_3 *vs.* a corresponding SiO_2 film deposited under identical conditions of temperature and flow rates of SiH_4, O_2, and N_2. The curves labeled "BSG" and "SiO_2" are the normal infrared spectra taken *vs.* an identical covering layer of 400Å SiO_2 deposited on a bare Si wafer in the reference beam.

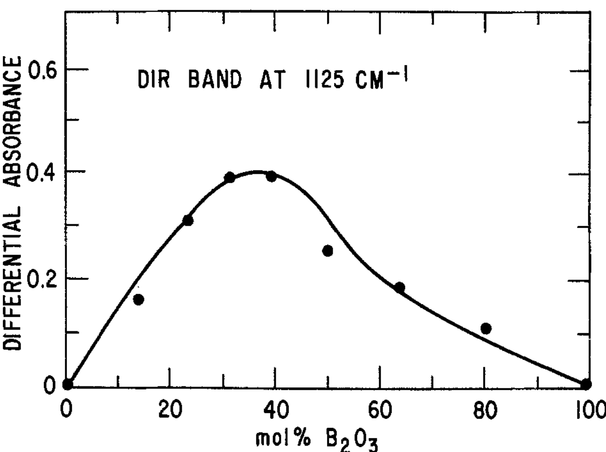

Fig. 5. Compositional variation of the intensity of the DIR band at 1125 cm^{-1} shown in Fig. 3. The plotted differential absorbance is normalized for 1 micron film in all cases.

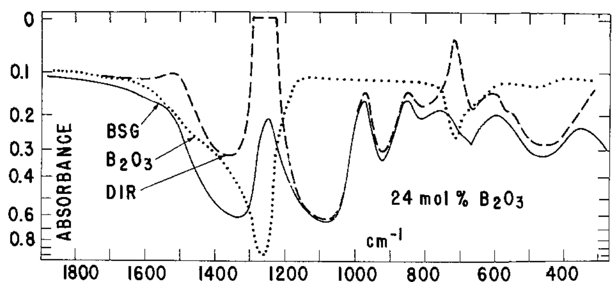

Fig. 6. DIR spectrum of an as-deposited borosilicate film containing 24 m/o B_2O_3 vs. a corresponding pure B_2O_3 film deposited under identical conditions of temperature and flow rates of B_2H_6, O_2, and N_2. The curves labeled "BSG" and "B_2O_3" are the normal infrared spectra taken vs. an identical layer of 400Å SiO_2 deposited on a bare Si wafer in the reference beam.

shown in Fig. 7. With increased B_2O_3 concentration, there is a gradual increase in both the halfwidth and intensity of the differential band at ~1300 cm^{-1}, exhibiting in both cases a maximum around 40 m/o B_2O_3. The frequency of maximum absorption, however, decrease continuously from 1380 cm^{-1} at 85 m/o B_2O_3 to 1260 cm^{-1} for pure B_2O_3. This mode is clearly associated with the stretching vibration of the B-O sublattice and is perturbed by the presence of the less polarizing Si^{4+} cation substituting for an equally polarizing B^{3+} cation as the next-nearest neighbor; thus effectively increasing the force constant of the B-O bond in the mixture. The spectral variations of this differential B-O mode lend further support to the existence of the B-O-Si linkage in CVD B_2O_3-SiO_2 films and its distribution as a function of film composition deduced earlier in a described analysis of the 930 cm^{-1} band in the normal infrared spectrum (8).

Effects of Annealing at 700°C on Binary Films

Because of the metastable nature of materials in the glassy state, their properties are very much dependent on the mode of preparation as well as on thermal history. This is more so in the case of glass films that can be made by a variety of methods and at various deposition temperatures. In fact, the deviation from the most stable equilibrium state, *i.e.*, the crystalline state, can be much greater in vapor deposition than in melt-quenching processes. Technologically, CVD films are often heat-treated at temperatures above their deposition temperature during processing (2). The effects of annealing on the structure and hence properties of these films are therefore of fundamental interest. In the case of pure CVD B_2O_3 discussed above, annealing at 700°C for 10 min in N_2 brought about ~100% increase in the half-width of the B-O band at 1260 cm^{-1} in the infrared spectrum. We proceeded to study the effect of similar annealing on the binary films.

In Fig. 8 the normal infrared spectra of a 24 m/o B_2O_3 film before and after annealing at 700°C for 10 min in N_2 are given. Changes in bandwidth $\Delta\nu_{1/2}$ and/or absorbance at band maximum A are observed at

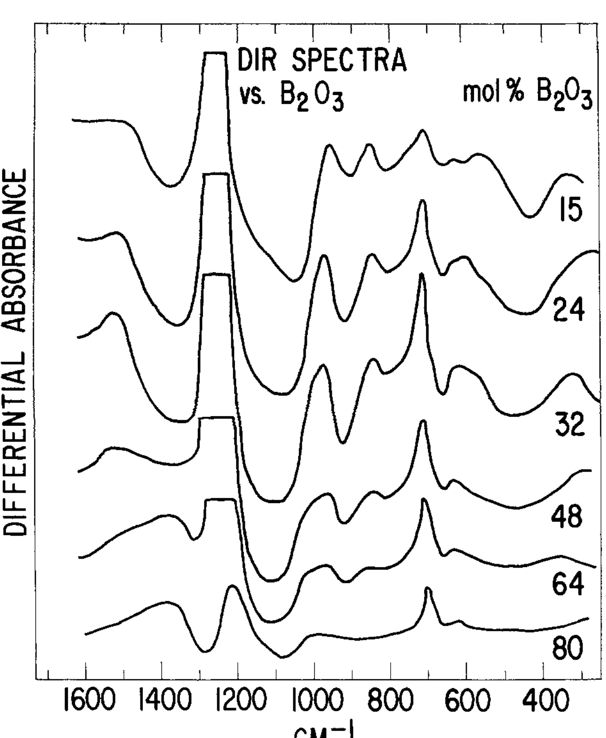

Fig. 7. DIR spectra of a series of as-deposited BSG films containing 15-80 m/o B_2O_3; each spectrum was taken vs. the corresponding B_2O_3 film and covering SiO_2 layer.

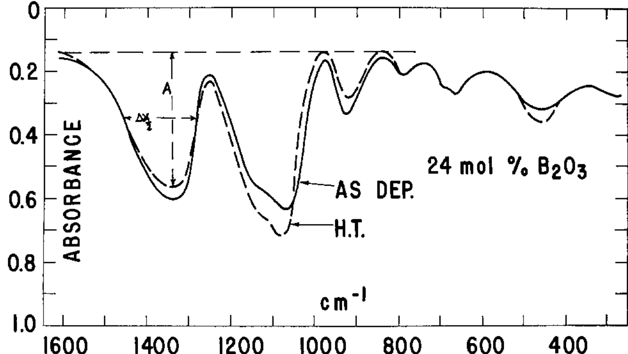

Fig. 8. Room temperature infrared spectra of a BSG film containing 24 m/o B_2O_3 before and after being heat-treated at 700°C for 10 min in N_2. Measurements of band absorbance A and bandwidth $\Delta\nu_{1/2}$ of the B-O band at ~1300 cm^{-1} for the heat-treated film (dotted trace) are illustrated.

~1300 cm^{-1}, 1100 cm^{-1}, 930 cm^{-1}, and to a lesser extent at 450 cm^{-1}. These spectral variations were studied as a function of film composition and are summarized as follows.

Upon annealing at 700°C, the B-O band at ~1300 cm^{-1} in all films containing up to 48 m/o B_2O_3 shows an increase in $\Delta\nu_{1/2}$ accompanied by a corresponding decrease in A so that, within an experimental accuracy of ±5%, there is no change in (integrated) band intensity due to heat-treatment, (Table I). The increase in $\Delta\nu_{1/2}$ is indicative of a "quenching-in" of high temperature B-O configurations having a broader distribution.

As shown in the section of DIR spectra, the absorption in the region 1100 cm^{-1} is complex and consists at least of two types of oscillators: Si-O and B-O-Si. With annealing the width of this band remains essentially constant for all compositions studied. However, the absorbance at band maximum and, hence, the integrated intensity, increases. The ratio of band intensity of heat-treated to that of the as-deposited film is given in Table I as a function of B_2O_3 content.

On the other hand, the absorbance of the B-O-Si band at 930 cm^{-1} decreases at constant bandwidth upon annealing. The ratio of the band intensity of heat-treated to that of the as-deposited decreases with increased B_2O_3 content in the film. Since the intensity decreases at constant bandwidth, this implies that there is an apparent decrease in the number of B-O-Si oscillators upon annealing, which in turn may be brought about by phase separation, resulting in a change of the distribution of the B-O-B, Si-O-Si, and B-O-Si linkages from the ideal distribution (8). This qualitatively correlates with the increase of band intensity of the Si-O band at 1100 cm^{-1}. Thus, the B-O-Si band at 930 cm^{-1} is a very sensitive probe to structural changes in the borosilicate system.

Finally, a two-layer thin-film structure consisting of a 400Å CVD film of pure SiO_2 on a 4000Å film of pure B_2O_3 vapor-deposited sequentially at 350°C in a single crystal Si substrate was annealed *in situ* in the CVD reactor at 700°C. At this temperature the expansivity of B_2O_3 is large enough to cause material ejection through pinholes in the SiO_2 layer which is rigid and has almost zero expansivity, thus resulting in the "exploded" flow pattern shown in Fig. 9. This is a color micrograph taken with reflected white light. The dark fringes in the middle of the pinhole indicate a "punch-through" of the glass layers exposing the surface of the Si substrate. The band of jagged circular color fringes indicates a radial thickness gradient of the B_2O_3 layer about the center of the pinhole. The green and yellow regions in the radial pattern correspond to ridges and valleys respectively of the ejected B_2O_3. This multilayer of configuration constitutes a novel method of pinhole detection in thin films and is applicable to a variety of thin films, whether metallic, dielectric, or semiconducting with thickness ranging from 100Å to 1 μm or more.

Table I. Effect of annealing on band intensities expressed as ratio of integrated intensities [a],[b] of heat-treated and as-deposited film

Film composition (m/o B_2O_3)	B-O band at ~1300 cm^{-1}	Si-O band at ~1100 cm^{-1}	B-O-Si band at 930 cm^{-1}
15	0.95	1.09	1.13
24	0.97	1.19	0.84
32	1.04	1.26	0.77
39	0.94	1.15	0.65
48	1.05	1.11	1.03

[a] Integrated intensities are approximated by the product $\Delta\nu_{1/2} \times A$ where $\Delta\nu_{1/2}$ is the half-width and A is absorbance of band maximum. (Cf. Fig. 8.)
[b] Estimated accuracy of intensity ratio ±5%.

Concluding Remarks

The infrared transmission spectra of thin borosilicate glass films vapor-deposited on Si from B_2H_6-SiH_4-O_2 source at low temperatures have been studied systematically across the whole composition of the binary system. The effect of thermal history on the structure

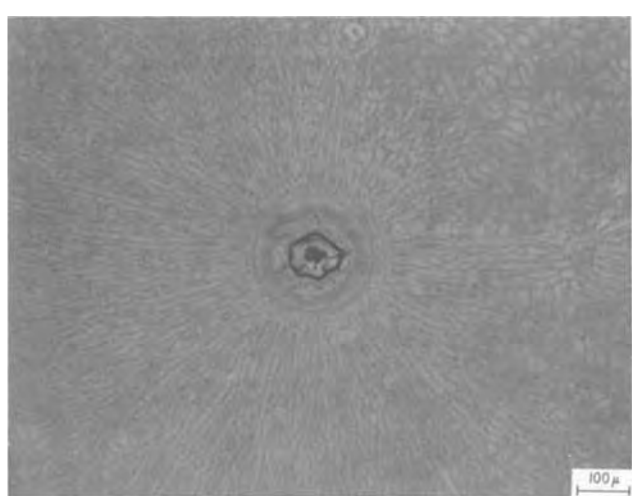

Fig. 9. Reflected light micrograph of an "exploded" flow pattern of liquid B_2O_3 through a pinhole defect in a coverng layer of SiO_2. See text for descripton of the thin film structure.

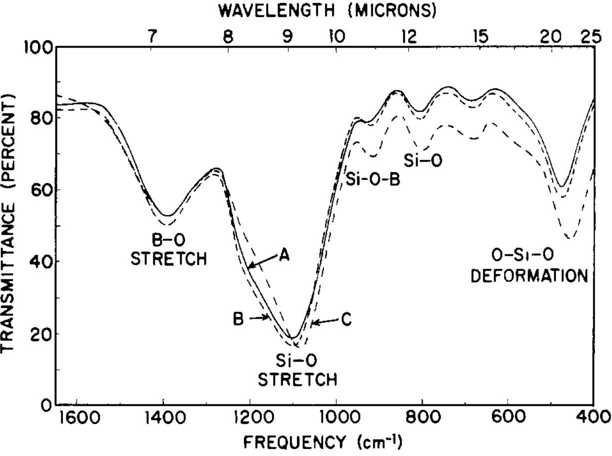

Fig. 10. Infrared spectra of Corning Pyrex films (23) illustrating the similarity and usefulness of the binary borosilicate spectra in understanding more complex borosilicate system. (A) Sedimented powder; (B) annealing (A) at 450°C; (C) fusing (A).

of CVD glasses deposited above T_g as in the case of B_2O_3 is contrasted with that of CVD SiO_2 deposited at temperatures far below the T_g of the bulk material. In the former case, where configurational relaxation is possible at deposition temperatures, the infrared spectrum and hence the structure of as-deposited B_2O_3 is not dependent on deposition temperature even when deposited as a liquid film at 600°C. Heat-treating the as-deposited film further to 700°C, however, results in an increase in the bandwidth of the B-O band at 1265 cm^{-1}, suggestive of a quenching-in of high temperature liquid configurations which in general exhibit a broader distribution. In the latter case, the infrared spectrum of as-deposited CVD SiO_2 exhibits broader absorption bands which progressively narrow with increasing heat-treatment temperature and finally approach the bulk values after heat-treating at 1000°C. The spectral observation is associated with a densification process in glass films deposited far below its T_g and is substantiated by other physical property changes such as increases in density, refractive index, etch rate, etc.

Differential infrared data on the binary glasses lead to the resolution of a band at $\sim$1130 cm^{-1} assigned to a bond-stretching vibration of the Si-O-B linkages in the glass structure. The intensity variation of this band with composition lends further support to the structural model proposed earlier for the B_2O_3-SiO_2 glass system in which the boron and silicon are three-fold and four-fold coordinated with oxygen, respectively, and each oxygen is bridging a pair of B and/or Si atoms to form a three-dimensional random network. Deviation from this ideal distribution was observed for glasses containing 15-48 m/o B_2O_3 upon annealing at 700°C, as a result (possibly) of phase separation. It is also concluded that the B-O-Si at 930 cm^{-1} is a very sensitive probe to structural changes in the borosilicate system.

Finally, the analysis of the infrared spectra of the binary B_2O_3-SiO_2 system may serve as a basis of interpreting and understanding the vibrational spectra of more complex borosilicate glasses such as those studied by Pliskin (23) shown in Fig. 10. It is clear from the present DIR data that in Fig. 10 the absorption at 1100 cm^{-1} has in addition to the Si-O stretch, a B-O-Si band at $\sim$1125 cm^{-1} (cf. Fig. 3-5 and discussion thereof). Similarly, in the absorption at $\sim$450 cm^{-1} in the complex borosilicate glass shown in Fig. 10 has a O-B-O deformation mode at 500 cm^{-1} superimposed on the O-Si-O band (cf. Fig. 3).

Anodic Oxidation of GaP in N-methylacetamide for Electrical Profiling of Ion-Implanted GaP

Taroh Inada* and **Yasuhide Ohnuki**

College of Engineering, Hosei University, Koganei, Tokyo 184, Japan

ABSTRACT

The anodic oxidation of gallium phosphide in properly pH-adjusted NMA solutions was carried out under constant current conditions. Uniform oxides have been reproducibly grown in NMA with 10% H_2O. The pH was adjusted to 12 using NH_4OH and readjusted to 8.5-10 using citric acid. The oxide thickness-forming voltage relationship is linear, with a slope of approximately 11 $Å \cdot V^{-1}$, independent of current density from 0.125-4.0 $mA \cdot cm^{-2}$. The thickness of GaP consumed during the oxide growth (x_c)-forming voltage (V_f) relationship is also linear, but its slope varies with current density (J, $mA \cdot cm^{-2}$) and is described empirically as $dx_c/dV_f = 5 \cdot J^{-0.12}$ ($Å \cdot V^{-1}$). Electrical carrier-concentration and mobility profiles in Zn-implanted GaP were obtained by differential Hall-effect and sheet-resistivity measurements combined with an oxide growth-stripping process, where anodization is performed under optimumly defined conditions.

Investigation of electrical properties of ion-implanted semiconductors (1-3) is an important requirement for device application. This is due to the many crystal defects introduced by ion implantation into structure-sensitive semiconductors. Measurements of both carrier concentration and mobility profiles in ion-implanted semiconductors are needed. Many researchers have dealt with electrical profile measurements as functions of implantation parameters such as ion species, dose, implant energy and temperature, and annealing conditions (4-6).

Electrical profiling was performed by Hall-effect and sheet-resistivity measurements followed by a layer removal technique. In layer removal, a very thin layer (100Å or less) must be stripped reproducibly at every step. Two different semiconductor-layer removal techniques have been employed. One is a chemical etch (7) and the other is anodic oxidation stripping (8). The chemical etch rate varies over a wide range depending on temperature, and changes in composition of the etchant due to volatile components such as HF, H_2O_2, and H_2O. The effect of crystallinity of semiconductor to be removed on the etch rate is not small (9), and can affect the layer stripping of ion-implanted samples, where concentrations of impurities and defects are not uniform in the thickness direction.

An anodic oxidation may provide a uniform thickness oxide layer and thickness control can be achieved electrically if a proper electrolyte is used. Much data has been published on the anodization of GaAs (8, 10-13), and layer stripping has been employed in electrical profiling of ion-implanted GaAs (2, 3). Lorenzo *et al.* (14) reported on the use of anodic oxidation as a means of layer stripping in profiling electrical carrier concentration of ion-implanted InP. Few publications report on the anodization of GaP (15-17) and none report on electrical profiles in ion-implanted GaP. In this paper we will report the anodization conditions of GaP and the properties of the anodically oxidized layers. Optimum conditions or the anodization of GaP are proposed for the oxide growth-stripping cycle.

Experimental

The anodic oxidation of GaP was carried out in a Teflon beaker, which had a 4 mm diam opening in the bottom. A rubber gasket was placed between the beaker bottom and the GaP wafer to prevent leakage of electrolyte. The GaP wafer was placed on a copper contact plate. The GaP wafers used in this experiment were either undoped or sulfur-doped n-type (111)-oriented single crystals with net carrier concentrations of $0.5\text{-}1.2 \times 10^{16}$ or $1.6\text{-}2.8 \times 10^{17}$ cm^{-3}, respectively. Anodization was also done on p-type GaP layers formed by Zn implantation and annealing in these n-type substrates.

Prior to anodization chemical-mechanically polished GaP wafers were cleaned ultrasonically in TCE and methanol, dipped in dilute H_3PO_4, rinsed in deionized water, and dried in N_2 gas flow. All anodic oxidations were done by a constant current method at current densities from 0.125 to 4.0 $mA \cdot cm^{-2}$. Voltage applied between the copper contact plate and a platinum cathode (cell voltage) was monitored on a high impedance (1000 MΩ) recorder.

Electrolyte solutions were N-methylacetamide (NMA) containing 10 weight percent (w/o) H_2O adjusted to a pH between 6.8 and 14 by adding NH_4OH and citric acid. A conventional pH meter with a glass electrode was used for the pH measurement. Electrical conductivity of the electrolyte was measured by an a-c method using separated platinum electrode plates (1 cm^2). After anodization, half the grown oxide area was removed from the sample by masking and etching in dilute H_3PO_4. The thickness of the oxide layer was determined as a depth difference between the unetched oxide surface and the GaP surface using an interferometer. To get high resolution, the sample surface was coated with a vacuum-deposited Al layer prior to the interferometric measurement.

The thickness of GaP layer consumed during the oxide growth was measured as a depth difference between the original GaP surface (nonoxidized area) and the GaP surface exposed after the oxidation and oxide stripping. If the anodization was terminated at a low predetermined voltage of 10V, the GaP thickness consumed during the oxide growth was too thin to measure by interferometric technique. Therefore the oxidation and the oxide layer removal process was repeated until the total forming voltage reached 200V.

Concentration profiles of Ga, P, and O in grown oxide layers were measured by Auger electron spectroscopy (AES) combined with an Ar ion-sputter etching. The AES depth profiling was carried out using a Physical Electronics Industries cylindrical mirror-analyzer (Model 10-234G). The primary electron current and energy were 5 μA and 3 keV, respectively. After pumping to a pressure of 5×10^{-8} Torr, high purity argon (99.9995%) was introduced into the AES chamber until the pressure reached 5×10^{-5} Torr. The Ar

ion energy used for sputter-layer stripping was 0.5 keV.

Carrier-concentration and mobility profiles of Zn-implanted GaP layers were measured by a differential Hall-effect and sheet-resistivity method. The implantation was carried out into the sulfur-doped n-type GaP with mass-separated Zn ions at an energy of 100 keV and at room temperature. After implantation, samples were annealed at 900°C in flowing N_2. Both front and rear surfaces were coated with sputter-deposited 1500Å thick SiO_2 films to prevent the thermal dissociation of the GaP surface layers during annealing. The van der Pauw configuration (18) for the Hall measurements was made by a standard photoresist technique with hot aqua regia (~55°C) etchant. Ohmic contacts were made by vacuum evaporation of Au metal (19). These contacts were used as anode contact during the anodic oxidation of Zn-implanted layers.

Results and Discussion

Anodic oxidation of GaP.—The anodic oxidation of GaP was carried out in NMA solutions having a *p*H of 6.8-14. Since pure NMA has a melting point of around 27°C, 10 w/o of H_2O was introduced into the pure NMA to lower the melting point before *p*H adjustment. The *p*H of NMA varied from 7.0 to 6.8 on adding H_2O, indicating that the NMA solution became acid.

Cell voltage *vs.* anodization time obtained from oxidations in different *p*H NMA solutions at a constant current density of 1.0 $mA \cdot cm^{-2}$ are shown in Fig. 1. The numbers in parentheses show the *p*H used. The pH adjustment was achieved through two different procedures. The *p*H of Type A solutions was obtained by adding NH_4OH and that of Type B solutions was obtained by adding NH_4OH and citric acid. Type B solutions can be considered as "buffered solutions". A linear relationship between cell voltage and anodization time was obtained when the anodization was done in a solution with a *p*H between 8.0 and 10. However, as seen in Fig. 1, many spikes appeared on the cell voltage-time curves for solutions of *p*H between 6.8 and 7.5, independent of electrolyte type.

Surface morphology of oxide layers grown in solutions of different *p*H were examined in an optical microscope. A distinct relationship was found between the creations of spikes on cell voltage-time curves and of surface pits on oxide layers. A very smooth surface, and linear cell-voltage time curves, were obtained by anodization in solutions of *p*H between 8.5 and 10. Typical smooth surface of an oxide grown in Type A solution with a *p*H of 9.0 is given in Fig. 2(a). However a number of surface pits were observed on oxide layers grown both in Type A and B solutions with *p*H below 7.5 as shown in Fig. 2(b). Many spikes were observed on the cell voltage-time curve for this growth (see Fig. 1). When surface pits were formed in oxide layers, deep pits were also produced on the surface of the GaP substrate.

Electrical resistance of NMA solution was measured as a function of *p*H. Figure 3 shows the decrease in the electrical resistance observed on increasing the *p*H from 7.2 to 8.3 (Type A solution). Electrical resistance tended to be relatively insensitive to *p*H above 8.5 and homogeneous or pit-free oxide layers could be grown. Reduction in electrical resistance with increasing *p*H of NMA has also been reported by Muller *et al.* (8).

In preparing Type B solution, NH_4OH was added to the NMA solution to a *p*H of 12 and then citric acid was added. As the *p*H of the solution was decreased by citric acid, the electrical resistance decreased as illustrated in Fig. 3. The electrical resistance of Type B solution (*p*H = 7.5) was ~ 30 times less Type A solution (*p*H = 7.2). Anodization of GaP in this solution (Type B, *p*H = 7.5), gave a nonhomogeneous oxide layer, indicating that *p*H is a more critical factor than electrical resistance of the solution. A 20% reduction

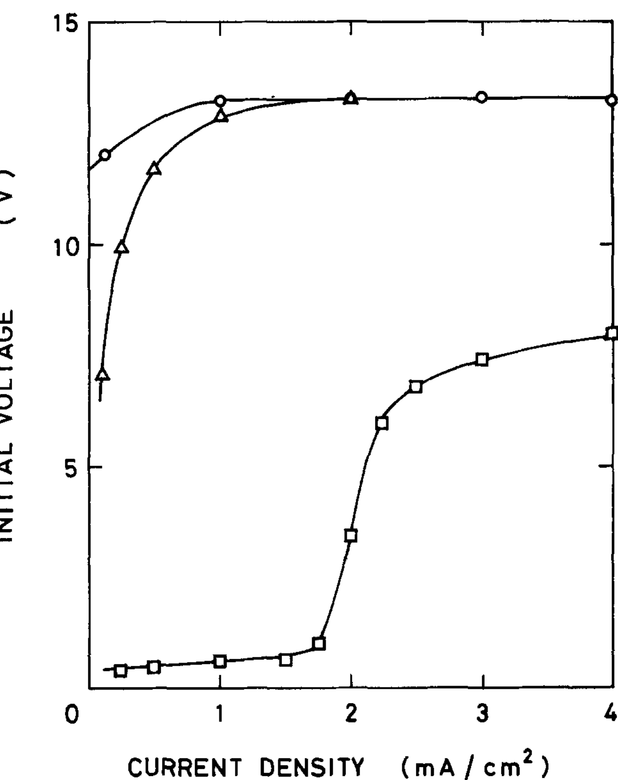

Fig. 4. Initial voltage vs. anodization current density for anodization in Type B solution pH = 9.0 under dark (○), and illuminated conditions; △: light intensity of 3.3 × 10^{16} quanta · cm^{-2} · sec^{-1}, and □: light intensity of 1.7 × 10^{17} quanta · cm^{-2} · sec^{-1}.

in the pH of Type A solutions within several hours after these solutions were prepared was attributed to evaporation of volatile NH_4OH from the electrolyte. Thus, experimental data for Type A solutions shown in Fig. 1 and 3 were obtained by using freshly prepared solutions. No detectable change in the pH of Type B solutions was observed for at least two months.

It was concluded that the use of Type B solution with a pH between 8.5 and 10 was essential to achieve reproducible anodization of GaP with a homogeneous oxide layer. All experimental data given in the following section were obtained from the anodization in Type B solution with a pH of 9.0.

If anodic oxidation is carried out at constant current density, measured cell voltage can be divided into the following two components, *i.e.*, a forming voltage (V_f) and another voltage drop (V_i). The V_f is a voltage drop due to oxide growth and increases with thickness of the oxide. The V_i depends on such external parameters as contact resistance originating from the interface between electrolyte and GaP surface, resistance of electrolyte, contact resistance between the rear surface of GaP and the copper contact plate, and bulk resistance of GaP substrate. Therefore, V_i is independent of anodization time or thickness of the oxide layer and can be estimated as an initial voltage appearing at anodization time = 0 on a cell voltage-time characteristic curve.

Figure 4 shows measured initial voltages as a function of current density. The effect of illumination on the initial voltage was also examined using white light (2854°K) from tungsten lamps having different wattages. The light was focused to a 5 mm spot by a condensing lens and passed through the 4 mm diam opening in the bottom of the anodization cell. The light intensity was measured by replacing the GaP wafer with a standard GaP p-n junction photodetector whose absolute quantum efficiency had been calibrated as a function of wavelength. The initial voltage was reduced from 13.2 to 0.5V by illuminating the GaP surface at a light intensity of 1.7 × 10^{17} quanta·cm^{-2}·sec^{-1}, where the anodization was done on n-type GaP at a current density of 1.0 mA·cm^{-2}. Note that the photon flux density gives intensity of light with energy above the bandgap of GaP. The results in Fig. 4 indicate that the major part of the initial voltage occurs at the GaP surface-electrolyte interface, since it is a highly photosensitive parameter.

The forming voltage (V_f) is plotted in Fig. 5 as a function of anodization time, and at current densities ranging from 0.125 to 4.0 mA·cm^{-2}. The V_f was obtained by substracting the initial voltages from measured cell voltages. The forming voltage increased linearly with anodization time for the current densities studied. The rate of increase with time (dV_f/dt) was approximately proportional to current density.

Oxide thickness and GaP consumed during the oxide growth at a current density of 1.0 mA·cm^{-2} are shown in Fig. 6 as a function of V_f. Growth rate of the oxide layer was defined as dx_o/dV_f, where x_o is the thickness of the oxide layer. From the slope shown in Fig. 6, the growth rate was found to be 11 Å·V_f^{-1}. The ratio of the thickness of oxide to thickness of GaP consumed was 2.2 at this current density over the forming voltage range studied.

As shown in Fig. 7, the oxide layer growth rate was independent of anodization current density from 0.125 to 4.0 mA·cm^{-2} and no Tafel slope (20) could be calculated. However, the amount of GaP consumed during the oxide growth within an increase of unit forming voltage (dx_c/dV_f) slightly increased with increasing

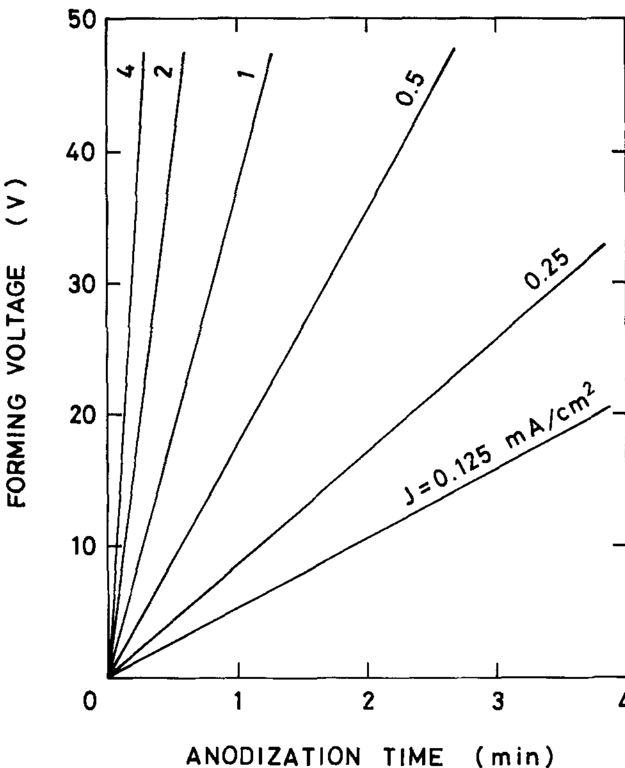

Fig. 5. Forming voltage vs. anodization time in Type B solution, pH = 9.0, at various current densities.

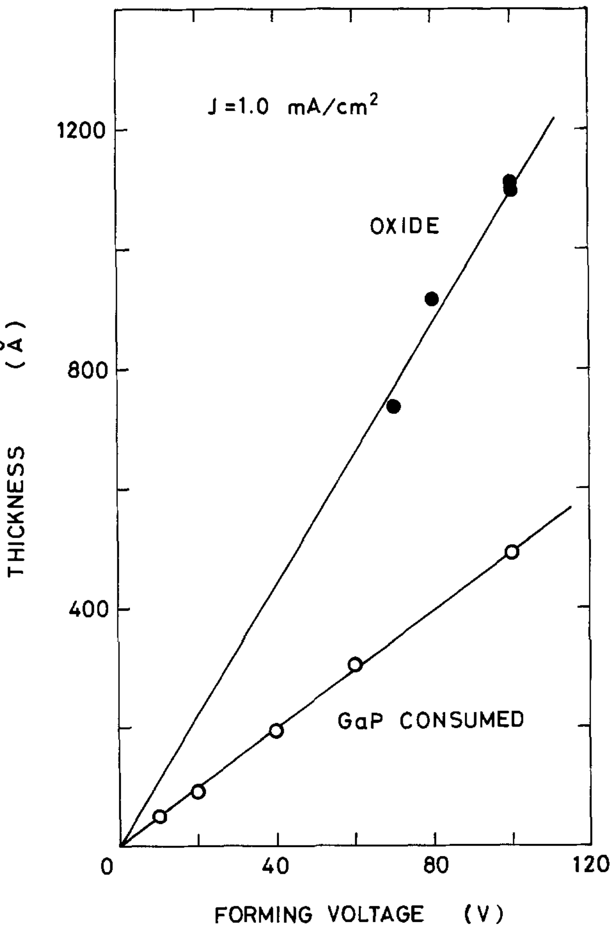

Fig. 6. Oxide thickness and amount of GaP consumed vs. forming voltage during anodization in Type B solution, pH = 9.0.

anodization current density and was described empirically as follows

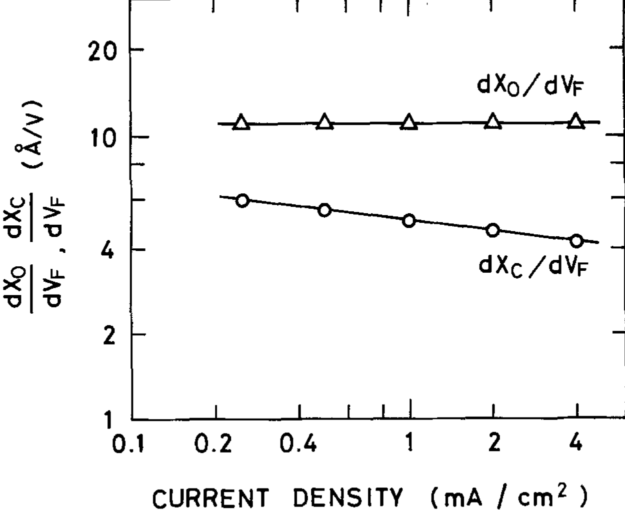

Fig. 7. Oxide growth rate (dx_o/dV_f) and amount of GaP consumed per unit forming voltage (dx_c/dV_f) vs. anodization current density for anodization in Type B solution, pH = 9.0.

$$\frac{dx_c}{dV_f} = 5 \cdot J^{-0.12} \qquad (\text{Å} \cdot \text{V}^{-1})$$

where J is an anodization current density in $\text{mA}\cdot\text{cm}^{-2}$.

When anodic oxidation is used to thin GaP for differential electrical profiling, it is extremely important to know exactly the thickness of GaP removed at each stripping step. In general, the thickness of the GaP layer removed is calculated from the increase in V_f if the anodic oxidation is carried out at constant current. The results shown in Fig. 7 indicate that the layer stripping of GaP has to be carried out at a given current density throughout the in-depth electrical profile measurements when forming voltage is used to calculate the thickness of GaP removed.

AES measurements on anodically oxidized GaP layers.—Atomic concentration profiles in anodically grown oxide layers on GaP wafers were examined using Auger electron spectroscopy (AES) with an Ar ion-sputter stripping. The concentrations of oxygen, gallium, and phosphorus were measured by peak-to-peak height of Auger signals originated from O KLL-transition at 505 eV, the Ga LMM-transition at 1068 eV, and the P LMM-transition at 117 eV, respectively. The Auger signal due to the P KLL-transition at 1858 eV was also measured.

Figure 8(a) displays typical depth profiles for 500Å thick oxide layers grown at a current density of 2.0 $\text{mA}\cdot\text{cm}^{-2}$. The O concentration decreases with depth while the Ga concentration (LMM) and P concentration (KLL) are almost constant throughout the oxide layer. However, P LMM level increases gradually, corresponding to the decrease of O level, and becomes constant in the GaP bulk region. Previous work has shown that the variation of P LMM level with depth can be attributed to the chemical shift in the P LMM (21). Thus oxidized P atoms decrease along with decrease of the O concentration while nonoxidized P atoms increase in the oxide. The atomic ratio of P/Ga is uniform throughout the oxide layer. Concentrations observed by AES after the oxide layer was removed by dipping in a dilute H_3PO_4 solution are shown in Fig. 8(b). The trace O signal is believed to be a native oxide grown during sample handling.

Auger depth profiles from a 500Å thick oxide layer grown on n-type GaAs ($n = 1 \times 10^{18}$ cm^{-3}, Si-doped) using the same electrolyte (Type B, pH = 9.0) are shown in Fig. 9. The signals of Ga, As, and O were constant through the oxide layer with no decrease in O KLL level with depth.

Depth profiles of oxide layers formed on GaP at a current density of 0.25 $\text{mA}\cdot\text{cm}^{-2}$ are illustrated in Fig.

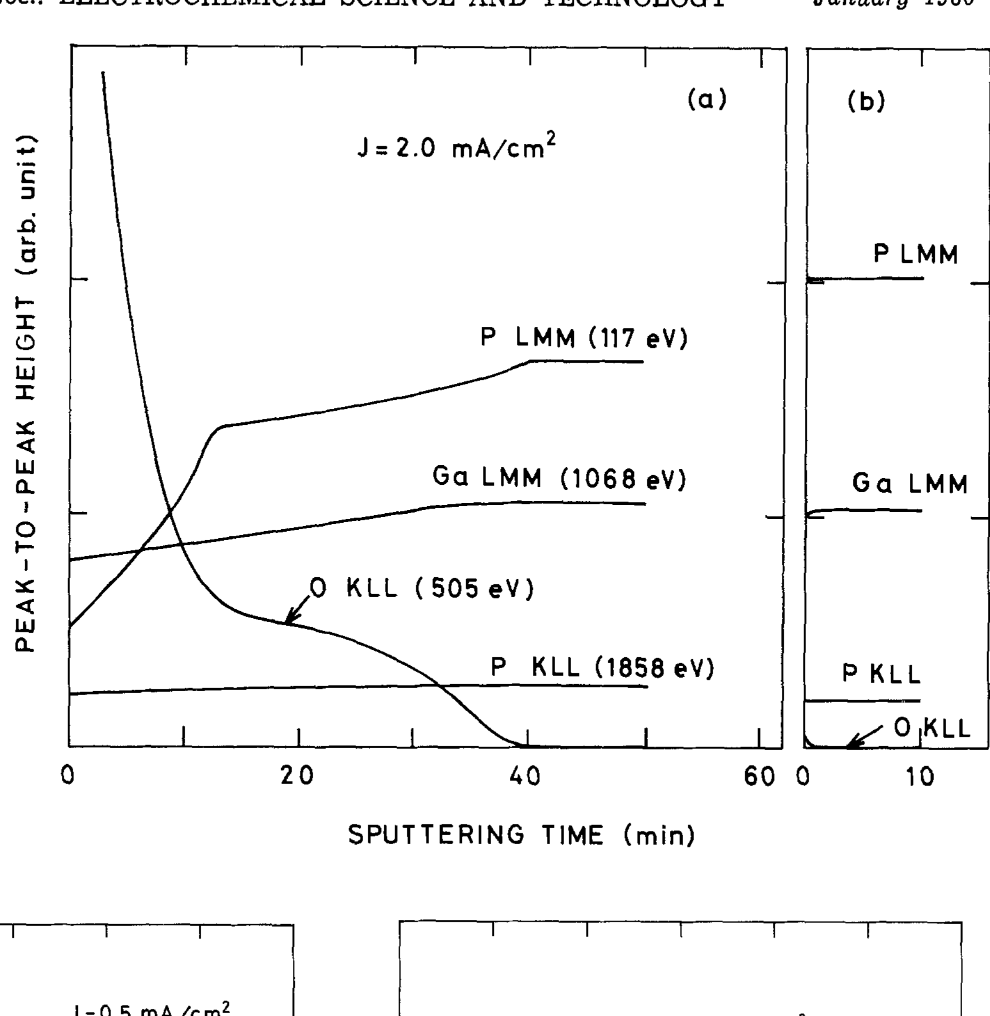

Fig. 8. Auger depth profiles for GaP anodically oxidized in Type B solution, $pH = 9.0$, $J = 2.0$ mA $\cdot$ cm^{-2}: (a) as-grown, (b) after dipping in dilute H_3PO_4.

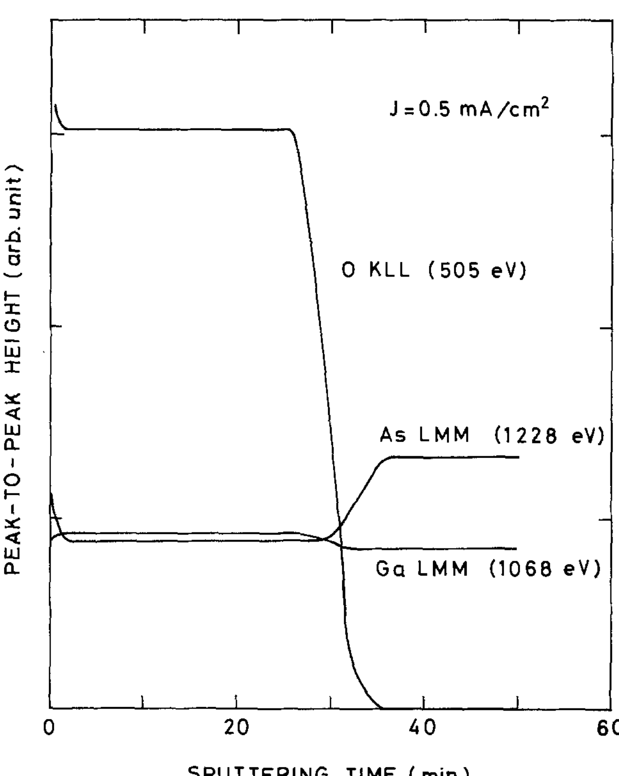

Fig. 9. Auger depth profiles for GaAs anodically oxidized in Type B solution, $pH = 9.0$, $J = 0.5$ mA $\cdot$ cm^{-2}.

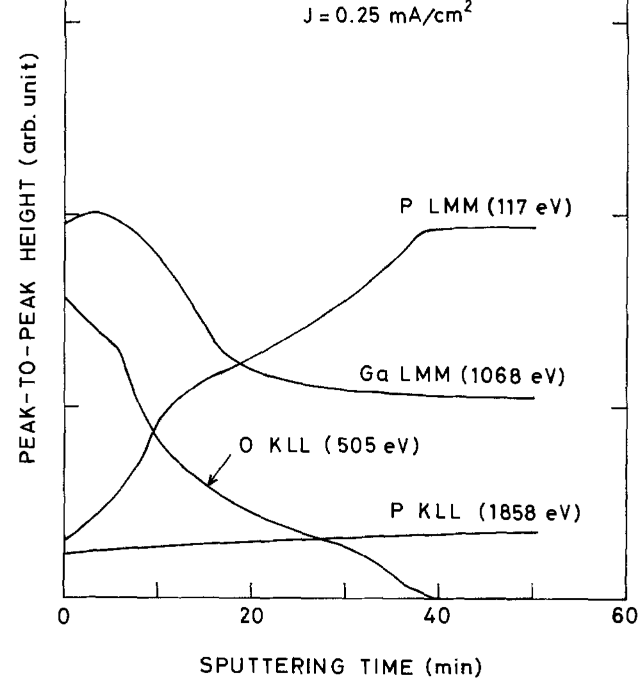

Fig. 10. Auger depth profiles for GaP anodically oxidized in Type B solution, $pH = 9.0$, $J = 0.25$ mA$\cdot$cm^{-2}.

10. A decrease of O with depth was also observed in this sample. However the Ga profiles differ from those in oxide layers grown at higher current density. The Ga LMM levels near the surface are approximately two times higher than that in GaP bulk region, indicating an accumulation of Ga near the surface, after which the Ga and O KLL levels decreased in a similar way to oxide grown at a current density of 2.0 mA$\cdot$cm^{-2}. The reduction in P KLL level, which originates from total P atoms, was observed in this sample. This reduction was greater near the oxide surface, particularly at low anodization current density. These results suggest that the relative increase of Ga is related with preferential dissolution of the P oxide during anodization, and is consistent with the observation that oxide thickness is independent of anodization current while the thickness of GaP consumed increases at low current density.

Aging effect of anodically oxidized GaP.—To use anodically oxidized layers for surface passivation, a stable oxide is desired. Examination of surfaces of anodic oxide layers on GaP showed deterioration of oxide layers, which was attributed to a localized increase of the oxide thickness after storage in a laboratory atmosphere.

Anodic oxide layers on GaP of 1100Å thickness were prepared at six different current densities in the range from 0.125 to 4.0 $mA \cdot cm^{-2}$. As-grown oxide surfaces were uniform and showed an interference color of blue. Typical surface morphologies of an oxide grown at 2.0 $mA \cdot cm^{-2}$ are shown in Fig. 11. The as-grown surface is shown in (a) with the appearance of mesas after one day (b), which increased after two weeks (c), and 6 months (d). Almost all of the original oxide surface was covered with additional oxide after six months. Maximum thickness of the oxide layer was around 1400Å, in agreement with a change of color from blue to golden yellow.

Formation of mesa on anodically oxidized GaP layers strongly depended on the anodization current density used. Oxides grown at 0.25 $mA \cdot cm^{-2}$ had no mesas after two weeks storage, although mesas were observed after one month which grew as the storage time was prolonged [see Fig. 11(e)]. Results obtained from a series of surface observations for oxide films grown at different current densities are summarized in Fig. 12.

To obtain more stable oxides, anodic oxidation of GaP in NMA should be done using a low current density. However, the amount of oxide dissolved during the oxidation increases at low current density. To employ anodic oxidation thin layer removal for differential Hall-effect measurements on GaP, a knowledge of the exact thickness of the GaP removed *vs.* forming voltage and suppressed oxide dissolution are desired.

Electrical profiling of Zn-implanted GaP.—Carrier-concentration and mobility profiles in Zn-implanted GaP layers were obtained from successive Hall-effect and sheet-resistivity measurements following anodized layer stripping. The Zn-implanted GaP layers were anodized in Type B solution, pH = 9.0, at 1.0 $mA \cdot cm^{-2}$. The thickness of the GaP layer stripped at each removal step was 50Å, obtained at a forming voltage of 10V. No difference in the ratio x_o/x_c was observed between S-doped n-type and Zn-implanted p-type layers. The initial voltage for the anodization of p-type GaP was small (0.6V at J = 1.0 $mA \cdot cm^{-2}$) even if the anodization was done under a dark condition. The illumination effect of reducing the initial voltage could not be observed in p-type GaP.

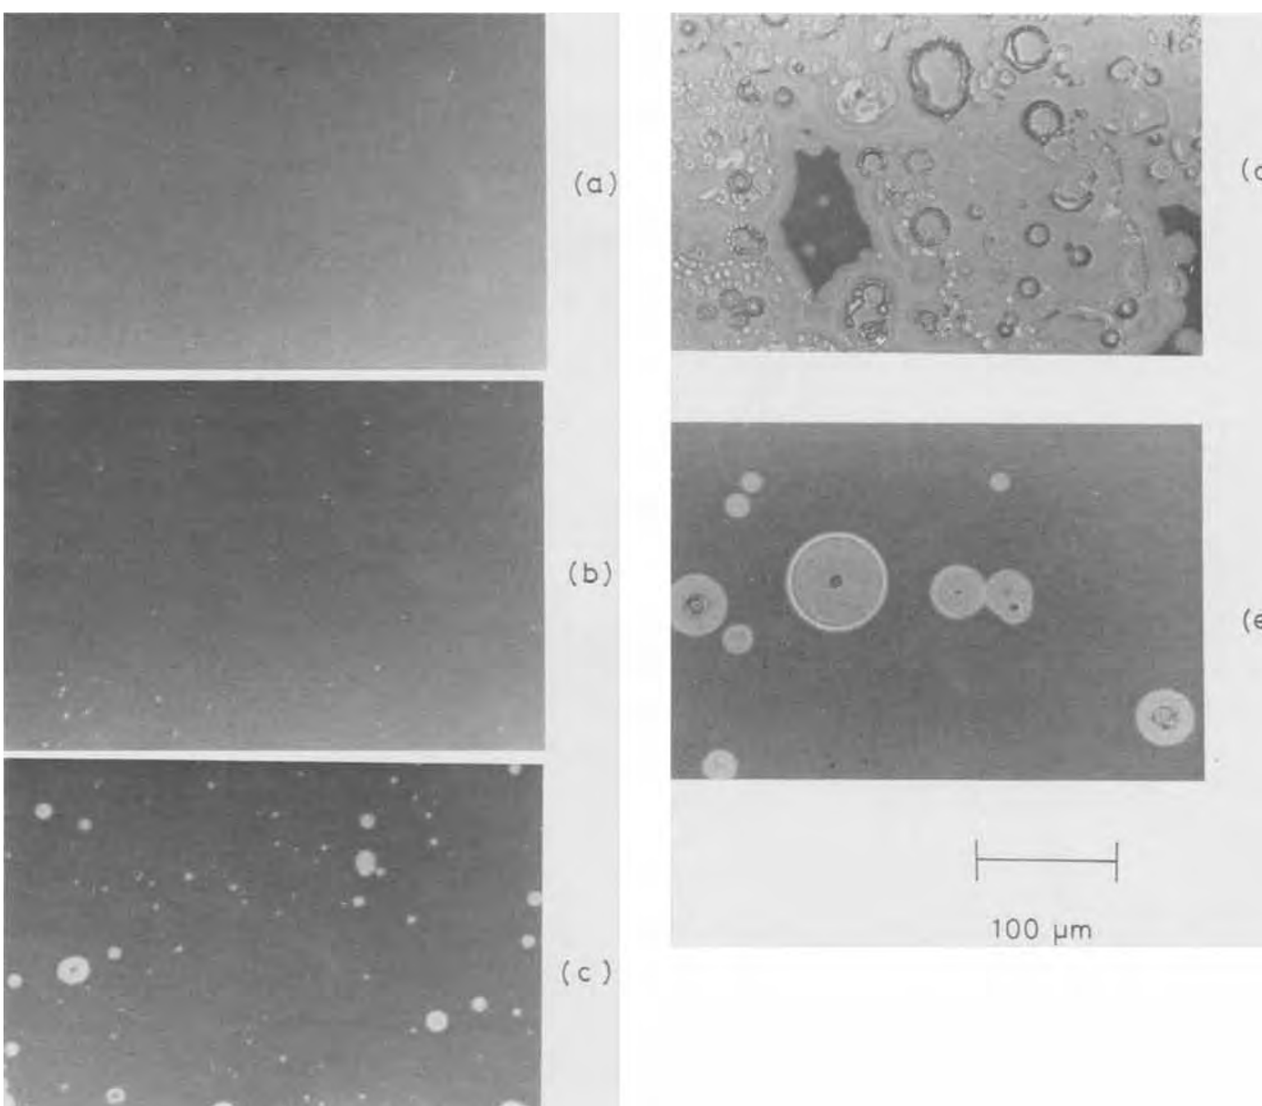

Fig. 11. Photographs showing changes of surface morphology of GaP anodically oxidized in Type B solution, pH = 9.0, after storage: (a) as-grown surface, (b) after one day, (c) after two weeks, (d) and (e) after six months. The sample shown in (a)-(d) was anodized at J = 2.0 $mA \cdot cm^{-2}$ and (e) was anodized at J = 0.25 $mA \cdot cm^{-2}$.

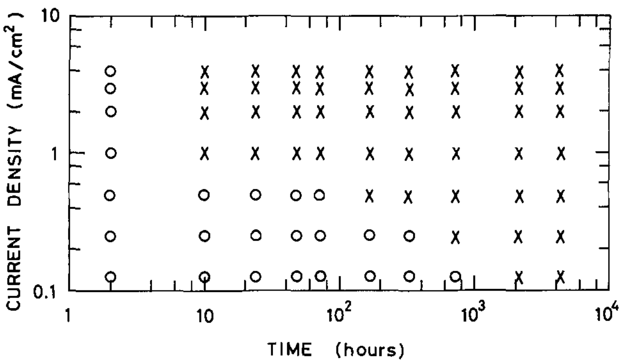

Fig. 12. Relationship between anodization current density and storage time when surface morphology changed from as-grown (○) to deteriorated (×). Anodization was done in Type B solution, *p*H = 9.0.

Typical carrier-concentration and mobility profiles for samples implanted at a Zn ion dose of 2.0×10^{14} cm^{-2} are shown in Fig. 13. From the carrier-concentration profile, the p-n junction depth can be estimated to be around 0.35 μm which agreed with that measured by angle-lap ($\theta = 1.5°$) and staining. The measured carrier-concentration profile differed from the profile predicted by the LSS range-energy theory (22, 23). Apparently, diffusion of Zn during annealing determines the final carrier-concentration profile as previously reported for GaP (24), GaAs (25), and GaAsP (26). Mobility in the Zn-implanted layer agreed with mobility in bulk GaP for hole concentrations equal to the measured carrier concentrations (27). Electrical profiles and electrical characteristics of Zn-implanted p-n junction diodes will be separately reported.

Summary

Conditions for anodic oxidation of GaP in electrolytes consisting of NMA, water, NH_4OH, and citric acid were defined for reproducible differential electrical profiling of GaP. The best conditions were: (*i*) NMA with 10% H_2O adjusted to pH = 12 with NH_4OH and readjusted to 8.5-10 with citric acid, (*ii*) 0.5-1.0 mA·cm^{-2} anodic current density, (*iii*) 10-100V forming voltage, consuming 50-500Å GaP at $J = 1.0$ mA·cm^{-2}, (*iv*) oxide growth rate 11Å per unit forming voltage, and (*v*) illuminated sample to reduce the initial voltage. Since the amount of GaP consumed depends on current density a constant current density is required.

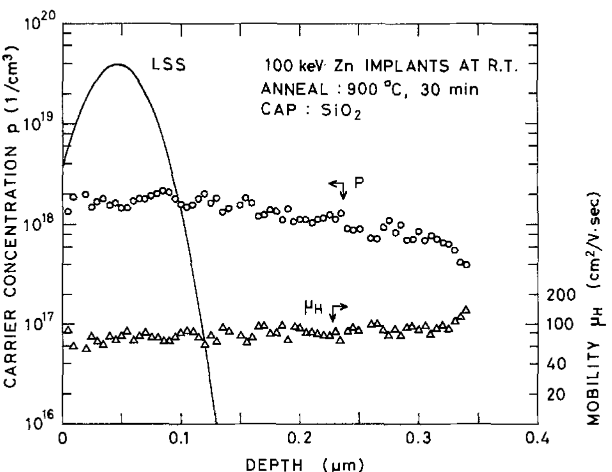

Fig. 13. Electrical carrier-concentration and mobility profiles in GaP Zn-implanted at 2.0×10^{14} ions · cm^{-2} and annealed 30 min at 900°C. Anodization for layer stripping was done in Type B solution, *J* = 1.0 mA · cm^{-2}.

Surface deterioration of the grown oxide occurred during storage and was worse for oxides grown at a higher current density. This limits the use of grown oxide for passivation and diffusion masks but does not affect electrical profiling as was shown in this work.

Acknowledgments

We would like to express our appreciation to A. Okada of RCA Research Laboratories, Inc. for the use of the AES analyzer and for his fruitful discussion on the AES data.

Vapor Transport of Zirconium and Silicon during Heat-Treatment of Zircaloy in Silica

D. R. Knittel and D. Cubicciotti*

SRI International, Menlo Park, California 94025

ABSTRACT

When pieces of Zircaloy are heated above 600°C in sealed silica capsules, silicon is deposited on the Zircaloy surface as zirconium silicides and zirconium is deposited on the silica in two forms: as an oxide layer in the high temperature region and as a metallic mirror on lower temperature surfaces. Samples of Zircaloy were heated in silica capsules under various conditions and analyzed by scanning electron microscopy. The results indicate that the deposits resulted from vapor transport processes involving volatile zirconium and silicon fluorides. Residual fluoride on Zircaloy surfaces, remaining from acid pickling treatments, was observed by Auger electron spectroscopy and mass spectroscopy in amounts sufficient to cause the transport. The thermodynamics of the vapor transport reactions are in accord with the fluoride mechanism.

Heat-treatment of small pieces of zirconium or its alloys is often performed in sealed silica capsules; however, that procedure results in significant changes. In particular, the metal surfaces become contaminated with silicon. Demant and Wanklyn (1) observed that Zircaloy samples become contaminated during heat-treatment in silica capsules and this leads to an increase in the initial oxidation rate of the metal. Cox (2) ascribed this contamination to a deposit of Si transported by gaseous SiO during the heat-treatment.

In addition to silicon deposition on the Zircaloy, zirconium-containing compounds form on the silica. Feuerstein (3) found that when Zircaloy was heated to 600°C and higher in evacuated silica tubes a white-gray deposit formed on the silica wall around the capsule. Neutron activation analysis showed the deposit contained Zr and traces of Sn (3). Feuerstein (3) also found that when open Zircaloy capsules containing ZrI_4 were heated to 800°C in evacuated silica tubes, a mirror-like metallic deposit formed on the silica around the open capsule. The deposit also formed on surfaces of ZrO_2 and Al_2O_3. Analysis showed the mirror deposit to be Zr with a few percent Sn (3). During the process, the Zircaloy capsule turned gray and the surface became roughened. Feuerstein associated the transport of zirconium with small amounts of adventitious iodine remaining in the system.

These examples show that when Zircaloy is heated in silica there is transfer of Zircaloy to the silica surface and silicon to the metal. As Cox (2) has noted, the silicon on the Zircaloy surface probably has a significant influence on corrosion rates. Silicon on the Zircaloy surfaces may have influenced corrosion results obtained on samples heat-treated in silica.

We have investigated reactions that occur during heat-treatment of zirconium alloys in silica. Our results indicate that silicon and zirconium are vapor-transported by volatile fluorides of these elements under the conditions of our experiments. Residual fluoride is found on the surfaces of zirconium alloys after bright-dipping or pickling treatments. [Under other experimental conditions, especially in the absence of fluoride, vapor transport by SiO may be important, as suggested by Cox (2).]

Experimental

Pieces of Zircaloy-4 sheets 1 × 3 × 0.08 cm obtained from Teledyne Wah Chang Albany (batch number Ht. 393533Q Zr-4) were used. The samples were cleaned in acetone, methanol, and water in an ultrasonic cleaner. They were then tested: (*i*) as received and after the following treatments: (*ii*) heating in a dynamic vacuum at 900°C to remove volatile surface species, (*iii*) argon ion etching for 2 hr, which removed a surface layer of about 2 μm, and (*iv*) chemical etching in $HF-HNO_3-H_2O_2$ pickling solution. Each sample was inserted into a silica capsule (1.5 cm in diam, 14 cm long), which was evacuated and sealed. The end of the capsule containing the Zircaloy foil was then heated to 900°C, and the other end heated to 650°C. A photograph of a typical capsule and a diagram of the temperature gradient is shown in Fig. 1. In other experiments the whole capsule was heated at a uniform temperature of 900°C. Transport of zirconium and silicon was also observed when capsules were maintained at 700°C. Samples were heated for times varying from 2 min to 50 hr. Shorter time experiments showed less pronounced effects.

Physical and chemical characteristics of the samples were studied in a scanning electron microscope (SEM). A Cambridge Research Laboratory instrument was used in which x-ray fluorescence analyses were performed with a wavelength dispersive detector (Microscope Corporation, Sunnyvale, California), and an energy dispersive analyzer (Kevex Corporation, Burlingame, California). With that system we could detect oxygen, carbon, nitrogen, and heavier elements. It was not possible to detect fluorine, since its peaks were masked by those of zirconium.

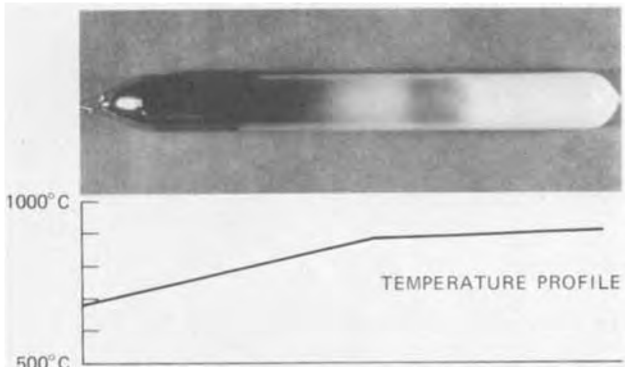

Fig. 1. Photograph of a sealed silica tube containing Zircaloy foil which had been heated in a temperature gradient for 6 hr. The Zircaloy foil is difficult to discern but is inside the white region at the right end. The metallic mirror deposit extends over about 4 cm at the left end. The tube had an inside diameter of 1.5 cm and is 14 cm long.

* Electrochemical Society Active Member.

Key words: evaporation, mass transport, ceramics, metals.

Surface analyses for fluorine were performed with an Auger electron spectrometer (Varian Cylindrical Mirror Analyzer). To investigate the volatile species a surface layer was machined from the inner surface of a Zircaloy-4 tube (Sandvik Special Metals Corporation) and those turnings were heated in a molybdenum effusion cell in a direct-inlet, high temperature mass spectrometer. The mass spectrometer system is described elsewhere (4).

Results

The effects of heating as-received Zircaloy (6 hr at 900°C) in an evacuated silica capsule are illustrated in Fig. 1. There were three distinct regions on the inner wall of the capsule: (*i*) a white (sometimes gray) deposit around the Zircaloy foil in the 900°C region, which was heaviest on the side of the foil closest to the silica, (*ii*) a region in which there was no deposit, in the 800°-900°C temperature zone, and (*iii*) a metal-mirror deposit, heaviest in the 750°-800°C region and becoming thinner towards the cooler end of the capsule. No metallic deposit was observed when the cooler end of the capsule was maintained at 400°C.

SEM analyses showed the presence of Zr on the silica in both the white deposit and the metal-mirror deposit regions and the presence of Si on the Zircaloy foil. The ratio of the peak height in SEM of Zr to Si was ~4 in the white deposit region and 3-4 in the metal-mirror deposit region. No other elements besides Zr and Si (and oxygen) were observed on the silica. Figure 2 shows the structure of the white deposit. X-ray diffraction of that deposit showed it was primarily monoclinic ZrO_2. In a one hour experiment the white deposit was found by SEM to be about 0.3 μm thick from which we estimate that about 1.5×10^{-3}g of Zr had been deposited. The metal-mirror deposit was thinner and less dense than the white deposit. In the same one hour experiment the metallic deposit was found to be about 0.1 μm thick and contained about 0.5×10^{-3}g of Zr (assuming the metallic deposit was ZrSi and had a density of 4 g/cm^3). The electrical resistance of the mirror deposit, as determined by a simple two-probe test, was low in keeping with its metallic appearance. The x-ray diffraction pattern of the metal mirror deposit could not be identified with the ASTM patterns.

The Zircaloy surface of the sample exposed in the same one hour experiment, was found in SEM to have a coating which was about 1 μm thick and had a Zr to Si ratio of about 1.5. Figure 3 shows the surface of a Zircaloy sample heated under similar conditions for 50 hr. The surface had a honeycomb structure and had a silicon to zirconium ratio of about one. It was found to be from 10 to 15 μm thick. The x-ray diffraction pattern of the surface showed the presence of small amounts of Zr_2Si but the more intense peaks could not be identified with the ASTM (5) patterns. We believe they were due to zirconium silicides whose diffraction patterns have not been reported (6). No oxygen was detected on the surface of the foil (however oxygen transported could have diffused into the bulk and not been detected).

When a silica capsule containing a Zircaloy sheet was heated in a constant temperature zone, no metallic deposit was found. A large amount of a white deposit of ZrO_2, compared with the temperature gradient experiments described above, formed on the silica wall. In a 12 hr experiment, SEM observation of the metal surface showed that it was covered with a layer of material having a columnar structure 3-5 μm thick. X-ray diffraction analysis showed that Zr_2Si was the major species present.

The surface of a Zircaloy sample heated in a silica capsule at a uniform temperature of 900°C for 15 min is shown in Fig. 4. We analyzed the ridges which apparently decorated grain boundaries and found they contained only Zr and Si. The surface regions between the ridges also had silicon.

Some Zircaloy foils were heated in silica capsules that were not sealed but were kept under dynamic vacuum for 6 hr at 900°C. SEM examination showed no zirconium deposited on the silica walls and no silicon on the Zircaloy. One of these capsules was subsequently sealed under vacuum and heated an additional 6 hr at 900°C. SEM examination showed a little transfer of zirconium to the silica and some silicon on the Zircaloy. This suggested that only a small fraction of the transporting species remained after the heat-treatment in the dynamic vacuum.

Fig. 2. SEM photograph of the fractured edge of white deposit on the silica in the 900°C temperature range. The silica capsule had been heated in the temperature gradient described in Fig. 1 for 50 hr. Analysis of the layer in the middle of the photograph showed mainly Zr with some Si and x-ray diffraction showed it to be ZrO_2. The layer is very porous so that volatile species could readily permeate it. The layer near the bottom of the photo was silica.

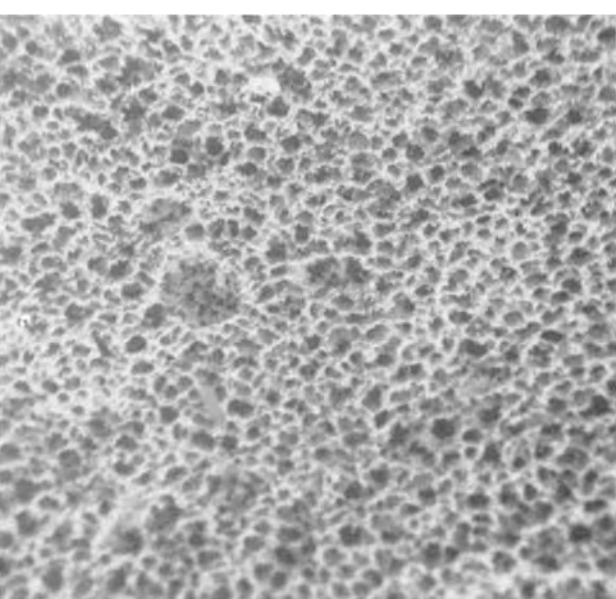

Fig. 3. SEM photograph of the surface of a Zircaloy-4 sample that had been treated in the temperature gradient described in Fig. 1 for 50 hr. Analysis of the surface showed Zr and Si in a ratio of ~1. Width of photograph = 0.1 mm.

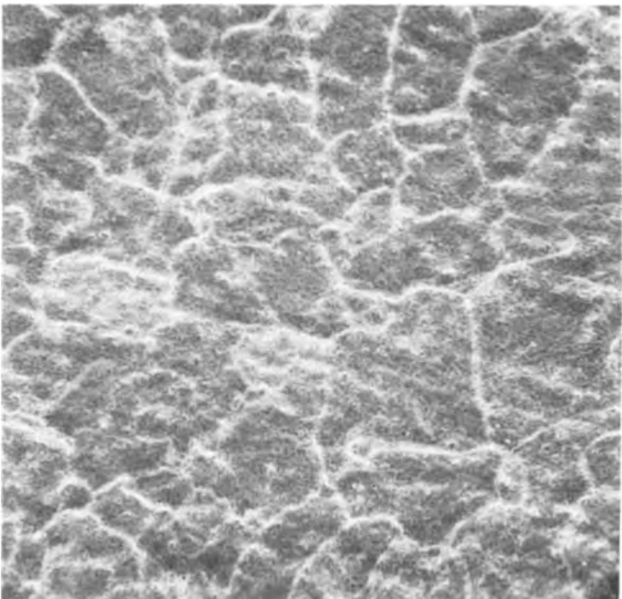

Fig. 4. SEM photograph of the surface of a Zircaloy-4 sample that had been heated at uniform temperature of 900°C for 15 min in a silica capsule. Analysis of the surface showed Si and Zr in both the ridges and valleys at a ratio of about 0.7. Width of the photograph = 0.1 mm.

To learn whether the species causing the transport was initially on the Zircaloy surface, we removed a 2 μm surface layer from a sample by Argon ion-etching for 2 hr. That treatment was presumably enough to remove the fluoride since others have shown that residual fluoride occurs only in the first 0.5 μm of a surface (7, 8). The sample was sealed in a silica tube and heated at 900°C for 6 hr. No transport of silicon to the Zircaloy or zirconium to the silica was observed.

Another sample was chemically etched with HF-HNO_3-H_2O_2 solution. Transport similar to that described for the as-received Zircaloy foil was observed after a 6 hr test. These results suggest that the species that causes the transport is on the Zircaloy surface. It is removed by heat-treatment in a dynamic vacuum, but remained after chemical etching. Thus we suspected that the transport was due to residual fluoride in the Zircaloy surface.

Zircaloy surfaces were examined by Auger electron spectroscopy (AES) for surface impurities. Fluorine (as well as O, C, Sn, and Zr) was found by AES on the surfaces of both the as-received and the chemically etched samples at about the same concentration and equivalent to about 2% of the surface atoms. The surfaces were ion etched in the AES apparatus to examine subsurface layers. Fluoride was detectable until about 0.1 μm of the surface had been removed. A rough estimate of the surface concentration of fluoride, based on these AES results, indicates there was about 0.2 $\mu g/cm^2$ of F on the Zircaloy surface. This compares well with Mackintosh (7) and Golicheff *et al.* (8). On the sample that had been heated in a dynamic vacuum, the AES study showed that about 0.1% of the surface atoms were F, which indicates that the dynamic vacuum heat-treatment removed most of the surface fluorine. We calculate that all the fluoride (0.2 $\mu g/cm^2$ of metal surface) in one of our typical experiments would produce a total pressure of about 1.3×10^{-5} atm of volatile metal tetrafluoride in the capsule.

Mass spectrometry was used to identify the volatile species. A surface layer was machined (without cutting oils) from the inside surface of a 50 cm length of 1 cm diam Zircaloy-4 tubing. The cuttings were placed in a molybdenum effusion cell and heated slowly in a direct-inlet mass spectrometer. When the temperature of the cell reached 370°C, ion peaks corresponding to ZrF_4 were observed. The major ion peak observed was $Zr^{90}F_3^+$. Relative isotope intensities were in accord with natural isotopic abundances. No other vapor species were observed. The sample was heated at 900°C and ZrF_3^+ disappeared in about one hour.

We then tried to establish whether there was a volatile species containing both zirconium and silicon which could have caused the transport of zirconium because the vapor pressure of zirconium itself was too small to account for the transport. A sample of Zircaloy was heated in a sealed silica capsule for 50 hr. A Zr-Si coating was found on the surface by SEM. That sample was then heated at 900°C for 50 hr in a silica tube open to a dynamic vacuum (10^{-5} Torr). A thin mirror-like deposit was formed on the cool walls of the tube; SEM examination showed that deposit contained no zirconium but was rich in chromium. Apparently the chromium component of the Zircaloy had evaporated. However, no zirconium had been transported. The partial pressures of any zirconium-bearing species must have been quite small, we estimate less than 10^{-13} atm. Therefore the transporting gas species was not a Zr-Si molecule.

Discussion

The experiments described showed that zirconium and silicon were both transported in sealed capsules but were not transported in capsules open to the vacuum system. That result and the uniformity of the deposits over a wide area indicate that vapor transport was the primary mechanism. In the temperature gradient experiments two kinds of deposits contained zirconium (a ceramic deposit near the Zircaloy and a metallic Zr-Si deposit at the cooler end of the capsule), presumably formed by different mechanisms. The mass spectrometer study showed that ZrF_4 was the principal volatile species formed when Zircaloy was heated. Auger surface analyses showed that fluoride was present on surfaces of as-received Zircaloy, and that samples that had been treated to remove the original surface fluoride (ion milling or heating in dynamic vacuum) did not show Zr/Si transport. From those results, we conclude that the observed transfer of zirconium and silicon occurs by vapor transport, with gaseous fluorides acting as transporting species under the conditions of these experiments.

In the chemistry of the Zr-Si-F-O system, there are several gaseous species known: ZrF_4, ZrF_3, SiF_4, SiF_3, SiO, and that the divalent and monovalent fluorides of Zr and Si that are not important here. There are also several potential solid phases: ZrO_2, SiO_2, and several binary Zr-Si compounds. The following two-step cycle could cause vapor transport of zirconium and silicon and not consume the small amounts of fluoride available

$$ZrF_4(g) + SiO_2(s) = ZrO_2(s) + SiF_4(g) \quad [1]$$

$$SiF_4(g) + 3Zr(s) = Zr_2Si(s) + ZrF_4(g) \quad [2]$$

When the capsule is first heated, the surface fluoride evaporates as ZrF_4. In this scheme, reactions [1] and [2], the surface coating formed on the Zircaloy is Zr_2Si (observed by x-ray diffraction of foil heated in constant temperature zone of 900°C). For other experimental conditions (higher temperature or temperature gradients described in Fig. 1) compounds richer in Si are formed (SEM showed Zr/Si $\simeq$ 1.5 to 1). Reaction [2] should be rewritten for these situations, but the same principles apply.

The free energy changes for these reactions can be evaluated from available data (JANAF (9), Kubaschewski *et al.* (10), and our estimate of the absolute entropy of Zr_2Si at 298°K to be 30 cal/mole deg) with the result

$$\Delta G^\circ \text{ (reaction [1], cal)} = -30{,}600 + 6.6T$$

$$\Delta G^\circ \text{ (reaction [2], cal)} = -64{,}000 - 10.9T$$

At 1200°K the free energy changes are −23 and −77 kcal, respectively. Thus both reactions have favorable free energies, and the net result will be formation of a ZrO_2 deposit on the silica walls and a Zr_2Si deposit on the Zircaloy. Those reactions can occur only if the capsule is sealed so that the volatile fluorides (ZrF_4 and SiF_4) are not removed. The temperature coefficients of the free energies are small and, thermodynamically, the process should occur at any reasonable temperature. We observed that transport was slow below 600°C.

The second type of coating containing zirconium was observed on the silica wall at the cooler end of the capsule, for temperatures below 800°C when the foil end was 900°C. That transport must have occurred by a different chemical mechanism, because the deposit was metallic and formed only at lower temperatures. (X-ray diffraction patterns showed that it was not a zirconium oxide and SEM showed $Zr/Si \simeq 1$). To deposit a metallic film, the transporting vapor species must be a species lower valent than tetrafluoride to allow disproportionation to occur. ZrF_3 and SiF_3 are the most likely candidates since the divalent and monovalent species would occur only at much lower pressures than the trifluorides. If the species is ZrF_3, then the deposition reaction (in the cool end, 800°C or lower) would be

$$8ZrF_3(g) + SiF_4(g) = ZrSi(s) + 7ZrF_4(g) \quad [3]$$

and regeneration of trifluoride would occur at the hot end (900°C) by

$$3ZrF_4(g) + Zr(s) = 4ZrF_3(g) \quad [4]$$

The equilibrium constants for these two reactions can be combined to give the following condition

$$\frac{P(ZrF_4)}{P(SiF_4)} = K_3 \text{ (at 800°C)} \times K_4^2 \text{ (at 900°C)}$$

which can be evaluated from thermodynamic data (JANAF (9) and estimate of 20 cal/mole deg for the entropy of ZrSi), so that when $P(ZrF_4)/P(SiF_4) = 10^{16.6}$, deposition of ZrSi can occur (hot end 900°C, cool end 800°C). If the cool end temperature is above 800°C for that pressure ratio, no deposition can occur.

If the lower valent fluoride is SiF_3, a comparable set of transport reactions can be derived. For either case, it is possible to understand from the thermodynamic data why the mirror deposit forms only below a certain temperature, not throughout the tube. At the present state of our knowledge, we have no way of knowing whether the predominant vapor species in the capsules is ZrF_4 or SiF_4 (and whether ZrF_3 or SiF_3 accounts for the mirror). The relative rates of reactions [1] and [2] would determine which species dominated. That species might be different for different capsule conditions or geometries.

Cox (2) suggested that SiO(g) may be important in transporting Si to the zirconium surface. Our results suggest that transport of Si via SiO(g) is small compared to the fluoride mechanism because transport was greatly reduced when the residual fluoride was removed by heating in a dynamic vacuum or by ion etching. Under conditions for which SiO transport was dominant there would be no mechanism for zirconium transport because the volatilities of the zirconium oxides are very small.

A Performance and Current Distribution Model for Scaled-Up Molten Carbonate Fuel Cells

V. Sampath and A. F. Sammells*

Institute of Gas Technology, Chicago, Illinois 60616

and J. R. Selman*

Department of Chemical Engineering, Illinois Institute of Technology, Chicago, Illinois 60616

ABSTRACT

The performance of scaled-up (100 cm²) fuel cells with cross flow of fuel and oxidant has been modeled using the polarization characteristics of small-scale (3 cm²) fuel cells. The model also yields the two-dimensional (superficial) current distribution. The performance predicted by the model approximates to within 4% the experimental data if a suitable average value is assigned to the effective cell impedance. The latter depends on the inlet gas composition but does not vary much with the current; its value may be estimated from small-scale cell data. Carbon monoxide conversion contributes appreciably to the performance of low Btu cells; it tends to make the current distribution less uniform. The presence of methane must be considered in pressurized cells, but it does not appear to be formed to a significant extent. The relative contribution of mass transfer and kinetic resistance to the cell impedance are discussed in light of recent experimental results.

Mathematical modeling of cell performance has two distinct objectives:

1. To identify the rate-limiting factors in cell performance.
2. To predict the performance of scaled-up cells from small-scale cell data.

The present work concerns the latter type of modeling; the specific objective is to predict the current distribution in, and the performance of, 100 cm² molten-carbonate fuel cells in which the fuel gas and the oxidant gas (Table I) flow at right angles to each other and in which the fuel conversion is 75%. The ohmic resistance of such cells may be measured using conventional current-interruption techniques. Polarization, however, is not usually measured in scaled-up cells because reference electrodes are not easy to build into these cells. Also, polarization, as well as current density, varies over the electrode surface as a function of conversion, therefore, a single polarization measurement yields only limited information.

However, polarization data are available for small-scale (3 cm²) cells equipped with reference electrodes (1, 2) which operate at differential conversion. These data are specific for the input gas composition and may be used as input for the cross-flow cell performance model.

Small-Scale Cell Polarization

Figure 1 illustrates the *IR*-free overpotential at a porous nickel anode and at a porous nickel cathode in a 3 cm² cell, for 7.5% conversion of 80% H_2-20% CO_2 fuel gas with standard oxidant (70% air-30% CO_2) (1). Typically, these polarization curves are approximately linear. Quasi-linear polarization behavior of a porous electrode in molten carbonate was observed at IGT as early as 1967 by Argano *et al.* (3) using a nickel anode of appreciably larger pore size and smaller internal area than the electrodes of Fig. 1. An example is shown in Fig. 2.

Because the overpotential is well above $RT/2F$ (40 mV at 650°C), this linear polarization behavior cannot be explained exclusively by kinetic rate limitations. Also, it is only approximate; the linear fit is usually less than satisfactory near the origin, and for some gas compositions the cathode polarization is better represented by two straight lines, with a transition in the range of 150-200 mA/cm², than by a single line. These features suggest that the porous electrodes operate under combined control of kinetics and mass transfer, while ohmic potential drop in the pores may also be significant.

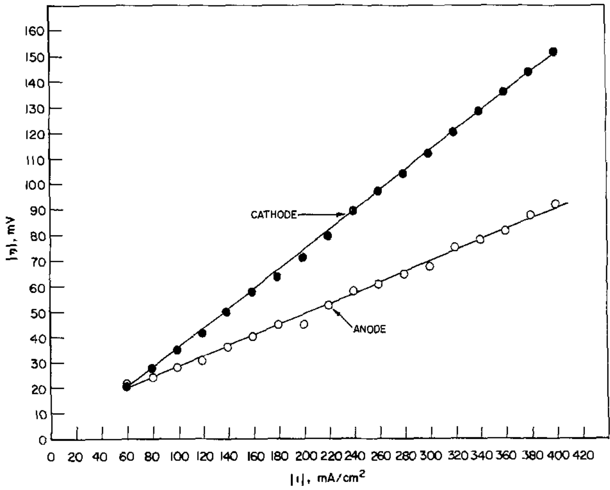

Fig. 1. Polarization (*IR* free) in a 3 cm² fuel cell [from Ref. (1)]

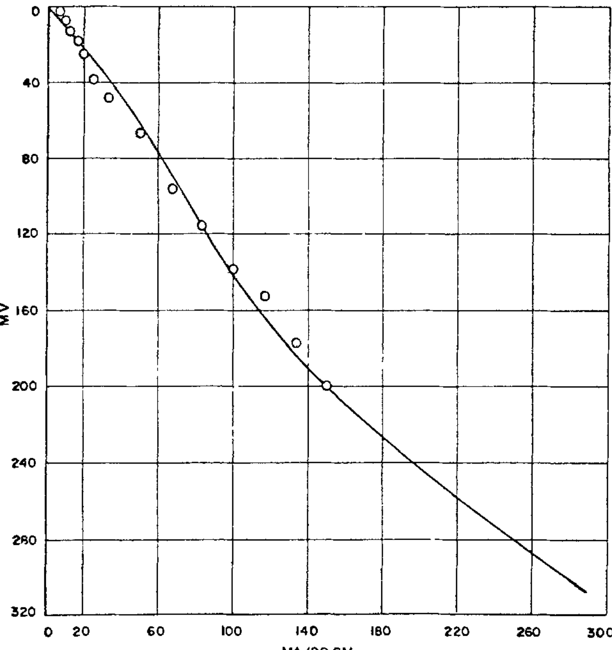

Fig. 2. Anode polarization (*IR* free) in a 3 cm² fuel cell [from Ref. (3)].

A porous electrode model may be used to interpret the rate processes in the electrodes. Porous electrode models applied to fuel cells have been reviewed by Bockris and Srinivasan (4) and by Austin (5). Although such models have been fairly successful in correlating or predicting the performance of room-temperature fuel cells, there have been few publications concerning molten-carbonate fuel cell modeling (6-9).

Wasan *et al.* (6) and Sood (7) modeled the oxidation of hydrogen in a porous anode, using a thin-film model of the electrode pores. In Fig. 2, the solid line indicates the polarization predicted by the model of Wasan. The flooded-pore model was rejected because it predicted a limiting current of hydrogen oxidation, which was not observed.

Recent calculations (10, 11) suggest that a limiting current would probably not be observed in a flooded pore because of factors such as hydrogen transport in the metal (nickel) and the relatively important ohmic drop in the electrolyte film. Thus, a more appropriate physical representation may be a composite of flooded and filmed pores (agglomerate model). However, there is no reliable information about the nature and extent of the active surface in each of the porous electrodes. Thus, the film model remains the most acceptable simple representation of the electrode operation.

Although the film model is relatively simple, several of its input parameters are not known and need to be estimated. At least three dimensionless parameters are to be adjusted in fitting the experimental curve to the film model in addition to Butler-Volmer transfer coefficients and stoichiometric coefficients of the electrode reaction (11). This leaves one a considerable latitude in the assignment of parameter values or reaction mechanisms, without any guarantee of physical realism.

Therefore, the present work aims to predict cell performance and current distribution without resort to a microscopic model. Whereas at least three adjustable parameters are used in most porous electrode models, Fig. 1 and 2 show that, as a first approximation, a linear polarization expression adequately represents the data for the purpose of cell performance modeling. This conclusion was also reached by Dharia (8) who utilized an "effective cell resistance" to model the performance of a cell in which fuel and oxidant gas flow co-currently (co-flow). In the present work, the linear-polarization assumption is combined with mass balances for a cross-flow configuration of fuel and oxidant gases, as employed currently in scaled-up cells.

Basic Model

Figure 3 is a schematic diagram of the gas flows to the cell. It also shows how the cell is divided into sections for computation purposes.

Mass balances on the anode and the cathode result in one equation each for local hydrogen and CO_2 conversion. The two equations are coupled by the local current density. In the initial modeling, only hydrogen was assumed to react. The water-gas shift reaction was not considered, and CO was not assumed to be electrochemically active. In this case, mass balance equations at the anode are obtained as follows

$$H_2:\quad \frac{P}{RT\,L_C/n}\frac{\partial}{\partial x}\left(\frac{\Phi_A}{n}X_H\right) = -\frac{i_A}{2F} = -\frac{i}{2F} \quad [1]$$

$$CO_2:\quad \frac{P}{RT\,L_C/n}\frac{\partial}{\partial x}\left(\frac{\Phi_A}{n}X_{CA}\right) = \frac{i_A}{2F} = \frac{i}{2F} \quad [2]$$

$$H_2O:\quad \frac{P}{RT\,L_C/n}\frac{\partial}{\partial x}\left(\frac{\Phi_A}{n}X_W\right) = \frac{i_A}{2F} = \frac{i}{2F} \quad [3]$$

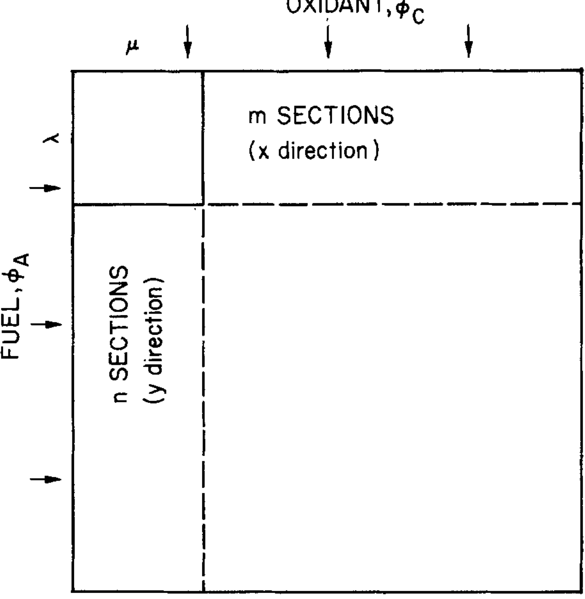
$$CO:\quad \frac{P}{RT\,L_C/n}\frac{\partial}{\partial x}\left(\frac{\Phi_A}{n}X_{CO}\right) = 0 \quad [4]$$

The corresponding cathode mass balances are

$$CO_2:\quad \frac{P}{RT\,L_A/m}\frac{\partial}{\partial y}\left(\frac{\Phi_C}{m}X_{CC}\right) = \frac{i_C}{2F} = -\frac{i}{2F} \quad [5]$$

$$O_2:\quad \frac{P}{RT\,L_A/m}\frac{\partial}{\partial y}\left(\frac{\Phi_C}{m}X_O\right) = \frac{i_C}{4F} = -\frac{i}{4F} \quad [6]$$

$$N_2:\quad \frac{P}{RT\,L_A/m}\frac{\partial}{\partial y}\left(\frac{\Phi_C}{m}X_N\right) = 0 \quad [7]$$



ϕ_A = FUEL FLOW RATE
ϕ_C = OXIDANT FLOW RATE
λ = ANODE GAS CONVERSION
μ = CATHODE GAS CONVERSION

Fig. 3. Schematic diagram of the fuel and oxidant flows to the cell.

By defining conversion of hydrogen, λ, as

$$\lambda = \frac{\text{moles of } H_2 \text{ consumed}}{\text{moles of } H_2 \text{ in}} = \frac{\Phi_A{}^\circ X_H{}^\circ - \Phi_A X_H}{\Phi_A{}^\circ X_H{}^\circ} \quad [8]$$

where the ° superscript refers to the inlet conditions; and conversion of CO_2 at the oxygen electrode μ, as

$$\mu = \frac{\text{moles of } CO_2 \text{ consumed}}{\text{moles of } CO_2 \text{ in}} = \frac{\Phi_C{}^\circ X_{CC}{}^\circ - \Phi_C X_{CC}}{\Phi_C{}^\circ X_{CC}{}^\circ} \quad [9]$$

the mass balances (1-4) can be combined in one equation

$$\frac{Pm}{RTL_C L_A} \Phi_A{}^\circ X_H{}^\circ \frac{\partial \lambda}{\partial \xi} = \frac{i}{2F} \quad [10]$$

and the cathodic-side mass balances (5-7) in a second equation

$$\frac{Pn}{RTL_A L_C} \Phi_C{}^\circ X_{CC} \frac{\partial \mu}{\partial \eta_d} = \frac{i}{2F} \quad [11]$$

Here ξ and η_d are dimensionless distances in the x and y direction, respectively, as defined by

$$\xi = \frac{x}{L_A/m} \qquad \eta_d = \frac{y}{L_C/n} \quad [12]$$

L_A/m is the length of one section in the x direction and L_C/n is the length of one section in the y direction (Fig. 3).

For the purpose of computation, Eq. [10] and [11] were further simplified by defining a dimensionless current density

$$J = \frac{i}{A} = \frac{i}{I_{max} m} \quad [13]$$

where

$$A = \frac{2FP\Phi_A{}^\circ X_H{}^\circ m}{RTL_C L_A} \quad [14]$$

and I_{max} is the current density that would result if 100% conversion of the anode gas took place and the resulting current were uniformly distributed over the entire cell.

Then, the mass-balance equations reduce to

$$\frac{\partial \lambda}{\partial \xi} = J \quad [15]$$

and

$$\frac{\partial \mu}{\partial \eta_d} = \frac{i}{SA} = \frac{J}{S} \quad [16]$$

where S denotes the stoichiometric ratio of CO_2 flow in the cathode to H_2 flow in the anode

$$S = \frac{X_{CC}{}^\circ \Phi_C{}^\circ n}{X_H{}^\circ \Phi_A{}^\circ m} \quad [17]$$

The local current density, i, is also dependent on the conversion via the cell potential balance; at each point in the cell the sum of the local equilibrium potentials, overpotentials, and ohmic potential drop must equal the cell terminal potential. The latter is considered uniform in the x and y directions. The cell potential is thus given by

$$V = (V_{CN} - V_{AN}) - iZ_{ohm} + \eta_C - \eta_A \quad [18]$$

where the equilibrium potentials at the electrodes are

$$V_{AN} = V_A{}^\circ + \frac{RT}{2F} \ln \left(\frac{X_W X_{CA}}{X_H} \right) \quad [19]$$

and

$$V_{CN} = V_C{}^\circ + \frac{RT}{2F} \ln (X_O{}^{1/2} X_{CC}) \quad [20]$$

Here the $CO_3{}^{=}$ activity gradient through the cell is considered to be zero. V_A and V_C are the standard anode and cathode potentials. Assuming a linear current-overpotential relationship

$$\eta_A = i_A Z_A = iZ_A \quad [21]$$

$$\eta_C = i_C Z_C = -iZ_C \quad [22]$$

where Z_A and Z_C are effective electrode resistances (Ω-cm^2). The dependence of overpotential and ohmic potential drop on the current density may now be represented by an effective resistance

$$Z = R_{ohm} + \frac{\eta_{an}}{i} - \frac{\eta_{cath}}{i} \quad [23]$$

Using the definition of conversions λ and μ from Eq. [8] and [9], Eq. [18] can be written as

$$\frac{V + V_A{}^\circ - V_C{}^\circ}{RT/2F} - \ln \left[\frac{X_{CC}{}^\circ (X_O{}^\circ)^{1/2} X_H{}^\circ}{X_W{}^\circ X_{CA}{}^\circ} \right] = \ln \left\{ \frac{(1-\mu)\left(1 - 1/2\mu \frac{X_{CC}{}^\circ}{X_O{}^\circ}\right)^{1/2} (1-\lambda)(1+\lambda X_H{}^\circ)}{(1 - 3/2\mu X_{CC}{}^\circ)^{3/2} \left(1 + \lambda \frac{X_H{}^\circ}{X_W{}^\circ}\right)\left(1 + \lambda \frac{X_H{}^\circ}{X_{CA}{}^\circ}\right)} \right\} - \frac{JZA}{RT/2F} \quad [24]$$

The first term on the right-hand side is the "Nernst loss" compared to inlet conditions. The second term is the overpotential and ohmic loss.

Equations [15], [16], and [24] are solved simultaneously to give λ, μ, and the current density. The computation starts at $\xi = 0$, $\eta_d = 0$ (fuel and oxidant inlet) and marches down the fuel flow and oxidant flow directions simultaneously. The fuel conversion, λ, is adjusted following each step in the ξ direction; so is the CO_2 conversion, μ, following each step in the η_d direction. Computations were carried out for a 10 × 10 cm fuel cell (100 cm^2 electrode area) using 10 sections in each direction. No significant differences were found when the number of sections was increased to 20 each; thus a 10 × 10 grid appeared to yield sufficient accuracy.

Experimental

The equations were solved simultaneously using a Harris System 120 computer.

The predicted current distributions were compared with experimental data generated on 100 cm^2 fuel cells (94 cm^2 electrode area). Here the anode consists of porous nickel, having a thickness of 30 mils and a mean pore size of around 5 μm. The cathode also initially consists of porous nickel which, under operating potential (to which it is subjected), oxidizes to NiO. This electrode has a 15 mil thickness and a mean pore size of between 12 and 14 μm. The electrolyte tile typically consists of a eutectic mixture of 62% Li_2CO_3-38% K_2CO_3 supported on a $LiAlO_2$ matrix.

Results and Discussion

In the computations reported here, Z was assigned an average value for the entire cell. Initially, this value was based on polarization measurements at small-scale fuel cells, as in Fig. 1, using reformed natural gas. Fairly good agreement was obtained between prediction and experimental data for this gas (Fig. 4). However, the fuel conversion predicted by the model exceeded 75% at most current densities;

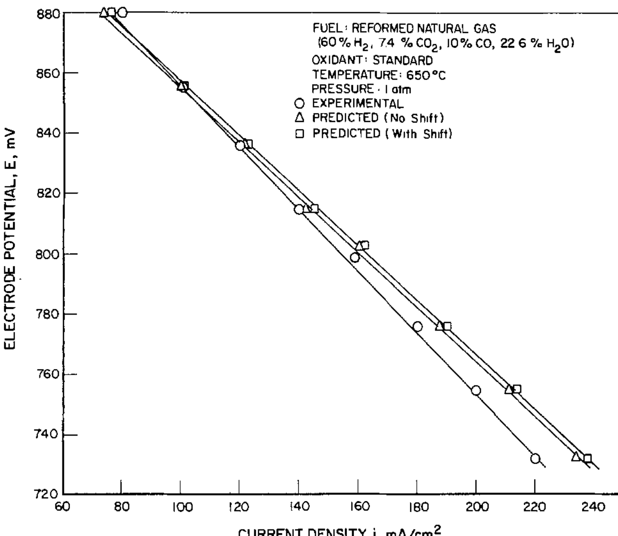


Fig. 4. Predicted polarization curves for reformed natural gas compared with experimental data. The effective resistance, Z, was assigned the value of 1.00 Ω-cm^2.

thus it appeared that the impedance was underestimated by the value based on the feed gas composition. This point was therefore investigated in more detail (see "Effective cell resistance" below).

Water-gas shift reaction.—In the case of low-Btu feed gas, the model's prediction was quite unsatisfactory. Here, conversion of CO to hydrogen

$$CO + H_2O \rightarrow CO_2 + H_2 \quad [25]$$

may be presumed to occur as H_2O product is formed in the cell. Therefore, local equilibrium conversion was assumed and included in the model. The results, using the same resistance value as before,[1] show that the effect of CO conversion is negligible in the case of reformed natural gas, but important for low Btu gas (Fig. 5) and other CO-rich feed gases. Here too, it became evident that resistance values based on polarization measurements with reformed natural gas yield unsatisfactory predictions for CO-rich, H_2-lean feed gases; fuel conversion is overestimated.

Effective cell resistance.—To investigate the dependence of the effective cell resistance on current density and gas composition, the performance of the fuel cell was simulated for three different gas compositions (see Table II), at 75% conversion with respect to H_2 and CO. The value of Z was adjusted at each cell potential until 75% conversion resulted.

[1] Except for an adjustment of the ohmic component using experimental data.

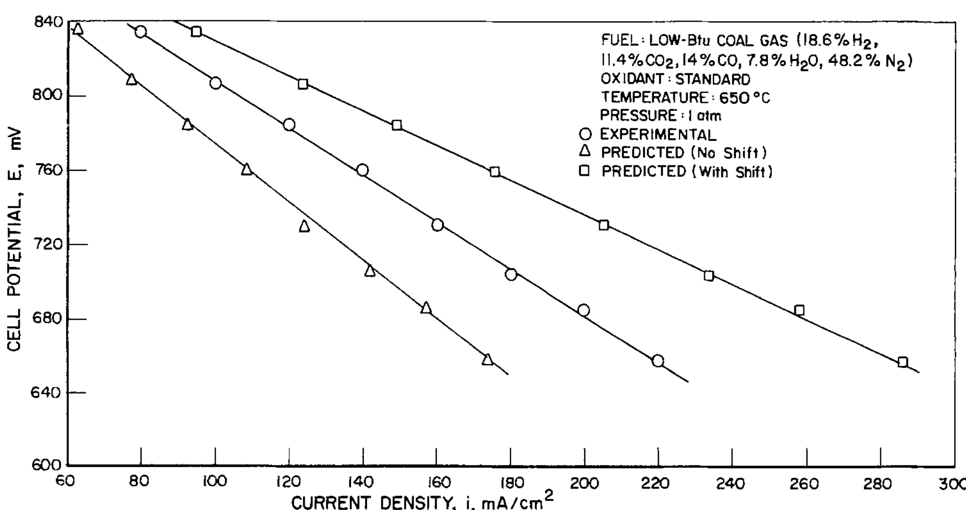
Table II. Estimated and measured cell resistance values

Gas composition (in mole percent) averaged between inlet and outlet, at 75% conversion

		Fuel electrode			Oxygen electrode
		RNG	Low Btu		Standard
	H_2	35.0	11.2	O_2	11.9
	CO_2	23.7	23.5	CO_2	23.9
	CO	7.2	9.0	N_2	60.8
	H_2O	34.1	12.7	H_2O	3.4
Estimated resistance					
Z_a or Z_c	Z_a:	0.315	0.455	Z_c:	0.428
$Z_a + Z_c$		0.743	0.883		
R_{ohmic}		0.400	0.446		
Z_{total}		1.14	1.33		
Measured resistance	at 200 mA/cm^2 (computed from exp. data)				
		1.05	1.49		

The current densities thus obtained agree to within 4% with experimental results. Figure 6 illustrates this for reformed natural gas and low Btu coal gas. Apparently, the assumption that CO is completely converted to hydrogen is justified. Figure 7 shows that the CO conversion makes a major contribution to the current in the case of low Btu gas.

For a particular feed gas, the effective cell resistance (Z) values at 75% conversion do not change by more than 10% as the total cell current is increased (Fig. 8). This finding gives support to the assumption that cell performance may be modeled satisfactorily by using an average Z value, rather than adjusting Z from point to point to account for local fuel oxidant gas compositions. In Table II, the effective resistance values found by fitting experimental curves are compared with estimates obtained by using small-cell polarization data. From the latter, the electrode impedances corresponding to the average gas compositions in the fuel and oxidant electrodes are calculated. Although small-cell data are not available for the full range of fuel and oxidant gas compositions, preliminary estimates can be made based on the fraction hydrogen in the fuel gas and oxygen in the oxidant (2). Ohmic resistances are added as determined *in situ* for the crossflow cell. Table II shows that in this manner, adequate predictions ($\pm$10%) of the effective cell resistance of scaled-up cells may be made, solely on the basis of small-scale cell polarization data and *in situ* ohmic resistance measurements (see Fig. 8). As more data become available for the polarization of small cells and the dependence of the anode polarization on the CO, CO_2, and H_2O concentrations is accounted for, one may expect that the estimates will become more accurate, especially for low Btu gases.



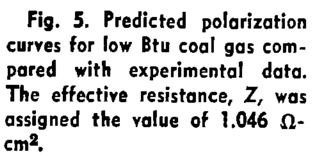


Fig. 5. Predicted polarization curves for low Btu coal gas compared with experimental data. The effective resistance, Z, was assigned the value of 1.046 Ω-cm^2.

Current distribution.—The current distribution as expected shows a maximum at the inlet of both fuel and oxidant. and a minimum at the outlet of the fuel, though not necessarily at the outlet of the oxidant. Figure 9 illustrates this for reformed natural gas at 160 mA/cm² (0.8V cell potential). As the value of Z increases, the current distribution for the same conversion becomes more uniform. Thus, for low Btu gas it is more uniform than for reformed natural gas.

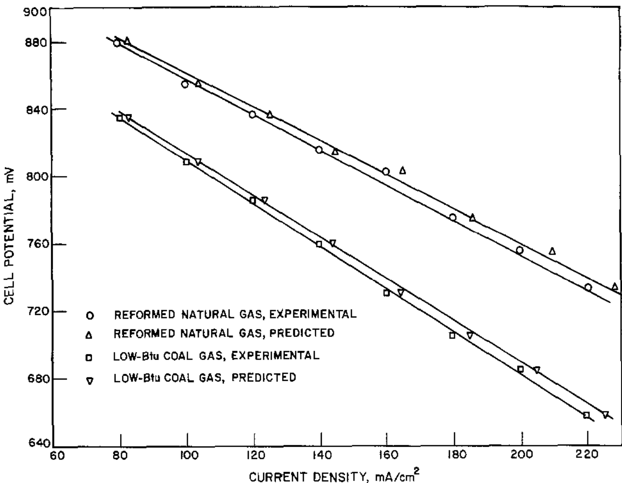

Fig. 6. Comparison of predicted and experimental polarization curves. The effective resistance, Z, has been adjusted for 75% conversion.

Pressurized operation.—Increasing the operating pressure of the fuel cell results in increased emf, because of the increase in partial pressure of the reactants. Higher pressures may also be expected to produce increases in gas solubilities and, hence, additional improvements in cell performance. However, pressure also favors methane formation

$$CO + 3H_2 \rightleftarrows CH_4 + H_2O \qquad [26]$$

and carbon deposition

$$2CO \rightleftarrows C + CO_2 \qquad [27]$$

The latter is prevented by humidifying the gas following compression, before it enters the cell. So far, there is not sufficient evidence to establish whether or not equilibrium [26] is actually attained, either after compression or inside the fuel cell.

In the model calculations, the gas composition at the fuel cell entrance was at first assumed at equilibrium with respect to Eq. [26]. Table II illustrates this

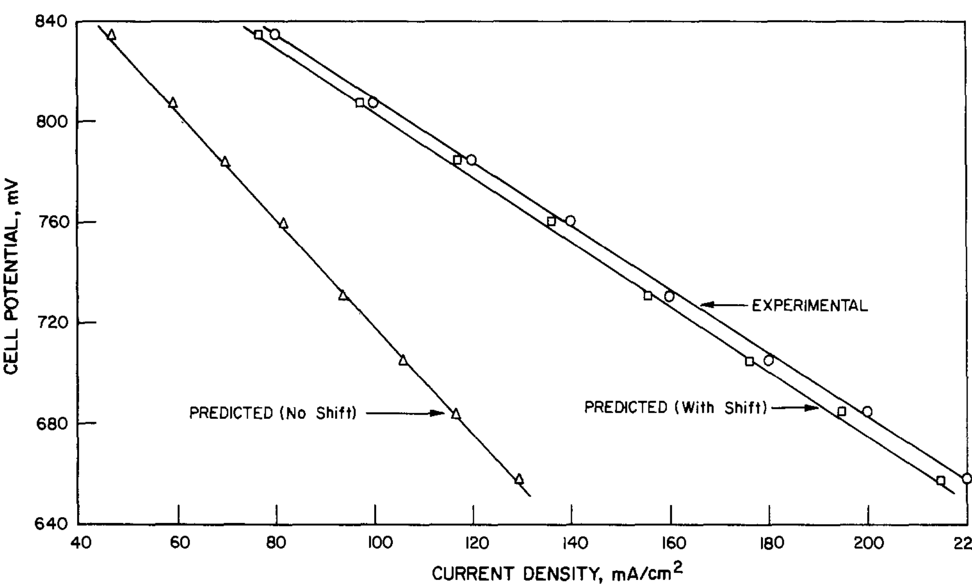

Fig. 7. Comparison of the experimental current density with computed current densities (fuel: low Btu coal gas). The Z value has been adjusted for 75% conversion (1.40-1.55 Ω-cm²).

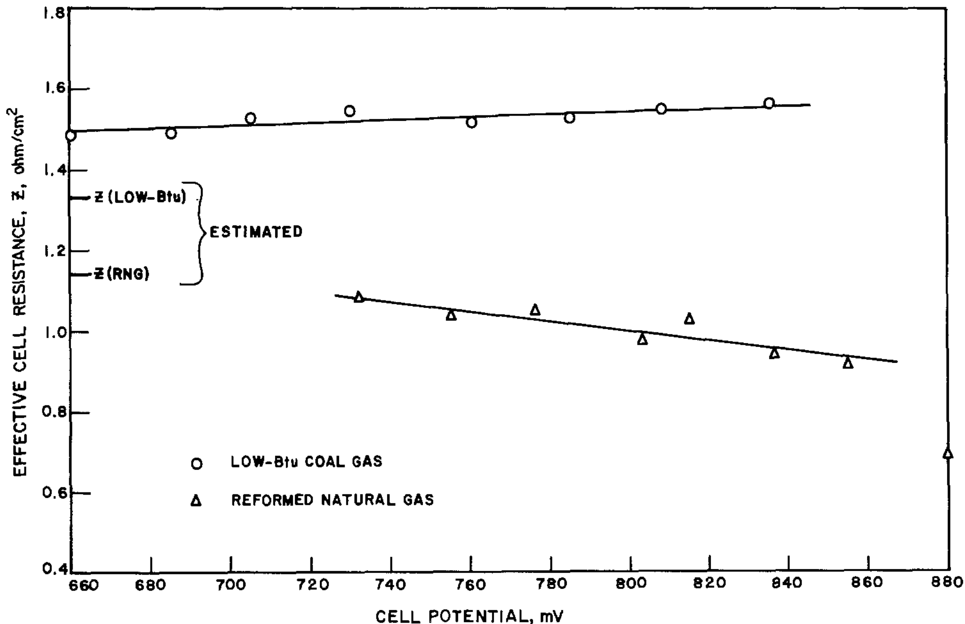

Fig. 8. Effective resistance as a function of current load in cell operation.

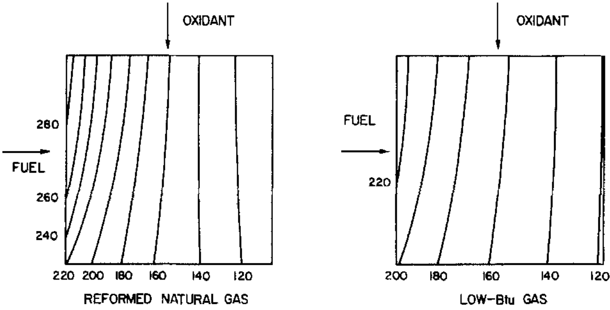

Fig. 9. Current distributions calculated for reformed natural gas and low Btu gas, both with standard oxidant, at 75% conversion and average current density of 165 mA/cm².

for steam-reformed naphtha. Since H_2O is produced by anodic oxidation of hydrogen, some steam-reforming of CH_4 may take place. Therefore, equilibrium 26 has been included in the model for pressurized cell operation.

The predicted average current density (or conversion) was compared with experimental data (11) obtained for a pressurized cross-flow cell at constant flow rate (rather than at constant 75% conversion, as in the cells operated at atmospheric pressure). The cell resistance, Z, was varied until good agreement was obtained at an arbitrary cell potential, *e.g.*, 0.830V, and the same Z value was then used to generate a complete performance curve.

For a flow rate identical to that used in the cell, an average current density of 120 mA/cm² was the maximum that could be generated by the cell at 0.830V, even for very low values of Z. Thus, it appears that equilibrium [26] is far from complete at the entrance to the cell; the compressed gas contains more hydrogen than equilibrium [26] would predict (31 m/o) and this excess is, at least initially, responsible for the better than predicted performance of the cell.

This is also evident from the result obtained when one uses the composition equilibrated only with respect to the water-gas shift reaction, as input to the pressurized operation model. The current density then agrees with the experimental value (160 mA/cm² at 0.83V) for a cell resistance not very different from that at atmospheric pressure (see Table III and Fig. 10).

The current distribution is not significantly altered by increasing the pressure. The ratio of highest to lowest current density is 2.11 at 1 atm and 1.94 at 10 atm for reformed naphtha.

Conclusion

A linear-polarization model has been used successfully to compute performance and current distribution

Table III. Gas composition (in mole fractions) and cell performance of steam-reformed naphtha at 650°C (constant flow rate)

Mole fraction	1 atm*		10 atm**		10 atm*
H_2	0.497		0.310		0.497

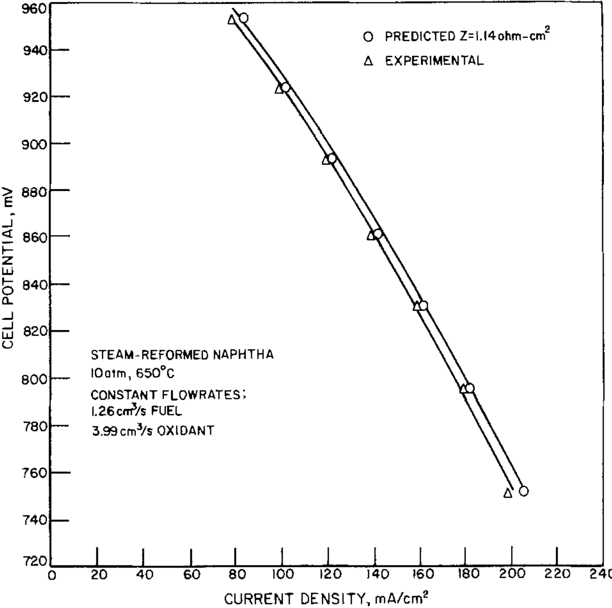

Fig. 10. Experimental and predicted current density in pressurized operation using steam-reformed naphtha at constant flow velocity. Prediction is based on inlet gas in equilibrium with respect to water-gas shift, but not methanation. Resistance Z was assigned a constant value of 1.14 Ω-cm².

of a scaled-up fuel cell as a function of gas compositions, flow rates, and operating pressure. The effective cell resistance used in the linear-polarization model may be estimated with satisfactory accuracy from small-scale cell polarization data and ohmic resistance measurements *in situ*. In pressurized operation, the formation of CH_4 may be accounted for, as well as CH_4 steam reforming in the fuel cell, but, at least for steam-reformed naphtha, the composition of the compressed gas at the fuel cell inlet appears not to be in equilibrium with respect to CH_4 formation. The highest local current density in a fuel cell is approximately two times the lowest local current density, both in atmospheric and in pressurized operation.

Capacitance Study of Thermally Grown Oxide Films on Iron

K. S. Yun,* S. M. Wilhelm,* S. Kapusta, and N. Hackerman*****

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

The dielectric properties of thermally grown oxide films on iron were determined by measuring the frequency and the temperature dependence of the capacitance in aqueous electrolyte solutions. The oxide films behave similarly to n-type semiconductors. The ionization energy of donor states in the oxide was obtained from calculation of the conductivity profile (0.64 eV) and from Mott-Schottky plots (0.69 eV).

Recently the current-potential characteristics and the photoresponse of thermally grown iron oxide were studied in this laboratory (1, 2). Thermal iron oxide electrodes were shown to be potentially useful as photoanodes in photoassisted electrolysis of water because of their relatively low bandgap (2.1 eV) and good corrosion stability.

The physical properties and the crystal structure of thermally formed iron oxide have been reported in detail by a number of authors (3-8). Up to about 570°C the high temperature oxidation of iron leads to formation of a two-layer scale of Fe_3O_4 and Fe_2O_3. A three-layer scale of FeO, Fe_3O_4, and α-Fe_2O_3 is formed at higher temperatures. The latter oxide film consists mainly of FeO and Fe_3O_4, the outer layer of α-Fe_2O_3 accounting for only 1-5% of the total thickness. The two inner layers have a metal-like conductivity (9) so that the semiconducting properties of the iron oxide are due only to the nonstoichiometry of the α-Fe_2O_3 layer. The oxide film is structurally highly disordered and may be described as glassy with short range crystalline order. The mean diameter of the crystal grains is approximately 1-2 nm.

A capacitance investigation is useful for obtaining information on the electronic structure of semiconducting oxide films in contact with an electrolyte. Recently, Kennedy and Frese (10) reported on a capacitance study of high purity polycrystalline α-Fe_2O_3 and discussed the flatband potentials and the donor densities. From the change in slope of the Mott-Schottky plots they suggested a deep donor level. A similar effect was observed for thermally grown oxide films (2).

The change in slope of the Mott-Schottky plot also can be observed for thin film covered metal electrodes without any deep donor levels and therefore the capacitance change alone is not a sufficient criterion for a second donor level. In order to clarify the semiconducting behavior and deep donor levels of thermally grown iron oxide, films of the oxides have been studied here via the frequency and temperature dependence of the capacitance.

Experimental

The procedure for growing the oxide films on iron has been reported (1, 2). Electrodes were made from zone-refined iron. Impurities higher than 5 ppm were Cu (10 ppm) and Ca (5 ppm). An oxide-covered iron rod (diameter 0.7 cm, length 1 cm) was embedded in a Teflon cylinder which was preheated (120°C) in an oven. After cooling, the edge was coated with silicon adhesive (Dow Corning) so that a circular area (approximately 0.3 cm^2) was exposed. Electrical contact was made by an iron rod inserted through a glass tube into the Teflon holder. The same electrode was used for each experiment.

The electrolyte was a 0.1M H_3BO_3 + NaOH buffer solution with 1M $NaNO_3$ supporting electrolyte (pH = 8.4). All chemicals were reagent grade and the water was triply distilled. A saturated calomel electrode (SCE) was used as a reference electrode and all potentials are referred to SCE. For the temperature studies the cell was placed in a constant temperature water bath (± 0.5°C).

Capacitance measurements were made with a General Radio Type 1603-A Z-Y Bridge, with a Type 1323-P

Key words: differential capacitance, iron oxide films, donor levels.

Preamp and a Type 1232-A Tuned Amp and Null Detector. A Model 505B Exact Waveform Generator was used as an oscillator and the amplitude was adjusted to 10 mV with an HP Model 350B Attenuator Set. Most capacitance measurements were carried out under potentiostatic conditions at 1 kHz. The bias voltage was supplied by a Princeton Applied Research Model 373 Potentiostat. To prevent oscillation of the potentiostat a variable frequency filter was placed between the counter and the reference electrode outputs of the potentiostat. The time constant of the filter (0.5 sec) was such that the open-circuit condition could be duplicated in the frequency range of 500 Hz-10 kHz. The series capacitance (C_s) and resistance (R_s) could be measured directly by balancing the working electrode against the internal components of the bridge.

To measure the capacitance a potential pulse technique was used. The electrode potential was changed in a 1 μsec risetime to the potential of measurement, the bridge balanced ($<$ 5 sec), and the potential returned to initial condition (usually 0.0V). The pulse was alternately anodic and cathodic, with the same amplitude. The measured differential capacitance of a particular electrode could be reproduced within 1% after 24 hr immersion in the electrolyte solution. During the initial 24 hr period the capacitance values varied randomly within 5% of their initial values.

Results and Discussion

Film thickness.—The experimentally accessible total capacitance, C, consists of the space charge capacitance, C_{sc}, and the Helmholtz capacitance, C_H, in series

$$1/C = 1/C_{SC} + 1/C_H \quad [1]$$

C can be equated with C_{SC} as long as C_H is much larger than C. The situation is then analogous to a parallel plate condenser between metal and electrolyte with a semiconducting film as a dielectric. All capacitance values were corrected by Eq. [1] by assuming a constant Helmholtz capacitance of 20 μf cm^{-3} (11-13).

At sufficiently positive electrode potentials, low donor densities, and with thin surface films, the charge necessary to change the electrode potential is predominantly stored in the metal. The differential capacitance is then independent of the electrode potential and is a measure of effective film thickness, d. It can be expressed as

$$1/C_{SC} = d/\epsilon\epsilon_0 A \quad [2]$$

where ϵ and ϵ_0 are the dielectric constants of the oxide and of vacuum and A is electrode area.

The dependence of reciprocal capacitance on film growing time is shown in Fig. 1. Capacitance values were taken at an electrode potential of +0.5V and a frequency of 1 kHz. The growing rate of the oxide films is a parabolic function with time (4, 7-9). This is substantiated by the linear dependence between C_{SC}^{-1} and $t^{1/2}$. The proportionality factor (6.94 nm/sec$^{1/2}$) was found by using $\epsilon = 80$.

The value $\epsilon = 80$ was estimated from the capacitance value by assuming a thickness (10.3 nm) based on a golden brown oxide interference color (14). For thicker gray films, however, ϵ assumed values up to 120. This discrepancy is due to the fact that thicker films contain a lower percentage of oxygen in the film. The minimum value was taken as the dielectric constant and is in good agreement with the value given in Ref. (10). It should be noted that the dielectric constant of α-Fe_2O_3 has also been measured as 8 at 1 kHz (15) and 120 at 1 MHz (16).

Frequency dependence.—Randomly oriented microcrystalline oxides such as anodic and thermally produced oxide films are asymmetric. The concentration of oxygen vacancies (or metal excess) as compared with a strict stoichiometry is greater near the metal than near the surface. This asymmetric constitution results in rectification, photoeffects, and other semiconducting

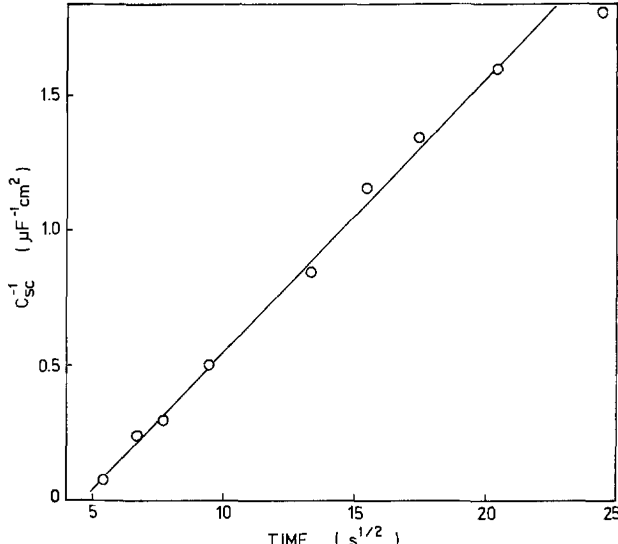

Fig. 1. Reciprocal space charge capacitance, C_{SC}^{-1}, vs. square root of time, $T = 25°C$, $f = 1$ kHz, pH = 8.4.

properties. The impedance of an asymmetric oxide layer is approximated by a resistance R_s and a capacitance C_s in series and can be directly measured with an a-c bridge as a function of frequency (17).

Young (17) derived the frequency dependence of $R_s(f)$ and $C_s(f)$ under the assumption that the oxide film consists of an infinite number of parallel RC units in series. Within certain frequency limits (f = 50 Hz-8 kHz) and at room temperature the following relationships were found to hold for an anodically formed niobium oxide film

$$R_s = R_o + a/f \quad [3]$$

$$1/C_s = 1/C_\alpha + b \log f \quad [4]$$

$$b/a = 9.2 \quad [5]$$

where R_o, C_α, a, and b are constants.

The compliance of the thermal iron oxide with these relationships is demonstrated in Fig. 2 and 3. The ratio, b/a, is 9.8 which is in good agreement with Young's theoretical value. A relationship equivalent to Eq. [3], [4], and [5] was derived independently by Winkel and de Groot (18) by assuming relaxation of the dielectric under the influence of an external field

$$d(C_s^{-1})/d \ln f = 4R_s f \quad [6]$$

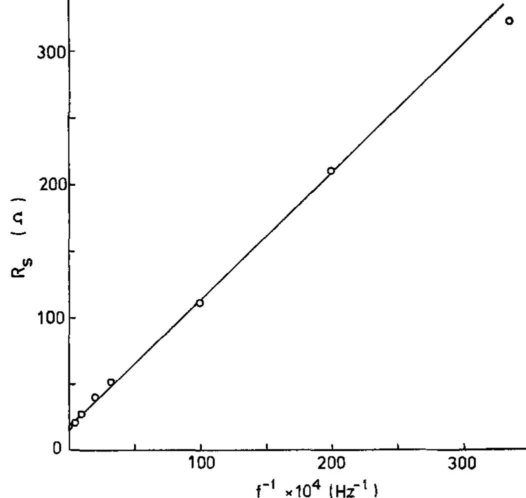

Fig. 2. Series resistance vs. reciprocal frequency, $T = 25°C$, pH = 8.4, open circuit.

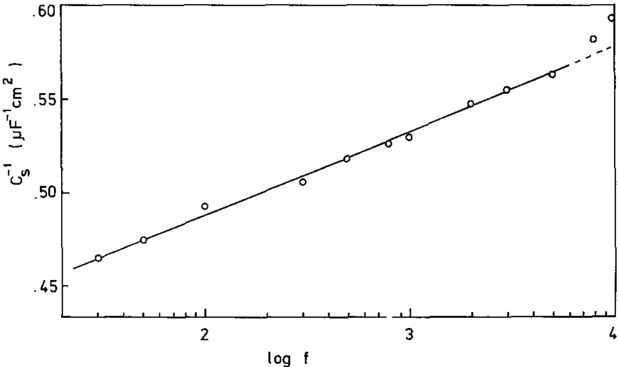

Fig. 3. Reciprocal capacitance vs. logarithm of frequency, $T = 25°C$, pH = 8.4, open circuit.

As Winkel and de Groot suggested, the equivalency of the two derivations is related to the exponential relationship of the conductivity defined by

$$\sigma = \sigma_0 \exp (d/d_0) \quad [7]$$

which was Young's theoretical basic concept[1] and of the relaxation time, τ, of polarizable particles in the dielectric defined by

$$\tau = \tau_0 \exp (q/kT) \quad [8]$$

where σ_0, d_0, and τ_0 are constants and q is the depth of the potential valley. There is a linear correlation between σ and τ (19). Recently Van Meirhaeghe *et al.* (20) also reported that the equivalency should be a consequence of the validity of Eq. [4].

R_0 can be obtained by extrapolation of R_s to $f^{-1} \rightarrow 0$ in Fig. 2. At sufficiently high frequencies, R_s corresponds to the ohmic resistance of the electrolyte. R_0 was found to be 17Ω from Fig. 2.

Equation [7] can be rewritten with $d/d_0 = C_0/C$ via Eq. [2] as

$$\sigma = \sigma_0 \exp (C_0/C) \quad [9]$$

According to Smyth *et al.* (21) the conductivity is directly proportional to the frequency of measurement

$$\sigma = 2\pi f \epsilon \epsilon_0 \quad [10]$$

Using Eq. [9] and [10] σ can be calculated as a function of position in the dielectric film. The frequency therefore determines the conductivity and the capacitance determines the position in the oxide. In order to determine this position it is necessary to have the absolute value of C_0. C_0 can be obtained at high frequency, where the dielectric behaves like an ideal parallel plate condenser. It was not possible, however, to measure the capacitance at frequencies above 10 kHz. However, it was possible to obtain C_0 from the temperature dependence of the capacitance.

Temperature dependence.—In Fig. 4 the temperature dependence of capacitance is shown. The capacitance is corrected for the Helmholtz capacitance (assuming 20 μF cm^{-2}) using Eq. [1]. The capacitance is directly proportional to the temperature

$$C_{SC} = C_0 + B\,(T - T_0) \quad [11]$$

where B is a proportionality factor and T_0 is defined as a critical temperature at which C_{SC} approaches C_0. The accessible temperature is not sufficient to observe C_0 and extrapolation of C_{SC} to $T \rightarrow T_0$ (Fig. 4) is not possible because T_0 is undetermined.

C_0 and T_0 can be obtained by varying the proportionality factor B. It was found experimentally that B depends on the electrode potential. The results are shown in Fig. 5. The extrapolation of C_{SC} for different electrode potentials to low temperatures intersect the same point ($C_0 = 1.5$ μF cm^{-2} and $T_0 = -26$°C). Smyth *et al.* (21) also found the value of T_0 to be around -30°C for heat-treated anodic tantalum oxide films.

[1] The original equation was expressed in terms of resistivity.

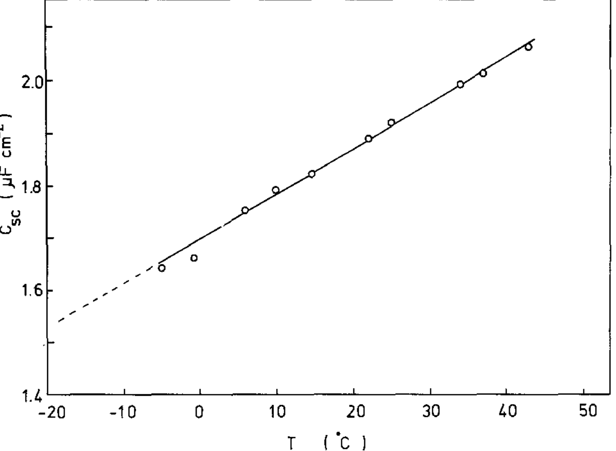

Fig. 4. Space charge capacitance vs. temperature, $f = 1$ kHz, pH = 8.4.

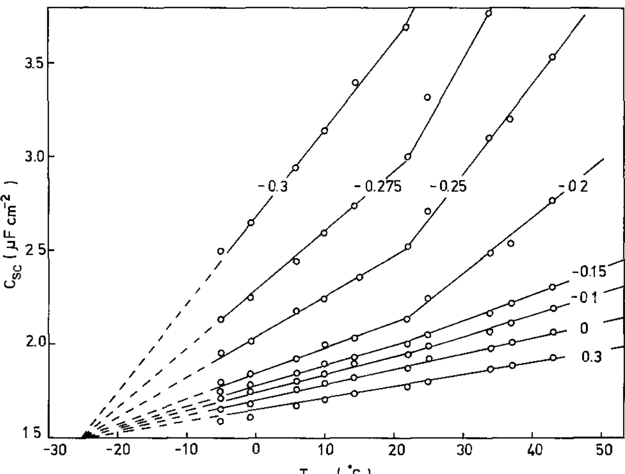

Fig. 5. Capacitance vs. temperature for different electrode potentials, $f = 1$ kHz, pH = 8.8.

The dependence of B on electrode potential could be explained by local dissociation equilibria of the donors

$$O_V \rightleftarrows O_V^+ + e^- \quad [12]$$

where O_V is an oxygen vacancy (or Fe^{2+}) and O_V^+ is a singly ionized donor. At negative electrode potentials the local dissociation equilibrium is shifted to the left resulting in a higher temperature sensitivity. At strong anodic potentials the donors are more dissociated and the total amount of the charge in oxide is less affected by temperature. The capacitance is then constant and the effective thickness d approaches the actual thickness d_0.

The abrupt slope increase at around 20°C suggests that the polycrystalline iron oxide has two donor levels, *i.e.*, shallow and deep donor levels as suggested by Kennedy and Frese (10) from their Mott-Schottky plots. The deep donors affect the total amount of charge at this temperature. Mott-Schottky plots also show an abrupt change in slope at this temperature (see next section). The extrapolation of the higher slopes in Fig. 5 also intersect at $C_0 = 1.5$ μF cm^{-2}. Thus C_0 is independent of the deep donor concentration as expected, since C_0 represents the actual thickness of the oxide film. Having determined C_0, d_0 can be calculated from Eq. [2] ($d_0 = 67$ nm).

Using Eq. [9] it is possible to calculate the conductivity, σ, at the reduced position C_0/C_{SC}. The results are shown in Fig. 6. The calculated values of σ at fre-

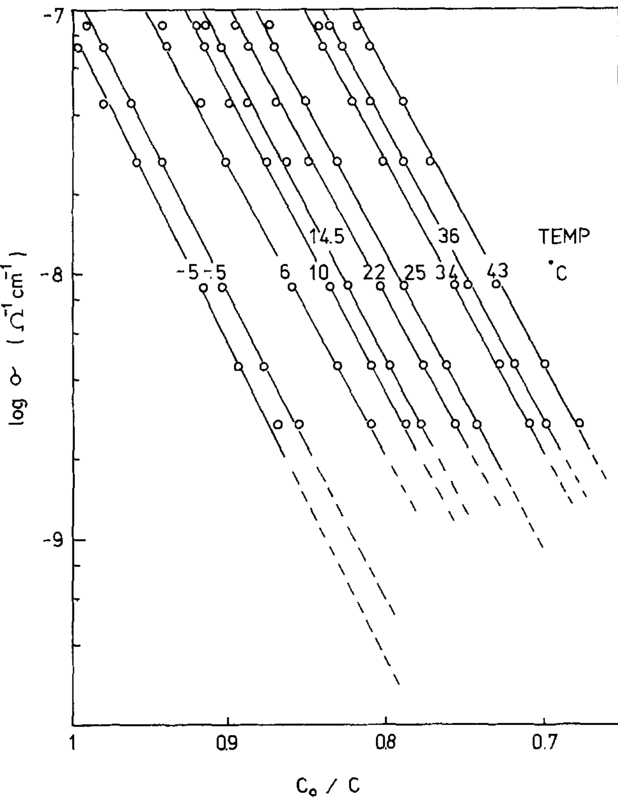

Fig. 6. Conductivity profile for different temperature, pH = 8.4

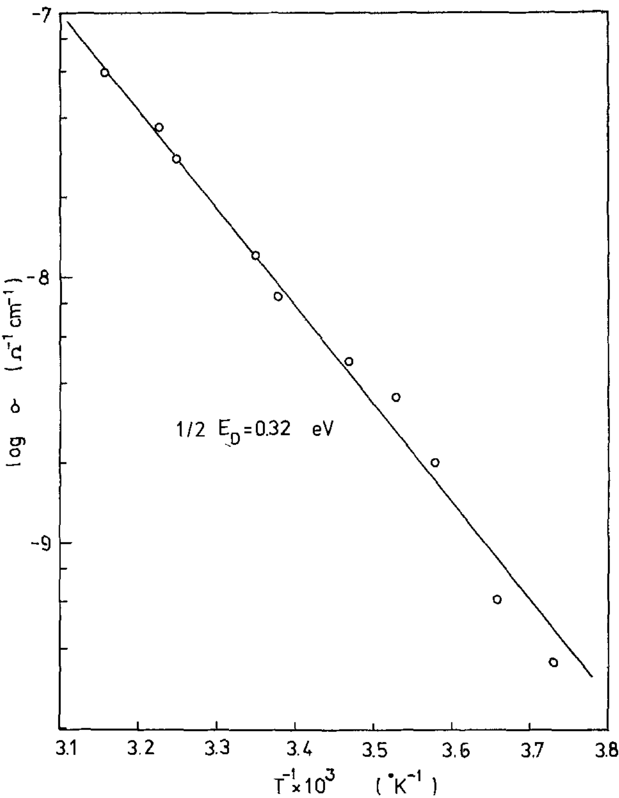

Fig. 7. Temperature dependence of conductivity at C_o/C = 0.8, pH = 8.4.

quencies lower than 200 Hz are not shown, because in this range σ does not follow Eq. [9]. The uniformity in slope suggests that the oxide is homogeneous for at least 30% of the total film thickness. The ionization energy, E_D, of donors does not depend on oxide position, ionized donor concentration, $N_D{}^+$, or the electron concentration in the conduction band.

The electron concentration, n, of an n-type impurity semiconductor can be expressed as

$$n = (N_D N_C)^{1/2} \exp(-E_D/2kT) \quad [13]$$

where N_C is the effective density of states in the conduction band. Hence the conductivity is

$$\sigma = \sigma_0 \exp(-E_D/2kT) \quad [14]$$

A plot of ln σ *vs.* T^{-1} gives a straight line, where the slope corresponds to the half of the ionization energy (Fig. 7). The value of σ was taken at the point C_o/C_{SC} = 0.8 (from Fig. 6). The slope gives E_D = 0.64 eV. This value is in good agreement with the value E_D = 0.69 eV obtained from the Mott-Schottky plots (see next section) and with reported values (10, 22, 23).

Mott-Schottky plots.—The simplified Mott-Schottky relation (24) is

$$C_{SC}{}^{-2} = (2kT/e^2\epsilon\epsilon_0 N_D)(-y - r + \ln r) \quad [15]$$

where y is the reduced potential drop in the space charge layer (V_{SC}) expressed as

$$y = eV_{SC}/kT = (V - V_f)e/kT \quad [16]$$

and r is the degree of dissociation of donors expressed as

$$r = N_D{}^+/N_D \quad [17]$$

V_f is the flatband potential.

A plot of $C_{SC}{}^{-2}$ *vs.* V_{SC}, if linear, yields the donor density, N_D, from the slope and a characteristic potential V_o at $C_{SC}{}^{-2} \rightarrow 0$. In Fig. 8 and 9 the effects of frequency and temperature on Mott-Schottky plots are shown. The characteristic potential, V_o, as well as the slopes are a function of temperature and frequency. The potential at which the slope changes has been de-

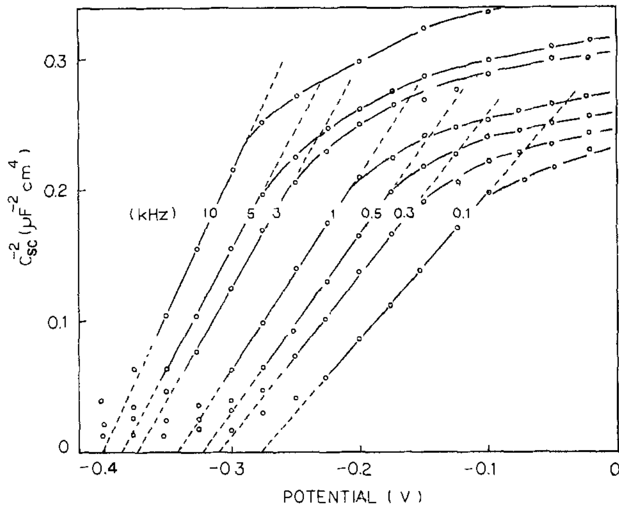

Fig. 8. Mott-Schottky plots for different frequencies, T = 25°C, pH = 8.4.

scribed by Kennedy and Frese as a "critical potential" for ionization of deep donors. However, it should be noted that in this case the film thickness is also a factor.

For $C_{SC}{}^{-2} \rightarrow 0$, Eq. [15] can be rewritten as

$$V_o - V_f = (-r + \ln r)kT/e \quad [18]$$

If r = 1, *i.e.*, the donors are completely dissociated, the potential difference, $V_o - V_f$, has its minimum value (kT/e) so that V_o is approximately equal to the flatband potential, V_f. If $r << 1$, as would be expected for deep donors, V_o is cathodic with respect V_f, *i.e.*, a one-order decrease in r corresponds to 60 mV cathodic shift of V_o at room temperature. The frequency dependence of V_o is linear with logarithm of f (Fig. 10) and the slope $dV_o/d \log f$ is −63 mV. From the theory and the experimental results there should be a correlation between r and f in a manner consistent with $r \propto f^{-1}$. This is not unusual for impurity semiconduc-

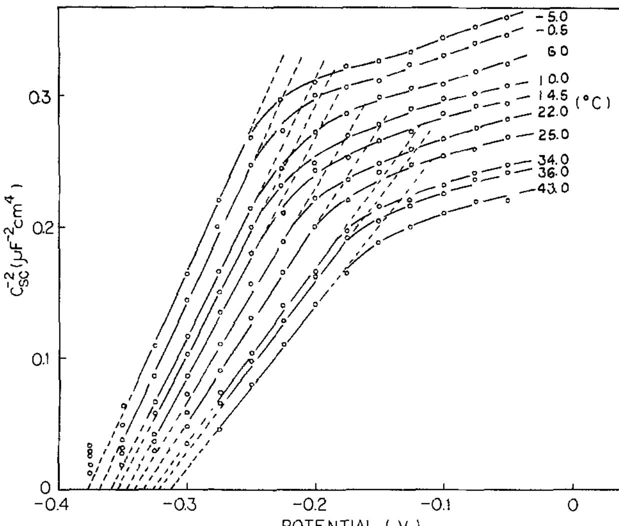

Fig. 9. Mott-Schottky plots for different temperatures, $f = 1$ kHz, pH = 8.4.

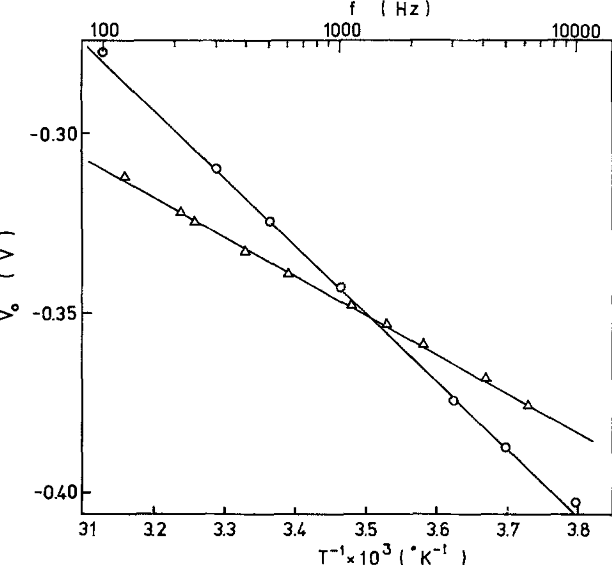

Fig. 10. Characteristic potential vs. frequency (○ symbol) from Fig. 8 and vs. reciprocal temperature (△ symbol) from Fig. 9.

tors, because the local ionization equilibrium of donors is influenced by the measurement frequency. The experimental result ($dV_o/d \log f = -63$ mV) is not general, since it can be dependent on pH, the frequency dependence of the dielectric constant, the Helmholtz layer capacitance, the contact potential at the metal-semiconductor interface, etc.

Bockris and Uosaki (25) have observed for p-SiC that V_O depends differently on frequency in acidic and alkaline solutions. Their results show that in 1N NaOH, V_o is shifted to anodic potentials with increasing frequency and in 1N H_2SO_4, V_o is not affected by frequency. No explanation was given for this observation. As would be expected, however, the pH value can change the shape of band bending. In strong acidic solution the band bending is large enough that the donors can be completely dissociated. In this case V_o is not affected by frequency. On the other hand, in strong alkaline solution, the band bending is small or even inverted. V_o is then shifted to anodic potential with increasing frequency. For n-type semiconductors the situation is reversed. Observations on anodic niobium oxide films by Stützle and Heusler (26) substantiate this suggestion. V_o can also be independent of frequency (27, 28) without regard to pH, if $r = 1$.

The measurement of V_f from Mott-Schottky plots is somewhat uncertain, especially for a highly doped impurity semiconductor electrode. For the exact determination of V_f several methods have been reported (2, 29-31). In this paper the flatband potential is defined as the potential where the photocurrent vanishes. This potential corresponds to V_o, when measured at 1 kHz at any pH. This will be discussed in detail in a future paper.

The temperature dependence of V_o shows that V_o is directly proportional to T^{-1} (Fig. 10). According to Eq. [13] and [17] the degree of dissociation, r, can be reexpressed as

$$r = (N_C/N_D)^{1/2} \exp(-E_D/2kT) \quad [19]$$

under the assumption that $E_D >> 2kT$ and $n = N_D^+$. For $r << 1$ and from Eq. [18] and [19] the potential difference ($V_o - V_f$) is directly proportional to T^{-1} and expressed as

$$(V_o - V_f)e/kT = \tfrac{1}{2} \ln (N_C/N_D) - E_D/2kT \quad [20]$$

The plot V_o vs. T^{-1} yields a straight line and E_D can be calculated from the slope. The slope in Fig. 10 yields $E_D = 0.69$ eV at $T = 300$°K. This value is in good agreement with the value obtained from the conductivity. This method, however, has several advantages. The experimental technique and the theoretical treatment are simpler. Also the experiment can be carried out at fixed frequency so that the frequency dependence of adsorbed species or dipoles is eliminated.

The frequency and the temperature dependences of the donor density, N_D, are shown in Fig. 11. The apparent break around $T = 20$°C is similar to the already observed potential dependence of the capacitance (Fig. 5). This reinforces the previous assumption that the deep donors begin to affect the total amount of the space charge at this temperature. On the other hand, the frequency dependence of N_D shows a linear relationship to log f. However, it cannot be fully ruled out that the slope change of Mott-Schottky plot is mainly due to the frequency response of the dielectric constant. This can be assured only if V_o is not frequency dependent.

ABSTRACT

Chemisorption of ruthenium ions decreases both the rate of carrier recombination at grain boundaries and the surface recombination velocity on thin film, polycrystalline n-GaAs grown by chemical vapor deposition. Charge collection scanning electron microscopy reveals a pronounced improvement in charge collection at gold n-GaAs Schottky barriers following ruthenium treatment. After chemisorption of ruthenium ions, a solar to electrical conversion efficiency of 4.8% was reached in the n-GaAs/0.8M K_2Se-0.1M K_2Se_2-1M KOH/C liquid junction cell with semiconductor grains of 3-7 μm diameter. The ruthenium effect here is much more dramatic than that shown in single crystal substrates, increasing the power conversion efficiency by up to a factor of four over etched specimens.

It is particularly advantageous to fabricate solar cells based on polycrystalline, direct gap semiconductors with a liquid, rather than solid-state, junction as the active element. The formation of a rectifying junction by immersion of the semiconductor into an electrolyte solution is almost trivially simple. The complex requirements for forming matched expansion, or matched lattice, solid-state p-n or Schottky barrier junctions on the polycrystalline material are thus bypassed. Schottky barrier solar cells formed on micron crystalline sized GaAs films at present have reported solar to electrical conversion efficiencies such as 1.3 (1), 2.8 (2), 5 (3), and 6.3% (4). These values are all low with respect to the 17% range (5) achieved with single crystal or large crystallite devices. On the other hand, efficiencies of 5.1%, or 70% relative to single crystal values, have been obtained for hot-pressed polycrystalline CdSe in a semiconductor-liquid junction (SCLJ) cell (6). The failure to obtain efficiencies in polycrystalline GaAs solid-state cells closer to those in single crystal cells has variously been ascribed to excessive surface recombination velocities, recombination at grain boundaries, and/or shunting from heavily doped grain boundaries.

Recent results from this laboratory demonstrated a 12% solar to electrical conversion efficiency for a single crystal semiconductor n-GaAs/$Se^{=}$-$Se_x^{=}$-OH^{-}/C cell with a hillocked surface topography achieved through appropriate etching and with modification of

Key words: semiconductor, solar, energy conversion.

the interfacial chemistry by Ru(III) chemisorption (7, 8). These efforts encouraged us to evaluate some polycrystalline thin film materials as photoanodes. This paper is concerned with chemically vapor deposited films from $(CH_3)_3Ga\text{-}AsH_3$ reactions which form an n-type layer on graphite substrates, the characteristics of electrodes so formed in selenide-polyselenide regenerative electrolytes, and the effect of Ru(III) treatment on the electrode properties. Besides observing the consequences of Ru chemisorption by voltammetry of the redox electrolyte-GaAs junction cells, we studied, by charge collection scanning electron microscopy (CCSEM), the effect of the Ru treatment prior to Au deposition on these films to form Au-GaAs Schottky barriers.

In CCSEM an energetic, focused electron beam is scanned over the thin barrier metallization and penetrates the semiconductor to produce carrier pairs. These are collected by the barrier field and the resultant current is employed as the video signal of a synchronously scanned CRT display (9). In this way, an image of local charge collection is formed and the influence of the Ru treatment on this process can be examined.

Experimental

The GaAs films were grown on substrates of high density graphite from Carbone-Lorraine (Type 5890-PT) after evaporative deposition of 500Å of germanium which ensured an ohmic contact. In one case (sample 70) a smooth molybdenum substrate, also precoated with 500Å of Ge, was employed. The GaAs layer is formed by the pyrolytic reaction (10)

$$Ga(CH_3)_3 + AsH_3 \xrightarrow{\Delta} GaAs + 3CH_4$$

The $Ga(CH_3)_3$ was Alfa-Ventron Electronic grade, 99.9995%, with detected impurities of Si and Al, 2 ppm each, and Cu and Mg not detected. AsH_3 was Matheson Electronic grade, 99.995%, supplied as a 2% dilution in ultrahigh purity H_2 (99.999%, total hydrocarbon < 0.5 ppm). The substrate was held at 700°C on a Mo or graphite susceptor with rf induction heating.

A flow of 5-20 cm³/min of palladium-diffused hydrogen was passed through the trimethyl gallium bubbler, held at −11°C. The mole fractions of trimethyl gallium and arsine were approximately 10^{-4} and 10^{-3}, respectively. These conditions resulted in a growth rate of 10-12 μm/hr. The total flow rate of H_2 was 4 liters/min.

Photoelectrodes were constructed with GaAs films 10-30 μm thick by attaching a copper wire with conductive silver epoxy to the back of the graphite substrate and masking all nonsemiconductor surfaces with epoxy. The electrodes were etched in either 1:1 H_2SO_4-30%H_2O_2, or in the same etchant diluted 1:4 with distilled water. The electronics, light measurement systems, and cell geometries were similar to those described previously (11). The ruthenium treatment solution was 0.01M $RuCl_3$-0.1M HNO_3. The preparation of the 1M KOH-1M K_2Se electrolyte and adjustment of polyselenide content have been described elsewhere (12).

Surfaces of polycrystalline GaAs subjected to the various treatments described below were evaluated by charge collection scanning microscopy after vacuum deposition of 200-500Å of Au to form a Schottky barrier. Prior to the deposition the specimens were simply washed and air dried. Nonblocking contacts to the graphite substrates were made with silver paint.

Results and Discussion

Table I summarizes some of the physical properties of the polycrystalline GaAs prepared by organic pyrolysis. The surface topography of the materials that exhibited the best solar conversion efficiencies was dominated by columnar grains of 3-7 μm dimensions, as measured from SEM photographs. The thickness of the films was kept at 10-30 μm, both to examine the efficiency of thin films and to minimize the number of grain boundaries perpendicular to the carrier drift field. Mobilities and dopant concentrations were estimated from Hall measurements made on single crystal substrate films grown in the same run as the polycrystalline samples.

Table I.

Specimen	Thickness (μm)	Mobility ($cm^2 V^{-1} sec^{-1}$)	Dopant conc. (cm^{-3})	Avg. crystallite grain size (μm)	Misc.
37	15	—	—	—	500A Ge
49	10	3400	1×10^{17}	1-3	Some O_2
53	12	1460	4×10^{17}	3-5	O_2
63	24	2900	4×10^{16}	3-5	No O_2
70	12	—	2×10^{15}	1-3	Mo, no pinholes
93	23	2900	4×10^{16}	3-5	Pinholes
105	30	4000	4×10^{16}	3-7	Cracks, little O_2

The film (sample 70) grown on a molybdenum surface exhibited a uniform, pinhole-free structure in SEM photographs, with relatively small, partly columnar grains 1-3 μm in size. This specimen was grown to evaluate the combined effects of fewer leaks (via pinholes) to the substrate and a more electrochemically passive substrate material.

Oxygen contamination may pose a problem during the growth of the films due to the tendency of oxygen to form deep donors in GaAs (13). The extent of the contamination is small and difficult to characterize accurately. For present purposes, it was qualitatively estimated from the perfection of the single crystal epitaxy.

The current-voltage curves for an illuminated anode (sample 63) in a selenide-polyselenide liquid junction cell are shown in Fig. 1, as a function of surface treatment. This set of curves is representative of the voltammetric behavior of all the films relative to surface treatment, independent of their relative effectiveness for light to electrical energy conversion. Curve 1 shows the response of a film immersed in the cell without prior treatment. Curve 2 indicates the improved behavior shown after a short exposure (1-5 sec) to sulfuric acid-hydrogen peroxide etchants. [Neither the exact composition of the etchant nor the time the electrode is etched have any effect on this curve so long as the etch is not prolonged (> 10 sec) or overly repeated.] Substantial improvement in the characteristics following etching is seen in all the semiconductor samples.

Curve 3 results after the electrode of curve 2 is removed from the selenide electrolyte, washed, dipped for 30-60 sec in the 0.01M Ru(III)-0.1M HNO_3 solution, washed again, and returned to the cell. Dramatic improvements are found in the short-circuit current, open-circuit voltage, and fill factor, beyond those reached by etching alone. The relative improvements (curve 3 *vs.* curve 2) are even more substantial than those seen with ruthenium-treated single crystal GaAs electrodes in the same system. Ruthenium enhancement of the single crystal performance is manifest as an increased operating voltage and fill factor of the cell. In that case, no increase (or decrease) in short-circuit current was observed, as the voltage bias on most single crystal electrodes at short circuit is sufficient to collect the photogenerated carriers at high quantum efficiency (a light-limited current region is reached). For the particular example in Fig. 1 the power output was increased by a factor of four after the ruthenium treatment. Substantial improvements using the ruthenium treatment were observed in all the polycrystalline materials examined in this study, with the exact level a function of both substrate and experimental conditions. The fill factor and power

conversion efficiency, as determined from Fig. 1 for which limiting current is not attained, ought to be sensitive to current (illumination) level. The relative performances of untreated and Ru-treated specimens under varying intensity are shown in Fig. 2 and 3, respectively, for the same set of normalized light intensities, all other factors being kept constant. The 105 electrode was used untreated and then the same set of data was repeated after it was ruthenium treated. Although this sample does not show as large an overall increase in power output from ruthenium chemisorption as sample 63, the fill factor is clearly maintained at high intensities much better in the electrode after it has been treated with ruthenium. The maximum power outputs from these curves are plotted *vs.* intensity in Fig. 4. These plots show more clearly that the ruthenium-treated electrode has a better relative efficiency than the untreated one under the higher kinetic stress of increased illumination level.

Table II contains a summary of open-circuit voltages (OCV), fill factors (ff), and qualitative ranking (poor to very good) of short-circuit current (ISC) for the specimens physically characterized in Table I. Tungsten-halogen illumination of approximately one-sun equivalent intensity was used for these measurements. Comments on the dark currents refer to the cathodic (forward diode) current observed in the unilluminated cell at potentials of the semiconductor that are negative with respect to that of the selenide-polyselenide couple at carbon. High dark currents mean more metallic-like behavior of the electrode (forward conduction at potentials more positive than that of the expected flatband level) and are related both to film properties and the activity of pores which may reach through to the substrate.

The solar efficiency values quoted in Table II were measured using natural sunlight for the samples (63, 93, and 105) which had the better laboratory characteristics. The current-voltage curve obtained for the best specimen (sample 63) at an insolation of 96 mW/cm² is shown in Fig. 5. The power conversion efficiency is 4.8% as compared to 12% for single crystal n-GaAs electrodes that were handled and measured similarly.

Under tungsten-halogen laboratory illumination producing a similar power output as the solar runs, the efficiency decreased by about 15% after 11,000 C/cm² of charge passage. Doubling the light intensity at that time increased the rate of decline which was associated with the appearance of gas evolution. Failure appears to be associated with attack at pores. Cross-sectional examination showed a much reduced rate of over-all material loss than the approximately 25 μm annual rate estimated earlier for single crystal electrodes not treated with ruthenium. Further work would be required to refine photocorrosion rates this low in magnitude and suggest or estimate the long term stability.

For the CCSEM experiment, the 63 photoanode described above was removed from the liquid junction cell, metallized with gold, and examined along with a parallel metallized sample not otherwise exposed. Figure 6 compares results obtained from ruthenium-treated and untreated material. In both cases the light, rod-like feature is that of the silver contact to the top layer. The darker the image of the barrier area, the higher the local collection efficiency. The improved

collection efficiency of the ruthenium-treated barrier is readily apparent.

The contrast between the untreated barrier (a) and the background region (*i.e.*, the silver contact) is nearly zero, indicating a low collection efficiency. In comparison, the ruthenium-treated material (b) exhibits substantial collection over the entire device area. The Schottky barriers in both cases exhibit uniform contrast except in the regions of cracks in the GaAs films and contaminants on the surface of the Au Schottky barrier metallization. These macroscopic defects are observed in secondary electron micrographs as regions of reduced emission, and their contrast in the charge collection micrographs is at least partially accounted for by the variations in absorbed energy that accompany the topographical features of the defects.

A higher magnification comparison of the samples shown in Fig. 6 is presented in Fig. 7. In this figure, the improvement in collection efficiency of the ruthenium-treated device is observed to be associated with an increase in both the number of individual crystallites that are active and a decrease in the propensity of the intercrystallite boundaries to act as recombination sites. Although collection efficiency is reduced at the grain boundaries in both devices, the decrease is smaller in the ruthenium-treated chemical.

The improved quantum efficiency that is qualitatively apparent in Fig. 6 and 7 was investigated more quantitatively by measurement of the local charge collection currents. For this experiment a freshly prepared GaAs film was sequentially etched and exposed

to the selenide and Ru(III) solutions, each operation being performed on a successively smaller portion of the sample. In this way, the final sample contained exposed areas of untreated, etched, etched and selenide-treated, and finally etched, selenide- and Ru(III)-treated material. A single Schottky barrier was fabricated over the entire sample and the charge collection was determined in each region by recording the current collected during a single linear scan of the electron beam over a 1 mm portion of each region.

As seen in Fig. 7, the current collected during each scan varied from maximum values at the grain interiors to lower levels at the grain boundaries. The average value of the current was taken for the determination of collection efficiency.

The results, normalized to the electron beam current,[2] are plotted *vs.* electron beam energy in Fig. 8. This plot shows that the average collected current is markedly affected by the various surface treatments. The untreated surface is essentially inactive while the Ru dipped material exhibits the largest collection effi-

[2] The measurement of collection current was conducted with beam currents in the 10^{-10}A range to insure low injection level conditions.

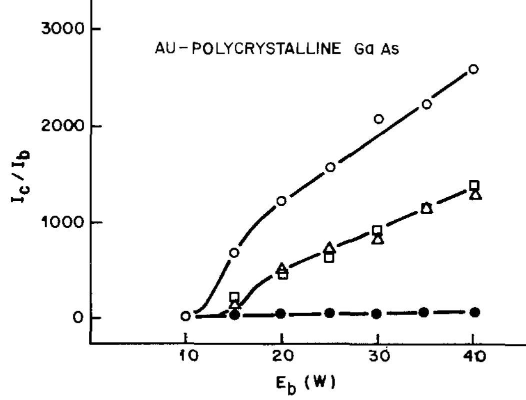

Fig. 8. Average scan current, I_c, normalized by electron beam current, I_b, plotted *vs.* electron beam energy as a function of GaAs treatment prior to gold metallization. ●, Untreated; □, etched; △, etched and selenide dipped; ○, etched, selenide dipped, and ruthenium dipped.

ciency at all accelerating voltages. Furthermore, while etching the surface improves the collection efficiency of the device, a subsequent selenide dip alone does not cause further improvement, in agreement with our experience with the liquid junction cells. We note, however, that ruthenium is not effectively adsorbed without the preceding selenide step.

Charge collection in all instances declines to zero at electron beam accelerating voltages below 10 kV. This is attributable to absorption of the beam electrons by the 500Å Au metallization. At higher voltages, the linear rise in collected current indicates a constant charge collection efficiency that is independent of the depth distribution of injection up to ~5 μm.[3] This suggests that charge collection is not diffusion length limited in this experiment. Although all of the treated areas are similar in this regard, the improvement imparted by the Ru(III) step amounts to an approximately 100% increase in collected current relative to the freshly etched surface on which no ions were intentionally chemisorbed. If the standard value for pair generation energy, 4.6 eV, is employed, an approximately 50% increase in quantum efficiency (from 20 to 33%) may be obtained from the data of Fig. 8.[4]

Summary and Conclusions

The solar efficiencies and cell parameters under laboratory illumination, when related to other data of Table I and II, allow certain conclusions about film properties. For example, oxygen contamination appears deleterious. Porosity, while it introduces metallically behaving shunts, is clearly not the only source of reduced voltage and fill factor. The sample grown on the smoother Mo substrate, which should have negligible leakage due to pores, behaved poorly. Grain size distribution plus the level of recombination at, or current shunting through, the boundaries appears to be important as well.

The effect of ruthenium in enhancing the current-voltage behavior of the cells is much more prominent than it is in the single crystal material described previously, consistent with the CCSEM data on the Au-GaAs Schottky barrier after the various stages of chemical treatment. That the effect is due to chemisorbed Ru and not to the removal of deleterious impurities was shown (14) by direct detection with Rutherford backscattering. The chemisorption of ruthenium raises the current collection efficiency of the device. The maximum observed solar conversion efficiency of 4.8% is 40% of that which we have reported for cells with single crystal photoanodes. We feel that better film quality for this application should be possible and this goal should be pursued. The results also suggest that the chemisorption of ruthenium might improve the current collection and over-all conversion efficiency of n-GaAs based Schottky junction (metallized) solar cells.

Ruthenium treatment appears to further reduce the already low level of photocorrosion in the GaAs-selenide system but extensive measurements of the stability of the more efficient film anodes must be made before conclusions on the viability of these materials can be drawn. The failure mode of the film electrodes is related to the pore structure and the polycrystalline cells consequently exhibit greater variability in output than the single crystal cells.

The model previously outlined for the reduction by ruthenium chemisorption of carrier traps or of output reducing shunts as the origin of the beneficial effects is consistent with the independent CCSEM data. Recent observations by luminescence methods (14) of a reduction in surface recombination velocity at single crystal GaAs-air interfaces with the ruthenium treatment further strengthens the case for such interpretation.

[3] The electron range, R, in GaAs is given by $R = 0.027E_b^{1.40}$ μm with E_b in kV.

[4] These figures were computed following correction for absorption within the gold metallization.

Doping Density Dependent Attachment of RhB on TiO_2 Electrodes

R. Schumacher,[1] R. H. Wilson,* and L. A. Harris

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

In this study a technique to sensitize TiO_2 electrodes with rhodamine B bonded to the surface is presented. To study both the attachment process and the mechanisms of spectral sensitization the system TiO_2/dye/electrolyte/Pt was investigated. The photocurrent produced by visible light illumination was studied as a function of electrolyte *p*H, illumination time, wavelength, and doping density. The observed photoresponse increased with doping density by a factor of 8 over the range investigated. Dye states were not removed from the surface during the course of illumination. The oxidized dye states were observed to be re-reduced after biasing at sufficiently negative voltage. The observation that the amount of dye deposited on the TiO_2 surface is affected by the doping density of the samples used is discussed in terms of the nature of the bonding between dye and surface. The photocurrent quantum efficiency per absorbed photon was calculated to be about 0.01.

There has been much interest in photochemical work on sensitized semiconductor electrodes with dyes in solution (1-3). Also of interest are dye-modified semiconductor electrodes because of their response to visible light quanta. Excited dye molecules sitting at the surface are able to transfer an electron to the conduction band of the semiconductor if both energy levels are in the same range. In order to link those molecules at the surface different types of bonding are described in the literature up to now: monolayer assemblies generated by the Langmuir-Blodgett technique (3-7) and covalently bonded dye molecules on semiconductor electrodes (8, 9). Even in the case of dyes in solution, most of the photocurrent is due to an adsorbed layer of dye on the surface of the electrode, at least for dyes with short excited-state lifetimes (10, 11). Photoresponses in the visible light range have been reported for all of these.

In this work we present a new technique to fix rhodamine B on the surface of TiO_2 electrodes. A correlation of the amount of dye deposited on the semiconductor surface and the doping density of the samples was observed. The electrodes were characterized by electrochemical and/or optical measurements. The attachment process of the dye on the surface is discussed in terms of (*i*) an influence of the electric field strength, (*ii*) adsorption sites, and (*iii*) the presence of negatively charged species, at the surface of TiO_2.

When the dye-coated electrode is illuminated with light that is absorbed by RhB a photocurrent is observed. The current decreases in time as the RhB becomes oxidized. The dye can be reduced by applying a negative bias so that the initial current level is regained. This indicates that the attachment is stable.

Experimental and Sample Preparation

Materials and measuring setups.—Two different types of rhodamine B (RhB) coated TiO_2 samples were used in this work: single crystals and polycrystalline material deposited on fused silica substrates. The rutile single crystal slabs about 1 mm thick were sliced from a boule obtained from NL Industries. The (001) faces of these samples were coated with RhB after polishing, cleaning, and reduction as have been described previously (12).

The polycrystalline samples were prepared by using the chemical vapor deposition (CVD) technique. Fused silica disks 4 mm thick were used as substrates. Thin films in the range of 500-1000Å were deposited via the hydrolysis reaction of $TiCl_4$ in the presence of water vapor at approximately 500°C. In order to bring these samples to a uniform starting condition they were oxidized in a dry oxygen stream for 30 min at 900°C. Various doping densities N_D were made by reduction in a dry hydrogen-stream for 30 min but at different temperatures.

The experimental setup for characterizing the photoresponse of the RhB-coated single crystals in the visible range was the same as previously described (13, 14). Second order light quanta >3 eV(<400 nm) were eliminated from the grating monochromator output by using an appropriate filter (Corning CS3-74). All electrochemical measurements were carried out in 0.5*M* Na_2SO_4 aqueous solution in which the *p*H was adjusted by adding sulfuric acid or sodium hydroxide. The exposed sample area (0.125 cm^2) remained constant as the crystal was pressed against a gasketed opening in the side of the cell.

Absorption measurements of dye molecules coated on polycrystalline samples were carried out in a Perkin-Elmer Spectrophotometer Model 575. An untreated fused silica disk was used as reference. The reported absorbance data were obtained by comparison of spectra recorded before and after RhB coating. Absorption measurements in aqueous RhB solutions were carried out using RhB solution of $10^{-4}M$/liter. Different *p*H values were adjusted as described above.

The rhodamine B was obtained commercially. The electrolytes were prepared using distilled water and reagent grade chemicals.

Coating technique.—The coatings of TiO_2 single crystal samples as well as the polycrystalline samples were achieved by simple immersion in an about 0.02 *M*/liter RhB/CH_3OH solution. A typical reaction time was 5 min. Thereafter the samples were immersed in distilled water for 5 sec to remove the excess dye molecules from the surface, followed by a short rinse under flowing distilled water. Finally the specimens were dried in a slight air stream.

Reproducible results for both kinds of TiO_2 materials were obtained only with freshly reduced samples. Prior to each coating process the samples were cleaned in hot conc sulfuric acid (50°C) for 5 min.

Results

Typical photocurrent *vs.* wavelength behavior obtained from the difference between data recorded before and after RhB coating is shown in Fig. 1. For this measurement the RhB coated single crystal used

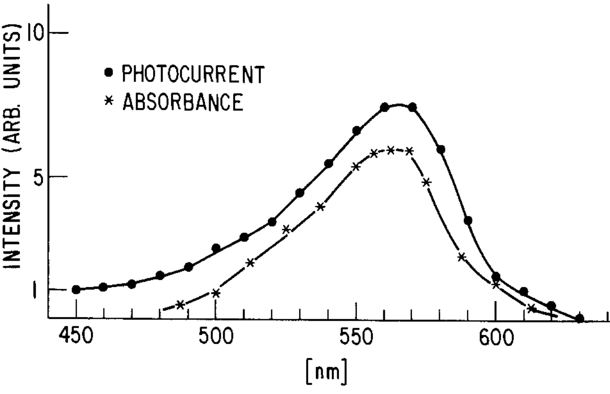

Fig. 1. Comparison of initial photocurrent spectrum obtained from coated single crystal(—●—) and absorbance spectrum obtained from coated polycrystalline (—*—) TiO_2 samples.

was maintained at a bias of 0.5V (SCE) with an 0.5*M* Na_2SO_4 electrolyte of *p*H 1. The doping density of the sample was $N_D = 5 \times 10^{19}$ cm^{-3} as determined from capacitance-voltage measurements. As seen from the graph the initial anodic photocurrent of a freshly prepared sample shows a single peak with its maximum value around 565 nm but with a shoulder at about 520 nm. The absorbance of a dye-coated polycrystalline sample is also included in this figure. The data were obtained using a specimen which was reduced at 615°C (see below). As can be seen, the maximum intensity of photocurrent and absorbance are observed at identical wavelengths. Similar results were reported for covalently (8, 9) bonded RhB on SnO_2 as well as for simply adsorbed (11, 15) dye molecules on ZnO surfaces.

Except for the shoulder in the photocurrent response curve the present results do not clearly indicate the presence of a distinct dimer peak at 520 nm as reported by others (8, 11). The coating technique used in the present work, however, differs from those used in this earlier work.

The influence of the hydrogen ion concentration on the photoprocess on dye-sensitized TiO_2 single crystals was investigated. The results can be seen in Fig. 2 along with the *p*H dependence of the absorbance in an aqueous RhB solution. All points are taken from measurements at $\lambda = 560$ nm.

The distinct structure of the absorbance characteristic for *p*H < 2 shown on the graph was explained by Ramette and Sandell (16) as being due to different molecular arrangements in strong acid solutions. The slightly decreasing absorbance for *p*H > 2 has been explained by the same authors as dilution effect.

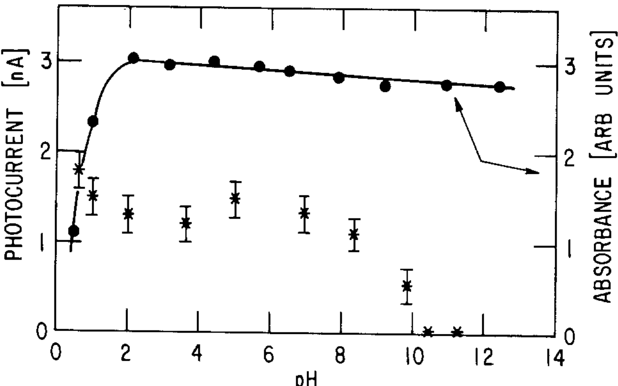

Fig. 2. Dependence of initial photocurrent and absorbance data on *p*H. The currents were taken from measurements of a dye-sensitized single crystal sample (*) and the absorbance in aqueous 10^{-4}*M* RhB solution (●).

Unlike the absorbance results described above, the behavior of the electrochemically observed photocurrent shows little change in the range *p*H 0.6-8. No sharp decrease of the photocurrent intensity for *p*H < 2 was observed. Apparently, the attachment of an additional proton which blocks the ring resonance and which causes the drop in absorbance at low *p*H is impeded if the dye is attached to the surface. For *p*H values > 10 the photocurrent fell below the sensitivity range of the experimental setup.

This fall off in photocurrent at high *p*H can be explained using Fig. 3. This graph shows the energy situation of TiO_2 and RhB in terms of a Pourbaix-like diagram. The data shown, taken from the literature (17), are valid when semiconductor surface and dye are not in contact. As shown by the diagram the energy level for rhodamine B in its excited state, RhB*, lies above the TiO_2 conduction bandedge as long as the *p*H is smaller than 12. In this region electron transfer from excited dye molecules to the conduction band is possible. This argument to explain the *p*H dependence of dye-sensitized semiconductors has been used frequently (11, 15). The coating process apparently does not affect the band situation at the TiO_2 surface because a shift in the flatband potential could not be measured.

According to the theory of photoprocesses on dye-sensitized semiconductor electrodes, illumination leads to a decrease of photocurrent intensity as the surface dyes become oxidized (1, 2). At a bias of 0.5V (SCE) the course of this bleaching process with time is shown in Fig. 4 using a sensitized TiO_2 single crystal sample with $N_D = 10^{19}$ cm^{-3}. The time dependence of a freshly prepared sample is characterized by the symbol (●); the decay rates depicted as (*, ◇) were observed after biasing for 60 sec at −0.5V (SCE) and then returning to +0.5V (SCE) for measuring the

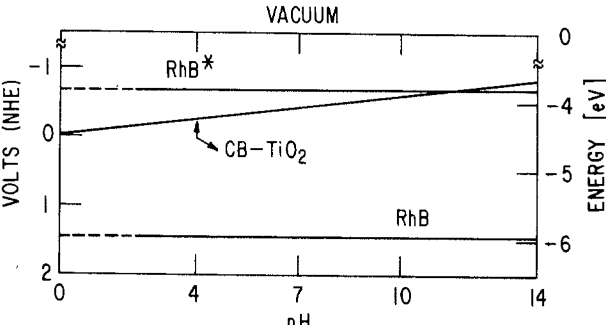

Fig. 3. Electron energy levels for rhodamine B in the ground and the excited state. The energy level of the TiO_2 conduction bandedge is also shown.

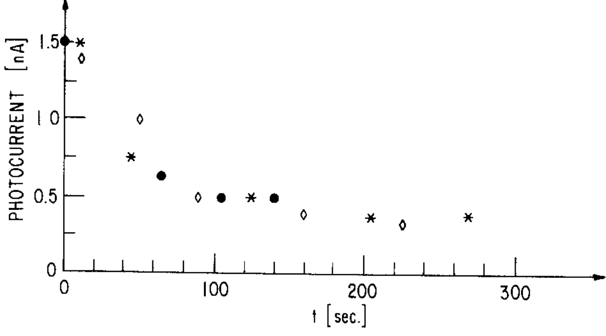

Fig. 4. Time dependence of the photoresponse under illumination at 560 nm in *p*H 1 electrolyte. The points describe the decay at a potential of 0.5V (SCE). The initial decay of a freshly prepared sample is characterized by the symbol (●); for the same sample points (*, ◇) were obtained subsequently after reduction at −0.5V (SCE).

photocurrent. As can be seen from the figure all three plots follow similar decay laws. Furthermore it is worth noting that after applying a negative potential of −0.5V (SCE) the photocurrent returned to its initial value of 1.5 nA [point (●) on the ordinate]. From these observations it can be deduced that no dye molecules were lost from the surface when illuminated, but the oxidized surface dye was reduced by operation of the electrode at −0.5V (SCE).

Variable photocurrents were observed when TiO_2 single crystals of different doping densities N_D coated with RhB were used. The results for samples with N_D ranging from 5×10^{17}-5×10^{22} [2] cm^{-3} are shown in Fig. 5. In this range the photocurrent changes by about a factor of 8. The points are obtained from the difference in measurements in acid solution of $pH = 1$ and at $\lambda = 560$ nm taken before and after RhB coating. Furthermore, at the applied voltage of 0.5V (SCE) for the samples investigated the initial photocurrent was found to be independent of potential.

In order to clarify this observation, absorption measurements were made to quantify the amount of surface coverage as a function of doping density. For this purpose fused silica disks coated with thin films of TiO_2 as described above were used. Prior to coating with dye the doping density of those quartz TiO_2 samples was changed by hydrogen treatment at different temperatures. The quantitative determination of the doping density for such thin films is difficult because the film thickness may not exceed that of the space charge region. A typical visible absorption spectrum for the sample reduced at 615°C has already been shown in Fig. 1.

The data taken from the maximum intensity of the absorbance spectra at 560 nm are listed in Table I along with the surface layer thickness of RhB calculated in fractions of a monolayer coverage. The calculations were made by using the molar absorption coefficient of 1.05×10^5 for a near-neutral aqueous RhB solution (18) and a dye molecule area of 100Å^2 as reported by Spitler and Calvin (11). The reduction temperatures of the specimens range from 475°-615°C. A sample sensitized just after the course of oxidation at 900°C yielded an absorbance of 2×10^{-3} but not listed in the table.

To check whether thermal etching during the course of reduction affected the results reported in Table I the samples marked (*) were reoxidized and again coated with dye. The absorbance for both samples after reoxidation was 2×10^{-3}. Thus, a change in effective surface area cannot be used to explain the observations in Table I.

Discussion

As was shown in the experimental section the doping density N_D of the semiconductor samples affects the amount of dye deposited on its surface. The density of the dye layer was determined by absorption measurements on polycrystalline material. Although the amount of dye deposited on single crystals was not measured optically, the results shown in Table I suggest that the coverage would increase with doping density since the doping density is known to increase with temperature during reduction. This increased dye coverage readily explains the increased photocurrent seen in Fig. 5.

[2] The unrealistically high doping density of $N_D = 5 \times 10^{22}$ cm^{-3} obtained from capacitance-voltage measurements is most likely due to surface roughness caused by etching.

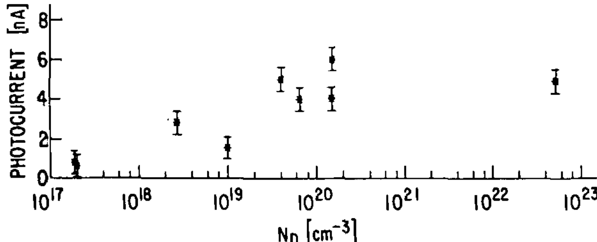

Fig. 5. Dependence of the photoresponse on the TiO_2 doping density N_D. The data were obtained in *pH* 1 electrolyte and for an illumination wavelength of 560 nm.

Table I. Absorbance and dye layer thickness for sensitized polycrystalline TiO_2 material prepared after reduction at different temperatures

Reduction temperature (°C)	475	510	560*	590	615*
Absorbance (10^{-3})	2	4	5.2	7.2	11.2
Dye layer thickness (monolayer)	0.12	0.23	0.30	0.42	0.64

As can be seen from Fig. 4, the photocurrent decreases with time to some lower value. It is instructive to calculate the surface density of RhB that is represented by the decaying portion of the current. For the data in Fig. 4 this is approximately 6×10^{12} cm^{-2} assuming one electron per RhB molecule. For comparison, the absorbance value in Table I for 510°C gives a RhB surface density of 2.3×10^{13} cm^{-2} if the solution molar extinction coefficient of 1.05×10^5 is used (18). This suggests that only a fraction of the RhB on the surface is participating in the rapid decay and that the remainder has a much lower probability of electron transfer and is responsible for the photocurrent remaining after 5 min.

Of course, the surface density of RhB on the electrode is only inferred from measurements on the TiO_2 films. Without some method to determine the density of RhB on the surface of the electrode itself it is not possible to be more quantitative in discussing the current decay. In this preliminary report, the point that should be emphasized in Fig. 4 is the ability to return to the initial current by applying a negative voltage. This illustrates the stable nature of the RhB attachment. Based on the data in Table I the calculated over-all quantum efficiency per absorbed photon is less than 0.01.

Now the question arises on the nature of the linkage between dye molecules and the semiconductor surface and how it is affected by the doping density. The reactivity of highly doped TiO_2 samples was the subject of a number of investigations in recent years (19-27). The affinity of those samples to interact with chemicals is a well-known phenomenon. It was shown (24, 26, 27) that small molecules such as O_2, NO_2, and N_2O undergo a reaction upon exposure to activated TiO_2 surfaces. For example, the reaction with air or oxygen leads to the formation of O_2^-. Such reaction products were identified by ESR spectroscopy.

As our results have shown, rhodamine B does not lose its dye character when coated on reduced TiO_2 surfaces. This observation excludes a chemical reaction with the dye center of the molecule as the attachment process. On the other hand a negatively charged ion, such as the O_2^- described above could attract the positive ring system of the dye molecules, thus giving rise to an ionic bond. This ionic bonding would not be expected to change the character of the dye. This mechanism can explain the influence of reduction temperature on the density of RhB since the generation of the negative surface species depends on the reduction of the TiO_2 (27).

On the other hand it is known that the doping density affects the electric field strength, E_s, at the semiconductor surface. The value of E_s is proportional to the one-half power of the doping density N_D. Thus an increase of the amount of dye molecules deposited on the surface caused by an increase in field strength seems possible.

It is also possible that an increase of active adsorption sites accompanies an increase in N_D. Making the

reasonable assumption that all sites within 20Å of the surface are able to interact with the attached surface states, a density of sites can be estimated to be 10^{13} sites/cm^2 for a sample with $N_D = 5 \times 10^{19}$ cm^{-3}. Thus, the predicted density of surface sites due to donors is about one-tenth of a monolayer at this doping density yet this is approximately the doping density at which monolayer coverage by RhB occurs. On the other hand, due to the approximate nature of this comparison, the introduction of surface adsorption sites by donors cannot be excluded as an explanation for the RhB attachment process.

Conclusion

Two results of the present work are considered to be the main features: the dependence of the attachment process on the semiconductor doping density and the complete reduction of oxidized dye states after a cathodic sweep.

As already argued in the discussion a final answer on the nature of the bonding between dye molecules and TiO_2 that is based on experimental results cannot be given. The bonding is most likely due to several contributions. Further experiments using different solvents, dyes, and electrode materials would provide additional information about this process.

It is supposed that the reduction of oxidized dye states occurs via conduction band electrons which return the RhB to its initial condition. This illustrates the stability of the bond between the dye and the surface.

Surface States Formation due to Impregnated Hydrogen at p-Type Gallium Phosphide Electrodes with Metal Adatoms

Hiroyuki Uchida, Hiroshi Yoneyama,* and Hideo Tamura

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka, Japan

ABSTRACT

p-Type GaP electrodes with and without metal adatoms showed noticeable photoresponse at wavelengths longer than the intrinsic absorption threshold, if surface states were formed by hydrogen impregnation. The formation mechanism of the surface states was analyzed and the role of metal adatoms was evaluated. The energy levels of the surface states formed are determined by analysis of the cathodic current in the dark.

In a recent paper (1) we reported that the spectral response of p-type GaP electrodes was successfully extended to longer wavelengths by depositing a monolayer of any of several kinds of metal such as gold, silver, palladium, or copper onto the electrode surface and then cathodically polarizing the electrode under illumination. Impregnated hydrogen seemed to be responsible for the enhanced photocurrent spectra.

* Electrochemical Society Active Member.

Key words: semiconductor, photocathode, spectra, catalysis.

However, a detailed mechanism of the hydrogen impregnation and the nature of surface states formed has remained ambiguous. In order to develop more information on these points, the present study has been conducted.

Experimental

The same p-type GaP ($N_A = 4 \times 10^{17}/cm^3$) as reported previously (1) was used as the electrode material. The surface pretreatment of GaP and metal deposition on it were also the same as in the previous study, except for the deposition of Pb. The deposition potential of Pb was set at 0.25V *vs.* SCE in the present study, which was found to be more suitable than the potential selected in the previous study, although no appreciable difference was observed in results obtained.

A 500W xenon lamp was used as a light source, and a monochromator with a 600 lines/mm grating (JASCO, Model CT-25) was employed to obtain monochromatic light. The second-order diffraction was eliminated by employing suitable colored glass filters, and the slit width chosen was 2 mm, by which the resolution of monochromatic light was $\pm$ 6 nm. The intensity of light was measured by using a calibrated thermopile (The Eppley Laboratory, Incorporated). The number of photons incident on the electrode surface was determined by correcting the absorption in the electrolyte. For this purpose, absorption in a quartz cell of 1 cm path length was measured, and the incident photons were estimated by taking into account the distance between a quartz window and the electrode surface.

Measurements of photocurrent in the order of nA was made by employing the lock-in amplifier technique. A lock-in amplifier (N. F. Circuit Design Block Company, Model LI-572B) was tuned to a light chopper of 30 Hz for this purpose, and a photocurrent signal was monitored by an oscilloscope (Iwatsu, Model 056). The minimum photocurrent detected was 10 Pa.

All the measurements were carried out in the dark room at room temperature. Prior to measurements, purified nitrogen was bubbled into electrolytes for more than 30 min.

Cathodic polarization to cause hydrogen evolution was essential to obtain enhanced photocurrent spectra at p-type GaP electrodes covered with the monolayer amount of deposited metal ($M(\theta = 1)$/p-GaP). This treatment was termed here as "activation treatment" as in the previous study for the purpose of convenience. The activation treatment was made in 0.5M H_2SO_4. After the activation treatment, the electrode was repeatedly subjected to potential sweep polarization at 1 V/min in the dark in a potential range between -1.0V *vs.* SCE and the potential at which the cathodic current commenced, until stable current-potential curves were obtained. The electrode was then subjected to a variety of measurements. Where the nature of electrolytes for measurements was different from 0.5M H_2SO_4, the electrode was shortly immersed in distilled water and then inserted in the electrolyte of interest.

The other details were already reported (1).

Results and Discussion

Quantum yield of p-type GaP.—In our previous paper (1), we did not discuss the quantum yield of activated electrodes, because of poor purity of the monochromatic light. Figure 1 shows spectra of quantum yield of saturated cathodic photocurrent giving the hydrogen evolution reaction (HER) at p-type GaP electrodes with and without the monolayer of deposited gold, which were obtained in 0.5M H_2SO_4 at -0.5V *vs.* SCE. As already described previously (1), the developed photoresponse covered wavelengths between 500 and 1200 nm. The maximum quantum yield in the developed spectra, which was observed between 600 and 850 nm, was about 1%.

The shape of spectra of the quantum yield in the intrinsic absorption region was in good agreement with

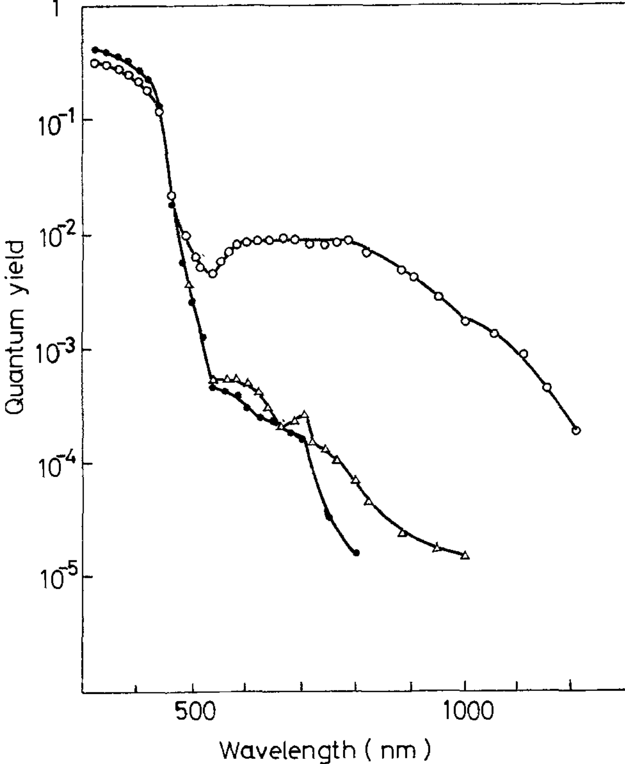

Fig. 1. Spectra of quantum yield of saturated cathodic photocurrent at p-type GaP electrodes in 0.5M H_2SO_4 at -0.50V *vs.* SCE. (—●—) nonactivated p-type GaP, (—△—) nonactivated Au(θ = 1)/p-GaP, (—○—) 1 hr activated Au(θ = 1)/p-GaP.

the results by Bockris *et al.* (2), but not with our previous results (3). Since the absolute value of the maximum quantum yield obtained at the present electrode ($N_A = 4 \times 10^{17}/cm^3$) agreed very well with that of Ref. (3), the inaccordance of the previous spectrum is attributable to the difference of purity of light.

It is seen in Fig. 1 that GaP shows weak photoresponse up to about 800 nm (1.55 eV) even if no activation treatment was made. Referring to the bandgap of GaP (4, 5), the result is not understandable from band-band transitions. Therefore, the phenomenon seemed to be caused by band-original surface states transition. The results in this figure indicate that the concentration of surface states is enhanced by the activation treatment with almost the same energetic distribution.

As already described, the magnitude of photoresponse of activated $M(\theta = 1)$/p-GaP electrodes depends on the kind of the deposited metal (Au, Ag, Pd $>$ Cu $>>$ Pb, none). In order to elucidate the nature of this phenomenon, it will be useful to obtain information on (*i*) the energy levels of the deposited metals and (*ii*) the role of the deposited metal on the activation treatment.

Surface states formed by metal adatoms.—Kolb, Przasnyski, and Gerischer (6) showed that the energetic position of metal adatoms on n-type semiconductors can be determined by measuring photocurrent caused by excitation from the adatoms into the conduction band under anodic bias. If the situation for n-type semiconductors is similar to that for p-type semiconductors, it may be possible to observe cathodic current caused by excitation either from the valence band into the metal adatoms, or from the metal adatoms into the conduction band. Attempts to measure photocurrent of this nature were made in 10^{-3}M $K_3Fe(CN)_6$/3M NaOH for nonactivated $M(\theta = 1)$/p-GaP at the potential at which preferential reduction of $Fe(CN)_6^{3-}$ occurs, *i.e.*, at -0.35V *vs.* Hg/HgO (7). Since the cathodic current via the va-

lence band, which is observed in the dark, was large in this electrolyte (7), the lock-in amplifier technique was employed to detect the cathodic photocurrent of interest. The results obtained are shown in Fig. 2, for the deposition of Ag and Au. In this figure, photocurrent is given in a relative scale in such a manner that it was unity when a photocurrent of 1 nA/cm^2 was measured for photon incidence of $1 \times 10^{13}/cm^2 \cdot$ sec. According to this figure, the shapes of photocurrent spectra of Au(θ = 1)/p-GaP and Ag(θ = 1)/p-GaP are quite similar to the electrode with no metal adatoms, and hence no determination of energetic positions of metal adatoms is possible from the results obtained. It is evident that original surface states play a more significant role in appearance of the observed photoresponse than metal adatoms.

Activation process of electrodes and role of deposited metals.—As already described, both activated and nonactivated electrodes show photoresponse to light of wavelength longer than the intrinsic absorption threshold, but the intensity of the response is different between these, which must be the result of concentration differences in surface states. Therefore, if the nonactivated electrodes are cathodically polarized at a constant potential under illumination with monochromatic light of wavelength longer than the intrinsic threshold, then the concentration of surface states sensitive to this light must be increased with polarization time.

Figure 3 shows increasing trends of photocurrent with polarization time under illumination with monochromatic light of 620 nm for a variety of nonactivated M(θ = 1)/p-GaP electrodes, which were obtained by the lock-in technique. The cathodic polarization was made at −0.5V *vs.* SCE in 0.5M H_2SO_4. The results show that illumination with 620 nm light produced surface states sensitive to this light. If one rearranges

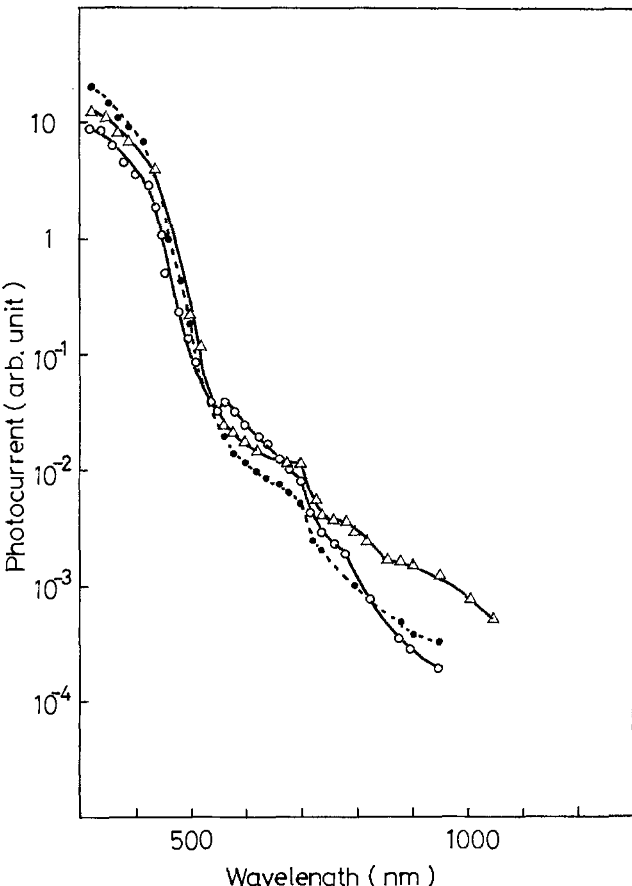

Fig. 2. Relative photocurrent spectra of nonactivated GaP having the monolayer amount of various metals in 10^{-3}M $K_3Fe(CN)_6$/3M NaOH at −0.35V vs. Hg/HgO. (—○—) Ag, (—△—) Au, (---●---) none.

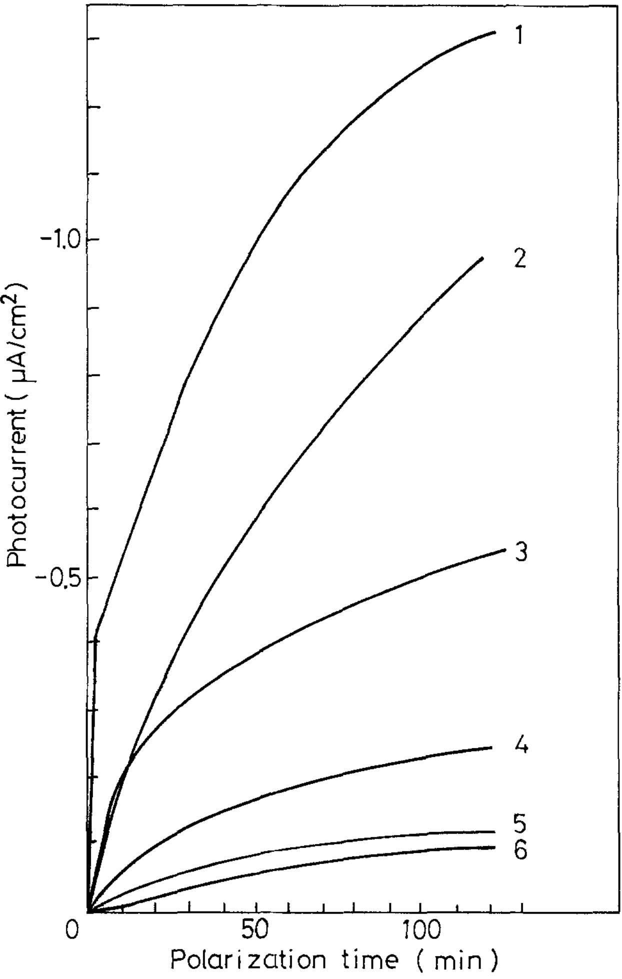

Fig. 3. Increases in photocurrent with polarization time under illumination with 620 nm light for a variety of nonactivated M(θ = 1)/p-GaP electrodes. Curve 1, Pd; curve 2, Au; curve 3, Ag; curve 4, Cu; curve 5, none; curve 6, Pb. Solution = 0.5M H_2SO_4, E = −0.50V vs. SCE.

the results in this figure in the form of photocurrent at any time *vs.* the charge consumed up to this time, then linear relations are found to be established between the two. Typical examples are given in Fig. 4 for the cases of p-GaP and Au(θ = 1)/p-GaP. This result implies that the photocurrent at 620 nm is proportional to the charge consumed, Q, which leads to discharge of water into hydrogen.

Considering that the photocurrent at λ = 620 nm is proportional to the surface states concentration, N, and

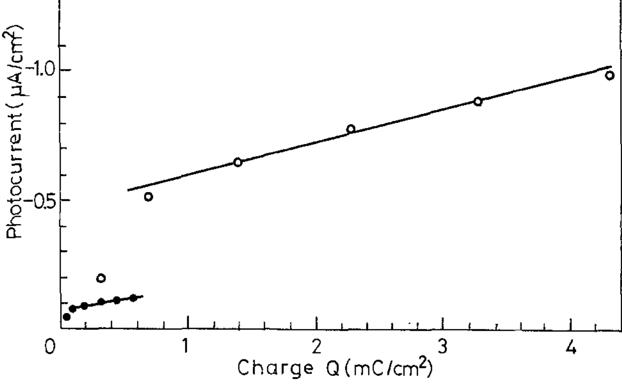

Fig. 4. Dependency of photocurrent on the amount of charge consumed during the activation treatment. (—○—) Au(θ = 1)/p-GaP, (—●—) p-type GaP. Solution = 0.5M H_2SO_4, E = −0.50V, λ = 620 nm.

that the magnitude of the photocurrent was proportional to the charge consumed during the cathodic polarization, then one is led to believe that the discharged species are impregnated into the electrode to form effective surface states; impregnation of atomic hydrogen is the most likely source of these surface states. Since the amount of charge to cover the monolayer of GaP is 0.38 mC/cm^2, the charge consumed up to the polarization time of 120 min corresponds to about two and ten monolayers for p-GaP and Au($\theta = 1$)/p-GaP, respectively. Judging from I-t traces in Fig. 3, the activation has not been completed within 120 min, although in the case of irradiation of full light from the xenon lamp, the polarization for 1 hr was sufficient.

The impregnation of hydrogen must proceed via a diffusion process, according to Eq. [1]

$$i_{diff} \propto (AD^{1/2}zFC_s\pi^{-1/2}) \cdot t^{-1/2} \quad [1]$$

where i_{diff} is the diffusion current, D the diffusion coefficient, C_s the surface concentration, A the surface area, and t is the polarization time. Since Q almost corresponds to diffusion current times t, the following relation should hold

$$N \propto i_{diff} \cdot t = (kC_sD^{1/2}) \cdot t^{1/2} \quad [2]$$

If an assumption is made that photocurrent at $\lambda = 620$ nm is proportional to N, then one can expect that the photocurrent at $\lambda = 620$ nm is proportional to the square root of the polarization time with the gradient of $kC_s\sqrt{D}$. Figure 5 shows that such a relation holds for the present results except for initial stages. In the initial stage, at least some portion of photocurrent must be consumed in the adsorption process of hydrogen to cover the electrode. The degree of the steady-state coverage must be dependent on the kind of metal adatoms (8). Table I shows the charge consumed in the initial stages in which the deviation from a photocurrent *vs.* $\sqrt{t}$ relation was observed. If the adsorption of hydrogen preferentially occurs in the initial stage, the photocurrent should be invariant, which was different from the observed results. Therefore, both impregnation and adsorption of atomic hydrogen must compete with each other in this stage.

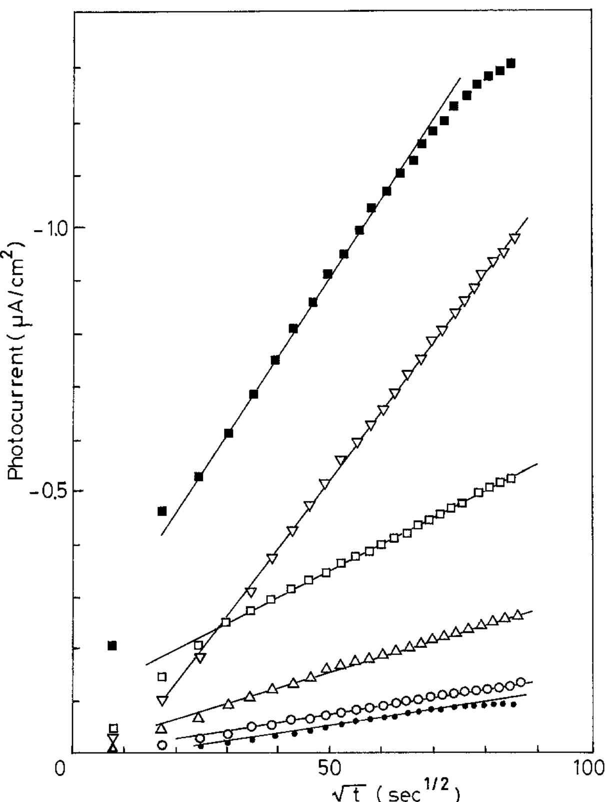

Fig. 5. Plots of photocurrent against square root of the polarization time for M($\theta = 1$)/p-GaP electrodes. (—■—) Pd, (—▽—) Au, (—□—) Ag, (—△—) Cu, (—○—) none, (—●—) Pb. Solution = 0.5M H_2SO_4, $E = -0.50V$, $\lambda = 620$ nm.

Table I. The charge consumed in the initial stages in which the deviation from a i_{photo} vs. $\sqrt{t}$ relation was observed

M($\theta = 1$)/p-GaP	Charge ($\mu C/cm^2$)
Pd	111
Au	15
Ag	69
Cu	8
None	9
Pb	8

It is seen in this figure that the gradient of the linear relations is different from one another. This implies that $kC_s\sqrt{D}$ is different depending on the kind of deposited metal. Since the diffusion coefficient of hydrogen atoms in GaP, D, must be the same independently of the kind of metal, the difference in the gradient must reflect differences in the surface concentration of atomic hydrogen among the deposited metals.

It is well known that the rate of the HER at metal electrodes is dependent upon the kind of substrate. If one plots $kC_s\sqrt{D}$ against log i_0 (9). of deposited metal for the HER, a fairly good relation is found to hold (Fig. 6). Although the magnitude of log i_0 for the HER is not necessarily related to the surface concentration of atomic hydrogen which is formed as a reaction intermediate (8), the results in Fig. 6 indicate that C_s at metal adatoms of M($\theta = 1$)/p-GaP is empirically related to log i_0.

Energy levels of the surface states due to impregnated hydrogen.—For charge transfer via surface states, two models can be imagined (Fig. 7). In one of the models, "model 1," which was discussed previously (1), electrons are photoexcited to the surface states from the valence band, and then are transferred to the electrolyte. In the other model, "model 2," electrons are photoexcited to the conduction band from the occupied

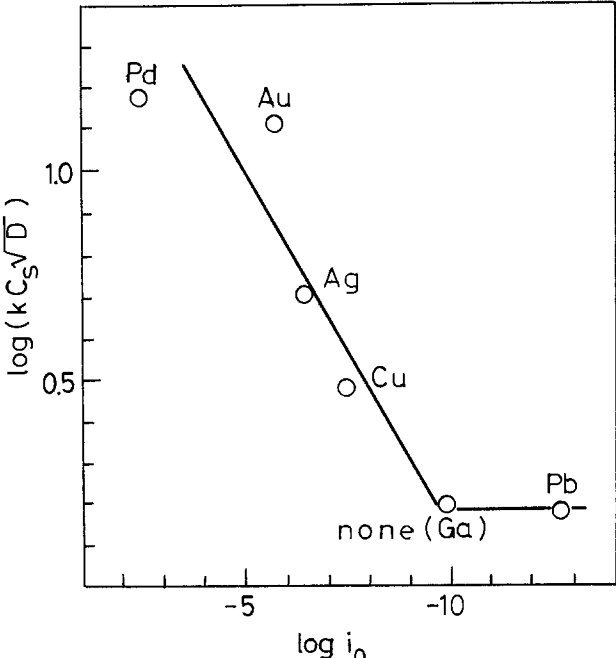

Fig. 6. Relation between log ($kC_s\sqrt{D}$) and log i_0 for hydrogen evolution reaction of deposited metals.

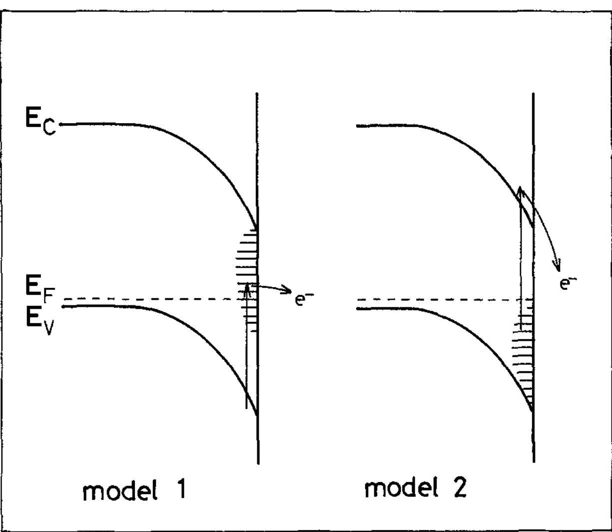

Fig. 7. Schematic diagrams of the charge transfer via the surface states for p-type GaP electrodes.

surface states and then are transferred to the electrolyte. The spectral response obtained is very broad, and hence, it seems difficult to definitely determine the fixed energetic positions of the surface states. Therefore, we assume that the energy levels of the surface states are distributed according to the spectral response obtained. Thus, for "model 1," surface states are distributed from just below the conduction band (2.3 eV above the valence bandedge) to the middle of the forbidden band (1.2 eV above the valence bandedge). For "model 2," the states are distributed between the top of the valence bandedge and the middle of the forbidden band. In order to draw a definite answer to which model is more appropriate, the following experiments were conducted.

Figure 8 shows the cathodic polarization curves in the dark for p-type GaP and Ag(θ = 1)/p-GaP in 10^{-3}M $K_3Fe(CN)_6$/3M NaOH. For this measurement, the electrodes were polarized at −0.4V *vs.* Hg/HgO and after 2 min, the potential sweep was started towards the negative potential region. The sweep rate was 20 mV/sec and the first cathodic sweep is shown in this figure. One can determine from the results the potentials E_t at which appreciable cathodic current commenced to flow, and these are given in Table II together with flatband potentials E_{fb} of the electrodes. In this table, potential drop in the space charge layer at E_t,

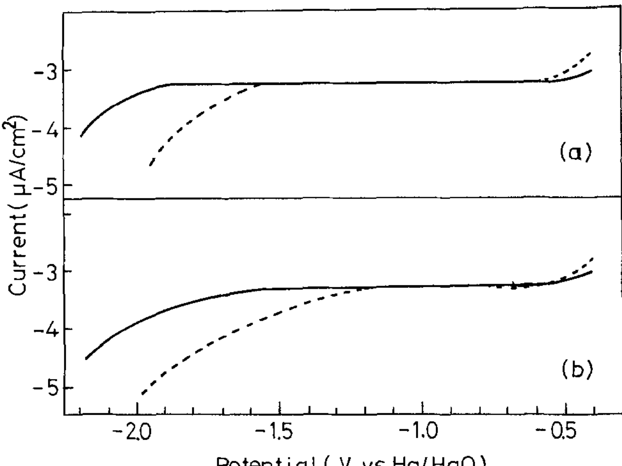

Fig. 8. Current-potential curves for p-type GaP (a) and Ag(θ = 1)/p-GaP (b) in the dark in 10^{-3}M $K_3Fe(CN)_6$/3M NaOH. (———) nonactivated, (– – – –) activated.

Table II. Flatband potential E_{fb} in 3M NaOH and onset potential of cathodic current in the dark E_t in 10^{-3}M $K_3Fe(CN)_6$/3M NaOH at p-GaP and Ag (θ = 1)/p-GaP electrodes

		E_{fb} (*V vs.* Hg/HgO)	E_t (*V vs.* Hg/HgO)	$\Delta\phi_{sc}$ (*V*)
p-GaP	Nonactivated	−0.03	−1.90	1.87
	Activated	−0.20	−1.60	1.40
Ag(θ = 1/ p-GaP	Nonactivated	0.10	−1.50	1.60
	Activated	0.00	−1.20	1.20

$\Delta\phi_{sc}$, is also given. Although the $Fe(CN)_6^{3-}$ solution was used as the electrolyte, the hydrogen evolution seemed to take part in the cathodic current flow, because the current-potential characteristics of the nonactivated electrodes became near to that of the activated electrodes by repeating the sweeps.

It is noticed from Fig. 8 and Table II that E_t was shifted towards anodic potentials by the activation treatment, in spite of the fact that E_{fb} became negative by the activation [1]. As a result, the cathodic current at the activated electrodes commenced to flow with small bandbending compared to that of the nonactivated electrodes. Considering that the activation treatment enhances the concentration of surface states alone without changing energetic distribution profiles, a conclusion is drawn that the cathodic behavior of the electrodes was greatly affected by the surface-state density.

By analyzing the nature of the cathodic current on the basis of this knowledge, we can determine which model of the surface states, "model 1" or "model 2," is more reasonable. If the cathodic current is due to conduction band electrons, which is very scarce, E_t will not be influenced by enhancement of the surface-state concentration. To date, many studies have suggested participation of surface states in electrode reactions at semiconductors, but none has shown that such a small current as several $\mu A/cm^2$ is influenced by the surface-state concentration. The bandbending can assist electrons in reaching the surface from the bulk, and so the depth of surface states is not primarily important at least at a very small current.

On the other hand, if the cathodic current is due to the valence band mechanism, growth of the surface states into the interior of the electrode is feasible for valence band electrons to be transferred into the electrolyte. An electronic interaction between the valence band and surface states becomes large with an increase in the depth of impregnated hydrogen when the band is bent downwards. One can have a clear image on this point by illustrating bandbending profiles at the potential of E_t. Examples are given in Fig. 9 for the activated and nonactivated Ag(θ = 1)/p-GaP. The figure was obtained by using Eq. [3] (10) and [4] (11)

$$x_0 = (2\epsilon\epsilon_0\Delta\phi_{sc}/e_0N_A)^{1/2} \quad [3]$$

$$\phi_b - \phi = [e_0(N_D - N_A)/2\epsilon\epsilon_0](x - x_0)^2 \quad [4]$$

where N_A and N_D are acceptor and donor concentration of the electrode, respectively, x_0 is the thickness of the space charge layer, x is the distance from the electrode surface, and ϕ_b is the bulk potential of the electrode.

Thus, the cathodic current in the dark is likely to be brought about by electron transfer from the valence band into the electrolyte via the surface states probably with "electron tunneling" mechanism (12). From discussion described here, "model 2" is more reasonable for the energy level of surface states than "model 1."

Electrogenerated Chemiluminescence

XXXVI. The Production of Steady Direct Current ECL in Thin Layer and Flow Cells

George H. Brilmyer* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Studies of the ECL of rubrene in thin layer cells containing two gold electrodes separated by 20-500 μm and viewed parallel to the electrode surface are reported. The agreement between calculated and experimental currents and intensities was good and operating lifetimes of 30 min to 4 hr were observed. Flow cells in which solution is recirculated through two mesh electrodes into a mixing chamber where electron transfer and emission occurs are also described. Higher light intensities were obtainable with the flow cells, which appear to be a more favorable configuration for application to ECL devices.

Electrogenerated chemiluminescence (ECL), in which an electron transfer reaction of electrogenerated species produces an electronically excited state (1-2), has been proposed for several types of electrochemical devices, including displays (3), lasers (4-7), and upconversion devices (8-9). The practical applications of ECL to such devices have been largely hindered by lifetime problems. For directly pumped ECL lasers, which have been discussed but never reduced to practice, two other problems exist. For most ECL cells the reaction zone thickness, which is governed by the distance the reactants can interdiffuse before reaction, is too narrow to utilize because of optical constraints in laser design. Moreover the current densities achieved with ECL cells have been judged insufficient to generate the needed level of excited states, even with fairly efficient ECL systems (5).

One possible configuration of an ECL laser device involves a thin layer cell in which the solution is confined between closely spaced generating electrodes. A previous study of this cell configuration utilizing transparent tin oxide electrodes spaced a fixed distance (50 μm) (3) apart, with the ECL observed through the electrode, demonstrated the feasibility of this type of cell. To utilize such a cell for a laser in a

Key words: electrochemiluminescence, rubrene, thin layer electrochemistry, electrochemiluminescent devices.

waveguide mode, interelectrode spacings of 500-1000 nm are required. We report here experiments with a thin layer cell employing solid electrodes and an adjustable gap, with ECL viewed end-on (*i.e.*, parallel to the electrode surfaces) and an investigation of the effect of interelectrode spacing on ECL intensity, risetime, and lifetime.

An approach to obtaining a wider ECL zone and the required higher current densities (*i.e.*, reactant fluxes) for a laser involves the use of a flow cell arrangement in which the precurser species are brought to the electrodes by convection (as well as diffusion) and the reactants flow together to cause ECL. The construction of flow ECL flow cells is difficult, because the high purity requirements of the solutions and the necessary pretreatment procedures preclude the use of large solution volumes and many solution pumping arrangements. To date the only flow cells reported have been those utilizing the rotating ring-disk electrode (10); this configuration is not useful for the desired applications. We report here the construction of an all-glass recirculating flow cell in which the solution containing the electroactive species is circulated through oppositely polarized Pt mesh electrodes where the reactant radical ions are generated. The solution streams are then mixed in the area just beyond the electrodes and the resulting emission intensity studied as a function of interelectrode voltage and solution flow velocity. The operation, current densities, and lifetime of such a cell is described.

Experimental

Chemicals.—Rubrene, obtained from Aldrich Chemical Company, was recrystallized from hot xylene (under subdued red light) with cold methanol. The orange-red crystals obtained were dried under vacuum at 10^{-5} Torr for 24 hr. Tetra-n-butylammonium perchlorate (TBAP) (polarographic grade, obtained from Southwestern Analytical Chemical Company) was recrystallized from ethanol and dried under vacuum at 100°C. The solvent system used for all thin layer experiments was benzonitrile (BZN) and benzene (BZ). BZN (reagent grade, purchased from Eastman Organic Chemicals) was purified by a previously reported procedure (11) and then distilled from calcium hydride under vacuum. BZ (spectrograde, obtained from Mallinckrodt Chemical Company) was purified as previously reported (12) and then vacuum distilled on to a sodium mirror, permitted to stand for 2 hr, and then distilled into a flask containing Woelm Alumina (Research Organic/Inorganic Chemical Company, Sun Valley, California). Both BZN and BZ were then stored in a Vacuum Atmospheres Corporation (Hawthorne, California) glove box. 1,2-Dimethoxyethane (DME) (Eastman Chemical Company) was vacuum distilled several times from lithium aluminum hydride and then into a clean flask. AN was purified as previously reported (8). Both the AN and DME were stored on a vacuum line and distilled directly into the electrochemical cell.

Apparatus.—The electrochemical cells used are shown in Fig. 1 and 2. The adjustable thin layer cell contained two gold disk electrodes and a platinum quasi-reference electrode. The disk electrodes were constructed by silver soldering a 4 mm diameter, 1 mm thick gold disk to the head of a 2 mm brass bolt. The disk was then machined into a conical shape with the face of the cone perpendicular to the bolt. The electrode could be wrapped with Teflon tape and pressure fit into a Teflon holder. The adjustable holder employed a modified Teflon needle valve (Fischer-Porter Company). The arms of the cell were aligned to ensure that the electrodes were parallel when in position. The electrode separation was determined by measuring the distance between the external electrode contacts with a 4-5 in. micrometer (J. T. Slocomb Company) and normalizing this to the distance mea-

sured when the separation was zero. All wire and disk electrodes were mechanically polished prior to use with a 0.3 μm polishing alumina (Precision Scientific Company). A Bausch and Lomb dissecting microscope was used to observe the position of the reaction zone and the emission between the electrodes. The flow cell was designed to permit the use of vacuum techniques for solution preparation as well as continuous circulation of the solution. An integral part of the cell is the pump which was made by sealing a Teflon stirring disk (Markson Science Incorporated, Del Mar, California) into a glass cylinder whose dimensions permitted constrained rotation of the stirrer. The solution enters the pump normal to the plane of rotation of the stirrer and exits off-axis and parallel to this plane. The solution is then electrolyzed by two platinum mesh electrodes which are separated by a coarse frit. These two separate streams containing the radical ions then mix efficiently to produce the emission in a confined area (Fig. 3).

All electrochemical experiments were conducted with a combination of a PAR Model 175 universal programmer and a PAR Model 173 potentiostat (Princeton Applied Research Corporation, Princeton, New Jersey). Photometric measurements were conducted with the cell inside of a dark box, using an EG & G Radiometer/Photometer (Model 550-1). The cell current and light intensity were monitored simultaneously on a Moseley Model 7100B dual pen recorder. The rotation rate of the magnetic stirring bar was measured with a Type K53K-AB Strobotac (General Radio Corporation, Concord, Massachusetts).

Procedure

A solution consisting of 4 mM rubrene (R), 0.05*M* TBAP in a 1:1 mixture of BZN/BZ was used for all thin layer experiments. Although the thin layer cell was air tight, it could not be placed under high vacuum. Thus the solution was prepared in a separate vessel, freeze-pump-thawed several times and returned to the dry box. The cell was then filled, removed from the dry box and reproducibly positioned above the radiometer inside the dark box. The thin layer experiment consisted of first using cyclic voltammetry to characterize the solution and insure system purity. ECL was generated in the two electrode mode by applying a potential, ΔE, between the electrodes [$\Delta E \cong E_{pa}$ ($R^{+\cdot}/R$) $-$ E_{pc} ($R^{-\cdot}/R$) $+ iR_s$] (where E_{pa} and E_{pc} are the cyclic voltammetric peak potentials for the anodic and cathodic waves, i is the current, and R_s is the cell resistance). The equal areas of the electrodes yields equal current densities at anode and cathode and the chosen ΔE value prevents formation of the very reactive dication or dianion species. Because the process involved is diffusion controlled, the cell current, ECL intensity and diffusion time can be studied as a function of the distance separating the electrodes. These experiments were carried out and results compared to the theoretically expected values.

Flow cell experiments were conducted using 4 m*M* rubrene and 0.1*M* TBAP in AN/BZ solutions. The flow cell was equipped with a side arm where the solution was prepared, freeze-pump-thawed and then gravity transferred to the cell itself. The solution could then be circulated through the cell and the potential difference (ΔE) applied to the two electrodes.

Results and Discussion

Thin layer cell.—Typical results of thin layer cell experiments are shown in Fig. 4-9. When the voltage step ΔE is applied, current flow begins and quickly attains a steady-state value; the emission commences when the diffusing reactant streams merge after a time controlled by the interelectrode separation (Fig. 4). Experimental values obtained for the steady-state

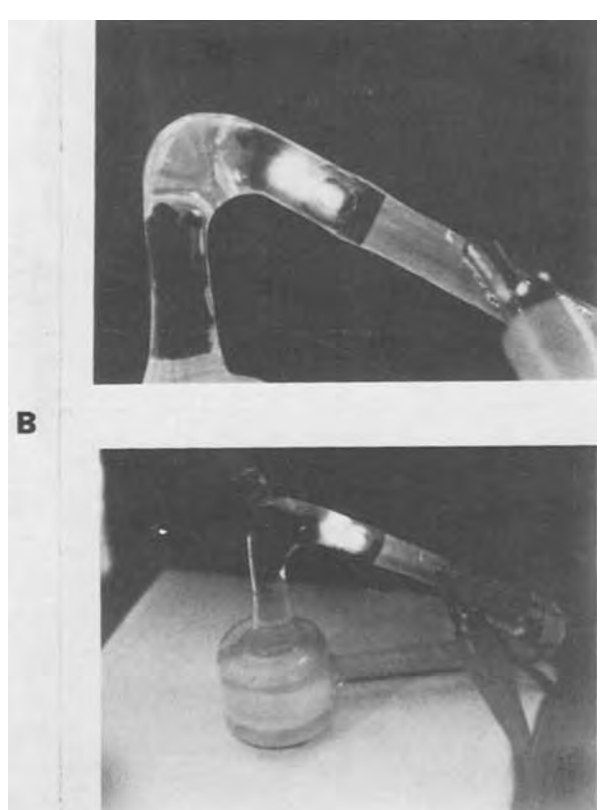

Fig. 3. Flow cell in operation. (A) Reaction chamber, (B) entire pump cell.

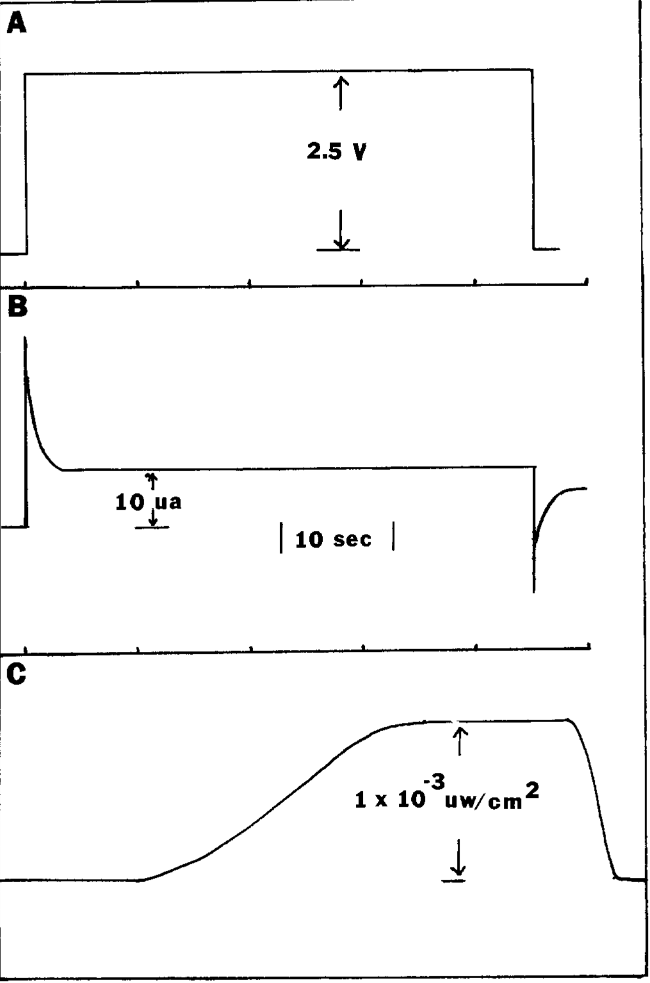

Fig. 4. Typical thin layer experiment. (A) Potential program, (B) current response, (C) resulting ECL intensity. 4 mM rubrene 0.05M TBAP in 1:1 mixture of BZN:BZ, electrode separation = 0.02 cm.

current, i_{ss}, compared to those calculated as a function of electrode separation by Eq. [1] are shown in Fig. 5

$$i_{ss} = n\mathbf{F}AD\ (\Delta C/\Delta X) \quad [1]$$

where n is the number of electrons consumed per molecule in the electrode reaction; **F** is the Faraday (96,487 C/equiv.); A, the average electrode area (0.141 cm^2); D, the diffusion coefficient of rubrene; $\Delta C/\Delta X$, the concentration gradient of radical species at steady state. D for rubrene was determined by chronoamperometry (14) to be 3.1×10^{-6} cm^2/sec; this value agrees with that previously found for rubrene in BZN (15) and was used in all theoretical calculations. The i_{ss} values were calculated by assuming that a complete annihilation reaction occurs at the center of the cell so that the rubrene concentration there is equal to its initial value, C (4 mM), while the concentration at each electrode was essentially zero. Thus $\Delta C = C$ for $\Delta X = d/2$ or

$$i_{ss} = 2n\mathbf{F}AD\ C/d \quad [2]$$

The experimental results obtained are in good agreement with those calculated from [2] at electrode separations above 200 μm. At smaller separations the deviation from the theoretical behavior can be rationalized by uncertainties in the determination of the interelectrode distance, d.

The d-c emission that appeared was less intense than that found with 1 Hz alternating pulses in the same solutions but was easily visible. As expected the intensity and time for the appearance of the ECL resulting from d-c electrolysis was a function of the electrode separation. The ECL intensity can be related to cell current by Eq. [3] (16)

$$I_{ss} = \phi_{ECL}\, i_{ss}/n\mathbf{F} \quad [3]$$

where ϕ_{ECL} is the ECL efficiency and I_{ss} the total emission from the cell at steady state. I_{ss} can be calculated from the measured ECL intensity by using a detector of known area and then making the appropriate geometric corrections (for the amount of emission which does not strike the detector).

In this experiment the geometric corrections are based on the fact that the emission is formed in a very thin disk-shaped reaction zone sandwiched between two zones of highly absorbing radical ions which are in turn bounded by the gold disk electrodes. The presence of such high concentrations of radical ions on either side of the reaction zone has several effects on the geometry of the system. First, no corrections need be made for electrode reflectivity effects. Second, a correction must be made for the fraction of the ECL absorbed by the radical ions. This was estimated to be 97% based on the dimensions of the area between the electrodes. Finally, one must realize that the emission which is not absorbed leaves the reaction zone at a very restricted, slightly diverging, angle. Therefore, the photodiode (area = 1 cm^2, diam 1.13 cm) was placed 3.6 cm below the cell to insure that the width of the emission was smaller than that of the diode. For this reason the projected image was taken as a ring (radius = 3.6 cm, width = 1.13 cm) and a surface area correction (25.6 cm^2 : 1 cm^2) could be made. No corrections were made for solution absorbance or inner filter effects because the fluorescence efficiency was taken as unity (15) and the photodetector was wavelength independent. The resulting ECL intensity ($\mu W/cm^2$) was converted to number of photons using Eq. [4] (17)

$$I\ (\text{photons/sec}) = \frac{(\text{total watts})\ (6.24 \times 10^{18})}{1239.8/\lambda\,(\text{nm})} \quad [4]$$

and plotted *vs.* electrode separation in Fig. 6. A plot of i_{ss} *vs.* I_{ss} for different values of electrode separation is shown in Fig. 7. Although the data are very scattered the slope of the line (least squares) corresponds to $\phi_{ECL} = 0.013$, which is within the accepted range of reported values for the rubrene system.

The time required [after the application of the voltage (ΔE) to the cell] for the reactants to diffuse together and for ECL to appear can be approximated by Eq. [5] (3)

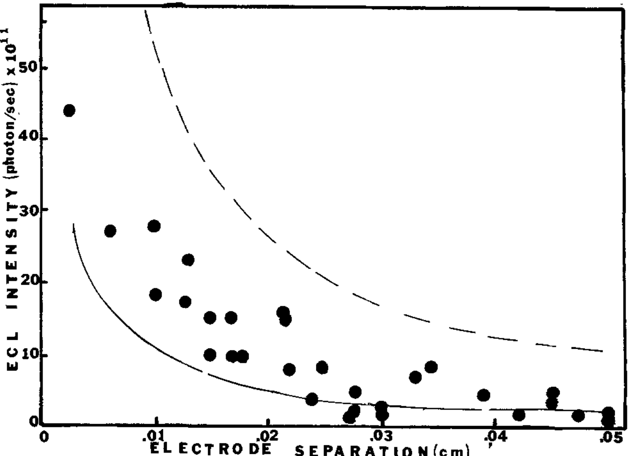

Fig. 6. Plot of ECL intensity vs. electrode separation. ---, Theory ($\phi_{ECL} = 0.025$); ●, experimental; ——, theory ($\phi_{ECL} = 0.005$). Solution the same as in Fig. 4.

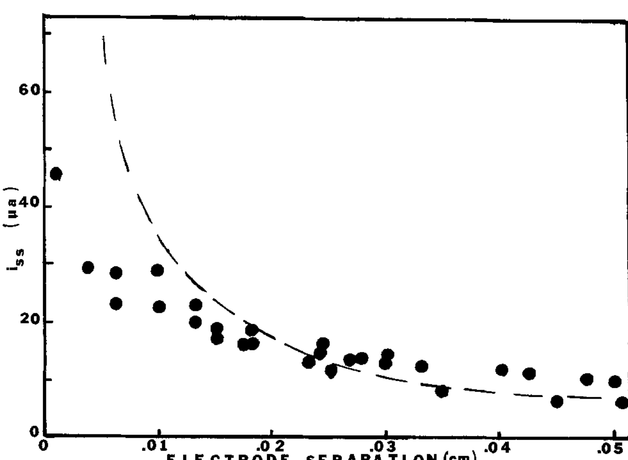

Fig. 5. Plot of steady-state current (i_{ss}) vs. electrode separation. ----, Theoretical; ●, experimental. Solution the same as in Fig. 4.

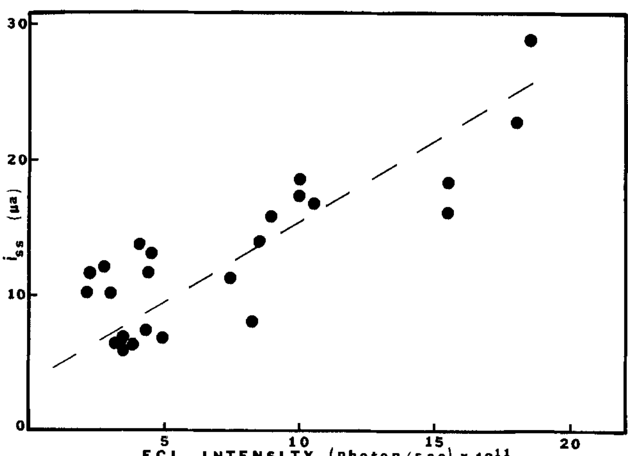

Fig. 7. Plot of steady-state current (i_{ss}) vs. steady state ECL intensity for various values of electrode separation. Solution same as in Fig. 4.

$$t(\text{sec}) = \frac{d^2(\text{cm})}{16D} \quad [5]$$

From this equation and the previously calculated diffusion coefficient, a comparison can be made between the calculated time needed for ECL to appear and the experimental results at different values of d. The results given in Fig. 8 show quite good agreement with the approximate equation. When the thin layer gap was observed under 8× magnification with a simple dissecting microscope, we found that the ECL did not occur in the exact center of the spacing between the electrodes. The reaction zone was clearly closer to the cathode with BZN/BZ as solvent and closer to the anode with DME. This can be explained by the slight instability of the anion or cation in the various solvents.

The operating lifetime of a single thin layer experimental cell was studied because of the great interest in application of the technique for displays or for use as a laser. The solutions were first subjected to cyclic voltammetry and fluorescence measurements before the experiment was actually begun. An initial cyclic voltammogram is shown in Fig. 9. The experiments were then conducted as described. The cell was permitted to remain on until the light intensity reached its steady-state value (200 sec). The cell was then turned off, and the ECL intensity decayed to zero. The results were very reproducible (within 5%) for repetitive experiments (ca. 30) over a period of 4 hr. When the cell was kept turned on and the experiment was permitted to continue well beyond 200 sec, the light intensity would remain relatively constant for 30 min. After this time the light would decrease at a constant rate until it finally dropped below a detectable level (~5 hr). When another experiment was attempted immediately, no light was detected. If the electrodes were separated, the solution stirred, and the electrodes repositioned with fresh solution from the reservoir in the gap, ECL was obtained but the intensity was about an order of magnitude smaller than the original experiment. Cyclic voltammetry revealed a reducible impurity with this solution, and fluorescence measurements showed a small amount of product that emits a 420 nm. If these experiments are continued, eventually all the electroactive species is consumed. Note also that successful long duration electrolysis in a solution containing 0.05M TBAP was accomplished here, while in a previous study (3) lifetimes of only 3-5 min were found.

Flow cell.—The results of the flow cell experiments showed this technique to be capable of producing stronger and longer lasting emission. In this mass transfer controlled system, the cell current and ECL intensity attained their limiting values very quickly

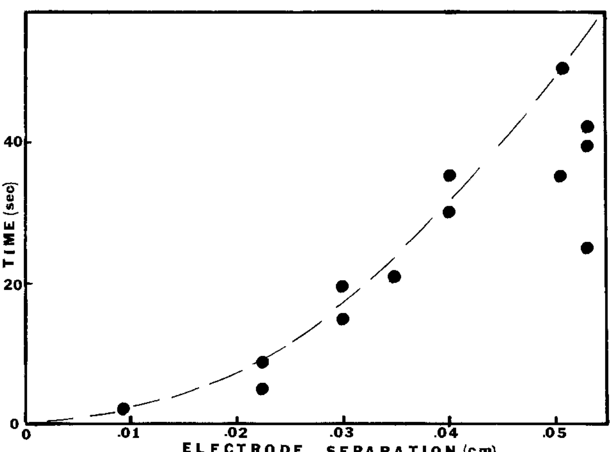

Fig. 8. Effect of electrode separation on time of ECL appearance. ----, Theoretical; ●, experimental. Solution same as in Fig. 4.

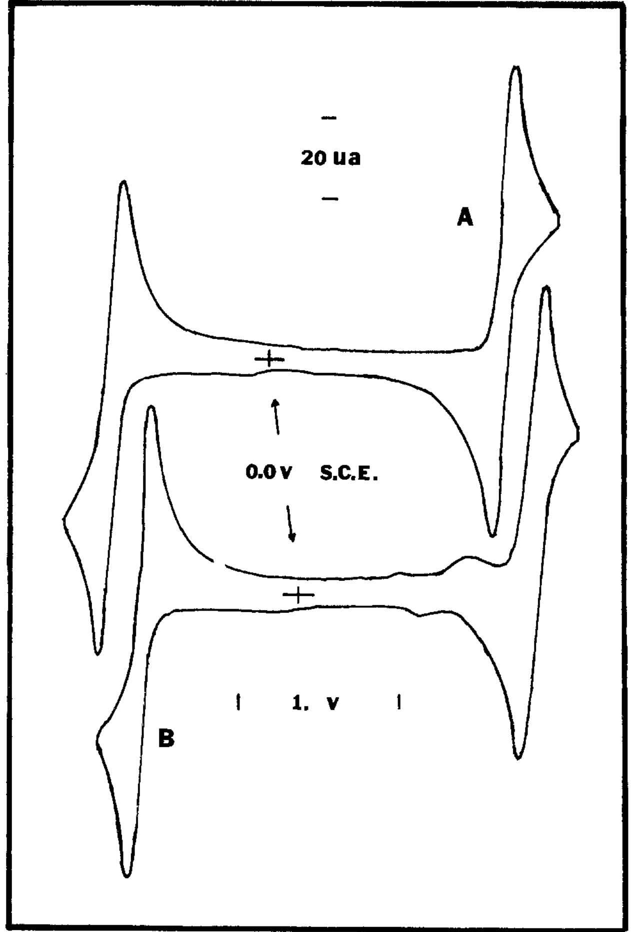

Fig. 9. Cyclic voltammograms of 4 mM rubrene/0.05M TBAP/BZN/BZ solution; (A) before thin layer experiment, (B) after 4 hr of thin layer experiments. Scan rate (v) = 100 mV/sec. Solution same as in Fig. 4.

after application of the d-c voltage (Fig. 10). Both of these quantities oscillated slightly because of fluctuations in the flow rate of the solution. This effect is also seen in Fig. 11 and 12 which show the dependence of the cell current and ECL intensity on the stirring rate and cell potential. The operating lifetime of this system greatly exceeded that of the thin layer cells. This can be attributed to the larger flux of radical ions and shorter lifetime required for the radical ions before the electron transfer reaction. In a typical experiment the ECL initially occurred solely in the mixing chamber. The emission produced was continuous and could be controlled by the flow rate of the solution. During electrolysis, if the flow rate was stopped for 30 sec and then restarted, light pulses an order of magnitude more intense than the continuous level were obtained. At this point in the experiment the radical ions were very stable. In fact, during a stop flow experiment, the electrolysis could be stopped for several minutes before the pump was restarted and the light pulse obtained was relatively unchanged. After about 2 hr when the ECL began to fail, the emission was observed to stream from one of the electrodes. This can be attributed to a difference in the radical ion stabilities, as observed also in the thin cell experiments. In this case, an instability of one of the species causes an excess of the opposite species after the mixing process. This excess is circulated throughout the whole solution volume, and results in emission at the electrode where the less stable radical ion is formed as the more stable radical ion reaches it. This was verified by producing an excess of the less stable species (using a 3 electrode system). By purposeful generation at an excess of one species the

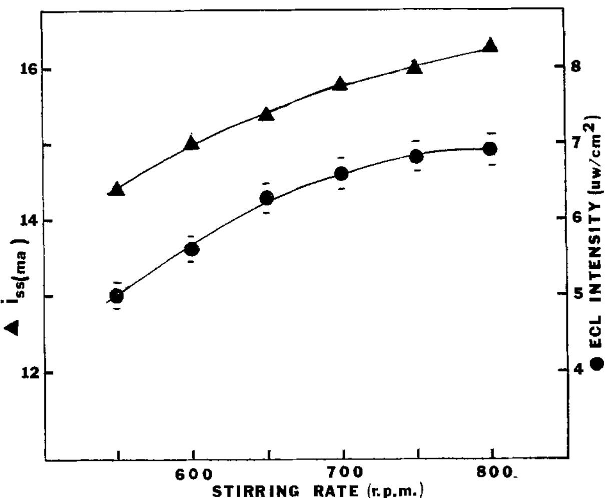

Fig. 11. Flow rate dependence of ECL. No geometric corrections made. Solution same as in Fig. 10.

streaming effect could not only be eliminated but it could be forced to occur at the opposite electrode. Such an ion degradation process tends to cascade and eventually all of the emission appeared at one electrode and not in the mixing chamber. Finally after about 30 hr the ECL ceased.

Fluorescence analysis showed only a trace amount of rubrene remained while revealing a large amount of product emitting at 420 nm. Further extraction shows two crystalline products (yellow and brown) with fluorescent maxima corresponding to 400 and 425 nm. Mass spectroscopic data showed that the products were isomers of dihydrorubrene. This finding is in agreement with that described by Moreu *et al.* (18) in the synthesis of dihydrorubrene.

Conclusions

In this paper the feasibility of the development of an ECL device has been studied. Parameters affecting the electrically induced emission have been examined in both diffusion and convective modes. The results show that flow techniques do indeed have advantages over thin layer techniques for the production of continuous ECL. The thin layer mode of ECL formation is seen to be an impractical source of emission for an ECL device. The emission from this diffusion-controlled process is weak and is confined to a very narrow area, sandwiched between two zones of the highly colored radical ions. The lifetime of this d-c emission (5 hr) proved to be much greater than that previously published (3), but still unsatisfactory for any practical application. A major problem with this configuration appears to be the very small volume of solution confined between the electrodes. This volume is very susceptible to impurities which are either initially introduced or electrochemically generated. Detrimental side reactions which occur under these conditions, cause depletion of the electroactive species or formation of species which can effectively quench the ECL. These findings, along with the reaction zone geometry problem, suggest that the thin layer cell will not be useful for laser applications.

A better approach to this problem would be to utilize a flow system for the production of ECL. This method produces stronger emission due to the larger radical ion flux and the shorter radical lifetimes necessary for anion-cation annihilation. Buildup of impurities is minimized, and they are distributed through a much larger volume of solution. By making physical improvements on cell design (*e.g.*, larger electrodes, faster mixing) one could perhaps increase the ECL intensity an order of magnitude but probably not much more than this.

These experiments were performed using one of the better chemical systems known for the production of ECL. Even this system eventually failed. The mechanism for this failure is still not well understood, but at least partially occurs because of degradation of the parent molecule.

Acknowledgment

We would like to thank Mr. John Somerville and Mr. William Bruton whose artful glass work made this

project possible. The support of the research by the U.S. Army Research Office is gratefully acknowledged.

The Warburg Impedance in the Presence of Convective Flow

Daniel A. Scherson and John Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The Warburg impedance of a rotating disk electrode is analyzed by means of an inverse Laplace transformation of the governing differential equation. This new formulation reduces the problem to a partial differential equation for which approximate solutions are known. The results obtained agree with exact numerical values for a wide range of low and high frequencies.

The impedance associated with changes in concentration induced by sinusoidally varying boundary conditions at the electrode surface was first analyzed by Warburg (1) and Kruger (2). Later Rosebrugh and Lash-Miller (3) extended these studies to account for a diffusion layer of finite thickness. Based on this model, Schuhmann (4) derived an analytic expression for the impedance which predicts more realistic values in the low frequency regime. Recently Levart and Schuhmann (5) proposed a general method for evaluating the concentration impedance of a uniformly accessible rotating disk electrode. By defining a frequency related complex variable, these authors obtained an asymptotic solution valid for high frequencies and any finite value of the Schmidt number found in electrochemistry. Homsy and Newman (6) analyzed this specific problem by a regular perturbation expansion showing that the stagnant Nernst diffusion layer concept is valid only for very high frequencies. A comparison of these solutions (7) concluded that the expression derived by Levart and Schuhmann best represents the behavior of the system for a wide range of frequency values.

This contribution constitutes a new approach, establishing an interesting connection between transient convective diffusion and the Warburg impedance of a rotating disk electrode.

Radial diffusion and convection, as well as migration effects, will be neglected. Furthermore, it will be assumed that the Schmidt number is large, and that dilute-solution theory, with constant transport and thermodynamic properties, is applicable.

* Electrochemical Society Active Member.
Key words: rotating disk, convective diffusion, alternating current.

Mathematical Formulation

According to Homsy and Newman (6) the time varying concentration, $\tilde{c}$, for an alternating current of frequency ω, can be expressed as

$$\tilde{c} = a\theta \exp(jKt^*) \quad [1]$$

where

$$K = \omega\nu \left(\frac{3D}{a\nu}\right)^{2/3} \bigg/ \Omega D$$

and

$$t^* = t\Omega D \left(\frac{a\nu}{3D}\right)^{2/3} \bigg/ \nu$$

are the dimensionless frequency and time respectively.

By substituting Eq. [1] into the convective diffusion equation [Eq. [1], Ref. (6)] these authors arrived at the following complex equation

$$\theta'' + 3\zeta^2\theta' - jK\theta = 0 \quad [2]$$

subject to the boundary conditions

$$\theta = 1 \text{ at } \zeta = 0, \quad \theta \to 0 \text{ as } \zeta \to \infty \quad [3]$$

where $\zeta = y\sqrt{\Omega/\nu}\,(a\nu/3D)^{1/3}$ is a dimensionless distance from the disk. A generalization of Eq. [2] can be obtained by defining a complex parameter, $p = \xi$

$+ jK$, where the real part, ξ, can be understood as arising from some simple homogeneous reaction at the surface

$$\theta'' + 3\zeta^2\theta' = p\theta \quad [4]$$

It can be shown that a formal inverse Laplace transformation of Eq. [4] yields the following partial differential equation

$$\frac{\partial^2\tilde{\theta}}{\partial\zeta^2} + 3\zeta^2\frac{\partial\tilde{\theta}}{\partial\zeta} = \frac{\partial\tilde{\theta}}{\partial\tau} \quad [5]$$

and boundary conditions given by

$$\tilde{\theta} \to 0 \quad \text{as} \quad \zeta \to \infty$$
$$\tilde{\theta} = 1 \quad \text{at} \quad \zeta = 0, \quad \tau > 0 \quad [6]$$
$$\tilde{\theta} = 0 \quad \text{at} \quad \zeta \geq 0, \quad \tau = 0$$

If the real variables $\tilde{\theta}$ and τ are regarded as a dimensionless concentration and time respectively, it becomes clear that Eq. [5] describes transient convective diffusion to a rotating disk. Moreover the boundary conditions specified in Eq. [6] refer to a buildup case after a step increase in the concentration at the surface.

The problem, so stated, has been analyzed independently by Krylov and Babak (8) and Selman (9) yielding results valid for short times in terms of parabolic cylinder functions. Nisancioglu and Newman (10) have derived a long-time series by solving numerically for the eigenvalues and eigenfunctions of a Sturm-Liouville system. Excellent agreement with the short time series cited above was found for a wide interval of time.

It is interesting to note that the function that prescribes the Warburg impedance for this particular system [Eq. [6], Ref. (6)] is precisely the Laplace transform of the flux at the surface. Therefore, an expression valid for high frequencies, $\theta_{HF}'(0)$, can be obtained from the short-time series (8, 9)

$$\mathcal{L}\left(-\frac{\partial\tilde{\theta}}{\partial\zeta}\bigg|_{\zeta=0}\right) = -\theta_{HF}'(0)$$
$$= p^{1/2} + \frac{3}{4p} + \frac{9}{32}p^{-5/2} + 0(p^{-4}) \quad [7]$$

and correspondingly the long-time series (10) determines a relation applicable in the low frequencies regime, $\theta_{LF}'(0)$

$$\mathcal{L}\left(-\frac{\partial\tilde{\theta}}{\partial\zeta}\bigg|_{\zeta=0}\right) = -\theta_{LF}'(0)$$
$$= \frac{1}{\Gamma(4/3)} + p\sum_{n=0}^{\infty}\frac{B_n}{p+\lambda_n} \quad [8]$$

where B_n and λ_n are the coefficients and eigenvalues of the Sturm-Liouville system respectively.

In the absence of mechanistic complications ($\xi = 0$), the frequency dependent part of the Warburg impedance will be simply given by replacing the value of p in Eq. [8] and Eq. [9] by jK where K is the original dimensionless frequency

$$-\theta_{HF}'(0) = \sqrt{jK} - \frac{3j}{4K} + \frac{9}{32}(jK)^{-5/2} \quad [9]$$

$$-\theta_{LF}'(0) = \frac{1}{\Gamma(4/3)} + jK\sum_{n=0}^{\infty}\frac{B_n}{jK+\lambda_n} \quad [10]$$

The result obtained in Eq. [9] is identical to that reported by Homsy and Newman (6) [Eq. [12], Ref.

(6)]. However, these authors arrived at an erroneous expression for the real and imaginary part of $(-\theta_{HF}'(0))^{-1}$. The correct components are given by

$$\mathrm{Re}\left\{-\frac{1}{\theta_{HF}'(0)}\right\} = \frac{a}{a^2+b^2},$$

$$-\mathrm{Im}\left\{-\frac{1}{\theta_{HF}'(0)}\right\} = \frac{b}{a^2+b^2} \quad [11]$$

where

$$a = \frac{\sqrt{2}}{2}\left(K^{1/2} - \frac{9}{32}K^{-5/2}\right) \quad [12]$$

$$b = \frac{\sqrt{2}}{2}\left(K^{1/2} + \frac{9}{32}K^{-5/2}\right) - \frac{3}{4K} \quad [13]$$

Similarly, from Eq. [10]

$$\mathrm{Re}\left\{-\frac{1}{\theta_{LF}'(0)}\right\} = \frac{r}{s^2+r^2},$$

$$-Im\left\{-\frac{1}{\theta_{LF}'(0)}\right\} = \frac{s}{s^2+r^2} \quad [14]$$

where

$$r = \frac{1}{\Gamma(4/3)} + K^2 \sum_{n=0}^{\infty} \frac{B_n}{\lambda_n^2 + K^2} \quad [15]$$

$$s = K \sum_{n=0}^{\infty} \frac{B_n \lambda_n}{\lambda_n^2 + K^2} \quad [16]$$

Numerical values obtained from Eq. [11], [12], and [13] are listed in Table I. As it can be clearly seen, the analytic results derived from the high frequency series are in excellent agreement with the exact solution and do not differ significantly from those reported by Levart and Schuhmann (7).

The first ten eigenvalues, λ_n, and the related coefficients, B_n, of the eigenfunctions [Table I, Ref. (10)] were used to calculate the corresponding components for the low frequency spectrum from Eq. [14], [15], and [16]. These are given in Table I where the few available exact results are also shown for comparison.

In addition, Table I and Table II contain values for $(-\theta'(0))^{-1}$ obtained from an analysis based on a stagnant Nernst diffusion layer (4, 6) *i.e.*

$$-\frac{1}{\theta_N'(0)} = \Gamma\left(\frac{4}{3}\right)\frac{\tanh\sqrt{j\omega\delta^2/D}}{\sqrt{j\omega\delta^2/D}} \quad [17]$$

where the Nernst diffusion layer thickness, δ, is given by

$$\delta = \Gamma\left(\frac{4}{3}\right)\sqrt{\frac{\nu}{\Omega}}\left(\frac{3D}{\alpha\nu}\right)^{1/3} \quad [18]$$

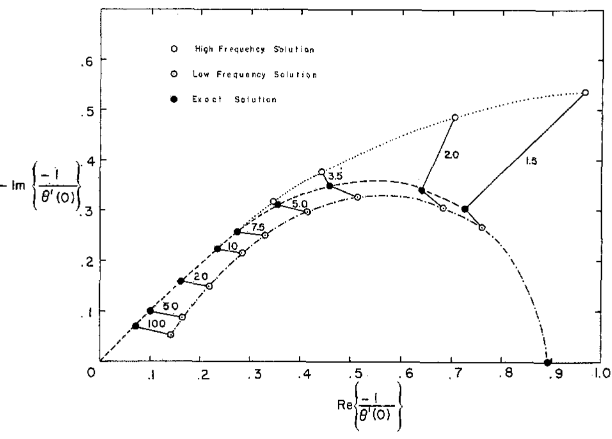

Fig. 1. Representation of the function $(-\theta'(0))^{-1}$ in the complex plane.

A graphical representation of $(-\theta'(0))^{-1}$ in the complex plane is depicted in Fig. 1, where solid lines connect equal values of the dimensionless parameter K. It is interesting to note that although in the real space the short-time (8, 9) and the long-time series (10) overlap within a few tenths of a percent in a wide interval of time, that behavior is not reproduced in the complex plane after a Laplace transformation. This problem is presently under investigation in this laboratory.

Summary

Laplace transform techniques have been utilized in order to determine the Warburg impedance of a rotating disk. The solution obtained for high frequencies has been shown to reproduce within one percent exact numerical results for values of K greater than 7.5.

Polarization Phenomena Associated with Reduction of a Doped Ceria Electrolyte

Da Yu Wang* and A. S. Nowick*

Henry Krumb School of Mines, Columbia University, New York, New York 10027

ABSTRACT

The steady-state and transient polarization behavior of doped ceria solid electrolyte cells at 700°-900°C was studied in the current range above the cathodic limiting current, where electrolyte reduction sets in. The current interruption method was used together with a reference electrode, to measure separately the anodic and cathodic overpotentials (η_a and η_c) and the ohmic polarization for various oxygen pressures, types of electrodes, and dopant levels. The cathodic steady-state curves ($\ln I$ *vs.* η_c) show a linear region of slope e/kT which is interpreted in terms of the Wagner polarization cell theory, and it is shown that this theory is applicable to the cathodic polarization even when ionic blocking is incomplete. Values of the electronic transference number are obtained for various electrolyte compositions and temperatures which agree well with values obtained by other methods. The observed anodic steady-state overpotential is related to a residual ionic current. The transient anodic curves following current interruption show behavior in which $\eta(t)$, starting positive, changes sign and eventually joins the cathodic curve; subsequently both decay to zero. At higher initial overpotentials, a very slow decay occurs in which both decay curves show anomalous humps after long time periods. These phenomena have been interpreted in terms of simple models which involve primary diffusion of electrons (from cathode to anode), secondary diffusion (into the region of the reference electrode), and oxygen uptake from all of the electrodes.

The present study was carried out to obtain a fuller understanding of polarization phenomena occurring in systems that use solid electrolytes. In previous papers (1, 2), we made use of the current interruption method in combination with a reference electrode, to study the nature of electrode phenomena at relatively low overpotentials occurring at platinum paste electrodes on a doped CeO_2 electrolyte. This method makes it possible to determine separately the anodic and cathodic overpotentials as well as the ohmic polarization of the electrolyte. It was shown that, at high oxygen partial pressures (p_{O_2}), data for the steady-state current (I) *vs.* overpotential (η) obey the Butler-Volmer equation both for anodic and cathodic polarizations. This behavior was interpreted as controlled by a charge transfer (or activation) mechanism, and the nature of the rate-determining step of this process was studied. At relatively low p_{O_2}, on the other hand, the cathodic polarization showed limiting-current behavior, characteristic of concentration polarization. It is believed that the limiting process is the rate at which oxygen adatoms can be supplied at the cathode.

As reported in the previous papers, when η is made sufficiently cathodic, I rises above the limiting current I_l, and the IR drop in the electrolyte is no longer ohmic. Previous workers (3-5) have shown that reduction of the electrolyte sets in at such high cathodic potentials. The present work was carried out to explore this behavior more quantitatively. In so doing, we have applied Wagner's treatment (6) of current-voltage behavior, for a polarization cell in which ionic current is blocked. This treatment was, in fact, derived for the idealized case in which one electrode is totally block-

* Electrochemical Society Active Member.
Key words: electrode polarization, solid electrolytes, cerium dioxide, electronic diffusion.

ing to ions while the other is an electronic conductor which is completely reversible to ionic flow, and at which no overpotential is developed. Nevertheless, it is shown that the present experimental method, which permits the separate determination of the two electrode overpotentials and the IR drop in the electrolyte, makes it possible to apply the Wagner treatment even under less ideal conditions.

In addition to steady-state (I *vs.* η) behavior, we have also studied the transient overpotential following interruption of the current. While several unusual aspects were observed, it was found that they could all be explained in terms of the reduction of the electrolyte, the diffusion of electrons, and the uptake of oxygen from the electrodes.

Ceria doped with calcia or yttria was chosen for the present work, because its high oxygen-ion conductivity above 600°C make it suitable for many electrochemical applications, and because its electrical properties have been well studied, particularly its ionic and electronic conductivity as a function of temperature and p_{O_2}.

Theory

We present a modification of the Wagner treatment (6) suited to the type of cell used in these experiments. By employing an electrode which is blocking to ionic flow (the cathode, in the present case), ionic conduction is suppressed under steady-state conditions and conduction takes place only because of the migration of electronic carriers. Wagner assumes that the electronic carriers are dilute enough to obey ideal solution laws and to have a mobility that is constant. He then obtains, for the electronic conductivity at any position x in an oxide electrolyte

$$\sigma_e = \sigma_e^0 \exp[(\mu_{O_2}^0 - \mu_{O_2})/4kT] \quad [1]$$

where μ_{O_2} is the chemical potential of oxygen and super 0 refers to values at a reference position which is in equilibrium with the ambient gas. Wagner further shows that the electronic current density across an electrolyte of thickness L is

$$J_e = \frac{1}{4eL} \int_{\mu_{O_2}^a}^{\mu_{O_2}^c} \sigma_e d\mu_{O_2} \quad [2]$$

where $\mu_{O_2}^a$ and $\mu_{O_2}^c$ are values at the anode and cathode, respectively. Substituting Eq. [1] into [2] and integrating gives

$$J_e = (kT\sigma_e^0/eL)\{\exp[(\mu_{O_2}^0 - \mu_{O_2}^c)/4kT] - \exp[(\mu_{O_2}^0 - \mu_{O_2}^a)/4kT]\} \quad [3]$$

The Nernst equation gives for the cathodic and anodic overpotentials, respectively (both defined as positive quantities)

$$4e\eta_c = \mu_{O_2}^0 - \mu_{O_2}^c; \quad 4e\eta_a = \mu_{O_2}^a - \mu_{O_2}^0 \quad [4]$$

which combined with Eq. [3] gives

$$J_e = J_e^0[\exp(e\eta_c/kT) - \exp(-e\eta_a/kT)] \quad [5]$$

where

$$J_e^0 = kT\sigma_e^0/eL \quad [6]$$

Wagner considered the idealized case in which the nonblocking electrode (here, the anode) is reversible to the conducting ions, so that $\eta_a = 0$, and any IR drop in the current leads and contacts is negligible. In that case

$$\eta_c = E \quad [7]$$

where E is the total potential across the cell, and Eq. [5] becomes

$$J_e = J_e^0 [\exp(eE/kT) - 1] \quad [8]$$

(The validity of Eq. [8] also requires that E never exceed the decomposition potential of the electrolyte.) However, it is clear that even if $\eta_a \neq 0$, Eq. [5] takes on the useful asymptotic form when a sufficiently large cathodic potential is applied

$$\ln J_e = \ln J_e^0 + (e/kT)\eta_c \quad [9]$$

i.e., a plot of $\ln J_e$ *vs.* η_c should give a straight line with slope e/kT and intercept determined by Eq. [6]. The advantage of a direct measurement of η_c by the current interruption method is that η_c can be obtained separately from η_a and the IR drop in the current leads so that Eq. [9] can be utilized even when η_a and IR are not zero. For the case where the normal conductivity is primarily ionic so that the equilibrium electronic transference number, $t_e^0 << 1$, we can insert $\sigma_e^0 \cong t_e^0\sigma_i^0$ (σ_i^0 being the ionic conductivity) into Eq. [6] to obtain

$$J_e^0 = (kT/eL)\sigma_i^0 t_e^0 \quad [10]$$

Thus, the intercept of Eq. [9] can be used to determine t_e^0 under the conditions where this equation is valid.

In considering the type of polarization cell with which we will be dealing, it is advantageous to be able to relax the requirement of complete blocking of ions. Brook *et al.* (3) have considered the case in which ionic blocking is incomplete, but nevertheless, large, so that a residual ionic current density J_{ir} is present. They show that Wagner's Eq. [8] then becomes

$$J_e = J_e^0 \left[\exp\left\{ \left(1 - \frac{J_{ir}}{J_i}\right) \frac{eE}{kT} \right\} - 1 \right] \quad [11]$$

where J_i is the ionic current in the absence of polarization. If we assume that J_{ir} is invariant over a large range of E, while $J_i = E/R_iS$, S being the electrode area and R_i the corresponding resistance, we obtain for large E

$$\ln J_e = [\ln J_e^0 - eJ_{ir}R_iS/kT] + eE/kT \quad [12]$$

i.e., the correction term goes into the intercept. However, if the current interruption method is used, the additional term enters only in the IR drop, which is separately measured, so that a relation of the type of Eq. [9], involving the cathodic overpotential, is unaffected. At the same time, if $\eta_a > 0$ because of the ionic flow, Eq. [9] will be unchanged. It may be concluded that Eq. [9] should be valid even with only partial blocking of the ionic current. The validity of this equation can be verified experimentally in several ways: (*i*) from the e/kT slope; (*ii*) from the correct determination of t_e^0 from the value of the intercept combined with Eq. [10]; (*iii*) by the shift in the $\ln J_e$ *vs.* η_c plots for two samples of the same electrode but different electrolyte thicknesses, L_1 and L_2, given by

$$\Delta\eta_c = \eta_{c2} - \eta_{c1} = (kT/e) \ln (L_2/L_1) \quad [13]$$

and (*iv*), by the shift in the same plots with a change in the ambient p_{O_2}

$$\Delta\eta_c = (kT/4e) \ln (p_{O_2}^{(2)}/p_{O_2}^{(1)}) \quad [14]$$

This last equation comes from the pressure dependence of σ_e^0 for doped ceria (as well as stabilized zirconia) which has been shown (7, 8) to obey

$$\sigma_e^0 \propto p_{O_2}^{-1/4} \quad [15]$$

Experimental Methods

Doped ceria electrolytes and platinum paste electrodes were prepared as described previously (1). Three electrodes were applied to the samples in the geometrical arrangement shown schematically in Fig. 1. The arrangement for the current interruption method is also described in Ref. (1). Most of the transient studies were carried out with the aid of a storage oscilloscope (Tektronix 564). For those cases in which the decay time was longer than 5 sec, however, a Hewlett-Packard 7128A two-pen strip chart recorder was used. The two pens were connected to the outputs of Keithley 640 and Keithley 150A voltmeters, the first voltmeter connected between the electrode under investigation

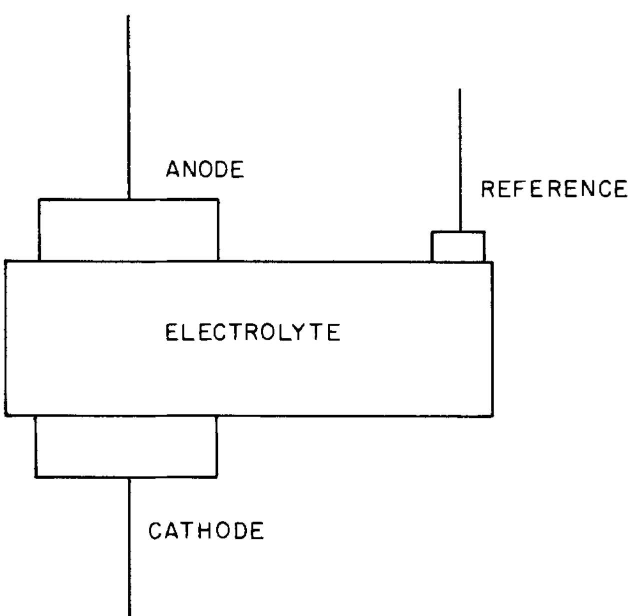

Fig. 1. Schematic diagram of the electrode arrangement

and the reference electrode with input impedance $> 10^{12}\Omega$, and the second one connected between the anode and cathode with an input impedance $10^9\Omega$. The response time of the recorder is ¾ sec.

In addition to Pt paste electrodes, two new types of electrodes were used in this study: gold paste (Engelhard A-2123) and platinum foil (120 μm thickness). Gold paste was brushed onto the surface of the electrolyte, then fired at 800°C for 4 hr. For the platinum foil electrode, an unfluxed Pt paste (Engelhard 6926) was first applied, the platinum foil was pressed on under an alumina disk weighing 23g, and this combination was fired at 1400°C in an argon atmosphere for 3 hr.

The gases and the gas treatments are as described previously (1), except that in this study we added one stopcock just before the gas enters the sample chamber. By controlling this valve, we can rapidly change the ambient gas composition during an experiment. Argon-oxygen gas mixtures were used in this study, covering the range of p_{O_2} from 10^{-5} to 10^{-2} atm, as well as CO/CO_2 mixtures whose p_{O_2} was measured with the aid of a cell utilizing a calcia-stabilized zirconia electrolyte.

The absence of polarization of the reference electrode was demonstrated by varying the input impedance of the oscilloscope and observing that the voltage readings are unchanged [see Ref. (1)].

Steady-State Behavior

The "instantaneous" potential drop, which occurs in a time $\lesssim 10^{-7}$ sec after current interruption, is taken as the IR drop, while the initial value after this drop is taken as the steady-state overpotential, η, at the electrode under investigation. This overpotential, measured as a function of the current, I, that flowed prior to interruption, constitutes the steady-state data.

Figure 2 shows typical examples of plots of log I vs. η_c (cathodic overpotential) at low p_{O_2}, showing the limiting-current region and the current increase at higher cathodic values. Data are presented for electrolytes of two thicknesses at temperatures of 700° and 800°C. In each case a straight line region of slope $e/2.3$ kT (represented by the solid line) is obtained at high η_c. The dashed lines in the lower η_c region are fitted curves based on the assumption that concentration polarization dominates this region. [Detailed analysis can be found in Ref. (1)]. Figure 2 shows that the position of the straight-line region depends on the

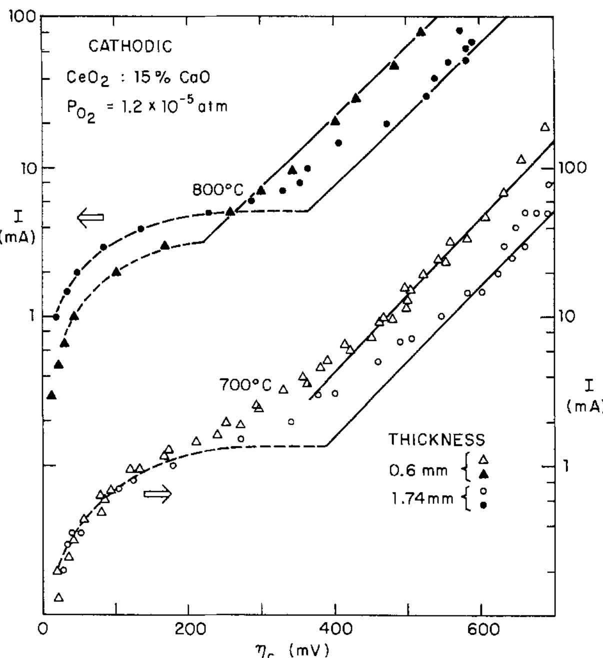

Fig. 2. Plots of steady-state cathodic overpotential as a function of log I for two different temperatures and sample thicknesses, showing the increase in current above the limiting-current range and the fit to straight lines of slope $e/2.3$ kT (solid lines).

thickness of the electrolyte, for samples having the same electrode area. The observed overpotential difference of the two samples with electrolyte thickness 0.6 and 1.74 mm is 95 mV at 800°C, and 90 mV at 700°C; these results compare favorably with the values 98.5 mV for 800°C and 89.4 mV for 700°C calculated from Eq. [13]. This electrolyte thickness dependence is also observed with other electrolyte samples containing different dopants and dopant concentrations, and Eq. [13] always fits the data well.

In the region of the $e/2.3$ kT slope, the electrolyte resistance is no longer constant. An example is shown in Fig. 3, where the departure from ohmic behavior (represented by the 45° line) at high currents is apparent, indicating that the electrolyte is being reduced. As further evidence that reduction of the electrolyte is indeed taking place in this range, we showed that the

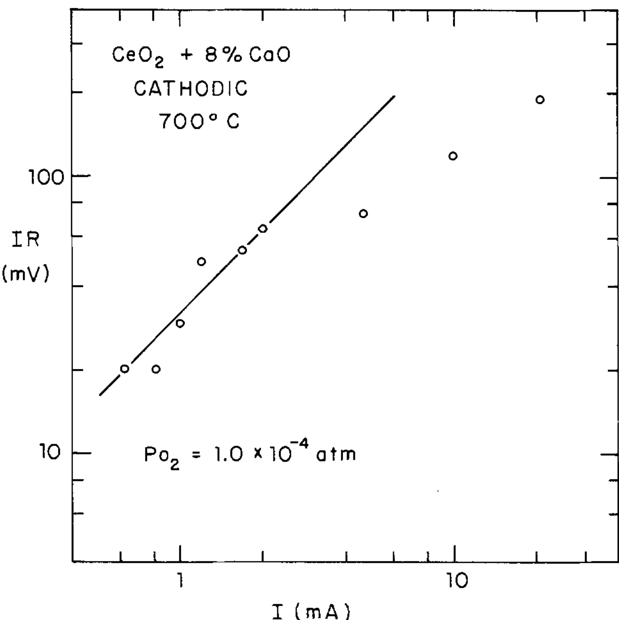

Fig. 3. A log-log plot of cathodic IR drop vs. I. The 45° line represents a constant resistance, R.

total resistance of the cell (~ 4-6Ω) in this range is mainly that of the Pt leads.

Since reduction occurs at the cathode, it is a matter of concern as to whether the reference electrode is also reduced. As verification that it is not, we note that the steady-state curves were independent of separation of the reference from the adjacent electrode (for separation greater than 5 mm), and also independent of whether the reference is on the same side of the sample as the cathode or as the anode.

To block ionic flow at the cathode more effectively than is obtained with the porous Pt paste electrode, a similar experiment was carried out using a Pt foil electrode at the cathode and Pt paste at the anode—both with the same nominal area. The result, shown in Fig. 4 at $p_{O_2} = 1.2 \times 10^{-5}$ atm, shows that the cathodic overpotential can be fitted with the Wagner Eq. [8] over a much more extended region than for the case where the cathode is Pt paste. (The comparison shown in Fig. 4 was made simply by reversing the polarity of the same sample.) However, the more important result is that the linear regions for the two cases closely overlap each other. (The observed 10 mV difference between them is probably not significant when we consider the possible error in attempting to match the actual electrode areas of the two electrodes.) This result shows that the behavior at high η_c is independent of whether only partial ionic blocking or more-or-less complete blocking takes place.

Figure 4 also shows that the linear region can be shifted by changing p_{O_2}. The observed shift of cathodic overpotential is 250 mV between p_{O_2} values of 2.3×10^{-10} and 1.2×10^{-5} atm. Comparison with the calculated value 251.3 mV based on Eq. [14], shows that there is very good agreement.

By changing the electrode material from Pt paste to Au paste, it was demonstrated that the reduction phenomenon is unrelated to the type of metal used for the cathode. We first prepared a sample with both sides having Pt paste electrodes, and then in turn, replaced each electrode with Au paste, measuring the cathodic I-η curve in each case. The results are shown in Fig. 5, which demonstrates that Pt paste and Au paste give the same cathodic curve in the linear region. (The deviation from linearity at the upper current limit will be discussed later.) On the other hand, Fig. 5 shows that the anodic overpotential is very dependent on the type of metal electrode. Figure 6 shows that it also depends strongly on the structure of the electrode and on the p_{O_2} of the ambient gas. The corresponding cathodic curves, however, consistently show

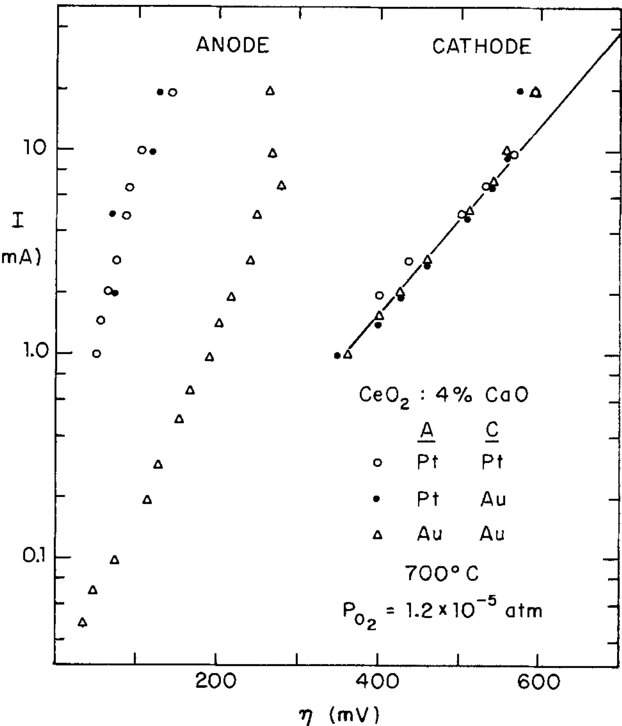

Fig. 5. Anodic and cathodic I vs. η curves for different combinations of Pt paste and Au paste electrodes. (For clarity of the figure, cathodic data at lower overpotentials are omitted.)

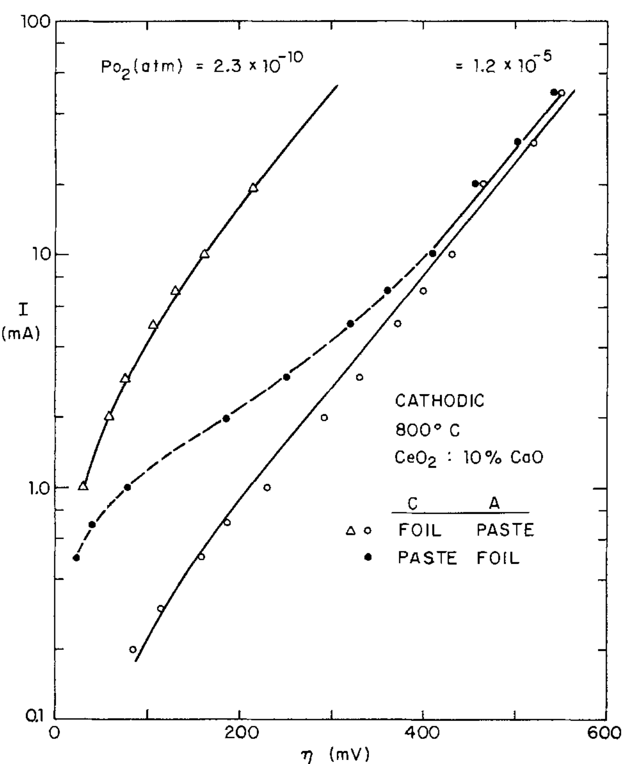

Fig. 4. Comparison of cathodic overpotential curves for Pt paste and Pt foil cathodes at two different oxygen partial pressures. The reference electrode is always Pt paste. Solid lines are the fit to the Wagner equation.

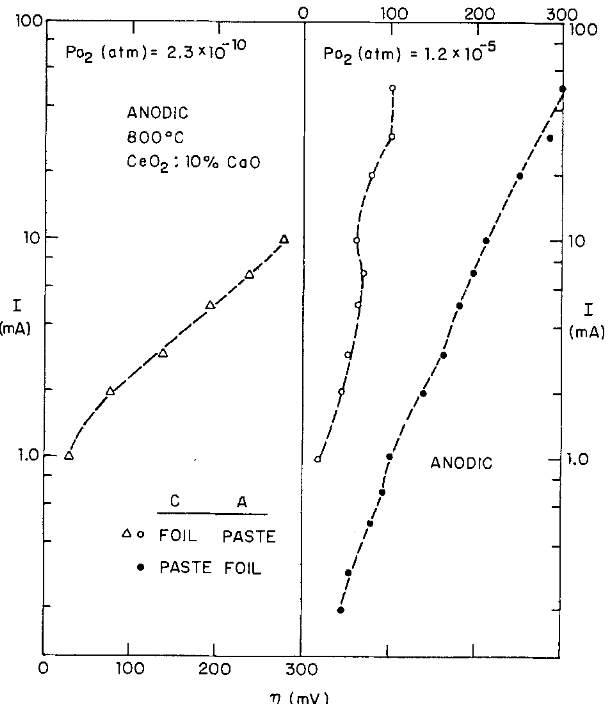

Fig. 6. Anodic I vs. η curves for different electrode materials and different oxygen partial pressures.

the linear region with slope $e/2.3\ kT$ and intercept determined by Eq. [13] and [14].

As a final test of the applicability of the Wagner model to cathodic behavior in the reduction range, we employed Eq. [10] to calculate values of t_e^0 from the intercepts, $\ln J_e^0$, of the linear plots, after obtaining σ_i^0 either from d-c four-probe measurements or from the *IR* drop in regions where the Butler-Volmer equation is obeyed (1). In this way, t_e^0 was obtained over the temperature range 500°-900°C with calcia concentration in the electrolyte ranging from 1 to 15%. These t_e^0 values are collected in Fig. 7 and compared with values from other sources (7, 9), obtained by using Eq. [15] and the fact that σ_i^0 is independent of p_{O_2}. In general, good agreement is obtained.

In these experiments, the use of the reference electrode was very important for the correct determination of t_e^0. In fact, if the cathode-to-anode potentials were used to determine t_e^0, values at least three times smaller would have been obtained, and much of the good agreement in Fig. 7 would be lost. It would therefore appear that the failure of Brook *et al.* (10, 11) to obtain satisfactory values of t_e^0 relates to their application of the theory with the full anode-to-cathode potential, *E*.

In view of the fact that all four tests suggested at the end of the Theory section have given the predicted results, we conclude that it is valid to apply the modified Wagner theory (Eq. [9] and [10], or [8] with η_c substituted for *E*) to the present experiments, even though blocking is not complete and $\eta_a \neq 0$.

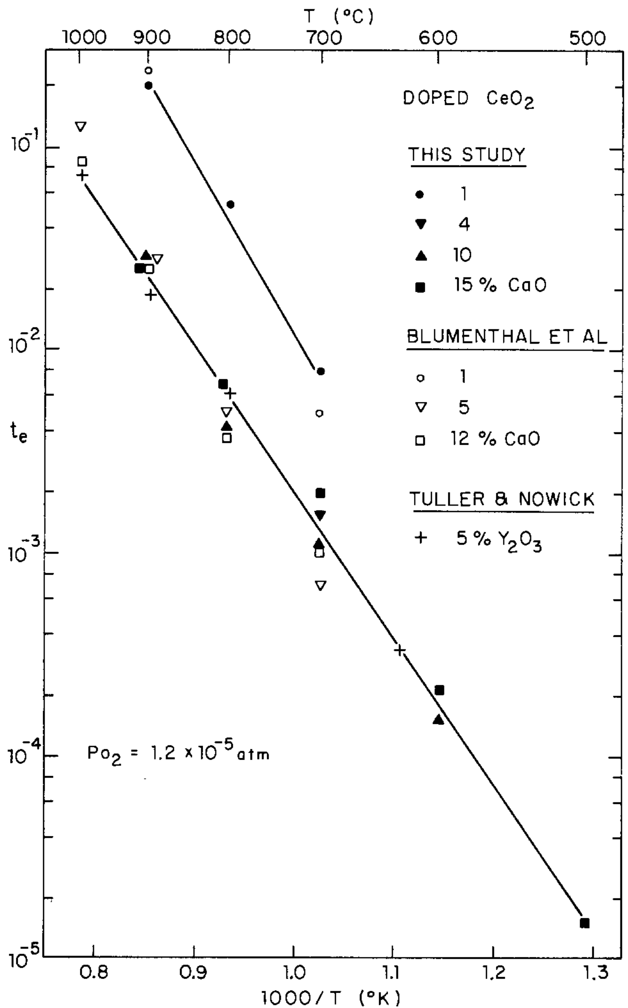

Fig. 7. Values of the equilibrium electronic transference number t_e^0 as a function of temperature for various doped ceria electrolytes. Results obtained from the present work are compared with those obtained previously by other methods.

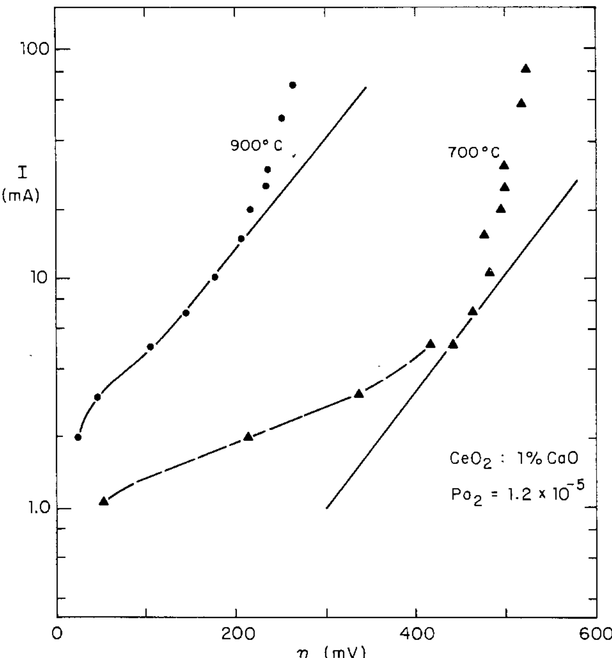

Fig. 8. Cathodic *I* vs. η curves for a CeO_2:1% CaO electrolyte at two temperatures, showing early departure from the straight lines of slope $e/2.3\ kT$ (the solid lines).

If we consider the straight-line region with slope $e/2.3\ kT$ as the first increase of current beyond the cathodic limiting-current region, then, as already noted in Fig. 5, a second increase of current (to values above the straight line) occurs at still higher overpotentials. This phenomenon manifests itself more strikingly the lower the dopant concentration in the electrolyte. For example, Fig. 8 shows the cathodic results for a 1% calcia-doped ceria sample at 700° and 900°C, compared against straight lines of slope $e/2.3\ kT$ (the solid lines). Clearly, the departure from linearity occurs sooner in this case than for the electrolytes with higher CaO content. Table I further demonstrates that the point of departure from Eq. [9] occurs earlier the lower the CaO dopant concentration in the electrolyte, and that this departure is correlated with the ionic conductivity. The reason for this second increase of current is still somewhat obscure, although it may be related either to a nonconstant chemical potential of oxygen ions (12) or to electrons no longer obeying ideal solution theory (13).

It is desirable next to discuss the substantial anodic polarization that is observed in these experiments. Undoubtedly, such polarization must be traced to the presence of a residual ionic current, for it has been shown (1) that the charge transfer process gives rise to an anodic overpotential obeying a Tafel equation. Relating the anodic overpotential to a residual ionic current is also consistent with the observation that the anodic overpotential is larger with Au paste or Pt foil at the anode than with Pt paste (see Fig. 5 and 6). According to a separate study of polarization phenomena at lower overpotentials with Au paste and Pt foil electrodes (14), both of these electrodes yield anodic

Table I. Effect of CaO content on the value of η_c at which departure from the Wagner equation occurs, and comparison with ionic conductivity (σ_i^0). (All results obtained at 700°C and $p_{O_2} = 10^{-5}$ atm.)

currents considerably lower than that obtained with Pt paste electrodes for a given anodic overpotential, because the electrode reaction is limited by lateral diffusion along the interface rather than by the charge transfer reaction.

Transient Behavior

Moderate time-scale effects.—The anodic and cathodic decay curves, $\eta(t)$, following current interruption behave quite differently in the reduction range than they do in the concentration-polarization range (2). Most strikingly, while the decay occurs in periods less than 10^{-2} sec for the lower overpotentials, in the reduction range the cathodic overpotential remains close to its initial value after current interruption for periods as long as 10^0-10^2 sec, depending on the degree of polarization, the ambient gas, and the temperature. Typical cathodic recovery curves for the reduction range are shown as solid circles in Fig. 9 on a log time scale and in Fig. 10 on a linear time scale. The time for complete recovery, τ_R, is dependent on the thickness of the electrolyte, and, in fact, increases approximately in proportion to the thickness. Thus, in Fig. 10, τ_R is 60 and 200 sec for lines A (thickness 0.60 mm) and B (thickness 1.74 mm), respectively.

In the same polarization range, the anodic overpotential decay curve behaves abnormally, relative to its behavior at lower overpotentials (2). Starting from a positive overpotential, it decays across the zero line and then becomes negative. After reaching a maximum negative value, it then recovers to the zero line, as shown by the open circles in Fig. 9. Usually, we observe that the maximum negative value reached by the anode is close to the corresponding cathodic value at the same time, and that the subsequent course of recovery is almost the same for both electrodes. Correspondingly, the decay curve from anode to cathode (which we call the "total decay curve") stays at or close to zero during this recovery period.

The return of the anodic overpotential to zero following interruption of the current is attributed to the discharge of the double layer associated with the anodic polarization (2). The subsequent crossing of the zero line, with the anodic overpotential going substantially negative before decaying back to zero, suggests that

Fig. 9. the oxygen activity at the anode falls below the thermal equilibrium value.

At steady state, the region of the electrolyte adjacent to the cathode is reduced, and, after the interruption of the current, the concentration of oxygen must return to its original thermal equilibrium value. The results of Fig. 9 suggest that, on a short time scale, the uptake of oxygen from the gas phase proceeds very slowly, *i.e.*, the cathode is effectively baffled from the oxygen gas. Therefore, in the meantime, oxygen diffuses across from the anode (which also has essentially no uptake of oxygen on this time scale). Thus, the concentration of oxygen at the anode will first be depleted until it reaches approximately the same value as that of the cathode, at which point diffusion will cease. This explains qualitatively why the anodic decay curve crosses over the zero line and goes negative to the point where it joins the cathodic curve. In attempting to develop this concept more quantitatively, we employ a model similar to that of Weiss (15), except that the boundary conditions involved are different.

There are two types of charge carriers inside the reduced electrolyte: oxygen vacancies and electrons, and these must diffuse together to maintain charge balance (ambipolar diffusion). Since the concentration of electrons is much smaller than that of the oxygen vacancies (when the current is not too great), the redistribution of oxygen activity is controlled by the diffusion of the electrons (16). Considering the structural arrangement of the electrodes (Fig. 1), we initially use the one-dimensional diffusion equation. Assuming $f(x, t)$ is the electron concentration at position x and time, t, Fick's equation is then given as

$$\partial f(x,t)/\partial t = D_e \partial^2 f(x,t) \partial x^2 \qquad [16]$$

D_e being the diffusion coefficient of the electrons.

For complete blocking at the electrodes, the boundary conditions at the anode ($x = L$) and cathode ($x = 0$) are

$$\partial f(0,t)/\partial x = \partial f(L,t)/\partial x = 0 \qquad [17]$$

In order for the diffusion flux to be constant across the sample, the initial distribution of electron concentration must be linear along the sample and given by

$$f(x,0) = f(0,0) + [f_0 - f(0,0)]x/L \qquad [18]$$

where f_0 is the thermal equilibrium concentration of electrons at the anode. With these conditions, Eq. [16] can be easily solved to obtain, for $x = L$ and $x = 0$, the respective solutions

$$f\left({L \atop 0},t\right) = [f_0 + f(0,0)]/2 \pm (4/\pi^2)[f_0 - f(0,0)] \sum_{\substack{n \\ \text{odd}}} (1/n^2) \exp(-D_e n^2 \pi^2 t/L^2) \qquad [19]$$

Now, using the Nernst law together with Eq. [15] we find that the anodic and cathodic transient overpotentials (relative to a reference electrode in equilibrium) are given, respectively, by

$$\eta_a(t) = (kT/e) \ln f_0/f(L,t) \qquad [20]$$

$$\eta_c(t) = (kT/e) \ln f(0,t)/f_0 \qquad [21]$$

Inserting Eq. [19] into Eq. [20] and [21] gives the desired expressions for the decay curves. For numerical computation, the ratio $f(0,0)/f_0$ is determined from the value of the initial cathodic overpotential following interruption. This leaves only the diffusion coefficient D_e as an adjustable parameter. The fitted curves to the data of Fig. 9, both for the anode and cathode, are presented by the solid lines. This fitting was obtained with the value $D_e = 10^{-4}$ cm^2/sec, which, for 800°C, is consistent with the results of a previous study (17). We see that the calculated cathodic overpotential remains almost constant, decaying only slightly, while the anodic overpotential changes rapidly until it finally joins the cathodic curve. The data of Fig. 9 also show that for two different electrolyte thicknesses, $L_1 = 0.06$ cm and $L_2 = 0.174$ cm, the two anodic curves are shifted in their time scales by an amount proportional to $(L_2/L_1)^2$, as required for a diffusion process.

Figure 9 shows fair agreement between the calculated curve and the initial negative anodic data. At the tail end of the region of fitting, however, the result is poor, showing that the total number of electrons remaining at the end of this stage is lower than calculated. Possible reasons for such a departure are related to electrolyte reoxidation as well as to the occurrence of secondary diffusion out of the region of the electrodes (as will be discussed later). On the other hand, because of the porous structure of the electrodes, some lateral diffusion must be required, so that treatment in terms of one-dimensional diffusion must inevitably be too idealized.

Thus far, we have attempted to interpret only the first stage of decay curves such as those of Fig. 9. The recovery that takes place after the anodic curve has joined the cathodic is considered to be the second stage. As found in Fig. 10, the total time, τ_R, needed for recovery in this stage is approximately proportional to the thickness of the electrolyte. The simplest assumption we can make for this stage is that the rate of uptake of oxygen from the electrodes is a constant. (Clearly, this condition must break down at some point before the electrolyte is completely reoxidized.) Since, during the first stage, the concentration gradient between anode and cathode levels out, we can describe the recovery stage in terms of an average electron concentration, say $c(t)$, instead of $f(x,t)$. Thus, the equation for $c(t)$ can be given as

$$SLdc(t)/dt = -2KS \qquad [22]$$

the solution for which is

$$c(t) = c(0) - (2Kt/L) \qquad [23]$$

where S is the surface area of the electrode and K is the constant rate of uptake oxygen atoms per unit area of either electrode. The quantity $c(0)$ is the initial value of $c(t)$, which is obtained from Eq. [19], setting $t \to \infty$. Thus, the predicted recovery curve is

$$\eta(t) = -(kT/e) \ln \left\{ \frac{(c(0) - (2Kt/L))}{f_0} \right\} \qquad [24]$$

As soon as $c(t) = f_0$ the recovery process must stop. Therefore the time to complete recovery, τ_R, is given by

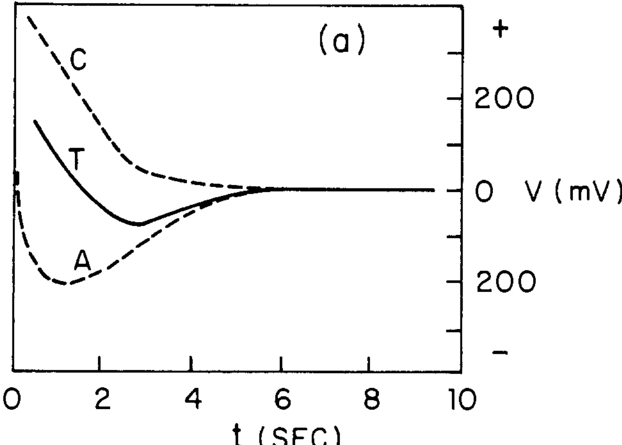
$$\tau_R = (L/2K)[c(0) - f_0] \simeq (L/2K)c(0) \qquad [25]$$

where the last inequality holds because $c(0) >> f_0$. At $t = \tau_R$, $\eta(t)$ must abruptly become zero.

The data of Fig. 10 have been fitted to Eq. [24] with the initial value and τ_R as the only parameters. The results of this fitting are shown by the solid lines. Considering the simplicity of the assumptions made, the fit is quite good, and the data indeed show a discontinuity in $d\eta/dt$ at $t = \tau_R$. The K values obtained for curves A and B differ slightly from each other, K for curve B being 15% smaller than that for curve A.

In order to obtain a numerical value for K, an estimate of f_0 is required. Using $D_e = 10^{-4}$ cm^2/sec and the values of t_e^0 and σ_i^0 determined for this sample, allows a rough calculation of f_0. The corresponding value of K, expressed as a current density, is ~4 mA/cm^2 which is similar in magnitude to the limiting current, I_l. This is not surprising, since both quantities are manifestations of the limiting rate at which the electrodes can furnish oxygen.

In all cases of transient behavior reported thus far, we have made every effort to keep both anode and cathode alike in both structure and geometry. If, how-



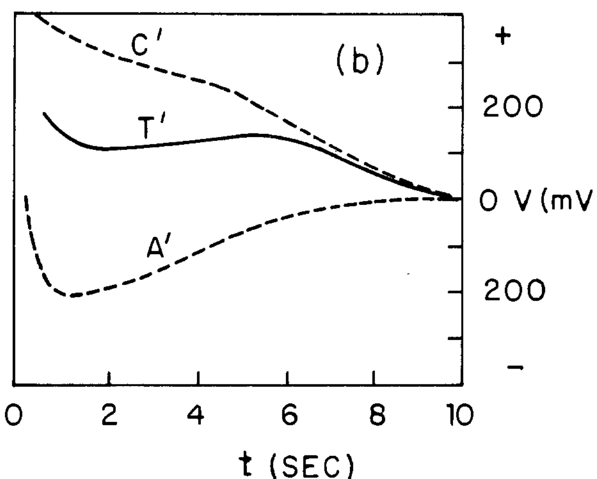


Fig. 11. Decay curves for anodic (A and A′), cathodic (C and C′) and total (T and T′) overpotential for a CeO_2: 8% CaO electrolyte at 900°C and $p_{O_2} = 0.94 \times 10^{-8}$ atm. Polarization current had been 30 mA. Two electrodes are used: Pt paste and a composite (Pt paste/Pt foil): (a) case where anode is the composite electrode; (b) cathode is the composite.

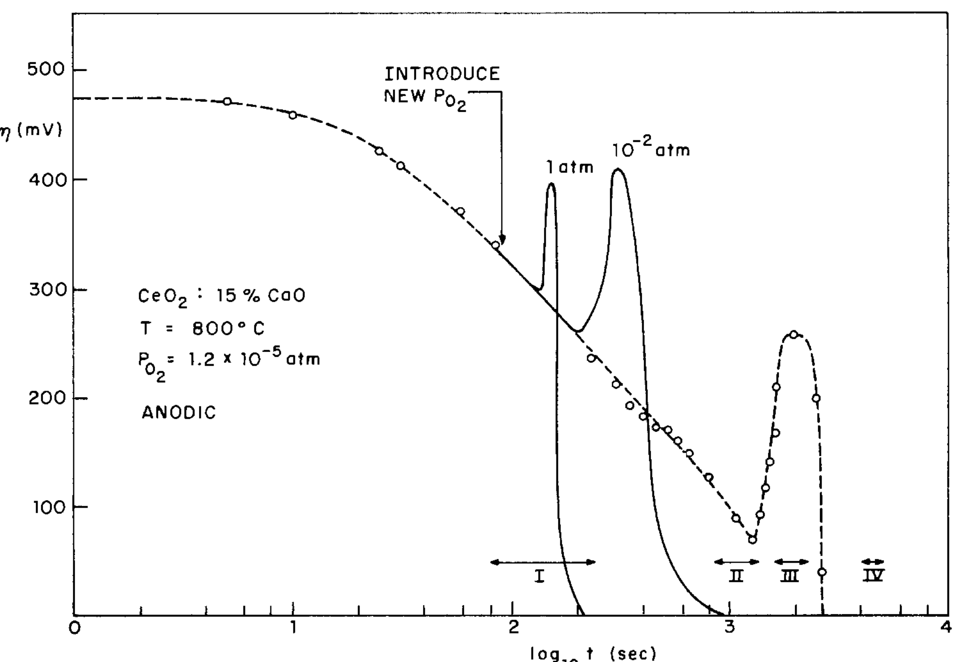
ever, one of the electrodes is baffled to the ambient oxygen gas, its recovery proceeds more slowly than that of the other one. For example, for the data of Fig. 11a, the anode was composed of two layers: platinum paste/platinum foil, while the cathode was the usual platinum paste. As shown in this figure, the second-stage recovery of line A (anodic) was much slower than that of line C (cathodic). Therefore, the total decay curve (line T) now crossed the zero line and became negative. With reversed polarity, the result is shown in Fig. 11b; the cathodic overpotential (line C′) now decayed more slowly than the anodic (line A′), while the total decay curve (line T′) showed a hump and did not cross the zero line. (In both cases, lines A and A′ started from a positive potential, but the initial decay was so rapid that only the part of decay curve after the sign reversal can be seen.) Such results indicate that the uptake of oxygen is a property of the electrode, which functions as a catalyst. At this point we cannot say what is the rate-determining step for this process, but the similarity between K and I_1, suggests that it may be related to adsorbed oxygen on the Pt surface.

Results such as these, especially the possibility for the total decay curve to become negative are of interest because such observations are occasionally reported (18) and questioned (19).

Long time-scale effects.—If we polarized the electrolyte at higher currents, but still in the straight line (e/kT slope) region, the decay curve for both anode and cathode could persist beyond 10^3 sec. Also, as shown in Fig. 12, the pattern of the curves changed dramatically in the tail of the decay, *viz.*, $\eta(t)$ rose to produce a hump. Both anode and cathode gave the same type of decay curve, except that the hump did not appear at exactly the same time for the two electrodes. Thus, the total decay curve, after remaining at zero for some time, rose to give a hump owing to this asymmetry.

Because the decay proceeded over such a long time, it became possible to use a small a-c signal to study the conductivity of the electrolyte at various stages. Four different regions (as marked in Fig. 12) were studied. The results are in Table II, where the parallel resistance measured at 10 Hz is listed. As shown, this resistance, R, increased steadily to region IV. This continuous increase in R suggests that reoxidation of the reduced electrolyte is taking place over the time period of the hump.



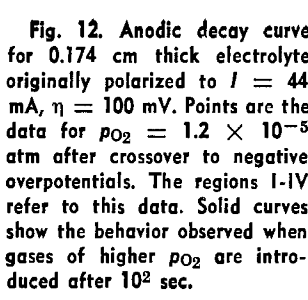


Fig. 12. Anodic decay curve for 0.174 cm thick electrolyte originally polarized to $I = 44$ mA, $\eta = 100$ mV. Points are the data for $p_{O_2} = 1.2 \times 10^{-5}$ atm after crossover to negative overpotentials. The regions I-IV refer to this data. Solid curves show the behavior observed when gases of higher p_{O_2} are introduced after 10^2 sec.

Because of the long decay time, it was also possible to study the effect of a change in the partial pressure of oxygen, by introducing new gas into the sample chamber during the course of the decay. As shown in Fig. 12, the hump could be shifted, such that the higher the p_{O_2}, the earlier it appeared. Also, the size of the hump was smaller, the higher the p_{O_2} of the introduced gas. In addition, the response of the decay to the changed gas was very much dependent on the flow rate of the gas, a greater flow rate giving the same effect as a higher p_{O_2}.

In our interpretation of the first stage of the decay curves as electronic diffusion and the second stage, or recovery, as the uptake of oxygen from the electrodes, we neglected to consider secondary diffusion, by which electrons migrate out of the region between the two working electrodes, causing partial reduction of the area adjacent to the reference electrode. This process clearly involves a longer time constant than the primary (cathode-to-anode) diffusion because the electrode separation is larger ($\sim$6-10 mm as against 1 mm from cathode to anode). It is this process that we believe is responsible for the long time decay in samples carried to higher overpotentials, as in Fig. 12.

In order to see why secondary diffusion enters in this case and not in those for lower overpotentials, we make a comparison of various relevant time constants. For primary diffusion a time constant τ_D may be defined by

$$\tau_D = L^2/D_e\pi^2 \qquad [26]$$

based on Eq. [19], where L is the cathode-to-anode distance. A smilar quantity τ_D', for secondary diffusion may be defined by the same expression, except that L', the distance from reference to working electrode, replaces L. Finally, for the recovery process we have defined the time, τ_R, to complete recovery by Eq. [25]. In Table III, these three time constants are compared for three cases: A and B are the corresponding two runs in Fig. 10, while C is the run represented by open circles in Fig. 12. In the latter case, the calculation of τ_R is made using the same K value as for A and B; however, since p_{O_2} is substantially lower in this case, K should actually be lower, and therefore τ_R larger than the value calculated. For cases A and B, Table III shows that $\tau_D << \tau_R$, and that τ'_D is large enough that appreciable secondary diffusion is not expected before recovery is complete. This result vindicates our previous neglect of the secondary diffusion process. In case C, however, τ_R is so large [because $\eta(0)$, and therefore $c(0)$ is large], that there is sufficient time for secondary diffusion to occur prior to the recovery process. In fact, the value of τ_D' is consistent with the observed decay time in Fig. 12. Accordingly, we interpret the decay process prior to the hump in Fig. 12 as due to secondary diffusion.

It then remains to explain the hump. The fact that the time of occurrence of the hump depends on p_{O_2} (Fig. 12) and on the rate of gas flow, all suggest that the hump is related to the uptake of oxygen from the electrodes. The results of the a-c study (Table II), showing that the resistance continues to increase throughout the range of the hump, is also consistent with the idea that reoxidation of the electrolyte is taking place.

In interpreting the hump, we propose that uptake of oxygen occurs at the reference as well as the working electrodes. Since secondary diffusion is incomplete, the chemical potential of oxygen at the reference electrode is closer to that of the ambient gas than that of either the cathode or anode. Thus, the reference starts at a lower value of $c(0)$ and will reach equilibrium before the working electrodes. The result is that $|\eta|$ increases as long as the reference is being reoxidized; once it reaches equilibrium, however, the decay process continues in the usual way. Therefore, a hump is produced. A more quantitative examination of this model gives a good fit to the data of Fig. 12 for the time period $>10^3$ sec.

Table II. Values of a-c parallel resistance measured at 10 Hz in the four regions shown on Fig. 12

Region	R (Ω)*
(a) from anode to cathode	
I	11.3
IV	102.1
(b) from reference electrode to anode	
II	138
III	175
IV	413

Table III. Calculated time constants for primary diffusion (τ_D), secondary diffusion (τ_D'), and recovery (τ_R) for three cases of a CeO_2:15% CaO electrolyte at 800°C. (In each case, L' is taken to be 8 mm, and $D_e = 10^{-4}$ cm²/sec.)

	$\eta(0)$ (mV)	L (mm)	p_{O_2} (atm)	τ_D (sec)	τ_D' (sec)	τ_R (sec)
A	310	0.60	10^{-4}	3.6	650	60
B	310	1.74	10^{-4}	31	650	200
C	480	1.74	10^{-5}	31	650	>1255

Summary

The results for the steady-state behavior show that the Wagner polarization cell treatment describes well the cathodic data (η_c *vs.* I) even though blocking of the ionic flow is incomplete. From these data, reliable values of the electronic transference number have been obtained.

The transient behavior following current interruption can be interpreted according to the following concepts:

1. Primary diffusion of electrons from cathode to anode constitutes the first stage of the decay curves, in which the anodic overpotential crosses the zero line and goes negative to join the cathodic overpotential.
2. Secondary diffusion of electrons out of the region of the working electrodes causes reduction in the region near the reference electrode. This stage only occurs if $\eta(0)$ is sufficiently high that $\tau_D' > \tau_R$.
3. Recovery of both working electrodes takes place by means of a constant rate of uptake of oxygen through the electrodes. This stage can be a monotonic decrease in $|\eta|$, or it can give rise to a hump if partial reduction of the region near the reference electrode had occurred.

Acknowledgments

The authors are deeply indebted to Dr. D. O. Raleigh whose extensive comments led to a great improvement of this paper. Part of the experimental work was carried out under a grant (DMR 76-80157) from the National Science Foundation. The later experiments and much of the interpretation was sponsored by the Department of Energy, under contract ER-78-S-02-4693.

Manuscript received June 14, 1979. This was Paper 146 presented at the Seattle, Washington, Meeting of the Society, May 21-26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Columbia University.

The Electrochemical Behavior of Aluminum in the Low Temperature Molten Salt System n Butyl Pyridinium Chloride: Aluminum Chloride and Mixtures of This Molten Salt with Benzene

J. Robinson[1] and R. A. Osteryoung*[,2]

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The aluminum deposition and stripping processes at tungsten, platinum, and glassy carbon electrodes in the low temperature molten salt system, n butyl pyridinium chloride: aluminum chloride, and the 50 volume percent (v/o) mixture of this molten salt with benzene have been investigated, using a variety of electrochemical techniques. At all three electrodes, and in both solvent systems, the deposition reaction in slightly acidic melts, the reduction of $Al_2Cl_7^-$ ions, was found to involve a nucleation process while at the tungsten and platinum electrodes underpotential deposition was also observed. Reduction of the n butyl pyridinium cation was found to occur at $-1.1V$ *vs.* Al(2:1 melt) which is positive of the reduction potential of $AlCl_4^-$ ions and therefore aluminum deposition in basic melts was not observable. Studies of the stripping of aluminum from inert substrates showed that aluminum is very slowly corroded in acidic melts, and melt-benzene mixtures, by traces of oxidizing impurities while in basic systems aluminum reduces the n butyl pyridinium cation. Potentiometric titration of the 50 v/o melt-benzene mixture showed that the acid-base properties of this system are defined, as in the pure melt, by the equilibrium

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^-$$

with an equilibrium constant of 2.2×10^{-13} at 30°C.

Chloroaluminate melts (alkali metal chloride-$AlCl_3$ mixtures), in view of their interesting acid-base properties, have recently received considerable attention from molten salt chemists, and a number of reports of electrochemical and spectroscopic studies of both organic, and inorganic, species in these media have appeared in the literature. One of the most thoroughly investigated areas has been the electrochemistry of aluminum, both at aluminum electrodes (1-5) and also at foreign substrates (6). Initial reports of the anodic dissolution of aluminum in molten NaCl:$AlCl_3$ (7, 8) indicated that at low current densities the observed current efficiencies, as determined by weighing the electrode, were significantly greater than required for the three electron oxidation described by Eq. [1]

$$Al(0) - 3e^- \rightleftarrows Al(III) \quad [1]$$

This behavior was attributed to the formation of univalent aluminum which was in some way stabilized by the melt. A subsequent study (5) has however shown that the dissolution current efficiencies in excess of 100% were in fact caused by corrosion of the aluminum electrode by impurities in the melt, and that by careful melt purification procedures current efficiencies very close to 100% can be achieved for both the aluminum deposition and the anodic stripping process.

It is well known (9) that as the alkali metal chloride:$AlCl_3$ ratio in a chloroaluminate melt is varied the nature of the aluminum containing ion changes; in basic melts (excess alkali metal halide) mainly $AlCl_4^-$ ions are present whereas in acid melts the $Al_2Cl_7^-$ ion

Key words: anode, voltammetry, metals.

becomes predominant. Letisse and Tremillon (1) have proposed that aluminum deposition is possible from either of these ions. In acidic melts the reaction is

$$4Al_2Cl_7^- + 3e^- \rightleftarrows Al\downarrow + 7AlCl_4^- \quad [2]$$

whereas in basic melts it becomes

$$AlCl_4^- + 3e^- \rightleftarrows Al\downarrow + 4Cl^- \quad [3]$$

Rolland and Mamantov (6) have observed both these deposition reactions at glassy carbon, platinum, and tungsten electrodes and have made a thorough study of the reduction of $Al_2Cl_7^-$ ions in slightly acidic melts. They have shown that nucleation processes are important at all three electrodes and also that alloy formation occurs on the platinum electrode.

In this laboratory we have recently been particularly interested in the development of low temperature nonprotonic molten salt systems analogous to the alkali metal chloroaluminates. This work has shown that suitable solvents can be made from mixtures of alkyl pyridinium halides and aluminum halides. The first such system studied was the 2:1 $AlCl_3$: ethyl pyridinium bromide mixture, which was molten at room temperature, and it was demonstrated that this solvent, and its mixtures with benzene, could be successfully used for organic and organometallic electrochemistry (10-12), as well as for photochemical investigations (13). Unfortunately as the $AlCl_3$:ethyl pyridinium bromide ratio was varied from 2:1 the melting point of this system increased sharply, the mixture being molten at room temperature only for the 2:1 system. It has recently been shown (14) that mixtures of n butyl pyridinium chloride (BuPyCl) and $AlCl_3$ are molten at, or near, room temperature for the entire composition range from 2:1 to 0.75:1 ($AlCl_3$:BuPyCl). This system should therefore be very useful for studying the Lewis acidity dependent chemistry and electrochemistry of a variety of inorganic species and of organic species which are too volatile to be studied in the alkali metal chloroaluminates. As with these latter melts, variations in the composition of the low temperature molten salt system cause changes in the aluminum-containing species in the melt. This behavior has been investigated by Raman spectroscopy (15) and potentiometric techniques (16) and it has been shown that the acid-base properties of the melt are fully described by the equilibrium in Eq. [4] (16)

$$2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^- \quad [4]$$

for which the equilibrium constant, K, was shown to be less than 3.83×10^{-13} at 30°C. The exact determination of K from potentiometry with an Al electrode is precluded as Al reduces the butylpyridinium cation in basic melts; however use of an $NiCl_2$ electrode (17) to measure the Cl^- ion concentration in basic melts suggests that the true value of K lies close to the above value (18). This very low value for K implies that in the 1:1 melt nearly all the aluminum is present as $AlCl_4^-$ ions with only very small concentrations of Cl^- and $Al_2Cl_7^-$ ions being present; any $AlCl_3$ added to a 1:1 melt complexes with $AlCl_4^-$ ions, according to Eq. [4] to form $Al_2Cl_7^-$ ions such that in the 2:1 system the Al is present almost entirely as $Al_2Cl_7^-$. Any BuPyCl added to a 1:1 melt results in an increase in the free Cl^- ion concentration. This is in contrast to the behavior observed in alkali metal chloroaluminates where large concentrations of free Al_2Cl_6 molecules are also present in acid melts (9).

Low temperature baths for the electrolytic deposition of aluminum have long been of interest and Hurley and Weir (19) have shown that bright aluminum deposits, several tenths of a millimeter thick, can be formed by electrolysis of a 2:1 mixture of $AlCl_3$ and ethyl pyridinium bromide to which either benzene or toluene has been added until a two-phase system starts to form. By careful engineering and the use of addition agents the deposition of even thicker layers is possible (20). Recent work in this laboratory (21) has shown that the addition of benzene to $AlCl_3$: BuPyCl melts results in an increase in the conductivity of the medium due to a sharp reduction in the viscosity, but ^1H and ^{13}C NMR studies (21) indicate that the benzene does not complex with any species in the melt. This present paper is concerned with an investigation of the electrochemical behavior of Al in the $AlCl_3$:BuPyCl and the 50 v/o benzene-$AlCl_3$: BuPyCl systems. A variety of electrochemical techniques have been used including cyclic and pulse voltammetry, potentiometry, and coulometric techniques at three different electrodes, tungsten, glassy carbon, and platinum. The results obtained are compared to those observed in the alkali metal chloroaluminates.

Experimental

The procedure for the preparation of n butyl pyridinium chloride from n butyl chloride and pyridine (Fisher ACS) has been given in a previous publication (14) and consists essentially of refluxing the two reactants together and purifying the resulting product by recrystallization from acetonitrile-ethyl acetate mixtures. The $AlCl_3$:BuPyCl melts are then prepared by adding carefully sublimed $AlCl_3$ (Fluka A.G. iron-free) to the BuPyCl. This mixing is highly exothermic and care must be taken to ensure that the temperature does not rise above 100°C or decomposition may occur. The melt-benzene mixtures were drilled to permit the introduction of the reference and secondary electrode compartments which were isolated from the bulk of the melt by fine porosity glass frits. Holes were also drilled in the cap for the working electrode and the thermocouple well. Unless otherwise stated the reference electrode was an Al wire (5N Alfa inorganics) immersed in a 2:1 $AlCl_3$:BuPyCl melt, and all potentials are quoted with respect to this electrode. The secondary electrode was also a coiled Al wire. The essential details of the experimental techniques, electrochemical instrumentation, construction of electrodes, and operation of the dry box (Vacuum Atmospheres Company), in which all experiments were carried out have been presented in an earlier publication (22).

In order to achieve reproducible electrochemical results, great care had to be taken in preparing the electrode surfaces. All the electrodes were polished to a mirror-like finish using alumina (Type B Fisher), washed and dried, and then transferred into the dry box where they were again polished on alumina to remove any surface oxide films. The platinum and glassy carbon electrodes were then introduced into the melt and held at 1.5V *vs.* Al for about 20 min prior to commencing experiments. To obtain reproducible results on the tungsten electrode, the electrode potential was cycled into aluminum deposition several times before voltammograms were recorded.

Previous studies (15, 16) indicate that any $AlCl_3$ added to a 1:1 melt will complex with tetrachloroaluminate ions to form $Al_2Cl_7^-$. Melts of known $Al_2Cl_7^-$ concentration were therefore prepared by adding volumes of a 2:1 melt (all aluminum present as $Al_2Cl_7^-$) to a 1:1 melt or a 1:1 melt to which 50% by volume of benzene had been added.

The titration of Cl^- ions in a 50 v/o benzene-melt mixture with $Al_2Cl_7^-$ ions was carried out in the following manner. A 46:54 $AlCl_3$:BuPyCl melt was prepared and benzene was added to give a 50 v/o mixture (attempts to make 50 v/o benzene mixtures with melts more basic than this resulted in the precipitation of BuPyCl). An Al indicator electrode was then introduced into the melt and the potential between this and an Al reference electrode in a 50 v/o benzene-2:1 melt was measured using a high impedance voltameter. Weighed amounts of 50 v/o benzene-2:1

melt were then added and the potential difference between the indicator and reference electrodes was recorded after each addition. From this data the potentiometric titration curve was constructed.

Results and Discussion

Potentiometric titration of the benzene-containing melt.—The titration of Cl^- with $Al_2Cl_7^-$ in chloroaluminates has proved a useful technique for determining the equilibria that govern the acid-base properties of these melts (9, 16). It was decided therefore that this would be a useful approach for investigating the properties of $AlCl_3$:BuPyCl melt diluted to 50 v/o with benzene. Figure 1 shows such a potentiometric titration which was performed in such a way as to maintain the volume percentage of benzene constant. The circles represent the experimental points and the solid line is the 'best fit' theoretical curve, *vide infra.*

The equilibrium potential of an Al wire in an acid melt is determined by the equilibrium in Eq. [2] and the potential difference between two Al wires in melts of different composition is given by Eq. [5]

$$\Delta E = \frac{4}{3}\frac{RT}{\mathbf{F}}\ln\frac{[Al_2Cl_7^-]_1}{[Al_2Cl_7^-]_2} + \frac{7}{3}\frac{RT}{\mathbf{F}}\ln\frac{[AlCl_4^-]_2}{[AlCl_4^-]_1} \quad [5]$$

while a similar expression exists for Al wires in basic melts. If it is assumed that the benzene only dilutes the melt and does not complex with any of the species present it is possible, from the experimental data of Fig. 1 and Eq. [5], to calculate a value for the equilibrium constant, K, for the equilibrium described by Eq. [5]. The value of K determined in this way was 2.2×10^{-13}, which is very similar to the value determined for the pure $AlCl_3$:BuPyCl melt (16). The solid line in Fig. 1 is the potentiometric curve calculated using the above value for K; the agreement is excellent in the acid region and fairly good for basic melts. The experimental potential values for the basic melts were found to be rather unstable since, as in the pure melt the Al wire indicator electrode reduces the melt. The reduction potential of the melt is $-1.1V$ *vs.* Al and therefore all experimental potentials greater than this (the first five points of Fig. 1) represent mixed potentials; thus, as with the pure melt the calculated value for K is only an upper limit. [The mechanism of the melt reduction process will be the subject of a future publication (23).]

That the potentiometric data can be fitted successfully using the single equilibrium in Eq. [4] provides proof that the assumption that the benzene is not involved in any complexation equilibria with any of the aluminum-containing ions or Cl^- is justified. Further support for this assumption comes from the potential difference between Al wires in a 2:1 melt and a 50 v/o benzene-2:1 melt mixture which is 12 ± 1 mV; assuming that the liquid junction potential is negligible (using the redox potential of the ferrocene-ferrocinium couple as a reference it appears that this assumption is justified) the experimental potential difference agrees very well with the value of 13 mV calculated for the potential difference between an Al wire in a 2:1 melt and an Al wire in a melt in which the concentrations of $Al_2Cl_7^-$, $AlCl_4^-$ and Cl^- ions are half their values in the 2:1 system. On the basis of this evidence it can be concluded that any $AlCl_3$ added to a 50 v/o benzene-1:1 melt will complex with $AlCl_4^-$ to form $Al_2Cl_7^-$ ions as in the pure melt.

The aluminum deposition reaction.—The deposition behavior observed in the pure melt and the melt + benzene was qualitatively the same and therefore the two solvents will be discussed simultaneously. Figure 2 shows a typical cyclic voltammogram for the deposition of aluminum at a tungsten electrode in a slightly acidic melt. The large peak observed at $-0.43V$(I) can be attributed to the reduction of $Al_2Cl_7^-$ ions. Table I shows the dependence of the peak current and peak potential (at a sweep rate of 100 mV sec^{-1}) of this peak on the concentration of $Al_2Cl_7^-$ ions. It can be seen that the peak current is proportional to the concentration of this species while, as predicted for the formation of an insoluble product, the peak potential varies linearly with $\log[Al_2Cl_7^-]$. The peak labelled II corresponds to the anodic stripping of the Al deposit. This behavior is essentially the same as was observed by Rolland and Mamantov (6) in the NaCl-$AlCl_3$ system except that in the present case there is also a small peak, III, positive of the main deposition process and a corresponding stripping wave IV. The nature of these peaks is more readily investigated when the potential sweep is restricted to the potential region of peaks III and IV and is not permitted to go into bulk Al deposition; Fig. 3 shows such voltammograms at various sweep rates. It can be seen that the peak heights are directly proportional to the sweep rate and it was also observed that provided the melt remained acidic the peak height, at a fixed sweep rate, was independent of the concentration of $Al_2Cl_7^-$. When the melt was made basic the peaks III and IV disappeared. From this behavior it can be concluded that these peaks correspond to the formation and stripping of a

surface layer. Since the activity of the aluminum metal is not fixed at the start of the reduction process it is possible that underpotential deposition, *i.e.*, deposition at potentials positive of the bulk deposition, can occur. The charge, Q_m, under either of the peaks III or IV is approximately 2.4 × 10^{-4} C cm^{-2}, which if it is assumed that peak III corresponds to the underpotential deposition of Al accounts for about 1/3 of a monolayer (this value was calculated assuming the electrode to be perfectly smooth, *i.e.*, to have its geometric area. Any roughness would reduce the calculated degree of coverage). It therefore appears that a surface phase is formed which consists either of a 1/3 of a monolayer of Al or alternatively a greater degree of surface coverage occurs but only partial charge transfer takes place.

A similar type of behavior is observed at platinum electrodes, Fig. 4, except that now the underpotential deposition process appears as a slowly rising current prior to bulk deposition rather than a distinct peak. The behavior at platinum electrodes is also different in the respect that the underpotential deposition corresponds to several monolayers of aluminum and if the potential is held at a value corresponding to the underpotential deposition region for long periods of time the number of monolayers deposited can be increased somewhat. It is probable that this process at platinum electrodes corresponds therefore to alloy formation. A similar conclusion was reached concerning the deposition of Al from $AlCl_3$:NaCl melts at platinum electrodes (6). No underpotential deposition processes were observed at glassy carbon electrodes.

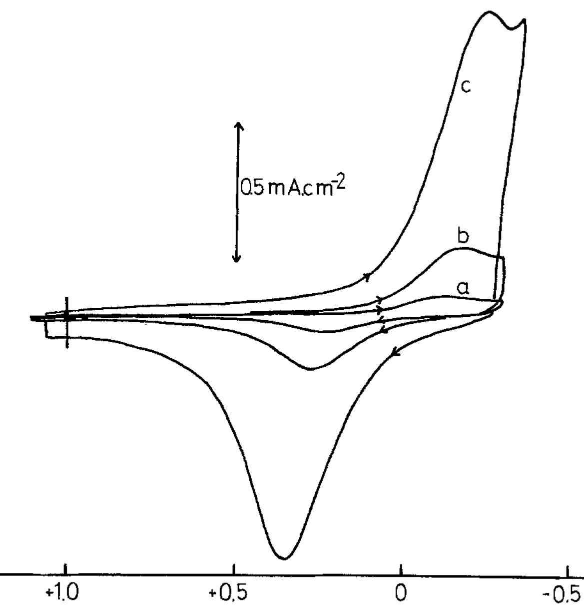

Fig. 3. Cyclic voltammograms at a tungsten electrode of 2.32 × 10^{-1}M $Al_2Cl_7^-$ in the $AlCl_3$:BuPyCl melt at 60°C. Sweep rates (a) 0.05 V sec^{-1}; (b) 0.2 V sec^{-1}; (c) 1 V sec^{-1}.

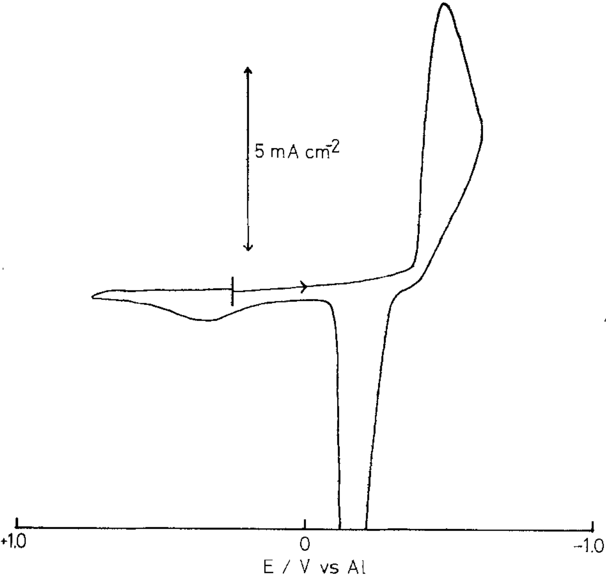

Fig. 4. Cyclic voltammogram at a platinum electrode of 1.72 × 10^{-1}M $Al_2Cl_7^-$ in the $AlCl_3$:BuPyCl melt at 60°C. Sweep rate = 0.1 V sec^{-1}.

Analysis of the voltammograms at all three electrodes and in both solvent systems shows that the peak currents for bulk Al deposition were proportional to the concentration of $Al_2Cl_7^-$ ions and the value of the peak potential became more negative as the sweep rate increased. As shown in Table II the value of the function $i_p/\nu^{1/2}$ was a constant at slow sweep rates (less than 1 V sec^{-1}) but decreased with increasing sweep rate. This type of behavior is identical to that observed by Rolland and Mamantov (6) in $NaAlCl_4$ and was attributed to the presence of nucleation processes in the deposition reaction. That this is true can readily be shown by chronoamperometry, *vide infra*, and also by the potential difference between an Al wire in the melt and the potential at which the cyclic voltammetry current increases rapidly due to bulk Al deposition. The values of this voltage difference, the nucleation overpotential, are 40 mV for tungsten and about 80 mV for platinum and glassy carbon in the pure melt at a temperature of 60°C, and are between 40 and 70 mV higher in the melt + benzene. These overpotentials are significantly greater than those observed in $AlCl_3$:NaCl melts at 175°C (6). From the peak currents at low sweep rates ($<$500 mV sec^{-1}), assuming that the deposition reaction proceeds according to Eq. [2], it is possible to calculate the value of the diffusion coefficient, D, of $Al_2Cl_7^-$. This calculation was made assuming that the peak corresponds to the reversible formation of an insoluble product and that the electrodes had their geometric areas. The values

of D calculated from the data obtained at the three different electrodes in the melt, and in the melt-benzene mixture, are given in Table III. It can immediately be seen that there is a lack of agreement between the values obtained at the three electrodes for both solvents. Similar behavior was observed for the D values calculated for $Al_2Cl_7^-$ ions in $NaAlCl_4$ at 175°C (6) and was attributed to the presence of the nucleation process. The difference in the D values calculated for the melt and the melt + benzene is very similar to the difference found for the diffusion coefficient of ferrocene in pure 2:1 $AlCl_3$:ethyl pyridinium bromide and the 50 v/o benzene-melt mixture (11). Higher values are observed in the benzene mixtures due to the much lower viscosity of this medium compared to the pure melt (21).

It can be seen in Table III that no value of D was determined when using glassy carbon electrodes in the melt-benzene mixtures. This is because reproducible cyclic voltammograms could not be recorded. This was also true of the pure melt at 40°C, with the glassy carbon electrodes, but increasing the temperature to 60°C appeared to overcome this problem and therefore all experiments in the pure melt were carried out at this temperature. A lower temperature had to be used for the melt-benzene mixtures to minimize the benzene evaporation losses. It was also observed that the glassy carbon electrode had to be maintained at a potential of about 1.5V for at least 15 min between voltammograms if reproducible results were to be obtained. This presumably allows the electrode surface to return to its initial state, a process which was accelerated by increasing the temperature. The tungsten and platinum electrodes did not require such prolonged treatment between experiments, about a minute sufficing.

As was stated earlier, chronoamperometry provides an excellent means of observing nucleation processes. At all three electrodes, rising transients were observed in both the melt and the melt + benzene when the electrode potentially was pulsed cathodically from a value of 1.0V to a value corresponding to Al deposition, indicating that the Al deposition at all the electrodes involves a nucleation step. Figure 5 shows such transients in $AlCl_3$:BuPyCl melt at the three electrodes for the same overpotential while Fig. 6 shows the result of analyzing the rising portions of some of these transients at a tungsten electrode in a slightly acidic melt-benzene mixture. It can be seen that the current varies linearly with $t^{1/2}$ which indicates that instantaneous three-dimensional nucleation is occurring followed by hemispherical diffusion controlled growth of the nuclei (24). Similar behavior was observed in the pure melt and with the other two electrodes. From Fig. 5 it can be seen that the time between the application of the pulse and the current maximum, t_{max}, was greatest for the glassy carbon electrode and least for the tungsten; the t_{max} values observed in the benzene-melt mixture were about twice those observed in the pure melt at the same overpotential.

At times greater than t_{max} the current shows the usual i proportional to $t^{-1/2}$ behavior and from a series of such chronoamperograms at a tungsten electrode it is possible to construct pulse voltammograms as is shown in Fig. 7 for the pure melt. (The larger nucleation effects observed at platinum and carbon electrodes and in the melt-benzene mixture precluded the construction of voltammograms for these conditions.) The shape of this curve is as would be predicted for the deposition of an insoluble product and a plot of $\log(i_d - i)$ vs. E (where i is the current at the potential E and i_d is the limiting plateau current) is linear

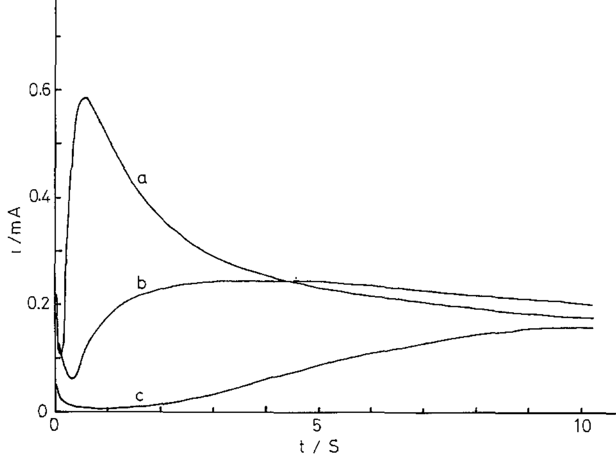

Fig. 5. Chronoamperograms for Al deposition from $AlCl_3$:BuPyCl at 60°C. The electrode materials were: (a) tungsten (0.00785 cm^2), (b) platinum (0.0612 cm^2), and (c) glassy carbon (0.0707 cm^2). The current axis for the tungsten electrode has been expanded by a factor of 10. The $Al_2Cl_7^-$ concentration was 3.6×10^{-1}M. The potential step was from +1.0V to an overpotential of −85 mV.

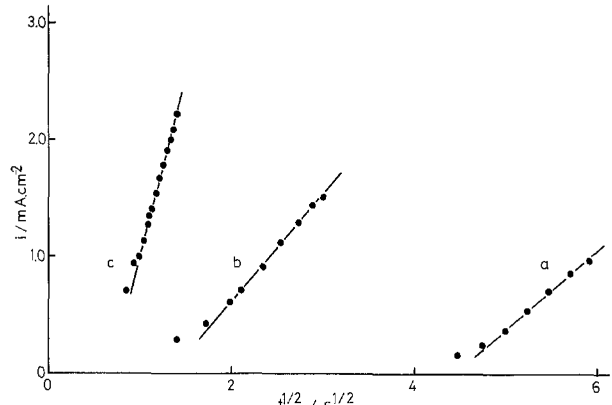

Fig. 6. i vs. $t^{1/2}$ plots for chronoamperometric data obtained at a tungsten electrode in the 50 v/o benzene-$AlCl_3$:BuPyCl system at 30°C. The $Al_2Cl_7^-$ concentration was 1.13×10^{-1}M and the overpotentials were (a) 80 mV; (b) 100 mV; and (c) 120 mV.

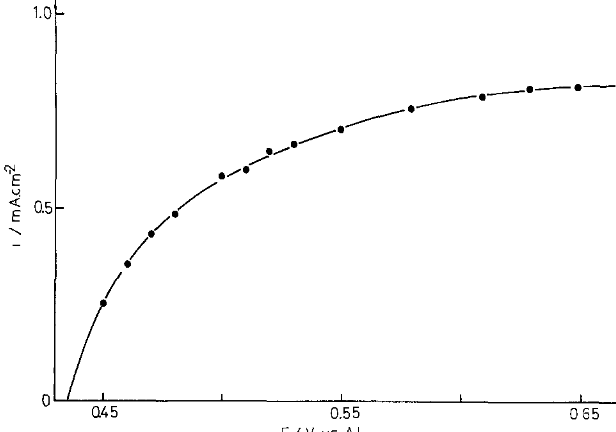

Fig. 7. Reconstructed pulse voltammogram at a tungsten electrode in a solution of 1.17×10^{-1}M $Al_2Cl_7^-$ in the $AlCl_3$:BuPyCl melt at 60°C. The pulse length was 17.5 sec.

with a slope of 144 ± 2 mV. At 60°C RT/F has a value of 66 mV therefore the observed slope corresponds to an αn_α value of 0.46. In the $AlCl_3$:NaCl melt at 175°C the deposition reaction was, on the basis of the pulse voltammetric data, found to be perfectly reversible; the quasi reversibility found in the $AlCl_3$:BuPyCl system is probably in part due to the lower temperature of the solvent. At potentials corresponding to the plateau current the current at the three electrodes shows a linear dependence on $t^{-1/2}$, for pulse times greater than about 1 sec and less than about 20 sec, indicating that the process is diffusion controlled (the high viscosity of these molten salts permits diffusion control to be maintained for much longer times than in more conventional solvents before convection effects are observed). From these straight line plots it is possible to calculate the value of D for $Al_2Cl_7^-$ ions. The values calculated for the three electrodes in both solvents are given in Table IV. As observed in the cyclic voltammetric results, there are differences in the values calculated for the three electrodes, and also between the values calculated from the chronoamperometry and cyclic voltammetry for the same electrode. The values of D calculated from diffusion controlled $i - t$ transients (those showing linear i *vs.* $t^{-1/2}$ behavior) should not be affected by nucleation effects. The reason for the poor agreement between the values obtained with the different electrodes is not known.

It will have been observed from the above discussion that the behavior at glassy carbon electrodes is rather irreproducible at temperatures below 60°C whereas this was not true of the other electrode materials studied. In previous studies (14) where both the reactant and product were soluble in the melt this problem was not, however, observed. Even at temperatures above 60°C it was required to hold the glassy carbon electrode at 1.0V for long periods to achieve reproducible behavior. This pretreatment presumably removed any oxide films, adsorbed oxygen, or previously deposited Al from the electrode surface. The lack of reproducible behavior at the lower temperatures is probably due to incomplete removal of these layers. In view of this evidence it is perhaps better to use tungsten and platinum electrodes when studying deposition processes in these media.

The aluminum stripping reaction.—While studying the NaCl:$AlCl_3$ system Gale and Osteryoung (5) employed a totally electrochemical method for investigating the anodic stripping efficiencies of Al. A known amount of Al was deposited on an inert electrode and this was then stripped off at known current densities. The stripping time was determined by monitoring the electrode potential on a y-t recorder. While the Al was being stripped the electrode potential changed very little but when this process was complete, the potential rose rapidly to that of Cl_2 evolution. The transition time, τ, was determined from the potential-time curves by extrapolation of the maximum gradient value at the completion of the stripping. This same technique was used in the present work to investigate the Al stripping in the $AlCl_3$:BuPyCl system. Aluminum was plated on the tungsten electrode at 10 μA for 100 sec and then it was immediately stripped off at anodic currents of 50, 20, 10, 5, 2, and 1 μA. The apparent stripping efficiencies determined in this way are given in Table V, as percentages of the deposition charge, both for the pure 2:1 $AlCl_3$:BuPyCl melt and the 50 v/o

Table IV. Diffusion coefficient values, D, for the $Al_2Cl_7^-$ ion calculated from chronoamperometry

0.127	93.7	95.0

* 0.127 C cm^{-2} (1.27 mA · cm^{-2} plate for 100 sec).

2:1 melt mixture. At high stripping current densities the stripping charge as a percentage of the deposition charge is close to 100% but on reducing the stripping current the percentage drops. A similar reduction in this percentage was observed in the NaCl:$AlCl_3$ system (5) and was attributed to corrosion processes (the lower stripping currents require longer times and hence more corrosion can occur). It was readily shown that similar corrosion was occurring in the low temperature systems. Aluminum was deposited on the tungsten electrode at 10 μA for 100 sec and the electrode was then left on open circuit for periods of 500, 1000, and 2000 sec before stripping at an anodic current of 10 μA. The stripping charges as percentages of the deposition charge were 95.7, 93.7, and 89.5, respectively, for the pure melt and 97.5, 96.5, and 94.5 for the melt + benzene. The above results imply that when left for long periods of time impurities in the melt will corrode Al, the corrosion rate in the 2:1 $AlCl_3$:BuPyCl melt being 2.1×10^{-11} moles cm^{-2} sec^{-1} and for the melt + benzene 1.1×10^{-11} moles cm^{-2} sec^{-1}. That the corrosion rate in the melt + benzene is approximately one half the value obtained for the pure melt suggests that the benzene does not introduce any corroding impurities.

All the above corrosion results refer to the tungsten electrode and very similar results were also obtained with platinum but rather lower stripping percentages were obtained with the glassy carbon electrodes. Similar behavior in the NaCl:$AlCl_3$ system was attributed to there being higher impurity levels in the glassy carbon than in the tungsten resulting in an increased corrosion rate (5). A more probable explanation is that, as was observed earlier in the cyclic voltammetry experiments, there are some slow kinetic steps involved in the Al stripping process at glassy carbon resulting in low τ values being determined from the potential-time curves. It was observed that the 'end points' of the curves for carbon were considerably less sharp than for tungsten and platinum. The corrosion rates observed in this work are very similar to those observed in the preelectrolyzed NaCl:$AlCl_3$ system (5); the $AlCl_3$:BuPyCl melts have, however, not been preelectrolyzed and it is therefore possible that such treatment could reduce the corrosion rate significantly.

All the above stripping data was obtained using either the 2:1 $AlCl_3$:BuPyCl melt or the 50 v/o mixture of this melt with benzene. Similar results were found with other acidic melts but if the concentration of $Al_2Cl_7^-$ was below that required to maintain the applied plating current density low apparent stripping percentages were observed. This is because the efficiency of the plating process is reduced. In the high temperature alkali metal chloroaluminate deposition is also possible from the $AlCl_4^-$ ions and therefore if the $Al_2Cl_7^-$ concentration drops below that required for the applied current density then deposition from $AlCl_4^-$ will also occur. 100% plating efficiencies are therefore observed for all melt compositions (5). In the $AlCl_3$:BuPyCl system the next most readily reduced species after the $Al_2Cl_7^-$ ions is the butyl

pyridinium cation. Therefore if the $Al_2Cl_7^-$ ion concentration drops below that required to sustain the applied current density, reduction of the butyl pyridinium cation occurs and the plating efficiency drops below 100% hence resulting in the apparently low stripping percentages.

In conclusion it can be said that, as anticipated, the aluminum deposition and stripping reactions in the low temperature $AlCl_3$:BuPyCl melts and mixtures of the melt with benzene are very similar to those observed in the $AlCl_3$:NaCl system. As was suggested many years ago by Hurley and Weir (19), these low temperature aprotic systems, particularly the benzene mixtures, are worthy of investigation as potential Al plating baths.

A Method of Forming Thin and Highly Reliable Gate Oxides

Two Step HCl Oxidation

C. Hashimoto, S. Muramoto, N. Shiono, and O. Nakajima

Musashino Electrical Communication Laboratory,
Nippon Telegraph and Telephone Public Corporation, Tokyo, 180, Japan

ABSTRACT

A new two step HCl oxidation has been developed as a method of forming thin and highly reliable gate oxides used in MOS LSI's. It consists of initial HCl oxidation at low temperature with low HCl concentration and following HCl treatment at high temperature in a mixture of N_2, O_2, and HCl gases. This report mainly covers oxide defect reduction effect and passivation effect of oxides formed by the two step HCl oxidation. The oxide defect density depends on the condition of the initial oxidation and following heat-treatment. Concretely, it is effective, for defect reduction, to use HCl oxide as the initial oxide and give it high temperature treatment for over 20 min. The passivation effect depends on the HCl concentration and the treatment time at the HCl treatment. It became evident that over 90 min treatment is necessary for passivation at 1150°C with 3% HCl. According to SIMS analysis, the mechanism of this passivation is fundamentally similar to that of a usual HCl oxidation. Many applications may be expected for this two step HCl oxidation.

Recent remarkable improvements in electron beam lithographic techniques, in addition to other developments such as ion implantation and dry etching techniques, will ensure that far smaller dimensions in silicon semiconductor device fabrication than those made today are achieved. Therefore, attempts to develop very large integrated circuits are now being advanced in the field of MOS technology. According to the scaling method (1), which is an effective principle to realize smaller devices, gate oxide needs to be far thinner. For this reason, techniques to form thin and highly reliable oxides are required. The oxides must have good uniformity and reproducibility in thickness, high dielectric breakdown voltage, small defect density such as pinholes, small surface charge and interface state density, and large passivation ability.

In recent years, oxidation of Si in a mixture of O_2 and HCl gases has attracted special interest. It has been made clear that this so-called HCl oxidation has many benefits: a reduction of instabilities due to the presence of mobile ions in the oxide (2), a reduction in oxide defects, an improvement in dielectric breakdown characteristics of the oxide (3), a reduction in surface charge density in the oxide, a reduction in interface state density at the oxide-silicon interface (4), an increase in minority carrier lifetime in the underlying silicon (5), and a reduction in stacking fault density in the underlying silicon (6).

Therefore, it was attempted to form thin and highly reliable oxides by use of HCl oxidation. After some investigation, however, it became evident that usual HCl oxidation methods were not suitable for forming thin and highly reliable oxides. This problem was solved by two step HCl oxidation and highly reliable thin oxides were obtained. First, an oxide of considerable thickness was formed, using usual HCl oxidation at relatively low temperatures and containing relatively low HCl concentrations in the atmosphere. The oxide formed under this condition has good uniformity and reproducibility in thickness, and small defect density (3). Then, passivation ability was furnished to the oxide and, simultaneously, desired thickness oxide was obtained by heat-treatment in a mixture of N_2, O_2, and HCl gases at relatively high temperature. This paper reports why the two step HCl oxidation was proposed and characteristics of the oxides formed by the two step HCl oxidation.

Key words: MOS, silicon dioxide, reliability, chlorine oxidation.

Problems in HCl Oxidation for Thinner Oxides

The preceding section gave some benefits of HCl oxidation. However, all those benefits are not obtained under the same oxidizing conditions. For instance, the oxide defect density obtained from the dielectric breakdown voltages of MOS capacitors becomes smaller as oxidation temperature becomes lower. Conversely, it becomes as large as that of dry O_2 oxides in a temperature range of over 1100°C (3). On the other hand, only oxides grown at over that temperature have passivation effects (7). So, it is necessary to choose the most suitable method according to each purpose when forming a thin oxide.

Self-aligned gate structures are already indispensable for smaller devices in the MOS LSI fabrication technology. For their gate electrode materials, polysilicon and refractory metals (Mo, W, etc.) are used today. When polysilicon is used, it is mainly required for the gate oxide to have small defect density, because electrical stabilization of MOS structures is

achieved by use of passivation ability of P or As contained in polysilicon as an impurity. On the other hand, when one of the refractory metals is used, passivation ability is also required for the gate oxide because the gate electrode material has no passivation ability.

In spite of the demerit mentioned above, refractory metals may be still favorable for achieving higher speed and higher density MOS LSI's because of their lower resistivity and better manufacturing precision than polysilicon. Experiments were made concerning forming thin and highly reliable gate oxides keeping refractory metal, Mo, in mind as a gate electrode. (100), 8-12 Ω-cm, p-type Si slices were used in most of the investigations described below.

As indicated in Fig. 1, the oxidation rate of silicon is increased in the presence of HCl over 900°C. So, it is difficult to control the thicknesses of thin oxides growing at over the 1100°C necessary for passivation effects, because of too short an oxidation time. Two methods are considered fundamentally to solve this problem: (*i*) To decrease the oxidation rate by diluting a given HCl/O_2 mixture by N_2; and (*ii*) to give the HCl treatment in the HCl/N_2 mixture at a high temperature for achieving passivation ability for oxides prepared beforehand.

The passivation effects of the oxides grown by the two methods mentioned above were examined. However, it became evident that the oxide grown by method (*i*) appeared "grainy" when the HCl concentration was large enough to get a passivation ability, and that method (*ii*) was not applicable as the substrate silicon was etched by the chlorine species passed through the oxide pinholes and reached the substrate surface during HCl treatment.

It is obvious from the above examination that the problems occurring when forming thin oxides by HCl oxidation are mainly due to the very strong reaction between silicon and chlorine at over 1100°C. Therefore, the following method is proposed to solve these problems and form thin oxides. First, a uniform oxide of which the thickness is under the desired thickness and near it, is formed using another method. Then a passivation ability is given to the oxide using the HCl treatment at over 1100°C and making the chlorine species diffuse into the oxide. In this case, etching of substrate silicon is prevented by making the atmosphere a little oxidizing. The desired oxide thickness is obtained simultaneously by doing so. It is considered that highly reliable oxides can be obtained by employing this method, because the reaction between substrate silicon and chlorine can be made more indirect and the oxides can be stabilized electrically, while retaining their uniform thickness.

In practice, it was possible to obtain thin and highly reliable oxides using HCl oxides, as initial oxides, grown at low temperature (under 1000°C) and with low HCl concentration (a few percent) which are known to have small oxide defect densities, and using HCl treatments as following treatments, which are the treatments in the mixture of N_2, HCl, and O_2 gases where mixing a little O_2 gas is necessary to protect the silicon substrates from etching. Hereafter, we call this method "Two Step HCl Oxidation." Investigation results for the characteristics of the two step HCl oxidation are reported in the following.

Characteristics of Two Step HCl Oxidation

Thickness vs. time for two step HCl oxidation.—The two step HCl oxidation consists of two processes and oxide thickness increases at the HCl treatment as well as the initial oxidation. Therefore the relation between thickness and time must be known, not only for initial oxidation but also for HCl treatment. This HCl treatment is a kind of oxidation in very low oxygen partial pressures. The oxidation kinetics of silicon in an O_2/N_2 mixture have been studied (8) and it is said that the Deal-Grove relationship (9) cannot be applied under an oxygen partial pressure range of 10^{-2} atm. However, no detailed study about the growth kinetics of SiO_2 films while adding HCl gas to the above atmosphere, as in the present work, is found. Probably, the mechanism will become more complicated. Moreover, the thickness we need to know is that of the oxide increased by HCl treatment after initial oxidation by another method. So it is difficult to analyze the mechanism systematically.

In this study, the following simple power law was assumed to first approximation

$$X = kt^n \quad [1]$$

where X = oxide thickness, t = virtual HCl treatment time which means the summation of the time necessary to form the same thickness as the initial oxide, assuming the use of HCl treatment and the time of the practical following HCl treatment. Both k and n are complex functions of temperature, mixing ratio of gases, and oxide thickness. The HCl oxides grown at 1000°C with 3% HCl were used as initial oxides. Two kinds of oxides, ~350 and ~500Å thick, were prepared, referring to Fig. 1. Then, HCl treatments under several conditions were given to these oxides for 60 or 120 min and the final thicknesses were measured. In this study, an ellipsometer was used to determine oxide thickness. k and t were determined to give the nearest values to the measured thicknesses for HCl treatment conditions. Examples of the results are shown in Fig. 2.

As seen from this figure, the values obtained from the experimental equations agreed with the measured values within ±5% errors in this experimental range. Using one of these equations for the desired HCl treatment condition, and deciding the final oxide thickness and the HCl treatment time, one can obtain the initial oxide thickness and the oxidation time from Fig. 2 and Fig. 1, respectively.

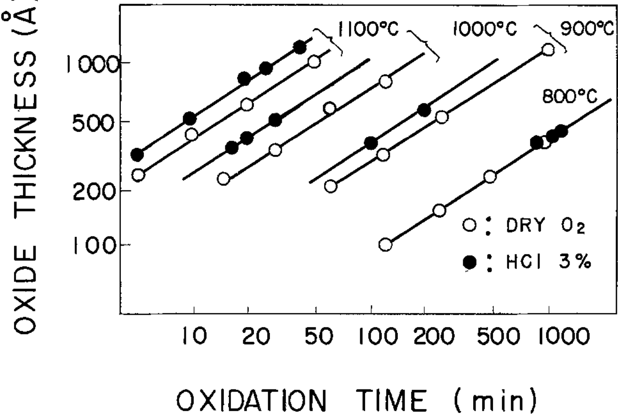

Fig. 1. Oxide thickness vs. oxidation time in dry O_2 and O_2/HCl mixture at various temperatures.

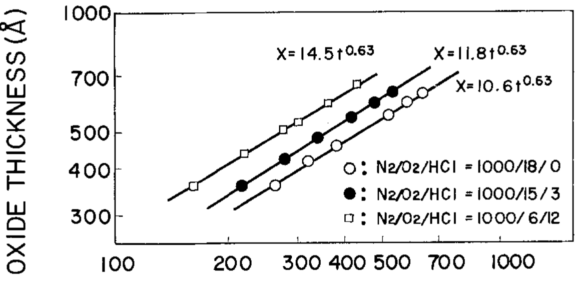

Fig. 2. Oxide thickness vs. virtual HCl treatment time at 1150°C in various N_2/O_2/HCl mixtures.

Here, it is very interesting that n is constant for all treatment atmospheres and only k increases as HCl concentration increases within the experimental range shown in Fig. 2. However, it is considered that n may change when oxide thickness becomes much thinner. Therefore, it is necessary to accumulate more data to explain the oxidation kinetics in detail.

Reduction of oxide defect density.—According to data reported by Osburn (3), oxide defect density is reduced by HCl oxidation at low temperatures with low HCl concentration, in comparison with that of dry O_2 oxides.

In this report oxide defects were detected by the copper decoration method, using methanol as the bath medium (10). This method has a merit to detect not only pinholes in insulator films but also defects other than so-called "pinholes," since the defect density changes depending on the applied electric field. It was confirmed experimentally that the copper decoration density at 1 MV/cm applied electric field and above roughly corresponds respectively to the oxide pinhole density and to the other defect density.

Figure 3 shows the copper decoration density dependence on the applied electric field for dry O_2 oxide, HCl oxide, and two step HCl oxide. From this figure, it was confirmed that the defect density of a HCl oxide grown at low temperatures with low HCl concentration is less than that of a dry O_2 oxide and that the defect density of a two step HCl oxide is still more reduced by a high temperature HCl treatment.

Since oxide defect density considerably depends on the surface condition of the prepared wafer, the evaluation of the defect density in this report was performed by comparison among wafers cut from the same ingot so as to reduce the influence of initial wafer condition. The wafers were prepared and cleaned simultaneously and only oxidation conditions were changed.

The experiment to vary the atmosphere of the high temperature treatment was carried out to investigate the cause of this newly discovered effect of the two step HCl oxidation to reduce oxide defect density. The results are shown in Fig. 4.

This figure shows that every oxide which received the high temperature treatment had a smaller defect density than the as-grown oxide. In addition, the higher the HCl concentration in the treatment atmosphere becomes, the smaller the oxide defect density becomes.

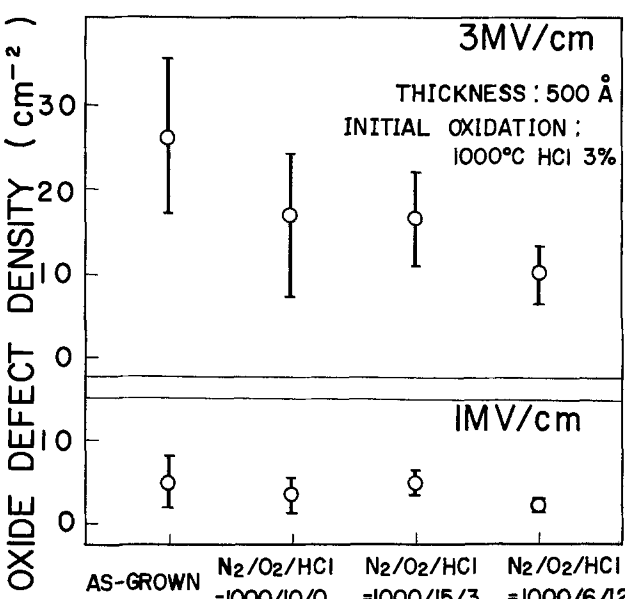

Fig. 4. Ambient effect on oxide defect density during following heat-treatment at 1150°C for 30 min.

In this case, however, differences in initial oxide thickness among these oxides may affect these results, because the initial oxide thickness was controlled to make the final thickness of every oxide 500Å. Therefore, defect density dependence was investigated for HCl oxides grown at low temperatures with low HCl concentration on the oxide thickness. As indicated in Fig. 5, little dependence was found within the thickness range from 250 to 500Å. Therefore, the results in Fig. 4 depend only on the atmosphere of the high temperature treatment.

As the above corroboration was obtained, the oxide defect density dependence was investigated for HCl treatment time under the same condition as to make the final oxide thickness 500Å. The atmosphere is that in which the smallest oxide defect density was gotten in Fig. 4. Figure 6 indicates results where rapid effect appears at a treatment time of between 10 and 20 min above 2 MV/cm applied field, and that

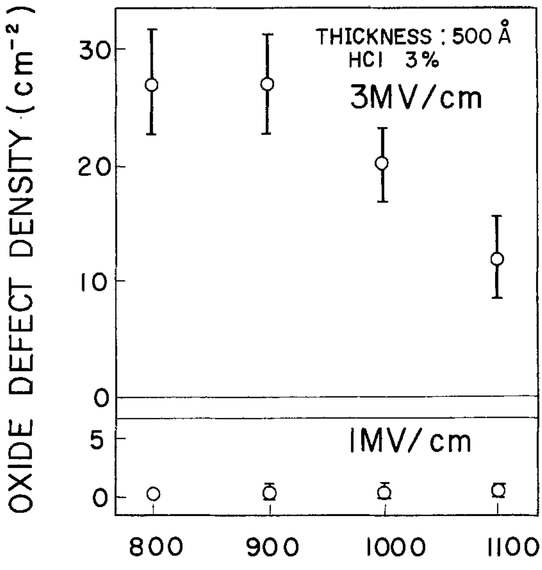

Fig. 8. Oxidation temperature dependence of oxide defect density for 3% HCl oxide.

more effect appears as the treatment time becomes longer at 4 MV/cm. From this, it became evident that the HCl treatment, at least over 20 min, is practically necessary to obtain an oxide with small defect density by two step HCl oxidation.

According to the results of the above investigation, the following two factors are assumed as the cause of this oxide defect density reduction effect by high temperature treatment. (*i*) Since the treatment is a very slow oxidation at high temperature, the oxidation of the parts proceeds where sufficient oxidation has not been accomplished at the initial oxidation for some unknown reasons. (*ii*) The composition of the parts which have been weak electrically, for some reasons other than the thickness nonuniformity changes being strong due to the high temperature treatment.

To separate these two factors, the size of the defect densities was compared between the oxide receiving the high temperature treatment in N_2 gas which is not an oxidizing atmosphere and the as-grown oxide. Both oxides were formed by HCl oxidation at low temperature with low HCl concentration. If factor (*i*) is dominant, the oxide defect density must not reduce by the high temperature treatment in N_2 gas, because oxidation cannot proceed.

It is obvious, from Fig. 7, that the defect density of the oxide receiving the high temperature treatment is smaller than that of the as-grown oxide. Therefore, it may be said that the change in oxide composition by high temperature treatment is dominant as the cause of the oxide defect reduction effect. The fact that a certain reduction effect exists for the treatment in pure N_2 gas suggests that HCl gas contained in high temperature treatment atmosphere has a rather secondary effect and the composition of the initial oxide has an essential effect.

As is shown in Fig. 8, the result was also obtained that oxide defect density detected by copper decoration method decreases as the oxidation temperature increases within the temperature range from 800° to 1100°C. There is much probability that this phenomenon is due to the same cause as above.

These tendencies are contrary to that of the defect density which Osburn obtained from the measurement of the initial dielectric breakdown voltage distributions, and rather agree with his results obtained for the wear-out characteristics (3). This improved wear-out reliability was attributed to the presence of hydrogen rather than halogens.

It is necessary, for analyzing completely the oxide defect density reduction effect of the high temperature treatment mentioned in this report, to determine details about defects detected by copper decoration method. For the first step, an investigation was made to clarify which attributes to this reduction effect, hydrogen or chlorine. The results of the investigation performed so far are indicated in the following.

First, dry O_2 oxides were prepared which contain neither hydrogen nor chlorine within themselves, and then gave high temperature N_2 treatments for some of them and high temperature HCl treatments for others. The size of the defect densities was compared between oxides receiving these heat-treatments and as-grown oxides. The results are shown in Fig. 9 and Fig. 10. For both cases, the defect density increases by heat-treatment for 30 min. A report was published that the oxide breakdown field is degraded by N_2 anneal at high temperature (11), and the above

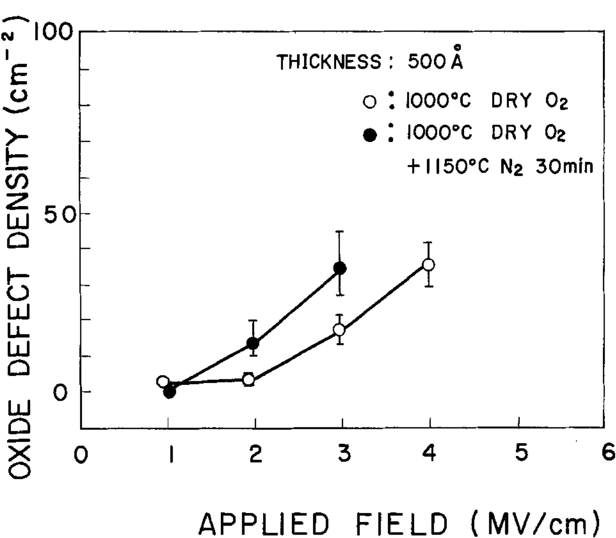

Fig. 9. High temperature N_2 treatment effect on dry O_2 oxide defect density.

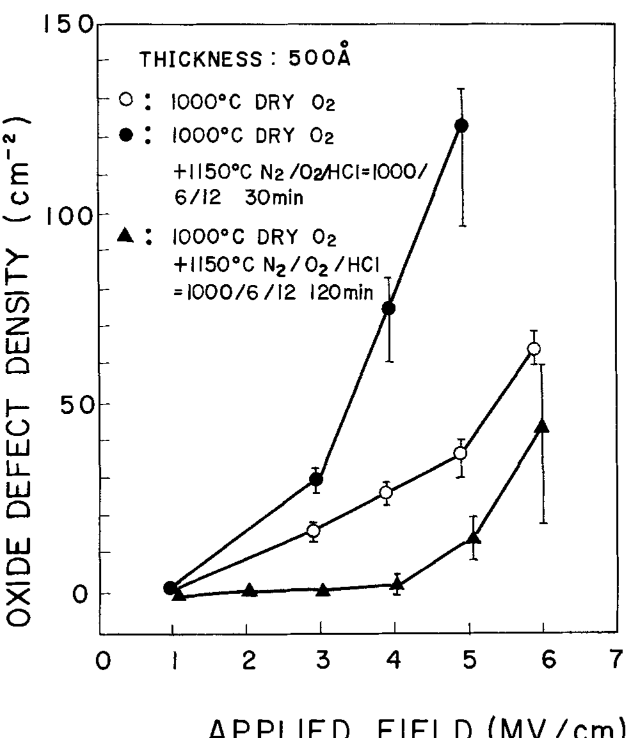

Fig. 10. High temperature HCl treatment effect for 30 and 120 min on dry O_2 oxide defect density.

phenomenon may be caused by the same reason as in the report. The result shown in Fig. 10 especially supports the previously mentioned assumption that HCl gas contained in high temperature treatment atmosphere has only a secondary effect. The defect density, however, decreases when the HCl treatment time extends to 2 hr. This property is not that of dry O_2 oxide, but that of the oxide grown in the term of the HCl treatment.

Next, an investigation was made on wet O_2 (95°C H_2O) oxide and steam (H_2 burning) oxide containing hydrogen but no chlorine. As in the case of the wet O_2 oxide, the defect density of the as-grown oxide is very large, but decreases by N_2 anneal at high temperature, as is shown in Fig. 11. On the other hand, Fig. 12 indicates that the defect density of the steam oxide is relatively small and still decreases by high temperature N_2 treatment.

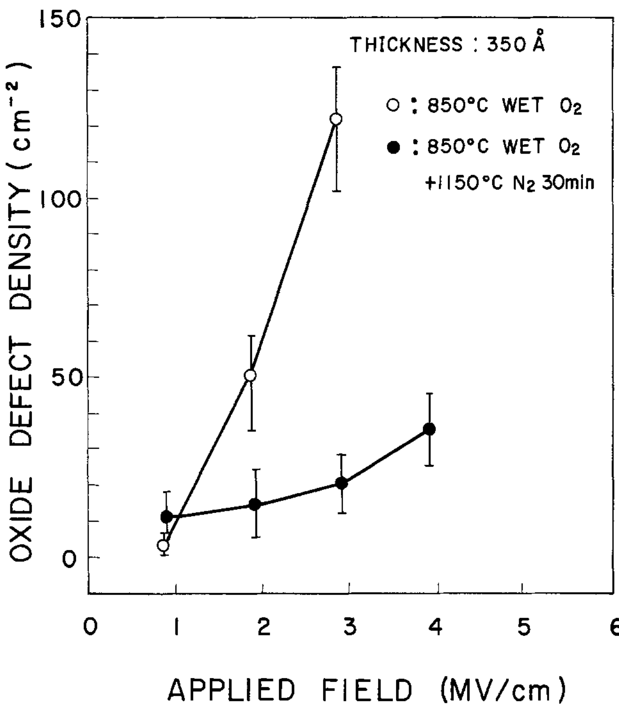

Fig. 11. High temperature N_2 treatment effect on wet (95°C) O_2 oxide defect density.

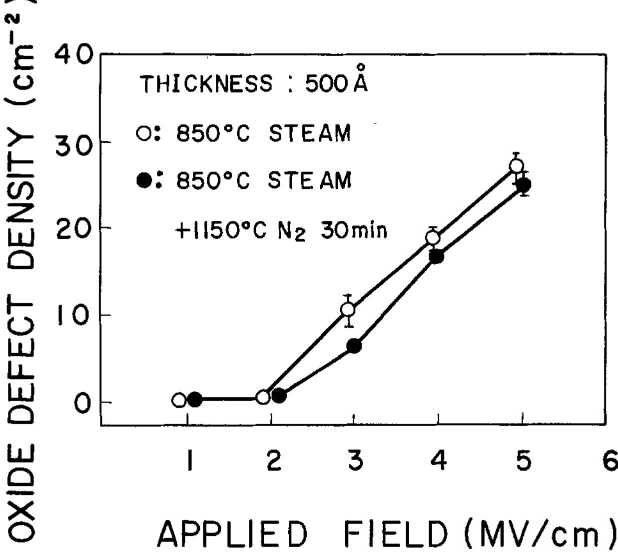

Fig. 12. High temperature N_2 treatment effect on steam (H_2 burning) oxide defect density.

Finally, a comparison is made on the size of the defect density between the as-grown Cl_2 oxide and that with a following high temperature N_2 anneal, where Cl_2 oxide means the oxide grown in a mixture of O_2 and Cl_2 gases. Not hydrogen but chlorine is contained within Cl_2 oxide. As is shown in Fig. 13, the defect density of the Cl_2 oxide is considerably small and further decreases by N_2 anneal at high temperature. Therefore, the defect density reduction effect of high temperature treatment is proved to not be limited to one oxidation method or the behavior of a certain element.

The results of the above investigation are summarized as follows. (*i*) The defect densities of HCl oxide, steam oxide, and Cl_2 oxide are smaller than that of dry O_2 oxide. In addition, the oxide defect density decreases as the oxidation temperature increases within the 800°-1100°C range. (*ii*) The defect densities of HCl oxide, wet O_2 oxide, steam oxide, and Cl_2 oxide decrease by high temperature treatment on the order of 1150°C.

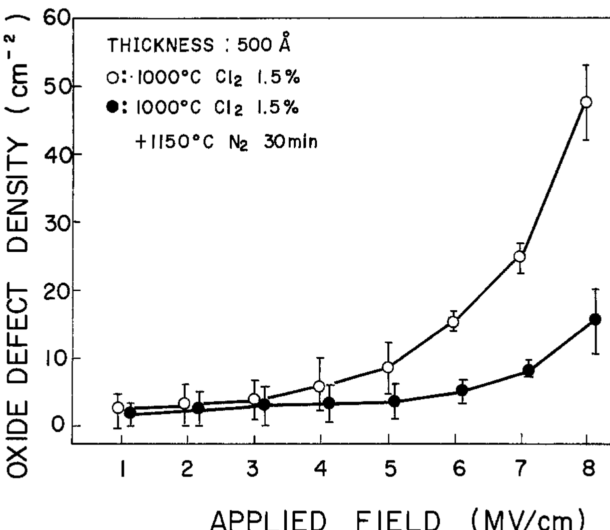

Fig. 13. High temperature N_2 treatment effect on Cl_2 oxide defect density.

It is difficult to explain these phenomena systematically by only one factor. It is necessary to consider at least two factors. The phenomenon described in (*i*) is a problem during oxidation. Since defect density decreases by oxidation mixing of very corrosive gases such as HCl or Cl_2, it is assumed that certain impurities that have strong resistance against oxidation, such as heavy metals, exist at the surface or inside of the substrate silicon, which act as nuclei of oxide defects at oxidation and are gettered by existence of the corrosive gases. On the other hand, the phenomenon described in (*ii*) is a problem after oxidation, and cannot be explained without the concept of the change in the oxide composition caused by heat-treatment. Unfortunately, it is not yet possible to clarify the mechanism.

Passivation effect.—Recently, purification of work environment in the semiconductor technology has been developed, and contamination at a gate oxidation process in the MOS fabrication process almost need not be taken into consideration. Therefore, there only remains the photolithography processes of gate electrodes patterning and later processes as possible processes for incorporating contaminations into MOS structures. Especially, as in the case of a self-aligned gate structure, contaminations can easily diffuse into a gate oxide during the heat-treatment to form source and drain regions after the photolithography. So it is desirable that the gate oxide has a passivation ability prepared for an unexpected situation when using an Mo gate electrode for which no stabilization effect is expected from a diffusion source. Many investigations on passivation effect of HCl oxidation have been performed by several persons, but it cannot be asserted that passivation effects have been sufficiently studied for thinner oxides and for contaminations incorporated into oxides during heat-treatment accompanying a self-aligned gate process. The passivation effect was investigated using two step HCl oxidation.

To fabricate the evaluation MOS diodes, Mo evaporated from an E-gun heated source was used as gate electrodes, 500 μm □ electrodes were formed by photolithography and annealed for 15 min in N_2 at 1000°C, assuming the annealing process activates the source and drain-implanted impurity layers, where the quantities of contamination on the wafers were controlled by omitting a step in the washing process, usually carried out after the photolithography process, in order to clarify the passivation effect.

500Å thick dry O_2 oxide was prepared as the standard reference oxide, and "passivation efficiency," P, was defined as

$$P = \frac{\Delta N_{FBD} - \Delta N_{FBH}}{\Delta N_{FBD}} \quad [2]$$

where ΔN_{FBD} and ΔN_{FBH} are, respectively, mobile ion density in the dry O_2 oxide and that in the two step HCl oxide after positive BT stress. Both oxides were manufactured in the same lot after the Mo evaporation process.

Figure 14 shows the HCl concentration effect on passivation efficiency in oxides grown at 1000°C with 3% HCl to 350Å thick and received HCl treatments for 2 hr. It is seen that the passivation effect takes place rather suddenly between $N_2/O_2/HCl$ = 1000/6/18 and $N_2/O_2/HCl$ = 1000/6/24. This HCl concentration is less than 3% to the carrier gas, and smaller than about 4% necessary for a usual HCl oxide to gain a passivation effect (12). However, there are only a few studies about O_2-adding HCl treatment. Especially, no investigation has been reported about the oxides receiving as long as 2 hr HCl treatment and receiving heat-treatment after forming electrodes. There is sufficient possibility that these factors exert some influence on passivation effect, that a more detailed investigation will be needed.

Next, an investigation was made on treatment time dependence of passivation effects of oxides grown under the same initial condition as the above oxides and which received HCl treatment at 1150°C in the mixture of $N_2/O_2/HCl$ = 1000/6/24. As indicated in Fig. 15, the passivation effect appears suddenly at between 60 and 90 min treatment time. As in the case of usual HCl oxidation, 20-30 min are needed for an

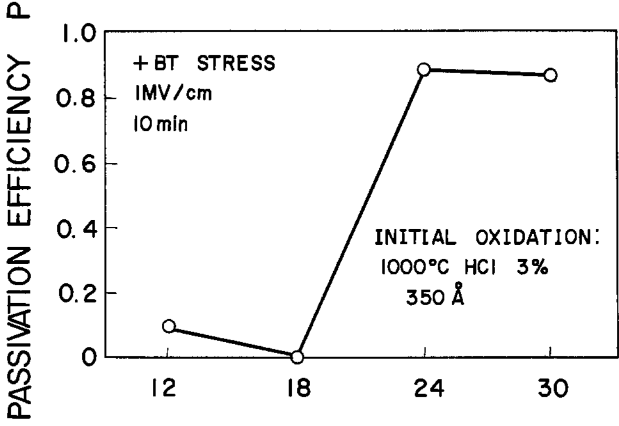

Fig. 14. HCl concentration = x dependence of passivation efficiency during HCl treatment at 1150°C in $N_2/O_2/HCl$ = 1000/6/x mixture for 120 min.

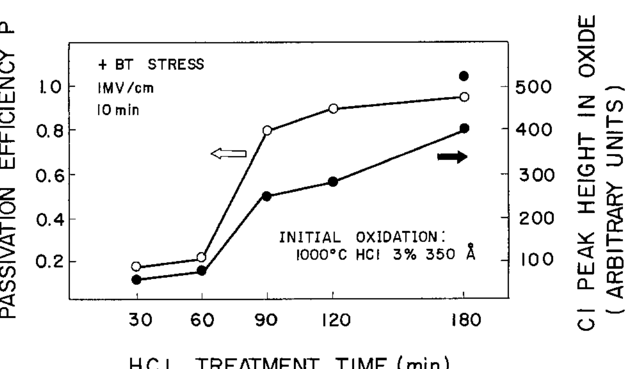

Fig. 15. Treatment time dependence of passivation efficiency and Cl peak height in oxide during HCl treatment at 1150°C in $N_2/O_2/HCl$ = 1000/6/24 mixture.

oxide to obtain a sufficient passivation effect (12). It is considered that this difference is due to the relatively low HCl concentration of the above HCl treatment.

An attempt was made to measure Cl distribution in two step HCl oxides by use of secondary ion mass spectroscopy (SIMS) to investigate the passivation mechanism of those oxides. The results show that Cl piles up in SiO_2 close to the Si interface and the size of the peak height corresponds well to the passivation effect as shown in Fig. 15. These phenomena are very similar to that of usual HCl oxides. Also, the following results were obtained by SIMS analysis. No pile-up of Cl in the oxides exists after initial oxidation at 1000°C within the HCl concentration range from 0 to 6%. These pile-up phenomena depend completely on following HCl treatment at 1150°C. Therefore, it is only necessary to consider the following HCl treatment condition in regard to passivation.

As there are many parameters in the two step HCl oxidation, such as HCl concentration, O_2 concentration, and treatment time at the HCl treatment, many variations are expected in the method of forming an oxide having a passivation effect.

Summary

A method has been reported, called two step HCl oxidation, to form a thin and highly reliable gate oxide used in the MOS LSI fabrication process. First, an oxide of considerable thickness is formed using usual HCl oxidation at relatively low temperature with relatively low HCl concentration. Then, the oxide is given an HCl treatment in a mixture of N_2, O_2, and HCl gases at relatively high temperature. Forming an oxide like this, oxide surface roughness, which is a drawback of the HCl oxidation with high HCl concentration, does not arise. Oxide defect density decreases and electrically stabilized oxide is obtained.

It was clarified that HCl oxide as initial oxide, followed by high temperature treatment for over 20 min, is necessary to reduce oxide defect density. It also became clear that passivation effect is sufficiently obtainable for an oxide by HCl treatment with about 3% HCl concentration for over 90 min. However, clarification of the detailed oxidation kinetics and the mechanisms of the above mentioned effects are retained as the subject for a future study.

This two step HCl oxidation is considered to be widely applicable by choosing a proper oxidizing condition according to individual requirements, because of its many changeable parameters.

Acknowledgments

The authors would like to thank Drs. M. Hirai, M. Kondo, H. Araki, and T. Yashiro for their advice and encouragement through the present work. They are also indebted to a number of colleagues for sample preparations and measurements, in particular to Mr. M. Seki for performing Cl analysis of oxides, Mr. T. Amazawa for evaporating Mo, and Mrs. E. Watanabe for measuring oxide thickness.

Manuscript received Aug. 11, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Silver Halide-Chalcogenide Glass Inorganic Resists for X-Ray Lithography

K. D. Kolwicz[1] and M. S. Chang*[,2]

Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Silver halide-chalcogenide glass composite thin film structures are evaluated as inorganic x-ray resists at Al K_α line. The sensitivity is shown to be a factor of 2 better than the PMMA 2041 for a 300 nm thick resist layer. A comparable contrast is indicated. A high resolution capability is expected because of the amorphous nature of the composite. A possible mechanism of this inorganic resist action is discussed.

Current integrated circuit technology restricts itself to the use of organic polymer resists (OPR) in routine photolithographic processes. Success with these materials has precluded the consideration of alternatives to OPR by the solid-state electronics industry on the grounds that OPR could be modified to meet all requirements. The new submicron technologies such as electron and ion beam processing and x-ray or synchrotron radiation sources are resist dependent. Organic materials tend to have low Z numbers and low stopping cross sections for electrons and x-rays. Inorganic materials are far more flexible and are used extensively as sensitizers in OPR. For x-ray lithography (1), current activity on resist technology (2-8) is concentrated on incorporating heavy atoms into existing resists to achieve higher sensitivity. Polymethyl methacrylate (PMMA) has the highest resolu-

Key words: inorganic resists, x-ray lithography, negative x-ray resists.

tion of all existing resists and has a very high contrast. Its sensitivity, however, is low. Other new x-ray resists such as Bell Laboratories' DCPA (5) and Texas Instrument's XR79 (6) have a much higher sensitivity but their resolution is poor, limited to 0.5 μm. In this paper, we report a novel inorganic thin film composite structure that shows promise as an x-ray resist with high sensitivity as well as high resolution and contrast.

Inorganic resists (9-13) have received some attention in the past for metallic and oxide pattern delineation for direct device fabrication. Recently, chalcogenide glasses (14, 15) have been employed as inorganic resists, but poor sensitivity limits these materials in practical applications. By photodoping with silver, chalcogenide glasses are made insoluble in alkaline solutions (16) which makes them attractive for lithographic applications (17), and a high contrast electron beam resist has been reported (18). Most recently, the compatibility of inorganic resists with plasma etching for pattern development has been demonstrated (19). The utilization of this dry processing technique for microstructure fabrication is very attractive.

In this work, a silver halide-chalcogenide glass composite thin film structure is considered, and an inorganic x-ray resist is described, for the first time. Silver halides are chosen for the following reasons: they can be vacuum deposited; they do not decompose during evaporation; they dissociate into metallic silver and halogen gases upon irradiation, providing a source of silver for the photodoping effect; and they readily dissolve in solutions of sodium thiosulfate, well known to the photographic industry as a fixing agent (20). Pure silver films are not used because autodoping (21) into the chalcogenides prior to irradiation has been noticed, apparently due to the procedure of vacuum deposition. Very recently, silver halide emulsions have been reported independently as highly sensitive resists but defects remain as serious limitations (22).

Experimental

Exposure systems.—The x-ray exposures were carried out using a converted electron beam evaporator with an aluminum anode, giving the resulting emission of the Al K_α line at 8.34Å. The electron beam power used to excite x-ray emission was 4 kV at 25 mA, and the target to substrate distance was 6 cm. A 2.5 μm thick Al filter was placed between the anode and the target to reduce infrared heating and the Bremsstrahlen. The mask used was a 6.25 μm thick Mylar membrane stretched over a quartz ring with a 0.5 μm thick gold absorber patterned by photolithography. The optimum x-ray exposure time for PMMA 2041 was determined to be 5 hr (corresponding to approximately 4 J/cm^2 energy) as a reference.

The light source used for the photolithographic characterization was a Kasper Model 17A mask aligner equipped with a 200W high pressure Hg lamp. The intensity at the sample plane was 90 mW/cm^2.

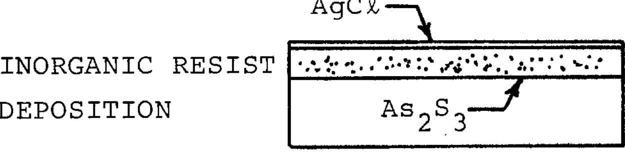
Thin film preparation.—Thin films of As_2S_3 chalcogenide glass were evaporated using a hot wall deposition system. Glassy chunks of Servofrax® were melted in a molybdenum boat in a vacuum system at pressures of 1×10^{-6} Torr or less. Deposition rates were typically 10-20 Å/sec. Initial As_2S_3 film thicknesses were all 300 nm. Substrates were cleaned borosilicate slides for photolithography and freshly oxidized silicon wafers for x-ray lithography. On top of the As_2S_3 film, an overlayer of AgCl 20 nm thick was then evaporated to form the composite. Thereafter, the composite structure was stored in darkness or handled in a red safelight. After exposure, the remaining AgCl was removed in a standard solution of Kodak rapid fixer solution A mixed with water at a ratio of 1:3 for 10 min, and the undoped As_2S_3 was then etched in a 0.03*N* NaOH solution. The lithographic process is shown schematically in Fig. 1.

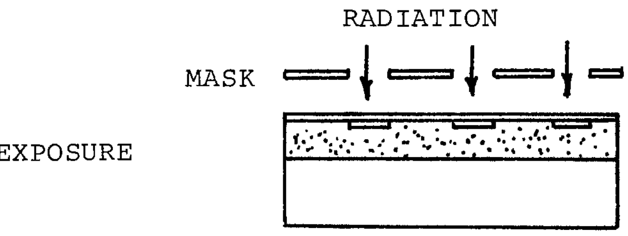
Etch rate and thickness determination.—An optical *in situ* monitoring technique (23) was used to determine the etch rate. In the 0.03*N* NaOH solution at room temperature, an etch rate of 41 Å/sec for the unexposed As_2S_3 film and 23 Å/sec for the exposure-saturated As_2S_3 film without any AgCl overlayer has been obtained. Silver-doped As_2S_3 has essentially zero etch rate in the NaOH solution. The remaining film thickness of the delineated image was measured with a Sloan Angstronmeter.

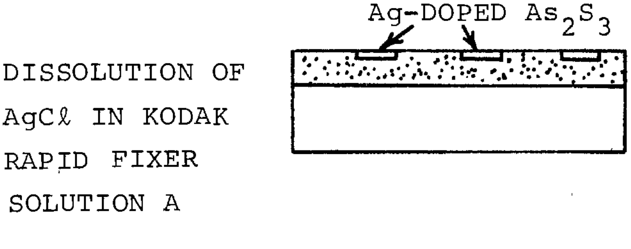
Results and Discussions

The AgCl-As_2S_3 composite is evaluated first as a photoresist. It was found to possess the negative resist property that the exposed region remains after development. The characteristic curve of percent remaining film thickness as a function of the exposure energy is shown in Fig. 2; a threshold for the onset of insolubilization was observed. The resist sensitivity is defined as the minimum exposure to obtain 100% film thickness remaining. For the composite the sensitivity was 3 J/cm^2, which is a factor of 5 less sensitive than the common Kodak negative polymer photoresist KPR (24).

The simple As_2S_3 layer is also photosensitive, as shown in Fig. 2. Its etch rate decreased when exposed to light and reached a saturated but nonzero value when fully exposed. Since the exposed and unexposed portions of the film etch concurrently, a maximum of 38% of the initial 30 nm film thickness remains after etching when the unexposed layer has just been removed by a 75 sec etch in 0.03*N* NaOH at room temperature. The etch rate characteristics of As_2S_3 have been studied in detail elsewhere (23). If the corresponding exposure is taken as the reciprocal sensitivity, an improvement in sensitivity by a factor of 10 is obtained by going to the AgCl-As_2S_3 composite structure.







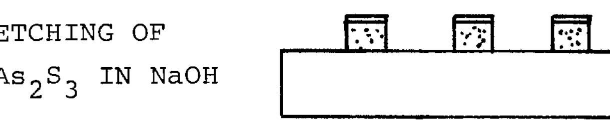


Fig. 1. Schematic relief pattern generation in AgCl-As_2S_3 composite inorganic resist.

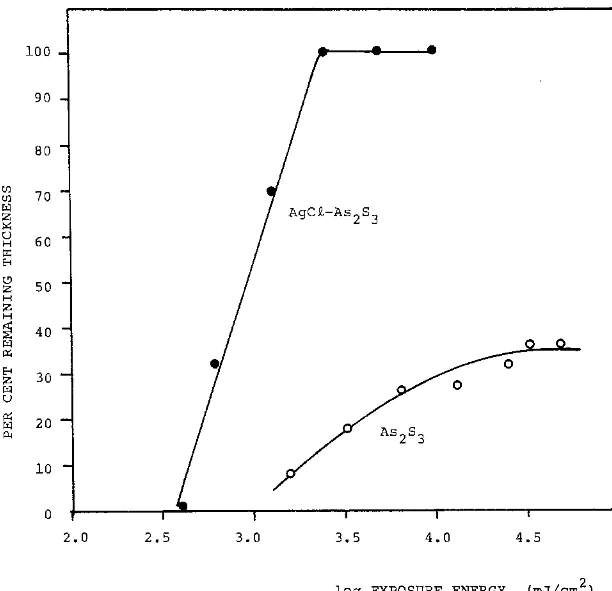

Fig. 2. Percent remaining thickness as a function of the log exposure energy for $AgCl-As_2S_3$ (●) and As_2S_3 (○). The light source power density was 90 mW/cm^2. The saturation energy for the $AgCl-As_2S_3$ corresponds to a 30 sec exposure. The larger saturation exposure in the simple As_2S_3 system reduces the etch rate to 38% of the rate without exposure.

Encouraged by this observation, we attempted to evaluate the composite as an x-ray resist. The characteristic curve of remaining film thickness as a function of the exposure time with our x-ray system is shown in Fig. 3 A. similar curve for the well-known PMMA 2041 x-ray resist was also obtained under the same exposure conditions followed by development in a 1:3 solution (1) of methyl isobutyl ketone (MIBK) and isopropyl alcohol (IPA) for 1 min. With a remaining film thickness of 300 nm as a criterion, a 5 hr x-ray exposure time was required for PMMA. Compared to the 2.5 hr required for the $AgCl-As_2S_3$ composite, we have an improvement in sensitivity of a factor of two. The slopes of the two curves are approximately the same, indicating equally high resist contrast obtainable in this inorganic resist. Figure 4 shows a pattern delineated by x-ray lithography in this inorganic resist. The linewidth is about 6 μm. From the published data (1), an exposure of about 4 J/cm^2 is required to give a PMMA dissolution rate of 300 nm/min. Assuming linear time dependence of delivered x-ray energy for our lithographic system, we obtain an optimum exposure of 2 J/cm^2 for the composite resist.

Using available data (25) for the x-ray cross sections of arsenic and sulfur, it is estimated that 30% of the x-ray energy is absorbed by an As_2S_3 film 300 nm thick, the thickness being arbitrarily chosen for this study.

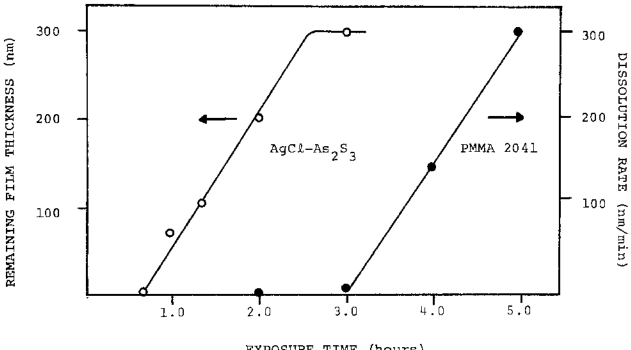

Fig. 3. X-ray resist characteristics for $AgCl-As_2S_3$ composite inorganic resist (○) and for PMMA 2041 (●) as a function of exposure time. The 5 hr exposure time corresponds to an x-ray energy of approximately 4 J/cm^2.

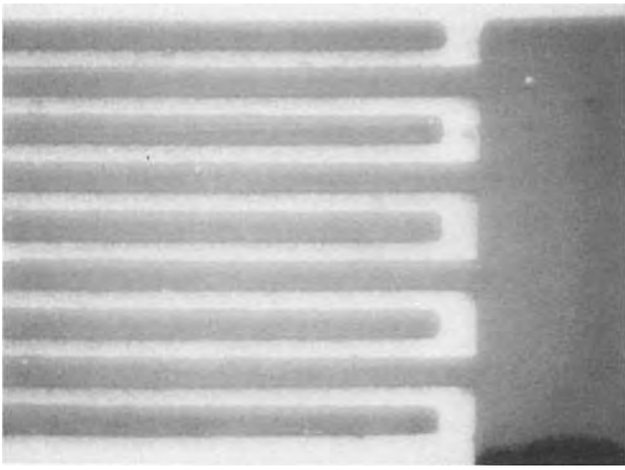

Fig. 4. A scanning electron micrograph of a pattern generated by x-ray lithography in $AgCl-As_2S_3$. The remaining film thickness is 100 nm and the linewidth is 6 μm. The material remaining between the lines is an artifact due to the x-ray lithography system (*i.e.*, penumbral blurring and vibration) and is not related to the resist properties.

Optimization of film thickness along with other exposure parameters (*e.g.*, wavelength, etc.) could result in improved performance. The comparison with PMMA in MIBK: IPA = 1.3 developed is also arbitrarily chosen. One is a positive resist, while the other is a negative resist. Nevertheless, the x-ray inorganic resist property is clearly demonstrated, and a different concept to achieve more sensitive x-ray resists is established.

The mechanism that permits the $AgCl-As_2S_3$ composite to form relief structures is tentatively attributed to the silver doping effect (16, 21). The process can be represented by two equations

$$AgCl \xrightarrow{h\nu} Ag + \tfrac{1}{2} Cl_2 (gas)$$

$$Ag + As_2S_3 \xrightarrow{h\nu} (Ag\text{-}As_2S_3)$$

The silver halide decomposes into metallic silver and halogen gas upon absorption of irradiation, and thus provides the source for silver doping. The silver-doped As_2S_3 is insoluble in the NaOH solution thereby generating a pattern. The linear relationship between the doping depth and the square root of exposure time has been established (16), typical of a diffusion-controlled process. An x-ray photon absorbed by the inorganic resist produces a shower of secondary electrons which will carry most of the energy of the incident photon and is responsible for the silver doping process.

To obtain information about the doping depth required for resist application, the following experiment was performed. A layer of metallic Ag 20 nm thick was sandwiched between the 300 nm As_2S_3 and the glass substrate as shown by the insert in Fig. 5. Several samples were exposed to the mask aligner light source for different exposure times. Then, all the samples were etched at the same time in a 0.03*N* NaOH solution for 2 min, which is a little more than enough time to remove the 300 nm of exposure saturated As_2S_3. The thickness of the resulting insoluble Ag-doped layer formed in the exposed area was measured. Figure 5 shows the doping depth as a function of exposure time. It is seen that with a limited source of silver (*i.e.*, 20 nm), the doping depth consists of only a fraction of the bulk, even for long exposure times. This depth is reached in a relatively short exposure, and further exposures do not drive the silver further into the bulk. This observation lends credence to the idea that the x-ray resist action of $AgCl-As_2S_3$ is due to the formation of a thin layer of As_2S_3 into which silver has penetrated and changed its chemical solubility. The re-

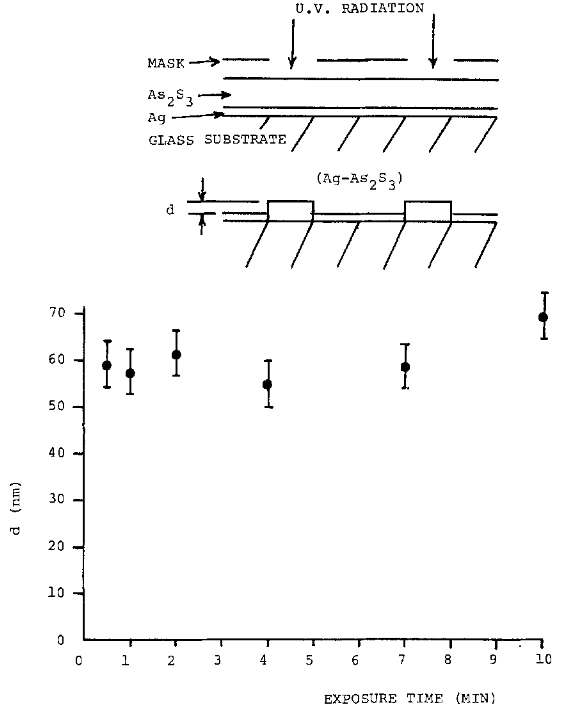

Fig. 5. Establishment of doping depth with a limited silver source of 20 nm thickness. The inserts show the procedure for establishing the doping depth. The exposure source is the mask aligner with a power density of 90 mW/cm².

sulting thin "cap" about 80 nm thick or less protects the underlying undoped As_2S_3 film from being etched. The pattern of this thin cap gives the pattern of the final image. It is anticipated that a thinner cap would suffice for the protective action. In an isotropic etching environment this would be a problem in fine line lithography, but it is not insurmountable as As_2S_3 has been shown (19) to be suitable for plasma etching. The minimum cap thickness is yet to be determined.

Since both the silver halide and chalcogenide glass are amorphous, the resolution capability of this composite inorganic resist is expected to be extremely high. We are at present limited by our mask making capability to 6 μm linewidth as shown in Fig. 4. Since the pattern-forming layer is thin (50 nm or less), in an anisotropic etching medium the ultimate resolution should be very good for a reasonable height-to-width aspect ratio. Recently, a minimum linewidth of 100 nm has been delineated through the holographic exposure technique in this laboratory (26, 27). A similar high resolution capability is expected through the x-ray replication process. The resolution limit may fall in the 10 nm range, which is the diffusion length of the excited carriers (17).

Conclusion

The composite thin film structure $AgCl-As_2S_3$ has been characterized as a photoresist and an x-ray resist. As a photoresist, it is found to be about 5 times less sensitive than organic resists in popular use, while as an x-ray resist, it is shown to be about twice as sensitive as PMMA. In both cases, the sensitivity cannot at this point favorably compete with the sensitivities of organic resists now being used in practice, but sensitization techniques for silver halides known by the photographic industry and optimization of resist thickness parameters provide room for improvement. The resist action is shown to be essentially due to the radiation enhanced reaction at the interface of the $AgCl-As_2S_3$ thin films, with the subsequent pattern defining layer being of the order of tens of nanometers. This fact coupled with the compatibility of the As_2S_3 to plasma etching and the amorphous nature of the resist materials would mean a high resolution capability for pattern generation.

Electrical Breakdown

I. During the Anodic Growth of Tantalum Pentoxide

V. Kadary[1] and N. Klein

Faculty of Electrical Engineering, Technion-Israel Institute of Technology, Haifa, Israel

ABSTRACT

Observations are presented on breakdown events during the anodic growth of tantalum pentoxide in characteristics which plot the rate of breakdown as function of oxide thickness at constant field, F. The characteristics shift to lower thicknesses for an increase in field, or a decrease in temperature. The breakdown process is interpreted by the stochastic succession of avalanche breakdown model. An approximate relation was derived for the rate of breakdown as function of insulator thickness. This relation could be well fitted to experimental data at various fields. The fitting procedure permits the evaluation of the coefficient of impact ionization α, finding for a set of anodizations $\alpha = 4.4 \times 10^6 \exp(-21.5/F)$/cm with F in MV/cm, in the range of fields 6.1-6.7 MV/cm. There is an uncertainty of roughly ±10% in α, due to shallow minima in fitting procedures, to fluctuations in the rate of breakdown, and to some uncertainty in the magnitude of F.

Since the extensive studies of Güntherschulze and Betz (1), electrical breakdown during the anodization of "valve metals" has been the subject of many investigations. Recent reviews found difficulties both in the definition of breakdown and in the interpretation of the processes (2-4). Several mechanisms were proposed to explain breakdown, such as fissure formation in the oxide (5), or local crystallization in the amorphous insulator. Evidence was not found, however, in support of these mechanisms and it was shown that crystallization does not precede breakdown, but is a side effect caused by local heating (6).

Already Güntherschulze and Betz (1) suggested that breakdown during anodization is connected with electronic impact ionization and avalanching. This view was shared by other investigators (3, 7), and recently an avalanche breakdown theory was developed by Ikonopisov (8). The feasibility of the avalanche breakdown mechanism is supported by observations on electroluminescence and anodic growth. Van Geel *et al.* (9) observed in aluminum oxide that the intensity of electroluminescence accompanying anodization increases as some exponential function of oxide thickness. The nature of this increase was interpreted with the assumption of electronic avalanche formation. Fritzsche (10) investigated the rate of oxide growth and current transients during the anodic growth of silicon dioxide, also interpreting observations with avalanche formation.

It has been more difficult to obtain experimental evidence for avalanche mechanisms from breakdown observations. This may in part be due to the fact that even the definition of breakdown is subject to discussion (3, 4). Since the electric field is constant during anodization, breakdown has been defined by some voltage value. As such, various voltages were proposed: the voltage at which sparking starts, the maximum voltage which can be reached on anodization, or the voltage at which a deflection from linearity arises in the voltage *vs.* time curve.

These voltages certainly describe, more (or less) important aspects related to breakdown during anodic growth. They do not account, however, for individual observations of numerous breakdown events. To provide this information, new approaches were proposed for the description of breakdown properties during anodization. These are based on the measurement of the total number of breakdowns as a function of anodization voltage in the work of Orlov *et al.* (11) and Albella *et al.* (12), and on the determination of the rate of breakdown as a function of thickness by Kadary and Klein (13).

This paper applies the latter approach, plotting the rate of breakdown *vs.* voltage, or thickness in breakdown characteristics. Detailed experimental data are presented on the characteristics as a function of anodization field. Results are examined for interpretation by thermal or by electronic impact ionization mechanisms. Examination shows that, applying the stochastic succession of avalanche breakdown theory (14), good agreement is found between calculations and experimental data. Agreement is found also for breakdown during the anodization of aluminum and will be described in Part II (15), the companion paper.

Samples and the Experimental System

Anodizations were carried out on 5000Å thick, sputtered, lightly nitrogen-doped, β tantalum layers, supplied by courtesy of the Bell Telephone Laboratories, Allentown, Pennsylvania. The layers were deposited on borosilicate glass covered with about 150Å thick tantalum pentoxide for better adherence.

Samples were needed for the observations in which breakdown and light emission were not enhanced at the edges of the tantalum layer, and which could be placed horizontally in the electrolytic bath for ease of light measurement. This was achieved with the samples shown in Fig. 1: These had photolithographically delineated tantalum areas which were 9 mm in

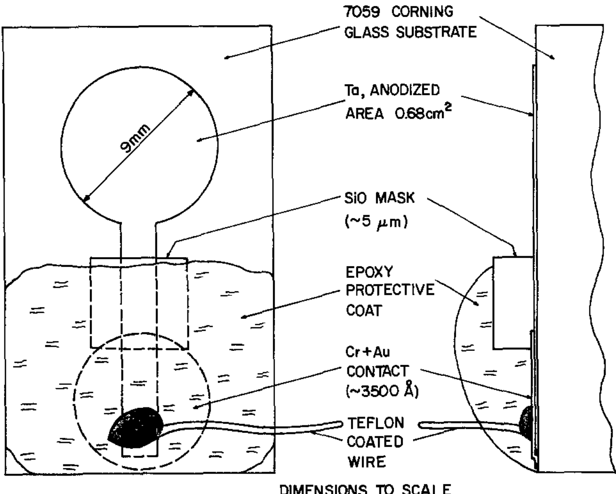

Fig. 1. Tantalum sample for anodization

[1] Present address: Israel Aircraft Industries, Yahud, Israel.

diameter and contained a contact strip. The latter was contacted by a Cr-Au land, to which a Teflon-coated wire was soldered. For insulation from the electrolyte, the contact strip and land were covered by a 5 μm thick vapor-deposited silicon oxide layer and by a thick epoxy coat. The tantalum area exposed to anodization was 0.68 cm^2.

The electrolytic bath was contained in a Pyrex dish 37 mm deep and 74 mm diam. The sample was held at the bottom center of the dish with silicone grease. A tantalum ring 15 mm wide and 0.1 mm thick served as cathode. The electrolytic bath was an aqueous solution of citric acid with a range of concentrations from 2.5×10^{-3} to 1.8 weight percent (w/o), the corresponding resistivities at 1 kHz varying from 21,000 to 260 Ω-cm. All the anodizations were carried out at constant current densities ranging from 0.5 to 10 mA/cm^2; temperature rises were reduced by magnetic stirring.

The experimental setup for the measurement of breakdown events and light emission is illustrated in Fig. 2. The events, as discussed later, are detected by a current pulse in the external circuit and often also by a spark at the breakdown spot. For the detection of the current pulses in the system a parallel capacitor C_p of a few μF capacitance and a series resistor $R_s = 10$ kΩ were added to the anodization circuit. On breakdown, discharge of C_p through the breakdown filament produced a current pulse, which was monitored on the series resistor R_s.

The source of anodization was a constant current Elscint HVS power supply for the current range 10^{-4}-10^{-1}A. A low-pass filter reduced current ripples from the supply to about 0.01% of the anodization current. This prevented the transmission of external current pulses to the C_pR_s detecting circuit, except in the case of extremely large breakdown events, which usually occurred beyond the range of useful observations.

The light emitted from the sample was measured with an RCA Type 1P28 photomultiplier which was coupled to the sample with a 100 mm long, 10 mm diam quartz light guide. The collecting face of the light guide was concentric with and 10 mm above the sample. This distance was a compromise of the opposing requirements of uniform anodization and maximum light collection. The sensitivity of the photomultiplier extended over the spectral range 2200-6200Å, with a maximum close to 3300Å. The photomultiplier had potted leads and was cooled with solid CO_2. The electrolytic bath, the light guide, and the photomultiplier were enclosed in an aluminum box, impervious to external light.

To register the anodization voltage, the voltage across the parallel capacitor C_p was measured with a Keithley 610B voltmeter and the voltage across the oxide layer was obtained by subtracting voltage drops in the electrolyte and the series resistor R_s.

Four quantities were recorded during each anodization run: the oxide voltage, current pulses associated with breakdown, the intensity of electroluminescence, and sparks. The electroluminescence (not discussed in this paper) was recorded against time of anodization on a pen-type Moseley 7100 BM, Hewlett Packard strip-chart recorder. The current pulses, sparks, and voltage *vs.* time of anodization were recorded on a Honeywell 906T visicorder oscillograph equipped with Heiland M8000 plug-in galvanometers. The response of the galvanometers was flat within 5% in the frequency range from 0 to 4800 Hz. Chart speeds varied from 5 to 100 mm/sec. A typical anodization run to 350-400V as function of time was recorded on roughly 6m length of chart paper.

Records of Breakdown Events

Güntherschulze and Betz (1) established that an individual breakdown event during anodization is due to temporary current runaway through a filament in the oxide. Such breakdown events can be studied with oscillograms of the current pulse arising in the series resistor R_s and the pulse due to a spark as function of time. This is illustrated by the oscillogram of Fig. 3, showing two events, one of which was accompanied by a spark.

Records of the sequence of breakdown events *vs.* time during anodization were obtained with the visicorder and are illustrated by three typical sections of a chart record in Fig. 4. In this chart spikes protruding from the noise on the upper trace denote current pulses on a compressed time scale. The slowly rising line is the trace of the anodization voltage, while the noisy bottom trace is due to the photomultiplier output current. On the latter trace, spikes are of interest, denoting sparks. The anodization recorded in Fig. 4 was carried out in an electrolyte of 2.3 kΩ-cm resistivity, at a current density of 1 mA/cm^2. The three chart sections represent the voltage ranges (a) 35-48V, (b) 245-247V, and (c) 305-305.5V. In these sections, the time scales change. The typical anodic growth represented by Fig. 4 produced no current pulses below 30V, and the few current pulses between 30 and 100V were not accompanied by light pulses as indicated by the chart of Fig. 4(a). Figure 4(b) characterizes the voltage range in which the rate of current pulses begins to rise rapidly with voltage, in this case above 220V. In this chart, light pulses coincident with current pulses are observed in part of the events. Occasionally light pulses without coincident current pulses are found. Visual observation of the breakdown sparks suggests that events occur at random places, and the traces of Fig. 4(b) indicate inde-

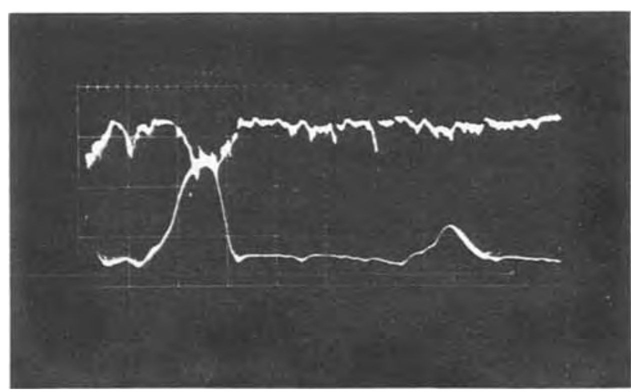

Fig. 3. Oscillogram of two current pulses (lower trace), and one of light pulse (upper trace) during anodization. Horizontal scale time, 2 msec/div; vertical scale, pulse amplitudes in relative units.

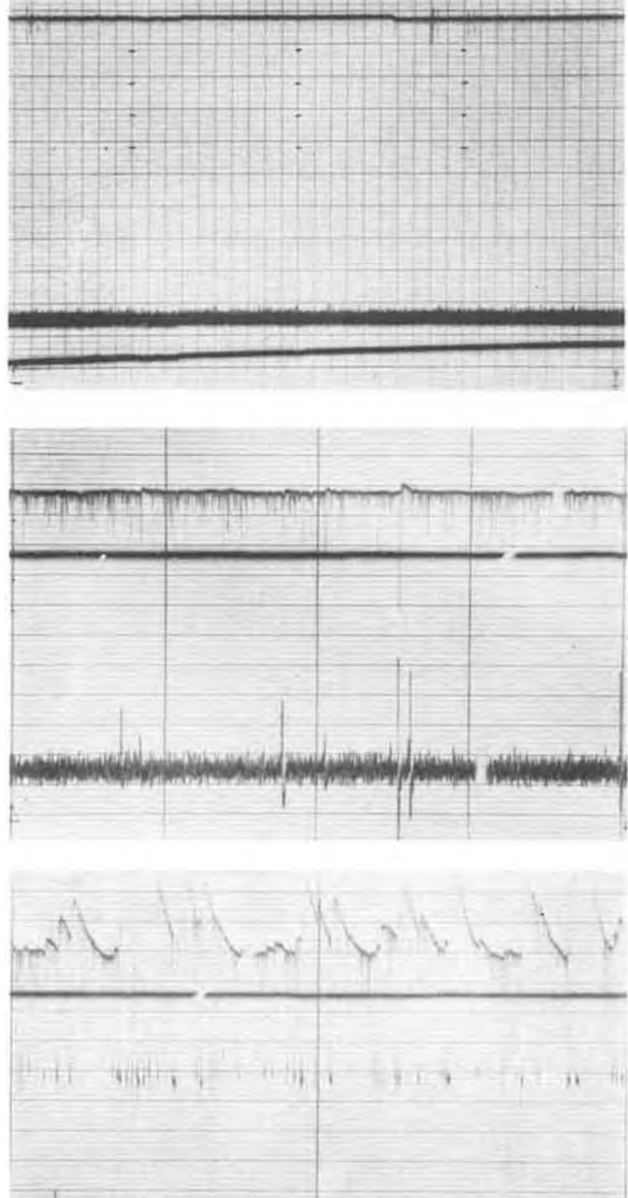

Fig. 4. Three visicorder charts vs. time during anodization. Upper traces, current pulses, 3.3 μA/large vertical division. Slowly rising traces voltage, 30 V/large vertical division; bottom traces, sparks and a-c component of electroluminescent light. Voltage range of charts: (a) 35-48V, (b) 245-247V, and (c) 305-305.5V. Chart speeds: (a) 5 mm/sec; (b) 35 mm/sec; (c) 100 mm/sec.

pendent events of varying magnitudes occurring at random times.

Roughly above 300V prolonged events begin to appear, illustrated by the current pulse traces in the chart of Fig. 4(c). Oscillograms show that subsequent pulses are not independent, but overlap. Visual observations reveal persistent sparking, involving large areas. Breakdowns are propagating in this upper voltage range, events follow each other at adjacent places and are often the consequence of changes produced in the properties of the oxide by the prior breakdown. Since we were interested in the causes of the initiation of breakdown, determined by the original properties of the oxide, we made use of observations in the two lower voltage ranges only, where events appear to be random and independent.

To evaluate the information of the chart records, the current pulses were counted in small time intervals in which the effect of voltage changes could be considered small. With these data the rate of current pulses as function of anodization voltage, or insulation thickness, was calculated and the relationship plotted in a current pulse characteristic. Since any point of the characteristic was determined from a limited number of events, the standard deviation of the pulse rate was added, denoted by bars on the characteristics where feasible. When the time intervals for the counting of current pulses were very small, considerable fluctuations were found in the characteristics. This will be illustrated for the anodic growth of aluminum oxide in Fig. 1 of the companion paper (15). The rate of sparks was determined in the same manner as the rate of current pulses.

The characteristics were usually based on the count of current pulses of all sizes. Occasionally counts were classified according to the amplitude range of the current pulses and classified characteristics were obtained, as shown in Fig. 5. In this case the anodization was carried out with a current density $j = 1$ mA/cm^2 in an electrolytic bath of 2.3 kΩ-cm resistivity. The pulse rate is plotted *vs.* anodization voltage for five groups of current pulses indicating an increase in mean pulse size with increasing voltage.

Current Pulses due to Filamentary Current Runaway

Breakdown events revealed by sparks are clearly the consequence of filamentary current runaway. Examination of spark-affected breakdown spots shows structural changes with a pit in the tantalum, one to a few micrometers in diameter. This pit seems to indicate the final size of the breakdown filament. The event appears to be a destructive breakdown, followed by some anodic regrowth of the damaged spot (1).

The question that arises immediately relates to the nature of the events unaccompanied by a spark. In such a case is the current pulse also due to local current runaway or due to a different process?

A direct answer is not available since for sparkless events structural changes were not detected in the oxide. Examination of breakdown charts as presented in Fig. 4b and comparison of current pulse charac-

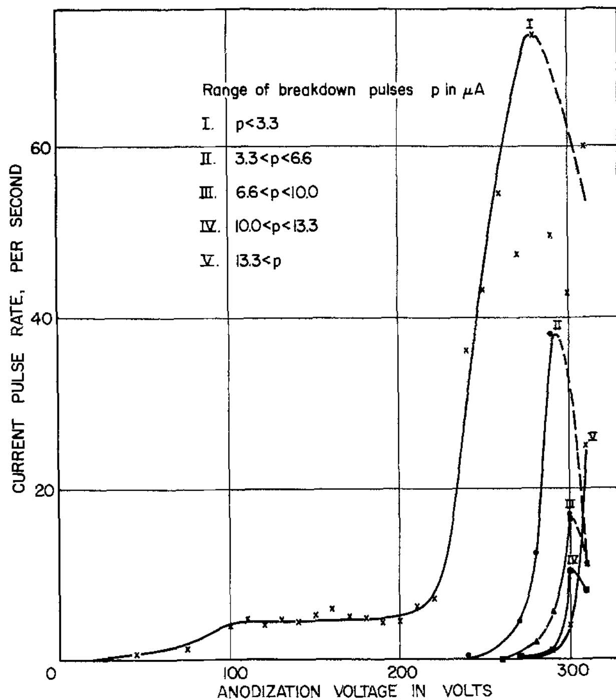

Fig. 5. Rate of current pulse vs. anodization voltage characteristics, classified by pulse amplitude.

teristics as shown in Fig. 5 with spark characteristics indicated in all cases that: (*i*) sparkless and spark-accompanied events are intermixed in a random manner; (*ii*) the likelihood of the occurrence of a spark increased with current pulse size, and (*iii*) the fraction of spark-accompanied events gradually increased with voltage to near unity, as the average current pulse amplitude increased.

These observations can be explained with the assumption that sparkless and spark-accompanied events have the same origin but differ in their development. This implies that not only events accompanied by a spark, but also sparkless events start with filamentary current runaway. Very large drops are expected, therefore, in the resistivity ρ_f of filaments during current pulses; to examine the validity of this assumption drops in ρ_f were calculated with the help of experimental results. Data were needed for this purpose on the magnitude of the filament radius, r_f, but were not available. Bounds were assessed instead on the magnitude of r_f. A lower bound was indicated by the oxide thickness during breakdown observations, roughly 5000Å, and this assessment is confirmed by the breakdown model developed later. An upper bound for r_f was indicated by the size of breakdown pits on spark accompanied events. The calculations were extended, therefore, over the range $0.5 < r_f < 5$ μm.

For the calculation of ρ_f the sample and the experimental setup were represented by the simplified equivalent circuit of Fig. 6. In this figure, C_i and R_i are insulator capacitance and resistance, respectively, and R_e is the electrolyte series resistance. R_f is the resistance of a breakdown filament, R_{ef} is the electrolyte resistance in series with the filament, and R_c is the resistance of the ionic charge layer at the oxide interface for cylindrical current flow into the filament. The resistance, R_c, is calculated with

$$R_c = \frac{w}{2\pi\epsilon_o\epsilon\mu V} \ln \frac{r_c}{r_f} \quad [1]$$

where r_c is the sample radius, w the oxide thickness, μ the ionic mobility, ϵ_o the permittivity of empty space, ϵ the relative permittivity of the oxide, and V the voltage across the oxide. The resistance R_{ef} is calculated as a hemispherical spreading resistance and

$$R_{ef} = \rho_e / 2\pi r_f \quad [2]$$

with ρ_e the resistivity of the electrolyte. A local breakdown is represented by a temporary closure of the switch. On breakdown the capacitors C_p and C_i discharge through the filament.

R_s was 10 kΩ and R_e in ohms was numerically about equal to ρ_e in Ω-cm in the experiments. Drops in the values of ρ_f on the occurrence of current pulses are illustrated by calculations with $V = 300$V as a representative voltage and $j = 1$ mA/cm^2 as current density of anodization. For these values of V and j, $w \simeq 4.8 \times 10^{-5}$ cm, $C_i = 3.1 \times 10^{-8}$F with $\epsilon = 25$ and the oxide resistivity $\rho_i = 6.3 \times 10^{-9}$ Ω-cm. The sample radius $r_c = 0.45$ cm; assuming for the ionic mobility in the electrolyte $\mu = 3 \times 10^{-4}$ cm^2/Vsec, the resistances R_c and R_{ef} were evaluated with Eq. [1] and [2]. The calculations were carried out for four limiting cases, when $2r_f = 1$ and 10 μm and $\rho_e = 260$ and 21,000 Ω-cm, respectively. Results are presented in Table I showing that both R_c and R_{ef} are much larger than R_e or R_s.

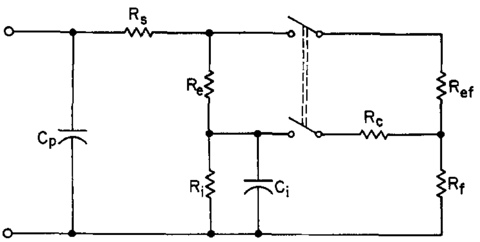

Fig. 6. Equivalent circuit for the interpretation of a breakdown event.

Since $C_p >> C_i$, the voltage drops on the capacitors were in most current pulse observations small and ρ_f was calculated neglecting these voltage drops. The smallest current pulses which could be discerned above the noise of the measurements were 5×10^{-7}A. Calculation of ρ_f for 5×10^{-7}A pulses with the switch closed in the circuit of Fig. 6 resulted in the values presented in the last line of Table I.

Comparison of these ρ_f values with the oxide resistivity of 6.3×10^9 Ω-cm shows that the resistivity in a filament drops by several orders of magnitude even for the smallest current pulse and largest filament size. The resistivity drops increase as the filament size decreases and as the current pulse size increases. Therefore, it appears clearly that current pulses represent temporary current runaway processes. For smaller current pulses events are largely sparkless and such events can be considered as nondestructive breakdowns. Since for the understanding of the initiation of breakdown all current runaway processes are of interest, irrespective of whether the event is destructive or nondestructive, the investigation is based on the study of current pulse breakdown counts and characteristics

The values calculated for the electrolyte resistances R_c and R_{ef} are in the $10^8\Omega$ range (Table I), showing that breakdown filaments are protected by large series resistances during anodic growth. This is in marked contrast to conditions in samples flanked by solid electrodes. In such samples a small resistance is in series with filaments, a few ohms when aluminum electrodes are 1000Å thick (16).

Reliable counting of the insulator current pulses depends on the parameters of the detecting circuit. The circuit of Fig. 6 indicates that for this purpose a capacitance C_p is needed, which is much larger than that of the sample C_i. This was found also experimentally, shown by the current pulse characteristics in Fig. 7a. The current pulse rate increases with increasing C_p and saturates for $C_p > 10^{-6}$F. Usually a 2×10^{-6}F capacitor was selected for C_p.

It is interesting to note from curve c of Fig. 7a that some current pulses on R_s were observed even in the absence of a parallel capacitor. In this case only the most powerful breakdown events were observed with unusually large voltage drops of more than 10V on C_i. It was found that in the case of largest voltage drops small current pulses penetrated the low-pass filter from the power supply and were detected on R_s.

Figure 7b presents the spark rates measured at the same time as the current pulses of Fig. 7a. Relative to the current pulse characteristics the spark characteristics are shifted to higher voltages. It appears that the magnitude of the external capacitor affects but little the spark pulse characteristics and the occurrence of a spark depends mainly on the local development of the breakdown event.

Experimental Results

Experimental observations were made mainly at anodization current densities $j = 0.5$, 1, 5, and 10

Table I. Filament resistivity

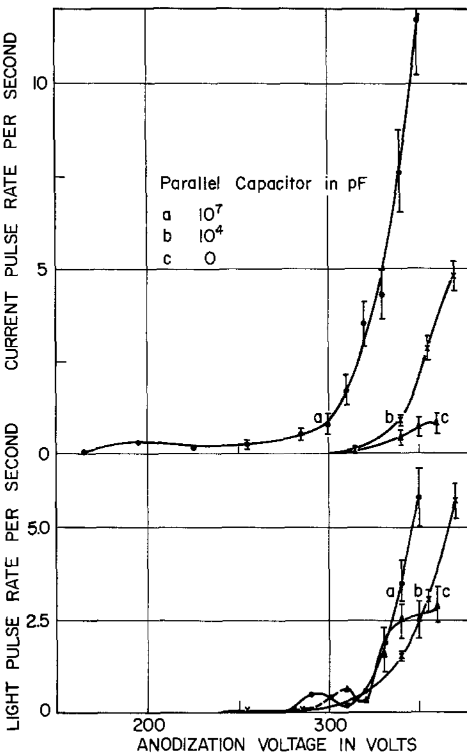

Fig. 7. Current and light pulse vs. anodization voltage with parallel capacitor size as parameter. $j = 1$ mA/cm², $\rho_e = 7000$ Ω-cm.

mA/cm². The magnitude of mean oxide fields, F, which produce these current densities is not known accurately. For the anodization of sputtered β tantalum films at a temperature $T = 298°K$ and $j = 1$ mA/cm² Mills *et al.* (17) found $F = 6.45 \times 10^6$ V/cm, but Simmons *et al.* (18) arrived at 6.0×10^6 V/cm. Nitrogen doping of the tantalum by 2 atomic percent (a/o) N was observed to increase the field by about 1% (18).

For present purposes a relationship giving j as function of F and T is needed. Such a relationship was obtained by Young (19) for the anodization of bulk tantalum giving j in A/cm² as function of both F and T in V/cm and °K, respectively, and

$$j = 1.74 \times 10^8 \exp\left[\frac{1.16 \times 10^4}{T}(-2.185 + 3.497 \times 10^{-7}F - 1.675 \times 10^{-14}F^2)\right] \quad [3]$$

Since with this relation $F = 6.17 \times 10^6$ V/cm is obtained for $j = 1$ mA/cm² at $T = 298°K$ and since the slopes of the j-F characteristics $d(\ln j)/dF$ differ little for the anodizations of bulk and sputtered β tantalum (17), Eq. [3] was used for the calculation of the fields in the experiments. Results for the temperature of anodizations of 292°K are presented in Table II. At breakdown voltages 4°-5°C temperature rises were found at current densities of 5 and 10 mA/cm² and for these conditions corrected field values were calculated shown in the third line of Table II. While there is some uncertainty in the absolute field values of Table II, the relative magnitudes of fields for varying current densities agree well with the experimental results for sputtered β tantalum (17).

Table II. Anodization fields

Current density, mA/cm²	0.5	1	5	10
Mean electric field, MV/cm	6.14	6.26	6.56	6.70
Fields corrected for temperature rise in the breakdown range, MV/cm	6.14	6.26	6.50	6.63

The effect of the uncertainty in field values on the evaluation of experimental results are discussed later.

The observations that are presented are characteristics giving R_r the rate of the total number of current pulses. Typical current pulse characteristics as function of voltage are presented in Fig. 8a with the current density of anodization as parameter. Since for the discussion on the breakdown mechanism the thickness dependence of the characteristics are of prime interest the data of Fig. 8a are replotted *vs.* thickness in Fig. 8b. The figures show that with increasing current density the characteristics shift to lower voltages and thicknesses and the current pulse rates increase rapidly. At the upper end of the characteristics, the slope of the curves tends to decrease. This may be unexpected, the slope decrease is however

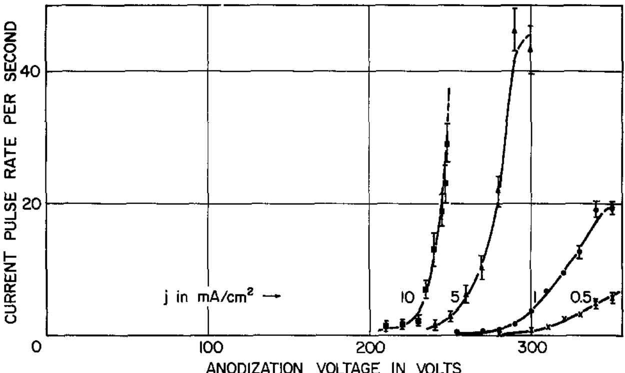

Fig. 8a. Current pulse rate vs. anodization voltage with current density as parameter. Experimental data are connected by full lines. Electrolyte resistivity 7000 Ω-cm.

consistently observed, when propagating breakdowns do not interfere in the measurements. The characteristics were found to be reproducible within a few percent on the thickness scale. The rate of breakdown could not be determined for $R_r > 30$/sec for the characteristic of $j = 10$ mA/cm^2, because breakdowns were propagating.

The rate of breakdown was measured not only at constant field and growing insulator thickness, but also at practically constant thickness and varying field conditions. To obtain such results, the anodic growth was stopped at some voltage and the rate of current pulses measured at decreasing voltages with the sample remaining in the electrolyte. This is illustrated by the experiment of Fig. 9 for a 5700Å thick oxide, anodized with 0.5 mA/cm^2 current density to 350V. The rate of current pulses was found to decrease with increasing inverse field exponentially. Such a behavior was observed also in tantalum pentoxide films flanked by solid electrodes (16).

A series of experiments were carried out to study the influence of electrolyte concentration on the breakdown characteristic. The measurements extended over a range of resistivities from 260 to 2.1×10^4 Ω-cm, with a maximum citric acid concentration of 1.8 w/o. The breakdown characteristics as a rule were not much influenced by variations in ρ_e, although often inconsistent behavior was observed. On the whole a small tendency for shifts of the characteristics to lower voltages appeared with decreasing ρ_e. Earlier workers found larger decreases of the sparking voltage with decreasing ρ_e and increasing concentration (1, 3, 20, 21). These differences may in part be due to the larger range of concentrations in earlier work and also to the possible inclusion of sparks at weak spots, when the sparking voltage was determined.

A few experiments were carried out at electrolytic bath temperatures varying from 3° to 50°C, and characteristics for a given current density were found to shift to higher voltages with increasing temperature. Since the anodization field decreases with increasing temperature, the field decrease appears to be the dominant factor determining the shift in the characteristic.

The characteristics of Fig. 5 and 7 show small flat peaks for the rate of breakdowns at relatively low voltages, below the rising range of the characteristics. An unusually large peak of this kind was obtained for an anodization with $j = 1$ mA/cm^2 in an electrolyte of 2340 Ω-cm resistivity, illustrated by Fig. 10.

On many anodizations such low voltage peaks were not observed. They seem, however, to occur more frequently on anodizations in a low resistivity electrolyte and the magnitude of the peak and its voltage

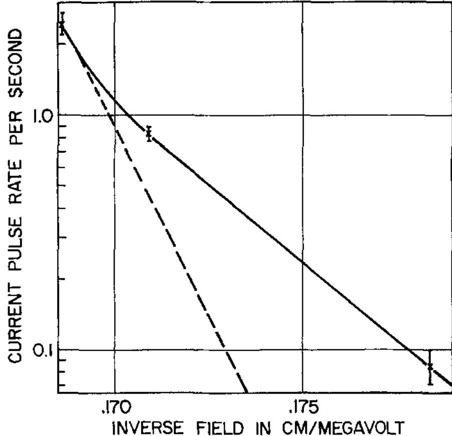

Fig. 9. Current pulse rate vs. inverse field below the anodization field for a 5700Å thick oxide sample. Full line, measurements; broken line, calculated results.

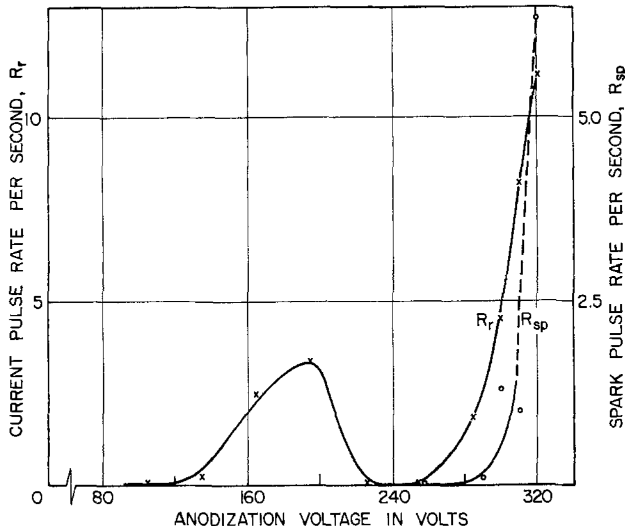

Fig. 10. Breakdown characteristics for a sample with a large current pulse rate peak at low voltages. $j = 1$ mA/cm^2 and $\rho_e = 2340$ Ω-cm.

range were found to vary widely. The low voltage peak events thus do not exhibit regularity, in contrast to the events observed in the rising part of the characteristics. It is possible that the events in the low voltage peaks of the characteristics are breakdown pulses at defects, indicating that breakdown characteristics could provide information for quality control.

Breakdown Mechanism

Identification of the breakdown mechanism is usually a complex problem. Difficulties arise for experimental and also for theoretical reasons. Experimental problems are connected with weak spots, fluctuations, and shorting breakdowns, although shorting does not disturb observations during anodic growth. Theoretically a good understanding of the high field conduction properties, of the energy band structure of the insulator, and of the relevant breakdown mechanisms is needed but is often only incompletely available. Such difficulties are found also in the discussion of breakdown in tantalum pentoxide.

The bandgap of tantalum pentoxide was found to be 4.6 eV from measurements of photoconduction (22), and the Fermi level of the parent tantalum metal was located 1.1 eV below the conduction bandedge of very thin oxides (23). In samples flanked by metallic electrodes, high field conduction in the range 0.5-3 MV/cm proved to be bulk limited and interpreted at room temperature by the Poole-Frenkel mechanism (24). Electrons were believed to be the dominant charge carriers. The Poole-Frenkel conduction mechanism was connected with coulombic trapping centers of 3×10^{18}/cm^3 density, located 1.0 eV below the conduction bandedge (25, 26). The Fermi level of the oxide was estimated to be 1.4 eV below the conduction bandedge (26). No information seems to be available on conduction by holes and on their trapping properties in the insulator.

Conduction processes are very complex during anodic growth since in principle two ionic and two electronic species transport the current (27). In tantalum pentoxide the oxide field for a given current density remains constant during anodic growth and the ionic current component is two to three orders of magnitude larger than the electronic component (2). Models for the ionic current mechanism were therefore developed independently of the electronic current flow. No satisfactory model was established however (2), and it is as yet unclear whether the ionic current is bulk or interface limited, and whether space charges influence the ionic current flow. The

nature of the electron injection process from the electrolyte into the insulator has not been clarified either.

Diverse mechanisms were proposed for the explanation of breakdown events (28). Some of them like the electromechanical, the high temperature ionic, and the mechanism connected with asperities do not seem to be appropriate to the present case. Theories were not elaborated for mechanisms based on low temperature ionic, bond-breaking, and double injection processes and their relevance for tantalum pentoxide cannot be assessed. The mechanisms examined here are the thermal, because some temperature rises were observed in the oxide in the breakdown range of voltages, and that due to impact ionization, which was proposed by several earlier investigators (1, 3, 7, 8, 12).

Thermal breakdown.—The slope of the voltage *vs.* time curves was found to decrease roughly 1% at voltages close to the breakdown range, when anodizations were carried out at 5 and 10 mA/cm^2 current densities. The decrease in the slope was interpreted as a field decrease, the consequence of temperature rise by Joule heat (29). The temperature rise was calculated for a field decrease of 1% with Eq. [3]. A temperature rise of 4°-5°C was found, raising the question whether thermal instability was the cause of breakdown events during anodic growth at higher current densities.

Equation [3] shows that for anodic growth at a constant field, the conductivity of the oxide σ can be expressed in the form $\sigma = N \exp(-M/T)$, M and N being constants. For this conductivity relation thermal instability arises at a temperature T_m, calculated with (30)

$$T_m = \frac{M}{2}\left[1 - \sqrt{1 - 4T_o/M}\right] \qquad [4]$$

Here T_o is the ambient temperature and for a selected field M is determined with Eq. [3]. Calculations result in $T_m - T_o = 11.7°C$ for a field $F = 6.1$ MV/cm and $T_m - T_o = 13.5°C$ at $F = 6.7$ MV/cm. These results remain practically unaltered in more accurate constant current calculations which account for the small field decreases, when the temperature rises to T_m. Since the calculated values of $T_m - T_o$ are much larger than observed in the experiments, thermal instability cannot be the cause of the breakdown events at $j \leq 10$ mA/cm^2. This finding is reinforced by the circumstance that current runaway can only be localized and filamentary because the total current is constant and thermal filamentary current runaway occurs usually at temperatures larger than T_m (30).

Deterministic models of breakdown by impact ionization.—A number of mechanisms were proposed to explain breakdown by impact ionization (16, 28). Early theories of "intrinsic" breakdown ascribed it to the onset of impact ionization; Forlani and Minnaja (31) ascribed it to the destructive effect of large current flow. Newer theories based on O'Dwyers' (32) model interpret breakdown as an instability process causing current runaway.

Intrinsic theories cannot interpret the observations during anodic growth, because theories postulate that breakdown is independent of thickness. Ikonopisov (8) applied recently Forlani and Minnaja's model to interpret breakdown during anodization. This model assumes that carriers injected from the electrolyte into the oxide multiply by avalanching and breakdown arises, when the current density becomes high enough to cause destruction. Simple relations were derived which give the breakdown voltage V_b and the oxide thickness at breakdown and explain the dependence of V_b on current density, j. The theory was not developed further to account quantitatively for the spread in V_b values with thickness and for the localization of breakdown events and the theory could not be verified by comparison with experiments.

This model does not account for current instability effects, which arise far below the temperature rise required for destruction. In case that the current increases with temperature, thermal instability and current runaway arise at a few tens of degrees temperature rise of the insulator (16). When the current runaway is connected with nearly immobile holes left by avalanches (32), the initial temperature rise can be insignificant.

Thus some form of instability is expected to trigger breakdown at a lower field than found with Ikonopisov's theory stipulating temperature rise to destruction (8). Since thermal instability was discounted, breakdown observations are examined with models based on instability by electronic impact ionization. To make the treatment tractable, we assume that the low mobility ionic current components do not influence the rapid breakdown events, except by determining the average field.

Theories of breakdown due to instability by electronic impact ionization are based on O'Dwyers (32) positive feedback model. The model assumes that electrons injected into an insulator multiply by impact ionization leaving trapped holes behind. The holes increase the cathode field increasing electron injection and carrier multiplication. This regenerative process is successfully opposed below the critical current runaway field, F_r, by hole-electron recombination and/or by hole drift to the cathode. For fields larger than F_r breakdown arises after a time t_r, decreasing rapidly with increasing field. On anodization at constant field breakdown occurs only above a critical thickness, w_r.

This positive feedback process was elaborated for three models: (*i*) The IR model, applicable when the effect of ionization is opposed by recombination (33, 34). (*ii*) The small ionization ID model, when hole drift opposes ionization and the product of the ionization coefficient α and insulator thickness w, $\alpha w < 1$ (32, 35). (*iii*) The large ionization ID model; as described under (*ii*), but with $\alpha w > 1$.

Relations were derived for F_r, w_r, and t_r (34, 35) assuming that electron injection into the insulator is by Fowler-Nordheim tunneling and the electron current density, j_e

$$j_e = AF^2 \exp(-B/F) \qquad [5]$$

with A and B constants. For the ionization coefficient the expression

$$\alpha = \alpha_0 \exp(-H/F) \qquad [6]$$

was used with α_0 and H constants.

For the IR and the small ionization ID model the relation for the time to runaway t_r was found to be approximately (34)

$$t_r \simeq \frac{2\epsilon_0\epsilon}{AB\alpha_0 w} \exp\left(\frac{B+H}{F_r}\right) \qquad [7]$$

The relation is applicable above the critical thickness w_r, predicting that the rate of breakdown R_r, the inverse of t_r, is proportional to w. Examining the experimental results of Fig. 8b, we assume that w_r, the critical thickness for current runaway, is found where the R_r *vs.* w curve starts to rise. The rise of the curve above w_r is seen to be much steeper than predicted by Eq. [7] and this model does not fit the experimental results.

For the large ionization ID model (35) with $w > w_r$

$$t_r \simeq \frac{2\epsilon_0\epsilon \exp[(B/F) - \alpha w]}{AB} \qquad [8]$$

To test this model the data of Fig. 8 were replotted on a semilogarithmic scale in Fig. 11. The curves do not fit an exponential relationship between R_r and w well, except at a current density of 5 mA/cm^2.

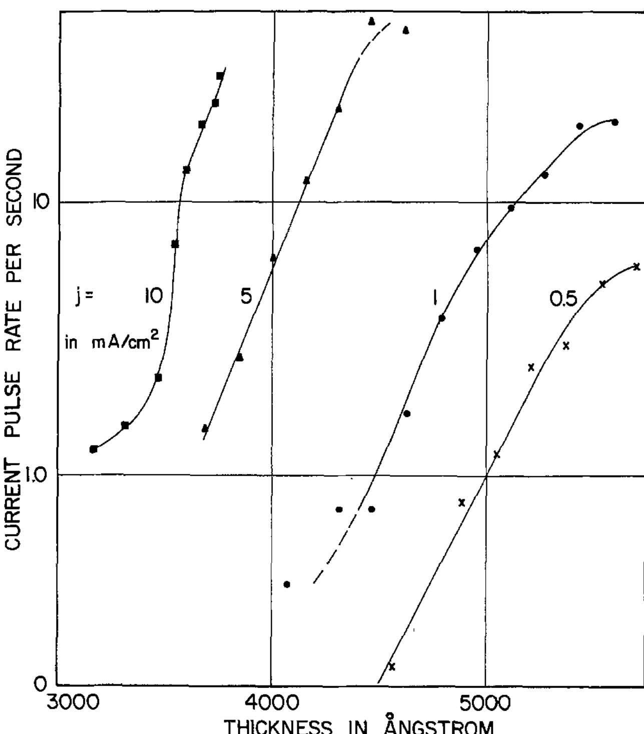

Fig. 11. Semilogarithmic plot of the experimental results of Fig. 8b vs. thickness.

We calculated α from the straight line sections of the curves for 0.5, 1, and 5 mA/cm^2, but as an average value for the curve at 10 mA/cm^2. α was found to increase from 3.5 to 5.5 $\times$ 10^5/cm for a field increase from 6.14 to 6.63 MV/cm. The αw products at the upper ends of the straight line sections were close to 20 implying avalanche sizes of exp 20 $\simeq$ $5 \cdot 10^9$. Such avalanche sizes are impossibly large. Owing to the effect of positive charges opposing the development of avalanches, their sizes are restricted to magnitudes, smaller by about six orders of magnitude (36, 14). The α values derived from Fig. 11 are therefore unrealistic and the oxide observations cannot be interpreted with the model of Eq. [8].

The relations presented in this section were derived by a continuum treatment of the breakdown models. The equations for F_r, w_r, and t_r are deterministic, not accounting for the effects of the finite properties of the electronic charge and of fluctuations. These effects can have significant influence on breakdown events: They can cause localization and randomness of breakdown events, breakdown fields lower, and times to breakdown shorter than given by the deterministic relations (14). Since the deterministic models did not explain observations a stochastic breakdown model is examined in the continuation.

The stochastic succession of avalanche breakdown model.—Account is taken of the finite properties of the electronic charge in the succession of avalanche model (14). This is a stochastic large ionization ID model also based on O'Dwyers' (32) instability mechanism by one carrier impact ionization. We recount here the essential features of the model and modify it for the purposes of this work.

In the succession of avalanche model, primary electrons injected produce avalanches by impact ionization leaving very low mobility holes in the insulator. The positive charges are centered in avalanche clusters spaced apart, and the hole density is grossly nonuniform. This is illustrated in the cross-sectional sketch of an insulator in Fig. 12a. The vast majority of the hole clusters drift out of the insulator without further effect. There is, however, a chance that a second electron is injected into a hole cluster before it leaves

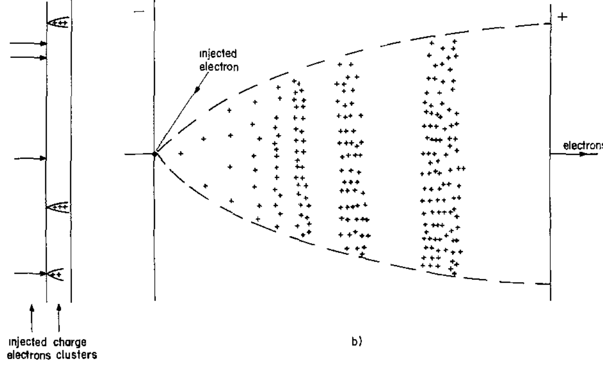

Fig. 12. (a) Cross-sectional sketch of an insulator with positive avalanche clusters spaced apart; (b) Schematic picture of positive charges produced in an avalanche (neglecting large fluctuations).

the insulator. A second avalanche arises, which locally enhances the cathode field, greatly increasing the chance for the injection of a third electron, etc. The regenerative effect of successive avalanches leads to current runaway and local breakdown, when an additional electron is always injected before the hole cluster leaves the insulator.

The average number of electrons, n, in an avalanche produced by an electron injected at the cathode is

$$n = \exp\left(\int_0^w \alpha dw'\right) \qquad [9]$$

Alternatively, considering individual ionizations

$$n = 2^i \qquad [9a]$$

i being the average number of ionizing collisions. There is an upper limit to the avalanche size, since the positive charges produced and left behind keep decreasing the field at the progressing front of the avalanche, until impact ionization stops (36, 14). Since the avalanche size is an exponential function of i, the effect of the positive charges becomes significant for the last few ionizing steps only. This is illustrated in Fig. 12b by the schematic picture of the positive charges of an avalanche produced by a primary electron. When the effect of holes is negligible the mean avalanche size produced by a primary electron

$$n = \alpha w \qquad [9b]$$

The largest possible avalanche contains N_l carriers, has a length w_l and a cross section A_v at the front. Approximate relations derived for N_l, w_l, and A_v are (14)

$$N_l = 4\pi\epsilon_0\sigma\kappa i_l \epsilon l_p V_i/3q = 2^{i_l} \qquad [10]$$

$$w_l = \kappa i_l V_i/F \qquad [11]$$

$$A_v = 4\pi\kappa i_l l_p V_i/3F \qquad [12]$$

Here $\sigma < 1$ is a form factor accounting for the localized effect of the opposing field of the positive charge; κ accounts for the average increase of the mean free path of impact ionization toward the anode (see Fig. 12b); i_l is the number of impact ionizations by the injected electron producing the avalanche of size N_l; l_p is the mean free path for electron-optical phonon collisions, and V_i is the mean voltage drop for an impact ionization in the vicinity of the cathode.

A relation for N_l as function of field will be needed below. This is obtained by replacing $V_i = F \ln 2/\alpha$ and $i_l = \ln N_l/\ln 2$ in Eq. [10] resulting in

$$N_l/\ln N_l = 4\pi\epsilon_0\sigma\kappa\epsilon l_p F/3q\alpha \qquad [10a]$$

Relations were derived (14) for the rate of breakdown, when fluctuations in the size of the avalanche

$N \leq N_l$ produced by a primary electron are disregarded We denote in this case the rate of breakdown by R_{rN}, in distinction from R_r, which will apply when account is taken of fluctuations in the avalanche size N. For the case of electron injection by Fowler-Nordheim tunneling (Eq. [5])

$$R_{rN} = K \exp(-L_f B/F) \quad [13]$$

was obtained. Relatve to the exponential factor, K depends weakly on F in this relation and will be assumed constant here. L_f is larger than unity and increases with the number of successive avalanches required for current runaway. The number of successive avalanches is the larger, the smaller the cathode field enhancement by the individual avalanches. The slope of the ln R_{rN} *vs*. $1/F$ plot is L_f times larger than that of the ln j_e (Eq. [5]) plot and L_f is denoted the slope enhancement factor.

L_f is a complex function of the primary avalanche size N (14) and will for present purposes be roughly approximated by

$$L_f = 1 + \gamma/N \quad [14]$$

with γ a constant. Replacing in Eq. [13]

$$R_{rN} = K \exp\left[-\frac{B}{F}\left(1 + \frac{\gamma}{N}\right)\right] \quad [13a]$$

A form better suited for calculations is used below

$$R_{rN} = C \exp(-B/F) \exp(bFN) \quad [13b]$$

with C and b constants. These two equations show a rapid increase in R_{rN} with increase in N, the size of the primary avalanches.

The increase in R_{rN} is limited by the maximum value of the avalanche size N_l. We denote R_{rN} by R_{rl} and L_f by L_{fl}, for the case, when $N = N_l$ and obtain with Eq. [13] and [13a]

$$R_{rl} = K \exp\left[-\frac{B}{F}\left(1 + \frac{\gamma}{N_l}\right)\right] = K \exp(-L_{fl}B/F) \quad [15]$$

For thicknesses $w > w_l$ the avalanche size remains N_l and R_{rl} is constant.

We show in the Appendix that calculations with Eq. [13a] can be well fitted to the experimental data of Fig. 8b. The fitting procedure, however, results in insignificant magnitudes for γ/N_l representing the effect of field enhancement on the breakdown process for N_l size avalanches. The value of γ/N_l has to be at least 10 times larger according to the succession of the avalanche breakdown model and Eq. [13a] is not applicable to the observations.

We will show in the continuation that the succession of avalanche model becomes applicable, if account is taken of the effect of fluctuations in the avalanche size N and a modified relation will be derived for R_r as function of F and w. The treatment is based on approximations, because a rigorous derivation seems to be prohibitively complex.

The effect of fluctuations in the avalanche size on the rate of breakdown equation.—Fluctuations in avalanche size around a mean avalanche size n at a thickness w were investigated by Wijsman (37). The probability density $p(N, w)$ for the production of an avalanche of N electrons by an electron injected at the cathode into a w thick insulator is given by

$$p(N, w) \simeq \frac{1}{n} \exp(-N/n) \quad [16]$$

The relation is valid for $n >> 1$, which is usually the case and in the thickness range in which the field distortion by positive charges is unimportant. An analytical relation is not available for thicknesses in which the effect of positive charges is significant. At thicknesses larger than w_l fluctuations in N are expected to be small and avalanches tend to grow to the size N_l.

In the thickness range in which Eq. [16] is valid $p(N, w)$ has a broad exponential distribution and fluctuations in avalanche size are considerable. Breakdown events can therefore be initiated at a given thickness w by primary avalanche sizes N varying from the smallest size to N_l and the rate of breakdown R_r is obtained by summing the breakdown contributions at all primary avalanche sizes. A first approach in finding the breakdown contribution dR_r at a thickness w and at primary avalanches between the sizes N and $N + dN$ is to equate dR_r with $p(N, w)dN \times R_{rN}$, with the product of the differential fraction of N size avalanches and of the rate of breakdown by N size avalanches at the thickness w_N. Such an assumption, however, overestimates the contribution dR_r at a thickness $w < w_N$, since the avalanches succeeding the N size primary avalanche at w are smaller than at w_N. The contribution dR_r is therefore smaller at w than at w_N and to account for this, the product for dR_r is multiplied by a function $c(n)$ and

$$dR_r = c(n) R_{rN} p(N, w) dN \quad [17]$$

$c(n)$ increases with w and hence with the mean avalanche size. The relationship $c(n)$ is not known and the simplest assumption is that

$$c(n) = \eta n \quad [18]$$

with η a constant.

Replacing for the factors of Eq. [17] from Eq. [13b], [16], and [18] and integrating over all primary avalanche sizes from $N \simeq 0$ to $N = N_l$ we obtain

$$R_r = \frac{\eta C \exp(-B/F)}{bF - 1/n} [\exp(bFN_l)\exp(-N_l/n) - 1] \quad [19]$$

In this expression the product $C \exp(-B/F) \exp(bFN_l) = R_{rl}$, the value of R_{rN} for $N = N_l$ (see Eq. [13b]). Numerical results obtained from experimental data show that at thicknesses in which breakdown events are registered $1/n$ can be neglected in the denominator and unity in the square brackets. Equation [19] obtains then the simple form

$$R_r \simeq \frac{\eta}{bF} R_{rl} \exp(-N_l/n) \quad [19a]$$

Since the field changes little η/bF is approximately constant and

$$\eta/bF = k \quad [20]$$

Replacing for n in Eq. [19a] from Eq. [9b] the relation for the rate of breakdown is obtained for thicknesses in which R_r is not affected significantly by positive charges

$$R_r \simeq kR_{rl} \exp[-N_l \exp(-\alpha w)] \quad [21]$$

Alternatively replacing for R_{rl} from Eq. [15]

$$R_r = kK \exp\left[-\frac{L_{fl}B}{F} - N_l \exp(-\alpha w)\right] \quad [21a]$$

These two relations are based on the approximations contained in Eq. [13b], [16], [18], and [20]. Comparison of Eq. [21a] with Eq. [5] shows that R_r increases strongly with the rate of electron injection into the insulator.

Since the probability density $p(N, w)$ is not known at thicknesses with significant positive charges, a relation for R_r is not available in this thickness range. We may extend, however, the validity of Eq. [19a] for this range in rough approximation by replacing for n from Eq. [9], obtaining

$$R_r \simeq kR_{rl} \exp\left[-N_l/\exp\left(\int_0^w \alpha dw'\right)\right] \quad [22]$$

The dependence of R_r on thickness expressed by Eq. [22] is schematically illustrated in Fig. 13 by a solid line curve. The lower part of the curve rising at increasing slopes corresponds to the range of validity of Eq. [21]. Beyond the range of its validity Eq. [21] is represented by the broken line curve. When the effect of positive charges becomes significant the slope of the solid line curve decreases with increasing thickness and the rate of breakdown saturates at $R_r = kR_{rl}/e$ for $N = N_l$.

Comparison of the succession of avalanche breakdown theory with experiments.—Breakdown characteristics, illustrated by Fig. 8a, were found to have slopes increasing with thickness, except at largest R_r values. Experimental data were compared therefore with Eq. [21] and [21a], examining the fit of the functional relationship and evaluating the breakdown coefficients α, N_l, and kR_{rl}. The field dependence of α and kR_{rl} was determined too and compared with the functional relationships of Eq. [6] and [15].

Examinations started with a modified form of Eq. [21] obtained by taking logarithms twice

$$\ln [\ln (kR_{rl}/R_r)] = \ln N - \alpha w \quad [21b]$$

Equation [21b] predicts a linear relationship between $\ln [\ln (kR_{rl}/R_r)]$ and w. This relationship was found to be reasonably well observed. We illustrate this with the experimental data of Fig. 8b, which are replotted in Fig. 14, using α, kR_{rl}, and N_l values evaluated below. The bars of standard deviations were omitted in Fig. 14 for clarity. Good linearity was found for the data of anodizations especially at 0.5, 1, and 10 mA/cm^2. The linear range of the data is connected by solid lines, but by broken line curves at extreme values of R_r, where deviations from linearity are observed. The deviations at the upper ends of the characteristics indicate that Eq. [21] is not applicable for very small values of R_r. These deviations may, however, be due also to very rare breakdown events at defects. Deviations at the largest w values are expected from theory and will be shown to result from the effect of positive charges.

Using double logarithmic plots and Eq. [21b] best fit straight lines to experimental data were computed by the least squares method. The coefficients α, N_l, and kR_{rl} were determined with the straight lines and the following results were obtained from a large series of anodizations of tantalum layers produced in different sputtering runs:

1. kR_{rl} was found to increase with $1/F$ as shown in Fig. 15, bars indicating a spread in R_{rl} values. This spread may be partly due to variations in electron injection properties from the electrolyte into the

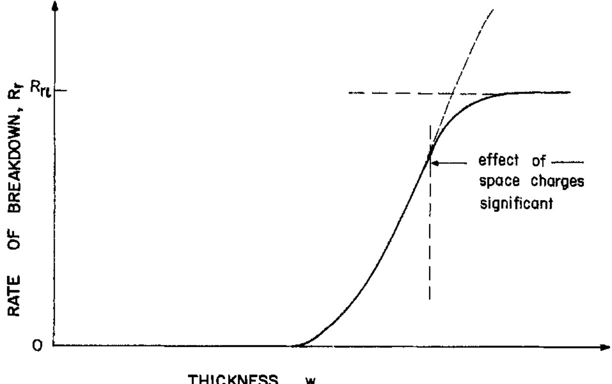

Fig. 13. Schematic representation of rate of breakdown vs. thickness according to Eq. [22].

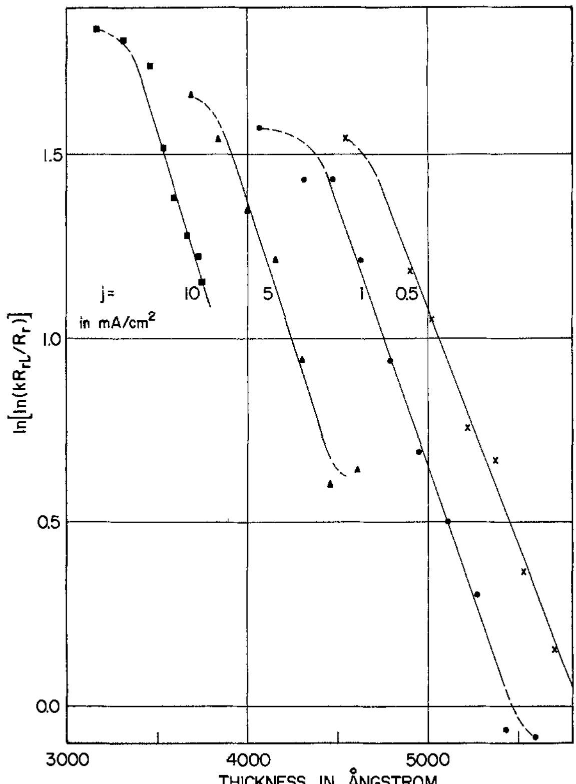

Fig. 14. Double-logarithmic plot of the experimental results of Fig. 8b vs. thickness as dots. Straight lines are calculated.

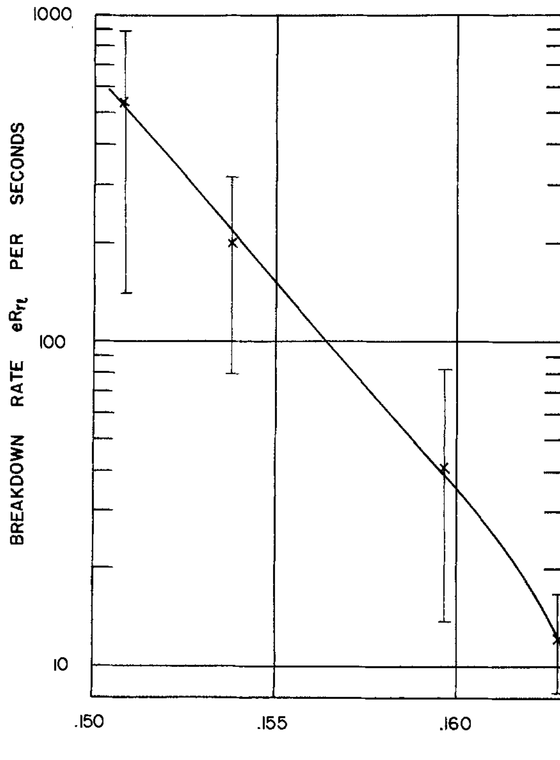

Fig. 15. The coefficient kR_{rl} vs. the inverse field

oxide. The functional relationship of the plot in Fig. 15 agrees fairly well with that predicted by Eq. [15] and the slope of the straight line part of the plot gives $L_{fl}B \simeq 290$ MV/cm.

2. The coefficient of impact ionization was determined from the slope of the straight lines. A set of ten anodizations of randomly selected tantalum layers resulted in $\alpha = (1.58 \pm 0.21) \times 10^5$/cm at a field of

6.26 MV/cm. Values of α found for other fields differed little and since the variance of the α values was large, the field dependence of α could not be established with anodic growths on randomly selected tantalum layers.

3. A large uncertainty was experienced in the determination of N_l with the double logarithmic plots, values varying between 1500 and 3500 for anodizations at 6.26 MV/cm.

Variations found in the values of the coefficients were in part due to experimentation with tantalum layers from differing sputtering runs. An important part of the variations was, however, due to shallow minima in the best fit procedures and to fluctuations in the rate of breakdown, which diminish the accuracy of the best fit procedure. The shallow minima manifested themselves in fairly reasonable fits of calculated curves and experimental data for a range of variation in α by roughly $\pm 10\%$. Such changes in α resulted in slightly larger changes of opposite sign in R_{rl} and in much larger changes in N_l. The nature of these changes are illustrated numerically with the example of the characteristics of Fig. 8b in Table III.

To find the field dependence of the coefficient of impact ionization α, the coefficients were determined with anodizations carried out at increasing fields on tantalum layers from the same sputtering run. Results of such anodizations are presented by the data of Fig. 8b. In the calculations best fit procedures were applied only to the determination of the coefficients for anodization at one field. These coefficients were used for the calculation of the coefficients at other fields providing an additional test for the validity of the theory. The calculations are illustrated with the data of Fig. 8b.

The best fit procedure was applied to the 6.26 MV/cm characteristic in Fig. 8b resulting in $\alpha = 1.4 \times 10^5$/cm, $kR_{rl} = 48.9$/sec, and $N_l = 2082$. With these data the curve marked $j = 1$ mA/cm^2 was obtained in Fig. 8b, agreeing well with observations, except at the upper R_r values. To calculate the coefficients at other fields changes of the thickness w with field F at a constant rate of breakdown were investigated.

Equation [21a] shows that when R_r is constant, the exponent in the expression

$$\frac{L_{fl}B}{F} + N_l \exp(-\alpha w) = C \qquad [23]$$

is a constant, C. C is determined from data at a given field and thickness and for calculations of α and N_l at other fields and thicknesses Eq. [23] gives

$$\alpha = \frac{1}{w} \ln \frac{N_l}{C - L_{fl}B/F} \qquad [24]$$

A second relation for the calculation of α and N_l, is presented by Eq. [10a], which shows that $N_l/\ln N_l$ is proportional to F/α. A third relation for the evaluation of kR_{rl} is presented by Eq. [21].

Using the three relations the coefficients were determined by numerical methods. As an example we quote figures calculated with data for $R_r = 6$/sec in the observations of Fig. 8b: For $j = 1$ mA/cm^2 $R_r = 6$/sec is found at a thickness $w = 4910$Å. Using the previously determined values $\alpha = 1.4 \times 10^5$/cm, $N_l = 2082$, and $L_{fl} = 290$ MV/cm, $C = 48.5$ is obtained with Eq. [23]. With this value of C the coefficients were evaluated for $j = 0.5$, 5, and 10 mA/cm^2 anodization current densities and the results are tabulated in Table IV. Changes in the value selected for R_r did not alter the results significantly.

The breakdown characteristics calculated with the values derived for the coefficients are plotted as solid line curves in Fig. 8b. Except at the upper ends of the curves, good agreement is found with experimental results at 0.5 and 10 mA/cm^2, but the agreement is not as good for 5 mA/cm^2 current density. The straight lines of Fig. 14 were also obtained with the α and R_{rl} values of Table IV, although for better fit the N_l values were altered by a few percent.

The values presented for α in Table IV fit reasonably well the relationship of Eq. [6] for the coefficient of impact ionization, which can be expressed by $\alpha = 4.4 \times 10^6 \exp(-21.5/F)$/cm with F in MV/cm. Comparison of the magnitude of $H = 21.5$ MV/cm with the fields of anodization indicates a "high field range of ionization," in which α increases relatively slowly with field.

To examine the reason for the deviations of experimental results from Eq. [21] at the upper end of the breakdown characteristics, avalanche sizes, n_m, unaffected by positive charges were calculated. With Eq. [9b] $n_m = \exp(\alpha w_m)$, w_m being the largest oxide thickness at which R_r was observed. The magnitudes of n_m were compared with N_l and the ratios n_m/N_l are presented in Table IV. The ratios show clearly that positive charges affect the breakdown rate at the upper ends of the characteristics, that avalanche sizes are smaller than n_m and should be calculated with Eq. [9]. It follows from Eq. [22] that a decrease in the slope of the characteristics is expected at the upper ends, as indeed demonstrated by the experimental data of Fig. 8b.

In the case of the 5 mA/cm^2 characteristic even a decrease was found in R_r at w_m and this may be a fluctuational effect. Propagating breakdowns prevented observations in tantalum pentoxide at thickness larger than w_m. It will be shown in Part II (15) that observations could be extended to larger thicknesses during the anodic growth of aluminum oxide. The results show a saturation in the rate of breakdown with increasing w, as predicted by Eq. [22].

The coefficients of the characteristics of Fig. 8b could be determined with good accuracy basing calculations on the value $\alpha = 1.4 \times 10^5$/cm at 6.26 MV/cm. This value of α was, however, found by best fit procedure, involving an uncertainty in its magnitude. To study the effect of this uncertainty we recalculated the parameters kR_{rl}, N_l, α_o, and H for Fig. 8b assuming an uncertainty of $\pm 10\%$ in the value of α at 6.26 MV/cm. Results of the calculations presented in Table III show that the constant H is little affected, the effect on R_{rl} and α_o is somewhat larger than on α, and that the value of N_l is subject to a considerable uncertainty.

The magnitude of the field, known to a few percent accuracy only (see section on Experimental Results) is another source of uncertainty. A change in the field value assumed produces an inversely proportional change in the oxide thickness calculated from

Table III. Variations in the coefficients for the characteristic of $j = 1$ mA/cm^2 in Fig. 8b

				The uncertainty
$\alpha \times 10^{-5}$/cm	1.26	1.4	1.54	$\pm 10\%$
N_l	1130	2082	3850	+85 −46
kR_{rl}/sec	56.8	48.9	43	−12 +16
H, MV/cm	21.1	21.5	21.9	+1.9 −2.1

l_o, Å	3.7	6.9	13	

Table IV. Parameters derived from data of Fig. 8b

F, MV/cm	6.14	6.26	6.5	6.63
$\alpha \times 10^{-5}$ cm	1.31	1.40	1.57	1.70
N_l	2195	2082	1909	1788
kR_{rl}/sec	20.9	48.9	288	688
n_m/N_l	0.78	1.1	0.56	0.41

voltage observations. The effect of the thickness change is eliminated in Eq. [21a] by a change in α proportional to the change in field and the uncertainty in the field produces an uncertainty of the same magnitude in α.

The uncertainty in the value of the parameters is largely removed, when one constant is well known at a given field. While such a value is not available for Ta_2O_5 some independent indication of bounds for α and N_l is obtained by calculating the mean free path for phonon collision, l_p, with Eq. [10a]. We replace for this purpose the α and N_l values found in Table III and the approximate values $\sigma = 0.85$ and $\kappa = 1.8$ (14) in Eq. [10a] and evaluate data presented in the last line of Table III for l_p.

Information does not seem to be available on l_p in Ta_2O_5 for comparison. A value of about 6Å was found for l_p in amorphous aluminum oxide films at high fields (38, 39) and 1.7Å was derived for l_p in thermally grown silicon dioxide films at breakdown fields (33). It is likely that a few angstroms is the length of l_p also in amorphous tantalum pentoxide and Table III indicates that the calculations from breakdown observations resulted in reasonable values for l_p.

It is of interest to consider further avalanche properties. An individual avalanche of size N_l produces a temperature pulse θ at the breakdown spot. Assuming that θ is due to the instantaneous heating effect of electrons, θ can be evaluated with the relation $\theta \simeq \sigma\epsilon_0\epsilon F^2/4c$ (14), with c the specific heat of the oxide, 0.8 W/cm^3°K. For a field of 6.26 MV/cm $\theta \simeq 23$°C is found. Such a temperature pulse cannot result in breakdown, because the pulse dissipates within nanoseconds (14) and calculations show that thermal instability cannot arise within this short time interval (30).

The stochastic properties of the succession of avalanche model were shown to be connected with the wide spacing between positive charge avalanche cones drifting toward the cathode (Fig. 12a). A fraction f of the oxide volume only is assumed to be occupied by avalanche cones. Stipulating a maximum value in f for the validity of the model, a lower bound can be estimated for the hole mobility, μ_p with the equations

$$f = j_e A_v t_t / q \quad \text{and} \quad t_t = w/\mu_p F \qquad [25]$$

where j_e is the electron current density injected from the electrolyte, A_v is the largest avalanche cross section, and t_t is the transit time for holes through the oxides. Assuming that j_e is one thousandth of the ionic current density, 10^{-6} A/cm^2, $f = 0.1$, $w = 5 \times 10^{-5}$ cm, $F = 6.26$ MV/cm, and $A_v = 2.8 \times 10^{-11}$ cm^2 from Eq. [12] using data of Tables III and IV, a hole mobility of 1.4×10^{-8} cm^2/Vsec is obtained with Eq. [25]. This value of μ_p indicates deep trapping of holes.

We examined also whether trapping of electrons influences the development of avalanches. The electron trapping levels are 1 eV below the conduction bandedge (24), and calculation of the trap occupancy τ at room temperature (40) shows that τ is 50% at 3.1 mV/cm. The trap occupancy drops rapidly with increasing field and electron trapping appears to have no significance in the range of the breakdown experiments during anodic growth.

The breakdown observations of Fig. 9 at constant thickness and at fields varying below fields for anodic growth were also examined with Eq. [21]. For the calculation of the field dependence of R_r, $w = 5700$Å, $L_{fl}B = 290$ MV/cm, $N_l = 2082$, and $\alpha = 4.4 \times 10^6 \exp(-21.5/F)$/cm ($F$ in MV/cm) were replaced in Eq. [21a]. The results are plotted by a broken line curve in Fig. 9. This curve agrees with the experimental data at highest values for R_r only, but drops off rapidly below experimental data at lower fields. It appears that Eq. [21a] is not applicable at lower fields, when the rate of breakdown becomes very small. Figures 8b and 14 show that Eq. [21b] is not applicable at anodization fields either, when R_r is very small. The field dependence of the rate of breakdown is not known in this range of R_r.

It should be noted that as the field drops, the mean avalanche size and probably the hole mobility drop rapidly. The law governing electron injection into the oxide may alter too and these effects may change the mode of the breakdown mechanism. This may be illustrated by breakdown observations on 2300Å thick tantalum pentoxide films flanked by metallic electrodes at fields as low as 4.5 MV/cm (14). Avalanches are hardly expected to arise at such low fields, but mainly single ionizations by collision. The IR or the small ionization ID model may explain breakdown events in this case.

Summary

Breakdown observations made during the anodic growth of tantalum pentoxide were presented in characteristics, which plot the rate of breakdown as a function of oxide thickness at constant field. The breakdown events could not be interpreted by thermal instability or by mechanisms based on impact ionization at low rates, but by the stochastic succession of avalanche breakdown model.

An approximate relation derived for this model, giving the rate of breakdown, R_r, as function of insulator thickness, shows that R_r depends strongly on the electron current injected from the electrolyte and on electron multiplication in the oxide. The relation explains the observed shifts of the breakdown characteristics to lower thicknesses, with increasing field, or with decreasing temperature.

Characteristics calculated with the relation for R_r could be well fitted to experimental observations at various fields. Theory predicts a decrease in the slope of breakdown characteristics at larger R_r values, when the effect of the positive charges of the avalanches becomes significant. This has been consistently observed. The relation for R_r is not applicable at very low rates of breakdown, observed at relatively small insulator thicknesses, or at fields lower than those for anodic growth.

The coefficients in the relation for R_r were evaluated by best fit methods and with data on the variation of oxide thickness with field at a constant rate of breakdown. We found for the set of samples of Fig. 8b the mean values $\alpha = 1.4 \times 10^5$/cm and $N_l = 2082$ at a field of 6.26 MV/cm, and for the coefficient of impact ionization the relation $\alpha = 4.4 \times 10^6 \exp(-21.5/F)$/cm, with F in MV/cm for the range of fields 6.1-6.7 MV/cm.

These results are subject to uncertainties owing to shallow minima in the best fit procedures, to fluctuations in R_r, and to some uncertainty in the value of the electric field. Assessing the uncertainty in the magnitude of the coefficient of impact ionization to ±10%, a somewhat larger uncertainty is found for the saturation value of $R_r = kR_{rl}/e$, but a large uncertainty in N_l, the largest avalanche size. The uncertainty in the magnitude of the parameters could be largely removed, if one coefficient was known at one field.

JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

APPENDIX

The Magnitude of the Slope Enhancement Factor in Eq. [13a]

Equation [13a] does not account for the effect of fluctuations in avalanche size. Replacing for $N = n$ from Eq. [9b] into Eq. [13a]

$$R_{rN} = K \exp\left[-\frac{B}{F} - \frac{B}{F}\gamma \exp(-\alpha w) \right] \quad [13c]$$

is obtained. This equation has the same formal dependence on F and w as Eq. [21b], which accounts for the effect of fluctuations in N. Equation [13c] can therefore be fitted to the experimental data of Fig. 8b just as well as Eq. [21b] and the numerical results of the section Comparison of the Succession of Avalanche Breakdown Theory with Experiments can be applied to the coefficients of Eq. [13c].

B and $B\gamma/F$ in Eq. [13c] correspond to $L_{fl}B$ and N_l in Eq. [21b], respectively. Thus in Eq. [13c] $B =$ 290 MV/cm and $B\gamma/F = 2082$ for a field of 6.26 MV/cm (see Table IV), resulting in $\gamma \simeq 45$. The slope enhancement factor $L_f = 1 + \gamma/N$ (Eq. [14]) is smallest for the largest avalanche size N_l and $L_{fl} \leq 1.045$, assuming $N_l \geq 1000$ with Eq. [10] and Table III.

The relation derived for L_f in Ref. (14) is

$$L_f = 1 + (1 - R)(1/\beta_1 + 1/\beta_2 + \ldots + 1/\beta_{n-1}) \quad [26]$$

$(1 - R)$ is close to unity and accounts for the effects of the removal of positive charge by drift. The coefficients $\beta_1, \beta_2, \ldots$, are the factors of field enhancement at the cathode after the first, second, etc. avalanche at the breakdown spot. The magnitude of the coefficients β falls between 1 and 2 and $\beta_1 < \beta_2 < \beta_3 \ldots$. The number of the $1/\beta$ terms resulting in breakdown are smallest when $N = N_l$. For this case the slope enhancement term $(1 - R)(1/\beta_1 + 1/\beta_2 + \ldots + 1/\beta_{n-1})$ can hardly be less than 0.5 and may reach 2.5 (14). The upper limit 0.045 found for this term from experimental results contradicts therefore, the succession of avalanche breakdown model and Eq. [13a] is not applicable to the observations.

Electrical Breakdown

II. During the Anodic Growth of Aluminum Oxide

N. Klein, V. Moskovici,[1] and V. Kadary[2]

Faculty of Electrical Engineering, Technion-Israel Institute of Technology, Haifa, Israel

ABSTRACT

Breakdown characteristics found during the anodic growth of aluminum oxide start with a range of rapid increase in the rate of breakdown R_r. This is followed by a range of saturation, when observations are not disturbed by propagating breakdowns. The mean value of R_r can be subject to some variations in the saturation range. The breakdown characteristics shift to lower voltages with increasing field of anodization. The observations agree with predictions of the succession of avalanche breakdown theory. The reason for variations of R_r in the saturation range is not clear. The coefficient of impact ionization at a field of 8.7 MV/cm was found to be roughly 2×10^5 mcm. Compared with tantalum pentoxide the breakdown characteristics of aluminum oxide show a relatively poor reproducibility.

Samples and Some Oxide Properties

Investigations of Part I of this paper (1) were extended to electrical breakdown during the anodic growh of aluminum oxide. Experimental setup and methods applied were the same as in the tantalum pentoxide observations (1). The samples had the dimensions and buildup shown in Fig. 1 of Part I (1) for tantalum samples. The samples produced in vacuum by thermal vaporization of high purity aluminum were deposited on borosilicate glass substrates. The aluminum layers, 5000Å thick, had a mirror-like surface.

We were interested in examining nonporous films, which are not attacked by the electrolyte (2). The pH of the electrolytes used was limited, therefore, to the range of 5.5-6.5 (3). The anodic growths were performed with an electrolyte of an aqueous solution of 0.1M ammonium tartarate adjusted with tartaric acid to a pH of 6. Deionized water with a resistivity of several MΩ-cm was used. The resistivity of the electrolyte measured at 1 kHz was 70 Ω-cm. Electron diffraction showed that the oxide layers grown were amorphous.

We review briefly data on the properties of anodic aluminum oxide relevant for this work: Experimental results published on the electric field of formation, F, as function of current density of anodization, j, vary, roughly within ±7% (4-6) and this spread introduces some uncertainty in the evaluation of experimental results. We use here the F-j relation obtained by Siejka *et al.* (7) for room temperature

$$j = 1.72 \times 10^{-25} \exp (5.76 \times 10^{-6}F) \qquad [1]$$

with j in A/cm² and F in V/cm. Table I presents values of F at the current densities selected for the observations. Equation [1] was obtained for polished sheet samples and we assume its applicability to the mirror-like thin film samples of this work.

Optical measurements of Arakawa and Williams (7) for the determination of the bandgap of anodically grown Al_2O_3 showed the onset of appreciable absorption at 6.8 eV. This was connected with excitonic transitions, while band to band transitions were ascribed to energies above 9.4 eV. Powell (8) found band to band transitions with photoconduction experiments in chemically vapor-deposited (CVD) films with photon energies larger than 7.8 eV. Measurements of the barrier at the aluminum-CVD aluminum oxide interface resulted in energies of 3-3.5 eV (9-11). Conduction experiments at high fields in CVD films were interpreted with trapping of injected electrons roughly 1.35 eV below the conduction bandedge (12). Observations indicated deep trapping of holes, but quantitative data were not obtained (13). The electronic current component during anodization was found to amount to less than 2% of the ionic current on polished aluminum samples (6).

Experimental Results

Experimental observations are illustrated by the breakdown characteristics plotted in Fig. 1-3. Figure 1 presents the characteristic for an anodization at 1 mA/cm² current density at room temperature. Dots with bars of standard deviation in the figure represent experimental results and the solid line is calculated. The characteristic rises rapidly between 200 and 230V. This range is followed by one of saturation, in which the rate of breakdown R_r fluctuates around a mean of about 7/sec.

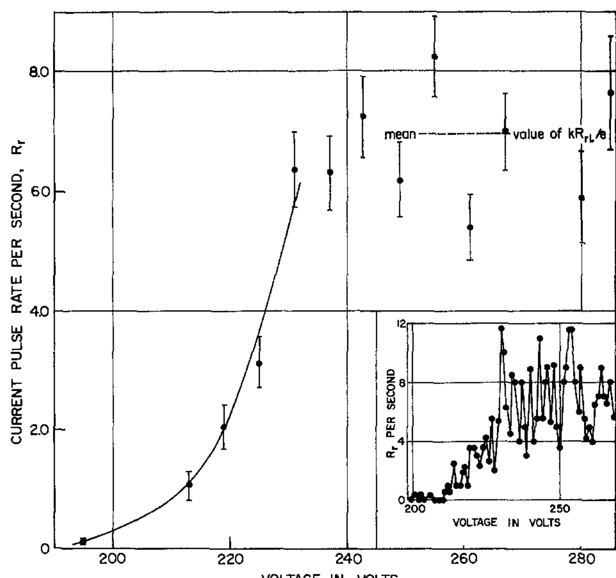

Fig. 1. Rate of breakdown vs. anodization voltage at a current density of 1 mA/cm². Dots are experimental results and the solid line curve is calculated. The insert gives part of the characteristic counting breakdown events in 1V intervals; dots are connected by lines for clarity.

A saturation range for R_r could not be observed in tantalum pentoxide owing to the prevalence of propagating breakdowns above the voltage, where the slope of the characteristic begins to decrease. In contrast, propagating breakdowns were usually not numerous in the saturation range of aluminum oxide. In the case of the experiment of Fig. 1, for instance, propagating breakdowns occurred only over 10% of growth time and the frequency of such breakdowns was roughly constant over the saturation range. The great majority of breakdowns were individual, randomly distributed events. The rate of breakdown could therefore be determined in good approximation for Fig. 1, counting all current pulses, including those found in the traces of propagating breakdowns. To assess the error due to this counting procedure, we determined R_r also by disregarding current pulses found in the traces of propagating breakdowns and by correcting for the time lost to observation by the propagating breakdowns. These R_r values were a few percent smaller than those plotted in Fig. 1.

Fluctuations in R_r were considerable and to illustrate their nature, R_r is plotted *vs.* the anodization voltage V in the inset of Fig. 1, counting breakdown events in 1V intervals. For clarity, successive R_r values are connected by solid lines. This plot indicates a periodic variation in the mean value of R_r over periods of 10-12V. Other kinds of variations in the mean value of R_r in the saturation range were observed as well, such as a peak in R_r at the beginning of the range, or a decrease in R_r in the middle of the range. The saturation range was followed by a range filled by propagating breakdowns. Owing to prevalence of propagating breakdowns, a saturation range was not observed in all experiments. This was experienced especially with samples in which breakdowns started at voltages lower than the average starting voltage.

Figure 2 presents breakdown characteristics for anodizations at 1 and 5 mA/cm^2 on two samples produced in one production run. The characteristic shifts to a lower voltage range and R_r increases with increase of field, as found also for tantalum pentoxide (1). The rate of breakdown in the saturation range for $j = 1$ mA/cm^2 is roughly 2/sec. This is about three and one-half times smaller than found for R_r in the saturation range in Fig. 1. Such a spread in observations was frequently found with anodic growth experiments of aluminum oxide. Characteristics obtained shifted on the anodization voltage scale around a mean by $\pm 15\%$ for anodization current densities of $j = 0.5$ and 1 mA/cm^2 and $\pm 10\%$ for $j = 2$ and 5 mA/cm^2.

Stopping anodic growth, the rate of breakdown was measured at fields lower than fields of formation, with the sample remaining in the electrolyte. Results of such an experiment are presented in Fig. 3 for a 2700Å thick oxide sample.

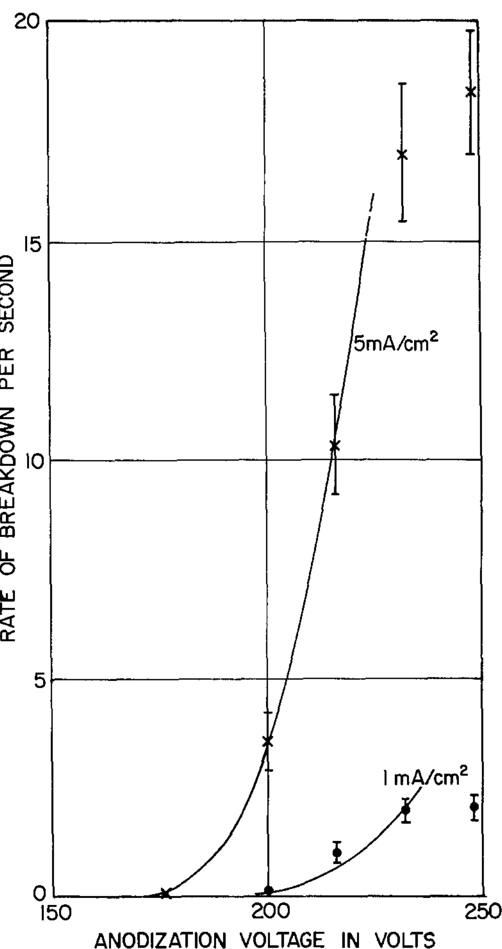

Fig. 2. Rate of breakdown vs. anodization voltage at current densities of 1 and 5 mA/cm^2. Dots are experimental results and the solid line curves are calculated.

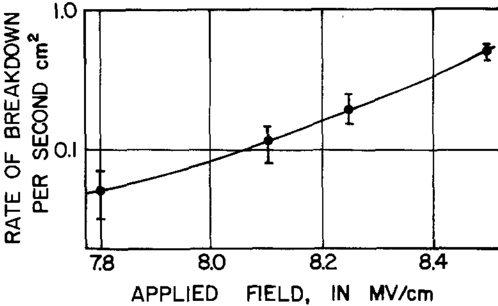

Fig. 3. Rate of breakdown as function of fields smaller than fields of formation in an oxide approximately 2700Å thick.

Discussion

The examination of the experimental results was performed in the same manner as for tantalum pentoxide (1). The observations could not be interpreted by thermal breakdown or with the deterministic impact ionization breakdown theories. We examined, therefore, the applicability of the succession of avalanche model. For this model the rate of breakdown is given by Eq. [21] of Part I (1), valid in the thickness range in which the effect of positive charge is not important and

$$R_r = kR_{rl} \exp[-N_l \exp(-\alpha w)] \quad [2]$$

The notation of the symbols of Eq. [2] is the same as in Part I (1).

Calculations with Eq. [2] based on $w \propto V$ resulted in reasonably good fits to experimental data and this is illustrated in Fig. 1 and 2 by the solid line curves. However, the fitting procedure was within limits successful for differing sets of the coefficients α, N_l, and kR_{rl}; the uncertainty found in the determination of the coefficients for tantalum pentoxide was enhanced in the case of aluminum oxide owing to poorer experimental reproducibility and less accurate knowledge of the magnitude of the field.

Fortunately Eq. [12a] of Part I (1) for the size of the largest avalanche N_l could also be applied to the determination of α, N_l, and R_{rl}, since experimental data are available on l_p, the mean free path of electron-optical phonon scattering in aluminum oxide. Equation [12a] has the form

$$\frac{\alpha N_l}{\ln N_l} = \frac{4\pi\epsilon_0}{3q} \epsilon F \sigma l_p \kappa \quad [3]$$

The notation of the symbols is given in Part I (1). The coefficients α, N_l, and kR_{rl} can, in principle, be accurately calculated with Eq. [2] and [3] and the experimental results. The magnitude of the factors σ, l_p, and κ of Eq. [3] is, however, not well known and only

bounds could be estimated for the coefficients α, N_l, and kR_{rl}.

The magnitude of the factors σ and κ was discussed in Ref. (14). $\sigma < 1$ is a form factor accounting for the localized effect of the positive charges opposing further ionization by an N_l size avalanche. The magnitude of σ was estimated to vary between 0.7 and 0.9. $\kappa > 1$ is a factor accounting for the average increase of the mean free paths of impact ionization toward the anode. The magnitude of κ depends strongly on the field dependence of the coefficient of impact ionization α. κ was estimated to vary between 1.4 and 2.

Several experimental methods were applied to find the magnitude of l_p. A number of investigators attempted to determine l_p from observations of hot electron transport in very thin aluminum oxide films in a range of fields which include fields of anodization (15-18). Handy (15) found near isotropic electron-optical phonon scattering with an energy loss of 0.12 eV and 4Å free travel in the field direction. In reasonable agreement with these results, Savoye and Anderson (16) found isotropic scattering with an energy loss of 0.1 eV and a mean free path $l_p = 6$Å. The determination of l_p by observations of internal photoemission (19) resulted in $l_p = 10$Å near an aluminum-aluminum oxide interface.

Accounting for the uncertainties in the magnitudes of σ, κ, and l_p, breakdown characteristics were calculated with Eq. [2] and [3], fitting experimental results. We assumed for the product $\sigma\kappa l_p$ the bounds $6 \leq \sigma\kappa l_p \leq 18$ in angstroms and $\epsilon = 8.5$. The coefficients of the characteristics evaluated for the experiments of Fig. 1 and 2 are presented in Table II. The columns marked M contain the coefficients for the arithmetic mean of the calculated bounding α values. The bounds of the α values differ by $\pm 13\%$ from the mean value of α.

The mean avalanche size n_m was evaluated at w_m, at the thickness corresponding to the upper end of the calculated characteristics, assuming that n_m is not affected by positive charges and $n_m = \exp(\alpha w_m)$. The ratios n_m/N_l were formed and tabulated in Table II. The magnitude of the n_m/N_l ratios indicate that positive charges are significant at w_m and that Eq. [2] is not applicable for thicknesses $w > w_m$.

The last line of Table II presents $V_i = F \ln 2/\alpha$, the mean voltage drop for an impact ionization. The qV_i values found are more than three times larger than the oxide bandgap (7, 8).

The rate of breakdown is kR_{rl}/e in the saturation range according to Eq. [22] of Part I (1). Since the magnitude of k is not known, R_r could not be calculated in the saturation range. The fluctuations in R_r were examined by plotting in Fig. 4 the histogram of the number of current pulses which were observed in 1 sec growth intervals. The observations extended over 110 sec from the anodization voltage 233 to 273V. The average number of current pulses was 6.86/sec in this voltage range. Using this average, the Poisson distribution of the number of pulses in 1 sec intervals was calculated and plotted as a solid line in Fig. 4. Comparison of this curve with the histogram reveals a surplus of intervals observed with low and large numbers of current pulses, but some lack in intervals below the peak of the curve.

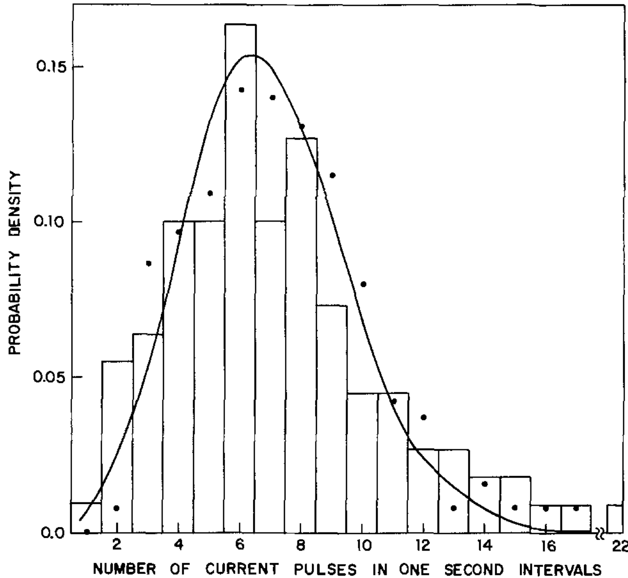

Fig. 4. Histogram of the number of current pulses in 1 sec intervals for the data of Fig. 1 in the saturation range. Solid line curve the Poisson distribution with an average number of current pulses of 6.86 in a 1 sec interval. Dots represent the corrected histogram.

At first sight, the results of Fig. 4 indicate that the breakdown events in the saturation range are not random and independent. This may be partly due to the occurrence of propagating breakdowns. A more significant cause may be the periodic variation of the mean breakdown rate (see Fig. 1) which enhances the histogram at low and large numbers of current pulses. To test the latter assumption the periodic variations were subtracted from the observed R_r values, representing the variation in R_r by $\Delta R_r = 1.2 \cos [2\pi(t - 590)/30]$ per second, with t time in seconds and $t = 590$ sec at 233V. The correction decreased the average number of current pulses, but by 1 ‰ only. The histogram of the corrected R_r values is represented by dots in Fig. 4. A chi-square test for the corrected histogram resulted in a P-value of 0.6, indicating a good fit to the Poisson distribution.

The reason for the periodic variations in the mean of R_r has not been ascertained. If it is assumed that the periodic variations are not directly connected with the breakdown mechanism, the corrected histogram indicates that the breakdown events are likely to be random and independent, as expected with the succession of avalanche breakdown theory.

Avalanche properties were examined in the manner described for tantalum pentoxide. We found that trapping by 1.35 eV deep traps (12) does not affect conduction band electrons at fields of anodization and the hole mobility was estimated to be larger than $3 \cdot 10^{-8}$ cm^2/Vsec. The temperature pulse produced by an avalanche was calculated to be 15°C.

Equation [21a] of Part I (1) for the rate of breakdown could not be fitted to the experimental results of Fig. 3 for aluminum oxide at fields lower than fields

Table II. The coefficients of the anodic growths of Fig. 1 and 2

Experiments	Fig. 1			Fig. 2			Fig. 2		
		M			M			M

The product $\sigma\kappa l_p$, A	6	10.4	18	6	10.2	18	6	10.6	18
$\alpha \times 10^{-5}$/cm	1.66	1.91	2.16	1.75	2.0	2.26	1.95	2.25	2.54
N_l	359	590	985	338	548	919	310	513	846
kR_{rl}/sec	507	259	154	47	27	18	178	102	68
$\exp(\alpha w_m)/N_l = n_m/N_l$	0.23	0.27	0.31	0.31	0.38	0.45	0.35	0.44	0.53
V_i, V	36	32	28	34	30	27	32	28	24

of anodization. The rate of breakdown is very small in such experiments. As with tantalum pentoxide, it was found also with aluminum oxide that Eq. [21a] is not applicable, when R_r is very small.

In conclusion it is found that the succession of avalanche breakdown theory agrees with observations during the anodic growth of aluminum oxide, predicting a rising range in the rate of breakdown followed by one of saturation in R_r. The reason for the variations in the mean value of R_r in the saturation range is not clear. A magnitude of roughly 2×10^5/cm is obtained for the coefficient of impact ionization α at a field of 8.7 MV/cm. Compared with the breakdown characteristics of tantalum pentoxide, the characteristics of aluminum oxide show a relatively poor reproducibility.

Acknowledgments

Thanks are due to Dr. P. Feigin for fruitful discussions and to E. Yashchin for help with the statistical calculations. This work was submitted to Technion by V. M. in partial fulfillment of requirements for the M.Sc. degree.

Manuscript submitted July 31, 1978; revised manuscript Aug. 10, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Low Resistivity CdTe-Te Films by a Combined Hot-Wall-Flash Evaporation Technique

Cornelius A. Menezes

Department of Physics, Centro de Investigacion y de Estudios Avanzados del Instituto Politecnico Nacional, Apartado, Mexico

ABSTRACT

We have developed a new technique utilizing a combination of hot-wall chamber and flash evaporation for the preparation of low resistivity (10-100 Ω^{-1} cm^{-1}) p-type CdTe-Te films. Both thin and thick films can be produced by this technique. The films are characterized by excellent stability during heating and cooling cycles and high reproducibility of resistivity values from batch to batch. Potential probe measurements indicate excellent homogeneity. An optimum hot-wall and substrate temperature has been determined for obtaining low resistivity specimens. We have also studied electrical and optical characteristics like contact characteristics, thermoelectric power, and optical transmission. The high stability and low resistivity CdTe-Te films obtained by this technique may have wide ranging applications in solid-state devices.

We describe in this paper a rather novel deposition technique, which we call the hot-wall-flash evaporation technique (HWFE), involving the combined use of high vacuum flash evaporation and a hot-wall precondensation chamber for preparation of low resistivity CdTe-Te films. These films have the following electrical and mechanical properties: Low electrical resistivity with either gold or indium-gallium contacts. Resistivities are in the range 10^2-10^{-2} Ω-cm. The film surfaces are metallic gray and specular in aspect. On well-cleaned substrates pin-hole free films can be obtained. Film adhesion on glass substrates was remarkably good. This was evaluated by pressing adhesive (Scotch) tape and attempting to strip off the film (8). Reproducibility of resistivity values was good. In measurements made on different runs under similar conditions, the resistivity values in Ω^{-1} cm^{-1} were within 10% of each other.

Electron microprobe analysis of the lowest resistivity films has revealed the presence of 25-50% free tellurium in these films. No data are yet available on the composition of higher resistivity films prepared by the HWFE technique.

Though thin films of CdTe have been investigated before, previous attempts to evaporate CdTe by conventional high vacuum techniques have produced films with very high resistivity (10^7-10^8 Ω-cm at room temperature) (1-7). Glang *et al.* (8) state that "regardless of deposition temperature all films have resistivities of 10^7 Ω-cm or higher, even if impurities are added to the source material." Cusano's method (9) which uses a hydrogen ambient cannot be described as a high vacuum technique for reproducible preparation of low resistivity high stability CdTe films. It was recently shown by Wald (10) that one of the major impediments to the wider use of CdTe based

devices was the lack of techniques whereby problems of (*i*) erratic and nonreproducible behavior of thin films of CdTe and (*ii*) lack of good contacts to low resistivity CdTe p-type material could be solved. In this context there appears to be a need for an improved understanding of the physical mechanism of CdTe deposition. The HWFE technique has the potential to substantially change the composition of the film with respect to the starting material through control of the temperature of the hot-wall or substrate or both of these. There is a possibility that the results obtained with hot-wall flash evaporation of CdTe may help in solving the problem of obtaining low resistivity CdTe, though the present results show that a gross excess of Te is incorporated in the CdTe films.

The hot-wall technique has been used to grow thick films of ZnTe by Behrndt and Moreno (11). Though the actual physics of the process remains uncertain, it appears that a kind of molecular beam is formed by exchange of energy of the Cd and Te atoms with the hot-wall. Thus the beam that impinges on the substrate has a much higher incident energy and a higher pressure compared with that in a normal evaporation process.

The great (approximately 20%) increase in the substrate temperature on initiation of the flash deposition through the hot-wall points to such an increase in the energy of the incident Cd and Te atoms. This high energy could lead to the relocation of Cd and Te atoms to more favorable positions (of minimum lattice energy, corresponding to greater symmetry) after first impinging on the substrate. We believe that this is partly responsible for obtaining the low resistivity CdTe-Te films with highly stable characteristics.

In our experiments we used two brands of high purity CdTe powder as the evaporant, Balzers CdTe specified to be 99.999% pure and Eagle-Pitcher CdTe powder (High Purity). Both these powders, being undoped with In, Ga or Cd, produced p-type layers.

Previous attempts to obtain low resistivity CdTe have relied upon ion implantation or high temperature annealing of high resistivity p-CdTe in an atmosphere of Cd-P or Te-P (12). There is no report on the stability of these films with regard to thermal cycling. The hot-wall flash evaporation technique, however, enables the reproducible and direct preparation of low resistivity p-CdTe-Te with conductivities about two orders of magnitude higher than those reported (12) for CdTe including those that have been intentionally doped by In, Ga, Al or subjected to high temperature annealing treatment in a Cd-P or Te-P atmosphere.

Experimental

The basic vacuum system used was of an unusual design (a Balzers Model B300). It has a cross-shaped work chamber with 4 ports, covered by demountable aluminum vacuum covers, sealed by O-ring seals. A cross section of the chamber is shown in Fig. 1. The flash evaporation system consists of an a-c solenoid-powered vibrating feeder, 1, into which the material to be evaporated is placed.

The funnel attached to the vibrating bowl, 2, is aligned above a rectangular chute, 3, inclined over the molybdenum trough, 7, which forms the evaporation source. We have used two such feeders opposite to each other in two parts of the vacuum chamber. The evaporation source (a molybdenum trough of rectangular shape) is supported on electrical feed throughs mounted on the lower part.

The feed chutes (Fig. 1, 3) are mounted on a stainless steel disk just above the molybdenum trough and are adequately baffled to prevent spattering of the evaporant material from the trough. The hot-wall, 4, is a quartz tube around which is a heating spiral of 0.6 mm diam tungsten wire. This spiral is electrically isolated from the source heating circuit and has electrical feed throughs in the top part. The hot-wall has a diameter of 28 mm and a height of 60 mm. The lower end of the hot-wall fits over a hole of 18 mm diameter in the baffle surrounding the evaporation trough. Thus, a well-defined beam of vapor is obtained when evaporant material impinges upon the heated trough and this beam then proceeds to the substrate axially through the hot-wall chamber. The substrate mounting, 6, is just above the top end of the hot-wall and allows a circular area of 200 sq mm to be deposited at a time. Thermocouples of Chromel-Alumel were used to monitor the trough temperature, the hot-wall temperature and the substrate temperature. Substrate heating was accomplished by a molybdenum radiant strip heater mounted 10 cm above the plane of the substrate. An important feature of the assembly is the provision of a pair of polished semicircular stainless-steel reflectors, 5, coaxial with the hot-wall chamber but situated at a distance of 50 mm (radially) from it. This virtual radiation concentrator helps to focus the radiant energy at the center of the hot-wall chamber. The temperature rise in the axial center of the hot-wall chamber was nearly doubled by the use of these reflecting mirrors, besides avoiding the troublesome and unnecessary heating of the glass walls of the vacuum chamber. Typical power input to the hot-wall heater was 100W; the temperature that could be attained very easily with this input was about 600°C. All metal surfaces were molybdenum or stainless-steel.

Liquid nitrogen cooled traps (both, of the Miessner type, and above the diffusion pump) were in use at all times during heating and evaporation cycles. The residual air pressure in the chamber was better than 3×10^{-6} Torr. Pyrex microscope slides were the preferred substrates for deposition, though other substrates like quartz or soda glass could also be used.

Temperatures at all relevant points were monitored during trial runs. The hot-wall temperature was measured under the same vacuum conditions at its axial center, and a calibration was obtained between the heating current and the average hot-wall temperature. This is the temperature referred to in the course of this work. The current passing through the molybdenum trough was 250A for a temperature of 930°-950°C. The preheater current was 22A, while the current through the hot-wall heater was 9A. The operation of the vibrating feeder has to be done skillfully to prevent too much charge from falling in a short time into the trough. Too rapid charging of the heating trough can cause unevaporated powder to impinge upon the substrate and seriously impair the surface.

Because of the multiple heating circuits and the possibility of internal shorts between the various heaters, isolation transformers are used in all the heater circuits. These serve the dual purpose of giving good isolation of each circuit and providing high currents at low voltage for individual heaters in the system.

Film thickness of the films was measured with a Varian Model 980-8000 Interferometer. Films used for resistivity measurements had a thickness of 0.41 μm.

A specific problem that is often encountered in the flash evaporation technique is the sudden increase in pressure in the evaporation chamber when the particles of CdTe impinge upon the heated molybdenum boat. This was suspected to be due to degassing from the interstices of the granular CdTe powder. It was found that the use of an additional preheater positioned about 8 cm above the CdTe feeder to heat the powder in vacuum for 10-25 min, prior to evaporation by flashing, eliminated this undesirable pressure rise.

Figure 2 shows the plot of pressure rise in the chamber before and after the use of the preheater above the CdTe feeder.

We have thus eliminated, by the use of the charge preheater, an important drawback to the flash evap-

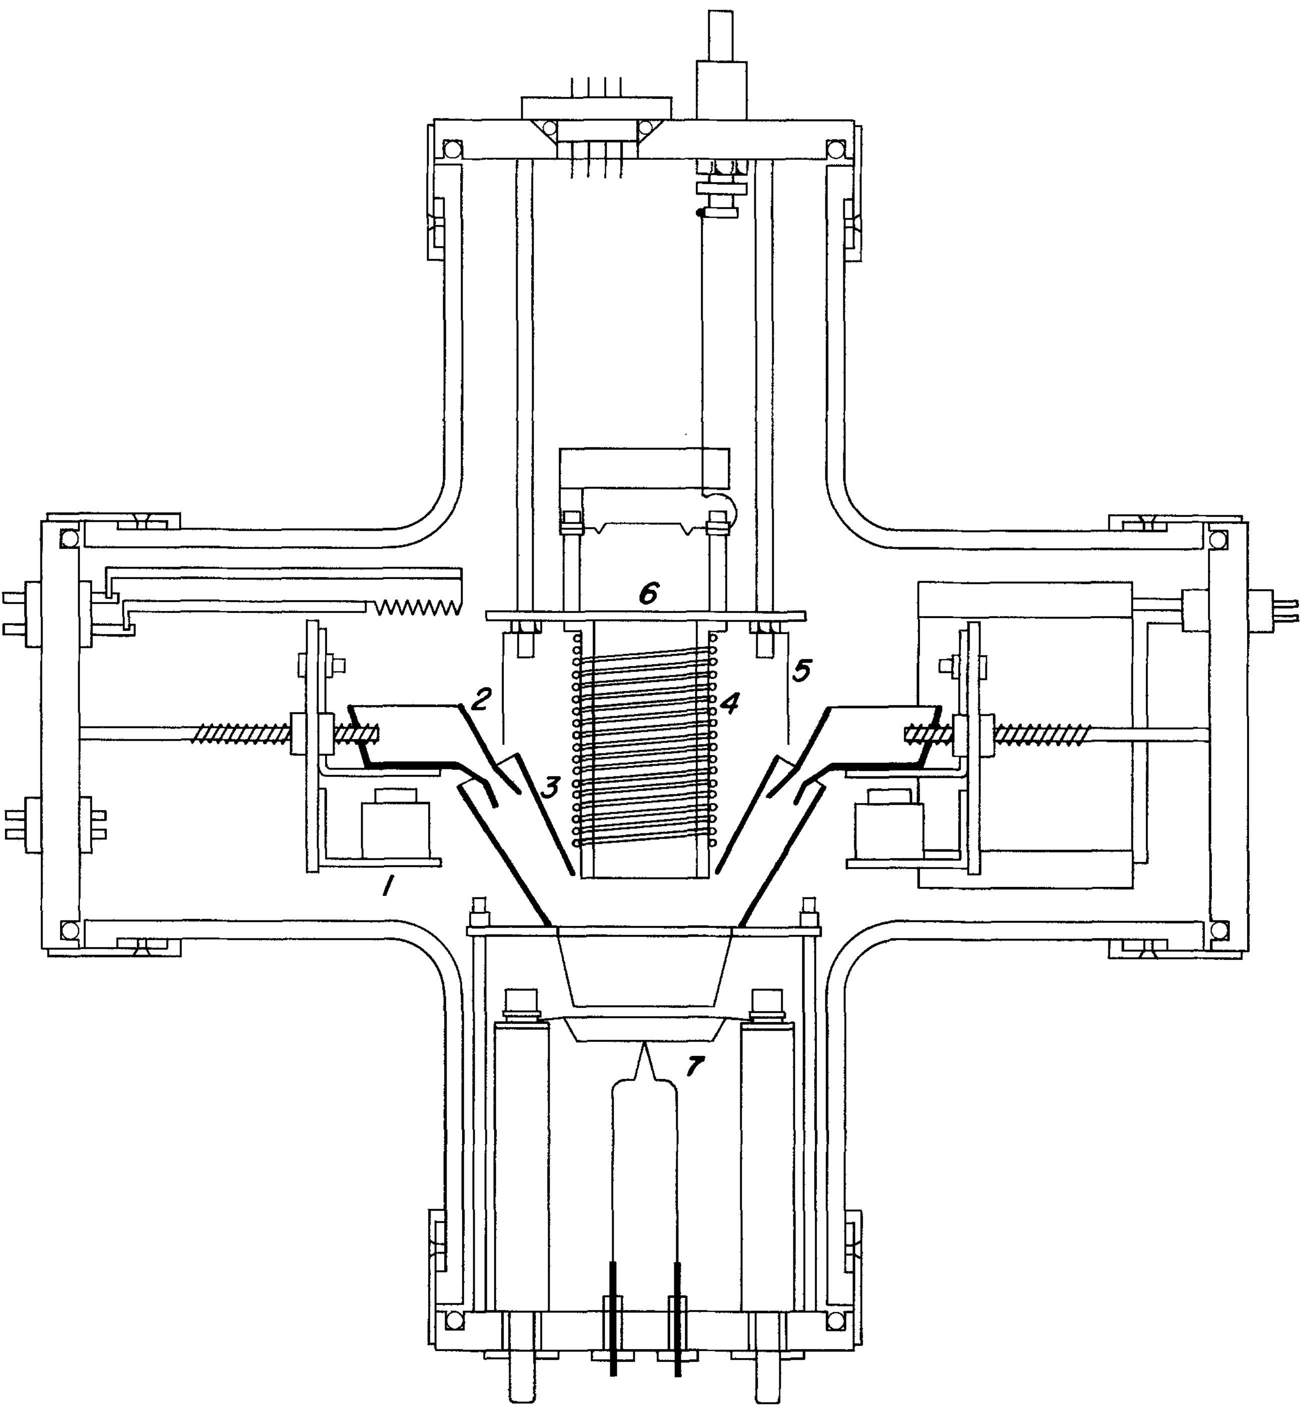

Fig. 1. Cross-section drawing of cross-shaped vacuum chamber showing the vibrating feeders, 1, vibrating bowl, 2, feed chutes, 3, hot-wall chamber, 4, substrate holder, 6, stainless-steel reflectors, 5, and molybdenum heater trough, 7.

oration technique which has been well recognized by previous workers in this field. For instance, Chopra (13) states that, "Since the large amount of rapidly released gas produces spattering of particles from the evaporant this method (flash evaporation) is not easily controllable."

The amount of gas released during evaporation is inversely proportional to the preheating time and temperature. By keeping a constant heater temperature (around 1000°C) and changing the heating time, we have found that heating times of 10-15 min are adequate (for a charge of up to 1g) to reduce pressure rise on flashing to negligible amounts.

Results

The cadmium telluride-tellurium films produced by this technique have extremely smooth and shiny surfaces. Typically these films are free from pinholes and are dense in appearance. We have studied the effect of hot-wall and substrate temperature and have found that both the hot-wall temperature and the substrate temperature have a pronounced influence on the properties of the films produced. In a series of experiments, Balzers high purity CdTe powder was evaporated under as similar conditions as possible, while the substrate temperature and hot-wall temperature were systematically changed. With low substrate temperatures (100°C or lower) and hot-wall temperatures below 450°C the resulting films had a very high resistivity (10^7 Ω-cm or higher). However, when the substrate temperatures were raised to 200°C and the hot-wall temperature was in the range 500°-600°C we were consistently able to obtain films with resistivity of 10^{-3} Ω-cm.

Still higher substrate temperatures are possible, but the efficiency of deposition in terms of thickness

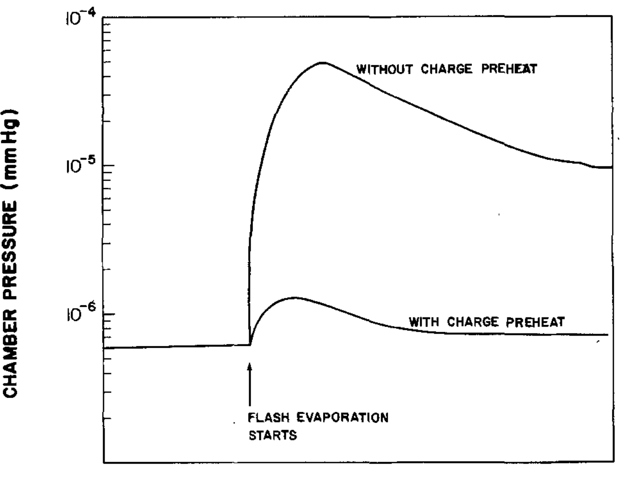

Fig. 2. Plot of pressure rise in the vacuum chamber as a function of time from initiation of flash evaporation for *(i)* without (CdTe) charge preheater and *(ii)* with charge preheater.

of deposit per unit weight of starting material used, is impaired. We thus feel that the optimum temperature of hot-wall and substrate for obtaining low resistivity (10^{-3} Ω-cm) CdTe-Te films is 560° and 200°C, respectively. Table I gives a few examples of conductivity values obtained for various substrate and hot-wall temperatures. It is clear from the data that low resistivity CdTe-Te can be obtained using a hot-wall temperature in the range 500°-600°C and substrate temperatures in the range 100°-250°C.

Control experiments where either flash evaporation alone or hot-wall was used alone (with conventional evaporation from a heated boat) showed that the desired low resistivity films with optimum properties (physical and electrical) were obtained only when both flash evaporation and the hot-wall were used together. In either of the above cases where only one of the two techniques (hot-wall or flash evaporation) was used alone, the result was high resistivity ($\sim 10^7$ Ω-cm) CdTe.

Stability during thermal cycling.—Since the instability and erratic behavior of vacuum deposited CdTe films has often been cited as a major drawback in device applications (10), we decided to study the stability behavior of these films.

The high stability of resistivity of these films became apparent first during measurements of conductivity *vs.* temperature. In order to establish the high stability further, a sample of 10 Ω^{-1} cm^{-1} CdTe-Te film (1-2 μm thick) was placed on the lower end of a cold finger projecting into a high vacuum chamber. The specimen could thus be cycled repeatedly and rapidly by electrical heating and cooled by liquid nitrogen to about 80°K.

In our experiments the specimen was cycled over 25 times. At the end of the cycling as well as during it, the resistivity at 25°C was within 1% of its initial value. The specimens were also completely stable against changes in the ambient pressure or gas composition. There was no measurable change in the resistance values when rapidly evacuated to 10^{-6} mm

Table I.

Substrate temp (°C)	Hot-wall temp (°C)	Conductivity (Ω^{-1}-cm^{-1})	
200	560	6.5	High conductivity
166	560	2.5×10^{-1}	High conductivity
130	560	1.2×10^{-1}	High conductivity
95	425	$\sim 10^{-7}$	Very low conductivity

Hg from atmospheric pressure. A typical plot of resistivity values for several consecutive cycles is shown in Fig. 3.

Contact characteristics.—Because of the established difficulty in making ohmic contacts to p-type low resistivity material, as recently reviewed by Wald (10), we have specially investigated the nature of contacts made to films produced by the hot-wall flash evaporation system (HWFE). The linearity of an *I-V* characteristic in the case of a suspected blocking contact is only a necessary but not sufficient condition (14) for true ohmic behavior. It is also necessary to probe the potential distribution along the length of the film to make sure that there is no abnormal potential drop at the extremities where current contacts are made.

We have measured both the *I-V* characteristics, down to millivolt levels, using a variety of contact metals. For the potential probe, a special mask with several very thin (0.6 mm) probes was fabricated by photolithographic techniques. The interprobe spacing was 3 mm. The measurements of potential were done with a Keithley 610 electrometer to ensure that no loading of the probes occurred. The metals used for the contacts were indium, indium-gallium, gold, nickel, chromium. We found that good contacts could be obtained with the first three metals, but only when the CdTe was evaporated onto the predeposited contact metals. The linear plots obtained with the potential probe technique (Fig. 4) show the absence of contact barriers and also demonstrate the good electrical homogeneity of the specimens.

For specimens with indium or gold end contacts, the linear *I-V* plot of Fig. 5 shows that the contacts are reasonably ohmic down to the millivolt level.

Electrical conductivity.—Electrical conductivity was measured in CdTe-Te films evaporated by the HWFE technique. Films were deposited on Pyrex substrates through molybdenum masks which defined the resistive pattern in the form of a bar. Evaporated indium contacts were used. Measurements were carried out in a low temperature vacuum cryostat down to about 90°K. A feature of the measurements was that the values of resistivity at any temperature were extremely reproducible (within 1%) and the specimen showed no drift or hysteresis on heating and cooling. The plot of conductivity *vs.* reciprocal temperature is shown in Fig. 6.

Thermoelectric power.—Thermoelectric power measurements were carried out in a vacuum cryostat with

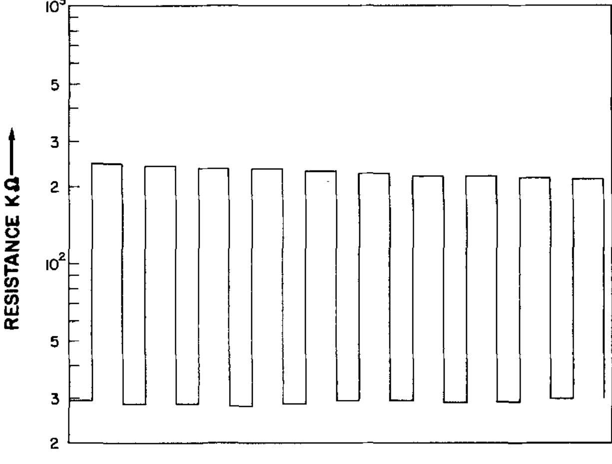

Fig. 3. Plot of resistance of a (HWFE) CdTe-Te thin film specimen during part of continuous thermal cycling experiments. Steady base line indicates return to initial value after each cycle. Total change after all cycles was less than 1%.

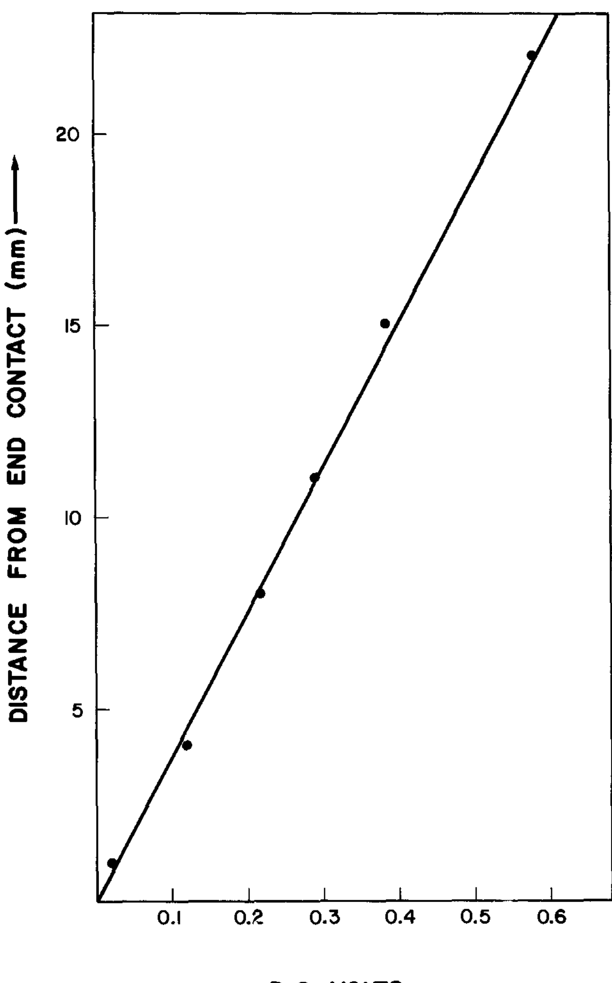

Fig. 4. Plot of distance from an end contact as a function of potential drop in the CdTe-Te film (potential probe experiment).

the sample of CdTe-Te mounted on a copper strip with the hot end heated by a 5W wire-wound resistor of 575Ω. Power to the heater was supplied from an HP regulated supply. The cold end was in contact with a large copper sink which could be cooled to —180°C.

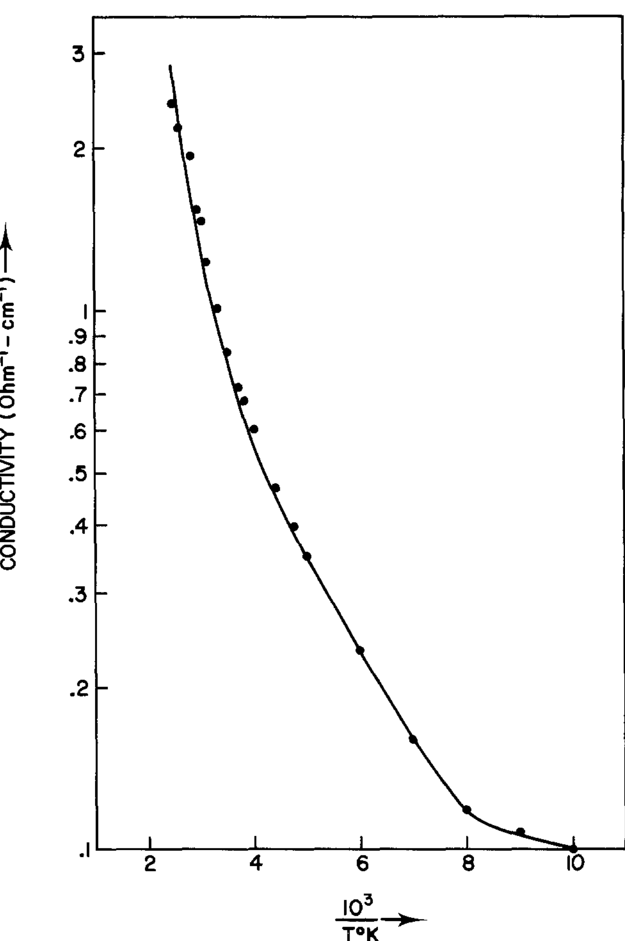

Fig. 6. Electrical conductivity of CdTe-Te film prepared by hot-wall-flash evaporation.

Typical gradients were of the order of 5°-7°C. Thermoelectric power measurements showed conclusively that the specimens were p-type with a thermoelectric power of 173 μV/°K at 223°K. The temperature gradient was constant within 0.1% during the experiments.

Optical transmission.—Optical transmission data were obtained for typical CdTe-Te HWFE specimens evaporated onto Pyrex glass slides. A typical transmission spectrum is shown in Fig. 7 for a low resistivity (10^{-1} Ω-cm) CdTe-Te film. The spectrum is uncorrected for reflectance effects.

The spectrum shows considerable absorption at wavelengths beyond the absorption edge of CdTe and this can be attributed to the presence of excess Te in the films.

Stoichiometry and structure.—Electron microprobe measurements on three specimens of the lowest resistivity (10^{-3} Ω-cm) have revealed the presence of from 25 to 50% free tellurium in the CdTe-Te films. In this context some of the comments on the stoichiometry of CdTe films by previous workers may be pertinent. According to Glang *et al.* (8) CdTe films deposited at temperatures below 150°C had excess tellurium, but these authors go on to say that regardless of deposition temperature, all films had resistivities higher than 10^7 Ω-cm. Further, according to these authors (8), deviations from stoichiometry in CdTe films condensed between 25° and 250°C must be considerably smaller than 10^{16} cm^{-3}. Apparently, under hot-wall conditions the equilibrium between the elemental species, Cd and Te condensing on to the substrate shifts appreciably towards Te, resulting in a CdTe matrix with Te in considerable excess. The exact nature of the distribution of Te in the CdTe matrix is not yet known but would seem to warrant further

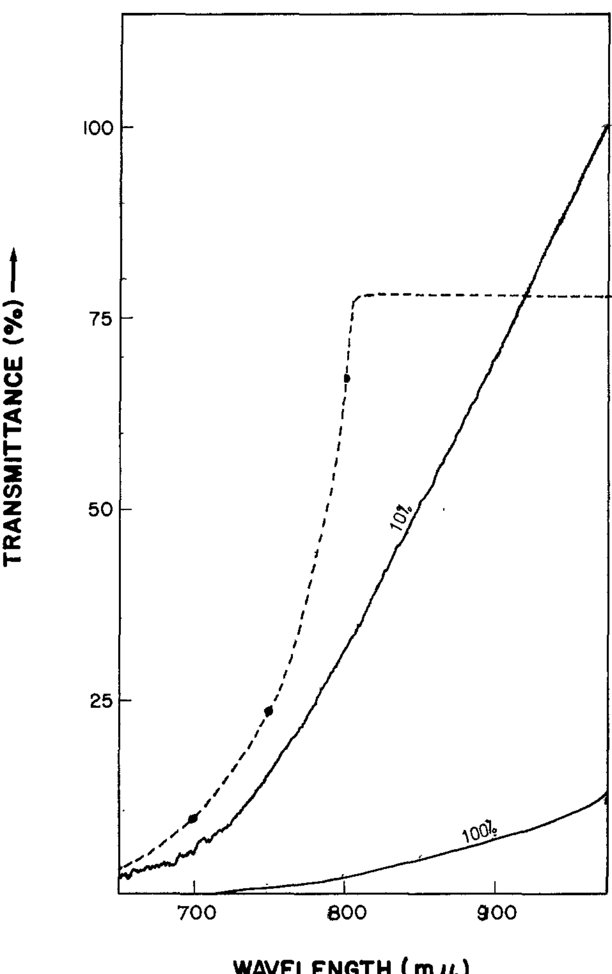

Fig. 7. Optical transmission spectrum for a CdTe-Te film (0.5) prepared by hot-wall-flash evaporation technique, drawn in full-scale corresponding to 10% transmission and to 100% transmission. The dashed curve is a calculated curve for single crystal CdTe using appropriate optical constants.

study. Since very little is known about the exact mechanism of condensation of CdTe, it is hoped that the fact that a considerable stoichiometric excess of Te can be introduced into CdTe in a more or less controlled manner, would help advance the understanding of CdTe deposition. It remains to be seen if the HWFE technique can be adapted or modified to provide CdTe films with only a slight (10^{17}) excess of Te, sufficient to give a substantial p conductivity at room temperature. It is interesting to note that even after prolonged heat-treatment under inert gas conditions the CdTe-Te films retain some of their conductivity. Further studies are in progress on such films, which show sharp x-ray reflections, to determine their carrier concentration, mobility and contact behavior.

X-ray diffraction was utilized in an attempt to determine the structure of the CdTe-Te films. No spectrum could be obtained for an as-deposited film on a glass substrate. However on heat-treatment in a neutral atmosphere sharp reflection patterns were obtained. Figure 8 shows an x-ray spectrogram of a CdTe film. Comparison of the data with A.S.T.M. 19-193 indicates that the structure corresponds to that of hexagonal CdTe, prepared by the sublimation of the cubic modification onto a glass substrate between 500° and 800°C in argon.

It is noteworthy that no lines corresponding to Te appear which indicates that Te has sublimed during the heat-treatment (300°C) or is in an amorphous state. Most films showed a great increase in the I/I_0 ratio after heat-treatment.

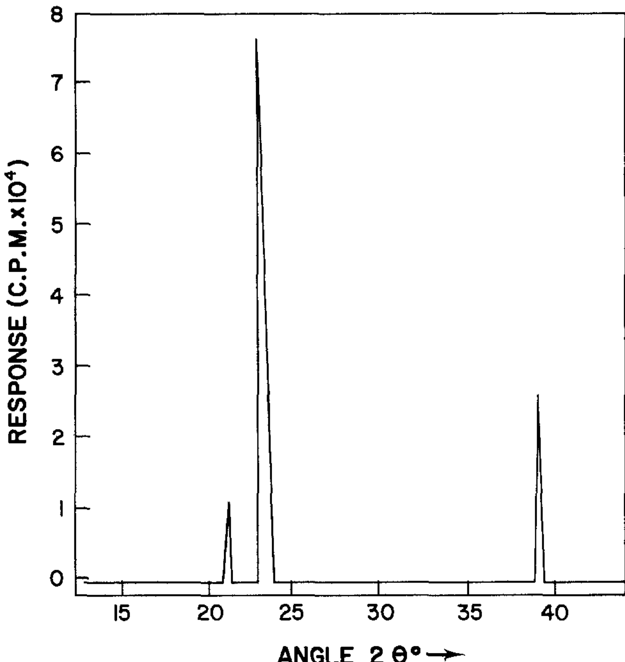

Fig. 8. X-ray spectrogram of a well-oriented HWFE CdTe film showing hexagonal structure.

Summary

The hot-wall-flash evaporation technique is described in detail. It has been applied to the preparation of CdTe-Te films which are characterized by low resistivity, ohmic contacts to common contact metals, specular surfaces, and stability during rapid thermal cycling between 250° and 350°K. A notable improvement in flash evaporation technique has been the incorporation of a charge preheater to eliminate troublesome outgassing during flash evaporation. Electron microprobe analysis has revealed that up to 50% free tellurium may be present in the films. The optical absorption spectrum shows a shift in absorption towards longer wavelengths, consistent with the microprobe data. X-ray data for heat-treated films show good orientation of CdTe with hexagonal structure.

Acknowledgments

The author is grateful to Dr. Feliciano Sánchez-Sinencio for useful discussions in the course of the work. The interest and guidance of Dr. Richard H. Bube are also gratefully acknowledged. The author is indebted to Dr. Richard H. Bube and Dr. Alan L. Fahrenbruch for obtaining the optical transmission data and electron microprobe analysis at Stanford University. The author would like to thank Ricardo A. Chávez for help in preparing specimens. Lastly, I thank Dr. Alfonso Lastras-Martínez, Dr. Juan Luis del Valle, and Mr. Manuel Saucedo for useful discussions.

The Intermediate Role of Gd^{3+} in the Energy Transfer from a Sensitizer to an Activator (Especially Tb^{3+})

J. Th. W. de Hair and W. L. Konijnendijk
Philips Lighting Division, Eindhoven, The Netherlands

ABSTRACT

Energy transfer from a sensitizer to an activator via Gd^{3+} ions is discussed. This is done for the $Bi^{3+} \rightarrow Dy^{3+}$ and $Sb^{3+} \rightarrow Dy^{3+}$ transfer in $GdPO_4$, and for the $Bi^{3+} \rightarrow Tb^{3+}$ transfer in GdB_3O_6. The phosphor $Gd_{0.98}Bi_{0.01}Tb_{0.01}B_3O_6$ shows Tb^{3+} luminescence with a quantum efficiency of 80% for excitation of Bi^{3+}. After excitation of Bi^{3+}, energy transfer takes place to Gd^{3+} ions. Then the energy may migrate from one Gd^{3+} to another until energy transfer from Gd^{3+} to Tb^{3+} occurs. Compared to the energy transfer in other sensitized Tb^{3+} phosphors, this process has a high efficiency at relatively low activator concentrations. The energy transfer from Bi^{3+} to Gd^{3+} and between Gd^{3+} ions mutually has been investigated for $Gd_{0.99-x}La_xBi_{0.01}B_3O_6$. For $x < 0.4$ energy transfer between Gd^{3+} ions is observed. The quantum efficiency of the Gd^{3+} luminescence for Bi^{3+} excitation of $Gd_{0.59}La_{0.4}Bi_{0.01}B_3O_6$ amounts to 75% and decreases for increasing Gd concentrations.

Trivalent gadolinium can act as a sensitizer in processes of energy transfer. Bril and Wanmaker (1) describe the energy transfer from Gd^{3+} to Tb^{3+} in $CaNaBO_3$. Ozawa and Nishikawa (2) report the energy transfer to other rare earths in $(Y,Gd)_2O_3$ solid solutions, whereas Reisfeld *et al.* (3) have investigated the transfer of energy from Gd^{3+} to Tb^{3+} in borate glass. Bozhevolnov *et al.* (4) give evidence of energy transfer from Gd^{3+} to Mn^{2+} in CaF_2. In all these cases the excitation spectra of the activator (A) luminescence show up excitation lines of Gd^{3+}. The optical transitions of Gd^{3+} occur within the 4f shell and are observed in the ultraviolet region. These transitions are parity and spin forbidden and have a very low absorption strength. Thus, sensitization with Gd^{3+} ($Gd^{3+} \rightarrow$ A transfer) where the energy must be absorbed by Gd^{3+}, does not result in phosphors which luminesce with high intensity.

On the other hand, sensitization of Gd^{3+} luminescence (S $\rightarrow Gd^{3+}$ transfer) is also known. Blasse and Bril (5) have observed energy transfer from TaO_4^{3-} groups to Gd^{3+} in $GdTaO_4$. Reisfeld and Morag (6) report the energy transfer from Tl^+ to Gd^{3+} in borax and phosphate glasses. In these cases, the intensity of the Gd^{3+} luminescence is enhanced, due to the strong absorption by Tl^+ or TaO_4^{3-} groups followed by energy transfer to Gd^{3+}.

So far the sensitization of Gd^{3+} (S $\rightarrow Gd^{3+}$) and the energy transfer from Gd^{3+} to a sensitizer ($Gd^{3+} \rightarrow$ A) have been considered separately. It seems worthwhile to investigate the possibilities of the combination of both processes in phosphor luminescence. We have studied, therefore, the intermediate role of Gd^{3+} in the energy transfer from a sensitizer to an activator. Recently, we have shown (7) that the energy transfer from Bi^{3+} to Tb^{3+} in GdB_3O_6 occurs almost exclusively via the Gd^{3+} ions. Before that, only indications of a possible intermediate role of Gd^{3+} can be found in the literature. Blasse and Bril (5) have suggested that energy transfer from TaO_4^{3-} groups to Dy^{3+}, Sm^{3+}, and Er^{3+} in $GdTaO_4$ occurs via Gd^{3+}. Indications can also be found in a paper by Grisafe and Fritsch (8) on the luminescence of Eu^{3+} and Tb^{3+} in $LnNbO_4$ (Ln = La, Gd, Y). Recently, Blasse (9) has described how in $GdNbO_4$:Eu^{3+} the Gd^{3+} ions play an important role.

In this paper we discuss in more detail the energy transfer in GdB_3O_6 activated with Bi^{3+} and Tb^{3+}. First, we describe the $Bi^{3+} \rightarrow Gd^{3+}$ transfer in $Gd_{1-x}La_xB_3O_6$ activated with Bi^{3+}. Next, we will show that thanks to the intermediate role of Gd^{3+} the energy transfer to Tb^{3+} is complete at relatively low Tb concentrations. Low Tb concentrations have a great advantage for commercial Tb^{3+} phosphors since the price of these phosphors is determined mainly by the Tb contents. Finally, we show the intermediate role of Gd^{3+} in the energy transfer from Bi^{3+} or Sb^{3+} to Dy^{3+} in $GdPO_4$.

Experimental

Powder samples were prepared by the usual solid-state reaction techniques. Stoichiometric proportions of the starting compounds were intimately mixed together and then heated twice at 1040°C. The metaborates were prepared starting with an excess of 10 mole percent (m/o). The samples activated with terbium were heated in a nitrogen atmosphere.

Formation of the compounds was checked by x-ray analysis with a Philips diffractometer using CuKα radiation.

Key words: luminescence, phosphor, quantum efficiency.

All optical measurements were performed at room temperature with equipment described elsewhere (10). The spectra given in Fig. 1-3 have been corrected for the characteristics of the experimental setup.

Results and Discussion

The compound GdB_3O_6 shows very weak Gd^{3+} luminescence. This luminescence can be excited at the ^6I_J (~273 nm) or ^6D_J (~250 nm) levels of Gd^{3+}. Because of the forbidden nature of 4f → 4f transitions, the absorption strength is very low (see Fig. 1a for the diffuse reflection spectrum of GdB_3O_6).

The luminescence of Gd^{3+} is more intense when GdB_3O_6 is activated with Bi^{3+}. The emission spectrum of $Gd_{0.99}Bi_{0.01}B_3O_6$ is shown in Fig. 1b. The Gd^{3+} luminescence consists of the $^6P_{7/2} \rightarrow {}^8S_{7/2}$ transition (near 312 nm) and the $^6P_{5/2} \rightarrow {}^8S_{7/2}$ transition (near 306 nm). The excitation spectrum of the Gd^{3+} luminescence of $Gd_{0.99}Bi_{0.01}B_3O_6$ is shown in Fig. 1a. This spectrum consists of the $^8S_{7/2} \rightarrow {}^6I_J$ transitions of Gd^{3+} at 273 nm and two strong and broad excitation bands which correspond to electronic transitions of Bi^{3+}. The band with a maximum at 240 nm is due to the $^1S_0 \rightarrow {}^3P_1$ transition, whereas the one peaking near 200 nm corresponds to the $^1S_0 \rightarrow {}^1P_1$ transition. The $^8S_{7/2} \rightarrow {}^6D_J$ excitation of Gd^{3+} near 250 nm is hidden under the $^1S_0 \rightarrow {}^3P_1$ band of Bi^{3+}. The presence of Bi^{3+} excitation bands in the excitation spectrum of the Gd^{3+} luminescence indicates the occurrence of energy transfer from Bi^{3+} to Gd^{3+}. We did not observe any Bi^{3+} emission from Bi^{3+}-activated GdB_3O_6. The quantum efficiency of the Gd^{3+} luminescence of $Gd_{0.99}Bi_{0.01}B_3O_6$ amounts merely to 20%, which is due to concentration quenching of the Gd^{3+} luminescence. On replacing a part of Gd by La according to the formula $Gd_{0.99-x}La_xBi_{0.01}B_3O_6$ we find that the quantum efficiency of the Gd^{3+} luminescence upon excitation at the maximum of the Bi^{3+} excitation band ($^1S_0 \rightarrow {}^3P_1$) increases up to 75% when $x = 0.4$. For higher La contents both Gd^{3+} and Bi^{3+} luminescence is observed. The intensity of the Gd^{3+} luminescence decreases whereas that of the Bi^{3+} luminescence increases. The Bi^{3+} luminescence in the lanthanum-rich region of $Gd_{0.99-x}La_xBi_{0.01}B_3O_6$ is given in Fig. 2 for $La_{0.99}Bi_{0.01}B_3O_6$. In the light of current theories on nonradiative energy transfer (11), the emission band of Bi^{3+} in GdB_3O_6 must overlap the energy levels of the Gd^{3+} ion ($^6P_{7/2}$, $^6P_{5/2}$, and $^6P_{3/2}$). Reisfeld and Morag (6) describe the energy transfer from Tl^+ to Gd^{3+} in inorganic glasses. The emission of Tl^+ in these glasses peaks between 300 and 330 nm. Blasse and Bril (5) have found that in the solid solutions series $Y_{1-x}Gd_xTaO_4$, the Gd^{3+} luminescence is sensitized by the TaO_4^{3-} groups. The emission band of $YTaO_4$ peaks at 335 nm. One of us (7) has described the energy transfer from Bi^{3+} to Gd^{3+} in $YAl_3B_4O_{12}$. The Bi^{3+} emission in $YAl_3B_4O_{12}$

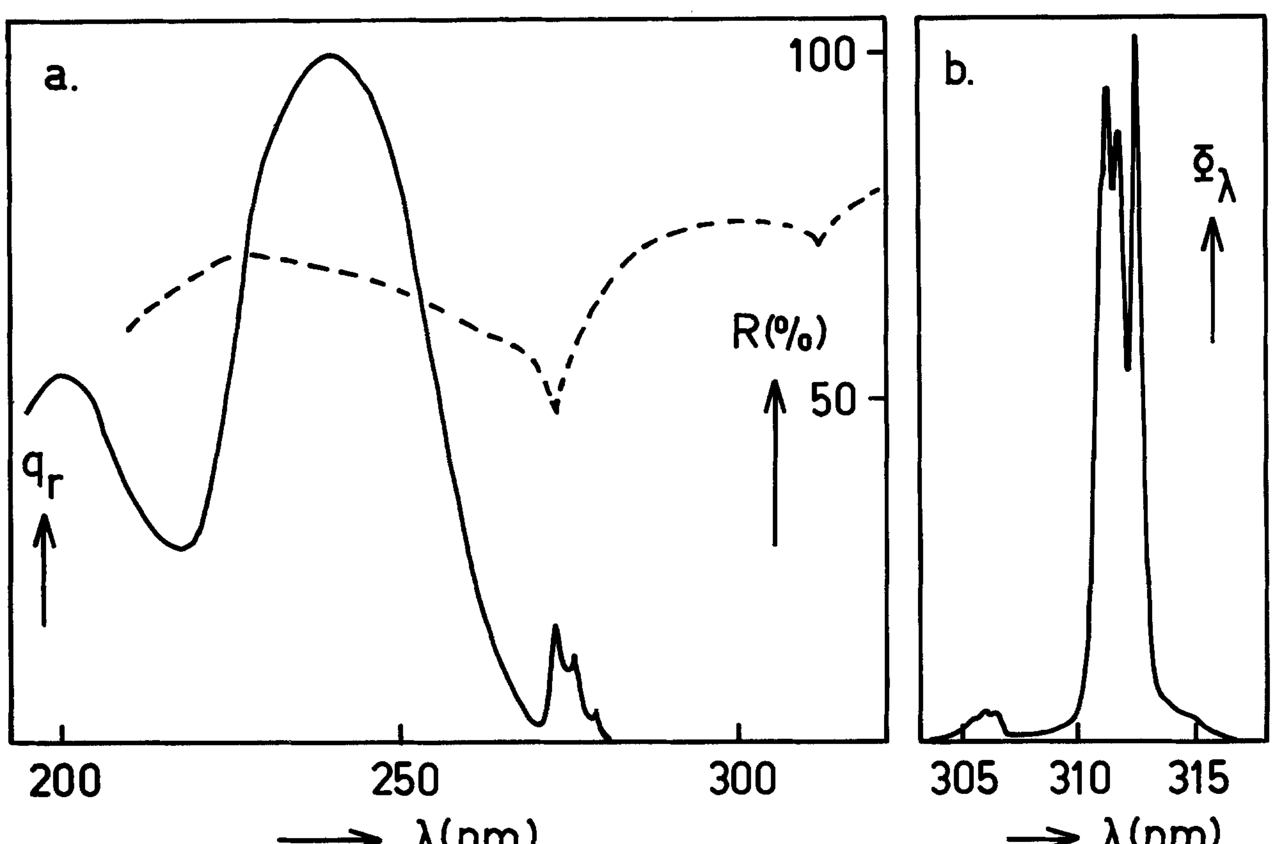

Fig. 1. (a) Diffuse reflection spectrum of GdB_3O_6 (broken line) and excitation spectrum of the Gd^{3+} luminescence of $Gd_{0.99}Bi_{0.01}B_3O_6$ (solid line), q_r in this and other figures denotes the relative quantum output, R gives the percentage reflectance. (b) Spectral energy distribution of the luminescence of $Gd_{0.99}Bi_{0.01}B_3O_6$ for 254 nm excitation. Φ_λ in this and other figures denotes the radiant power per constant wavelength interval.

peaks at 300 nm. Energy transfer also occurs from Ce^{3+} to Gd^{3+} in CeF_3 (12) (Ce^{3+} emission peaking near 290 nm). In all these examples complete energy transfer to Gd^{3+} occurs since the sensitizer emission shows a considerable overlap with the ^6P_J energy levels of Gd^{3+}. The Bi^{3+} emission in LaB_3O_6 (Fig. 2), however, is situated at too long wavelengths to have a good overlap. According to Blasse (13), the Bi^{3+} emission is influenced by a variation in the size of the site occupied by Bi^{3+}. Van der Steen *et al.* (14) have reported on the luminescence of Bi^{3+} in $NaLaO_2$ and in $NaGdO_2$. $NaLaO_2$-Bi^{3+} emits in the red, $NaGdO_2$-Bi^{3+} in the blue region. Possibly the virtual emission of Bi^{3+} in GdB_3O_6 will be at shorter wavelengths than in LaB_3O_6.

The compound with composition $Gd_{0.98}Bi_{0.01}Tb_{0.01}B_3O_6$ shows very intense, characteristic Tb^{3+} luminescence at room temperature under 254 nm excitation (7). The quantum efficiency of this luminescence is 80% for excitation of Bi^{3+}. This value is remarkably high for the low Tb^{3+} concentration present, since direct $Bi^{3+} \rightarrow Tb^{3+}$ transfer is very improbable. The virtual emission of Bi^{3+} in GdB_3O_6 does not show overlap with the 4f → 5d band of Tb^{3+} which is observed near 200 nm in this host lattice. There is only overlap with the 4f → 4f transitions of Tb^{3+}. In such a case, the probability of $Bi^{3+} \rightarrow Tb^{3+}$ transfer is low and the transfer distance short. A high Tb concentration would be required for efficient, direct $Bi^{3+} \rightarrow Tb^{3+}$ transfer in GdB_3O_6. The high transfer efficiency in GdB_3O_6 at low Tb concentrations must be accounted for with a different transfer process. We have proven (7) that the Gd^{3+} ions play an important role in the energy transfer from Bi^{3+} to Tb^{3+}. Excitation of Bi^{3+} will be followed mainly by $Bi^{3+} \rightarrow Gd^{3+}$ transfer. The energy can now migrate from Gd^{3+} to Gd^{3+} until it reaches a Tb^{3+} ion.

Because of the involvement of Gd^{3+} in the energy transfer, efficient transfer in $Gd_{0.98}Bi_{0.01}Tb_{0.01}B_3O_6$ is observed for relatively low Tb concentrations. Let us now compare some sensitized Tb^{3+} phosphors listed in Table I. In this table, we indicate the presence of energy transfer between the sensitizers (S — S) and the occurrence of spectral overlap between the sensitizer emission and the 4f → 5d excitation bands of Tb^{3+} (4f → 5d). We also give the quantum efficiency of the Tb^{3+} luminescence for excitation in the maximum of the sensitizer-excitation band. Generally speaking, the energy transfer from a sensitizer to Tb^{3+} is efficient when the sensitizer emission overlaps the 4f → 5d absorption band of Tb^{3+}, as in $Y_{1-x}Tb_xTaO_4$, or when energy transfer between the sensitizers occurs, as in $Ce_{1-x}Tb_xBO_3$. In both cases, a low Tb concentration is sufficient to obtain an efficient energy transfer. When there is no energy transfer between the sensitizers and there is no overlap with the 4f → 5d band, as in $Ce_{1-x}Tb_xB_3O_6$, $Ce_{1-x}Tb_xF_3$, and $Ce_{1-x}Tb_xMgAl_{11}O_{19}$, then a high Tb concentration is necessary to achieve efficient energy transfer. With Gd^{3+} as the intermediate the $Ce^{3+} \rightarrow Tb^{3+}$ transfer in CeF_3 is complete at lower Tb concentrations (compare $Ce_{0.8}Tb_{0.2}F_3$ and $Ce_{0.75}Gd_{0.2}Tb_{0.05}F_3$). We have already mentioned that energy transfer from Bi^{3+} to Tb^{3+} in GdB_3O_6 is complete for 1 atomic percent (a/o) Tb (compare the Tb concentration in the isostructural phosphor $Ce_{0.67}Tb_{0.33}B_3O_6$). In $Gd_{0.98}Bi_{0.01}Tb_{0.01}B_3O_6$ the direct energy transfer $Bi^{3+} \rightarrow Tb^{3+}$ over relatively long distances (maximum ~13Å) cannot compete with the energy transfer from Bi^{3+} to a Gd^{3+} ion as nearest neighbor (~4Å). After the energy transfer from Bi^{3+} to the ^6P_J levels of Gd^{3+}, the losses of energy at Gd^{3+} are small. The energy-level scheme of Gd^{3+} shows a large gap of about $32 \cdot 10^3$ cm^{-1} (the difference between the $^6P_{7/2}$ and $^8S_{7/2}$ states of Gd^{3+}). Radiationless relaxation of Gd^{3+} is very improbable. Mutual energy transfer between Gd^{3+} ions may occur by interaction between the ^6P_J levels of different Gd^{3+} ions. After this energy transfer there remains, however, an energy gap of $32 \cdot 10^3$ cm^{-1}. The only way of losing energy is by transfer from Gd^{3+} to "killer sites." This explains why the quantum efficiency of the Gd^{3+} luminescence of $Gd_{0.99}Bi_{0.01}B_3O_6$ amounts merely to 20%. In view of the high quantum efficiency of the Tb^{3+} luminescence of $Gd_{0.98}Tb_{0.01}Bi_{0.01}B_3O_6$ (~80%) $Gd^{3+} \rightarrow Tb^{3+}$ transfer competes successfully with the losses of energy from Gd^{3+} to "killer sites." On substituting La for Gd up to the composition $Gd_{0.58}La_{0.4}Bi_{0.01}Tb_{0.01}B_3O_6$ the quantum efficiency of the Tb^{3+} luminescence decreases slightly to 75% for excitation of Bi^{3+}. If energy transfer between Gd^{3+} ions can in fact be ignored with this composition (as we have assumed above), this means that Gd → Tb transfer can take place over nearly 13Å. This result is in fair agreement with those of Reisfeld *et al.* (3). They found that the efficiency of $Gd^{3+} \rightarrow Tb^{3+}$ transfer in borate glasses is 50% for transfer over 13Å.

Evidence of the intermediate role of Gd^{3+} has also also been obtained for energy transfer from Sb^{3+} and Bi^{3+} to Dy^{3+} in $GdPO_4$. In this compound complete energy transfer from Sb^{3+} and Bi^{3+} to Gd^{3+} is observed. The excitation spectra of the Gd^{3+} luminescence are pictured in Fig. 3a for $Gd_{0.99}Bi_{0.01}PO_4$ and $Gd_{0.99}Sb_{0.01}PO_4$. The excitation bands of the sensitizer (Bi^{3+} or Sb^{3+}) are well separated from the Gd^{3+} excitation lines at 273 nm. Upon coactivation with Dy^{3+}, the emission consists of Gd^{3+} and Dy^{3+} luminescence for excitation of the sensitizer (see Fig. 3b for the emission spectrum of $Gd_{0.985}Bi_{0.01}Dy_{0.005}PO_4$ for 254 nm excitation). The ratio of the intensities of Gd^{3+}/Dy^{3+} luminescence does not depend on whether the sensitizer or Gd^{3+} is excited. Moreover, this ratio is the same for $Gd_{0.985}Sb_{0.01}Dy_{0.005}PO_4$ and $Gd_{0.985}Bi_{0.01}Dy_{0.005}PO_4$ upon excitation of the sensitizers. These observations demonstrate unambiguously the intermediate role of Gd^{3+} in the energy transfer. Note that the height of the sensitizer-excitation band relative to the height of the Gd^{3+}-excitation lines in Fig. 3a depends on the nature of the sensitizer. Probably the nonradiative losses in Bi^{3+} are larger than in Sb^{3+}.

In this paper, we have paid attention only to Tb^{3+}- or Dy^{3+}-activated phosphors. We have also found, however, that Gd^{3+} can play an intermediate role in energy transfer to Eu^{3+}, Sm^{3+}, and Mn^{2+}. This will be the subject of further investigations.

In conclusion, we have illustrated the intermediate role of Gd^{3+} in energy transfer from a sensitizer to an activator. This energy transfer can occur almost exclusively via Gd^{3+} and can have a high efficiency even for relatively low activator concentrations. In this way, highly efficient Tb^{3+} phosphors can be obtained with much lower Tb concentrations than the hitherto known sensitized Tb^{3+} phosphors with high efficiency, such as $Ce_{0.65}Tb_{0.35}MgAl_{11}O_{19}$ (17). The involvement of Gd^{3+} in the energy transfer opens up new possibilities for the development of phosphors.

Heavy Metal Gettering in Silicon-Device Processing

Livio Baldi, Gianfranco Cerofolini, and Giuseppe Ferla*

Direzione Tecnica, Divisione MOS, SGS-ATES, Milano, Italy

ABSTRACT

Heavy metal gettering in silicon devices has been investigated. The best results have been obtained with $POCl_3$ predeposition followed by annealing at moderate temperature. A model, previously developed for gold, is applied to the description of heavy metal gettering. Once inserted into a standard device process, our gettering step allows us to obtain leakage currents about 100 pA/cm^2 and 1 pA/cm for diodes and storage time around 10^3 sec for capacitors.

A whole class of LSI devices, dynamic RAM's, is based on low reverse currents in junctions and high storage times in capacitors. In addition, all other LSI devices (static RAM's, ROM's, microprocessors) have dynamic nodes whose behavior depends also on leakage current in junctions and capacitors. The leakage current in junctions is also responsible for the quiescent dissipation of CMOS devices (essentially produced for their low dissipation) so that, especially in MSI-CMOS

* Electrochemical Society Active Member.

Key words: phosphorus gettering, silicon defects, diode, capacitor.

devices, the leakage current must be kept low enough.

Since dissipation is the main factor which limits size and complexity of large systems (fast computers, electronic switching systems), it is of great interest to reduce these leakages. As dissipation is an activated process (activation energy $\simeq$0.5 eV), the most obvious approach to its reduction is to operate at low (liquid nitrogen) temperature (1). In view of the great technological difficulties that this approach implies, it is highly desirable to reduce leakages in MOS devices without lowering temperature. In the next section we show that this objective can be accomplished almost completely if heavy metals are removed from the active zones of the devices.

Techniques to selectively remove atoms of a given class are known as gettering, and various gettering procedures for heavy metals have been proposed. Many of them are based on the high affinity of heavy metals toward damaged regions. The damage was produced far from the active regions (*i.e.*, on the wafer back surface) in many ways: mechanical damage (2), ion implantation (3), heavy phosphorus diffusion (4), and stress by mechanical mismatch (5). Other techniques are based on phosphorus deposition followed by high temperature annealing (6-8). In this work we show that a very effective gettering effect can be obtained by phosphorus deposition followed by segregation annealing at moderate temperature: this process must be performed before metal deposition and allows heavy metals to segregate in the contacts or at the back surface.

This paper contains a short description of the principal causes of leakage current; describes three experiments where gettering by phosphorus and by damage are compared; presents a simple description of the gettering theory by segregation annealing; gives the experimental details of our main test-vehicle, the diode; considers the effect of our gettering technique on another device, the capacitor; and finally, contains a discussion of our procedure in comparison with other known processes.

Leakages

We confine ourselves to the n^+/p junction, though, *mutatis mutandis*, the following discussion can be extended to the p^+/n junction and to the MOS capacitor. Leakage current can be ascribed to the following causes: diffusion current, extended defects, and generation/recombination phenomena on Shockley-Read-Hall (SRH) centers.

The diffusion current depends on temperature (through the intrinsic carrier concentration), doping, and trap density; this current can be thought of as the unavoidable contribution to the leakage current.

Extended defects (dislocations, stacking faults, etc.) in active zones once decorated by metal atoms are responsible for a strong increase of reverse current, soft junctions, and so on. Their presence in a device is often catastrophic and may influence both process yield and device performances. Extended defects either are present in the starting slice or are introduced during wafer processing. Care must be used to avoid the second possibility. For instance, high temperature HCl treatment (9, 10) and argon or nitrogen annealing before oxidation (11) have lately been proposed to remove stacking fault nuclei. Thermal or mechanical stresses must be avoided so as not to generate dislocations in active zones. This is easily obtained if high temperature ($\gtrsim$ 1000°C) process steps are avoided. If high temperature steps, such as reflow annealing (12), are required then one must use slow push/pull.

The third quantity, generation/recombination on SRH centers, can largely be varied during device processing. Chemically, SRH centers are heavy metal atoms that can exchange both electrons and holes with the lattice; the current they produce is proportional to the atom concentration in the active zone.

The program previously outlined can operatively be restated as follows: to reduce heavy metal concentration in active zone by a procedure (gettering) compatible with the MOS process.

Before describing in short our gettering procedure and how we arrived at it, we would point out that the parameter to test quality of a procedure was the leakage current in suitably prepared diodes. This choice has a clear operative meaning; its physical relevance is discussed later.

Gettering by Damaging

A first idea to reduce SRH center concentration comes directly from tables of the segregation coefficient between solid and liquid silicon (Table I) (13). According to this table we attempted to simulate the liquid structure by damage and to getter heavy metals by the damaged zones.

Initially, we damaged the back side by lapping. Leakage currents and defect density in wafers with damaged back sides were found to be lower than in as-received wafers (polished back sides), in spite of the unwanted front damage introduced during the lapping step. Residual defect density was, however, rather high, and leakage currents still were above the diffusion current limit.

Therefore, we considered two other ways to create largely defective zones: (*i*) deposition on the back side of a layer of CVD polycrystalline silicon, and (*ii*) damaging by formation of SiP precipitates.

In the first experiment, shown in Fig. 1, we prepared diodes in the "standard" (see section on Diode Test) way and simulated the liquid silicon structure by depositing a 2 μm thick layer of poly-Si. Poly-Si is actually composed of many grains (ranging in size from 100 to 10,000Å) in which lattice order is maintained. We may suppose that only the atoms in the first 2-3 layers at the surface of the crystallites are in a quasi-liquid state, *i.e.*, active for gettering. Total surface area is

$$A = aV/R$$

where a is a shape factor (6 for cubic and spheric grains), R a suitable linear dimension of grains (diameter for spheric, edge for cubic ones), and V the total volume. For a layer of thickness t the number of active atoms is given by

$$n = saN_{Si}^{2/3}t/R$$

where s is the number of liquid-like layers (s = 2-3) and N_{Si} the atomic density of silicon ($N_{Si} = 5 \times 10^{22}$ cm^{-3}). Letting $a = 6$ and $R = 1500$Å, we have for a 2 μm thick poly-Si layer $n \simeq (2 \div 3) \times 10^{17}$ cm^{-2}. Using the segregation coefficient given above, the poly-Si layer should be able to getter as much as 80% of gold from 500 μm thick wafers. Annealing temperatures, 700° and 800°C, and duration, 60 min, were chosen because they are high enough to allow the migration of fast diffusing, metal impurities from one side of the wafer to the other. The resulting gettering activity was negligible (see Fig. 1) showing that the Si-damaged layer (formed by chemical vapor deposition) does not succeed in simulating the liquid layer in the considered temperature range.

In a second experiment the lattice damage was produced by phosphorus predeposition. In our deposition conditions electrically inactive phosphorus is surely formed; indeed V/I after predeposition is typically

5 ÷ 6Ω and decreases to about 3Ω after the drive-in step. LAMEL researchers have clearly described how during phosphorus deposition from $POCl_3$ in oxidizing environment SiP orthorhombic precipitates are formed inside the silicon matrix (14). Because of the lattice mismatch, the SiP precipitates are the source of a complex network of dislocations and defects of various kinds which can be thought of as simulating the liquid structure. The experiment, shown in Fig. 2, was carried out with the same annealing conditions as the first experiment; in spite of this, the results (Fig. 3) were completely different. Since it looked unlikely that the amount of damage introduced by SiP precipitates was greater than that contained in poly-Si, we tentatively admitted that, at the considered temperatures, gettering takes place preferentially by phosphorus rather than by damage. That phosphorus is able to getter impurities was recognized in earlier work (6, 15).

To clarify if gettering was due to single P atoms or to SiP precipitates we performed an experiment where gettering in n^+ regions without precipitates was compared with gettering in n^+ regions with precipitates. As the leakage current was low and practically the same in the two cases[1] (Fig. 4), we could deduce that gettering requires phosphorus atoms and segregation annealing at moderate temperature.

We have arrived at this statement according to the results of only three experiments; actually we performed about thirty different experiments which can be explained, in their generality, only by the previous model.

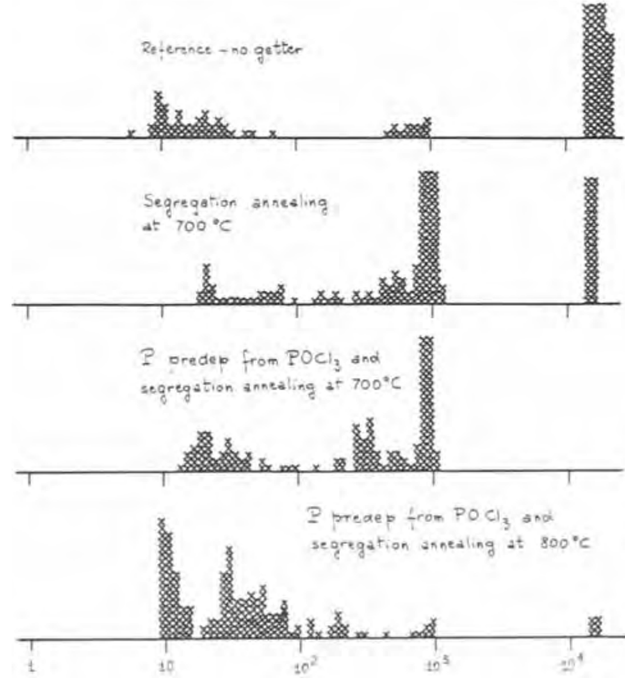

Fig. 3. Leakage current distributions for diodes processed during the second experiment.

[1] However, recently, Tseng *et al.* (16) at the California Institute of Technology have clearly given evidence for gold gettering by dislocations in addition to gettering by single phosphorus atoms. In fact, they observed that after annealing at 800°C for 100 hr the Au profile roughly follows the P concentration except in a dislocation-rich region, where Au concentration is higher.

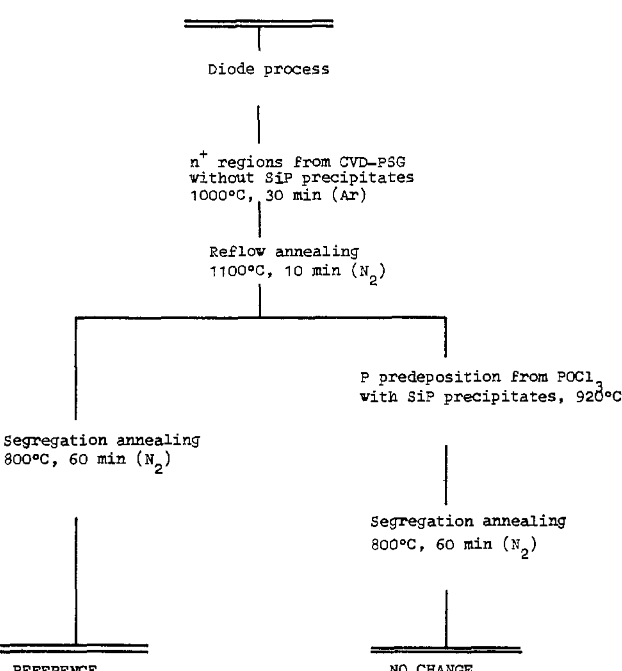

Fig. 4. Structure of the third experiment: gettering by $POCl_3$ predeposition with precipitates compared with gettering by predeposition without precipitates.

A Model for Gettering by Phosphorus Atoms

The conclusions of the previous section suggest that gettering takes place preferentially on sites associated with phosphorus atoms, in agreement with the theoretical analysis of Meek and Seidel (7).

In equilibrium conditions atomic concentration of metals in undoped silicon is given in Ref. (17)[2]

$$N = N_{Si} \exp(-E/k_B T)$$

where E is a suitable energy factor and k_B is the Boltzmann constant.

If phosphorus produces getter sites, metal dissolution in phosphorus-doped silicon is described by

$$N' = N_{Si} \exp(-E/k_B T) + N_P \exp(-E_*/k_B T) \quad [1]$$

where the number of getter sites is supposed to increase in proportion to the atomic concentration of phosphorus through an activated process (activation energy E_*) (17). It is supposed that, once formed, the getter site is filled. Formula [1] is the limiting case, for low phosphorus concentration and temperature not too high, of the result obtained by Meek and Seidel for copper and gold.

The segregation coefficient between doped and intrinsic silicon is given by the ratio of N' to N

$$K = 1 + (N_P/N_{Si}) \exp[(E - E_*)/k_B T] \quad [2]$$

Relationship [2] suggests that gettering by segregation annealing is feasible only if $E_* < E$, and, in this case, the upper temperature where it is effective is given by this condition: $k_B T \lesssim E - E_*$. The lower temperature limit is determined by the annealing duration: The temperature must be high enough to allow a complete segregation.

For a particular impurity, gold, the calculation of $E - E_*$ was possible from known thermodynamic data, suggesting an annealing temperature in the range 700°-800°C[3] (17). Graphs of the segregation coefficient *vs.* temperature for various phosphorus concentrations (metal impurity: gold) are shown in Fig. 5. The conclusion obtained for gold can tentatively be assumed to hold for other heavy metals (7, 15).

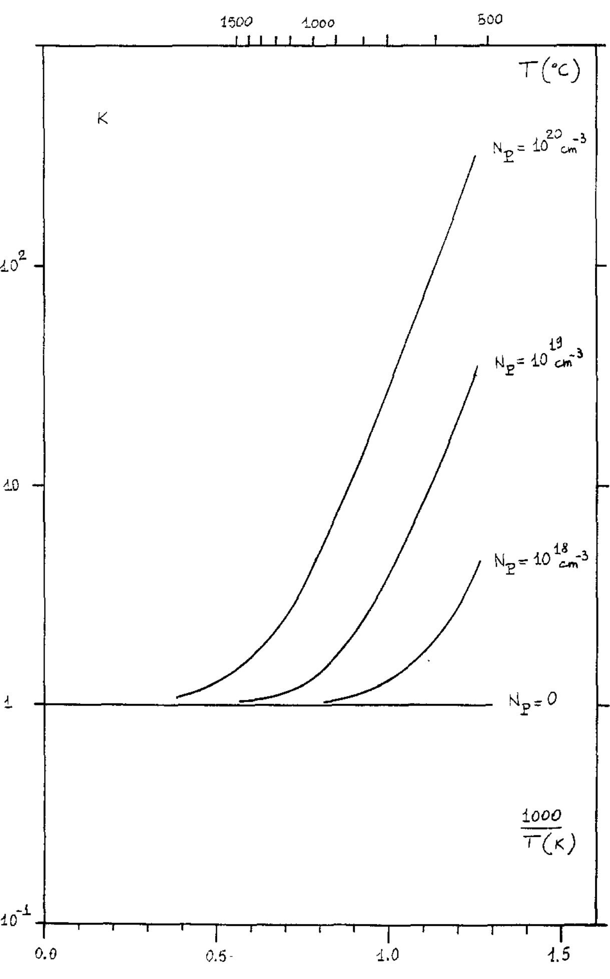

Fig. 5. Segregation coefficient of gold in P-doped silicon *vs.* temperature for various phosphorus concentrations.

The Diode Test

The gettering procedure previously described can be applied to any standard n-channel MOS or CMOS process and allows us to obtain diodes which at room temperature currently have leakages in the range 50-150 pA/cm², irrespective of substrate growth method (CZ or FZ). Leakage current is low enough to be close to the diffusion value so that some indications on the process are required.[4]

This process requires a boron field implantation to avoid surface inversion in high resistivity materials. The various steps are reported in Table II (no cleaning is indicated) and are taken from an n-channel silicon-gate process simplified by avoiding gate oxide growth and poly-Si deposition. We hope that further published reductions in leakages will be accompanied by the associated diode process.

As previously stated, diodes processed in this way reproducibly have at a reverse bias of 15V an area leakage current of about 100 pA/cm²; in addition, the perimeter leakage current is of the order of 1 pA/cm and typical electric defect density on good materials is less than 1 defect/cm² (19). The diffusion limits are roughly the following: area leakage current is 35 pA/cm² [calculated by the equation $J = e\sqrt{D_n/\tau_n}\, n_i^2/N_A$ (20), assuming an electron diffusion coefficient $D_n = 30$ cm²/sec, a minority electron carrier lifetime[5] $\tau_n = 10$ μsec,

[2] Metal atoms are supposed to reach this concentration coming from a source at unit activity.

[3] Obviously, annealing time must increase as temperature decreases to permit heavy metals to diffuse. The results of the experiments of Fig. 2 can be explained by observing that annealing at 700°C for 1 hr is a time shorter than that required for full segregation.

[4] Leakage current of the same order has been reported by Brotherton and Gill in a recent communication (18). This paper is also of interest for the estimate of the value of the diffusion current.

[5] This value is typical for CZ-grown silicon slices with resistivity in the MOS range. However, this parameter is continuously increasing with the development of the technology of silicon production.

* Diodes prepared according to this process currently have a reverse current in the range 50-150 pA/cm² at a bias of 15V. Diodes prepared simultaneously are distributed very sharply around the mean value, and only a small portion of the whole population (about 5%) has high leakages (1 nA/cm² or more). We ascribe this portion to electrically active defects (19).

an intrinsic carrier concentration $n_i = 1.6 \times 10^{10}$ cm^{-3}, and an acceptor concentration $N_A = 2 \times 10^{15}$ cm^{-3}; e is the proton charge], perimeter leakage current is 5×10^{-3} pA/cm (calculated considering the perimeter as a 90° arc of cylindrical junction with radius equal to the junction depth, 1.5 μm, and assuming the same current density calculated for area). Incoming slices were declared dislocation free by the producer and the claim was found true by incoming inspection.

From the comparison we easily realize that the attempt to reduce the defect density and area leakage current have been accomplished to a great extent; but the objective to reduce the gap for the perimeter leakage current has not yet been reached. At present we do not know if the high perimeter leakages must be ascribed to the ion-implant damage, to the vicinity to the field oxide, or to the competitive gettering action of the boron-implanted region (we are indebted to one referee for this suggestion). The perimeter leakage current is a parameter of increasing relevance as the device complexity increases and the feature sizes decrease.

A Review of Gettering Effects on Dynamic RAM's

Though diodes are both conceptually and operatively a good vehicle for testing a gettering efficiency, it is always possible that the efficiency of a getter procedure is lost in a complete (dynamic RAM) process. This process is roughly the same as the one previously described for diodes, with the addition of gate oxidation and annealing (1100°C), poly-Si deposition (660°C), and masking between steps 8 and 9.

For this kind of device, the most important contributions to the over-all leakage current are given by perimeter leakage current and recombination current in MOS capacitors. A typical parameter depending on the latter current and of significance in dynamic RAM's is the storage time of MOS capacitors. In Fig. 6 we have plotted this parameter measured on capacitors processed in our facility as test patterns on the same wafers as 4 K dynamic RAM's. The graph starts with the storage time after the introduction of a rough back side for wafers. This constituted an improvement over the previously used back-polished wafers since the rough back side behaved as a getter region for impurities and prevented the formation of etch pits on the wafer front. The next increase in storage time took place when the P diffusion was also allowed to take place on the back side of the wafers thus improving the getter efficiency at the back side. A third increase in storage time took place when automatic pullers were introduced for all high temperature annealing. This avoided wafer warping and reduced the density of crystal defects induced by processing. A decrease in storage time took place simultaneously with the introduction of sputter-gun deposition of Al/Si. Since the previously used process required the deposition of a thin layer of poly-Si at the temperature of 660°C before Al deposition, we now assume that this step acted as segregation annealing. The last improvement shown took place with the introduction of the cool-down for reflow annealing (19) and of the above-mentioned gettering step.

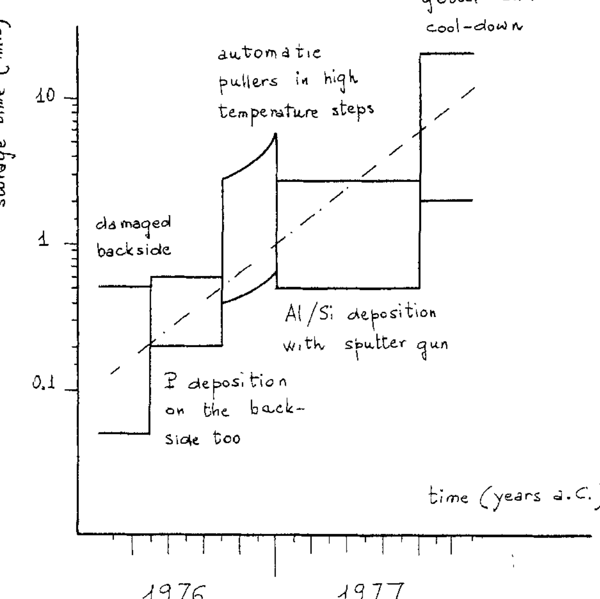

Fig. 6. Improvement in storage time after process changes

In conclusion, the results of this figure provide strong evidence that our gettering procedure, though set up to reduce area leakage currents in diodes, is also efficient in reducing recombination current in gate oxide capacitors.

Discussion

The gettering technique we have described is based on phosphorus deposition followed by segregation annealing at moderate temperature.

In the short history of microelectronics several other gettering techniques have been proposed. Many of them, irrespective of the mechanism proposed to explain the gettering activity, were based on phosphorus deposition followed by high temperature ($\gtrsim$ 1000°C) annealing (6-8). This does not agree with our results that the final annealing should be performed at moderate ($\simeq$800°C) temperature. This discrepancy can be overcome by the following argument.

Considering Eq. [1], it is seen that the solid solubility of metal impurities increases quickly as temperature increases. Thus, if heavy metals are present in the slice in the (catastrophic) form of precipitates, phosphorus deposition followed by high temperature annealing dissolves them. This mode of gettering (*i.e.*, removing metal precipitates) is clearly recognized even in the early work of Goetzberger and Shockley (6) but is not effective in modern materials. Silicon is now furnished with a very low content of heavy metals, especially if float-zone grown. Accordingly, no precipitates are present in the slice and dissolved atoms must be segregated far from the active zones. The phenomenon to be used is selective segregation which is effective at moderate temperature.

If the silicon slice contains metal precipitates, the two processes can be carried out in this order: phosphorus deposition plus high temperature annealing and segregation annealing at moderate temperature. Thus, the objective outlined at the beginning of this work can be considered almost reached, with the remarkable exception of the periphery leakage current. The decrease of this quantity is the obvious, next objective.

Study of Anodization Process on GaAs by *In Situ* Differential Reflectance

C. Yamagishi, A. Moritani, and J. Nakai

Department of Electronics, Faculty of Engineering, Osaka University, Osaka 565, Japan

ABSTRACT

The anodic film growth on GaAs during the anodization process and the dissolution process of the grown film in the open-circuit condition have been observed with the *in situ* differential reflectance technique. The initial phase of anodic oxidation process has also been investigated in this study. The experimental results strongly suggest that the two-dimensional growth of the anodic nuclei takes place in the initial phase and that the substrate-dissolution process is controlling the film formation. A "less soluble region" has been observed in the dissolution curve. The film keeps growing in the open-circuit transient region due to the residual ions within the grown film. It is also shown that the dissolution curve of the grown film is useful in characterization of the film rather than the anodization curve. The obtained value of parameter from the best-fitting to the dissolution curve is 0.2Å sec^{-1} for the dissolution rate at pH 2.4 in tartaric acid-water-propylene glycol electrolyte and 1.79 ± 0.05 for the refractive index of the anodically grown film at 6328Å.

In recent years oxidation of GaAs has been studied for prepartion of the passivation film and gate-insulating film for GaAs-MOSFET. The anodic oxidation has been considered to be one of the most promising techniques to form the native oxide film on GaAs and several performances of the GaAs-MOSFET devices with the anodic films have been reported (1).

The fundamental study of the anodic oxidation on GaAs, however, has not been extensively studied yet. In recent publications, Hasegawa and Hartnagel (2) have shown that Anodization of GaAs in Glycol and Water (AGW process) can provide a stable and reproducible process in forming the anodic oxide films on GaAs and the films possess low conductivity and high dielectric breakdown field-strength. Another interesting report on the initial phase of anodic oxidation on GaAs has been made by Szpak (3). His experimental observation with the use of scanning electron microscope (SEM) indicates that the two-dimensional growth of the oxide film takes place in the initial phase of film formation. We have also shown in our previous report (4) that different type of film formation from that in the region of passive film fomation takes place in the initial phase of anodic oxidation.

It is the purpose of this paper to show some further investigations on the anodic oxidation of GaAs using the new technique of *in situ* differential reflectance with a double beam-single detector system and double specimens (4). It will be shown in this paper that the present technique is available to the study of anodic oxide film formation of thick films grown on GaAs or on the other semiconductors. The initial anodization process and dissolution process of the grown film will also be discussed in this paper.

Key words: semiconductor, anode, reflectance, passivity.

Theory

We consider the thickness modulation with uniform-film growth on a substrate. The description with the Jones matrix representation for a stratified media is very convenient and gives the generalized form for the system in question (5). The intermediate layer is only the anodic film as shown in Fig. 1, so that the basic vector in the electrolyte is represented by

$$\begin{bmatrix} E_{r1} \\ E_{l1} \end{bmatrix} = \begin{bmatrix} (1+n_2/n_1)/2 & (1-n_2/n_1)/2 \\ (1-n_2/n_1)/2 & (1+n_2/n_1)/2 \end{bmatrix} \times \begin{bmatrix} \exp(ikd) & 0 \\ 0 & \exp(-ikd) \end{bmatrix} \times \begin{bmatrix} (1+n_3/n_2)/2 & (1-n_3/n_2)/2 \\ (1-n_3/n_2)/2 & (1+n_3/n_2)/2 \end{bmatrix} \begin{bmatrix} E_{r3} \\ E_{l3} \end{bmatrix} \quad [1]$$

where E_{rj} and E_{lj} are the complex amplitudes of the rightward and leftward propagating plane-wave states in the jth layer, n_j is the complex refractive index of the jth layer, (the subscripts 1, 2, and 3 mean the electrolyte, the film, and the substrate, respectively), k is the complex propagation constant in the film, and d is the film thickness. The boundary condition is $E_{r3} = 0$ which means that energy propagates only to the left in the substrate. The complex reflectance ratio, r, is defined as

$$r = E_{r1}/E_{l1} \quad [2]$$

and the reflectance, R, for the system follows from the definition

$$R = |r|^2 = r^*r \quad [3]$$

The relative change in r, $\Delta r/r$, resulting from the thickness change is expressed by Eq. [4], using Eq. [1] and [2]

$$\frac{\Delta r}{r} = \frac{r(d) - r(0)}{r(0)} = \frac{r(d)}{r(0)} - 1$$

$$= \frac{(n_1 + n_3)}{(n_1 - n_3)} \times \frac{(n_1 + n_2)(n_2 - n_3)\exp(ikd) + (n_1 - n_2)(n_2 + n_3)\exp(-ikd)}{(n_1 - n_2)(n_2 - n_3)\exp(ikd) + (n_1 + n_2)(n_2 + n_3)\exp(-ikd)} - 1 \quad [4]$$

It follows that the relative change of reflectance, $\Delta R/R$, observed experimentally is given by

$$\frac{\Delta R}{R} = \frac{R(d) - R(0)}{R(0)} = \frac{(r + \Delta r)^*(r + \Delta r) - r^*r}{r^*r}$$

$$= 2\,\mathrm{Re}\left(\frac{\Delta r}{r}\right) + \left|\frac{\Delta r}{r}\right|^2 \quad [5]$$

For a very small change, or, a very thin surface film in the thickness modulation, the last term in the right-hand side of Eq. [5] is negligible and the linear approximation theory becomes valid (6). Now, $\Delta R/R$ in the thickness modulation can be evaluated by Eq. [4] and [5] for relatively thick films.

Experimental

Zn-doped p-GaAs wafers with carrier concentration of 1×10^{18} cm^{-3} and (100) face were used in the present experiment. The effect of illumination on the cell voltage, V_C, may be negligible when p-GaAs samples with high carrier concentration are used since holes play an important role in the anodization process. The ohmic contact was formed by deposition of In-Ag alloy in vacuum, followed by a brief annealing in hydrogen atmosphere at 500°C. A typical size of the sample surface area was 7×7 mm^2. Samples were chemomechanically polished and etched by the etchant of $3H_2SO_4 : 1H_2O_2 : 1H_2O$ for one minute. Each sample was subjected to a series of cleaning procedures with organic solvents and boiling in HCl in order to get rid of the native oxide which might have grown during the sample preparation. All the measurements were made in 3 weight percent (w/o) aqueous solution of tartaric acid mixed with propylene glycol in the volume ratio 1:2, buffered by NH_4OH to obtain a desired pH-value, if necessary (2). The pH-value of the electrolyte without adjustment was typically 2.4. Distilled water was used to prepare the electrolyte. The electrolyte was not agitated in the experiment since agitation causes the noise in the optical signal. The experimental setup and measurement techniques on the differential reflectance measurement are as follows.

A double beam-single detector system as shown in Fig. 2 was introduced in order to minimize the drift caused by the optical components. The light beam is divided into the sample and reference channels by a half-circular chopper mirror. A 1 mW He-Ne laser with the wavelength of 6328Å was used as the light source. The polarizers were used only for the attenuation of the light intensity, since the measurements were made in the normal incident configuration at present. We put a reference electrode of GaAs (GaAs-1 in Fig. 2) prepared in the same way as the sample electrode (GaAs-2 in Fig. 2) in order to minimize the difference in the reflected light intensities between the two and then set it to zero prior to the anodization by adjusting the gate width of the delay-gate switching circuit, which has been reported elsewhere (7). The waveform of the signal obtained from the photomultiplier is also shown in the insert of Fig. 2. The gate width was adjusted such that only the flat portion of the signal was picked up to avoid any spike signal which had resulted from the edges of the chopper mirror, and each gate width is adjustable independently so that the initial difference in the light intensities between the two, if it exists, can be set to zero. The output signal in the reference channel was kept constant by a servo-system which controls the high voltage of the photomultiplier. The mirrors and electrodes were set such that the two beams were near-normally in-

E_{r3} E_{l3} n_3 SUBSTRTE | E_{r2} E_{l2} n_2 OXIDE FILM | E_{r1} E_{l1} n_1 ELECTROLYTE

Fig. 1. Schematic diagram of thickness modulation on three-phase model. Semi-infinite substrate is at left, transparent electrolyte at right.

cident onto the sample and reference electrodes and that the reflected-light beams struck the same area of the photocathode of the photomultiplier. We were careful to set the electrodes near the window of the cell as much as possible in order to minimize the noise caused by contaminants or bubbles in the electrolyte used, and all the measurements were made on the table which was made to absorb the ground vibration. Thus, the $\Delta R/R$ *vs.* time ($\Delta R/R - t$), $\Delta R/R$ *vs.* cell-voltage ($\Delta R/R - V_c$), cell-voltage *vs.* time ($V_c - t$), and/or current-density *vs.* time ($J_d - t$) characteristics were simultaneously measured and recorded with a two pen recorder. The magnitude of the drift in this system was estimated below 1% of the signal.

Results and Discussion

Outline of $\Delta R/R$ characteristics.—In the first place, we point out the stability of the electrolyte used. The $V_c - t$ characteristics measured above the critical current-density needed for the initiation of film formation in two electrolytes of the same composition are shown in Fig. 3, where F-electrolyte is freshly prepared just before the anodization and O-electrolyte was prepared a week before. Such fresh and old electrolytes show a difference in the $V_c - t$ curves under the condition of constant current (c.c.); in the F-electrolyte the duration time in the initial portion of the $V_c - t$ curve with smaller gradient is longer than that in the O-electrolyte under the same constant current condition. The experimental data, except Fig. 3 and 10, shown in the following were obtained with the F-electrolyte.

Typical experimental results of the $\Delta R/R$ characteristics under the three important situations for practical production of the anodic oxide film for GaAs-MOS devices are shown in Fig. 4-6. Figure 4 shows the $\Delta R/R - t$ (solid line) and $V_c - t$ (broken line) curves under the condition of c.c.-to-open-circuit. The point designated as "OFF" is the time when the circuit was opened. The current-density was 295 μA cm^{-2} in this case. In the initial phase of anodization both $\Delta R/R - t$ and $V_c - t$ curves have slowly varying portions with the duration time t_c followed by steeply changing portions. The observation of the $\Delta R/R$ signal in the initial phase indicates a "nonpassive" film growth (8) or the quasi-two-dimensional growth of the passive film which is recently reported by Szpak (3). After the circuit was opened, the $\Delta R/R$ signal increased to the initial zero value indicating the dissolution of the anodically grown film. The film is found to be in "less soluble region" for the time t_d and to complete the dissolution in the time t_p as shown in Fig. 4.

The $\Delta R/R - t$ (solid line) and $J_d - t$ (broken line) curves under the condition of constant voltage (c.v.)-to-open-circuit are shown in Fig. 5, where J_{df} is the final current-density. The applied constant voltage was 11.0V in this case. It is found in Fig. 5 that the $\Delta R/R$ signal decreases to a constant value defined by the formation voltage V_f which is the difference between the final cell-voltage and initial voltage drop and corresponds to the grown film thickness, and then it increases in the open-circuit condition in the same manner as in Fig. 4. The "less soluble region" also appeared in this case though the initial flat portion is hardly observed in $\Delta R/R - t$ characteristics.

Lastly, the result under the condition of c.c.-to-c.v.-to-open-circuit is shown in Fig. 6. This condition is commonly applied to the anodic oxidation for the practical use. It is noted that the film formation still continues after the change from the c.c. condition to the c.v. condition.

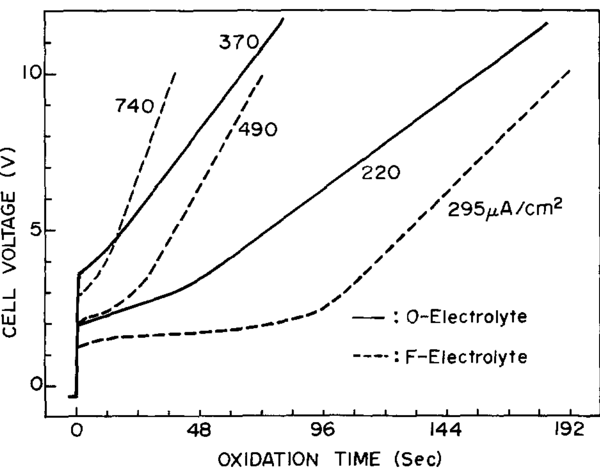

Fig. 3. $V_c - t$ characteristics under the c.c. condition in old- and fresh-electrolyte.

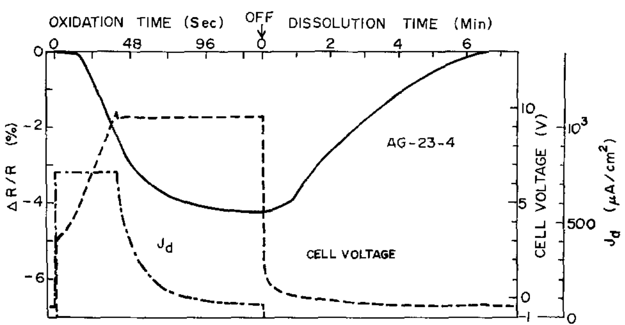

Fig. 6. $\Delta R/R - t$ (——), $V_c - t$ (– – – –), and $J_d - t$ (–·–·–) characteristics under the condition of c.c.-c.v.-open circuit.

After the complete dissolution we repeated the experiments with the same sample and the same electrolyte. Such experimental results under the condition of c.c.-to-open-circuit are shown in Fig. 7, where it is seen that the reproducibility of this experiment is excellent. It is also suggested that the dissolution rate varies with the final thickness of the grown film; it increases as the grown film thickness increases.

Initial phase of anodization process.—A few investigations on the initial phase of anodization of GaAs have been reported. Harvey and Kruger (8) studied the behavior of GaAs anode and observed the active-passive transition under a certain condition. They also observed nonpassive film growth in the active region. Hasegawa and Hartnagel (2) studied the anodic oxidation of GaAs in the AGW process and also observed the active-passive transition. More recently Szpak (3) studied the initial phase of anodization of GaAs in the AGW process with SEM and suggested that the quasi-two-dimensional growth from nucleation site is taking place in the initial phase.

In this section, we will explain the observation of the surface coverage-*vs.*-time ($\theta - t$) derived from the $\Delta R/R - t$ curves in the initial phase of anodic oxidation in terms of the two-dimensional growth assuming that cylindrical nuclei grow in two dimensions in the initial phase. For the growth of an anodic film at constant thickness, the value of $\Delta R/R$ may be determined by an "average thickness $d_0\theta$", where d_0 is the constant thickness of the cylindrical nuclei and θ the surface coverage which is a ratio of the area covered with anodic film to the whole area of electrode, since the wavelength of light used is so long as compared with the dimensions of the nuclei. Thus one may be able to argue the surface coverage as described in the following. The first derivative of the surface coverage θ may be written by

$$\frac{d\theta}{dt} = \frac{J_f M}{z\mathbf{F}\rho d_0} = \frac{J_f}{q_m} \quad [6]$$

where J_f is the current-density consumed for the film formation, M the average molecular weight of the anodic oxide film, ρ the density of the film, z the number of ionic charge, $\mathbf{F}$ the Faraday constant, and $q_m = z\mathbf{F}\rho d_0/M$ the charge amount which is necessary to have the full surface coverage. The problem in the two-dimensional growth of anodic film is what is the slowest process which controls the rate of film formation. Two situations of interest may exist for the two-dimensional growth; (A) the dissolution of the anode material into the electrolyte is the slowest process, called "metal-dissolution-controlling," (B) the growth of anodic film is the slowest process, called "film-formation-controlling" (9). In each case, the surface coverage θ is given by Eq. [7] or [8]

(A) metal-dissolution-controlling case

$$\theta = 1 - \exp\left(-\frac{t}{\tau_d}\right) \quad [7]$$

(B) film-formation-controlling case

$$\theta = 1 - \exp(-at^2) \quad [8]$$

where τ_d and a are constants. The metal-dissolution-controlling is more likely in the present experimental results than the film-formation-controlling since it is found in Fig. 8 that the film thickness, which refers to θ below the full surface coverage, has similar time dependence of type (A) of Eq. [7], as written by Eq. [9]

$$\theta = 1 - \exp\left(-\frac{t}{\tau}\right) \quad [9]$$

In Fig. 8, the theoretical curve (broken line) is drawn assuming that the time constant τ is 6.5 sec and the thickness of cylindrical nuclei d_0 is 35Å. Both curves coincide with each other though the coincidence is broken near the critical time from which the passive film starts to grow in three dimensions. According to Eq. [6], J_f is given by the first derivative of θ so that differentiating the experimental equation, Eq. [9], gives

$$J_f = \frac{q_m}{\tau}\exp\left(-\frac{t}{\tau}\right) = J_1(1-\theta) \quad [10]$$

Equation [10] is likely to correspond to the concept of the metal-dissolution-controlling (9), so that $J_1 = q_m/\tau$ may be considered to be the current-density on the uncovered surface at $t = 0$ and nearly equal to the applied current-density J_d at $t = 0$, if any current-loss is negligible at $t = 0$. Value of q_m is estimated as 4.8 mC cm^{-2} from the time constant τ and current-density J_d in Fig. 8. This value corresponds to the charge amount which four atomic layers of (100) face of GaAs have. If it is assumed that four atomic layers

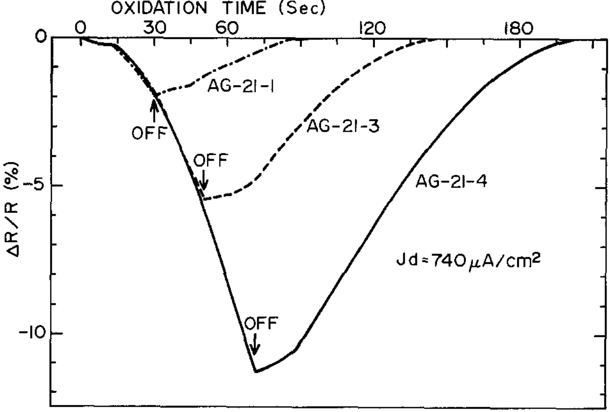

Fig. 7. Reproducibility of the $\Delta R/R$ characteristics with the same sample under the condition of c.c.-to-open-circuit. The initial phase of anodization is reproduced well under the same current-density condition. Time scale after OFF for each curve refers to dissolution time, and has been multiplied by a constant factor 1/10.

dissolve into the electrolyte as ions of Ga^{3+} and As^{3+} and their whole charges are consumed for the formation of oxide film with thickness of 35Å in this case, the consumption ratio was estimated to be 1.5_5. This value is in good agreement with that calculated using the previously reported data of the growth rate and consumption rate (2).

Next we will derive the velocity of radial growth v, cm sec^{-1}, assuming that the nucleation of anodic film is taking place progressively under the c.c. condition. The contribution of nuclei which generated at time u to the surface coverage θ at time t, with no consideration of overlapping is given by

$$d\theta_{ex} = Z\{1 - \theta(u)\}du\pi \left\{ \int_u^t v(t)dt \right\}^2 \quad [11]$$

where Z is the nucleation rate, cm^{-2} sec^{-1}, and θ_{ex} is the surface coverage with no account taken of overlapping. Integrating Eq. [11] gives

$$\theta_{ex} = \int_0^t Z\pi\{1 - \theta(u)\} \left\{ \int_u^t v(t)dt \right\}^2 du \quad [12]$$

Substituting Eq. [9] into Eq. [12] with use of Abrami's equation (10), $\theta = 1 - \exp(-\theta_{ex})$, gives,

$$\frac{t}{\tau} = \int_0^t Z\pi \exp\left(-\frac{u}{\tau}\right) \left\{ \int_u^t v(t)dt \right\}^2 du \quad [13]$$

Differentiating Eq. [13] twice and rearranging gives

$$\left(\frac{1}{v}\right)\frac{d}{dt}\left(\frac{1}{v}\right) = 2\pi\tau Z \int_0^t \exp\left(-\frac{u}{\tau}\right) du$$

$$= 2\pi\tau^2 Z \left\{ 1 - \exp\left(-\frac{t}{\tau}\right) \right\} \quad [14]$$

Solving Eq. [14] with boundary condition, $1/v = 0$ at $t = 0$, which means that there is almost infinite space for nucleation and radial growth at the start of anodization under the constant current condition so that the velocity of radial growth should be substantially large at $t = 0$ (11), one may obtain

$$v(t) = (4\pi\tau^3 Z)^{-1/2} \left\{ \exp\left(-\frac{t}{\tau}\right) + \frac{t}{\tau} - 1 \right\}^{-1/2} \quad [15]$$

or in another form of v as a function of θ

$$v(\theta) = (4\pi\tau^3 Z)^{-1/2} \left(\ln\frac{1}{1-\theta} - \theta \right)^{-1/2} \quad [16]$$

Figure 9 shows the plots of $v(\theta)$ given by Eq. [16]. In Fig. 9, the work by Armstrong and Harrison (11) is also shown for reference. They assumed no current-loss and instantaneous nucleation. On the other hand, Szpak (3) considered that the velocity of radial growth has a linear relationship with the available surface area and gets substantially higher as critical time is approached.

In our present case it is found that the fundamental Eq. [9] is valid and the derived $v - \theta$ curve of the solid line in Fig. 9 gives qualitative understanding of the kinetics of the surface coverage on GaAs until the critical time. However, the velocity of radial growth v will substantially increase so as to fill the small pores among the nuclei as the critical time is approached.

"Less soluble region".—The region where the dissolution rate appears to be small is found in the dissolution curves and we call it "less soluble region." The dependences of the two parameters, t_d and t_p, upon the formation voltage V_f are shown in Fig. 10. It is observed that t_p has linear dependence upon V_f, while t_d has little dependence upon V_f, though t_d is dependent on the pH-value of the electrolyte used and current-density. It is also observed that the dissolution rate appears to be smaller in the O-electrolyte than in the F-electrolyte. Figure 11 shows the dependence of t_d upon the final current-density J_{df} which was already indicated in Fig. 5. It seems that t_d is proportional to the square root of J_{df}. This resut strongly suggests that the anodic film keeps growing after the circuit is opened due to the residual ions within the anodically grown film and thus "less soluble region" appears. Figure 12 shows the thickness and dissolution rate of the grown film after the open-circuit derived from the best-fitting to the $\Delta R/R - t$ curve. The extrapolation of the linear portion to the zero dissolution time yields the thickness $d = 190$Å which is in good agreement with that calculated using the previously reported data of the growth rate (2). This fact also suggests the

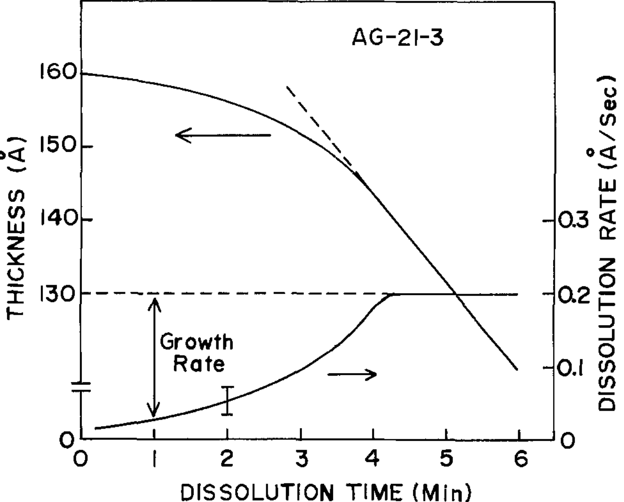

Fig. 12. Thickness and dissolution rate as function of the dissolution time.

passive film growth in the open-circuit transient region. The dissolution rate is found to be constant, 0.2 Å sec^{-1}, in this sample beyond t_d. The growth rate in the transient region would be represented as marked in Fig. 12 assuming that the dissolution takes place at constant rate throughout the reaction process.

Best-fit calculation.—The dissolution curve is considered to be little influenced by the initial condition of anodization so that it is available to apply a best-fit calculation to one of the dissolution curves apart from the "less soluble region" in order to obtain the optical constant and dissolution rate. The anodization curve of $\Delta R/R - t$ (or $-V_f$) characteristics contains in the initial stage the contribution of the nonpassive film, or the two-dimensional growth of the passive film which depends on the surface treatment, current-density, and electrolyte used. On the other hand, the dissolution curve may result from the clean surface of the substrate at the anodic film-GaAs interface so that it is much less dependent upon the surface treatment. The best-fit calculation for the dissolution curve was made with inversely considering that the film grows on the clean surface of the substrate and assuming that the growth rate (the dissolution rate, in truth) is constant during the process. It is shown in Fig. 13 that the theoretical curve fits well with the experimental $\Delta R/R - t$ curve. In Fig. 13, the circles represent the experimental points and the solid line is the theoretical curve of the three-phase model, electrolyte-anodic film-substrate, with use of Eq. [4] and [5] assuming $n_1 = 1.40$ (the average value of the refractive indexes of water and propylene glycol) and $n_3 = 3.85 + 0.19i$ (12). It is found that the dissolution rate is surely constant from $t = t_d$ to t_p and its value is obtained to be

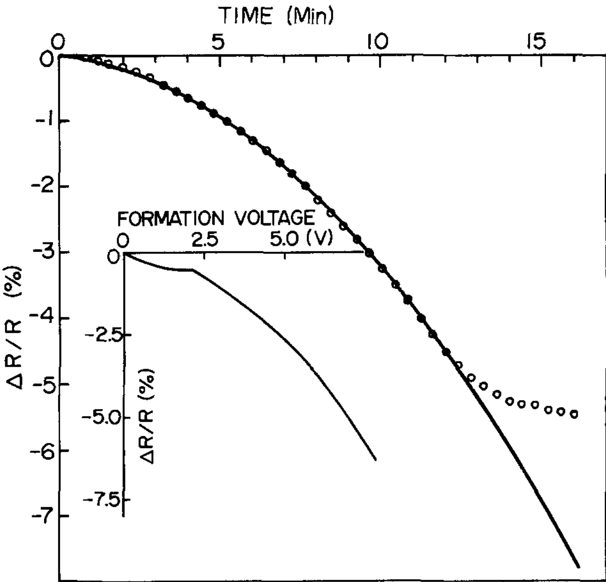

Fig. 13. Result of best-fitting to one of the dissolution curves of the $\Delta R/R - t$ characteristics. Open circles represent the experimental data, and solid line the theoretical curve.

0.2 Å sec^{-1} in this sample. This value is about one order of magnitude larger than that obtained in the AGW process and one order smaller than that obtained in the AAS (anodization in aqueous solution without glycol) process by Hasegawa and Hartnagel (2). The value of the other parameter obtained from this best fitting is 1.79 ± 0.05 for the refractive index of the anodic oxide film at 6328Å. This value seems to be in good agreement with the previously reported data of the refractive index (13-17).

Summary and Conclusions

We have observed the anodic oxide film growth and dissolution on GaAs in the *in situ* differential reflectance measurements and demonstrated its availability to the investigation of the anodization process. The main conclusions are summarized in the following:

1. The initial shoulder has been observed in the anodization curve of the film thickness *vs.* time characteristics. This initial shoulder is due to the two-dimensional growth rather than due to the deposition of the nonpassive film which has a different refractive index. The time depedence of the surface coverage $\theta(t)$ suggests that the substrate-dissolution is the rate-determining process of the film formation in the initial phase of anodization on GaAs. The time dependence of the velocity of radial growth has also been derived assuming the progressive nucleation.

2. The "less soluble region" has been observed in the dissolution curve of $\Delta R/R$ *vs.* time characteristics. The duration time t_d for which the "less soluble region" exists is proportional to the square root of the final current-density J_{df} and has weak dependence upon the formation voltage V_f. These observations suggest that the "less soluble region" appears due to the anodic film formation by the residual ions within the grown film.

3. It is clarified that the growth or dissolution rate is constant except in the initial phase or the "less soluble region" from the best-fitting to one of the dissolution curves of the $\Delta R/R - t$ characteristics. The value of the parameter obtained from the best-fitting is 0.2 Å sec^{-1} for the dissolution rate and 1.79 ± 0.05 for the refractive index of the anodic oxide film at 6328Å. It is also shown that the dissolution curve is more suitable for characterization of the anodically grown film than the anodization curve since the former is considered to be produced with the clean film-substrate interface.

Acknowledgment

The authors would like to acknowledge H. Kubo, S. Tachi, and A. Shimano for their important assistance

and useful discussions. They would like to thank Professor H. Hasegawa of Hokkaido University for his useful suggestions and sending the preprint prior to publication. They wish to express their gratitude to K. Matsumoto of Sumitomo Electric Industries, Limited for providing the GaAs single crystals. This work is partially supported by the Grant-in-Aid for Scientific Research on Surface Electronics from the Ministry of Education of Japan.

Manuscript submitted Oct. 11, 1978; revised manuscript received July 22, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Osaka University.

Liquid Phase Growth of HgCdTe Epitaxial Layers

C. C. Wang,* S. H. Shin, M. Chu, M. Lanir, and A. H. B. Vanderwyck
Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

Epitaxial layers of mercury cadmium telluride ($Hg_{1-x}Cd_xTe$) with Cd composition (x value) from 0.17 to 1.0 have been grown in Te solution by a liquid phase epitaxial (LPE) technique. The layers are grown on CdTe substrates with (100), (110), (111)Cd, and (111)Te orientations. The best surface is obtained on the (111)Cd surface. Typical hole concentration of HgCdTe layers with Cd composition of 0.2 is on the order of $5 \times 10^{16}/cm^3$ with a Hall mobility of 400 cm^2/Vsec at 77°K. X-ray topographic analysis indicates that these epilayers have as good a crystalline structure as that of the substrates.

A number of crystal growth techniques have been developed with varying degrees of success in the preparation of bulk and epitaxial HgCdTe crystals (1-8). Because of difficulties associated with the epitaxial crystal growth techniques, the development of HgCdTe device technology has been restricted to that of bulk photovoltaic and photoconductive detectors. Although charge-coupled devices in bulk HgCdTe (9) have recently been realized, these devices are limited to a frontside-illuminated mode (10), unless back-side-thinned (11). This limitation, however, will be alleviated by the development of HgCdTe epitaxy on CdTe substrates, from which back-side-illuminated heterostructure HgCdTe/CdTe detectors can be made. This paper reports on results on liquid phase epitaxy (LPE) of HgCdTe layers on CdTe substrates.

LPE is a relatively low temperature growth process that has been developed extensively in preparing high quality III-V (12) and IV-VI (13) semiconductors. LPE growth of II-VI compounds has not been widely studied (14) in the past, mainly because of the high vapor pressure of column II elements and the low solubility of column VI species in column II solutions at low temperatures. In the work reported here, a modified LPE dipping technique is used, from which HgCdTe layers with Cd composition from 0.17 to 0.4 have been grown in Te solutions. Pure CdTe epilayers have also been grown when Hg is not added to the system. As a result, it was possible to fabricate the first back-side-illuminated HgCdTe/CdTe heterostructure diodes using these epilayers (15).

The high pressure system is utilized to control the high mercury vapor pressure over the molten materials, and the growth system is shown in Fig. 1. The apparatus consists of an inner quartz reaction tube and an outer quartz tube that is mounted between two stainless steel flanges to keep high argon gas pressure. The pressure inside the tube is maintained at 200-300 psi during growth. We have not determined the Hg vapor pressure during the growth which is found not to be a critical parameter in growing a 20% HgCdTe layer reproducibly under high external pressure. The outer quartz tube is mounted in a vertical furnace that is controlled to within ±0.05°C. A thermocouple is inserted into the melt to monitor the actual melt temperatures. The inner reaction tube is plugged with high purity quartz wool to prevent excess mercury evaporation from the melt. A cold zone is established just below the quartz wool in order to condense mercury vapor.

In a typical growth, CdTe substrates are first lapped and chemically polished in a Br_2:HBr solution (10% Br_2 in volume) followed by a Br_2:CH_3OH etch (5% Br_2 in volume) before loading in the growth chamber. Prior to growth, appropriate amounts of high purity (99.9999%) Hg and Cd are reacted in the Te melt at ~700°C for an hour. For example, a typical ratio of CdTe:Hg:Te for 20% HgCdTe growth is 0.004:0.251:0.745. Subsequently, the melt and the oriented substrate are brought to the saturation temperature, typically at ~500°C. The saturation tempera-

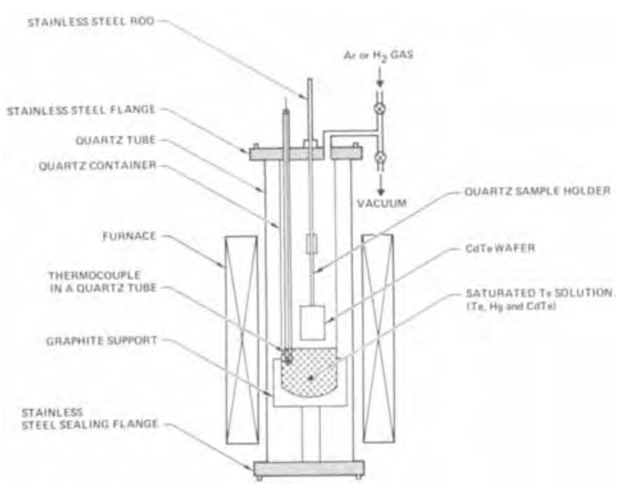

Fig. 1. Schematic of the liquid phase epitaxy growth system

ture is determined empirically in the growth system shown in Fig. 1. The epilayers grown from solutions initially are either saturated or unsaturated by as much as ~15°C. In the latter case, examination of the epilayers shows that the substrates are melted back by the solution prior to growth. Through an interaction process it is possible to determine the liquid composition by dipping the known weight of CdTe into the melt of Hg and Te solutions at growth temperatures. The growth temperature normally drops at a rate of from 0.2 to 1°C/min with a typical value on the order of 0.25°C/min. In order to eliminate an Hg vapor diffused layer obtained during the heat-up cycle, the substrate is melted back at 550°C for 15 sec in the growth solution prior to growth. A temperature profile of LPE is shown in Fig. 2. The actual LPE growth time takes about an hour for a ~20 μm epilayer on the (111) oriented substrates, resulting in a growth rate of ~1 μm/°C.

Table I provides a summary of growth conditions of HgCdTe with a Cd composition of 0.2. The HgCdTe epilayers are nominally p-type when undoped CdTe substrates are used. These layers exhibit n-type conduction when grown on In-doped CdTe presumably as a result of indium diffusion from the substrate.

The HgCdTe epilayers are grown on CdTe substrates with (100), (110), (111)Cd, and (111)Te orientations. Layers with thickness of from 1 to 300 μm have been grown. Under normal growth conditions, the deposition rate in (100) orientation is about 2 μm/°C, which is twice as fast as that in (111) orientation.

Figure 3 shows the surface of an HgCdTe epilayer grown on a (111)Cd oriented substrate. The surface is mirror-like and free of residual melt. The size of the wafer is on the order of 1.5 × 1.5 cm and the layer is about 30 μm thick. Notice the surface quality of this

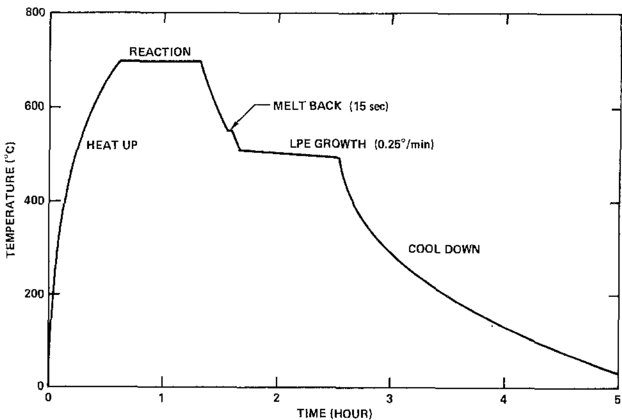

Fig. 2. Temperature profile for LPE growth

Table I. Growth conditions and properties of as-grown HgCdTe epilayers

(I) Growth conditions		
Melt composition	CdTe:Hg:Te = 0.004:0.251:0.745	
Container pressure	200 psi	
Substrate orientations	(111) A	
Growth temperature	~500°C	
Reaction temperature	~700°C	
Growth time	60 min	
Cooling rate	0.25°C/min	
(II) Epilayer characteristics

Electron mobility	1×10^5 $cm^2/Vsec$	
Carrier concentration (p-type)	$5 \times 10^{16}/cm^3$	Undoped Substrate
Hole mobility	400 $cm^2/Vsec$	

layer. The inch scale of a ruler is clearly shown. As in all the other LPE growth of semiconductors, the surface quality is dependent on the orientation of the substrate (16). It is found that the epilayer on (111)Cd oriented substrate always has a better surface morphology than that on the (111)Te oriented surface. In fact, the quality of (111)Cd oriented surface is also better than that on (110) and (100) surfaces.

Detailed examination of the epilayer surface quality on the (111)Cd face reveals that it is mirror smooth for a thickness of less than 10 μm and shows facets and sometimes terrace substructures for layers thicker than 30 μm. The terrace surface may be due to the substrate being slightly off the (111)Cd orientation (16) and/or liquid-solid interface instabilities (17); it becomes more pronounced as the thickness increases. The surface of a (111)Te epilayer usually exhibits voids across the wafer, and the density of these voids increases as the layer becomes thicker. Figure 4(a) shows the surface morphology of a thick HgCdTe layer grown on the (111)Cd surface and Fig. 4(b) is that of a layer grown on the (111)Te surface. It is not clear what mechanisms are responsible for the voids on the (111)Te surface. It appears, however, that these defects may originate from the Te metal atoms on the (111)Te surface. Indeed, a similar development of void defects was observed on GaAs LPE layers (18), and it was hypothesized that the defects on the surface were caused by small particles which induce the formation of depressions and voids in the epilayers. The remainder of this paper presents properties of HgCdTe epilayers grown on the (111)Cd face of the substrate.

Figure 5 is the cross section of a typical HgCdTe single layer. Notice the planarity of the interface. The etchant used for delineating the interface attacks CdTe, not HgCdTe; and as a result, HgCdTe shows a white stripe while CdTe exhibits a gray color. Electron microprobe analysis indicates that a major transition region

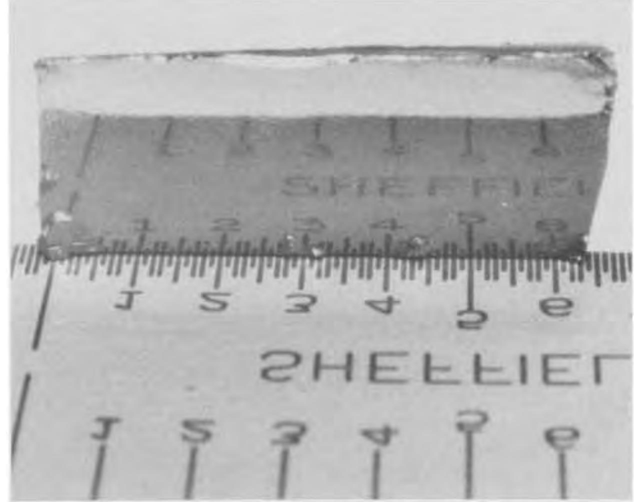

Fig. 3. The surface of an HgCdTe epilayer grown on an (111)Cd oriented substrate. The number scale is 0.1 in.

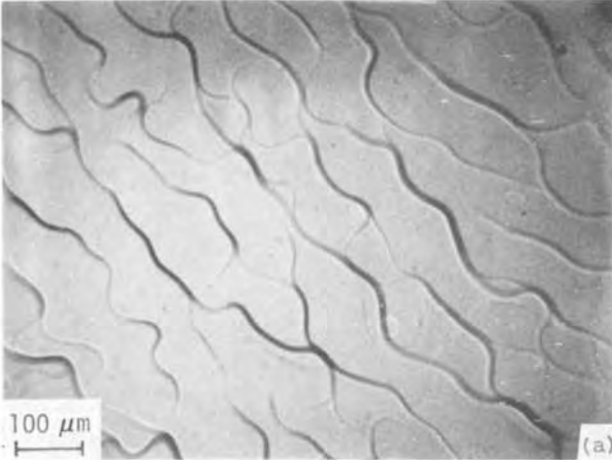

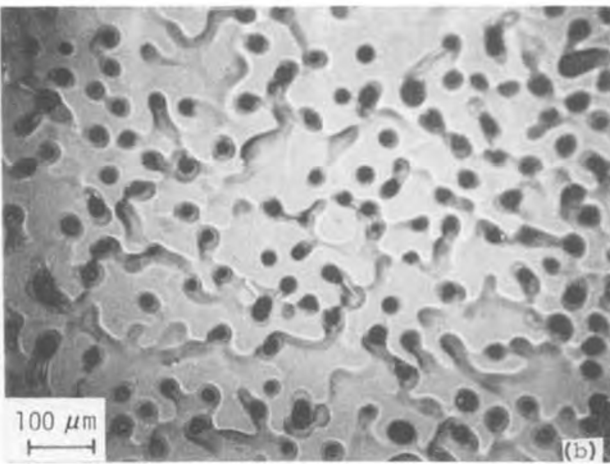

Fig. 4. (a) The surface morphology of an HgCdTe layer grown on the (111)Cd surface; (b) the surface morphology of an HgCdTe layer grown on the (111)Te surface.

between the HgCdTe epilayer and the substrate is on the order of 2 μm for thick layers ($d \approx 100$ μm), and is less than 0.5 μm for thin layers ($d \sim 15$ μm). An electron microprobe analysis of an HgCdTe layer with a Cd composition on the order of 0.2 is shown in Fig. 6. A major transition is observed within 0.5 μm region at the metallurgical interface. The gradual compositional change in the epilayer and the substrate may be due to interdiffusion during growth and has been found to have no direct effect on device performance, *e.g.*, uniformity, since the ion-implanted junction is formed in less than a micron from the surface.

The infrared transmission at 300°K is usually used for determining the layer composition in addition to the electron microprobe analysis. Figure 7(a) shows the transmission edge of five typical HgCdTe epilayers for Cd compositions from 0.17 to 0.28. This nondestructive test provides a rapid feedback to assess and improve the LPE growth parameters. A typical infrared transmission spectrum for a HgCdTe epilayer with a Cd composition of 0.3 is shown in Fig. 7(b). The spectrum exhibits a sharp cut-on at 4.2 μm and also oscillates beyond that wavelength due to infrared interference in the HgCdTe epilayer. It is not clear at this time what causes the short wavelength tail; it may be due to the gradual compositional change in the epilayer. Since the epilayer has a refractive index that is different from that of the substrate, these oscillations are interference fringes produced by the superposition of light transmitted through the layer and the internal reflection from the interface of HgCdTe and CdTe. If N is a positive integer, then the interference satisfies the equation $2nd = N\lambda$, where d is the thickness of the epilayer and λ is the wavelength at which the transmission maximum occurs. From this information, we can calculate the average index of refraction, n, of these HgCdTe epilayers. The results give a value of 3.33 for HgCdTe with a Cd composition of 0.3, which is in good agreement with reflectance measurements (19).

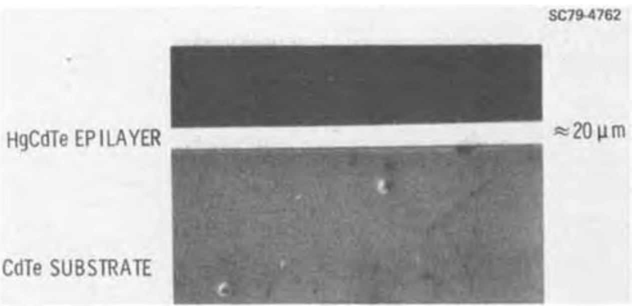

Fig. 5. The cross section of a typical HgCdTe epilayer

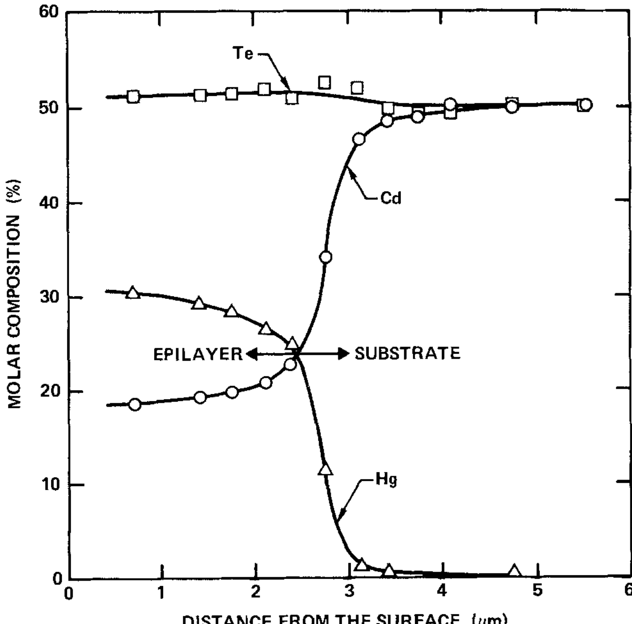

Fig. 6. The composition profile of an HgCdTe epilayer

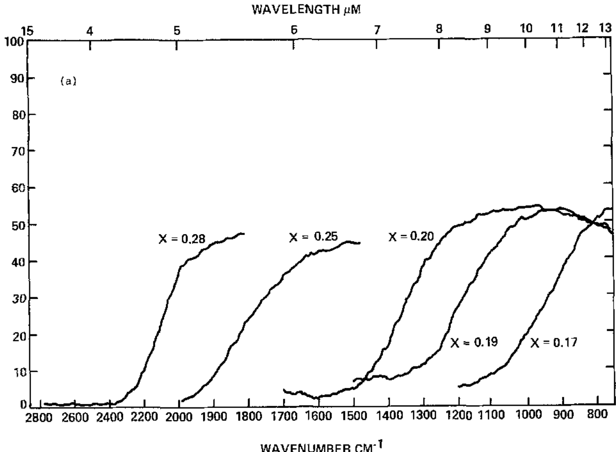
Typical electrical characteristics of as-grown n-type and p-type HgCdTe epilayers are shown in Table I. In Table I, properties of HgCdTe layers with a Cd composition of 0.2 and a thickness on the order of 20 μm are given. Since the CdTe substrate can be made semi-insulating, the conventional Van der Pauw-Hall measurement technique provides unambiguous results if HgCdTe layers are grown on these substrates. Typical hole concentration is on the order of $5 \times 10^{16}/cm^3$ with a Hall mobility of 400 cm^2/Vsec at 77°K. From a device point of view, this as-grown carrier concentration is suitable for fabricating high performance photovoltaic detectors (15).

X-ray topography was used for analyzing the HgCdTe film crystallinity and for comparing it with the CdTe substrate. This kind of study is important since dislocations generated due to difference in thermal expansion coefficient, lattice mismatch, or significant difference in doping levels between the substrate and the epilayer have been observed by x-ray topography in a variety of crystal systems (20-22). We used an AMR Hart Topographic camera with 100 × 1000 μm source. The $CuK\alpha_1$ microfocused beam take-off angle is 6° and the divergence slit is 100 μm. Figure 8 shows an x-ray topograph of a CdTe wafer with an HgCdTe epilayer grown on a section of it. This photograph represents a wafer of the size of 1.5 × 1.5 cm. The x-ray picture shown is a (440) reflection. Other reflections were also examined, but no additional information was obtained. In Fig. 8, the band in the center is due to edge solidification of the melt. The bubbles near the bottom of the epilayer (left of photograph) are due to residual melts on the surface. The substructure near



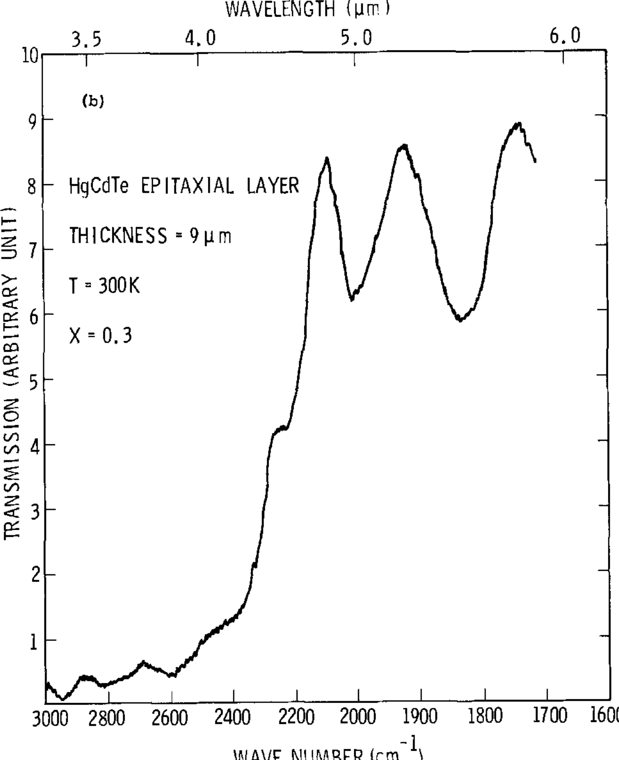


Fig. 7. (a) Infrared transmission spectra of five selected HgCdTe epilayers with various x at room temperature; (b) an infrared transmission spectrum which exhibits interference fringes due to HgCdTe epilayer.

the top of the CdTe substrate (right of photograph) is due to the gripping from the sample holder. Since the diffracted x-ray comes almost entirely from a surface region about 5 μm thick, the epilayer image on the left of photograph represents only diffraction from the HgCdTe. Careful examination of Fig. 8 reveals no dislocation pattern; the substructure of the layer can be seen to be very similar to that of the substrate. It may be concluded, therefore, that the crystalline perfection of the epilayer is currently limited by the CdTe quality.

In summary, we have demonstrated that device quality HgCdTe epilayers can be grown by liquid phase epitaxy. The best surface is obtained with the (111)Cd orientation; this surface is mirror smooth to the naked eye and free of residual melts. The metallurgical interface between the substrate and the epilayer is planar; the major interdiffusion region is less than 0.5 μm for thin HgCdTe epilayers ($d \approx 15$ μm). Finally, the crystalline quality of HgCdTe is as good as that of the CdTe substrate. The results presented here indicate that the LPE technique offers a viable approach to preparation of device grade HgCdTe epitaxial materials and advanced device structures (15).

Quantitative Measurement of Stress in Silicon by Photoelasticity and Its Application

H. Kotake and Shin. Takasu*,[1]

Toshiba Research and Development Center, Saiwai-ku, Kawasaki 210, Japan

ABSTRACT

Quantitative evaluation method for stress in crystal was established by photoelasticity. It consists of three procedures: measurement by plane polarized light, measurement by circularly polarized light, and piezo-optical coefficients calculation. The last method is indispensable for stress evaluation in crystal. Piezo-optical coefficients for silicon in the [110] [$\bar{1}$10] [001] and [112] [$\bar{1}$10] [$\bar{1}\bar{1}$1] coordinate system were calculated from the values in the [100] [010] [001] coordinate system measured by Giardini. Practical approximation was made to correlate each isochromatic line directly to the difference between two principal stresses. This method was applied to the evaluation of the stress in silicon semiconductor pellet caused in the mounting and molding process. Observation of isochromatic lines according to temperature was practical for determination of the zeroth order of retardation.

Photoelastic measurement is one of the important methods used for crystal characterization. However, crystal anisotropy makes its application to quantitative evaluation rather difficult. Photoelastic study of silicon crystals was started by Bond and Andrus (1) and Giardini (2). Application of photoelasticity to silicon processing was reported by Laderhandler (3), Hornstra (4), DeNicola (5), and Takasu (6). Except for the reports by Takasu and Edmonds (7), these were reports on crystal defects due to crystal growth or grinding. Quantitative measurement was made by Laderhandler (3) for silicon. However, there is no complete report on piezo-optical coefficients in various coordinate systems for the purpose of crystal characterization, although there are some reports on the experimental determination of these values (8).

Quantitative measurement has been made easy by piezo-optical coefficients calculation in various measurement coordinate systems. A slight approximation was made to correlate each isochromatic line directly to the difference between the two principal stresses perpendicular to the observation direction.

This quantitative evaluation method can be applied to various fields of crystal characterization, such as crystal growth and its processing. Among those, silicon semiconductor pellet stress measurement in the mounting and molding process is very important from the device fabrication reliability viewpoint.

Evaluation Procedure

The ultimate photoelastic measurement aim is to determine the principal stress directions and magnitudes. Quantitative evaluation procedure of stress distribution in crystal by photoelasticity is shown in Fig. 1.

Principal stress line can be obtained through the measurement by plane polarized light, because the isoclinic line obtained by this method corresponds to the region where principal stress directions coincide with those of polarizer and analyzer. Isochromatic lines, which correspond to stress magnitude, can be obtained through the measurement by circularly polarized light.

The apparatus used in these observations is schematically illustrated in Fig. 2. The quarter wave plates were used only in the observation by circularly polarized light. Silicon was observed by infrared radiation of 1.1 μm wavelength with 0.2 μm bandwidth, which was obtained by the combination of tungsten lamp, silicon filter, and PbO-PbS vidicon. Therefore, it is effectively monochromatic.

Piezo-optical coefficients have to be determined to correlate each isochromatic line to a stress value. This is indispensable in crystal study, for piezo-optical coefficients in the same sample coordinate system have to be used. Calculations of these values are shown in the following section.

Another important point is to determine the isochromatic line of the zeroth order of retardation, which becomes the standard for stress determination. This must be done according to circumstances by assuming sample stress distribution.

For more accurate measurement, Tardy's method can be used to determine the suborder of retardation.

(c) Principal axes directions, P_1: IR polarizer, P_2: IR polarizer (analyzer), Q_1: 1/4 wave plate, Q_2: 1/4 wave plate, T_1,T_2: Sample principal stresses, ϕ: angle between T_1 and P_2.

The conoscopic figure, obtained in the observation by converging rays, gives three-dimensional stress information. It is especially helpful for the determination of principal stress directions.

Piezo-Optical Coefficients Calculation

Piezo-optical coefficient.—There is a relation between refractive index n_i and stress T_i, where subscript i means the ith component in the coordinate system, as follows

$$\Delta\left(\frac{1}{n_i^2}\right) = \sum_j \pi_{ij}T_j \quad [1]$$

π_{ij} in this formula is called the piezo-optical coefficient and can be described in the next equation for cubic crystals in the [100] [010] [001] coordinate system

$$\pi_{ij} = \begin{bmatrix} \pi_{11} & \pi_{12} & \pi_{12} & & & \\ \pi_{12} & \pi_{11} & \pi_{12} & & 0 & \\ \pi_{12} & \pi_{12} & \pi_{11} & & & \\ & & & \pi_{44} & & \\ & 0 & & & \pi_{44} & \\ & & & & & \pi_{44} \end{bmatrix} \quad [2]$$

These values were measured for silicon by Giardini (2)

$$\pi_{11} - \pi_{12} = -14.4 \times 10^{-14}\ \text{cm}^2/\text{dyne}$$
$$\pi_{44} = -10.0 \times 10^{-14}\ \text{cm}^2/\text{dyne} \quad [3]$$

In the case that two principal stress directions are [100] and [010], and the sample is observed from [001], T_i is

$$T_i = \begin{bmatrix} T_1 \\ T_2 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad [4]$$

From Eq. [1]

$$\Delta\left(\frac{1}{n_i^2}\right) = \begin{bmatrix} \pi_{11}T_1 + \pi_{12}T_2 \\ \pi_{12}T_1 + \pi_{11}T_2 \\ \pi_{12}T_1 + \pi_{12}T_2 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad [5]$$

Then, the difference between refractive indexes of light waves vibrating in [100] and [010] directions is

$$\Delta\left(\frac{1}{n_1^2}\right) - \Delta\left(\frac{1}{n_2^2}\right) = (\pi_{11} - \pi_{12})(T_1 - T_2) \quad [6]$$

The same relations can be obtained in other observations.

Transformed values of piezo-optical coefficients.—When coordinate axes are transformed from [100], [010], and [001] to other directions, corresponding piezo-optical coefficients π_{ij}, stresses T_i, and refractive indexes n_i are also transformed. Results were summarized in Table I in the case of [110] [$\bar{1}$10] [001] and [112] [$\bar{1}$10] [$\bar{1}\bar{1}$1] coordinate systems. The primed values are with respect to the new system of axes. In this table, transformed refractive indexes n_i' were expressed by original piezo-optical coefficients π_{ij} and transformed stresses T_i'. The value of $\{\Delta(1/n_i'^2) - \Delta(1/n_j'^2)\}$ is not always proportional to the difference between the principal stresses $(T_i' - T_j')$. It is very convenient to make a slight approximation. Coefficient of $(T_i' - T_j')$ was obtained from the average of coefficients of T_i' and T_j', in some cases, in Table I.

Retardation.—Phase difference between two light waves which travel, vibrating parallel to the two principal stress directions (T_k and T_l), can be defined as

$$h = \frac{d}{\lambda}(\Delta n_k - \Delta n_l) \quad [7]$$

where h is the retardation measured in wavelength unit λ and d is the light path distance in the crystal. On the other hand

$$\Delta n_k - \Delta n_l = \frac{n_0^3}{2}\left\{\Delta\left(\frac{1}{n_l^2}\right) - \Delta\left(\frac{1}{n_k^2}\right)\right\}$$
$$= \frac{n_0^3}{2}A(T_l - T_k) \quad [8]$$

where n_0 is the refractive index in crystal free from stress and value A is shown in Table I. Then, the relation between the difference in principal stresses and retardation is

$$T_l - T_k = \frac{2}{n_0^3 A}\frac{h\lambda}{d} \quad [9]$$

The value $T_l - T_k$ in the case of $\lambda = 1.1\ \mu$m, $h = 1$, $d = 10$ mm are shown in Table II for various cases of observation.

Stress Gradient Direction

It is important and helpful to know the stress gradient direction in a sample. Tardy's method, which is used for the determination of the suborder of retarda-

2	** [$\bar{1}$10]	$\approx \frac{1}{2}\left\{\left(\frac{1}{6}\pi_{11} - \frac{1}{6}\pi_{12} + \frac{5}{6}\pi_{44}\right) + \pi_{44}\right\}(T_1' - T_3')$
3	* [$\bar{1}\bar{1}$1]	$= -10.4 \times 10^{-14} (T_1' - T_3')$
1	** [112]	$\Delta\left(\frac{1}{n_2'^2}\right) - \Delta\left(\frac{1}{n_3'^2}\right) = \left(\frac{1}{6}\pi_{11} - \frac{1}{6}\pi_{12} + \frac{5}{6}\pi_{44}\right) T_2' - \pi_{44} T_3'$
2	* [$\bar{1}$10]	$\approx \frac{1}{2}\left\{\left(\frac{1}{6}\pi_{11} - \frac{1}{6}\pi_{12} + \frac{5}{6}\pi_{44}\right) + \pi_{44}\right\}(T_2' - T_3')$
3	* [$\bar{1}\bar{1}$1]	$= -10.4 \times 10^{-14} (T_2' - T_3')$

tion, is one way to do this. However, before that, it is desired to consider the circular polariscope first.

Light wave electric field vector in circular polariscope is shown in Fig. 3, when a quarter wave plate pair is placed such that the x' component in Fig. 2(c) increases by $\pi/2$ in phase after the first quarter wave plate (Q_1), and decreases by $\pi/2$ in phase after the second quarter wave plate (Q_2).

In Tardy's method, the sample is placed so that principal stress directions (T_1, T_2) at the point in problem in the sample coincide with those of polarizer (P_1) and analyzer (P_2) in Fig. 2(c), and the angle between T_1 and P_2 is zero ($\phi = 0$). Then, analyzer (P_2) is rotated clockwise or counterclockwise until the intensity at the point becomes a minimum. The analyzer rotation angle corresponds to the suborder of retradation. The shift direction of the dark isochromatic line means that of the increase in ($T_1 - T_2$) or that of the decrease in retardation (h) when the analyzer is rotated clockwise. The result becomes opposite if the directions of the quarter wave plate pair are changed with each other.

Table II. The principal stress difference which causes 1λ ($\lambda = 1.1$ μm) retardation in 1 cm light path

Observation directed	Principal stress directions	Principal stress difference for 1λ retardation (kg/cm^2)
[001]	[100] [010]	36
[001]	[110] [$\bar{1}$10]	52
[$\bar{1}$10]	[110] [001]	43
[$\bar{1}\bar{1}$1]	[112] [$\bar{1}$10]	45
[$\bar{1}$10]	[112] [$\bar{1}\bar{1}$1]	50
[112]	[$\bar{1}$10] [$\bar{1}\bar{1}$1]	50

It is very convenient to use a standard sample whose stress gradient direction is well-known, to check the optical system of the apparatus. A standard sample example is a beam bent at four points, as shown in Fig. 4. In this case, the upper half is under compressive stress and the lower half is under tensile stress.

Application

This quantitative evaluation method was applied to stress measurements on IC pellets in Dual Inline Package with 42 pins (53 × 13 × 3.5 mm). A silicon pellet obtained from (100) wafer had the orientation of [110] [$\bar{1}$10] [001] and 5 × 5 × 0.5 mm dimensions. The pellet was mounted on a Kovar metal frame (230 μm thick) by epoxy resin at 175°C. This was molded in epoxy resin by a transfer molding machine at 165°C and cured.

Photoelastic measurement of silicon pellet stress after mounting was made through optically polished parallel side surfaces [Fig. 5(a)]. For the molded pellet, epoxy resin was removed to the size of the pellet by cutting and grinding and a pair of side surfaces on the pellet were optically polished [Fig. 5(b)]. Observation was made through these parallel side surfaces by placing the sample so that these surfaces were perpendicular to the observation direction.

It was ascertained by the conoscopic figure in the observation by converging rays that two principal stresses were in the plane parallel to the optically polished surfaces.

Observed isochromatic lines by parallel rays are shown in Fig. 6 for a mounted pellet and in Fig. 7 for a molded pellet. Evaluated stress values are also shown in these figures although they are only approximate ones. In these measurements, isochromatic lines of the zeroth order of retardation had to be determined. This was done by observing the change in isochromatic lines

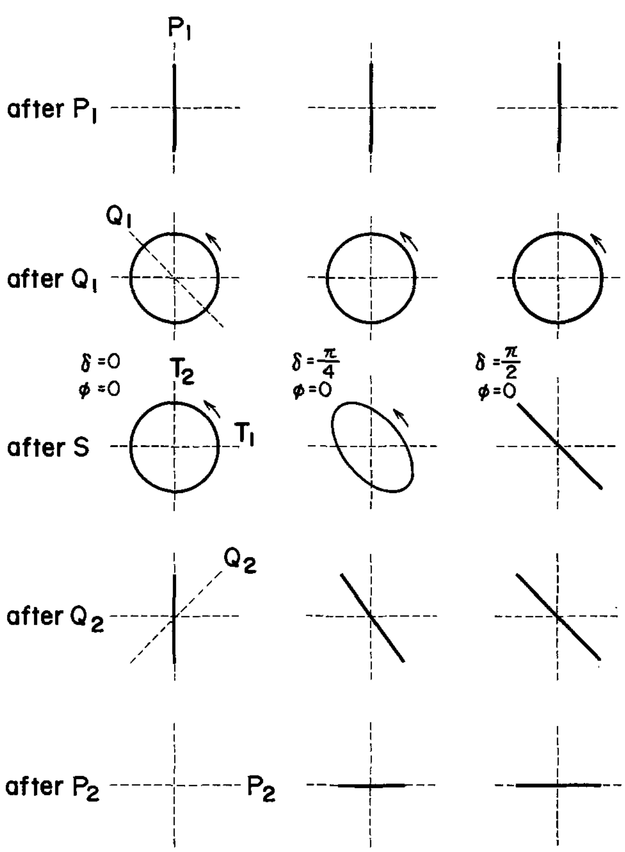

Fig. 3. Electric field vector after each plate of circular polariscope. P_1: polarizer, P_2: analyzer, Q_1: 1st 1/4 wave plate, Q_2: 2nd 1/4 wave plate, S: sample, T_1,T_2: sample principal stresses, ϕ: angle between P_2 and T_1, δ: retardation for $T_1 - T_2$ ($\delta = 2\pi h$).

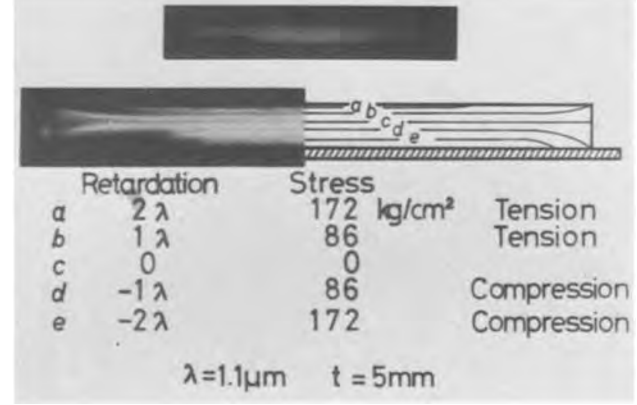

Fig. 6. Silicon pellet stress distribution after mounting. Stress values are approximate ones.

according to the temperature (Fig. 8). Silicon pellet is thought to be free from stress at the mounting and molding temperature as it was observed to be dark at these temperatures. Stress is induced and the number of isochromatic lines increases as the sample is cooled to room temperature. It is natural to think that the first dark isochromatic line corresponds to the zeroth order of retardation.

The results in Fig. 6 and 7 show that the pellet became upward convex after mounting whereas it became concave after molding. It is clear that stress distribution changes drastically during the molding process. This information is important for semiconductor device fabrication reliability concerned with the pellet crack problem. Proper structure design and assembling technique would reduce silicon pellet stress and photoelastic measurement can be applied in these studies.

In molded IC pellet observation, sample preparation by epoxy resin cutting and grinding is not thought to change the stress distribution very much, for it was ascertained that stress distribution was more dependent on epoxy resin thickness than on its lateral size.

Discussion

A slight approximation was made to correlate each isochromatic line directly to the two principal stress differences. This approximation is practical, for it makes stress distribution easy to understand. Calculated values of piezo-optical coefficients in three coordinate systems [100] [010] [001], [110] [$\bar{1}$10] [001], and [112] [$\bar{1}$10] [$\bar{1}\bar{1}$1], shown in Table I, will cover

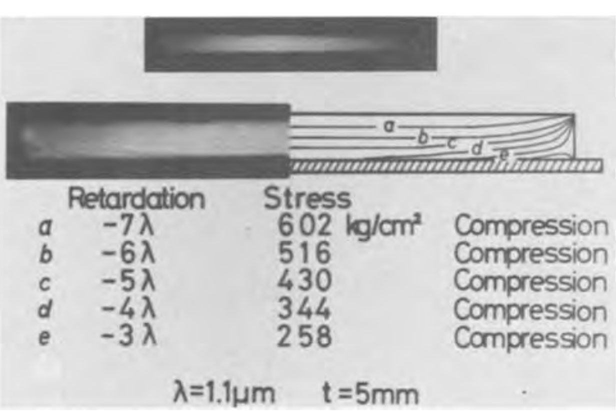

Fig. 7. Silicon pellet stress distribution after molding. Stress values are approximate ones.

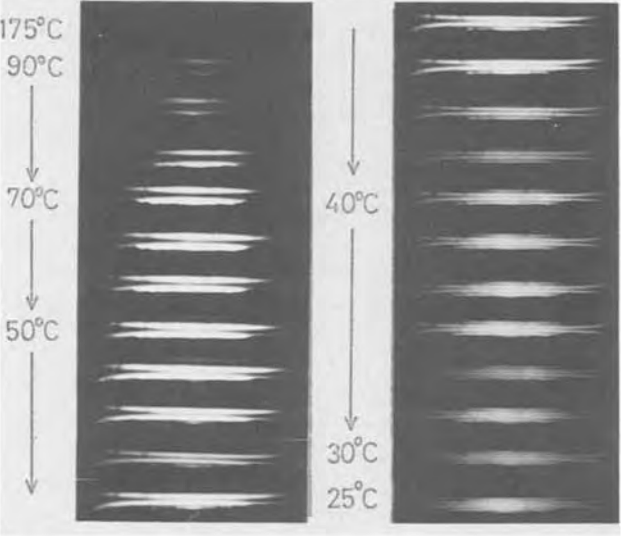

Fig. 8. Temperature dependence of isochromatic lines in silicon pellet mounted on Kovar metal by epoxy resin.

nearly all the cases of semiconductor crystal measurement in the usual device fabrication process although those in other coordinate systems can be calculated in the same way.

Changes in isochromatic lines according to temperature were observed to determine the zeroth order of retardation. Another method for this is to observe with more than two light waves with different wavelengths. In this case, an isochromatic line of the zeroth order of retardation remains in the same position of the sample, but other isochromatic lines change their positions according to the wavelengths. Nevertheless, this method is thought to be impractial for silicon, because it is transparent only to infrared radiation, and the choice of wavelength is limited.

From the result in Fig. 6 and 7, stress distribution in silicon pellet after mounting or molding can be understood as bending of flat plate. In the case of mounting, an experimental value can be compared with a theoretical one calculated from bimetal theory. According to the bimetal theory stress σ at the point z mm apart from the interface in material a in Fig. 9 is

$$\sigma = \frac{(C_1 - C_2 z)(\gamma_b - \gamma_a)(T - T_0)}{C_3} \frac{E_a}{1 - \nu_a} \quad [10]$$

where

$$C_1 = \frac{1 - \nu_a}{1 - \nu_b} \frac{E_b}{E_a} \left(\frac{t_b}{t_a}\right)^2 + 4\frac{t_a}{t_b} + 3$$

$$C_2 = 6\left(\frac{1}{t_a} + \frac{1}{t_b}\right)$$

$$C_3 = \frac{1 - \nu_b}{1 - \nu_a} \frac{E_a}{E_b} \left(\frac{t_a}{t_b}\right)^2 + \frac{1 - \nu_a}{1 - \nu_b} \frac{E_b}{E_a} \left(\frac{t_b}{t_a}\right)^2 + 4\frac{t_a}{t_b} + 4\frac{t_b}{t_a} + 6$$

and t_a and t_b are thickness of material a and b respectively, E_a and E_b are Young's modulus of material a and b respectively, ν_a and ν_b are Poisson's ratio of material a and b respectively, γ_a and γ_b are thermal expansion coefficients of material a and b respectively, T_0 is the temperature at which the plate is flat and free from stress, and T is the temperature at which stress is calculated. In this case, material a is (100) silicon pellet and material b is Kovar, $t_a = 0.05$ cm and $t_b = 0.023$ cm, $E_a = 1.69 \times 10^{12}$ dyne/cm² and $E_b = 1.40 \times 10^{12}$ dyne/cm², $\nu_a = 0.361$ and $\nu_b = 0.3$, $\gamma_a = 2.4 \times 10^{-6}$ 1/deg and $\gamma_b = 5.0 \times 10^{-6}$ 1/deg, $T_0 = 175$°C and $T = 25$°C. Then $\sigma = -540 + 17{,}500z$ [kg/cm²].

Experimental values were compared with these calculated ones in Fig. 10. Calculated values were twice or three times larger than the experimental ones. The reason for this difference may come from the neglect of the epoxy resin layer between silicon and Kovar and the temperature dependency of mechanical properties.

Quantitative measurement of crystal stress distribution by photoelasticity can be applied to various engineering fields. IC pellet stress measurement done here is just one application. Other applications are to stress distribution of as-grown crystals and crystal processing such as cutting, grinding, and scribing. This method can also be used in the study of other crystals, such as GaP, GaAs, etc., using their piezo-optical coefficients.

Conclusion

A quantitative measurement procedure for stress in silicon by photoelasticity was established by calculating piezo-optical coefficients in various coordinate systems for observation. A slight approximation was made in the calculation for practical purposes. This method was applied to the study of semiconductor pellet stress distribution in the mounting and molding process, and important information was obtained for semiconductor device fabrication reliability.

Acknowledgment

During this study, valuable discussions and encouragement were received from Y. Matsushita and T. Wada. The authors wish to express their gratitude to Dr. S. Nagakura and Dr. O. Nittono for valuable discussions and critical reading of the manuscript. They also thank T. Sugahara for his helpful work with the apparatus and sample making.

Power Conversion Efficiency Monitoring in Photoelectrochemical and Other Solar Cells

B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A device is described which incorporates a superimposed a-c voltage signal, current-voltage product generation, synchronous detection, and a feedback loop to bias a photovoltaic converter to its point of maximum power output. Examples of its operation as a continuous monitor of power conversion efficiency are given for p-n junction and photoelectrochemical cells. Applications to studying the design fundamentals of the latter are illustrated, based on control derived with two- and three-electrode configurations to evaluate response to efficiency determining parameters such as light intensity and mass transport in the cell. The circuit stably responds with the average values of power output under periodically interrupted light up to at least 10 Hz. These characteristics open the way to external power conversion spectroscopy in the ultraviolet to near infrared range.

The power output characteristics of photovoltaic devices are easily obtained with two-terminal current (I) or voltage (V) scanning circuits. From these curves one calculates the maximum deliverable power (V_mI_m) between the zero limits at open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}), and divides by the radiant input to get the maximum conversion efficiency. Since the external efficiency is obviously crucial to these converters, a scheme for its continuous monitoring under varying illumination and as a function of other experimental conditions would benefit evaluation of basic relations and design parameters of such cells. Apparatus to such ends is described in this paper.

Immediate motivation for providing this capability rose from recent active development of an electrochemical class of photovoltaic converters, semiconductor-liquid junction cells (1) (SCLJ), application to which we stress. In these systems determination of maximum power output and efficiency may be subject to greater experimental restraints than that of solid-state junction cells because redox chemistry must occur at both cell electrodes for current passage. Net local chemical alteration of the interfacial region, reflected in V-I curve hysteresis or long term trends, may result if the system deviates from the ideal of cancelling chemical reactions at the two electrodes or displays surface modification or cumulative mass transfer effects such as concentration overpotentials or varying light absorption.

Holding the electrode at the maximum power point during a series of experimental variations reduces the possibility of extraneous conditions changing the comparative results and gives a closer picture to steady state. Thus it provides the most realistic way to evaluate design and environmental factors for which E_{oc} and I_{sc} monitoring are insensitive and for which the recording of full current-voltage curves may cause a perturbation of the experiment in liquid junction systems. Given V_mI_m capacity, a further extension would be direct spectroscopic examination of wavelength response for this quantity of primary interest. Conventional spectroscopies with I_{sc} (quantum efficiency) or V_{oc} (difficult to interpret) inputs *vs.* wavelength to analyze the quality of the semiconductor and the junction would be usefully supplemented by this method. Some preliminary measurements are cited in this regard.

A circuit for tracking the maximum power output, and thus efficiency when simultaneous light input measurements are made, is described here with data illustrating its functions. Although the above discussion is oriented toward photoelectrochemical cells, the method is obviously applicable to other photovoltaics and a p-n silicon cell was first used to establish its claimed performance. A photoanode arrangement of good re-

* Electrochemical Society Active Member.

Key words: energy conversion, servo systems, synchronous detection.

producibility involving metallized semiconductors was employed to illustrate the electrochemical applications.

Circuit Design

A schematic of the voltage controlled circuit is given in Fig. 1, and its operation first described for two terminal operation. In summary, the peak power output is found through superimposing a sinusoidal voltage of 10-20 mV at 800 Hz on the cell, synchronously detecting the VI product of the cell at that frequency, and returning the phase sensitive d-c output of the synchronous detector in a servo loop minimizing the a-c signal, *i.e.*, finding the operating point at which $d(VI)/dV \rightarrow 0$ or VI is a maximum. Some of these quantities are shown schematically in the Fig. 1 inset. (800 Hz provides a sufficient cell amplitude response at a frequency significantly above both those generated in rotating disk electrodes by geometric asymmetries and by the light chopping experiments. No further optimization of this value was sought.)

Amplifier 1 applies the a-c and feedback d-c voltages to the positive output terminal of the solar cell. The negative electrode (the n-type semiconductor photoanode in the liquid junction cell example) is held at virtual ground by the current measuring amplifier 2. Product VI from the multiplier X is recorded and also fed to the signal input of the synchronous detector (PAR 128). V_mI_m tracking is initiated from a zero or bias condition (bias input not indicated on schematic) by applying the small a-c signal of 10-20 mV at 800 Hz from an internal oscillator to amplifier 1 while using the same source for the lock-in reference channel.

The feedback from the lock-in output to amplifier 1 is adjustable with the variable resistor to provide gain of 1-100. With no feedback ($V < V_m$), the phase is adjusted for maximum negative lock-in output. Closing the loop at the lowest gain setting then moves V toward V_m. The gain, for a suitable lock-in sensitivity and time constant, is increased to a level at which VI is acceptably unchanging, say within 1%, or $VI \geq 0.99V_mI_m$. Excessive over-all gain leads to oscillation.

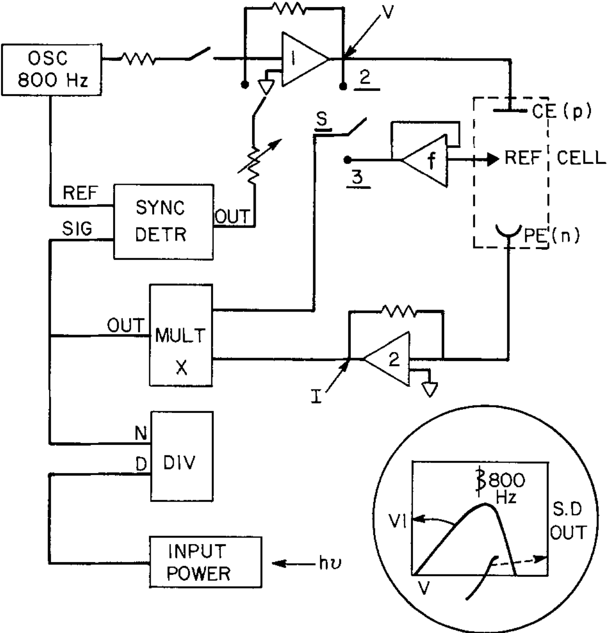

Fig. 1. Schematic of maximum power detection circuitry. CE = counterelectrode, PE = photoelectrode, Ref = reference electrode. p and n refer to contacts to respective Si cell regions. Multiplier X = Burr-Brown 4204, Divider = Burr-Brown 4291, Synchronous Detector = PAR 128, Input Power Meter = Metrologic 60-530 Radiometer, Amplifiers 1 and 2 = Burr-Brown 3440, Amplifier f = Burr-Brown 3420. Inset shows schematic relation of VI and synchronous detector output, with 800 Hz signal on voltage axis.

With phase and gain adjusted, the circuit will track V_mI_m over a wide range of input radiation or other output modifying variable. A lock-in time constant of 0.3 sec and capacitive damping for amplifiers 1 and 2, $\leq$ 0.1 msec, provide stable operation and speed of response adequate to most solar cell operating needs.

If the light intensity is simultaneously monitored, the quotient of output to input power, P_o/P_i, can be obtained from the analog divider arrangement shown. Since the multiplier output is VI/10, an unshown preceding V follower with selectable gain (usually 10) is inserted to compensate. Initial amplifier 2 load is set so that the maximum anticipated current will provide several volts to maximize the range over which the circuit will respond to the above limits.

Isolation from counterelectrode effiects in electrolytic cells is normally done by three electrode operation with a reference electrode added. The reference electrode in these cases is conveniently the dark electrode material in a geometric position to sense the minimum feasible fraction of the cell electrolyte IR drop. The reference level is thus very close to the redox potential corresponding to the common point of an idealized cell at short circuit with no electrolyte resistance or counterelectrode losses. Three electrode operation gives the maximum power output possible with the photovoltaic electrode without counterelectrode or almost all cell IR drop. Power loss sources may be analyzed both by comparing two and three electrode operation and by examining the three electrode configuration, altering photovoltaic electrode conditions such as light intensity and stirring. Thus the maximum power monitoring circuitry was made adaptable to two working electrode or working electrode-reference electrode potential differences as a voltage signal, simply by switching the input to the multiplier from the reference electrode follower instead of the counterelectrode lead from amplifier 1, as shown in Fig. 1.

Experimental

The practical version of the schematic circuitry of Fig. 1 was constructed with additional switching to provide direct reading of V_{oc} and I_{sc} as well as V_mI_m so as to obtain fill factors or monitor these other parameters as a function of experimental variables. The apparatus also contains a conventional analog ramp generator with input to amplifier 1 to run conventional scanned voltage I-V curves (with simultaneous VI multiplier output) to compare the accuracy of V_mI_m found by the servo loop procedure.

Input irradiance for these experiments was obtained from a 10 mW He-Ne laser (Hughes Industrial Products) combined with a three Glan Laser prism polarizer based optical attenuator (Karl Lambrecht Corporation) containing a rotatable element driven by an added 1 rpm motor for intensity scanning experiments (2). A quartz plate in the beam directed about 4% of the light to a Metrologic Corporation silicon power detector whose analog output, proportional to the actual P_i incident on the cell, was used for the analog divider denominator in efficiency monitoring experiments. Since the experiments here were only used for relative efficiency comparisons, calibration was not performed and the input called P_i is the reflected part of the beam in the figures.

The silicon p-n cell was standard and its area was only partially illuminated by the laser beam, diffused to about 0.5 cm diam in these experiments.

The electrolytic cell utilized as photoanode a gold plated n-GaAs electrode whose preparation and properties are elsewhere described (2). The redox electrolyte was 0.2M $K_4Fe(CN)_6$-0.05M $K_3Fe(CN)_6$ in a pH 5 acetate buffer (0.5M). These hybrid electrodes (3, 4) have the metal-semiconductor Schottky junction isolated from the electrolyte to inhibit photocorrosion but otherwise are light-controlled and are sensitive to cell resistance, surface kinetics, and transport just

as electrolyte-exposed semiconductor cells. These electrodes were used for the demonstration experiments here because of their stable voltammetric behavior. Exposed semiconductor electrodes have been used with the system equally well. These electrodes, however, often show time dependent features. Although the circuitry is designed to study such characteristics, to give confidence in its performance for that work it was decided to use systems here in which V_mI_m measured from repeated V-I scans and from the steady-state servo scheme data ought normally to be identical and could be more rigorously compared.

The electrode was mounted as a rotating disk in a cell with an optical flat bottom into which the light beam was reflected by a mirror. Counter and reference electrodes were spectroscopic grade carbon rods. Air was not excluded from the cell which was at ambient temperature.

Results and Discussion

Voltage scans plotting I-V and VI-V for four normalized light irradiances (as read from the calibrated attenuator) are shown for the p-n Si cell in Fig. 2. Superimposed on the curves are noted the recorder pen points for the correspondingly determined I_m-V_m and I_mV_m-V_m points for the same light settings found separately by the servo loop circuitry. The tracking of maximum product was initiated as described above with phase and gain adjustment only at the $P_i = 1$ point. The correspondence between the scan I_mV_m maxima and the servo maxima is within chart reading error for the decade range of power input and confirms the circuit function. The unity normalized value of average P_i here is about 10 mW/cm^2. The power with the small beam size is not spatially uniform, but not disturbing to this test.

A similar experiment but with motorized intensity scanning and direct recording of both P_o and the conversion efficiency P_o/P_i *vs.* P_i for the p-n Si cell is shown in Fig. 3. The efficiency follows input intensity in this range, as is known (5). This experiment corresponds to the use of the circuit to monitor cell efficiency continuously under fluctuating light, such as sunlight. The circuit easily handles a decade change in P_i or P_o without any I range resistor change and is, in fact, stable down to zero current.

The current-voltage characteristics of the Au-n-GaAs/$Fe(CN)_6^{-4}$-$Fe(CN)_6^{-3}$/C cell with an additional 220Ω resistance in the counterelectrode lead are shown in Fig. 4 from a single voltage scan (a fritted disk separating the counterelectrode already contributes about 130Ω; the series external resistor emphasizes the *IR*

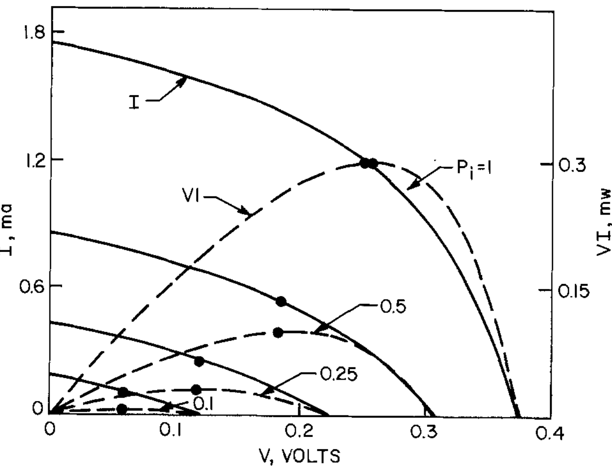

Fig. 2. Current, voltage, and power recorded under voltage scan for silicon p-n cell at four different relative light power levels (P_i), as indicated for each pair of curves. Points are V_m, I_m, and V_m I_m found by maximum power circuitry for same conditions. 800 Hz signal is 17 mV pk-pk.

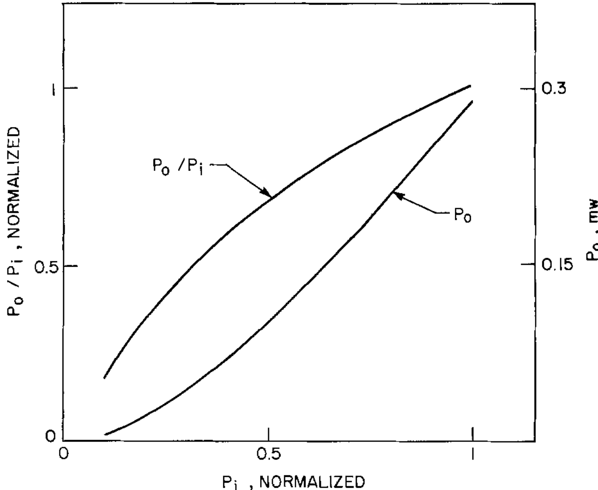

Fig. 3. Normalized maximum power efficiency (P_o/P_i) and power output (P_o) *vs.* normalized light input power (P_i) for silicon p-n cell.

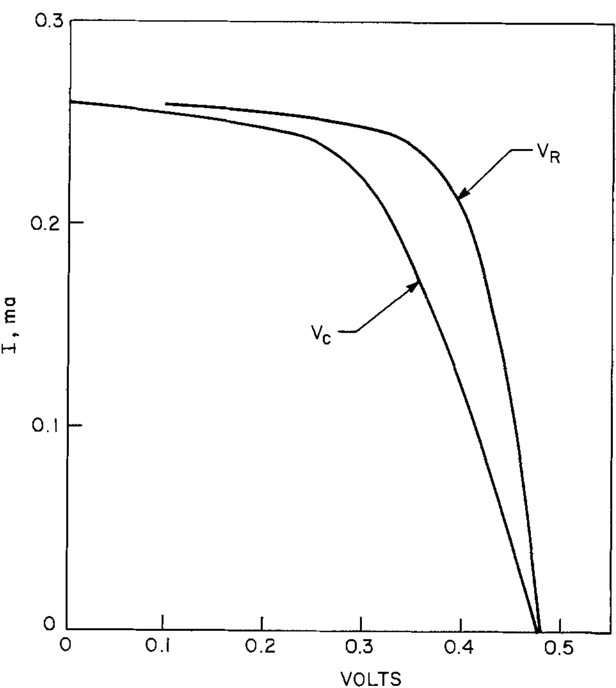

Fig. 4. Current *vs.* cell voltage (V_c) and reference electrode-photoelectrode potential difference (V_R) with V_c scan control in Au on n-GaAs/$Fe(CN)_6^{-4}$-$Fe(CN)_6^{-3}$/C cell with C reference electrode, laser illumination. External 220Ω resistor drop included in V_c. Photoelectrode rotated at 900 rpm.

loss effect). Both cell voltage, V_c, including external resistor drop, and the difference of reference and photoanode potentials, V_R, were recorded *vs.* cell current.

Approximately 100 mV difference exists between these two voltages at the short-circuit condition of the two current passing electrode leads ($V_c = 0$) and the maximum power represented by the V_R curve is 30% greater than that of the V_c curve. This translates to a nearly 30% higher fill factor since V_{oc}, as measured in both cases, is identical and I_{sc} at $V_r = 0$ will only be slightly greater (~2%) than at $V_c = 0$. The V_{oc} and I_{sc} parameters are thus not different, or only slightly so, in a case with simulated large internal losses and their monitoring may be poorly indicative of cell performance.

With the same gold plated n-GaAs electrode, cell configuration, and initial intensity level, a further comparison of two- and three-electrode cell (V_cI and V_RI) behavior was made in Fig. 5. This plot is anal-

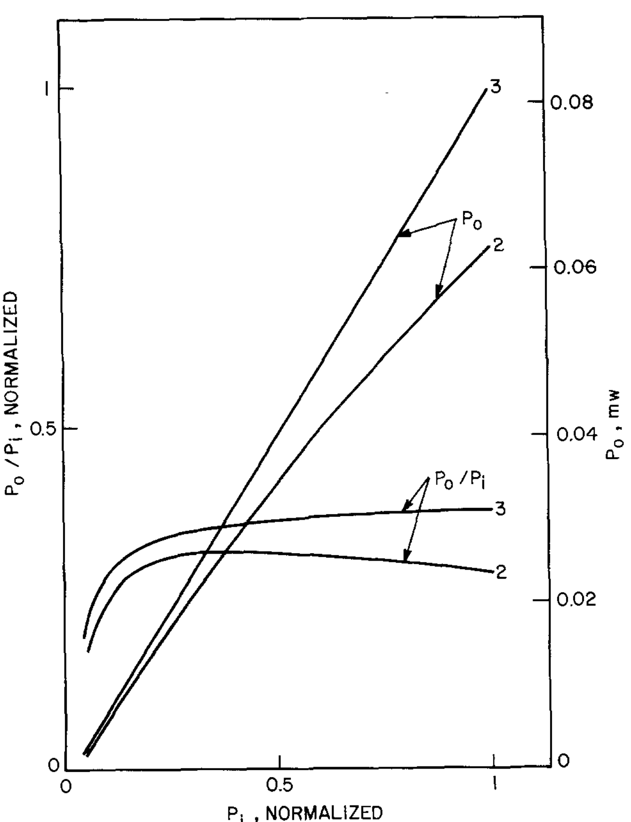

Fig. 5. Plot as in Fig. 3 for cell and conditions of Fig. 4. $P_i = 1$ is illumination level of Fig. 4. Curves marked 2 and 3 have maximum power controlled from V_c and V_R, respectively. 800 Hz signal is 20 mV pk-pk.

ogous to that of the solid-state junction experiment in Fig. 3, but here with the two different SCLJ cell maximization arrangements selected by switch S in Fig. 1. The ratio of the initial ($P_i = 1$) values of $V_R I_m$ and $V_c I_m$ from Fig. 5 is 1.31, within experimental error of the value calculated (1.30) from the V-I plots in Fig. 4, again confirming the circuit accuracy.

The limiting efficiency of the photoanode expressed by the maximum $V_R I$ product increases monotonically with intensity and only levels off at the highest P_i. Current densities at this point (5 mA/cm^2) correspond closely to those a gold plated electrode generates in approximately AM2 (75 mW/cm^2) sunlight (6). Because of the combined electrolyte and external resistor losses, the two current-carrying terminal $V_c I$ maximum efficiency peaks at about $P_i = 0.4$. The two efficiencies approach most closely when the IR drops become minimal and overpotential ascribable to the large counterelectrode is nil.

Application of such cell design analysis data to study of the mass transport parameter is shown in Fig. 6. The P_o/P_i ratio, under the $V_R I$ maximization condition to be essentially free of IR or counterelectrode effects, is displayed *vs.* time as a function of rotation speed, starting at 900 rpm. An increase to 1600 rpm raises P_o less than 1%. A decrease to 400 rpm from 1600 rpm (factor of two for a mass transport limited current) produces a 1% decline. At 100 rpm the power is 3% less than the initial 900 rpm value, but when rotation is stopped efficiency drops steadily, reaching about an additional 18% loss after only 80 sec when the 900 rpm speed was resumed. The output then returned to within 1% of its initial 900 rpm level.

Even with a 0.2M solution of ferrocyanide reducing agent, the 4 mA/cm^2 current density causes substantial concentration gradient effects at the electrode surface when convective diffusion assistance (stirring) is absent. Such effects become more important as cells achieve higher efficiencies, even when redox electrolytes are quite concentrated. The 12% n-GaAs/$Se^{=}$-$Se_2^{=}$-OH^-/C cell with a 1M total selenium concentration has a fill factor detectably sensitive to stirring at high solar irradiance (7). Experiments such as shown here will be useful to analyze operating parameter influences on mass transport at the photoanodes, both alone and combined with counterelectrode effects.

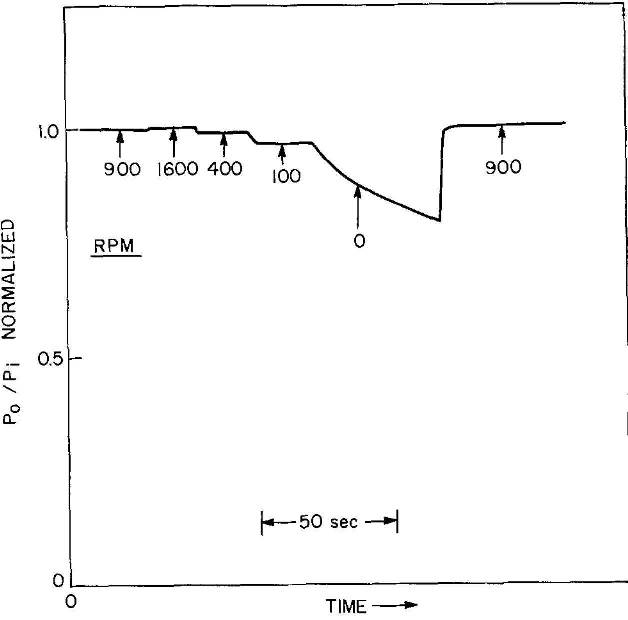

Fig. 6. Normalized maximum power efficiency for Fig. 4 cell and illumination level as a function of photoelectrode rotation speed, as marked, with time. Circuitry conditions of Fig. 5.

The circuitry shown is capable of measuring average maximum cell power in two- or three-electrode configurations for practical alternating light intensity frequencies. An experiment similar to that of Fig. 5 was performed along with one in which the same scanned intensity laser beam was modulated by square wave chopping with a two sector wheel driven at 10 Hz by a PAR 192 variable speed chopper. The lock-in time constant was increased to 1 sec to enhance the averaging process. In both cases here the multiplier (P_o) and light power detector (P_i) outputs were heavily filtered to produce d-c averaged outputs and a steady P_o/P_i reading even in the chopped light case. The two (d-c and 10 Hz) efficiency *vs.* average P_i scans are shown in Fig. 7.

The 10 Hz chopped light trace starts at $P_i = 0.5$ because of the 50% duty factor. Otherwise the curves are essentially superimposable. Proper processing of the chopped signals (preferably originally sinusoidal) by bandpass filters with gain prior to analog division, then rectification, would permit power conversion efficiency spectroscopy to be done directly with a scanned monochromatic beam as light source. Although this process does not eliminate d-c effects on the multiplier output, extraneous light can be experimentally reduced. Of course where chopping offers little advantage the d-c response spectroscopy could be obtained.

The advantages of direct P_o/P_i recording *vs.* wavelength, as opposed to that of I_{sc} or V_{oc}, are considerable for the analysis of photoelectrode characteristics since P_o/P_i is the deciding factor in their over-all performance possibilities and thus in diagnostic examination. The results of Fig. 7 are sufficient to show that the method is feasible. At 40 Hz the circuit remains stable with only the sacrifice of a fraction of the response which may not affect the relative shape of a spectrum.

Summary and Conclusions

A circuit for monitoring the maximum power of a photovoltaic device has been constructed and demon-

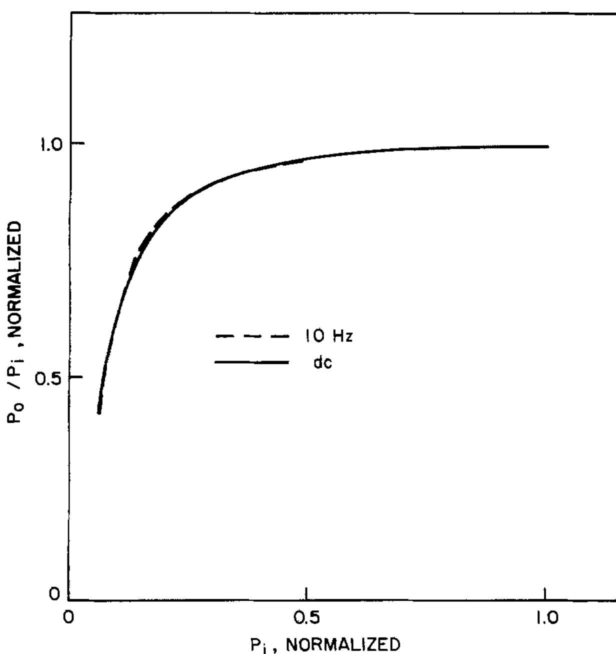

Fig. 7. Normalized maximum power efficiency (P_o/P_i) vs. normalized light input power (P_i) with 10 Hz chopped input (dashed line) and d-c illumination (solid line). Other conditions as with V_R multiplier input of Fig. 5.

strated to serve this function under a variety of conditions. In semiconductor-liquid junction configurations its use with both current-carrying terminals and with semiconductor plus reference terminal as voltage input allows analysis of efficiency loss mechanisms in the cell. Mass transport, light intensity, and internal resistance effects were viewed clearly in a well-controlled system by the maximum power tracking circuit. When combined with analog division by the input power, the quotient of conversion efficiency is directly monitored. The latter will be useful for continuous solar measurements, light concentrator experiments, and for long-term stability studies. The frequency response of the circuitry combined with proper averaging permits light chopping and shows stability even with square wave light intensity transitions. Application of either the d-c or chopped light methods with the maximum power circuitry to an external power conversion efficiency vs. wavelength spectroscopy has interesting advantages for photovoltaic studies.

High-Efficiency GaAs Photoanodes

Rommel Noufi* and Dennis Tench**

Rockwell International Science Center, Thousand Oaks, California 91360

ABSTRACT

The photoresponse of large-grained polycrystalline and single crystal n/n^+-GaAs in aqueous selenide/polyselenide solution is compared with that of single crystal n-GaAs. Use of the n/n^+-structure is shown to significantly improve performance, and the power conversion efficiency for the large-grained n/n^+-material is found to approach that for n/n^+-single crystals. For single crystal n/n^+-GaAs, the measured conversion efficiencies for white light from a xenon lamp were 14% (uncorrected) and 19% (corrected for absorption in the solution).

Considerable attention has been focused recently on n-GaAs as a candidate photoanode for use in electrochemical solar cells (1-3). This material has an ideal bandgap for utilization of the solar spectrum (1.4 eV), but like other common narrow-bandgap semiconductors is prone to photodissolution in ionizing solutions. Although significant progress has been made in stabilizing GaAs against photodecomposition (1, 2), only single crystal electrodes have been considered. Polycrystalline materials, however, will almost certainly be required for any practical solar conversion device not involving concentrators.

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: n/n^+-GaAs, polycrystalline, photoelectrochemical cell, efficiency.

Since the photosensitive junction in electrochemical solar cells is extremely abrupt compared to a p-n junction and one side is practically transparent to the solar spectrum, more of the incident light is absorbed within the region of high electric field at the interface where charge carriers are more efficiently separated and collected. Thus, in electrochemical cells, the efficiencies of polycrystalline films can more closely approach those of single crystals (4, 5). For the semiconductors studied to date, however, this promise has only been realized to a limited extent, *e.g.*, 5% solar

conversion efficiencies for polycrystalline CdSe (5) compared to 7.2% for single crystals (6), and considerable improvement is needed. The present work was undertaken to provide a comparison between large-grained polycrystalline and single crystal GaAs photoanodes, and to determine the extent to which internal losses in the electrodes can be mitigated by utilizing layered n/n^+-material.

Experimental Details

Electrode materials investigated were large-grained polycrystalline and single crystal n/n^+-GaAs and single crystal n-GaAs. The designation n/n^+ denotes a layered structure of a lightly doped film deposited on a more heavily doped substrate of the same material. One advantage of this arrangement is that the film can be doped at the level that provides optimum separation and collection of photogenerated charge carriers at the interface ($\sim 10^{16}$ carriers/cm^3 for GaAs) without paying the penalty of a high resistive loss in the bulk of the electrode. Also, since the Fermi level of the n^+-material is slightly higher, a back surface field (BSF) is created at the n/n^+-junction which opposes diffusion of holes from the n-layer to the n^+-bulk, while favoring transport of electrons (7). Thus, the BSF enhances charge carrier separation and tends to confine holes to the surface n-region away from the ohmic back contact (where the recombination rate is infinite). The net result is an improvement in the conversion efficiency for the n/n^+-material compared to n-type. Details of the effect of a BSF on the short-circuit current and open-circuit voltage are given in Ref. (7).

To prepare the polycrystalline and single crystal n/n^+-GaAs, Sn-doped n-layers were grown epitaxially on 0.5 mm thick polycrystalline or single crystal substrates, respectively, doped with Si ($\sim 10^{18}$ carriers/cm^3). The polycrystalline epilayer, which had a grain size of 100-1000 μm, was grown by molecular beam epitaxy and was 2.5 μm thick with $\sim 10^{17}$ carriers/cm^3 having a mobility of ~ 3100 $cm^2V^{-1}sec^{-1}$. The single crystal epilayer was grown by liquid phase epitaxy and was 3 μm thick with $\sim 10^{16}$ carriers/cm^3 having a mobility of ~ 6000 cm^2 V^{-1} sec^{-1}. The n-GaAs single crystal, which was investigated for comparison, was Si-doped to 3×10^{16} carriers/cm^3. Ohmic contacts were made using indium/gold alloy and the GaAs electrodes were sealed in epoxy resin. In each case, the area of electrode exposed to the solution was 0.3 cm^2.

Electrochemical measurements were made in nitrogen-saturated selenide/polyselenide solution ($1M$ K_2Se + $0.1M$ Se + $1M$ KOH) which has been shown to be effective in suppressing photodecomposition of GaAs (1). The counter and reference electrodes were platinum (10 cm^2) and saturated calomel (SCE), respectively. The cell was sealed and had a flat quartz window to admit the light from a 1000W xenon lamp, the spectrum of which is shown in Fig. 1. The light intensity falling on the cell was measured by a Hewlett-Packard radiant flux meter to be 115 mW/cm^2 (unless otherwise noted). Absorption losses by a 5 mm layer of the polyselenide solution reduced the intensity at the electrode surface to 85 mW/cm^2. The n-GaAs electrode was etched in a 1:1 sulfuric acid-hydrogen peroxide mixture (3), whereas the n/n^+-materials were used as grown.

Results and Discussion

The photocurrent response in selenide/polyselenide solution for polycrystalline and single crystal n/n^+-GaAs and single crystal n-GaAs is shown as a function of the electrode potential in Fig. 2. It is evident from the higher currents at the same electrode potential (approximately the same degree of band bending) that the separation and subsequent collection of photogenerated charge carriers is more efficient for the n/n^+-materials. Furthermore, the conversion efficiency for

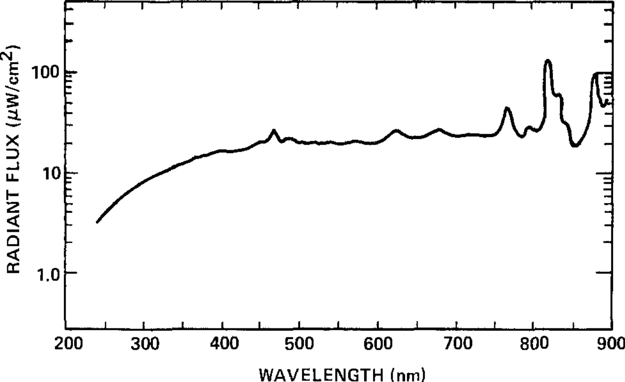

Fig. 1. Spectral output of a 1000W xenon lamp as measured with a Hewlett-Packard radiant flux meter.

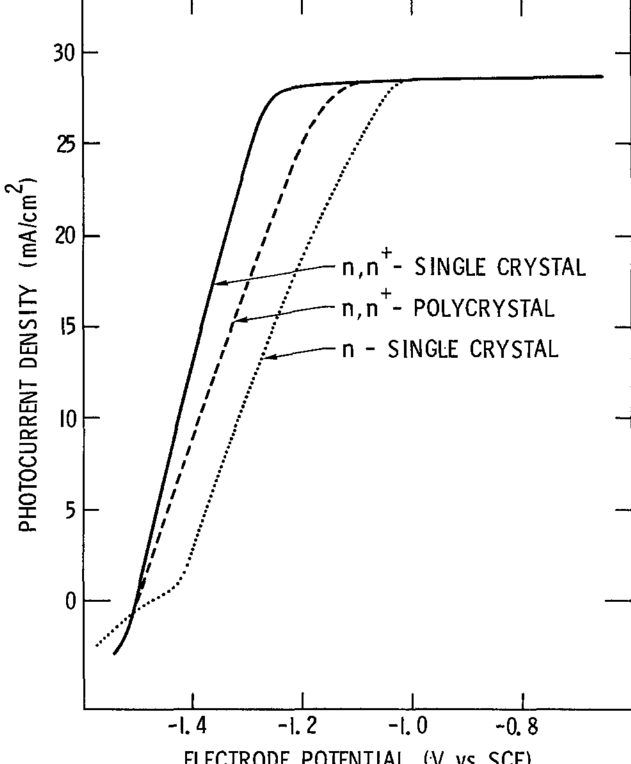

Fig. 2. Photocurrent vs. electrode potential for GaAs photoanodes illuminated with white light of 115 mW/cm^2 (uncorrected for solution absorption) in aqueous selenide/polyselenide solution.

the polycrystalline n/n^+-electrode approaches that for the n/n^+-single crystal. As discussed above, the efficiency enhancement for the n/n^+-electrode is attributable to the effect of the BSF in enhancing charge carrier separation and hindering the diffusion of the holes to the ohmic back contact.

Figure 3 shows the relationship between the current density and the cell voltage for cells based on polycrystalline and single crystal n/n^+-GaAs. The polycrystalline material compares favorably with the single crystal, yielding practically the same short-circuit current (29 mA/cm^2) and an only slightly smaller open-circuit voltage (0.68V). The fill factor for the polycrystalline electrode is also somewhat smaller (0.67) than that for the single crystal (0.80), presumably because of the lower parallel resistance due to leakage along grain boundaries (7).

Characteristics of the two cells are summarized in Table I. The 19% value is 45% of that theoretically attainable for this system under xenon lamp illumination from 250 to 885 nm (42%). These efficiency values have not been corrected for Carnot limitations arising

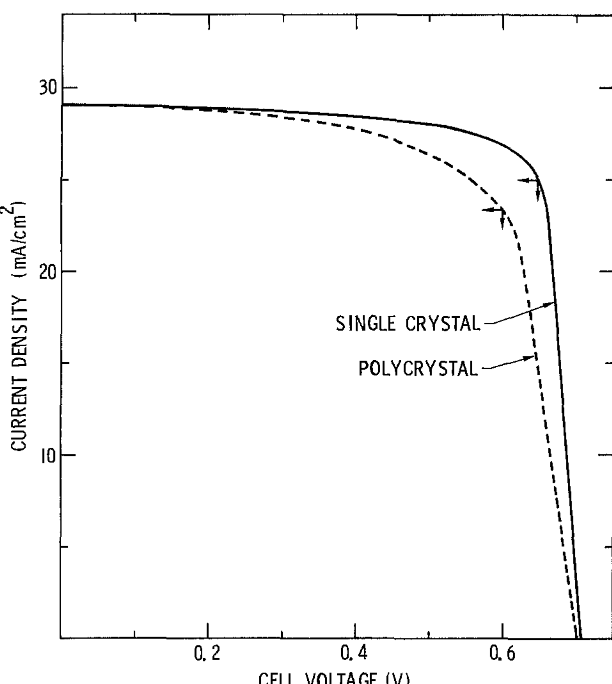

Fig. 3. Current density vs. cell voltage for n/n$^+$-GaAs photoanodes under illumination with white light of 115 mW/cm^2 (uncorrected for solution absorption). Curves are the average of forward and reverse scans at 100 mV/sec.

from the temperature difference between the source and the converter (8). The conversion efficiencies for the n/n$^+$-polycrystalline material are only slightly less (2-3%), as might be expected when the grain size is large (100-1000 μm) compared to the thickness of the space charge layer ($\sim$0.1 μm).

Conclusions

The results reported here demonstrate that the conversion efficiency for large-grained polycrystalline GaAs in photoelectrochemical cells approaches that for single crystals. In either case, the use of a layered n/n$^+$-structure significantly improves the performance which approaches that theoretically attainable. The challenge in attaining a practical solar conversion device is to duplicate such results for materials fabricated economically on a large scale.

Table I. Characteristics of photoelectrochemical cells based on n/n$^+$-GaAs in selenide/polyselenide solutions under illumination with white light (115 mW/cm^2) from a xenon lamp

Parameter	Poly-crystalline	Single crystal
Open-circuit voltage	0.68V	0.7V
Short-circuit current	29 mA/cm^2	29 mA/cm^2
Fill factor	0.67	0.80
Maximum power output	14 mW/cm^2	16 mW/cm^2
Power conversion efficiency		
Uncorrected	12%	14%
Corrected for solution absorption	16%	19%

The Effect of Hot Electron Injection on Interface Charge Density at the Silicon to Silicon Dioxide Interface

Yoshio Miura, Kikuo Yamabe, Yoshio Komiya, and Yasuo Tarui

VLSI Technology Research Association, Cooperative Laboratories, Kawasaki, Japan

ABSTRACT

The avalanche injection of hot electrons at the silicon to silicon dioxide interface causes an anomalous N-shaped shift of flatband voltage in accordance with the injected charge density and generates an interface state with widely distributed time constants. To explain the N-shaped behavior, we propose a model which assumes electron trapping in the silicon dioxide and the generation of the donor-type interface state. It is also observed that the orientation of silicon substrate strongly affects the generated interface-state density. The generated interface-state density of a (100) capacitor has a value approximately half that of a (111) capacitor. The energy level of the generated interface state is distributed near the middle of the energy gap of silicon. The dominant electron capture cross sections are approximately 1×10^{-18} cm^2 for both (100) and (111) capacitors.

With the development of short channel MOS devices, significant instability due to the emission of electrons from the silicon into the silicon dioxide has become an important problem. Subsequent trapping of the hot electrons in the silicon dioxide causes instabilities in the form of threshold voltage shift and transconductance degradation (1-4). A large amount of work has been done on hot electron instability in MOS structure (5-11). It has been shown that some of the injected electrons are trapped in the silicon dioxide and that the flatband voltage increases in proportion to the number of injected electrons. The flatband voltage has a tendency to saturate in relation to the filling of the electron traps in the silicon dioxide. But a reversal of the flatband voltage shift for a larger number of injected electrons is reported by Gdula (6) and is explained likely due to fast surface-state generation. There are few reports about the interface state density generated by the hot electron injection (7).

In the present study, hot electrons are injected by the avalanche injection technique (8) in order to examine the interface charge density at the silicon to silicon dioxide interface.

The results confirm the reversal of the flatband voltage shift (6). Furthermore, we observe that the flatband voltage appears to increase again after a large number of electrons have passed through the silicon to silicon dioxide interface. It is also observed that the injection of hot electrons generates interface states with widely distributed time constants. The interface-state density is strongly affected by the orientation of the silicon substrate in the same manner as the fixed charge density at the thermally oxidized silicon surface (12). The purpose of this paper is to clarify the changes of flatband voltage which occur with the avalanche injection of hot electrons at the silicon to silicon dioxide interface.

Experiments

Sample preparation.—MOS capacitors are fabricated using p-type silicon wafers with an approximately 0.3 Ω-cm (100) plane, and 2 Ω-cm (100) and (111) planes. The thickness of the silicon dioxide film is about 800Å for the 0.3 Ω-cm capacitor, 850Å for the 2 Ω-cm (100) capacitor, and 1000Å for the 2 Ω-cm (111) capacitor. The oxidation is performed in an all-quartz system at 1000°C in dry oxygen. All oxide growth is followed by 30 min of annealing in dry nitrogen at growth temperature. Aluminum electrodes are evaporated from an electron gun source, followed by postmetallization at 450°C for 30 min in dry nitrogen.

Measurement technique and condition.—Starting with a previously unused capacitor, the complete capacitance-voltage (C-V) characteristic is measured at various frequencies (1 MHz-17 Hz) with low amplitude signals. Hot electrons are injected into the silicon dioxide by the avalanche injection technique. The avalanching field is provided by a 100 kHz constant-voltage square wave generator. The square waves are interrupted periodically to automatically measure the flatband voltage at 1 MHz as a means for monitoring the interface charge density at the silicon to silicon dioxide interface. The capacitor is then reconnected to the C-V measuring apparatus and complete C-V data at various frequencies is determined. The avalanche injection current density is in the range from 10^{-5} to 10^{-4} A/cm^2. As the variation of pulse width for the avalanche injection at 100 kHz shows little effect on the injected current density, most of the injected electrons will be hot electrons. The generated interface-state density is obtained from the C-V data before and after the capacitor is avalanched for specified injected electronic charges. The estimated flatband voltage shift due to the generated interface state, V_{FBI}, is obtained from

$$V_{FBI} = N_{ss}/C_{ox}$$

where N_{ss} is the generated interface-state density and C_{ox} is the oxide capacitance of the MOS capacitor. An electron capture cross section is obtained from the flatband voltage data as a function of the injected charge density (13).

Results

The characteristic shown in Fig. 1 is a typical result of the variation of the flatband voltage as a function of the injected charge density for the 0.3 Ω-cm (100) capacitor with a pulse bias of 37V. The flatband voltage typically increases for some initial range of injected charge and then gradually decreases as injected charge increases. However, the flatband voltage appears to increase again when large number of electrons are injected. This is called "N-shaped" behavior. Figure 2 shows a typical set of complete C-V characteristics at various injected charge levels with the signal frequency as a parameter. Figure 2 [A]-[D] are results for injected charge levels of 0, 0.75×10^{18}/cm^2, 4.5 ×

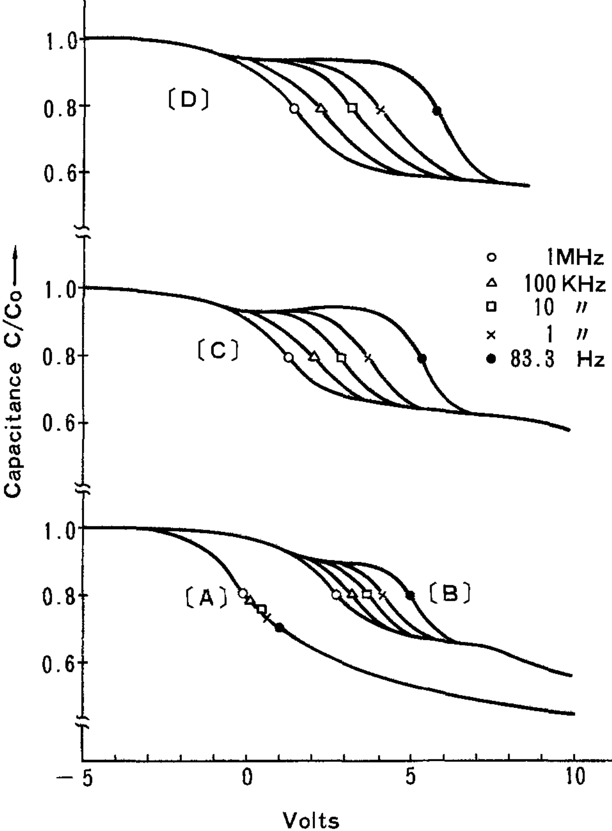

Fig. 2. Typical set of C-V characteristics at various injected charge levels with signal frequency as a parameter. [A] = 0; [B] = 0.75 × $10^{18}/cm^2$; [C] = 4.5 × $10^{18}/cm^2$; [D] = 10.8 × $10^{18}/cm^2$.

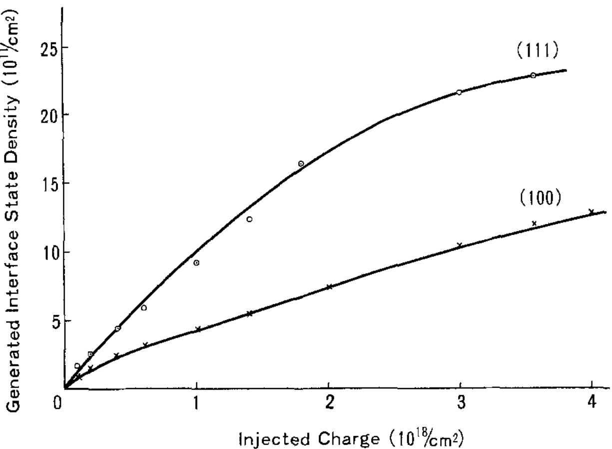

Fig. 3. The generated interface-state density as a function of the injected charge density for 2 Ω-cm (100) and (111) capacitors.

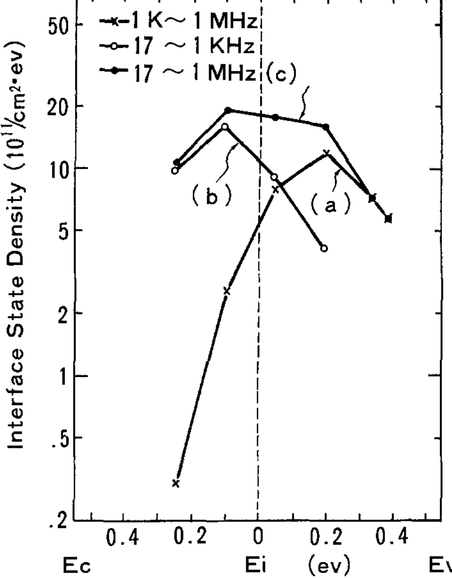

Fig. 4. Energy distribution of generated interface state for the (100) capacitor at injected charge density of 3 × $10^{18}/cm^2$; at signal frequency ranges: (a) = 1 kHz-1 MHz, (b) = 17 Hz-1 kHz, and (c) = 17 Hz-1 MHz.

$10^{18}/cm^2$, and 10.8 × $10^{18}/cm^2$, respectively. We can see large increases in interface-state density with widely distributed time constants as the injected charge density increases. But a smaller increase is noted in Fig. 2 [D] in comparison with [C].

Similar experiments are also carried out for the 2 Ω-cm (100) and (111) capacitors with a pulse bias of 95V. The characteristic of the flatband voltage *vs.* the injected charge density of the (100) and (111) capacitors is similar to Fig. 1. However, for the (100) capacitor, the maximum is approached more slowly than for the (111) capacitor. The dominant electron capture cross sections obtained from the data are 1.3 × $10^{-18}/cm^2$ for the (100) capacitor, and 1.0 × $10^{-18}/cm^2$ for the (111) capacitor. The generated interface-state density obtained from the *C-V* characteristics is shown in Fig. 3 for the (100) and (111) capacitors with the injected charge density as a parameter. It is seen that the (100) capacitor has approximately half the generated interface-state density of the (111) capacitor at equivalent injected charge densities.

Figure 4 shows the energy distribution of the generated interface states for the 2 Ω-cm (100) capacitor at the injected charge density of 3 × $10^{18}/cm^2$. The results given in Fig. 4 (a)-(c) are obtained from the *C-V* characteristics in response to the frequency range of (a) 1 kHz-1 MHz, (b) 17 Hz-1 kHz, and (c) 17 Hz-1 MHz, respectively, where (a) + (b) = (c). The energy level of the interface state for (c) is distributed near the middle of the energy gap of silicon; however the energy level of the interface state for (a), with the shorter time constant, is distributed on the valence band side; while (b) with the longer time constant is on the conduction band side. Similar characteristics of the energy distribution are obtained for the different injected charge levels as predicted from Fig. 2. And approximately the same distributions are obtained for the (111) capacitor, except for the density distribution.

Discussion

As seen in Fig. 1, the flatband voltage exhibits N-shaped behavior in proportion to the avalanche injection of hot electrons. This N-shaped behavior cannot be explained by detrapping because hot electrons are injected at a constant applied voltage. It is observed that the interface states with widely distributed time

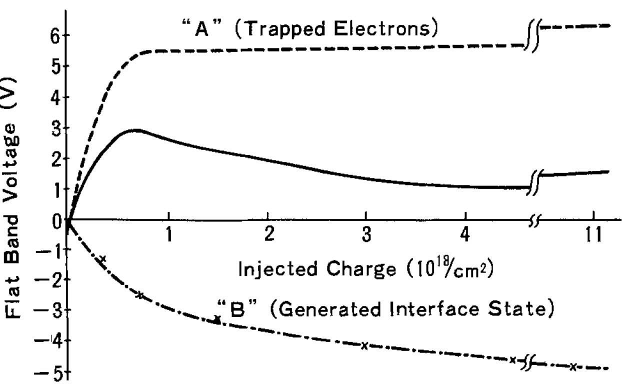

Fig. 5. Resultant N-shaped behavior with flatband voltage shift due to trapped electrons and the generated interface state.

constants are generated by hot electron injection at the silicon to silicon dioxide interface and that density increases with increasing injected electronic charge (Fig. 2).

The N-shaped behavior can be explaned by the following model. As some of the injected electrons are trapped in the silicon dioxide, the flatband voltage increases in proportion to the number of injected electrons (denoted as "A" in Fig. 5). If the generated interface is assumed to be the donor type of interface state, the shifting direction of the flatband voltage is opposite to the direction resulting from the electron trapping in the silicon dioxide ("B" in Fig. 5); thereby decreasing the flatband voltage. Thus, the anomalous N-shaped phenomenon shown in Fig. 1 can be explained by considering the above two factors; *i.e.*, by summing the shift of the flatband voltage due to electron trapping in the silicon dioxide with that due to the generation of a donor-type interface state at the silicon to silicon dioxide interface. These two factors are illustrated in Fig. 5 by "A" and "B" along with the N-shaped resultant variation.

It is also observed in Fig. 3 that the generated interface-state density with widely distributed time constants is strongly affected by the orientation of the silicon substrate. The interface-state density values of the (100) capacitor are about half the values for the (111) capacitor. Since the interface state is considered a result of a broken or strained bond in the vicinity of the silicon to silicon dioxide interface, the generated interface-state density can be expected to have a strong dependence on the orientation of the silicon substrate, in a similar way to the fixed charge density at the thermally oxidized silicon surface (12). Thus it may be said that the reliability of short channel V-MOS devices which are composed on the (111) plane must be inferior to (100) plane devices, assuming that the same amount of hot electrons are injected.

To determine the true (corrected) electron capture cross section, it must be obtained from curve "A" in Fig. 5 which shows the flatband voltage shift only due to electron trapping in the silicon dioxide. The electron capture cross section obtained from the N-shaped characteristic is not true, because it includes the shift of the flatband voltage due to the generated interface state. The dominant electron capture cross section obtained from the N-shaped variation (uncorrected) is about 1.5 times larger than the corrected capture cross section obtained from curve "A" in Fig. 5. The corrected and uncorrected electron capture cross sections for (100) and (111) capacitors are given in Table I for the dominant electron traps. As an e-gun is used for aluminum evaporation, there will be neutral traps having a capture cross section of about 10^{-14}-10^{-15} cm^2 as pointed out by Aitken *et al.* (14). But the neutral trap density of the capacitor used is much smaller (less than $5 \times 10^{10}/cm^2$) than the density of dominant trap (about $2.5 \times 10^{12}/cm^2$). Then the neutral trap will affect the flatband voltage shift and the capture cross section.

Table I. Corrected and uncorrected electron capture cross sections of dominant electron traps for (100) and (111) capacitors

	(110) (cm^2)	(111) (cm^2)
Corrected	8.6×10^{-19}	6.7×10^{-19}
Uncorrected	1.3 % 10^{-18}	1.0×10^{-18}

The physical cause of the generated interface state with widely distributed time constants has not been determined, and the correlation between e-gun aluminum and interface-state generation by injected electron current is not clear yet. More detailed studies are warranted.

Summary

The avalanche injection of hot electrons at the silicon to silicon dioxide interface causes an anomalous N-shaped shift of flatband voltage.

Interface states with widely distributed time constants are generated by the avalanche injection of hot electrons.

The N-shaped shift of the flatband voltage is explained by a model assuming a combination of electron trapping and the generation of a donor-type interface state.

The orientation of the silicon substrate strongly affects the generated interface-state density.

The generated interface-state density of the (100) capacitor has a value approximately half that of the (111) capacitor. Short channel V-MOS devices which are composed on the (111) plane are less reliable than (100) plane devices, assuming the same amount of hot electrons are injected.

The energy level of the interface state is distributed near the middle of the energy gap of silicon. The energy level of the interface state with the shorter time constant is distributed on the valence band side and that with the longer time constant is on the conduction band side.

The dominant electron capture cross sections are approximately 1×10^{-18} cm^2 for both (100) and (111) capacitors.

The Nucleation of CVD Silicon on SiO_2 and Si_3N_4 Substrates

I. The SiH_4-HCl-H_2 System at High Temperatures

W. A. P. Claassen and J. Bloem*

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The grain size in polycrystalline silicon layers is subject to various external conditions among which the initial nucleation of silicon on the substrate may play a decisive role. This article describes experiments with silicon on SiO_2 and Si_3N_4 substrates in the SiH_4-HCl-H_2 system for temperatures between 925° and 1200°C. The saturation cluster densities are determined as a function of gas phase composition and temperature and could be varied between 10^4-10^{11} cm^{-2}. The experimental results are compared with predictions of existing nucleation theories using analysis of the monomer silicon adatom concentration. In this way the nucleation can be described satisfactorily and approximate values for the size of the critical cluster can be derived.

Polycrystalline silicon layers, which are grown by pyrolysis of silane, are widely used in the electronic industry, *e.g.*, in the fabrication of MOS (metal-oxide-silicon) field effect transistors and integrated circuits. The electrical properties of these layers closely depend on the size of the polysilicon grains in the layers (1). It is not very well known how the grain size depends on the total number of nuclei and whether nucleation of new grains continues in the course of further growth.

Nucleation experiments with silicon on amorphous, polycrystalline, and monocrystalline substrates have been reported (2-15), but attempts to make a more systematic study and quantitative evaluation of the results are relatively scarce. Joyce and Bradley (3) (pyrolysis of silane in vacuum) and Brooker and Unvala (4) (vacuum-evaporation) observed three-dimensional nuclei in the deposition of silicon on a monocrystalline silicon substrate. However, in a more recent article Joyce *et al.* (5) in collaboration with Charig and Skinner (6) showed that the initial growth becomes two dimensional if surface contaminants such as C and O are removed by heat-treatment up to 1300°C in UHV. Nishizawa and co-workers (7) formed perfect {111} facets on nearly {111} oriented silicon substrates. By hydrogen reduction of $SiCl_4$ at 1200°C nuclei in the form of pyramids are formed on the perfect {111} facet, with a density depending on growth temperature and $SiCl_4$ concentration. Since these pyramids are distributed homogeneously on the facet and have a uniform size, the conclusion was drawn that they correspond to growth nuclei without lattice defects. Abrahams *et al.* (8), Blank and Russell (9), Mercier (10), Bicknell *et al.* (11), and Cullen *et al.* (12) investigated nucleation processes of silicon on monocrystalline Al_2O_3 substrates. They observed three-dimensional islands. However, at temperatures higher than 800°C, the Al_2O_3 surface reacts with the deposited silicon. High temperatures and relatively low silane pressures, or a silicon compound containing chlorine, favor this etching reaction. Brown *et al.* (13) have reported a similar etching reaction for low silane input concentration on a monocrystalline quartz substrate. On amorphous and polycrystalline substrates, such as given by Si_3N_4 and SiO_2, three-dimensional nuclei are observed as shown by Alexandrov *et al.* (14) (pyrolysis of silane on Si_3N_4 and SiO_2 substrates in vacuum) and Kamins and Cass (15) (pyrolysis of silane in an H_2 atmosphere on SiO_2 substrates). It has been shown that nucleation of silicon on a foreign substrate like SiO_2 or Si_3N_4 needs a higher supersaturation than nucleation on a clean silicon surface. This prompted studies on selective epitaxial growth of silicon on silicon slices partly coated with an oxide or nitride layer. Selective epitaxial growth of Si has been studied by Ogawa *et al.* (16) on windows in Si_3N_4 layers ($SiCl_4$-H_2 system), by Ray-Choudhury and Schroder (17) on windows in SiO_2 layers ($SiCl_4$-H_2 and SiH_4-H_2 systems), by Druminski and Gessner (18) on windows in SiO_2 and Si_3N_4 layers (SiH_4-HCl-H_2 system), and by Sirtl and Seiter (19) on windows in SiO_2 layers ($SiCl_4$-Br_2-H_2 system). Ogawa *et al.* determined a critical $SiCl_4$ pressure for the nucleation on Si_3N_4 substrates as a function of growth temperature. In the SiH_4-H_2 system it was necessary to use a relatively high deposition temperature (>1200°C) in order to prevent growth on the SiO_2 mask. In the $SiCl_4$-H_2 system the SiO_2 was entirely removed for high $SiCl_4$ concentrations (>1200°C), while the Si_3N_4 film was not deteriorated at all for any growth condition. Sirtl and Seiter used Br_2 instead of HCl because the purity of Br_2 is much higher than that of HCl. The bromine added to the SiH_4-H_2 mixture is converted to HBr by the hydrogen, while thermodynamically HBr acts as HCl.

In order to obtain a more coherent picture of the nucleation of silicon as a function of gas phase composition and temperature a systematic experimental study was started to study nucleation and growth of silicon on SiO_2 and Si_3N_4 substrates. It was found that the total number of nuclei could be varied between 10^4-10^{11} cm^{-2} by variation of temperature, input con-

* Electrochemical Society Active Member.

centration of silane, and by the addition of small quantities of HCl to the carrier gas.

Experimental

Most of the nucleation experiments were performed in a horizontal epitaxial rf heated reactor, consisting of a rectangular water-cooled fused silica tube, provided with a pyrographite-coated carbon susceptor covered with a thin layer of silicon. Nucleation of silicon was performed on silicon slices (2 in. wafers) covered with amorphous, 1500Å thick LP-CVD SiO_2 and Si_3N_4 layers. The effective cross section of the reactor was about 13 cm^2. The gas system was provided with AFC 550 automatic flow controllers for the H_2 carrier gas and the SiH_4 source (5% SiH_4 in H_2). The flow rate of pure undiluted HCl was determined by a conventional Brooks flowmeter. Some experiments were performed in a horizontal air-cooled rf heated reactor. The system was also equipped with a mass flow controller for HCl. The equipment is shown schematically in Fig. 1. The carrier gas was purified of H_2O (<1 ppm) and O_2 (<1 ppm) with a A.S.M. gas purifier. Before each experiment the slices were cleaned by etching with 0.2 volume percent (v/o) HCl in H_2 at about 1000°C for 5 min. After this the reactor was flushed with a stream of H_2, while the substrate was brought to the desired nucleation temperature. During the nucleation experiment hydrogen loaded with SiH_4 and HCl was passed over the slices. To ensure stable gas flow conditions a room temperature gas velocity of about 50 cm/sec was chosen. Because of the rapid nucleation only short pulses of specific SiH_4-HCl mixtures were often sufficient. It was found that reproducible results could be obtained with a constant HCl flow and a short additional pulse of SiH_4 gas. This procedure was followed throughout, including the experiments in which longer deposition times were used. The temperature of the slices was measured with an optical pyrometer focused on the surface of an uncoated silicon slice; the readings were corrected for the emissivity of silicon and the absorption and reflection of the system. SEM and TEM photomicrographs were made from each slice in order to determine the morphology of the layer during the initial stage of deposition. These photomicrographs provided an easy means of measuring the density of observed silicon islands.

Experimental Results

To study the initial stages of deposition of polycrystalline silicon on SiO_2 and Si_3N_4 substrates, we carried out a series of short depositions at different temperatures and different combinations of SiH_4 and HCl concentrations. For a constant substrate temperature and fixed SiH_4 and HCl concentrations the density of nuclei was measured as a function of the time of growth. After an incubation period the density of Si clusters very quickly reached a saturation value with respect to exposure time where the exposure time is defined as the duration of the SiH_4 pulse in the mass flow controller. After this hardly any new clusters were formed. The existing clusters showed a very narrow size distribution. The initial

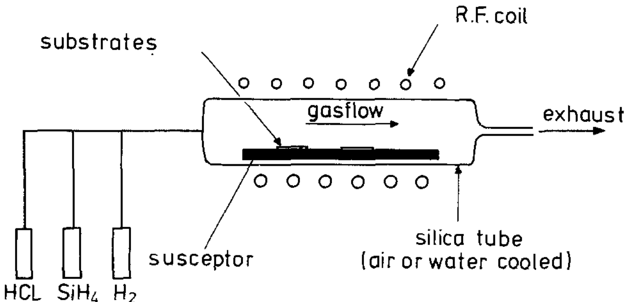

Fig. 1. Schematic view of the equipment

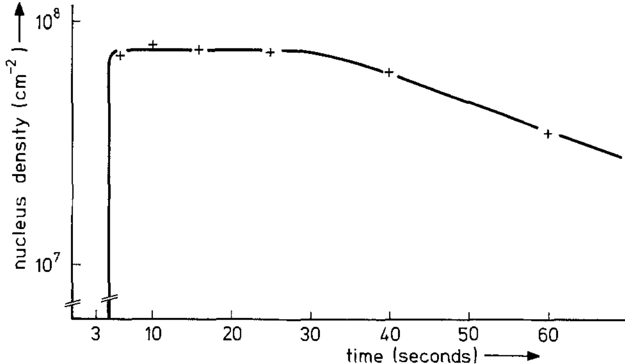

Fig. 2. The nucleus density as a function of the exposure time for $p_{SiH_4} = 8.8 \cdot 10^{-4}$ bar and $p_{HCl} = 4.4 \cdot 10^{-3}$ bar at 1000°C on an SiO_2 substrate.

nucleation took place in a short time, after which the clusters merely increased in size until coalescence occurred. Figure 2 gives a typical example for a constant ratio of SiH_4 and HCl at 1000°C and a SiO_2 substrate, where the nucleus density is plotted as a function of growth time. A corresponding SEM photomicrograph is shown in Fig. 3. Up to 3 sec no clusters were observed on SEM (Fig. 2) or TEM photomicrographs. In the case of TEM the detection limit is 150Å. A constant nucleus density is present between 6 and 25 sec in which time the mean radius of the nuclei increases from 0.1 to 0.25 μm (Fig. 3), after which coalescence occurs. It could be observed that the existing clusters show a narrow size distribution which supports the argument that the initial nucleation takes place in a very short period of time. It was also observed that the time needed to reach the saturation density is shorter for a Si_3N_4 substrate than for a SiO_2 substrate, also these periods are longer for high HCl concentrations and low SiH_4 concentrations. Further these periods decrease with increasing temperature. It is found that, for the SiH_4-HCl-H_2 system in the temperature range of 925°-1200°C, this incubation time is of the order of 1-60 sec.

If we assume that the clusters are hemispherical, we can calculate the number of deposited atoms. From the experiments it can be concluded that the total deposited volume is small until coalescence is reached. After this the deposited volume increases linearly with time with the same slope as obtained on silicon substrates. In the latter case no incubation time is observed. This behavior is an additional indication of the incomplete condensation in the early

stages of nucleation and growth on the foreign substrates.

Nucleation on a SiO_2 substrate.—The experimentally observed saturation densities of Si clusters are collected in Tables I and II. Figure 4 presents SEM photomicrographs for different input concentrations of SiH_4 and HCl and a SiO_2 substrate at 1000°C. In Fig. 5 the saturation density of Si clusters is plotted as a function of temperature for different input concentrations of SiH_4 and HCl on a SiO_2 substrate. It is apparent that the introduction of HCl reduces the number of nuclei and increases the temperature dependence of the formation process. It is also observed, but not shown here, that the nucleus density decreases at temperatures below 925°C. In a later publication this feature will be discussed. Further it was measured that at 1200°C the SiO_2 surface partly deteriorates when relatively low input concentrations of SiH_4 and long exposure times are used. It will be shown in the discussion that between 925° and 1200°C the experimental data on the saturation density of nuclei (N_s) as a function of temperature and gas phase compositions can be described by

$$N_s = A \left\{ \frac{B^\circ p_{SiH_4}}{C^\circ p^2_{HCl}+1} \right\}^a \exp \frac{E}{kT} \quad [1]$$

where $C^\circ = 6 \cdot 10^6$ when p_{SiH_4} and p_{HCl} are expressed in bars. The exponent a and the activation energy E still depend on gas phase composition. In Fig. 6 the saturation density of clusters at 1000°C is plotted as a function of $p_{SiH_4}/(6 \cdot 10^6\, p^2_{HCl}+1)$. For SiH_4 the equilibrium vapor pressure (above which decomposition of SiH_4 can be expected) is $\sim 10^{-6}$ bar (20). This value is nearly independent of temperature in the range of interest and in good agreement with the results given in Fig. 6. From experiments as given in Fig. 5 (log N_s *vs.* $1/T$) for temperatures above 925°C an apparent activation energy can be obtained from the Arrhenius plot. The experimental values of E are given in Fig. 7 as a function of the gas phase composition, the latter expressed as $p_{SiH_4}/(6 \cdot 10^6\, p^2_{HCl}+1)$. It is observed that at high supersaturations the activation energy comes to a limiting value of 1.9 eV. At lower supersaturations the activation energy increases, this behavior is accompanied by a strong decrease in the number of nuclei.

Table II. Saturation nucleus densities (cm^{-2}) for the SiH_4-HCl-H_2 system (air-cooled rf reactor) on SiO_2 and Si_3N_4 substrates at 1000°C. *t* is the exposure time and x means that coalescence occurs (7).

Nucleation on a Si_3N_4 substrate: difference compared with a SiO_2 substrate.—Tables I and II also present experimental data for the saturation densities of stable clusters in the SiH_4-HCl-H_2 system for Si_3N_4 substrates. From the tables it can be observed that the saturation density of Si clusters is always larger for a Si_3N_4 substrate than for a SiO_2 substrate (other things being equal). This means that coalescence takes place much earlier on a Si_3N_4 substrate than on a SiO_2 substrate. In spite of the rapid nucleation and coalescence we were able to observe the saturation cluster density by choosing an appropriate exposure time. Figure 8 gives a plot of the saturation nucleus density for two different mixtures of SiH_4 and HCl as a function of temperature for both substrates. In the case of the Si_3N_4 substrate, too, the addition of HCl reduces the number of clusters and increases the temperature dependence of the saturation density, though to a smaller degree than for the SiO_2 substrate. The experimentally found expression for the saturation nucleus density (Eq. [1]) as a function of gas phase composition for the SiO_2 substrate can also be used for a Si_3N_4 substrate between 1200°-925°C, as will be shown in the discussion. The nucleus density as a function of $p_{SiH_4}/(6 \cdot 10^6\, p^2_{HCl}+1)$ for a Si_3N_4 substrate at 1000°C is plotted in Fig. 6. For temperatures above 925°C an apparent activation energy can be obtained from the Arrhenius plot (log N_s *vs.* $1/T$). The experimental values of E for Si_3N_4 substrates are included in Fig. 7 which also gives E values for SiO_2 substrates. It is observed that with increasing supersaturation the activation energy decreases and this decrease is stronger for the SiO_2 substrate than for the Si_3N_4 substrate.

Discussion

Nucleation theory.—The growth of thin films on a substrate starts with the formation of small cap-shaped clusters if the cohesive forces between the atoms in the cluster are greater than the adhesive forces between adsorbed atoms (adatoms) and the substrate. The formation of the small clusters begins with the arrival of atoms or molecules from the vapor. After adsorption, and perhaps chemical reaction, adatoms are formed on the surface. These adatoms diffuse across the surface where, through statistical fluctuations in local con-

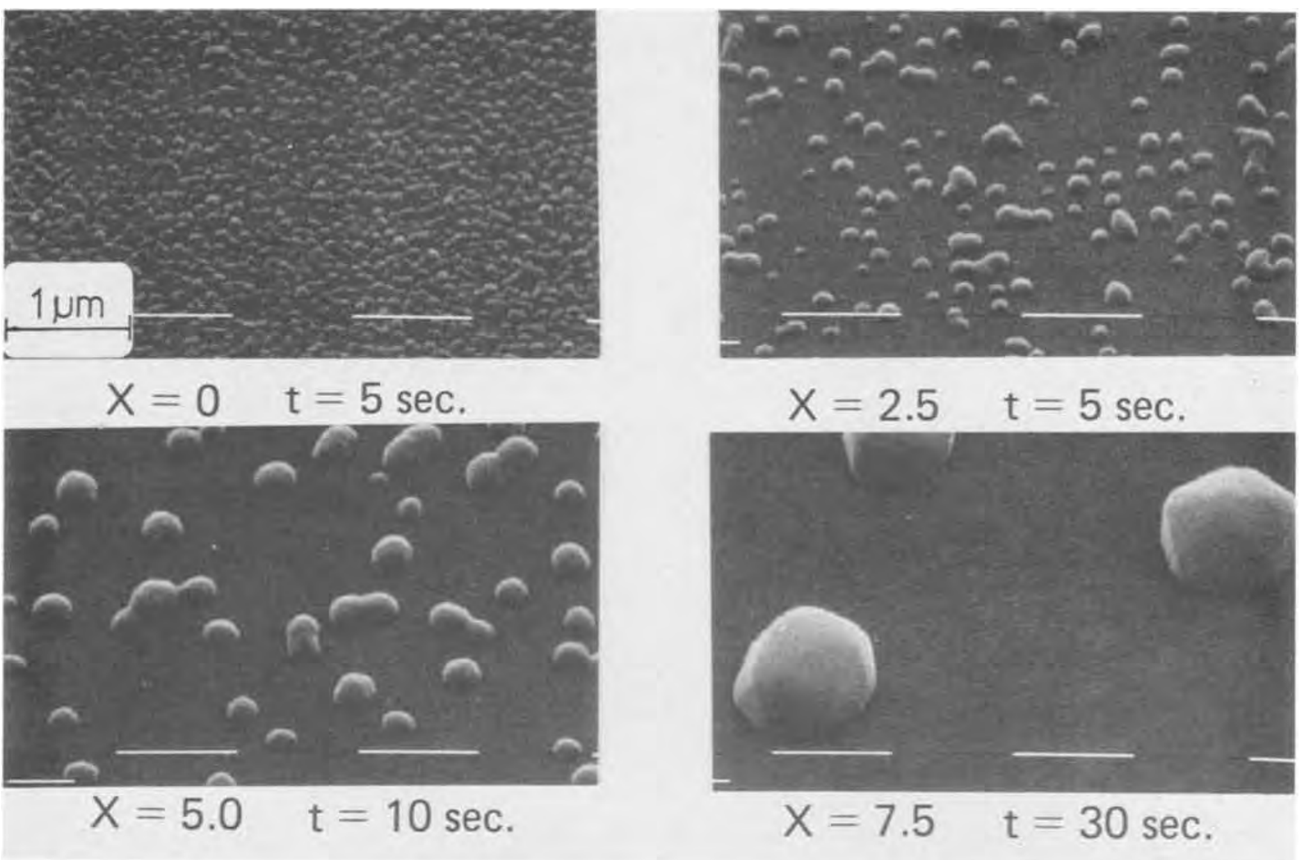

Fig. 4. SEM pictures of the nucleus densities for $p_{SiH_4} = 8.8 \cdot 10^{-4}$ bar and $p_{HCl} = X \cdot p_{SiH_4}$ (where $X = 0$, 2.5, 5.0, and 7.5) at 1000°C on an SiO_2 substrate. t is the exposure time.

centration, they form small clusters of atoms which grow and decay by addition or loss of single atoms. If the cluster exceeds a critical size (supercritical cluster) further growth becomes energetically favorable. Clusters that are smaller than the critical size (subcritical) can decay.

In the chemical thermodynamic approach we can write for the radius r^* of the critical cluster

$$r^* = \frac{2\delta v}{kT \ln p/p_e} \quad [2]$$

where δ is the surface free energy which is taken isotropic, v is the atomic volume, and $kT \ln p/p_e$ is the supersaturation function giving the gain in free energy on crystallization. Using the experimental results we can give an estimation of r^*. In Fig. 6 the saturation density of Si clusters is plotted as a function of the gas phase composition. This gives us the opportunity to calculate the supersaturation p/p_e, where $p_e \sim 10^{-6}$ bar is the equilibrium vapor pressure of SiH_4. Using Eq. [2] with $v = 2 \cdot 10^{-21}$ cm^3 and $\delta = 10^{-4}$ J/cm^2 (21) gives $r = 1.5$ nm for $p/p_e = 5$ and $r = 0.4$ nm for $p/p_e = 10^3$. This means that for high supersaturation the radius of the critical cluster approaches molecular dimensions, but in that case the

The saturation cluster density of Si clusters as a function of temperature for two SiH_4-HCl mixtures on SiO_2 and Si_3N_4 substrates (△, ▲: $p_{SiH_4} = 7.3 \cdot 10^{-4}$ bar and $p_{HCl} = 1.8 \cdot 10^{-3}$ bar. □, ■: $p_{SiH_4} = 1.4 \cdot 10^{-3}$ bar and $p_{HCl} = 7.2 \cdot 10^{-3}$ bar).

thermodynamic interpretation of surface energies is no longer justified. These difficulties are avoided when the nucleation process is treated by writing the partition function and potential energies for the adatoms and clusters as is done in the atomistic nucleation theory. Walton (22), in an approximate treatment, considered the potential energy difference E_i between i adatoms and a cluster of i atoms. For the reaction on the surface

$$in_1 \rightleftharpoons n_i$$

he found for the density of critical clusters n_i if no stable clusters are present and $n_1 > n_i$

$$\frac{n_i}{n_o} = C_i\left(\frac{n_i}{n_o}\right)^i \exp\frac{E_i}{kT} \quad [3]$$

where n_1 is the concentration of adatoms, n_o is the number of surface sites, C_i is a statistical weighting factor, and E_i is the heat of formation of the cluster consisting of i atoms. Equation [3] is generally used in the atomistic nucleation theories to find a general expression for the saturation density of stable clusters.

The rate of formation of adatoms as a function of exposure time t and the incoming flux J_1 can be given by

$$\frac{dn_1}{dt} = J_1 - \frac{n_1}{\tau_{ev}} - \frac{n_1}{\tau_r} - \frac{n_1}{\tau_g} - \quad [4]$$

where τ_{ev} is the mean residence time before evaporation, τ_r is the τ value if adatoms are removed by chemical reaction, and τ_g is the τ value for the capture of adatoms by stable clusters. In the case of complete condensation the τ_{ev} and τ_r values are supposed to be so great that no desorption or etching of adatoms occurs. The adatom concentration increases with time until the diffusional flux has grown sufficiently to substantially reduce the value of n_1. Evaporation or reaction comes into play for incomplete condensation and the smallest τ values in the series determines the value of τ_s and therefore the value of n_1 giving

$$n_1 = J_1\tau_s \quad \text{for} \quad t >> \tau_s \quad [5]$$

The surface concentration n_1 is attained before nucleation starts. As nucleation proceeds τ_s will decrease because adatoms also disappear by incorporation in stable clusters. Between the clusters the value of n_1 eventually drops below the initial steady-state concentration, whereupon the production of new nuclei ceases. The maximum cluster density is one of the easily measurable quantities when the nucleation rate is too high to be measured. Following Venables (23) we can write for the formation rate of stable clusters

$$\frac{dn_x}{dt} = U_i - U_c - U_m \quad [6]$$

where n_x is the density of stable clusters at the time t. U_i is the nucleation rate and U_c and U_m are the rates at which stable clusters are lost due to coalescence and cluster mobility, respectively. In the SiH_4-HCl-H_2 system at temperatures between 925° and 1200°C, n_x reaches a saturation value N_s long before coalescence occurs (see Fig. 2), hence $U_c << U_m$. Stowell's analysis of data on the nucleation of Au and Ag on alkali halide substrates shows that cluster mobility becomes important at temperatures above 400°C (24). Lewis (25) assumes that the detachment of peripheral atoms of hemispherical clusters determines the activation energy of the mobility process. In that case the activation energy for cluster diffusion is independent of cluster size, while the actual cluster mobility strongly depends on the size, viz., via a preexponential entropy term.

Masson *et al.* (26) measured relatively large diffusion coefficients, which are probably caused by nonepitaxial orientation of the clusters. According to Behrndt (27) liquid nuclei, with consequently a relatively high surface mobility, are also possible at temperatures which are much lower than the melting point of the condensate. For the case where all stable clusters are mobile, at least initially until n_x saturates, Venables gives an expression describing the maximum cluster density N_s for incomplete condensation

$$\frac{N_s}{n_o} \simeq \left(\frac{J}{n_o v}\right)^{(i+1)/2} \exp\frac{(i+1)E_a + E_i + E_m - E_d}{2kT} \quad [7]$$

where E_a is the activation energy of desorption, E_x the activation energy for surface diffusion of mobile clusters, E_d the activation energy for surface diffusion of adatoms, n_o the number of surface sites, and v the adatom vibration frequency; the other parameters have already been defined (Eq. [3] and [5]). In the SiH_4-HCl-H_2 system there is an incubation period for the formation of a significant number of stable clusters and a nonlinear increase of the deposited volume in the early state of growth (see above) which supports

the arguments for incomplete condensation. The relation deduced by Venables (Eq. [7]) can be compared with the experimentally found relationship between the saturation cluster density and the supersaturation with the help of Eq. [5] and the calculated adatom concentration (n_1) as given in Eq. [A-16] of the Appendix.

Adatom concentration and surface coverages.—To arrive at an expression determining the adatom concentrations of Si on the substrate the main processes responsible for formation and removal are summarized in the Appendix. It is concluded that the following steps may be important: (*a*) diffusion of silane toward the surface; (*b*) adsorption of silane, diffusion across the surface, and chemical reaction (formation of adatoms); (*c*) etching reactions of HCl, H_2, and SiO_2 with silicon adatoms; (*d*) desorption of reaction products; and (*e*) diffusion of reaction products away from the surface. Since the value of the diffusion coefficient in the gas phase is rather insensitive to temperature (ideal gas $D \propto T^{3/2}$) the processes (*a*) and (*e*) will have a low activation energy.

In order to obtain realistic information about the concentration of adatoms and free surface sites some additional information may be helpful:

(*i*) From nucleation experiments in the SiH_2Cl_2-H_2-N_2 system at temperatures between 900° and 1100°C on SiO_2 and Si_3N_4 substrates (28) it is found that hydrogen strongly influences nucleation on SiO_2 substrates. In the case of Si_3N_4 substrates there is hardly any difference in saturation density between the results in H_2 or N_2 ambient.

(*ii*) The saturation cluster density in the SiH_2Cl_2-N_2 system is equal for both substrates at temperatures between 925° and 1100°C.

(*iii*) From nucleation experiments in the SiH_4-H_2 system at temperatures between 900° and 600°C (28) we know that for SiO_2 substrates the saturation density decreases with decreasing temperature, whereas Si_3N_4 substrates show the opposite behavior.

The observations mentioned above suggest that the adsorption of hydrogen has a great influence on the nucleation kinetics, especially for the SiO_2 substrates. Under normal operating conditions (925°-1200°C, $p_{H_2} \cong 1$ bar) it is thus likely that hydrogen adsorption will occur, but it is only below 900°C that hydrogen adsorption will influence nucleation on SiO_2 substrates by limiting the number of surface sites where SiH_4 adsorption may occur.

For the silicon adatom concentration on a SiO_2 substrate Eq. [A-16] can be used. If hydrogen adsorption does not limit the number of surface sites and with $n_o >> [SiH_4^*], [Cl^*]$ one obtains

$$\frac{n_1}{n_o} = \frac{K_1 k_2 p_{SiH_4}}{(k_{-2}p^2_{H_2} + k_6 p^2_{HCl} + k_9)} \quad [8]$$

For nucleation on Si_3N_4 substrates also, Eq. [A-16] can be used. In that case k_9 can be disregarded on thermodynamic grounds as reaction of Si with Si_3N_4 will be slow, also hydrogen adsorption is not rate limiting. It is observed, moreover, that the number of stable clusters saturates at high concentrations and $[SiH_4^*]$ cannot be neglected. Therefore n_1 can be given as

$$\frac{n_1}{n_o} = \frac{K_1 k_2 p_{SiH_4}}{(k_{-2}p^2_{H_2} + k_6 p^2_{HCl})(1 + K_1 p_{SiH_4})} \quad [9]$$

For $p_{HCl} = 0$ and $K_1 p_{SiH_4} < 1$ the temperature dependence of n_1 is determined by $K_1 K_2$ which, in the temperature region of interest, is nearly independent of temperature. According to the JANAF Tables (20), $d(\ln K_p)/d(1/T) \cong 0$ around 1000°C.

Interpretation of results.—In this section we compare the expression obtained by Venables (Eq. [7]) with the results of the nucleation experiments in the SiH_4-HCl-H_2 system on SiO_2 and Si_3N_4 substrates in the temperature region of 925°-1200°C. Equation [7] can be modified by introducing $n_1 = J_1 \tau_s$, where n_1 is given by Eq. [8] or [9] and τ_s is defined as $\tau_s = v^{-1} \exp E_a/kT$, E_a being the enthalpy of desorption and v the adatom vibration frequency. The modified expression (Eq. [7]) then reads for SiO_2 substrates

$$\frac{N_s}{n_o} \simeq \left\{ \frac{K_1 k_2 p_{SiH_4}}{(k_{-2}p^2_{H_2} + k_6 p^2_{HCl} + k_9)} \right\}^{(i+1)/2} \exp \frac{E_i + E_m - E_d}{2kT} \quad [10]$$

It should be realized that the expression between curly brackets already presents a simplified version of a more complex expression. A possible activation energy from this relation has to be added to the exponential term. This, however, depends on which of the terms in the denominator prevails and whether HCl is present or not. In order to put Eq. [10] into a form that permits evaluation of the experimental data we can write

$$N_s = A \left\{ \frac{B p_{SiH_4}}{C p^2_{HCl} + 1} \right\}^{(i+1)/2} \exp \frac{E_i + E_m - E_d}{2kT} \quad [11]$$

in which A is a constant (equal to n_o)

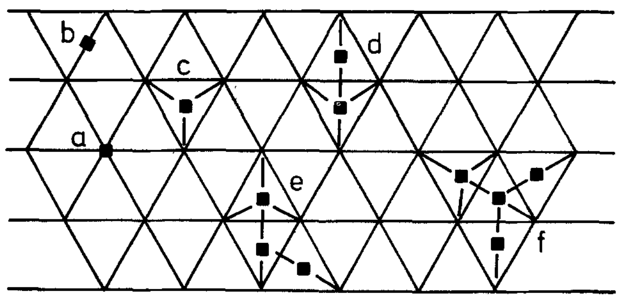
$$B = \frac{K_1 k_2}{(k_{-2}p^2_{H_2} + k_9)} = B^o \exp \frac{-E_{r,1}}{kT} \quad [12]$$

$$C = \frac{k_6}{(k_{-2}p^2_{H_2} + k_9)} = C^o \exp \frac{-E_{r,2}}{kT} \quad [13]$$

The values of i, B, and C thus depend on temperature and gas phase composition and will be different for nucleation on different substrates. For the SiO_2 substrate the constants A, B^o, and C^o can be calculated as follows. From Fig. 6 we know that, for pure SiH_4, N_s is proportional to p_{SiH_4}. This means that $(i + 1)/2 = 1$ for p_{SiH_4} ranging from $9 \cdot 10^{-5}$ to $1.7 \cdot 10^{-3}$ bar. Making use of the corresponding values of E (Fig. 7) we find $AB^o = 2 \cdot 10^5$. The mixture $p_{SiH_4} = 2.6 \cdot 10^{-3}$ bar and $p_{HCl} = 1.8 \cdot 10^{-3}$ bar gives a cluster density higher than the corresponding one for the lowest pure SiH_4 concentration. This leads to the conclusion that $(i + 1)/2 = 1$ for this SiH_4-HCl mixture as well. Inserting $AB^o = 2 \cdot 10^5$, $(i + 1)/2 = 1$, and $E = 1.9$ eV (the activation energy for this special SiH_4-HCl mixture) in Eq. [11] we obtain $C^o = 6 \cdot 10^6$. The linear relationship $[(i + 1)/2 = 1]$ between N_s and p_{SiH_4} for silane pressures between $9 \cdot 10^{-5}$ and $1.7 \cdot 10^{-3}$ bar leads to a critical cluster size of $i = 1$. In that case ($p_{HCl} = 0$) the experimentally found activation energy for cluster formation (E) becomes

$$E = \tfrac{1}{2}(E_i + E_m - E_d - 2E_{r,1}) = 1.9 \text{ eV} \quad [14]$$

As to the value of E_i, a cluster can be called stable when half of the possible bonds are formed between atoms in the cluster and between cluster and substrate (29). For silicon, therefore, two bonds have to be realized per silicon atom. In order to arrive at a relation between the binding energy E_i of a cluster of i atoms on SiO_2 and the Si-Si bond energy (E_b) a triangular lattice of oxygen atoms on the substrate is shown schematically in Fig. 9. For amorphous SiO_2 a triangular lattice is acceptable because short-range order (regions of crystallinity 10-100Å in size) may exist (30). Amorphous SiO_2 forms a random three-dimensional network where each silicon atom is tetrahedrally surrounded by four oxygen atoms and each oxygen atom is bonded to two silicon atoms with an average Si-O distance of 1.62Å, an average O-O distance of 2.65Å, and an average Si-Si distance of 3.00Å (31). At the surface, however, a silicon atom can be



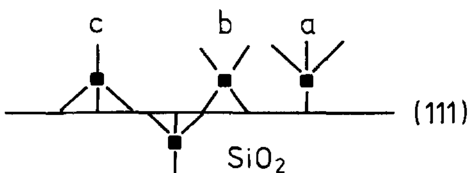


Fig. 9. Binding energies of atoms and clusters on a nearest neighbor bond model of nucleation on a triangular oxygen lattice: (a) single bonded, (b) double bonded, (c) triple bonded, (d) critical cluster size, $i = 1$, (e) critical cluster size $i = 2$, (f) critical cluster size $i = 3$.

bonded in three different ways to the oxygen lattice. In the first place a Si atom can have a single bond to an oxygen atom (Si-adatom). Further a double and a triple bonding of a Si atom with the oxygen lattice is possible. The triple bonding, which is the most stable one, can be seen in Fig. 9(c). In this simple model a Si-Si bond is formed only when a Si atom [(a) in Fig. 9] on the surface forms a bond with the triple-bonded Si atom [giving (d) in Fig. 9]. In this case the critical cluster consists of one atom only (the triple-bonded Si atom belongs to the SiO_2 lattice). This model can be extended to clusters containing more than two Si atoms [(e) and (f) in Fig. 9 for $i = 2$ and $i = 3$], so that for the critical cluster it leads to an energy gain over the binding energy of one Si-Si bond

$$E_i \cong iE_{Si\text{-}Si} \quad [15]$$

For $i = 1$ and $E_{Si\text{-}Si} = 2$ eV (32) Eq. [14] leads to

$$E_m - E_d - 2E_{r,1} = 1.8 \text{ eV} \quad [16]$$

If we compare the results for the Si_3N_4 substrate and the SiO_2 substrate in the temperature region 925°-1200°C we see that the composition of the gas phase where nucleation is no longer observed (Fig. 6) is almost the same for both substrates. This justifies the use of Eq. [11] for the saturation density on Si_3N_4 also. From Fig. 7 we know that E is nearly constant at silane pressures between $5 \cdot 10^{-5}$ and 10^{-3} bar. This means that the cluster size is constant in this region. From Fig. 6 (log N_s *vs.* p_{SiH_4eff}) it can be observed that in this particular region the tangent changes from 1 to ½. At high supersaturation N_s probably saturates because the concentration of free surface sites is a function of the SiH_4 pressure (Eq. [9]). Thus, at silane pressures between $5 \cdot 10^{-5}$ and 10^{-3} bar we have $i = 1$, and in that case E becomes

$$E = \tfrac{1}{2}(E_1 + E_m - E_d - 2E_{r,1}) = 1.2 \text{ eV} \quad [17]$$

With $E_{Si\text{-}Si} = 2$ eV (32) this gives

$$E_m - E_d - 2E_{r,1} = 0.4 \text{ eV} \quad [18]$$

Introducing $E_{r,1} \cong 0$ eV for Si_3N_4 (as discussed above) into Eq. [18] gives $E_m - E_d = 0.4$ eV. Lewis expects $E_m \geq 2E_d$ (25), which then should give $E_m \cong 0.8$ eV and $E_d \cong 0.4$ eV as maximum values.

Coming back to the nucleation on SiO_2 substrates, we note that Eq. [16] with $E_m - E_d = 0.4$ eV, as obtained above, leads to $E_{r,1} = -0.7$ eV. The difference between $E_{r,1}$ for SiO_2 (−0.7 eV) and $E_{r,1}$ for Si_3N_4 ($E_{r,1} \cong 0$ eV) can be explained as being due to reactions with the substrate and the formation of SiO (k_9 in Eq. [8]), but for Si_3N_4 substrates this reaction is absent. This means that k_9 has an activation energy of 0.7 eV, and the formation of SiO is promoted by the presence of hydrogen. The reaction between a silicon adatom and the SiO_2 substrate can be described as

$$Si + O_{substrate} + H_2 \xrightarrow{k_9} SiO\uparrow + 2H_{ad} \quad [19]$$

In this way the coverage of the substrate with the first silicon layer is impeded, the more so the higher the temperature, as found experimentally for SiO_2 substrates in hydrogen, where at 1200°C the SiO_2 surface partly deteriorates.

If $6 \cdot 10^6 \, p_{HCl}{}^2 > 1$, the activation energy for cluster formation becomes

$$E = \tfrac{1}{2}[E_i + E_m - E_d - (i + 1)(E_{r,1} - E_{r,2})] \quad [20]$$

In the experiment on SiO_2 with $p_{SiH_4} = 2.6 \cdot 10^{-3}$ bar and $p_{HCl} = 1.8 \cdot 10^{-3}$ bar, where $i = 1$ as discussed before, the activation energy equals that of pure silane (Fig. 7). From this it can be expected that $E_{r,2}$ is small and can be disregarded in the first approximation. For low supersaturations the activation energy increases because of the increasing value of i and E_i.

The highest value found for E_i of 6.2 eV, with $E_m - E_d \cong 0.4$ eV, $E_{r,2} \cong 0$, and $E_{r,1} \cong -0.7$ eV and using Eq. [15], gives a critical cluster with $i = 4$.

For Si_3N_4 the highest E value is $E \cong 2$ eV and a similar approach then leads to a critical cluster of $i = 2$.

Conclusions

In an attempt to understand and be able to monitor the crystallite size in polycrystalline silicon layers we have studied the nucleation of silicon on various substrates. Experiments on the nucleation of Si on SiO_2 and Si_3N_4 substrates are reported for the SiH_4-HCl-H_2 system in the temperature range of 925°-1200°C.

The differences and conformities between the two substrates are discussed. It is observed that the saturation nucleus density increases with decreasing temperature for both substrates. This effect, which is stronger for the SiO_2 than for the Si_3N_4 substrate, is attributed to the size and the formation energy of the initial critical cluster and to the reaction with the substrate, especially in the case of SiO_2 in which the H_2 ambient plays an important role. The introduction of HCl strongly reduces the nucleus density, resulting in an increased grain size in the polycrystalline material. The experimental results can be explained by the application of an expression as obtained by Venables, together with an analysis of the silicon adatom concentration on the substrate as a function of gas phase composition. It is found that the number of silicon atoms in the critical cluster varies between 1 and approximately 4 in the experimental range under discussion. It will be obvious that the values of the activation energies are open to criticism, because slightly different assumptions could change the picture. However, the impression remains that nucleation of silicon on SiO_2 and Si_3N_4 substrates at temperatures higher than 900°C can be explained semiquantitatively on the basis of existing statistical nucleation theory supplemented by arguments of a chemical and kinetics nature.

APPENDIX

Calculation of Adatom Concentrations

The main process responsible for nucleation and growth of silicon on a monocrystalline silicon substrate in the SiH_4-HCl-H_2 system is described by Bloem and Giling (33). Nucleation of silicon on a SiO_2 substrate will differ from that on a monocrystalline silicon substrate, but the processes which take place are approximately of the same nature.

(*a*) Supply of SiH_4 by means of gas phase diffusion

$$SiH_4(b) \xrightarrow{k_a} SiH_4(g) \quad [A\text{-}1]$$

where SiH_4(b) is the concentration of SiH_4 in the bulk of the gas phase and SiH_4(g) the concentration of SiH_4 near the surface.

(*b*) Adsorption of SiH_4 on a free site on the surface (denoted by an asterisk)

$$* + SiH_4(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SiH_4^* \quad [A\text{-}2]$$

(*c*) The reaction of SiH_4 at the surface

$$SiH_4^* \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Si^* + 2H_2 \quad [A\text{-}3]$$

(*d*) Adsorption of hydrogen, chlorine, and $SiCl_2$

$$\tfrac{1}{2}H_2 + * \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} H^* \quad [A\text{-}4]$$

$$HCl + * \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} Cl^* + \tfrac{1}{2}H_2 \quad [A\text{-}5]$$

$$SiCl_2(g) + * \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} SiCl_2^* \quad [A\text{-}6]$$

(*e*) Etching of adatoms by chlorine

$$Si^* + 2HCl \xrightarrow{k_6} SiCl_2\uparrow + H_2 + * \quad [A\text{-}7]$$

(*f*) Growth of silicon by diffusion of Si adatoms on the surface and incorporation into a stable cluster

$$Si^* \xrightarrow{k_7} Si(s) + * \quad [A\text{-}8]$$

(*g*) Evaporation of silicon adatoms

$$Si^* \xrightarrow{k_8} Si(g) + * \quad [A\text{-}9]$$

(*h*) Reaction of Si adatoms with the substrate

$$Si^* + SiO_2 \xrightarrow{k_9} 2SiO\uparrow + * \quad [A\text{-}10]$$

(*i*) Reaction of SiH_4 in the gas phase

$$SiH_4(g) \xrightarrow{k_{10}} Si(g) + 2H_2 \quad [A\text{-}11]$$

Formation of silicon-containing compounds other than $SiCl_2$, such as SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$, can be disregarded on the grounds of thermochemical data available in literature (34, 35).

In a steady-state situation the Si* and SiH_4* concentrations are constant, given by

$$n_1 = [Si^*] = \frac{k_1[SiH_4^*]}{k_{-2}p^2_{H_2} + k_6p^2_{HCl} + k_7 + k_8 + k_9} \quad [A\text{-}12]$$

$$[SiH_4^*] = \frac{k_1p_{SiH_4}(g)[*] + k_{-2}n_1p^2_{H_2}}{k_2 + k_{-1}} \quad [A\text{-}13]$$

In [A-13] the second term in the numerator can be expected to be small compared with the first term, in which case

$$n_1 = \frac{k_1k_2[*]\,p_{SiH_4(g)}}{(k_2 + k_{-1})(k_{-2}p^2_{H_2} + k_6p^2_{HCl} + k_7 + k_8 + k_9)} \quad [A\text{-}14]$$

For nucleation of Si on an SiO_2 substrate in the SiH_4-HCl-H_2 system, several approximations can be made. We have seen that, after an incubation period, the nucleus density very quickly reached a saturation value. On the basis of these experiments it will be assumed that the time taken to attain the population of adatoms is short, so that n_1 reaches a constant value before nucleation occurs. Then k_7 can be omitted until nucleation takes place. The existence of an incubation period further means that the reaction is surface-controlled and the greater part of the silane will desorb before reacting ($k_{-1} > k_2$). Because of the surface-controlled reaction, and provided gas phase nucleation can be left out of account, we can put $p_{SiH_4(g)} = P_{SiH_4(b)}$ during the induction period ($k_1 < k_a$). The presence of a carrier gas prevents evaporation ($k_8 < k_{-2}p^2_{H_2}$). The desorption of $SiCl_2$ in the initial stage before nucleation is not expected to be rate limiting, and therefore the surface coverage of $SiCl_2$ will be low and can be disregarded. In that case we can write for the concentration of free surface sites

$$[*] = n_o - [SiH_4^*] - [H^*] - [Cl^*] - n_1$$

where n_o is the total number of sites at the surface. In adsorption equilibrium for every species an expression can be found as for [H*], where Eq. [A-4] leads to

$$[H^*] = K_3p^{1/2}_{H_2}[*]; \quad K_3 = k_3/k_{-3}$$

For $n_1 << n_o$ this gives

$$[*] = \frac{n_o}{1 + K_1p_{SiH_4} + K_3p^{1/2}_{H_2} + K_4p_{HCl}/p^{1/2}_{H_2}} \quad [A\text{-}15]$$

With the above approximation the steady-state Si adatom concentration becomes

$$\frac{n_1}{n_o} = \frac{K_1k_2p_{SiH_4}}{(k_{-2}p^2_{H_2} + k_6p^2_{HCl} + k_9)} \cdot \frac{1}{\left(1 + K_1p_{SiH_4} + K_3p^{1/2}_{H_2} + \dfrac{K_4p_{HCl}}{p^{1/2}_{H_2}}\right)} \quad [A\text{-}16]$$

In this equation the formation of silicon adatoms is governed by the equilibrium adsorption of SiH_4 (K_1), the rate of reaction of SiH_4 (k_2), and the total amount of free surface sites (as given by Eq. [A-15]), divided by the ways in which adatoms are removed from the surface in the initial stages before the actual nucleation starts, *i.e.*, etching by HCl and H_2 and reaction with the SiO_2 substrate (k_9).

AZ1350J as a Deep-U.V. Mask Material

B. J. Lin

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The conventional near-u.v.-and-visible(310-430 nm) resist AZ1350J is found to be useful as a mask opaque material for deep-u.v.(200-260 nm) lithography because of increased optical absorption at wavelengths below 300 nm. Only 0.2 μm is required to obtain a contrast of 100 using a Xe-Hg arc lamp and polymethyl methacrylate(PMMA) as the photoresist. The AZ mask does not deteriorate when exposed to light if kept in a vacuum below 10^{-2} Torr. Otherwise, about 300 passes can be expected. Experimental printing results show 1 μm images in 1.5 μm of PMMA. Special applications in projection printing, contact printing, and the portable conformable mask technique are discussed.

As the minimum feature size of integrated circuit patterns approaches the one micrometer range the near-u.v. and visible spectral region 310-430 nm used in conventional u.v. lithography becomes inadequate. The deep-u.v. wavelengths 200-260 nm make it possible to print 0.5 μm features spaced 0.25 μm apart in 1.8 μm of resist (1). Polymethyl methacrylate (PMMA) and many other E-beam resists are used as deep-u.v. resists instead of AZ1350J. Conventional Hg sources and the more efficient deuterium lamp supply the deep-u.v. exposing light. Quartz and sapphire are good transparent materials for the mask substrate. Conventional mask opaque materials such as chromium and iron oxide are also satisfactory for deep u.v.

In this paper, the use of the near-u.v. photoresist AZ1350J as a deep-u.v. mask opaque material is reported. The photoresist can be easily spun onto the substrate for pinhole-free coverage and can be stripped, permitting reuse of substrate without repolish. The developed image is readily used, thus eliminating the extra etching step and the rough edges caused by it. Being transparent in the visible region, the AZ mask facilitates alignment just as the dichroic iron oxide mask (2). However, because of less resistance to abrasion, it is most suited for projection printing and specific applications in contact printing.

Key words: photoresists, mask material, deep u.v. lithography, lithography, IC fabrication.

Spectral Transmission Characteristics

The spectral transmission of 0.2 μm of AZ1350J spun on a 0.25 mm quartz substrate was evaluated with a Beckman GT spectrophotometer in the region 200-460 nm. Considering that it is a photoresist and would be affected by exposure to light, measurements were taken at different exposure levels. The exposing light source was a 1 kW Xe-Hg arc lamp with a 0.07 NA condenser consisting of quartz and lithium fluoride elements. The power level is estimated to be of the order of 20 mW/cm^2 in near-u.v. and 1 mW/cm^2 in deep-u.v. An exposure of 0.5 sec adequately exposes the 0.2 μm of AZ1350J for a 1 min development in a 1:1 mixture of AZ developer and deionized water. An exposure time of 7 min is required to expose 1 μm of PMMA for a 1 min development in methyl isobutyl ketone (MIBK).

The measurements were taken at 0, 0.5, and 1 sec, then 1, 10, 40, and 100 min, and 3.7, 5.7, 9.7, 16.7, 33.3, 53.5, and 60 hr of near-u.v. and deep-u.v. exposure of the AZ resist to simulate the radiation effects on the mask during its lifetime. The 0, 1 sec, 10 min, 5.7, 33.3, and 60 hr curves are shown in Fig. 1. From an unexposed resist to that of 1 sec exposure, the transmission increases in the regions 310-460 nm and 245-295 nm. The former is due to bleaching of the photoactive compound in the near-u.v. region and the latter accounts for the deep-u.v. sensitivity of AZ1350J observed by Nakane and Mifune (3). With further u.v.

Table I. System parameters for wavelengths between 205 and 255 nm

Wavelength (nm)	205	215	225	235	245	255
Xe-Hg arc lamp (relative)	2	8	13	22	30	29
Deuterium lamp (relative)	0.363	0.431	0.467	0.440	0.386	0.363
Photosensitivity of PMMA (cm^2/W-min)	255	131	62.5	15.6	3.22	0.214
Transmission of quartz	0.880	0.891	0.898	0.902	0.910	0.913
Transmission of unexposed AZ	0	0	0	0.015	0.18	0.285
AZ after 5.7 hr	0	0.002	0.007	0.015	0.026	0.039
AZ after 60 hr	0.06	0.062	0.07	0.09	0.11	0.14
AZ after 51 hr in vacuum	0	0	0	0	0.007	0.016

exposure, the transmission decreases to a minimum after 5.7 hr then increases indefinitely. This latter bleaching effect is probably due to oxidation during exposure, because it is eliminated and the absorption becomes even higher for another wafer exposed 51 hr in 10^{-2} Torr of vacuum.

Figure 2 shows the change of transmission as a function of exposure time at 220, 258, 280, and 340 nm. From 230 nm and below, AZ1350J is not photosensitive as indicated by the absence of the first bleaching and it is also very opaque making it suitable to mask off deep-u.v. light. After 5.7 hr, it starts to bleach out if left exposed in the atmosphere, implying that the masking property would be lost if the mask is not used in a vacuum environment. The 258 and 280 nm lines are respectively the local maximum and minimum transmission points in the spectrum. The 340 nm line represents a typical line in the near-u.v. region and was chosen for convenience.

System Spectral Response

Because PMMA is not sensitive above 260 nm, any contribution to partial exposure through the AZ mask is in the region 200-260 nm. The local transmission peak at 258 nm may reduce contrast, especially when the 254 nm Hg line is present. Fortunately the photosensitivity of PMMA at 250 nm is two orders of magnitude lower than that at 220 nm (1), thus, offsetting the strong 254 nm emission. To gain a better insight, the total system response which includes the radiation spectrum of the light source, the transmission spectrum of the 0.2 μm AZ mask, and that of a 0.25 mm quartz substrate, and the spectral photosensitivity of PMMA, is evaluated quantitatively.

The spectra used are shown in Table I in increments of 10 nm. The spectra of the Xe-Hg and deuterium lamps are taken from manufacturer's manuals. The photosensitivity of PMMA is taken from Ref. (1). For the transmission spectrum of AZ1350J, the unexposed case and those exposed 5.7 and 60 hr as well as that aged 51 hr in vacuum are chosen.

The spectral response with the opaque part of the mask is obtained by multiplying the respective components at each wavelength interval. The transmission of quartz is not included since it has been already taken into account in the transmission measurements. For the transparent part of the mask, the transmission of AZ is replaced by that of quartz. Then, a summation in wavelength is taken for each response. Taking the ratio of the sum for the transparent part to the sum of the opaque part results in the contrast that can be achieved with the AZ mask. It is shown in Table II. A discussion of implications of Table II and printing results is given in the following section.

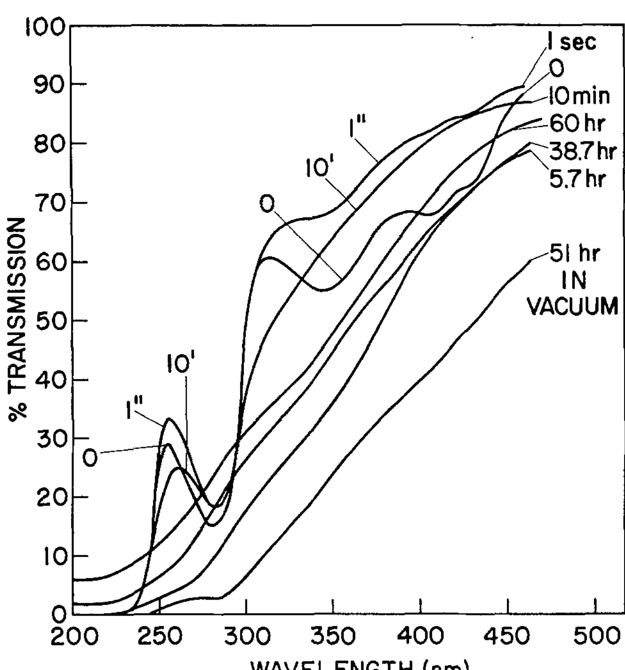

Fig. 1. The transmission spectrum of 0.2 μm of AZ1350J in different aging conditions.

Printing Results

The C-bar magnetic bubble propagation circuit pattern is used for our printing experiment. The C-bars have 1 μm arms spaced 1 μm apart. The original mask was delineated by E-beam in chromium on quartz substrate. AZ copies, with 0.2 and 1 μm of AZ1350J were made with near-u.v. light by con-

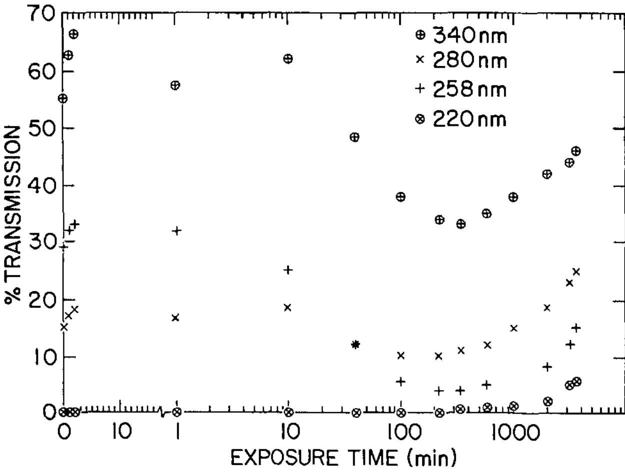

Fig. 2. Optical transmission of 0.2 μm of AZ1350J as a function of exposure time.

Table II. The contrast obtained with the AZ mask under different aging conditions and different light sources. The spectral characteristics of the sources, the mask, and the deep-u.v. resist are included

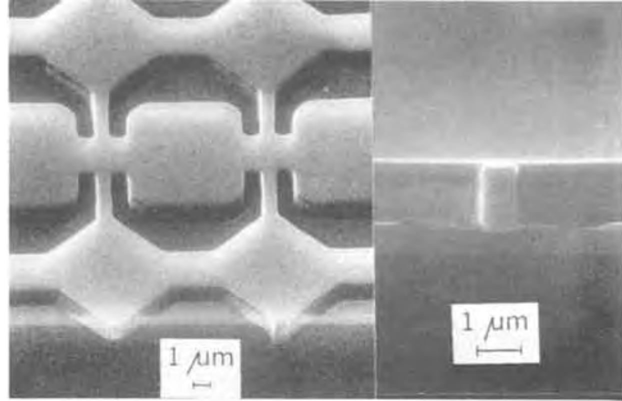
	Unexposed AZ	After 5.7 hr	After 60 hr	51 hr in vacuum
Mercury lamp	104	160	13	3,244
Deuterium lamp	474	363	14	16,600

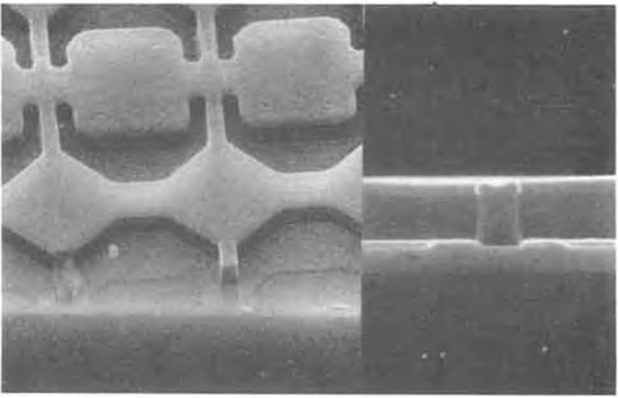
formable printing. A layer of 1.5 μm of PMMA 2041 was spun on Si wafers with 0.6 μm of SiO_2. Then, deep-u.v. conformable printing (4) was done with the original chromium mask and the two AZ masks, using an exposure of 8.3 min and a development of 1 min in MIBK. This exposure-development level is chosen so that the exposed resist is just completely developed.

The image delineated by the chromium mask is seen in Fig. 3a and 3b, at angles of 45° and 90° respectively. The side view Fig. 3b shows the line between the C's. The 0.1 μm aluminum evaporated for SEM purpose is also seen above the oxide layer. These are typical PMMA images that are routinely obtained by deep-u.v. conformable printing. The opened lines are slightly larger than the spacing exactly like those on the mask. Figures 3c and 3d show the image obtained with the 0.2 μm AZ mask aged by exposing for 0.5 sec. Though the calculated contrast is in the order of 100, the resist covered by AZ is still slightly exposed and appears as faint ghost lines along the edge of the patterns and pinholes in the corners. This exposure penetrates only 0.1 μm into PMMA as seen in the little indentation at the top of the 1 μm line between the arms of the C's in Fig. 3d. Therefore, inspite of the less appealing appearance, the image is usable. The image obtained with the 1 μm AZ mask is shown in Fig. 3e and 3f. Now, because of higher contrast in the mask, the ghost lines and pinholes are eliminated. However, the opened lines are much smaller when compared to that of the original mask, because the resist image in AZ has a natural overcut profile (5). When the pattern at the top of the AZ resist is controlled to resemble that of the original mask, the pattern at the bottom of the AZ resist is much smaller. This effect is useful for the AZ mask technique, because it offers a means to change the width-space ratio when copying from an existing mask. The method is easy to control as the resist thickness can be precisely varied by changing the spin speed. The range of control well exceeds the usual method of exposure-development manipulation.

When absolutely no ghost lines are allowed, a deuterium lamp can be used instead of the mercury lamp. From Table II, a 4.6 time increase in contrast is obtained. This is sufficient to eliminate the low contrast ghost lines as seen in Fig. 4 where 0.8 μm lines spaced 0.8 μm apart are delineated in 1.5 μm of PMMA. With a 200W deuterium lamp, an exposure time of 30 min is required for a 57 mm wafer to develop in a minute.

For conventional mask applications where the mask is prepared independently of the wafer, the contrast can be improved by aging the mask with a blanket exposure longer than 1 min. As seen in Fig. 2, the transmission maximum at 258 nm is eliminated to improve the contrast. It can be dramatically improved, if the mask is aged in a vacuum. In fact, if the mask is used in the atmosphere, the service life is limited to less than 300 passes because of the decrease in contrast due to bleaching. If the mask is used always in vacuum, its contrast ratio continues to increase.





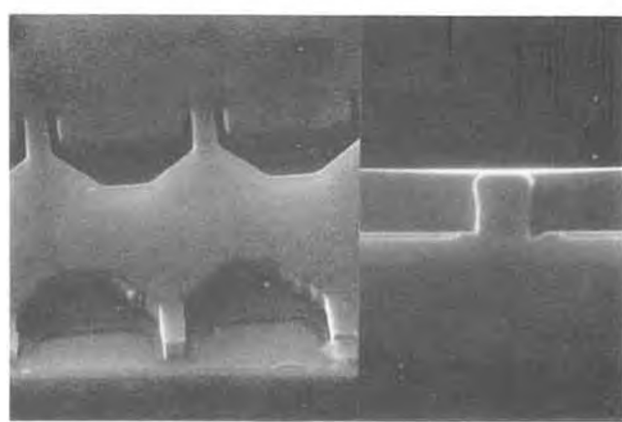


Fig. 3. (a) top left, 1 μm C-bar images in 1.5 μm of PMMA made with deep-u.v. conformable printing using a regular chromium mask and a Xe-Hg arc lamp; (b) top right, side view of 3 (a); (c) middle left, same pattern obtained with a 0.2 μm AZ mask; (d) middle right, side view of 3 (c); (e) bottom left, same pattern obtained with a 1 μm AZ mask; (f) bottom right, side view of 3(e).

Applications

Projection printing.—In a projection system, the mask does not come in contact with the wafer, therefore, it can be soft. The AZ mask is potentially very suitable for a Perkin-Elmer-type (6) all mirror system using deep-u.v. light to expose. The surface of the mask would be flooded with nitrogen or a simple vacuum fixture would be used to protect the mask from deterioration. If an optical window is used, the imaging optics has to be corrected for the extra window introduced. In this type of 1:1 system, an identical window can be placed at the wafer side to be symmetrical to that at the mask side.

The projection printer can also be used to make near-u.v. working master masks from a master AZ

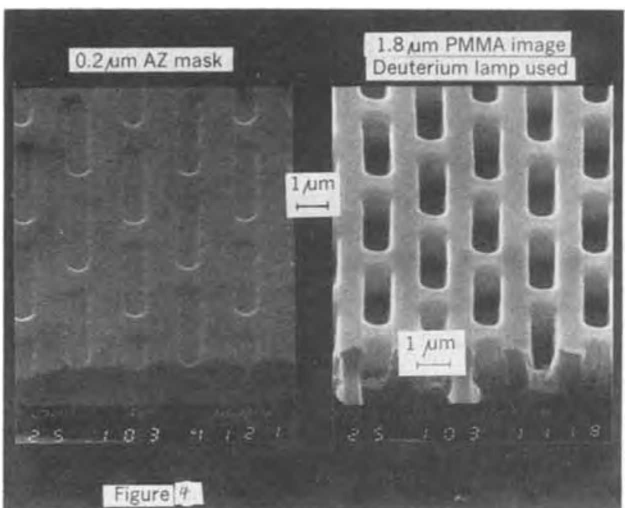

Fig. 4. 0.8 μm lines spaced 0.8 μm apart delineated in 1.5 μm of PMMA with a deuterium lamp.

mask directly fabricated with a photorepeater or an E-beam machine. Copying in deep-u.v. ensures adequate resolution on the working masks for near-u.v. applications. Using noncontact mask replication eliminates defects generated by the usual contact replication method.

Proximity printing.—With a mask-to-wafer gap of over 10 μm and flushing of nitrogen in between, AZ mask can be used for mass production in proximity printing. However, it is not feasible to use AZ mask when physical contact between the mask and wafer is inevitable. Then it can only serve as an intermittent mask to change the polarity, create a mirror image, or fine tune the width-to-space ratio of an existing mask.

Portable conformable masks.—The AZ layer can be directly spun on PMMA. After exposing in near-u.v. light, the AZ layer is developed to become an intimately contacted mask on PMMA for blanket exposure. An amplification of aspect ratio by a factor of 10 can easily be obtained. Existing near-u.v. machines can expose faster, with better resolution, and produce width-to-height aspect ratios only attainable with deep-u.v. lithography. A detailed report was published elsewhere (7).

Conclusion

The conventional mask opaque materials such as chromium and iron oxide cannot be completely substituted with AZ1350J, due to differences in durability. However, the advantages associated with the AZ mask are very desirable. It eliminates the etching of chromium and iron oxide which has long been troublesome. Evaporation or sputtering which requires a vacuum system and extreme cleanliness to prevent pinhole defects is no longer necessary. Substrate recycling is done by simply stripping the photoresist instead of an additional etching and expensive repolishing. Alignment becomes easier because of the dichroic property. Therefore, it is preferred whenever softness is not disadvantageous.

Arsenic Ion Channeling through Single Crystal Silicon

Yasuo Wada, Shigeru Nishimatsu,* and Norikazu Hashimoto

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo, 185 Japan

ABSTRACT

The main mechanism of anomalous tail generation in arsenic ion implanted layers is examined using silicon gate MOS capacitance flatband voltage and MOSFET threshold voltage measurements. Primarily, this approach measures the quantity of arsenic ions incorporated in silicon substrates as functions of polycrystalline silicon grain size. This method can measure ion amounts as low as 10^{11} cm^{-2} in the substrate. Only samples with large grains which extend across the polycrystalline silicon layer show flatband and threshold voltage shifts. Therefore, the mechanism of anomalous tail generation is attributed to arsenic ion channeling through single crystal silicon. Variations in the implant angle, as well as formation of a surface amorphous layer, are not sufficient to prevent channeling.

High dose arsenic ion implantation technology has attracted attention recently for the fabrication of high packing density MOS LSI source and drain regions (1, 2), due to its precise control and flexible application. Nevertheless, designers continue to ask for higher packing density LSI's. Therefore, it is necessary to fabricate even better-controlled source and drain regions than ever.

In order to control precisely the arsenic profile in these regions, it is imperative to control the initial arsenic profile, as well as diffusion conditions such as temperature, time, and ambient. However, arsenic ion implantation into single crystal silicon has been reported to generate an anomalous tail in deep substrate regions which exceeds the main peak profile (3, 4). This phenomenon has been observed using the neutron activation analysis. The possible causes were attributed to channeling (3), and to anomalous diffusion (4) through single crystal silicon. The concentration of the anomalous tail was reported to be less than 10^{17} cm^{-3}, which is almost too low a concentration to be detected by conventional analyses other than neutron activation analysis. Therefore, in order fully to investigate and identify this phenomenon, it was necessary to develop a new method which enables the determination of anomalous profiles in impurity implanted silicon layers.

This paper describes a highly sophisticated, yet simple method to determine the cause of anomalous arsenic profile in silicon. This new method utilizes conventional silicon gate MOS LSI technology (5), combined with controlled polycrystalline silicon grain growth phenomenon (6).

Fundamental Concept

In order to determine whether the arsenic incorporation mechanism is anomalous diffusion or channeling, polycrystalline silicon (poly-Si) gate MOS capacitor (MOS C) was used. The crystalline state of poly-Si can be controlled by impurity doping and annealing (6). Therefore, arsenic ions can be implanted through a gate, with the crystalline state between small grain poly- and single crystal. A schematic representation of the MOS C is shown in Fig. 1. If ion channeling takes place in the poly-Si layer with large crystals which extend across the thickness, some fractions of the implanted ions would reach the substrate and change the flatband voltage (V_{FB}) of the MOS C. On the other hand, V_{FB} would not shift, regardless of the implantation conditions, if the main cause of the anomalous profile in arsenic ion implanted layers is diffusion through single crystal silicon. This is because the gate oxide layer underneath the poly-Si layer prevents the arsenic ions from diffusing into the silicon substrate.

Experimental Procedures

MOS capacitor fabrication and capacitance-voltage measurements.—An MOS C was fabricated on a p-type, (100) oriented, 10 Ω-cm silicon wafer. The gate oxide thickness was 50 nm, and the poly-Si gate was 0.4 μm thick. Phosphorus (P) ions were implanted at a 50 keV acceleration energy to doses of between 0-4 × 10^{16} cm^{-2}. The dose rate was less than 3 μA/cm^2, keeping the substrate temperature during ion implantation less than 150°C (7). Therefore, anomalous effects due to substrate heating do not occur. The samples were then annealed at 1000°C for 20 min.

A 1 mm square poly-Si gate was delineated by conventional photolithographic technology. Then, arsenic (As) ions were implanted between 50-180 keV, to a dose of between 1 × 10^{15}-3 × 10^{16} cm^{-2}. The dose rate was also less than 3 μA/cm^2. Therefore, the substrate temperature rise during ion implantation was less than 150°C (7). The implantation angle was varied from 0 to 15 degrees in order to examine the channeling effect. Annealing, at 1000°C for 20 min in dry nitrogen, was performed to activate the implanted As ions. Low temperature annealing in a hydrogen atmosphere was carried out to eliminate unnecessary surface states almost completely.

The As ions in the anomalous tail distribute within less than 5 times as deep as the projected range (R_p) of the Gaussian distribution (3, 4). In this experiment, R_p was less than 0.1 μm (9). Therefore, considering the sample dimensions shown in Fig. 1, As ions should

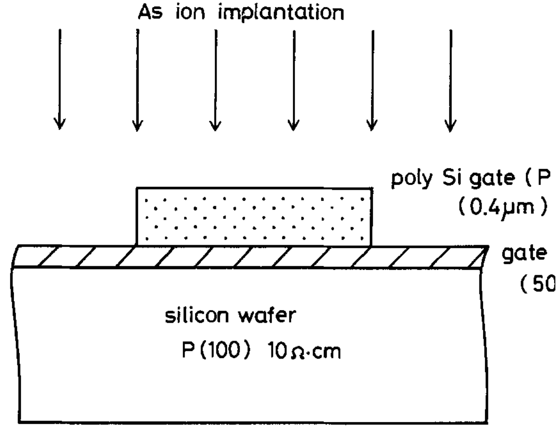

Fig. 1. Schematic representation of poly-Si gate MOS C utilized in this experiment: poly-Si thickness, 0.4 μm; gate oxide thickness, 50 nm.

* Electrochemical Society Active Member.

Key words: poly-Si grain growth, ion implantation, channeling, MOS LSI.

distribute within 0.1 μm from the gate oxide-silicon substrate interface. In addition, As ions have a diffusion coefficient as low as 3×10^{-2} μm/hr$^{1/2}$ at 1000°C (8); these experimental conditions do not cause As ions to diffuse into silicon substrate. Therefore, the implanted ions can be measured in terms of surface states (Q_{ss}). Furthermore, these thermal treatments after ion implantation almost completely eliminated the parasitic effects that might affect the flatband voltage shifts.

High frequency capacitance-voltage (C-V) measurements were carried out to evaluate flatband voltage shift (ΔV_{FB}) of the MOS C thus fabricated. The amount of ions incorporated into the substrate (N_i) is derived from the following equation (11)

$$N_i = \Delta V_{FB} C_{ox}/qA \quad [1]$$

where, C_{ox} and A are oxide capacitance and the area of the MOS C, respectively.

MOSFET fabrication.—MOSFET's were fabricated using conventional silicon gate technology (5). The gate oxide thickness was 50 nm, and the poly-Si gate was 0.4 μm thick. The poly-Si gate was doped with various concentrations of phosphorus, and annealed in dry nitrogen in order to control the grain size. As ions were implanted at 150 keV acceleration energy to a dose of 1×10^{16} cm^{-2}. Then the samples were annealed at 1000°C for 20 min in dry nitrogen. After metallizing with aluminum, the samples were annealed in hydrogen to minimize the surface states.

The electrical characteristics of MOSFET's thus fabricated were then measured. These characteristics, such as threshold voltage and tailing current, were measured under the conditions listed in Table I.

Results and Disscussion

Phosphorus doping concentration dependence of grain growth.—The crystalline state of heavily phosphorus-doped poly-Si is briefly reviewed first to provide a common reference point. Typical transmission electron micrographs (Hitachi HU 12A type) are shown in Fig. 2. These results indicate that, in the case of less than 2.5×10^{20} cm^{-3} phosphorus doping, the film consists of 0.1 μm mean grain diameter poly-Si. Therefore, there are four separate grains stacked vertically in 0.4 μm thick films. On the other hand, the poly-Si layer contains large crystals which extend throughout the thickness with more than a 5×10^{20} cm^{-3} doping. Although the mean grain diameter of the grains is approximately 0.8 μm, the poly-Si films are equivalent to single crystal silicon with regard to the masking effect against implanted ions.

Therefore, it is possible to examine the behavior of the arsenic ions implanted into various crystalline states from poly- to single crystal. The main orientation of the grown grains measured by electron diffraction was (110). The surface roughness of the poly-Si film remained almost the same as in as-deposited samples even after thermal annealing at 1100°C for 30 hr. A typical cross-sectional scanning electron micrograph is shown in Fig. 3. Therefore, implanted ion leakage through the thinner part of the gate need not be taken into consideration.

Flatband voltage shift.—Phosphorus doping concentration dependence of flatband voltage shift (V_{FB} shift) was measured for poly-Si gate samples with various grain sizes. Arsenic ions (As ions) were implanted at a 150 keV acceleration energy where the projected range and deviation are 0.0845 and 0.0292

μm, respectively, in silicon (9). The calculated profile was located well within the poy-Si layer, as shown in Fig. 4.

Typical results are shown in Fig. 5, in which the phosphorus doping concentration dependence of poly-

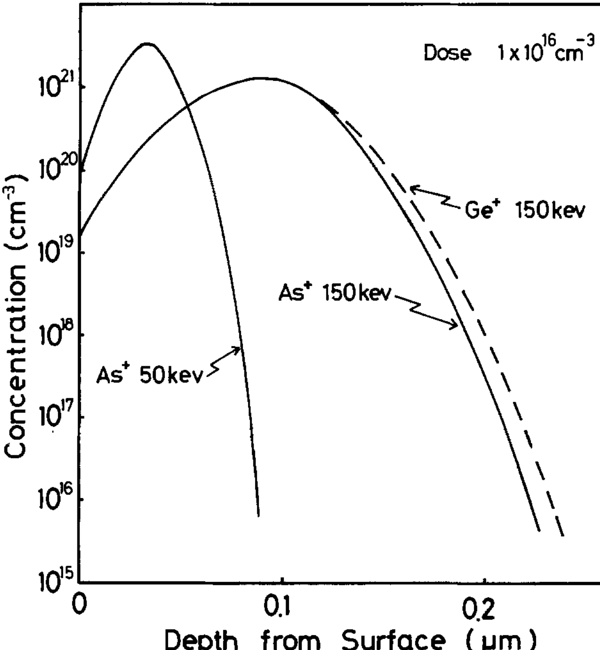

Fig. 4. Calculated ion profiles in Si

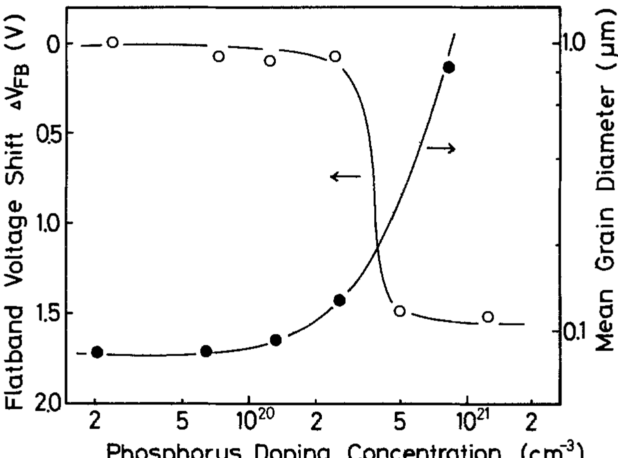

Fig. 5. Phosphorus doping concentration dependence of flatband voltage shift and mean grain diameter: poly-Si thickness, 0.4 μm; gate oxide thickness, 50 nm; arsenic ion implantation condition, 150 keV 1×10^{16} cm^{-2}.

Si grain growth is also depicted. The results clearly indicate that there is a correspondence between V_{FB} shift and poly-Si grain diameter. The samples with poly-Si grains extending across the gates show a V_{FB} shift of about 1.5V. The As^+ ion dose incorporated in the silicon substrate was approximately 10^{12} cm^{-2}, which is 10^{-4} of the total As dose.

These results indicate that anomalous diffusion in the large grain poly-Si layer does not take place. One possible reason for this phenomenon is As ion channeling through the large crystal poly-Si gate. However, some other mechanisms, which could contribute to the phenomenon, are considered in the following sections.

V_{FB} shift mechanism identification.—Possible reasons for the V_{FB} shift, or donor incorporation into substrate, are as follows:
(*i*) As^+ ion penetration through poly-Si region with single crystals extending across the thickness (channeling); (*ii*) Knock-on of P atoms into the silicon substrate by the implanted As^+ ions; (*iii*) Enhanced diffusion of donor ions through the gate oxide.

The following experiments were conducted to clarify the phenomenon and make identification of the mechanism possible: (*i*) Ge^+ or As^+ ion implantation, with the same profiles, in silicon; (*ii*) As^+ ion implantation at lower implantation energies.

The calculated As and Ge profiles are shown in Fig. 3. They show that nearly all the implanted ions in the profile are located well within the poly-Si layer. Therefore, if only the high energy As^+ ion implanted sample shows V_{FB} shifts, the cause of the V_{FB} shift is As^+ ion penetration through the large crystal poly-Si gate. If As and Ge implanted samples both show a V_{FB} shift, the main mechanism is P knock-on by the implanted ions. If all As^+ implanted samples show a V_{FB} shift, the cause must be anomalous diffusion through the gate oxide.

The experimental results revealed that only high energy As ion implanted samples exhibited V_{FB} shifts. Typical results for the acceleration energy dependence of V_{FB} shift are shown in Fig. 6. As^+ ions penetrate into the substrate when implanted at more than 140 keV. These experimental results indicate that the main mechanism of this phenomenon is As channeling through the large crystal poly-Si gates.

Location of arsenic ion penetration.—The TEM micrographs shown in Fig. 1 tend to indicate that some fraction of As^+ ions would channel through the grain boundaries and change the flatband voltage. Therefore, in order to define the location of As ion penetration, the tailing current of MOSFET's was measured.

The tailing current of a MOSFET (I_t) is expressed as (15)

$$\log I_t = \alpha V_g \quad [2]$$

Where, V_g is the gate voltage and α is the tailing factor, given by the following equation

$$\alpha = k \cdot T/q \cdot \log(1 + k_s t_{ox}/k_{ox} W_d) \quad [3]$$

where, the notations are listed in Table II.

The tailing current was then compared with conventional channel doping technology (10). If As ion penetration occurred uniformly over the poly-Si gate, these two results should coincide. On the other hand, if the As ions penetrate along specified paths, such as grain boundaries, then these two results should differ. This is because the effective channel width, W_d in Eq. [3], differs between these samples. Therefore, the gradient of the log I_t — V_g relationship (α) should be different.

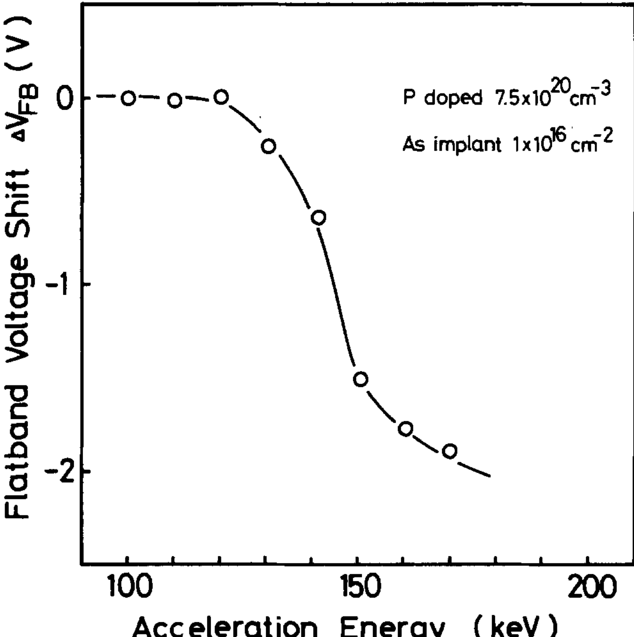

Fig. 6. Arsenic acceleration energy dependence of flatband voltage shift: poly-Si thickness, 0.4 μm; gate oxide thickness, 50 nm; arsenic ion dose, 1×10^{16} cm^{-2}.

Table II. Symbols in Eq. [3]

k	Boltzmann constant	1.38×10^{-23} JK^{-1}
T	temperature	298°K
q	elementary charge	1.60×10^{-19} C
k_s	dielectric constant of silicon	11.7
k_{ox}	dielectric constant of oxide	3.9
t_{ox}	oxide thickness	50 nm
W_d	channel width	15 μm

Typical results are shown in Fig. 7. They clearly reveal that the tailing current of the As-incorporated MOSFET's, shown by solid lines, is almost the same as that of the depletion-mode MOSFET's, calculated using Eq. [2], shown by the broken line. The larger the As incorporation amount becomes, the smaller becomes the gradient of the line. This is due to the residual current effect in heavily doped MOSFET's (15).

These results show that the As penetration occurs uniformly in the channel region. Therefore, the As incorporation into the silicon substrate is caused by As channeling through large poly-Si grains extending across the poly-Si gate.

Arsenic ion channeling through single crystal silicon.—The As ions incorporated by channeling into the substrate amount to as much as 10^{-1} of the total dose (3). In this experiment, the As ions in the substrate come to about 10^{-4} of the total dose. Therefore, the channeling phenomenon reported here should differ from that of previous reports.

The critical angle for As channeling is less than 8° (4), which is as low as that of P (13, 14). The implantation angle dependence of V_{FB} shift was measured and the results are shown in Fig. 8. They depict that V_{FB} shift does not depend on an implantation angle of less than 15°. Similar results were also reported, where the implantation angle was varied from 0 to 50° (4). Such off-angle channeling also takes place in the case of P or B ion implantation (12). This off-angle channeling should cause nonuniform sheet resistivity in ion implanted-annealed samples, and can be attributed to planar channeling in the silicon crystals (16).

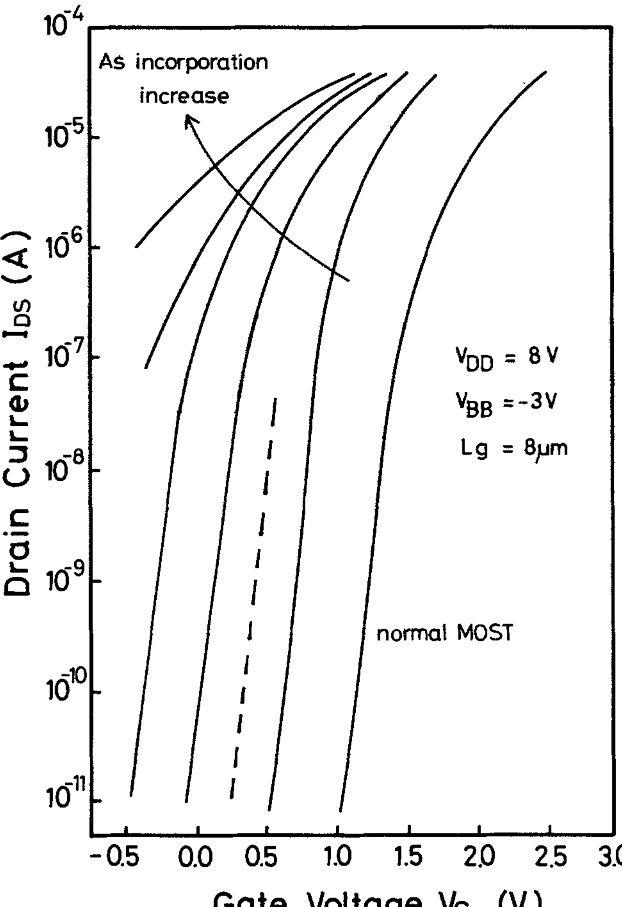

Fig. 7. Arsenic incorporation amount dependence of MOSFET tailing current, measured under the conditions listed in Table I. ———, experiment; – – –, calculation.

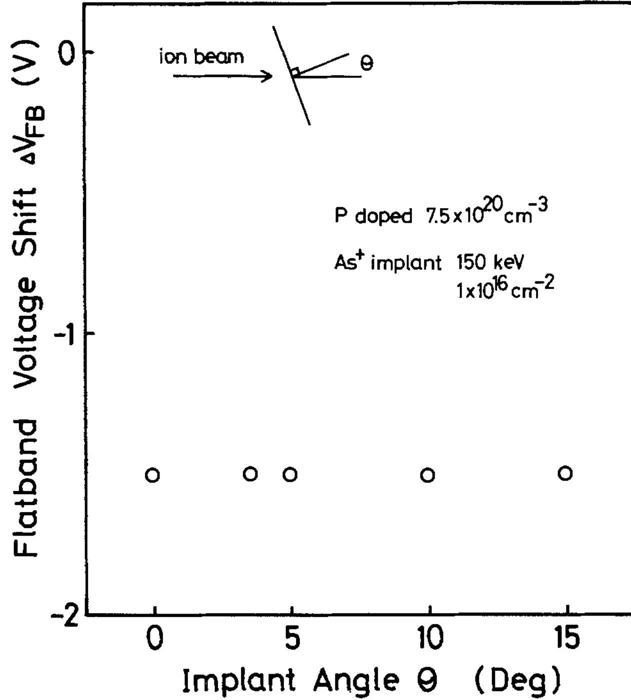

Fig. 8. Arsenic ion implantation angle dependence of flatband voltage shift: poly-Si thickness, 0.4 μm; gate oxide thickness, 50 nm; implanted at 150 keV to 1×10^{16} cm^{-2} dose.

In addition to these phenomena, dose dependence of V_{FB} shift was observed in this experiment. As expressed in the previous section, the substrate heating was less than 150°C. Therefore, an amorphous layer was formed under these heavy ion implantation conditions. Typical results are shown in Fig. 9, which indicate that the surface amorphous layer, generated by more than a 10^{14} cm^{-2} As$^+$ ion dose (3), does not prevent implanted ion channeling. The generally reported channeling phenomena are impeded by the surface amorphous layers, such as a silicon dioxide films or implanted-amorphized layers (3).

These results clearly show that the measurment method reported here is highly sensitive for measuring ion channeling through single crystal silicon. With large grains extending across the polycrystalline silicon layer, a kind of planar channeling could take place (16).

As shown in Fig. 6, the poly-Si gate, composed of single crystals, reduces the apparent stopping power for implanted ions. The reduction was approximately 30% in the case of samples with a 0.4 μm thick poly-Si gate and 50 nm thick gate oxide. Therefore, every precaution is necessary to prevent implanted ions from channeling, or being incorporated into the substrate. This might limit the practical application of ion implantation technology for source and drain region formation in silicon gate MOS LSI fabrication.

Conclusion

The anomalous profile of As$^+$ ion implanted layers was investigated by silicon gate MOS LSI technology, combined with the effect of the poly-Si grain growth phenomenon. The main mechanism of the anomalous

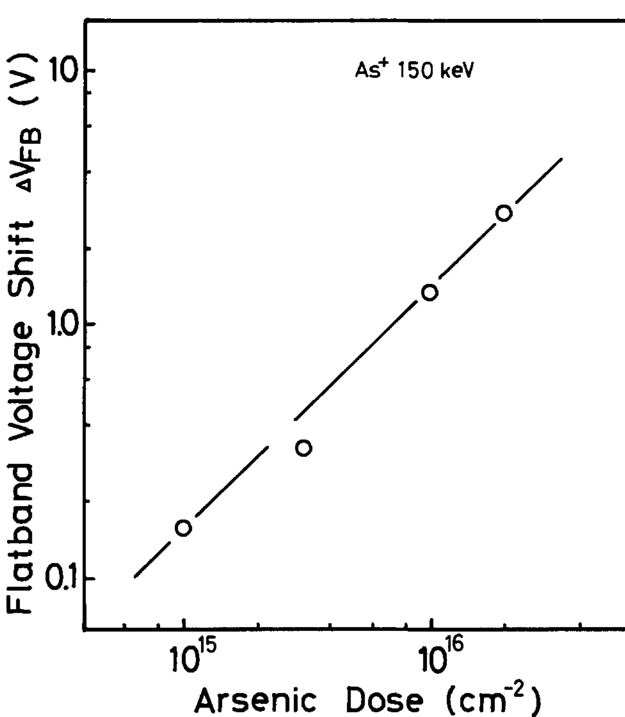

Fig. 9. Arsenic ion dose dependence of flatband voltage shift: poly-Si thickness, 0.4 μm; gate oxide thickness, 50 nm; implanted at 150 keV.

As profile was found to originate from As^+ ion channeling.

This channeling phenomenon at the 10^{-4} level is beyond the scope of channeling generally investigated. The surface amorphous layer generated by heavy As ion implantation, as well as by larger implantation angles, could not prevent this channeling phenomenon. Therefore, every care is necessary to control the As profile in single crystal silicon, such as source and drain regions of MOS LSI's and bipolar LSI emitters.

In addition, this phenomenon might limit the practical application of ion implantation technology when employing the self-aligned gate structure. This is because of the reduction of the singly crystallized poly-Si gate stopping power against the implanted As ions.

Acknowledgments

The Liquid Phase Epitaxial Growth of High Purity $Ga_{1-x}Al_xAs$

Amitabh Chandra and Lester F. Eastman

School of Electrical Engineering, Cornell University, Ithaca, New York 14853

ABSTRACT

We report the obtainment of high purity in the LPE growth of n $Ga_{1-x}Al_xAs$ ($0 \leq x \leq 0.3$) at 700°-675°C. Carrier concentrations at or below 1×10^{15} cm^{-3} have been consistently obtained, the lowest value achieved being under 3×10^{14} cm^{-3} at $x = 0.15$. It has been shown that these low carrier concentrations do not result from a high compensation ratio. In fact, $(N_D + N_A)$ has been measured to lie in the range 1-2 $\times 10^{15}$ for all but one of the ten samples examined. The Hall mobilities of these samples drop gradually from $\approx$100,000 cm^2 Vsec for $x = 0$ to 24,000 for $x = 0.18$ at 77°K, and from 8600 for $x = 0$ to 5100 for $x = 0.18$ at 295°K. We believe that a dominant shallow donor impurity (thought to be sulfur) is introduced into the melt with the aluminum. We find that the second epi-growth from a melt is significantly purer than the first, presumably due to the extra baking.

Gallium Aluminum Arsenide [$Ga_{1-x}Al_xAs$, or (Ga,Al) As] was first prepared in the late sixties by both a vapor transport technique (1) and liquid phase epitaxy (2), and its usefulness in electroluminescent devices was demonstrated (2, 3). Its importance as an electronic material was established in 1969-1970 with the development of the heterostructure laser (4-6), and later, the GaAs-(Ga,Al) As solar cell (7). For these applications, the (Ga,Al) As is required to be heavily doped, so that the background purity is not critical. Most reports of background net doping in (Ga,Al) As range from mid-10^{15} to mid-10^{16} cm^{-3} (8-12). In contrast, GaAs has been grown, with $(N_D + N_A) \lesssim 10^{14}$ cm^{-3} (13-15).

High purity and high quality (Ga,Al) As is desirable for fundamental studies such as alloy scattering and n-n heterojunction current rectification (16). Also, new device concepts such as the heterojunction FET (17) have arisen that require (Ga,Al) As of higher purity.

In this paper the growth of high purity $Ga_{1-x}Al_xAs$ by LPE is reported. We use the term high purity to denote material with $(N_D - N_A) \lesssim 10^{15}$ cm^{-3}, that is not heavily compensated. Our approach to obtaining purity has been to (*i*) start with a clean growth environment, (*ii*) grow at a relatively low temperature (700°C), and (*iii*) study the effect, on the layer purity, of the amount of aluminum in the melt, and of baking the melt.

LPE Procedures

The horizontal sliding boat LPE growth system used in these experiments is similar to the one described by Morkoc and Eastman (15, 18), with a continuously flushed nitrogen glove box added for substrate and melt loading. During the loading and unloading operations, the boat and melts are hence exposed only to trace amounts of oxygen. Substrates and melt components are transferred across the glove box walls through a 1½ in. diam hole that is normally kept sealed. During the transfer operation, a high N_2 flow rate (50-100 ft^3/hr) minimizes the introduction of air into the glove box.

Standard procedures (15, 18) for purifying the growth environment were followed. The quartzware was cleaned in electronic grade organic solvents and deionized water, and then soaked in aqua regia before a final rinse in deionized water and drying in a laminar flow hood. After assembly, the furnace tube and the pushrods were baked under flowing hydrogen at 950°C for 4 hr and at 900°C overnight. The graphite boat was Rf baked to 1200°C in a 10^{-7} Torr vacuum (followed by backfilling the vacuum chamber with ultrahigh purity nitrogen). The boat, loaded with gallium, was then hydrogen baked in the assembled tube at 850°C for 24 hr. The boat was used for several LPE experiments with several melts before conducting the experiments reported here.

Two series of (Ga,Al) As epilayers were grown. In the first (series F), ten layers of $Ga_{1-x}Al_xAs$ were grown on semiinsulating GaAs: Cr substrates from five melts, with x ranging from 0.02 to 0.18. Each melt was used for growing two layers before being discarded. The first layer grown from each melt is called a 'type-A' layer, the second is called a 'type-B' layer.

The second series of layers (series H) were grown at $x \approx 0.3$, and will be discussed later.

Practical thermodynamic calculated data for the Ga-Al-As system was obtained from the techniques described in Ref. (19) and (20). Figure 1 shows the equilibrium value of x as a function of the amount of Al added to a 10g gallium melt at 700°C. Shown also is the mass of GaAs required to saturate the Ga-Al melt.

0.01 in. MARZ grade Al wire supplied by Materials Research Corporation was used. The thin wire allowed the weight to be carefuuly selected by measuring the length (1.33 mg/cm). Crystal Specialities undoped

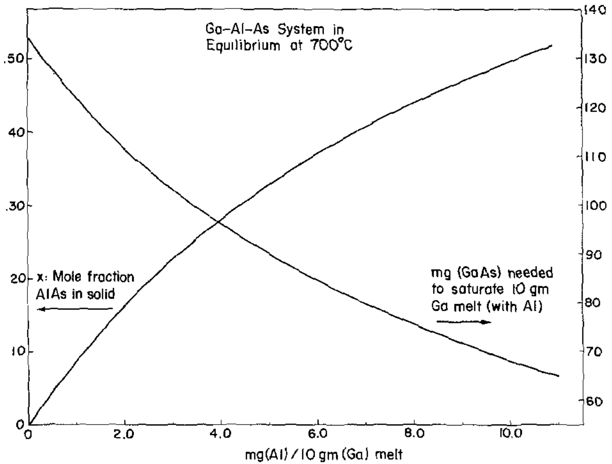

Fig. 1. Solidus isotherms for the Ga-Al-As system at 700°C, [from Ref. (19) and (20)].

Key words: $Al_xGa_{1-x}As$, high purity, LPE, III-V alloy semiconductor.

GaAs (with $\mu_{300} = 5500$ cm²/Vsec) was used as the source of arsenic. About 95% of the amount of GaAs required for saturation was added to the melt.

Growth melts were prepared as follows. The amounts of Al and GaAs required were first weighed out. Two pieces of aluminum, each of the required mass, were taken. The GaAs source material was standard cleaned, etched, and loaded into the growth well of the boat with a 10g ingot of six nines gallium (supplied by Alusuisse). The Ga + GaAs melt was baked for 36 hr at 700°C before adding the aluminum. Both pieces of aluminum were ultrasonically cleaned in organic solvents, and then etched in HF: methanol (1:1) in a plastic beaker at room temperature for 3 min. After the etching step, the Al oxidation was minimized by rinsing in methanol, and transferring under methanol into the nitrogen atmosphere of the glove box, where one of the pieces was dried in a flowing stream of dry nitrogen and added to the melt. The second piece of aluminum was weighed to estimate the weight loss of the loaded piece due to etching.

Types A and B epilayers were grown from the melts according to the following steps: (*i*) Load first set of source-seed substrate (s-s, undoped GaAs) and main substrate (m-s, nonconverting S.I. GaAs) in the boat at the same time the Al is added to the melt. (*ii*) After purging reactor with H_2 for 75 min (flow rate = 750 ml/min), bake at 700°C for 23 hr. (*iii*) Bring s-s under melt to saturate melt for 1 hr. (*iv*) Start ramp cooling (at 12°/hr). (*v*) After 15 min of growth on the s-s, initiate growth on m-s. (*vi*) Grow on m-s for 135 min, then end growth and cool reactor. (*vii*) Unload m-s and s-s. Load new m-s and s-s for 2nd run (type B) from melt. (*viii*) Repeat steps 2 through 6. (*ix*) Unload m-s and s-s. Discard melt. Prepare next melt.

It was not established whether or not it was necessary to reduce the air exposure of the etched aluminum. Dawson (21) and others (22) have emphasized the need to prevent any aluminum oxide being formed in the melt if good quality epitaxial layers are desired. They accomplish this by using techniques described in Ref. (21) and (22) and obtain shiny oxide-free melts. In our experience, a thin light brown oxide scum was observed on the Ga-Al-As melts, although it did not interfere with the growth of epilayers, which always had excellent surface morphologies (Fig. 2). However, the s-s's usually attained poor surface morphologies showing incomplete wetting (Fig. 3). We believe that the s-s was instrumental in wiping clean any oxide slag present at the bottom of the melt, thus providing a clean melt interface to the m-s.

As expected, the slag increased with each run. One melt (not of the F-series) was used for four growth runs. Only in the fourth run were any major morphology problems observed, and that over less than half the substrate area.

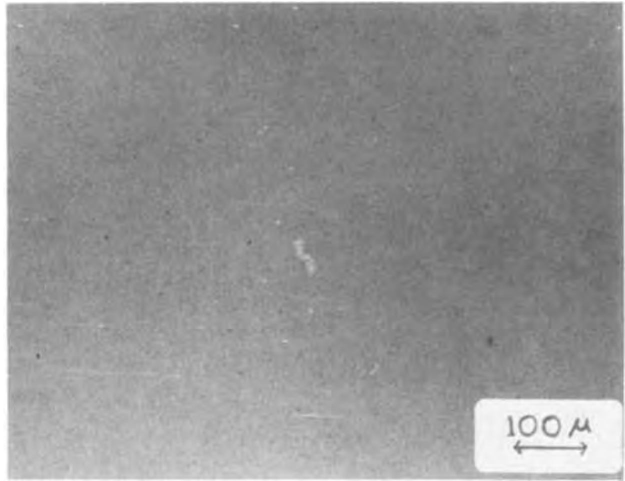

Fig. 2. Photomicrograph of the typical surface morphology of grown $Ga_{1-x}Al_xAs$ layers.

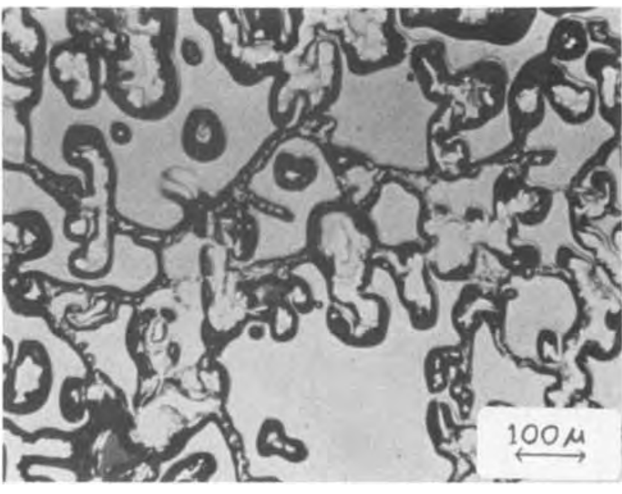

Fig. 3. Photomicrograph of the source-seed after a growth run, showing incomplete wetting presumably caused by oxide under the melt.

Composition Determination

Layer compositions were obtained from 5°K photoluminescence (PL) measurements. Radiative efficiencies were found to be significantly lower than normally observed for $Ga_{1-x}Al_xAs$. A likely cause was the postgrowth immersion in concentrated HCl to dissolve small melt droplets. It was suspected that HCl affected surface stoichiometry to greatly enhance the nonradiative recombination processes.

Values of x measured by PL correspond to the layer surface. We studied the uniformity of x with depth for sample F-18, using secondary ion mass spectroscopy (SIMS). The Al response was found to increase almost linearly by ~12% from the layer surface to the substrate interface, over a thickness of 9.2 microns.

Results of composition measurements are compared in Table I with values predicted theoretically from Fig. 1. For simplicity, layer compositions were assumed constant and equal to the surface values measured by PL. The theoretical compositions for type A layers correspond to the weight of Al added to the melt. For type B layers, the lowering of the aluminum content of the melt was estimated from the composition and thickness of the corresponding type A layer. Good agreement between theory and experiment supports the validity of the thermodynamic calculations of Ref. (19) and (20).

Carrier Density and Mobility Determination

Van der Pauw Hall samples were made from each $Ga_{1-x}Al_xAs$ epilayer with x below 0.2, and tin dots were alloyed in a hydrogen atmosphere using a strip heater. Good ohmic contacts were easily obtained. However, this technique did not work for the series of $x \simeq 0.3$ samples, with a native oxide on the surface preventing the tin from alloying with the semiconductor.

The results of room temperature and 77°K electron concentrations and mobilities determined by Hall measurements at B = 2000G are presented in Table II, which also lists the n_{295} determined by *C-V* profiling using Au Schottky barriers. "Uncorrected" Hall carrier densities were obtained by assuming the electrical thickness of the epilayers to be equal to their metallurgical thickness. Fairly large discrepancies were observed between the uncorrected n_{Hall} and $n_{C\text{-}V}$. However, by accounting for the depletion of free carriers near the surface and the substrate interface of the epilayers (23), so that the electrical thickness was lower

than the metallurgical thickness, this discrepancy was reduced significantly.

Carrier freezeout in these samples, on cooling from 295° to 77°K, was well within experimental error, and was therefore not considered to be significant. This indicated that the donors in the $Ga_{1-x}Al_xAs$ epilayers were predominantly shallow, thereby ruling out the possibility that the main donor species was oxygen.

The electron mobility of $Ga_{1-x}Al_xAs$ was found to drop rapidly with x. Figures 4 and 5 show the μ_{77} and μ_{295} of the F series layers plotted against x. At both temperatures, the experimental points fall along two distinct curves, one for the type A samples, and the other for the type B samples. For each A-B pair grown from the same melt, the type B sample has a significantly higher mobility than the type A sample, at both temperatures. The decrease in x can account for only a small fraction of the increase in μ, as is clearly seen in Fig. 4 and 5. It is therefore reasonable to infer that the type B samples are significantly purer than the type A samples.

The large reduction of μ_{77} with x cannot be accounted for by the relatively small increase in the electronic effective mass m* in the range $0 < x < 0.2$ (24). Hence the decrease in mobility must be largely caused by increased electron scattering. Upper valley transport and intervalley scattering at low fields are negligible for $x < 0.2$ at 77°K (9), while phonon scattering is expected to remain approximately constant as x increases. That leaves ionized impurity scattering and alloy (25) space-charge (26) scattering.

To determine the cause of the increase in scattering with x in our samples, we undertook a study of the intravalley scattering mechanisms in $Ga_{1-x}Al_xAs$. The details of this investigation will be described elsewhere (27). Use was made of the different temperature dependence of alloy scattering and ionized impurity scattering. Hall data was taken on the $Ga_{1-x}Al_xAs$ samples at 25°-110°K at B = 2000G. Figure 6(a) and (b) show the plots of μ_H *vs.* temperature measured. By fitting this data to our theoretical model, we were able to obtain estimates of N_A and N_D, as well as information on alloy scattering for each sample.

The alloy and space charge scattering mechanisms were grouped together because two scattering cross sections have the same energy and temperature dependence (28). Kaneko *et al.* (28) and Stringfellow (29) have found space charge scattering to dominate over alloy scattering in their samples. The same empirical x-dependent space charge scattering factor

$$N_SQ = 5 \times 10^3 + 6.3 \times 10^5 x \ (\text{cm}^{-1}) \quad [1]$$

is used by both authors to obtain good agreement between theory and experiment. In our layers, however, the extent of alloy/space-charge scattering was only a fraction (7-15%) of that suggested by Eq. [1], and could be accounted for by alloy scattering alone. We could therefore conclude that our (Ga,Al)As samples were high quality with a minimal density if any of the space-charge scatterers described in Ref. (26).

The increase of phonon and alloy scattering and the decrease of ionized impurity scattering with increasing temperature causes the μ *vs.* T curves to peak at a temperature T_{max}, which is lower for purer samples. The curves in Fig. 6 show T_{max} to be in the range 50°-60°K, indicating that (*i*) these samples are pure, rather than heavily compensated, and (*ii*) the type B samples are purer than their type A counterparts.

Values of N_A and N_D obtained from this analysis are plotted in Fig. 7. The heavy lines connect values of type A samples, while thin lines connect type A points to corresponding (same melt) type B points. The following observations are clear: (*i*) For type A samples, N_D increases with x, while N_A remains approximately constant, (*ii*) For each A-B pair, both N_A and

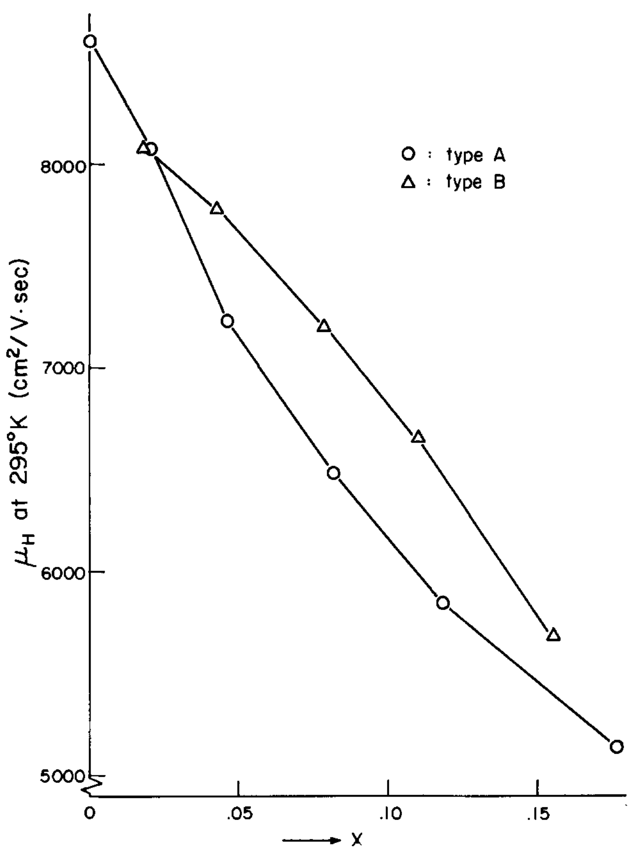

Fig. 5. Room temperature Hall mobility data (at 2 KG) of $Ga_{1-x}Al_xAs$ layers, plotted against x.

N_D are lower for the type B sample. However, the decrease in N_D is larger, resulting in a lower net carrier concentration, and (*iii*) The compensation ratio $(N_D + N_A)/(N_D - N_A)$ is ≈ 2 for most samples, and < 4 for all samples, as is typically observed in undoped GaAs.

Discussion

An explanation of these experimental results is that a donor species is introduced into the melt with the aluminum. Examining the supplier's material analysis (30) reveals that the major impurities present in the aluminum are O(30 ppm), C(20 ppm), N(5 ppm), S(5 ppm), H(3 ppm), Ca(0.3 ppm), and Mg(0.26 ppm). All other impurities have quoted concentrations below 0.1 ppm. Segregation coefficients of Sn and Si in GaAs are too low to account for the increase in the donor densities. The group VI donors, however, namely S, Se, and Te, have estimated segregation coefficients (K) of ~45, 14, and 4.5 (31, 32) respectively at 700°C. We have already ruled out oxygen as a possibility. Thus the donor introduced with the aluminum is most likely to be sulfur.

A simple calculation for sample F-14 (for example) shows that there is approximately one atom of Al present in the melt for every 3870 atoms of Ga, and 5 ppm S in Al corresponds to one atom of sulfur for every 7.8×10^8 atoms of gallium. Using $K = 45$ gives a donor incorporation of about 1.3×10^{15} cm^{-3}, which is the correct order of magnitude. (The close agreement of this number with the experimental value of N_D for F-14 is, of course a coincidence.) Thus our contention that the donor is sulfur is quite plausible.

The donor density in the melt drops quite significantly for the second (type B) epigrowth. Donor incorporation into the type A epilayer can account for only a 1% reduction of the donor concentration in the melt. Some other mechanism of donor loss from the melt must therefore exist.

Further experiments (H-series) were conducted in an effort to obtain purity in $Ga_{1-x}Al_xAs$ at $x = 0.3$. With a total bake time of 40 hr at 700°C after the addition of aluminum, the carrier concentration obtained in the first epilayer (type A) was 2.5×10^{15} cm^{-3} (± 25%). For a second melt, a total bake time of 92 hr at 700°C after adding aluminum gave a first epilayer with $n = 1.4 \times 10^{15}$ cm^{-3}. A third melt was baked after adding aluminum at 900°C for 13 hr followed by 92 hr at 700°C, before growing the first epilayer. The carrier concentration obtained was 1.1×10^{15} cm^{-3}. In each of the three cases, the substrates were loaded and baked along with the melt for 22 hr prior to growth.

In their study of Cr doping of high purity n GaAs epilayers grown at 700°C, Woodard and Eastman (32) have used the technique of baking the Ga-As-Cr melt at 900°C for 15 hr to remove a volatile donor impurity that is introduced with the chromium. This, however, increases the silicon contamination of the melt, which must then be baked at 700°C to lower the silicon concentration. They have shown that about 96 hr of baking at 700°C brings the total Si incorporation to $\lesssim 2 \times 10^{14}$ cm^{-3}. Our observations on growth from Ga-Al-As melts show the positive effect of such baking techniques on layer purity, but also indicate that the purification process is slower than in the Ga-As-Cr case. This is probably because the oxide on the melt prevents the sulfur from escaping, except through cracks.

We suspect that the oxide slag itself is responsible for gettering the impurities from the melt. We speculate that each time the boat is taken out of the furnace tube into the glove box, trace amounts of oxygen are trapped between the surfaces of the boat. On baking, some oxygen diffuses to the melt forming aluminum oxide which collects at the melt's surfaces. The extent of impurity gettering by the slag is limited by the amount (of slag) produced; hence the correlation between the number of previous epi-runs from a melt and the layer purity.

In conclusion, we have obtained the highest purity in $Ga_{1-x}Al_xAs$ ($x < 0.3$) reported so far to our knowledge by growing at 700°C in a clean environment, and by following baking procedures after adding aluminum to the melt. These layers were grown in a reactor which gives a μ_{77} of only 100,000 cm^2/Vsec for undoped GaAs, compared with 150,000-170,000 cm^2/Vsec obtained in the best systems in our laboratory, indicating room for furher improvement. Also, the possibility exists of using Woodard's (33) 900° + 700°C baking technique to obtain even higher purity, provided oxide slag formation can be prevented by using Dawson's methods (21).

Bird's Beak Configuration and Elimination of Gate Oxide Thinning Produced during Selective Oxidation

T. A. Shankoff, T. T. Sheng, S. E. Haszko, R. B. Marcus, and T. E. Smith

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In the selective oxidation scheme for processing Si MOS devices, Si_3N_4 is used to mask gate oxide areas against the isolation oxidation. After removing the Si_3N_4, gate oxide is grown. This scheme produces three topographical features which have ramifications in subsequent processing and in device properties: a notch in the isolation oxide, penetration of the isolation oxide under the masking Si_3N_4, and thinning of the gate oxide at the isolation oxide edge; the first two features form the bird's beak configuration. The transmission electron microscope was applied to thin film (<1 μm) cross sections through the bird's beak in order to obtain an accurate description of these features. The bird's beak extended typically 1.5 and 0.8 μm in the n- and p-channel structures, respectively, leading to a corresponding decrease in the active device length of 3.8 and 2.3 μm for the 1.4 μm thick isolation oxide. Gate oxide at the edge of the bird's beak was thinned 35-100% in the n-channel samples and 20-50% in the p-channel samples. It was found that oxidation subsequent to the isolation oxidation and Si_3N_4 removal destroys the oxidation barrier (wet oxidation seemingly more effective than dry and more convenient). Thus, a method which incorporates an additional, short, sacrificial wet oxidation step between isolation and gate oxidations, in order to overcome the thinning phenomenon, is described.

One of the Si IC device processing schemes designed to minimize surface texture is the selective oxidation process. According to this method the initial isolation oxide is formed by selective thermal oxidation using a Si_3N_4 mask over regions of the chip that will later become active device areas. In this manner, the SiO_2 step at the surface is reduced by $\sim$ 50% compared with the step height in conventional processing.

It has been observed that this processing scheme produces a bird's beak configuration (1-4) at the edge of the isolation oxide, and that subsequent gate oxidation (after removal of masking Si_3N_4) often results in a thinning of the gate oxide next to the isolation oxide. The thinning of the gate oxide has been attributed to the presence of a thin layer of a Si nitride (or oxynitride) on the Si which serves as a barrier to oxida-

tion; the nitride is believed to occur as a result of NH_3 generation from the masking Si_3N_4 during isolation oxidation followed by interaction of the NH_3 with the Si substrate (2). One processing procedure that has been introduced in an attempt to minimize the frequency of occurrence or magnitude of this anomalous thinning is the use of an additional Si_3N_4 etch (4). After the isolation oxide is grown, the masking oxide or oxynitride over the Si_3N_4, the Si_3N_4, and the underlying oxide layer (called the "pad oxide") are removed by BHF, hot H_3PO_4, and BHF, respectively. An additional hot H_3PO_4 treatment is used to dissolve any Si nitride that might exist on the Si surface. However, oxide thinning is sometimes observed even after the additional Si_3N_4 etch is used and is sometimes not observed without the second etch. Gate oxide thinning has an important influence on the properties of the transistor subsequently built in that region, and the fact that the magnitude of the oxide thinning is variable only emphasizes the serious nature of the problem.

This study was initially intended to describe in some detail the configuration at the bird's beak region which results from selective oxidation processing, with particular attention directed to gate oxide thinning.[1] During this work, sufficient understanding of the thinning phenomenon was generated so as to result in the development of a convenient method for its elimination. We will address this topic after an initial discussion of the typical selective oxidation structure.

Experimental

Samples were examined at various stages of selective oxidation processing by making thin film cross sections through the bird's beak using a technique described earlier (6) and performing the examination with the transmission electron microscope. Some studies were also made by scanning electron microscopy. Seven p-channel (111) wafers were studied. These wafers were processed through the intermediate dielectric stage; they were then sectioned and examined in the TEM. Six samples from three (100) wafers receiving n-channel processing also were examined; these samples represented five stages in processing. The processing sequence is outlined in Table I; a list of samples is shown in Table II.

The samples studied with the transmission electron microscope were sections through the bird's beak along a plane orthogonal to both the sample surface and the edge of the isolation oxide on the device surface. The samples were prepared by (*i*) cleaving small pieces from the wafer, (*ii*) mounting 6-8 pieces on their sides, embedding in epoxy, (*iii*) lapping the composite to a thickness of 100-150 μm, and (*iv*) ion mill thinning to a final thickness of < 1 μm. Studies were performed on a JEM200A transmission microscope at 200 keV. In some cases the device surfaces of samples were coated with $\sim$ 0.5 μm polysilicon before thinning to protect the surfaces during handling.

Some samples were also examined with a Cambridge Stereoscan scanning electron microscope at 20 keV.

Results and Discussion

Structural study.—The main features of the isolation and gate oxides formed during both n- and p-channel processing are shown in the low magnification electron micrographs of samples A and B in Fig. 1. Figure 1(a) shows the 1.5 μm isolation oxide at the sides, and 1000Å SiO_2 under the 1200Å Si_3N_4 at the center. The isolation oxidation left notches in the oxide at the edges of the Si_3N_4 (N). After removal of the Si_3N_4 and the underlying oxide, the notch features are made softer [Fig. 1(b)] and after gate oxidation, some

[1] A similar study of a gate oxide thinning was just concluded for the case of conventional processing, where it was shown that thinning results from the slower oxidation rate at the instep at the Si-isolation oxide interface, in turn controlled by the steepness of the field oxide wall and the angle of the instep (5).

thinning of the gate oxide is seen (T) at the typical location, just outside the bird's beak (B).

Higher magnification electron micrographs of the bird's beak region in three samples (C, D, E) from a p-channel wafer are shown in Fig. 2. The length of the bird's beak (measured from the lowest point of the notch) is shown for the three samples, and the average value is $\sim$ 0.8 μm. Gate oxide thinning produces a dip only in the upper surface of the gate oxide (at the

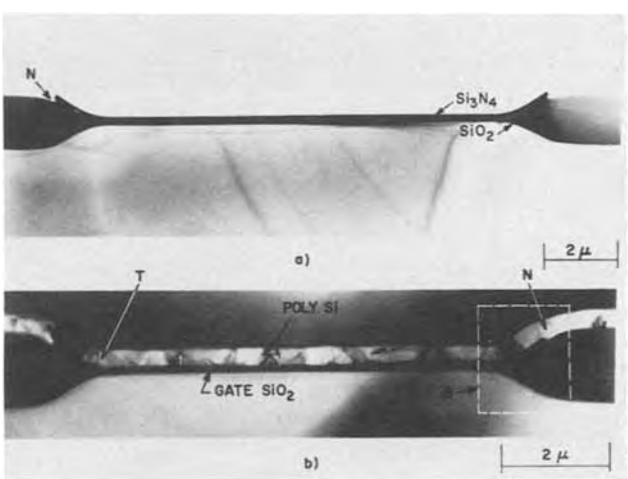

Fig. 1. TEM of cross section of p-channel samples (a) after isolation oxidation (sample A) and (b) after gate oxidation (sample B). The notch left in the isolation oxide following oxidation (N) and the site of gate oxide thinning (T) are shown. The region commonly referred to as the bird's beak is outlined (B).

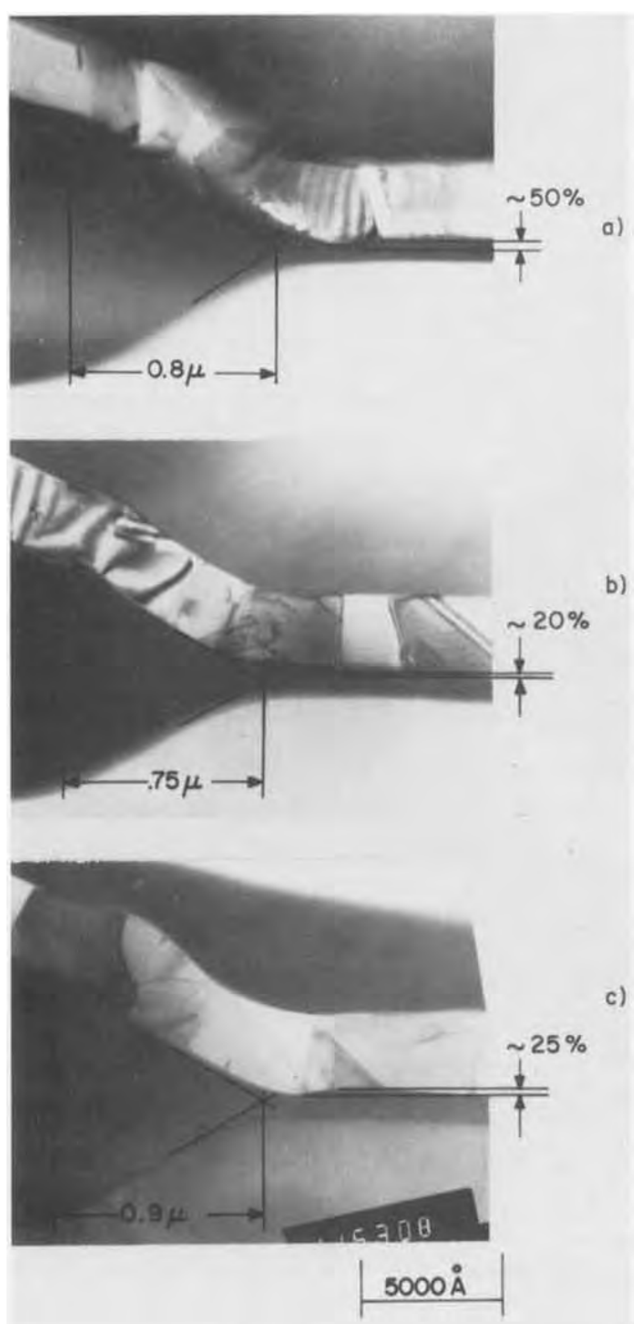

Fig. 2. TEM of cross section of p-channel samples at bird's beak. Figures 2(a), (b), and (c) show samples C, D, E, respectively. The bird's beak length is 0.7-0.9 μm and the percent gate oxide thinning at the sites T are shown.

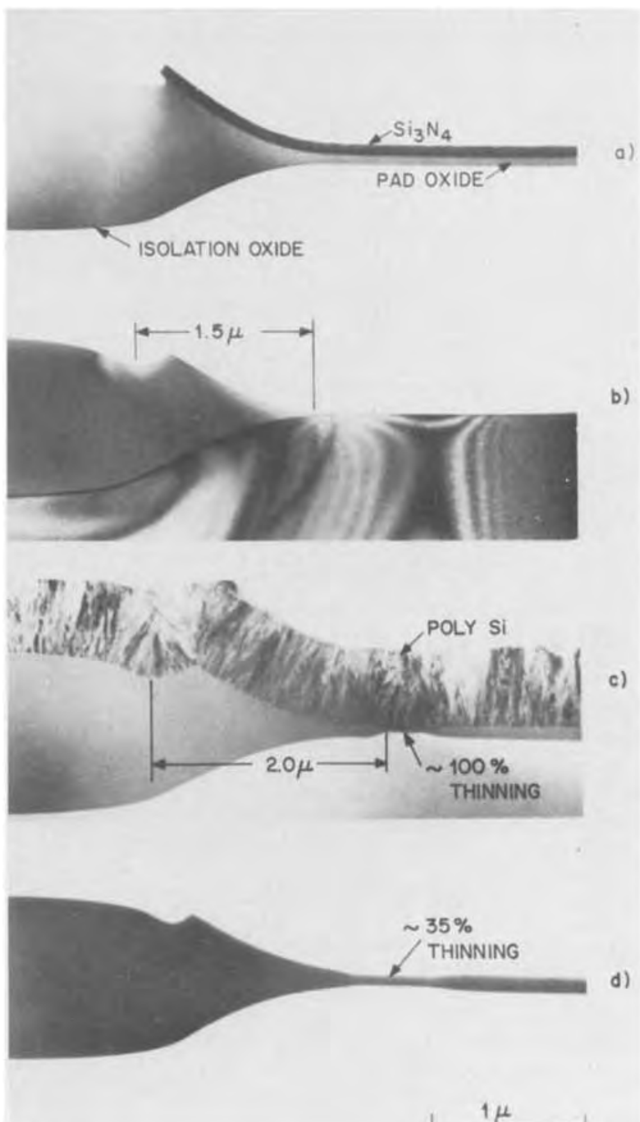

Fig. 3. TEM of cross sections of n-channel samples at bird's beak. Figures 3(a)-(c) show samples F, G, H taken from wafer 4 at different stages of processing; Fig. 3(d) shows sample I. The length of the bird's beak in 3(b) is 1.5 μm, and ~100% and ~35% gate oxide thinning are seen in Fig. 3(c) and (d), respectively.

gate oxide-poly-Si interface) on all the p-channel samples examined. The percentage thinning is indicated for these samples, and the average value is ~ 30%. This value is only approximate since the samples were tilted to varying degrees while being photographed making it difficult to take accurate measurements.

Cross sections of n-channel structures are shown in Fig. 3(a)-(d) (samples F-I, respectively). Figure 3(a)-(c) show parts of the same wafer after the wafer has undergone successive processing treatments. The distance from the point of the bird's beak to the notch [Fig. 3(b)] is 1.5 μm. It is noteworthy that nearly 100% gate oxide thinning was found on sample H [Fig. 3(c)] which had received the second Si_3N_4 etch, while sample I which did not get the second Si_3N_4 etch showed only ~ 35% gate oxide thinning [Fig. 3(d)]. It should be pointed out that the thinning seen on the n-channel samples is symmetrical, *e.g.*, both surfaces of the gate oxide move together, as would be expected if a barrier caused slower oxidation at that site. This is contrary to the case observed with the p-channel samples (Fig. 2) where thinning was one-sided.

Another sample from wafer No. 4 is shown at higher magnification in Fig. 4. Superimposed on the micrograph is an outline of the bird's beak obtained from Fig. 3(d). It is clear that the 0.38 μm oxide thinned region (~ 90% thinning) begins near the tip of the beak of the isolation oxide. Some further oxidation at the isolation oxide edge of the beak clearly has occurred during gate oxidation, and it would therefore seem that the barrier to gate oxidation extended only over a distance of ~ 0.38 μm on the Si surface and was not present over most of the bird's beak region. The lack of coincidence of the superposition at the notch is attributed to the undulating character of the notch as one moves along the surface, shown in the scanning electron micrographs of Fig. 5. A top view of wafer K is shown in 5(a) and two parallel lines corresponding to the notch (N) and oxide thinning (T) are visible even through the 1 μm thick P-glass and through the 6000Å polysilicon. SEM photographs of a cross section of sample L and a top view of the same sample are shown in Fig. 5(b) and 5(c), respectively; the undulating nature of the notch is due to the shape of the masking

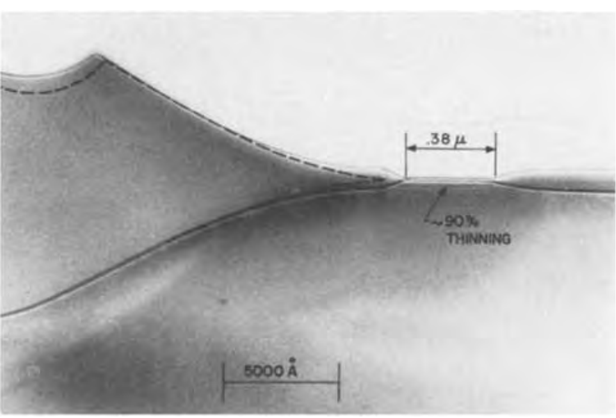

Fig. 4. TEM of cross section of sample J showing ~90% gate oxide thinning and superpositioning of bird's beak profile prior to gate oxidation [obtained from Fig. 3(b)].

Si_3N_4 edge which in turn is a result of photolithographic processing.

The bird's beak can be defined as the horizontal distance between the site where the isolation oxide begins to thicken and the projection of the notch minimum. This value is 1.5 μm (Fig. 3(c), 3(d), 4). The

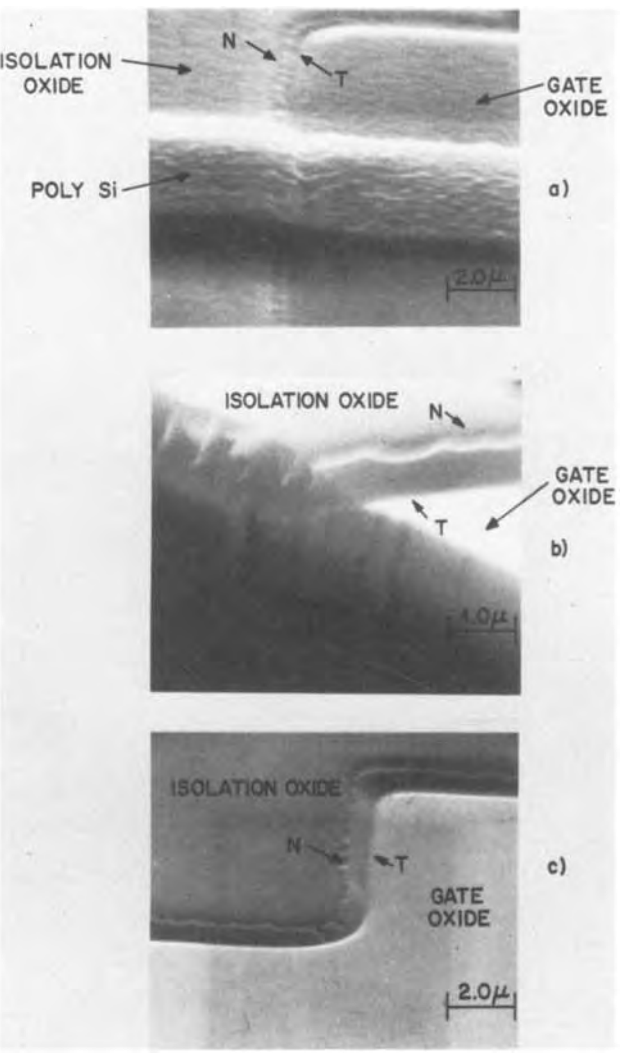

Fig. 5. SEM of samples K (a) and L (b), (c). The isolation oxide notch (N) and gate oxide thinning (T) are indicated. The undulating shape of the notch is partially responsible for the lack of coincidence of the notch in Fig. 4 with the superimposed profile of Fig. 3(b).

source and drain region will be shorter than the measured length of the masking Si_3N_4 before isolation oxidation by 1.5 μm × radial factor. For samples used in the present study with 1.4 μm isolation oxide, the shortening is 1.9 and 1.2 μm per edge for the n- and p-channel samples, respectively.

The bird's beak length in the p-channel samples is 0.8 μm (Fig. 2) and the pad oxide thickness under the 1200Å Si_3N_4 was 730Å. In a published study on geometrical features at the bird's beak in a selective oxidation processing scheme (1), a direct correlation was found between beak length and thickness of underlying pad oxide; for a Si_3N_4 thickness of 500Å and isolation oxide thickness of 0.65 μm, the bird's beak length changed from 0.55 to 0.75 μm as the underlying oxide thickness varied from 100 to 500Å. The data in Ref. (1) do not permit an easy extrapolation to the thicknesses of isolation oxide and Si_3N_4 used in the present study, and work is in progress to determine the relationship between Si_3N_4 thickness, pad oxide thickness, and beak length.

It is obvious that a barrier to oxidation is present of a type described by Kooi *et al.* (2). The mechanism proposed for formation of the barrier involves reaction of steam and the masking Si_3N_4 in the formation of SiO_2 and NH_3 (or NH_3-like species) followed by NH_3 diffusion through the oxide pad beneath the Si_3N_4 to the Si substrate at the boundary of the thick and thin oxide regions; subsequent reaction produces some form of Si nitride or oxynitride. The present study shows that in the processed n-channel selective oxidation structure the barrier forms a band which begins near the tip of the bird's beak and extends less than one micron away from the tip. Additional oxidation occurs at the isolation oxide edge during gate oxidation, and the barrier does not extend in a direction into the beak. Sample H [Fig. 3(c)] was from a wafer which received a second Si_3N_4 etch which was added to dissolve the oxidation barrier which is presumed to be a Si nitride or an oxynitride. Sample H shows more gate oxide thinning than sample I [Fig. 3(d)] which did not receive the second etch. It is clear that the gate oxide thinning phenomenon is variable and not predictable, at least for the samples studied here.

A solution of the thinning problem.—Tentatively making the assumption that NH_3, or a closely related species, is responsible for formation of the oxidation barrier, (100) Si wafers were exposed to various NH_3 ambients, and the subsequent oxidation behavior was noted (7). In that study it was shown that oxidation, though impeded, would commence once the barrier was overcome. In particular, steam oxidation was found to be more effective than dry oxidation in breaking down the NH_3 induced barrier. It was also shown that, once the barrier layer is consumed by oxidation, a normal wet or dry oxide growth curve is obtained. Experiments were continued on patterned wafers processed according to a typical selective oxidation schedule.

After a 1050°C wet isolation oxidation masked by a composite 1200Å Si_3N_4/1000Å pad oxide layer, a 3 in. B-doped <100> wafer was treated in 160°C H_3PO_4 for 60 min and BHF for 90 sec to expose the Si substrate in the gate regions. After dry oxidation at 1000°C to a 1000Å thickness (typical gate oxide), the wafer was evaluated to determine the degree of oxide thinning. The photograph in Fig. 6(a) is a TEM profile of this wafer after this first gate oxidation, while Fig. 6(b) shows a TEM micrograph of the same wafer after a second 90 sec BHF treatment and dry reoxidation to 1000Å. It is clear that the initially present thinning is completely eliminated by the reoxidation process. In addition, the profile has approached planarity because of the additional etchback step, but some thick oxide has been lost.

Having found that a certain amount of oxidation either removes the barrier or renders it ineffective as an oxidation inhibitor, we endeavored to identify the

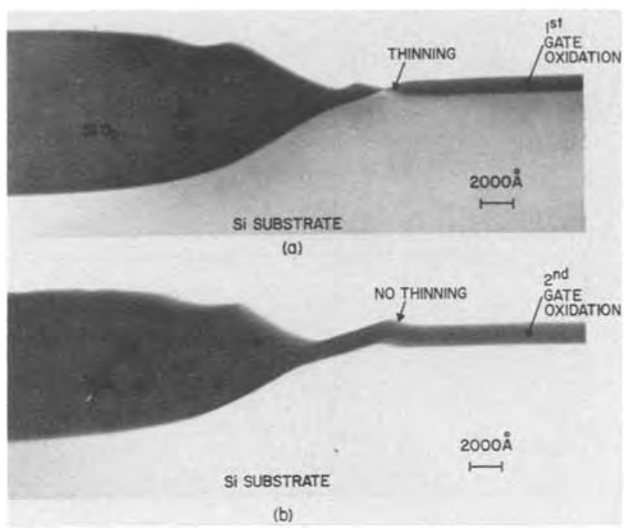

Fig. 6. TEM profiles of the isolation oxide edge as seen on a test wafer. In (a) the initial 1000Å oxide pad was removed in BHF in a 90 sec etch just after the masking Si_3N_4 etch, and a 1000Å dry gate oxide was grown. The thinned region in the gate oxide is clearly seen. In (b) the initial gate oxide was removed by etching for another 90 sec in BHF, and a second 1000Å dry gate oxide was grown. Absence of a thinned region is obvious on this sample.

various processing conditions required to minimize or eliminate the thinning phenomenon. The parameters and processing procedures studied included initial pad oxide thickness, type and degree of oxidation to be used between the isolation and gate oxidations, possible etching alternatives to the intermediate oxidation, and viable etchback schedules.

Because of the tedious nature of the TEM method of study (see experimental section), another means was used to evaluate each experimental sample. It was found that the Talystep surface profilometer with a 1000Å stylus could trace the Si wafer surface at the bird's beak and graphically detail the surface features defined by a TEM photograph. The only ambiguity which arose was definition of oxide thinning for cases where pad oxide etchback was used. In the etchback step, some isolation oxide is removed, and a dip is produced at the edge of the isolation oxide. After subsequent gate oxidation, it is impossible to resolve the oxide thinning because of the overpowering Si dip. For this reason the bulk of our work dealt with samples which did not receive an etchback of the initial pad oxide in procesing.

Two different initial pad dry oxidation thicknesses and two types of thermal oxidation were selected for study. Both wet (950°C) and dry oxidations (1000°C) respectively were used for pad oxide thicknesses of 300 and 1000Å. After isolation oxidation (1.2 μm wet at 1050°C), the Si_3N_4 oxidation mask was stripped in BHF (1 min, removes oxynitride surface) and 160°C H_3PO_4 (45 min); the underlying initial pad oxide was left in place. The wafers were cleaned and reoxidized in 500Å steps and were evaluated using the Talystep surface profilometer to determine the degree of oxide thinning in each case.

The control oxidation curves shown in Fig. 7 and 8 were determined from the wafers being measured, by thickness measurement of large thin oxide regions. The curves in each figure for oxidation over the barrier were obtained from Talystep data assuming equal oxide growth both above and below the silicon surface. Thus, where the control data shows that an additional 500Å of oxide was grown, a Talystep depression of 150Å would be taken as only 200Å growth in the barrier region (500Å less 2 × 150Å). Examples of the detail of the Talystep trace in this application may be seen in Fig. 9. From the data it can readily be seen that the

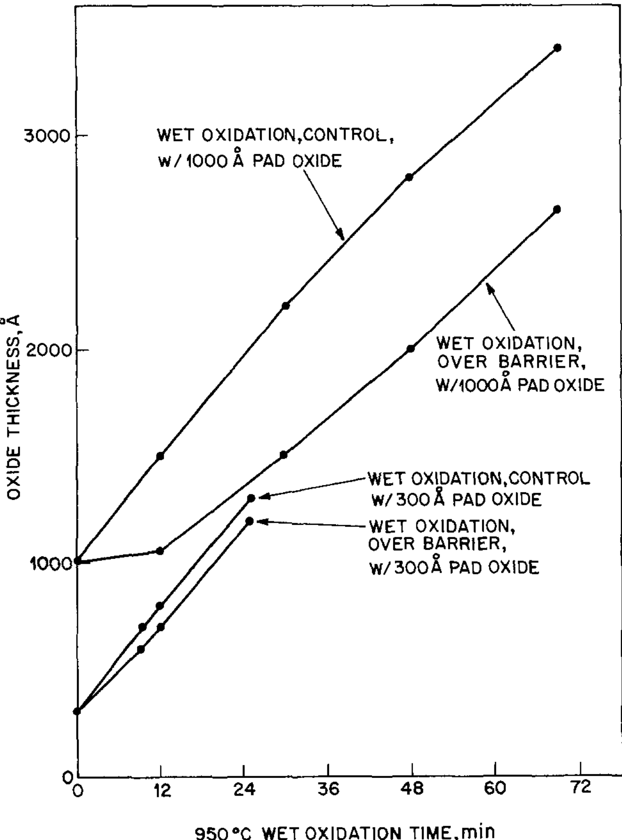

Fig. 7. Wet oxidation curves for wafers having initial pad oxide thicknesses of 300 and 1000Å. Since the pad oxides were in place at the onset of the additional wet oxidation, the curves begin at the respective pad oxide thicknesses. Additional oxidation with time is readily noted in the figure. Control data are from Si regions outside the oxidation barrier regions, while the lower curves in each pad oxide set are within the barrier regions.

wet oxidation is more effective than the dry oxidation, and the presence of the thin initial oxide pad makes removal of the barrier easier than with the thicker pad oxide. Thus, even an additional 300Å wet oxidation of a 300Å pad oxide sample brings the oxidation curve

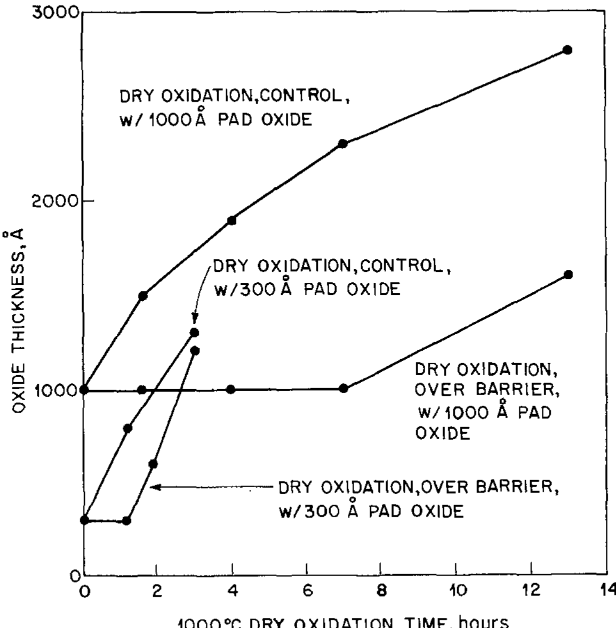

Fig. 8. Dry oxidation curves for wafers having initial pad oxide thicknesses of 300 and 1000Å.

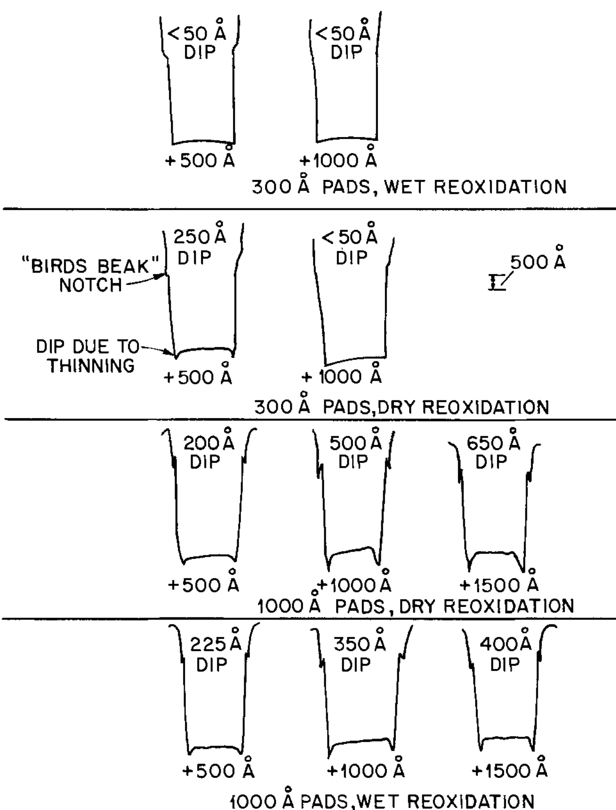

Fig. 9. Typical Talystep traces used to obtain oxidation curves in Fig. 9 and 10. Noted "Dips" must be multiplied by 2 to determine total oxidation inhibition since thinning is symmetrical above and below the Si surface for these samples.

parallel to the control curve, where nearly 2000Å additional dry oxidation is required for a thick 1000Å pad oxide wafer. In three of the four pad oxide thickness-oxidation type curve sets, the onset of normal sample oxidation in the barrier region is indicated by a growth curve which becomes parallel to the control curve, while in the dry oxidation of a 300Å pad oxide, the barrier oxidation appears to "catch up" to the control.

Since the thin pad oxide seemed to be so much more effective in facilitating subsequent removal of the oxidation barrier, the question arose as to whether the thin oxide appeared to be more effective simply because the gaseous oxidation species could reach the barrier layer in the silicon in much higher concentration than in the thicker pad oxide samples. It seemed possible that for the same degree of barrier, the thick oxide simply acted as a much more effective oxidation block. In order to answer this, a thick pad sample was thinned from 1000 to 300Å in BHF just after nitride removal and was halved for wet and dry oxidation treatments. In both the wet and dry oxidations, the samples gave oxidation curves in the barrier region exactly the same as for a thick pad oxide wafer. We are forced to conclude that a thick oxide pad results in an oxidation barrier which is more severe than for thinner pad oxides. Other experiments with samples having no oxide pads which were shown to have no oxidation barrier at all are consistent with this result. Unfortunately, processing without a pad oxide (a stress buffer) generally results in dislocation growth at feature edges due to high Si_3N_4 stress.

As mentioned earlier the underlying oxide pad was not removed in order to facilitate the use of the Talystep as a diagnostic tool. An even more important point is that etching of the pad oxide, no matter how minimal the overetch, will always expose the Si barrier region to chemical attack and thus confuse the data. This had perhaps been noted in our earlier diagnostic work as evidenced by the variability in the percent thinning of samples oxidized after the pad was removed in BHF. As will be mentioned later, extended BHF treatment can minimize the thinning effect. However, experiments with the pad oxide left in place become complicated by the possibility of an additional oxidation barrier which might form in the pad oxide itself, making the thicker pad appear anomalously worse than the thin one. The last described experiments in which the 1000Å pad, thinned to 300Å, behaved exactly like the thick pad on reoxidation, tends to discount this possibility because the etchback step in BHF should certainly etchback an in-pad barrier layer along with the oxide in the uppermost 700Å layer.

As a result of these experiments, the recommended selective oxidation processing sequence includes a thin pad oxide (200-400Å) with a wet reoxidation step after nitride removal. This is most easily achieved by leaving the thin initial dry oxide pad in place for the wet oxidation step. An initial pad oxide thick enough to survive early cleaning steps is recommended as well as wet reoxidation of a minimum of 1000Å to insure statistical success of the procedure. A 90 sec BHF etchback prior to gate oxidation is the only additional requirement. This removes all oxide in the gate region but does not overly consume the isolation oxide.

A final note must be made regarding the alternative method of barrier etching from the substrate after initial etchback of the selective oxidation Si_3N_4 and pad oxide layers. We have tried several times to evaluate the method using a second 160° or 180°C H_3PO_4 etch to remove the barrier. What was found is that the Si substrate is etched at a rate varying from 3-10 Å/min. The variability depends on temperature, the particular Si wafer, and the H_3PO_4 used. Talystep data show much less etching at the oxidation barrier position (supposedly a type of Si nitride) than on the remainder of the exposed Si surface. This indicates either that the barrier is not attacked by H_3PO_4 or is attached more slowly than is the Si surface. We have found, however, that a correlation exists between amount of exposure of the Si substrate in the gate regions to BHF and subsequent oxide thinning. Exposure of the Si to BHF beyond the time required to strip the pad (1-2 additional min) generally reduces the potential for thinning. Since the second etch procedure incorporates exposure of the Si surface to BHF prior to H_3PO_4 treatment, it is possible that the combination of the two etchants proves effective. At any rate, excessive exposure to BHF loses isolation oxide, and our proposed procedure, which involves only 90 sec BHF treatment, results in loss of only 1500Å isolation oxide.

Conclusions

TEM and SEM studies of n-channel and p-channel selective oxidation processed wafers show a bird's beak shape of the edge of the isolation oxide, with a notch at the top at the site of the edge of the masking Si_3N_4, and bird's beak lengths of 1.5 and 0.8 μm on n-channel and p-channel samples respectively. The bird's beak length is defined as the distance between the site where the isolation oxide begins to thicken and the horizontal projection of the minimum in the isolation oxide notch. The active device length is decreased due to the presence of two beaks bordering the active region. For a given isolation oxide thickness, this decrease is greater for n-channel samples than for p-channel samples by about 50% (here 3.8 μm compared to 2.3 μm).

There is a barrier on the Si surface to gate oxidation This barrier forms a band beginning near the tip of the bird's beak and extending a short distance (<1 μm) away from the tip on the n-channel samples. Gate oxide thinning of 20-50% was found on processed p-channel selective oxidation wafers, and 35-100% oxide thinning was found on processed n-channel wafers.

A convenient means for elimination of the thinning phenomenon is presented. Since it was found that wet oxidation subsequent to the isolation oxidation and

Si_3N_4 removal rapidly destroys the oxidation barrier, a method which incorporates an additional, short wet oxidation step between isolation and gate oxidations is described and recommended for selective oxidation processing.

Applications of Electrochemical Methods for Semiconductor Characterization

I. Highly Reproducible Carrier Concentration Profiling of VPE "Hi-Lo" n-GaAs

Thomas Ambridge, John L. Stevenson,[1] and R. Martin Redstall

Post Office Research Centre, Martlesham Heath, Ipswich, IP5 7RE, Great Britain

ABSTRACT

Factors which influence the accuracy and reproducibility of semiconductor carrier concentration profiling via capacitance-voltage measurements and dissolution at an electrolytic Schottky barrier are critically examined. Attention is centered upon the capacitance contributions from the edge regions of the electrolyte contact area. It is shown that several properties of the electrolyte, and the measurement frequency, as well as the physical means of electrolyte confinement have an important influence. In particular, a suitable combination of electrolyte conductivity, wetting, and dissolution behavior can be met by 0.1M Tiron, for the profiling of GaAs using the "Post Office Profile Plotter." Examples are given which demonstrate the high degree of reproducibility, both short- and long-term, attainable for the profiling of "hi-lo" structures. Optimization of the approach for other semiconductor materials, for which an "ideal" electrolyte may not be available, is also discussed.

The Post Office Profile Plotter[2] (1, 2) has been shown to provide an uncomplicated and convenient method for measurements of carrier concentration in GaAs and some other III-V compound semiconductor materials. It employs the semiconductor specimen as one electrode in an electrochemical cell, under controlled conditions where the differential capacitance of the Schottky barrier formed at the semiconductor/electrolyte interface is measured to give carrier concentration, and where, simultaneously, anodic dissolution is arranged, yielding a continuous depth profile of this parameter. Uniform illumination of the interface is required, to promote the dissolution reaction for n-type material. The sample wafer needs no pretreatment whatsoever, and the profile is obtained in one continuous, automatic sequence. These are notable advantages compared with most conventional "measure and strip" practices including capacitance-voltage profiling using metal/electrolyte Schottky barriers, where individual steps are limited by reverse-bias breakdown.

In principle, the electrochemical technique can be applied over wide ranges of carrier concentration and depth, and should be particularly advantageous for "hi-lo" profiling (1, 3), where the conventional approach would be especially tedious, due to the early onset of breakdown in "hi"-doped material. Special care is needed, however, in relation to the area of electrolyte contact with the semiconductor specimen. A molded plastic sealing ring is used to define the area of contact and illumination. In practice the limits of the wetted area may extend somewhat beyond those of the illuminated area. The difference is termed "excess area," and needs to be taken into account for accurate profiling, since, whereas dissolution is restricted to the illuminated zone, the whole of the wetted area may contribute to the capacitance measurement.

In this paper, after a brief reminder of details of the profiling technique, we shall first describe experiments aimed at defining, precisely, the actual area(s) of electrolyte/semiconductor contact. Following this, the specific roles of electrolyte conductivity and measurement frequency are examined. Some detailed profiles obtained from "hi-lo" VPE n-GaAs (modified Read IMPATT material) are also presented. Emphasis is placed on the very high levels of reproducibility required from the profiling technique in this area of application (4, 5).

Experimental Technique

The principles of the profile measurement technique, and the prototype automatic instrument have already been described in detail (1, 2). For convenience, however, some of the essential information is briefly repeated here, and recent refinements highlighted. Ini-

tially, we restate the profiling equations, and related instrumental parameters

I. Net donor concentration

$$N_D - N_A = \frac{2\epsilon\epsilon_0}{q} \frac{\delta V}{\delta(W_D^2)}$$

where ϵ_0 = permittivity of free space, ϵ = relative permittivity of the semiconductor, δV = modulation component of potential (100 mV rms, 30 Hz).

II. Depletion width

$$W_D = \frac{\epsilon\epsilon_0 A}{C}$$

where A = barrier area, C = capacitance (test signal: 50 mV rms, 3 kHz).

III. Width removed

$$W_R = \frac{M}{NFDA} \int I dt$$

where M = molecular weight, D = density of the semiconductor, N = the number of charge carriers transferred per molecule dissolved (= 6 for GaAs, this work), F = the Faraday, I = instantaneous dissolution current.

IV. Plotted depth

$$x = W_D + W_R$$

The electrochemical cell used in this work was the commercially supplied unit, which incorporated several changes from that earlier described. Several of the essential features, including the vertical specimen mounting arrangements are depicted in Fig. 1. Also incorporated, but not shown, are a saturated calomel electrode (SCE), as a reference, a carbon d-c working cathode, a platinum wire secondary cathode (for a-c measurements) close to the specimen, and a nozzle device for the initial clearance of bubbles. The electrolyte is stationary, in this design, but is refreshed for each profile measurement.

As before, the illumination provided for hole generation in n-type material is restricted to short wavelengths (below about 550 nm) corresponding to strong absorption, within a region of the semiconductor much narrower than the depletion width, in all but the most highly doped specimens ($\gtrsim 10^{18}$ cm^{-3}). This ensures that, in most epitaxial material, the availability of holes at the surface, for the dissolution reaction, is independent of lateral variations in carrier concentration (and diffusion length); thus at a well-chosen anodic potential microscopically smooth dissolution is usually obtained (1, 2).

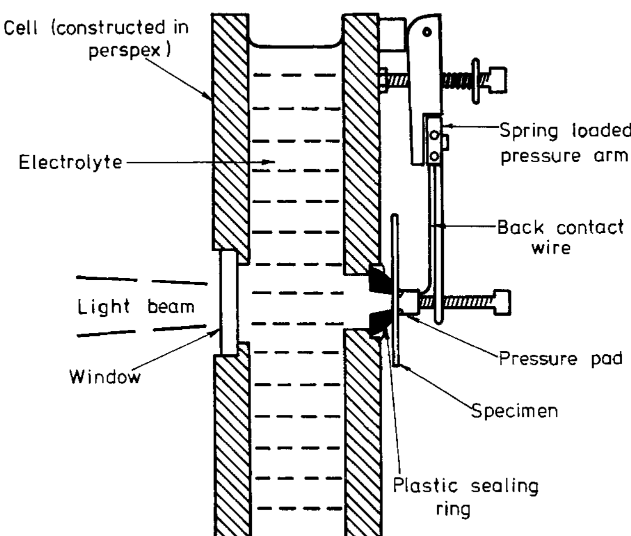

Fig. 1. Part of the electrochemical cell unit, showing specimen mounting. (Polaron Limited).

Over-all uniformity of illumination has been substantially improved through the use of an optical lens system, and aperture arrangement, giving a slightly convergent (4°) beam. With proper alignment, a near-ideal etched well is obtained, as depicted in the "Talysurf"[3] profile of Fig. 2, which indicates a maximum variation of ±3%. The final intensity of illumination typically used is about 6.0 mW cm^{-2}, yielding a dissolution rate of approximately 3.0 μm hr^{-1}.

The electronic instrumentation of the Post Office Profile Plotter has remained much as described earlier. However, an important recent refinement has been the incorporation of an automatically controlled electronic shutter. This provides an operational mode whereby dissolution under illumination is interrupted, at frequent intervals, by short periods of darkness during which the capacitance analysis, and point plotting of carrier concentration, is automatically performed. (The profile remains essentially continuous, comprising up to 300 points.)

In the present work, during profiling, both measurement and dissolution were performed, under potentiostatic control, at a common potential of about 0.3V anodic ("reverse biased") with respect to the dark rest value, regardless of the electrolyte employed. This choice of potential was based on criteria, aimed at avoiding defect-sensitive dissolution modes, and departures from ideal barrier characteristics, as discussed in previous publications (1, 2). Briefly, the main practical requirements are that the dissolution current should be negligible in the dark, and that dI/dV (both under illumination, and in the dark) should be minimal, whenever possible. For separate, frequency-dependent electrochemical C-V measurements, confined to high quality epitaxial material, a potential range from rest to about 1.5V anodic was spanned; standard phase-sensitive techniques were used for capacitance determination.

Contacted Area Definition

Physical area determination.—The accuracies of all carrier concentration profiles obtained from measurements of Mott-Schottky capacitance characteristics are critically dependent on the area of semiconductor contact and its edge definition (6). Where the conducting medium is a liquid, the problem is particularly severe (7).

Direct observation of the contact outline at the electrolyte/semiconductor interface has been aided by the use of samples upon which a uniform anodic native oxide has been formed (8) specially for this purpose. In the worst cases the area of electrolyte contact comprises several zones, as shown in Fig. 3(a). Here the n-GaAs test sample oxide was subjected, after loading onto the sealing ring, to open-circuit dissolution in an electrolyte of 2M KOH in aqueous solution. This was followed by anodic dissolution, under illumination, of 0.5 μm of GaAs.

The innermost boundary which appears on the photograph is that of A_C, the "central" area, which received illumination and thus was the only region within which

[3] The "Talysurf" moving stylus surface measuring instrument is manufactured by Rank Taylor Hobson, Leicester LE2 0SP, England.

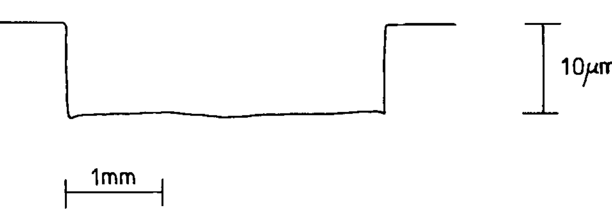

Fig. 2. "Talysurf" trace over an area, electrochemically stripped to an average depth of 10 μm.

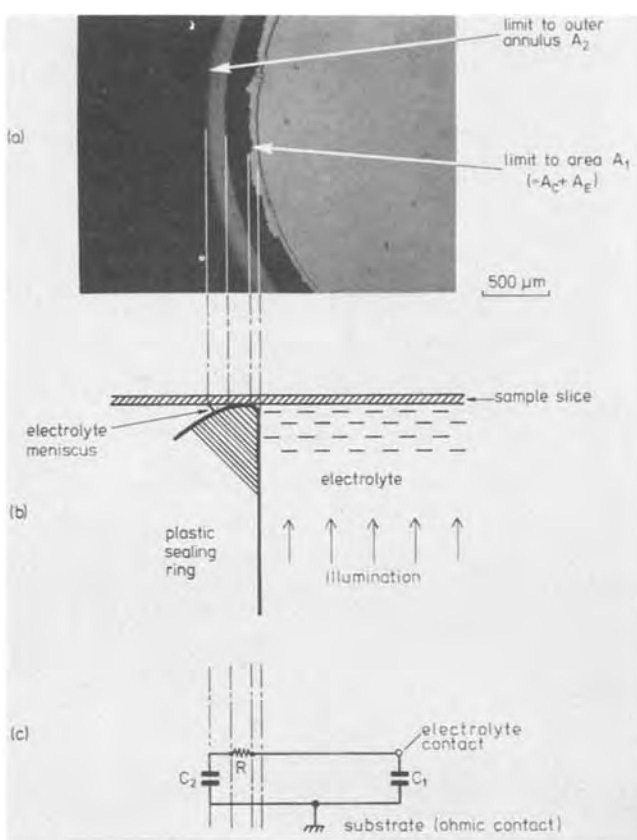

Fig. 3. The electrolyte/sample contact: (a) Contact zones observed for 2M KOH/n-GaAs, (b) physical model, and (c) electrical model.

GaAs dissolved. A_E is that excess wetted area which arises from simple shadowing of the illumination, due to slight rounding of the edge profile of the sealing ring. The existence of this has long been recognized (2), and the facility to compensate for the excess capacitance contribution (assumed to remain constant during dissolution profiling) is incorporated within the Profile Plotter. The sum of the areas, $A_C + A_E$, has been designated A_1, and is approximately 0.1 cm^2 in the present work.

The existence of an outer excess wetted area A_2, also revealed by the dissolution of oxide, requires an extension of our earlier model for the contact. Figure 3(b) shows the probable model for the formation of the additional zone A_2; this "meniscus contact" is particularly invidious, being potentially highly variable both in radial and circumferential extent. In the depicted circumstances its formation may be envisaged as a result of seepage across the flattened rim of the sealing ring, although, clearly, individual imperfections in the rim could provide a direct path.

Frequency-dependent "excess capacitance" model.— The electrical "interface circuit" model of Fig. 3(c) was adopted in order to investigate the participation of the specimen area A_2 in capacitance measurements. The resistive element R is proposed to represent a thin film of electrolyte present at the sealing rim, and as a result should have a conductance dependent on the dimensions of the peripheral capillary, and the electrolyte conductivity. In contrast, the capacitance C_2 depends upon the specimen doping only. An immediate consequence of a contact such as shown in Fig. 3 is that the apparent carrier concentration will show a variation with the measurement frequency, depending upon the relative impedances of R and C_2.

Experimental confirmation was obtained by making electrochemical C-V measurements on uniformly doped specimens (with $N_D - N_A \geqq 3 \times 10^{15}$ cm^{-3}) at both 3 kHz (as used in the Profile Plotter) and 100 kHz, which revealed marked frequency dependence, especially for the lowest doped specimens. No frequency dependence was detected, over the range 30 Hz-1 MHz for the same specimens subjected to C-V measurements via conventional metal Schottky barriers; fairly close agreement with the higher frequency electrochemical measurements was obtained.

By assuming that 100 kHz electrochemical measurements gave a "correct" value for $N_D - N_A$, for a specimen doped at about 10^{17} cm^{-3}, a value for R was estimated (at about 25 kΩ) by comparing the additional capacitance measured at 3 kHz with that calculated directly on the basis of the measured value of area A_2. A calculation was then made of the percentage error in carrier concentration, over a wide range due to the effective excess capacitance (limited by R) at the two frequencies. The result is shown in Fig. 4. Note that the error becomes small (less than 5%) at 100 kHz for carrier concentration values greater than about 3×10^{15} cm^{-3} in uniformly doped material. For measurements at 3 kHz the model predicts much larger errors than those shown, for material in the "lo" region of a typical "hi-lo" structure (*e.g.*, as demonstrated later and depicted in Fig. 5). However the corresponding errors should be negligible at 100 kHz, since the condition $R = \omega C_2^{-1}$, at which the absolute value of effective excess capacitance is at a maximum, occurs at a very low value of carrier concentration.

It is worth reemphasizing here that we have modelled frequency-dependent capacitance-voltage behavior entirely on the basis of peripheral contact phenomena in the electrochemical system. Certain other possible sources of frequency dependence, such as the presence of deep states, which may be invoked (9) are ruled out in the present investigation by the "solid-state" measurements. Thus, clearly, although other sources may dominate in other reported studies of capacitance behavior at the semiconductor/electrolyte interface (10-12), a frequency-dependent contribution related to that of the present model should not be overlooked entirely in such cases, even though the precise details of area definition may differ.

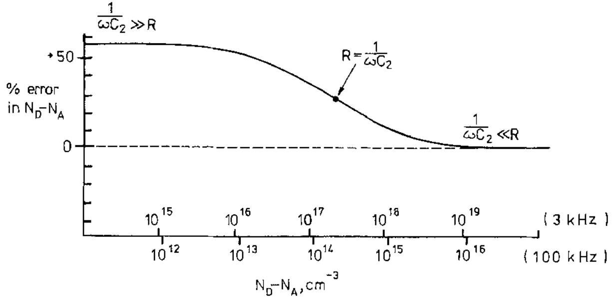

Fig. 4. The calculated dependence of error in carrier concentration upon absolute values, at measurement frequencies of 3 and 100 kHz, for the contact system of Fig. 1.

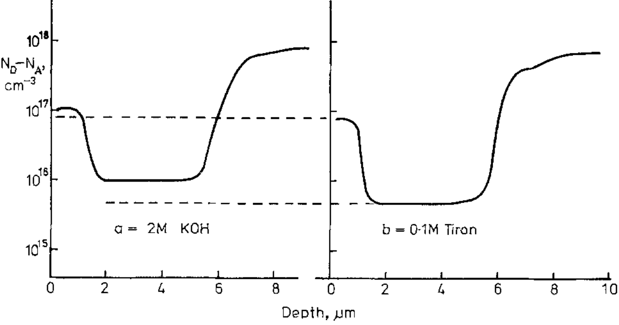

Fig. 5. "Hi-lo" profiles obtained from the same VPE n-GaAs specimen, using (a) 2M KOH and (b) 0.1M Tiron electrolyte.

Choice of Electrolyte

It is apparent from the model that two principal options exist for reducing the measurement errors of Fig. 4: (*i*) a decrease in electrolyte conductance, and (*ii*) an increase in measurement frequency. For GaAs it has proved to be sufficient simply to pursue (*i*) alone while retaining the standard Profile Plotter frequency of 3 kHz (which is most suited to measurements of the absolute values of capacitance encountered); it is not yet clear that this approach would be successful for other materials however (see Discussion).

Some initial attempts were made to increase R by employing KOH electrolyte of reduced concentration, or alternative alkaline solutions. These attempts were unsuccessful, due to the accumulation at the interface of insoluble (and only slowly soluble) hydrated oxides during anodic etching (8), causing a loss of Mott-Schottky capacitance characteristics. However, complexant electrolytes, in which the GaAs is reacted electrochemically to produce soluble chelated compounds, have proved to be suitable alternatives, even in quite dilute form. We have made specific use of Tiron (1,2 dihydroxybenzene-3,5 disulfonic acid, disodium salt) (13), which in 0.1M solution has a conductance approximately 4% of that of 2.0M KOH solution as used earlier. Assuming that R is proportional to the electrolyte resistivity, the substitution of 0.1M Tiron for 2.0M KOH should produce a change in impedance ratio ($\omega C_2{}^{-1}$: R), and hence in the over-all carrier concentration measurement error, approaching that obtained from the frequency increase as previously explored, as depicted in Fig. 4.

The effect of changing the electrolyte is shown by the two profiles of Fig. 5; each was recorded for an adjacent area on a "hi-lo" VPE n-GaAs structure. The discrepancy between the two measurements of $N_D - N_A$ for the "hi" avalanche region is 33% in this case, whereas the data of Fig. 4 would predict an error approaching 38% (for 2.0M KOH at 3 kHz). Thus, in this region at least, it appears that the use of Tiron has virtually eliminated the effective capacitance contribution from any outer excess area, A_2. Clearly the influence on the "lo" region is even more marked, although a more rigorous experimental approach is required (see the following section) to allow quantitative assessment. The validity of the electrical isolation model has been further reinforced by measurements in the presence of gross leakage of electrolyte (promoted by temporarily reducing the loading pressure of the specimen onto the sealing ring); even here relatively small, although somewhat variable, effects were noted when using 0.1M Tiron, compared with extreme changes when using 2M KOH.

Subsequent investigations, employing oxide dissolution tests, have shown that, under suitable loading conditions, over-all peripheral seepage can apparently be avoided when Tiron is used as the electrolyte. The remaining mechanism for outer excess area formation is then via small individual perfections in the sealing ring edge. As shown in Fig. 6, the extent of the excess area may be quite restricted in this case. Although electrical isolation is apparently still fairly effective in this situation, the distinction between A_E and A_2 in the model is less clear. Thus, for the high accuracy measurements described in the following section, employing Tiron electrolyte, only selected sealing rings, having no imperfections detectable by oxide dissolution tests, were utilized. Nevertheless it must be emphasized that for less demanding tasks (*e.g.*, routine profiling of fairly uniformly doped material with better than 10% reproducibility), the use of Tiron provides a considerable degree of immunity from minor imperfections in the seal, due to its reduced electrical conductivity.

It should be pointed out that the increased series path resistance within the electrochemical cell, when using 0.1M Tiron, should not normally introduce significant error (*i.e.*, more than 5%) into the measured carrier concentration, for values below about 3×10^{18} cm^{-3} (at the measurement frequency of 3 kHz). This assumes that the semiconductor barrier impedance is predominantly capacitative, which is generally true for high quality VPE layers. Under certain circumstances however, abnormally high parallel leakage conductance within the semiconductor depletion region can introduce complications, which will be discussed in a later contribution (14).

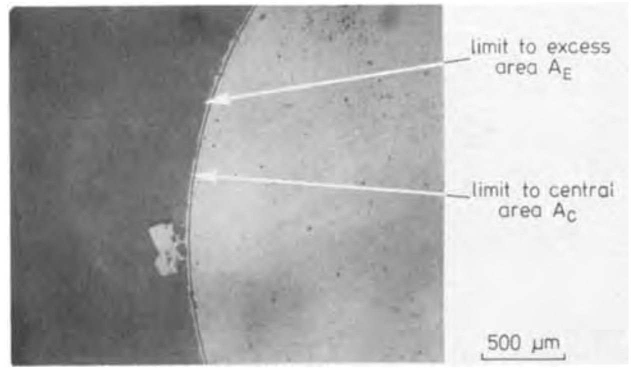

Fig. 6. Modified electrolyte/sample contact, for 0.1M Tiron/n-GaAs, under conditions where the outer contact zone is related to an individual imperfection in the seal.

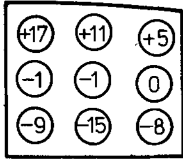
Application to High Accuracy Measurements

Surface uniformity mapping.—Lateral uniformity is an important requirement in material grown for device fabrication, and where comparative measurements are made on different areas of a given slice, for assessment of measurement techniques (as in Fig. 5). The Post Office Profile Plotter can be used to assess the lateral uniformity of doping, by determination of carrier concentration under conditions of negligible dissolution. Two uniformity maps made in this way (again for the "avalanche" layer of Read IMPATT material), are shown in Fig. 7. The two slices used here were produced in successive growth experiments, but at different vertical locations in the VPE horizontal furnace tube, and receiving different patterns of gas flow during epitaxy. The marked improvement in geographical uniformity in slice B corresponded with its having been centrally placed in the furnace tube.

This form of measurement provides the simplest useful test situation in which the electrochemical contact can be assessed. For reproducible measurements, the physical contact area must be kept constant over the duration of the experiment. By repeated remapping of slice B, it was established that the distribution of carrier concentration could indeed be reproduced closely. This implies that short-term area redefinition is significantly better than 2%, and is probably comparable with that typical of the mercury probe contact system (also used for Schottky barrier capacitance measurement), which was claimed initially by Hammer to be



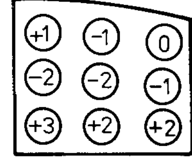


Fig. 7. Surface carrier concentration uniformity maps (using 0.1M Tiron electrolyte) for VPE n-GaAs specimens grown under different conditions. The figures represent percentage deviations from the mean values of 6.9 and 9.7 $\times$ 10^{16} cm^{-3} for A and B respectively.

about 1% of the total area (7). We note that the indicated total variation in carrier concentration is about 0.5×10^{16} cm^{-3} for the avalanche region of slice B. This is a substantial improvement over work reported by Niehaus and Schwartz (5) where minimum nonuniformities amounting to a total variation of 1×10^{16} cm^{-3} were reported on Read IMPATT material of similar specification.

"Hi-Lo" profiles.—Two profiles, obtained from neighboring areas of an IMPATT slice, are shown in Fig. 8. The inset shows the $N_D - N_A$ measurements made initially at the surface. One full profile, as shown (designated "a") was taken of the complete "hi-lo" structure (and was virtually indistinguishable from one taken to a depth of 5 μm at position "c"). The second shown profile (labelled "b") was recorded after removal of 1 μm of epitaxial material from the whole surface area of the slice, using an electrochemical trimming procedure previously termed replication etching (13). The two values of $N_D - N_A$ obtained for the drift region are in good agreement, the maximum difference between the plots being 5% at the point where the profile "b" was initiated. These results clearly demonstrate the elimination of any significant contribution to the measurement from an outer area A_2. The same conclusion has been arrived at from comparisons with results from mercury probe measure and strip procedures applied to "hi-lo" structures.

In the absence of significant errors due to "outer excess area" the major remaining influence on accuracy is the reproducibility of the central area A_C, and the "inner excess area" A_E. The errors in $N_D - N_A$ in the "hi" and "lo" sections of a profile, due to differences between the assumed and actual values of A_C and A_E can easily be shown to be given by

$$\frac{(N_D - N_A)_{\text{HI actual}}}{(N_D - N_A)_{\text{HI plotted}}} = \left[\frac{A_{1\text{ assumed}}}{A_{1\text{ actual}}}\right]^2 \qquad [1]$$

and

$$(N_D - N_A)_{\text{LO actual}} = \left[(N_D - N_A)^{1/2}{}_{\text{LO plotted}} + \left(\frac{A_E}{A_1}\text{assumed} - \frac{A_E}{A_1}\text{actual}\right) \frac{(N_D - N_A)^{1/2}{}_{\text{HI plotted}}}{(A_C/A_1\text{ assumed})}\right]^2 \left[\frac{A_{C\text{ assumed}}}{A_{C\text{ actual}}}\right]^2 \qquad [2]$$

The derivation assumes that the measured capacitance is machine-corrected for the contribution of that proportion of the initial capacitance corresponding to the area $A_{E\text{ assumed}}$. Also, second order effects (such as carrier concentration dependent band bending) are neglected.

The expression [2] for $(N_D - N_A)_{LO}$ can be simplified by taking typical values $(N_D - N_A)_{HI}/(N_D - N_A)_{LO}$ $= 25$ and $A_C = 0.1$ cm^2, to give the approximation

$$\frac{(N_D - N_A)_{\text{LO actual}}}{(N_D - N_A)_{\text{LO plotted}}} \simeq [1 + 100\,(A_{E\text{ assumed}} - A_{E\text{ actual}})]\left[\frac{A_{C\text{ assumed}}}{A_{C\text{ actual}}}\right]^2 \qquad [3]$$

Thus, for example, an error of 5% in $(N_D - N_A)_{LO}$ could arise from an error of 2.5% in A_C, or 10% in A_E (having an actual value of 0.005 cm^2), or a combination of errors in both. Successive measurements, using the oxide dissolution procedure, have shown that while area variations can be much less than this in the short term (as confirmed by profile reproducibility), these values can be exceeded in the longer term (periods exceeding a few days), depending on the exact conditions of instrumental use. In practice we have been able to maintain a profiling reproducibility of this order, on "hi-lo" structures over a period of many months by regular daily monitoring of areas, using oxide-coated specimens, and if necessary applying corrections to plotted data, on the basis of the above formulas.

It is useful to note that electrochemical profiles showing geographically systematic variations of less than 0.25×10^{15} cm^{-3} have been obtained in the "lo" region ($N_D - N_A = 5.5 \times 10^{15}$ cm^{-3}) of samples similar to slice B (Fig. 7), with data taken at six locations covering a total area of 2 cm^2. This compares favorably with the work of Niehaus and Schwartz (5) who reported that a target value of $(N_D - N_A)_{LO} = (2.0 \pm 0.24) \times 10^{15}$ cm^{-3} could not be met over a complete grown wafer. We also note earlier work by Wisseman *et al.* (4) who reported on the attainment of abrupt transitions between $(N_D - N_A)_{HI}$ and $(N_D - N_A)_{LO}$. Profiles taken using a mercury probe system showed that the total level change required (from 1×10^{17} cm^{-3} to 5×10^{15} cm^{-3}) could be achieved within 0.3 μm, but only by performing the epitaxy in a complicated furnace, with two deposition zones, and involving the mechanical resiting of the substrate in each zone during growth. Although such a technique was not used during the production of the layers examined here, equally sharp transitions have been obtained according to the electrochemical profiles [see, for example, profile a in Fig. 8, and also the work of Bass (3)].

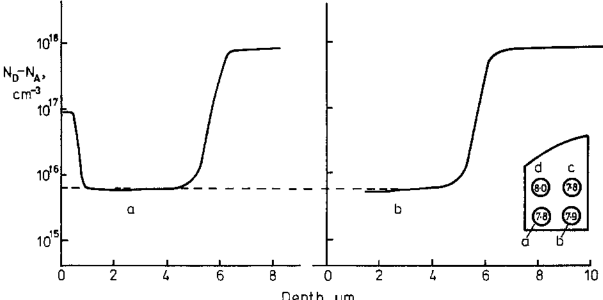

Fig. 8. (a) A full "hi-lo" profile and (b) the profile for an adjacent area of the same n-GaAs specimen after independent removal of 1 μm of material. The inset shows the locations, and initial surface carrier concentration measurements over the slice, in units of 10^{16} cm^{-3}. 0.1M Tiron was used as the electrolyte.

Discussion

Successful profiling, with a negligible influence from an "outer excess area" capacitance has been demonstrated for GaAs, through an optimization of electrolyte characteristics. Unfortunately it cannot be foreseen that a similar combination of electrical conductivity, wetting, and dissolution behavior will be attainable in electrolytes applicable to other semiconductor materials. For example, Tiron is unsuitable for profiling either InP or GaP, due to the accumulation of phosphorus at the semiconductor surface.

A viable approach is much needed here, due to important applications which include profiling of the quaternary GaInAsP, as well as InP, in double heterostructure laser material, and also because alternative measurement techniques are limited; considerable difficulty is encountered in the fabrication of simple metal Schottky barriers suitable for carrier concentration measurement on InP (15). It must be anticipated that it may be necessary to resort to fairly concentrated (high conductivity) electrolytes for satisfactory dissolution.

The possible use of a higher measurement frequency (*e.g.*, 100 kHz), in order to exclude the capacitance contribution from A_2, has already been introduced. However, for the presently employed barrier area, the sample impedance at high carrier concentrations ($N_D - N_A \geq 10^{18}$ cm^{-3}) would approach the same order as the simple "ohmic" contact impedances, leading to significant errors. Nevertheless, for much smaller areas,

higher frequency operation would be more appropriate to the sample impedances encountered. This would also be compatible with a requirement to reduce the area in order to minimize material consumption, such as has been applied to the profiling of LPE GaAs/GaAlAs heterostructures, with $A_C \leq 0.01$ cm² (16). Unfortunately, the relative size of A_E tends to increase as A_C is reduced, so that the reproducibility of "hi-lo" profiling must suffer.

Electrolytic contact area definition has also been obtained by masking using evaporated wax films (10), or photoresist (17). However, for accurate measurements at low carrier concentration levels the mask would need to be quite thick (*e.g.*, 100 μm) in comparison with the maximum depletion width (*e.g.*, > 1 μm for $N_D - N_A \leq 10^{15}$ cm^{-3}); otherwise an "excess" capacitance would be measured through the mask. The thickness requirement could lead to difficulty in achieving sharp edge definition of the masking material; in addition undercutting of the mask during dissolution profiling would be a problem unless the mask could be made opaque. The masking material would of course need to be impervious to the electrolyte employed. The approach would always suffer the disadvantage of the additional amount of preparation required, compared with the inherent simplicity of the sealing ring method.

Taking into account the various factors discussed above, perhaps the best approach to elimination of outer excess area contributions for other semiconductors, and to improved reproducibility of absolute area, lies in the optimization of the geometry, surface finish, and material composition of the sealing ring. In conjunction with this, given that it may not be practicable to tailor the electrical conductivity of the electrolyte, consideration should be given at least to the wetting characteristics, with the objective of avoiding seepage, as was apparently achieved for Tiron under "ideal" conditions. Reliable results would then depend upon the preservation of the sealing edge, to be confirmed by regular monitoring, in the manner already described in detail.

The influence of illumination on accurate profiling deserves some comment. As pointed out, the present system allows the carrier concentration measurement data to be obtained in the dark. In practice, the computed carrier concentration has usually been found to have negligible dependence upon illumination (at the "standard" level), for high quality epitaxial material, as in this work. However in certain classes of "imperfect" material, departures from ideal barrier behavior, under illumination, have provided useful qualitative information, as will be discussed in a forthcoming paper (14). In principle, depth scale information does not depend upon the precise level of illumination, or in-depth variations in corresponding dissolution photocurrent, since the depth removed is determined electronically from the dissolution rate integral. Lateral variations in dissolution rate will, however, introduce a loss of resolution, especially at the deepest interfaces. The precautions taken to minimize this problem have already been mentioned, and the experimental evidence suggests that it is insignificant in the present work. Nevertheless, this is an aspect of the technique where vigilance is needed. In particular, exceptional situations can arise, for example when profiling damaged material, where significant in-depth variations in photocurrent do occur, and could compound the effects of any lateral nonuniformity in illumination (14).

We have so far not referred to any possible long-term variability of results due to drift in the analogue electronics of the Profile Plotter. In practice the commercial instrument is easily maintained in precise calibration on a day-to-day basis using readily accessible front panel trimmers; over-all reproducibility of the combined analogue functions can be spot-checked over a wide carrier concentration range, using a specimen simulator (comprising solid-state varactors) and generally confirmed to be everywhere within about 2%. Thus contact area definition remains the major potential source of irreproducibility.

Note that throughout the present work, we have limited the consideration of measurement accuracy and reproducibility to technological aspects of the electrochemical system. Other aspects generally applicable to capacitance-voltage based profiling techniques, *e.g.*, concerning the possible influence of deep levels, and Debye spreading limitations on the resolution of interfaces, have been considered at length elsewhere (9, 18-20).

Conclusion

With the widening realization that successful fabrication of many advanced devices in GaAs, and other semiconductor materials, will require an exact and consistent knowledge of carrier concentration profiles, we have demonstrated here that the electrochemical technique can be entrusted with the determination of accurate and highly reproducible data. The necessary attention to choice of electrolyte, contact area definition, and simple well-defined routine checks have been fully discussed.

In forthcoming papers we shall describe further extensions of the electrochemical technique applicable to: (*i*) "damage" profiling in relatively imperfect material, including, specifically, ion-implanted layers; (*ii*) compositional, as well as carrier concentration (both n- and p-type), profiling of heteroepitaxial material, including LPE double heterostructures grown for laser fabrication; and (*iii*) Hall mobility, and carrier concentration profiling, in MBE, VPE, and ion-implanted layers, including those produced for microwave FET fabrication.

Acknowledgments

The authors wish to thank Dr. R. H. Moss for providing epitaxial structures, P. J. O'Sullivan for making available measurements using solid-state Schottky diodes, J. C. Regnault and C. J. Allen for performing some of the other measurements, and Dr. M. M. Faktor for helpful discussions. Acknowledgment is made to the Director of Research of the British Post Office for permission to publish this paper.

Manuscript submitted April 16, 1979; revised manuscript received Aug. 13, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by the Post Office Research Centre.

Observation and Analysis of Surface States on TiO_2 Electrodes in Aqueous Electrolytes

R. H. Wilson*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

When a TiO_2 electrode in an aqueous electrolyte is biased enough positive of its flatband potential and then photoexcited with light of wavelength shorter than 400 nm, photocurrent is observed. If the electrode is subsequently swept to more negative voltages in the dark a negative current is observed which is in excess of the normal dark current observed on a subsequent sweep with no photoexcitation between sweeps. The excess current is observed to have a maximum at a voltage positive of the flatband potential. In this paper, the growth and decay of this reduction peak are investigated experimentally. The peak is analyzed as a reduction by conduction band electrons of surface states that were oxidized by valence band holes during the photoexcitation. The observations favor the interpretation that these states are intermediates of the reaction leading to O_2 evolution. This interpretation, however, is not unequivocally established. It is clear that the conduction-band electron reduction of a state that was previously oxidized by a valence-band hole is in effect an electron-hole recombination. This recombination controls the onset of photocurrent with voltage. There are 10^{13}-10^{14} of these states per cm^2 and the cross section for electron interaction with this surface state is estimated to be 10^{-16}-10^{-17} cm^2 based on the analysis used to describe the peak. The usefulness of this analysis in investigating these states and surface states due to surface coatings is discussed.

Since the first report (1) of stable, photoelectrochemical oxygen evolution on TiO_2, a substantial effort has been made to improve on those early results. This work has been the subject of several recent reviews (2-5). The work reported here is part of a continuing effort to understand the processes that occur on TiO_2 during O_2 evolution as a guide to the use of narrower bandgap semiconductors for that purpose.

In a previous report (6) observation of a reduction current peak produced by photoexcitation of a TiO_2 electrode was discussed briefly. In this paper the experimental measurement of this peak is reported in more detail and a model to describe the effect is developed. Data are presented to support the view that this reduction current is due to an electron transfer to a relatively stable surface species that was produced by a reaction with a hole in the valence band of the TiO_2 during illumination. A model for this process is presented. The possibility that this stable surface species is an intermediate of the series of reactions leading to oxygen evolution is discussed. It is further argued that this reduction by a conduction band electron is a reversal of a previous oxidation by a valence band hole. The net results of these two processes is an electron hole recombination and this recombination is the controlling factor in the onset of photocurrent with increasing positive voltage applied to the n-type TiO_2 electrodes.

Experimental Procedures

All measurements were made using a cell with a 4 mm diam opening to which a larger single crystal TiO_2 electrode was pressed using a thin silicone gasket as a seal. A saturated calomel electrode (SCE) connected by a Luggin capillary was used as a reference electrode. The counterelectrode was a platinized platinum electrode. Light to the TiO_2 electrode entered the cell through a vitreous silica window and passed through 1 cm of electrolyte before falling on the electrode. The light source was a 150W xenon lamp with a Bausch and Lomb grating monochromator. The measurements were made using a PAR Model 173 potentiostat and a Model 175 universal programmer. The current-voltage curves were recorded on an X-Y recorder. The TiO_2 electrodes were prepared using methods previously described (7). The electrolytes were prepared using distilled water and reagent grade chemicals.

Observations

The nature of the observations to be described is illustrated in Fig. 1 where the current-voltage characteristics of a TiO_2 electrode are shown when the voltage is swept from zero volts (SCE) at -200 mV/sec in 1*M* KOH under the following conditions: (*i*) in the dark with no illumination subsequent to the previous negative voltage sweep; (*ii*) illuminated with 350 nm light; (*iii*) in the dark after 30 sec illumination with 350 nm light at 0 volts (SCE). As can be seen in curve 3 of Fig. 1, additional cathodic current occurs as a result of the short period of illumination at 0 volts. The principal features of this reduction peak are observed to be independent of the crystal face of the TiO_2 (they are also observed on $SrTiO_3$) and the doping density of the TiO_2. Factors that do affect the reduction peak will be discussed here.

The growth of the reduction peak as a function of illumination time is illustrated in Fig. 2(a). In each case there is a 5 sec delay between the light-off and

* Electrochemical Society Active Member.

Key words: photoelectrolysis, semiconductor, interfaces, photoelectrochemistry.

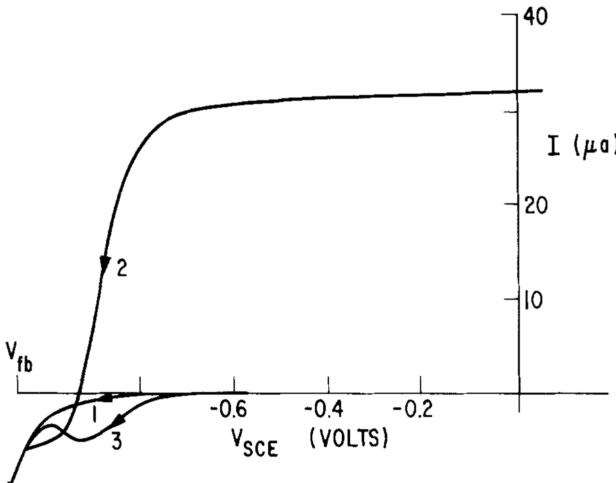

Fig. 1. Current-voltage curves of a TiO_2 electrode in 1.0M KOH with −200 mV/sec scan from 0 volts (SCE). Curve 1, in dark; curve 2, with 350 nm light on; curve 3, in dark after 30 sec illumination with 350 nm light at 0 volts (SCE).

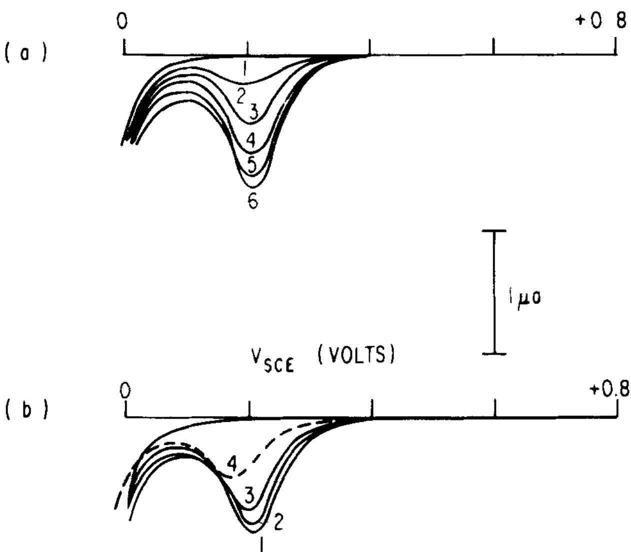

Fig. 2. Current-voltage curves of a TiO_2 electrode in 0.5M H_2SO_4 with a −200 mV/sec scan from +0.8V (SCE) in dark (a) after exposure to 350 nm light for curve 1, 0 sec; curve 2, 0.1 sec; curve 3, 1.0 sec; curve 4, 5 sec; curve 5, 30 sec; curve 6, 180 sec with 5 sec delay before initiating voltage sweep; and (b) after exposure to 350 nm light for 30 sec and curve 1, 5 sec; curve 2, 30 sec; curve 3, 120 sec; curve 4, 6000 sec delay before initiating voltage sweep.

the beginning of the sweep. As can be seen, there is a rapid initial growth with a subsequent saturation. The growth can be approximated by

$$N = N_o(1 - e^{-t/\tau}) \qquad [1]$$

where t is the time of exposure to light, N is the area under the peak (to be expressed as the number of electrons per unit electrode area), N_o is its saturation value and τ is a time constant which is inversely proportional to the photocurrent density during illumination. An approximate empirical relationship is

$$\tau = 2 \times 10^{-4} \frac{\mathrm{C}}{\mathrm{cm}^2} \bigg/ j \qquad [2]$$

where j is the current density during illumination. Greater precision in this measurement is not considered to be justified at this time. The value of N_o was observed to be independent of light intensity and current density.

The decay of the peak for different delay times before the sweep is initiated is shown in Fig. 2(b). In each case the electrode was illuminated for 30 sec before the beginning of the delay period. No functional relationship was found to describe the remaining peak size as a function of time. It is readily seen from the figure that the rate of decay decreases with time and a substantial fraction of the peak is left after 100 min. The decay rate was the same at +0.8 or +0.6V during the delay period.

The rates of growth and decay of the peak were independent of the electrolyte, stirring of the electrolyte, and the presence or absence of dissolved O_2 in the electrolyte. As will be discussed, some features of the current during the sweep do depend on the electrolyte and stirring.

Figure 3 shows the effect of scan rate on the reduction peak. The solid curves were made at −500 mV/sec and the dashed curves were made at −50 mV/sec both in 0.5*M* H_2SO_4. Note that the current scale differs by a factor of ten for the two sets of curves. Curves 1 were after illumination with 350 nm light at +0.8V for 30 sec and then a 30 sec delay before initiating the voltage sweep. Curves 2 were subsequent sweeps in the dark with no illumination at +0.8V. It is obvious that the area under the peaks is approximately proportional to the scan rate, *i.e.*, the amount of charge transferred is independent of scan rate. The shift in peak position is noteworthy and will be discussed in the next section.

All of the following observations of the reduction peak were made using a −200 mV/sec sweep rate, 30 sec illumination with 350 nm light at 0 volts in 1*M* KOH or +0.8V in 0.5*M* H_2SO_4 with a 5 sec delay between light-off and the beginning of the voltage sweep.

Figure 4 shows a series of measurements made on a TiO_2 electrode. Figure 4(a) shows measurements made in 1*M* KOH. The solid curves were initial measurements and the dashed curves after 0.1C of charge was passed by illuminating the electrode with 350 nm light at 0 volts (SCE) (current about 18 μA). Curves 1 were made after 30 sec illumination at 0 volts after a previous sweep to −1.2V. Curves 2 were made after curve 1 with no intervening illumination. Several features can be noted in these curves. One is the development of a second peak at −0.95V after 0.1C. This peak continues to grow with further passage of photocurrent. Its rate of growth is nonlinear with current density growing more per unit of charge passed at higher current density. While this extra reduction peak is interesting. it will not be discussed in detail in this report. As will be seen, it slowly disappears in 0.5*M* H_2SO_4.

Another feature is a shift of the initial peak at −0.85V to a slightly more positive voltage. This shift is probably due to a change in the flatband potential during the 0.1C charge transfer, since a corresponding

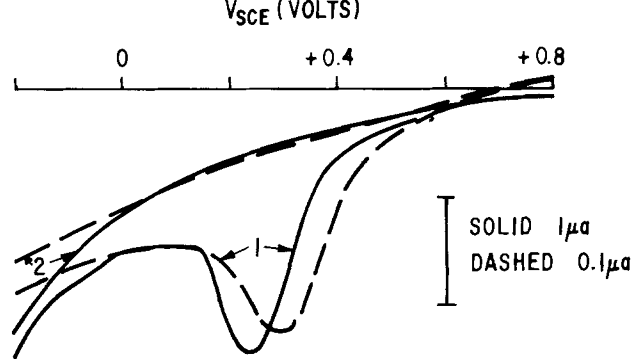

Fig. 3. Current-voltage curves of a TiO_2 electrode in 0.5M H_2SO_4 in dark after curves 1, 30 sec exposure to 350 nm light with 30 sec delay before initiating voltage sweep at: solid curve 500 mV/sec; dashed curve 50 mV/sec; curve 2, no exposure before sweep.

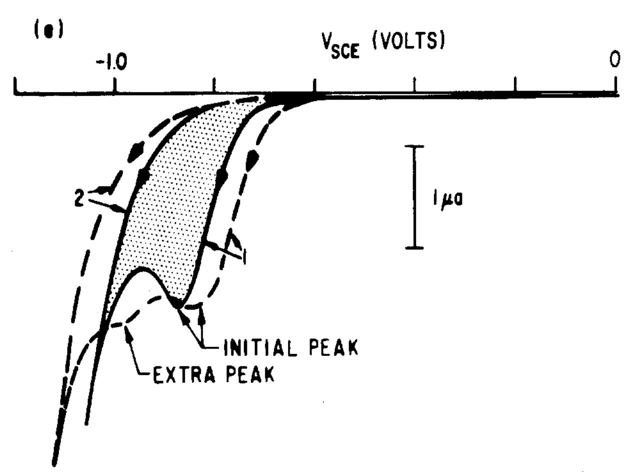

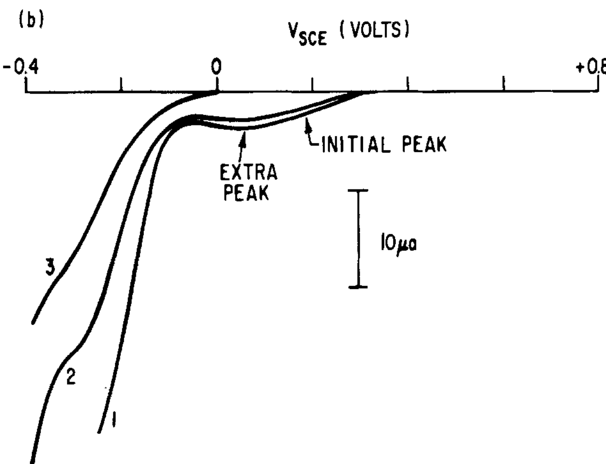

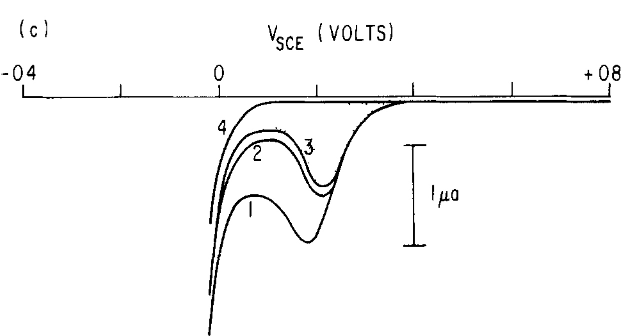

Fig. 4. Current-voltage curves of a TiO_2 electrode in dark with a —200 mV/sec scan from extreme positive voltage shown with either 30 sec exposure or no exposure to 350 nm light with 5 sec delay before scan. All measurements on the same electrode with a series of uses between measurements: (a) in 1M KOH, curve 1, 30 sec exposure; curve 2, no exposure; solid curves—initial; dashed curves—after 0.1C photocurrent passed; (b) (note scale change) in 0.5M H_2SO_4 after extensive use in KOH since (a). Curve 1, 30 sec exposure; curve 2, 30 sec exposure with electrolyte in vicinity of the electrode stirred in the 5 sec delay period; curve 3, no exposure; (c) in 0.5M H_2SO_4 after sitting 60 hr in that electrolyte since (b), curve 1, initial; curve 2, 30 sec exposure after 0.016C photocurrent passed; curve 3, 30 sec exposure after another 0.034C photocurrent passed; curve 4, after 3 but no exposure. Shaded areas in (a) and (c) correspond to 6.7×10^{13} and 1.9×10^{13} electrons/cm^2 of TiO_2 respectively.

shift occurs in the capacitance-voltage curve. The shift is reversible in the dark. This can be seen in the position of curve 4 in Fig. 2(b). Again, this shift, while interesting, will not be discussed further here. In addition, it should be noted that this shift and the associated capacitance change come after long periods of photocurrent. There is no change in capacitance at 0 volts as a result of the 30 sec illumination responsible for the reduction peak.

The existence, location, and size of the initial peak are the features of interest here. These features will be considered further in the discussion section.

After more use in KOH during which the extra peak grew further, the electrode of Fig. 4(a) was measured in 0.5*M* H_2SO_4. The results are shown in Fig. 4(b) and 4(c). The observations in Fig. 4(b) were made shortly after the removal of KOH and the addition of H_2SO_4. Note that a less sensitive current scale is used in 4(b). Curve 1 is after 30 sec illumination with 350 nm light at +0.8V with no stirring of the electrolyte. Curve 2 is for the same conditions but with the electrolyte stirred in the vicinity of the electrode during the 5 sec delay between illumination and voltage sweep. Curve 3 was with no illumination before the sweep. The current increase at more negative voltages in curve 3 is a function of the amount of dissolved oxygen in the electrolyte. Oxygen is unavoidable since it is produced during the period of illumination. Figure 4(b) is intended to illustrate the effect of stirring and the additional structure at −0.3V and to point out that these features are not those under consideration here. In addition, some of the extra peak that grew in KOH can still be seen at +0.05V.

Figure 4(c) shows the behavior of the same electrode after sitting over a weekend in 0.5*M* H_2SO_4. Curve 1 is an initial measurement. Curve 2 is after 0.016C passed through the electrode using 350 nm illumination at +0.8V, a subsequent sweep to −0.4V, and then the usual 30 sec illumination at +0.8V before the sweep. Curve 3 is after another 0.034C with the same procedure. Curve 4 is a sweep with no illumination after curve 3.

Again, several features can be noted in Fig. 4(c). One is the absence of the second peak that developed in Fig. 4(a) and was still evident in 4(b). The states responsible for the peak are apparently removed by 0.5*M* H_2SO_4.

A second feature is the shift in peak position to more positive potentials similar to that seen in Fig. 4(a). It also is accompanied by a corresponding shift in the capacitance-voltage curve and is probably due to a change in flatband voltage.

A third feature is the variable background current from which the peak at +0.2V rises. This current is apparently the tail of some of the effects seen in Fig. 4(b) at more negative voltages.

The features of interest in this report are the size and location of the peak itself. These will be dealt with quantitatively in the discussion section. There is an obvious difference in the size of this peak in H_2SO_4 and KOH. When the 0.5*M* H_2SO_4 was removed after curve 3 of Fig. 4(c) and was replaced by 1*M* KOH, the peak was very similar to the initial peak shown in Fig. 4(a).

The behavior of the reduction peak described in this section has been reproduced on many TiO_2 electrodes with different preparation and different doping densities. The peak, however, is not always as clean and sharp as illustrated thus far. This is seen in Fig. 5 where initial measurements on a TiO_2 electrode which had sat in the laboratory several weeks between the time it was prepared and the time it was first measured are shown in the solid curves. No cleaning procedure was used prior to the measurement.

The dashed curves are measurements on the same electrode after further use in 1*M* KOH, subsequent measurement in 0.5*M* H_2SO_4, and then measurement in 1*M* KOH. Sharpening of the reduction peak (curves 3) is obvious. This sharpening developed gradually

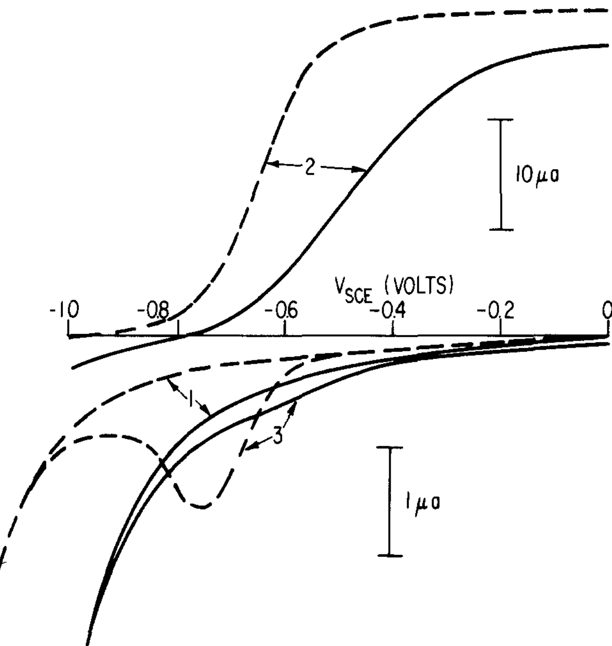

Fig. 5. Current-voltage curves of a TiO_2 electrode in 1.0M KOH with —200 mV/sec scan from 0 volts (SCE), curve 1, in dark, no light exposure; curve 2, with 350 nm light on; curve 3, in dark after 30 sec illumination with 350 nm light and 5 sec delay before voltage scan: solid curves—initial measurement on electrode with no cleaning before use; dashed curves—after 0.02C photocurrent in KOH and 0.01C photocurrent in H_2SO_4.

as more photocurrent was passed in both 1*M* KOH and 0.5*M* H_2SO_4. The photocurrent-voltage curves (curves 2) shown in Fig. 5 show corresponding changes as do the background dark current curves (curves 1) on which the reduction peak rides. Similar changes were produced by cleaning the electrode in concentrated H_2SO_4 at temperatures above 50°C. No attempt was made to analyze the surface to establish the cause of this behavior. It is described here to emphasize the importance of surface cleaning and to point out the correspondence between the reduction peak and the photocurrent-voltage curves.

Discussion

Peak size and position.—Few quantitative treatments have been published of charge transfer processes between electrolyte species and the bands of semiconductors when the electrolyte energy levels are in the range of the bandgap of the semiconductor. A tunneling analysis (8) has been applied to explore the distribution of electrolyte energy levels. The strong doping density dependence of the tunneling analysis precludes that as an explanation of the observations presented here. The brief, small polaron treatment published (9) does not seem to apply to the present case.

A number of investigators have used localized states at the interface in a qualitative way to explain this charge transfer process. Quantitative treatments using an interaction cross section between semiconductor carriers and interface/electrolyte states have been made for majority carriers (10, 11) and photoexcited minority carriers (12) and the applicability of this approach to a variety of interface states has been suggested (6). It will be applied to the observations reported here.

Assume a surface density of empty electron states, N, at the surface of an n-semiconductor with a bulk electron density, n_b. The density of electrons at the surface of the semiconductor, n_s, is given by

$$n_s = n_b \exp[-q(V - V_{fb})/kT] \quad [3]$$

where V is the voltage applied to the semiconductor relative to some reference in the electrolyte and V_{fb} is the flatband potential of the semiconductor relative to the same reference, q is the magnitude of the electron charge, T is absolute temperature, and k is Boltzmann's constant. The discussion will be restricted to $V > V_{fb}$ where the value of V_{fb} will be considered independent of V. The current density, j, of electrons reacting with the surface states is given by

$$j = qn_sN\sigma v \quad [4]$$

where v is the thermal velocity of the electrons (about 10^7 cm/sec) and σ is the cross section for interaction between the electrons and the surface states. If it is further assumed that each state that is filled by this electron current is not reemptied then

$$\frac{dN}{dt} = \frac{dN}{dV}\frac{dV}{dt} = -\frac{j}{q} \quad [5]$$

If the initial voltage is large enough so that n_s is very small and the voltage is swept negative at a constant dV/dt, Eq. [3], [4], and [5] can be combined and approximately integrated as

$$\int_{N_i}^{N} \frac{dN}{N} = -\frac{v\sigma n_b}{\frac{dV}{dt}} \int_{\infty}^{V} e^{-\frac{q(V-V_{fb})}{kT}} dV \quad [6]$$

to get

$$N = N_i \exp\left\{ v\sigma n_b kT \exp[-q(V - V_{fb})/kT]/q\frac{dV}{dt} \right\} \quad [7]$$

Combining Eq. [3], [4], and [7] an expression for $j(V)$ can be determined.

The voltage, V_p, for the maximum in the $j(V)$ expression can readily be obtained as

$$V_p - V_{fb} = \frac{kT}{q}\ln\left(-\frac{n_b\sigma vkT}{qdV/dt}\right) \quad [8]$$

Using Eq. [8], the current density can be written as a function of $(V - V_p)$.

$$j = qN_i\left(-\frac{q}{kT}\frac{dV}{dt}\right)e^{-\frac{q(V-V_p)}{kT}} \exp\left[-e^{-\frac{q(V-V_p)}{kT}}\right] \quad [9]$$

Thus, the shape of the reduction peak is fixed and its size determined by N_i and the voltage sweep rate. Equation [8] can be rearranged to give

$$\sigma = -\frac{dV}{dt}\frac{q}{kTn_bv}\exp\left[\frac{q(V_p - V_{fb})}{kT}\right] \quad [10]$$

from which the cross section for electron capture can be calculated from V_p if V_{fb} and n_b can be determined.

In Fig. 6 calculated $j(V - V_p)$ curves are compared with experimental results taken from the shaded areas of Fig. 4(a) and 4(c). For the calculations the values of N_i were determined from the areas under the experimental curves. These were 6.7×10^{13} and 1.9×10^{13} per cm^2 respectively. The position of the peak in the calculated curve was matched to the experimental peak. As can be seen the experimental curves are broader than the calculated curves. This does not necessarily indicate that the model used to describe the charge transfer process is not appropriate. The calculations assume a single value for σ, a uniform doping density, and a uniform flatband voltage across the surface of the electrode. A spread in the value for any of these could explain the width of the experimental peaks. The very broad peak in Fig. 5 is probably due to a spread in flatband voltage due to surface contamination. Since this effect can be elim-

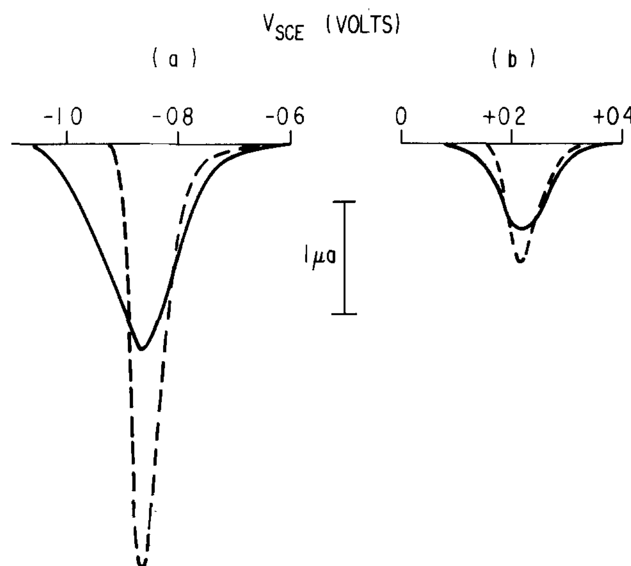

Fig. 6. Comparison of experimental reduction peaks (solid curves) corresponding to the shaded areas of (a) Fig. 4(a); and (b) Fig. 4(c) with curves calculated (dashed curves) from Eq. [9] using $N_i = 6.7 \times 10^{13}$ cm^{-2} and 1.9×10^{13} cm^{-2} respectively and matching the peak position to the experimental curve.

inated by proper surface preparation it will not be considered further here.

The model correctly describes the effect of voltage sweep rate illustrated in Fig. 3. Equation [9] shows the current proportional to the sweep rate. Equation [8] shows the peak position decreasing 0.06V for a factor of 10 increase in sweep rate. Both of these effects are readily seen in Fig. 3. The background current on which the peak rides also increases with scan rate as expected since it is capacitive current due to a changing voltage across the depletion region of the semiconductor.

Frequency dependent capacitance and nonuniform doping density prevent precise flatband voltage determination. The capacitance *vs.* voltage measurements at 1000 Hz that were made in conjunction with the experimental reduction peak measurements in Fig. 6 show nonuniform doping density with depth. Using capacitance-voltage measurements it is possible, however, to determine a difference in flatband potential of more than 1V for the electrode in 1*M* KOH and 0.5*M* H_2SO_4 corresponding to the two measurements in Fig. 6. This differs from the 0.8V difference expected from the 0.059V/pH shift usually attributed to TiO_2. This discrepancy could be due to surface effects determined by the sequence of measurements. It could affect the relative values for σ but does not affect the principal conclusions of this report. Using $V_{fb} = -0.3$V and $V_p = +0.21$V in 0.5*M* H_2SO_4 and $V_{fb} = -1.3$V and $V_p = -0.85$V in 1*M* KOH the values of $\sigma = 3.6 \times 10^{-16}$ cm^2 and 3.6×10^{-17} cm^2 respectively are obtained. [A value of $n_b = N_d = 7 \times 10^{17}$ cm^{-3} was used. It can be shown that for nonuniform doping with depth the appropriate value for n_b in Eq. [3] is its value at the edge of the depletion region. This value for n_b can be determined from the slope of A^2/C^2 *vs.* V at the voltage corresponding to the peak (13).]

No attempt has been made to determine values of σ with greater precision to see if there are sample to sample and electrolyte to electrolyte variations or if σ is approximately the same under all conditions. A better understanding of the origin of the states responsible for the peak will provide the driving force for more precise measurements. The values for σ determined here are smaller than the geometric cross section of a state localized on a single atom. This suggests that the state is not positively charged (the coulombic attraction could make the cross section much larger than geometric). A cross section smaller than geometric could be due to poor electronic or phonon coupling between the state and the semiconductor. The model developed here could be used to study factors that affect this coupling in the experimental situation described here or in other experimental circumstances involving charge transfer between surface coatings and semiconductors.

Growth of peak.—Two possible circumstances will be analyzed to describe the observed growth of the reduction peak. One of these assumes a fixed density, N_s, of electron states on the surface of the electrode. After a negative voltage sweep and before illumination these states are assumed to be filled with electrons. When the illumination is started the density of holes at the surface increases by p_s. These holes move with a thermal velocity, v (assuming the same effective mass as electrons gives $v = 10^7$ cm/sec for both holes and electrons), and interact with the filled states with a cross section, σ_h. The density of empty states, N, grows according to

$$\frac{dN}{dt} = p_s(N_s - N)\sigma_h v - n_s N \sigma v - Nr \qquad [11]$$

where r is the spontaneous hole emission constant, *i.e.*, Nr is the capture rate of electrons from the valence band (n_s and σ were defined at Eq. [3] and [4]). Neglecting hole emission and operating at a voltage well positive of the flatband voltage (in the saturation region of curve 2, Fig. 1) so that n_s can be neglected

$$N = N_s[1 - \exp(-p_s\sigma_h vt)] \qquad [12]$$

is readily obtained if p_s is assumed constant and t is the time the electrode is illuminated. If the light is stopped at time t and a negative voltage sweep is started the N of Eq. [12] becomes the N_i of Eq. [9] if spontaneous decay of N during the initial period of the sweep is neglected. Neglecting hole emission and assuming p_s constant in time are probably not precisely justified but are acceptable in this semiquantitative treatment intended to contrast different approaches to describe the processes involved. It will be noted that Eq. [12] and Eq. [1] are of the same form. Furthermore, p_s is proportional to light intensity (12) and consequently to j in the saturation region of the photocurrent for the current densities used here. This is consistent with Eq. [2].

Another approach to describe the origin of the reduction peak is to treat it as due to an intermediate of the water splitting reaction

$$2H_2O + 4h^+ \rightarrow O_2 + 4H^+ \qquad [13]$$

where h^+ is a hole in the valence band of the semiconductor. If S_1 is a rate constant for the rate-limiting step of a series of reactions in which a hole produces an intermediate with surface density, N, and σ_p is the cross section for a hole to react with this intermediate as a next step in O_2 evolution the rate equation for this process is

$$\frac{dN}{dt} = p_s S_1 - p_s N \sigma_p v - n_s N \sigma v - Nr \qquad [14]$$

where the other terms are as before. Using the same assumptions as for Eq. [12], ($r = 0$; $n_s = 0$)

$$N = \frac{S_1}{\sigma_p v}[1 - \exp(-p_s\sigma_p vt)] \qquad [15]$$

is obtained. All the caveats applied to Eq. [12] should be used for Eq. [15] also. The interesting comparison is that the saturation value of N in Eq. [15] comes naturally as a result of the relative rates of a first and second oxidation by photoexcited holes. The larger value for the reduction peak in KOH compared to H_2SO_4 is readily explained as an increase in S_1 due

to some difference, *e.g.*, the Helmholtz layer, between KOH and H_2SO_4. N_s in Eq. [12] is purely ad hoc.

In most other respects the two approaches give similar results. Both predict saturation values of N independent of light intensity but growth rates dependent on light intensity.

The fact that the observed capacitance is independent of the states being filled or empty, however, suggests that the states are neutral in both cases. This favors the reaction-intermediate model in which a chemical process such as H^+ leaving the surface after hole capture or OH^- leaving the surface after electron capture could maintain this neutrality.

More precise analysis of the processes and/or new experimental observations are necessary to distinguish between the two approaches analyzed here.

Decay of peak.—The process by which the reduction peak decreases during the delay period between turning the light off and initiating the voltage sweep is probably hole emission to the valence band. Some alternative explanations can be eliminated, others seem too arbitrary.

Electron capture from the conduction band can be eliminated by noting that the decay rate is the same at +0.6V and +0.8V in 0.5*M* H_2SO_4 as noted in the observation section. The electron density at the surface changes by more than three orders of magnitude for that voltage change.

Electron capture from an impurity can be eliminated since the decay rate is independent of stirring during the delay. Other electrolyte levels are not able to donate an electron. Furthermore, the decay rate is approximately the same in 1*M* KOH and 0.5*M* H_2SO_4.

Electron capture from H_2O in the electrolyte is a possible explanation if a thermal activation to surface states distributed in energy is assumed to explain the long term stability of some of the states. The subsequent chemistry implied by this water oxidation step makes this process seem untenable.

A straightforward explanation is contained in the last term of both Eq. [11] and [14]. With the light off and at high voltages both p_s and n_s are negligible and the equation can be integrated to

$$N(E) = N_o(E)e^{-rt} \quad [16]$$

where a distribution in energy is emphasized. Since hole emission from a surface state of energy, E, above the valence band is an endoenergetic process, thermal activation is required and r can be written in the form

$$r = v\sigma_e\eta_v e^{-E/kT} \quad [17]$$

where $\eta_v = 10^{19}$ cm^{-3} is the estimated effective density of states in the valence band and σ_e is the cross section for a valence band electron to react with the surface state. Using a decay constant $\tau = 100$ sec and $\sigma_e = 10^{-16}$ cm^2 a value of $E = 0.7$ eV is obtained. As can be seen from Fig. 2(b) about 30% of the peak area is lost in 120 sec. Under the above assumptions 70% of the states would be more than 0.7 eV above the valence band. The numbers used for σ_e and η_v are only estimates, however, the logarithmic dependence makes the value of E weakly dependent on these parameters. This explanation is plausible and if the states involved are intermediates of O_2 evolution it suggests that they are 2-2.5 eV below the hydrogen potential.

Summary and Conclusions

In this report experimental results have been presented which indicate that oxidized states are produced on the surface of TiO_2 electrodes in aqueous electrolytes when the TiO_2 is illuminated under conditions which produce a photocurrent in the cell. Most of these states are still there after several minutes. They decrease at a rate consistent with thermally activated hole emission from states several tenths of an eV above the valence band with at least a tenth of a volt distribution in energy. Measurements on other stable electrodes with valence bands higher in energy could test this hypothesis.

The observed reduction peak produced by these states during a negative voltage sweep has been analyzed as a reaction with electrons in the conduction band at the surface of the semiconductor. They interact with a cross section which can be determined by the position of the reduction peak. Preliminary measurements indicate that the cross section is about 10^{-16} cm^2, *i.e.*, smaller than the geometric cross section. This model describes all of the observed behavior and can be used to analyze other surface state interactions with semiconductor electrons, *e.g.*, attached surface layers. A correlation between electron-capture cross section and attachment process of the layer could be very useful.

The saturated density of these oxidized states was explained as an intrinsic density of surface states or as the result of the relative rate of production and consumption of intermediate states of the O_2 evolution process. Kinetic considerations in the growth in density of these oxidized states were discussed but a detailed analysis was not developed.

Evidence supporting the view that the surface state is an intermediate in the O_2 evolution process was discussed. The argument in favor of this view is not conclusive at this point. Measurements in other solvents such as acetonitrile might be useful in resolving this question.

What is clear is that the surface state produced by oxidation by a hole from the valence band can also be reduced by an electron from the conduction band. The net effect is an electron hole recombination. It is this recombination that controls the onset of photocurrent with voltage in a manner previously described (12). If the state is an intermediate of the O_2 evolution process it represents an inherent limitation in attempts to use narrower bandgap semiconductors if its cross sections and energy levels are the same for other semiconductors.

Technical Notes

End Point Detection in Plasma Etching by Optical Emission Spectroscopy

Kadou Hirobe and Takashi Tsuchimoto*

Computer Development Laboratories Limited, Kodaira, Tokyo 187, Japan

Optical emission spectroscopy has been applied to precise end point detection in plasma etching (1-4) and the method has many advantages superior to the others such as mass spectroscopy (5), visual observation of change in interference colors, and ellipsometry (6). The purpose of this paper is to introduce a measure for the end point detection method using an optical emission and to evaluate the lower limit of detection for etching polycrystalline silicon (poly-Si) and silicon nitride (Si_3N_4).

Figure 1 shows a block diagram of etching apparatus and optical emission observation system which has been used in the experiment. Plasma etching was carried out in a volume loading, barrel type apparatus (Model 2005-1813 SC from International Plasma Corporation). Wafers were placed in a quartz wafer boat inside a quartz chamber. $CF_4 + O_2$ (4%) was used as an etching gas. Typical etching condition was 100W rf power and 0.5 Torr (66.5 Pa). Poly-Si and Si_3N_4 films were prepared using the reaction of chemical vapor deposition on thermally oxidized silicon substrates. The optical emission observation system was composed of a spectrometer (Model 139 from Hitachi, Limited), a photomultiplier, an amplifier, and a recorder. The resolution of the system was 0.5 nm. The emission was viewed through the thick quartz window at one end of the chamber. No optical lens was used. In the experimental measurement. the wavelengths of 674 and 777 nm were selected for those spectra which were most useful for Si_3N_4 and poly-Si etching, respectively. It is considered that the 674 nm line is from N_2 molecule and the 777 nm is from SiF molecule, and N_2 and SiF come from the reaction products of Si_3N_4 and poly-Si with CF_4 in the plasma, respectively.

* Electrochemical Society Active Member.

Key words: rf discharge, barrel type etching apparatus, polycrystalline silicon, mass spectroscopy, carbon tetrafluoride.

Figure 2 shows a typical change in emission intensity of the 674 nm line during etching Si_3N_4 films. The emission intensity increased gradually with increasing temperature of the chamber and of wafers which were warmed up by rf discharge, and then decreased rapidly as the surface area of the remaining Si_3N_4 film decreased, and finally leveled off after etching was completed. The end point was clearly detected at the point where the curve suddenly drops off in the figure. Similar characteristic changes in the intensity of the 777 nm line emission were obtained for etching poly-Si film.

A new measure is introduced for expressing the lower limit of detection of the end point. The measure is defined as the ratio of the change in emission intensity at the end point (B) to the maximum emission intensity (A), namely B/A. In order to evaluate the lower limit of detection of the method for poly-Si and Si_3N_4, the relations between B/A and the area

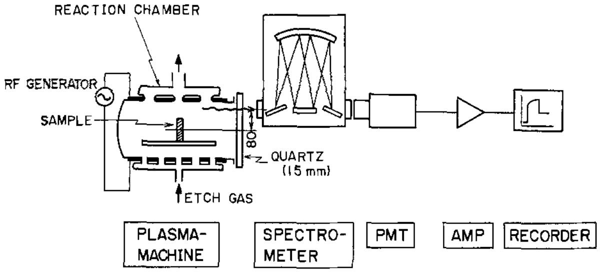

Fig. 1. Block diagram of the etching apparatus and optical emission observation system.

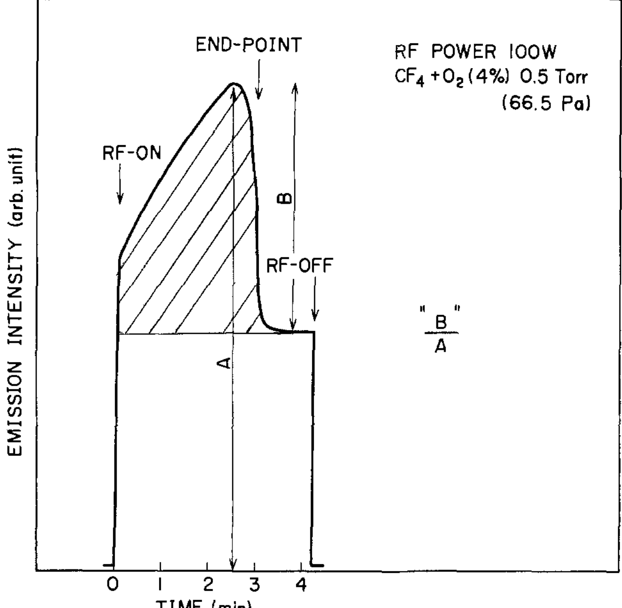

Fig. 2. Typical emission intensity of 674 nm as a function of time.

of the sample were examined. The experimental results are presented in Fig. 3. The intensity ratio B/A was dependent on materials to be etched. The B/A for Si_3N_4 was much greater than that for poly-Si. The end point was precisely detected on the recorder chart when B/A was larger than 1%. Therefore, the end point could be precisely detected when the surface area of the samples was larger than 0.3 cm² for Si_3N_4 and 2 cm² for poly-Si.

In order to explain the differences in the lower limit of detection between poly-Si and Si_3N_4, the relations between photons emitted from the plasma and the surface area of samples were investigated using the following assumptions. (*i*) The number of photons emitted from SiF or N_2 is proportional to the volume of etched area, (*ii*) the volume is proportional to the surface area, (*iii*) the number of photons detected is proportional to integrated emission intensity, (*iv*) the integrated intensity is proportional to the area shown as the shaded area in Fig. 2. From these assumptions, the integrated intensity can be expressed by the equation

$$\int Idt = K \cdot S^n \quad [1]$$

where I is the emission intensity (photons sec^{-1}), t is the etching time (sec), K is a constant (photons cm^{-2}) and S is the surface area of sample (cm²). Experimental relations are shown in Fig. 4. The integrated intensity of 674 nm spectrum was linear with the area of sample and the value of n was nearly unity, while for 777 nm the integrated intensity was not proportional to the surface area and n was 1.71. The deviation of n from unity in case of monitoring poly-Si etching by 777 nm spectrum will be explained as the SiF molecule also comes from the reaction between the quartz chamber and the CF_4 plasma. On the other hand, for Si_3N_4 etching N_2 molecules are formed only by the reaction of Si_3N_4 with the plasma. Therefore, the change in the 674 nm emission intensity is thought to be proportional to the change of amount of N_2.

Experimental results obtained in this study have shown that optical emission spectroscopy is able to detect the end point in etching small surface areas of poly-Si and Si_3N_4 films precisely and the method has wide applications in the control of plasma etching.

The Effects of Different Environments on the Thermal Stability of Powdered Samples of $LiAlO_2$

P. A. Finn*

Argonne National Laboratory, Argonne, Illinois 60439

The second generation fuel cell presently being developed by the Department of Energy is the molten carbonate fuel cell (1). The system, which will be coal-fueled, is anticipated to be a high-efficiency electric generator. Lithium aluminate is used in molten-carbonate fuel cells as the matrix support material for the carbonate electrolyte (1-3). Powdered mixtures of $LiAlO_2$ and alkali carbonate are blended and then hot-pressed into a thin electrolyte structure (tile) which is sandwiched between the two electrodes. Changes in the physical form of $LiAlO_2$ at the cell operating temperature (925°K) will alter both the strength and the electrolyte-retention properties of the tile.

The three allotropic forms of $LiAlO_2$ (α-, β-, and γ-) belong to the following crystal groups, hexagonal (4), orthorhombic (5), and tetragonal (6), and have densities of 3400 (4), 2610 (7), and 2615 (6) kg/m^3, respectively. Lehmann and Hesselbarth (8) and Lejus (9) found that in air in the absence of carbonate, γ-$LiAlO_2$ was the stable allotrope at temperatures $\geqq$ 1173°K. In the presence of lithium carbonate in air, the temperature at which α-$LiAlO_2$ transforms to γ-$LiAlO_2$ is lowered to $\leqq$ 973°K (10, 11). Fischer noted that the transformation of β- to γ-$LiAlO_2$ occurred at 1173°K (7) (no details were given); however, the effect of lithium carbonate on the phase transformation of β- to γ-$LiAlO_2$ was not reported. Studies on the crystal growth of $LiAlO_2$ as a function of time, temperature, or gas environment were not found in the literature. To increase our knowledge of the $LiAlO_2$ system, the thermal stability of α-, β-, and γ-$LiAlO_2$ to both allotropic transformation and crystal growth has been studied as a function of time, temperature, and environment.

Experimental

To obtain information useful to fuel-cell operation, we have heated powdered samples in gold crucibles for 24-1000 hr at 875°-1200°K, in three gas environments—air, CO_2, and 80% H_2-20% CO_2 saturated with H_2O at 295°K. All samples containing alkali carbonate consisted of 45 weight percent (w/o) $LiAlO_2$ and 55 w/o Li_2CO_3-K_2CO_3 [(62-38 mole percent (m/o)], the electrolyte composition presently being used in molten-carbonate fuel cells. The three allotropic forms of $LiAlO_2$ were prepared in this laboratory (see Table I). Clump-shaped particles of α-$LiAlO_2$ were prepared by heating a mixture of Degussa γ-Al_2O_3 and reagent grade Li_2CO_3 (1:1.5 mole ratio) at 873°K for 24 hr in air enriched in CO_2. To produce β-$LiAlO_2$, an aqueous slurry of γ-Al_2O_3-LiOH-KOH in the mole ratio of 1.0:4.1:1.2 was evaporated to dryness. The residue was ground before exposure to air enriched in CO_2 for 6 hr at 295°K, and then 4 hr at 873°K (12). The γ-$LiAlO_2$ was obtained by heating α-$LiAlO_2$ in the presence of Li_2CO_3 at 973°K for 17 hr in air. Carbonate was removed from samples by washing with a 50:50 volume mixture of glacial acetic acid and acetic anhydride, followed by a methanol wash. Samples were characterized by x-ray diffraction, scanning electron microscopy, and BET surface areas.

Experimental Results

A summary of the test results for the allotropic transformation of α- or β-$LiAlO_2$ to γ-$LiAlO_2$ are presented in Table II. Initial tests were conducted in the absence of carbonate to verify the temperatures at which the transformation of either α- or β- to γ-$LiAlO_2$ occurred. A sample of α-$LiAlO_2$ that was heated at 1110°K for 64 hr remained α-$LiAlO_2$. Another sample that was heated at 1210°K for 40 hr transformed to γ-$LiAlO_2$; a minor amount of $LiAl_5O_8$ (a decomposition product formed by the loss of Li_2O) was also present. The material after transformation to γ-$LiAlO_2$ consisted of small bipyramidal-shaped particles with a surface area of 15 m^2/g. Our results are consistent with Hesselbarth (8) and Lejus (9) who found that α-$LiAlO_2$ transformed to γ-$LiAlO_2$ at ~1173°K. A sample of β-$LiAlO_2$ that was heated at 1030°K for 23 hr remained β-$LiAlO_2$. Another sample of β-$LiAlO_2$ that was heated at 1110°K for 24 hr transformed to γ-$LiAlO_2$,, and a minor amount of β-$LiAlO_2$ remained. The particles, after transformation to γ-$LiAlO_2$, retained the rod configuration. The transformation of β- to γ-$LiAlO_2$ thus occurs in air in <24 hr at temperatures <1110°K but >1030°K. Our results complement those of Fischer (2) which were obtained at 1173°K. In air in the absence of carbonates, β-$LiAlO_2$ transformed to γ-$LiAlO_2$ at a temperature lower than that at which α-$LiAlO_2$ transforms to γ-$LiAlO_2$. This result would indicate that β-$LiAlO_2$ is less stable to allotropic transformation than α-$LiAlO_2$.

Table I. Physical characteristics of untreated $LiAlO_2$

Allotrope	Surface area (m^2/g)	Particle shape	Particle dimension (μm)
α-$LiAlO_2$	60	Clumps of small particles	< 0.25
β-$LiAlO_2$	12	Rods	1 × 0.2
γ-$LiAlO_2$	3	Bipyramids	0.5

Table II. The stability of α- and β-$LiAlO_2$ to allotropic transformation to γ-$LiAlO_2$

Allotrope	Environment	Temp (°K)	Time (hr)	Product
α	Air	1110	64	α
α	Air	1210	40	γ
α	Air, Li/K[1]	875	24	γ(ma)[2], α(me)[3]
α	HCH[4], Li/K	875	160	α(ma), γ(mi)[5]
α	CO_2, Li/K	975	442	α
α	CO_2, Li/K	975	1062	γ
β	Air	1030	23	β
β	Air	1110	24	γ, β(mi)
β	Air, Li/K	945	352	γ
β	HCH, Li/K	945	787	β
β	HCH, Li/K	975	107	γ
β	CO_2, Li/K	975	991	γ

[1] Li/K = 62 m/o Li_2CO_3 − 38 m/o K_2CO_3 (55 w/o).
[2] ma = major
[3] me = medium
[4] HCH = 80% H_2-20% CO_2 saturated with H_2O at 295°K.
[5] mi = minor

In further thermal tests, powdered samples containing $LiAlO_2$ and 55 w/o carbonate were heated for 24 hr to ~1000 hr at temperatures of 875°-975°K in three gas environments—air, CO_2, and 80% H_2-20% CO_2 saturated with water at 295°K. The test results are summarized in Table II. A sample of α-$LiAlO_2$ that was held for 24 hr at 875°K in air, transformed to γ-$LiAlO_2$, a medium amount of α-$LiAlO_2$ remained. The sample after heat-treatment consisted of small bipyramidal-shaped particles with a surface area of <5 m^2/g. At 925° and 975°K, only very minor amounts of α-$LiAlO_2$ remained after ~24 hr, and the shape of the particles, small bipyramids, was similar to that observed at 875°K. Thus, in the presence of carbonates, a sample of α-$LiAlO_2$ with high surface area (60 m^2/g) was unstable when heat-treated in air above 875°K. In an environment consisting of 80% H_2-20% CO_2 saturated with water at 295°K, a sample of α-$LiAlO_2$ contained a minor amount of γ-$LiAlO_2$ after either 160 hr at 875°K or 24 hr at 925°K. However, after 121 hr at 975°K, significant amounts of both α- and γ-$LiAlO_2$ were present. The samples after heat-treatment at 875°, 925°, or 975°K consisted of small bipyramidal-shaped particles with surface areas of ~5 m^2/g. These results indicate that, in the presence of carbonates, α-$LiAlO_2$ is unstable when heat-treated in a 80% H_2-20% CO_2-H_2O environment. A sample of α-$LiAlO_2$ held in CO_2 for 140 hr at 875°K remained α-$LiAlO_2$. A second sample held 442 hr at 975°K did not transform to γ-$LiAlO_2$; but after 1062 hr at 975°K, γ-$LiAlO_2$ was the major species present. Bipyramidal-shaped particles were produced with surface areas of <5 m^2/g. Evidently, a long period is required in the presence of CO_2 to accomplish the transformation of α- to γ-$LiAlO_2$. The samples held in CO_2 exhibited crystal growth, but the rate of growth was slower in CO_2 than in air or 80% H_2-20% CO_2-H_2O. In the presence of carbonate, pure CO_2 slows both the transformation of α- to γ-$LiAlO_2$ and the rate of loss of surface area of the samples.

In air, β-$LiAlO_2$ in the presence of 55 w/o carbonate was stable for 2400 hr at 925°K to allotropic transformation; crystal growth was minimal. At 945°K, β-$LiAlO_2$ was still present after 112 hr but γ-$LiAlO_2$ was the only species present after 352 hr. At 975°K, more than 100 hr was required to transform completely β- to γ-$LiAlO_2$. The γ-$LiAlO_2$ consisted of bipyramidal-shaped particles with a surface area of <2 m^2/g. In the 80% H_2-20% CO_2-H_2O environment, β-$LiAlO_2$ was stable for 2400 hr at 925°K and for 787 hr at 945°K; but after 107 hr at 975°K, only γ-$LiAlO_2$ was present. Thus, as the temperature is increased, γ-$LiAlO_2$ becomes the only stable allotrope in 80% H_2-20%CO_2-H_2O. In CO_2, β-$LiAlO_2$ was present after 212 hr at 925°K. After 991 hr at 975°K, only γ-$LiAlO_2$ was present; a minor amount of γ-$LiAlO_2$ was detected after 211 hr at 975°K. The γ-$LiAlO_2$ product consisted of bipyramidal-shaped particles. From these results, it appears that β-$LiAlO_2$ transforms to γ-$LiAlO_2$ at a lower temperature in the presence of carbonates than in their absence. In all the environments studied, β-$LiAlO_2$ transformed to γ-$LiAlO_2$ when held at temperatures of 945°K or greater for periods of $\geq$ 1000 hr.

No transformations of γ-$LiAlO_2$ in the presence of carbonates to either α- or β-$LiAlO_2$ were detected under the conditions studied (*i.e.*, powders held at 875°, 925°, and 975°K for times of 24-1000 hr in the three gas environments). Because the γ-$LiAlO_2$ sample had a low initial surface area, 3 m^2/g, crystal growth was detectable only at 975°K in all three gas environments. The growth rate was highest in air and lowest in CO_2.

Discussion

A solubility of $LiAlO_2$ (form unspecified) of $3 \times 10^{-4}M$ at 975°K in the ternary carbonate (Li_2CO_3-Na_2CO_3-K_2CO_3) has been reported (3). At this concentration, an appreciable amount of $LiAlO_2$ is in solution in the form of Li^+ and AlO_2^-. The mobility of these dissolved species would play an important role in the growth mechanism of $LiAlO_2$ particles. Therefore, a solution-deposition mechanism is quite feasible in the $LiAlO_2$-carbonate system. The carbonates themselves are subject to both thermal decomposition and reaction with water. The dissociation constant of Li_2CO_3 at 925°K is $\simeq 9 \times 10^{-6}$ (13)

$$Li_2CO_3 = 2Li^+ + O^{2-} + CO_2 \quad [1]$$

The hydrolysis constant of Li_2CO_3 at 925°K is $\simeq 4 \times 10^{-4}$ (14)

$$Li_2CO_3 + H_2O = 2Li^+ + 2\,OH^- + CO_2 \quad [2]$$

The constants for K_2CO_3 are two orders of magnitude smaller. High concentrations of CO_2 would suppress both these reactions. However, in an air environment, the low partial pressure of CO_2 and high partial pressure of H_2O would favor the production of significant amounts of Li^+ and O_2^- in reaction [1] and Li^+ and OH^- in reaction [2]. Preliminary experiments in this laboratory indicate that, in the presence of large amounts of LiOH and KOH, in an air atmosphere, the transformation of α- and β-$LiAlO_2$ to γ-$LiAlO_2$ at 925°K proceeds rapidly. Crystal growth is extensive in less than 5 hr, producing γ-$LiAlO_2$ with surface areas <5 m^2/g. These data suggest that $LiAlO_2$ is more soluble in hydroxide-containing melts than in pure carbonate melts. The presence of hydroxide species in the carbonate melts facilitates both crystal growth and the transformation of either α- or β- to γ-$LiAlO_2$.

Conclusions

The experimental data on the behavior of the three forms of $LiAlO_2$ in the presence of molten carbonate suggest the following conclusions. First, the transformations of both α- and β-$LiAlO_2$ to γ-$LiAlO_2$ occur at lower temperatures in the presence of carbonate than in its absence, *i.e.*, 873°K *vs.* 1173°K for α- and 945°K *vs.* 1110°K for β-. Thus, in the presence of carbonate at fuel cell operating temperatures, the β-form is stabilized relative to the α-form at temperatures $\leq$ 945°K. Second, in the presence of carbonate, both α- and β-$LiAlO_2$ transform to γ-$LiAlO_2$, the rate being greatest in air and lowest in CO_2. This suggests that CO_2 slows the transformations of α- and β- to γ-$LiAlO_2$ by suppressing the hydrolysis of Li_2CO_3 and/or K_2CO_3, thus limiting the formation of Li^+ and OH^-. Third, crystal growth occurs with all three allotropes and proceeds at a much higher rate in the presence of the carbonate melt, thereby suggesting a solution-deposition mechanism. The rate of crystal growth for all three allotropes of $LiAlO_2$ is highest in air and lowest in CO_2. Therefore, by suppressing OH^- formation, CO_2 decreases the solubility of $LiAlO_2$ in the carbonate melt and reduces both crystal growth and the transformation of α- and β- to γ-$LiAlO_2$. On the other hand, a large partial pressure of H_2O would increase the solubility of $LiAlO_2$ in the carbonate melt increasing crystal growth and the rate of transformation of α- and β- to γ-$LiAlO_2$.

The Use of Etching Techniques in the Characterization of Degraded GaAs-GaAlAs Lasers

T. van Dongen, R. P. Tijburg, and J. Bakker

Philips Research Laboratories, Eindhoven, The Netherlands

The appearance of nonluminescent areas in stripe geometry GaAs-GaAlAs double heterostructure (DH) lasers has previously been identified by Deloach and co-workers as related to a major degradation mechanism (1). The correlation between the dark lines and dislocations in the active layer itself or the adjacent GaAlAs layers has been demonstrated by means of transmission electron microscopy (TEM) (2) and subsequent use of a dislocation etchant and a selective etchant (3). The authors of the latter reference used bars of DH material in which dark line patterns were generated by optical pumping with a krypton laser. With etching, they only found textured patterns correlated with the degradation-related dark features in the GaAlAs layer close to the interface with the active layer.

In the study of degraded lasers it may be useful to detect in which layer degradation-related phenomena are present and what may be their starting point. With a combination of selective etching and photoetching, we are able to reveal the presence of degradation-related phenomena in several layers of a DH laser including the active layer.

Selective etching of the various compounds present in DH material has already been described in Ref. (4) and (5). For the selective etching of the GaAs capping layer we used a rough copy of the *p*H-7 etchant consisting of 25 ml H_2O_2, 25 ml H_2O, and 8 drops NH_4OH. The p-type GaAlAs layer was removed selectively with a solution of 50 mg $Ce(SO_4)_2 \cdot 4H_2O$, 50 mg $Ce(NO_3)_3 \cdot 6H_2O$, and 500 mg $Fe_2(SO_4)_3 \cdot H_2O$ in 50 ml H_2O. The $Fe_2(SO_4)_3$ was added to keep the *p*H of the solution lower than or equal to two.

Selective photoetching has been shown to be a sensitive technique for the determination of crystal imperfections in GaAs. Recently, Kuypers and van Gils of this laboratory (7) showed a one-to-one correlation between nonluminescent spots in epitaxial (100) GaP and features revealed by selective photoetching. Their etchant, consisting of 20 ml H_2SO_4 (96%), 20 ml H_3PO_4 (85%), and 0.2 ml H_2O_2 (30%), was used for our experiments.

The time needed to reveal defects depends on the incident light intensity; 30 sec to 1 min is generally sufficient to reveal the desired features at room temperature, using a tungsten 45W microscope lamp, focused to a spot of 1 cm^2.

The degraded lasers studied were cleaved from a standard double heteroslice composed of four epilayers grown by liquid phase epitaxy on a (100) substrate. The lasing area was restricted by a proton bombardment or a pyrolytic silicon dioxide layer on top of the capping layer. In most cases, the dimensions of the stripes were $10 \times 300\ \mu m^2$.

Key words: diodes, lasers, etching.

After life test a laser was desoldered from the mounts. The indium solder had been removed from the surface with concentrated HCl. The chromium-platinum contact on the capping layer had been removed also in the etchant since the chromium dissolves readily when it is in contact with platinum. Next, each subsequent layer was treated with the photoetchant in order to reveal any defect present. After photoetching, the appropriate selective etchant was used to remove the whole layer. In the diodes studied, we found with photoetching the same degradation-related pattern as was present in the spontaneous emission as viewed through the substrate and as revealed by EBIC. Mostly, the textured pattern became visible only in the active layer. Only crystal defects generated during the growth could be revealed in the matching GaAlAs layers. Figure 1a shows the EBIC pattern of a degraded oxide stripe laser diode. Figure 1b shows the same diode with a similar pattern revealed by photoetching of the active layer.

Figure 2a shows a dark line pattern in the spontaneous emission viewed through a window in the substrate contact. The same pattern revealed by etch-

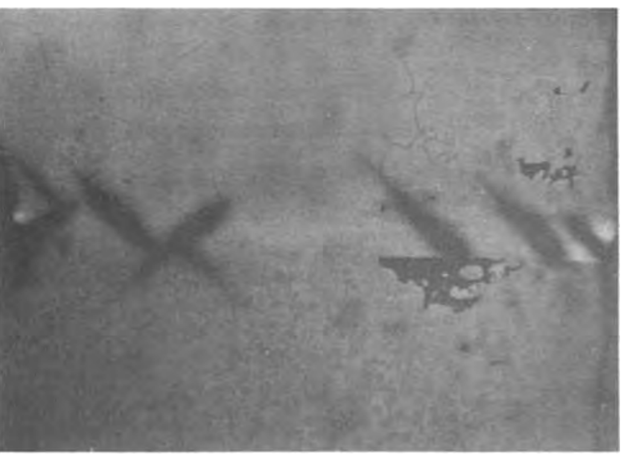

Fig. 1a. Electron beam induced current topograph of a degraded oxide stripe double heterojunction laser diode.

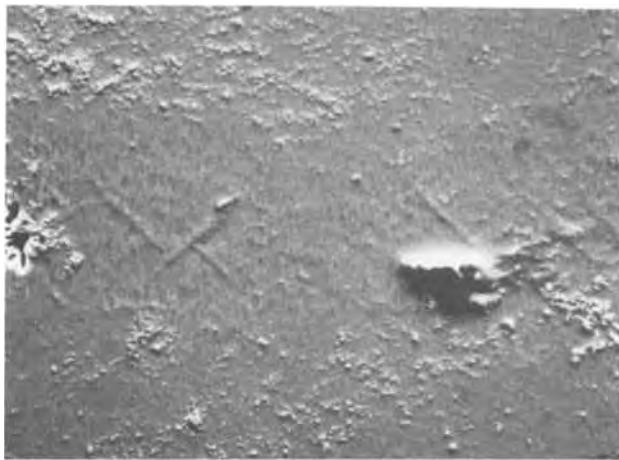

Fig. 1b. The dark lines of 1a revealed by photoetching of the active layer. The etch rate of the dark lines is lower than that of the undisturbed material.

ing of the active layer under illumination is shown in Fig. 2b. Since this figure gives a view of the surface opposite to that of the spontaneous emission, the direction of the etched pattern is opposed to that of the dark lines.

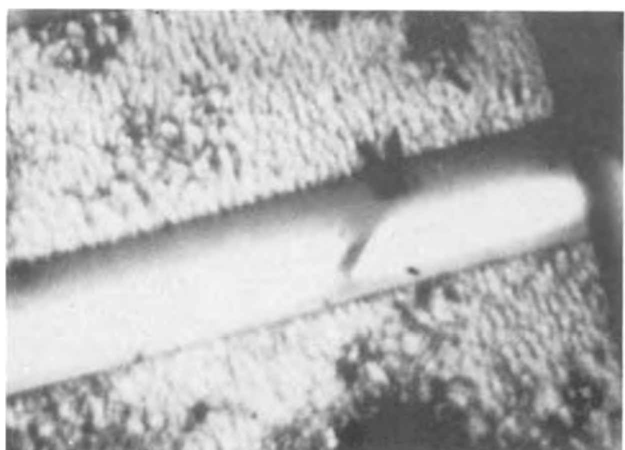

Fig. 2a. Dark lines in the spontaneous emission of a laser diode viewed through a window in the substrate contact.

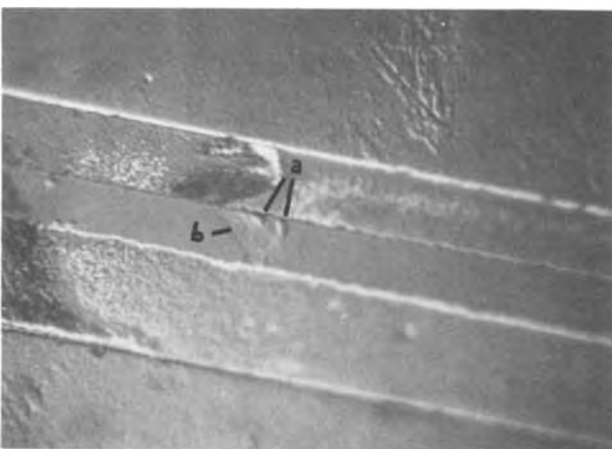

Fig. 2b. The dark lines of Fig. 2a revealed by photoetching of the active layer. This figure gives a view of the surface opposite to that of the spontaneous emission. The direction of the etched pattern is opposed to that of the dark lines. The crystal imperfections, a, show a higher etch rate than the dark lines, b.

Fig. 3. This dark line structure revealed by photoetching is typical for a dark line initiated at a mirror of a GaAs-AlGaAs double heterojunction laser.

In the textured pattern of Fig. 2b obtained with photoetching, we see a difference between the dark lines and the crystal imperfections. The dark lines show a lower etch rate than the adjacent undisturbed material. The crystal imperfections, however, show a higher etch rate than the adjacent undisturbed material. This latter behavior is in accordance with the results observed by Kuhn-Kuhnenfeld on dislocations in p-type GaAs [Ref. (6)]. As yet, the lower etch rate of the dark lines remains unexplained.

If we study the etched samples with secondary emission in a scanning electron microscope, the resolving power is many times better than that of pictures obtained from the spontaneous emission through the substrate. Since details of micron size are clearly observable, the resolution is also better than that of EBIC pictures. As is already known, the dark features initiated at the mirror and associated with catastrophic failure are attributed to crystallographic damaged regions (8). With photoetching of the active layer, it can be made visible that these defects are of different structure than the dark lines which arise elsewhere in the active layer (see Fig. 3).

Acknowledgments

The authors are indebted to Mr. P. de Waard for providing the picture of the luminescence pattern and to Mr. J. de Poorter for his contribution in making the SEM photographs.

Electrochromism at Niobium Pentoxide Electrodes in Aqueous and Acetonitrile Solutions

Benjamin Reichman* and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

Display devices based on electrochromic effects on metal oxides are currently being investigated intensively. For example a number of studies on the electroreduction of WO_3 to form the blue hydrogen tungsten bronze, H_xWO_3, which can be reversibly bleached upon oxidation have been reported (1-4). However the slow dissolution of WO_3 in the aqueous sulfuric acid solutions used as the electrolytes in most cells has prevented application of this system to practical devices. Systems with WO_3 based on nonaqueous solvents, such as glycerol and acetonitrile, with formation of H- or Li-bronzes have also been described (5-8), but these also have problems (dissolution, irreversible coloring, or slow response). We report here preliminary experiments demonstrating electrochromic behavior of Nb_2O_5 in both aqueous and acetonitrile (AN) solutions. This oxide, which is insoluble in many media, shows reasonable response times and reversible coloring and bleaching, and so appears to be a promising system for electrochromic devices. Moreover the excellent stability of Nb towards corrosion in mineral acids because of the protective Nb_2O_5 layer (9) suggests that this material should form stable systems.

The Nb_2O_5 electrodes were prepared by heating a niobium metal disk (12.7 mm dia., cut from a rod of 99.8% Nb obtained from Alfa Ventron) in air to ∿500° C for about 10 min which produced a white layer of Nb_2O_5 about 15 µm thick. Electrical contact was made to the Nb metal by scraping off part of the oxide and connecting a Cu wire to the Nb with silver epoxy cement. A typical current-potential curve recorded with this electrode in 1 M H_2SO_4 with a Pt wire as a counter electrode and vs. a Hg/Hg_2SO_4/1 M H_2SO_4 reference electrode, is shown in Fig. 1. The cathodic current which started at ∿0 V vs. NHE is associated with coloration of the Nb_2O_5 layer and the anodic current, which appeared after reversal of the potential scan direction, is associated with the bleaching process. Upon reducing this electrode in the aqueous 1 M H_2SO_4 with a potential step to -0.6 V vs. NHE, a dark blue color appeared on the electrode surface. The blue color disappeared upon oxidation by a step to + 1 V vs. NHE. The electrochromic process was reversible with a response time of less than 1 sec.

Electrochemical reduction and coloration of the Nb_2O_5 electrode could also be carried out in AN solution containing 0.8 M $LiClO_4$. All solutions were prepared in an inert atmosphere glove-box by dissolving the $LiClO_4$ (dried by heating under vacuum at 110° C for three days), in AN (distilled before use by a previously described procedure (10)). The electrochemical cell containing a Pt counter electrode and bleached Nb_2O_5 quasi-reference electrode was filled in the glove box, then sealed with vacuum grease and removed for the electrochemical experiments. A current-potential curve of the Nb_2O_5 electrode in the AN/$LiClO_4$ solution is shown in Fig. 2. The cathodic current which started at about 0 V vs. the Nb_2O_5 reference electrode is associated with coloration of the film. The electrode surface was bleached during passage of the anodic current which appeared following potential scan reversal. Upon stepping the electrode potential between -0.8 V and +1.5 V in these solutions, the electrode could be colored and bleached reversibly with a response time of 1 to 2 sec. Continuous coloring and bleaching (1 sec steps) was carried out three days with no apparent changes in behavior.

The Nb_2O_5 appeared to be stable in the aqueous-sulfuric acid and the AN solutions

*Electrochemical Society Active Member. Key words: semiconductors, displays, voltammetry.

under cycling and at open circuit, although in the case of the aqueous solutions some hydrogen evolution appeared during the coloration process.

While we have not yet investigated the mechanism of this reaction in any detail, as a working hypothesis we propose that the coloring process in aqueous and AN solutions occurs either by niobium bronze formation (by analogy to the tungsten bronzes) or by reduction of niobium(V) (9):

$$xH^+ + xe^- + Nb_2O_5 \rightleftarrows H_xNb_2O_5 \quad (aq.\ H_2SO_4) \qquad [1]$$

$$xLi^+ + xe^- + Nb_2O_5 \rightleftarrows Li_xNb_2O_5 \quad (LiClO_4/AN) \qquad [2]$$

The Advantages of RHEED over LEED for Surface Studies of Emersed Electrodes

D. M. Kolb and G. Lehmpfuhl

Fritz-Haber-Institut der Max-Planck-Gesellschaft, D-1000 Berlin 33, Germany

Investigations on the structural properties of bare and adsorbate covered electrode surfaces by electron diffraction are among those which cannot be performed directly in situ. The most obvious approach to this problem which has been chosen in the past by several groups (1-5) is the removal of the electrode from the electrochemical environment and subsequent transfer into a vacuum chamber where highly structure-sensitive electron diffraction methods can be employed. The obvious choice at first thought for structural investigations in vacuo is LEED (low energy electron diffraction) and this technique has been used nearly exclusively for the study of the structure of removed electrode surfaces. The results obtained so far show definite promise, although they differ somewhat from group to group. We have chosen an alternative approach. In two recent publications we reported first results on structural investigations of electrode surfaces and adsorbates using RHEED (reflected high energy electron diffraction) (6,7). In the present communication we reemphasize those advantages of RHEED over LEED which are of crucial importance to these combined electrochemical and vacuum studies to effect genuine information transfer.

In diffraction experiments we observe a section through the reciprocal lattice. In case of a surface lattice due to a two-dimensional array of atoms the reciprocal lattice consists of reciprocal lattice rods. In LEED we observe the vertical section through these rods, while in RHEED only a nearly tangential (or horizontal) section by the Ewald sphere through a reduced number of rods is observed.

LEED requires ultra high vacuum (UHV) conditions while RHEED does not. Usually a LEED pattern is not observed from a newly inserted sample unless it is annealed or/and ion bombarded. This is well documented in many surface science articles. Such a pretreatment, however, inevitably destroys the "electrochemical" information of the surface, i.e., with LEED we no longer view that surface which experienced electrochemical manipulation. E.g. in ref. (5) it is stated that no LEED pattern is obtained by observation directly after removal of the Pt electrode and transfer into the UHV chamber. Therefore a 500 eV Ar bombardment was employed until reasonably sharp diffraction spots appeared. It was assumed that this procedure removed the adsorbed impurities only (mainly C and O containing species) leaving the underlying Pt surface unchanged. This is a highly disputable assumption which we question, since a 250-500 eV ion bombardment is standard procedure not only to clean but also to renew surfaces by removing several substrate surface layers. It seems therefore that after such a treatment the surface is no longer the same as that which was in the electrolyte.

RHEED, on the other hand, is not bound to UHV conditions since impurity layers are easily penetrated by the high energy electrons and are not observed as long as they are arranged randomly. The latter, however, is the usual case. If it were not, it would be interesting information in itself. The grazing angles of incidence yield an information depth of about five atomic substrate layers for perfectly flat surfaces, which makes RHEED comparable with LEED in surface sensitivity. While information on the surface structure and on facetts can be gained about equally well with LEED and RHEED, the latter technique can yield additional information on the bulk properties of the sample and on the smoothness of the surface, which is not accessible by LEED (8). Besides, the efficiency of ordinary high vacuum RHEED in terms of time and expenditure is also a significant advantage over LEED.

In the following some examples are given which demonstrate the power of RHEED for surface analyses of emersed electrodes. We have stated in a recent publication (7) that the pronounced desorption peak at -0.14 V (SCE) in the

Key words: electrode emersion, surfaces, RHEED.

current-potential curve for Pt in 1 N H_2SO_4 is due to hydrogen on Pt(110), while H on Pt(111) yields a rather unstructured desorption spectrum. Furthermore, we found that several potential excursions into the oxide region with an initially perfect Pt(111) surface gives rise to the peak at -0.14 V, characteristic for the (110) face (see e.g. Fig. 4 in ref. (7) and compare with Fig. 11 in ref. (5)). Obviously a surface change occurs and our RHEED data support this view. The shape of the diffraction spots which contains information on the size and surface orientation of the coherent scattering areas, indicates facetting of the (111) surface during these potential excursions, with (110) facets being the most likely ones, in agreement with the electrochemical finding.

Drastic surface distortions on the Pt(111) surface by repetitive potential cycling into the oxide region, have also been observed with LEED, however, only as an increase in the angular width of the LEED spots and their gradual disappearance (5). More subtle changes on electrode surfaces, such as superstructures from bare reconstructed or adsorbate covered surfaces, will certainly not be found in LEED after the ion bombardment. Using RHEED we have observed such reconstructions on Au and Ag single crystal surfaces due to adsorption or surface reactions (e.g. Cu adsorption on Au(111) (6) or AgCl formation on Ag(111) (9)). Such reconstructions proved to be very delicate. Some of the superstructure features disappeared slowly during observation because of the electron bombardment. It is clear that weakly bound states would not withstand the ion bombardment pretreatment which is required for observation of LEED patterns.

In the very interesting and beneficial combination of electrochemical and surface physics techniques the transfer of the electrode from the electrochemical cell into the vacuum chamber is a crucial and delicate step. To be sure that the surface is changed as little as possible after electrochemical manipulation the choice of a diffraction technique is important which accepts the electrode surface as it is and does not demand further preparation cycles. This seems to be the case with RHEED rather more than with LEED.

Synthesis of Diamond

Shigeto Yamaguchi* and Nobuo Setaka

National Institute for Researches in Inorganic Materials, Sakura-mura Niihari-gun Ibaraki-ken, 300-31 Japan

It was attempted to produce fine particles of diamond by means of chemical explosion. A mechanical mixture of carbon monofluoride and copper in their powdered states was submitted to a shock-wave compression in a closed vessel of steel. The ratio of both materials was 1:9 by weight. The maximum pressure of this shock-wave compression amounted to about 0.6 mega-bars, whose duration was about one pico-sec. The technique and the apparatus for generating this shock-wave and for transmitting it to the steel vessel should be referred to the report published (1). The reaction vessel reached over 1000°C in temperature during the shock-wave compression concerned. In fact, one discerned the surface of the steel vessel sintered. The reaction products found in the vessel were immersed in conc. nitric acid containing potassium chlorate for several hours in order to dissolve carbon, copper and copper fluoride. The yellowy residue obtained after this chemical treatment has been scrutinized in terms of electron diffraction. The diffraction pattern observed is reproduced in Fig.1. Fig.2 is a double exposure, in which Fig.1 is superimposed onto the reference pattern of gold in order to measure the interplanar spacings of the sample in question. The spacings and the Miller indices determined for the reflections on Fig.1 coincide with those of diamond crystal registered (2). Carbon fluoride was converted

*Electrochemical Society Active Member. Key words: diamond, carbon monofluoride, explosion.

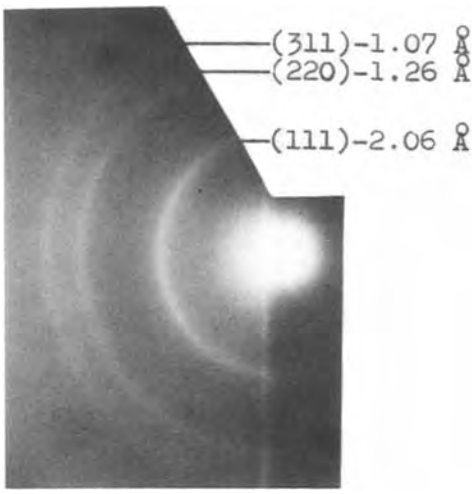

Fig. 1. Electron diffraction pattern from the diamond crystallites produced by exploding a powdered mixture composed of carbon fluoride and copper. Wavelength: 0.0349 Å. Camera distance: 50 cm. Positive enlarged 2.3 times.

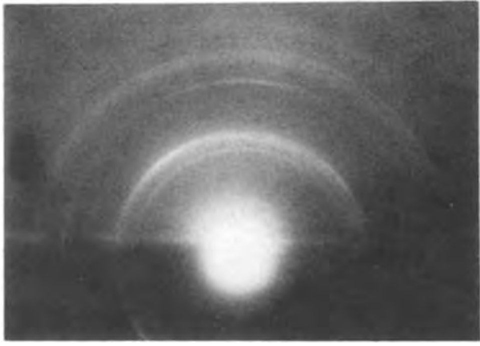

Fig. 2. Double exposure, in which Fig. 1 is superimposed onto the reference pattern of gold for measuring the interplanar spacings of the sample.

into diamond by about twenty percent by weight. The mean particle size of the diamond crystallites here synthesized is estimated to be about 100 Å from the half-width value of the reflections in Fig.1. The powder sample corresponding to Fig.1 was able to scratch the surface of sapphire when used as an abrasive. This also demonstrated that the sample contained diamond.

The chemical reaction that allowed to produce diamond under the conditions laid down can be expressed by the equation

$$(CF)_n + nCu = nCuF + nC \qquad /1/$$

Here the copper powder acted on carbon fluoride not only as a defluorinator, but also as a thermal medium for quenching the diamond powder formed to the purpose. Carbon atoms in the $(CF)_n$ crystal are characterized by the same sp^3-bond as in diamond (3). This implies that carbon in a nascent state as produced by the reaction /1/ can readily be converted into diamond circumstances permitting. Thus the result obtained in this work suggests another way for preparing diamond. Carbon tetrachloride and the Na-K alloy should be employed instead of $(CF)_n$ and Cu, respectively. It is known that the liquid alloy is formed easily at room temperature when sodium and potassium are brought into contact with one another, and that this alloy wetted with carbon tetrachloride explodes violently when shocked mechanically. It is therefore plausible that a mixture of both reagents which is enclosed in a firm vessel gives rise to diamond as the product of an internal explosion when triggered by means of shock-wave. The present experiment corresponds to a preliminary to the diamond preparation by the explosion method.

There are the reports regarding the procedures of preparing diamond with carbon halogenides and metals at high temperature and under high static pressure (4). They differ from the present method, however, insofar as the latter employs the instantaneous dynamic compression.

Electrostatic Binding of Metal Complexes to Electrode Surfaces Coated with Highly Charged Polymeric Films

Noboru Oyama* and Fred C. Anson*

Arthur A. Noyes Laboratory, California Institute of Technology, Pasadena, California 91125

Previous reports in which metal complexes have been attached to electrode surfaces coated with polymeric molecules have depended upon the formation of covalent or coordination bonds in the attachment procedure (1-4). Such schemes can be quite successful but depending, as they do, on rather specific surface chemistry, they are not applicable to as wide a variety of metal complexes as might be desirable. We have observed that coating graphite electrodes with polymers bearing charged ionic groups produces surfaces which strongly bind multiply-charged metal complexes bearing charges opposite to that on the attached ionic polymer. By exploiting this observation it is entirely possible that virtually any desired metal ion can be attached in large quantities to electrode surfaces by coordinating the metal ion with ligands that produce a multiply-charged complex ion.

EXPERIMENTAL

The source and mounting of the pyrolytic graphite electrodes and procedures for coating them with adherent films of poly (4-vinylpyridine) (M.W.= 7.4 x 10^5) have been previously described (1,4) along with the electrochemical measuring techniques employed. Potentials are quoted vs. a sodium chloride saturated calomel electrode.

RESULTS AND DISCUSSION

The effective pK values of polyelectrolytes such as poly (4-vinylpyridine) (PVP) depend somewhat upon molecular weight. However, it is likely that PVP is largely protonated at pH values below ca. 3 and essentially neutral at

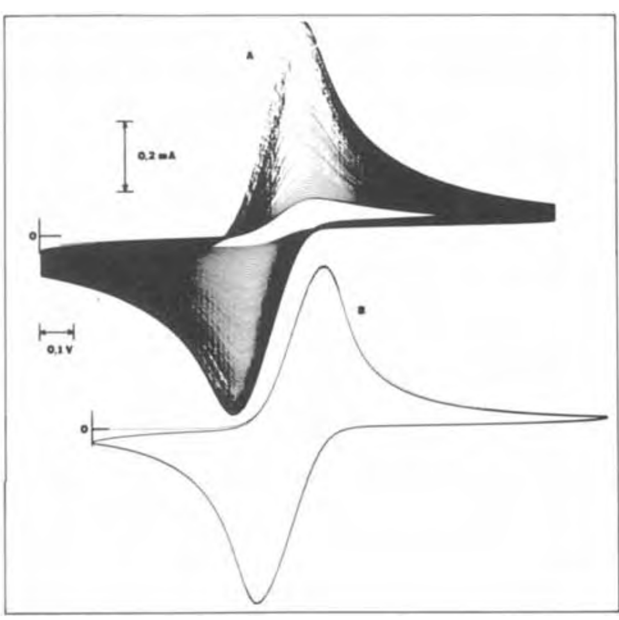

Figure 1: A - Cyclic voltammograms of 5 mM $Fe(CN)_6^{3-}$ at a pyrolytic graphite electrode (0.17 cm^2) coated with 4.6 x 10^{-7} moles cm^{-2} of pyridine as PVP. Supporting electrolyte: 0.2 M CF_3COONa at pH 3.8. The potential was cycled continuously at 200 mV s^{-1} between +0.8 and -0.7 volt. The voltammogram reached a steady state after 20 minutes of cycling. B - Cyclic voltammogram resulting after the electrode used in A was washed with water and replaced in 0.2 M CF_3COONa at pH 2.9.

*Electrochemical Society Active Member

Key Words: Electrode coatings, polyelectrolyte films, ion incorporation

pH values above ca. 8 (5). To prepare a highly positively charged electrode surface a graphite electrode was coated with PVP and exposed to supporting electrolyte at pH 3.8. The resulting electrode was used to record the series of cyclic voltammograms for $Fe(CN)_6^{3-}$ shown in Figure 1A.

The peak current obtained immediately after the electrode was introduced into the solution is somewhat smaller than the current at uncoated electrodes because the polymer film retards the $Fe(CN)_6^{3-/4-}$ electrode reaction somewhat (4). However, in sharp contrast with uncoated electrodes, the voltammetric currents increase as the potential is cycled continuously and they reach extraordinarily large values. (The currents also increase, although somewhat less rapidly, if the electrode potential is not cycled.) If the electrode is removed from the solution, rinsed and transferred to an acidic solution containing only supporting electrolyte the voltammogram shown in Figure 1B is obtained and its magnitude is virtually unaffected by repeated cycling for periods up to one hour. The voltammogram in Figure 1B disappears if the electrode is removed, washed with electrolyte at pH 10 and replaced in the supporting electrolyte. These observations seem clearly to demonstrate that the protonated PVP film on the electrode surface preferentially incorporates the multiply-charged ferricyanide as the counter ion, even though much larger concentrations of singly-charged trifluoroacetate anions are present in the supporting electrolyte. The behavior is quite analogous to that of polyelectrolytes in homogeneous solutions under conditions where the polyion is highly charged (6). The fact that multiply-charged counter ions incorporated into PVP films are not replaced rapidly by ion exchange upon exposure to simple univalent electrolytes containing none of the multiply-charged ion indicates that a significant activation barrier impedes the break-up of the electrostatic binding within the polyionic film.

Figure 2 emphasizes this point for the case in which the dinegative anion, $IrCl_6^{2-}$, is held electrostatically within a protonated PVP film. Initially after transfer of the coated electrode from the solution of $IrCl_6^{2-}$ to a solution containing only supporting electrolyte at pH 2.8 there is a fairly rapid loss of a fraction of the $IrCl_6^{2-}$ from the surface - presumably from the portion of the polymer most accessible to the electrolyte. However, after a few minutes of repetitive scanning the voltammogram settles down to the one shown in Figure 2 which undergoes no further change during several additional minutes of scanning. If the pH of the supporting electrolyte is raised to 4.5 the release of $IrCl_6^{2-}$ from the surface resumes as revealed by a steadily diminishing voltammetric response.

The extent of the electrostatic attachment is not related simply to the charge carried by the counter ion being attached. For example, exposing a PVP coated electrode to a solution containing both 5 mM $Fe(CN)_6^{3-}$ and 5 mM $IrCl_6^{2-}$ leads to greater binding of the less highly charged anion. Thus, chemical differences among the incorporated ions appear to modulate purely electrostatic factors in controlling the extent of incorporation.

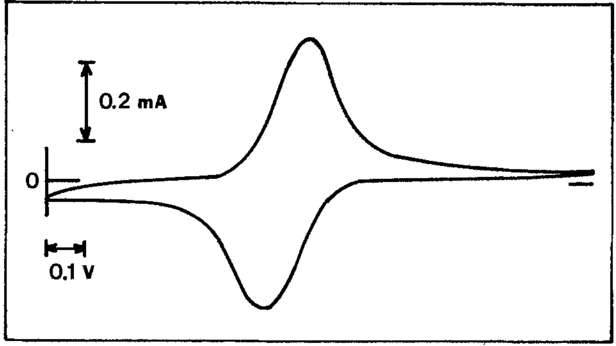

Figure 2: Steady-state cyclic voltammogram for an electrode coated with 4.6 x 10^{-7} moles cm^{-2} of PVP, soaked in a 5mM solution of $(NH_4)_2IrCl_6$ at pH 2.8 (CF_3COOH) for 60 seconds, rinsed with water and transferred to supporting electrolyte solution (0.2 M CF_3COONa at pH 2.6). Scan rate: 200 mVs^{-1}. Potential range: +1.3 to -0.1 volt.

Electrostatic Binding of Metal Complexes to Electrode Surfaces Coated with Highly Charged Polymeric Films

Noboru Oyama* and Fred C. Anson*

Arthur A. Noyes Laboratory, California Institute of Technology, Pasadena, California 91125

Under pressing conditions (high concentrations of incorporated ion, low concentration of supporting electrolyte, long exposure times) it is possible to incorporate greater quantities of ferricyanide into protonated PVP films than would correspond to electrostatic neutralization of all of the positive charge present on the fully protonated pyridine groups. For example, a PVP film containing 4.6 x 10^{-7} moles cm^{-2} of pyridine incorporated as much as 2 x 10^{-7} moles cm^{-2} of ferricyanide. We presume that under these conditions the $Fe(CN)_6^{3-}$ is incorporated in the form of an ion pair with a cation of the supporting electrolyte. With $IrCl_6^{2-}$ the maximum quantity incorporated into films never exceeded ca. 30% of the total possible cationic charge in the polyionic film.

Multiply-charged cationic complexes can also be incorporated electrostatically into polyanionic films. For example, Figure 3 shows voltammograms

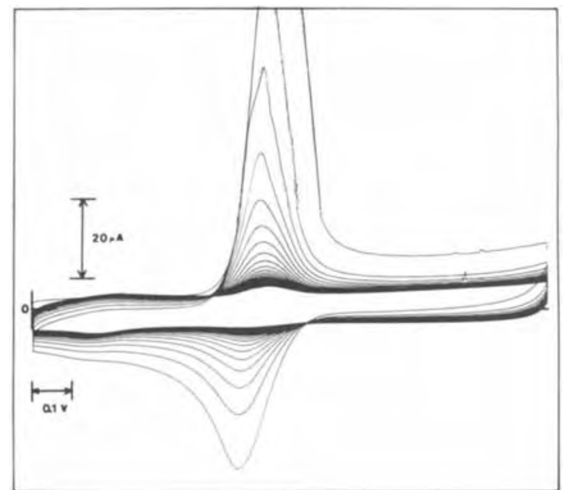

Figure 3: Cyclic voltammograms for $Ru(NH_3)_6^{3+/2+}$ attached to a pyrolytic graphite electrode coated with ca. 4 x 10^{-7} moles cm^{-2} of carboxylic acid as polyacrylic acid (M.W.=2.2 x 10^5). The coated electrode was soaked for 5 min. in 1 mM $Ru(NH_3)_6^{3+}$ at pH 6.1, washed for 10-20 s. with water, transferred to supporting electrolyte (0.2 M CF_3COONa + 5 mM $Na_2B_4O_7$; pH 8.1) and the potential cycled continuously between +0.3 and -1.0 volt at 200 mV s^{-1}. The time elapsed between the first and last scans was ca. 7 min.

for an electrode that was coated with polyacrylic acid, soaked in a 1 mM solution of $Ru(NH_3)_6^{3+}$ at pH 6.1 (where the polymer is converted to a polyanion) and transferred to pure supporting electrolyte solution. Large quantities of the tripositive cation are clearly incorporated into the polyanionic film (ca. 10^{-8} moles cm^{-2} of $Ru(NH_3)_6^{3+}$) but repetitive cycling of the potential leads to continuous departure of the $Ru(NH_3)_6^{3+}$ from the film. The loss of $Ru(NH_3)_6^{3+}$ occurs whether or not the potential is cycled but the rate of loss is greater during cycling when the charge on the incorporated cation is diminished by one unit during each half-cycle. The less permanent binding of $Ru(NH_3)_6^{3+}$ by the polycarboxylate coating may be associated with the more hydrophilic nature of this film compared with PVP: The latter polymer is insoluble in aqueous acid while polysodium acrylate is water soluble (although films deposited on pyrolytic graphite resist dissolution). The activation barriers for entry or departure of cationic reactants from the polycarboxylate layer are apparently considerably smaller than for PVP.

The attractive simplicity of the electrostatic binding procedure for holding large quantities of metal complexes on electrode surfaces is complemented by the variety of ionic polymers that are available to serve as anchoring matrices. In addition, the procedure allows complexes to be introduced on electrode surfaces without change in their primary coordination sphere, a factor that could be of considerable importance with catalytically active complexes. These attributes have encouraged us to explore more broadly the combinations of charged complexes and ionic polymers that may be exploited to produce electrode surfaces laden with desired ionic reactants.

NH Cu Cl (I Cl), a New Highly Conducting Solid Electrolyte

S. Geller, J. R. Akridge,*,[1] and S. A. Wilber

Department of Electrical Engineering, University of Colorado, Boulder, Colorado 80309

ABSTRACT

A new solid electrolyte, with a very narrow solid solution range, $NH_4Cu_4Cl_3(I_{2-x}Cl_x)$, $0.09 \leq x \leq 0.13$, isostructural with $RbAg_4I_5$ and $RbCu_4Cl_3I_2$ is reported. The corresponding lattice constant range is 9.985-9.982 ± 0.003Å. The new solid electrolyte is thermodynamically stable between 130° and 170°C. Certain formulations which are not phase pure appear to have improved stability below 130°C. Room temperature conductivities as high as 0.21 $(\Omega\text{-cm})^{-1}$ have been attained. At 150°C, conductivities as high as 0.73 $(\Omega\text{-cm})^{-1}$ have been attained.

Recently, Takahashi *et al.* (1) have reported a new solid electrolyte $Rb_4Cu_{16}Cl_{13}I_7$ with a high electrolytic conductivity. We have reported (2) the crystal structure and conductivity of $RbCu_4Cl_3I_2$ and our continued investigation has shown that there is a solid solution range $RbCu_4Cl_3(I_{2-x}Cl_x)$ with $0.0 \leq x \leq 0.4$ (3). This range includes the composition reported by Takahashi *et al.* which should be written $RbCu_4Cl_3(I_{1.75}Cl_{0.25})$.

We write the general formula $RbCu_4Cl_3(I_{2-x}Cl_x)$, because there is clear evidence[2] that the twelvefold sites are filled with chloride ions exclusively, and when excess chloride ions are present, they replace iodide ions in the eightfold sites. That is to say, in the solid solutions, none of the iodide ions appear to be in the twelvefold sites. Crystals of these substances are isostructural with $RbAg_4I_5$ for which structural details are given in several papers (2, 4-6).

The highest solid electrolyte conductivities in the moderate range of temperature 70°-450°K have been reported by us (2) for $RbCu_4Cl_3I_2$; at room temperature the value is at least 0.47 $(\Omega\text{-cm})^{-1}$. The analogous value reported for $RbCu_4Cl_3(I_{1.75}Cl_{0.25})$ by Takahashi *et al.* (1) is 0.34 $(\Omega\text{-cm})^{-1}$.

In this paper we report a new highly conducting solid electrolyte. For simplicity, we give the formula as $NH_4Cu_4Cl_3(I_{1.9}Cl_{0.1})$ in the title of the paper, even though a narrow solid solution range exists close to this formula. This solid electrolyte is closely related to the materials discussed above.

Preparation of the Materials

Preparation and purification of CuI and CuCl have been given in Ref. (2). NH_4I was used without further purification, but was carefully dried, after which it was stored over P_2O_5 in a desiccator.

The materials studied in this investigation were prepared by first melting appropriate amounts of reactants in an evacuated, then sealed Pyrex tube, quenching, grinding the sample in a nitrogen-filled glove box, pelletizing, heating at some temperature below the melting point, and continuing by solid-state reaction (*i.e.*, further regrinding, repelletizing, reheating when found necessary as judged from x-ray powder diffraction photographs). Alternatively, the mixture of reactants was not premelted; that is, all steps were carried out in the solid state. It was found that an optimum reaction temperature is 150°C.

Numerous attempts to prepare stoichiometric $NH_4Cu_4Cl_3I_2$ were unsuccessful. Furthermore, unlike the case for the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system, the range of composition we were able to attain was very narrow; the measured range of lattice constant is 9.982-9.985Å. In the next section, we show how the estimate of composition was made.

Determination of the Composition

Because it did not seem possible to prepare the stoichiometric compound $NH_4Cu_4Cl_3I_2$, and because it is not a simple matter to ascertain the phase purity of these materials from powder diffraction data, we resorted to the following method of estimating the composition.

The values of the lattice constants of $RbAg_4I_5$ (4, 7) and of $NH_4Ag_4I_5$ (7) have been reported: 11.24 and 11.19Å, respectively. However, these were not sufficiently precise for the purpose. New samples of these materials were prepared; powder photographs were taken with CrK radiation. The lattice constants obtained are 11.244 and 11.204Å, respectively, giving a difference of 0.040Å. The lattice constant of $RbCu_4Cl_3I_2$ is 10.032Å (2). If a linear dependence on the ionic size is assumed, then we might expect a lattice constant of 9.992Å for stoichiometric $NH_4Cu_4Cl_3I_2$. In the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system, we have found (3) that the substitution of 0.1 Cl^- for 0.1 I^- produces a decrease of 0.0075Å in lattice constant. Our measured lattice constants have a range of 9.982-9.985 ± 0.003Å. If we take 9.992Å as the lattice constant of the stoichiometric compound, these measured values give a "most probable" solid solution range: $NH_4Cu_4Cl_3I_{1.87}Cl_{0.13}$ to $NH_4Cu_4Cl_3(I_{1.91}Cl_{0.09})$.

This approach has been corroborated as follows. An unsuccessful attempt was made to produce the material

* Electrochemical Society Active Member.

[1] Present address: Union Carbide Corporation, Parma Research Center, Parma, Ohio 44130.

Key words: electrolyte, thermodynamics, conduction.

[2] This comes from an experiment carried out during investigation of the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system (3) which indicates that a content of more than two iodides per formula unit is unattainable, at least under the conditions of preparation described in the text.

with formula $[Rb_{0.5}(NH_4)_{0.5}]Cu_4Cl_3I_2$; unreacted CuI was present even after five regrindings and a total of 80 hr of heating at 150°C. The lattice constant of the solid electrolyte material was 10.008Å. If it is assumed that the ratio of Rb^+ to NH_4^+ is 1 and attribute the low lattice constant (it should be 10.012Å) to dissolved Cl^-, the formula should be $[Rb_{0.5}(NH_4)_{0.5}]Cu_4Cl_3(I_{1.95}Cl_{0.05})$. Such a specimen was prepared; it appears to be single phase and it still has the lattice constant 10.008Å. This, therefore, implies a lattice constant of 9.992Å for a hypothetical $NH_4Cu_4Cl_3I_2$, equal to the predicted value. It should be mentioned that in the $RbCu_4Cl_3(I_{2-x}Cl_x)$ system (3), the lattice constant is linear in x.

Crystal Structure Analysis

A very small crystal (largest dimension 0.10 mm; smallest dimension, 0.06 mm) was obtained by heating a specimen of nominal composition $NH_4Cu_4Cl_3(I_{1.5}Cl_{0.5})$ which was clearly not single phase, at 150°C for 14 days. The solid electrolyte in this material has a lattice constant of 9.982Å implying the composition $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$ as discussed earlier. Photographs taken with a Buerger precession camera confirmed that the crystal is isostructural with $\alpha RbAg_4I_5$ (4) (space group, $P4_132$ or $P4_332$).

The intensity data were collected with an automated Buerger-Supper single crystal diffractometer; Zr-filtered, $MoK\alpha$ radiation was used, with 0.5°/min scanning rate and scan width (1.5 + 0.5 Lp), where L is the Lorentz and p the polarization factor. No corrections were made for absorption. Calculations were made with computer programs and with atomic scattering factors for which references are given in Ref. (2).

Only highlights of the results need be given here. Tables of parameters, of interionic distances and of calculated and observed structure amplitudes are given in Tables I, II, and III. The agreement factor $\Sigma\Delta F/\Sigma F_{obs}$, where $\Delta F = ||F_{obs}| - |F_{calc}||$, for 125 observed intensities is 5.3%. The low total number of observed reflections results from the very small size of the crystal. However, the data were of sufficient number to give convergence of parameters.

Over-all, there is really no statistically significant difference of positional and occupancy parameters between $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$ and $RbCu_4Cl_3I_2$ and the same is true essentially of the interionic distances. One should expect, of course some difference between the $(NH_4)^+$-Cl^- and Rb^+-Cl^- distances in $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$ and $RbCu_4Cl_3I_2$. The results, 3.368 (σ = 0.005) and 3.381 (σ = 0.003)Å are in the right direction, even though the difference does not have statistical significance. [It should be recalled (2) that in both compounds, only chloride ions surround the large cations.]

For completeness, the following results should be mentioned. At one point in this investigation, we thought that the crystal had the stoichiometric formula $NH_4Cu_4Cl_3I_2$, and the structure was refined on this basis. The agreement factor was only slightly higher, 5.6%, and the parameters and interionic distances were almost identical with those of the aforementioned analysis. It is somewhat disappointing that the data and method of calculation could not make a better distinction in this case.

Stability of $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$

The compound $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$ is not thermodynamically stable except at temperatures above 130°C and below its melting point of approximately 170°C, indeed a narrow stability range. The compound could not be made by solid-state reaction below 130°C. Several other experiments also showed that although the compound could be quenched to room temperature where it would remain for considerable time (>1 month), it was not thermodynamically stable. For example, a material made to have nominal composition $NH_4Cu_4Cl_3(I_{1.67}Cl_{0.33})$, containing the solid electrolyte $NH_4Cu_4Cl_3(I_{1.86}Cl_{0.14})$, that is, not phase pure but not containing excess CuI, when quenched from 120°C, showed the presence of CuI in the powder photograph.

A powder photograph taken of material with nominal composition $NH_4Cu_4Cl_3(I_{1.67}Cl_{0.33})$ at a temperature of 100°C (8 hr exposure) showed complete decomposition of the material.

The conductivity measurements also showed that the material is not thermodynamically stable at temperatures below 130°C. However, the presence of excess CuCl and other unidentified phases, not readily seen in the powder photographs, did seem to increase the stability and, in one case, substantially.

Conductivity

This material is unusual in several respects. It is not unique, however, in the respect that only a solid solution is attainable. [See for example Ref. (8, 9).] It is possible that under conditions we have not tried, the stoichiometric compound is attainable; it does not seem to be quenchable to room temperature in any case. (Needless to say, we have tried such experiments.) We have not been able to make conductivity measurements on the material with the formula given.

Our approach is as follows: We prepare a pellet of dimensions approximately 0.64 cm diam by 0.44 cm long with copper electrodes. The copper powder is freshly prepared and compressed onto the ends of

solid electrolyte. That is to say, first the copper powder is put into the die and smoothed, then the solid electrolyte, and then the copper powder. The composite is then compressed at 500 bars. The resulting pellet is then placed between the electrodes of the measuring device and heated uniformly to 150°C. We have found that this results in improved contact of the electrodes and in densification of the solid electrolyte.

In the case of samples made up with nominal composition $NH_4Cu_4Cl_3(I_{1.67}Cl_{0.33})$ (but we emphasize, not single phase), we first obtain a conductivity of approximately 0.21 $(\Omega\text{-cm})^{-1}$ at room temperature. As the sample is heated we notice a substantial decrease in the conductivity, undoubtedly a result of decomposition. On heating to above 130°C, there is a large increase in the conductivity. On further heating to 150°C, the conductivity increases as shown in Fig. 1(a). On decreasing the temperature, the conductivity decreases normally until 130°C is reached, and then substantially as shown in Fig. 1(a). Powder photographs taken of the material after such experiments show, as expected, a decomposition of the solid electrolyte that was present. Between 130° and 150°C, the solid electrolyte is surely present.

With a sample of the composition which we have deduced for the solid electrolyte and which we believe to be single phase, the above procedure fails. At room temperature, we obtained an initial value of 0.13 $(\Omega\text{-cm})^{-1}$, but as the sample was heated the conductivity decreased markedly and did not increase again even above 130°C. Powder photographs showed that the solid electrolyte had decomposed considerably. This experiment was repeated with Ag electrodes with similar results.

On the other hand, with a sample made up with nominal composition $NH_4Cu_4Cl_3(I_{1.5}Cl_{0.5})$ which previously (as seen in powder photographs) contains a marked excess of CuCl (and therefore other phases, not readily identifiable), the situation is considerably different. Again the specimen first shows a high initial room temperature conductivity of 0.23 $(\Omega\text{-cm})^{-1}$. On heating, there does not appear to be the strong indication of decomposition observed in the two other cases. On cooling, there appears to be a transition at 130°C [see Fig. 1(b)], but it is much unlike the other two cases and substantial conductivities are observed down to 10°C. A sudden decrease in conductivity occurs on cooling to 5°C. On reheating to room temperature from 5°C, there is still a substantial conductivity, 0.13 $(\Omega\text{-cm})^{-1}$, but markedly lower than obtained either before or after heating. A powder photograph showed the presence of CuI.

Other experiments show that excess CuCl by itself does not stabilize the material as does preparation of solid solutions as though they really did exist. We emphasize that the solid electrolyte has a very narrow composition range and that materials with compositions containing more Cl^- ion are not single phase.

The conductivities were measured with the vector impedance meter[3] used to make the measurements on $RbCu_4Cl_3I_2$ (2). In Fig. 1(a), below 130°, experiments were run at two different cooling rates. The lower curve is for the slower cooling rate; it is seen that under the slower cooling rate, the decomposition is greater as would be expected. Above 130° the slope

[3] The frequency range has been expanded from 10^{-1} Hz to 650 kHz.

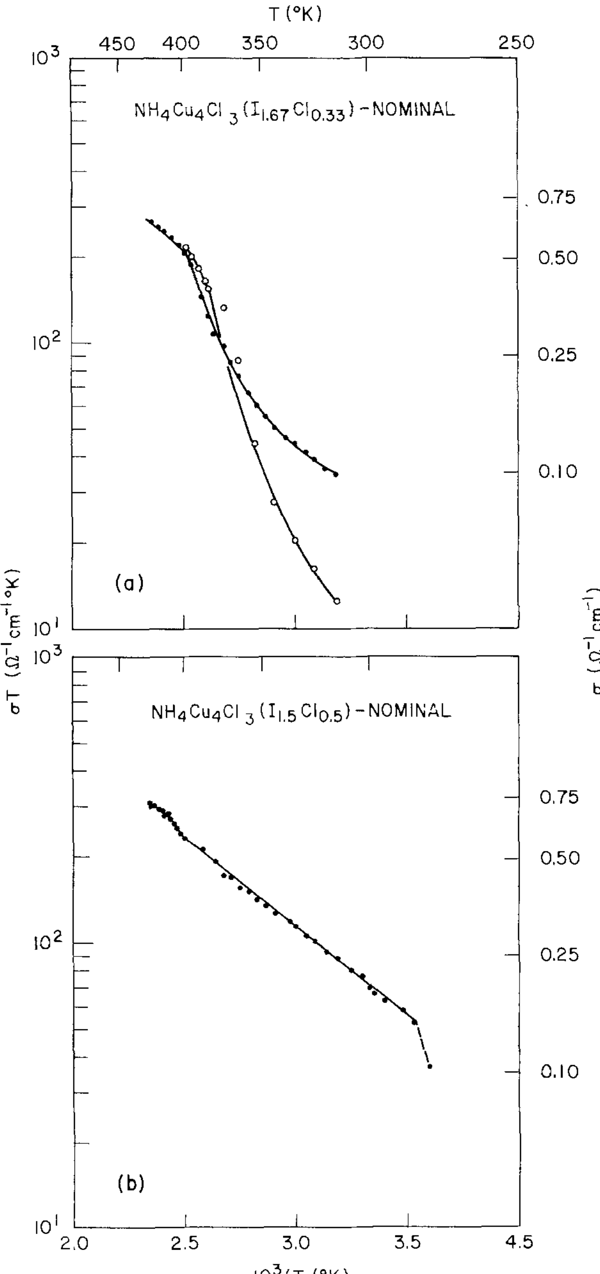

Fig. 1. (a) Specific conductivity multiplied by absolute temperature vs. reciprocal temperature for the nominal composition $NH_4Cu_4Cl_3(I_{1.67}Cl_{0.33})$ (not single phase). Also shown are the absolute temperature and specific conductivity. The upper and lower curves are the results for faster and slower cooling, respectively. Note that the curves meet at $T = 400$°K where the solid electrolyte phase is thermodynamically stable. (b) Specific conductivity multiplied by absolute temperature vs. reciprocal temperature for the nominal composition $NH_4Cu_4Cl_3(I_{1.5}Cl_{0.5})$ (not single phase). Instability appears at 280°K.

of log (σT) *vs.* $1000/T$ yields 0.15 eV for the enthalpy of activation of motion.

Figure 1(b) shows a small anomaly at 130°C, indicating perhaps an onset of decomposition of the solid electrolyte present, but this is not confirmed by x-ray powder photography. The slope of log (σT) *vs.* $1000/T$ gives 0.13 eV for the enthalpy of activation of motion.

Additional Discussion

The instability of the new solid electrolyte prevents an exact determination of its electrical transport properties. One should expect the conductivity to behave similarly to that of the analogous rubidium materials. In any case, there is no doubt that the solid electrolyte $NH_4Cu_4Cl_3(I_{1.87}Cl_{0.13})$ has high conductivity, and that from a practical viewpoint it has been proved that the solid electrolyte can be stabilized at least down to 5°C. Further experiments toward stabilizing this solid electrolyte are in progress. Needless to say, such experiments are worthwhile from an economic point of view because NH_4I is much less expensive than RbI and CuI and CuCl are much less expensive than AgI.

Selective Dissolution of Cd-Mg Alloys

I. Static Samples

J. I. Gardiazábal[1] and J. R. Galvele*

Comisión Nacional de Energía Atómica, Departamento de Materiales, 1429 Buenos Aires, Argentina

ABSTRACT

The susceptibility to selective dissolution of Cd-Mg alloys in deaerated 0.5M $NaClO_4$ solutions, at room temperature to 75°C, was studied. The range of compositions studied was Cd-11 a/o Mg (Cd-2.6 w/o Mg) to Cd-50 a/o Mg (Cd-18 w/o Mg). Between −0.9 and $-0.5V_{(NHE)}$, selective dissolution of magnesium was found. Cadmium was accumulated on the surfaces as a soft, crystalline, metallic film, most probably as a porous layer. The selective dissolution rate was four orders of magnitude faster than that reported in literature for similar compositions of Cu-Zn brass in NaCl solution. The selective dissolution became faster as the temperature and the magnesium content of the alloy increased.

One important type of corrosion of alloys is the selective dissolution or dealloying. By this process the more active component is leached away from the alloy. The nobler metal remains on the corroded alloy surface, usually as a sponge-like product. Although extensive work has been done on the subject, there is still considerable disagreement about the mechanism of selective dissolution. While some authors have suggested that both metals dissolve, and the nobler of the two is redeposited (1, 2), others have suggested that only the less noble of them is dissolved. In the latter case, the nobler metal is rearranged on the alloy surface, either by volume diffusion (3, 4) or by some type of surface diffusion (5). Arguments against the volume diffusion stem from the fact that at room temperature dealloying is observed in high melting point alloys. The diffusion coefficients at room temperature, if extrapolated from high temperature measurements, seem to be too low to account for the dealloying process by volume diffusion.

In the present work, a low melting point alloy was selected for the investigation in the expectancy that fast dealloying processes would be observed. To avoid the difficulties introduced by the formation of intermetallics, an alloy with a complete solid solubility range was selected. The system chosen was cadmium-magnesium. This alloy shows complete solubility at all the compositions (6). From the dealloying point of view, the alloy seemed to be promising because of the difference of almost 2V in the standard equilibrium potentials of the two components. On the other hand, since hydrogen evolution on cadmium shows a high overvoltage, no strong interference was expected by this cathodic reaction. This was confirmed in Part II, where calibration measurements were made with Cd-disk, Cu-ring rotating electrodes. The collection factor, *N*, showed a difference of less than 1%, compared to the theoretical value. This showing that if there was a cathodic reaction of hydrogen evolution, its contribution to the current density was a minor one.

This work is divided into two parts. The first one shows that a dealloying process takes place in this system. In the second part, ring-disk rotating electrodes are used. This part attempts to determine if a process of simultaneous dissolution of Cd and Mg, with the redeposition of cadmium, is operating.

Experimental

The samples were prepared by melting 99.99% cadmium and 99.99% magnesium in an iron crucible, as described in (7). The melting was done under an argon atmosphere, and the melt was made homogeneous by mechanical stirring. Eight mm diameter ingots of samples were cast in graphite crucibles, which were previously dried for 24 hr at 110°C. The as-cast ingots were etched in a 5% HNO_3 solution and sealed in quartz tubes, with a 400 mm Hg argon pressure. To make the ingots homogeneous, they were annealed for 40 hr at the temperatures indicated in Table I, followed by water quenching. Finally, the ingots were machined down to 6 mm diameter rods, and stored in a desiccator. Five different compositions were used, with the nominal values of Cd-50Mg; Cd-31Mg; Cd-26Mg; Cd-23Mg; and Cd-11Mg, in atomic percentage (a/o). The analytical compositions are shown in Table I.

Polarization samples were prepared from the 6 mm diameter rods cut into pieces 10 mm long. A copper electric lead was fastened to one end of the rod. The electric lead and the rod surface were covered with an epoxy resin (ARALDIT "D" CY 230 plus HY 951), leaving one end of the rod exposed. The exposed face was abraded with 600 silicon carbide paper immediately before exposing the sample to the test solution.

Polarization measurements were made in a double-walled Pyrex glass cell, with a platinum counterelectrode. The temperature of the cell was controlled with a Haake FS thermostat. A saturated calomel electrode was used as reference. All the potentials are reported in the normal hydrogen electrode scale (NHE). The potential was controlled by means of a LYP-Electronica potentiostat, and the current recorded with a Honeywell Electronik 19 recorder.

The electrolyte used was 0.5M $NaClO_4$, *p*H 5.5, made up from a $HClO_4$ solution, and with the *p*H adjusted with an NaOH solution. This electrolyte was chosen to minimize the formation of Cd complexes in the solution. For the same reason, no buffers were used in the present work.

Results

Polarization curves.—Anodic polarization curves were drawn for Cd-50Mg and Cd-26Mg alloys in 0.5M $NaClO_4$ solution at 25° 50°, and 75°C. The measure-

Table I. Chemical composition and annealing temperatures of the Cd-Mg alloys

Alloy	Magnesium content w/o	Magnesium content a/o	Annealing temperature (°C)
Cd-11Mg	2.6	11.0	270

Key words: alloy, anode, corrosion, dissolution.

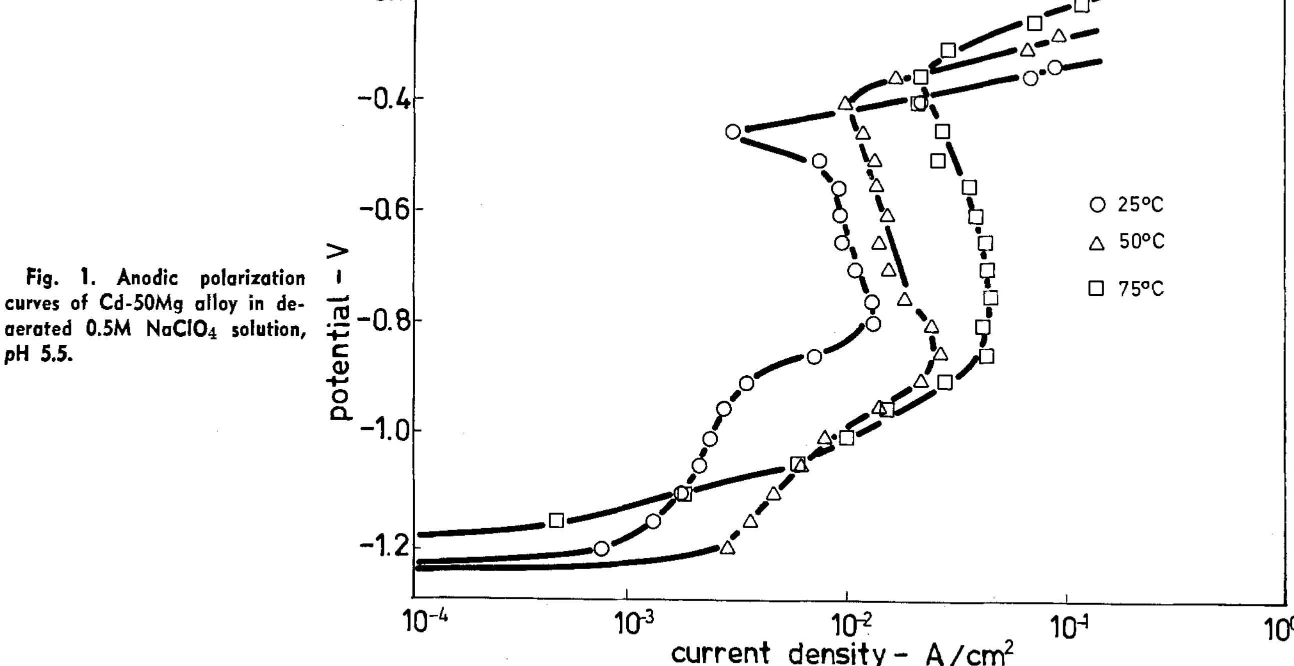

Fig. 1. Anodic polarization curves of Cd-50Mg alloy in deaerated 0.5M $NaClO_4$ solution, pH 5.5.

ments were performed in steps of 50 mV, waiting 5 min at each potential. Figure 1 shows the results for Cd-50Mg alloy, similar results were obtained with the Cd-26Mg alloy. Above the corrosion potential the current increased to a potential around −0.9 to −0.8V. Above this potential there was a region where the current was potential-independent. Around −0.4V, a new current increase was found. As confirmed by separate experiments which are described below, up to about −0.5V selective dissolution of magnesium was taking place. Above −0.5V, the current increase was followed by the simultaneous dissolution of magnesium and cadmium. The exact potential at which cadmium begins to dissolve simultaneously was measured in the second part of this work by using ring-disk rotating electrodes. An increase in the temperature increased the rate of selective dissolution of the alloy at potentials lower than −0.5V. After the polarization experiments, a thick, poorly adherent film was covering the samples.

The curves in Fig. 1 are similar in shape to those reported by Pickering and Byrne (8) for the selective dissolution of Cu-Zn brass. However, the dissolution rates in Cd-Mg are considerably higher. The Cd-Mg system seems to dealloy at a rate about four orders of magnitude higher than Cu-Zn. Pickering and Byrne reported for gamma-brass (Cu 65 a/o Zn) a potential-independent dissolution rate of the order of 10^{-6} A/cm^2. On the other hand, Cd-50Mg showed a potential-independent dissolution rate of the order of 10^{-2} A/cm^2.

From the anodic polarization curves three potentials (−0.51, −0.71, and −0.91V) were chosen for the study of the dealloying process. These were the potentials used in most of the remaining experiments.

Surface film composition.—Samples of the Cd-Mg alloys were exposed to the $NaClO_4$ solution at 25°C for 3 hr at constant potentials. The potentials used were the three reported above. The corroded samples were mounted for metallographic cross sectioning. The cross-sectioned samples were polished down to ¼ μm diamond powder, observed under the optical microscope, and analyzed with a CAMECA M.S. 46 Microprobe Analyzer.

Figure 2 shows the cross-section micrograph of a sample of Cd-31Mg exposed for 3 hr at −0.51V and 25°C in the 0.5M $NaClO_4$ solution. Figure 3 shows the microprobe analysis of the same sample. The identification of the various regions is as follows: R, mounting resin; F, surface fim; A, alloy. The cps number shows the full-scale range of the meter, in counts per second. The number of counts per second is proportional to the concentration of the analyzed element in the sample. The cadmium analysis (top of Fig. 3), shows that the cadmium content in the film was higher than that in the alloy. The magnesium content in the film, on the other hand, was very low. There was no concentration gradient of magnesium in the film.

Since the number of counts per second is proportional to the concentration of the analyzed element, an estimate can be made of the composition of the film. From the count-reading for cadmium in the alloy and that in the film, a semi-quantitative estimate of the cadmium content in the film was made (Table II). No similar estimate of the Mg content could be made, because the Mg readings in the film were in the range of the background noise of the equipment. In all the cases, the Mg content in the film was smaller than 1 weight percent (w/o). As shown in Table II, the surface film was mainly composed of cadmium. The film could either be Cd metal, or some Cd oxide or hydroxide.

The nature of the film was determined by means of a Debye-Scherrer x-ray diagram. A sample of Cd-50Mg exposed for 3 hr at −0.71V in the $NaClO_4$ solution at

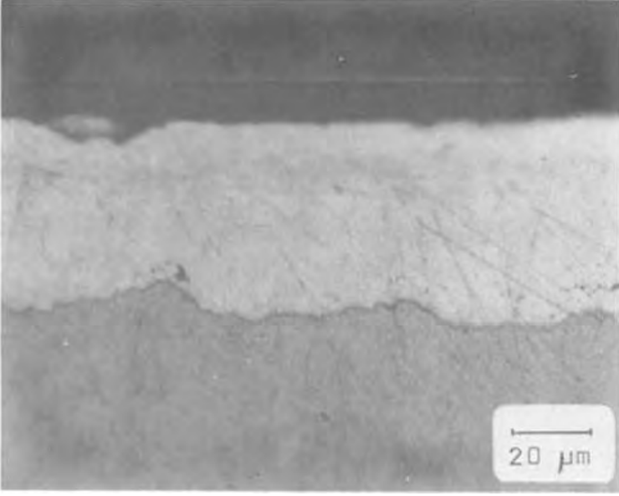

Fig. 2. Cross-section micrograph of corroded Cd-31Mg alloy after 3 hr dissolution in 0.5M $NaClO_4$ solution, at −0.51V and 25°C.

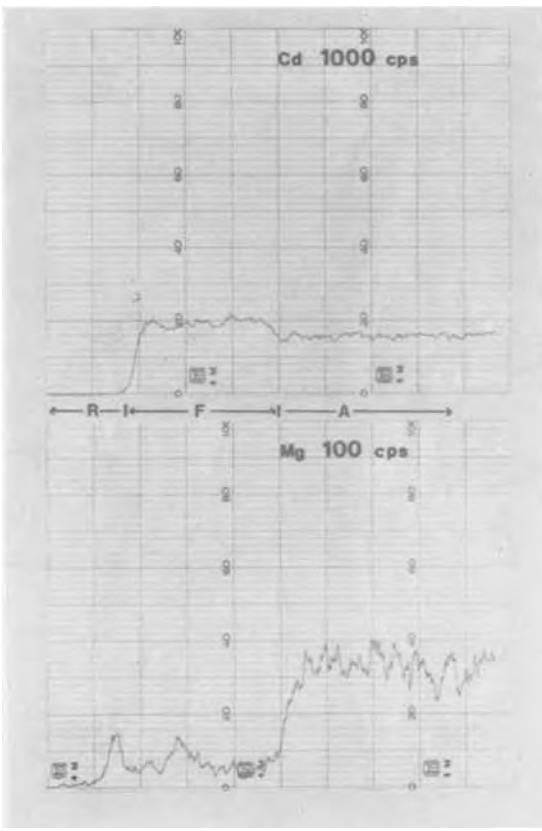

Fig. 3. Cd and Mg concentration profiles on the sample in Fig. 2. R, mounting resin; F, surface film; A, cadmium-magnesium alloy; cps, counts per second from the Electron Microprobe Analyzer.

25°C, was used for this purpose. The surface film was carefully peeled off and ground to powder. A Debye-Scherrer diagram was obtained after a 4 hr exposure with a cobalt x-ray tube and an iron filter. The calculated spacings are reported in Table III, and compared with those for metallic Cd (9). The diagram showed that the film was crystalline, and that it was composed of metallic Cd. The possibility of an oxide or some other Cd compound was ruled out.

Effect of temperature on the dealloying.—Constant potential measurements were performed at the three mentioned potentials at 50° and 75°C, for Cd-11Mg, Cd-26Mg, and Cd-31Mg. Figure 4 shows the cross-section micrograph of a Cd-26Mg sample exposed for 3 hr at −0.71V and 75°C. Figure 5 is the concentration profile for cadmium and magnesium for the same sample. In general, it was observed that at higher temperatures the dealloyed region was thicker. At the same time, numerous cracks were found in the film, which were filled by magnesium corrosion products. No cadmium was found inside those cracks.

Current-time curves.—Duplicate current-time measurements were made for every one of the alloys and at each of the three chosen potentials. The exposure

time was 20 hr. At the end of each exposure, the *p*H of the solution was measured. It was found that the *p*H of the solution changed considerably during the experiment, reaching values close to *p*H 10. The anodic reaction product was Mg^{++}, while on the counterelectrode hydrogen evolution was taking place. These reactions lead to the formation of $Mg(OH)_2$ in the bulk solution. This process explains the observed *p*H increase. The high *p*H values produced incipient precipitation of magnesium corrosion products on the samples. This magnesium precipitation explained the presence of regions rich in magnesium observed in Fig. 5. The effect of *p*H changes on the dealloying process is currently being studied (10).

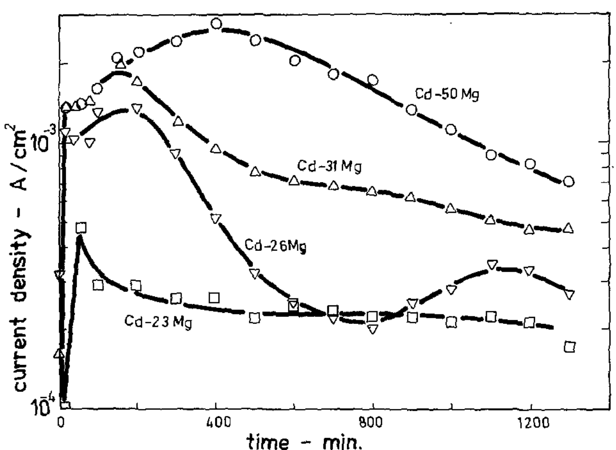

Fig. 6. Current-time curves for Cd-Mg alloys in 0.5M $NaClO_4$ solution at −0.71V and 25°C.

Figure 6 shows typical current-time curves observed with the different alloys. A current decay is observed, although the current decreases at a much lower rate than that predicted by the Pickering and Wagner mechanism (3). Fluctuations in the current during the run were observed. These were attributed to the cracking of the surface film. In general, the lower the content of magnesium, the lower the dealloying rate. The potential had no noticeable effect on the dealloying rate at the potentials tested.

According to the dealloying mechanism by Pickering and Wagner, a linear relation should be found between the current density and $I/\sqrt{t}$. But, in Fig. 6 almost stationary currents are observed. However, as it was pointed out by Pchelnikov *et al.* (11) that relation should be found only at the very early stages of dealloying, or in very dilute solid solutions. Deviations of the linear behavior will be due to crystal lattice parameter changes, or to the formation of new phases. In the particular case of the Cd-Mg alloys used in the present work, considerable changes in volume should take place. After the dissolution of magnesium, the remaining cadmium should undergo volume shrinkage of the order of 20-50%. If the criterion introduced by Pilling and Bedworth (12) is used in the present case, the corrosion product will be found to have a Pilling and Bedworth relation considerably lower than one. This would indicate that no protective film should be formed by the cadmium on the surface.

Conclusions

It was found that Mg-Cd alloys show selective magnesium dissolution in $NaClO_4$ solutions. The rate of selective dissolution increases with the increase of magnesium content in the alloy, as well as with the increase of the temperature in the solution. A soft porous layer of cadmium is formed on the dealloyed alloy. X-ray analysis shows that the film is crystalline. This film has been identified as metallic cadmium.

Due to the important volume shrinkage of the corrosion product, no protective film is formed on the dealloyed alloy for composition between Cd-50Mg and Cd-11Mg. Cd-Mg alloys seem to be a very promising system for the study of the mechanism of dealloying of metals. The high mobility of cadmium atoms at room temperature could account for the high dealloying rate found in these alloys.

Selective Dissolution of Cd-Mg Alloys

II. Rotating Ring Disk Electrode

J. I. Gardiazabal and J. R. Galvele*

Comisión Nacional de Energía Atómica, Departamento de Materiales, 1429 Buenos Aires, Argentina

ABSTRACT

Selective dissolution was found for Cd-Mg alloys in 0.5M $NaClO_4$ solutions, pH 5.5. Below $-0.51V$ (NHE) the anodic dissolution of the alloys led to the formation of Mg^{2+} ions. No evidence of formation of Cd^{2+} ions, under the same condtiions, was found. The anodic current densities were high, showing a fast dealloying process. In addition, they became higher at higher temperatures, and with a higher magnesium content of the alloy. The results are discussed in view of the published mechanisms of selective dissolution. A selective dissolution process is assumed, where a collapse in the cadmium film leads to a nonprotective surface layer. The anodic current density dropped to zero for alloys in the range of Cd-7.4 ($\pm$1.7) a/o Mg. This indicates that for lower magnesium contents a continuous protective film of metallic cadmium is formed on the alloy surface.

The rotating ring disk electrode is a powerful research technique. It has been frequently used in the study of selective dissolution of alloys. With this technique, it is possible to detect and collect on the inert ring electrode the dissolution products from the alloy disk electrode. An approximate solution to the theory of transfer of the rotating ring disk electrode is due to Ivanov and Levich (1). The exact solution was derived later by Albery (2). A fundamental parameter in this technique is N, the collection efficiency. N is defined as the proportion of material electrochemically produced on the disk electrode, which reaches the ring electrode

$$N = \text{ring current/disk current} = -i_R/i_D$$

The negative sign is included because i_R and i_D have opposite signs. Tables for N, for different ring disk radius ratios have been published by Albery and Bruckenstein (3).

The rotating ring disk electrode has been used in the study of selective dissolution of alloys by the following authors: Pickering and Wagner (4) for Cu-Au and Cu-Zn; Feller (5) for Cu-Zn; Miller (6) for Cu-Zn; Taylor (7) for Cu-Zn; and Marshakov, Bolychev, and Potapova (8) for Cu-Zn, Ag-Zn, and Ag-Cd alloys.

As shown by Pickering and Byrne for Cu-Zn alloys (9), and for Au-Cu alloys (10), two different regions are observed in the anodic polarization curves of alloys during the dealloying process: one, at low potentials, where only the active metal dissolves; the other, at higher potentials, where both metals dissolve. Most rotating ring disk studies of dealloying were done with galvanostatic control (4, 5, 7). In this way, since the potential was not fixed, it was not evident in what region of potentials the disk was dissolving. For this reason, in the present work it was decided to use simultaneous potential control of the ring and disk.

Following the study of dealloying of Cd-Mg alloys with stationary electrodes by the authors (11), the selective dissolution was studied with the rotating ring disk electrode. The results show no evidence of simultaneous dissolution of cadmium and magnesium, during dealloying, below $-0.51V$. Only magnesium was dissolving, leaving a film of metallic cadmium on the alloy surface. The activation energy values for dealloying are in the range of those expected for volume diffusion in the metal. It was also observed that the anodic dissolution current dropped to zero for magnesium contents below 7.4 atomic percent (a/o). This change is assumed to be related to a change in the nature of the metallic cadmium surface film.

Experimental

Several designs of rotating ring disk electrodes were tested. Those based on metal plus Teflon had to be discarded, because crevices could not be avoided between metal and Teflon. Those crevices gave collection efficiency factors, N, different from the theoretical N values. The best results were obtained with rotating ring disk electrodes based on a metal-epoxy resin design. Figure 1 shows schematically the electrodes used in the

present work. With these electrodes, the difference between the theoretical and the experimental N values was found to be less than 1%. Table I shows the dimensions of some of the electrodes used in the present work. Electrodes with lower N values were initially prepared, but the final measurements were done with the electrodes described in Table I. The same electrode was used several times, after abrading the corroded surface with 600 silicon carbide paper.

The ring metal was copper. The disk metal was composed of some of the alloys reported in Part I (11), with the following nominal compositions, in a/o: Cd-11Mg; Cd-23Mg; Cd-26Mg; Cd-31Mg; and Cd-50Mg. Rotating ring disk electrodes with copper and cadmium disks were also used for calibration purposes.

The measurements were made in a double-walled Pyrex glass cell. The temperature in the cell was regulated by circulation of water through a Haake FS thermostat. The Luggin capillary was positioned close and normal to the disk electrode (12). The cell contained approximately 360 ml of solution. The Luggin capillary was connected, through a salt bridge, to a saturated calomel reference electrode. All the potentials are reported in the normal hydrogen electrode scale (NHE).

The potentials of ring and disk were independently controlled by using a double potentiostat based on the circuits published by Napp *et al.* (12). The electrolyte used was 0.5M $NaClO_4$, pH 5.5, made up from $HClO_4$ solution, and with the pH adjusted with NaOH solution. No buffers were used in the present work. Prior to the measurements, the solutions were deaerated by bubbling prepurified nitrogen for 7 hr (13). During the measurements a stream of purified nitrogen was maintained above the solution. The potential of the disk was scanned with a LYP-Electronica potential scanner, with a scanning range from 1×10^{-4} to 1×10^3 V/sec. The currents on the ring and disk were simultaneously recorded with a 2 FAM X-Y Hewlett-Packard Recorder. The rotation speed of the electrodes was regulated with a LYP-Electronica electronic controller.

The experimental parameters were determined with a rotating cadmium-disk copper-ring electrode, in a deaerated 0.5M $NaClO_4$ solution, with pH values ranging from 3.0 to 7.0. A pH dependent cathodic reaction interference was found on the ring and disk electrodes at low pH values. This interference was attributed to H_2O_2 produced by the platinum counterelectrode (14). The interference was found to be negligible for pH values above 5.0.

At potentials above -0.49V, the cadmium-disk dissolved actively, with a Tafel slope of about 0.050V. However, at pH values above 6 the active anodic dissolution was replaced by an active-passive transition. Since the effect of such an active-passive transition on the dealloying process was unknown, it was decided to work at pH 5.5.

Cathodic deposition experiments were performed with a rotating copper-disk electrode, in a deaerated 0.5M $NaClO_4$ solution, pH 5.5, containing 0.001M Cd^{++} ions. The electrode potential was changed at a scanning rate of 6 mV/sec and various rotation speeds were used. The results are shown in Fig. 2. A limiting cathodic current was found for cadmium deposition. The linear relation between this limiting current and the square root of the rotation speed showed it to be a pure diffusion process (15). From all these measurements, a potential of -0.76V was chosen for the deposition of cadmium on the ring electrode in all the rotating ring disk electrode experiments with the Cd-Mg alloys.

Results

Polarization curves.—Figures 3-7 show ring disk electrode measurements for Cd-50Mg, Cd-31Mg, Cd-26Mg, Cd-23Mg, and Cd-11Mg alloys in deaerated, pH 5.5, 0.5M $NaClO_4$ solution at various temperatures. The initial potential of the disk alloy electrode was -1.56V, and it was increased with a scanning rate of 0.001 V/sec, while the potential of the copper ring electrode was kept at -0.76V. The electrode was rotated at a speed of 314 radians/sec.

The alloys showed a corrosion potential below which the cathodic reaction of hydrogen evolution was predominant. Above the corrosion potential, the anodic currents observed were the result of alloy dissolution. The corrosion potential was not clearly affected by the temperature, but it was a function of the cadmium content of the alloy. The higher the content of cadmium, the higher the corrosion potential. It went from

−1.36V for the Cd-50Mg alloy, to −0.91V for the Cd-11Mg alloy.

Above the corrosion potential the measured anodic current increased, showing a maximum somewhere between −0.92 and −0.84V. In the Cd-11Mg alloy (Fig. 7), on the other hand, if such a maximum existed it was obscured by the cathodic reaction. This maximum current was a function of the temperature of the solution and the composition of the alloy. From the temperature effect, an estimate of the activation energy of the process could be made. Table II shows the activation energy values found for the various alloys. These values are in the range of those expected for volume diffusion in metals. For example, the activation energy reported for diffusion of cadmium in disordered Mg_3Cd alloy is 12.8 kcal/mole (16).

The anodic current density was equal to that found on static samples (11), and was not affected by the speed of the rotating electrode. This current was a function of the composition of the alloy: the higher the content of cadmium, the lower the anodic current density. An empirical relation was found between the current density and the alloy composition. A linear relation between the square root of the current density and the alloy composition was observed (Fig. 8). This linear relation was found at all the temperatures tested, and was checked for −0.61, −0.71, and −0.81V. By extrapolation, an alloy composition was found, for which the current density should be zero. This would indicate that either no selective dissolution occurs for lower magnesium contents, or that there is a change in the mechanism of selective dissolution. Table III shows the extrapolated values, and a good coincidence was found between them, for all the temperatures and potentials tested. Potentiostatic values, from the cadmium stripping experiments described below, were also included. The mean value of the extrapolated composition was Cd-7.4 (± 1.7) a/o Mg.

If the potential was increased (Fig. 3-7), the current, after reaching a maximum, showed little change

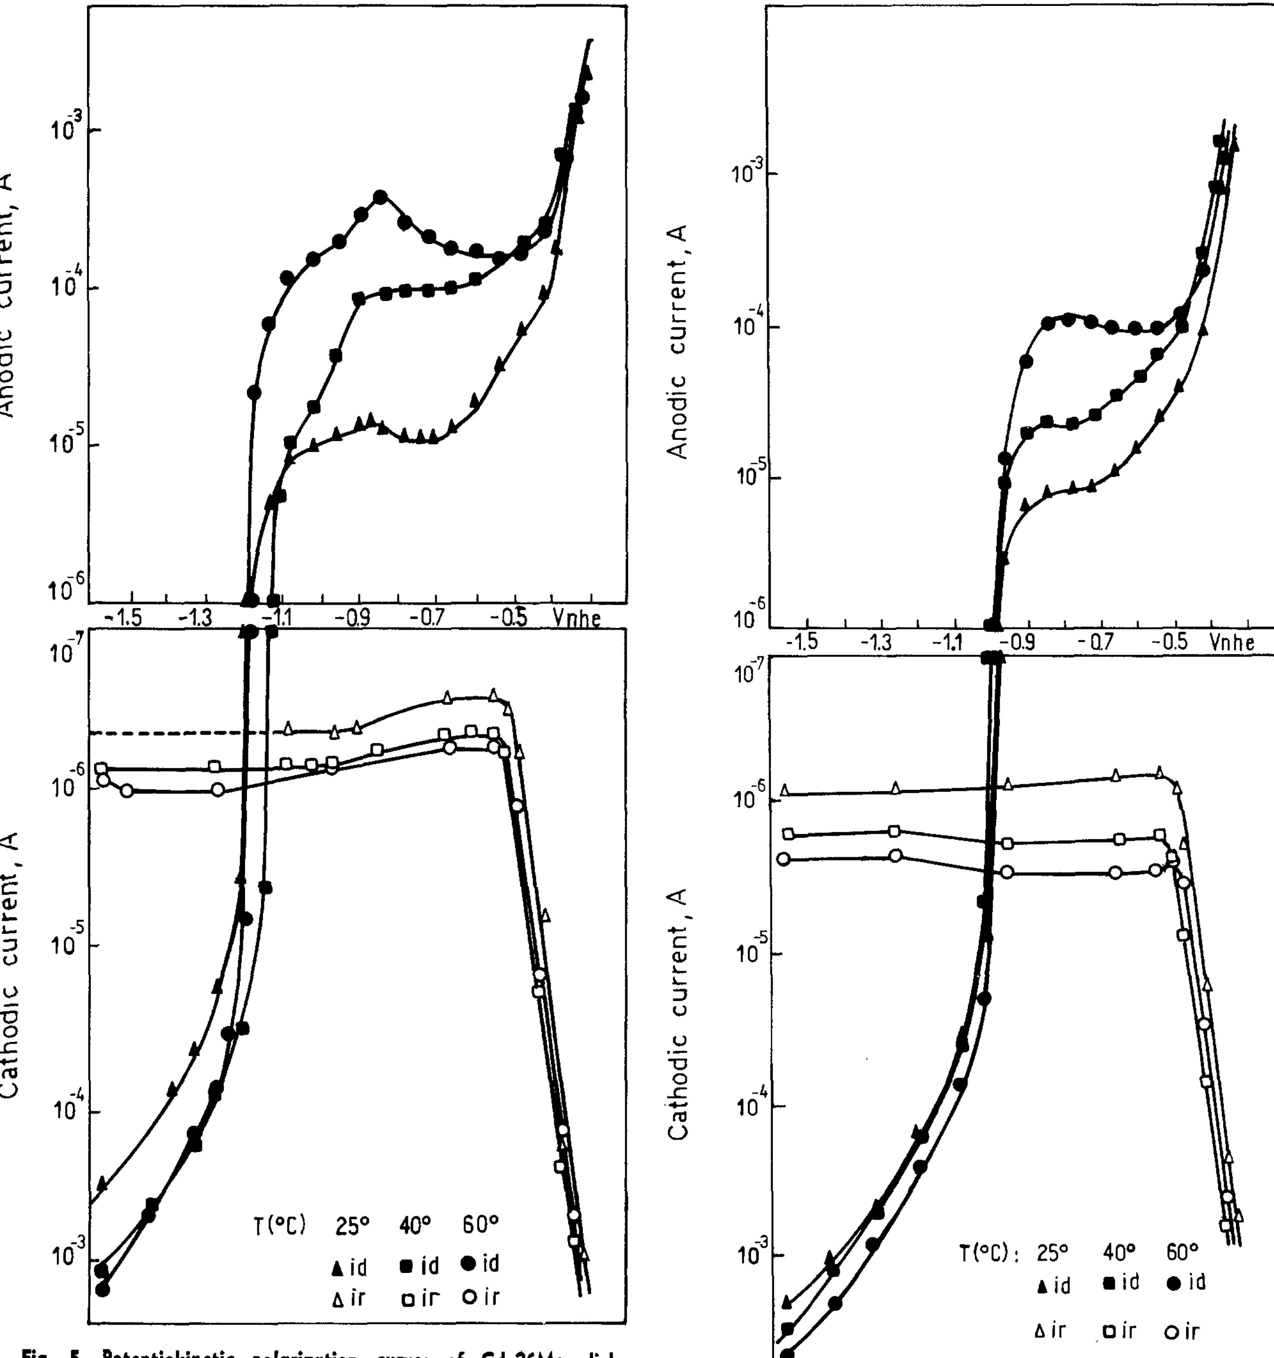

Fig. 5. Potentiokinetic polarization curves of Cd-26Mg disk electrode alloy in deaerated 0.5M $NaClO_4$ solution, pH 5.5, at various temperatures: i_d, disk electrode current; i_r, ring electrode current; rotation speed of the electrode, 314 radians/sec; potential scanning rate of the disk, 0.001 V/sec; potential of the ring: −0.76V, electrode No. 5.

Fig. 6. Potentiokinetic polarization curves of Cd-23Mg disk electrode alloy in deaerated 0.5M $NaClO_4$ solution, pH 5.5, at various temperatures. i_d, disk electrode current; i_r, ring electrode current; rotation speed of the electrode, 314 radians/sec; potential scanning rate of the disk, 0.001 V/sec; potential of the ring, −0.76V; electrode No. 3.

with the potential up to about −0.42V. At this potential, for all the alloys tested and for all the temperatures used, a sharp increase in the current was found, leading to severe corrosion of the disk.

If the ring is kept at a potential of −0.76V, the presence of dissolved cadmium in the solution should be detected as a cathodic current on the ring. For disk electrode potentials between −1.56 and −0.51V a potential independent background current was observed on the ring. As shown in experiments described below, no cadmium was found on the ring for this range of potentials. It was concluded, then, that between −1.56 and −0.51V no soluble cadmium was produced during the anodic dissolution of the Cd-Mg alloy. At and above −0.51V the cathodic current on the ring showed a sharp increase, and deposition of cadmium was detected on the ring. This shows that between −1.56 and −0.51V the anodic current on the disk was solely due to the dissolution of magnesium. At −0.51V and above, on the other hand, the anodic current on the disk was the result of the simultaneous anodic dissolution of magnesium and cadmium. Below −1.56V, dissolution of magnesium was, most probably, to be found too, but it was obscured by the cathodic reaction of hydrogen evolution. The potential at which dissolution of cadmium from the disk began, −0.51V, was not affected either by the composition of the alloy or by the temperature. The independence of the potential with respect to the composition of the alloy was due to the fact that the cadmium ions were produced by the dissolution of the dealloyed film, the composition of which should be the same for all the alloys tested.

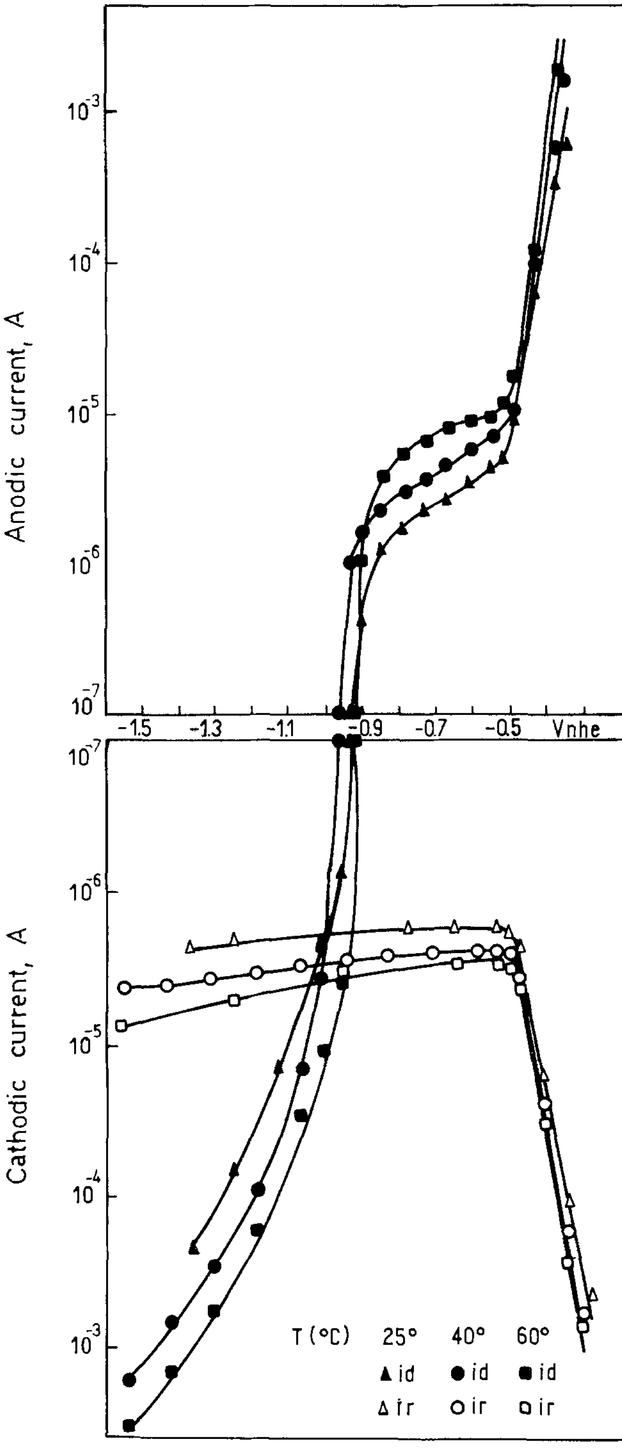

Fig. 7. Potentiokinetic polarization curves of Cd-11Mg disk electrode alloy in deaerated 0.5M $NaClO_4$ solution, *p*H 5.5, at various temperatures. i_d, disk electrode current; i_r, ring electrode current; rotation speed of the electrode, 314 radians/sec; potential scanning rate of the disk, 0.001 V/sec; potential of the ring, —0.76V, electrode No. 2.

Cadmium deposition on the ring electrode.—Electron microprobe analysis was used to confirm the observations made in the electrochemical measurements. The presence of cadmium, electrodeposited on the ring electrode, was investigated with the electron microprobe. The ring disk electrode was introduced in the electron microprobe analyzer through a specially designed sample holder. In one set of experiments, samples of all the alloys were exposed to the deaerated 0.5M $NaClO_4$ solution, for 3 hr at —0.51V for the disk electrode, and —0.76V for the ring electrode. After the 3 hr exposure, the ring disk electrode was retrieved from the cell and taken to the electron microprobe analyzer. The analysis showed the presence of cadmium on the ring electrode. Similar results were obtained with all the other alloys.

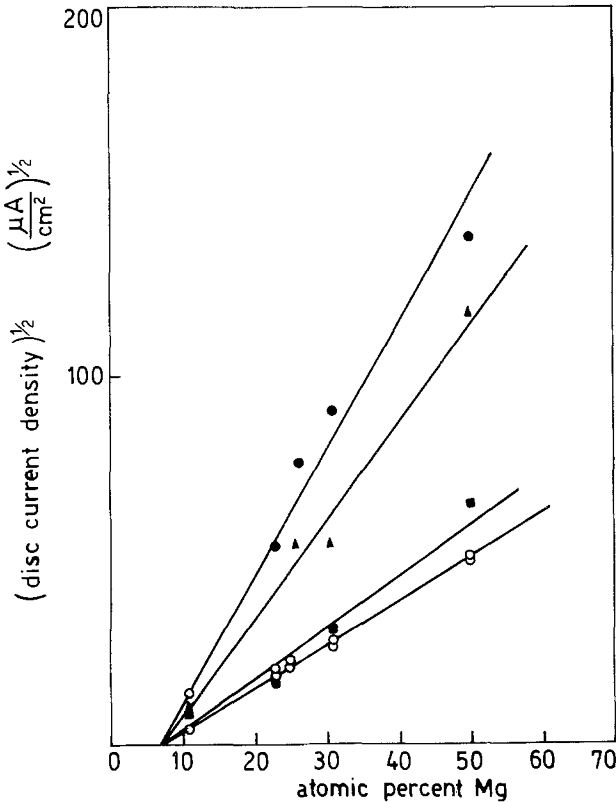

Fig. 8. Effect of the alloy composition on the anodic current density of Cd-Mg alloys in deaerated 0.5M $NaClO_4$, *p*H 5.5, at —0.71V, and various temperatures. Potentiokinetic measurements: ●, 60°C; ▲, 40°C; and ■, 25°C. Potentiostatic measurements: ○, 25°C.

The deposition of cadmium on the ring at lower disk potentials was also investigated. To prevent air-formed films from being chemically dissolved in the solution and redeposited on the ring, a double set of experiments was made. In all these experiments the potential of the alloy-disk was kept at —0.71V. In a first set of experiments, the potential of the ring was first maintained at —0.76V for 2 hr and then at —0.26V for another 2 hr. In this way, any cadmium deposited

* Potentiostatic measurements.

during the first two hours was anodically stripped at the higher potential. The initial 2 hr exposure was chosen to allow the system to reach a stationary state. After this treatment, the electrodes were taken to the electron microprobe and analyzed for cadmium on the ring. In this way, the background current for cadmium analysis on the ring was found. In a second set of experiments, after exposing the ring at $-0.76V$ for 2 hr and then at $-0.26V$ for 2 hr, the ring electrode was exposed for another 2 hr at $-0.76V$. After it, the ring-disk electrodes were taken to the electron microprobe and an analysis was made for cadmium deposited on the ring. No difference was found for any of the alloys between the cadmium-deposited and the cadmium stripped ring electrodes. In both cases only the background current on the ring was observed with no discernible difference between the two treatments. It was concluded that no cadmium ions were liberated to the solution when the disk was anodically corroding at $-0.71V$. Confirming the electrochemical results reported above, and those described in Part I of this paper (11), selective dissolution of magnesium was found to take place during the anodic polarization of Cd-Mg alloys. Up to $-0.51V$ the only anodic reaction product was dissolved magnesium, while at and above $-0.51V$, simultaneous dissolution of cadmium and magnesium was found.

Discussion and Conclusions

From the results in Part I (11) and those reported in the present work, it is concluded that Cd-Mg alloys are susceptible to selective dissolution in $NaClO_4$ solutions. Between the corrosion potential and $-0.51V$, magnesium leaches away from the alloy, leaving a surface film of pure metallic cadmium. No soluble cadmium ions are produced during this dealloying process. Cadmium ions are produced only when the potential of the alloy is $-0.51V$ or higher. The dealloying process rate is accelerated by an increase in the temperature. And an estimation of the activation energy for the process gives values close to those found for volume diffusion in similar alloys. This dealloying rate is a function of the alloy composition. The higher the magnesium content, the higher the dissolution rate, at a fixed potential. A linear relation was found between the square root of the current density and the magnesium content of the alloy. By extrapolation, this current density would be zero for an alloy of Cd-7.4 Mg.

Several mechanisms have been proposed for the dealloying process (4, 5, 17-21). These mechanisms are usually divided into three groups: (*i*) dissolution of the entire alloy, followed by redeposition of one of the components (20); (*ii*) selective dissolution of one of the species, leaving the nobler species on the alloy surface (4, 5, 18, 21); and (*iii*) a combination of (*i*) plus (*ii*), where both mechanisms are active at different potentials (17, 19). Mechanism (*ii*) requires a redistribution of the noble metal on the alloy surface. Various possibilities have been suggested. According to Pickering and Wagner (4), the noble metal remains as a continuous film on the alloy surface, and selective dissolution proceeds by volume diffusion of the active metal through the noble metal layer. Feller (5), on the other hand, suggested that the redistribution of the noble metal atoms takes place through surface diffusion and clustering. For low noble metal contents, this surface diffusion will lead, according to Swan (18), to tunneling. Pchelnikov *et al.* (21) showed experimental evidence supporting the Pickering and Wagner mechanism, while Fort and Verink (17), raised doubts about such a mechanism.

As for the results of the present work, we will concentrate on the measurements below $-0.51V$ where dealloying is found. The ring-disk measurements showed that in this range of potentials no soluble cadmium ions are formed. Otherwise, they should be detectable on the ring electrode. This means that a mechanism of dissolution and redeposition is not operative at a macroscopic level. It could be argued that it takes place at a microscopic level, not detectable by the ring disk electrode experiments. But in that case, it would not be discernible from mechanism (*ii*).

As pointed out by Pchelnikov *et al.*, a mechanism of selective dissolution by volume diffusion through a solid film is easily detectable. This mechanism should give a linear relation between the dealloying current density and $I/\sqrt{t}$. But, as these authors pointed out, such a relation is only found either in solid solutions with a very low content of the negative component, or in the very early stages of dealloying. Otherwise, too high stresses would be created in the dealloyed surface film, and it will therefore not remain continuous.

For the Cd-Mg alloys studied in the present work, the dealloying current density does not decay linearly with $I/\sqrt{t}$ (11), but almost remains constant with time. A criterion, similar to that introduced by Pilling and Bedworth (22) for oxidation of metals, can be applied to the surface dealloyed film. According to this criterion, a corrosion product film will be continuous and protective only when it has at least the same volume as the metal consumed. If the relative volume of the product film is lower, the film will not be protective. For the case of Cd-Mg alloys, the Pilling and Bedworth relation would be

$$\frac{W \cdot d}{w \cdot D} = K$$

where w is the weight of the alloy containing one atom gram of cadmium, W is the atomic weight of cadmium, D the film density, and d the alloy density. The film, as shown in Part I, is pure cadmium. The values of alloy density were taken from (23). According to Pilling and Bedworth, K values lower than one will give nonprotective films. The calculated values were: Cd-15 Mg, $K = 0.86$; Cd-10 Mg, $K = 0.91$; and Cd-5 Mg, $K = 0.95$. If allowance is made for some redistribution of stresses in the film, for values close to one, it is concluded that no continuous film should be expected for alloys with magnesium contents above 10 a/o.

From the results of the present work, it is concluded that Cd-Mg alloys show selective dissolution, most probably by a volume diffusion mechanism. Due to differences in the relative volume between the alloy and the corrosion product, the cadmium film formed on the surface becomes discontinuous and nonprotective. This film becomes protective when formed on high cadmium alloys, thus explaining the current zero found for the Cd-7.4 Mg alloy. Further studies are being made to detect the initial dealloying stages, where the linear relation with $I/\sqrt{t}$ should be found. The morphology of the nonprotective film is also being studied.

Contamination of Electronic Equipment after an Extended Urban Exposure

G. B. Munier, L. A. Psota, B. T. Reagor,* B. Russiello, and J. D. Sinclair*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

Water soluble contaminants on electromechanical telephone switching equipment exposed for up to 40 years to the New York City environment have been chemically analyzed by a combination of methods, and their moisture pickup characteristics have been monitored by instrumental gravimetric techniques. Samples were collected from structural surfaces by extraction with filter paper squares moistened with distilled water. Elements with atomic numbers greater than 11 were identified by energy dispersive x-ray analysis. Selected anions were identified by microchemical tests and infrared spectroscopy. Nitrate and sulfate concentrations of 46 samples from one location were measured using nitrate and lead ion selective electrodes (the latter for titration of sulfate). Several hundred samples from this and four other locations were analyzed using a chloride ion selective electrode. On zinc surfaces, chloride concentrations averaged 27 $\mu g/cm^2$ for typical locations, while sulfate and nitrate concentrations averaged 48 and 6 $\mu g/cm^2$, respectively. On aluminum surfaces, chloride concentrations averaged <2 $\mu g/cm^2$, while sulfate and nitrate concentrations averaged 25 and 3 $\mu g/cm^2$, respectively. Moisture pickup by contaminants on zinc and aluminum surfaces was found to occur above 26 and 46% RH, respectively.

The cumulative contamination of electronic devices and equipment during long term exposure to urban atmospheres is a continuing concern for the electronics industry. In some cases, the contamination consists of dusts that have collected on surfaces and that may have reacted chemically with the surfaces. In other situations, the contamination consists of the products of attack by pollutant gases, such as SO_2, NO_x, H_2S, mercaptans, organic sulfides and disulfides, ozone, and chlorine-containing species. Gases generated by the equipment itself can also contaminate and produce corrosion. These gases may be volatile components of plastics or other insulating or packaging materials that evolve after equipment installation for periods ranging from a few hours to many years, or they may be volatile degradation products from oxidation or from photochemical processes. Generally a combination of dusts and complex films containing oxides, sulfides, sulfates, oxyanions of nitrogen, chlorides, oxyanions of chloride, and other substances is found. Passive oxide films are usually not appropriately classified as contaminants.

The composition of the dusts will be determined by contributions from outdoor aerosols and aerosols generated within the equipment room by human activity, equipment operation (wear products), and deterioration of equipment and building surfaces due to a variety of aging processes, including oxidation and thermal or photochemical degradation. The composition of the outdoor component will be modulated by the air handling and filtration system for the equipment room. Modern high efficiency filters (85% NBS dust spot rating) remove most particles with diameters greater than 1 μm (1), in which case the contribution from the typical outdoor component in the New York metropolitan area will be primarily anthropogenic in origin (except along the seacoast) and rich in ammonium and sulfate ions (2-4). At seacoast locations, the submicron aerosols can have sodium and chloride ion concentrations (3, 4) that approach those of the ammonium and sulfate ions. Many buildings, however, are equipped with air filtration systems of much lower efficiency, in which case dusts of mineralogical origin will become prevalent. Equipment that has been in operation for 40 years has generally experienced exposures to unfiltered air during its first 10-20 years of operation. Most of the equipment studied in this work falls in this category. Even in recent years the equipment has generally not had the benefits of air purified by high efficiency filters. Thus, particles in the one to

* Electrochemical Society Active Member.

Key words: condensation, contamination, pollution, water.

ten micron range will be common, and a high percentage of these will have originated naturally from local crustal materials.

Internally generated dust will have a high carbon content from human activity. Weschler (5) has found that the dust generated in the Bell Laboratories facility at Holmdel, New Jersey, which is equipped with high efficiency filters, contains 40% carbon by weight. There may also be incidents of high sodium chloride influx when winter salting activity is prevalent (2). Particles generated by the equipment will often include phenolic plastics, ABS, calcium carbonate (which is used as a filler in many types of insulation and plastics), glass fibers (from reinforced plastics and insulation), and textile materials (from wire insulation, carpeting, etc.).

The water soluble components of contamination are of particular concern to the electronics industry because they may form electrolyte solutions in the presence of moisture, as occurred in Los Angeles when airborne nitrates, which tend to be hygroscopic at relative humidity (RH) levels above 50%, caused electrolytic stress corrosion cracking of nickel brass (6). Similarly, the corrosion rates of exposed substrate material in gold-plated connector contacts in the presence of various pollutants have been related to RH (7-10). In other situations, degradation may be caused by electrical leakage through the electrolyte (11-15). The leakage itself may be the cause of circuit failure, or coincidental corrosion of the circuit member serving as the anode in a leakage pathway may disrupt current flow. Metallic dendrite growth will often occur in this situation.

Electrical leakage is enhanced at high relative humidity, particularly if a hygroscopic contaminant is present. Vernon (16) first called attention to the importance of the concept of critical relative humidity (CRH) in assessing the corrosion hazards associated with contamination. In many cases a CRH can be identified, either through knowledge of the composition of the contaminant or through experimental measurement, as with instrumental gravimetric methods (17). Exposure of contaminated devices to an environment in which the CRH of the contaminant is exceeded may lead to moisture acquisition, followed by electrical leakage, disruption of current flow, and eventual device failure.

Convenient procedures for analyzing water-soluble contaminants and measuring their moisture pickup characteristics are valuable in assessing the causes of equipment failure and in determining procedures for dealing with the failure mechanism. For large equipment installations, correlations between contaminant distributions and equipment problems can often be found. In some cases it is possible to specify humidity ranges or improved air filtration equipment that can be expected to alleviate the problem. In other cases device modification may be necessary.

This paper presents the methods that were used to analyze problems occurring in electromechanical switching equipment that has been exposed for up to 40 years to the New York City (Manhattan) environment at five locations. Contamination data for equipment in one location (hereafter designated as Location I), which developed switching problems during and after a high humidity event, are discussed in some detail.

The most difficult aspect of analyzing equipment surfaces is the selection of a sampling procedure, because the equipment must usually be sampled while it is operating. Since the water-soluble contaminants are of principle concern, surfaces must be water extracted in a way that will permit complete removal of the soluble species from a fixed surface area, without allowing moisture to come in contact with active equipment components. Structural or otherwise inactive surfaces that can be expected to provide the necessary chemical information to appraise contaminant effects on active surfaces must therefore be selected. In this study, structural surfaces that were zinc plated and surfaces of aluminum equipment covers were chosen. A sampling procedure suited to the requirements of this work has been investigated by Hermance *et al.* (6). In their work, nitrate salts were extracted from equipment surfaces with small sections of filter paper that had been moistened with distilled water, laid on the surfaces, and allowed to dry. The soluble components of the contamination remain in the paper after the water evaporates and can be readily transported to the laboratory for analysis. In this work, chemical identification was accomplished by x-ray techniques, standard microchemical tests, and infrared spectroscopy. For the urban environment of this study, chloride, nitrate, and sulfate were the anions of particular concern. These were determined quantitatively using ion selective electrodes (18). Clyster and Adams (19) and Ross and Frant (20) have described procedures for the analysis for sulfate. Baucke (21) has discussed chloride selective electrodes. Nitrate selective electrodes are described in a compilation of selected analytical methods by Gallay *et al.* (22). In the studies by Weschler (2, 5), chloride, nitrate, and sulfate extracted from indoor dust particles were determined by these methods.

In combination with the chemical analysis, knowledge of the CRH and the moisture pickup characteristics of the water-soluble contaminants can provide a basis for assessing the cause of equipment problems and for devising methods to deal with these problems. One of the authors has developed instrumental gravimetric procedures for determining the CRH and total moisture pickup characteristics of dusts, contaminants, and corrosion products (17). These methods have been applied to several types of samples from Location I.

Experimental

Surface extractions were accomplished with square sections (one-half in. on a side) of Whatman 3MM filter paper. The papers were moistened with triply distilled water (18 mΩ resistivity) that had been equilibrated with atmospheric carbon dioxide. The papers were briefly drained to eliminate excess water that otherwise would significantly increase the effective area of the sampled surface. The volume of water in each paper was determined to be approximately 0.06 ml. The papers were placed on flat surfaces in either a horizontal or vertical plane and were removed from the surfaces after drying. The sampling interval was approximately 30 min but was somewhat dependent on the relative humidity. The procedure was carried out three times on each sampled area to insure complete removal of water-soluble contaminants.

The sample papers were then stored in separate containers and transported to the laboratory. Ten ml portions of distilled water were used to extract the contaminants from the papers in the laboratory. In most cases, the three papers from each sampled area were extracted together, but in a few cases each paper was extracted separately. The samples were divided into several groups for several types of quantitative and qualitative analysis. The residue remaining after evaporation of several of the extracts was analyzed by SEM/x-ray techniques using an AMR-1000 scanning electron microscope in conjunction with a Princeton Gamma Tech Si(Li) energy dispersive x-ray analyzer and a Tracor Northern NS-880 multichannel analyzer. The technique is capable of identifying elements having atomic numbers greater than 11. Samples were analyzed for multielement anions by standard microchemical tests (nitrate and chlorate by the nitron test, sulfate by barium chloride precipitation, carbonate and bicarbonate by hydrochloric acid in glycerine) and by infrared spectroscopy (on silver chloride crystals). Quantitative analyses for chloride, nitrate, and sulfate

were carried out with Orion ion selective electrodes. A 90-02 double junction electrode, using the Orion proprietary solution for the inner chamber and 10% KNO_3 in the outer chamber, was employed as the reference electrode (except the outer solution for nitrate analysis was 0.1*M* KF). The 10 ml extract from the papers was directly analyzed for chloride with a 90-17 solid-state chloride electrode. The extract was then split into two 5 ml portions. Nitrate analysis was accomplished on one portion with a 90-07 nitrate electrode after a 5 ml portion of 0.2*M* KF solution was mixed with it to provide a constant ionic strength. Phenylmercuric acetate was included as a preservative. Sulfate analysis was carried out on the other 5 ml portion by titration with 0.001*M* $Pb(ClO_4)_2$ after adding 5 ml of methanol. A 94-82 solid-state lead specific electrode was used to monitor the end point.

Paper blanks were analyzed for chloride, nitrate, and sulfate. The average quantities of these anions per paper were 2, 4, and 2 μg, respectively. The hydrogen ion concentrations of the distilled water extracts from blank paper squares and from moistened squares that had been placed in contact with equipment surfaces for brief periods were measured with Tridicator *p*H paper.

Moisture pickup characteristics of the residues of some of the paper extracts from aluminum and zinc plated surfaces and of a green corrosion product contaminating electrical contact surfaces (collected by brushing) were measured by gravimetric methods using a du Pont 951 Thermogravimetric Analyzer coupled to a 990 Thermal Analyzer. Samples were equilibrated for several days or weeks with the laboratory atmosphere (RH approximately 40 $\pm$10%) before they were analyzed in the microbalance.

Continuous pickup rates for the various materials were determined by passing a stream of air (maintained at approximately 23°C), which had been humidified by bubbling it through distilled water maintained at 23°C, through the microbalance sample tube (2.5 cm diam by 12 cm long). The relative humidity of the airstream was close to 100%. Weight was recorded graphically as a function of time, and each run was allowed to proceed until the rate of weight gain approached zero or reached an extended steady state.

CRH measurements were made using the same balance with a modified airstream apparatus. A minimum RH in the balance housing (maintained at 23°C) of 22% was achieved by passing a stream of dry air through a dispersion frit submerged in distilled water cooled to 0°C. The water was warmed from 0°C to nearly 23°C at a rate of 0.25°C/min, thereby increasing the RH from 22 to nearly 100%. A recording of weight *vs.* time was translated to weight *vs.* RH. The relative humidity at which an onset in weight gain occurred was taken to be the CRH. Further details on these methods for measuring moisture pickup characteristics are given elsewhere (17).

Results and Discussion

Microchemical tests on several dust samples from Location I and on residues remaining after extraction of several papers with distilled water established the presence of significant amounts of nitrate ion and sulfate ion. Carbonate was detected in the dust samples but not in the extract residues. Chlorate ion was not detected. Other multielement anions such as sulfite and nitrite were presumed to be present only at very low levels, which would not contribute significantly to equipment problems. Infrared spectroscopy confirmed the presence of nitrate and sulfate. SEM/x-ray analysis of the extracts from zinc surfaces established the presence of large amounts of sulfur, chlorine, calcium, and zinc, a small amount of potassium, and traces of iron. Similar analyses of the extracts from aluminum surfaces showed that sulfur and calcium were present in large amounts, chlorine and potassium in small amounts, and iron, copper, and zinc in trace amounts. SEM/x-ray analysis of the residue remaining after extraction of several papers with distilled water and evaporation of the resulting solution to dryness indicated that the paper contained low but significant levels of sulfur, chlorine, calcium, potassium, copper, and iron.

The approximate *p*H of the solution associated with the filter paper squares during sampling was determined with *p*H paper. The *p*H paper was placed over moist filter paper squares that had been laid on the appropriate surfaces. Distilled water that had been equilibrated with the atmosphere (*p*H approximately 5.7) was used for all procedures. The approximate *p*H's observed for zinc and aluminum surfaces were 6.0-6.5 and 5.0-5.5, respectively. These *p*H's are a result of the combined effects of the atmosphere equilibrated distilled water and the sampled surface. Separate measurements with *p*H paper in the absence of filter paper squares indicated the filter paper had no detectable effect on the *p*H. The somewhat less acidic *p*H of the zinc surface is consistent with the solubility products of the hydroxides of zinc and aluminum, which are 10^{-16} and 2×10^{-32}, respectively, and with our experimental observation that solutions created by exposing distilled water (with dissolved carbon dioxide eliminated) to excess zinc oxide are somewhat alkaline. The oxide film on zinc surfaces is a weak buffer, which will tend to drive the surface solution towards the alkaline *p*H range, whereas the oxide film on aluminum surfaces will have a negligible effect compared to the atmospheric influence of carbon dioxide with moisture on the surface.

Based on the chemical analyses, the extracted species of greatest concern in terms of potential for equipment degradation were the anions chloride, nitrate, and sulfate. Since these appeared to be the major anions present, it was felt the quantitative measurements of surface concentrations of these species could be used to estimate cation concentrations from charge and mass balance requirements. Proportions for the cations present could be approximated from qualitative results determined in this work, coupled with data on New York City air quality that were available in the literature (2-6, 23, 24) and from the Environmental Protection Agency (25).

Forty-six samples (each consisting of three papers) from Location I were selected for chloride, nitrate, and sulfate analysis from the more than 75 samples that were collected. Several hundred samples from four other locations in Manhattan (hereafter designated Locations II-V) were analyzed for chloride. Experimentation indicated that extraction of water-soluble contaminants was generally 80-90% complete after two extractions. On this basis, three samplings of each area were considered to provide complete extraction of the surface.

Table I summarizes the types of surfaces extracted, the year of their manufacture (vintage), and the measured chloride, sulfate, and nitrate concentration levels for the 46 samples from Location I. For samples 1 to 5, the three papers used to extract the surface were stored and measured separately to verify that nearly complete extraction of the surface was achieved with three papers. For all other samples, the three papers were combined for storage and measurement. In the cases of nitrate and chloride, this procedure reaffirmed that three papers provide essentially complete surface extraction, but in the case of sulfate another problem was found. The usual procedure for end-point determination when titrating with $Pb(ClO_4)_2$ is to plot electrode potential *vs.* quantity of titrant added, the end point being taken as the point of greatest inflection. Ross and Frant (20), using dioxane rather than methanol to sharpen end points (through decreased $PbSO_4$ solubility), found the minimum titratable sulfate concentration for standard solutions was about $10^{-6}M$. However, the time required to reach equilibrium after each

* Values in parentheses are the concentrations extracted by the first paper.

addition of titrant was considered impractically long for sulfate concentrations less than $5 \times 10^{-5}M$. Their data on the effect of interferences indicate that NaCl, which is a significant contaminant in the samples studied in this work, can obscure the end point. For the range of concentrations found in this study ($7 \pm 4 \times 10^{-5}M$), the point of greatest inflection was not always readily apparent or, in some cases, was ambiguous. Experimentation with standard solutions indicated that if the end point was selected to be −200 mV, satisfactory agreement between known and measured concentrations was obtained. An error of 25-50% for the lowest concentrations of sulfate was considered acceptable for this work. The total sulfate levels from the three papers for samples 1-5 were, however, very high relative to other 1947 vintage surfaces. In the case of chloride, the concentrations of samples 1-5 were not extraordinary. This suggests that an interfering effect, caused by a species other than sulfate (possibly sodium chloride), increased the apparent concentrations to unrealistically high levels. The effect appeared to have a similar magnitude for each titration, whether the three papers were run simultaneously or separately. The sulfate concentrations indicated for samples 6-46 thus include this effect only one time, while samples 1-5 include it three times, once for each paper. A correction factor for the effect was not readily derivable, and thus it was decided that the sulfate concentrations for samples 1-5 should be based on the extract from the first paper only. These values are given in parentheses in Table I. Concentrations for samples 6-46 are high by perhaps 7-15 $\mu g/cm^2$. Concentrations for samples 1-5 may or may not be high, but they are certainly lower than they would have been had all three papers been analyzed simultaneously.

Nitrate concentrations were found to be very low, approaching the sensitivity limit of the method. Samples 1-19 were analyzed and found to have concentrations below the region of linearity in the potential-concentration electrode calibration plots from which concentrations were determined. It was originally anticipated that most of the samples would have concentrations in the linear regime, but it was apparent after completing these 19 analyses that this would probably not be the case. For the remaining samples, concentrations were determined by extrapolation into the nonlinear regime. The data were treated very conservatively, based on results for standard solutions, so the concentrations listed are lower limits for nitrate. Unfortunately, only an upper limit can be set for samples 1-19 because the solutions were discarded before the extrapolation procedure was initiated. In retrospect, it appears that in situations in which nitrate surface concentrations are likely to be less than 30 $\mu g/cm^2$, the spectroscopic procedure with chromotropic acid described by West (26) would be a preferable method of analysis. The nitrate selective electrode is somewhat more convenient and faster but is at least one order of magnitude less sensitive and tends to drift.

Average concentrations of chloride, sulfate, and nitrate on 1947 vintage equipment are shown in Table II, along with average contamination rates for the 30 year exposure period. Indiscriminate application of these contamination rates to locations outside the New York City area is not advised, but for environments comparable to that of New York City, the contamination rates are probably reasonable guides for locations that have not, except for perhaps a brief period, been equipped with high efficiency air filtration systems. It also should be kept in mind that the implicit assumption that contamination rates are constant is probably not strictly valid. Some surfaces will tend to passivate as corrosion processes occur or dust layers collect, while others will be activated. Fine dust particles (less than 1 μm diam) tend to be mobile and may serve as a continuing source of a contaminant until the accumulation of less mobile particles restricts their interaction with the surface. Furthermore, pollution levels have varied substantially over the past 30 years. Evidence of these complicating factors is provided in Table III, which shows chloride and sulfate contamination rates on zinc surfaces for 1947, 1956-1957, and 1964

Table II. Contamination data for 1947 vintage equipment at Location I

	Chloride	Sulfate	Nitrate

Aluminum surfaces:			
Concentration ($\mu g/cm^2$)	<2*	28	3
Contamination rate ($\mu g/cm^2$ yr)	<0.07	0.93	0.1

* This number is based on all values <2 $\mu g/cm^2$ being 0; if all values less than 2 are assumed to be 1, the average is 2.

Table III. Contamination rates on zinc surfaces of various equipment vintages from the vintage year through 1977

($\mu g/cm^2$ yr)			
	Vintage year		
	1947	1956-1957	1967
Sulfate	1.8	1.9	2.8
Chloride	1.2	0.5	0.5

vintage equipment based on concentration averages for each vintage group. Only four samples were available for the calculation of 1964 rates, and thus the averages are very approximate. The results suggest, however, that sulfate contamination rates have increased over the past 30 years, while chloride contamination rates have decreased. Keeping these complicating factors in mind, the contamination rates provide estimations of contaminant concentrations.

Concentrations of chloride, sulfate, and nitrate in airborne particulates taken from the data of Hermance (6), The National Air Sampling Network (NASN) (24), The National Air Surveillance Network Summary (NASNS) (25), Patterson and Wagman (P + W) (3), and Leaderer (4) are compared in Table IV with the average concentrations found on the zinc and aluminum surfaces (computed for all samples neglecting vintage effects). The similarities are striking. Except for comparisons involving chloride on zinc surfaces, the relative proportions of these anionic species are roughly the same in the airborne particulates and on the surfaces tested. The scavenging ability of zinc for chlorine-containing species obviously plays a dramatic role in the contamination of zinc surfaces. The data also suggest that the surface texture and moisture content of surfaces may be important factors affecting the collection and retention of dust particles. The higher sulfate and nitrate concentrations on zinc as compared to aluminum surfaces are consistent with the unpolished nature and higher surface area of the zinc surfaces relative to those of aluminum and with the lower CRH associated with the zinc surfaces (to be discussed later). The differences are probably not related to surface configuration, because approximately the same number of horizontal and vertical surfaces were sampled for both zinc and aluminum, and the concentrations on horizontal and vertical surfaces of the same metal were quite similar.

In order to determine if the total anion concentration can be accounted for by the combination of the average chloride, nitrate, and sulfate concentrations found on the surfaces, it is necessary to select an approximate composition for the associated cations and to obtain an average extract weight per sample. The latter was accomplished with another set of samples, also from Location I, with very similar vintage distributions. Contamination levels for this group of samples were assumed to be similar to the levels of the group used for chloride, nitrate, and sulfate determinations. Twenty-six paper extract samples that had been collected from zinc surfaces were combined and extracted with 10 ml of distilled water. The extract was filtered and then evaporated to dryness and weighed. An identical procedure was followed for 12 samples from aluminum surfaces. From these weighings, it was determined that the average weight of material extracted from a single sampling location on zinc surfaces (after subtracting an experimentally determined value of 21 $\mu g/cm^2$ for the solids extracted from three paper blanks) was 117 $\mu g/cm^2$, while the average for aluminum surfaces was 61 $\mu g/cm^2$.

Table IV. Concentration comparisons

Airborne particulate:	Chloride	Sulfate	Nitrate
Hermance (1959)	2.5 ($\mu g/m^3$)	18.3 ($\mu g/m^3$)	2.6 ($\mu g/m^3$)
NASN (1958)		22.8	2.4
NASN (1963-1964)		32.2	2.5
NASNS (1971-1974)		15.9	0.9
P + W (1970)	0.3-1.9	2-21	0.8-9.7
Leaderer (1976)	0.1-0.5	2-41	0-4
Water extractable contaminants:			
Zinc surfaces	27 ($\mu g/cm^2$)	48 ($\mu g/cm^2$)	6 ($\mu g/cm^2$)
Aluminum surfaces	<2*	25	3

* This number is based on all values <2 $\mu g/cm^2$ being 0; if all values less than 2 are assumed to be 1, the average is 2.

SEM/x-ray analysis was also carried out on these extracts and makes possible, in conjunction with information available in the literature and reasonable assumptions about likely surface chemistry, an estimate of the predominant cations associated with chloride, nitrate, and sulfate on zinc surfaces and on aluminum surfaces.

The SEM/x-ray results on extracts from zinc surfaces established the presence of large amounts of sulfur and chlorine, consistent with the presence of sulfate and chloride, in addition to large amounts of calcium and zinc. Potassium and iron were identified as minor components. As discussed above, zinc is an excellent scavenger for chlorine-containing species and thus chlorine was presumed to be present exclusively as zinc chloride. While some of the chlorine may have originated from the marine influence on this seacoast location and thus would have sodium associated with it, the very low chloride levels found on aluminum surfaces suggest the sea salt influence is small. (It should be noted that the lack of appreciable chloride on aluminum surfaces in spite of the seacoast influence may be due in part to the submicron size of sea salt aerosol. Such particles will tend to be mobile and could serve as a continuing source of chloride on reactive zinc surfaces but would have little effect on less reactive aluminum surfaces. This potential effect was assumed to be unimportant in this work, but further study is needed on this point, particularly on the reaction mechanism and the fate of the sodium. Sulfate is a major water soluble component of the outdoor aerosols at this urban location, as are ammonium, calcium, and sodium ions.) Morrow and Brief (23), using emission spectrography, found ambient concentrations of calcium and sodium in the New York metropolitan area in 1969-1970 of 1.17 and 1.08 $\mu g/m^3$, respectively. Hermance *et al.* (6) reported ambient concentrations for ammonium, calcium, and sodium ions of 4.9, 1.9, and 2.7 $\mu g/m^3$ for samples collected in New York City in 1959. Patterson and Wagman (3) found ammonium ion concentrations ranging from 1.8 to 11.4 $\mu g/m^3$, while the survey compiled by Leaderer *et al.* (4) reports a range of <0.11-11.5 $\mu g/m^3$. The National Air Surveillance Network Summary for 1971 through 1974 (25) reported an average ambient concentration of 0.9 $\mu g/m^3$ for ammonium ion.

While the available data show a range of concentrations for the various cations, as a rough approximation it seems reasonable to describe the "composite" cation associated with sulfate on zinc surfaces as

$$1/4(NH_4^+)_2 + 1/4(Na^+)_2 + 1/4\,Ca^{+2} + 1/4\,Zn^{+2}$$

Zinc is included because it is the surface metal, and it was found in high concentration in the surface extract. The proportions of some of the cations may be in error, but examination of the cation formula weights that would react with one formula weight of SO_4^{-2} indicates that substantial deviations will not have a major effect on the composite cation formula weight. If the cation formula weights, which are 36.0, 46.0, 40.0, and 65.4, respectively, are each weighted by 1/4, as above, the composite equivalent weight is 46.8. If, instead, the proportions of the cations were 2/6, 1/4, 1/4, and 1/6, respectively, the composite cation equivalent weight would be 44.4. Using similar reasoning for the cations associated with nitrate on zinc surfaces, the composite cation can be approximated as

$$1/4(NH_4^+) + 1/4(Na^+) + 1/4(Ca^{+2})_{1/2} + 1/4(Zn^{+2})_{1/2}$$

Average Cl^-, NO_3^-, and SO_4^{-2} concentrations were used for comparing the experimental weight measurements with the weights calculated from the concentrations of anions and cations, since the vintage distributions of the two sample sets were comparable. Using the surface concentrations of Cl^-, NO_3^-, and

SO_4^{-2} given in Table IV, the average extract from zinc surfaces was calculated to weigh 128 $\mu g/cm^2$, which is judged not to be significantly different from the 117 $\mu g/cm^2$ value measured experimentally for a different set of samples collected from the same location. Alternatively, if the extreme case is considered in which no mixing of cations and anions occurs on the surface, it is reasonable to associate Zn^{+2} exclusively with Cl^-, NH_4^+ with SO_4^{-2}, and Na^+ with NO_3^-. If the role of Ca^{+2} is ignored, the average extract from zinc surfaces is calculated to weigh 126 $\mu g/cm^2$. The fact that a consistent number is obtained even if Ca^{+2} is ignored is important because of solubility limitations for Ca^{+2} in the presence of SO_4^{-2}. Based on the solubility product of $CaSO_4$ (1.2×10^{-6}), Ca^{+2} cannot be a 25% contributor to the composite cation except for the lower range of SO_4^{-2} concentrations.

The reasonably close agreement between measured extract weights and those calculated from a range of models is evidence that the water-extractable matter can be accounted for as chloride, sulfate, and nitrate salts. Perhaps more importantly, the fact that close agreement is attained, almost regardless of how the cations are apportioned or distributed, serves to emphasize that quantifying the anions will usually provide sufficient information to quantify total contamination levels for water soluble species.

The SEM/x-ray analyses of extracts from aluminum surfaces indicated that the major element present having atomic numbers greater than 11 were sulfur and calcium. The presence of sulfur is consistent with the sulfate analysis. The aluminum oxide surface on aluminum metal is relatively nonreactive and tends to protect the underlying metal from chemical attack. On the basis of the SEM/x-ray data, the literature data cited above on the ambient aerosol composition in New York City, and the nonreactive nature of aluminum surfaces, the composite cation associated with Cl^- and NO_3^- as presumed to be

$$1/3(NH_4^+) + 1/3\,Na^+ + 1/3(Ca^{+2})_{1/2}$$

while the composite cation for SO_4^{-2} was approximated as

$$1/3(NH_4^+)_2 + 1/3(Na^+)_2 + 1/3\,Ca^{+2}$$

On this basis, the weight of extract contributed by all the salts is calculated to be 42 $\mu g/cm^2$. The total extract weight of 61 $\mu g/cm^2$ measured experimentally indicates that most of the extractable material can be accounted for as chloride, sulfate, and nitrate salts. It is not certain whether the 30% difference in these numbers represents unaccounted for species, inappropriate assumptions in the calculations, experimental error, or a combination of these, although, in view of some of the experimental difficulties and the fairly crude nature of the approximations, the first seems unlikely. Other inorganic anions would very likely have been detected if they and their associated cations were present in sufficient quantity to account for 30% of the total weight.

Several other locations in the same urban environment as Location I, which have equipment with similar vintage distributions, were sampled and analyzed for chloride ion concentrations on surfaces. The results for zinc surfaces, based on the average concentrations, are as follows: Location II — 34 $\mu g/cm^2$;Location III — 23 $\mu g/cm^2$; Location IV — 27 $\mu g/cm^2$; and Location V — 24 $\mu g/cm^2$. The value for Location I (27 $\mu g/cm^2$) is identical to the average from the other locations (27 $\mu g/cm^2$), indicating that the chloride contamination in Location I is typical for this urban environment.

Knowledge of the composition of a surface contaminant is important not only for understanding and predicting the reaction chemistry of a surface but also for evaluating the tendency of the contaminated surface to pick up moisture. A number of compilations of the CRH of common salts exist, the most extensive of which is a listing of 140 pure substances by Balarev *et al.* (27). Contaminants that are rich in a salt with a low CRH will have moisture pickup characteristics that are dominated by the influence of the salt. In many cases, however, a complex mixture of cations and anions exists, and it is not possible to predict with certainty which, if any, of the possible salts will dominate. Furthermore, a mixture often will not exhibit the reversible behavior typical of a pure salt. In any event, even if the CRH can be estimated, the rate of moisture pickup will be unknown. To deal with complex mixtures it is necessary to measure the CRH and moisture pickup rates experimentally. Instrumental gravimetric techniques (17) have been used for these measurements in this work.

The moisture pickup characteristics of a green corrosion product that contaminated the springs and contacts of switching equipment and of the residues from the moistened paper extracts from zinc surfaces and aluminum surfaces at Location I are summarized in Table V, along with similar data for some pertinent pure salts. A detailed explanation of the parameters used to characterize hygroscopicity and an expanded listing containing 41 different substances and materials appear elsewhere (17).

The CRH was determined experimentally, except where indicated in Table V. Measurements were made by passing an air stream over the sample at a sufficiently rapid flow rate (1500 ml/min) to cause rapid weight gain as the RH in the flow chamber was raised above the CRH of the sample. In a separate experiment, the sample was exposed to a water-saturated atmosphere flowing at a rate of 10 ml/min over the sample. Weight gain was monitored as a function of time from which the moisture pickup rate parameters indicated in columns 3-5 in the table could be calculated. The

Table V. Moisture pickup characteristics of various samples

Sample	Critical RH (%)	Initial rate of moisture pickup at 100% RH (%/min)	Rate of moisture pickup at termination at 100% (%/min)	Average weight gain rate at 100% RH (%/min)	Total weight gain (%)	Sample weight (mg)
Green corrosion product	80					
Nickel sulfate	91†			0.001	0.144	
Extract from zinc surfaces	26	0.49	0.048	0.060	153	5.1
Zinc chloride	<10	0.28	0.19	0.256	8.7	34
Extract from aluminum surfaces	46 (35)	0.79	0.02	0.075	84	1.9
Calcium sulfate		0.17	0.07	0.123	4.9	107
Calcium chloride	31↓	0.34	0.34	0.338	8.1	53
Sodium chloride	76↓	0.03	0.04	0.035	3.8	87
Dust (Location I)	27	0.10	0.01	0.012	36.0	20

* A minor component was responsible for a slight moisture pickup at this RH.

experiment was continued until the moisture pickup rate stabilized at a constant value. Generally speaking, the average weight gain rate throughout the experiment is an indication of the relative hygroscopicity of the sample. In some situations it may be more important to know the rate of moisture pickup in the first few minutes of exposure to elevated RH, in which case the initial rate of moisture pickup may be a more appropriate index of relative hygroscopicity.

The major problem that the switching equipment in Location I experienced was caused by the green corrosion product, which was found on the surfaces of the noble metal contacts. From the contamination data on the zinc and aluminum surfaces, sulfate or possibly chloride salts are likely causes of the corrosion products. SEM/x-ray analysis indicated that the green substance was rich in nickel and sulfur. This result was consistent with the observation that the corrosion product was always observed in the vicinity of the nickel base on which the electrical contacts were mounted. The effective CRH of the green corrosion product was approximately 82%. The CRH of a pure sample of nickel sulfate was measured to be 91%, which is reasonably consistent with the chemical analysis. This rather high CRH indicates that the nickel sulfate corrosion product will not pose a moisture hazard in normal building environments. Consideration of the temperature-humidity conditions that existed during a series of equipment malfunctions in a high humidity period indicates, however, that the 91% RH level was exceeded at equipment surfaces. The acquired moisture resulted in the creepage of the corrosion product onto the electrical contact surfaces and also provided low resistance leakage paths that led to equipment problems. Insulating films resulted as the moisture evaporated when normal humidity levels were restored. Unfortunately, an insufficient amount of the green corrosion product was available to measure the rate of moisture pickup at 100% RH.

The water-soluble contaminants extracted from zinc surfaces exhibited a low critical RH and a moderate rate of moisture pickup at 100% RH. The moisture pickup of zinc chloride, a major contaminant on these surfaces, has also been measured and is shown in Table V. The CRH for zinc chloride is known to be $<10\%$, though it has not been measured precisely. Unfortunately, the apparatus used for CRH measurements in this work is currently limited to RH levels above 22%. Nevertheless, the low upper limit that has been reported for the CRH and the rapid and large moisture pickup observed at high RH in this work readily account for the moderate tendency of the extract from zinc surfaces to acquire moisture.

The water extract from aluminum surfaces, which was found to be a mixture of several salts, as discussed above, is moderately hygroscopic. The measured CRH is lower than that for several of the salts that could be present and for which data are available (17, 27), including ammonium sulfate (80%), ammonium chloride (77%), sodium sulfate (approximately 90%), sodium chloride (75%), sodium nitrate (74%), and calcium sulfate (65%). Calcium chloride, which is also likely to be present, has a CRH of approximately 31% and may be the major contributing factor to the low CRH of the extract. Hydration to form the various hydrates of calcium sulfate occurs at low RH but the formation of hydrates usually does not produce a sudden surge in weight gain as the RH is increased. Data are lacking on calcium and ammonium nitrate, but the nitrate salts for which information is available generally have CRH's well above 50%.

A dust sample that was brushed from equipment surfaces at Location I was analyzed for comparison to the extracts from the zinc and aluminum equipment surfaces. The dust included fibers, hairs, and organic substances that are not water-soluble. Consequently, the average weight gain rate (0.012%/min) was substantially lower than those of the zinc and aluminum extracts (0.060 and 0.075%/min, respectively). The low CRH is attributable to adsorption processes on the dust with its large surface area rather than the salt dissolution event normally associated with CRH.

Summary and Conclusions

Water-soluble contaminants existing on zinc and aluminum switching equipment surfaces that have been exposed for up to 40 years to typical New York City indoor environments have been identified and to some extent quantified. The major water-soluble contaminants on zinc surfaces include Zn^{+2}, Ca^{+2}, Na^{+}, NH_4^{+}, Cl^{-}, and SO_4^{-2}, with somewhat lesser amounts of NO_3^{-}. The most prevalent water-soluble contaminants on aluminum surfaces include Ca^{+2}, Na^{+}, NH_4^{+}, and SO_4^{-2}, with lesser amounts of Cl^{-} and NO_3^{-}. In the case of aluminum, only roughly 70% of the total amount of extractable material could be accounted for by Cl^{-}, NO_3^{-}, and SO_4^{-2} and an approximated composite cation. The discrepancy may be caused by a combination of experimental errors and inappropriate assumptions, or it may indicate that there is another anion that is a significant component.

The anions Cl^{-}, NO_3^{-}, and SO_4^{-2} are often associated with corrosion susceptibility, which can lead to electrical leakage in many types of devices and can cause open circuits, particularly with thin film conductors. The device hazard associated with their presence is often a result of moisture acquisition. The CRH's determined in this work for the extracts from the zinc and aluminum surfaces were sufficiently low (26 and 46%, respectively) and the moisture pickup rates were sufficiently high to warrant concern about the potential for equipment degradation at the higher humidity levels (55-65%) that are encountered for indoor environments with typical air handling equipment. During the high humidity incident that occurred at Location I, the RH at equipment surfaces rose to nearly 100% for a brief period. In this situation, the CRH of nickel sulfate (91%), which is a "normal" contaminant on nickel surfaces in New York City and ordinarily does not pose a serious equipment hazard, was exceeded, leading to dissolution and redistribution of nickel sulfate at critical equipment surfaces, such as relay contacts.

This study has shown that a thorough analysis of contaminant concentrations on operating electrical equipment can be accomplished using paper sampling methods and routine analytical procedures. By combining analytical results with knowledge of the CRH, which can be readily determined by instrumental gravimetric methods or found in one of several compilations, and the moisture pickup rates, which can also be experimentally determined, useful conclusions about the environmentally induced causes of equipment malfunction and recommendations about environmental parameters that will reduce equipment degradation can be made.

Acknowledgments

The Anodic Rhodium Oxide Film: A Two-Color Electrochromic System

S. Gottesfeld*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The oxide film grown on a rhodium metal substrate in alkaline solutions by potential multipulsing behaves as a fast two-color electrochromic system. Reversible yellow $\rightleftarrows$ dark green or yellow $\rightleftarrows$ brown-purple coloration changes are obtained in either 1M or 5M KOH solutions. The films suffer very small charge losses after 10^5 cycles in either 1M or 5M KOH electrolytes. The response is faster, but the open-circuit memory is shorter in the more concentrated alkaline solution. The response time of the Rh oxide film in alkaline solutions is comparable to that of the Ir oxide electrochromic in acid solutions, but the open-circuit memory is longer in the latter system. A loss of electrochromic activity was found to be caused in both rhodium and iridium oxide films by excessive cathodic pulse potentials.

The electrochromic properties of anodic iridium oxide films grown on iridium substrates by potential multicycling in acid electrolytes were described in several recent publications (1-4). These oxide films were shown to exhibit fast coloration and bleaching (τ = 50-80 msec), excellent open-circuit memory and very satisfactory stability when subjected to coloration-bleaching multicycles in sodium sulfate electrolytes. In a recent paper Burke and O'Sullivan reported the growth of oxide layers on rhodium electrodes in alkaline solutions by a similar potential multicycling procedure (5). The last authors also reported a color change which could be observed during film growth, from yellow at the cathodic end of the potential range scanned to green at the anodic end. Such coloration changes were reported to be detectable only for thin films while thicker films were reported to maintain a dark green color during potential cycling (5).

In this communication some measurements of the electrochromic properties of anodic rhodium oxide films will be described. The results show that rhodium oxide films grown and pulsed in alkaline solutions can exhibit a reversible coloration change with response times similar to those reported for the anodic iridium oxide films.

Experimental

Measurements of electrochemical characteristics and reflectance changes were performed with the spectroelectrochemical apparatus used previously (1, 2): The Rh sample was mounted from the top and along the axis of a Teflon cylindrical cell equipped with two

Key words: electrochromic oxides, iridium oxide, display.

quartz windows for light incidence and reflection at 45°. A stabilized monochromated light source and a photomultiplier served to monitor the reflectance variations. Electrolytes were prepared from reagent grade KOH and conductivity water. The rhodium disk electrode employed had an area of 0.45 cm^2. It was cut from a 0.015 in. thick Rh foil (Engelhard, >99.9%) mechanically polished to a mirror finish and spot welded to a Rh wire lead. Potentials were measured relative to a Hg/HgO electrode in the same KOH solution, separated by a Teflon stopcock from the main cell compartment. All potentials are reported relative to the reversible hydrogen electrode (RHE). [In KOH solutions $E_{Hg/HgO} = +0.926V$ *vs.* RHE) (6).] A Pt foil served as a counterelectrode. To dissolve the oxide film grown in a previous experiment, the Rh disk electrode was immersed for 3 hr in 5M H_2SO_4 at 80°C. Following such a treatment the large current peaks due to the reversible conversion of the oxide layer disappeared completely.

Results and Discussion

The nature of the electrochromic process.—A rhodium electrode completely free of oxide exhibits a very small charge capacity in the anodic potential region prior to O_2 evolution. On continuously pulsing the potential of the Rh electrode immersed in 1M KOH at a frequency of 0.5 Hz between 0.03 and 1.58V an oxide layer developed, in accordance with the results of Burke and O'Sullivan (5). It could be recognized by the large current peaks which developed in the cyclic voltammogram between *ca.* 0.9V and the onset of oxygen evolution at *ca.* 1.55V. Figure 1 shows voltammograms for a "bare" Rh electrode in 1M KOH and for the same electrode following alternating growth pulses of 1 sec width applied between 0.03 and 1.58V. Voltammograms of the shape shown in Fig. 1 were obtained immediately following oxide growth, but were modified later to show a well-resolved and more reversible early anodic process [similar to that observed in the voltammogram of Ir oxide (1, 2)], as demonstrated in Fig. 2. This type of modification could be usually detected after leaving the oxide-covered Rh electrode in the KOH solution for 24 hr at open circuit, and could be accelerated by alternating coloration pulses in which the applied cathodic potential was less negative than during film growth, *e.g.*, 1.58 ⇄ 0.5V (see discussion of these effects below). The pseudocapacitive currents which increase with oxide growth on Rh are the result of a redox process within the oxide layer, of the nature previously described for anodic Ir oxide

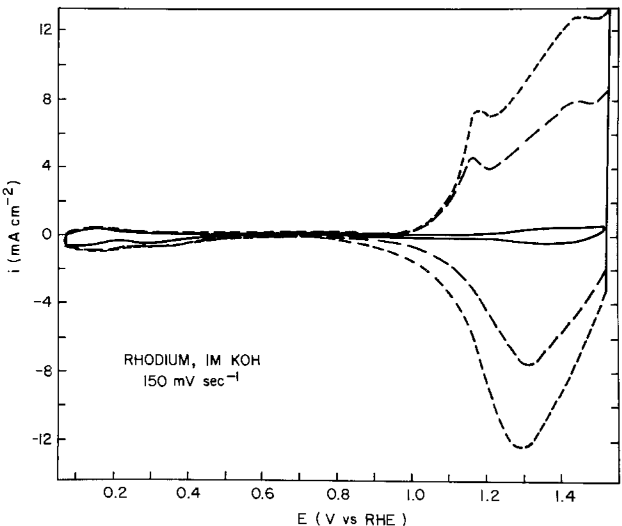

Fig. 1. Growth of oxide on Rh by potential multipulsing in 1M KOH. Solid curve, the "bare" electrode. Dashed curves, following 900 and 1800 pulse cycles applied at 0.5 Hz between 0.03 and 1.58V.

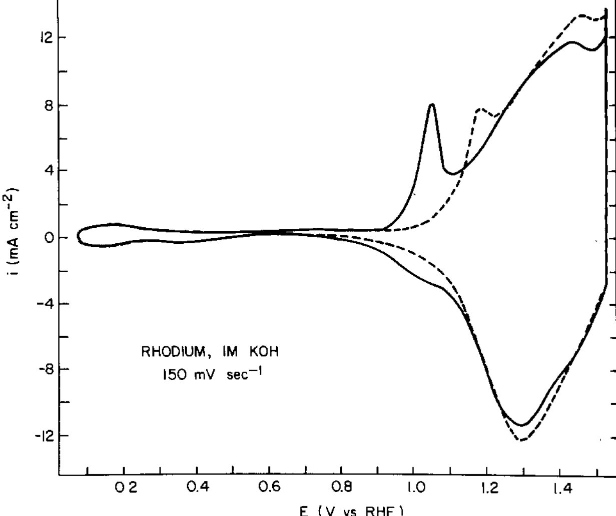

Fig. 2. Changes in the form of the voltammogram following a long immersion in the electrolyte at open circuit. Dashed curve, as-grown. Solid curve, following 24 hr at open circuit.

films (1, 2). Burke and O'Sullivan suggested that the over-all electrocoloration process probably proceeds by a double ejection and injection of protons and electrons according to

$$\underset{\text{yellow}}{\tfrac{1}{2}(Rh_2O_3 \cdot 5H_2O)} \rightleftarrows \underset{\text{dark-green}}{RhO_2 \cdot 2H_2O} + H^+ + e \quad [1]$$

An equivalent equation for the same over-all process, which takes into account that water molecules have to be the proton donors at this *p*H level and that the exact water content of the film is unknown, may be written as

$$\tfrac{1}{2}\,Rh_2O_3(\text{hydrous}) + OH^- \rightleftarrows RhO_2(\text{hydrous}) + \tfrac{1}{2}H_2O + e \quad [2]$$

The water molecules required for the cathodic process may be a part of the structure of the oxide film, in the form of water of hydration in excess of the stoichiometric formulas as well as "free" water molecules which reside in pores within the oxide layer (2). In both Eq. [1] and [2] a single electron process is assumed, while the voltammogram in Fig. 2 shows clearly an additional limited redox process at less positive potentials, which results in a shoulder during the cathodic half-cycle and in a relatively sharp peak during the anodic half-cycle at 1.0V. The charge under this early peak is smaller than that associated with the major reversible process, as found also in the voltammograms of iridium oxide. It is possible that it is due to a further lowering of the oxidation state (*e.g.*, from +3 to +2) in some specific regions (*e.g.*, grain boundaries) under stronger cathodic polarizations, which cannot advance further because of a severe lowering of the electronic conductivity in the reduced form of the oxide. The suggestion (5) that Eq. [1] describes the over-all process was based on colors of known hydrous bulk Rh oxides: The color of the bulk sesquioxide $Rh_2O_3 \cdot 5H_2O$ is reported to be light yellow, while hydrous rhodic oxide $RhO_2 \cdot 2H_2O$ is dark green (7). These particular colors were observed during this work at some oxide thicknesses, while at other film thicknesses the changes observed were yellow ⇄ brown or yellow ⇄ purple. In 1M KOH the color of the anodic form changed periodically during film growth from green to brown-purple and back to green, while the cathodic form was always yellow-gold. Such periodic changes of color with film thickness suggest that the observed colors may be caused in this case by both absorption in the film and interference effects (8). It is doubtful, therefore, if identification of the cathodic and anodic forms as known stoichiometric

bulk hydrous oxides can be made on the basis of the observed colors alone. The yellow ⇄ dark green coloration change seemed, however, to be the more pleasant to the eye and could be always obtained by growing the oxide in 1M KOH up to a stage where the perceived contrast viewed at normal incidence (with scattered light illumination) has reached a satisfactory level, while these particular colors were observed. Following the termination of film growth the observed colors of the oxide were not modified even after 10^5 cycles between the cathodic and anodic forms.

Color modulation at 100% charge efficiency in alkaline solutions.—Just as in the case of oxide growth on Ir (2) there are both anodic and cathodic potential thresholds for the growth of Rh oxide on Rh by alternating potential multipulsing. These growth characteristics are described in detail in Ref. (5). As a result of this behavior, an oxide-covered Rh electrode immersed in 1M KOH solutions can be cycled so as to induce coloration changes without further film growth, provided the potential limits are properly selected. In the selection of these limits the following factors had to be considered in the case of the Rh oxide film: (*i*) Since the potential of the color forming redox reaction lies in this case close to the anodic limit of the water stability range, the highest anodic coloration potential which can be applied without significant coevolution of oxygen has to be used to obtain good contrast. (*ii*) Although the available overpotential for the cathodic coloration is very large, the cathodic applied potential should not be more negative than 0.2V to avoid further film growth (5). An even less negative cathodic voltage is advisable to prevent the deactivation of the electrochromic film (see below). Considering these factors the pulsing potentials selected in both 1M and 5M KOH were 0.43 ⇄ 1.48V (−0.50 ⇄ +0.55V *vs.* Hg/HgO). Figures 3 and 4 show the electrochemical and optical characteristics recorded for an oxide-covered Rh electrode immersed in 1M and 5M KOH, respectively, in the limited potential region employed for the alternating coloration cycles. The reflectance of the oxide-covered rhodium electrode at the cathodic end of the region was designated as Ro, and is close to that of the metal substrate. The film thickness was selected so as to obtain the well perceived yellow ⇄ dark green coloration change, as explained above. The closed form of the charge *vs.* potential curves demonstrates that coloration cycles could be run at a 100% charge efficiency. The charge injection level required to produce a reflectance attenuation of 70% at 546 nm (viewed at 45°) was of the order of

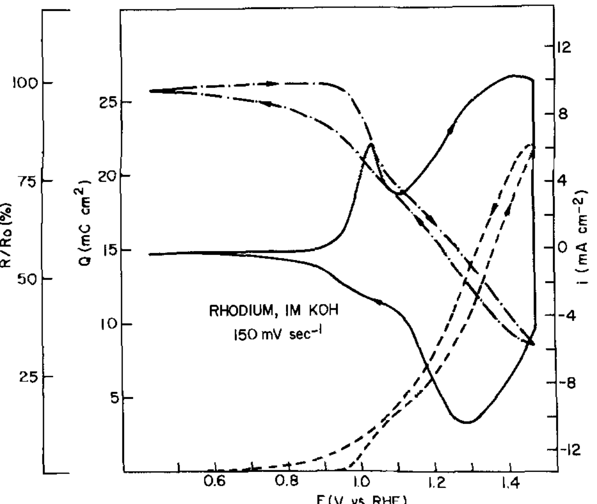

Fig. 3. Variations of the current (solid) charge (dashed) and reflectance at 546 nm, 45° (dashed-dotted) for the oxide-covered Rh electrode in 1M KOH during a triangular modulation of the potential in the range employed for the coloration cycles.

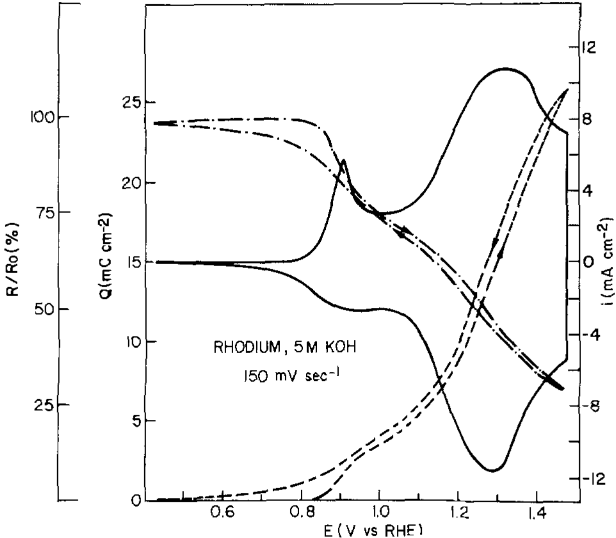

Fig. 4. Variations of the current (solid) charge (dashed) and reflectance at 546 nm, 45° (dashed-dotted) for the oxide-covered Rh electrode in 5M KOH during a triangular modulation of the potential in the range employed for the coloration cycles.

20 mC cm^{-2}, *i.e.*, comparable to that required to color the Ir oxide film (1, 2). Assuming a density of 5g cm^{-3} for the hydrous oxide and a molecular weight of 344 ($Rh_2O_3 \cdot 5H_2O$), this level of charge injection amounts to a uniform one-electron process throughout a film 1400Å thick. Since the Rh oxide film is a two-color electrochromic system, the reflectance attenuation (or contrast ratio) may not be a very satisfactory figure of merit for its evaluation. The strong reversible reflectance variations associated with the coloration change demonstrate, however, that there is also a large decrease in brightness going from the cathodic (yellow) to the anodic (dark green) form, which enhances the perceived contrast. (Similar reflectance changes were recorded at other wavelengths throughout the visible region.) The *R vs. V* curves show some hysteresis at the cathodic end of the cycle associated with a similar hysteresis in the *Q vs. V* curve. A similar behavior is found in the case of the Ir oxide film in acid solutions. In both cases the last stage of the cathodic process is the slowest step in the complete cycle when ohmic drops in solution are eliminated. Comparison of Fig. 3 and 4 reveals that the main process seems to be more reversible in 5M KOH and the major anodic peak is better developed prior to the onset of O_2 evolution. This is due in part to the smaller *iR* drop in 5M KOH, but may be also associated with a cathodic shift of the potential of the electrochromic reaction *vs.* RHE, as found for Ir in alkaline solutions (2).

Response, stability, and memory.—Figure 5(a) demonstrates the response of the Rh oxide electrochromic in 1M KOH to alternating coloration pulses of 1 sec width. In this case the response of the system to the anodic pulse can be seen to be relatively slow. This is due to a combination of a small effective coloration overvoltage and limited conductivity in solution. The cathodic process occurs relatively more rapidly (except for the slower tail) thanks to the larger allowed overvoltage. As shown in Fig. 5(b) both the anodic and cathodic steps were significantly enhanced in 1M KOH by compensating the *iR* drop in solution using the positive feedback circuit of the PAR potentiostat. Such an enhancement means that a solution of a higher conductivity (or an improved cell geometry) should allow a better response in this case. This was indeed verified by transferring the oxide grown in 1M to a 5M KOH solution. The response in 5M KOH without *iR* compensation is demonstrated in Fig. 6(a) and 6(b) on two different time scales. It is clear from Fig. 6

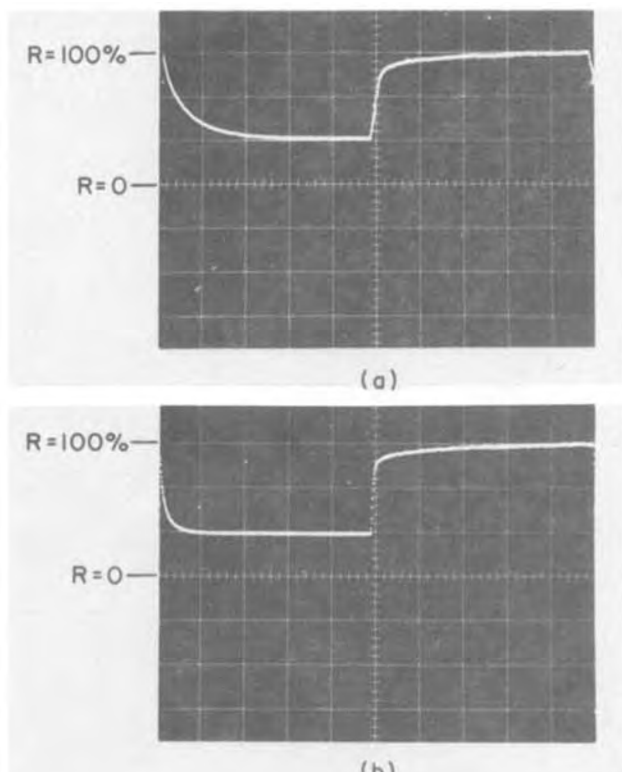

Fig. 5. Variations of the reflectance at 546 nm (45°) with time during alternating potential pulses 0.43 ⇄ 1.48V of 1 sec width, applied to an oxide-covered Rh electrode in 1M KOH: (a) without *iR* compensation; (b) with *iR* compensation.

that the inherent response of the Rh electrochromic oxide is as fast as that found for Ir oxide.

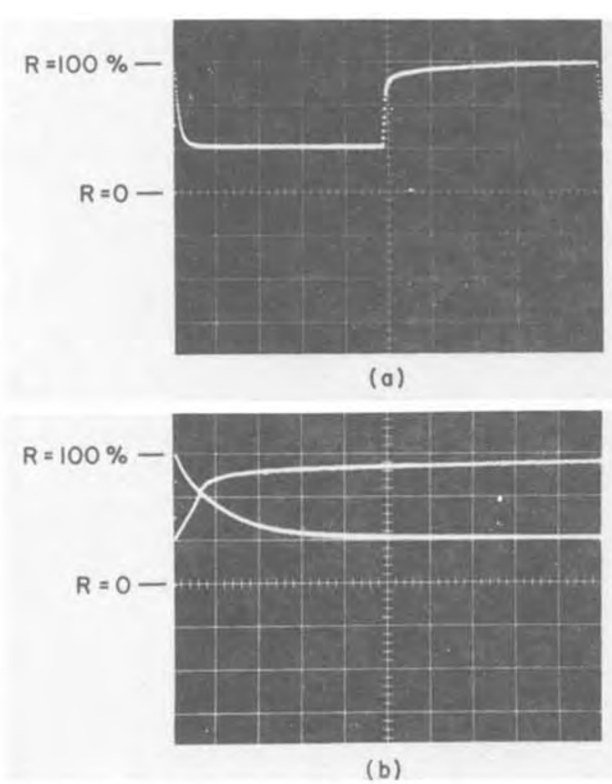

Fig. 6. Variation of the reflectance at 546 nm (45°) with time during alternating potential pulses 0.43 ⇄ 1.48V of 1 sec width, applied to an oxide-covered Rh electrode in 5M KOH (without *iR* compensation): (a) complete cycle shown (2 sec full scale); (b) the onsets of anodic and cathodic reflectance variations are shown on an expanded time scale (200 msec full scale).

Multipulsing experiments which lasted 30 hr each showed that the increased concentration of KOH did not cause any increase in the rate of charge loss: Following *ca.* 10^5 coloration cycles at 0.5 Hz between 0.42 ⇄ 1.47V the observed contrast and the monitored reflectance variations were practically unchanged in both 1M and 5M KOH, while the charge losses ranged in both electrolytes between 0-3%. The good stability found for Rh oxide film in these multipulsing experiments in spite of the relatively high anodic coloration potentials which have to be applied is in accordance with the reported difficulty in removing this film by anodizing it at high potentials (5). [The electrochromic Ir oxide film tends to dissolve under high anodic potentials (9).]

The rate of color loss at open circuit ("open-circuit memory") is demonstrated for the Rh oxide electrochromic in Fig. 7. The decay curves given in Fig. 7 should be compared with a loss of only 10% in light absorption after 5 hr at open circuit as measured for the Ir oxide electrochromic film in acid solutions (1). Thus, while the memory of the Rh oxide electrochromic may be satisfactory for some purposes (especially when immersed in 1M KOH), it is shorter than that found for Ir oxide. The shorter memory is a direct result of the high redox potential of the electrochromic reaction: The anodic form of the oxide [most probably Rh(IV) and perhaps partially Rh(VI)(5)] is formed at a very anodic potential and is expected thermodynamically to react with water. Furthermore, since the Rh(IV) ⇄ Rh(III) conversion is quite reversible (see the major peaks in the voltammograms) the decay of anodic coloration may indeed proceed at open circuit by the reaction of the higher oxide with the aqueous solution to yield the lower oxide and molecular oxygen. This reaction can be written as a sum of two electrochemical half-processes

$$2\,OH^- \rightarrow \tfrac{1}{2}\,O_2 + H_2O + 2e \qquad [3]$$

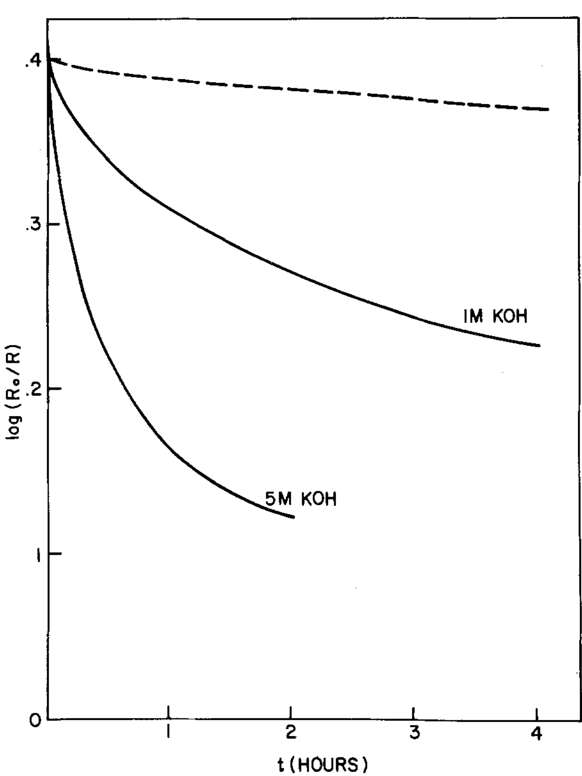

Fig. 7. The open-circuit decay of light absorption in the Rh oxide film immersed in 1M and 5M KOH electrolytes, following the application of a potential pulse of 1.48V. (Measured at 546 nm, 45°). The behavior of Ir oxide in 0.5M H_2SO_4 is given for comparison by the dashed curve.

$$2RhO_2(\text{hydrous}) + H_2O + 2e \rightarrow Rh_2O_3(\text{hydrous}) + 2\,OH^- \quad [4]$$

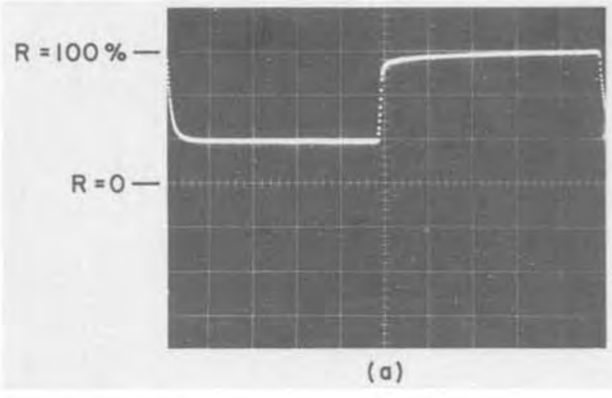
with the net result being

$$2RhO_2(\text{hydrous}) \rightarrow Rh_2O_3(\text{hydrous}) + \tfrac{1}{2}\,O_2 \quad [5]$$

When the rate is determined, as expected, by half-process [3], the open-circuit decay will be enhanced by a higher concentration of OH^- ions, as found experimentally (Fig. 7). Comparison of the open-circuit memories reported for the Ir, Rh, and W electrochromic oxides in aqueous solutions demonstrates the importance of the location of the electrochromic redox reaction on the potential scale: In the case of Ir oxide the potential range of the electrochromic reaction is located close to the middle of the water stability range. Thus, no component of a pure aqueous sulfate solution, even when open to the atmosphere, is expected to react with the colored form of Ir oxide. On the other hand, in the case of Rh oxide, where anodic coloration is obtained at a potential close to that of O_2 evolution, as well as in the case of WO_3 where coloration is obtained close to the onset of H_2 evolution, the colored forms are reactive in contact with water or dissolved oxygen, respectively, thus leading to shorter open-circuit memories.

The cathodic deactivation of the electrochromic Rh oxide film.—The Rh oxide films were found to lose their electrochromic activity following a short application of excessive cathodic pulse potentials. This behavior is demonstrated in Fig. 8 for a film pulsed in a 5M KOH electrolyte: Following the extension of the cathodic pulse potential down to 0.08V for only 2 min (60 cycles), while keeping the anodic pulse potential unchanged, the response during the cathodic half-cycle became very sluggish. Under such conditions the color of the film remained dark-green (or dark-brown) during alternating pulsing, as described by Burke and O'Sullivan for the thicker Rh oxide films which they observed during growth. Figure 9 shows the associated effects recorded in the voltammogram and in the charging curve: The early anodic peak seems to have disappeared completely at this scan rate, while the charging curve exhibits a stronger hysteresis. Following such a short deactivating treatment, the changes in the electrochromic response and in the form of the voltammogram could be reversed by the reapplication of the regular pulses between 0.43 ⇄ 1.48V, *i.e.*, by employing less negative cathodic pulse voltages. In other experiments it was found that a similar "rejuvenation" of cathodically deactivated Rh oxide films could be achieved by immersing the oxide-covered Rh electrode in a hot (75°C) KOH solution for *ca.* 15 min. It is clear from the charging curves in Fig. 9, as well as from the successful attempt to reverse the deactivating effect by immersion in hot KOH, that the cathodic deactivation is not associated with a permanent loss of charge but rather with some change in the structure of the film. [The term "deactivation" in the sense used here should be thus clearly distinguished from the terms "activation" and "deactivation" of Ir electrodes which were used before in the literature to describe the growth and the complete loss of the oxide layer (10).] It thus seems that the applied cathodic overvoltages have to be limited to prevent a loss of electrochromic activity. Fortunately, the cathodic process proceeds rapidly even at the lower overvoltages which were regularly employed (see Fig. 6), and the higher cathodic overpotentials associated with deactivation can be avoided without loss of speed. In fact no rate enhancement is recorded for an active Rh oxide film when the cathodic pulse potential is temporarily extended, because the cathodic process seems to reach a limiting rate which is probably controlled by diffusion in the film. This behavior is demonstrated in Fig. 10.

Very similar effects to those described in Fig. 8-10 were observed for the iridium oxide electrochromic film as well, in H_2SO_4 solutions, and will be described in more detail elsewhere. It should be stressed, however, that no loss of activity was encountered if the cathodic pulse potentials previously prescribed (1, 2)



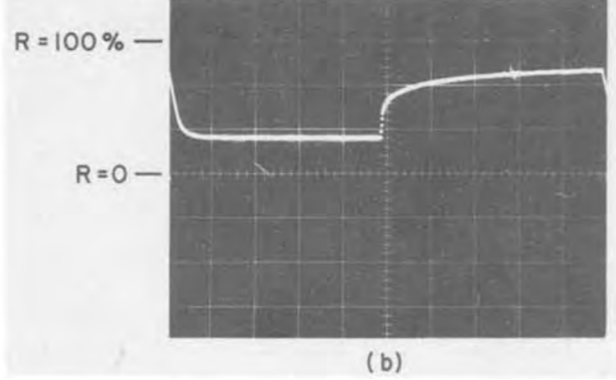


Fig. 8. The effect of an excessive cathodic pulse potential applied for 2 min (60 coloration cycles) on the response of the electrochromic Rh oxide film in 5M KOH. (a) Regular response at 633 nm (45°) recorded during pulsing between 1.48 and 0.43V. (b) Recorded during pulsing between 1.48 and 0.08V 2 min after the cathodic overvoltage had been extended.

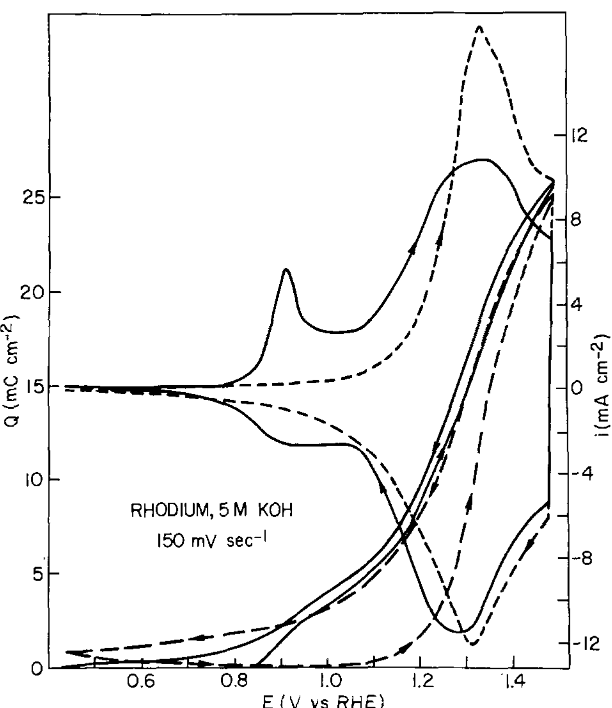

Fig. 9. The effects of cathodic deactivation on the voltammogram and the charging curve. Solid curves recorded for the active form. Dashed curves, recorded for the cathodically deactivated film.

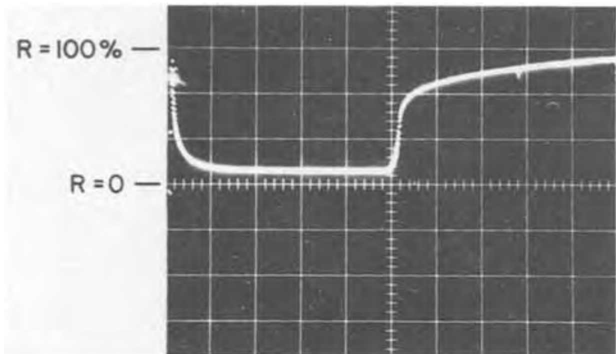

Fig. 10. The limiting rate of cathodic coloration in the Rh oxide film. The figures shows two superimposed reflectance time curves recorded at 440 nm (45°) during two cycles with different cathodic pulse potentials: +1.48 ⇄ +0.53V and 1.48 ⇄ +0.23V. (Pulse width, 1 sec).

were not exceeded. Restoration of the activity by lowering the cathodic overvoltage (while increasing temporarily the anodic applied voltage) was effective in the case of the Ir oxide films as well. Beni and Shay have described before a heat-treatment (immersion in hot electrolyte) for anodic iridium oxide films, which was reported to improve their electrochromic response (3). The results presented here indicate that a direct cause of deactivation in Ir oxide as well as Rh oxide electrochromic films is the use of excessive cathodic pulse potentials. If the cathodic potential is properly controlled no deactivation should occur. Furthermore, reactivation by immersion in a hot solution will not solve the problem if excessive cathodic potentials are further applied, because deactivation will occur again in exactly the same way, as found in this work for heat-treated Rh oxide films. The electrochromic response recorded following sufficiently long periods of multicycling will be thus determined by the electrochemical parameters of the display cell for both heat-treated and nontreated electrodes. In particular, since the growth of these films does require the application of potentials close to 0V *vs.* RHE, the as-grown films may be, in principle, somewhat less active (although the higher anodic potentials which are used during growth tend to continuously reactivate the film). However, with film thicknesses normally employed in this work, as well as before (1, 2), the stable rapid response was found to be established during the first few alternating coloration cycles. Examination of the voltammograms presented by Burke and O'Sullivan (5) reveals that the early anodic peak is very small compared with the one obtained for active Rh oxide films as presented in Fig. 3. Continuous cycling with the cathodic potential extended down to the onset of H_2 evolution (5) may have resulted in their case in a partially deactivated film, causing the decay of the reversible coloration changes.

One possible reason for the deactivation by excessive cathodic pulse potentials could be an irreversible lowering of the electronic conductivity in the film. Preliminary measurements of the electrical properties of these electrochromic oxide films suggest that this is indeed the case. Details of such measurements will be described in a forthcoming report.

Solution Growth of CdSe and PbSe Films

R. C. Kainthla, D. K. Pandya, and K. L. Chopra

Department of Physics, Indian Institute of Technology, Delhi, New Delhi 110029, India

ABSTRACT

Cadmium selenide and lead selenide films have been deposited by a solution growth technique on single crystal germanium and silicon, glass, mica, and copper substrates. The effect of bath parameters (pH, temperature, and relative concentration of reactants) and the nature of the substrate on the rate of deposition and terminal thickness has been established. The structure of the films has also been studied. Based on the experimental results, a growth model has been proposed.

Metal chalcogenides (sulfides, selenides, and tellurides) are important materials for such applications as photoconducting cells, photovoltaic cells, and other electrooptical devices. These materials can be obtained in thin film form by evaporation, sputtering, pyrolysis, and chemical deposition techniques (1). Of all these techniques, chemical solution growth is relatively inexpensive, simple, and convenient for large area deposition of II-VI and IV-VI compounds. By this technique, films can be deposited on a variety of sub-

Key words: chemical deposition, semiconductor films, metal-selenide films, growth kinetics.

strates (insulators, semiconductors, and metals) by allowing them to remain in an aqueous solution of the appropriate chemicals for a predetermined time. For example, films can be obtained by the reaction of a metal salt solution with an aqueous solution of a compound capable of giving chalcogenide ions under suitable conditions. Thiourea and selenourea are the commonly used compounds which furnish sulfur and selenium ions by hydrolysis in alkaline solution (2-5). Selenourea solution is very unstable and has to be stabilized using antioxidants like sodium sulfite. In addition, the compound cannot be synthesized easily. Another compound which can generate selenium ions is sodium selenosulfate. It can be synthesized easily by dissolving selenium in a sodium sulfite solution; the resulting solution is fairly stable. As the hydrolysis constants of selenourea and selenosulfate are different, the conditions under which film formation takes place are different in the two cases. To optimize conditions for deposition of selenide films using selenosulfate solution, a detailed study of film formation under different conditions is necessary. Second, although the technique has been used by some workers for preparing selenide films of cadmium (6) and lead (7), the growth mechanism is not understood clearly. With this in mind, we have studied the rate of growth of cadmium and lead selenide films on different substrates under different conditions.

Experimental Details

Cadmium and lead selenide films have been prepared by using the following over-all reaction

$$M(A)_n^{2+} + SeSO_3^{2-} + 2\,OH^- \rightarrow MSe + nA + SO_4^{2-} + H_2O$$

where M is a metal (Cd or Pb) and A is a complexing agent [NH_3, OH^-, or $C_6H_5O_7^{3-}$].

The experimental setup to deposit the films was the same as described by Kaur *et al.* (8). The reaction mixture was prepared from 0.5M cadmium acetate, 7M ammonia solution, 5M potassium hydroxide, and 0.125M sodium selenosulfate solution in the case of cadmium selenide films and 0.5M lead acetate, 0.820M trisodium citrate, 5M potassium hydroxide, and 0.125M sodium selenosulfate solution in the case of lead selenide films. Appropriate volumes of salt solution, ammonia or trisodium citrate and distilled water were mixed at room temperature and stirred continuously. Substrates were immersed vertically in the solution which was then heated to the required temperature of deposition. Potassium hydroxide was added to adjust the pH of the solution in the case of lead selenide films. For cadmium selenide film deposition, in one case potassium hydroxide was added to adjust the pH, while in the other case the pH was determined by the ammonia concentration. Appropriate volume of sodium selenosulfate solution was then added. The final concentrations of the reagents in the solution used to coat the substrate have been mentioned in the figure captions. Substrates were taken out at different times and the films washed with distilled water and dried. The substrates used in our study were (*i*) glass slides boiled in chromic acid and distilled water and cleaned ultrasonically before use, (*ii*) freshly cleaved mica, (*iii*) polished slices of silicon and germanium, and (*iv*) freshly cleaned copper foils or vapor-deposited thin films of copper on glass substrates. Mirror-like films of metal selenide are obtained on both sides of the substrate.

The film thickness was measured by Taylor Hobson Talystep instrument. For electron microscopy studies, the films were floated off the substrate in dilute nitric acid and lifted onto copper grids. The films were then transferred to the electron microscope specimen holder and examined in AEI-EM 802 electron microscope. The electron diffraction patterns were analyzed using conventional methods.

Results

Figures 1 and 2 show typical curves for film thickness as a function of dip time, for different pH values of the bath in the case of PbSe and for different ammonia concentrations in the case of CdSe films, respectively. In the initial stages of growth, the thickness increases at a fast rate. Subsequently the rate decreases resulting in a terminal thickness. To get larger thicknesses, the films, after cleaning in distilled water (to remove any precipitate adhering to the film), are immersed again in a fresh bath. The film thickness as a

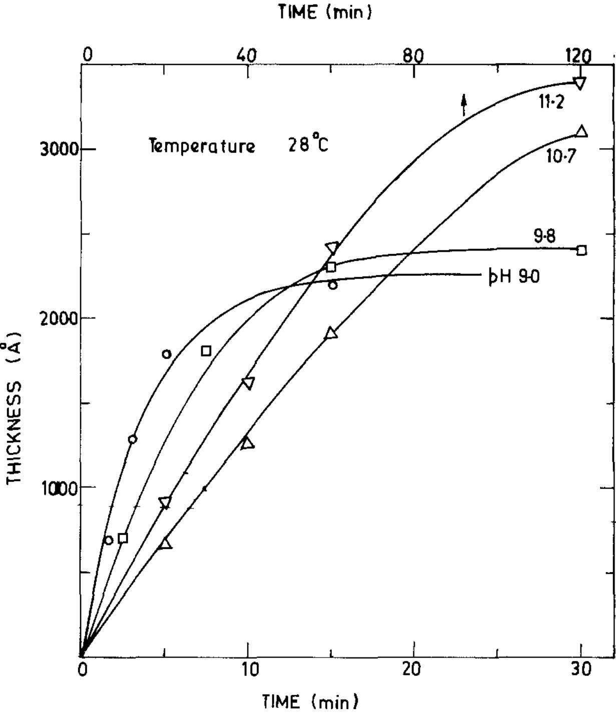

Fig. 1. PbSe film thickness as a function of time for a reaction mixture at 28°C and of composition: $7 \times 10^{-2}M$ $Pb(CH_3COO)_2$, $1.2 \times 10^{-1}M$ $Na_3C_6H_5O_7$, $5 \times 10^{-2}M$ Na_2SeSO_3, and various pH values (glass substrate).

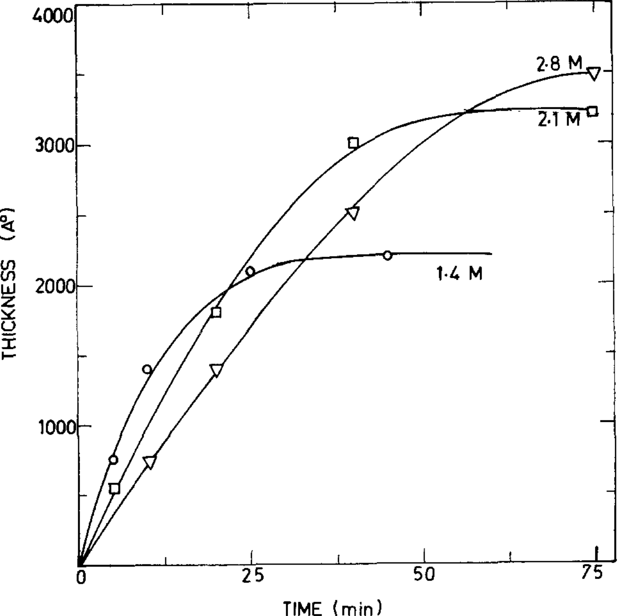

Fig. 2. CdSe film thickness as a function of time for a reaction mixture at 77°C and of composition: $4.8 \times 10^{-2}M$ $Cd(CH_3COO)_2$, $5.3 \times 10^{-2}M$ Na_2SeSO_3, and various NH_3 concentrations (glass substrate).

function of time shows a similar behavior in subsequent dips. The rate of deposition, obtained from the initial part of the curves, and the terminal thickness depend sensitively on the pH of the bath, concentration of the reactants, temperature of deposition, and the nature of the substrate. The effect of various parameters on the rate of deposition and terminal thickness of the films is discussed in detail in the following.

Effect of pH.—As is clear from Fig. 1, the rate of deposition decreases while the terminal thickness increases with increase in pH value. Figure 3 shows the rate of deposition as a function of pH for films deposited at 28° and 60°C. At 28°C, good quality (uniform, adherent, and specularly reflecting) films are obtained for pH between 9.0 and 11.4. Below pH 9.0, nonuniform and nonadherent films are obtained. Above pH 11.4 no reaction is observed to take place. Between pH 9.0 and 11.4, the amount of precipitate accumulated in the solution decreases with increasing pH value. The terminal thickness of the films increases with increase in pH value as shown in Fig. 4.

In the case of CdSe films, when potassium hydroxide is added to adjust the pH of the bath, the solution has a suspension of $Cd(OH)_2$. From this solution thin (terminal thickness ~800Å) films of CdSe are obtained. The terminal thickness decreases while the rate of deposition increases with increase in the pH value. Above a certain pH value, where precipitation dominates, film formation does not take place.

When potassium hydroxide is not added to the solution, the solution is clear and has to be heated to high temperatures ($\gtrsim$ 45°C) to obtain CdSe films. The rate of deposition decreases while the terminal thickness increases with increase in ammonia concentration. The rate of deposition and terminal thickness as a function of ammonia concentration are plotted in Fig. 5.

Effect of temperature.—In Fig. 3, the rate of deposition of the PbSe films is plotted as a function of pH for two different temperatures. For a particular pH value, the rate of deposition increases on increasing the temperature of the bath. At 60°C, the lower limit of pH to get good quality films is increased to 9.6 while the upper limit changes to 12.0. Similarly, at 5°C, the limiting pH values are 8.7 and 9.9. For CdSe films also, the rate of deposition increases with increase in temperature of deposition (Fig. 6).

Figure 4 shows the terminal thickness of PbSe films as a function of the pH for two different temperatures

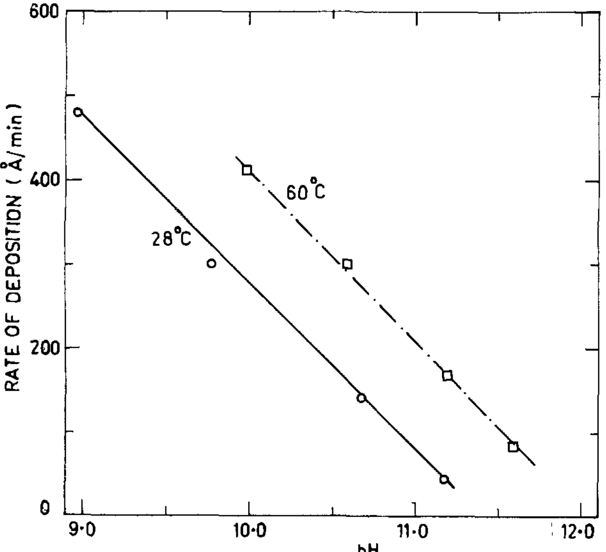

Fig. 3. Rate of deposition of PbSe films as a function of pH value for a reaction mixture of composition: 7 × 10^{-2}M $Pb(CH_3COO)_2$, 1.2 × 10^{-1}M $Na_3C_6H_5O_7$, 5 × 10^{-2}M Na_2SeSO_3 (glass substrate).

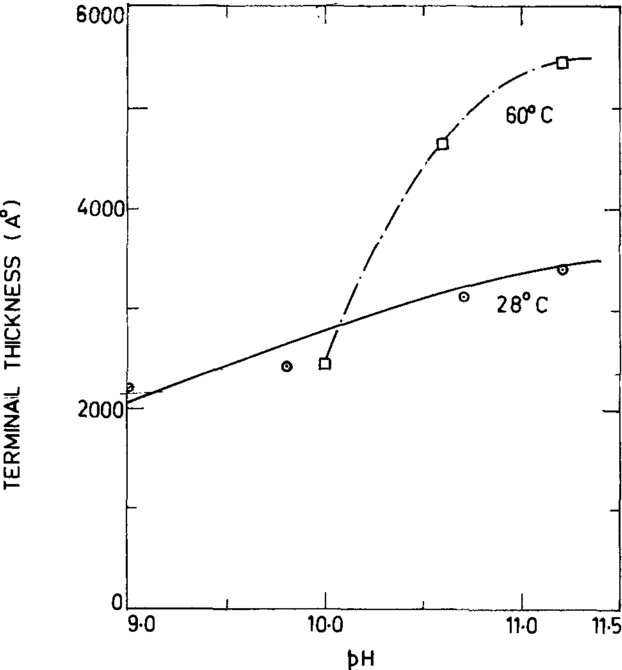

Fig. 4. Terminal thickness of PbSe films as a function of pH value for a reaction mixture of composition: 7 × 10^{-2}M $Pb(CH_3COO)_2$, 1.2 × 10^{-1}M $Na_3C_6H_5O_7$, 5 × 10^{-2}M Na_2SeSO_3 (glass substrate).

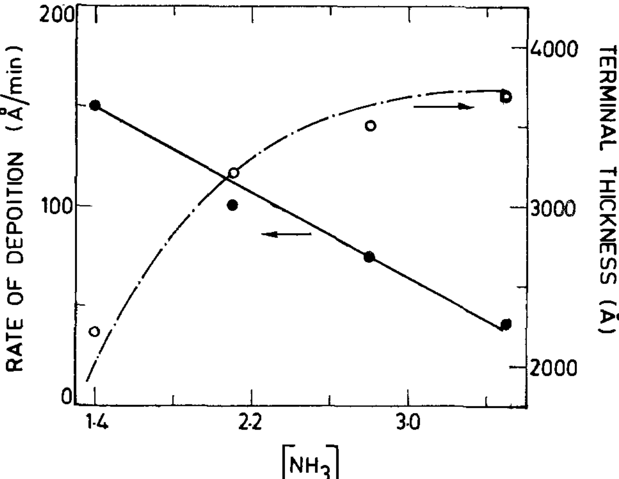

Fig. 5. Rate of deposition and terminal thickness of CdSe film as a function of NH_3 concentration for a reaction mixture of composition: 4.8 × 10^{-2}M $Cd(CH_3COO)_2$ and 5.3 × 10^{-2}M Na_2SeSO_3 at 77°C (glass substrate).

of deposition. The terminal thickness increases with increase in temperature of deposition at high pH values, whereas at low pH values, the terminal thickness decreases with increase in the temperature of deposition. For example, terminal thickness of the film deposited at 60°C is higher at pH 10.7 and lower at pH 10.0 as compared to the terminal thickness of the film deposited at 28°C. In the region of less precipitation, for CdSe films the terminal thickness also increases with increase in temperature of deposition (Fig. 6).

Effect of sodium selenosulfate concentration.—The effect of sodium selenosulfate concentration on the rate of deposition and terminal thickness is shown in Fig. 7 for CdSe films. The rate of deposition increases with increase in selenosulfate concentration. The terminal thickness first increases, passes through a maximum, and then decreases with increasing concentration of selenosulfate. Similar results are obtained for PbSe films.

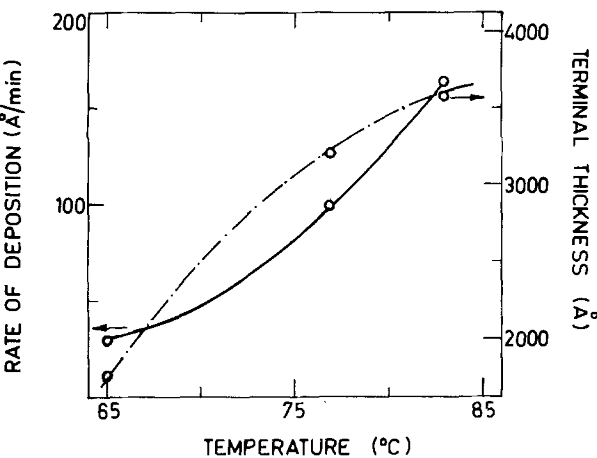

Fig. 6. Rate of deposition and terminal thickness of CdSe films as a function of temperature of deposition for a reaction mixture of composition: $4.8 \times 10^{-2}M$ $Cd(CH_3COO)_2$, $5.3 \times 10^{-2}M$ Na_2SeSO_3, and 2.1M NH_3 (glass substrate).

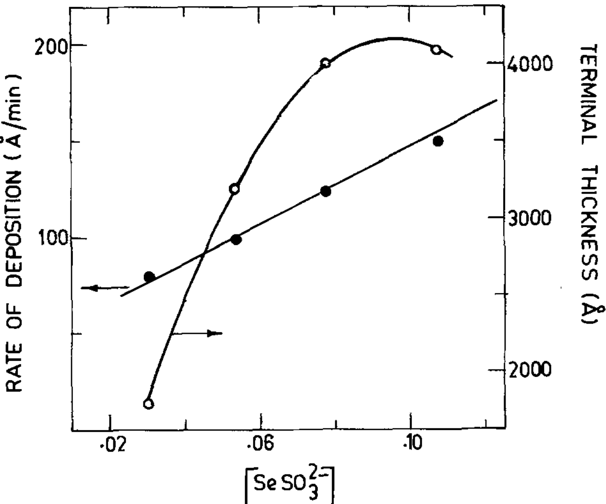

Fig. 7. Rate of deposition and terminal thickness of CdSe films as a function of Na_2SeSO_3 concentration for a reaction mixture of composition: $4.8 \times 10^{-2}M$ $Cd(CH_3COO)_2$ and 2.1M NH_3 concentration at 77°C (glass substrate).

Effect of substrate.—The effect of different substrates on the kinetics of growth of PbSe films deposited on glass, copper, polished slices of single crystal silicon, and germanium at 28°C and pH 10.4 is shown in Fig. 8. The rate of deposition and terminal thickness are maximum for single crystal germanium followed by silicon, copper, and glass. Similar results are obtained for CdSe also. The results are similar to that observed for PbS and $Pb_{1-x}Hg_xS$ films deposited by the same technique (9).

Structure.—The lead selenide films deposited are polycrystalline (grain size depending on the deposition conditions) and have fcc (NaCl-type) structure with lattice parameter a = 6.08Å which agrees well with the ASTM value of a = 6.124Å. The grain size increases with increase in temperature of deposition and pH value of the bath.

Cadmium selenide films, when deposited from a bath having a suspension of $Cd(OH)_2$, have mixed hexagonal and cubic phases. Films obtained from clear solution have cubic (sphalerite) structure with lattice parameter a = 6.063Å. The hexagonal phase has lattice parameters, a = 4.20Å, c = 7.01Å.

Discussion

Sodium selenosulfate (Na_2SeSO_3) hydrolyzes in alkaline solution to give Se^{2-} ions according to

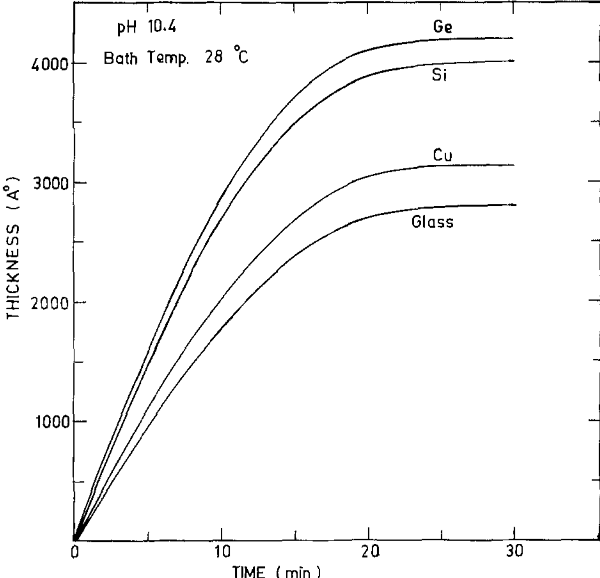

Fig. 8. PbSe film thickness as a function of time for a reaction mixture at 28°C and pH 10.4 of composition: $7 \times 10^{-2}M$ $Pb(CH_3COO)_2$, $1.2 \times 10^{-1}M$ $Na_3C_6H_5O_7$, and $5 \times 10^{-2}M$ Na_2SeSO_3 on different substrates.

$$Na_2SeSO_3 + OH^- \rightleftharpoons Na_2SO_4 + HSe^-$$
$$HSe^- + OH^- \rightleftharpoons H_2O + Se^{2-} \quad [1]$$

In the presence of metal ions (M^{2+}) in the solution, metal selenide (MSe) will be formed if the ionic product of M^{2+} and Se^{2-} exceeds the solubility product of MSe

$$M^{2+} + Se^{2-} \rightarrow MSe \quad [2]$$

To control the number of ions and hence rate of reaction, the metal ions are taken in the form of a fairly stable complex $M(A)_n^{2+}$. The complex dissociates to give controlled number of M^{2+} ions which then combine with Se^{2-} ions to form MSe. In the present study, the systems Cd salt (acetate)-NH_3-Na_2SeSO_3-KOH and Pb salt (acetate)-$Na_3C_6H_5O_7$-KOH-Na_2SeSO_3 have been taken for the deposition of CdSe and PbSe films, respectively.

CdSe film growth.—Ammonia hydrolyzes in water to give OH^- according to the equation

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad [3]$$

with hydrolysis constant $K_{hyd.} = 1.8 \times 10^{-5}$.

When ammonia solution is added to Cd-salt solution, $Cd(OH)_2$ starts precipitating when solubility product (SP) of $Cd(OH)_2$ is exceeded, *i.e.*

$$Cd^{2+} + 2\,OH^- \rightleftharpoons Cd(OH)_2$$

with

$$SP = [Cd^{2+}][OH^-]^2 = 2.2 \times 10^{-14} \; (pSP = 13.66) \quad [4]$$

The $Cd(OH)_2$ precipitate dissolves in excess ammonia solution to form the complex cadmium tetra-ammine ion $[Cd(NH_3)_4^{2+}]$

$$Cd^{2+} + 4NH_3 \rightleftharpoons Cd(NH_3)_4^{2+} \quad [5]$$

The stability constant of $Cd(NH_3)_4^{2+}$, $pK = 7.12$, *i.e.*

$$\frac{[Cd^{2+}][NH_3]^4}{[Cd(NH_3)_4^{2+}]} = 7.56 \times 10^{-8} \quad [5a]$$

Conversion to logarithmic concentrations and elimination of $p[Cd^{2+}]$ from Eq. [4] and [5] leads to

$$pH = 10.73 + ½\, p\,[Cd(NH_3)_4^{2+}] - 2p\,[NH_3]$$

If excess ammonia is added to dissolve the $Cd(OH)_2$ precipitate, $p[Cd(NH_3)_4^{2+}]$ can be approximated by pc_{salt}. Hence

$$pH = 10.73 + ½\, pc_{salt} - 2p\,[NH_3]$$

In the present case, $pc_{salt} = -\log(4.8 \times 10^{-2}) \simeq 1.3$. Therefore

$$pH = 11.38 - 2p[NH_3] \quad [6]$$

Equation [6] when plotted is a straight line A as shown in Fig. 9. Points lying on the line and in region I represent a homogeneous system consisting of stable $Cd(NH_3)_4^{2+}$ complex in equilibrium with Cd^{2+} ions. In region II, which can be reached by the addition of an alkali to the solution, conditions for the spontaneous formation $Cd(OH)_2$ exist so that the points lying in region II represent a heterogeneous system consisting of the complex $Cd(NH_3)_4^{2+}$ and a solid phase of $Cd(OH)_2$ simultaneously in equilibrium with Cd^{2+} ions.

CdSe films have been obtained in region II and for conditions corresponding to the points on the line A. In the heterogeneous system of $Cd(OH)_2$ and $Cd(NH_3)_4^{2+}$, the region enclosed by the two dotted lines B and C represents conditions for obtaining films of measurable thickness. The film formation in this region is explained on the basis of heterogeneous nucleation. $Cd(OH)_2$ present in the solution and that formed on the substrate act as nuclei for the formation of CdSe. More of CdSe is formed in the bulk of the solution and on the substrate surface by the addition of more Cd^{2+} and Se^{2-} ions from the solution to the initially formed CdSe and consequently with time a precipitate of CdSe is formed in the bulk and a film on the substrate. As the *p*H of the solution is further increased most of the Cd^{2+} and OH^- ions spontaneously react to form $Cd(OH)_2$ in the bulk of the solution and hence on addition of sodium selenosulfate most of the CdSe is precipitated resulting in lower terminal thicknesses at high *p*H values of the bath.

From clear solutions (*i.e.*, homogeneous system) at room temperature (~ 28°C) no film or precipitate is formed even when the solution is kept for a very long time. This is due to the fact that as most of Cd^{2+} ions are in the bound complex form $Cd(NH_3)_4^{2+}$, ionic product of Cd^{2+} and Se^{2-} does not exceed the solubility product of CdSe. To get higher concentrations of Cd^{2+}, the solution has to be heated. The heating results in dissociation of the complex and selenosulfate and, therefore, higher concentrations of Cd^{2+} and Se^{2-} are available for reaction. Also the increased kinetic energy of the ions with increasing temperature results in more frequent collisions so that the probability of CdSe formation increases. Thus from clear solutions containing 2.1M ammonia, CdSe films can be obtained only at temperatures above 45°C. The mechanism of film growth from clear solution is discussed in the following section.

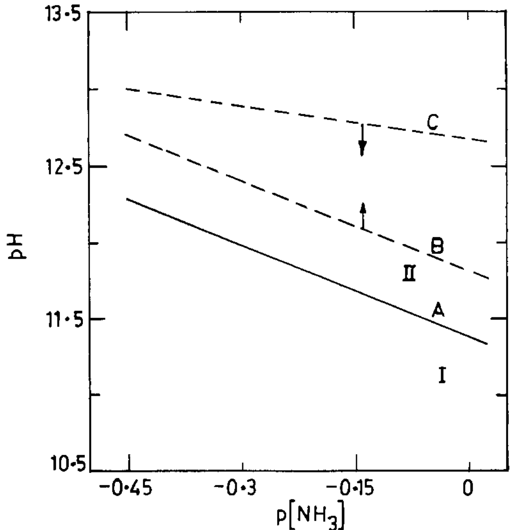

Fig. 9. Plot of Eq. [6]

Growth of PbSe films.—For PbSe film growth, the Pb^{2+} ions are complexed with $C_6H_5O_7^{3-}$ ions to give $Pb(OH)C_6H_5O_7^{2-}$ which dissociates to give Pb^{2+} according to the reaction

$$Pb(OH)C_6H_5O_7^{2-} \rightleftharpoons Pb^{2+} + OH^- + C_6H_5O_7^{3-} \quad [7]$$

The complex has stability constant $K = 1.4 \times 10^{-19}$ so that

$$\frac{[Pb^{2+}][OH^-][C_6H_5O_7^{3-}]}{[Pb(OH)C_6H_5O_7^{2-}]} = 1.4 \times 10^{-19} \quad [8]$$

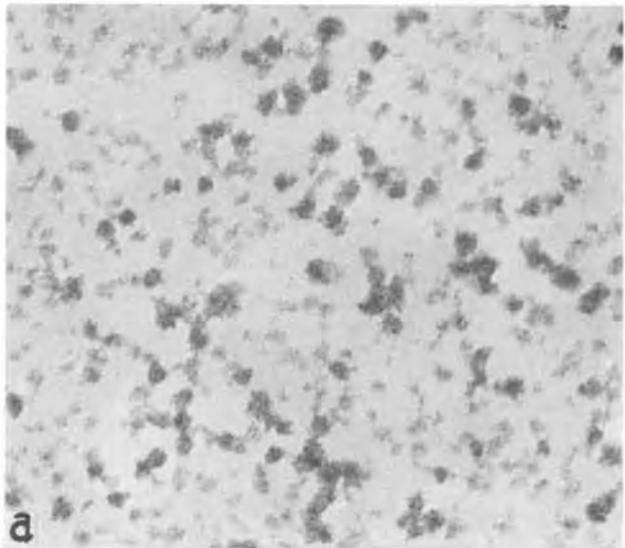
The Pb^{2+} ions formed according to Eq. [7] react with Se^{2-} ions formed in Eq. [1] to give PbSe.

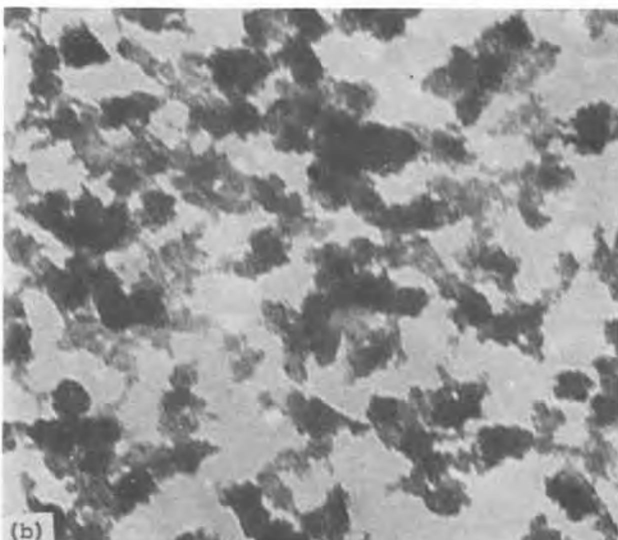
The concentration and the rate of generation of Pb^{2+}, Cd^{2+}, and Se^{2-} ions is determined by reactions [7], [5], and [1], respectively. Metal selenide is formed (according to reaction [2]) when the ionic product (*IP*) of M^+ and Se^{2-} exceeds the solubility (*SP*) of MSe. The ratio $IP/SP = S$ defines the supersaturation of the ions over the MSe and can be varied by choosing the appropriate initial concentrations of the reactants. When $S > 1$, the ions combine on the substrate and in the solution to form MSe nuclei which grow with time to give film and precipitate, respectively. Once MSe is formed it acts as catalyst for further deposition of fresh portions of MSe preferentially. The rate of deposition and terminal thickness is dependent on the reaction mixture since the latter determines the rate of formation and growth of nuclei. As the catalytic MSe surface develops both on the surface and in the volume of the solution, the proportion of MSe formed on substrate is determined by the ratio of nuclei formed on the substrate and in the over-all solution.

In their studies on the growth of PbSe films using selenourea in place of sodium selenosulfate, Lundin *et al.* have found that the initial induction period required to form PbSe nuclei from the initially homogeneous system on the substrate surface is not observed in the kinetic curves if the substrates are covered with a seeding layer of $Sn(OH)_2$ (5). As our thickness *vs.* time plots (Fig. 1 and 2) also do not show the initial induction period, we assume that the surface which is in contact with the solution has suitable impurities or foreign particles which initiate nucleation and growth of the MSe. Although the exact nature of these impurities/particles is not known, the assumption is supported by the known fact that in any precipitation system there are many particles of different nucleating efficiencies (10, 11). At low supersaturations, the most efficient group of particles will act as nuclei for MSe formation, which then grow to larger sizes. The experimental observation of large grain sizes at high *p*H values, where Pb^{2+} concentration is small and hence supersaturation low, suggests the existence of foreign particles on the nucleating surface. The nuclei grow and coalesce to form a continuous film. The nucleation and growth mechanism of formation of MSe films is supported by the electron microscopic investigations as seen in a series of electron micrographs in Fig. 10.

The above model of nucleation and growth of thin films is supported by our earlier observation that alloys of PbS and HgS can be prepared over a wide composition range ($Pb_{1-x}Hg_xS$, $0 \leq x \leq 0.33$) and the films can be grown epitaxially on a suitable substrate under controlled conditions (9). The observation that $Pb_{1-x}Hg_xS$ films containing α phase or β phase of HgS and CdS films with cubic, hexagonal, or mixed structure can be obtained by simply changing the deposition conditions also supports the mechanism of film formation by combination of ions on the substrate (8, 9). Note that the process of ion by ion deposition on the substrate is analogous to the atom by atom condensation process during vapor deposition.

Our observations can be understood on the basis of this mechanism of film growth as discussed in the following. The rate of deposition is high in the initial





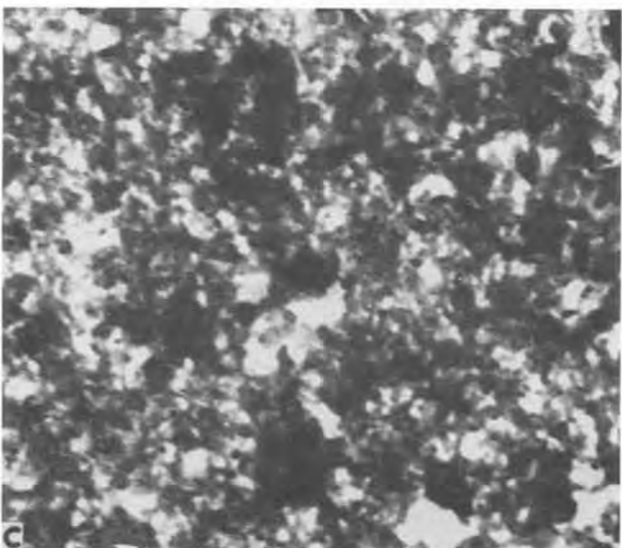


Fig. 10. Electron micrographs showing growth of PbSe films after (a) 3 min, (b) 6 min, and (c) 12 min. (×80K.)

stages of growth because the concentration of M^{2+} and Se^{2-} ions is high. As more and more of MSe is formed, the solution becomes depleted of ions, resulting in a lower rate of deposition. The rate of deposition becomes zero, resulting in a terminal thickness, when the concentration of M^{2+} and Se^{2-} ions decrease to a value such that $S < 1$.

Effect of pH.—The reaction rate and the rate of deposition depend on the supersaturation S. The lower the supersaturation, the slower is the formation of MSe. From Eq. [8], if the concentration of OH^- is more in the solution, the Pb^{2+} concentration is small resulting in low S and slow rate of reaction. With increase in pH as the Pb^{2+} concentration decreases, the rate of formation of PbSe is reduced. Above a certain pH, depending on the bath temperature (11.4 at 28°C), the concentration of Pb^{2+} decreases to a level such that the ionic product of Pb^{2+} and Se^{2-} becomes less than the solubility product of PbSe ($S < 1$). Above this pH value, PbSe is not formed. Thus the decrease in the rate of deposition with increase in pH value and no reaction above a certain pH value is explained. Similarly, in the case of CdSe film deposition, where Cd^{2+} concentration decreases with increase in NH_3 concentration, the rate of deposition decreases on increasing the NH_3 concentration.

In the clear solution, the formation of MSe takes place by homogeneous nucleation which takes place at relatively higher supersaturations than that for heterogeneous nucleation. With increase in pH/ammonia concentration, for the case of PbSe/CdSe, as the supersaturation decreases, the precipitation is decreased resulting in more MSe on the substrate and hence higher terminal thickness.

Effect of temperature.—The dissociation of the complex and selenosulfate depends on the temperature of the bath. At higher temperatures, the dissociation is greater and gives higher concentration of M^{2+} and Se^{2-} ions. This results in higher rates of deposition. Due to thermal dissociation being higher at higher temperatures, the pH value above which ionic product of Pb^{2+} and Se^{2-} decreases to a value below the solubility product of PbSe is more, resulting in an increase in the limiting pH value for PbSe formation from 11.4 at 28°C to 12.0 at 60°C. The increased kinetic energy of the ions and hence the increased interaction between them at high temperatures are also responsible for the increase in the rate of deposition.

The terminal thickness decreases or increases with increase in the bath temperature depending on the conditions under which films are prepared. At low pH values supersaturation is high even at low temperatures. Further increase in the temperature increases the supersaturation resulting in precipitation of most of the PbSe and consequently lower terminal thickness. At high pH values where supersaturation is low, precipitation is limited, and most of the PbSe is formed on the substrate surface. Further, the thermal dissociation of complex and selenosulfate is increased at higher temperatures so that more Pb^{2+} and Se^{2-} ions are available for PbSe formation and thus higher terminal thicknesses are obtained.

Figure 6 shows results for CdSe films deposited at different temperatures for 2.1M ammonia concentration. At this concentration, the supersaturation being low the precipitation is small and hence the terminal thickness increases with increase in temperature of deposition in agreement with the above argument.

Effect of selenosulfate concentration.—The increase in the selenosulfate concentration leads to an increase in Se^{2-} ion concentration. As the rate of any chemical reaction is proportional to the concentration of the reacting species, the rate of deposition increases with increasing selenosulfate concentration. The maximum in terminal thickness is obtained because of lower selenosulfate concentrations, the number of Se^{2-} ions being insufficient to combine with all the available M^{2+} ions. As selenosulfate concentration increases, more Se^{2-} ions become available to form MSe leading to larger thicknesses. Above a certain concentration, when rate of reaction becomes high, precipitation also

becomes important leading to a lesser amount of MSe on the substrate and hence lower terminal thicknesses.

Effect of substrate.—Film formation can take place only under certain conditions, that is, either under optimum conditions for MSe formation or when the substrate has special properties facilitating the formation of single crystal films. The second condition favors film formation because when the lattice of the deposited materials matches well with that of the substrate, the free energy change of nucleation is smaller thereby facilitating nucleation. As Si and Ge have the same lattice (cubic) as CdSe and PbSe, the nucleation on these substrates is facilitated leading to higher rates of deposition and larger terminal thicknesses.

Conclusions

1. Uniform, adherent, and specularly reflecting PbSe and CdSe films can be deposited on an insulating, metallic, and semiconducting substrates by a simple chemical growth technique.
2. The film formation takes place by the recombination of the ions on the substrate surface via a nucleation and growth process.
3. The rate of deposition of the films and the terminal thickness depend sensitively on *p*H, composition, and temperature of the bath and the nature of the substrate.

The Influence of Solution *p*H on Microstructure of Electrodeposited Cobalt

S. Nakahara* and S. Mahajan*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In this study we have attempted to elucidate the influence of *p*H on microstructures of electrodeposited cobalt using transmission electron microscopy. It is observed that at low *p*H (~1.6), the microstructure mostly consists of highly faulted fcc regions, and electron diffraction patterns are very complex. On the other hand, at high *p*H (~5.7) hcp phase is observed, and the density of faults is greatly reduced. From these observations together with results of chemical analysis, it is proposed that at low *p*H, the formation of fcc cobalt, probably in the form of metastable cobalt hydride, is greatly facilitated by the adsorption and subsequent incorporation of atomic hydrogen into the electrodeposits. However, later on these hydrogen atoms rapidly diffuse out of the film, thereby the resulting "fcc cobalt" (cobalt hydride) becomes unstable at room temperature and transforms martensitically into hcp cobalt.

It has long been known that the high temperature (>417°C) phase of cobalt (fcc) can be obtained by electrodeposition at ambient temperature. Polukarov (1) and Goddard and Wright (2) have reported that the *p*H of an electrolyte has a marked influence on the formation of the fcc phase. Electrodeposition from solutions with *p*H < 2.4 results in fcc cobalt, whereas from solutions with *p*H > 2.9, hcp cobalt is produced (2). However, it remained unresolved as to how fcc cobalt can be produced at room temperature.

Recently, Wright (3) and Gaigher and van der Berg (4) have reported on the influence of *p*H on the fcc ⇆ hcp phase transition during the early stages of cobalt electrodeposition. Wright (3) has suggested that fcc cobalt grows epitaxially onto fcc metal substrates, and, in addition, the incorporation of hydrogen into the fcc lattice during the deposition at low *p*H may make the fcc → hcp phase transition, based on energy considerations, unlikely. This conclusion strongly implies that the formation of fcc cobalt is characterized as the hydrogen-assisted state of extended pseudomorphism, which is similar in principle to that observed in vapor-deposited cobalt/copper bimetallic films (5). These suggestions, however, do not seem to be consistent with the fact that very thick fcc cobalt films, which are not affected by epitaxial growth, can be produced at low *p*H (2). With respect to the occurrence of the hcp cobalt at high *p*H, Gaigher and van der Berg (4) have suggested an association with the presence of colloidal hydroxides at the cathode surface during the deposition.

In this study, we have investigated the influence of *p*H on the microstructures of electrodeposited cobalt films by transmission electron microscopy, and these results constitute the present paper. A plausible explanation for the formation of fcc cobalt at low *p*H has been developed.

Experimental

Cobalt films were electrodeposited on a sheet of annealed OFHC copper. The composition of the plat-

* Electrochemical Society Active Member.

Key words: *p*H, electrodeposition, electron.

ing solution was 300 g/liter $CoSO_4$, 3 g/liter NaCl, and 6 g/liter boric acid (2). The *p*H was lowered and raised by the addition of H_2SO_4 and NaOH, respectively. Plating was conducted without any mechanical agitation at the current density of 10 mA/cm^2 and at room temperature (20°C).

Cobalt films were prepared from two solutions with *p*H = 1.6 and 5.7. This choice of *p*H values is based upon the previous investigation (2). For the purpose of convenient terminology, cobalt films obtained in these low and high *p*H solutions will be called, hereafter, low *p*H cobalt (LP-Co) and high *p*H cobalt (HP-Co) films, respectively. After masking the front surface of the plated films, the film-substrate composite was prepared for TEM examination by electropolishing from the substrate side using the conventional window technique. In this way, viewing can be done on the region in which the effect of the substrate on the microstructure of deposits would be minimal. Furthermore, as the thickness of all the films was well in excess of 50 μm, the role of substrate in inducing epitaxial growth should be negligible.

All TEM micrographs were obtained using a JEM 200 microscope operated at an accelerating voltage of 200 kV. Images of small inclusions in the deposits were taken using the defocus contrast technique, which has been described previously (6).

Results

The plating characteristics in the low and high *p*H solutions were quite different. In the low *p*H solution, plating was accompanied by the evolution of a large amount of hydrogen gas and, consequently, the current efficiency for the metal deposition was extremely low. It was apparent that both cobalt and hydrogen are depositing simultaneously at the cathode. In the high *p*H solution, on the other hand, only a small amount of hydrogen gas was seen to evolve at the cathode and the current efficiency for the metal deposition was nearly 100%.

Transmission electron microscopy studies have revealed that the microstructures of LP-Co films were markedly different from those of HP-Co films. In particular, the most dramatic structural difference was observed in their electron diffraction patterns. Figures 1(a) and (b) show electron diffraction patterns for LP-Co and HP-Co films, respectively. It is noted that the diffraction pattern for the LP-Co film is extremely complicated as compared to that of the HP-Co film. The observed streaking in the diffraction pattern, in fact, was found to originate from extensive faulting within individual grains. An example of the extensively faulted grains in the LP-Co film is shown in Fig. 2; trace of the fault plane is delineated by the dotted line AA'. From the analysis of electron diffraction patterns, it was found that the LP-Co film primarily contains faulted fcc cobalt with a small amount of hcp phase, whereas the HP-Co film consists entirely of the hcp phase. A summary of the diffraction analysis is shown in Table I. The present results confirm the earlier observations that fcc cobalt can be produced during electrodeposition from the low *p*H solution. Typical microstructures of the LP-Co film are further illustrated in Fig. 3. In most of the grains, faulting is observed only on one variant, but some grains, such as the one marked with a symbol, FCC, contain faults lying on two variants. In view of the fact that in fcc structure, faulting can occur on four {111} planes, the observed faulting on two planes within one grain appears to be consistent with the above electron diffraction results.

Figure 4 shows the structure of HP-Co film. The noticeable difference from the LP-Co films is that almost all grains are of hcp cobalt without any appreciable faulting, but contain a high density ($\sim 1.4 \times 10^{17}$/cm^3) of small ($\sim$10Å) inclusions. Very few faults are present. The three fine arrows point out three typical

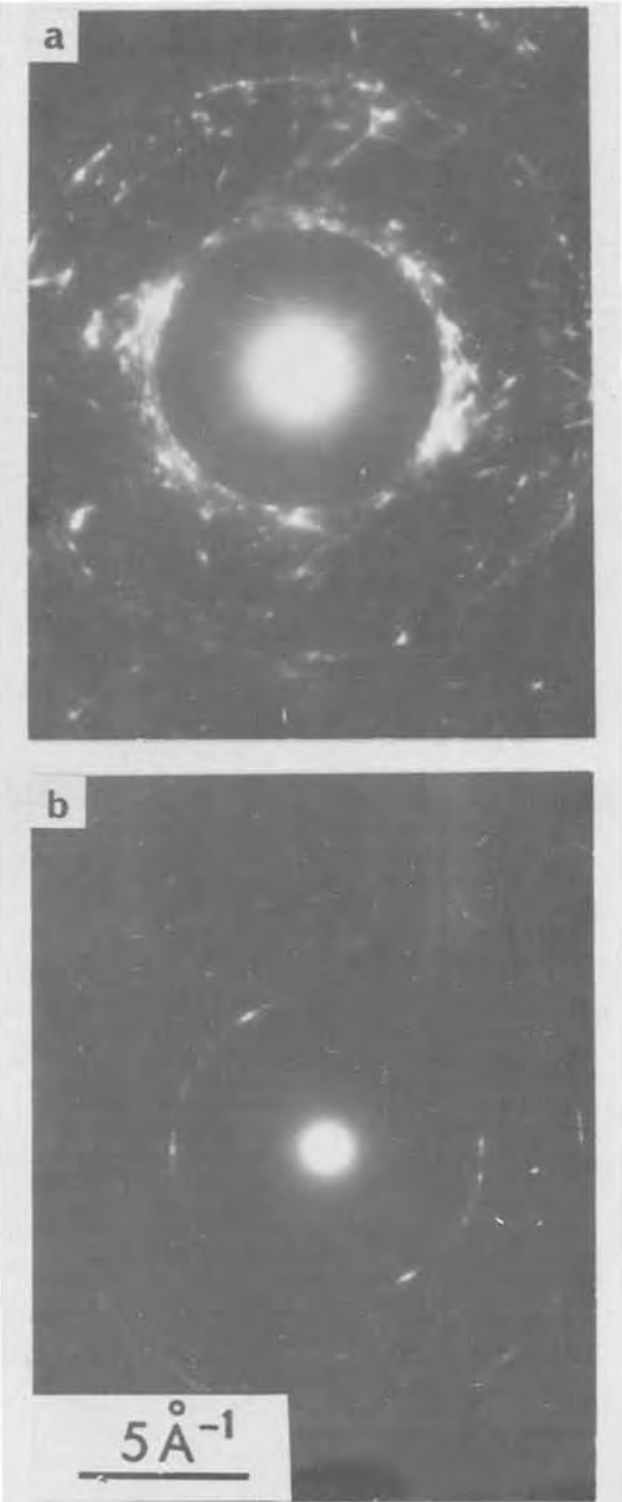

Fig. 1. Electron diffraction patterns from electrodeposited cobalt films obtained in a solution with (a) *p*H = 1.6 and (b) 5.7.

inclusions which are made visible using the defocus contrast technique (6). The fact that these inclusions are seen as white dots surrounded by black rings in the underfocused condition suggests that the inclusions have smaller mean inner potential than does the surrounding cobalt matrix. It is further noted that these inclusions are incorporated systematically along the (0001) basal plane of each grain. Figure 5 shows some zigzag steps due to slight misorientation in the film plane, in which lines of incorporated inclusions also follow systematically along the basal planes as indicated with a symbol, TT'. This crystallographic alignment of inclusions strongly suggests that they must

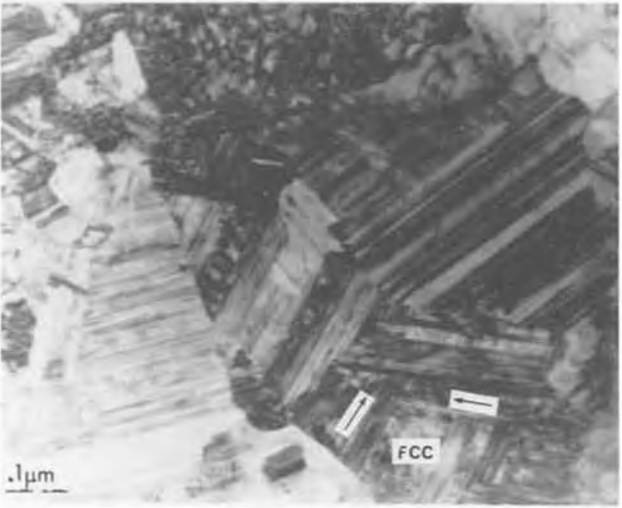

Fig. 3. Structure of an electrodeposited cobalt film (LP-Co) obtained in a solution with $pH = 1.6$. The film contains primarily fcc grains as indicated with a symbol, FCC, in which two faulting systems (see two arrows) are activated, indicative of fcc structure.

have been incorporated during the deposition on the (0001) basal plane which is also the growth plane for the cobalt metal.

In order to determine the amount of probable impurity content in the deposits, the LP-Co and HP-Co films were analyzed using vacuum fusion technique and mass spectrometry.[1] The LP-Co film was found to contain 33 ppm H_2 and 35 ppm O_2. On the other hand, the HP-Co film contained 230 ppm H_2 and 890 ppm O_2. The higher content of both hydrogen and oxygen in the HP-Co film suggests that these gases may have originated from cobalt hydroxides.

Discussion

It has been shown that fcc cobalt can be obtained during the electrodeposition from the low pH solution. It should be noted, however, that these cobalt grains observed in the LP-Co film are highly faulted. It is well known that the fcc → hcp structural transformation can be accomplished by faulting on alternate {111} planes (7). The microstructure of the LP-Co film, therefore, suggests that the fcc structure was originally formed during the deposition, but due to its instability at room temperature transformed into the more stable hcp phase via $\{111\}_{fcc}$ faulting. A question, then, can be raised as to how fcc cobalt is produced in the low pH solution, but not in the high pH.

In order to understand the basic mechanism of fcc cobalt formation, it is important to understand the electrochemical aspects of cobalt electrodeposition. A number of investigations (8-10) have discussed the peculiarities in the electrochemical behavior generally common to the iron group metals, *i.e.*, Fe, Co, and Ni. The electrolytic reduction of the iron group metal ions from aqueous solutions is accompanied by substantial overvoltage, and markedly varies with the pH of the solution. This high overvoltage is generally attributed to the high adsorption of foreign substances (hydrogen, hydroxide) on the electrode surface, which, in turn, influences the reduction rate of metal ions. In particular, when the deposition is made at low temperature (20°C), both the cathode potential and current effi-

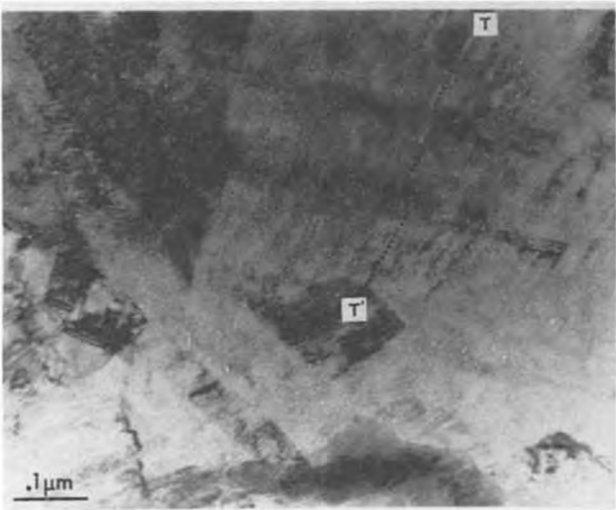

Fig. 5. Microstructure of an electrodeposited cobalt film (HP-Co) prepared in a solution with pH = 5.7. A dotted line, traced with symbols, TT', follows the systematic directional change in the line of inclusions. It is seen that these hcp cobalt grains are slightly misoriented to each other, forming a fanshaped morphology.

ciency for the metal deposition sharply decrease with decreasing *pH*. This phenomenon can also be explained by the increasingly high adsorption and subsequent codeposition of hydrogen atoms with decreasing solution pH. At high temperature (150°C), however, the irreversible adsorption of hydrogen or hydroxide is drastically decreased, and hence the inhibiting action of these foreign substances and the overvoltage for the metal reduction are also decreased. From these investigations, the following observations emerge. At low *pH* ($<2.0 \sim 2.2$) and low temperature, the current is used up chiefly for the reduction of hydrogen ions. At high *pH* (>3.0), the current is mainly consumed for the reduction of metal ions, but some retardation of the reduction of metal ions is due to the adsorption of hydroxide.

From the above electrochemical results, it is now clear that the effect of solution *p*H on the microstructures of cobalt electrodeposits can be closely related to the incorporation of foreign substances (hydrogen, hydroxide). In our experiment, hydrogen is likely to be incorporated in the LP-Co film, whereas hydroxide may be codeposited into the HP-Co film. Our microstructural results then can be conveniently discussed in terms of the codeposition of hydrogen and hydroxide.

The cobalt film prepared from the low *p*H solution is expected to contain an appreciable amount of hydrogen at least within a short period of time immediately after the film is formed. It is then conceivable that the film could have been cobalt hydride prior to the outdiffusion of hydrogen. Although cobalt hydrides or their complexes are reported to be prepared in the form of CoH (11) and CoH_2 (12) during chemical reactions involving cobalt salt under hydrogen, cobalt hydrides are predicted (13) to be nonexistent or, if any, very unstable. Thus, if cobalt hydrides can be produced, they will be extremely unstable. The assumption that metastable cobalt hydride may be produced during the cobalt electrodeposition is consistent with the fact that nickel, one of the iron group metals, is converted into metastable nickel hydride by cathodic charging with hydrogen (14). The cathodic charging of nickel with hydrogen produced nonstoichiometric nickel hydride NiH_n ($n = 0.7 \sim 1.0$) which has the same Bravais-type lattice as that of nickel, but has the lattice spacing by about 6% larger (15). This nickel hydride was apparently unstable under ambient conditions, but was stable enough to permit x-ray diffraction studies (14, 16). The cobalt electrodeposition mode at low *p*H resembles effectively the cathodic charging of nickel with hydrogen, as most of the current is used up for the reduction of hydrogen ions. In analogy to the nickel hydride, cobalt hydride can be assumed to have a fcc structure.

The stability of hydrogen in cobalt or alternatively cobalt hydride can be argued from the point of hydrogen solubility and diffusivity in cobalt. The solubility of hydrogen at room temperature is known to be extremely small (17). According to Vagramyan and Petrova (18), the hydrogen solubility in cobalt at 20°C is $<<0.05$ cm^3/g ($<<4.46$ ppm). The data obtained by Stafford and McLellan (19) show that the solubility of hydrogen in cobalt at 300°C is about 0.63 ppm. If we extrapolate their solubility curve to room temperature (20°C), it amounts to 0.041 ppm, consistent with the Vagramyan and Petrova data. Furthermore, in case nonequilibrium hydrogen is incorporated into cobalt during the deposition, it could escape out of the film very rapidly as it has a high diffusivity at room temperature. From the data obtained by Caskey *et al.* (20), the diffusivity of hydrogen in cobalt, extrapolated to room temperature (20°C), is 1.71×10^{-11} cm^2/sec for fcc cobalt. These diffusivities are extremely high, and, for example, a simple calculation based upon the random walk theory indicates that hydrogen included in cobalt films, 50 μm thick (our film thickness is about 75 μm), can diffuse out of the film between 51 hr and 18 days at room temperature after the film preparation. The fact that the gas analysis in the cobalt electrodeposits has been made 5 months after the film preparation suggests that dissolved atomic hydrogen has diffused out of the film, and, therefore, the origin of appreciable amount of hydrogen obtained in the analysis should be different. The amount of hydrogen found in this experiment probably originates from the decomposition of cobalt hydroxide.

It appears that the observed hydrogen content in both the LP-Co and HP-Co films originates from the decomposition of some form of cobalt hydroxide and not from dissolved atomic hydrogen. The observed ratio of H_2/O_2 (33/35) for the LP-Co film is consistent with the preceding suggestion. However, to rationalize the result for the HP-Co film, the existence of oxygen-rich cobalt hydroxide has to be invoked. The *p*H dependence of both hydrogen and hydroxide occlusion in cobalt electrodeposits obtained in cobalt chloride solution has been studied by Vagramyan and Petrova (20). Their results are shown together with our results in Fig. 6. Curves A and B represent hydrogen gas and gas arising from the decompostition of cobalt hydroxide, respectively, and a black dot with an arrow denotes our data. It is seen that our data follow the trend of curve B, suggesting that our gas content comes primarily from the decomposition of cobalt hydroxide. It is interesting to note that the amount of dissolved hydrogen at *p*H = 1.6 is very large, but it is negligibly small at *p*H = 5.7. Their results again confirm the electrochemical observation that a large amount of hydrogen is codeposited at low *p*H.

Inclusions observed in the HP-Co film are probably particles of cobalt hydroxide. From an electron diffraction analysis, however, we could not find any diffraction lines corresponding to crystalline cobalt hydroxide. These noncrystalline inclusions are probably in a colloidal form, as they are seen to have a much smaller mean inner potential than the cobalt matrix. That these inclusions are crystallographically aligned closely resembles the morphology of O-phenanthroline molecules incorporated into copper electrodeposits (21). It was found (21) that organic additives are generally first adsorbed at growth steps and subsequently incorporated into a deposit. The manner in which these molecules are incorporated, therefore, follows the geometry of growth steps. The crystallographic arrangement of cobalt hydroxide inclusions on the (0001) growth plane of hcp cobalt (see Fig. 7 for a schematic

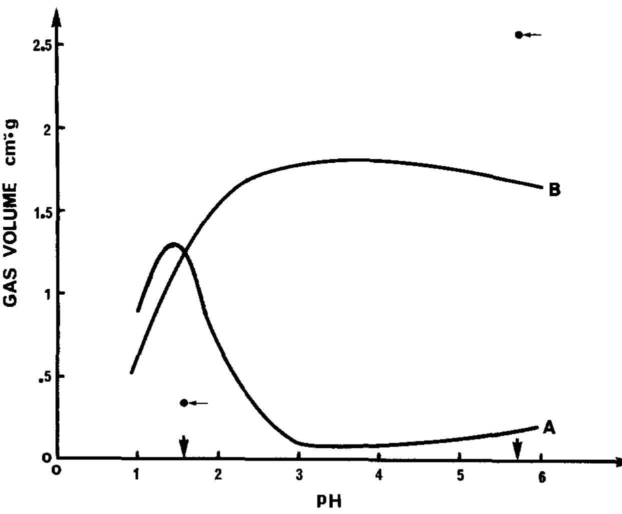

Fig. 6. The relation between the *p*H of the electrolyte and the amount of hydrogen present in cobalt electrodeposits. Curves A and B represent the amount of hydrogen and the amount of gas arising from the decomposition of hydroxides in cobalt electrodeposits obtained from 1*N* $CoCl_2$ at 25°C and a current density of 20 mA/cm^2 (due to Vagramyan and Petrova, 1962). The amount of hydrogen in cobalt electrodeposits in this experiment is indicated with black circles with fine arrows and is seen to follow closely with curve B.

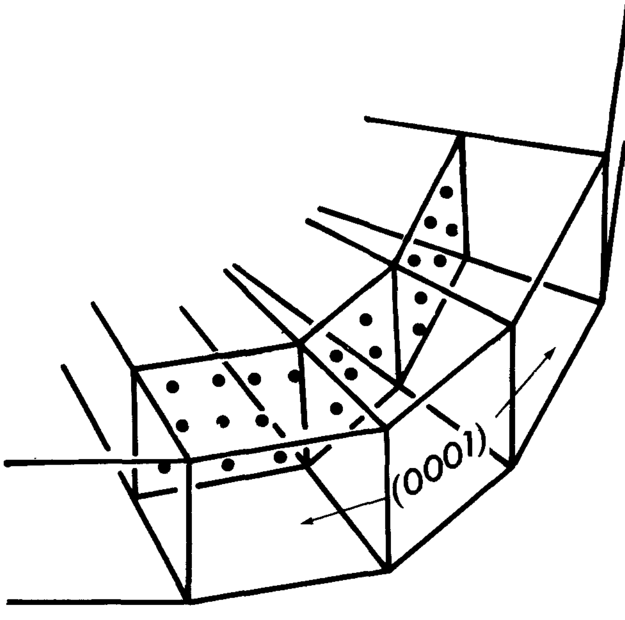

Fig. 7. Growth model illustrating the structure of hcp cobalt obtained at *p*H = 5.7. The incorporation of spherical cobalt hydroxides in the (0001) basal planes is also shown.

view) thus suggests that they behave very much like an organic additive. It should be pointed out that contrary to the previous conclusion (4), these colloidal inclusions do not contribute to the stability of hcp phase, but simply act as an addition agent, which generally inhibits a lateral growth and may promote a vertical growth by being adsorbed at advancing growth steps.

For the sake of comparison with the gas analysis, we listed the population density and volume percent (v/o) of inclusions which are determined from the TEM micrographs. These data, together with the estimated amount of cobalt hydroxide, $Co(OH)_2$, are summarized in Table II. It is noted that the trend of the amount also follows that of curve B in Fig. 6, lending further support to the idea that the inclusions are cobalt hydroxide particles. The calculated amount of $Co(OH)_2$ from the v/o of the inclusions is somewhat smaller than that determined by the gas analysis. This difference is probably due to smaller inclusions which are not detectable by TEM.

Table II. TEM analysis of inclusions in cobalt electrodeposits

Specimen	Population density of inclusions (cm^{-3})	Volume density (%)	Calculated $Co(OH)_2$
LP-Co	2.3×10^{15}	0.01	0.04
HP-Co	1.4×10^{17}	0.48 ~ 1.88	2 ~ 8

Conclusions

It has been shown that at low pH (~1.6), the microstructures of cobalt electrodeposits consist of highly faulted fcc regions with some hcp regions. At high *p*H (~5.7), on the other hand, the density of faults is greatly reduced and the microstructures consist entirely of hcp phase. Furthermore, a high density of inclusions, probably cobalt hydroxide, was observed in the high *p*H deposits. From these observations together with a chemical analysis, it is suggested that during the cobalt electrodeposition at low pH, the formation of apparent fcc phase, actually metastable cobalt hydride (fcc), is greatly promoted by the codeposition of atomic hydrogen, but during and after the deposition, the rapid diffusion of atomic hydrogen causes the fcc hydride phase to decompose and partially transform to hcp cobalt. This transformation involves the formation of faults on {111} planes.

Primary Potential and Current Distribution Around a Bubble on an Electrode

Paul J. Sides* and Charles W. Tobias**

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

An analytical solution for the primary potential and current distribution around a spherical bubble in contact with a plane electrode is presented. Zero at the contact point, the current density reaches only 1% of its undisturbed value at 30% of the radius from that point and goes through a shallow maximum two radii away. The solution obtained for spherical bubbles is shown to apply for bubbles having contact angles smaller than 17.5°. The incremental resistance caused by dilute arrays of bubbles is evaluated.

The evaluation of effective thermal or electrical conductance of heterogenous systems from the conductivities of the individual phases is a commonly occurring problem in science and technology. For suspensions of gas bubbles generated by discharge processes at electrodes, the problem is tractable because the discontinuous phase consists of spherical, nonconducting particles. As early as 1892 Maxwell (1) presented an analytical solution for the effective conductivity of a dilute random suspension of spherical particles. Rayleigh (2) developed an exact solution for a cubic array of spheres. Using an ingenious approximate treatment by Bruggeman (3), Tobias and co-workers (4, 5) proposed useful approximations for treating concentrated, random suspensions of spheres and applied these results in the evaluation of the effect of gas bubbles on the resistance and current distribution in electrolytic gas generators (6). Hine and co-workers (7) differentiated between a relatively concentrated dispersion of gases near the electrodes and the more dilute suspension in the bulk electrolyte. These semiempirical models, however, do not consider the effect of bubbles attached to the electrode surface. The effect of this layer of bubbles, present during electrolysis, differs from that of bubbles dispersed in the bulk electrolyte because the environment of a bubble sitting on the surface is asymmetric; the electrode, an equipotential surface, is in contact with a planar array of bubbles, while the electrolyte extends to a large distance on the opposite side of this array.

In the following, an analytical solution is presented which describes the potential field around a spherical bubble in point contact with a planar equipotential surface when the field far from the sphere is linear. The current distribution on the electrode plane and the incremental resistance caused by a dilute array of bubbles are also evaluated.

Theoretical

We use tangent sphere coordinates to solve Laplace's equation for the potential field and current distribution on the planar electrode around the insulating sphere. The coordinate planes are spheres tangent to a plane and toroids without center openings; they are related to Cartesian coordinates by

$$z = \frac{\nu}{\nu^2 + \mu^2}, \qquad x = \frac{\mu}{\mu^2 + \nu^2} \qquad [1]$$

The coordinates and their relations to the geometry appear in Fig. 1. ν corresponds to the inverse of radial distance from the contact point while μ is analogous to an angular coordinate. Infinity of both coordinates specifies the contact point. Moon and Spencer (8) present a rather complete discussion of various coordinate systems, including the one above, in their "Field Theory Handbook."

The variables, defined in dimensionless form, are as follows

$$\begin{aligned} z^* &= z/2a \\ x^* &= x/2a \\ \nu^* &= 2a\nu \\ \mu^* &= 2a\mu \\ \phi^* &= \phi/2a\phi_o \\ i^* &= i/\kappa\phi_o \end{aligned} \qquad [2]$$

The distance variables are normalized to the bubble diameter; therefore, $x^* = 1$ defines a plane parallel to the y^*z^* plane and located one bubble diameter from the axis passing through the center of the bubble and the contact point.

We write the potential as the sum of a disturbance and a linear term

$$\phi^* = \phi_d^* + z^* \qquad [3]$$

The second term already satisfies Laplace's equation and all boundary conditions except the one on the bubble surface; therefore

$$\nabla^2 \phi_d^* = 0 \qquad [4]$$

The disturbance must vanish both on the electrode and far away; the potential must be symmetric about an axis passing through the center of the bubble and the contact point; finally, no current passes through the bubble. In tangent sphere coordinates Eq. [4] and these boundary conditions are

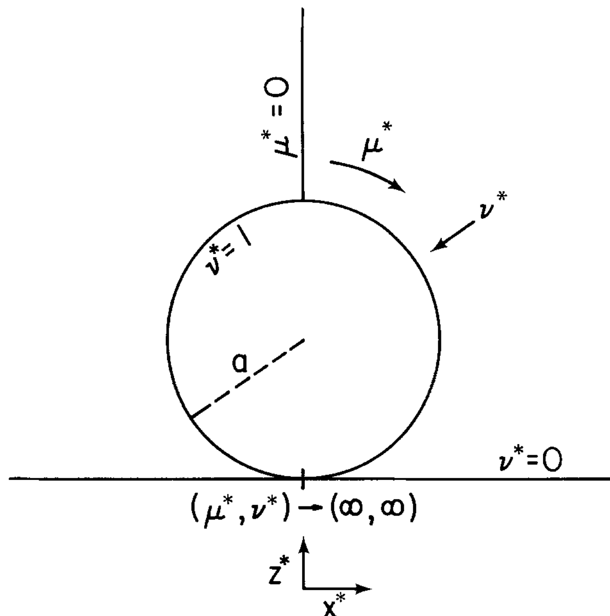

Fig. 1. Tangent sphere coordinates in two dimensions

$$\frac{(\mu^{*2}+\nu^{*2})^3}{\mu^*}\left[\frac{\partial}{\partial\mu^*}\left(\frac{\mu^*}{\mu^{*2}+\nu^{*2}}\frac{\partial\phi_d^*}{\partial\mu^*}\right)+\mu^*\frac{\partial}{\partial\nu^*}\left(\frac{1}{\mu^{*2}+\nu^{*2}}\frac{\partial\phi_d^*}{\partial\nu^*}\right)\right]=0 \quad [5]$$

$$\phi_d^*|_{\nu^*=0}=0=\phi_d^*|_{\substack{\nu^*=0\\ \mu^*=0}} \quad [6]$$

$$\left.\frac{\partial\phi_d^*}{\partial\mu^*}\right|_{\mu^*=0}=0 \quad [7]$$

$$\left.\frac{\partial\phi^*}{\partial\nu^*}\right|_{\nu^*=1}=0 \quad [8]$$

Moon and Spencer (8) give the separation criteria, the separated equations, and their general solutions. After applying conditions [6] and [7], we obtain

$$\phi_d^*=A\sinh(q\nu^*)J_0(q\mu^*)(\mu^{*2}+\nu^{*2})^{1/2} \quad [9]$$

Because the domain is infinite, the solution must include all values of q; therefore, [9] passes to an integral

$$\phi_d^*=(\mu^{*2}+\nu^{*2})^{1/2}\int_0^\infty A\sinh(q\nu^*)J_0(q\mu^*)dq \quad [10]$$

The insulation condition [8] determines A as a function of q. Upon differentiating the complete potential ϕ^*, evaluating this expression at $\nu^*=1$, and equating it to zero, we obtain

$$0=\frac{1}{(\mu^{*2}+1)^{1/2}}\int_0^\infty A\sinh qJ_0(q\mu^*)dq+(\mu^{*2}+1)^{1/2}\int_0^\infty Aq\cosh qJ_0(q\mu^*)dq+\frac{(\mu^{*2}-1)}{(\mu^{*2}+1)^2} \quad [11]$$

Following Witze, Schrock, and Chambré (9), we use the differential equation satisfied by J_0 and integrate twice by parts to obtain

$$\frac{1-\mu^{*2}}{(\mu^{*2}+1)^{3/2}}=\int_0^\infty qHJ_0(q\mu^*)dq \quad [12]$$

where

$$H(q)=\frac{1}{q}\left\{-\frac{d}{dq}\left[q\frac{d}{dq}(A\cosh q)\right]+A(q\cosh q+\sinh q)\right\} \quad [13]$$

After inverting the transform with the help of the Erdelyi Tables (10) and rearranging the equations, we obtain

$$\frac{dA}{dq}=\frac{1-q+e^{-2q}}{2\cosh^2 q}+\frac{C}{2q\cosh^2 q} \quad [14]$$

C must be zero for the derivative to remain finite at $q=0$

$$A=\int_\infty^q\frac{1-q+e^{-2q}}{2\cosh^2 q}dq \quad [15]$$

The potential is now given by

$$\phi^*=(\nu^{*2}+\mu^{*2})^{1/2}\int_0^\infty AJ_0(q\mu^*)\sinh(q\nu^*)dq+\frac{\nu^*}{(\mu^{*2}+\nu^{*2})} \quad [16]$$

and the primary current distribution is

$$i^*=\mu^{*2}\left.\frac{\partial\phi^*}{\partial\nu^*}\right|_{\nu^*=0}=\mu^{*3}\int_0^\infty qAJ_0(q\mu^*)dq+1 \quad [17]$$

Equations [16] and [17] were numerically evaluated by routines that calculated the Bessel functions and integrated their products with the hyperbolic functions over the appropriate domains.

Discussion

The potential map appears in Fig. 2(a) and (b). The potential is normalized so that equipotentials far from the bubble coincide with distance from the electrode (see Eq. [3]). As required by the insulation condition, Eq. [8], the equipotentials meet the bubble at right angles; they approach their undisturbed values far away. One can see from Fig. 2(a) that the displacement of equipotentials caused by the insulating sphere becomes negligibly small beyond one and a half diameters from its contact point along the electrode and three diameters perpendicular to the electrode.

The current distribution as a function of dimensionless distance appears in Fig. 3(a) and (b). The current density is normalized to be 1.0 at a great distance from the sphere; we call this the "undisturbed" value. The value 0.5 on the abscissa of Fig. 3 marks the outer-

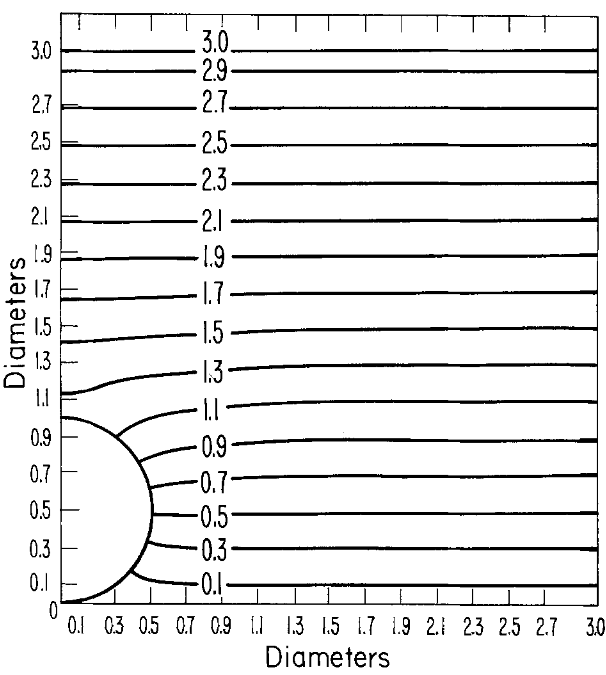

Fig. 2(a). Potential around an insulating sphere tangent to an electrode.

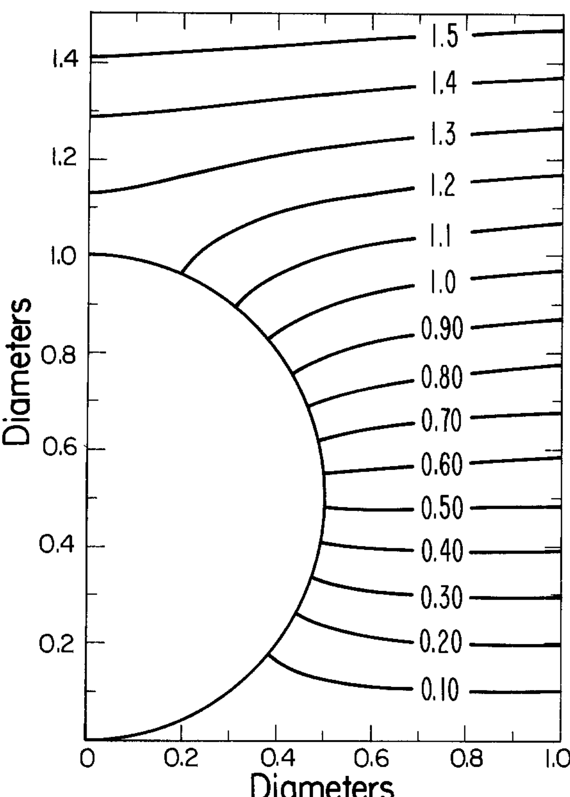

Fig. 2(b). Detail of potential close to sphere

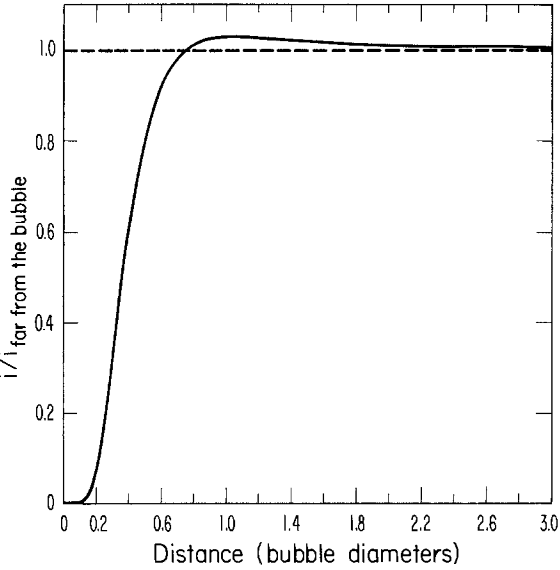

Fig. 3(a). Current distribution near a spherical insulator tangent to a surface.

most circle on the electrode shadowed by the bubble; here, the current density is 80% of its undisturbed value. The current density farther from the bubble exceeds 1.0 because the upper half of the sphere deflects the flux and thereby creates a maximum current density 2% greater than the undisturbed value at one diameter from the contact point. We conclude that fields around spheres separated by more than three diameters affect each other negligibly.

A detail of the current distribution near the contact point appears in Fig. 3(b). Zero at the axis, the current density reaches only 1% of its undisturbed value at 30% of the radius from the contact point; therefore, we can insulate the area inside this distance with a surface which coincides with a surface of flow. Thus the effect of a tangent insulating sphere on the current distribution approximates that of a bubble having a nearly

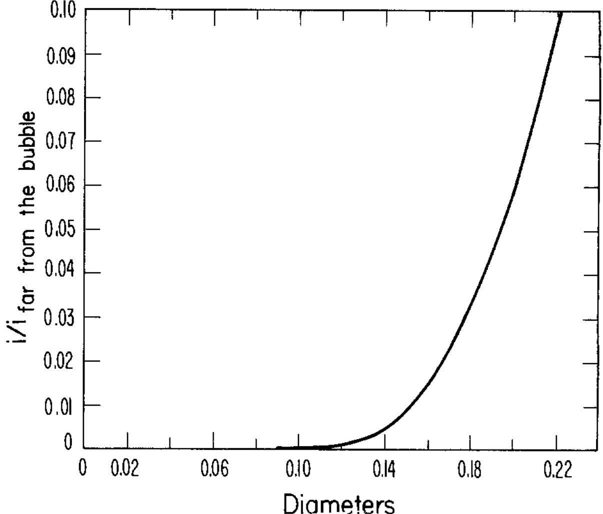

Fig. 3(b). Detail of current distribution near the contact point

spherical shape and a contact area less than 0.09 πa^2. Calculating the contact angle for this base area according to the geometry in Fig. 4

$$\theta = 90^\circ - \cos^{-1}(b/a) = 17.5^\circ \quad [18]$$

we conclude that the effect of a sphere on a plane approximates that of a nearly spherical bubble having a contact angle less than 17.5°.

The bubble increases the resistance by deforming the otherwise straight lines of current. We evaluate the effect by integrating the potential disturbance over a plane far from the electrode and parallel to it

$$\Delta\phi = 4a^2 \int_0^\infty 2\pi x^* \phi_d^* \Big|_{z^* \to \infty} dx^* = A_0 \pi a^2 \quad [19]$$

where

$$A_0 = 8 \int_0^\infty qA\,dq = 0.9015 \quad [20]$$

$\Delta\phi$ does not depend on distance from the electrode; it is the net disturbance of potential integrated with area. "n" bubbles per unit area, distributed such that their contributions are independent, cause a net potential disturbance

$$\Delta\phi^* = nA_0\pi a^2 \quad [21]$$

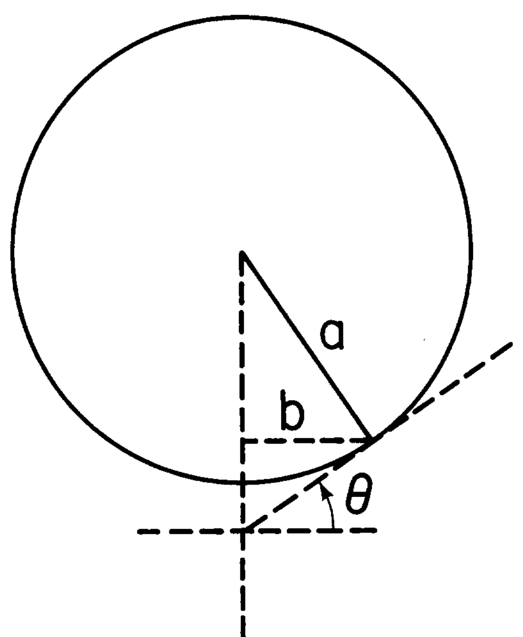

Fig. 4. Geometry for calculation of contact angle θ

One cannot deduce a conductivity analogous to Maxwell's because the layer of bubbles is two dimensional; the effect must be characterized as a polarization at the electrode surface. The increment of resistance caused by the bubbles on an electrode of area S is the net potential disturbance, [21], divided by the total current to the electrode, $\kappa\phi_o S$

$$\Delta R = \frac{\Delta\phi^*}{\kappa S \phi_o} = \frac{2A_o n\pi a^3}{\kappa S} \quad [22]$$

ΔR is a resistance increment related only to the disturbance caused by the bubbles. Its sum with the cell's resistance in the absence of gas gives the net cell resistance.

Bubbles whose contact points are three diameters apart in a planar hexagonal array give a number density $0.0321/a^2$. If the bubble diameter is a tenth of the interelectrode gap in a parallel plane cell geometry, Eq. [22] predicts a resistance increase of only 1%. This means that the resistance caused by a sparse collection of small bubbles is negligible. When closer than three diameters, the bubbles interact significantly and thereby disturb the potential more than predicted by Eq. [22]; nevertheless, this equation establishes that when the diameters are a tenth of the interelectrode spacing, the minimum added resistance caused by a close-packed array of bubbles on a surface is at least 8% of the cell resistance. In reality, because of the severe pinching of the field between bubbles, the effect must be substantially larger than this, perhaps by a factor of two to three. Experiments and additional theory are in progress which will determine the effect of dense single and multiple surface layers of bubbles on the resistance at electrodes.

Bubble Effects on the Solution *IR* Drop in a Vertical Electrolyzer Under Free and Forced Convection

Fumio Hine* and Koichi Murakami[1]

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

Effects of electrolytic bubbles on the *IR* drop of caustic soda solution in a vertical cell of one meter height were studied under both free and forced convection. Three pairs of Luggin-Haber probes were positioned near the anode and the cathode to determine the solution *IR* drop during electrolysis. A sectioned electrode having 10 segments was employed to obtain the current distribution from the bottom to the top of cell. The superficial resistivity of the solution containing gas bubbles agreed well with the Bruggemann equation. The solution *IR* drop decreased significantly when adequate conditions or cell geometry for solution circulation were provided. The anode-to-cathode gap was found to be the most important parameter for reduction of the solution *IR* drop in a vertical cell.

An important item in the voltage balance of an industrial electrolytic cell is the *IR* drop in the electrolyte across the gap between the electrodes. When the electrode reaction evolves gas, the presence of gas bubbles dispersed in the electrolyte may greatly increase the *IR* drop. This is particularly true if the electrode is not perforated, in which case all the evolved gas must pass through the electrolysis gap.

There are several ways of minimizing the unwanted "bubble effects."

1. Use of perforated electrodes, which permit some, if not all, of the evolved gas, to be removed from the electrolysis gap.

Thus, in amalgam-type chlorine cells equipped with horizontal block anodes of graphite, these blocks may be machined and perforated in various ways to minimize accumulation of chlorine gas bubbles on the underside of these blocks (1-4). Also, modern amalgam cells equipped with "spaghetti"-type metal anodes almost eliminate the bubble effect.

In modern diaphragm-type chlorine cells equipped with vertical dimensionally stable anodes (DSA), which are usually perforated, a major part of the evolved chlorine is removed from the electrolysis gap by passing through the perforations. This also permits closer spacing between anode and diaphragm. Thus the *IR* drop can be minimized.

2. Recirculation of electrolyte decreases the gas void fraction in the electrolysis zone, and thus improves the conductivity of the two phase mixture of electrolyte and gas in the gap.

Thus, in older diaphragm-type chlorine cells, equipped with solid graphite blade anodes, a return path is provided which allows the anolyte brine to recirculate freely. The recirculation is driven by the gas lift effect in the anode-diaphragm gap (5, 6).

In newer diaphragm-type chlorine cells, equipped with box-type DSA's, the inside of the DSA can be utilized as a downcomer for recirculating the anolyte.

Box-type electrodes can also be used in cells for water electrolysis, to improve the circulation of caustic potash electrolyte, thus decreasing the void fraction of hydrogen on one side of the diaphragm, and of oxygen on the other (7, 8).

3. Miscellaneous, such as electrolysis under high pressure, which decreases the volume of the gas bubbles, and improves conductivity (7, 9).

[1] Present address: Research Laboratory, The Japan Carlit Company, Sibukawa, Japan.
Key words: gas, cell, resistivity, convection.

This paper is concerned with Item 2, the effect of electrolyte circulation on the performance of gas-evolving cells, particularly with reference to current distribution and voltage drop in the electrolysis gap. The experiments were designed to reveal fundamental relationships, and thus to be useful in the design of industrial electrochemical cells.

In the previous report, an empirical equation for the conductivity of the gas-solution mixture as a function of the current density and the solution velocity in a narrow channel was presented (10). In addition to the articles quoted in Ref. (10), useful papers with respect to the bubble effects on the current distribution and the voltage balance in electrolytic cells can be found (11-13). Funk and Thorpe studied the void fraction and the current distribution in a water electrolysis cell (11). They concluded that the slip ratio, u_g/u_l, in this case was nearly unity, which was of great importance in defining the void fraction and in the analysis of hydrodynamics or pressure drop in electrolytic cell.

Although there is no doubt that the *IR* drop and the overvoltage near the electrode are affected by bubbles, enhancement of mass and heat transfer is also of importance to electrolytic gas evolution. The thickness of the hydrodynamic film or the boundary layer along the electrode is reduced, and hence the heat transfer coefficient in the cell is increased by circulation of the electrolytic solution (14-22). MacMullin *et al.* studied the enhancement of heat transfer in an electrolyzer, where hydrogen evolution took place at the cathode (17). The gas evolution promotes rapid circulation of the electrolyte resulting in a significant increase of the fluid film heat transfer coefficient, by a factor of 2 to 3.

Flow of the gas-electrolyte mixture along the vertical electrode during cell operation is a "two-phase flow" or a "backmix flow" depending on the liquid flow velocity and the void fraction of bubbles (23-25). In some cases, gas bubbles grow in size, and cover the electrode surface; thus the overvoltage becomes high. On the other hand, some gas bubbles leaving the electrode disperse in the solution, and the *IR* drop between two electrodes increases. That is, the "bubble effects" are classified into (*i*) the surface reduction of the working electrode, and (*ii*) increase in the resistivity of the electrolytic solution.

Tobias and his collaborators published a series of excellent papers on the effect of bubbles on the current distribution and the ohmic resistance (26-28). They propose Bruggemann's equation

$$\rho/\rho_0 = (1 - \epsilon)^{-3/2} \quad [1]$$

to correlate the resistivity *vs.* gas void fraction in electrolytic cells. The gas void fraction is closely related to the bubble size, *i.e.*, the larger the bubble size the smaller is the void fraction in general. Bubbles in water grow in size, but coalescence of electrolytic bubbles is very limited, and is affected greatly by the solution composition (29,30), for reasons that are unclear at present.

The experiments described in this paper were conducted in a vertical cell, one meter high, to determine the bubble effects on the operating conditions and the cell geometry. Solution circulation by gas lift action and forced flow is also discussed.

Experimental Procedure

A vertical Lucite cell one meter high, as shown in Fig. 1, was fabricated. The anode and the cathode, each 89 cm long and 3 cm wide, were made of 304 stainless steel (SS) plate 3 mm thick. Heavy copper bus bars were employed to minimize the *IR* drop in the SS electrodes. The anode-to-cathode gap was adjusted by the lead-in shafts with PTFE spacers of different lengths in the range 0.5-3 cm. A PVC backplate was positioned to provide a space of an adequate size for the electrolyte. For experiments under forced circulation, a shield plate was provided at the cell bottom as shown in Fig. 1B. The electrolytic solution was pumped up from the inlet to the cell top through the interelectrode gap, and sent back to the reservoir.

Three pairs of the Luggin-Haber probes made of PTFE were positioned at the cell bottom, the center, and at the top to obtain the solution *IR* drops at these respective points. The potential was referred to the Hg/HgO electrode. The Luggin probes were inserted into the electrode plate from the back side so as to avoid disturbance to solution flow. Because the outer diameter of the Luggin tip was thick (6 mm), an equation proposed by Barnartt was used to calibrate the potential deviation (31).

A sectioned electrode with 10 segments, also made of SS, was used to determine the current distribution. The distance of the segments from a flat plate counterelectrode was adjusted carefully to equalize the electrode gaps prior to the experiment. This procedure was important for obtaining reproducible results.

Each electrode segment had a shunt in series, and was connected to a common copper bus bar. The voltage drop in a shunt was measured to obtain the current passing. The gas void fraction and the solution resistance increase with the level from the bottom to the top of the cell. Therefore, the current distribution along the vertical electrode is demonstrated by the variation of the currents carried by the different electrode segments.

Electrolytic solution, mostly 2*N* NaOH at 40°C, was circulated between the thermostated reservoir and the space behind both electrodes to keep the temperature constant, even in the case of blocked convection.

Oxygen and hydrogen were liberated at the anode and the cathode respectively, during electrolysis, and were mixed because there was no separator in the cell. Thus, for one Faraday passed, ¼ mole O_2 plus ½ mole H_2 were evolved.

The polarization curves on a small SS electrode were obtained in a separate cell containing NaOH solution. The potential *vs.* current density was found to be a straight line over a wide range of current density above 2 A/dm^2. The sum of the slopes of both anodic and cathodic polarization curves was 0.340 Ω-cm^2 in 2*N* NaOH at 40°C.

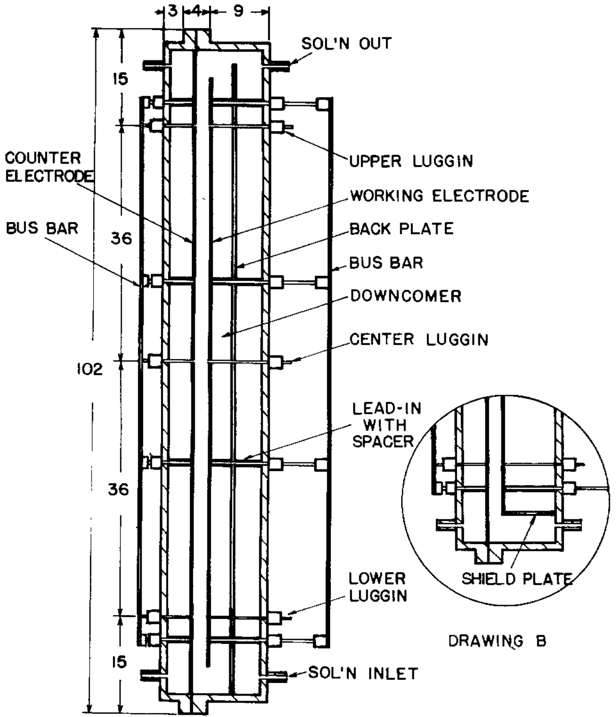

Fig. 1. A vertical cell. Drawing B shows a shield plate for experiments under forced circulation.

Results and Discussion

Solution resistivity vs. gas void fraction.—Figure 2 illustrates three types of flow pattern in a vertical cell: blocked convection (mode 1), natural circulation (mode 2), and forced circulation (mode 3). In mode 1, the gas-liquid mixture rises to the cell top, and the solution freed of gas bubbles comes down through a part of the electrode gap, thus complicating the flow pattern. In mode 2, the gas-solution mixture rises through the electrode gap by gas lift action and the solution flows down through the downcomer when the circulation path is provided. Separation of gas bubbles from the solution is stimulated by rapid flow, and hence the gas void fraction decreases in this case. On the other hand, when the solution containing gas bubbles is forced into the reservoir from the cell top by pump, the gas void fraction may be still further reduced, as in mode 3.

In Fig. 2, *H* represents the level of electrolyte before the current is turned on. With current on, the level increases by ΔH, due to hold-up of gas bubbles in the electrolyte.

For mode 1, $b = 0$, and the average gas void fraction ϵ_a is

$$\epsilon_a = \Delta H/[H + \Delta H], \text{ approximately} \quad [2]$$

For mode 2

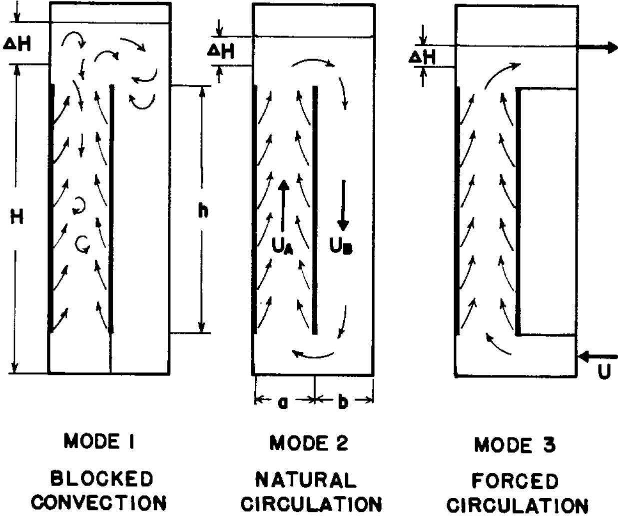

Fig. 2. Flow pattern in vertical cells

$$\epsilon_a = \frac{a+b}{a} \frac{\Delta H}{H + \Delta H}, \text{ approximately} \quad [3]$$

In this case, the solution in the downcomer is assumed to be bubble-free.

Suppose that the gas void fraction at the center level is ϵ_a. The current density at the center Luggin was confirmed to be almost average. Figure 3 shows the reduced resistivity ρ/ρ_0 at the center Luggin as a function of ϵ_a calculated by Eq. [2] (open points for mode 1).

The gas void fraction with a cell in mode 3 was also obtained. The solution level comes down by ΔH from the outlet when the polarizing current and the pump are turned off, thus, ϵ_a can be obtained by a similar manner. Although the experimental results fluctuated more in comparison with mode 2, the solution resistivity *vs.* average gas void fraction fitted roughly with Eq. [1] and was independent of the flow rate of solution. Therefore, Bruggemann's equation is valid for all cases.

In a previous work (10), we reported that the Bruggemann relation may not work well, especially under forced convection. That result differed from the present conclusion, probably due to different methods of experimentation. The solution *IR* drop was obtained from the voltage drop between the anode Luggin and the cathode Luggin in the present study, whereas the potential difference between the working electrode and the Luggin probe located on the front of the counterelectrode was measured in the previous work. The overvoltage of the working electrode was calibrated by the current interruption technique in this case, but the *IR* drop through a thin layer in the vicinity of the working electrode was, of course, involved. A solution layer near the electrode might be crowded with electrolytic gas bubbles just leaving the electrode surface, and the condition in this region differs from the bulk of solution. This may be the major reason for the different conclusions in the two papers.

Current distribution.—Figure 4 shows examples of the current distribution obtained with the sectioned electrode. At small current, the current distribution is quite uniform, and solution circulation is not required because the gas void fraction is small. On the other hand, the local current density varies with height at high currents. Variation of the current density without solution circulation is very large compared to that with circulation. Also, this figure shows that the average current density is achieved at about 40-50% of the electrode height from the bottom end, and is independent of the total current and solution circulation.

Tobias obtained a theoretical equation for the local current density i_x (26). With his equation, we have

$$i_x/i_a = 8(K+2)^2/(K+4)(KX+2)^3 \quad [4]$$

where K is the gas effect parameter, and X is the dimensionless vertical height, x/h. We confirm that this equation can be fitted to our data, if we make suitable corrections for the humid volume of the gas bubbles at local estimated pressures. Equation [4] is also valid for cells of different height as shown in Fig. 5, that is, the i_x/i_a *vs.* x/h is almost independent of the electrode height. The thick line shows the empirical equation obtained by the method of least squares with the data plotted. The thin line is the curve calculated by Eq. [4] with $K = 0.6$. However, in the experiments described, K varied in the range 0.2-0.7 depending on the electrode gap: the larger the electrode gap the smaller was the value of K.

Natural circulation.—In most of these experiments, the flow pattern was clearly a dispersion of gas bubbles in flowing electrolyte. However, at high current density in narrow channels (0.5 cm gap), slug flow could be observed.

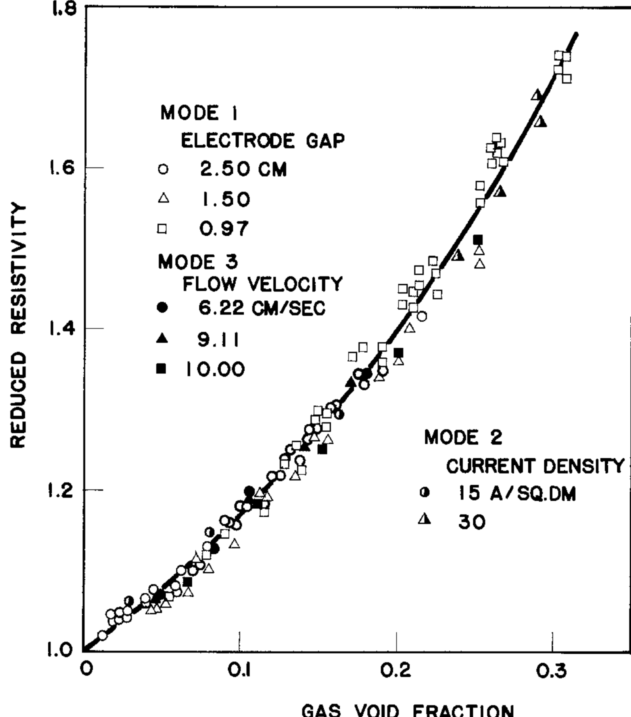

Fig. 3. Relationship between the reduced resistivity and the gas void fraction under blocked convection and forced circulation.

It is evident that the reduced resistivity is related to the current density and the flow velocity of the electrolyte. The open points in Fig. 6 show the experimental results obtained in the cell with forced circulation. The closed points are the results obtained with natural circulation, mode 2. The flow velocity by gas lift action increases when the gas void fraction increases at high current densities. From Fig. 6, flow velocity under natural circulation, mode 2, can be estimated to be about 14 cm/sec at 15 A/dm^2 and 20 cm/sec at 37 A/dm^2, for example. These estimates are valid because the ρ/ρ_0 *vs.* ϵ curve is independent of the solution flow as shown in Fig. 3. Figure 7 illustrates the estimated velocity of solution circulation as a function of the current density and the gap, which is obtained by the method described above. The velocity increases with decrease of the electrode gap, but is limited in narrow channels, less than 1 cm gap. In this discussion, and in Fig. 6-9, flow velocity is defined as the velocity of the gas-free electrolyte as it enters the gap; that is, it is the flow in cm^3/sec divided by the area of the gap in cm^2.

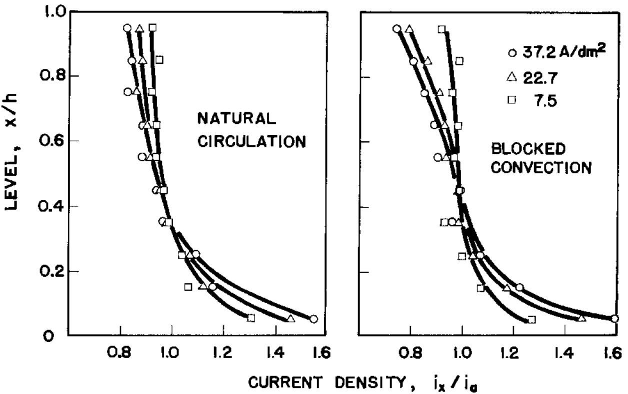

Fig. 4. Current distribution curves under natural circulation and blocked convection conditions. Electrode gap = 1.90 cm.

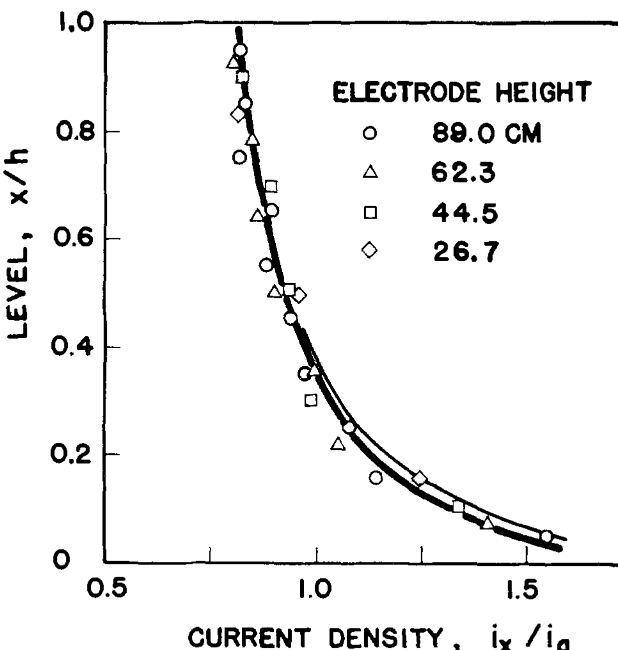

Fig. 5. Current distribution curve with electrodes of different heights. Electrode gap = 3.90 cm. Average current density = 37.4 A/dm². Thin line calculated by Eq. [3] with $K = 0.6$.

The solution flow velocity u_l is represented by

$$u_l = V_l/ac\ (1 - \epsilon) \quad [5]$$

Since the volumetric flow rate of solution, V_l, remains constant, u_l is only a function of ϵ.

Now, the current density i is a function of ϵ

$$i = \frac{\Delta E}{\rho a} = \frac{\Delta E}{\rho_0 a}(1 - \epsilon)^{3/2} \quad [6]$$

The voltage drop in the electrolyte, ΔE, is

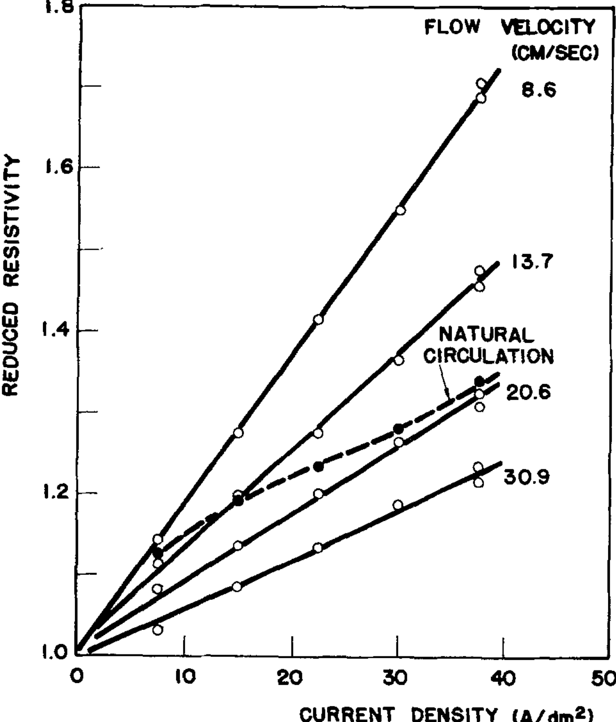

Fig. 6. Reduced resistivity vs. current density curves as functions of the flow velocity with forced circulation. The dotted line is a curve obtained under natural circulation conditions. Electrode gap = 0.97 cm.

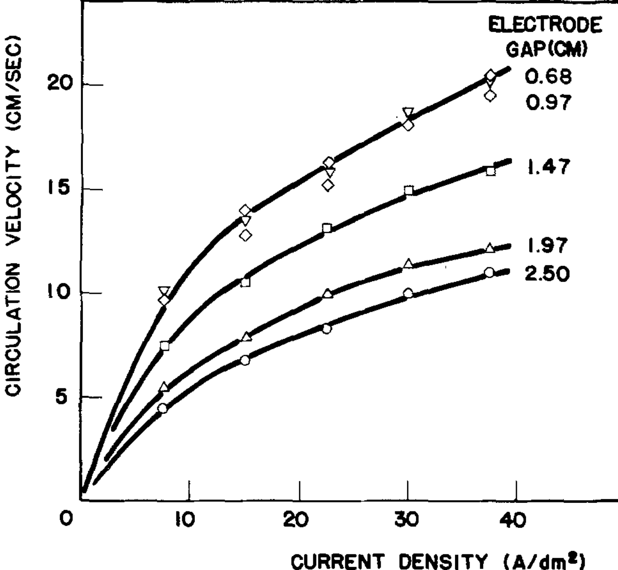

Fig. 7. Circulation velocity as a function of the current density and the electrode gap in a cell, mode 2.

$$\Delta E = E_T - E_o - \Sigma\eta \quad [7]$$

where E_T is the terminal voltage, E_o the decomposition voltage, and $\Sigma\eta$ is the sum of the overvoltage at anode and cathode. Suppose that E_T remains constant from the top to the bottom of the cell because heavy copper bus bars are employed in both anode and cathode sides, and E_o is, of course, constant. On the other hand, $\Sigma\eta$ and ΔE are functions of the current density. In practical cells, however, E_T is sometimes shown by a simple equation

$$E_T = A + B\,i^n \quad [8]$$

where A is the superficial decomposition voltage, B and n are coefficients depending on the overvoltage characteristics, the solution conductivity, and the cell geometry. Although n is unity in many cases, sometimes we see values of n ranging from 1.0 to 2.0 in electrolytic cells where gas evolution takes place. Generally, the overvoltage and its increment with the current density are relatively small compared to the IR drops in the solution containing gas bubbles, as was shown in Fig. 3 in the previous paper (10). Thus, we estimate that $E_o + \Sigma\eta$ in Eq. [7] is roughly equal to A in Eq. [8], and hence, $\Delta E \simeq B\,i^n$. Substituting it and Eq. [6] into Eq. [5], we have

$$u = C\,i^m \quad [9]$$

where

$$C = \frac{V_l}{ac}\left(\frac{B}{\rho_0 a}\right)^{2/3} \quad \text{and} \quad m = \frac{2(n-1)}{3}$$

Figure 8 shows the log-log plots of the flow velocity vs. average current density in a cell, mode 2, with different gaps. Straight lines with a slope of about 0.5 were obtained, and hence, $u_l \propto \sqrt{i}$. Also, $n \simeq 1.75$.

The flow velocity reaches a maximum at an electrode gap of 0.75 cm as shown in Fig. 9. The figure also shows the effect of solution flow on the reduction of the IR drop or the reduced resistivity of the solution (center).

The terminal voltage was a minimum electrode gap of 5-7 mm. In a narrow channel, less than 5 mm, the flow pattern becomes slug, and ρ/ρ_o is large. On the other hand, ρ/ρ_o is almost independent of the electrode gap when the gap is larger than 10 mm. Consequently, the solution IR drop and the terminal voltage at constant current density increases with the increase of the electrode gap (top figure).

The reduced resistivity in a cell without circulation, mode 1, is shown by the closed points. Since convection

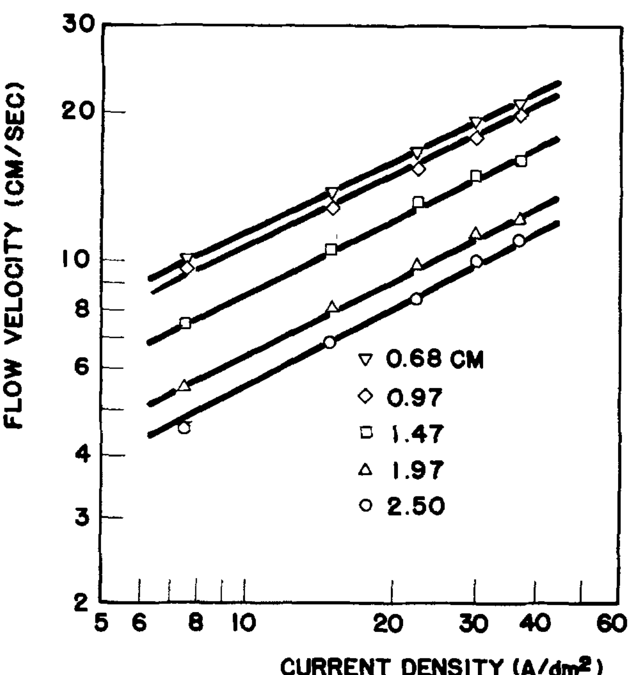

Fig. 8. Log-log plots of the flow velocity vs. current density at different gaps between two electrodes. Natural circulation, mode 2.

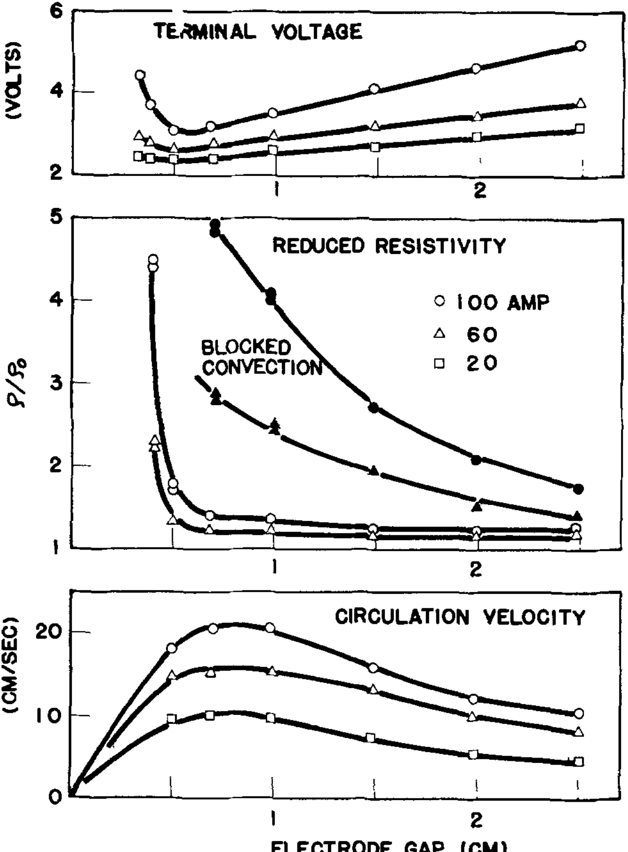

Fig. 9. Terminal voltage, reduced resistivity, and circulation velocity as functions of the electrode gap and the current. Average current density: 37.2 A/dm² at 100A, 22.7 A/dm² at 60A, and 7.5 A/dm² at 20A. Closed points = blocked convection (mode 1).

occurs only in the space between two electrodes, the larger the electrode gap the smaller is the resistivity. Also the ρ/ρ_0 is affected greatly by the current density, which indicates difficulty of separation of gas bubbles from the electrolytic solution.

In this connection, the size of the downcomer seems to be an important factor for natural circulation. According to experiments, the gap of 12-15 mm was sufficient for solution circulation.

A more exact mathematical approach to the problem of *a priori* calculation of the gas void fraction in the electrolysis gap, as a function of the various independent variables, would no doubt be desirable. However, this would depend on the ability to predict the gas rise velocity relative to the local liquid velocity, for swarms of bubbles of varying size, as generated at the electrodes. The problem is indeed complicated, and for its proper solution, additional experimental techniques must be developed. In the meantime, the present simplified approach has revealed interesting relationships in cells with gas-evolving electrodes.

The experiments described in this paper were conducted with solid electrodes, and hence the electrolysis zone was crowded with evolved gases. This was the case for the old style diaphragm-type chlorine cells using graphite blade anodes. In the new type cells using DSA's, the anodes are perforated, so that the evolved chlorine passes through the electrodes to the outer space, and hence, the gas void fraction in the electrode gap is reduced considerably, resulting in low voltage drops. This, of course, is of great interest to us, and will be investigated in the future.

Conclusion

Effect of the electrolytic gas bubbles on the solution *IR* drop and the terminal voltage of a vertical cell, one meter high, was studied. Experiments were conducted under blocked convection, natural circulation, and forced circulation conditions. The anode-to-cathode gap, the space of the downcomer, and the electrode height were varied. The superficial resistivity of electrolytic solution containing gas bubbles was confirmed to be a function of the gas void fraction, and agreed well with the Bruggemann equation.

The average gas void fraction in the gap is a measure of the gas hold-up in the gap, and depends strongly on the volumetric liquid flow rate in the gap. Other factors include the rate of rise of bubble swarms relative to the liquid rate, current density, overvoltage, etc.

The gas lift effect may be utilized to promote natural circulation of liquid through the gap, and thus to improve conductivity in the gap. The optimum area of downcomer used for recirculation should be about twice the area of the electrode gap.

The anode-to-cathode gap is, of course, a major component of the terminal cell voltage. The gas void fraction in a narrow channel is large and it causes a large increase in the solution *IR* drop. On the other hand, the solution *IR* drop increases with increase of the electrode gap. An optimum gap between anode and cathode is about 5-7 mm depending on the operating conditions such as current density and solution composition.

The local current density varies from the bottom to the top of cell due to the change of the gas void fraction along the electrode. But the current distribution is improved significantly by solution circulation. The current density near the center of electrode then takes the average value.

In conclusion, design of the cell configuration and choice of the operating conditions to yield sufficient flow of solution between the two electrodes are useful for reducing the gas void fraction, and thus the cell voltage.

Gas-Diverting Electrodes in the Chlor-Alkali Membrane Cell

Jacob Jorne*

and Joseph F. Louvar*

BASF Wyandotte Corporation, Wyandotte, Michigan 48192

ABSTRACT

The purpose of this investigation was to find an effective means of removing gas bubbles from the interelectrode space of a new chlor-alkali membrane cell. Gas evolution increases the ohmic resistance of the electrolyte and the current distribution becomes nonuniform in the vertical direction. It was observed that by using a gas-diverting electrode the gas bubbles were diverted to the back of the vertical electrode. Various expanded steel cathodes were very effective in diverting the H_2 gas, which resulted in a significant drop of the cell potential. The effectiveness was tested as a function of the spacing between the cathode and the membrane, the current density, the temperature, and the geometry of the expanded metal electrodes. An increase in current efficiency is reported as well, due to the induced turbulence at the surface of the membrane facing the cathode. In addition, the gas-diverting electrode removes the restriction on the cell's height and can result in capital investment savings. Membrane over-potentials are reported as well.

This investigation was aimed at evaluating new electrode geometries (expanded steel cathodes) as an effective means of removing the evolving hydrogen gas and reducing the terminal voltage of a new chlor-alkali membrane cell.

The overpotential and current distribution on vertical gas-evolving electrodes (chlorine and hydrogen) are affected by the bubbles, the hydrodynamics and the geometry of the cell. It is well accepted that gas evolution enhances mass transfer of reactants and products to and from the electrode's surface. However, an additional factor is the nonuniform increase of the resistivity of the electrolytic solution in the interelectrode space with the undesired consequence of increased ohmic drop and nonuniform current distribution in the vertical direction.

The theoretical effects of gas evolution on the ohmic resistance and current distribution are discussed by Tobias (1), Nagy (2), Hine *et al.* (3), and De La Rue and Tobias (4); experimental results are reported as well (5-11) concerning mass transfer and bubble effects. Tobias (1) presents a theoretical treatment for stagnant electrolyte and obtains analytical solutions of the void fraction, current distribution, and ohmic loss under restricted and simplified conditions. A general and qualitative understanding of the problem is thereby obtained. Nagy (2) extends the analysis for more realistic conditions by including linear kinetic polarization for an electrode built of vertical blades.

The studies mentioned above, utilized standard flat electrode configurations which did not divert the gas bubbles to the back of the vertical electrode. These results implied, however, that if it were possible to remove the gas from the interelectrode space, the result could be a substantial decrease in the terminal voltage. Taking the simple case of a flat sheet electrode, and following the approaches of Tobias (1) and Nagy (2), the effective solution resistance is given by

$$R_{eff} = \frac{2RT\rho I_T}{hW^2PmFS} \frac{1}{f_{av.}(1-f_{av.})(2-f_{av.})^2} \quad [1]$$

where I_T is the total constant current, $f_{av.}$ is the average void fraction, ρ is the resistivity of a gas free electrolyte, h is the electrode height, W is the electrode width, P is the pressure, m is the number of electrons, S is the bubble rise velocity.

Minimum resistance is obtained at

$$f_{av.} = 0.36 \quad [2]$$

The interelectrode spacing corresponding to $f_{av.} = 0.36$ is given by

$$\delta_{min} = 1.69 \frac{RT}{PmF} \frac{i_{av.} h}{S} \quad [3]$$

This important result deserves some illustrative calculations: If we consider an experimental cell of height $h = 10$ cm operating under current density $i_{av.} = 200$ mA/cm^2 and assume the bubble rise velocity $S = 1$ cm/sec (following Stokes' law), then

$$\delta_{min} = 0.4 \text{ cm}$$

For a realistic industrial cell of height $h = 100$ cm and current density of $i_{av.} = 200$ mA/cm^2 the optimal spacing is

$$\delta_{min} = 4.0 \text{ cm}$$

To illustrate the advantage of close proximity let us take an example where the distance between the membrane and the two electrodes is 0.4 cm. The approximate resistivities of NaCl and NaOH are 2 and 1 Ω-cm, respectively. The ohmic resistance of this geometry is approximately

$$R = (\rho_{NaCl} + \rho_{NaOH})\,\delta = (2+1)\,0.4 = 1.2\ \Omega\text{-cm}^2$$

If we operate under a typical current density of 200 mA/cm^2 then the total ohmic drop is 0.24V. If by introducing gas-removing electrodes we can reduce the spacing to 0.1 cm then the ohmic drop is 0.06V, and a substantial decrease in the cell's terminal voltage can be achieved.

The treatments of Tobias (1) and Nagy (2) are presented under restrictive assumptions, nevertheless the above examples demonstrate the desirability of finding a more efficient way to remove the gases from the interelectrode spaces.

Gas-diverting electrode.—As a possible solution to the adverse effect of the gas void volume on the resistance of the interelectrode spacing, it was proposed

* Electrochemical Society Active Member.

Key words: gas evolution, chlor-alkali cell, bubbles, membrane, Nafion, chlorine, hydrogen, caustic.

to investigate several electrode geometries which can divert the evolving gases (Cl_2 and H_2) to behind the electrodes. Inspecting commercially available unflattened expanded carbon steels it was expected that screens of special three-dimensional structure might promote the removal of the evolving gas. This would allow designing the cell in such a way that the electrodes could be placed in a very close proximity to the membrane and the ohmic drop would be reduced substantially. Promising geometries are the Standard Diamond, Standard Louver, Standard Honeycomb, and the Ramona Grid (see catalogs of Niles Expanded Metals, Chandler Expanded Metals Corporation, and Keen Penmetal Products).

The principle is illustrated in Fig. 1 where a schematic representation of an unflattened expanded metal electrode is presented.

It is generally accepted in the chlor-alkali industry that any saving over 50 mV is significant and worth looking into. The general approach was to test cathode geometries that divert the gas to the rear of the electrode, and decrease the interelectrode spacing and the resultant ohmic loss.

Due to the fact that expanded steel screens are commercially available, the experimental investigation concentrated only on the geometry of the cathode. However, it is believed that the same consideration can be applied to the chlorine anode in the form of an expanded ruthenized titanium anode.

Experimental

Various expanded metal geometries were tested. In general the unflattened expanded metals were preferred because it seemed that the three-dimensional structure diverts the evolving gas to the rear.

A Plexiglas cell was used throughout the investigation. The cell consisted of two identical compartments attached together with stainless steel bolts and clamps. A Nafion membrane (du Pont Type 031) was placed between the two compartments and the cell was sealed with ½ in. Gore-Tex type gasket material. The cell is shown schematically in Fig. 2. In the bottom of the cell grooves were located in order to place the electrodes at a fixed distance from the membrane. Six spacings were used on each side; the cathodic spacings were: 0.33, 0.85, 1.32, 1.85, 2.42, and 2.98 cm; the anodic spacings were: 0.30, 0.86, 1.37, 1.88, 2.42, and 2.98 cm. The electrodes were 7.6 cm wide and 10.2 or 15.2 cm high.

The electrodes were held and electrically connected from the top by a movable piece of Plexiglas. The area of the membrane was 155 cm^2. Each cell compartment was 10 cm wide, 20 cm high, and 5 cm deep. The gases (H_2 and Cl_2) were released to the hood through ½ in. holes at the top of the cell. The top of the anode compartment was flushed continuously with an air stream to remove the chlorine gas. The cell was heated by an

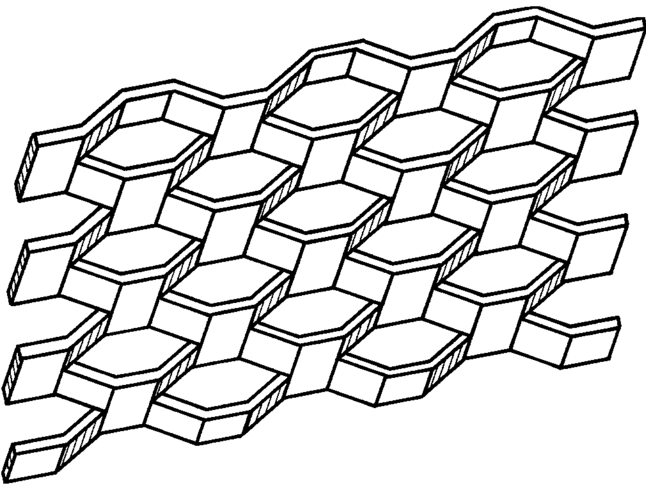

Fig. 1. Gas-diverting electrode

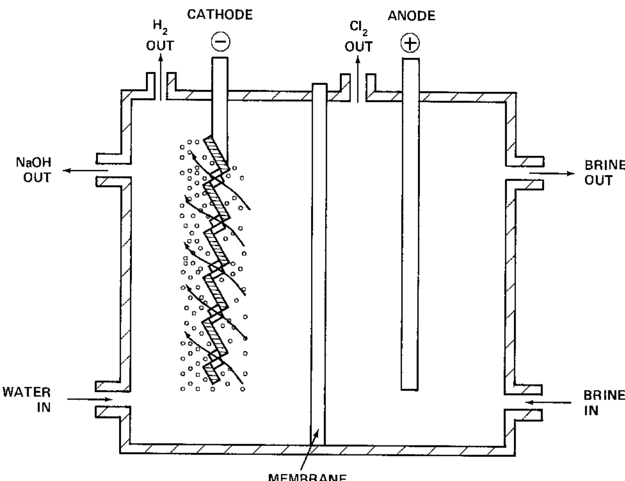

Fig. 2. The experimental cell with a diverting gas cathode (schematic).

electrical heater located in the anolyte, and the temperature was measured by a Weston thermometer No. 104 located in the catholyte.

The 5.5M NaCl and 3.5M NaOH solutions were prepared by dilution. The concentrations were measured gravitationally and by titration. The *p*H of the solutions was measured at the beginning and end of the experiment. The *p*H in the anolyte varied between 3 and 3.5. The solutions were fed into the cell through two funnels connected to the two compartments. During the experiments the solutions were replaced every hour in order to minimize concentration and *p*H changes. There was no flow-through of NaOH or NaCl through the cathode and anode compartments during the runs. Two standard calomel electrodes (Corning No. 104) were used and placed in syringe compartments connected by small Teflon capillaries (AWG No. 24, Penntube Plastics Company, Clifton Heights, Pennsylvania) to the catholyte and the anolyte solutions. The tips of the Luggin capillaries were located firmly in the middle of the electrodes facing the membrane. The tips were cut at an angle facing up to avoid accumulation of gas bubbles.

Constant current was supplied by 6261B d-c power supply, 0-20V, 0-50A (Hewlett Packard). The current was measured by a shunt and digital multimeter Fluke Model 8000A (Fluke, Seattle, Washington). The cell potential and the various potentials between the working electrodes and the two reference electrodes were measured by Electrometer Model 1455 (Data Precision Corporation, Wakefield, Massachusetts). Ohmic drops were measured using the current interrupter technique where the current is interupted and the potential drop is followed on a fast oscilloscope. Current interrupter Model 101 (Electrolytic Research Division, BASF Wyandotte) was used, and the pulse was applied by Universal Programmer Model 175, (PAR, Princeton, New Jersey) (pulse width 100 V/sec, 1 msec). The potential drop was followed on a Nicolet 1090 AR Explorer Digital Oscilloscope (1 μsec/point, 4V range), and the oscilloscope traces were copied directly to an XY recorder, Ohmigraphic 2000 Recorder (Houston Instrument). In all cases the potential drop was read directly from the digital oscilloscope.

Procedure.—The steel electrodes were degreased and cleaned in concentrated HCl. The cell was assembled with the electrodes under consideration and was placed in the hood. Electrical connectors were attached and the reference electrode compartments were filled with the corresponding solutions and pumped through the capillaries. The cell was filled with NaCl and NaOH solutions and different constant currents were applied at various cathode and anode positions. The electrodes were moved from one groove to the next and the measurements were repeated. Potentials were measured

between the various electrodes and across the membrane, and ohmic losses were estimated from the current interrupter measurements. The catholyte and anolyte solutions were replenished every hour so the changes in concentrations were kept below ±0.5M for NaOH and NaCl, respectively.

At the end of the day, the cell was drained, washed thoroughly, and the membrane was left overnight in distilled water. The membrane was always left in distilled water prior to the experiment, and in this way it remained stretched throughout the experiments. In all the experiments the same piece of membrane was used.

In some experiments the cell over-all impedance was measured by an impedance meter, Model 251 (Electro Scientific Industries, Portland, Oregon). The resistance measurements were conducted in the LR mode because of the range limitation of the instrument. The leads of the impedance meter were attached to noncurrent-carrying connectors. The frequency of measurements was held constant at 1 kHz.

The expanded metals are characterized by the following dimensions: SWD—nominal short way of design, LWD—nominal long way of design, SWO—short way of opening (actual), LWO—long way of opening (actual).

The following flattened and unflattened steel cathodes were tested:

1. The conventional flattened steel cathode. Design size: 0.25 in. SWD, 0.5 in. LWD. Opening size: ⅛ in. SWO, 5/16 in. LWO.
2. ¼ in. No. 18 std. Ca., unflattened, Niles Expanded Metals. 114 lb/ft^2. Design size: 0.25 in. SWD, 1.00 in. LWD. Opening size: 0.11 in. SWO, 0.718 in. LWO.
3. 3/16 in. No. 22, No. 104 louver (large structure) Niles Expanded Metals. Design size: 3/16 in. SWD, 7/16 in. LWD. Opening size: 3/16 in. SWO, ⅜ in. LWO.
4. ⅛ in. No. 24, No. 104 louver (fine structure) Niles Expanded Metals. Design size: ⅛ in. SWD, 5/16 in. LWD. Opening size: ⅛ in. SWO, ¼ in. LWO.
5. Ramona Grid, Keen Penmetal Products, Parkersburg, West Virginia 26101. Design size: ½ in. SWD, 1.0 in. LWD. Opening size: 1/16 in. SWO, ¾ in. LWO.

In all experiments the anode was made of flattened ruthenized titanium anode (coated on both sides).

The following parameters were investigated: (*i*) The effectiveness of expanded metal cathodes in moving the gas to the rear (visual observations). (*ii*) The effect of the spacing between the membrane and the cathode on the ohmic resistance of the cell. (*iii*) Effect of current density. (*iv*) Ohmic drop across the membrane. (*v*) Effect of temperature. (*vi*) Over-all cell terminal voltage and its dependence on the cathode structure, cathode spacing, current density, and temperature.

Results and Discussion

Visual observations.—All the new cathode geometries showed the ability to release the evolving gas to the rear. With Ramona Grid, Niles ¼ in. No. 18 std. Ca., Niles louver ⅛ in. and 3/16 in., even when placed far away from the membrane (3 cm spacing) the gas evolution was almost entirely at the back. The gas evolved smoothly through the inclined planes and there was no evidence of accumulation of gas in the interelectrode spacing.

The separation of the gas bubbles was quite slow in the catholyte compartment. Very fine H_2 bubbles were formed and the catholyte turned very quickly into a finely dispersed opaque suspension. It is quite possible that this behavior is due to the relatively large volume of the compartments and the back mixing of the gas in the volume behind the electrode. The gas-liquid separation was easier at the anolyte where the Cl_2 gas separated smoothly from the brine.

Figure 3 shows the cell potential as a function of the cathode-membrane spacing for the various expanded steel cathodes as well as for the flattened conventional cathode. The lines are extrapolated to zero spacing, and the cell potential at zero cathode spacing is taken as a measure of the cathode's ability to divert gas to the rear. The cell potential at zero cathode spacing is summarized in Table I. The anode spacing was kept constant at $d_a = 0.30$ cm. Comparing the results at 35°C indicates that all the new geometries show a significant drop in the cell potential of about 100-200 mV. The saving is less significant at higher temperature because the conductivity is higher and the saving is smaller. The crossing of lines in Fig. 3 indicates the changing abilities of the various electrodes to divert gas at various cathode spacings.

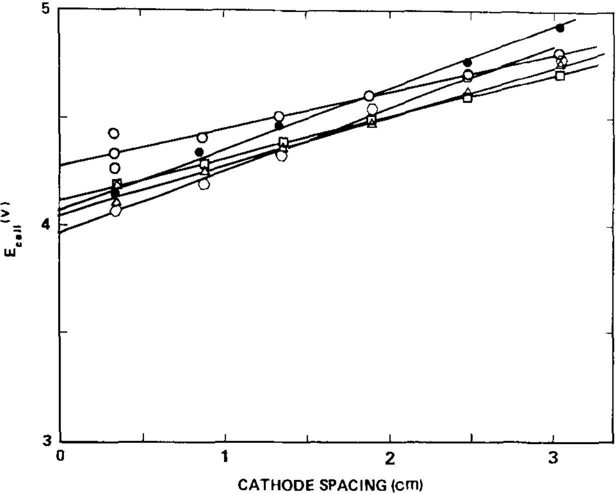

Fig. 3. Cell potential vs. cathode spacing for various cathodes. $i = 215$ mA/cm^2 $T = 35$°C. ○, Flattened conventional cathode; △, Niles std. Ca. 1/4 in. cathode; □, std. Louver 3/16 in. cathode; O, std. Louver 1/8 in. cathode; ●, Ramona grid cathode. The anode spacing is 0.30 cm.

Good results were obtained in particular with Ramona Grid and the std. louver ⅛ in. (fine structure) cathodes, however, the Niles ¼ in. std. Diamond also gave improved results and should be considered equal.

The electrode geometry is even more important in the design of the anode since the resistance of the solution is higher in the anolyte (NaCl solution). Therefore, it is expected that higher saving can be achieved by testing anodes of similar geometries. Since the conductivity of the caustic (catholyte) increases by a factor of about 2 by going from 35° to 80°C, the voltage saving on the anode side is expected to be of the order of 50-100 mV at 80°C. The conductivity of the brine (NaCl) is about half that of NaOH; therefore, the saving in voltage on the anode side by replacing the anode with a new geometry is expected to be of the order of 100-200 mV. These estimations are quite qualitative and based on the concept that the new geometries can be located very close to the membrane while the gas evolves from the rear. However, the dispersion and the void fraction of the chlorine bubbles are quite different from those of hydrogen.

Ohmic resistance of cell.—The cell resistance was measured using a current-interruption technique. Fig-

ure 4 shows the dependence of the cell's ohmic resistance on the current. The ohmic resistance is independent of the current over a wide range for all the gas diverting electrodes. The lack of increase of ohmic resistance at high current indicates the effectiveness of the new cathode geometries in diverting the gas from the electrode-membrane space. The ohmic resistance increases, however, for the conventional flattened cathode at 35°C, indicating a buildup of void fraction in front of the cathode. At low current densities the ohmic resistance increases with a decrease in the current density. This unexpected effect occurs at apparent current densities below ~30 mA/cm². It is speculated that the hydrogen bubbles at low current density are very small and their rising velocity is low. Consequently the electrolyte is cloudy due to insufficient coalescence of the bubbles and the void fraction is higher than expected. Hine and Sugimoto (11) showed that the hydrogen void fraction deviates from the straight line passing through the origin at low current density probably due to the small bubble and insufficient coalescence.

Figure 5 shows the ohmic voltage drop (*IR*) of a 77.5 cm² cell with various cathodes as a function of the cathode spacing. Linear dependence is observed for all the gas-diverting electrodes, which indicates that the gas evolution is from the rear and the ohmic resistance of the catholyte is not changing with the cathode-membrane spacing. The parallel lines indicate that the ohmic resistance is due mostly to the electrolytic resistance and not to buildup of void fraction. An exceptional case is that of the flattened conventional cathode at 35°C where a minimum can be observed at 1.02 cm spacing and the ohmic loss increases at smaller spacing, probably due to gas evolution and high void fraction in front of the cathode. For the same electrode the resistance of the cell increases with the current (see Fig. 4), indicating again that a flattened electrode is inefficient in diverting the hydrogen gas to the rear. In all other unflattened geometries the cell resistance drops linearly with the cathode spacing, which indicates an effectiveness in diverting the gas to the rear of the cathode. The best location of the electrode is in a very close proximity to the membrane. The cell's ohmic resistance for the Ramona Grid 116 cm² cell is linear with cathode spacing and increases the confidence in our current interrupting technique. The linear dependence indicates that the gas evolves at the rear and does not contribute significantly to the ohmic loss of the cell. Figure 5 shows again that the cell resistance increases monotonically with the cathodic spacing, again due to the effectiveness of the Ramona Grid cathode in moving the gas to the rear of the electrode.

Similar results were obtained for the louver-type cathodes, although a slight increase in resistance can be observed at small spacing, a possible indication of some gas evolution in the cathode-membrane space.

The Niles ¼ in. std. Ca. Diamond cathode shows similar behavior: however, the cell resistance decreases slightly with current at 35°C (Fig. 4).

Cathode polarization.—The individual cathodic polarizations were measured using a Luggin capillary reference electrode located in the center of the cathode. The surface overpotential, free of ohmic drop, at 215 mA/cm² and 80°C is about 300-400 mV. The polarizations of std. louver 3/16 in. and ⅛ in. and the Ramona Grid cathodes are quite similar to that of the flattened cathode.

In general all the cathodes show similar polarization curves and the cathodic overpotential is of the order of 300-400 mV. As expected, a rise in the temperature does not change the surface overpotential much, and the difference is due mainly to ohmic drop.

Impedance measurements.—Typical impedance measurements are shown in Fig. 6 for std. Louver 3/16 in. cathode and DSA anode. The potential, resistance, and inductance of the cell are plotted *vs*. the apparent current density. Similar behavior was observed for cells with different cathodes. The increase in the resistance of the cell at low currents can be explained by the higher charge-transfer resistance at lower overpotentials. The cell potential increases with the current and the larger slope at low currents corresponds to the higher resistance at this range. The inductance increases monotonically with the applied current although in some measurements a small minimum could be observed at a low current density of around 25 mA/cm². Generally as the resistance decreases with increasing current, the inductance increases. No explanation is available presently for these phenomena. The agreement between the resistances obtained by the a-c impedance measurements and the d-c inter-

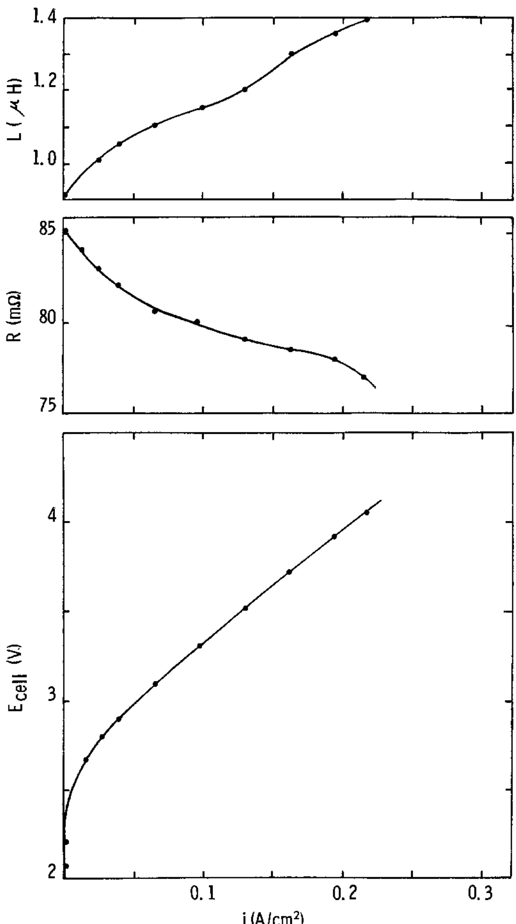

Fig. 6. A-C impedance measurements: cell potential, resistance, and inductance vs. apparent current density. Electrode area, 77.4 cm²; temperature, 40°C; cathode spacing, 0.33 cm; anode spacing, 0.30 cm; cathode, std. Louver 3/16 in.

ruption measurements is qualitatively reasonable: The resistance in Fig. 6 falls in the same range as the resistances in Fig. 4 which were obtained by d-c interruption. The qualitative agreement indicates that most of the cell resistance is ohmic in nature.

Membrane potential and resistance.—The potential across the membrane was measured using two calomel reference electrodes. It is important to realize that the potential difference E_{rr} includes some ohmic drop of the brine and the caustic solutions. However, these ohmic contributions are relatively small due to the close proximity of the Luggin capillary tips to the membrane.

The membrane potential E_{rr} shows generally linear dependence with the current at the practical range (see Fig. 7) although some kind of Tafel behavior can be observed at lower currents, probably due to the membrane activation potential and liquid junction contributions. The measurements were quite difficult due to the capture of the gas bubbles in the liquid junction, and the capillaries had to be flushed periodically.

In order to estimate the membrane resistance, free of the adjacent solution resistance, the potential between the two reference electrodes was measured at various cathode spacings (the cathodic reference electrode moved with the cathode). A linear dependence of E_{rr} on the cathodic spacing was obtained. The increase in E_{rr} is due to the increase in the catholyte resistance associated with the larger spacing. The potential E_{rr} can be extrapolated to zero spacing and the ohmic drop of the catholyte can be eliminated. Similarly the ohmic drop of the anolyte was estimated from the dependence of the cell's potential on the anolyte spacing and substracted from E_{rr} in order to obtain the true potential difference across the membrane.

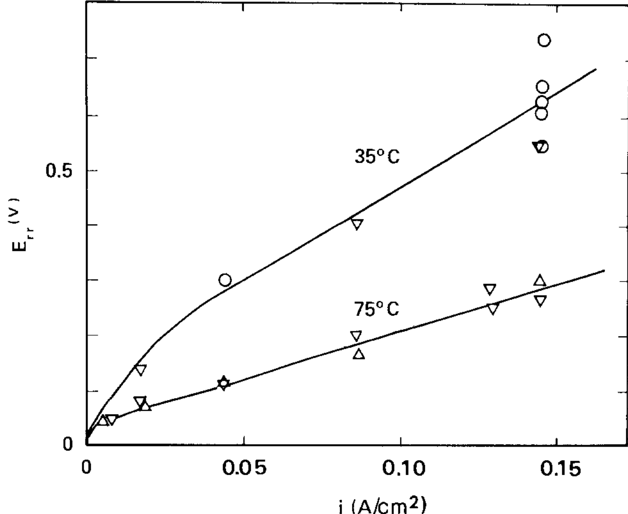

Fig. 7. Potential across Nafion membrane vs. apparent current density. Area, 77.4 cm²; cathode spacing, 0.33 cm; anode spacing, 0.30 cm; membrane, Nafion 031, effective area = 116 cm²; cathode, △ flattened conventional cathode, 75°C, ▽ std. Louver 1/8 in., 35° and 75°C, ○ std. Louver 3/16 in., 35°C.

The membrane potential drop is roughly 300 mV at a current density of about 215 mA/cm² at 75°C. At 35°C the membrane potential is about 600 mV.

The average extrapolated value for zero spacings is 0.43V at 35°C, so the *IR*-free potential difference across the membrane at 35°C is approximately 0.43V. The effective exposed area of the membrane is 116 cm². The resistance per 1 cm² membrane is therefore

$$\rho_{\text{membrane, 35°C}} = \frac{0.43\text{V}}{25\text{A}} (116\ \text{cm}^2) = 2.0\ \Omega\text{cm}^2$$

Similar estimation at 75°C show that the specific resistance of the membrane (per 1 cm²) is roughly

$$\rho_{\text{membrane, 75°C}} = \frac{0.27\text{V}}{25\text{A}} (116\ \text{cm}^2) = 1.3\ \Omega\text{cm}^2$$

It is not clear from the present measurements whether the resistance of the membrane is mostly ohmic or contains activation overpotential. Current-interruption measurements were not succesful in determining the nature of the membrane potential.

A practical conclusion, however, can be made: The Naion 031 membrane behaves like an ohmic resistance under industrial conditions, and the potential drop across the membrane can be estimated from the specific resistance obtained in the present report.

Current efficiency.—Additional advantage of using gas-diverting cathodes is reported by Creamer, Krumpelt, and Jorne (12). High current efficiency can be obtained by inducing turbulence in the catholyte by utilizing a gas-diverting cathode in close proximity to the membrane. An increase in the average current efficiency from 77 to 82% is reported by replacing the flattened cathode by an expanded-metal cathode which directed the gas away from the membrane. The cell was operated with Nafion membrane Type 313, under current density of 200 mA/cm², temperature of 82°-85°C and the pH in the anolyte varied from 3 to 3.5. The increase in current efficiency is due to the induced turbulence at the membrane surface and the resulting decrease in the hydroxide concentration at the surface of the membrane. The current efficiency of Nafion membranes is a strong function of the hydroxide concentration.

Conclusions

The three-dimensional structure and the inclined surfaces of the gas-diverting electrode enable the diversion of the gas to the rear of the electrode. This

results in ohmic drop saving because the electrode can be placed in a very close proximity to the membrane. In addition, an increase in the current efficiency is reported due to the induced turbulence at the surface of the membrane facing the cathode. The gas-diverting electrode can eliminate limitations on the electrode height with resultant capital investment savings.

ABSTRACT

Development of membrane chlor-alkali cells during this past decade represents a major advancement for commercial electrochemical technology. Chemical engineering applications of separation processes such as this involve diffusional mass transfer that can be treated as a rate process. The chlor-alkali application includes sodium, chloride, and hydroxyl ions plus water as mobile species in caustic soda and brine solutions and also between immiscible membrane and solution phases. These immiscible phases are brought into contact to allow selective transfer of sodium and water from brine to the caustic solutions. Previous data reported on NaOH diffusion through Nafion® membranes, D_{NaOH}, are difficult to interpret because not only do they involve hydroxide and sodium ion fluxes to give average diffusion coefficients, but also unknown gradients of electrolyte and water concentration are present in the membrane phase. This present work greatly simplifies these problems encountered by isolating and measuring the precise sodium ion self-diffusion coefficient, D_{Na^+}, with radio-tracer techniques in various du Pont Nafion® and EDA modified membranes. It then relates the D_{Na^+} to equivalent weight, surface treatment, and fabric backing in these membranes. These data for D_{Na^+} are very important in chlor-alkali cells because the sodium ion is the major current carrier; therefore, its value can be related to the relative activation energy and voltage drop among similar membranes.

The development of chlor-alkali cells which employ permselective ion exchange membranes as separators represents a major advancement in electrochemical technology. Nafion®[1] perfluorosulfonic acid ion exchange membranes have the necessary chemical stability and ionic transport properties which are needed for this application as well as for fuel cells of various designs. In order to bring these technologies to full commercialization, it is important to develop a thorough understanding of the physical and chemical properties of the membrane for solution environments in which it is to be used. Recently, several studies of Nafion have been reported which relate to fundamental properties (1-10) and its application to chlor-alkali (11-16) or fuel cell systems (17-20). The central morphological feature of Nafion is the aggregation of exchange sites and counterions into clusters, with a Bragg spacing of about 50Å (1, 13). Gierke discusses the ion clustering phenomenon with regard to ion transport and hydroxide rejection in chlor-alkali cells (13). The transport properties of Nafion have been found to vary considerably with external solution concentration (12, 16-18), presumably due to changes in membrane water and electrolyte content.

Membranes which are produced by du Pont for chlor-alkali applications are generally composites of two equivalent weights of polymer or of one equivalent weight where one surface has been chemically modified to change the nature of the ion exchange grouping

(12, 14-16). These modifications alter the membrane's dynamic properties; it has been found for experiments in which NaCl and NaOH solutions are separated by such membranes that the properties of the membrane side which is in contact with NaOH solution dominate the over-all membrane performance (16). Apparent membrane diffusion coefficients of NaOH have been measured for such systems (12, 16). Diffusion increases with lower equivalent weights and increasing NaOH concentration. Surface modification to produce sulfonamide exchange sites lowers diffusion rates by a factor of fifty while doubling the activation energy of diffusion (16).

A difficulty in the interpretation of these apparent NaOH diffusion coefficients is that not only are hydroxide and sodium ion fluxes coupled to produce an averaged diffusion coefficient, but unknown gradients of electrolyte and water concentration exist in the membrane phase. In order to remove these problems, we have measured the self-diffusion coefficient of Na^+ in various Nafion samples using a tracer method under equilibrium conditions. We wish to determine the influence of equivalent weight, surface treatment, and fabric backing on the membrane diffusion of Na^+, which is the major current-carrying species in the chlor-alkali membrane cell. Membrane water and NaOH concentrations have been determined also as a function of temperature and solution concentration. Finally, the membrane voltages of two Nafion materials which are produced for chlor-alkali applications have been measured in an operating cell.

Experimental

The properties of Nafion membranes which were studied are presented in Table I. Nafion 214 and 295 are manufactured for commercial chlor-alkali use and have one surface converted to sulfonamide exchange sites (14). This is accomplished by treating one surface of the polymer with ethylenediamine (EDA) while in the sulfonyl fluoride form. Open weave Teflon fabrics are used with these membranes to improve strength. The T-900 fabric, used in No. 295, provides a large open area because rayon threads present in the fabric can be chemically removed after lamination to the membrane. In practice the sulfonamide side of the membrane is exposed to NaOH solution in a chlor-alkali cell.

Membranes were pretreated by equilibration of the material for several hours in NaOH solution of given concentration and temperature to be used in the experiment. Equilibration times were 8 hr or longer. Since Nafion's properties are not completely reversible with temperature cycling (6, 18), data were taken using membrane samples which had not been heated to temperatures above that of the experiment. Water sorption measurements were made by a weight-drying method. Samples were dried at 150°C in vacuum before weighing, and completeness of drying was checked by measuring the infrared spectra of the dried materials. Corrections for sorbed electrolyte were applied to weight changes.

Table I. Properties of Nafion membranes

Membrane designation	Equiv. wt.	EDA conversion	Thickness, mm	Fabric (% open area)
1150 EW	1150	—	0.25	—
1200 EW	1200	—	0.25	—
1150 (EDA)	1150	~0.04 mm	0.18	—
EDA	1150	total	0.18	—
No. 214	1150	~0.04 mm	0.18	"T-24" (32%)
No. 295	1150	~0.04 mm	0.18	"T-900" (70%)

Membrane Na^+ concentrations were determined using a radiotracer method. Membrane samples were equilibrated with a NaOH solution which had been doped with $^{22}Na^+$. The membrane was then removed, carefully blotted, and counted using a well-counter with associated electronics. The radiotracer was obtained as a carrier-free aqueous solution from commercial sources, and was used as received. For membranes without fabric backing, dimensional changes with temperature and concentration were measured and used to calculate membrane Na^+ molarities. A wide flange micrometer (L. S. Starrett Company, Athol, Massachusetts) was used to measure the thickness of membrane samples, with a repeatability of about 0.01 mm. Fabric backed membranes showed minimal dimensional changes (<3%).

Sodium ion self-diffusion coefficients were also determined using $^{22}Na^+$ radiotracer. In this procedure, the membrane separates NaOH solutions of identical composition, and the radiotracer is added to one solution to initiate the experiment. At periodic intervals, 1 ml samples are withdrawn from the second solution. Steady-state conditions prevail as long as a small fraction of the total amount of tracer has been transferred (<2%). A diagram of the diffusion cell is shown in Fig. 1. The cell is constructed of borosilicate glass, with Teflon stirring paddles in each 100 ml compartment. Constant speed motors are used to drive the stirrers at 500 rpm. Silicone rubber gaskets hold the membrane in place; the exposed membrane area is 10 cm². Cold water condensers are mounted on the ports to prevent evaporation, Ascarite-filled drying tubes are used to prevent CO_2 uptake from the atmosphere, and the cell is thermostatted to ±0.1°C using a glass water jacket.

The steady-state flux of Na^+ is given by

$$J = -\overline{D}\overline{C}/d(1 + 2\overline{D}\overline{C}\delta/DCd) \quad [1]$$

where J is the flux in mole cm^{-2} sec^{-1}, D is the diffusion coefficient, C is molar concentration, d is membrane thickness, δ is the thickness of the unstirred liquid film at each membrane surface, and barred quantities refer to values within the membrane phase (21). With reasonable stirring and the high solution concentrations used here, the second term in the denominator is much less than unity and the expression simplifies to

$$J = -\overline{D}\overline{C}/d \quad [2]$$

A few experiments were performed in dilute solution. In these cases, δ was estimated from values which have been determined in the same cell under similar solution conditions (3, 5). The change in $\overline{D}$ from that neglecting film diffusion was about 20% in the most extreme case.

The voltage drop across Nafion 214 and 295 under conditions which duplicate an operating chlor-alkali cell was measured using a Teflon laboratory-scale cell. A steel cathode and a TiO_2-RuO_2 coated titanium anode were the working electrodes. Membrane area was 60 cm², the NaCl solution concentration was fixed at 4.8M, and the cell temperature was controlled at 85°C. The membrane voltage drop was measured using two probe electrodes and Luggin capillaries which extended to

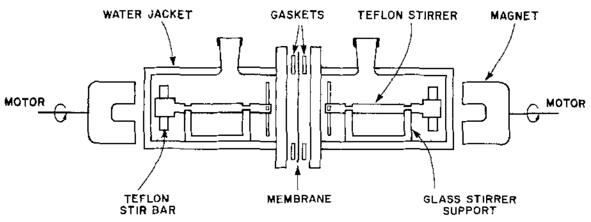

Fig. 1. Cell for membrane diffusion studies

each membrane surface. Current density was set at 2 kA m^{-2}.

Results and Discussion

Membrane water sorption and Na^+ concentration at several temperatures and NaOH solution concentrations are given in Tables II and III. The higher exchange capacity of 1150 equivalent weight (EW) produces higher sorption compared to 1200 EW, as expected. A comparison of results for the two backed membranes reveals the influence of the fabric. The much larger Na^+ and water concentrations for No. 295 probably result from void spaces within the membrane which are produced when rayon strands are chemically dissolved. It is also seen that membrane water contents are very sensitive to external solution concentration. The Na^+ membrane concentrations are essentially constant; this may be because the increasing tendency for NaOH sorption is balanced by lowered water contents as solution concentration increases.

Plots of typical tracer flux data are shown in Fig. 2 for the No. 214 membrane. At lower temperatures, transport is often extremely slow and only upper limits to Na^+ membrane diffusion coefficients can be made in some cases. Self-diffusion coefficients of Na^+ in all membrane samples are given in Table IV. Very similar trends can be seen for these diffusion coefficients as compared to membrane water concentrations, with higher water sorption producing enhanced diffusion. Self-diffusion coefficients for the two fabric backed membranes must be compared to those of the unbacked materials with caution, however. The measured area and thickness of No. 214 and No. 295 are not the effective values for a diffusing sodium ion. Errors in $\overline{C}$ and J which are caused by area measurements cancel in Eq. [2], but the error in d, and in $\overline{C}$ which employs d, will multiply. The presence of fabric approximately doubles the measured thickness; therefore we estimate that the actual Na^+ self-diffusion coefficients for these fabric backed membranes are about a factor of four smaller than the values listed in Table IV. This means that Na^+ diffusion in the fabric

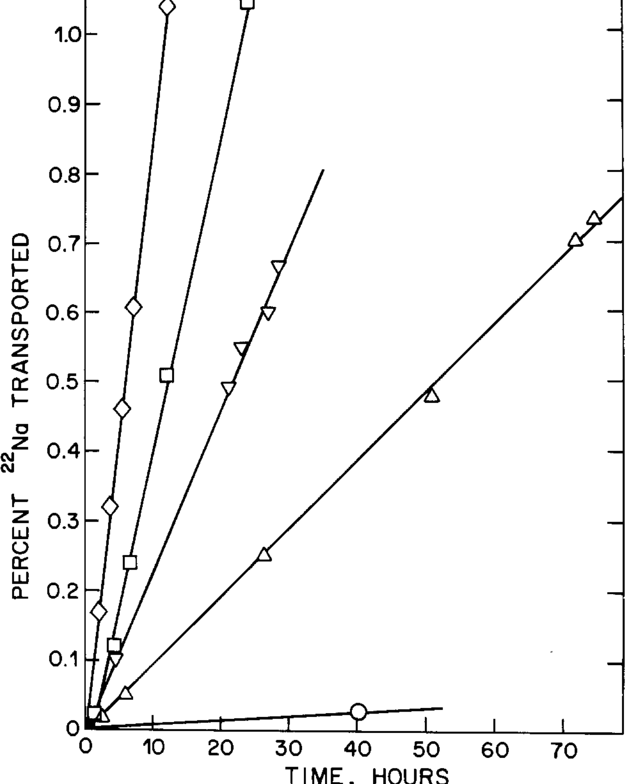

Fig. 2. Na^+ tracer flux in Nafion 214, 9.4M NaOH external solution. 25°C, ○; 40°C, △; 55°C, ▽; 70°C, □; 85°C, ◇.

backed membranes is more restricted than in their unbacked analogs, 1150 EW or 1150(EDA).

If ionic diffusion in Nafion can be treated as a simple kinetic process with a characteristic activation energy, then

$$\overline{D}_{Na^+} \propto \exp(-E_{ACT}/RT) \quad [3]$$

and a plot of log $\overline{D}$ *vs.* $1/T$ should be linear. This is found to be true for the unbacked membranes between 60° and 90°C, as shown in Fig. 3. Activation energies of diffusion were calculated from the slopes of these lines and are given in Table V. Values of 3-5 kcal $mole^{-1}$ are typical of ionic activation energies in aqueous solution, and therefore Na^+ diffusion may be solution-like in 1150 and 1200 EW. Conversion of some sulfonate exchange sites to weakly acidic sulfonamide groupings approximately doubles the activation energy. This is probably due not only to the reduced water content with 1150(EDA) but more importantly to the enhanced attraction of sulfonamide sites to counterions. This might be expected because of the much stronger basic properties exhibited by ionized sulfonamides relative to sulfonates in aqueous solution. Full conversion to the sulfonamide form with the (EDA) membrane

yields greatly reduced diffusion coefficients and a very high energy of activation.

Arrhenius plots for Nafion 214 and 295 are shown in Fig. 4 and 5. Linear relationships are again seen above 60°C. Results which were obtained for No. 214 at lower temperatures indicate that the activation energy of diffusion increases abruptly, especially at higher NaOH solution concentrations. This suggests that the mechanism of diffusion changes below a given temperature and solution concentration. This is similar to the results of ionic self-diffusion measurements in dilute solutions for Nafion 120 EW using water and other swelling solvents (5). Activation energies of diffusion for Na^+ were 7 and 4 kcal $mole^{-1}$ for water and methanol systems, respectively. However for Na^+ in acetonitrile or Cs^+ in all three solvent systems, activation energies were 15-20 kcal $mole^{-1}$. These much higher values were attributed to the inability of counterions to transport between ion clusters. This may explain the changes in slopes for the lines in Fig. 4 as well.

Activation energies calculated from the higher temperature data for No. 213 and No. 295 are larger than that of the analogous membrane without fabric backing, 1150 (EDA). Also, the two fabrics yield different increments to the activation energy. This suggests that the polymer morphology may be altered in the fabric lamination step of manufacturing such membranes, for in the absence of such changes the activation energy of diffusion should remain constant. The lowering of E_{ACT} near 11M NaOH solution concentration for both membranes is interesting. These values were remeasured with the same result. This suggests that an optimum NaOH concentration may be found with regard to the transport properties of Nafion membranes in chlor-alkali cells.

Table V. Activation energy of Na^+ diffusion in Nafion, kcal $mole^{-1}$

Membrane	NaOH conc. (M)	Temperature range (°C)	E_{ACT}
1150 EW	9.5	60-90	2.5

	11.0	55-85	9.1
	12.5	70-85	10.2

The dependence of the Na^+ self-diffusion coefficient on solution pH for Nafion 295 is shown in Fig. 6. Also plotted here is the change in the molarity of water in NaOH solution as a function of NaOH concentration, using standard chemical handbook data. The pronounced decrease of the diffusion coefficient in concentrated solution for No. 295 can be attributed to the dehydrating effect of the drop in solution water content, as illustrated in Fig. 6. At intermediate solution

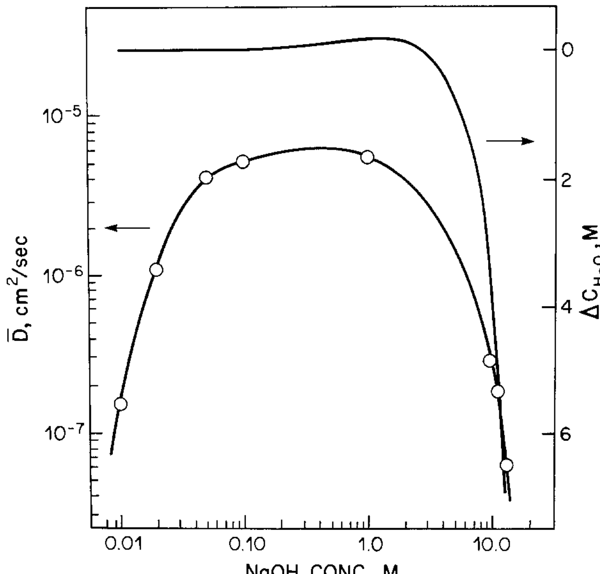

Fig. 6. Na^+ diffusion coefficient in Nafion 295 at 60°C, NaOH external solution; and change in water molarity in NaOH solution.

concentrations, membrane water contents increase and the diffusion of Na^+ rises by a factor of about 50. The reduction in diffusion coefficient in more dilute solutions is attributable to the sulfonamide exchange site layer in the membrane. These sites are weakly acidic, and if the internal membrane pH is not sufficiently high, the sites will protonate to remove the ion exchange capability of this layer of membrane. This would greatly reduce Na^+ diffusion. This result has relevance to the chlor-alkali cell. The pH gradient across the membrane separator will be affected by the adjustable brine acidity; the results in Fig. 6 suggest that brine pH may have a pronounced effect on membrane transport properties. We conclude that the operating properties of membranes such as Nafion 214 and 295 may be very sensitive to gradients in membrane pH and water content.

Membrane voltage drops for these membranes in a laboratory scale chlor-alkali cell are shown in Fig. 7. It is seen that the membrane voltage for No. 214 is about double that of No. 295, as would have been predicted from their respective Na^+ diffusion coefficients.

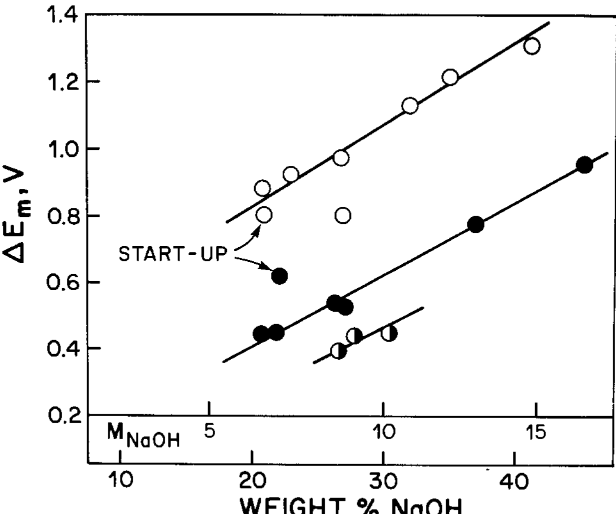

Fig. 7. Membrane voltage drop in operating chlor-alkali cell; 4.8M NaCl, 2 kA m^{-2} current density, 85°C. ○, Nafion 214; ●, Nafion 295; ◑, Nafion 295 after use.

Several other factors would need to be considered for more detailed comparisons of cell membrane voltages, however. These include the respective membrane Na^+ and OH^- concentrations, current efficiencies, and electro-osmotic water transport. Another feature of the operating properties of these membranes is shown in Fig. 7, where the membrane voltage of No. 295 has dropped by 0.15V after several weeks of operation. However this is accompanied by a decrease in current efficiency from 87 to 73%. Polymer degradation, long term morphological changes, or the slow accumulation of brine impurities are seen as possible contributing factors. Future work will examine the effect of gradients in membrane pH and water content, and imposed electrical current on the transport properties of these membranes.

Reduction of Cd_2SnO_4 and Cd_2SnO_4/CdO Thin Film Electrodes in Sulfuric Acid Electrolytes

D. E. Hall*

The International Nickel Company, Incorporated, INCO Research and Development Center, Sterling Forest, Suffern, New York 10901

ABSTRACT

The reductive decomposition of cadmium stannate thin film semiconductor electrodes in sulfuric acid electrolytes results in extensive depletion of cadmium from the electrodes. This was established from composition *vs.* depth profiles of Cd_2SnO_4 films obtained using Auger electron spectroscopy combined with sputter-etching of the Cd_2SnO_4 films at a controlled rate. The reduction process occurs at potentials positive of the estimated flatband potential of Cd_2SnO_4. When CdO is present in the Cd_2SnO_4 films, reduction is greatly accelerated. The effect is similar to that caused by increasing the acid concentration of the electrolyte. Scanning electron micrographs show that the films are preferentially attacked at grain boundaries, where CdO is believed to be concentrated.

Recently, the use of cadmium stannate thin film electrodes in iron-thionine photogalvanic cells was described (1). The power output of cells with Cd_2SnO_4 cathodes declined slowly with use. This was attributed to reductive decomposition of the Cd_2SnO_4 cathodes in their operating potential range, which was evident from current vs. potential curves of Cd_2SnO_4 in the supporting electrolyte. In this preliminary investigation of the electrochemical properties of Cd_2SnO_4, the flatband potential was estimated from Schottky-Mott plots of capacitance data, and the potentials of anodic and cathodic limiting processes were established. Cadmium stannate was found to reduce at potentials several tenths of a volt positive of the limiting cathodic process; the extent of reduction was dependent on acid concentration in the electrolyte.

The electrochemical behavior of other highly conductive oxide semiconductors has also received recent attention. Stannic oxide is the best characterized of these, having been used for many years as a working electrode in photoelectrochemical studies. Laitinen and co-workers (2) investigated the behavior of SnO_2 in strong acid solutions and provided evidence for surface electrolysis of SnO_2 at potentials positive of the cathodic limit, where SnO_2 is reduced to metallic tin. The surface reduction of SnO_2 was enhanced by increasing the acid concentration in the electrolyte, and also by the presence of specifically adsorbed anions such as chloride. A calculation was presented to show that the charge involved in the reduction process was considerably greater than that available from the first atomic layer of the electrode surface. The authors speculated that the surface roughness factor was greater than one and/or more than a monolayer of tin atoms was reduced.

Additional information on thin film semiconductor electrochemistry can be obtained by using instrumental techniques suitable for analysis of thin film composition and surface structure. Recently, Armstrong *et al.* (3) investigated the behavior of tin oxide and indium tin oxide thin films in acid electrolytes. Using Auger electron spectroscopy and ESCA, direct evidence of electrochemically induced changes in electrode stoichiometry was obtained. By depth-profiling SnO_2 electrodes which had been subjected to controlled-potential electrolysis, it was shown that the ratio of oxygen to tin in SnO_2 decreased as the electrolysis potential was made more negative. The O/Sn ratio was lowered in a region extending quite deeply into the film, supporting the observation by Laitinen and co-workers that several atomic layers of the electrode surface are probably involved in the electrochemistry of SnO_2.

In the present paper, the reduction of Cd_2SnO_4 in sulfuric acid electrolytes is described. It is shown that reduction of Cd_2SnO_4 causes compositional changes in the film which extend to great depths below the film surface. A mechanism for this effect is suggested, based on structural and compositional analyses of electrochemically etched films.

Experimental

Cadmium stannate thin films, with and without significant amounts of CdO, were sputter-deposited on low-alkali glass substrates and characterized by G. Haacke of American Cyanamid Company. The sputter deposition and characterization procedures have been discussed recently in detail by Haacke and co-workers (4). All Cd_2SnO_4 films had been annealed at 650°C after deposition and had sheet resistances between 2.5 and 3 Ω/□. A Cd_2SnO_4 film containing ≥10% CdO was annealed at 670°C; its sheet resistance was 3.6 Ω/□. This film was noticeably yellower than the others, which typically have a pale gray-green cast. [The adsorption-edge shift caused by the presence of CdO in Cd_2SnO_4 films has been reported by Haacke (5).] Each thin film was cut down to make electrodes approximately 0.3 cm^2 in area. Electrical contact was made to one edge of each electrode using indium metal or silver paint. The contact and connecting wires were then coated with silicone rubber sealant. Electrochemical measurements were made at 23°C in a cell containing a SCE reference and a platinum foil counterelectrode. The H_2SO_4 and Na_2SO_4 electrolyte solutions were made from reagent grade chemicals, using distilled water. Potential-cycling experiments were performed using a Princeton Applied Research 173 potentiostat and 175 universal programmer. The negative limit of potential cycles was not allowed to reach the cathodic limiting process, in order to study the reductive decomposition of Cd_2SnO_4 at more positive potentials which was reported in an earlier paper (1).

* Electrochemical Society Active Member.

Key words: cadmium stannate, semiconductor electrodes, Auger electron spectroscopy.

Auger electron spectroscopy (AES) was performed using a Physical Electronics Model 545 Scanning Auger Microprobe under a vacuum of 10^{-9} Torr. A 5 keV electron beam was rastered over an area of roughly 4×10^{-3} mm². To establish the composition of the film as a function of distance from its surface, a 2 kV argon ion beam was used to sputter-etch the film at a controlled rate. This rate was calibrated by an independent thickness measurement obtained by scanning electron microscopy. As described below, some Cd_2SnO_4 electrodes were visibly damaged by exposure to H_2SO_4 electrolytes and potential-cycling experiments, with the result that their composition changed. The sputtering rates of these electrodes were, by necessity, assumed to be equal to those of new Cd_2SnO_4 films. Spectra were recorded at preselected intervals during sputtering, until a strong silicon signal indicated complete removal of the film. Initial analyses of elemental composition used Cd, Sn, and O sensitivity factors obtained from other oxide materials, but these were found to be unsatisfactory. Accordingly, sensitivities were renormalized from data obtained midway through the depth-profile of a new Cd_2SnO_4 film, where the composition was nearly constant. In the AES results reported below, Cd + Sn + O + final Si analyses were used as the basis for normalization; carbon and small amounts of other surface impurities such as chlorine were subtracted from the raw data. A three-point smoothing treatment was used on the resulting normalized data. None of the major features of the depth profiles were significantly altered by this treatment, although minor ripples in compositional analysis were reduced.

During the AES investigation of Cd_2SnO_4 and Cd_2SnO_4/CdO films, it was discovered that the primary electron beam caused the Sn/Cd ratio to increase slightly with time (6). It was not determined whether this was caused by migration of Sn to the beam spot, or by Cd migration away from it. An investigation of this effect indicated that, during the time required for each depth profile to be made, this change in the Sn/Cd ratio was not large enough to interfere with the features of the depth-profile plots or the conclusions drawn from them.

The surface topographies of Cd_2SnO_4 films were examined with a Cambridge Stereoscan 180M scanning electron microscope. A 26 keV primary beam energy was used with 30k magnification. Lower magnifications were also used to examine prominent surface features. The elemental compositions of selected sites on Cd_2SnO_4 and Cd_2SnO_4/CdO electrodes were obtained by energy-dispersive x-ray spectrometry (EDS).

Results

Cd_2SnO_4 thin films in sulfuric acid electrolytes. The AES depth profile of a new Cd_2SnO_4 thin film is shown in Fig. 1. The expected analysis of stoichiometric Cd_2SnO_4 is 55 weight percent (w/o) Cd, 29 w/o Sn, and 16 w/o O. SEM photomicrographs showed that the Cd_2SnO_4 surface had a uniform structure consisting of ~0.2 μm diam knobs. The large surface defects on the SnO_2 films examined by Armstrong *et al.* (3) were not evident on Cd_2SnO_4, reflecting differences in film preparation methods.

The initial cyclic potential sweeps of Cd_2SnO_4 in 0.01M H_2SO_4 showed no distinctive features between 1.0 and 0.4 V/SCE. However, successive sweeps often showed a small but noticeable reduction wave at ~0.4 V/SCE. The reduction wave, shown in Fig. 2 (solid line), persisted in potential sweeps recorded at short intervals during a period of a few hours, but the reduction current gradually declined until a distinct wave was no longer observed (Fig. 2, dotted line). Between potential sweeps, the rest potential drifted slowly to ~0.4 V/SCE, indicating spontaneous decom-

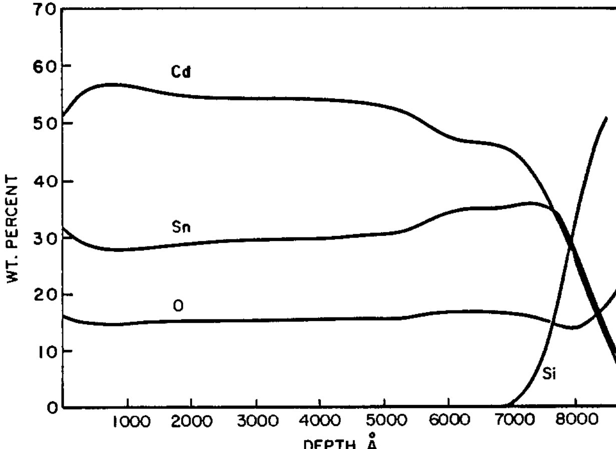

Fig. 1. Composition vs. depth profile of a Cd_2SnO_4 thin film (as-received).

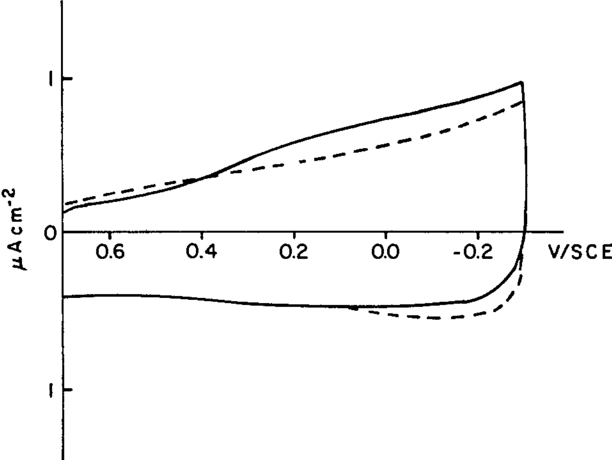

Fig. 2. Cd_2SnO_4 electrode in 0.01M H_2SO_4. Potential sweep rate = 5 mV sec^{-1}. Solid line: 4th cycle, 35 min after insertion of electrode into cell. Dotted line: after 148 min of exposure to electrolyte.

position of the film. Current-potential curves similar to the dotted-line curve of Fig. 2 were also obtained in 0.2*M* Na_2SO_4.

To determine more accurately the onset potential for Cd_2SnO_4 reduction, cyclic potential sweeps were performed with regular increases of the negative switching potential ($E_{sp,c}$) until no faradaic current could be detected on the positive sweep, thus indicating that no reduction had occurred on the previous negative sweep. It was necessary to obtain these measurements at slow sweep rates (5-10 mV sec^{-1}) because of the slowness of the faradaic process (1). Initially, no oxidation current was observed for $E_{sp,c}$ greater than approximately 0.4 V/SCE. After continued cycling, oxidation currents were observed for $E_{sp,c}$ as positive as ~1.0 V/SCE (Fig. 3), indicating that Cd_2SnO_4 reduction occurs over a much wider potential range than previously reported (1). The rest potential of the Cd_2SnO_4 electrode showed a similar shift. The observed reduction of Cd_2SnO_4 at potentials as positive as 1.0 V/SCE shows that Cd_2SnO_4 is apparently reduced at potentials positive of the flatband potential (1). Armstrong *et al.* (3) reported similar behavior for SnO_2 thin film electrodes.

When the Cd_2SnO_4 electrode was removed from the electrolyte, the film had a uniform reddish-green color at the electrode center, gradually changing to the original color of the Cd_2SnO_4 film at the edges, where the electrode had been partially shielded by the silicone resin. SEM photomicrographs showed that the electrode surface structure was essentially unchanged.

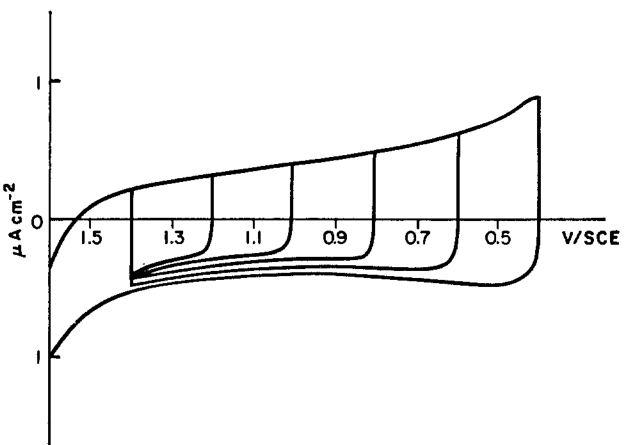

Fig. 3. Cd_2SnO_4 electrode in 0.01*M* H_2SO_4. Same electrode as in Fig. 2, after 192 min of exposure to electrolyte. Potential sweep rate = 10 mV sec^{-1}.

Thus, it appeared that fairly uniform surface electrolysis had taken place. The AES depth profile of the electrode (Fig. 4) showed a small decrease in film thickness, as well as extensive removal of Cd from the top 1000Å of the film. The drop in Cd content in the film surface region was apparently responsible for the lower reduction currents observed on the last cyclic potential sweeps, as shown in Fig. 2.

Reduction waves were established rapidly when potential sweeps were performed in 0.1*M* H_2SO_4, as shown in Fig. 5. These waves were similar to those reported previously when 0.05*M* H_2SO_4 was used [Fig. 2 of Ref. (1)], but were much sharper and at more positive potentials in the stronger acid. Laitinen *et al.* (2) also found that peak curent definition at SnO_2 electrodes increased with increasing acid concentration. Using lattice constants for Cd_2SnO_4 from Haacke *et al.* (4), it was determined that the charge passed on the cathodic sweep from Fig. 5 (solid line) would be sufficient to reduce completely the cadmium content of ~2 molecular layers of Cd_2SnO_4, assuming a surface roughness factor of one. This supports the above-mentioned observation of Laitinen *et al.* (2) that the electrochemical reduction of oxide semiconductors may well involve more than one molecular layer at the electrode surface concurrently. The abrupt truncation of reduction waves, and the erratic currents encountered with continued cycling, may be caused by the decreased accessibility of cadmium in succeeding layers of the electrode. The corresponding oxidation process was observed as a broad wave at ~0.6 V/SCE. A strong oxidation wave was also associated with the limiting cathodic process (Fig. 5, dotted line). With continued cycling, the reduction waves became less well-defined and currents were erratic.

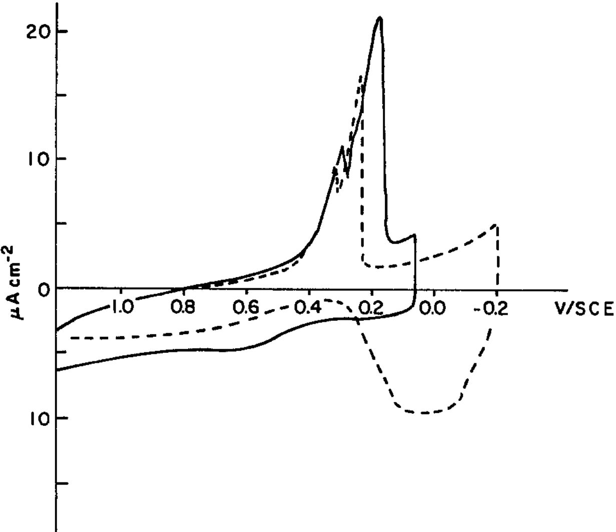

Fig. 5. Cd_2SnO_4 electrode in 0.10*M* H_2SO_4. Solid line: potential sweep rate = 10 mV sec^{-1}. Dotted line: potential sweep rate = 5 mV sec^{-1}.

Examination of the electrodes following potential sweeps in 0.1*M* H_2SO_4 showed that the Cd_2SnO_4 films were unevenly colored and contained many highly etched areas. The AES depth profile (Fig. 6) showed extensive Cd depletion in the top 2500Å of the film. Near the film surface, the composition was nearly that of SnO_2 (79 w/o Sn, 21 w/o O). The AES depth profile of a Cd_2SnO_4 film exposed to 0.1*M* H_2SO_4 for the same length of time without potential cycling was similar to Fig. 6, indicating that acid-induced decomposition of Cd_2SnO_4 was much more rapid than in 0.01*M* H_2SO_4.

The above results, taken with those from Ref. (1), describe the reduction and current *vs.* potential behavior of Cd_2SnO_4 in 0.01-0.25*M* H_2SO_4. Distinct cathodic waves are either absent or very small in 0.01*M* H_2SO_4, and the Cd_2SnO_4 surface is reduced uniformly. Considerable cadmium is removed from the film surface region, although this process occurs slowly. Similar current-potential curves are obtained in 0.2*M* Na_2SO_4. In the absence of potential cycling, open-circuit reduction occurs at a rate which is appreciable, but slower than that resulting from applying more negative potentials which do not reach the cathodic limiting process. Higher acid concentrations greatly accelerate the reduction of Cd_2SnO_4. In 0.05*M* H_2SO_4, two distinct

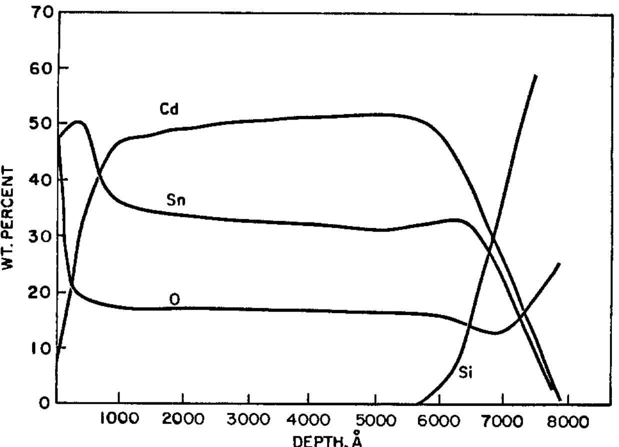

Fig. 4. Composition *vs.* depth profile of a Cd_2SnO_4 thin film after potential cycling in 0.01*M* H_2SO_4.

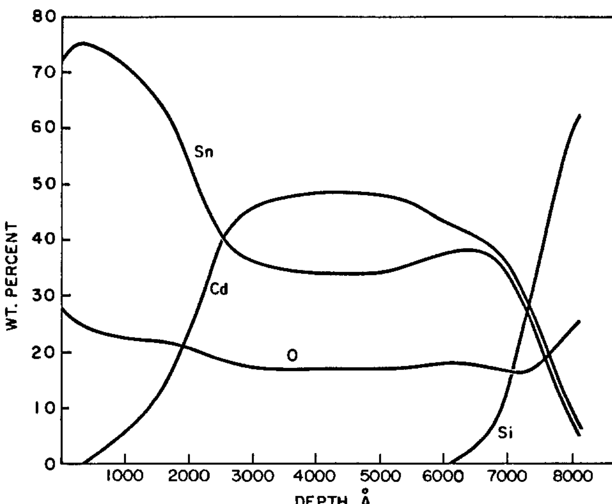

Fig. 6. Composition *vs.* depth profile of a Cd_2SnO_4 thin film after potential cycling in 0.10*M* H_2SO_4.

cathodic waves appear, and shift to more positive potentials as the H_2SO_4 concentration is raised to 0.1*M*. The Cd_2SnO_4 films are visibly etched, indicating more aggressive decomposition occurring preferentially at certain sites on the films. Reduction is also rapid at open circuit. In both cases, AES depth profiling shows deep Cd removal and the electrode composition approaches SnO_2. In 0.25*M* H_2SO_4, reduction waves are similar to those observed in 0.1*M* H_2SO_4, but are larger; the electrode film is rapidly destroyed.

The complexity of the depth profiles of reduced Cd_2SnO_4 films makes it difficult to draw conclusions regarding the reduction products (which could include $CdSnO_3$, for example). However, a reasonable interpretation of the above data is that Cd_2SnO_4 is converted ultimately to SnO_2. The time-dependent composition of the electrode surface region also makes it difficult to assign a particular electrode process to the anodic and cathodic current peaks observed in cyclic potential sweeps, as in Fig. 5. Laitinen *et al.* (2) ascribed similar peaks at SnO_2 electrodes to the slow reduction and oxidation of surface tin species. However, while the current peaks observed in the present work are at approximately the same potentials, they are larger than similar peaks observed by Laitinen at pure SnO_2, and occur in much weaker acid. In addition, cathodic current peak truncation, and the reduction of peak currents with continued potential cycling, both suggest depletion of electroactive material while the SnO_2 content of the Cd_2SnO_4 film surface is increasing. (This current-potential behavior might also be caused by mechanical breakdown of the film.) Thus, although the current *vs.* potential curves at SnO_2 and Cd_2SnO_4 thin film electrodes in the two studies have similarities, it is doubtful whether their current peaks in strong acids can be attributed to the same processes.

Cd_2SnO_4/CdO thin films in sulfuric acid electrolytes.—The AES depth profile of a Cd_2SnO_4 film containing CdO is shown in Fig. 7. The elemental composition of the film is similar to that found in Fig. 1 for Cd_2SnO_4, with a slightly higher percentage of Cd in the Cd_2SnO_4/CdO film.

When potential sweeps were imposed on Cd_2SnO_4/CdO thin films in 0.01*M* H_2SO_4, two distinct reduction waves at 0.4 and 0.3 V/SCE were obtained immediately, as shown in Fig. 8 (solid line). A corresponding, well-defined oxidation wave was present at 0.6 V/SCE. Repeated potential cycling caused the reduction waves to shift to more negative potentials, merging to form a single, sharp peak (Fig. 8, dotted line). The oxidation wave became less distinct. At the conclusion of potential sweep experiments, the Cd_2SnO_4/CdO films were visibly etched. in the same manner as Cd_2SnO_4 films in 0.1*M* H_2SO_4. Scanning electron microscopy

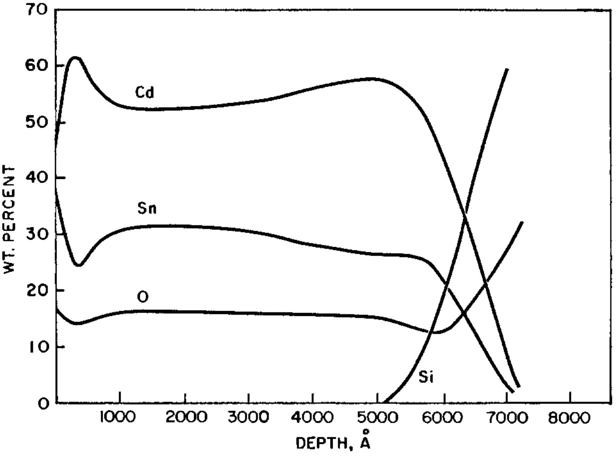

Fig. 7. Composition vs. depth profile of a Cd_2SnO_4/CdO thin film (as-received).

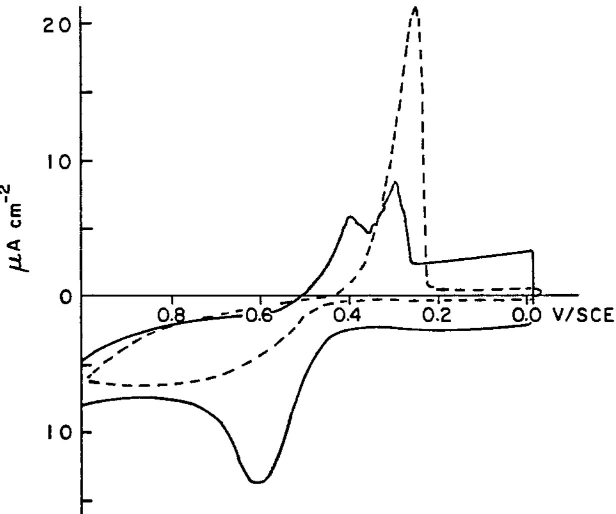

Fig. 8. Cd_2SnO_4/CdO thin film electrode in 0.01M H_2SO_4. Potential sweep rate = 5 mV sec^{-1}. Solid line: 3rd cycle. Dotted line: after repeated cycling.

revealed that the entire film surface was covered with deep crevices, separating the film into angular plates approximately 2-3 μm across [Fig. 9(A)]. In addition, larger eruptions of the film were observed, as shown in Fig. 9(B). An elemental analysis was performed by EDS at each of the numbered sites. In the crevice (site 1), a strong silicon signal together with the absence of any Sn or Cd signal indicated total loss of the film. At site 2, silicon and tin were both detected; the Cd signal was very weak. The majority of the film surface, represented by site 3, showed a strong tin signal and a very weak Cd signal.

The composition change of Cd_2SnO_4/CdO is much more extensive than for any similar reductive decomposition of thin film semiconductor electrodes reported to date. A typical AES depth profile of Cd_2SnO_4/CdO after potential cycling as described above is shown in Fig. 10. The decreased film thickness shows that a substantial amount of material was removed by the reduction process. More striking, however, is the nearly complete removal of Cd from the film. At depths of 1500-3500Å, the composition of the etched film is nearly that of SnO_2.

The behavior of Cd_2SnO_4/CdO thin film electrodes is probably due to film structure. Evidence has been obtained which suggests that the CdO phase is concentrated at Cd_2SnO_4 grain boundaries (7). The CdO phase is attacked more vigorously than the Cd_2SnO_4, resulting in the segmented appearance of electrochemically etched Cd_2SnO_4/CdO films [Fig. 9(A)]. Subsequent electrolyte penetration into the intergranular crevices results in removal of Cd from the Cd_2SnO_4 phase to a greater extent than in Cd_2SnO_4 films not containing CdO, which are attacked mainly at the surface. The EDS analyses given above, for example, show that Cd depletion is most extensive near the large crevice in Fig. 9(B), where electrolyte penetration occurs most readily. The quantity of Cd depleted from Cd_2SnO_4/CdO films, as seen from AES depth profiling, indicates that Cd_2SnO_4 within the film bulk is indeed reduced, for the amount of Cd removed is obviously much greater than that contained in the amounts of CdO present. The effect of CdO, therefore, is to provide sites at the grain boundaries which are more readily attacked at low acid concentrations. Equivalent results are obtained by exposing Cd_2SnO_4 films (without CdO) to higher acid concentrations.

During the course of this study and an earlier one (1), erratic current-potential curves with higher than normal reduction peaks were sometimes obtained at Cd_2SnO_4 electrodes in 0.01*M* H_2SO_4. Those curves were

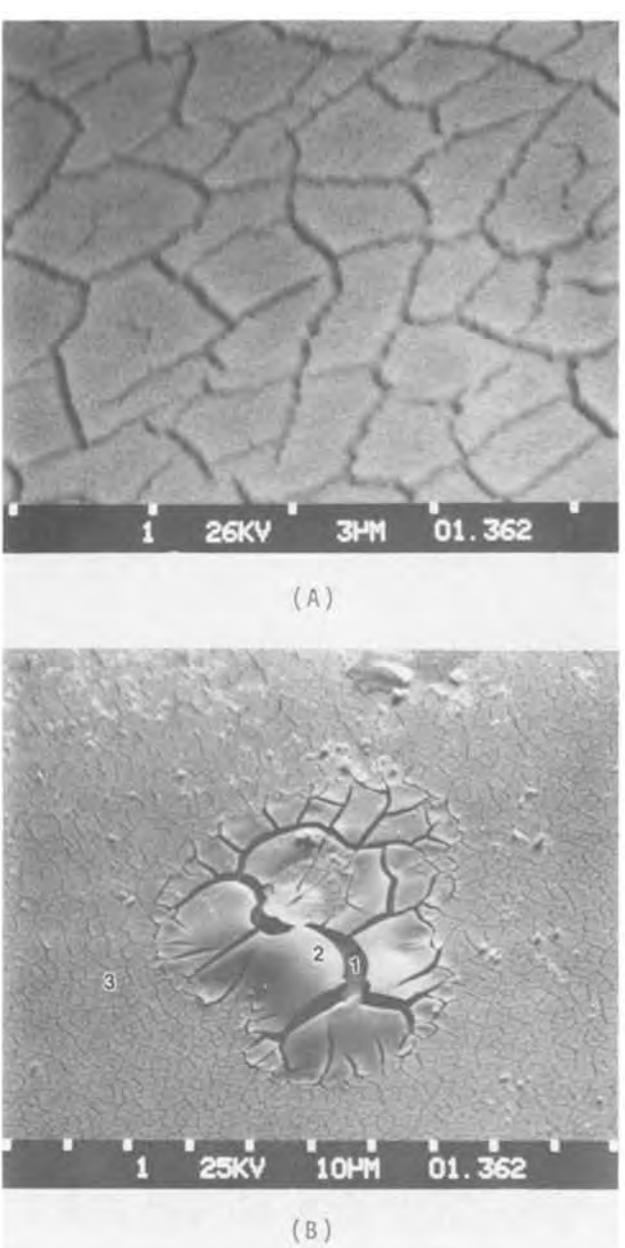

Fig. 9. Scanning electron micrographs of electrochemically etched Cd_2SnO_4/CdO thin film electrodes. (A) Network of crevices covering most of electrode surface, 7500×. (B) Large eruption of Cd_2SnO_4/CdO film, showing areas where EDS analyses were made, 1000×.

similar to ones obtained in the present work with electrodes known to contain CdO. Because of the difficulty in preparing truly single-phase films (4, 8), it is therefore likely that Cd_2SnO_4 electrodes displaying unusually vigorous reduction contained undetected quantities of CdO sufficient to promote intergranular attack.

Discussion

Changes in metal oxide electrode stoichiometry affect the semiconductor properties of the electrode surface region by changing its charge carrier density, conductivity, and even the oxide compounds present, as suggested in the present work. Both the composition of the oxide surface and the thickness of the oxide region are important. Armstrong *et al.* (3) have demonstrated the importance of composition changes at optically transparent thin film electrodes. Recent work, notably by Srinivasan and co-workers (9) has also emphasized the importance of obtaining an adequate description of the surface oxide layer at electrodes used for oxygen evolution and reduction.

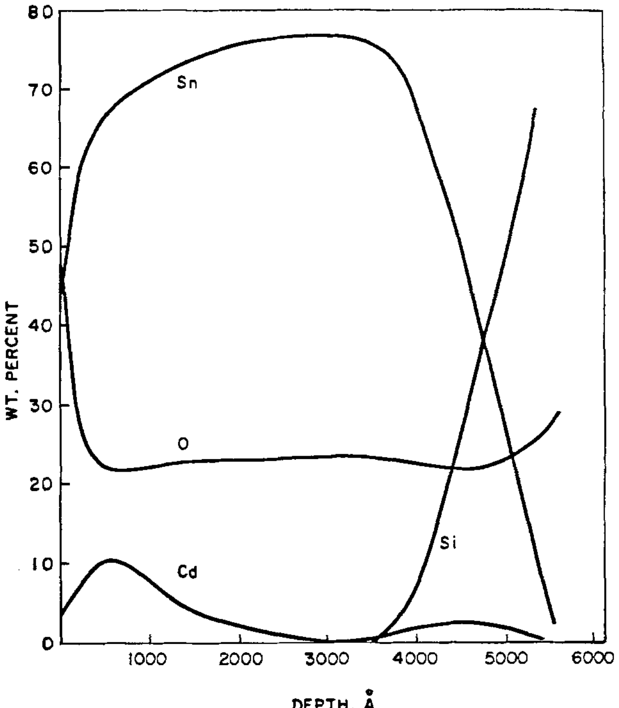

Fig. 10. Composition *vs.* depth profile of Cd_2SnO_4/CdO thin film after potential cycling in 0.01*M* H_2SO_4.

An important difference between tin oxide and cadmium stannate is that electrode processes at Cd_2SnO_4 which occur positive of the cathodic limit are not confined to charging and discharging of surface species. When the process is slow enough (as in weak acid electrolytes), the conversion of relatively unstable Cd_2SnO_4 to the more stable SnO_2 can be monitored, making it possible to observe stoichiometry changes to great depths. At higher acid concentrations, or when CdO is present at grain boundaries, the reduction process is accelerated, providing a physical picture of the electrode reduction. The grain-boundary corrosion of the thin film oxide semiconductor can be clearly seen.

The use of surface analysis techniques such as Auger electron spectroscopy, combined with sputter-etching to determine depth profiles of electrodes, involves certain assumptions. Following earlier practice (3), an equal sputtering rate was assumed for all elements in Cd_2SnO_4 thin films. An additional assumption was also made: thin films reduced to the point of having structure defects and large compositional differences were assumed to have the sputtering characteristics of unetched films. It is doubtful that truly quantitative data can be obtained under such circumstances. However, in the present work, such a method has proved useful in determining the essential features of Cd_2SnO_4 thin film reduction. These assumptions, and others which will be made in future studies, will doubtless be investigated in more detail as AES and other surface analysis techniques are used increasingly to study mixed metal oxide and other electrode surfaces.

Acknowledgments

The cadmium stannate electrodes used in this work were generously supplied by Dr. G. Haacke, whose interest in this work and useful information are gratefully acknowledged. Valuable discussions of depth profile results were held with Dr. H. L. Yeh and Mr. D. J. Hunt. This work was supported by the INCO Creative Research Program.

Determination of the Liquid Interaction Parameters of InP, InAs, GaAs, and GaP in the Range 580°-670°C

Ernesto H. Perea and Clifton G. Fonstad

Department of Electrical Engineering and Computer Science and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The liquid interaction parameters for InP, GaAs, InAs, and GaP have been measured in the 580°-670°C range. The procedure followed to determine these parameters, together with an account of the conditions under which the measurements were carried out in order to obtain reproducibility of the results, are described.

The III-V quaternary, $In_uGa_{1-u}P_vAs_{1-v}$, has recently received much attention because of its importance for optoelectronic and hot electron device applications (1-4). The accurate determination of the liquid interaction parameters (5) for InP, InAs, GaAs, and GaP is an important step towards the determination of the complete set of parameters that govern solid-liquid equilibrium of $In_uGa_{1-u}P_vAs_{1-v}$. In this work, a systematic determination of these parameters is reported, together with a complete description of the conditions under which the measurements were carried out in order to secure the reproducibility of the results.

Published data (6) is typified by high dispersion and least squares fits made over a large range of temperatures yield parameters that are inadequate in the restricted range of temperatures used in quaternary growths. Differences between experimentally measured liquidus temperatures and those calculated using liquid interaction parameters previously reported (6, 7) are in some cases quite significant. Using the parameters determined in this work, binary liquidus temperatures can be predicted to within ±0.5°C between 580° and 670°C.

The Binary Liquid Interaction Parameter

The solid-liquid equilibrium for a binary consisting of elements i and j is given in the simple solution model by (5)

$$\Delta S_F{}^{ij}(T_F{}^{ij} - T_l) + RT_l \ln (4x_i{}^l x_j{}^l) - \alpha_{ij}{}^l [0.5 - (x_i{}^l)^2 - (x_j{}^l)^2] = 0 \quad [1]$$

where $\Delta S_F{}^{ij}$ and $T_F{}^{ij}$ are the entropy and temperature of fusion, respectively, T_l is the liquidus temperature, and $x_i{}^l$ and $x_j{}^l$ are the atomic fraction of components i and j in the liquid. We note that $x_i{}^l + x_j{}^l = 1$.

The liquid interaction parameter $\alpha_{ij}{}^l$ is then given in terms of measurable quantities by

$$\alpha_{ij}{}^l(T_l) = \frac{\Delta S_F{}^{ij}(T_F{}^{ij} - T_l) + RT_l \ln (4x_i{}^l x_j{}^l)}{0.5 - (x_i{}^l)^2 - (x_j{}^l)^2} \quad [2]$$

In general $\alpha_{ij}{}^l$ is a function of T_l which as a first approximation is taken to be of the form (8)

$$\alpha_{ij}{}^l(T_l) = a - bT_l \quad [3]$$

This is a good approximation only if a limited temperature range is involved (typically less than 100°C). An example of this limitation can be seen in the data of Ilegems *et al.* for GaP (9).

Measurement Conditions

The conditions under which the liquidus temperature was measured have been carefully standardized in order to secure their reproducibility. All measurements were carried out in a pyrolytic graphite boat with three 8 × 8 × 10 mm wells, separated 10 mm from each other. A semitransparent, movable furnace with a flat temperature profile over the length of the boat was used with a temperature controller capable of stabilizing the temperature to within ±0.01°C. A programmer was used to produce the desired rates of temperature increase or decrease. The temperature was accurately measured by means of a calibrated Chromel-Alumel thermocouple with reference junction in DI ice and water. The liquidus temperatures were measured by direct visual inspection of the solutions (melts) through a microscope attached to the furnace.

The ability to slide the furnace was very useful in drastically reducing to total times the solutions were at elevated temperature because the furnace could be preheated initially and then moved over the boat, and after each run the boat could be cooled down very quickly by sliding the furnace away and directly cooling the boat with a fan.

The solutions were prepared by weighing both of the components of each melt, In and InP, Ga and GaAs, In and InAs, and Ga and GaP for InP, GaAs, InAs, and GaP, respectively. The binary compounds were weighed with an accuracy of ± 0.5%.

The liquidus temperature measurement technique was standardized as follows:

Initially, the solution was quickly heated to approximately T_l + 10° and periodically shaken in order to dissolve all the components completely in the least possible time. The solution was then cooled down so it solidified by sliding the furnace away; it was then reheated and stabilized at approximately T_l − 3°C.

Key words: semiconductor, solubility, equilibrium.

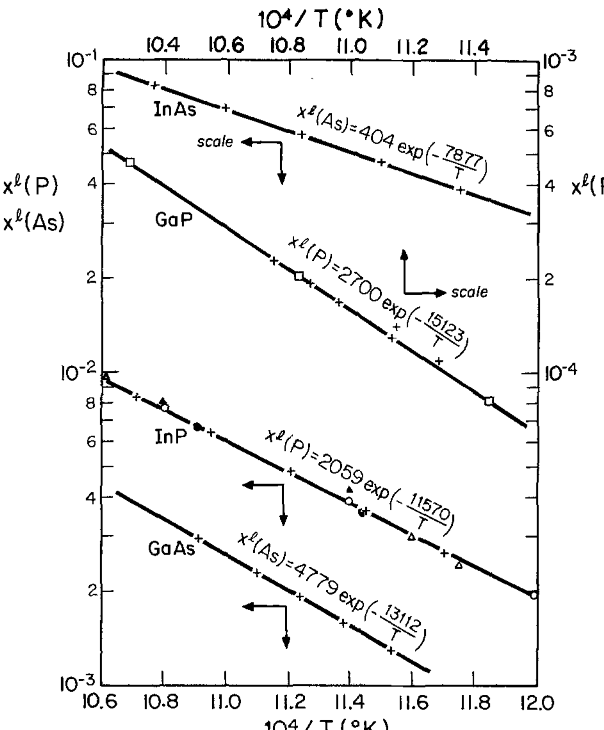

Fig. 1. In-P, Ga-As, In-As, and Ga-P solubility curves. Ref: +, This work; □, M. Ilegems *et al.* (9); ○, J. J. Hsieh (10); ●, N. Sol *et al.* (11); △, J. P. McVittie (12); ▲, R. N. Hall (13).

From there the temperature was increased slowly at 0.03°/min until the last piece of solid was observed to dissolve completely. The temperature at which this occurred was the measured value of T_l. The rate of decrease of T_l with time due to P evaporation was found to be in good agreement with the values reported for InP in Ref. (10). The heating rate used in the measurements reported here, 0.03°C/min, is slow enough so that there is thermodynamic equilibrium between the solid and liquid phases in the solution.

Table I. Measured liquidus temperatures, T^l, for (Ga-As), (In-As), (Ga-P), and (In-P) solutions containing the atomic fraction of arsenic or phosphorous indicated in the first column. The last column lists the liquid interaction parameter calculated from this data using Eq. [2].

	x^l	T^l (°C)	α_{lj} (cal/mole)

Liquidus Temperature Data and Liquid Interaction Parameter Values

The measured liquidus temperatures T, in the range 580°-670°C are listed in Table I and are presented in Fig. 1 together with data points in this temperature range from other workers. The agreement of our data with the few previously published points (9-13) is seen to be very good. A linear least squares fit to the experimental points in Fig. 1 yields the following expressions

$$\text{InP:} \quad x^l(\text{P}) = 2059 \exp(-11570/T) \quad [4]$$

$$\text{GaAs:} \quad x^l(\text{As}) = 4779 \exp(-13112/T) \quad [5]$$

$$\text{InAs:} \quad x^l(\text{As}) = 404 \exp(-7877/T) \quad [6]$$

$$\text{GaP:} \quad x^l(\text{P}) = 2700 \exp(-15123/T) \quad [7]$$

Values of the liquid interaction parameter were calculated at each liquidus temperature measured us-

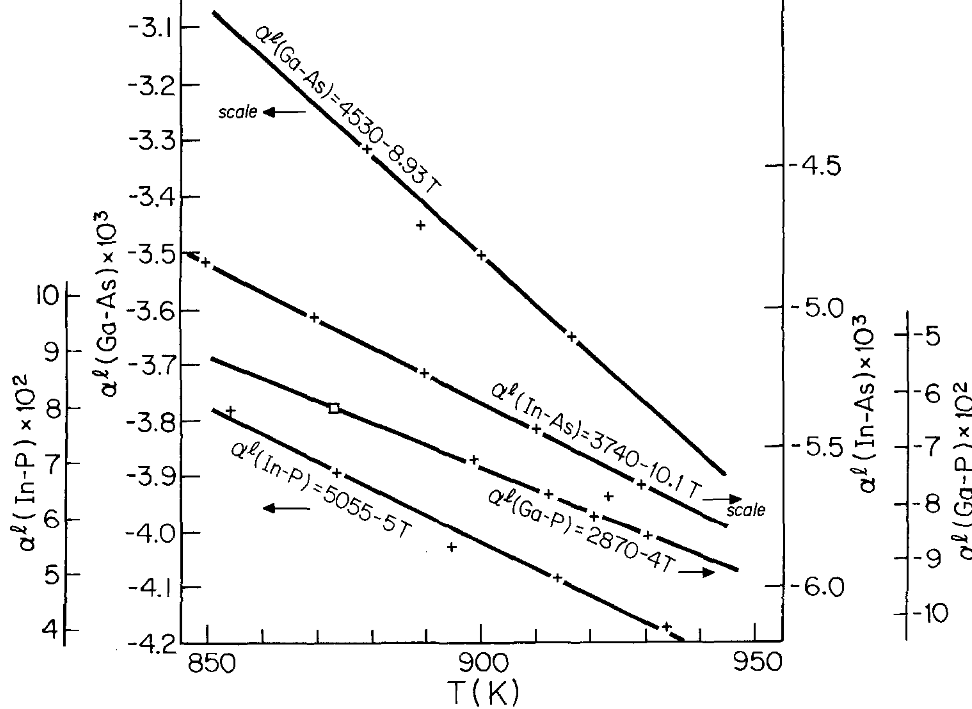

Fig. 2. The liquidus interaction parameters α^l(In-P), α^l(Ga-As), α^l(In-As), and α^l(Ga-P). The crosses are data measured in this work and the solid lines represent a least squares fit to a linear dependence on temperature.

Table II. Entropies and temperatures of fusion and liquid interaction parameters for InP, GaAs, InAs, and GaP.

	ΔS_F^{ij} (cal/mole-°K)		T_F^{ij} (°C)		α_{ij}^1 (cal/mole)
InP	15.2	[Ref. (6)]	1062	[Ref. (6)]	5055-5T
GaAs	16.64	[Ref. (5)]	1238	[Ref. (5)]	4530-8.93T
InAs	14.52	[Ref. (7)]	942	[Ref. (7)]	3740-10.1T
GaP	16.4	[Ref. (9)]	1470	[Ref. (9)]	2870-4T

ing Eq. [2]. The entropies and temperatures of fusion (S_F^{ij}, T_F^{ij}) used in this calculation, together with the resulting least squares linear fits of α_{ij} are presented in Table II, and Fig. 2.

While the data presented in Fig. 1 agree well with previously reported results, the interaction parameters presented in Table II differ significantly from previously reported values. This is true because the fit of a simple linear temperature variation for α_{ij} can only be made over a limited temperature range, as has been done here.

Rotating Ring Disk Electrode Study of the Hydrogen Peroxide Oxidation of Fe(II) and Cu(I) in Hydrochloric Acid

James F. Skinner

Department of Chemistry, Williams College, Williamstown, Massachusetts

Arnold Glasel, Li-chien Hsu, and B. Lionel Funt

Department of Chemistry, Simon Fraser University, Burnaby, Vancouver, British Columbia, Canada

ABSTRACT

The kinetics of the oxidation of electrochemically generated Fe(II) and Cu(I) by H_2O_2 in 2.0M HCl has been studied with a platinum rotating ring disk electrode over a range of concentrations and temperatures. The data have been analyzed with a digital simulation technique to give values of k_1 the rate constant for the rate-determining initial step in the oxidation. The value in the case of Fe(II) is $(2.2 \pm 0.5) \times 10^2 M^{-1} sec^{-1}$ at 25°C, considerably larger than the literature values of this reaction. Possible reasons for this discrepancy both in the experimental results and in the simulation technique are discussed. For the Cu(I) reaction, $10^2 k_1 = 1.5$, 2.6, and $4.0 M^{-1} sec^{-1}$, at 15°, 25°, and 35°C, respectively, giving an activation energy of 8.5 kcal. These are the first reported values for k_1 for the Cu(I) reaction.

The rotating ring disk electrode (RRDE) has been used in the investigation of diverse chemical systems (1-6) and a recent article (7) gave a very thorough review of the applications of this electrode system. Our previous results (8-10) have demonstrated the utility of such an electrode for the study of the steps in electrochemically initiated polymerizations. One of the most thoroughly investigated (11-14) redox polymerization initiators is the iron(II)-hydrogen peroxide system (Fenton's reagent), which generates the highly reactive hydroxyl radical.

Key words: oxidation, polymerization, kinetics.

Haberland and Landsberg (15) have reported a study of the kinetics of the iron(II)-hydrogen peroxide reaction using a gold rotating disk electrode (RDE), while Opekar and Beran (16) have studied this reaction on palladium, gold, and glassy carbon RDE. Bard and Prater (17) have used an RRDE for a limited study of the kinetics of this reaction, and they suggested a method (18) for determining rate constants based on a computer simulation of the appropriate hydrodynamic and reaction parameters. Bard and coworkers have subsequently analyzed the kinetics of a variety of reactions using the RRDE and the computer simulation.

The original purpose of the present study was to apply the RRDE to redox initiators other than Fenton's reagent, but our preliminary efforts to duplicate Bard's results suggested that a more thorough RRDE investigation of this system was necessary. An error in the numerical analysis led to a specific rate constant in apparently better agreement with the literature than was actually the case.[1] Data are reported here for an RRDE study of the iron(II)-hydrogen peroxide reaction over a range of concentrations and, in addition, the first kinetic data on the copper(I)-hydrogen peroxide reaction are reported over a range of concentrations and temperatures. The importance of certain experimental variables is discussed and the accuracy of the computer simulation method for analysis of RRDE data for kinetic parameters is reviewed.

Experimental

Apparatus.—The potentiostat used was similar to that described by Bruckenstein (19) and provided independent control of both electrodes. A Hewlett-Packard 3300A function generator was used to sweep the disk voltage and the currents were measured on a Hewlett-Packard T046A X-Y/Y′ recorder. The rotation speed, ω, was controlled to within 1% by a Carter motortachometer assembly with an electronic feedback circuit.

The cell has been described (8) and was thermostated to ±0.1°C. The ring and disk electrodes were constructed of bright platinum with dimensions $r_1 = 0.30$ cm, $r_2 = 0.33$ cm, and $r_3 = 0.43$ cm, where r_1, r_2, and r_3 are the outer radii of the disk, the insulating spacer, and ring, respectively. A heavy gauge, coiled platinum wire, was the counterelectrode in a side chamber isolated from the test solution by a porous glass frit. A saturated calomel electrode (SCE) was used as the reference electrode, in contact with the test solution through a Luggin capillary positioned 1 mm below the RRDE surface. The electrode was preconditioned immediately before each run, spinning for 5 min with zero potential applied in each of the following: 6M HCl, 2M H_2SO_4 saturated with $FeSO_4$, distilled water, and 2.0M HCl (the solvent used in the run). This treatment optimized the reproducibility of the electrode response.

For the measurements on the Fe(III) solutions, the ring was potentiostated at 1.00V (*vs.* SCE) while the disk was swept from 0.7 to 0.0V. The ring and disk currents were measured when the disk voltage was 0.20V, corrections being made for the residual solvent currents. For the Cu(II) solutions, the ring was held at 0.50V, while the disk was swept from 0.50 to −0.25V, with the currents being measured when the disk voltage was −0.2. The disk voltage was swept at approximately 10 mV/sec, the collection efficiency being essentially independent of sweep rate over the range 5-50 mV/sec for the test solutions. Currents were measured from the recorder traces with a precision of about 1%.

Reagents.—Certified reagent grade $FeCl_3 \cdot 6H_2O$ and $CuCl_2 \cdot 2H_2O$ were used as received. The 2.0M HCl solvent was prepared volumetrically from standardized concentrated reagent, and the 3% H_2O_2 was vigorously flushed with nitrogen and titrated against $KMnO_4$ before each run. The test solution containing the metal chloride was flushed with nitrogen before the run and nitrogen was passed over the surface of the solution in the cell during a run. Unless specifically noted as otherwise, currents were measured as a function of ω on the solution containing the metal ion, the H_2O_2 was then added with a syringe, the solution mixed, and purged with nitrogen. Currents were then measured in the presence of the H_2O_2.

Digital simulation.—The authors are indebted to Professor Bard for supplying a copy of the computer program for the digital simulation. The details of the technique have been presented (17, 20) and the same notation will be used here. The solution below the electrode is subdivided vertically and radially into small volume elements or boxes. The disk and ring currents depend on the concentrations of the electroactive species in the volume elements immediately below the electrode surfaces. The simulation takes into account changes in concentration resulting from convective flow due to the rotating electrode, from diffusion due to concentration gradients, and from the reactions occurring in the solution just below the electrode.

The relevant reactions are

$$Fe^{+3} + e^- \rightarrow Fe^{+2} \quad \text{at the disk}$$

$$Fe^{+2} + H_2O_2 \xrightarrow{k_1} Fe^{+3} + OH\cdot + OH^- \qquad [1]$$

$$Fe^{+2} + OH\cdot \xrightarrow{k_2} Fe^{+3} + OH^- \qquad [2]$$

$$Fe^{+2} \rightarrow Fe^{+3} + e^- \quad \text{at the ring}$$

where the following rate equations can be written for Eq. [1] and [2]

$$\frac{-d[Fe^{+2}]}{dt} = k_1[Fe^{+2}][H_2O_2] + k_2[Fe^{+2}][OH\cdot] = \frac{d[Fe^{+3}]}{dt} \qquad [3]$$

$$\frac{-d[H_2O_2]}{dt} = k_1[Fe^{+2}][H_2O_2] \qquad [4]$$

$$\frac{-d[OH\cdot]}{dt} = k_2[Fe^{+2}][OH\cdot] - k_1[Fe^{+2}][H_2O_2] \qquad [5]$$

If a steady-state approximation can be applied to $[OH\cdot]$, Eq. [5] can be equated to zero, and Eq. [3] rewritten as

$$\frac{-d[Fe^{+2}]}{dt} = 2k_1[Fe^{+2}][H_2O_2] = \frac{-d[Fe^{+3}]}{dt} \qquad [6]$$

In Eq. [1]-[6], Fe^{+3}, and Fe^{+2} may be replaced by Cu^{+2} and Cu^{+1}, respectively.

Defining $FA(J,K)$, $FB(J,K)$, and $FC(J,K)$ as the fractional concentrations of Fe^{+3}, Fe^{+2}, and H_2O_2, respectively, in a given volume element (J,K), the change in concentration due to the reaction within that volume element will be DEL, Eq. [7], and the corrected concentrations will be given by Eq. [8]-[10]

$$DEL = XKTC*FB*FC \qquad [7]$$

$$FA(J,K) = FA(J,K) + DEL \qquad [8]$$

$$FB(J,K) = FB(J,K) - DEL \qquad [9]$$

$$FC(J,K) = FC(J,K) - 0.5*DEL \qquad [10]$$

where $XKTC$ is a dimensionless rate parameter given as

$$XKTC = (2k_1C_A{}^o\nu^{1/3})/(\omega D^{1/3}(0.51)^{2/3}) \qquad [11]$$

$C_A{}^o$ is the bulk concentration of Fe^{+3}, ν is the kinematic viscosity, ω is the rotation speed, and D is the diffusion coefficient of Fe^{+3}. The result of the simulation is the solid curve shown in Fig. 1 where m is the bulk molarity ratio, $[H_2O_2]/[Fe^{+3}]$, and N, the collection efficiency, is the ratio of the ring current to the disk current at a given ω.

To simplify comparison of the present results with those of Bard and Prater (17), their values of 5.0×10^{-6} cm²/sec and 1.0×10^{-2} cm²/sec have been used for D and ν, respectively, in calculating k_1 [for both Fe(III) and Cu(II) at 25°C] from the interpolated values of $XKTC$ using Eq. [11]. Diffusion coefficients are not available for Cu(II) and Fe(III) in 2.0M HCl.

[1] Communication between the authors and Professors Bard and Prater confirm this error.

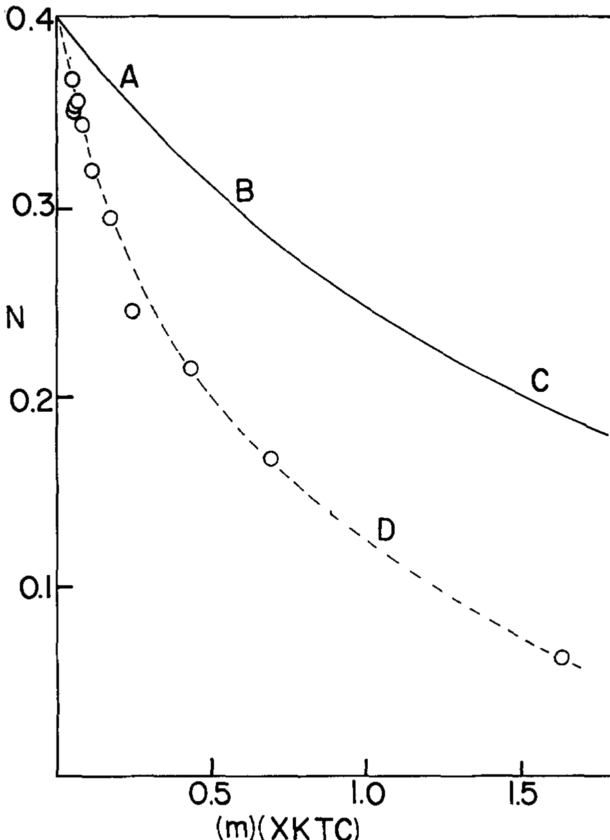

Fig. 1. Simulated collection efficiency *vs.* *(m) (XKTC)*. See Discussion for explanation of curve *D* and of points A, B, and C.

Jahn and Vielstich reported (21) a value (at 25°C) of 6.5×10^{-6} for Fe(III) in 1M $HClO_4$ using an RDE. Beran (16) reported a value of 5.2×10^{-6} in 0.1M HCl using an RDE. Kolthoff and Lingane (22) give a value of 7.2×10^{-6} for Cu(II) in 1M KCl, while Bruckenstein (23) reported a value of 5.7×10^{-6} for Cu(II) in 0.2M H_2SO_4.

An attempt has been made to correct both D and ν for the Cu(II)results at 15° and 35°C. Delahay (24) reported values for D for Fe(III) in 0.25M H_2SO_4 at two temperatures. The temperature dependence represented by these two values was used to correct the 25° value of 5.0×10^{-6} to 3.4×10^{-6}, and 6.6×10^{-6} at 15° and 35°C, respectively. Kinematic viscosities for 2.0M HCl have been measured (25) which allowed correction of the 1.0×10^{-2} value at 25° to 1.25×10^{-2}, and 0.82×10^{-2} for ν at 15° and 35°C, respectively.

Results and Discussion

The detailed results for one run are shown in Table I while the results for runs at other concentrations are shown in condensed form in Table II for Fe(III)-H_2O_2 and in Table III for Cu(II)-H_2O_2. An average value for k_1, with an average deviation, is given for each run as well as values, in parentheses, for additional runs at the same concentrations. Figure 2 shows current-voltage sweeps for the disk and the ring for the 2.0M HCl solvent, for the solvent with H_2O_2, and for an Fe(III)-H_2O_2 solution. In this case, the H_2O_2 was added first and then the $FeCl_3 \cdot 6H_2O$ was added to the same aliquot of solvent.

Figures 3 and 4 show the effect produced by the solution reactions (Eq. [1] and [2]) on the disk and ring currents for Fe(II)-H_2O_2 and Cu(II)-H_2O_2 (only the one-electron reduction of Cu(II) is shown). Figure 5 shows both the one-electron and two-electron Cu(II) disk reductions for the Cu(II)-H_2O_2 solution. The ring current disappears over the range of disk voltages where the Cu(II) is completely reduced and plated out

[1] Calculated from Eq. [15] $10^2k_1 = 2.1 \pm 0.3$
($10^2k_1 = 2.5 \pm 0.3$, 2.7 ± 0.5, 2.3 ± 0.3, 2.5 ± 0.5, 2.6 ± 0.4)

on the disk. The sharp rise in disk current at −0.2V in Fig. 3 and −0.5V in Fig. 5 indicates the onset of solvent decomposition. Figure 6 gives the linear dependence (without H_2O_2) of the currents on $\omega^{1/2}$ as predicted by the Levich equation. Figures 3-6 are in good general agreement with what has been previously reported (15-17, 19). Figure 7 shows the dependence of the collection efficiency on H_2O_2 concentration for fixed Fe^{+3} concentration.

The kinetics of the oxidation of metal cations by hydrogen peroxide has received considerable attention, with Fe(II) being the most thoroughly investigated. It is generally accepted that the reaction proceeds through the two one-electron transfer steps given in

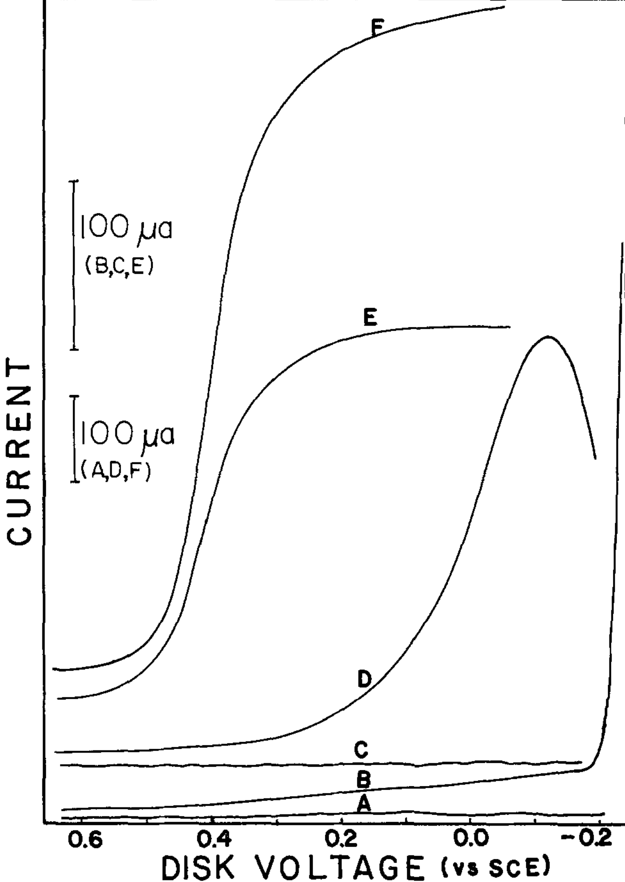

Fig. 2. Current-voltage sweeps in 2.0M HCl at 25°C: A and B for ring and disk, respectively, solvent only, ω = 143 rad sec^{-1}; C and D for ring and disk, respectively, 6.40 mmole H_2O_2, ω = 87; E and F for ring and disk, respectively, for 6.4 mmole $FeCl_3$-6.4 mmole H_2O_2, ω = 87. Ring at 1.00V (vs. SCE). The sweeps have been shifted vertically for clarity so that the current base lines do not coincide.

There are numerous literature values for k_1 for the Fe(II)-H_2O_2 reaction in a wide variety of supporting electrolytes. For the purpose of using the present results to test rigorously the digital simulation, a careful review of the literature has been made.

Baxendale (26) reported a value of $53M^{-1}$ sec^{-1} at 25°C in acidic perchlorate, sulfate, or chloride, Sutin (27, 28) reported values of 58-64 in chloride-perchlorate mixtures, while Wells (29) gave values of 50, 54, and 69 in 1M $NaClO_4$, 1M $HClO_4$, and 1M NaCl, respectively.

There have been four studies reported where Fe(II) was generated electrochemically from Fe(III), with the peroxide reaction catalytically regenerating the Fe(III). In a polarographic study at the dropping mercury electrode, Delahay (24) reported values at 0.6° and 31.4°C in 0.25M H_2SO_4 from which a value of approximately 59 can be interpolated for 25°C. At a gold rotating disk electrode, Haberland (15) calculated a value of 73 in 1M KCl at 25°C, using a graphical method of analysis, while Beran (16), using a method of moments developed by Bruckenstein (30), calculated a value of 92 at 25°C in 0.1M HCl using a rotating palladium disk electrode. In the publication of their digital simulation technique for the analysis of RRDE data, Bard and Prater (17) reported a value of 105 $\pm$ $5M^{-1}$ sec^{-1} for k_1 at 25°C for a 6.4 mmole $FeCl_3$, 3.2 mmole H_2O_2 solution in 2M HCl. Their calculations were incorrectly based on the $m = 1.0$ working curve (Fig. 1) rather than on the $m = 0.5$ curve (see Footnote 1). Recalculation of their data with the authors' form of the program (see Experimental) using an $m = 0.5$ working curve with the dimensions of their electrode gave $k_1 = 202 \pm 15$, in agreement with the values in Tables I and II.

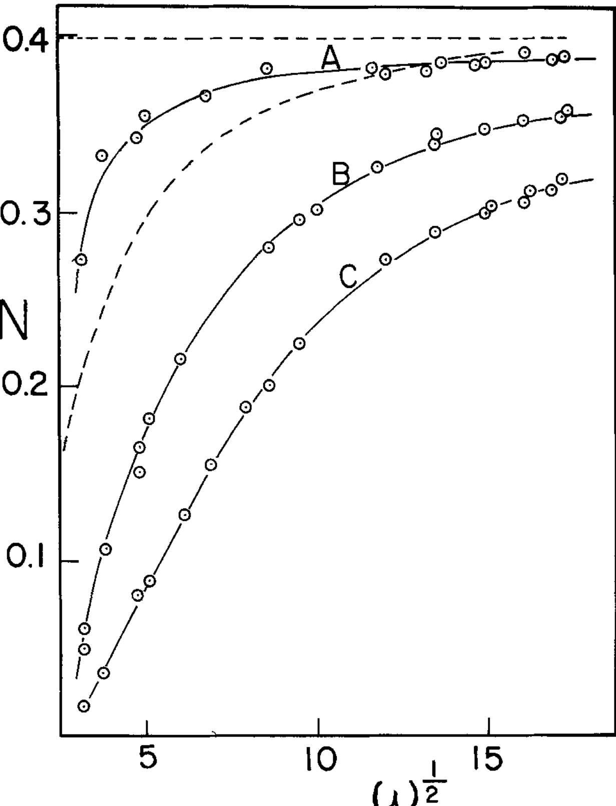

Fig. 7. Experimental collection efficiencies at 25°C for 6.45 mmole $FeCl_3$ in 2.0M HCl: A, 1.28 mmole H_2O_2; B, 6.45 mmole H_2O_2; and C, 12.8 mmole H_2O_2. See Discussion for explanation of dashed curve.

The authors are not aware of a literature value for k_1 for Cu(I) in either an aquo or chloro complex. This may reflect the well-known lack of stability of this oxidation state of copper in aqueous medium. An advantage of the present technique is that Cu(I) is generated immediately prior to its reaction with H_2O_2. Anbar (31) reported a value of $k_1 = 850M^{-1}$ sec^{-1} in the case of the bis(bipyridyl) copper (I) complex ion at 25°C. There have been numerous studies (14, 32-34) of the catalytic role played by the more stable Cu(II) in a variety of reactions, in some instances in the presence of Fe(II) and H_2O_2.

Czapski (35) reported values of k_1 of 2.8×10^4, 2.7×10^2, and $5.8M^{-1}$ sec^{-1} for chromium (II), titanium(III), and vanadium (IV) in $HClO_4$ at 25°C.

To use the simulated working curve in Fig. 1, a corrected collection efficiency is calculated from Eq. [15] at each ω

$$N = 0.3994(N^{w}/N^{wo})$$
$$= 0.3994((i_R^{w}/i_D^{w})/(i_R^{wo}/i_D^{wo})) \quad [15]$$

where the superscripts w and wo indicate iron or copper solutions with H_2O_2 and without H_2O_2, respectively, and 0.3994 is the value of the collection efficiency calculated from electrode dimensions. Although N^{wo} should be independent of ω, there appeared a small decrease in N^{wo} at the higher ω, from a value close to 0.3994. Equation [15] eliminates this dependence on ω, presumably due to turbulence from irregularities in the construction of the electrode.

Several points need to be made in regard to the rate constants presented in Tables I-III. Reaction concentrations have been varied from having a ten-fold excess of cation ($m = 0.1$), to concentrations equimolar in cation and peroxide ($m = 1.0$), to having a ten-fold excess of peroxide ($m = 10$). Assuming that the reaction is first order in each reactant, a one hundred-fold increase in reaction rate would be expected between the slowest and fastest cases. The computer simulation gives k_1 values (averaged over a run) in general agreement over this wide range of concentrations. However, the over-all average value of 240 ± 40M^{-1} sec^{-1} for the Fe(II)-H_2O_2 reaction is three to four times the literature values. On closer examination of the k_1 values for a given run, it can be seen that there is an increase in k_1 with increasing ω.

Figure 8 includes the Cu(I)-H_2O_2 results ($m = 1.0$) from Table III as well as literature values (26, 36) for the Fe(II)-H_2O_2 reaction. It is interesting to note that an activation energy of 8.5 kcal is found for the Cu(I) reaction, in general agreement with the 9.6 kcal found for the Fe(II) reaction (37). This satisfactory temperature dependence suggests strongly that k_1 values calculated for the copper reaction using the digital simulation are indeed rate constants for a homogeneous solution reaction and not for some more complicated process occurring at the electrode surface. The fact remains, however, that the absolute value of k_1 is high, at least in the iron case where good literature values are available.

Reasons for this discrepancy could be experimental in origin or could result from some of the approximations made in deriving the computer simulation. Both of these possibilities will now be discussed.

There is a question as to the state of complexation of the Fe(III)/Fe(II) and Cu(II)/Cu(I) during both the electrode processes and the homogeneous solution reactions. The formation constants of chloro complexes of Fe(III) and Cu(II) in aqueous solution (38-40) are in the range of 1-10, suggesting that several complexed species will be present in the 2.0M HCl: $FeCl^{+2}$, $FeCl_4^-$, $CuCl^+$, and $CuCl_3^-$. There is less information

on the stability of the chloro complexes of Fe(II) and Cu(I). Both Sutin (28) and Wells (29) have found a small dependence of k_1 for the Fe(II)-H_2O_2 reaction in going from 0-1M Cl^- at constant ionic strength, but nothing large enough to explain the discrepancy in the present results. It is unclear as to whether the complexation will change for the cation following its being reduced at the disk but before it reacts with the H_2O_2, and if such a change would affect the calculated rate constants.

Another possible source of error, most serious for the Fe(II)-H_2O_2 data at low ω, comes from the fact that in measuring the disk currents at 0.2V, conditions of limiting current flow were not always satisfied. This was not a problem with the ring currents which did level out (see Fig. 2-4). (While the ring and disk currents are anodic (−) and cathodic (+), respectively, the absolute magnitudes are shown in the figures). This is frequently a problem in polarographic investigations and, indeed, the current-voltage curves for Beran's RDE study (16) of the Fe(II)-H_2O_2 reaction showed considerable slope. The digital simulation is based on the assumption that ring and disk currents are measured under conditions of diffusion limited current flow. In selecting a less positive voltage, say 0.1V for measuring the currents, to insure better that a limiting current is being measured, the question of direct reduction of H_2O_2, in the case of iron, becomes more serious (see below). Going to a lower voltage would have the greatest effect on i_D^{w} in Eq. [15], giving a slightly larger value of N and, in turn, a smaller k_1.

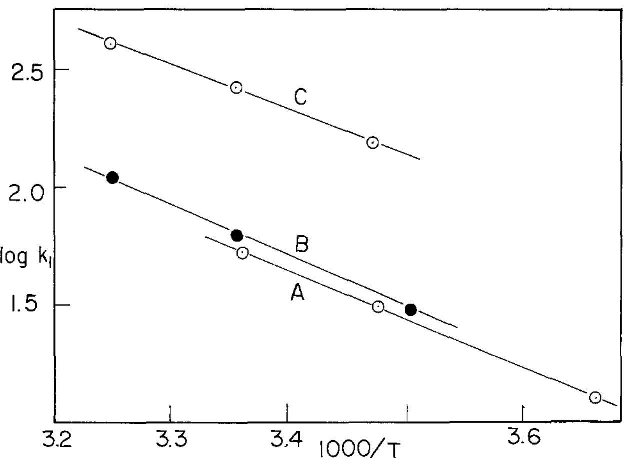

Fig. 8. Arrhenius plot: A, Fe(II)-H_2O_2, Ref. (27); B, Fe(II)-H_2O_2, Ref. (37); C, Cu(I)-H_2O_2, This work.

The slope of the disk current trace is greatest for low ω and hence this error in N would be greatest at low ω, but it is in the range of low ω that the N-$XKTC$ working curve is least sensitive to change in N. On balance, it is felt that this is probably not a serious source of error in k_1.

The most serious question that can be raised about the experimental validity of the results in Tables I-III concerns whether the H_2O_2, in addition to being reduced by Fe(II) in solution, is partially or completely reduced directly at the disk electrode, giving a larger disk current than would be found for the disk reduction of Fe(II) alone. The electrochemical reduction of both hydrogen peroxide and oxygen has been thoroughly studied as a function of pH at different metal electrodes, with particular emphasis on elucidating the role of the peroxide in the complete reduction of oxygen.

In some of the earliest applications of the RRDE, Nekrasov and Myuller (41) reduced O_2 to H_2O_2 at the disk and were able to detect the H_2O_2 at the ring electrode. The nonlinear dependence of the ring and disk currents on $\omega^{1/2}$ led them to postulate that the electrode reactions of O_2 and H_2O_2 are slow, not diffusion controlled, and generally irreversible. Extensive investigation by Bockris and Damjanovic (42, 43) on the electrochemical reduction of O_2 has confirmed these results in acidic and basic solution and pointed to the importance of the pretreatment of platinum electrodes in determining the degree of adsorption of H_2O_2. In the RDE study of the Fe(II)-H_2O_2 reaction, Beran (16) found such considerable reduction of H_2O_2 at a platinum electrode in 0.1M HCl that satisfactory measurements could not be made, while neither Haberland [(15), using a gold RDE] nor Bard [(17), using a carbon paste RRDE] made any reference to the problem for the solutions studied. Bard did report the appearance of bubbles at the electrode for very high H_2O_2 concentrations.

The current-voltage sweep for H_2O_2 in HCl in Fig. 2 clearly shows evidence of H_2O_2 reduction at the disk. Although the magnitude of this current, at a fixed H_2O_2 concentration and ω in the absence of Fe(III), was reproducible for a given solution, it did vary for a series of runs under apparently identical conditions. In the acidic medium used, there was never a ring current simultaneous with the increased disk current. Figure 9 shows that the magnitude of the disk current is proportional to the H_2O_2 concentration, but in Fig. 9 the maximum, present in Fig. 2 at -0.1V, is not apparent. Figure 10 shows that the electrochemical reduction of H_2O_2 is clearly quite different from the reduction of Fe(III), in that the former depends very markedly on the rate at which the disk potential is varied, at constant ω, while the disk current for the Fe(III) reduction is independent of this sweep rate. Different rates of electron transfer and degrees of adsorption of the electroactive species are indicated.

Figure 11 shows a current-voltage sweep of both the disk and ring in solution containing both reducible species, Fe(III) and H_2O_2. While the maximum in $i_D{}^w$ at -0.1V is clearly the result of H_2O_2 reduction (probably irreversible because of the absence of any corresponding increase in ring current), the authors suggest that at $+0.2$V, the predominant contribution to the disk current is the Fe(III) reduction.

Although the disk currents for H_2O_2 without Fe(III) were somewhat variable, Fig. 12 shows the largest disk currents that were obtained at 0.2V for 6.4 mmole H_2O_2. Two aspects of Fig. 12 are important. The currents are small in comparison to the disk current given in Tables I-III. At 6.4 mmole $FeCl_3$ in 2M HCl, a disk current of 423 μA was obtained at 0.2V at $\omega = 36$ radians sec^{-1}, while for 6.4 mmole H_2O_2 under the same conditions the disk current was about 50 μA. The second point is that the disk currents in Fig. 12 decrease with increasing ω, in marked contrast to the behavior predicted for diffusion-controlled current flow. For the run shown in Table I, for example, there is no certainty that there was a peroxide current of this magni-

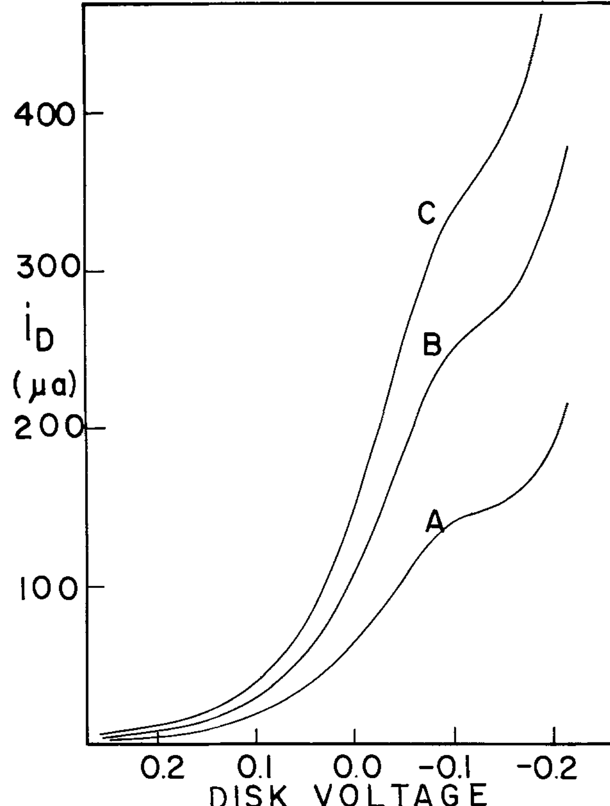

Fig. 9. Current-voltage sweeps in 2.0M HCl at 25°C: A, 5.95 mmole H_2O_2; B, 11.8 mmole H_2O_2; and C, 17.6 mmole H_2O_2. ω = 45 rad sec^{-1} and ring at 0.25V.

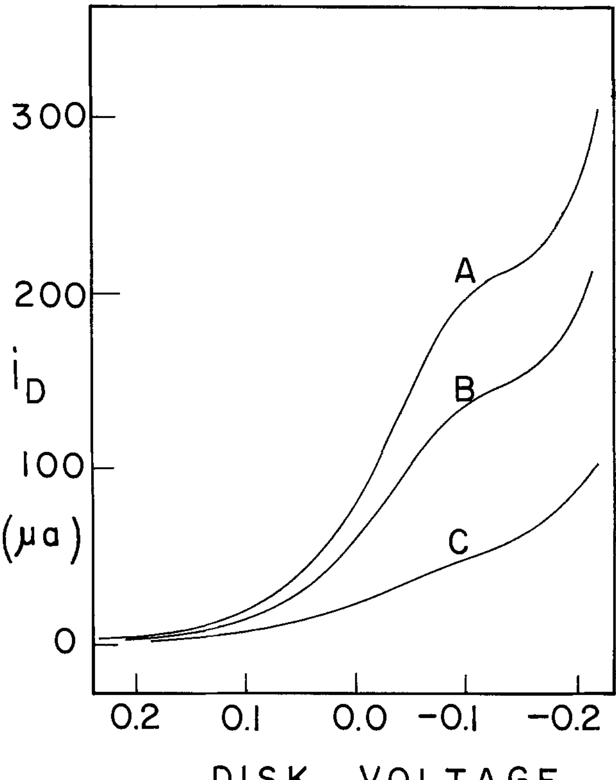

Fig. 10. Current-voltage sweeps for 5.95 mmole H_2O_2 in 2.0M HCl at 25°C at different sweep rates: A, 22 mV sec^{-1}; B, 9 mV sec^{-1}; and C, 4 mV sec^{-1}. ω = 45 rad sec^{-1} and ring at 0.25V.

tude. but our experience suggests that the values given in Fig. 12 represent the largest contribution that could have been expected. In all the runs given in Tables I-III, the $FeCl_3$ or $CuCl_2$ was dissolved first, with currents measured, and then the H_2O_2 was added and the resultant currents measured. It was not possible to measure the disk current for just the H_2O_2 for such a run. The disk currents given in Table IV are taken from Table I, corrected for the direct electrode reduction of H_2O_2 of a magnitude indicated by the data in Fig. 12. New values of N and k_1 are given in Table IV. The correction does decrease k_1 from 210 to 160, but this value remains considerably larger than the values 50-70M^{-1} sec^{-1} reported in the literature. It must be also emphasized that the $i_D^{H_2O_2}$ values in Table IV may represent too large a correction.

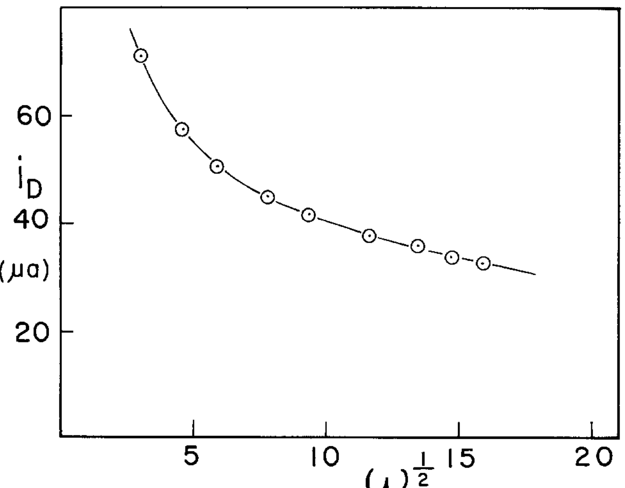

Fig. 12. Disk currents for 6.4 mmole H_2O_2 in 2.0M HCl at 25°C. Current measured at a disk voltage of 0.2V.

In the case of the Cu(I)-H_2O_2 reaction, a much stronger case can be presented for arguing that in the presence of both the Cu(II) and H_2O_2, only Cu(II) is reduced at the disk. In Fig. 2, the onset of solvent decomposition (H_2 evolution) at the disk becomes very pronounced in the 2.0M HCl at a disk voltage just negative of −0.2V. In Fig. 5, with Cu(II) and H_2O_2 in the 2.0M HCl, the solvent decomposition is shifted cathodically to about −0.5V, with the one electron reduction of Cu(II) occurring near −0.2V where the ring and disk currents were measured. Again in Fig. 2 and 9, the contribution to the disk current from the H_2O_2 reaches a maximum at about −0.1V, but in Fig. 5 there is no evidence of a maximum in the disk current which could be attributed to H_2O_2 reduction in the region of −0.1V.

In Fig. 13, the disk currents (all measured at −0.2V) are given as a function of $\omega^{1/2}$ for $CuCl_2$ in 2.0M HCl, for H_2O_2 in the same solvent, and for both $CuCl_2$ and H_2O_2 in this solvent. The current in the third case is clearly not the sum of the currents in the first two cases. In the presence of HCl, H_2O_2, and Cu(II), the only species that is reduced to a significant extent at −0.2V on the disk is the Cu(II). Bruckenstein (44) has suggested that Cu(I) is strongly absorbed on a platinum RRDE and this may be the cause of the elimination of the two other electrode reactions which clearly occur in the absence of Cu(II). In summary, there is little reason to believe that the Cu(II)-H_2O_2 data in Table III need to be corrected for direct reduction of H_2O_2 at the disk electrode.

While the authors believe that the direct reduction of H_2O_2 at the disk is not a major source of error, the direct disk reduction of the highly reactive hydroxyl radical, ·OH, produced in Eq. [1], is possible. An increase in the disk current as the result of reduction of ·OH would probably be offset by a decrease in disk current from reduction of Fe(III) as less of the latter will be produced in reaction [2]. Reaction [2] is extremely fast so the concentration of the radical will be low.

Included in Fig. 7 is a hypothetical curve calculated on the assumption that $m = 1.0$ working curve in Fig. 1 is correct and that $k_1 = 60M^{-1}$ sec^{-1}. The discrepancy between actual data ($m = 1.0$) and this calculated curve is very great and far exceeds any reasonable experimental error.

Having reviewed the possible sources of experimental uncertainty which might explain the high k_1 values, we would now like to look closely at the digital simulation which is used to generate the working curve (Fig. 1) from which k_1 is calculated from an experimental collection efficiency. An uncertainty of ±1% in each of the four currents used in Eq. [15] is realistic for the present work, which would result in a maximum uncertainty of ±4% in N. On the $m = 1.0$ curve in Fig. 1, an uncertainty of ±4% in N produces, on interpolation to the curve, values of $XKTC$ (and k_1) with uncertainties of ±45, 18, and 5% at points A, B,

and C, respectively. Therefore, the uncertainty in the k_1 values in Table I-III increases markedly in going to higher ω. This uncertainty, based on the use of the working curves, is given in Table IV in parentheses for the k_1 values. Within these limits of uncertainty, k_1 values are relatively constant over the range of ω values, although in some runs there does appear to be a more consistent increase in k_1 with increasing ω.

To generate a curve (Fig. 1) simulating the dependence of collection efficiency on the rate of the following reaction in solution, the program must calculate the time dependence and the location dependence of the concentrations of the electroactive species in a manner that closely resembles the actual reaction mechanism occurring in the solution. Equations [1] and [2] give what is generally assumed to be the reaction mechanism. It should be noted that k_2 is of the order of $10^8 M^{-1}$ sec^{-1}, making Eq. [1] the rate-determining step (45, 46). The computation steps specific to the kinetic processes are given by Eq. [8-10]. Bard (17) used neither the factor of 2 in Eq. [11] nor the factor of 0.5 in Eq. [10], and made no reference to the detailed reaction mechanism. The authors present what they believe to be a more consistent treatment.

Figure 1 shows both the simulated dependence of collection efficiency on the rate constant (solid curve) and the dependence of the observed collection efficiency (data from Table I) on rate constant (circles), using the literature value of $60M^{-1}$ sec^{-1} for k_1. Although there is no experimental evidence to support the idea, if one introduces a factor of 2 or 3 before the *DEL* terms in Eq. [8] and [9], a steeper working curve results, giving smaller k_1 values for a given ω. This arbitrary change has the effect of increasing the rate of change of the concentrations of Fe(III) and Fe(II), relative to the rate of disappearance of [H_2O_2], in the reaction volume beneath the electrode.

The digital simulation (17) gives not only the dependence of *N* on the kinetic parameter, XKTC, but also the dependence of the limiting disk and ring currents on *XKTC*. At a given ω, the disk current increases while the ring current decreases with increasing *XKTC*. For a given *m*, say 1.0, one can generate curves of i_R^w/i_R^{wo} *vs.* *XKTC*, and i_D^w/i_D^{wo} *vs.* *XKTC*. Table V shows the k_1 values calculated using just the ring currents, just the disk currents and, finally, both currents through Eq. [15]. A Cu(II)-H_2O_2 run was chosen for this analysis to minimize the possibility of an error in i_D^w resulting from reduction of H_2O_2 at the electrode. Findings very similar to those in Table V have been found for a recalculation of an Fe(III)-H_2O_2 run. Somewhat lower k_1 values are found when just the ring currents are used, while using just the disk currents gives much larger values of k_1, further from the literature values in the case of Fe(II). These results suggest that in the simulation, the dependence of the disk current on the reaction kinetics may need further study, specifically the treatment of the volume of solution immediately below the disk electrode as a single "box" in the (*J*,*K*) grid. It may be that in the catalytic mechanism, the current resulting from the repeated reduction of Fe(III) or Cu(II) at the disk is not being correctly calculated.

ABSTRACT

The cathodic dark current at n-type Nb-doped TiO_2 and H_2-treated $SrTiO_3$ electrodes in $Fe(CN)_6^{3-}$, Fe^{+3}, or $IrCl_6^{2-}$ aqueous solution was measured as a function of applied voltage, concentration of oxidizing agent, and pH. Two distinct current regimes were observed, differing by their Tafel slopes and by their concentration dependence. The most marked feature of the results was the saturation of the current as a function of concentration in the high current-density region. The experimental data were interpreted on the basis of a model involving electron transfer through surface states.

The study of the cathodic dark current-voltage behavior at n-type semiconductor electrodes is important from both the fundamental and the practical point of view. The fundamental importance lies in the possibility of testing the direct electron transfer model and in the elucidation of the reaction mechanism. This kind of study may lead to an extension of our knowledge on electrochemical reaction mechanisms on semiconductor electrodes in general and may hence also have a certain significance to photoelectrochemical reactions which are being used for solar energy conversion. A more direct connection between the cathodic dark current at n-type semiconductors and the problem of electrochemical solar energy conversion is that the cathodic current characteristics may enter into the expression for the open-circuit photovoltage as a function of light intensity [see, *e.g.*, Ref. (1)].

Cathodic dark current-voltage studies on n-ZnO in the presence of several oxidizing agents have revealed a behavior which is essentially in accordance with the

Key words: semiconductor, cathode, interface, voltammetry, kinetics.

simple direct electron transfer model (Tafel slopes of nearly 0.06V, proportionality between current density and oxidizing agent concentration) (2-4). More complicated behavior, including higher Tafel slopes and fractional powers in the relationship between current density and concentration, has been reported for n-CdS and n-CdSe and has been interpreted by assuming the participation of surface states in the electrode reactions (5). In a recent article (6), Schmickler interpreted several literature results on cathodic currents at oxide electrodes by assuming tunneling of electrons through a thin space charge layer. The present cathodic study pertains to n-TiO_2 and n-$SrTiO_3$ electrodes. Preliminary results on TiO_2 in aqueous solution by ourselves and other groups (7-9) led to Tafel slopes, considerably higher than the 0.06V expected by simple theory. In Ref. (9), this phenomenon was associated with the presence of surface states. The existence of such states has been assumed in order to interpret luminescence measurements as well in the case of TiO_2 (9, 10) as of $SrTiO_3$ (11) electrodes. The single crystal TiO_2 samples used in the present work were made semiconducting by doping with Nb during growth. Such samples were preferred to crystals reduced in H_2 with the idea of avoiding the possible complications of nonuniform doping. Since only insulating $SrTiO_3$ crystals were available to us, they were made semiconducting by partial reduction in hydrogen.

Experimental

Preparation of the electrodes.—A synthetic monocrystalline boule of Nb-doped rutile (TiO_2 + 0.05 weight percent (w/o) Nb_2O_5) and one of undoped $SrTiO_3$ were purchased from National Lead Industries (South Amboy, New Jersey). Several samples were cut perpendicularly to the growth direction. In what follows, the TiO_2 samples will be indicated as (a), (b), (c), (d), the $SrTiO_3$ samples as (v), (w), (x), (y), and (z). By x-ray analysis, it was established that the faces exposed to the electrolyte were (001) for rutile and (311) for $SrTiO_3$. The preparation of the electrodes of both substances was similar and consisted of sandpapering, followed by polishing with alumina powder of decreasing grain size. The samples were etched for 1 hr in molten NaOH and subsequently rinsed in HCl or HNO_3 and in distilled water. In order to make the $SrTiO_3$ crystals semiconducting, they were heated between 900° and 1000°C in a H_2 flow for several hours. The rear side of each specimen was connected to a metallic lead by means of In, which was melted onto the surface. Further details on the mounting of the samples have been given in a previous paper (12).

Donor concentrations, determined by capacitance measurements (13), were of the order of 10^{18}-10^{19} cm^{-3}. For TiO_2, this concentration range is in agreement with the value, calculated from the concentrations of Nb_2O_5 specified by the furnisher, whereas for $SrTiO_3$, it is consistent with the values deduced from Hall measurements by Perluzzo and Destry (14) under the same conditions of reduction in H_2. From impedance measurements, carried out on specimen (d), the flatband potential V_{fb} at $pH = 0$ was established to be at $-0.30V$ *vs.* SHE for Nb-doped TiO_2. It has not been established yet whether the difference between this value and that for H_2-treated TiO_2 [+0.15V *vs.* SHE (7)] is significant or not. Frequency-independent capacitance results on $SrTiO_3$ were obtained by our group (13) and by Tench and Raleigh (15), the V_{FB} values at $pH = 0$ being -0.60 and $-0.20V$ *vs.* SHE, respectively. Hitherto, no satisfactory explanation is available for the rather large discrepancy between both values. For the following discussion, the mean value ($-0.40V$ *vs.* SHE) will be adopted.

Apparatus.—The cell was identical to that described in a previous paper (12) and contained the electrode under investigation, a Pt counterelectrode, and a saturated mercurous sulfate reference electrode. Before each experiment, the electrodes were immersed for 12 hr in indifferent electrolyte solution of the same pH as the redox solution used in the cathodic experiment and for 3 hr in the redox solution at a voltage close to the region where the measurements were to be performed. Current measurements were carried out potentiostatically and potentiodynamically. Using a potentiostatic arrangement, the currents were read after a stabilization time which, in the case of measurements with varying concentration, could amount to 1 hr. Potentiodynamic measurements were performed with an apparatus allowing variable rate of potential sweep. In order to avoid hysteresis in the potential/current plot, the sweep rate was kept at a low value (≤ 70 $\mu V \cdot sec^{-1}$). The potentiodynamic results obtained this way were identical with potentiostatic measurements. All measurements were performed in darkness at room temperature while bubbling high purity nitrogen through the solution.

Electrolyte solutions.—All solutions used in the present work were prepared with deionized water and reagent grade chemicals. They all contained 0.25M K_2SO_4 as the indifferent electrolyte. The proton concentration was fixed at $pH = 9.4$ or 4.6 by making solutions of 0.1M $Na_2B_4O_7 \cdot 10\ H_2O$ and 0.05M HAc/0.05M KAc, respectively; pH values in the neighborhood of 2 or 12 were adjusted by adding H_2SO_4 or KOH. The concentration of Fe^{3+} was determined after reduction with a Jones reductor by titration with $KMnO_4$. The concentration of the oxidizing agents will be specified in the results.

Results

The cathodic dark current was measured for Nb-doped TiO_2 and for H_2-treated $SrTiO_3$, in a voltage range corresponding to the presence of a depletion region, as a function of applied voltage, of the nature and concentration of oxidizing agents in solution, and of pH.

j-V relationship.—Without any oxidizing agents added, the current density j within the voltage range of our experiments was negligibly low. Hence, effects due to the reduction of protons, mentioned in the literature for TiO_2 (16, 17), are not to be considered in our case.

In Fig. 1, typical log $|j|$ *vs.* V plots are shown, as observed on samples (a), (c), and (d) for TiO_2 and on samples (v), (w), (x), and (y) for $SrTiO_3$ upon addition of sufficiently large concentrations of $Fe(CN)_6^{3-}$, Fe^{3+}, or $IrCl_6^{2-}$. At high current densities, the relationship appeared to be linear. The corresponding Tafel slopes $|dV/d \log |j||$ were found for a given simple

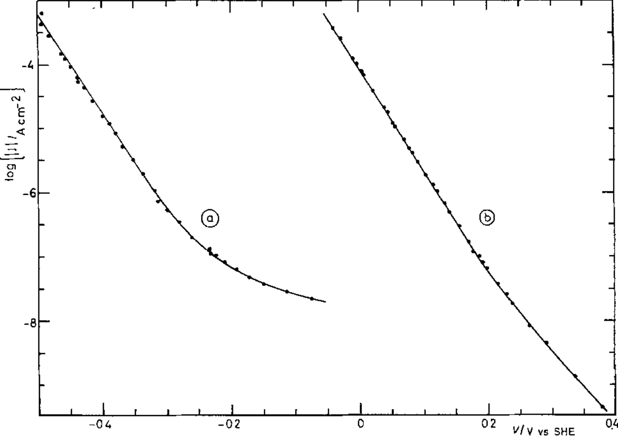

Fig. 1. Logarithm of the cathodic dark current density $|j|$ as a function of electrode potential. TiO_2 specimen (d): curve a $pH = 12.3$, curve b $pH = 4.8$.

and electrolyte composition, to be reproducible to within 2 mV, and to have values ranging around 63 mV. For the highest current densities ($> 10^{-4}$ A-cm^{-2}), dependence on nitrogen bubbling was observed, indicating diffusion limitation in the solution; in what follows, only those results will be considered which did not show this effect. For TiO_2 sample (b) and $SrTiO_3$ sample (z), higher and less reproducible Tafel slopes were found in this region (70-80 mV).

At low current densities, deviation from Tafel behavior was observed, in the sense opposite to that which would be expected from the anodic contribution to the total current (see Fig. 1). The current range corresponding to this deviation extends towards higher current densities when the *p*H increases (compare curves a and b in Fig. 1).

The log $|j|$ *vs.* V behavior at lower concentrations of oxidizing agent differs from that at higher concentrations in the values of $|dV/d \log |j||$ at high current densities, which are higher.

j-c relationship.—The relationship between the current density j and the oxidizing agent concentration c_{ox} appeared to depend, at given *p*H, on the electrode potential. Two extreme types of behavior exist.

At potentials which are rather positive with respect to flatband potential, *i.e.*, at sufficiently small current densities in the low current density region just mentioned, j at constant voltage depends linearly on c_{ox} (see, *e.g.*, Fig. 2).

In the high current density region (Tafel region), the current density at given voltage saturates as a function of concentration (see, *e.g.*, Fig. 3). Saturation due to slow diffusion from the electrode of products formed electrochemically can be excluded since the current density depends exponentially on applied voltage and since it was found to be independent of bubbling nitrogen through the solution.

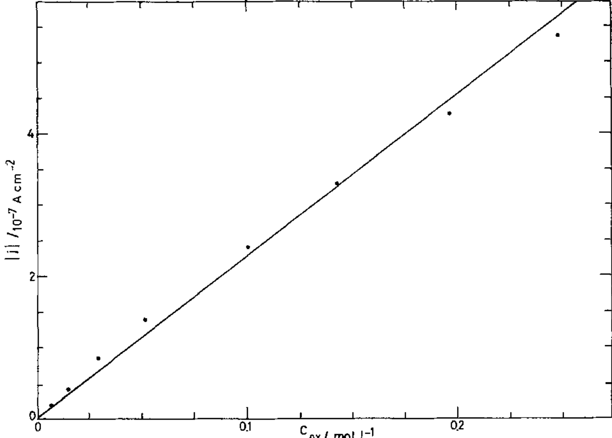

Fig. 2. Cathodic dark current density $|j|$ as a function of concentration of oxidizing agent c_{ox}. TiO_2 specimen (d), *p*H = 9.4, V = 0.150V *vs.* SHE, ox = $Fe(CN)_6^{3-}$.

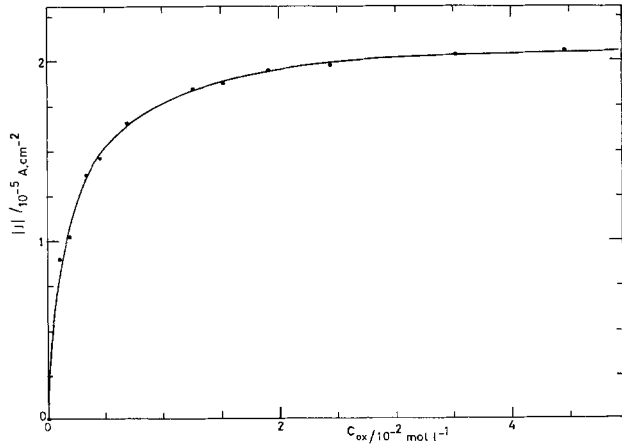

Fig. 3. Cathodic dark current density $|j|$ as a function of concentration of oxidizing agent c_{ox}. TiO_2 specimen (d), *p*H = 4.7, V = 0.056V *vs.* SHE, ox = $Fe(CN)_6^{3-}$.

The j *vs.* c_{ox} relationship can here be represented by

$$j = \frac{j_{sat} \cdot c_{ox}}{A + c_{ox}} \quad [1]$$

as appears from Fig. 4, where the data of Fig. 3 have been replotted as j *vs.* j/c_{ox}. Indeed, from Eq. [1], it follows that

$$j = j_{sat} - A\ (j/c_{ox}) \quad [2]$$

Values of j_{sat} and A have been experimentally determined under various circumstances.

The saturation current density j_{sat} was studied for Nb-doped TiO_2 and H_2-treated $SrTiO_3$ as a function of applied voltage V, of the nature of the oxidizing agent, of the identity of the sample, and of the *p*H.

The j-V relationship can be described by

$$\ln |j_{sat}| = \{\ln |j_{sat}|\}_{V=0} - \frac{\alpha FV}{RT} \quad [3]$$

with α close to unity. In the results which follow, a given j-V curve will be characterized by $(\ln |j_{sat}|)_{V=0}$, the saturation current density extrapolated to 0V *vs.* SHE. In Fig. 5 curve a and b. values of $(\ln |j_{sat}|)_{V=0}$ are plotted for TiO_2 and $SrTiO_3$, respectively, as a function of *p*H for different samples and oxidizing agents. The results show that the saturation current density is roughly independent of the sample and of the nature of the oxidizing agent, but is different for TiO_2 and for $SrTiO_3$ and varies over one order of magnitude per *p*H unit.

Additional experiments have been performed in which the saturation current, measured with a given oxidizing agent, was observed upon addition of another oxidizing agent; this addition was found to cause no significant change in the current, proving again that j_{sat} is independent of the nature of the oxidizing agent.

The coefficient A in Eq. [1] and [2] was found to depend on applied voltage, on the sample used, on the nature of the oxidizing agent, and on the *p*H. No attempts have been made yet to describe this complex behavior by analytical expressions.

Discussion

Although at first glance a relationship such as Eq. [1], which is of the Langmuir type, might suggest that the electroreduction mechanism would involve adsorption of the oxidizing agent, several arguments can be raised against this hypothesis. Firstly, one does not see

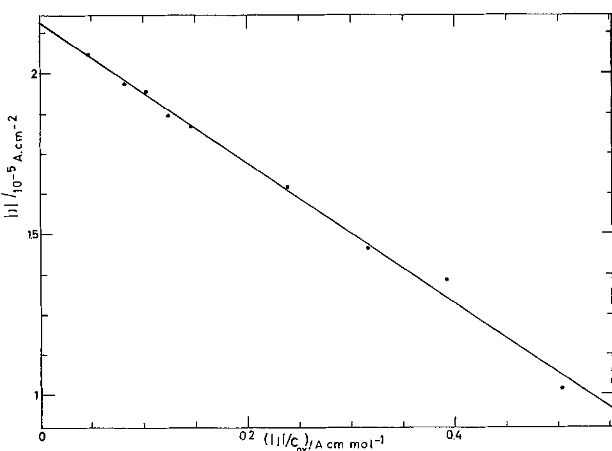

Fig. 4. $|j|$ *vs.* $|j|/c_{ox}$. TiO_2 specimen (d), *p*H = 4.7, V = 0.056V *vs.* SHE, ox = $Fe(CN)_6^{3-}$.

how an adsorption model would explain the fact that a given concentration corresponds to current saturation at high current densities and not at low current densities. Secondly, an adsorption model does not imply a saturation current which is independent of the nature of the reactant. Thirdly, in the case of TiO_2, it has been shown by capacitance measurements that the flatband potential is not influenced by the presence of the oxidizing agents used (7), indicating that they are not significantly adsorbed.

Tunneling of electrons through the space charge layer can hardly be responsible for the observed behavior, in view of the relatively low donor densities involved here; moreover, such a mechanism would be difficult to reconciliate with the validity of Eq. [1] as well as Eq. [3].

In order to explain our results, it appears necessary to postulate a mechanism involving at least two consecutive steps. Tentatively, we will assume a two-step mechanism in which surface states act as intermediates. In the first step, an empty surface state is filled by a conduction band electron; in the second step, this electron is transferred to an empty redox level (see Fig. 6). We will represent the forward and reverse rate constants for the first and second steps by k_1, k_{-1}, k_2, and k_{-2}, respectively. We will further represent the density of surface states and their occupation factor by N and f, respectively. The net filling rate $N\,df/dt$ of the surface states is then given by

$$N\frac{df}{dt} = k_1(1-f)Nn_s - k_{-1}fN - k_2fNc_{ox} + k_{-2}(1-f)Nc_{red} \quad [4]$$

n_s being the conduction band electron density at the surface and c_{ox} and c_{red} the concentration of oxidizing and corresponding reducing agent, respectively.

It is assumed here that the electron level distribution in the redox electrolyte is at equilibrium. Since the experiments are made under steady-state conditions, $N(df/dt) = 0$, we have from Eq. [4]

$$f = \frac{k_1 \cdot n_s + k_{-2} \cdot c_{red}}{k_{-1} + k_2 \cdot c_{ox} + k_1 \cdot n_s + k_{-2} \cdot c_{red}} \quad [5]$$

The current density j is given by

$$j = -eN\,[k_2 \cdot f \cdot c_{ox} - k_{-2} \cdot (1-f) \cdot c_{red}] \quad [6]$$

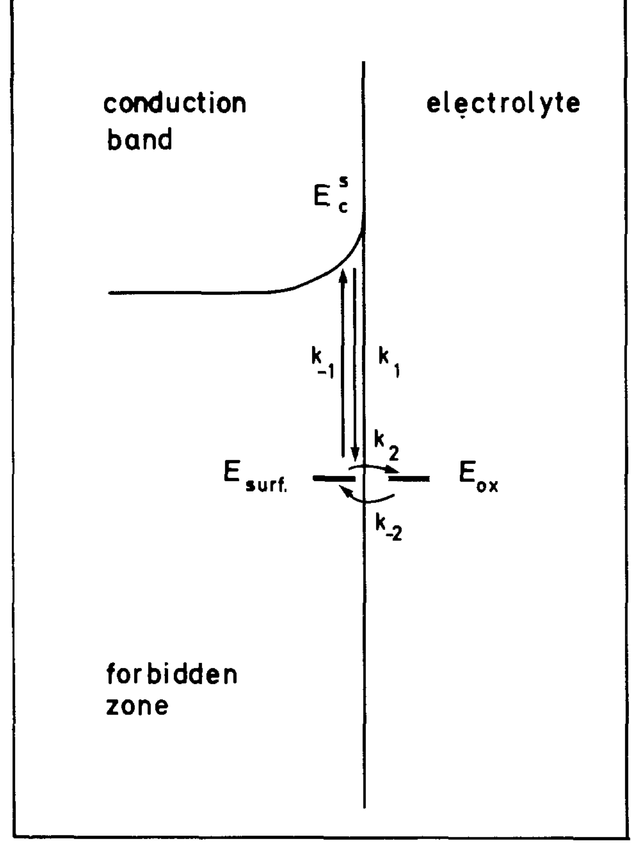

Fig. 6. Charge transfer through surface states. E_{surf}: energy of surface level; E_{ox}: energy of empty redox level in solution; E_c^s: energy of the conduction bandedge at the surface: k_1, k_{-1}, k_2, k_{-2}: rate constants of filling and emptying processes.

with e the absolute value of the elementary charge. Substituting Eq. [5] into Eq. [6], we obtain

$$j = -eN\frac{k_1 \cdot n_s \cdot c_{ox} - (k_{-1} \cdot k_{-2}/k_2)c_{red}}{(k_{-1} + k_1 \cdot n_s + k_{-2} \cdot c_{red})/k_2 + c_{ox}} \quad [7]$$

The relationship between j and c_{ox} as expressed in Eq. [7] reduces to the experimental one, expressed in Eq. [1], when the first term in the numerator of Eq. [7] is sufficiently large, *i.e.*, when n_s largely exceeds the value corresponding to electrode equilibrium. In this case, the value of j_{sat} is given by

$$j_{sat} = -eN\,k_1\,n_s \quad [8]$$

Since n_s varies over one order of magnitude per 0.06 eV band bending, the theoretical expression for j_{sat} (Eq. [8]), is in agreement with the experimental Eq. [3] describing the voltage-dependence, as well as with the observed pH dependence of j_{sat} at a given applied voltage which can then be ascribed to the pH shift of the flatband potential. Equation [8] also explains the experimental observation that j_{sat} is independent of the nature of the oxidizing agent if it is assumed that the same surface states are involved in the reduction of different oxidizing agents. It can be remarked here that Eq. [8] corresponds to the situation in which the capture of electrons by the surface states is rate-limiting. Moreover, since for a given material, j_{sat} was found to vary very little from sample to sample, acceptance of the validity of Eq. [8] leads to the implication that $N\,k_1$ is constant for a given material within the well-determined conditions of doping and pretreatment in our experiments. Numerical values of $N\,k_1$ can be obtained from our results, basing upon Eq. [8]; *e.g.*, for $SrTiO_3$ at $pH = 0$, $j_{sat} = 3 \cdot 10^{-3}$ A-cm^{-2} at 0V *vs.* SHE (see Fig. 5), *i.e.*, at a band bending of 0.4 eV. Hence, a value of $N\,k_1 \simeq 10^5$ cm·sec^{-1} is found. From

solid-state considerations, it follows that

$$k_1 = v\, S_n \quad [9]$$

v being the mean thermal speed of conduction band electrons and S_n the electron capture cross section of the surface states. Accepting $v = 10^7$ cm·sec^{-1}, we obtain $N\, S_n = 10^{-2}$. Assuming that the surface states are of the donor type, which implies $S_n \sim 10^{-12}$ cm^2, a reasonable value for the density of surface states is found, *i.e.*, $N = 10^{10}$ cm^{-2}. In an analogous way, $N\, k_1 = 4 \cdot 10^6$ cm·sec^{-1} is obtained for TiO_2 corresponding to $N = 4 \cdot 10^{11}$ cm^{-2}. It should be remarked that these values may be subject to a certain error, due to the uncertainty in the determination of the flatband potential (see the section "Preparation of the electrodes") and of S_n.

Still under conditions where $k_1 \cdot n_s \cdot c_{ox} >> (k_{-1} \cdot k_{-2}/k_2) c_{red}$ but at values of c_{ox} which are below the range corresponding to current saturation as a function of c_{ox}, the contribution of n_s in the denominator of Eq. [7] qualitatively explains the observed lowering of the voltage dependence of j, *i.e.*, the increase of the experimental Tafel slopes. The high Tafel slopes, observed by Dutoit *et al.* (7) on H_2-treated TiO_2 electrodes at relatively low c_{ox}, might be attributed to the same reason.

As mentioned in the results, the change in current-voltage behavior at increasing positive voltage (low current density range) cannot be interpreted on the basis of the anodic contribution to the total current, *i.e.*, referring to Eq. [7], to the term $(k_{-1} \cdot k_{-2}/k_2) c_{red}$ in the numerator.

Different mechanisms may lead to such behavior. For example, a small contribution of the valence band to the cathodic current (hole injection), which is voltage-independent, might be involved here. Another possibility is that two parallel current paths, j and j', over surface states of different types participate to the reaction, the first one being already described by Eq. [7], the second one by an analogous expression in which the corresponding rate constants will be denoted by k_1', k_{-1}', k_2', and k_{-2}' and the density of states by N' (the same situation might result from an energetic distribution of surface states). In view of the facts that the current increases over much less than one decade per -0.06V voltage shift and is proportional to c_{ox} (see Fig. 2), it can be assumed then that the term $(k_1'/k_2') n_s$ in the denominator of the expression for j' predominates. In the limiting case where all other terms in the denominator are negligible with respect to $(k_1'/k_2') n_s$, *i.e.*, at relatively high n_s, the expression for j' reduces to

$$j' = -\, e\, N'\, k_2'\, c_{ox} \quad [10]$$

in agreement with the observed concentration dependence and corresponding to rate-limiting charge transfer from the surface state to the reactant. This current might constitute a constant and negligible contribution to the total cathodic current in the high current-density range. The influence of pH upon the low current-density behavior, as demonstrated in Fig. 1, can be ascribed to the change in the relative position of energy levels at the semiconductor surface with respect to those in solution, causing a change in the value of k_2'. It may be remarked here that the hole injection mechanism, mentioned above, can be formally described by an expression similar to Eq. [10].

The current-voltage and current-concentration results mentioned above are not interpretable on the basis of the direct electron transfer model, in which conduction band electrons at the surface tunnel directly through the interfacial barrier toward empty redox levels. Indeed, the direct electron transfer model leads to a current, directly proportional to n_s and c_{ox}, a behavior which was not observed in any current range of our experiments. Especially in acid medium, this result is somewhat surprising, in view of the relative position of energy levels at the interfaces involved. Indeed, from V_{fb} values mentioned in the section "Preparation of the electrodes," the position of the conduction bandedge at the surface $E_c{}^s$ can be estimated to be at $+0.5$ eV for Nb-doped TiO_2 and at $+0.6$ eV for $SrTiO_3$ at $pH = 1.5$, being the lower pH limit of our experiments. Common literature values for the maximum of the empty level density curve $E_{ox}{}^m$ of the hexacyanoferrate couple are between $+0.1$ eV (18) and $+0.4$ eV (1). Accepting a value of about 1 eV for the rearrangement energy of the Fe^{3+}/Fe^{2+} couple (18), the corresponding $E_{ox}{}^m$ value may be located at about $+0.2$ eV. Hence, at least in acid medium, a noticeable contribution of the direct transfer mechanism would be expected; in other cases, the surface state model can be rationalized by the fact that $E_{ox}{}^m$ is markedly below $E_c{}^s$. Apparently, the reduction over surface states is fast enough so that the direct transfer mechanism is unable to compete under any circumstances of our experiments. Any discussion on this point is hampered by the lack of quantitative data on the parameters involved.

Surface Properties of Sodium Tungsten Bronzes

Michael Francis Weber,* H. R. Shanks, A. J. Bevolo, and G. C. Danielson

Ames Laboratory-USDOE and Department of Physics, Iowa State University, Ames, Iowa 50011

ABSTRACT

The surfaces of sodium tungsten bronze crystals have been examined by using cyclic voltammetry and Auger electron spectroscopy before and after electrochemical treatments. Compositional depth profiles of the sodium depletion layers were obtained and the formation of hydrogen tungsten bronze was observed and studied. Hydrogen tungsten bronze was found to form on the anodized cubic sodium tungsten bronze at two separate potentials, corresponding to the formation of semiconducting and metallic phases of H_xWO_3.

Sodium tungsten bronzes are members of a general class of nonstoichiometric compounds with the formula M_xWO_3 where M is a metal and $0 < x < 1$. The compound WO_3 is a semiconductor with a bandgap of 2.6 eV (1) and a monoclinic structure. The addition of increasing concentrations of different metal atoms, such as the alkali elements, results in a series of crystal structures with increasing symmetry and with differing electronic properties. For $x > 0.5$, Na_xWO_3 has a nearly cubic structure at room temperature (2). At a slightly elevated temperature, the material undergoes a phase transition to the true cubic perovskite structure. The crystals in this range of x-values will be referred to here as in the cubic phase. The unit cell of the cubic bronze structure consists of a tungsten atom at the cube center, oxygen atoms on the cube faces, and the sodium atoms at the cube corners. The oxygen atoms form an octahedron around the tungsten atom, so that the compound is composed of corner bonded WO_6 octahedra surrounding the sodium atoms.

Recent investigations (3-5) have shown that anodization of Na_xWO_3 in acid solutions removes sodium atoms to a depth of several hundred angstroms, leaving a semiconducting layer of low x-value Na_xWO_3 on the surface. After anodization, a reversal of the electrode polarity causes the crystal surface to change color from a light green to a deep blue. This color change has been shown to be associated with the movement of hydrogen into the empty sodium sites (4-6) and the formation of H_xWO_3.

Hydrogen tungsten bronzes have crystallographic and electrical properties similar to the other bronzes (7). Crystals of the orthorhombic and tetragonal II phases are semiconductors, and crystals of the tetragonal I and cubic phases exhibit metallic conductivities. The ranges of x-values corresponding to each phase is not well-known.

Two processes studied by cyclic voltammetry were the anodic dissolution of the bronze, and formation of hydrogen tungsten bronzes on the surface. The cubic sodium tungsten bronzes have been studied for both of these reactions (4, 8, 9). However, several questions still remain concerning the hydrogen bronze formation on cubic Na_xWO_3 and the crystal structure of the sodium depletion layer on this compound. Even though hydrogen bronze formation has been studied on cubic Na_xWO_3, the x-value of the resulting hydrogen bronze (H_xWO_3) surface has not been determined. Since the hydrogen x-value is unknown, the electronic state of the surface, semiconducting or metallic as a function of potential is also unknown.

Experimental

The sodium tungsten bronze crystals were prepared by the electrolysis of a fused salt of sodium tungstate and tungsten trioxide as described by Shanks. (10). Crystal growth was initiated from the tip of a gold wire drawn up a few millimeters into the end of a 2 mm OD quartz tube. Single crystals, approximately 2 cm or more on an edge, were normally obtained. Spark source mass spectroscopy showed total impurity concentrations of about 400 ppm with Mo being the major impurity.

For the electrochemical studies, the crystals were either cleaved or cut on a high speed diamond saw to a typical sample size of $4 \times 4 \times 6$ mm. Cleaved crystals were cleaned in boiling conductivity water, while the crystals cut on the diamond saw were first cleaned in boiling ethyl acetate, followed by hot concentrated NaOH, and finally in boiling conductivity water. The cut samples were then either polished or cleaved away on one end to ensure a fresh bronze surface. The crystals were mounted in Teflon using the method described by Nagy and McHardy (11). Details of the sample mounting and electrical connection are illustrated in Fig. 1. Polishing of the cut surface consisted of mechanical polishing with 0.05 μm alumina powder. The area of each sample was determined from a photomicrograph of the mounted crystal, with no corrections being made for surface roughness.

The experiments were conducted in a three compartment cell constructed of quartz and Teflon. Water used in the solutions was distilled directly into the test cell from an all-quartz still. Complete technical details of this equipment can be found elsewhere (12, 13). The only solution used in the cell for this study was $0.1N$ H_2SO_4 (pH 1.2) mixed *in situ* from Apache Chemicals 99.9999% pure (distilled in Vycor) sulfuric acid. The solution was not preelectrolyzed for any of these experiments. A palladium hydride electrode (14) was used as a reference electrode. The Pd-H electrode was repeatedly checked against a saturated calomel reference electrode since its potential tended to drift for a long time after recharging with hydrogen. Thus, all potentials were referenced to the normal hydrogen electrode using the relation $V_{NHE} = V_{SCE} + 0.242V$.

Immediately before insertion into the test cell, all samples were washed with acetone, and then with isopropyl alcohol, followed by a final cleaning with an isopropyl vapor phase degreaser. After insertion into the cell, the potential on each electrode was cycled between 0.1V and 1.6V NHE for approximately 20 min to clean the surface further. Only small changes in the cyclic voltammetry curves were observed during this time. Unless otherwise noted, all cyclic voltammetry curves shown in this paper are steady-state curves. A Keithley Model 640 electrometer was used to measure the potentials while a Princeton Applied Research Model 173/176 potentiostat/galvanostat was used to control the three electrodes. Anodization of the bronze surfaces were carried out galvanostatically, a given anodization treatment was specified by the applied current density, and the final voltage attained after a given time.

Chemical composition of the electrode surfaces was determined by Auger electron spectroscopy (AES).

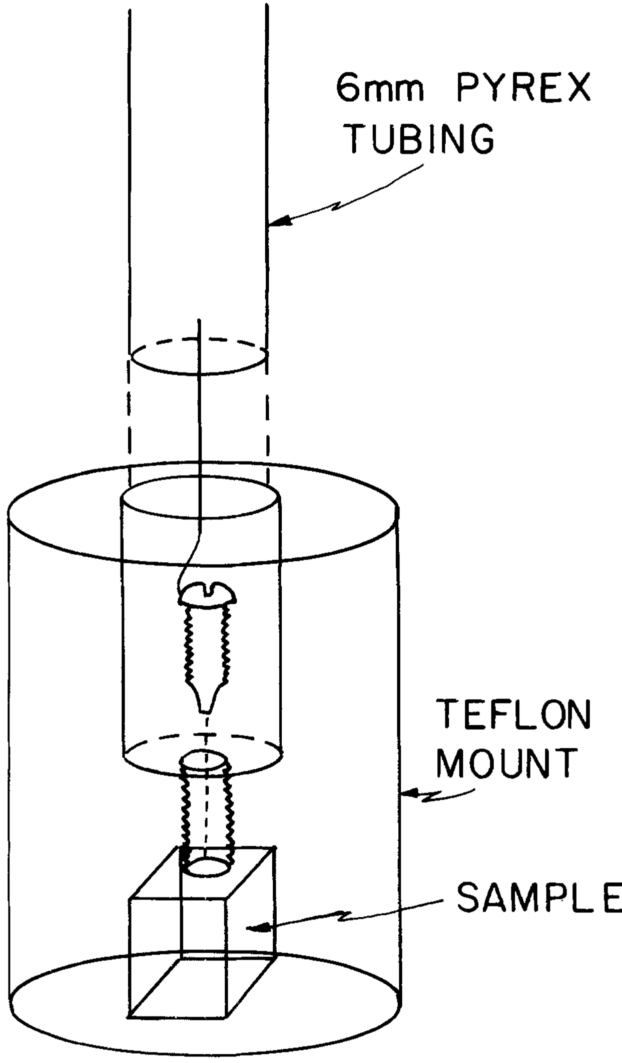

Fig. 1. Sample mounting and electrical connection for the tungsten bronze samples.

The primary electron beam current for the Auger analysis was 5 μA at 4 keV with a spot diameter of 40 μm. Elemental abundances were determined from the peak to peak AES signals after correction for the Auger sensitivity factor for each element. The Auger analysis was carried out during continuous sputtering of the crystal surface by argon ions at 2.5 keV. To eliminate any crater edge effects, the ion beam was rastered over a 3 mm² area, and the Auger electron beam was centered in this area. The sputtered depth was calculated by assuming an average sputtering yield of 2 for sodium tungsten bronze. The Auger electron energies monitored were: for tungsten, 38 eV, 48 eV, and a doublet of 163-179 eV; for oxygen 510 eV; and for sodium, 990 eV. Compositions were obtained by comparison with the observed stoichiometry of a bronze crystal of known composition which had been cleaned in the surface analysis vacuum chamber, since both electron beam induced desorption and preferential sputtering of the alkali metal can occur. In addition to the AES measurements, SEM photographs were used to reveal the surface morphology of some crystals. These studies were performed both before and after the electrodes were subjected to strong anodic and cathodic polarizations. All measurements were made at 25° ± 2°C.

Results and Discussion

Polished crystals of cubic Na_xWO_3 were found to have little or no sodium depletion layer when Auger depth profiled. Anodizing the crystals, however, resulted in sodium depletion at the surface. A polished $Na_{0.7}WO_3$ crystal which was anodized at 0.5 mA/cm² for 3 hr, during which time the potential slowly increased to 5.5V NHE, had a surface x-value of about 0.25 which extended for some 800Å into the crystal. Another crystal with an x-value of 0.6 was anodized at 1 mA/cm² for 9 hr with a final potential of 9.0V NHE. Sodium depletion extended to a depth of 1500Å with a surface x-value of about 0.1. Similar results were obtained on a number of crystals with comparable anodizing times.

Considering the high potentials needed to create the depletion layer, reports of depletion layers over 100 μm thick (15) must be viewed with considerable skepticism. The ion microprobe results of Bockris and McHardy (3) indicated depletion layers over 1000Å thick on samples anodized to only 2V. In view of the consistency of our measurements, a 1000Å depletion layer formed by only 2V seems excessive.

The C-V curve for an anodized $Na_{0.9}WO_3$ crystal is shown in Fig. 2. The redox reaction occurring at +0.15V (NHE) has several features. First, the potentials at which the peak current, i_p, occur approach a difference of 60 mV as the sweep rate, S, approaches zero. Second, i_p increases linearly with S. All cubic Na_xWO_3, with 0.6 x 0.9, that had been anodized, exhibited C-V curves nearly identical to those shown in Fig. 2.

These data present a dilemma that was first resolved by Randin and co-workers (4). The peak current separation approaching 60 mV as S approaches zero implies that a diffusion-limited redox couple is occurring. But such a reaction should have i_p proportional to the square root of S, whereas the data have i_p proportional

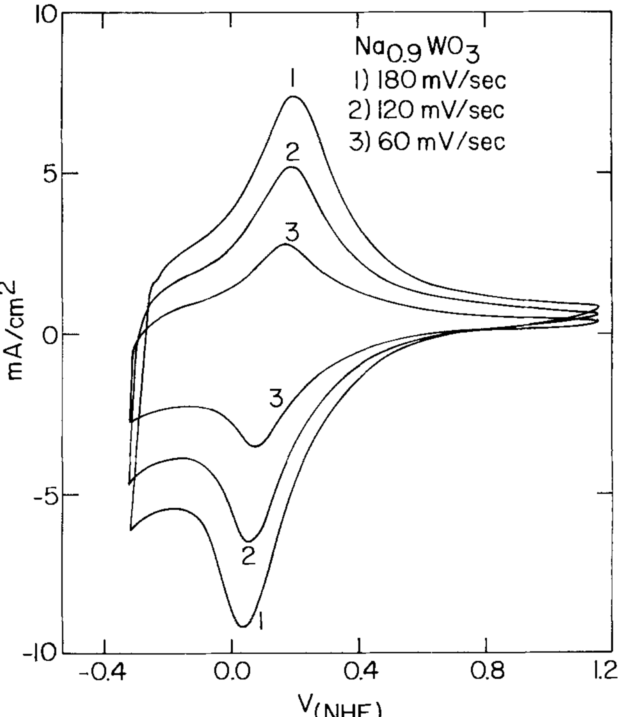

Fig. 2. C-V curves for an anodized cubic sodium tungsten bronze. The redox reaction at 0.15V is the formation of hydrogen tungsten bronze in the sodium depletion layer. The reaction is reversible and the surface undergoes no net change. No anodic corrosion currents were observed at anodic potentials up to 2.0V.

to S. This latter result implies that a surface reaction is occurring limited only by the activation energy and the surface coverage fraction (16, 17). Randin was able to reconcile these facts by assuming that the redox couple represents the formation of hydrogen bronze by

$$xH^+ + WO_3 + xe^- \rightleftarrows H_xWO_3 \quad [1]$$

This reaction was occurring on the surface of an anodized bronze with the diffusing species being the hydrogen ions. The key notion is that the hydrogen ions are diffusing through the empty sodium sites in the sodium depletion layer of the bronze electrode, rather than the electrolyte.

Freshly polished crystals of cubic Na_xWO_3 have C-V curves of the same form as those for anodized crystals, but the peak currents are an order of magnitude smaller at similar sweep rates. The C-V curve for such a crystal is shown in Fig. 3. These curves are further evidence that the large current peaks, centered around 0.15V, are due to Eq. [1], because a hydrogen bronze can be formed at 0.15V only if empty sodium sites are available for the hydrogen atoms to occupy. Some sodium is probably lost from the surface just by etching from the acid and by the C-V experiment itself, when potentials above 1V are reached on the C-V trace. The amount of sodium depleted by these processes is much smaller than the amount of sodium lost by anodizing the crystal at 5-10V, and the differences in the current peak heights in Fig. 2 and 3 are obvious.

On both anodized and unanodized crystals, the current approaches zero as the potential becomes more positive. Extended potential scans out to 2.0V show that no reactions occur in this potential region, or more specifically, the cubic Na_xWO_3 surface does not dissolve at these high potentials. Also, the integrated current on the positive going scan equals the integrated current on the reverse scan. This equality implies that a totally reversible reaction is occurring, with no net change of the bronze surface. However, the first scans on all freshly polished crystals exhibited a corrosion current above 1.2V, which disappeared after several voltage cycles. The corrosion reaction above 1.2V is probably the removal of sodium atoms from the first few layers of the crystal surface. The initial C-V traces on some crystals did not have well-defined peaks, but only broad current maxima. One explanation of the broadening is simply a dirty surface. On most samples, the peaks sharpened up after several voltage scans. The reason for the difference is unknown. After a strong anodization, 5V or greater, a cubic sodium tungsten bronze exhibited the curve shown in Fig. 2.

The hydrogen bronze formation peak (cathodic current peak) in Fig. 3 is only a shoulder on a larger background current, which introduces the question of the origin of this background current. One possibility was hydrogen evolution, but the high overvoltages on a hydrogen Tafel plot (12, 18-20) show that this background current cannot be hydrogen evolution. The extended cyclic voltammetry scan in Fig. 4 also shows this to be the case. Hydrogen evolution does not begin until about −0.6V, but a second reaction is occurring, with broad peaks, near −0.3V. The reaction at −0.3V could be greatly enhanced by holding the crystal at a potential below −0.3V. Figure 5 shows the C-V curves of a crystal after anodization to 2V, reduction at −0.7V for 3 hr, and reanodization to 6.8V. The C-V curves of this crystal show enhanced currents at −0.3V compared to those of an unreduced crystal such as those shown in Fig. 4. The second anodization did not restore the crystal to its original state, implying that the reduction process has irreversibly changed the surface of the electrode.

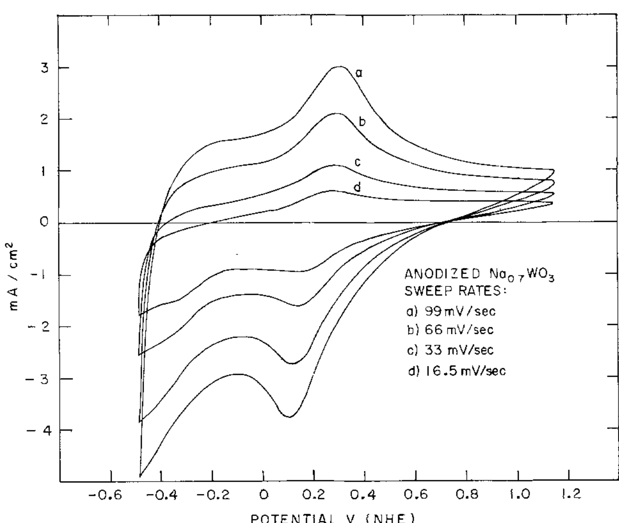

Fig. 4. C-V scans over an extended range of potentials. A second reaction is observed near −0.3V. The reaction near 0.15V is unaffected by the extended scan. Both reactions are shown to be due to hydrogen bronze formation.

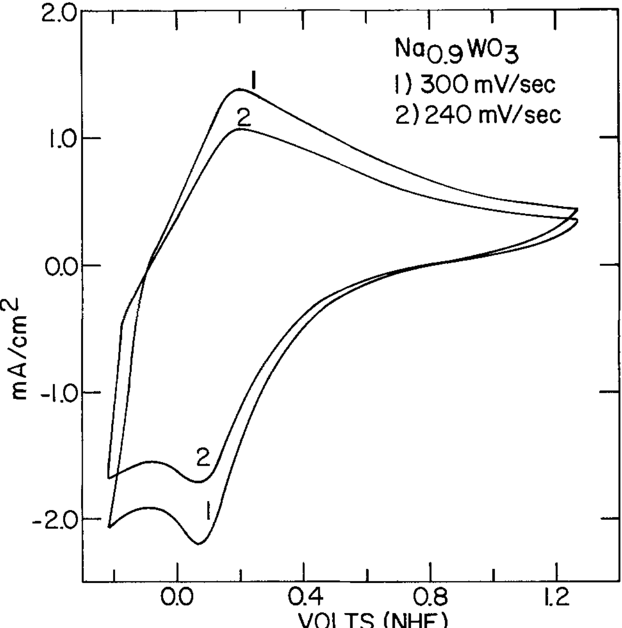

Fig. 3. C-V curve for a freshly polished cubic sodium tungsten bronze crystal. The peak currents are an order of magnitude lower than those on an anodized crystal because hydrogen occupies only the vacant sodium sites.

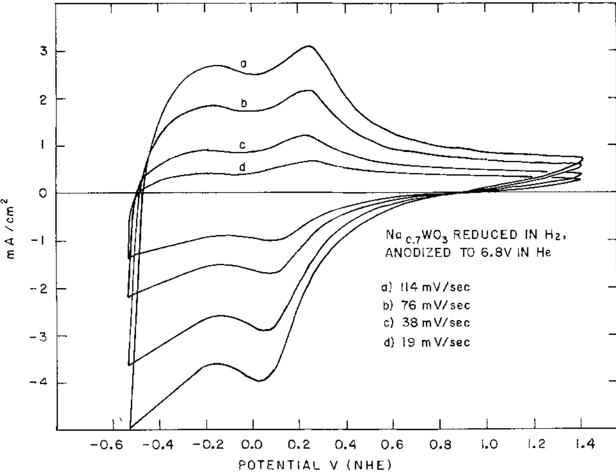

Fig. 5. C-V curves for the reduced crystal after it was anodized to 6.8V. The anodization process increased the peak currents at 0.15V as usual, but did not greatly affect the reaction at −0.3V. The reduction process irreversibly changed the crystal surface.

The positive current sections of the curves shown in Fig. 5 are almost identical to the curves obtained by Vondrak and Balej in their study of hydrogen absorption by sodium tungsten bronzes (9). Contrary to Randin (4), they did not attribute the current peak at 0.15V to hydrogen bronze formation, but attributed only the peak at −0.3V to that process. All researchers agree that a strong reduction of a sodium tungsten bronze crystal results in a severe blistering or cracking of the crystal surface. Such stresses must be associated with changes in the crystallographic properties of the crystal and are obviously irreversible. An SEM photograph of such a surface is shown in Fig. 6. The *C-V* curves in Fig. 4 and 5 indicate that the stresses on the crystal have caused a permanent change in the crystal which allows more hydrogen to enter the crystal at −0.3V.

The two reactions on the sodium tungsten bronze surface at 0.15 and −0.3V are thought to be the formation of the semiconducting and metallic phases of hydrogen tungsten bronze. There is both experimental and theoretical support for this hypothesis. First, Siclet *et al.* (21) studied the reduction of powdered WO_3 on a mercury electrode. By x-ray analysis of the powders, they found that orthorhombic $H_{0.1}WO_3$ was formed at potentials near +0.340V, and that either the tetragonal I or cubic phase, corresponding to $0.33 \leq x \leq 0.5$, was formed at potentials near −0.136V. The resolution of their equipment was insufficient to give an exact x-value for the latter compound.

The second clue to the nature of the two reactions on the surface of Na_xWO_3 is a simple visual observation made during *C-V* scans on all the anodized cubic sodium tungsten bronzes. The normal color of this oxide surface is a light green. As the electrode potential passes 0.15V on the cathodic scan, the surface turns dark blue and highly absorbing in appearance. When the potential passes through the region of the current peak around −0.3V, the surface turns orange and highly reflecting in appearance. The change in the observed reflectance is indicative of a semiconductor-metal transition between 0.15 and −0.30V. The bandgap of semiconducting H_xWO_3 is low enough, probably <1 eV, to absorb all visible light, and the reflectance at more negative potentials is due to metallic H_xWO_3. A sodium-depleted surface initially has a high bandgap close to that of WO_3 (3). This normal state of the anodized surface can be reinstated simply by returning to potentials more positive than 0.15V. The higher potentials drive out the hydrogen by means of the oxidation process described by Randin *et al.* (4). That the electronic nature of H_xWO_3 is similar to that of Na_xWO_3 is remarkably demonstrated by the succession of colors seen with progressively more negative potentials. The hydrogen tungsten bronze on the crystal surface proceeds through all the colors of the sodium tungsten bronzes corresponding to sodium x-values of zero, to higher sodium x-values of about 0.6 or 0.7. The separation in energy between the two reactions at 0.15 and −0.3V is 0.45 eV, which is consistent with our estimates of the bandgaps of semiconducting hydrogen tungsten bronzes.

Fig. 6. SEM photograph of the cracked surface of a strongly reduced $Na_{0.6}WO_3$ crystal. Here the cracks can be seen to be only in the sodium depletion layer which is flaking off the crystal.

Formation of the low x-value or semiconducting H_xWO_3 involves electron transfer to sites that are spatially well-separated but are at similar energy levels. The energy required to add more hydrogen is therefore constant at low x-values. On this basis, the current peaks around 0.15V would be expected to be rather sharp and well-defined, which we have observed to be the case. However, after the semiconductor-metal transition has occurred, the conduction electron wave functions overlap. The energy required to increase the electron density increases continuously as more electrons are added because of the increased electronic repulsive energy. Therefore, the current peaks at −0.3V associated with the formation of metallic H_xWO_3 can be expected to be very broad, as is observed experimentally (see Fig. 5).

Conclusions

Anodized sodium tungsten bronzes were shown by Auger depth profiling to have a greatly depleted sodium content on the crystal surface. The sodium depletion layer was 1500Å thick samples anodized to 9V, with a sodium x-value of between 0.05 and 0.1. The cyclic voltammetry curves provide strong evidence that the sodium depletion layer on Na_xWO_3 retains the crystal structure of the bulk. Hydrogen tungsten bronze is formed in the sodium depletion region of a sodium tungsten bronze crystal at low potentials. The hydrogen bronze is formed in two steps, one at 0.15 and the other at −0.3V, corresponding to the formation of semiconducting and metallic hydrogen tungsten bronze.

Semiconductor Electrodes

XXV. The p-GaAs/Heptyl Viologen System. Photoelectrochemical Cells and Photoelectrochromic Displays

Benjamin Reichman, Fu-Ren F. Fan, and Allen J. Bard*

Department of Chemistry, The Universtiy of Texas at Austin, Austin, Texas 78712

ABSTRACT

The photoreduction of aqueous solutions of 1,1′-diheptyl-4,4′-bipyridyl (heptyl viologen, HV^{2+}) bromide on p-GaAs was investigated. Under irradiation with light of wavelengths below 885 nm, the photoreduction of HV^{2+} to form a precipitate of violet HVBr occurs on p-GaAs at a potential of ~400 mV more positive than the reversible potential of the HV^{2+}/HVBr couple on Pt. Oxidation of HVBr back to soluble HV^{2+} occurs in the dark at more negative potentials. Photoelectrochemical low capacity storage cells based on this reaction with Cu, Ni, or $H_xNb_2O_5$ counterelectrodes were constructed. In such cells, under illumination, the p-GaAs electrode behaves as the cathode, a photovoltage develops, and current flows in the external circuit, while HVBr precipitates on the electrode surface, and the counterelectrode is oxidized. In the dark, the current flows in the opposite direction, the p-GaAs is the anode, and reduction occurs at the counterelectrode. Such a cell also produces an alternating electrical output under periodic illumination. Photoelectrochromic cells based on this reaction and utilizing simultaneous addressing with light and electrical signals are also proposed.

A number of photoelectrochemical (PEC) cells employing semiconductor electrodes for the conversion of radiant to electrical energy (liquid junction photovoltaic cells) have been described (1-17). Most have employed n-type semiconductors and have been used for the instantaneous production of electricity without chemical storage. The possibility of a photochargeable PEC cell using a third storage electrode or with production of soluble reactants has been discussed, however (8, 10-11). PEC cells employing p-type electrodes are less common (8-9, 15-17). Studies of aqueous systems with p-GaAs and p-GaP have been reported (15-16, 18), but the observed efficiencies of these were usually quite small and in many cases problems with electrode stability were encountered. Investigations of p-GaAs electrodes in acetonitrile solutions suggest good stability under strict water-free conditions (19).

We report here investigations of the p-GaAs electrode immersed in aqueous solutions containing 1.1′-diheptyl-4,4′-bipyridyl (heptyl viologen, HV^{2+}) bromide. The reduction of HV^{2+} bromide on metal electrodes yields a precipitate of the violet radical cation

$$C_7H_{15}-\overset{+}{N}\langle\bigcirc\rangle-\langle\bigcirc\rangle\overset{+}{N}-C_7H_{15}\quad HV^{2+}$$

salt (Eq. [1]) and this has been suggested as the basis

$$HV^{2+} + Br^- + e \rightleftarrows HV^+\cdot Br^- \quad [1]$$

of electrochromic displays (20-22). The formation of such a precipitate by photoreduction at a p-type semiconductor would allow low capacity energy storage via a solid material, just as occurs in secondary batteries. We will show that such a photoreduction does occur at p-GaAs at potentials ~400 mV less negative than that observed at a platinum electrode and that dark oxidation of the HVBr precipitate is possible. Moreover, the p-GaAs electrode is stable both in the dark and under illumination in the HV^{2+} solution so that PEC cells using suitable counterelectrodes (*e.g.*, Cu/CuO) which show a periodic electrical output under chopped illumination can be constructed.

A second aspect of these studies concerns the application of reaction [1] on p-GaAs for display purposes. Several devices for active displays based on combining electrogenerated chemiluminescence and semiconductors have been described (23). A passive photoactivated display based on metal deposition on a semiconductor electrode was recently reported (24). The principles of a similar display based on precipitation of HVBr at a point on a semiconductor electrode simultaneously

addressed by light and an electrical signal is described here.

Experimental

The single crystal p-GaAs was obtained from Atomergic Chemicals (Long Island, New York) with acceptor concentration 3×10^{18} cm^{-3} (Zn-doped) and was mounted as an electrode as previously described (13). The surface (face 111) was first polished with 0.5 μm alumina powder and then etched for 10-15 sec in a solution which contained $H_2SO_4:H_2O:30\%$ H_2O_2 in concentration ratio 3:1:1. In some experiments single crystal p-GaP was also employed. The surface of this crystal was etched in 11*M* HCl for 10 sec before use.

As light sources either a 450W xenon lamp or a He-Ne laser (1.6 mW power) was used. The potentiostatic measurements were carried out with a Princeton Applied Research (PAR) potentiostat Model 173, with a cell consisting of an aqueous saturated calomel reference electrode (SCE) and a Pt wire as the counterelectrode. The electrochemical cell was provided with Pyrex windows for the passage of light. Nitrogen gas was passed through the solution before the experiments and above the solution during the experiments, since viologen radical cations are very sensitive to oxygen.

In the two electrode PEC cell experiments the voltage of the photocell between the p-GaAs and the oxide counterelectrode was measured on an x-t recorder through a voltage follower. The photocell current was measured on an x-t recorder through a current-to-voltage converter. For short time measurements of the cell short-circuit current, a Nicolet Model 1090A digital oscilloscope was used. The light intensity at the semiconductor surface was varied by means of neutral density filters.

Results

Cyclic voltammetry.—The *i-V* curve at a p-GaAs electrode of an unstirred solution of 0.01*M* HV^{2+} and 0.2*M* KBr at a scan rate of 100 mV/sec is shown in Fig. 1. In the dark (curve a) there was only a small current in the cathodic region with a very small peak on scan reversal. Under illumination of the p-GaAs electrode surface with the full power of the 450W xenon lamp, a larger cathodic current beginning at ~0.1V *vs.* SCE appeared (curve b). Simultaneously with the appearance of this cathodic current, the precipitation of the violet HVBr was observed on the electrode surface. On reversing the scan direction, a sharp anodic current peak occurred, either in the dark or under illumination. During the passage of the anodic current the violet precipitate on the semiconductor surface disappeared. Thus the overall process is that shown in [1], with illumination necessary for the reduction process, as is usual for p-type semiconductors.

These cyclic voltammograms could be repeated many (at least 100) times with only a small change in the peak height of the cathodic photocurrents, demonstrating good chemical reversibility of the deposition and stripping process. Upon illuminating the electrode with the narrow beam of a He-Ne laser, violet spots appeared on the electrode surface at exactly the location and of the size of the laser beam spot. The response time of the process was investigated by potential steps under illumination or by irradiation with chopped light with the electrode held at a constant potential (Fig. 2). A good coloration was observed on the electrode surface within ~0.5 sec after illumination of the electrode. Although the intensity ratio for HVBr deposited on dark p-GaAs is not very high, the deposition was easily discernable and this type of process can be considered for use as an electrochromic display controlled by both light and electrode potential and may also be applicable to photoimaging purposes (24, 25).

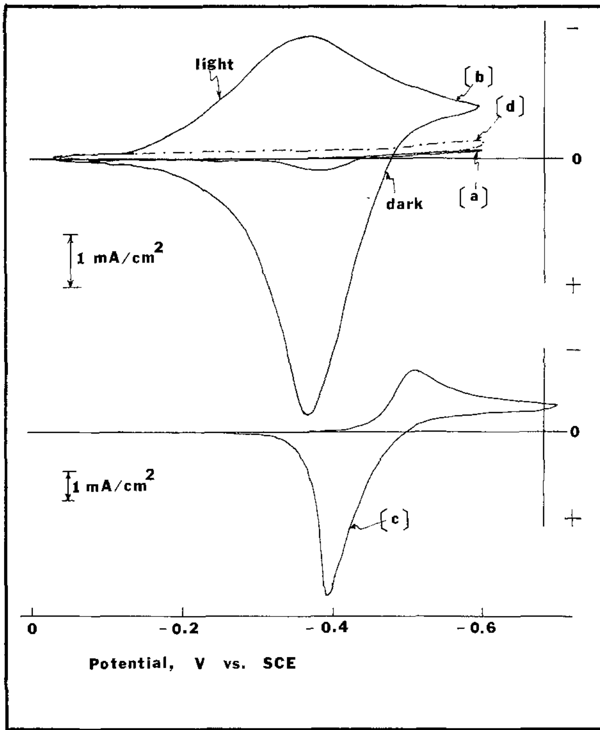

Fig. 1. Cyclic voltammograms recorded with p-GaAs at 100 mV/sec with aqueous solution containing 0.01*M* $HVBr_2$ and 0.2*M* KBr: (a) in the dark; (b) under illumination; (c) cyclic voltammogram recorded with the same solution on a Pt disk electrode (100 mV/sec); (d) cyclic voltammogram recorded with p-GaAs in solution containing only 0.2*M* KBr. Light source, 450W Xe lamp.

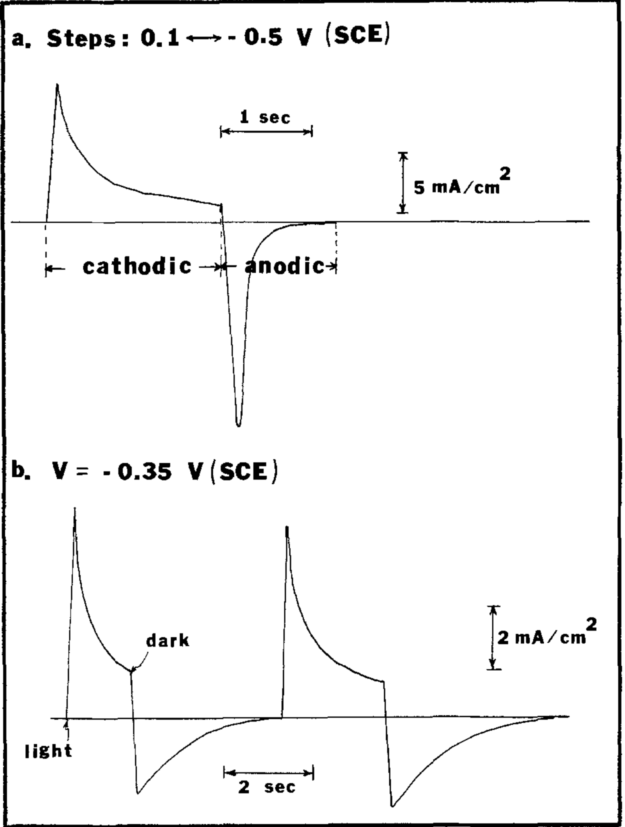

Fig. 2. Current-time transients in potential step experiments on p-GaAs in solution containing 0.01*M* $HVBr_2$ and 0.2*M* KBr: (a) potential stepped between —0.5-+0.1V under constant illumination; (b) the potential held at —0.35V *vs.* SCE under chopped illumination. Light source, 450W Xe lamp.

The cyclic voltammograms of the solution of 0.01*M* HV^{2+} dibromide and 0.2*M* KBr at a Pt electrode is shown in Fig. 1c. By comparison of this voltammogram with that obtained with p-GaAs under illumination, one can see that significant photoreduction of HV^{2+} can occur on p-GaAs at potentials ~400 mV less negative than on Pt. The photocurrent attributable to the reduction of protons on the p-GaAs in a KBr solution not containing HV^{2+} was very small (Fig. 1d). Photoreduction of HV^{2+} was also investigated with a p-GaP photocathode. In this case, the underpotential for the reduction process was even larger than in the case of p-GaAs, but the process was not very reversible and the back oxidation occurred only at more positive potentials than on a Pt electrode. Thus, upon scanning a p-GaP electrode over roughly the same potential region (Fig. 3), a gradual accumulation of HVBr occurred on the electrode surface and the cathodic current gradually decreased.

With the light intensity used in the experiments described above, the photoreduction current on p-GaAs was limited by the rate of diffusion of HV^{2+} to the electrode surface, as demonstrated by the proportionality of the cathodic photocurrent to the square root of the scan rate, v (Fig. 4). Moreover, as shown in Fig. 5, while the potential for photocurrent onset and the current at the foot of the wave depended upon the light intensity, at more negative potentials the maximum current was almost independent of intensity and was limited by the rate of diffusion of HV^{2+} to the electrode surface.

PEC cells.—Since the photoreduction of HV^{2+} occurs on p-GaAs with an underpotential of about 400 mV while the back-oxidation in the dark on p-GaAs occurs at the same potentials as on Pt, one can envision a sort of solar storage cell composed of a p-GaAs and another chemically reversible electrode (Fig. 6). This counterelectrode should have a redox potential between the potential for the photoreduction of HV^{2+} on p-GaAs and the potential for oxidation of HVBr in the dark (Fig. 6c). In such a cell, when light irradiates the p-GaAs, it is the cathode of the cell and HVBr precipitates (Fig. 6a). The HVBr precipitate on the p-GaAs is stable at open circuit, and can be oxidized in the dark back to the original HV^{2+}, while the counterelectrode becomes the cathode of the cell (Fig. 6b). Three counterelectrodes with redox potentials suitable for such a photocell, Cu/Cu-oxide, $H_xNb_2O_5/Nb_2O_5$, and Ni/Ni-oxide, were used. The open-circuit voltages, and the short-circuit currents of such cells composed of p-GaAs, and the three counterelectrodes under periodic illumination are shown in Fig. 7. The relative polarity of the p-GaAs shows the expected changes (Fig. 6) as the semiconductor is subjected to the chopped beam. In

the photocharged condition, the HVBr remained on the electrode surface and the open-circuit voltage was stable for at least 2 hr. The maximum open-circuit voltages were found with the Cu counterelectrode with potential excursions of up to 0.4V observed (Fig. 7A). The short-circuit currents of these cells are shown in Fig. 7B. In the light, current flows in the external circuit during which precipitation of the purple HVBr on the surface of the p-GaAs occurs. The current decays almost to zero in about 10 sec because a thick opaque film of HVBr builds up on the electrode surface and the HV^{2+} concentration is depleted near the electrode surface. The cell can be regarded as a storage battery. The precipitate of HVBr can be stored on the p-GaAs, and then oxidized in the dark to yield a current in a direction opposite to that observed under illumination. Obviously, the capacity of such a cell is very small; the maximum charge in the form of HVBr which can precipitate on the p-GaAs before the current drops to zero is about 10 mC/cm^2. Alternately, the cell can be considered as a type of a-c device under periodic illumination. In this mode the p-GaAs cell performance was very stable with all three cells and no deteriora-

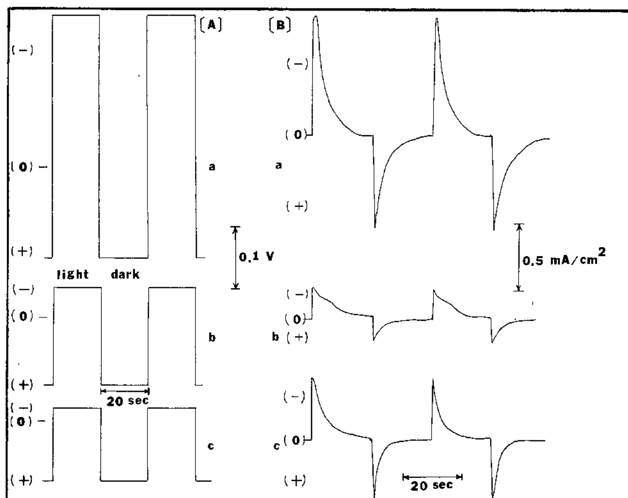

Fig. 7. (A) Open-circuit potentials and (B) short-circuit current under chopped illumination for the cells: (a) p-GaAs/HVBr/$HVBr_2$, KBr/Cu; (b) p-GaAs/HVBr/$HVBr_2$, KBr/Nb_2O_5; (c) p-GaAs/HVBr/$HVBr_2$, KBr/Ni. Light source, 450W Xe lamp.

tion or decrease in the current was observed after 4 days of continuous operation with 20 sec period illumination by the 450W xenon lamp. The open-circuit voltage, the current, and the amount of charge involved were all reproducible and stable to within 10%. The variation of the initial short-circuit current on light intensity under irradiation with the He-Ne laser (1.6 mW power) was examined with all three cells (Fig. 8). A linear dependence of the short-circuit current on light intensity was observed at the lower intensity levels. In the case of Cu counterelectrode, saturation of the current occurred at ~2.5 mA/cm^2. With Ni as the counterelectrode, no saturation of the short-circuit

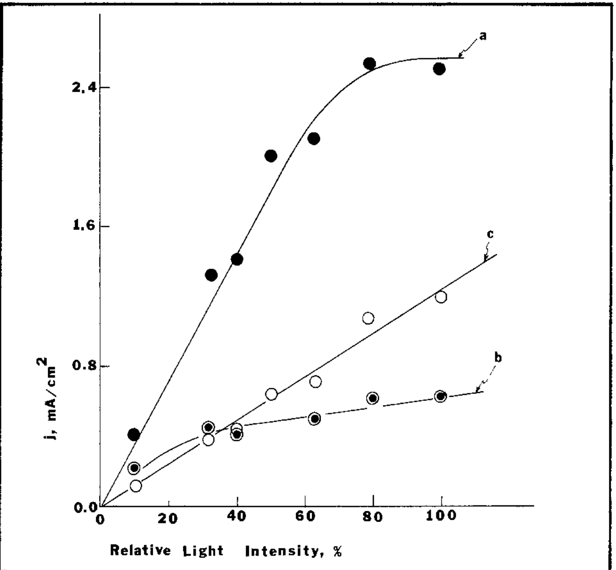

Fig. 8. Initial short-circuit photocurrents for the three cells described in Fig. 7 as a function of light intensity (He-Ne laser).

current occurred even at the highest intensity used, while with Nb_2O_5 as a counterelectrode a linear dependence was observed only at very low light levels. In all cases, the currents obtained were the highest for the Cu electrode. The current saturation observed in this case can probably be ascribed to the limitation by diffusion of HV^{2+} to the p-GaAs surface, since the magnitude of the saturation current density in Fig. 8a is similar to the limiting current found in the voltammograms, Fig. 1b, with identical HV^{2+} concentrations. With the Nb_2O_5 electrode, the short-circuit current reaches saturation earlier than in the case of Cu and was clearly limited by the oxidation reaction taking place on the Nb_2O_5 electrode. The maximum quantum efficiencies for the photocells were calculated from the slopes of the linear portions of the curves in Fig. 8, yielding values of ~20% (Cu), ~10% (Ni), and 2% (Nb_2O_5).

Discussion

The behavior of the p-GaAs/solution interface and a rationalization of the observed PEC cell behavior can be presented in terms of the surface controlled model for GaAs proposed elsewhere (26) (Fig. 9). In this model, the Fermi level of the semiconductor is pinned by surface states located about one-third of the way up in the gap (*i.e.*, ~0.4-0.5V above the valence bandedge) (Fig. 9a). The maximum open-circuit photopotential, V_{on}, observed under intense illumination would then be ~0.4V, and the open-circuit photovoltage would be the difference between V_{on} and V_{redox} of the counterelectrode reaction (Fig. 9b). In the dark after deposition of HVBr, oxidation of HVBr occurs via the surface states and the p-GaAs essentially behaves as an inert contact to the layer (Fig. 9c). The counterelectrode in a two-electrode PEC cell must have a redox potential between V_{on} and that of the HV^{2+}/HVBr system, so that only couples in a relatively narrow range of potentials are suitable.

Storage cells based on this type of electrode reaction will necessarily have small capacities, unless films which deposit on the electrode surface can be found which are both transparent to the wavelengths absorbed by the semiconductor and are electrical conductors. Moreover, higher concentrations of the soluble form are required to prevent mass transfer limitations to the photocurrent even before film formation causes current decay. Such cells may, however, find application in very low capacity batteries or as a-c devices under periodic illumination.

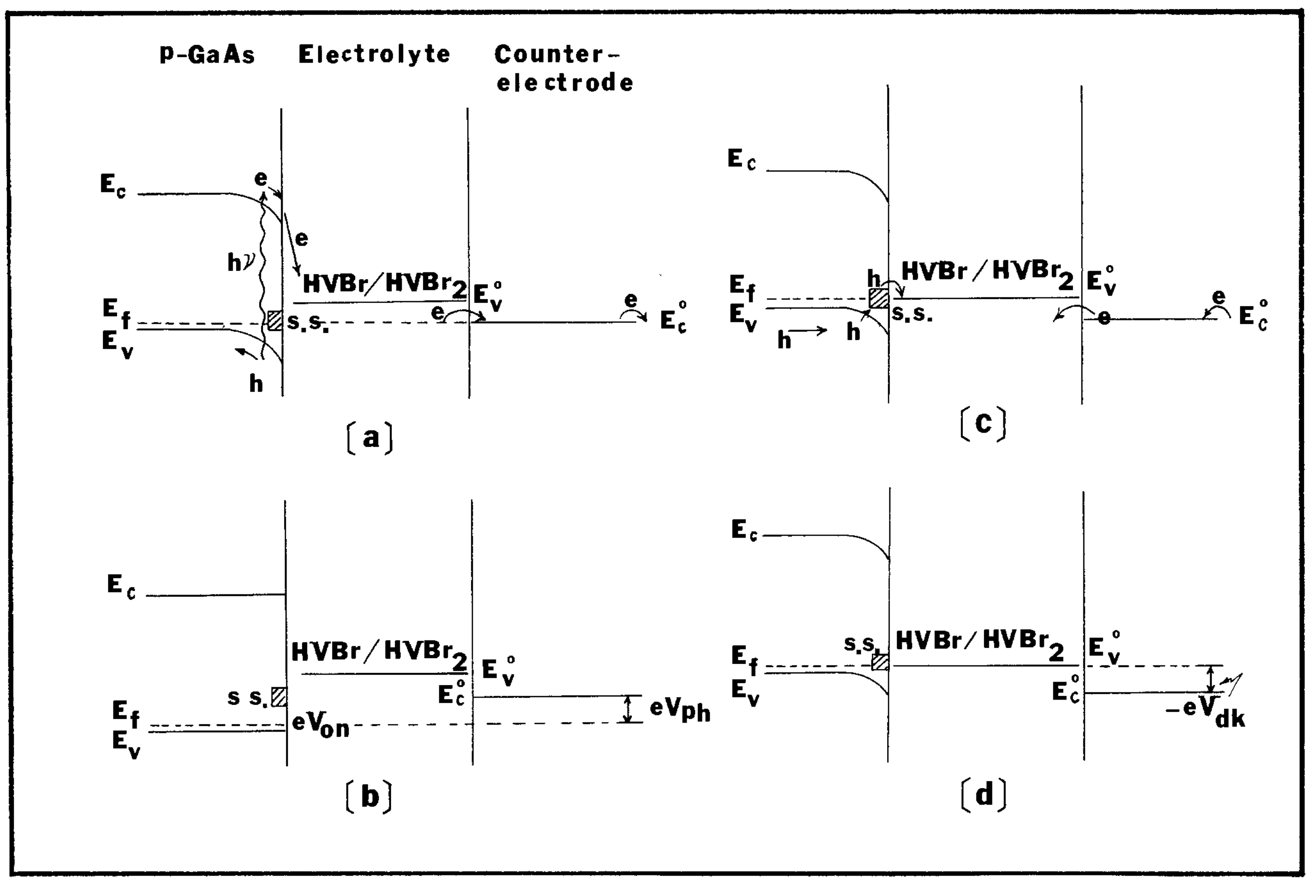

Fig. 9. Schematic description of the energy levels of the $HVBr_2$-based photoelectrochemical cells in the light at (a) short circuit, no HVBr film on p-GaAs initially, and (b) open circuit, no HVBr film on p-GaAs initially. In the dark at (c) short circuit, with HVBr film on p-GaAs, and (d) open circuit, with HVBr film on p-GaAs. E_c = conduction bandedge of p-GaAs; E_f = Fermic energy of p-GaAs; E_V = valence bandedge of p-GaAs; s.s. = surface state; $E_V{}^o$ = energy corresponding to the redox potential of heptyl viologen couple; $E_C{}^o$ = energy corresponding to the redox potential of the counterelectrode; V_{ph} = open-circuit voltage in the light; V_{dk} = open-circuit voltage in the dark; V_{on} = onset potential of photocurrent.

The application of such a system to produce a display addressable both optically and electrically (a photoelectrochromic display) is perhaps of greater interest (Fig. 10). One can envision the operation of such a device in which a light beam produces a raster on the electrode surface, and the electrode potential is switched to (*i*) the deposition potential (coloring), (*ii*) open circuit (hold), or (*iii*) the stripping potential (erase). The advantage of such a display, compared to the more familiar electrochromic ones, is that only two leads need be provided to the cell rather than the multiple leads and complicated electrical addressing required for a large screen or multi-character display. While the contrast ratio for HVBr on GaAs is not very good, in principle a wide bandgap semiconductor (*e.g.*, > 3 eV), which would appear white and would be addressed with an ultraviolet beam could be employed. For a display involving rapid scanning, a system with a faster response time is also required. Similar concepts involving semiconductors and metal depositions for photoimaging have been reported (24, 27).

Semiconductor Electrodes

XXIII. The Determination of Flatband Potentials from Differential Stress Measurements with Attached Piezoelectric Detectors

Lee J. Handley and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

A new method for the determination of the flatband potential, V_{fb}, of semiconductor electrodes by differential stress measurements of a piezoelectric detector bonded to the semiconductor is reported. Values of V_{fb} for single crystal n-$SrTiO_3$ and p-GaAs, and polycrystalline n-TiO_2 in 1*N* NaOH and 1*N* H_2SO_4 are shown to be in good agreement with previously determined values. Possible application of such measurements to the study of surface changes and breakdown is suggested.

The flatband potential, V_{fb}, of a semiconductor/electrolyte solution interface is an important parameter in explaining the electrochemical characteristics of the system in the dark and under illumination (1-3). V_{fb} is a function of both the semiconductor material and the solution composition, and is measured to determine the locations of the semiconductor valence and conduction bandedges with respect to solution energy levels. Usually V_{fb}-values are determined by direct measurements of the space charge differential capacity, C_{sc}, (Schottky-Mott plots) or by determinations of the open-circuit photopotential (or the potential for the onset of the photocurrent) under intense irradiation. Both of these methods often suffer from difficulties which result in large uncertainties in the V_{fb}-values estimated by them. In C_{sc} measurements the Schottky-Mott plots are frequently nonlinear and yield V_{fb}-values which are functions of the frequency used. This has been attributed to the effect of surface states and other factors (4). The estimation from photopotentials can also be perturbed by the existence of surface states or intermediate levels as well as by recombination effects which, for an n-type semiconductor, will yield onset photopotentials less negative than the actual V_{fb}-value (5).

V_{fb} can also be determined by observing the voltammetric response in the dark of couples spanning a potential range above and below V_{fb} (5, 6). Such measurements usually yield a V_{fb}-value with considerable uncertainty and may also be perturbed by electron transfers occurring via surface states. In this paper, we propose a method for the determination of V_{fb}, based on the measurement of differential stress (with a piezoelectric crystal attached to the semiconductor electrode) as a function of potential, which is experimentally simple and theoretically direct.

There have been several previous reports of the application of piezoelectric materials (which are materials which produce a potential when placed under a stress) to measurements at metal electrodes (7-10). From a modified form of the Lipmann equation that was used by Gokhstein (7) for metal electrodes, the differential surface stress ($\partial\sigma_s/\partial E$) is related to the surface charge density (q) and deformation by

$$\partial\sigma_s/\partial E = -q - \partial q/\partial\theta \qquad [1]$$

where θ is the ratio of the surface area before and after deformation. For an ideally polarized electrode, the term $\partial q/\partial\theta$ is zero, since the charge density does not depend upon the deformation of the electrode surface. Even for nonpolarizable electrodes this term may be small and is equal to zero at the flatband potential, because at V_{fb} there is no charge on the electrode.

For semiconductor electrodes, the excess charge q is distributed in the space charge region. At potentials negative of the flatband potential, the space charge region has an excess of electrons and the differential stress measurements will be positive. At the flatband potential there is no excess charge and the differential stress is zero. For potentials positive of the flatband potential there is an accumulation of holes in the space charge region and the differential stress will be negative. Thus, as implied by Eq. [1], the differential stress tracks the space charge, and the intercept of the dif-

Key words: piezoelectricity, capacitance.

ferential stress as a function of potential will be at the flatband potential.

Experimental

The experimental technique used for semiconductor electrodes is the same as the technique developed for metal electrodes (8-10). Three electrodes were prepared by bonding a ceramic piezoelectric disk (Edo Western Corporation, Salt Lake City, Utah) to the back of the semiconductor with Devcon 5-minute epoxy cement. The piezoelectric disk was electrically insulated from the semiconductor and the electrolyte with silicone cement (Fig. 1). The face next to the semiconductor was maintained at ground potential to insure that a-c potentials on the semiconductor would not affect the potential measured across the piezoelectric disk.

The three semiconductors studied were single crystal n-type $SrTiO_3$ (2 mm thick), which had been reduced in hydrogen at 800°C for 5 hr; single crystal p-type GaAs (1 mm thick), which was doped with Zn; and polycrystalline n-TiO_2 (0.2 mm thick), which was prepared by oxidizing titanium foil in an open flame. The electrolytes used were stock solutions of 1*N* NaOH and 1*N* H_2SO_4.

The measurement procedure generally followed that used with metal electrodes (8-10). An a-c modulating signal superimposed on a potential ramp generated the piezoelectric signal (see Fig. 2). For this experiment both the in-phase ($\phi = 0°$) and quadrature ($\phi = 90°$) piezoelectric signals were recorded simultaneously for each potential scan.

Results and Discussion

Separation of quadrature and in-phase signals.—If the semiconductor/electrolyte interface is represented as an equivalent circuit composed of a resistor and capacitor in series (where the resistor represents the bulk resistance of the semiconductor and the capacitance is that of the space charge region), then the a-c modulation voltage will produce two components of electrode stress. The first, attributable to the *IR* heating caused by the a-c current that flows through the bulk of the semiconductor, is proportional to the potential difference across the bulk resistance. It will be in-phase and proportional to the modulating signal amplitude. The second is due to the surface stress caused by a change in the charge density in the space charge region. This component is proportional to the potential difference across the space charge capacitance and will be 90° out of phase with, but still proportional to, the modulating signal. The assumption has been made that $\omega RC >> 1$, so that $\tan^{-1} (\omega RC) \sim 90°$. All of the data supports this assumption. This proportionality of the in-phase and quadrature signals to the modulating signal amplitude is shown in Fig. 3. Under these conditions, the in-phase signal is about an order of magnitude larger than the quadrature signal.

The determination of flatband potentials.—The in-phase signal should always have the same sign at all electrode potentials while the quadrature signal should change sign at the flatband potential. This is shown in Fig. 4 for n-$SrTiO_3$. At very positive potentials ($\sim$ +11V) the quadrature signal again changes sign, probably because of a breakdown phenomenon since this potential corresponds to the onset of d-c anodic current.

The quadrature signals near the flatband potentials for n-$SrTiO_3$ and n-TiO_2 in 1*N* H_2SO_4 and 1*N* NaOH are shown in Fig. 5 and 6. The V_{fb}-values determined from such differential stress measurements are listed in Table I. These results agree very well with values previously reported (3, 11, 12) and have an uncertainty of only ±25 mV or less, which is better than the usual methods for determining flatband potentials. The *p*H shift for these materials is near 59 mV/*p*H unit, as expected (3, 11, 12).

Frequency dependence.—The frequency dependence of the differential stress measurements is shown in Fig. 7 for the quadrature signal at three different frequencies and in Fig. 8 for the in-phase signal at the

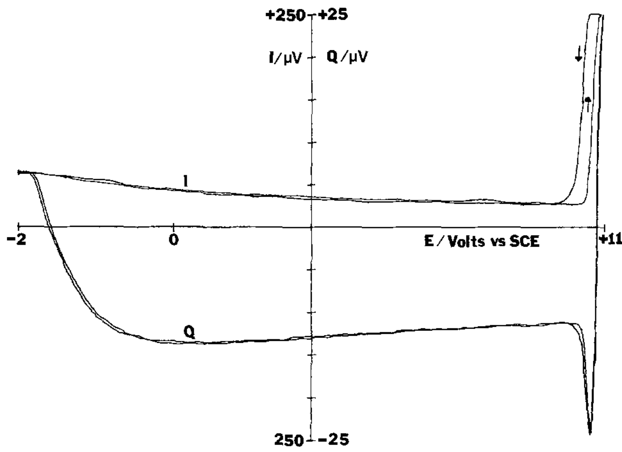

Fig. 4. In-phase (*I*) and quadrature (*Q*) differential stress signals for n-$SrTiO_3$ in 1*N* NaOH for cyclic potential sweep from −2 to +11V *vs.* SCE at 20 mV/sec with a modulating signal of 50 mV at 1 kHz. The in-phase signal scale is an order of magnitude larger than that for the quadrature signal.

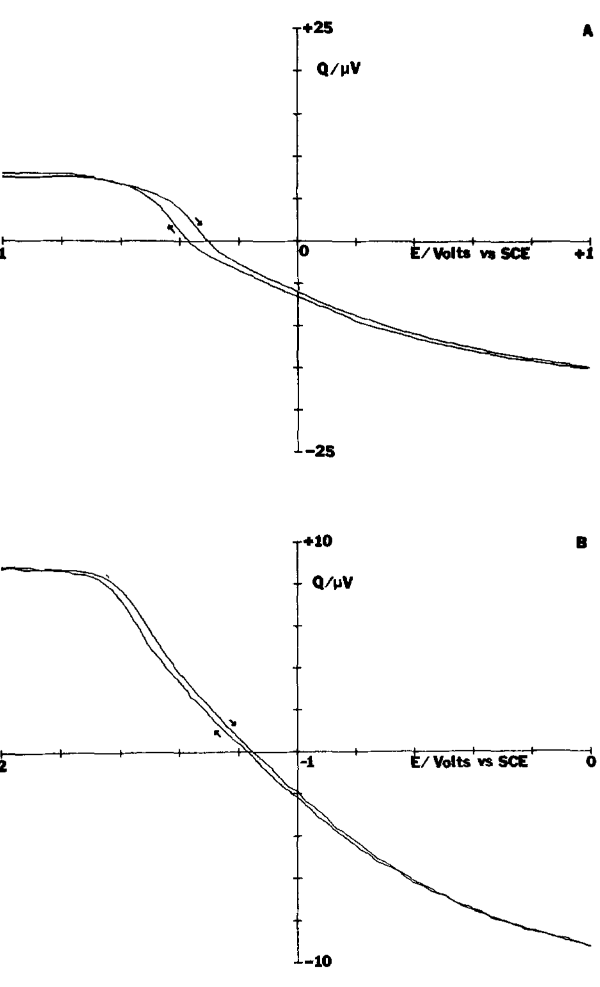

Fig. 5. A: Quadrature differential stress measurement for n-$SrTiO_3$ in 1*N* H_2SO_4 from −1 to +1V *vs.* SCE with a modulating signal of 50 mV at 1 kHz. B: Quadrature differential stress measurement for n-$SrTiO_3$ in 1*N* NaOH from −2 to 0V *vs.* SCE with a modulating signal of 50 mV at 1 kHz.

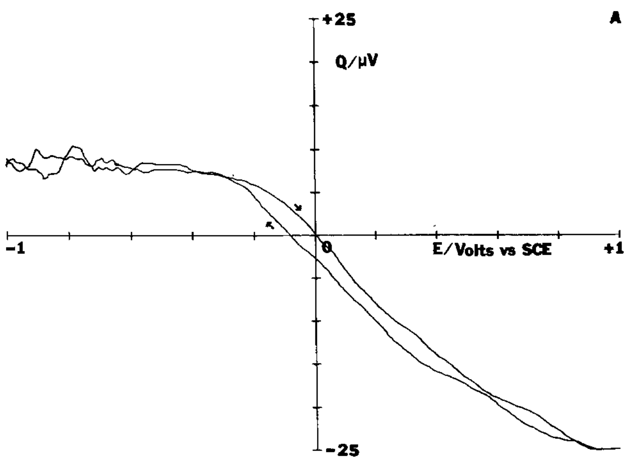
same three frequencies for n-$SrTiO_3$ in 1*N* H_2SO_4. The capacitive impedance of the space charge region increases with a decrease in frequency, therefore, increasing the absolute value of the quadrature signal at potentials other than the flatband potential. The intercepts for all three frequencies are within a range of 40 mV. Since the *IR* stress (in-phase) signal is an order of magnitude larger than the space charge (quadrature) signal, the changes in the quadrature signal have only a small effect on the in-phase signal.

Effects of chemical changes at the electrode surface. —The quadrature differential stress measurements for p-GaAs are shown in Fig. 9 and 10 for 1*N* H_2SO_4 and 1*N* NaOH, respectively. The extent of frequency dependence of intercept was similar to that for n-$SrTiO_3$. The V_{fb}-values, listed in Table I, are in reasonable agreement with previous measurements (13). An interesting point to note is the difference in hysteresis for p-GaAs for the acidic and alkaline electrolytes when the potential is scanned between +1.5 and −0.5V *vs.* SCE. The data for 1*N* H_2SO_4 show almost no hysteresis, while there is approximately 0.1V difference



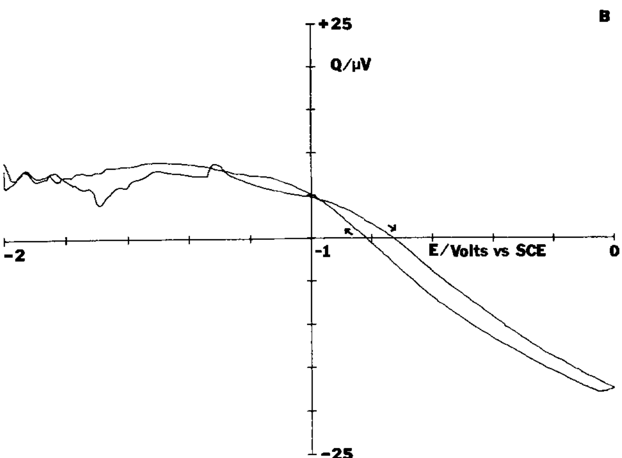


Fig. 6. A: Quadrature differential stress measurement for n-TiO_2 in 1*N* H_2SO_4 from −1 to +1V *vs.* SCE with a modulating signal of 50 mV at 1 kHz. B: Quadrature differential stress measurement for n-TiO_2 in 1*N* NaOH from −2 to 0V *vs.* SCE with a modulating signal of 50 mV at 1 kHz.

between the forward and reverse sweeps for V_{fb} in 1*N* NaOH. This can probably be attributed to instability of p-GaAs in alkaline solutions at potentials positive of the flatband potential. When the potential was scanned from −0.4 to +1V *vs. SCE*, the hysteresis was still present (Fig. 11). However, for a potential scan from −0.4 to 0V, the hysteresis near V_{fb} disappeared (Fig. 12). This suggests that differential stress measurements may also be useful for studying stability and changes in the surface of semiconductor electrodes.

Effects of illumination.—Since the space charge region will have an excess of majority carriers on one side of the flatband potential, and an excess of negative charge on the other side, the effects of illumina-

illumination (Fig. 13) agree with this prediction. The effect of illumination is to decrease the extent of band bending, thereby reducing the surface stress.

Conclusions

Preliminary experiments have demonstrated that V_{fb}-values of both p- and n-type semiconductor electrodes, single crystal and polycrystalline, can be determined from differential stress measurements as a function of potential. The only assumption that has been made is that a semiconductor electrode can be represented as an equivalent circuit consisting of a resistor and capacitor in series. The V_{fb}-values from the differential stress measurements are in excellent agreement with independent previous measurements and show the expected *p*H shift of 59 mV/*p*H unit for n-$SrTiO_3$ and n-TiO_2.

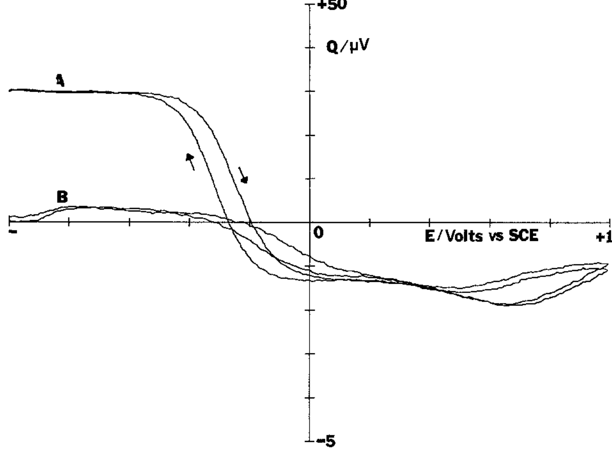

Fig. 13. Quadrature differential stress measurements for p-GaAs in 1*N* NaOH from +1 to −1V vs. SCE: (A) in dark and (B) under illumination. The modulating signal was 50 mV at 5 kHz.

In addition to determination of V_{fb}, the sharp change in the differential stress observed near the breakdown potential may be of use in elucidating the phenomena occurring in this region. As seen in Fig. 4, the quadrature signal has a sharp minimum near the breakdown potential; there is definite hysteresis in the inphase signal but none for the quadrature signal. The dependence of the differential stress signals on frequency and illumination is in qualitative agreement with the experimental results. Preliminary results also suggest that differential stress measurements may be useful in studying the stability and changes in the surface of semiconductor electrodes. Work is in progress to obtain a better understanding for these latter effects as well as extending V_{fb} measurements to other semiconductors and other solvent/electrolyte systems.

Application of A-C Techniques to the Study of Lithium Diffusion in Tungsten Trioxide Thin Films

C. Ho,* I. D. Raistrick,* and R. A. Huggins*
Stanford University, Stanford, California 94305

ABSTRACT

The small signal a-c impedance of the cell

Li|$LiAsF_6$ (0.75M) in propylene carbonate|
Li_yWO_3 thin film on tin oxide covered glass substrate

has been measured at room temperature as a function of frequency from 5×10^{-4} Hz to 5×10^3 Hz at various open-circuit voltages. The diffusion equations have been solved for the appropriate finite boundary conditions, and analysis of the impedance data by the complex plane method yields values for the chemical diffusion coefficient, the component diffusion coefficient, the partial ionic conductivity of lithium, and the thermodynamic enhancement factor for Li_yWO_3 as a function of y. The films of WO_3 were prepared by vacuum evaporation and were largely amorphous to x-rays. The chemical diffusion coefficient has a value of 2.4×10^{-12} cm²/sec at $y = 0.1$, increasing to 2.8×10^{-11} cm²/sec at $y = 0.26$. At short times ($t < 0.5$ sec) the interfacial charge transfer reaction is important, but at longer times the rate of lithium injection is determined by the diffusion kinetics.

Considerable interest has developed recently in the possibility of fabricating display devices based on the electrochemical injection of metal or hydrogen atoms into transition metal oxides, usually WO_3. The reaction may be written

$$WO_3(\text{colorless}) + yM^+ + ye^- \leftrightarrows M_yWO_3(\text{colored})$$

For each atom injected an electron enters the conduction band of the host oxide and a deep blue coloration develops. At the same time, the electronic conductivity of the oxide rapidly increases. The range of solid solubility of M in WO_3 may be quite extensive; typically a y value of about 0.1-0.2 is necessary for good optical contrast. The activity of M in M_yWO_3, and hence the electrode potential of the electrochromic oxide will vary continuously with y as long as a single phase solid solution is formed. If the reaction proceeds rapidly and reversibly, then the metal atoms may be repeatedly injected and removed by controlling the electrode potential of the oxide electrode with respect to a counterelectrode which acts as a source and sink of M.

Although reactions of this type have been known for several years, few data are available on basic electrochemical parameters, such as diffusion coefficients of M in the oxide or exchange current densities, even though the eventual response time of the device will be largely determined by these parameters. It is not even clear whether the rate of injection is limited by diffusion or by charge transfer at times of interest for display applications.

* Electrochemical Society Active Member.

Key words: diffusion, WO_3, lithium injection, electrochromic films, a-c technique.

This paper describes a steady-state a-c technique which may be used to determine the rate-limiting process and the important kinetic parameters of an electrochromic system. It is illustrated by results obtained for the lithium-tungsten trioxide system.

Although any of several transient techniques could, in principle, be used to study this system, an a-c method was chosen since it seemed likely that, using complex plane methods, data analysis could be much simplified, especially since semi-infinite diffusion conditions cannot be assumed for the case of thin film electrodes.

Few studies of the electrochromic effect of alkali metals in WO_3 have been reported (1-10). Green *et al.* have studied sodium and lithium injection in WO_3 using both liquid and solid electrolytes (2-5, 10). The diffusion coefficient of lithium was estimated to be 2×10^{-12} cm²/sec (3). Mohapatra (8), however, has recently reported a much higher value of 5×10^{-9} cm²/sec. Thermodynamic data for lithium in amorphous WO_3 films have recently also appeared (9, 10).

Theory of the A-C Method

Alternating-current and voltage methods have, of course, been extensively used in many kinds of electrochemical systems, and several review articles are available (11-13).

In general, either current or voltage may be the controlled variable, and the phase and magnitude of the dependent variable (voltage or current, respectively) are determined with respect to this. If measurements are made over a wide-enough frequency

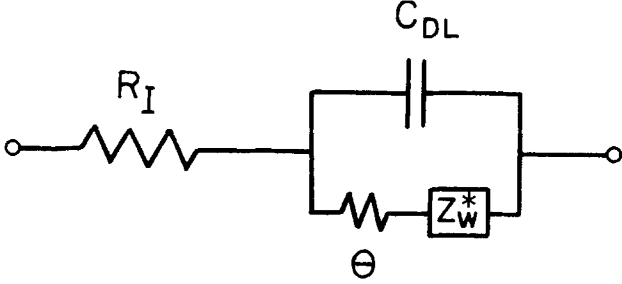

Fig. 1. The Randles equivalent circuit for the a-c response of a system with charge transfer and diffusion of the electroactive species.

range, then different physical processes may be separated through their different time constants.

The problem of the a-c response of a simple electrochemical system with either charge transfer or diffusion-limited kinetics has been considered by several authors. The equivalent circuit for this situation is due to Randles (14) and is shown in Fig. 1. This circuit will also be valid for the diffusion of a metal into an oxide electrode, if it can be assumed that diffusion is driven by a gradient in composition and not by an electric field.

In Fig. 1, R_I is the uncompensated ohmic resistance of the electrolyte and electrode, C_{DL} is the double layer capacitance of the electrode-electrolyte interface, θ is the charge transfer resistance, and Z_W^* is a complex impedance arising from the diffusion of the electroactive species.

For the case of semi-infinite diffusion

$$Z_W^* = A\omega^{-1/2} - jA\omega^{-1/2} \quad [1]$$

where ω is the radial frequency, $j = \sqrt{-1}$, and A is a constant which contains a concentration independent diffusion coefficient. Z_W^* is often known as the Warburg impedance (15). The explicit form of A, and a more general expression for Z_W^*, which is also valid for a finite diffusion situation, are derived below.

The charge transfer resistance θ, is related to the exchange current density (I_o), through a linearization of the Butler-Volmer equation for small overpotentials (δE)

$$\theta = \frac{\delta E}{i} = \frac{RT}{nI_o\mathbf{F}} \qquad \delta E << \frac{RT}{\mathbf{F}} \quad [2]$$

It is assumed in the derivation of this equivalent circuit that small signal conditions are met, since C_{DL}, θ and A are in general voltage or concentration dependent and lead to nonlinear behavior.

The frequency response of this circuit will be governed by the relative importance of charge transfer and diffusion in determining the current: for very slow diffusion $Z_W^* > \theta$, and for very slow charge transfer kinetics $Z_W^* < \theta$. Since Z_W^* is a function of frequency and θ is not, then an electrode reaction rate may be controlled by diffusion at low frequencies (long times) and by charge transfer at high frequencies (short times).

Derivation of Z_W^* for a thin film electrode.—The magnitude of the Warburg impedance Z_W^* is determined by the chemical diffusion coefficient of the neutral electroactive species (A) in the electronically conducting oxide electrode (B), and the explicit form of Z_W^* can be derived by solving Fick's laws with suitable initial and boundary conditions. The situation is fully analogous to the determination of chemical diffusion coefficients in solid solution electrodes by a transient galvanostatic technique discussed previously by Weppner and Huggins (16, 17).

Experimentally, the electrode is held at a constant potential E, with respect to a reference electrode of pure A, until equilibrium is reached. The composition of the sample at equilibrium is uniform and equal to A_yB. The chemical potential of A in A_yB is

$$\mu_A = \mu_A^o + RT \ln \gamma_A X_A \quad [3]$$

Here X_A is the mole fraction of A, and γ_A is its activity coefficient. If we choose $\gamma_A \to 1$ as $X_A \to 1$ then μ_A^o is the chemical potential of pure A at the same temperature. Thus

$$E = -\frac{RT}{z\mathbf{F}} \ln \gamma_A X_A \quad [4]$$

z is the charge carried by A cations, $\mathbf{F}$ and R are the gas constant and Faraday, respectively.

A small alternating voltage

$$\delta E = v_o \sin \omega t \quad [5]$$

is now applied between the A_yB working electrode and the reference electrode, which drives the surface of the working electrode to a new time dependent concentration $X_A + \delta X_A$ (which corresponds to a stoichiometry of $A_{y+\delta y}B$). Eventually, a steady state is reached and we require an expression for the amplitude and phase of the current flowing through the cell. Since the current density depends on the gradient in concentration at the interface, through Fick's law, and the voltage depends on the chemical potential at the interface, it is necessary to either make dilute solution assumptions or else to have knowledge of the activity coefficient of A in A_yB. Since the solid solutions under consideration here are quite concentrated (X_A may be as high as 0.3) dilute solution behavior cannot be assumed and an alternative approach is adopted here which is equivalent to a knowledge of γ_A as a function of y. If we can assume that for very small changes in voltage

$$\frac{\delta E}{\delta X_A} \cong \frac{dE}{dX_A} \quad [6]$$

We can substitute Eq. [6] into Eq. [5] and obtain

$$\delta X_A(t) = (dE/dX_A)_{X_A}{}^{-1} \cdot v_o \sin \omega t \quad [7]$$

This equation describes the change in mole fraction of A at the electrode-electrolyte interface for a very small change in applied alternating voltage. $(dE/dX_A)_{X_A}$ may be obtained by differentiation of the coulometric titration curve at the appropriate composition (X_A), or as will be seen later, may, in the present case, be obtained directly from very low frequency measurements. Equation [7] represents a linearization of the dependence of concentration on voltage. The mole fraction of A at the interface is therefore a sinusoidal function of time as long as $(dE/dX_A)_{X_A}$ is constant over the range of composition δX_A.

For a diffusion experiment it is convenient to write Eq. [7] in terms of the number of atoms per unit volume (C_A), and the stoichiometry (y)

$$\delta C_A(t) = \frac{N}{V_M} \cdot \left(\frac{dE}{dy}\right)_y^{-1} \cdot v_o \sin \omega t \quad [8]$$

Here N is Avogadro's number and V_M is the molar volume of A_yB, assumed constant over the range δy.

We therefore seek solutions of the equation

$$\frac{\partial[\delta C_A(x,t)]}{\partial t} = \tilde{D} \frac{\partial^2[\delta C_A]}{\partial x^2} \quad [9]$$

with the initial condition of uniform concentration

$$\delta C_A(x,0) = 0 \quad [10]$$

and the $x = l$ boundary condition given by Eq. [8]. Here l is the thickness of the oxide electrode; the coordinate system used is shown in Fig. 2. The second boundary condition is

$$\partial[\delta C_A(0,t)]/\partial x = 0 \quad [11]$$

corresponding to an interface impermeable to A. The diffusion coefficient used here is the chemical diffusion coefficient, which is appropriate for the diffusion of a species in an activity gradient (16). With certain assumptions, it can be related to the particle diffusion coefficient of the components (A^{z+} ions and electrons).

The solution of Eq. [9] for these conditions is given by Carslaw and Jaeger (18)

$$\delta C_A(x,t) = \alpha B \sin(\omega t + \phi) \quad [12]$$

with

$$\alpha = \frac{N}{V_M} \cdot \left(\frac{dE}{dy}\right)^{-1} v_o \quad [13]$$

$$B = |f| \quad [14]$$

$$\phi = \arg(f) \quad [15]$$

and

$$f = \frac{\cosh kx \cdot (1+j)}{\cosh kl \cdot (1+j)} \quad [16]$$

with

$$k = (\omega/2\tilde{D})^{1/2} \quad [17]$$

Note that this is the steady-state solution. There is also a transient caused by starting the sinusoidal oscillation at $t = 0$. The form of this transient is given in Ref. (18).

In order to determine the current density in the system, it is necessary to evaluate $(\partial[\delta C_A]/\partial x)_{x=l}$. From Eq. [12] it may be shown that

$$\left(\frac{\partial[\delta C_A]}{\partial x}\right)_{x=l} = \tau \sin(\omega t + \beta) \quad [18]$$

where

$$\tau = (\alpha k/\sqrt{2}d)(h^2 + s^2)^{1/2} \quad [19]$$

and

$$\beta = \arctan\left(\frac{h+s}{h-s}\right) \quad [20]$$

with

$$h = \sinh(2kl) \quad [21]$$

$$s = \sin(2kl) \quad [22]$$

$$d = \cosh^2(kl) \cdot \cos^2(kl) + \sinh^2(kl) \cdot \sin^2(kl) \quad [23]$$

Thus, the current density

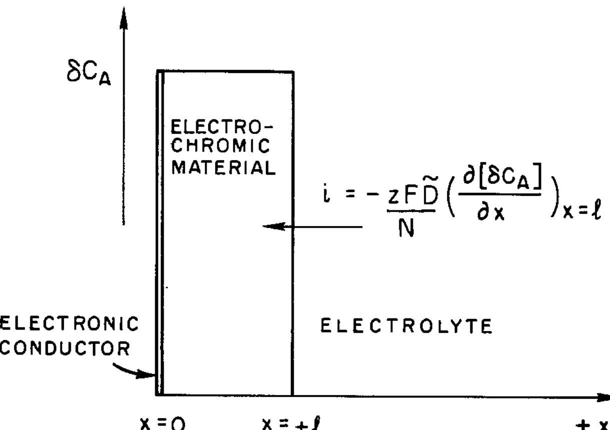

Fig. 2. The coordinate system used for the solution of the diffusion equations.

$$i_d = -\tilde{D}\left(\frac{\partial[\delta C_A]}{\partial x}\right)_{x=l} \cdot \frac{zF}{N} \quad [24]$$

has an amplitude

$$i_o = -\frac{zF}{2V_M}\left(\frac{dE}{dy}\right)^{-1} \cdot v_o(\omega\tilde{D})^{1/2}\left(\frac{h^2+s^2}{d^2}\right)^{1/2} \quad [25]$$

and a phase of β with respect to the applied voltage. Note that both the phase and the amplitude are frequency dependent.

Two extreme cases are of interest. First, consider the value of i_o for high frequencies, small $\tilde{D}$, or thick samples, *i.e.*, $kl >> 1$. Under these conditions $(h^2 + s^2)^{1/2}/d = 2$, and so

$$i_o = -\frac{zFV_o}{V_M}\left(\frac{dE}{dy}\right)^{-1} \cdot (\omega\tilde{D})^{1/2} \quad [26]$$

and

$$\beta = \arctan(1) = \pi/4 \quad [27]$$

Thus, the phase difference between the current and the voltage is independent of frequency and is equal to 45°. Expressing this result as a complex impedance

$$Z_W^* = |Z|\cos\left(\frac{\pi}{4}\right) - j|Z|\sin\left(\frac{\pi}{4}\right) = \frac{|Z|}{\sqrt{2}} \cdot (1-j) \quad [28]$$

where

$$|Z| = \left|\frac{v_o}{i_o a}\right| = \left|\frac{V_M(dE/dy)}{zF\tilde{D}^{1/2}a} \cdot \omega^{-1/2}\right| \quad [29]$$

where a = surface area.

Comparison of Eq. [28] with Eq. [1] shows that for these conditions the preexponential factor A in the Warburg impedance has the form

$$A = \left|\frac{V_M(dE/dy)}{\sqrt{2}\, zF\tilde{D}^{1/2}a}\right| \quad [30]$$

The other limiting case occurs at very low frequencies, for very thin samples or for large $\tilde{D}$

If

$$kl << 1 \qquad (i.e., \omega << 2\tilde{D}/l^2) \quad [31]$$

$$i_o = -\frac{zFv_o}{V_M}\left(\frac{dE}{dy}\right)^{-1} l\omega \quad [32]$$

$$\beta = \arctan(\infty) = \frac{\pi}{2} \quad [33]$$

Thus, under these conditions the current is 90° out of phase with the voltage and is independent of the diffusion coefficient.

Expressed as the imaginary (X) and real (R) parts of the complex impedance for these conditions

$$X = |Z|\sin\beta = |Z| = |V_M(dE/dy)/zF\omega la| = \frac{1}{\omega C_L} \quad [34]$$

$$R = |Z|\cos\beta = |Z|\, 2k^2l^2/3a \quad [35]$$

$$= R_L = \left|\frac{V_M}{zFa}\left(\frac{dE}{dy}\right)\left(\frac{l}{3\tilde{D}}\right)\right| \quad [36]$$

where C_L and R_L are the limiting low frequency capacitance and resistance. An interesting consequence of Eq. [34] and [36] is that for thin samples, it is not necessary to obtain a coulometric titration curve since simultaneous solution of these equations yields values for both the diffusion coefficient and $(dE/dy)_y$. Alternatively, if this last quantity is known independently, then the sample thickness may be calculated. Of course, no information about $(dE/dy)_y$ or l may be obtained

from the high frequency data since the diffusion is then semi-infinite in nature, and only $\tilde{D}$ may be determined.

At intermediate frequencies, when neither of the two limiting cases can be applied, the frequency response of the electrode must be analyzed using the full impedance expressions

$$Z_W^* = R_W - jX_W \quad [37]$$

with

$$X_W = |Z| \sin \beta \quad [38]$$

$$R_W = |Z| \cos \beta \quad [39]$$

where β is given by Eq. [20], and

$$|Z_W| = |v_o/i_o a| \quad [40]$$

where i_o is given by Eq. [25].

Complex plane representation.—Since the form of Z_W^* is now known, the impedance of the entire circuit of Fig. 1 can be computed as a function of frequency. The most useful way of representing this result is by plotting the real (R) and imaginary (X) components of the total circuit impedance *vs.* one another in the complex plane as functions of frequency. Three such computer generated plots are shown in Fig. 3.

In Fig. 3(a), the diffusional impedance is large and a straight line of 45° slope is seen over most of the frequency range. The kinetics of the system are limited almost entirely by the rate of the diffusional process. The high frequency real axis intercept gives the value of R_I and $\tilde{D}$ may be found by analysis of the straight line portion of the curve using Eq. [28] and [29].

In Fig. 3(b) a transition is obtained such that the kinetics pass from diffusion control at low frequencies to charge transfer control at high frequencies. The semicircle at high frequencies is due to the parallel combination of C_{DL} and θ, the values of which may in principle be obtained by analysis of the high frequency data. The extrapolated real intercept of the straight line region lies at [11]

$$R_S = R_I + \theta - r \quad [41]$$

with

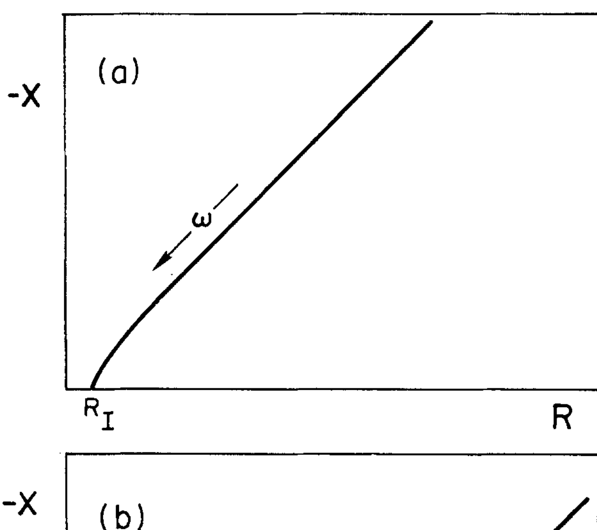
$$r = 2C_{DL}A^2 \quad [42]$$

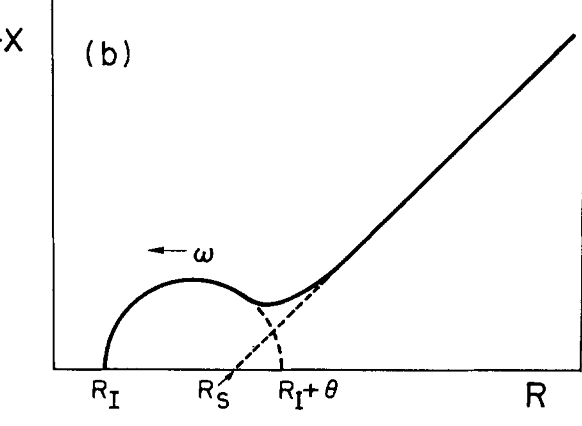
where A is given by Eq. [30].

At very low frequencies the phase angle begins to increase due to the onset of finite length effects. This process is complete in Fig. 3(c), where R has reached its limiting value given by the sum of R_L (Eq. [36]) and ($R_I + \theta$). If the diffusion kinetics are in the proper range, there can be good separation between the charge transfer semicircle at high frequencies, the 45° line of Z_W^* at intermediate frequencies, and the vertical line at very low frequencies, due to the finite thickness effect. $\tilde{D}$ may be obtained from either the 45° portion of the line or from R_L, determined from the limiting resistance, and Eq. [36].

Experimental Procedures

Sample preparation.—The diffusion experiments were carried out on thin films of tungsten trioxide deposited on tin oxide (700Å thick) covered glass substrates. Amorphous WO_3 films were prepared by thermal evaporation of the oxide at a rate of 30 Å/sec. The substrate temperature during evaporation was 100°C, and the pressure was maintained at 2×10^{-4} Torr of air. The method of preparation and the characterization of these films was discussed in Ref. (19), where it was also demonstrated that such films are stable in the electrolyte/solvent system used in the present experiments.





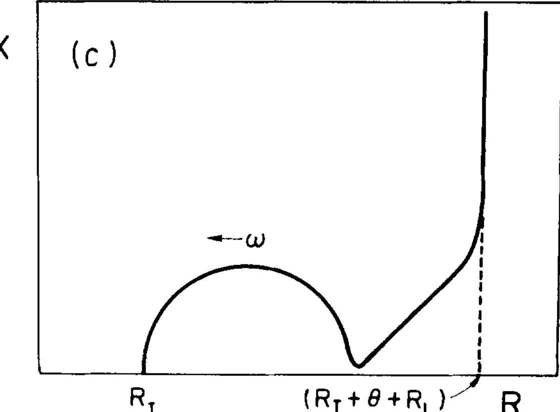


Fig. 3. Computer simulation of the complex impedance of the circuit shown in Fig. 1 for various values of the diffusion coefficient.

The results reported below were obtained on 1500Å thick films which had been heat-treated in pure oxygen for 6 hr at 350°C. This procedure was adopted in order to dry the films and to ensure that the stoichiometry was in fact WO_3. X-ray diffraction experiments indicated that the initially amorphous films, which showed only a broad diffuse scattering centered on a d value of 3.6Å, developed some crystallinity on undergoing this heat-treatment. Several sharp reflections developed, which could be indexed on the same unit cell as the high temperature tetragonal modification of WO_3 (in agreement with the observations of Green [10], but with slightly reduced lattice parameters). The sharp reflections were superimposed on a diffuse background similar to that of the unheated, treated films.

A density of 5.2 g/cm³ was used in the calculation of the results below, based on a comparison of the measured film volume (using interferometry) and chemical analysis (19).

Electrochemical measurements.—Measurements were made using a three electrode configuration. Both

counter and reference electrodes were pure lithium metal, and the electrolyte was 0.75M $LiAsF_6$ in propylene carbonate. The electrolyte was dried by prolonged agitation with lithium chips. All materials and the electrochemical cell were kept in a helium-filled dry box. Measurements were made at 300°K.

The thin film working electrode was held at constant voltage (and hence composition) by a Princeton Applied Research Model 173 potentiostat. A small alternating signal from a Hewlett Packard HP3110B oscillator was then superimposed on the constant voltage and the current flowing in the counter-working electrode circuit was monitored via a standard resistance. The circuit is shown in Fig. 4. The amplitude of the signal applied to the sample was always less than 10 mV and the frequency range covered extended from 5×10^{-4} Hz up to 5 kHz.

Above 20 Hz, the amplitude and phase of the current with respect to the applied voltage were measured directly using a PAR Model 5204 two-phase lock-in analyzer. Above about 100 Hz, small corrections were made to compensate for the attenuation and phase shift introduced into the signal by the potentiostat. This was achieved by comparing the a-c perturbation of the potential difference between the reference and working electrodes directly with the output of the oscillator.

Below 20 Hz, the signals corresponding to current and voltage were amplified using a PAR Model 113 preamplifier and fed to the analog-to-digital converters of a Digital Equipment Corporation Lab 8e computer, where the two signals were averaged over several cycles and compared.

Results

The change in open-circuit voltage (E) with composition (y) is plotted in Fig. 5. The order in which the points were taken is indicated, showing that the measurements were in fact made at equilibrium. Results of the two other thermodynamic studies are also shown for comparison (9, 10).

The complex impedance data are summarized in Fig. 6 and 7. In Fig. 6, the higher frequency data are shown for four open-circuit voltages. At the highest voltage (2.6V with respect to pure lithium), a straight line of slope 45° was obtained from about 0.01 Hz up to 5 kHz, corresponding to complete diffusion control of the electrochemical insertion reaction over the whole of the available frequency range. At lower open-circuit voltages (corresponding to higher lithium concentrations in the film), the separation of a semicircular region is evident at higher frequencies and, at the same time at lower frequencies, the 45° line begins to give way to a vertical line under the influence of finite length effects. The 5 Hz points are marked on the plots, and it can be seen that at this frequency a gradual transition from diffusion-controlled to charge transfer-controlled kinetics takes place as lithium is added to the film.

Complex impedance data for the lowest frequencies are shown in Fig. 7. In this frequency range, the rate

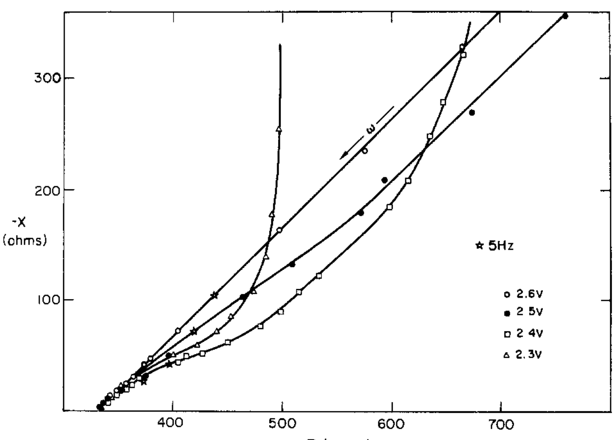

Fig. 6. High frequency complex impedance data

of lithium injection is always diffusion-controlled. The onset of finite length effects shifts to higher frequencies and the low frequency limiting resistance decreases as more lithium is added to the film, indicating that the diffusion coefficient is steadily increasing. Values of the chemical diffusion coefficient, $\tilde{D}$, were obtained from either the 45° straight line region or else from the low frequency limiting behavior. At high voltages, in the semi-infinite diffusion regime, data analysis presented no problems. Both the real and the imaginary parts of the impedance are proportional to $\omega^{-1/2}$. This is illustrated in Fig. 8 for the highest voltage case. $\tilde{D}$ was calculated from such plots using Eq. [28] and [29]. Alternatively, $\tilde{D}$ can be calculated from the low frequency limiting resistance (Eq. [36]). The low frequency limiting capacitance (obtained from Eq. [34]) yields values of $(dE/dy)_y$ which were used in the computation of $\tilde{D}$. Relevant data are given in Table I.

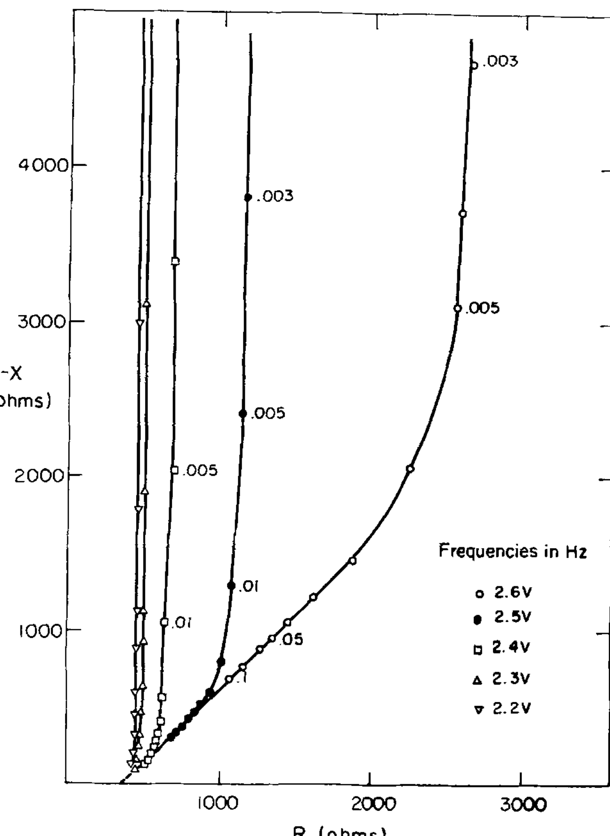

Fig. 7. Low frequency complex impedance data

Use of R_L for the calculation of $\tilde{D}$, however, has a disadvantage in the particular case of the data under consideration here. R_L is measured from the point at which the 45° straight line would intercept the real axis (see Fig. 3b), and thus, if this point is not well-defined, due to overlap of the diffusion- and charge transfer-controlled regions, an inaccuracy is introduced into the calculation of $\tilde{D}$. The overlap also prevents accurate evaluation of C_{DL} and θ.

These difficulties could, in principle, be overcome by fitting the low frequency impedance data to the full impedance expression (Eq. [38] and [39]). However, the complicated nature of these functions makes this a difficult task which was not attempted here.

Values of the diffusion coefficients calculated for lower voltages (2.2 and 2.3V) are, therefore, of lower accuracy than those for higher voltages.

Discussion

The a-c method.—The technique described in this paper shows itself to be a useful tool for the study of diffusion in thin film solid electrodes, although it is by no means limited in application to such systems. The method appears to have a number of advantages over alternative, transient techniques (such as voltage

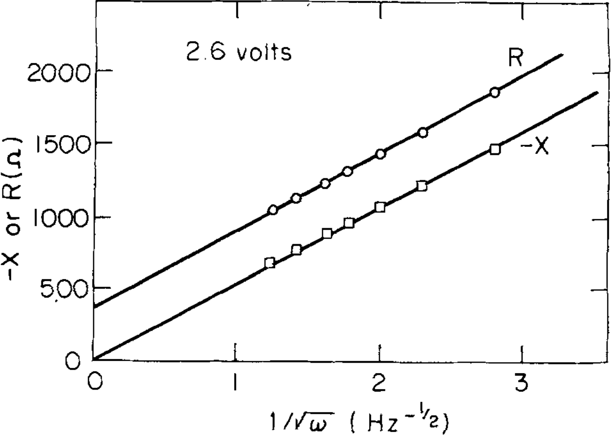

Fig. 8. Real and imaginary parts of the complex impedance plotted vs. $\omega^{-1/2}$.

or current step experiments), the most important being that more information is obtained through relatively simple data analysis procedures using the complex impedance plane method. Even in situations where there is extensive overlap of the charge transfer- and diffusion-controlled regions, or where the diffusion coefficient is sufficiently high to introduce finite length effects, much important information can be obtained by inspection of the complex impedance plot. The same information is, of course, also contained in the transient response of linear systems, but data acquisition (particularly at short times) and integral transform analysis so complicate the procedure that often only data obtained over a limited time period (for example, when the change in dependent variable is proportional to $\sqrt{t}$) are actually useful. As may be seen from the present results, the region in which the impedance is proportional to $\omega^{1/2}$ (or in which E would be proportional to $t^{1/2}$ in a current step experiment) may be very limited or nonexistent. Under these circumstances, the complex impedance method at the very least gives an indication of the experimentally important phenomena contributing to the time response of the system. Often a useful limiting region can be identified (for example, the very low frequency response for thin films) which can be used to extract numerical values for kinetic parameters.

A further advantage of using a steady-state method is that the response signal can be critically evaluated at each frequency, and further averaging (at low frequencies) or filtering (at high frequencies) can be employed.

Like the galvanostatic intermittent titration technique described by Weppner and Huggins (16), the a-c method is capable of very high resolution with respect to composition and is therefore applicable to phases with rather narrow ranges of stoichiometry.

The application of this method is, of course, dependent on the validity of a number of assumptions.

** Calculated from Eq. [34].
† $\tilde{D}$ calculated from Eq. [29].
†† $\tilde{D}$ calculated from Eq. [36].

The first of these is that the boundary conditions used in the solution of Fick's diffusion equation are correct. The greatest difficulty will usually lie in the assumption that the potential of the cell is a measure of the lithium activity at the interface between the electrolyte and the electrode. This is only true if the electrode is a predominantly electronic conductor. In the present case, there seems to be good evidence that this is so. The high electronic conductivity of tungsten bronze phases is well-established (20); values are much higher than ionic conductivities calculated from previous or present measurements of diffusion coefficients, although direct measurements of partial ionic conductivities have not been made.

A second assumption implicit in the derivation given above is that the driving force for diffusion is only a gradient in composition, and that the electric field in the electrode is negligible. This, of course, will be true in view of the high electronic conductivity mentioned above.

Thirdly, in order for the solution of the diffusion equations to be correct, it must be assumed that the system is linear. In other words, the diffusion coefficient is assumed to be independent of concentration over the range of alternating voltage applied. In practice, the applied voltage can be made very small, so that the measured impedance becomes independent of amplitude. This test is very easy to carry out due to the steady-state nature of the experiment. It seems likely that the diffusion coefficient will change rather slowly with composition, and hence voltage, except in very narrow phases where rapid variation of the thermodynamic enhancement factor may be expected (16). Similar considerations of linearity also apply of course at higher frequencies where the double layer capacitance and charge transfer resistance might also show voltage dependent behavior.

Kinetic properties of WO_3 thin film electrochromic electrodes.—The primary observation concerning the kinetics of lithium incorporation into WO_3 thin films is that both diffusion and interface kinetics are important. At long times (low frequencies), the interface is essentially at equilibrium, and diffusion of neutral lithium in a concentration gradient limits the rate of coloration of the oxide. At times shorter than about 0.5 sec however, charge transfer kinetics limit the rate of injection. The following considerations are relevant.

(*i*) Firstly, the thermodynamic and kinetic properties of WO_3 thin films are very dependent on the method of preparation (6), and in particular are dependent on the degree of crystallinity of the films. The results given here, although typical of films which show relatively rapid coloration on lithium injection, must not be regarded as applying to all WO_3 films. A detailed study of the thermodynamics and kinetics of different kinds of films is currently underway and the results will be published separately.

(*ii*) Secondly, the experiments reported here are small signal experiments. In a practical device much larger voltages or currents will be applied to the samples with several consequences. First, the reaction resistance θ will change with applied voltage due to both the change in lithium concentration at the interface and the inherent voltage dependence of the heterogeneous charge transfer reaction. Secondly, large voltage differences across the interface will have important effects on the rate of bleaching as discussed by Faughnan *et al.* (21). If the potential of the surface layer of WO_3 is increased beyond about 3V with respect to lithium, then the surface will become depleted of lithium and, since the electronic conductivity falls as lithium is removed, an electric field will develop in the electrochromic which will tend to increase the rate of lithium removal. This might happen, for example, when the WO_3 is bleached under constant current conditions, when the diffusion process cannot indefinitely support the current. A third effect of higher voltages will occur under rapid coloration conditions where the voltage falls to such low values that a concentration driven phase change on the surface of the oxide might be irreversible. Mohapatra and Wagner (9), for example, found that the chemical potential of lithium in amorphous Li_yWO_3 was constant for $y > 0.4$ (approximately 2V *vs.* Li). If this constant activity corresponds to a two- or three-phase region, then the new phase(s) formed may have very slow or irreversible kinetics.

In summary, therefore, small signal results should not be taken as a definitive measure of how an electrochromic device would operate under large signal conditions.

The charge transfer resistance of the interface was found to be 100-150 Ω/cm^2. As discussed in the Results section, an overlap of the diffusion response and the charge transfer response prevents an accurate evaluation of this resistance and its voltage dependence. The corresponding exchange current density is 8×10^{-5}-1.3×10^{-4} A/cm^2, a value which will depend on the concentration of Li^+ in the liquid electrolyte as well as electrode material parameters. Mohapatra (8) has suggested a value as high as 2×10^{-3} A/cm^2 for lithium injection. Somewhat smaller values (5×10^{-6}-3×10^{-5} A/cm^2) have been found by Crandall and Faughnan (22) for the injection of hydrogen into amorphous WO_3.

Chemical diffusion coefficients for low lithium concentrations are in good agreement with the value of 2×10^{-12} cm^2/sec suggested by Green (3). An increase with increasing lithium concentration of about one order of magnitude is observed, but the values are still much lower than the 5×10^{-9} cm^2/sec reported by Mohapatra (8). The thermodynamic results given by Mohapatra and Wagner in Ref. (9), however, were in very good agreement with the results of the present study. More recent results by Green (10) show a slightly smaller value for $\tilde{D}$ of 4×10^{-13} cm^2/sec on films which also have similar coulometric titration curves. Green also suggested that rapid diffusion along grain boundaries is followed by much slower diffusion into the bulk of the grains, with an associated diffusion coefficient of about 6×10^{-16} cm^2/sec. In the present study, no evidence for two diffusion processes, either in series or in parallel has been found, as the form of the results is adequately explained by a single diffusion coefficient.

As discussed by Weppner and Huggins (16), the chemical diffusion coefficient $\tilde{D}$ is related to the component diffusion coefficient D_k by the relation

$$\tilde{D} = D_k \frac{d \ln a_{Li}}{d \ln C_{Li}} \quad [43]$$

for the case where the electronic transference number is close to unity. In this equation the activity and concentration terms refer to neutral lithium. Hence

$$\tilde{D} = -D_k \frac{dE}{dy} \frac{zF}{RT} y \quad [44]$$

and since

$$D_k = kTb \quad [45]$$

and

$$\sigma_{Li} = z^2F^2C_{Li}b \quad [46]$$

where b is the general mobility and σ the partial conductivity of Li^+ ions

$$\sigma_{Li} = \frac{zF\tilde{D}}{V_M} \left(\frac{dE}{dy}\right)^{-1} \quad [47]$$

Numerical values for D_k and σ_{Li} are given in the table. Like the chemical diffusion coefficient, these quantities appear to increase with increasing lithium con-

tent, the most rapid rate of increase occurring around $y = 0.17$.

In summary, a general steady-state a-c method has been described which allows the diffusion coefficient of a species in an electronically conducting thin film electrode to be determined. In addition, qualitative information about the kinetics of the interface charge transfer reaction has been obtained, and it is believed that in some situations detailed interfacial kinetic data could be obtained. The method has a number of advantages over transient current or voltage step techniques, stemming partly from the method of analysis in the frequency domain which allows a clear distinction to be drawn between interface and bulk processes.

Acknowledgment

The computer program for the low frequency measurements was conceived and written by Dr. B. A. Boukamp of this laboratory, to whom the authors are most grateful.

Development of Sulfur-Tolerant Components for the Molten Carbonate Fuel Cell

A. F. Sammells,* S. B. Nicholson, and P. G. P. Ang*

Institute of Gas Technology, Chicago, Illinois 60616

ABSTRACT

The sulfur tolerance of candidate anode and anode current collector materials for the molten carbonate fuel cell were evaluated in an electrochemical half-cell using both steady-state and transient potentiostatic techniques. Hydrogen sulfide was introduced into the fuel at concentrations of 50 and 1000 ppm. At the higher sulfur concentration using low BTU fuel, both nickel and cobalt were observed to undergo a negative shift in their open-circuit potentials, and high anodic and cathodic currents were observed compared with clean fuels. Exchange currents measured using the transient potentiostatic technique were not greatly affected by 50 ppm H_2S introduced into the fuel. However, at higher sulfur concentrations, higher apparent exchange currents were observed, indicating a probable sulfidation reaction. Of the new anode materials evaluated, $Mg_{0.05}La_{0.95}CrO_3$ and TiC showed good stability in the anodic region. With the former material, exchange current densities in low BTU fuel were calculated to be $\simeq 8$ mA/cm² at 650°C, lower values than found for either nickel or cobalt anodes under similar conditions. Of the anode current collector materials evaluated, high stabilities were found for 410 and 310 stainless steels. The implications and relevance of these results on fuel cell performance are discussed.

The essential components which comprise the molten carbonate fuel cell are a porous nickel or cobalt anode, and a porous nickel oxide cathode, which are separated by an ionically conducting molten carbonate mixture supported on a lithium aluminate matrix. These components together are commonly referred to as the tile. To date, these fuel cell components have shown good electrochemical performance and corrosion stability under cell operating conditions over several thousand hours in the absence of sulfur-containing species in the fuel and oxidant. However, commercialization of this

* Electrochemical Society Active Member.

Key words: sulfur-tolerant anode, current collectors, molten carbonate fuel cell.

system for electric utility power plants will dictate that the fuel cell must operate on fuel oils in the short term and on the products of coal gasification in the longer term, all of which can be expected to contain sulfur.

Two general approaches can be followed towards solution of the sulfur problem in the molten carbonate fuel cell. The first approach is to remove completely the sulfur contaminants from the fuel cell before entry into the fuel cell anode. The second approach is to determine the sulfur tolerance of currently used cell components. When degradation in cell performance and materials stability becomes evident, the next step is to identify, characterize, and develop sulfur-tolerant components that show acceptable long-term electrochemical performance under defined sulfur concentrations within the overall system. The second of these two approaches is discussed here. Previous literature (1) has indicated that the catalytic activity of nickel may be poisoned because of the H_2S chemisorption at the temperatures of the molten carbonate fuel cell ($\simeq$650°C). This sulfur uptake may result in the formation of nickel sulfide (1) at the porous nickel anode, possibly resulting in a loss of both structural integrity and electrocatalytic activity (2, 3). This requirement will introduce to the cathode sulfur originating from the anode inlet. Under the oxidizing conditions of the cathode, this SO_2 can be expected to absorb readily into the molten carbonate mixture present.

No work has been reported on the corrosion of nickel by sulfide or sulfate while in the presence of molten carbonate under conditions representative of those in the molten carbonate fuel cell. Most work reported to date has focused on nickel in contact with various sulfur-containing gases. For example, the corrosion rate of nickel either in pure SO_2 or in SO_2/O_2 mixtures has shown parabolic gravimetric kinetics, which can result in the growth of external NiO and internal Ni_3S_2 scales. At temperatures above 645°C the eutectic sulfide in contact with nickel becomes liquid. Even at 603°C, an inner Ni_3S_2 layer is formed on nickel (4) via diffusion of SO_2 through open channels or crevices in the initial NiO oxide layer. The overall rate of this process is probably controlled by diffusion of nickel through the continuous Ni_3S_2 phase in the nickel oxide matrix.

Chromium oxide (Cr_2O_3) was also selected for evaluation as an anode material. Relatively pure Cr_2O_3 is an n-type semiconductor material at temperatures above 1000°C. However, at temperatures below this, the concentration of intrinsic defects will be less than the concentration of extrinsic defects present from impurity dopants. By the addition of monovalent (5) or divalent (6) cationic impurities at temperatures below 1000°C, p-type conduction can be promoted. But the reducing environment present at the anode of the molten carbonate fuel cell can be expected to favor a donor dopant such as Ti^{4+} rather than an acceptor such as Mg^{2+}. Sintered compacts of TiO_2-doped Cr_2O_3 were found susceptible to cracking in the course of this work.

Although extensive data are available on the free energy of formation for metal sulfides (7), as are Ellingham-type plots (8), no data appear to be available under conditions representative of those present in the molten carbonate fuel cell. Consequently, discussion of such thermodynamic data in reference to the equilibrium potential values obtained in this work during anode sulfidation can be considered too speculative and is therefore not covered.

Large-scale molten carbonate fuel cells will require the implementation of a catalytic burner between the anode outlet and the cathode inlet for CO_2 management to maintain the desired electrochemical process. This requirement will introduce to the cathode sulfur originating from the anode inlet. Under the oxidizing conditions of the cathode, this SO_2 can be expected to absorb readily into the molten carbonate mixture present both at the porous nickel oxide cathode and within the tile by the equilibrium reaction

$$M_2CO_3 + SO_2 + \tfrac{1}{2} O_2 \rightarrow M_2SO_4 + CO_2$$

which can be expected to favor strongly the formation of the alkali metal sulfate. The concentration of sulfur species at the anode may be influenced by electrochemical transport of sulfur species (initially present as sulfate) from the sulfur-contaminated cathode, and may have an impact on the long-term stability of the anode.

This work reports on electrochemical half-cell measurements on presently used anode and anode current collector materials with both clean and sulfur-containing fuels. By this means, the effect of such sulfur-containing species on the anode stability and electrode kinetics can be evaluated. The initial selection of candidate sulfur-tolerant components for the molten carbonate fuel cell included materials which had previously shown evidence of extended stability when used in applications such as methanation catalysis, positive electrode current collector components of high-temperature metal/sulfur batteries, and interconnect materials used in solid-oxide fuel cells. The latter materials, which included $Mg_{0.05}La_{0.95}CrO_3$, were of particular interest because they had shown high stability to both oxidizing and reducing conditions in the high-temperature solid oxide fuel cell. These materials were initially subjected to preliminary corrosion testing by simulating those chemical conditions expected in the anode environment of the system. Materials evaluated as sulfur-tolerant anodes in the electrochemical half-cell have included nickel, cobalt, CoMo, CoW, WC, TiC, $Mg_{0.05}La_{0.95}CrO_3$, Cr_2O_3 (doped with TiO_2), and NbN. Materials for the anode current collector have included Hastelloys, Kanthal, 400 and 300 stainless steels, and iron-aluminum-manganese and iron-aluminum-molybdenum alloys. The relative stabilities of these materials at the anode and anode current collectors for the molten carbonate fuel cell and a comparison of the electrocatalytic behavior of these candidate anodes will be discussed.

Experimental

The preliminary corrosion screening of selected materials was performed by partially submersing coupons in a lithium/potassium carbonate mixture at 650°C in ceramic boats. These boats were placed in an alumina tube through which the desired fuel composition could be passed. The corrosion stability of materials was evaluated with the molten carbonate equilibrated with both clean and sulfur-containing fuels.

Materials for the anode and anode current collectors were obtained from commercial sources (Materials Research Corporation, Orangeburg, New York, and CERAC, Incorporated, Milwaukee, Wisconsin). Electrochemical parameters were measured using an electrochemical half-cell. Working electrodes were attached to an alumina-sheathed lead wire of 316 stainless steel. For nickel and cobalt, however, the lead wires were made from nickel and cobalt, respectively. A gold wire bubbled with 33.3% O_2-66.7% CO_2 inside an alumina tube served as a reference electrode. The gold was in contact with the melt via a small hole (0.015 in. diam) at the bottom of the tube. All measurements were performed in an electrolyte of composition 62 Li_2CO_3-38 mole percent (m/o) K_2CO_3 at 650°C. The counterelectrode used in this work consisted of "Palau" of nominal composition 80% Au, 20% Pd, which proved to have a higher sulfur tolerance than a pure gold counterelectrode, the usual material used at IGT when clean fuels are used in electrochemical half-cell work. Fuels with a predetermined high sulfur content or pure H_2S were mixed into the primary fuel after the humidification step at the rate required to achieve the desired sulfur content. Experimental observations in this work indicated some apparent sensitivity of the open-circuit potential obtained at both nickel and cobalt electrodes to the presence of H_2S introduced into the fuel gas. At concentrations of 50 ppm and below, such variations in the open-circuit potential

were found to be somewhat erratic and not completely reproducible. Apart from some variations in the open-circuit potential, steady-state polarization curves for clean fuel and fuel containing 50 ppm H_2S exhibited an almost identical slope, indicating little evidence of electrode poisoning. Polarization data were performed in both low BTU fuels corresponding to the respective compositions 21.4% H_2, 17.7% CO, 9.2% CO_2, 1.1% CH_4, 45% N_2, 5.6% H_2O, and to high BTU fuel of 68.1% H_2, 23.4% CO, 3.39% CO_2, and 5.03% H_2O. Emphasis on this work was placed, however, on the low BTU fuels corresponding to coal gasification.

The potential of the working electrode was controlled by a Wenking Model 66TSI potentiostat. Steady-state currents were recorded on a Hewlett-Packard 7046A X-Y recorder. To eliminate errors caused by mass-transfer effects, transient potentiostatic techniques were employed using a Wenking ST72 potentiostat. This instrument has a risetime of about 7 μsec when a step voltage is applied. A Tacussel Type GSTP2B pulse-sweep generator was used to control this potentiostat with the output voltage being monitored with a Fluke Type 8020A digital voltmeter. Signals from the transient techniques were displayed and photographed on a Tektronix Type 547 oscilloscope. Electrodes made with this transient potentiostatic technique were performed using appropriate *IR* compensation within the potentiostat. Without such compensation, a large transient capacitive current was usually seen. Such an effect can cause some error in the current extrapolated to time zero. In order to achieve *IR* compensation, part of the voltage at the current recorder terminal of the potentiostat was picked up from an external potentiometric voltage divider (250Ω) and fed back into one of the potentiostat control inputs. The feedback voltage was then adjusted until the system almost started to oscillate. The positive feedback resulted in an increase of the control voltage proportional to the cell current. The temperature of the melt was maintained with an alumina-sheathed, Chromel-Alumel thermocouple.

Results and Discussion

To determine the effect of sulfur-containing fuels on the electrochemical performance of nickel and cobalt anodes, both steady-state and potential-step type measurements were performed in an electrochemical half-cell. Steady-state techniques were used to identify the enhanced currents caused by the anodic sulfidation reactions and changes that may occur in the open-circuit potential as a result of such reactions. Figures 1 and 2 compare steady-state polarization curves for nickel and cobalt anodes in low BTU fuel with and without 50 ppm H_2S. In both cases, introduction of sulfur as H_2S into the fuel was observed to perturb the open-circuit potential.

In the case of nickel (Fig. 1), the shift was 15 mV positive of the initial −1154 mV open-circuit potential, whereas in the case of cobalt (Fig. 2), the shift was in the cathodic direction by only around 7 mV. Other than these minor shifts in the open-circuit potential, the current voltage characteristics are very similar in each case.

In the fuel cell, sulfur can be expected to enter the cathode as SO_2, resulting in the formation of sulfate. Sulfate may then be available for migration to the anode, where it could be reduced to sulfide species under the reducing conditions present. Thus, sulfur introduced into the fuel cell by this means could result in locally high accumulations of sulfide in the proximity of the anode. Consequently, H_2S introduced at concentrations of around 50 ppm with low BTU fuel in the half-cell may not simulate the local high sulfur content that may occur in the real fuel cell.

The observation of erratic open-circuit potential readings with both nickel and cobalt anodes may be caused either by a mixed potential effect due to the formation of a metal sulfide species on the anode, or

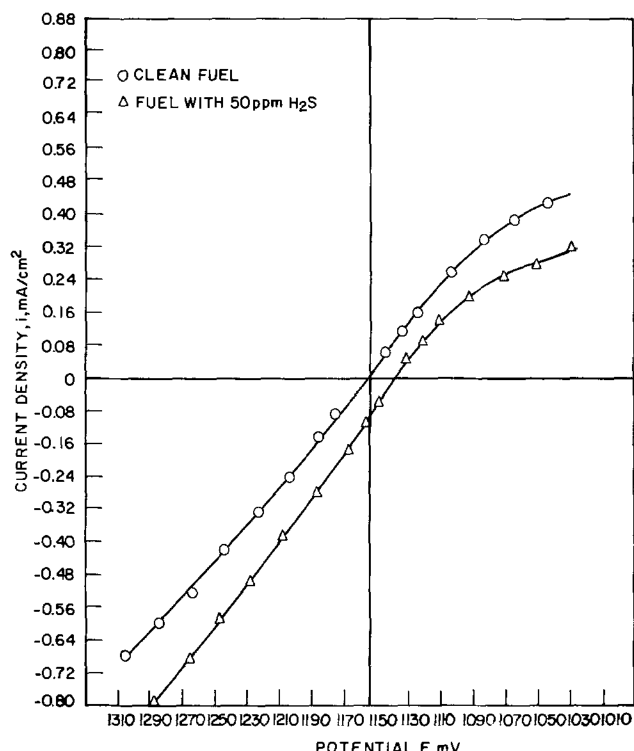

Fig. 1. Steady-state polarization curves for nickel using low BTU fuel with and without 50 ppm H_2S added (Li/K electrolyte, 650°C).

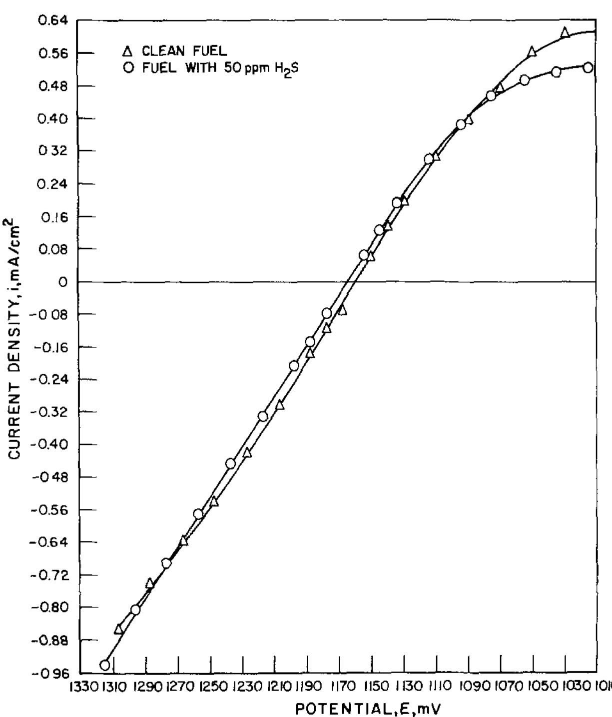

Fig. 2. Steady-state polarization curves for cobalt using low BTU fuel with and without 50 ppm H_2S added (Li/K electrolyte, 650°C).

due to some subtle changes in the fuel composition from one measurement to another.

Introduction of H_2S at concentrations of approximately 1000 ppm into low BTU fuel resulted in extensive sulfidation of both nickel and cobalt upon potentiostating anodically as shown in Fig. 3. In each case, the open-circuit potential was observed to be shifted to more negative values, possibly indicating a mixed-potential effect caused by the fuel oxidation

Fig. 3. Anodes from electrochemical half-cell after they had been potentiostated in Li/K carbonate melt in low BTU fuel containing 1000 ppm H_2S at 650°C

reaction and the presence of metal sulfide on the anode surface. For nickel at 650°C (in low BTU fuel), the open-circuit potential was shifted from −1154 to −1185 mV and for cobalt the shift was −1160 to −1200 mV. Clearly, neither of these two anode materials is stable at such high sulfur levels. With the electrochemical conditions present in the half-cell, the rate of the overall electrochemical reaction was found to be dependent not only upon fuel bubbling rate, but also on the voltage sweep rate used. Such observations indicated diffusion or mixed control. To assess the impact of introducing sulfur species into the electrolyte from the fuel, the electrode kinetics were compared for both nickel and cobalt with clean and sulfur-containing fuels to indicate whether any electrocatalytic poisoning effects occurred by the introduction of such sulfur impurities.

Transient potentiostatic measurements (9, 10) were performed for the separation of kinetic data under the probable diffusion (or mixed) control condition present in the half-cell. By this technique, the time dependency of the current for a given applied potential will be given by

$$i = i(0) \cdot \left(1 - \frac{2}{\sqrt{\Pi}} \cdot \lambda\sqrt{t}\right) \quad [1]$$

for the conditions $\sqrt{t} << 1$, where

$$\lambda = \frac{i_o}{2\mathbf{F}}\left[\frac{1}{\overline{C}_rD_r}\exp\left(\frac{\alpha z\mathbf{F}}{RT}\eta\right) + \frac{1}{\overline{C}_oD_o}\exp\left(\frac{(1-\alpha)}{RT}z\mathbf{F}\eta\right)\right] \quad [2]$$

and $i(0)$ the current density at time zero given by

$$i(0) = i_o\left[\exp\left(\frac{\alpha z\mathbf{F}}{RT}\eta\right) - \exp\left(\frac{-(1-\alpha)}{RT}z\mathbf{F}\eta\right)\right] \quad [3]$$

where $\overline{C}_o$ and $\overline{C}_r$ are the equilibrium concentrations of the oxidized and reduced species, and D_o and D_r are the corresponding diffusion coefficients, and the other symbols have their usual significance. By plotting i *vs.* $\sqrt{t}$ in Eq. [1] above, a current density at time zero, $i(0)$, can be extrapolated from the intercept with the current axis. In practice, however, excellent agreement was found between activation currents extrapolated from reaction [1] above and those $i(0)$ values obtained from the extrapolation of currents between 0.8 and 1.2 msec to time zero. Consequently, the majority of activation currents recorded were obtained using the latter technique with periodic comparison with those values obtained from relationships [1]-[3]. A voltage step was applied to the nickel or cobalt working electrode and the current was recorded as a function of time. Under such conditions of diffusion (or mixed) control, the assumption was made that at time zero, only activation control will be present, that is, sufficient supply of electroactive species will be present together with minimal reaction products, so that any mass transfer effects will be minimized. Figure 4 shows a typical oscillogram for nickel with and without 50 ppm H_2S in low BTU fuel, showing the decay of current with time for an applied anodic pulse of 40 mV for the equilibrium potential (two time scales shown).

Here, the exchange current density calculated from the $i(0)$ value was found to be around 25 mA/cm² in both cases, indicating that such low levels of sulfur (50 ppm H_2S) appear to have little effect upon the electrode kinetics for fuel oxidation, in essential agreement with the steady-state data.

A series of progressively more anodic and cathodic potential steps were applied to both nickel and cobalt in fuel with and without 50 ppm H_2S introduced into low BTU fuel at 650°C. The respective activation polarization curves for these two anodes are shown in Fig. 5 and 6, where they are compared with such data obtained using clean fuel. As was indicated earlier, 50 ppm H_2S does not appear to affect drastically the electrode kinetics for either the anodic or cathodic processes, although some small lowering in electrode activity does become apparent at higher applied overpotentials. Upon introduction of 50 ppm H_2S, the exchange current density was observed to become slightly lower, reducing from 26 to 25 mA/cm², and from 19.5 to 18.5 mA/cm², respectively, for nickel and cobalt, although such small variations in activation data can be considered to be well within the experimental error of this work. When potential step techniques are performed on these anode materials in fuel containing 1000 ppm H_2S, anodic and cathodic currents appear to be dominated by the sulfidaton reaction as indicated in Fig. 7 and 8, respectively, for nickel and cobalt.

When high sulfide concentrations build up in the proximity of the anode, either directly from sulfur-

containing fuel or indirectly from SO_2 introduced into the cathode, neither nickel nor cobalt appear to be viable anode candidates. There is considerable incentive, therefore, to identify potentially sulfur-tolerant anode materials for this fuel cell system.

Preliminary corrosion results for selected sulfur-tolerant candidate anodes are shown in Table I. Materials which showed apparent stability in this corrosion test were then subjected to steady-state potentiostatic polarization evaluation in the electrochemical half-cell. These results are summarized in Table II, where open-circuit potentials and anodic currents at 50 mV overpotential are compared.

Apart from nickel and cobalt anodes, which have already been discussed, highest stabilities were found for $Mg_{0.05}La_{0.95}CrO_3$ and TiC. Figure 9 compares steady-state polarization data on $Mg_{0.05}La_{0.95}CrO_3$ in low BTU fuel with and without 50 ppm H_2S. No shift in the open-circuit potential was observed, and current voltage characteristics were very similar in both cases, particularly in the anodic region. Introduction of fuel containing 1000 ppm of H_2S did not shift the open-circuit potential to negative values as observed with

nickel and cobalt anodes. Examination of this material afterwards indicated no surface corrosion even after anodic potentiostating.

Figure 10 compares activation data performed on this material using the potential step technique with that obtained for nickel. For $Mg_{0.05}La_{0.95}CrO_3$ exchange current densities of around 8 mA/cm^2 were obtained in low BTU fuel. As seen in Fig. 10, exchange current densities for fuel oxidation on nickel are greater than with $Mg_{0.05}La_{0.95}CrO_3$. On the basis of the kinetic data and the apparently high-sulfur tolerance of $Mg_{0.05}La_{0.95}CrO_3$, this material may be an interesting candidate as an anode material for the molten carbonate fuel cell, although the present high cost of this material would not favor its use in the immediate future.

Steady-state polarization measurements have been performed on TiC, Cr_2O_3 (1 m/o of TiO_2), WCo (75.5% W, 24.3% Co), Nichrome (80% Ni, 20% Cr), and NiAl in the lithium/potassium carbonate electrolyte at 650°C in low BTU fuel. Upon examination of all of these materials, evidence of surface corrosion became evident. Candidate anode current collector materials were subjected to an initial screening corrosion test as described previously for the selected anodes. The materials selected, together with the corrosion results, are shown in Table III. From these results, good corrosion stability was found for 446 and 310 stainless steels, together with Uniloy. More promising materials were subjected to steady-state potentiostatic evaluation. Figure 11 shows the steady-state current voltage characteristics obtained with 446 stainless steel. The results of such potentiostatic testing for the selected anode current collector materials are summarized in Table IV. Materials were anodically potentiostated at 75 mV in low BTU fuel with and without H_2S and the currents recorded as a function of time. A decay in current with time was taken as indicative of surface oxide

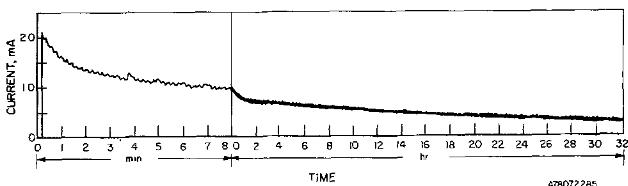

Fig. 12. Variation of current with time at an applied anodic overpotential of 75 mV for 446 stainless steel (low BTU fuel used).

Of those materials evaluated, high stabilities were found for 410 and 310 stainless steels. Open-circuit potentials were found for the stainless steels in low-BTU fuel were fairly close to those expected; nevertheless, some of the other candidates that readily corroded showed somewhat more cathodic potentials.

Conclusion

At low-sulfur concentrations ($\simeq$50 ppm) the electrode kinetics for fuel oxidation on both nickel and cobalt anodes do not appear to be effected in an im-

portant way. At high-sulfur concentrations (≃1000 ppm) shifts in the open-circuit potential of both these materials occurred together with evidence of sulfidation.

Promising anode materials which may show long-term sulfur tolerance include $Mg_{0.05}La_{0.95}CrO_3$ and TiC. However, their long-term performance as porous sintered anodes has yet to be evaluated. Anode current collectors showing the greatest stability included 410 and 310 stainless steels.

ABSTRACT

The exchange rate for mass transfer of sulfur across the sulfur-sulfur saturated sodium pentasulfide interface was investigated by S-35 tracer studies and found to be 0.19 ± 0.04g S/cm²/hr at 300°C. The self-diffusion coefficients of sulfur in Na_2S_4 and $Na_2S_{5.2}$ as determined by the capillary method using S-35 labeling were $2.3 \pm 1.1 \times 10^{-5}$ and $1.5 \pm 0.4 \times 10^{-5}$ cm² sec^{-1}, respectively, at 300°C. The diffusion coefficient of the electroactive species in Na_2S_4 was determined by chronopotentiometry at a rotating disk electrode. Its value is 7×10^{-7} cm² sec^{-1} at 300°C. Approximate values of the activation energy of diffusion and nC_{ox} in Na_2S_4 are given. A first attempt is made, in terms of a mechanistic model of the mass-transfer processes, to explain the different data obtained for D from tracer and electrochemical experiments, respectively.

During the discharge of the sodium-sulfur battery sulfur is transferred across the sulfur-sodium polysulfide interface to the melt and transported as polysulfide through the melt to the electrode where it is electrochemically reduced to a lower polysulfide (1-3). No data for the mass transfer of sulfur between the sulfur pool and the melt are available in the literature, and for its diffusion through the melt the

data are conflicting (1, 4). In the course of some work done on the Na/S battery in this laboratory it was therefore deemed desirable to study these transport phenomena and, if possible, determine whether the diffusion or the sulfur transfer is the rate-determining step in the sulfur transport to the electrode.

Experimental

Chemicals.—Sulfur flower (Merck) was purified according to the method of Bacon and Fanelli (5). Reagent grade sodium metal (Merck) was used as received after having been cleaned in ethanol.

Radioactive sulfur (isotope S-35, half-life 87d) was obtained from Amersham Buchler or prepared from purified sulfur by irradiation in the DIDO reactor of the Nuclear Research Center, Juelich. The activity of this stock supply was determined as described below and was between 15 and 100 μCi/g at the time of use. All experiments were performed under argon gas passed through a purification unit (Oxisorb; Messer Griesheim).

Polysulfide preparation.—Sodium tetrasulfide was prepared from the elements according to the method of Fehér and Berthold (6) in a glove box with a circulated and purified argon atmosphere (O_2 < 10 volume ppm; H_2O < 15 volume ppm). Its composition was determined as described by Fehér and Berthold (7). The ethyl alcohol content remaining after the product had been dried under vacuum was determined by gas chromatography to be below the detection limit of 0.01 weight percent (w/o).

Sulfur-saturated sodium pentasulfide ($Na_2S_{5.2}$) was prepared from Na_2S_4 by the addition of an excess of sulfur followed by mixing the liquid constituents at about 300°C with a vibrator (Vibro-Mixer E1 Chemap) for 15 min. The excess sulfur separates overnight from the pentasulfide melt and can be removed after solidification. The composition of the product thus prepared was determined analytically (7) to be $Na_2S_{5.2}$ within experimental error. Measurements of potential with respect to a sodium/β-alumina electrode confirmed the composition.

The active and inactive sulfide melts for the capillary experiments were prepared as follows. A charge of tetrasulfide was divided into two portions to one of which radioactive sulfur was added. To the other portion an equivalent amount of inactive sulfur was added so that both portions had the same composition differing only slightly from that of the starting material (1-2g of sulfur were added per 100g of tetrasulfide). The labeled pentasulfide was prepared as above except that the sulfur used contained S-35. The inactive pentasulfide was prepared from the same charge of tetrasulfide using an equivalent amount of inactive sulfur.

Equipment and Procedures

Sulfur transfer and self-diffusion coefficients.—The exchange of sulfur across the sulfur-sulfur saturated pentasulfide system was determined by labeling the sulfur phase with radioactive sulfur and measuring the increase of the activity of the sulfide phase with time.

The experiments were carried out in a Pyrex vessel (diam 3.5 cm) in a vertical tube furnace at temperatures between 297° and 305°C. First, molten pentasulfide (80g) and sulfur (50g) were left in contact at 300°C for 48 hr under slow stirring of both phases to ensure that equilibrium conditions had been established. Radioactive sulfur (40-85 μCi) was then added to the sulfur phase and samples of about 1-2 ml were taken from the bulk of the pentasulfide phase at intervals of usually 1 hr. Sulfur was precipitated from these samples and prepared for liquid scintillation counting as described below. During the 5-6 hr, which each run lasted, one or two samples were also taken from the sulfur phase to determine its activity. The pentasulfide and sulfur originally charged into the vessel and all samples taken from it were weighed since the amount of material left in the vessel during the course of the experiment as well as the activity removed from it by taking the samples were needed for the calculations.

The mass transfer of sulfur across the interface was alternatively determined by measuring the decrease of the activity in a capillary filled with radioactive sulfur and immersed in molten pentasulfide. This method has been used frequently to determine self-diffusion coefficients (8). The apparatus is shown in Fig. 1. The capillaries had an inside diameter of 0.08 cm, a length of 4.0 cm, and their upper end was closed by a flat seal. The capillary was filled by evacuating the Pyrex vessel, lowering the capillary into the radioactive sulfur (in position 1), and admitting argon into the vessel. The capillary was then raised and the sulfur pot replaced by the pot with the pentasulfide previously held in position 2. To start the experiment the capillary was lowered into the pentasulfide melt and the rotation of the pot was started. The decrease of the activity was determined after 3-4 hr and the experiments were carried out at 300° ± 2°C. The apparatus shown in Fig. 1 has the advantage over other arrangements [*cf., e.g.*, Ref. (9)] that the material in the capillary remains liquid throughout the experiment. This is especially advantageous for sulfur and compounds such as polysulfides, which form bubbles in the capillary on remelting.

The same procedure was followed for the determination of the self-diffusion coefficients of sulfur in its melt and in Na_2S_4 and $Na_2S_{5.2}$, the only difference being that the substances in the capillary again contained the labeled material.

Electrochemical measurements.—The chronopotentiometric measurements were performed on a tetrasulfide melt with a rotating disk electrode driven by a rotator with speed control (Model ASR; Pine Instru-

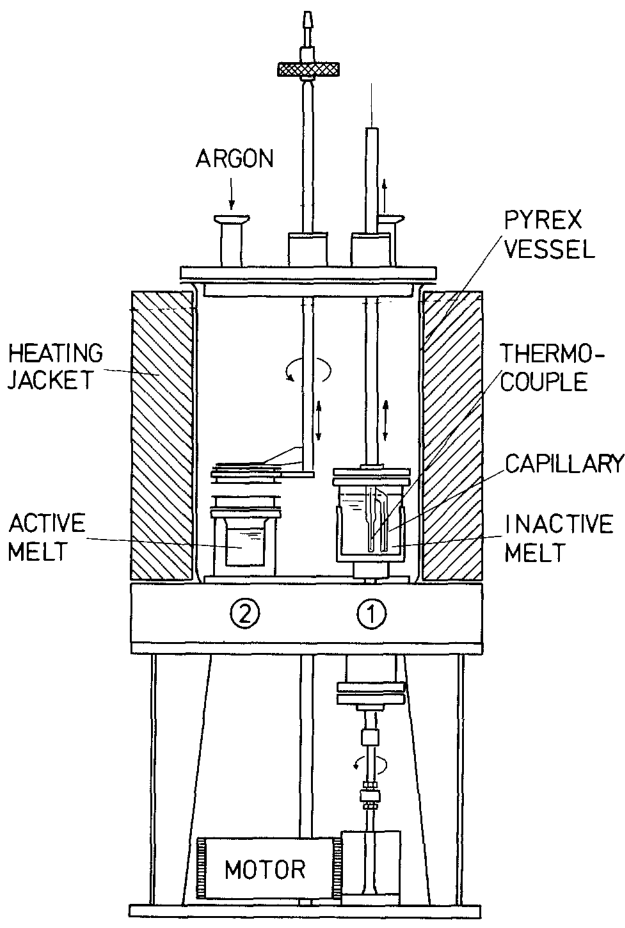

Fig. 1. Diffusion apparatus

ment Company). A disk electrode was constructed which proved to be suitable for high temperature work. Details are shown in Fig. 2. A PAR universal programmer (Model 175) served as pulse generator. The curves were drawn on an X-Y recorder (Model 7046 A; Hewlett Packard) from the memory of a digital oscilloscope (Model 1090 A with a Model 96 A Plug-In; Nicolet). A graphite rod in the melt served as reference electrode. It behaves reversibly and has a stable potential (2).

The voltammetric curves were obtained with the rotating disk electrode described above, employing a potentiostat with a continuous and automatic *IR* compensation built in this laboratory (10) in principle according to the method of Britz and Brocke (11). At a sufficiently large double-layer time constant the accuracy of the *IR* compensation of this instrument is about 1%. This condition was met here since the time constant in this melt system [(4), and own measurements] is about a factor of 100 larger than the current interruption period of the potentiostat.

Activity measurement.—The activity of the samples was determined by liquid scintillometry. The following is a short description of the procedure adopted. A weighed sulfide sample was dissolved in water from which sulfur was precipitated by adding HCl. Although one sulfur atom per molecule polysulfide escapes as H_2S, this can be accounted for in the calculations since S-35 is distributed proportionally among the decomposition products as was shown here by checking the radioactivity balance in some experiments [see also Ref. (12)]. The precipitated sulfur was dissolved in toluene (CS_2 could not be used due to its high degree of quenching). A mixture of this solution with Instagel (Hewlett Packard) was counted for one minute on a Corumat-2700 (INC Tracerlab). Since only the ratio of the activities of the samples in question was required for the calculations it was not necessary to determine the counting efficiency as long as the quenching due to sulfur itself remained constant. This was assured by always having the same amount of sulfur present in the solutions counted.

Results and Discussion

Mass transfer of sulfur.—A total of six runs were performed to determine the exchange of sulfur across the sulfur-sulfur saturated pentasulfide interface.

The amount of sulfur (in g) transferred during a measurement period was obtained by dividing the increase of the activity in the sulfide phase during that period by the activity of the sulfur phase per gram of sulfur at the beginning of the period. The calculations are straightforward. The following approximations were made. The activity of the sulfur phase was considered constant during the period and the transfer of radioactive sulfur in the reverse direction (*viz.*, from the sulfide to the sulfur phase) was neglected. Both approximations are justified since they produce errors of less than 3%. The overall accuracy of the measurements (estimated to be 15%) was considered such that it seemed unwarranted to correct for these changes.

The results obtained at various stirring rates are shown in Fig. 3. The least squares line of all data points with its confidence interval (13) was determined to check whether or not the transfer of S-35 is influenced by the stirring rate. It is, however, a moot point to decide this solely on the basis of these data although the values at 110 and 205 rpm are somewhat

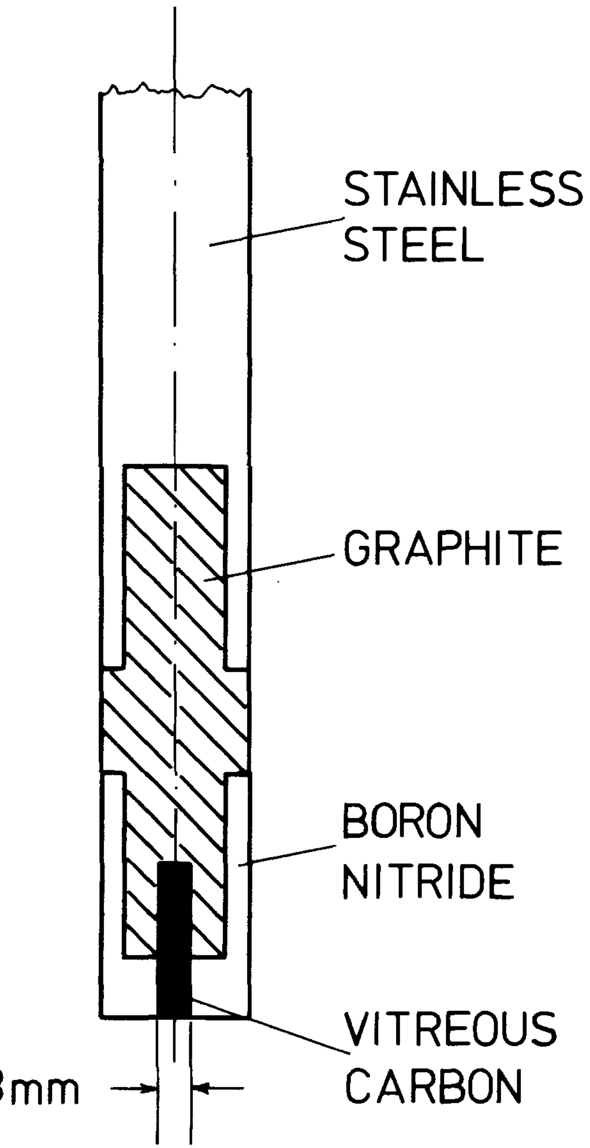

Fig. 2. Rotating disk electrode for high temperature studies

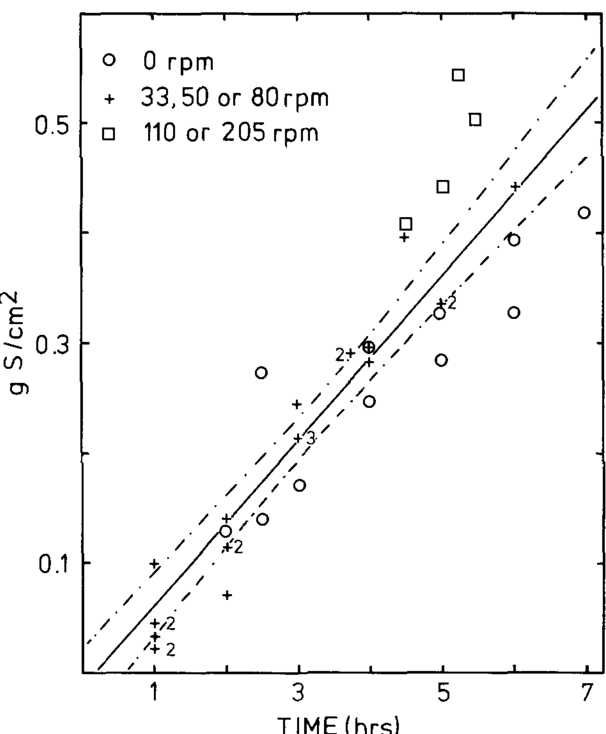

Fig. 3. Sulfur transferred in g/cm² sulfur-pentasulfide interface as a function of time and stirring speed (at 300°C). Least squares line of all data points (6 runs with a total of 43 points including 6 points 0, 0). Dashed curve is 95% joint confidence hyperbola [Ref. (13)]. Number indicates multiple points.

higher (0.10 g/cm²/hr) than those obtained from the least squares line (0.075 g/cm₂/hr), while those in the unstirred melt are somewhat lower (0.06 g/cm²/hr). Increasing the stirring rate above 200 rpm was not possible without disturbing the interface and obtaining an undefined area. It was therefore decided to carry out the same measurements with the aid of capillaries whereby a diffusion layer of labeled pentasulfide is essentially prevented. To calculate the amount of sulfur transferred in these experiments, Fick's second law with the appropriate boundary conditions

$$D\frac{\partial c(o,t)}{\partial x} = kc(o,t),\ c(x,o) = c^b,\ c(\infty,t) = c^b$$

has to be solved. The solution, for a cylinder of infinite length, has been given by Delahay (14) as

$$c(c,t) = c(x,o)\left[\mathrm{erfc}\left(\frac{x}{2D^{1/2}t^{1/2}}\right) + \exp\left(\frac{Qx}{D^{1/2}} + Q^2t\right)\mathrm{erfc}\left(Qt^{1/2} + \frac{x}{2D^{1/2}t^{1/2}}\right)\right]$$

where

$$Q = \frac{k}{D^{1/2}}$$

That the equation is also valid for a capillary with a length of 4 cm as long as the diffusion time is kept short (3-4 hr) is shown by the concentration profile of S-35 in the capillary calculated for a diffusion time of 4 hr and an infinite value of k (Fig. 4, curve a). A finite value of k only improves the situation since the section at the end of the capillary, where the concentration of S-35 remains at its initial value, becomes even longer (Fig. 4, curve b representing a typical run). The value of the self-diffusion coefficient (D) of sulfur in its melt required for calculating the curve was determined in other experiments (see below). With the values of D and t known the value of k was determined in the following manner. The concentration profile at time t was calculated for the experimentally determined amount of tracer at time $t = 0$ and a likely value of k. Then the amount of tracer remaining at time t was obtained by numerically integrating the area under the curve and compared with the amount experimentally determined at time t. The value of k was changed until these two values agreed to within 0.1%. The values of k determined in four experiments with $D = 5.07 \times 10^{-5}$ cm²/sec (see Table I)

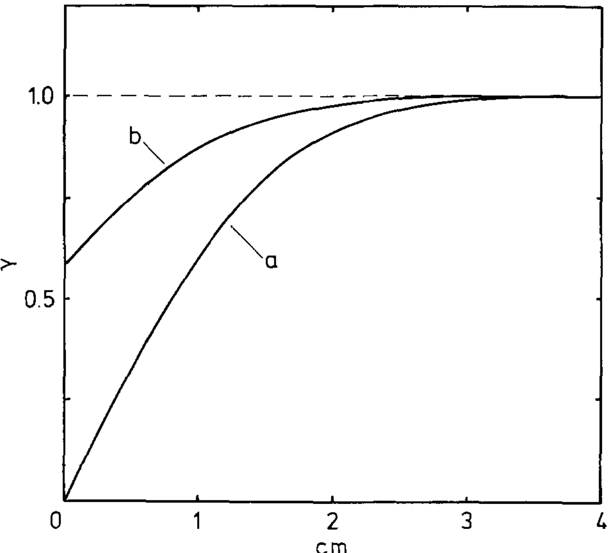

Fig. 4. Fraction of S-35 (γ) remaining in capillary as a function of the distance from the mouth of the capillary. Curve a, for an infinite value of k, curve b, represents a typical run.

were: 2.69, 2.81, 3.18, and 4.00 × 10^{-5} cm/sec at 296° ± 2°C. The amount of sulfur transferred was calculated from

$$\frac{dN}{qdt} = kc$$

where c = 1.69g S/cm³ and q is the area of the interface, here taken equal to the cross section of the capillary since visual inspection with a magnifying glass showed a practically flat interface between the two phases. The values thus obtained were 0.16, 0.17, 0.19, and 0.24 g/cm²/hr with an average value of 0.19 ± 0.04 g/cm²/hr. This value seems more justified than the one determined above since in those experiments a diffusion layer of S-35 must have been present.

The calculations of the mass transfer of sulfur from the capillary experiments depend on the condition that no convection disturbances occur inside the capillary since these would cause some of the liquid to be dragged out (15). If the liquids in the capillary and bath are the same (which is the case if self-diffusion coefficients are measured), the length of the region where the disturbances occur can be evaluated (16). This "Δl-region" leads to a diffusion path shorter than the geometric length of the capillary but the experiments can be carried out such that Δl becomes negligible compared to the length of the capillary as will be shown below in the section "Self-diffusion coefficients." If the liquids are not the same and form an interface the disturbances in the capillary will be smaller, if not all together absent, especially if the lighter liquid is in the capillary. It is, therefore, also justified to neglect the "Δl-effect" in the calculations of the mass transfer of sulfur since the same experimental conditions prevailed, except that an interface existed between the two liquids.

The net rate of sulfur transfer across the interface S/Na_2S_x, which is zero at equilibrium conditions ($x = 5.2$), will be positive or negative according to whether $x > 5.2$ or $x < 5.2$. However, the assumption seems to be reasonable that the net rate under such conditions is always smaller than the exchange rate at $x = 5.2$ ($k = 3$ cm/sec corresponding to 0.19g S/cm²/hr, see above). A distinct transfer rate has nevertheless been observed in a qualitative manner under conditions where the x value, in the immediate vicinity of the interface, is not far from equilibrium, as shown by the following experiment. An open ended Pyrex tube (diam 2 cm) was placed vertically in a large bath of tetrasulfide Na_2S_4 (350g) which effectively served as a sulfur sink. Some sulfur was added on top of the melt inside the tube so that it just covered the highest of four gold plated Pt wires which were sealed into the wall of the tube at a distance of about 1.5 mm of each other along the tube's vertical axis. The rest potentials of these wire electrodes was measured against a reference electrode consisting of a

graphite rod in the tetrasulfide bath. When steady-state conditions had been reached, there always existed a rather thick diffusion layer (several mm) the composition of which corresponded to $5.2 > x > 5$ within the range where the wires were placed (the error of the potential measurement was estimated at 5 ... 10 mV so that a more accurate determination of the composition was not possible). Both the transport through the diffusion layer and the limited rate of transfer across the interface must therefore in general be taken into consideration.

Self-diffusion coefficients.—The self-diffusion coefficients of sulfur in its melt and in tetrasulfide and pentasulfide melts were calculated with the simplified formula of McKay (17, 9)

$$D = \frac{7.7476 l^2 (1 - \gamma)^2}{\pi^2 t}$$

where γ is the fraction of tracer remaining at time t in a capillary of length l, closed at one end and immersed in a diffusion sink where the tracer concentration is effectively zero at all times. The formula can be applied if $1 > \gamma > 0.5$ which was achieved in these experiments by keeping the diffusion time between 3 and 4 hr.

The Reynolds number given by

$$N_{Re} = \frac{R \omega \rho d}{60 \eta}$$

where R (radius of rotation) = 0.8 cm, ω (angular frequency = $2\pi \times 33$ rpm, ρ (density of melt) = 1.8-1.9g cm^{-3} [from Ref. (18)], d (ID of capillary) = 0.08 cm, and η (viscosity of melt) = 0.43-0.57g cm^{-1} sec^{-1} from Ref (18)] had a maximum value of about 1 in these experiments. This results in a "Δl-region" (16)

$$\Delta l = d(1.35 \times 10^{-2} + 1.69 \times 10^{-1} N_{Re} - 1.30 \times 10^{-2} N_{Re}^2) = 0.014 \text{ cm (max.)}$$

which can be neglected here compared to the length of the capillary (4 cm). The value of γ was determined by taking the ratio of the experimentally measured activity remaining in the capillary at time t and that present initially at time $t = 0$. The results are listed in Table I.

The self-diffusion coefficient in liquid sulfur has been determined previously by Saxton and Drickamer (19), also with S-35. At 300°C they reported a value of about 2×10^{-6} cm^2/sec. The agreement is poor. This may be due to the method of analysis used at that time, *viz.*, of counting solid samples under a Geiger counter. This certainly presents problems regarding the counting geometry although the authors reported having taken considerable care in this respect. Furthermore, the experiments were carried out with a frit of which the effective pathlength had to be determined in another set of experiments and this may have introduced another source of error, especially since the latter experiments had to be carried out at a much lower temperature.

The self-diffusion coefficients in polysulfide melts have not been determined previously. The values here are in the usual range found in other melts.

Electrochemicals diffusion coefficients.—The chronopotentiometric measurements for determining the diffusion coefficient of the electroactive species in the tetrasulfide melt were carried out with a rotating disk electrode. This method has the advantage that no prior knowledge of the concentration of the electroactive species and no assumptions regarding the actual reaction(s) at the electrode are required. The only conditions are that the mass transport of the electroactive species must be controlled by convective diffusion according to Levich (20) and any equilibria in which the electroactive species may be involved within the diffusion layer must be kinetically sufficiently fast. The former condition is fulfilled as shown in Fig. 5 by the fact that the cathodic current at the disk electrode varied linearly with $\sqrt{\omega}$, while the anodic current was a quasi-linear (21) function of $\sqrt{\omega}$, due to blocking of the electrode surface by sulfur above certain anodic current densities (about 1 A/cm^2 in Fig. 7). The latter condition is met because the diffusion coefficient determined by this method at several rotational speeds remained constant within experimental error (see Table II).

At the anodic current densities used here the rotating electrode remains free of deposit. A stationary electrode, on the other hand, becomes blocked in both the anodic and cathodic directions by sulfur and an insoluble polysulfide, respectively, (1, 2), and is therefore less suitable for measuring diffusion coefficients in this melt system.

The calculations were carried out according to the mathematical solution derived by Hale (22) and by Nanis and Klein (23) whereby the general equation for convective diffusion

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} - V_x \frac{\partial c}{\partial x}$$

is solved for the galvanostatic boundary conditions

$$c(x,o) = c^b, \quad c(\infty,t) = c^b, \quad \text{and} \quad \left(\frac{\partial c}{\partial x}\right)_{x=o} = \text{constant}$$

by introducing the dimensionless variables

$$y = \frac{c - c^b}{c^b - c_{o,\tau}}, \quad \Theta = \frac{Dt}{\delta^2}, \quad \text{and} \quad z = \frac{x}{\delta}$$

where δ is a normalized form of the Levich layer ($1.62 D^{1/3} \nu^{1/6} \omega^{-1/2}$), $c_{o,\tau}$ the concentration at the electrode surface at transient time τ, and c^b the time independent bulk concentration. If a galvanostatic pulse is applied to the electrode the potential changes with time. At the transient time τ the potential becomes constant and the function Θ reaches a value of 2.5 according to the normalization of Hale (22). The diffusion coefficient can then be calculated from $\Theta = D\tau/\delta^2$ with the experimentally determined value of τ. In the experiments the current of the pulse in both anodic and cathodic directions was varied between 0.8 and 0.6 of the limiting current as measured with the disk electrode. The temperature was varied between 300° and 370°C. In all cases a double pulse was em-

ployed (24) although the charging of the double layer within the transient time was almost negligible. Typical curves are shown in Fig. 6.

As a check the transient times were also measured when the diffusion layer decayed after the current had been shut off. The values of τ thus measured were always equal to those of the "buildup" experiments.

The values of D thus obtained are listed in Table II where the values given in the last column are those obtained from the least squares curve. The lower and upper limits of D correspond to a 95% joint confidence interval [for details see Ref. (13)]. The correlation was 72% for the cathodic points and 48% for the anodic ones. The scatter of the latter points is relatively large and may be due to the fact that even with this method of measurement the problems associated with anodic deposition of sulfur cannot always be totally eliminated.

From the temperature dependence of the diffusion coefficients in Na_2S_4 the activation energy of diffusion can be calculated. The least squares line gives an approximate value of 12 and 11 kcal/mole for the cathodic and anodic diffusion, respectively, in the temperature range 300°-370°C. These values are in good agreement with those obtained from viscosity data (18) which give an activation energy of viscosity of 10.3 kcal/mole.

By combining the values of the cathodic limiting currents at the rotating disk electrode with the least squares values of D the values of nC_{ox} (number of electrons $\times$ concentration of reducible species) were found to be 6.5 (300°C), 7.7 (320°C), 6.5 (330°C), 8.1 (340°C), and 8.6 (350°C) mole/liter. Since the anodic

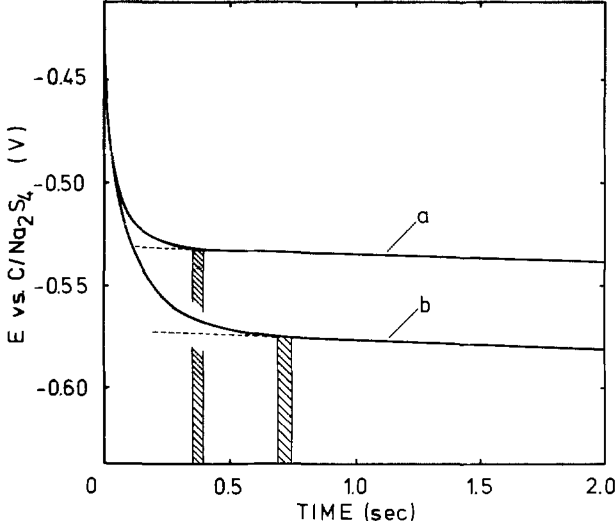

Fig. 6. Chronopotentiometric curves at the rotating disk electrode in Na_2S_4 at 350°C. Curve a, at 8000 rpm, curve b, at 4000 rpm. Shaded area indicates estimated error on τ.

"limiting" currents are due to blocking of the electrode surface by a deposit of sulfur they cannot be used to calculate values of nC_{red}. Attempts to determine the degree of blocking by applying the theory of Landsberg and Thiele (21) were undertaken but did not lead to unambiguous results.

Diffusion coefficients and nC values have been previously determined in polysulfide melts. Ludwig [Ref. (1), p. 430] combined various electrochemical measurements reported by different authors and obtained a value of $D = 6.3 \times 10^{-7}$ cm^2/sec and $nC = 18.2$ moles/liter for Na_2S_5 at 350°C. For Na_2S_4 he found $D = 2 \times 10^{-7}$ cm^2/sec at 300°C. From the Nernst-Einstein equation he estimated the latter value to be 7-9 $\times 10^{-7}$ cm^2/sec. Armstrong, Dickinson, and Reid (4) found values of $D = 9.8 \times 10^{-6}$ cm^2/sec for Na_2S_3 at 350°C and of $D = 1.4 \times 10^{-5}$ cm^2/sec for Na_2S_5 at 350°C. These authors also report values for the concentration of the oxidized and reduced species.

The values calculated by Ludwig (1) are in rather good agreement with those found here. A direct comparison of the results of Armstrong *et al.* (4) with ours, which are in a tetrasulfide melt, is not possible. However, since it seems unlikely that the values in Na_2S_3 and Na_2S_5, which lie close together, would differ much from those in Na_2S_4 it can nevertheless be said that the results do not agree. Their diffusion coefficients are an order of magnitude larger and the concentrations of the oxidized species lie between 1.3 and 1.7 mole/liter (for $n = 1$). The discrepancy must be due to the assumptions on which these authors base their calculations. In both Na_2S_3 and Na_2S_5 they postulate a reversible diffusion controlled reaction of the type $\nu_{ox}Ox + ne^- \rightarrow \nu_{red}$ Red. It seems plausible that the same situation should then also exist in the tetrasulfide melt. However, IR compensated voltammetric curves obtained in our laboratory with Na_2S_4 melts clearly show that there are two coupled redox systems present (Fig. 7). Other investigations (1) also point in this direction. The above assumptions seem, therefore, of questionable validity. Moreover, the diffusion coefficient of the electroactive polysulfide species has been determined in fused LiCl-KCl eutectic at 420°C by chronopotentiometry to be 3.1 $\times 10^{-6}$ cm^2/sec (25). From the Stokes-Einstein equation it is hard to imagine how the diffusion coefficient of a polysulfide species in Na_2S_3 or Na_2S_5 could be an order of magnitude larger when the viscosity is so much larger (approximately 20-40 cp *vs.* 2-3 cp in LiCl-KCl) and the temperature 70°C lower. The ratio of the radii of the two diffusing ionic species would have to be about 35. This seems unreasonable, even considering the fact that the diffusion of the ion takes place under different conditions (*viz.*, in a solvent in one case and in its molten salt in the other).

Conclusions

The rate of sulfur exchange under equilibrium conditions across the $S/Na_2S_{5.2}$ interface was determined

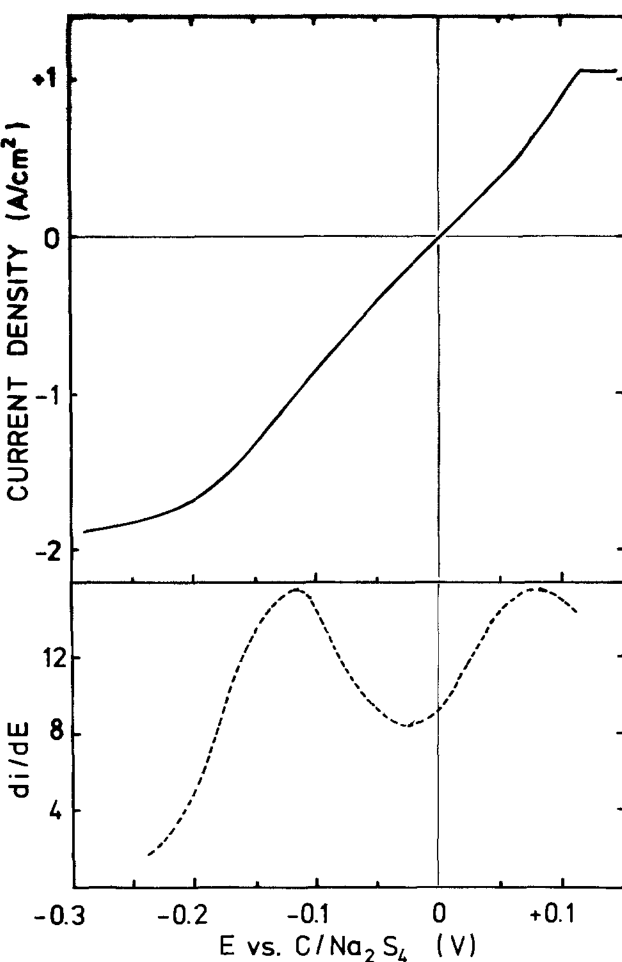

Fig. 7. Voltammetric curve (a, top) of Na_2S_4 at 340°C at the rotating disk electrode (4000 rpm). The differentiated curve (b, bottom) (*di/dE vs. E*) is drawn in to show the points of inflection of curve (a).

from the capillary experiments to be about 0.19g $S/cm^2/hr$. The experiments with a large $S/Na_2S_{5.2}$ interface exhibiting lesser transfer rates of S-35 (about 0.06g $S/cm^2/hr$ at conditions of thermal convection and up to about 0.1g $S/cm^2/hr$ at slow stirring) suggest the formation of diffusion layers on either side of the interface. Since the diffusion coefficient of S-35 in $Na_2S_{5.2}$ is markedly lower than in liquid sulfur (Table I), the effect of diffusion in the pentasulfide melt on the transfer rate will be even more pronounced than that in the sulfur phase.

Under practical conditions in a sodium-sulfur battery, with an actual mass transfer across the interface during charging or discharging, stirring is absent and convection will not be very vigorous. The transport through the convective diffusion layer and the transfer rate across the interface will then simultaneously limit the rate of charge or discharge. In general the transfer rate is expected to be lower than the exchange rate of 0.19g $S/cm^2/hr$ which would correspond to a current density of 0.06A per cm^2 of S/Na_2S_x interface. At large cell currents a sufficiently large interface must, therefore, be provided.

The diffusion coefficients which govern the mass transfer at the electrode/Na_2S_x interface (Table II) are more than one order of magnitude lower than those governing the sulfur exchange at the S/Na_2S_x interface. This difference is obviously due to different transport mechanisms. Apart from the question of which species are actually moving, the matter transported in both cases is different. While it is an uncharged sulfur species at the sulfur side of the melt, it is some sort of sulfide ion (and simultaneously sodium ion) at the electrode side of the melt.

A possible explanation could be as follows. The transport of sulfur takes place by a rapid exchange of sulfur atoms between the polysulfide ions, or "hopping" from one polysulfide ion to another without being strongly bound to and immediately incorporated into the ionic structure. These mechanisms do not necessarily lead to detectable amounts of free sulfur atoms and are not in contradiction with investigations by Cleaver and Davies (3) which showed that no free sulfur is present in polysulfide melts. On the other hand, the transport of sulfide (and sodium ions) requires the movement of complete ions because the exchange of S with charge does not occur for some reason.

Possible Use of Honeycomb-Type Structures for High Power Batteries and Fuel Cells

J. T. Kummer

Ford Motor Company, Research Staff, Dearborn, Michigan 48121

This note describes a possible method for constructing a Kapitza-type battery that differs from the usual thin plate approach, and may be simpler to make, and a possible method for constructing a fuel cell that may offer an economic advantage over present methods of construction.

One type of honeycomb structure that has been used by the Ford Motor Company as a substrate for auto exhaust catalysts has ~47 openings per cm^2 of front face surface and is manufactured for the most part by an extrusion process. The passageways which run the axial length of the honeycomb have a square cross section with an inside dimension of 1.1 mm, and are separated from one another by walls that are 150-250 microns thick and 35-40% porous (~10 micron pore diam) (1). When the porous walls are filled with electrolyte they can act as battery separators. The present ceramic material is essentially corderite ($2MgO \cdot 2Al_2O_3 \cdot 5SiO_2$), however, other ceramic or plastic materials could be used for the devices described here if they are chemically resistant to the electrolyte used and possess sufficient thermal stability. Passageway cross sections other than square can be extruded, the passageway wall thickness can be varied, and the diameter of the pores in the passageway walls can be varied (1).

If the alternate passageways in the honeycomb contain a positive and a negative electrode, respectively, the structure allows for a high interface area between electrodes with considerable strength. The power available, if it were limited only by the electrolyte resistance in the passageway walls, would be high. The resistance of the electrolyte in the porous walls (250 microns thick) of the passageways has been measured for 35% H_2SO_4 and is such that a 0.2V potential between alternate passageways of a round honeycomb 6 in. diameter (8500 openings total on front face) and 6 in. tall (weight 4.1 lb dry and 9.8 lb full of acid) would allow 9000A to flow between alternate passageways. If the electrodes were sufficiently active to allow the cell voltage to remain at 2V at the high current density represented by the 9000A (~2A per passageway or ~320 mA per cm^2 of passageway wall surface) one could obtain 18 kW from this size honeycomb. In order to construct a battery of cells with an output voltage of 12V and to increase heat removal during charge and discharge, the honeycomb could be cut into six cells 1 in. thick, 6 in. diameter to be connected in series. A plate would be required to seal the bottom of each section. In order to construct a high power lead acid battery, the passageways would have to be filled with a Pb-PbO mixture (prilled powder), acid added, and a top structure attached which pushed lead contacts into each opening. Every other lead contact would be connected together to complete the cell. An alternative design would have lead wires in the bottom seal plate project up into the honeycomb holes. This would require two metal (Pb alloy) sheets each with either a wire projection or a hole arranged in alternate sequence (47 per cm^2). The two sheets would be placed together separated by an insulator with the wires from the lower sheet passing through the holes in the upper. The two sheets would represent the battery terminals. For honeycombs ~1 in. thick the current in each wire would be ~400 mA. The use of a wire for the positive current collector could present a corrosion problem. Such metal sheets would simplify the construction of this device. Such a cell could be charged and discharged at the power level dictated by the electrode activity. As a high power cell with a limited amount of electrolyte, it would not have a high energy density. The 6 in. × 6 honeycomb + acid + PbO + terminals would weigh 25-30 lb.

Key words: battery, electrolyte, fuel cell.

Experimental

Battery.—Two adjacent honeycomb passageways 1.1 mm inside size were cut out of a honeycomb and sealed at the bottom with black wax. A Cu wire was put in one passageway (−) and a Pt wire in the other (+) passageway. A fine PbO powder was added to both passageways to a depth of 1.5 cm. This required some patience since the powder was not free-flowing but rather caked up. The cell was wrapped with masking tape, painted with waterproof cement at a small bottom section, and placed in 35% H_2SO_4. It was charged at 1/2 mA overnight. The open-circuit voltage was 2.13V.

When shorted with 47Ω (40 mA) the voltage dropped from 2.13 to 1.9V and slowly dropped to 1.8V after 1.4 min. This corresponds to 27 mA/cm length of passageway at a ΔV of 0.23V. The 18 kW cell required 143 mA/cm of passageway length.

When shorted with 22Ω (80 mA) the voltage dropped rapidly from 2.13 to 1.75V and then to 1.7V after 0.33 min. This corresponds to 55 mA/cm length of passageway at an overall voltage drop of 0.4V (IR + polarization).

The short-circuit current with a 1.6A meter was 0.26A. At a discharge current of 10 mA the cell voltage was 2V after 7 min and 1.95V after 10 min.

It is estimated that the first case represents 3.5 kW for the 6 × 6 in. honeycomb at 1.9V and the second case 6.7 kW for the 6 × 6 in. honeycomb at 1.75V. These values would improve somewhat if the cells had been surrounded by counter cells instead of only being adjacent and if a Pb-PbO mixture had been used (better positive electrode conductivity). These tests say nothing about durability or allowable charging rate. The benefits, if any, of this way to make a high power cell could best be evaluated by a battery company since the battery performance is determined princi-

pally by the electrode material, an area in which they have considerable expertise.

In addition to its use as a possible battery separator, the honeycomb structure can also be used for the construction of a fuel cell. The material from which the honeycomb is made need not be ceramic (although the ceramic allows high temperature processing of the electrode materials on the honeycomb before use) but must be an insulator, resistant to acid or base, and the walls must be porous. It is thought that the use of the honeycomb structure could reduce the cost of fuel cell construction.

Because the pore structure of the walls is small ($\sim 10\mu$) in size (1) the wicking action of the walls will cause the electrolyte to fill the pores.

In fuel cell use, each alternate passageway of the honeycomb would contain either fuel or oxidant. A plastic header attached to one end of the honeycomb is necessary to distribute the fuel and oxidant to the required passageway. The walls of the passageway would have to be coated with a catalytic material to promote the electrode reactions. This can be done by a simple dip procedure such as is used in applying a catalytic washcoat to the honeycomb for auto exhaust service. For the fuel cell, a washcoat would be a conductive electrode catalyst. If necessary, a different washcoat could be applied to different channels by the use of a suitable plug to block off alternate passageways.

In the case of fuel cells, however, the particle size of the washcoat as compared to the honeycomb pore size is quite critical. If the washcoat particle size is too small, it will penetrate from one side of the passageway wall to the other through the pores. Since the electrode catalyst must possess electrical conductivity, it may give a partial short to the fuel cell. If the washcoat particle size is too large, it may not adhere well. This problem can be alleviated by applying a coarse particle washcoat to the honeycomb of the honeycomb material and resintering to give a passageway wall of dual pore size, the outer layer having the larger pores to accommodate and hold a large particle size electrode catalyst.

It is necessary to make electrical contact to the washcoat by means of a small metal wire inserted into each opening with every other wire connected together. If the electrode catalyst is poorly conducting, a highly conductive washcoat would have to be applied before applying the electrode catalyst. In this case electrical connection need only to be made at one end of the passageway.

Fuel cell.—Two adjacent honeycomb cells, 1.1 mm inside size, of a Corning corderite honeycomb of ~ 47 openings per cm^2 with a 250 micron wall thickness, and a length of 3.8 cm were sealed with collodion and coated with a slurry of Ni powder (Sheritt NF-1M-P240) in water, and sintered in H_2 at 850°C for 1 hr. This gave an adherent, porous, and very conductive Ni coating to the inside of the passageways. NiO powder would be just as effective as Ni since it reduces to Ni. A mixture of NiO + MgO could also be used so that after reduction the MgO could be leached out with acid to give a more porous Ni coating. The honeycomb structure withstands the high temperature exposures without any difficulty.

A chloroplatinic acid solution (8 mg/cm^3) was added to the Ni containing honeycomb until the honeycomb walls were wet and then the honeycomb was dried at 110°C.

H_2 was passed through one passageway and air in the surrounding passageways. The electrolyte was 25% NaOH solution in the passageway walls. The open-circuit voltage was $\sim 1V$ and the short-circuit current was ~ 19 mA.

Manuscript submitted Nov. 27, 1979; revised manuscript received Sept. 8, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Ford Motor Company.

An Electrochemical Control System for Electroless Copper Bath

Milan Paunovic*

Kollmorgen Corporation, PCK Technology Division, Glen Cove, New York 11542

Electroless deposition of copper was studied from the chemical (1-3), electrochemical (4-7), kinetic (7, 8-16), and mechanistic (4-7, 17-22) aspects. The subject was reviewed in a number of articles (23-26) and books (27, 28). The number of chemical and electrochemical publications on electroless deposition of copper is relatively small (about twenty-two papers in the period 1948-1979) The number of publications is even smaller when automatic analysis and control of a production electroless copper bath is considered.

So far, as we know, there is no published paper describing a complete control system (an automatic analyzer) for the analysis of the composition and performance of the production electroless copper bath. The published papers on this subject describe only control of limited number of variables, the rate of deposition (29-31), and concentration of some reacting components (32). However, more complete control systems have been described at the fall meetings of The Electrochemical Society, 1976 (32, 33), and 1978 (34-36), and a brief description of these systems is available in the form of extended abstracts.

The subject of this paper is the application of electrochemical methods of analysis in study and control of the electroless copper bath. Duration of an electrochemical analysis is in the range of milliseconds, or seconds. This short time of analysis makes these methods very attractive.

Chronopotentiometry (37, 38), voltametry (4, 19, 20, 22, 38-40), and polarography (32) can be used to analyze (manually or automatically) an electroless copper bath. Polarographic method has been applied successfully for analysis of copper, formaldehyde, and cyanide (32, 34). This paper describes the applications of chronopotentiometry and voltametry (developed

* Electrochemical Society Active Member.

Key words: copper, formaldehyde, electroless plating, chronopotentiometry, sodium 2-mercaptobenzothiazole

1968-1971) in the study and control of the electroless copper bath. The same techniques can be used to analyze electroless deposition of other metals.

Experimental

An all-glass, two (or single) compartment cell with three electrodes was used. Platinum sheets of 1.1 cm^2, electroplated with copper, served as cathode and anode. Plating was done in an acid copper solution ($CuSO_4 \cdot 5H_2O$-188 g/liter, H_2SO_4-74 g/liter) at 10 mA/cm^2 for 5 min. A saturated calomel electrode (SCE), in a separate reference electrode compartment (at room temperature), was employed as a reference electrode. A platinum sheet electroplated with copper in a single compartment cell can be used as a reference electrode.

An EDTA (ethylenediaminetetraacetic acid) type electroless copper bath was used for these studies. This bath (41) contained: Na_4EDTA-52 g/liter, $CuSO_4 \cdot 5H_2O$-9-12 g/liter, CH_2O-5-10 ml (37%)/liter, NaCN-1-30 mg/liter, and NaOH to the desired *p*H. The solutions were prepared with analytical grade reagents and deionized water.

The mixed potential was measured with a vacuum tube voltmeter (*p*H meter) using the SCE as a reference electrode.

The voltammograms were obtained with a PAR (Princeton Applied Research, Princeton, New Jersey) Model 174A Polarographic Analyzer, and the current-voltage curves recorded on a Houston Instruments (Austin, Texas) Model RE0074 X-Y Recorder.

The chronopotentiograms were obtained with a transistorized constant current power supply, made in this laboratory. The potential-time curves were recorded on the Tektronix 564B storage oscilloscope. Oscilloscope traces were photographed with a Polaroid Camera C-27.

Results and Discussion

Chronopotentiometric determination of cupric ions.—Chronopotentiograms.—A typical chronopotentiogram for the reduction of cupric ions in the EDTA bath is shown schematically in Fig. 1. The starting potential of the chronopotentiogram is the mixed potential, E_{mp}. The current is switched on at the time $t = 0$. Reduction of cupric ions with measurable rate starts at the potential $E_{t=0}$ (defined according to Fig. 1). At the transition time τ the concentration of cupric ions at the electrode equals zero and the potential is E_τ.

After the elapse of time τ a part of the current at the test electrode is used for charging the double layer until the potential reaches the value when water is reduced.

The characteristic potentials of a chronopotentiogram at 20 mA/cm^2, 68°C, *p*H 11.90, 9.0 g/liter $CuSO_4 \cdot 5H_2O$, 5.5 ml/liter CH_2O are: $E_{mp} = -0.78$, $E_{t=0} = -1.06$, and $E_{t=\tau} = -1.24V$ *vs.* SCE.

Reproducibility of transition time measurements.—Change of potential in the vicinity of transition time is fast and large. This large increase of potential allows very precise determination of the transition time. The reproducibility studies on 27 chronopotentiograms show that the transition time of 0.87 sec can be reproduced with a ±0.02 sec deviation from the mean value.

Transition time as a function of cupric ion concentration.—Dependence of the transition time on the concentration of $CuSO_4$ was studied at *p*H 11.70, 11.80, and 11.90. When the concentration of $CuSO_4 \cdot 5H_2O$ varies from 9 to 12 g/liter, the transition time varies from 0.38 to 0.84 sec. The plot of $\tau^{1/2}$ *vs.* the concentration is shown in Fig. 2. It is seen from Fig. 2 that τ depends considerably on *p*H.

Chronopotentiometric determination of formaldehyde.—Chronopotentiograms.—Anodic chronopotentiogram at 4.5 mA/cm^2 at a copper anode exhibits two steps. A typical chronopotentiogram is shown schematically in Fig. 3. The starting potential of a chronopotentiogram is the mixed potential of the copper electrode, E_{mp}. The transition time τ_2 is measured from the first transition time, τ_1, to the second inflection point. Oxidation in the first step starts at the potential E_1 which is about +0.13V with respect to the mixed potential at the bath composition given for the cathodic chronopotentiograms. At the transition time τ_1 and τ_2 the potential is +0.21 and +0.33V with respect to the mixed potential, respectively. It is seen that there is a clear distinction between these two steps. E_2 is +0.22V with respect to the mixed potential.

Transition time as a function of formaldehyde concentration.—The dependence of transition time on the

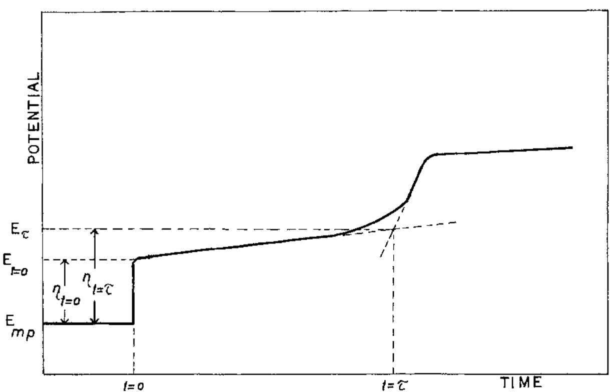

Fig. 1. Variation of the potential of the test electrode with time in cathodic chronopotentiometry of the EDTA electroless copper bath.

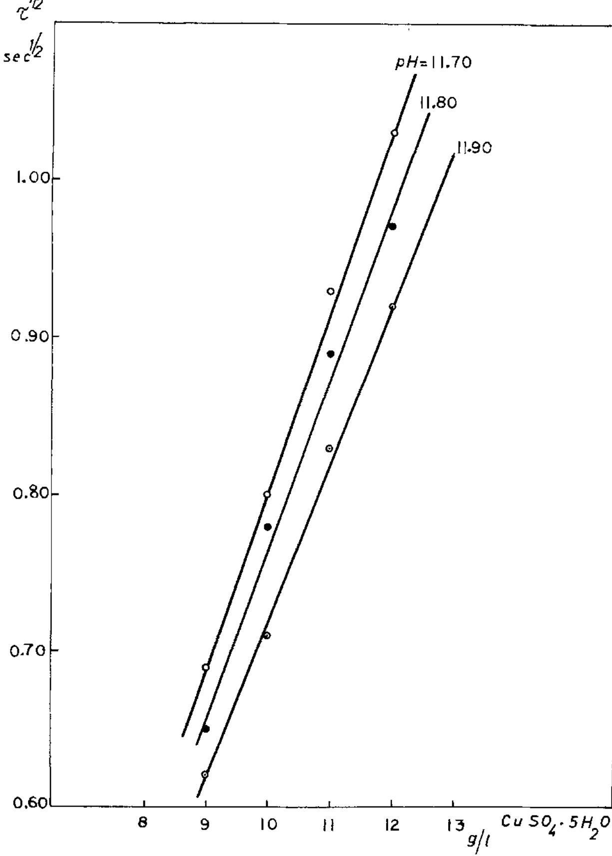

Fig. 2. Variation of $\tau^{1/2}$ with $CuSO_4 \cdot 5H_2O$; i = 20.0 mA/cm^2, 68°C.

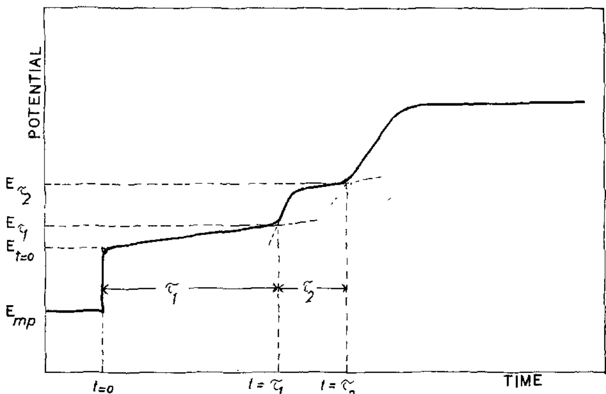

Fig. 3. Variation of the potential of the test electrode with time in anodic chronopotentiometry of the EDTA electroless copper bath.

concentration of formaldehyde in the bath is shown in Fig. 4. It is seen that for constant conditions when only the formaldehyde is a variable, $\tau_1^{1/2}$ and $\tau_2^{1/2}$ are proportional to the concentration of formaldehyde in the solution. Transition times τ_1 and τ_2 show differences in the following properties: the transition time τ_1 depends, and τ_2 does not, in practical limits, on the concentration of other components of the bath; the rate of change of the transition time τ_1 with the concentration of formaldehyde, $\Delta\tau_1/\Delta C$ (CH_2O) is faster than that for τ_2; $\tau_2^{1/2}$ is proportional to the concentration of formaldehyde in the bath, irrespective of the concentration of additives (in practical limits) and $\tau_1^{1/2}$ is proportional to the formaldehyde concentration only if other components of the bath are constant.

On the basis of the above observations, our present interpretation is that the first step in the anodic chronopotentiogram (τ_1) is due to oxidation of adsorbed species (H, CH_2O^-), or simultaneous oxidation of adsorbed and diffusing species (since the first step is sloping and not horizontal); the second step (τ_2) is due to oxidation of diffusing species. If the value of τ_1 depends on the amount of adsorbed formaldehyde, or adsorbed and diffusing formaldehyde, it could be a measure of the activity of the bath. The transition time τ_1 reflects the status of the competitive adsorption between additives, fragments of the dissociative adsorption of formaldehyde (H, CH_2O^-), OH^-, ligand, complexed copper ions, and water. Situation at the electrode is even more complicated due to the partial electrode surface oxidation, Cu to Cu_2O, starting at -0.54V *vs.* SCE. Since E_2 is about -0.45V *vs.* SCE, it follows that oxidation of formaldehyde in the time interval τ_2 occurs at the partially oxidized surface.

Adsorption effects.—Absence of additives.—At 20 mA/cm^2 and higher current densities chronopotentiograms show only one transition time due to the anodic oxidation of formaldehyde. This transition time will be called τ. The two transition times, τ_1 and τ_2, are recorded at current densities lower than 20 mA/cm^2.

Variation of τ with the current density i can be used to estimate the amount of the adsorbed electroactive species (37). The transition time τ varies from 5 to 41 msec when the current density varies from 20 to 87 mA/cm^2. The linear relationship was obtained for the plot of $i\tau$ *vs.* $1/i$ and $i\tau$ *vs.* $\tau^{1/2}$. Since both functions yield a straight line, it is not possible to make a conclusion on the mechanism of reactions, but it is possible to estimate the surface concentration of formaldehyde, Γ, from the intercepts (42). Γ, estimated from the intercepts, as a function of pH is shown in Fig. 5.

Presence of additives.—Effect of additives can be studied by recording potential time curves in the milliseconds (msec) or microseconds (μsec) range. In the msec range the usual chronopotentiograms exhibit the transition time, whereas in the μsec range the linear relationship, with the slope characteristic of the double layer capacity, is obtained.

Chronopotentiograms.—The partial coverage of the electrode by the adsorbed addition agents that are neither reduced nor oxidized at the electrode causes an increase in the actual current density i due to a decrease in the available surface area A ($i = I/A$, where I is the current). An increase in current density causes a decrease in τ. This change in the available surface area and the resulting change in the transition time is

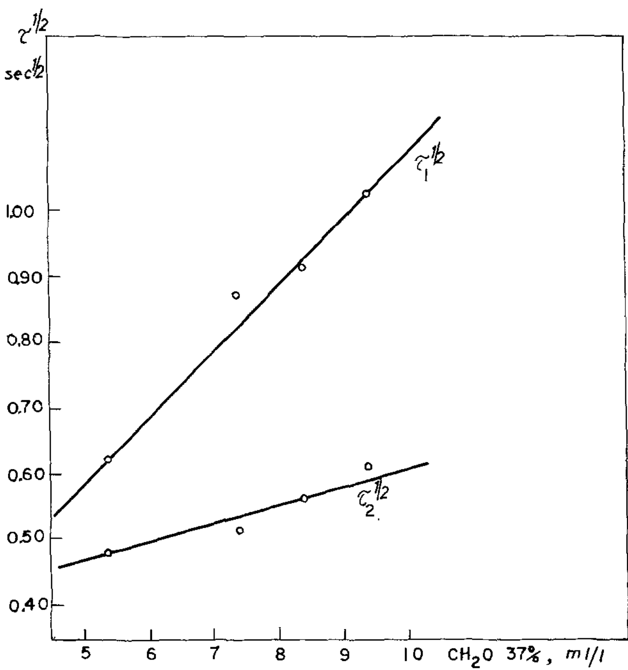

Fig. 4. Chronopotentiometric $\tau^{1/2}$ function for the first and second transition time; i = 4.5 mA/cm^2, 68°C.

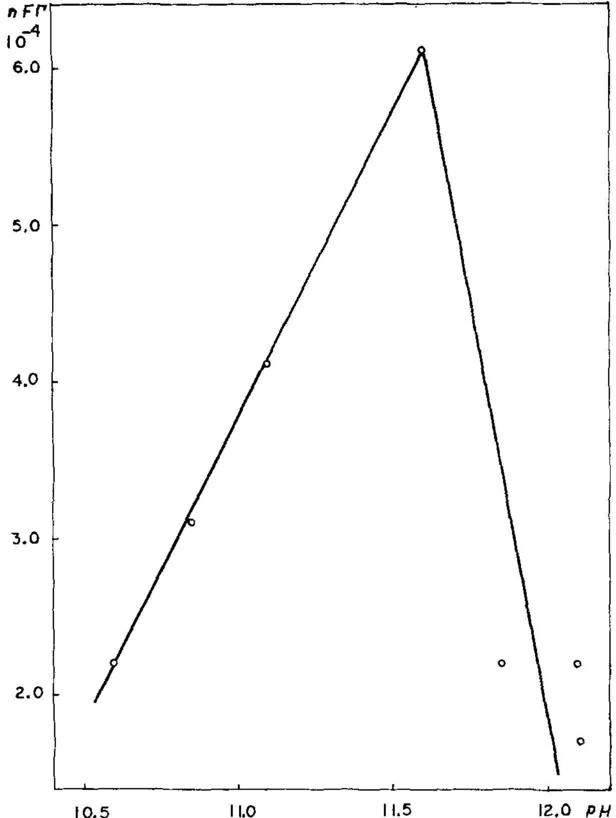

Fig. 5. The surface concentration of formaldehyde (Γ) as a function of pH.

a function of the bulk concentration of the addition agent. Thus, by determining the change in the transition time $\Delta\tau = \tau^\circ - \tau$, where τ° is the transition time in the absence, and τ in the presence of the adsorbed additive, one can obtain information on adsorption conditions at the electrode and, under certain conditions, the bulk concentration of the addition agent (43).

The difference $\Delta\tau$ caused by 30 mg/liter of NaCN, in the absence of other additives, at pH 11.60 and 12.10 is 51 and 9 msec, respectively. The difference $\Delta\tau$ caused by the adsorption of sodium 2-mercaptobenzothiazole as a function of pH is shown in Fig. 6.

Double layer capacity.—Galvanostatic potential time curves in the microseconds range can be used to estimate level of additives in an electroless bath (38). The slope of the recorded linear potential-time relationship is related to the electrode double layer capacity, $C_{dl} = i(dt/dV)$. Double layer capacity for the EDTA electroless copper bath varies from 200 $\mu F/cm^2$, for the bath in the absence, to 100 $\mu F/cm^2$ in the presence of additives. Double layer capacity for the supporting electrolyte and the ligand only, *e.g.*, 0.01M Na_2SO_4, and 0.01M EDTA at pH 13.0 and 70°C, is 58.8 $\mu F/cm^2$.

Polarization resistance.—The current-potential relationship in the range of the mixed potential (*e.g.*, from $/E_{mp}/-50$ to $/E_{mp}/+50$ mV) can be used for testing of the presence of impurities or general activity of the bath. In the vicinity of the mixed potential, the current-potential relationship is linear. The slope of this linear plot (44), the polarization resistance ($R_p = (d\eta/di)_{i=0}$), can be used as a characteristic parameter of a bath. An EDTA electroless copper bath plating at the mixed potential of -530 mV *vs.* SCE had the polarization resistance of 128Ω. The same bath after contamination showed the polarization resistance of 4200Ω. The potential sweep in these measurements was 1 mV/sec.

Summary

The data presented in this note show that the chronopotentiometry and voltametry can be used to analyze and control the operation of an electroless copper bath.

In our preliminary investigations the complete chronopotentiograms have been recorded. However, in the analytical applications this is not necessary. It is sufficient to detect the transition time only. This can be done automatically (45) by introducing a time interval counter into the electrolysis circuit. In automatic determination of the transition time, the electrolysis and the counter are started simultaneously by means of a switch. Electrical signal for the counter, to terminate counting, can be the potential of the test electrode at which the transition time is measured or the peak value of the first derivative curve at the transition time. The reading at the counter directly gives the transition time. The scale of the timer can be calibrated directly in concentrations of the species being determined.

An instrument based on the above-presented principles was constructed and used in the control of the production electroless copper bath. This control system is applicable to other electroless and electroplating baths.

It was shown that the transition time values for a specific bath component depend on pH and the concentration of other components of the bath. For this reason, it is necessary to have for each component a family of curves corresponding to the specific set of other parameters. A microprocessor, or a computer, can select the correct value of the observed component and use this value for the bath control instructions.

Photosensitization of Semiconductor Electrode by Cyanine Dye in Lipid Bilayer

W. Arden and P. Fromherz

Max-Planck -Institut für Biophysikalische Chemie, Molekularer Systemaufbau,

D 34 Göttingen-Nikolausberg, Germany

ABSTRACT

A thin film electrode is prepared by evaporation of indium-tin-oxide. It is covered by a bimolecular layer of lipid doped with a cyanine dye in direct contact to the electrode. The assembly is investigated in an electrochemical cell. The bilayer lowers the voltage dependent capacitance corresponding to the effect of a thin homogeneous dielectric with a hole fraction of about one percent. Illumination leads to a sensitized photocurrent which is enhanced by thiourea. The maximal yield at saturating potential and 3M thiourea is 0.7. The electron is transferred at a rate of about 10^{10} sec^{-1} and a yield of 0.8. An intermediate is formed consisting of the oxidized dye and an electron at the electrode surface. Supersensitization is due to the reduction of this intermediate by thiourea, the drop of current at low potentials is assigned to a reduction by occupied surface states.

Photocurrent through a semiconductor/electrolyte interface may be enhanced by organic dyes. The mechanism of such photosensitization process has been studied extensively because of its relevance to the photoelectric conversion of solar energy and to the electrophotographic process (1-4). The primary process of sensitization is generally assumed to be an electron transfer to the electrode from an excited state of the dye with a donor level above the edge of the conduction band (5, 6).

Prerequisite for electron transfer is a close contact of chromophore and semiconductor which may be achieved by four methods: (*i*) adsorption of the dye from the electrolyte (1-4), (*ii*) evaporation of a nonaqueous solution of the dye (7), (*iii*) deposition of an insoluble monolayer of the dye by the Blodgett technique (8, 9), and (*iv*) covalent binding of a reactive dye (10). Close contact may be indicated by a modification of the spectrum of absorption or of the sensitized current itself as compared to the absorption spectrum of the free dye (5, 6). The active state of the dye involved in transferring an electron may be the first excited singlet or triplet state (11).

Prerequisite for an observable sensitized photocurrent is, in the case of an n-type semiconductor, anodic polarization of the electrode such that the electric field in the space charge removes the transferred electron to the bulk of the semiconductor (2, 12). Photocurrent may be enhanced by supersensitizers which induce the electron transfer by reducing the excited dye (2, 13). Such type of supersensitization is connected with the quenching of fluorescence of the dye (14-16). Additional cosensitization is achieved by auxiliary dyes which enhance the excitation of the sensitizer by energy transfer (17, 18). The photocurrent is lowered by recombination mediated by surface states of the electrode (19).

Key words: membrane, capacitance, photoconductivity.

Photo-oxidation of the sensitizer leads to a decay of sensitized current under steady illumination (7, 14, 20). The photobleaching of the dye is observed directly by fluorescence or Raman spectroscopy (18, 21). Bleaching may be suppressed by addition of a redox couple which regenerates the oxidized dye (7, 14, 18, 20).

Sensitization of photocurrent in an electrochemical cell is in close relation to the photographic sensitization of silver halides (22). Of some relevance to the present study are the various modifications of spectral features by the adsorption of sensitizing dyes (23), the correlation of sensitizing efficiency and redox potential of the dyes (24), and the photographic sensitization by dye monolayers (25, 26).

The present paper is concerned with the sensitization of photocurrent through an interface made from an indium-tin-oxide electrode and a cyanine dye incorporated into an insoluble bilayer of lipids deposited onto the electrode. A schematical drawing of the structure of the electrode/electrolyte interface as well as of the energy levels of the components is given in Fig. 1. The reproducible preparation of immobilized sensitizer in the bilayer by monolayer deposition allows a rather detailed analysis of sensitization by simultaneous detection of photocurrent and fluorescence. The elementary processes involved in sensitization such as electron transfer, activation by supersensitizer, and inhibition by surface states are characterized and comprised in a kinetic scheme. The quantum yields of electron transfer, supersensitization, and recombination are evaluated quantitatively.

An extension of the present investigation is the construction of an antenna system of dye molecules located at the bilayer/water interface, which has been presented in a previous paper (18). These studies are elements of a more involved project considering the coupling of electron, photon, and proton in an

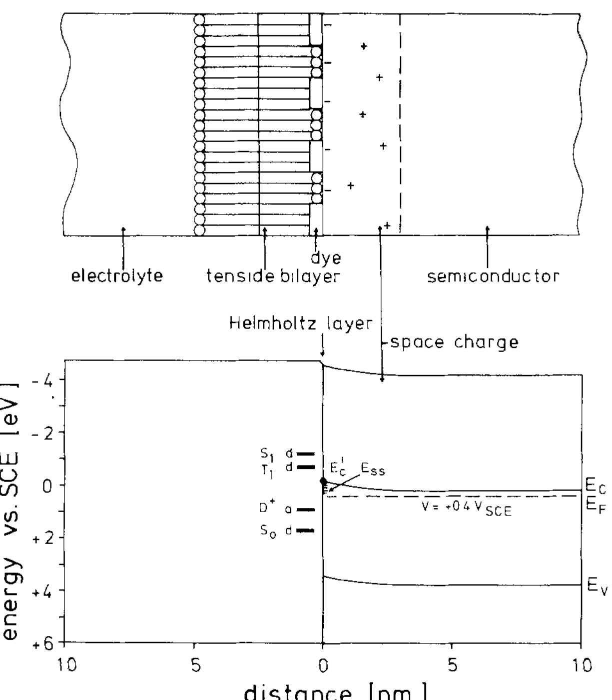

Fig. 1. Structure and energy levels of the dye-bilayer-semiconductor system. For the assignments of the energy levels see the sections on "Flatband potential" and "Photosensitization". The figure is drawn for pH 10 and an electrode potential $V = 0.4V_{SCE}$. Notations in the text.

artificial membrane doped with appropriate dyes and enzymes (27).

After a description of technical details, the present paper continues with the characterization of the electrode/bilayer system by determination of the edge of the conduction band, of the distribution of surface states, and of imperfections of the bilayer. Subsequently the mechanism of sensitized photocurrent is derived on the basis of a set of qualitative observations. Finally the quantum yields of some elementary processes of the sensitization such as electron transfer, recombination, and supersensitization are evaluated. The main results are stated in the summary.

Experimental

The semiconductor electrode.—Transparent polycrystalline films of indium-tin-oxide are prepared by thermal vacuum evaporation from pressed pellets (Merck) onto freshly cleaned glass slides (38 × 12 × 1 mm) using an alumina-coated tantalum boat. The vacuum unit is equipped with a diffusion pump and liquid nitrogen trap. Evaporation source current (300A) and evaporation rate (1.5 nm/sec) are carefully controlled such that reproducible electrodes are obtained. The thickness of the film as checked during evaporation by a quartz monitor is about 30 nm. The films are oxidized in air at 400°C for 15 min. The conductivity is 30-300 mho/cm, the mobility as determined by the Hall effect is 10-20 cm²/Vsec. Thus the density of charge carriers is 2-10 × 10^{19} cm^{-3}. The fraction of Sn atoms in the Sn/In-oxide is 30% as determined by x-ray fluorescence measurements. The donor action of most Sn-atoms is lost since they are bound as $(SnO_2)_2$ groups in the In_2O_3 (28). The bandgap of indium oxide is 3.6 eV (29) and the absorption coefficient at 350 nm is 7 × 10^4 cm^{-1} (29).

Lipid bilayers.—Monomolecular films are prepared by spreading arachidic acid at the air/water interface (*p*H 5.5, 5 × 10^{-4}M $CdCl_2$) (8). Two monolayers are transferred onto the hydrophilic electrode at a surface pressure of 30 dyne/cm and a speed of 25 cm/min within a few hours after preparation of the semiconductor electrodes. A Teflon trough with automatic control of surface pressure and film area and a precision transferring lift are applied (30). The lipid bilayers are doped with the monomethin-thia-cyanine dye (dye A) (31), by mixing the dye with arachidic acid in a molar ratio of 1:5 in a 10^{-3}M solution in chloroform before spreading. For the sensitization experiments the first monolayer transferred is doped, the second is undoped such that a structure is obtained as sketched in Fig. 1.

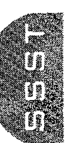
(dye A) ClO_4^- (N–$C_{18}H_{37}$, N–$C_{18}H_{37}$)

Electrochemical cell.—The electrochemical cell is a boring (diameter 9 mm, depth 15 mm) in a block of black PVC. The slide with the semiconductor-bilayer system is fixed onto the opening of this boring filled with electrolyte. The electrode is mounted in a trough under water in order to avoid damage to the transferred bilayer (27, 30). Electrical contact is made to the electrode by soldering with indium outside of the cell. A saturated calomel electrode serves as a reference. The *p*H is controlled by a glass electrode fitted into the cell. The electrolyte may be replaced during the measurements. Usually 10^{-3}M TRIS buffer of various *p*H is applied. Thiourea is used as a supersensitizer at concentrations up to 3M. For measurements of capacitance 10^{-2}M KCl is applied and a mask is introduced at the opening of the cell to reduce the area of the electrode to 0.1 cm².

Capacitance.—For determination of the capacitance of the electrode a sine wave signal (amplitude 10 mV, angular frequency $\omega = 10^3$ sec^{-1}) is superposed onto the d-c-potential of the electrode by means of a potentiostat (PAR). The output of a current-voltage converter is fed into a lock-in amplifier set on a phase difference of 90° between signal and reference. The output of the lock-in amplifier (being proportional to effective capacitance times frequency) is inverted and squared so that C^{-2} may be plotted continuously *vs.* applied voltage on a X-Y recorder as the electrode potential is scanned by a sweep generator (sweep time 10-100 sec). The series resistance of the semiconductor film (about 1 kΩ) is compensated by the internal resistance mode of the potentiostat. The whole circuit is calibrated with a set of capacitors with parallel and series resistances, with an accuracy better than 3% in the frequency range 0.05-5 kHz.

Photocurrent.—The semiconductor is illuminated through its glass support by a 150W Xe-lamp (Hanovia) through a monochromator (Bausch and Lomb, slit width 5 nm) driven by a stepping motor. The intensity at 400 nm is about 100 μW/cm². The light is chopped at a frequency of 2 sec^{-1}. The photocurrent is fed into a current voltage converter and amplified with a lock-in amplifier. Current spectra are recorded continuously on a X-Y recorder and corrected for constant photon flux.

Fluorescence and absorption.—The fluorescence emission from the semiconductor/bilayer system is detected through a monochromator (Jarrel and Ash, slit width 4 nm) with a photomultiplier (EMI 9558QB) simultaneously with the measurement of photocurrent (18). The signal is amplified with a lock-in amplifier and recorded as a function of excitation or emission wavelength. Absorption spectra of the dye/electrode system are measured wet and dry in a special vibrating high sensitivity photometer without applied voltage (8).



Semiconductor and Bilayer

Flatband potential.—The edge of the conduction band $E_C{}^i$ at the interface of the semiconductor (*cf.* Fig. 1) is derived from the flatband potential V_{FB}, according to Eq. [1]. e_o is the elementary charge, kT is the thermal energy, N_D is the density of donors in the n-type semiconductor, and N_C is the density of states in the conduction band

$$E_C{}^i = e_o V_{FB} - kT \ln N_C/N_D \quad [1]$$

The condition of zero space charge is determined from the dependence of the capacitance C_{EL} of the electrode on the potential V of the electrode: C_{EL} is given by the capacitances C_H and C_{SC} of the Helmholtz layer and of the space charge, respectively, according to Eq. [2], where C_{SC} is a function of the potential drop in the space charge V_{SC} (32) [$\epsilon\epsilon_o$ permittivity of the semiconductor, for indium oxide $\epsilon = 3.6$ (29)]

$$\frac{1}{C_{EL}} = \frac{1}{C_H} + \frac{1}{C_{SC}} = \frac{1}{C_H} + \sqrt{\frac{V_{SC} - kT/e_o}{\epsilon\epsilon_o e_o N_D/2}} \quad [2]$$

Elimination of V_{SC} (33) leads to Eq. [3]

$$\frac{1}{C_{EL}{}^2} = \frac{1}{C_H{}^2} + \frac{V - V_{FB} - kT/e_o}{\epsilon\epsilon_o e_o N_D/2} \quad [3]$$

In the limit of a very large capacitance C_H, V_{SC} may be replaced by $V - V_{FB}$ directly in Eq. [2].

The data of $C_{EL}{}^{-2}$ (V) are given in Fig. 2 for a series of *p*H values. The flatband potential is obtained from the linear extrapolation of the data to the abscissa considering the contribution of the Helmholtz layer $C_H{}^{-2} = 4.4 \cdot 10^{-3}$ [cm²/μF]² and the thermal potential $kT/e_o = 25$ mV according to Eq. [3]. (The slopes of the interpolating lines correspond to a density of donors $N_D = 1 \times 10^{20}$ cm^{-3}, which is in agreement with the density of free electrons in the bulk as obtained from the Hall effect if a correction for surface roughness is not considered.) At *p*H 10 one extrapolates $V_{FB} = 0.02V_{SCE}$. From this value one obtains $E_C{}^i = -0.15$ eV according to Eq. [1] considering $N_C = 3 \cdot 10^{22}$ cm^{-3} as given by the density of In-atoms (28).

This value of $E_C{}^i$ is the basis of the construction of Fig. 1. The vacuum levels in Fig. 1 are drawn with an electron affinity for In_2O_3 of 4.4 eV (34, 35), a normal potential of the saturated calomel electrode of 0.25V (36), and a Fermi level of the normal hydrogen electrode referred to vacuum of 4.5 eV (37). Lowering of *p*H leads to an increase of the flatband potential (Fig. 2), *i.e.*, to a lower "attachment" $E_C{}^i$ of the conduction band to the interface (Eq. [1]). This shift has to be attributed to a modification of the Helmholtz potential caused by chemical reaction or adsorption at the surface of the oxide (38-40).

Surface states.—The distribution of surface states is derived from the dependence of the intrinsic photocurrent on the electrode potential. Neglecting the contribution of the field-free region, the photocurrent per incident photon, i_{SC}, depends on the light absorption in the space charge layer (a_{SC}) and on the reaction of the photogenerated holes which diffuse to the interface (41). Considering that the fraction of charges which cross the electrolyte/electrode interface (rate S_t) in competition to the recombination reaction with occupied surface states (rate S_r) is $S_t/(S_t + S_r)$ the photocurrent is given by Eq. [4] (41)

$$i_{SC} = \frac{1}{1 + S_r/S_t} \cdot a_{SC} \quad [4]$$

An increase in the electrode potential leads on one hand to an enhanced absorption in the growing thickness d_{SC} of the space charge according to Eq. [5], where α is the absorption coefficient of the semiconductor and where d_{SC} is replaced by $\epsilon_o\epsilon/C_{SC}$ from Eq. [2] neglecting the slight difference of V_{SC} and $V - V_{FB}$

$$a_{SC} = \alpha d_{SC} = \alpha \cdot \sqrt{\frac{V - V_{FB} - kT/e_o}{e_o N_D/2\epsilon\epsilon_o}} \quad [5]$$

On the other hand, lowering the Fermi potential e_oV reduces the number of occupied surface states. Assuming an exponential decrease of the density of surface states in the bandgap from $E_C{}^i$ (41) with a depth ϵ_s and considering that S_r is proportional to the number of occupied states (41), *i.e.*, approximately to the number of states up to the Fermi level e_oV, one obtains S_r as a function of V according to Eq. [6], where $S_r{}^m$ is the maximal rate of recombination, when all surface states are involved

$$S_r = S_r{}^m \exp\left(\frac{E_C{}^i - e_oV}{\epsilon_s}\right) \quad [6]$$

Thus $i_{SC}(V)$ depends on V_{FB}, $E_C{}^i$, ϵ_s, and $S_r{}^m/S_t$ if Eq. [5] and [6] are inserted into Eq. [4]. The data of the intrinsic photocurrent for a wavelength of excitation of 350 nm and *p*H 10 are shown in Fig. 3. The absorption in the space charge drawn in the figure is calculated according to Eq. [5] with $V_{FB} = 0.02V_{SCE}$, $N_D = 6 \cdot 10^{19}$ cm^{-3}, and $\alpha = 7 \cdot 10^4$ cm^{-1} (28). The data of current are fitted by Eq. [4] with the two parameters $S_r{}^m/S_t = 500$, and $\epsilon_s = 0.15$ eV considering $E_C{}^i = -0.15V_{SCE}$. Addition of thiourea enhances somewhat the photocurrent, which can be fitted by $S_r{}^m/S_t = 70$, *i.e.*, an enhanced S_t with unchanged ϵ_s (Fig. 3).

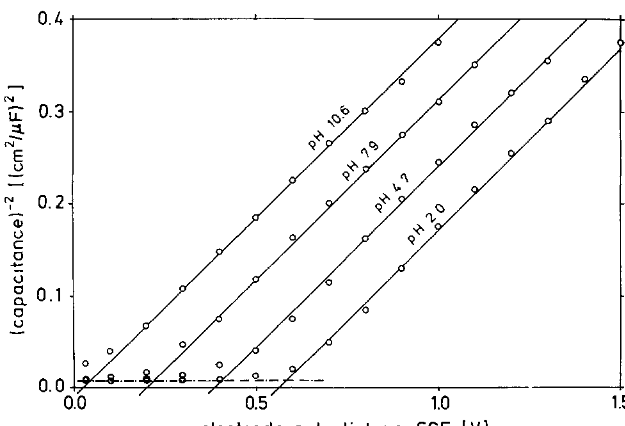


Fig. 2. Square of reciprocal capacitance $C_{EL}{}^{-2}$ of the uncovered electrode *vs.* potential *V* for a series of *p*H values. Solid lines according to Eq. [3] with $N_D = 1.10^{20}$ cm^{-3}. Dotted line indicates $C_H = 15$ μF/cm².

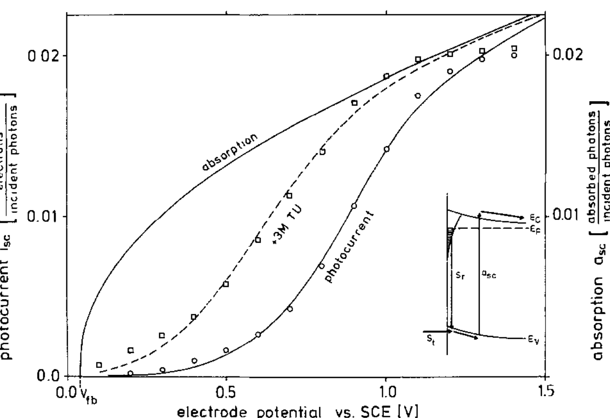

Fig. 3. Intrinsic photocurrent of uncovered electrode vs. potential *V* at *p*H 10 with illumination at 350 nm [action spectrum see Ref. (18)]. The data without and with thiourea are fitted according to Eq. [4]. The optical absorption of the space charge is calculated according to Eq. [5].

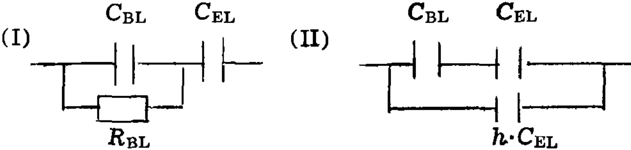
It is important to consider that the shape of a current-voltage relation as calculated from Eq. [4] depends critically on the character of the distribution of the surface states. A contribution of states of only one sharp energy or of a homogeneous distribution would not even lead to a rough fit of the data.

Bilayer.—The quality of the bilayer on top of the semiconductor is reflected in the effective capacitance of the covered electrode C_{eff} as a function of the potential applied. The modification of C_{eff}^{-1} by a bilayer as referred to C_{EL}^{-1} is considered for two limiting cases (I) a homogeneous bilayer of capacitance C_{BL} and loss resistance R_{BL}, and (II) a bilayer with C_{BL} perforated by holes such that a fraction of area h of the semiconductor remains in contact with the electrolyte. The two models are described by the equivalent circuits I and II. For model II the fraction of free electrode is assumed to appear in addition to the geometrical surface, *e.g.*, by roughness



C_{eff}^{-1} for the two cases is given by Eq. [7] and [8], where C_{EL} is given by Eq. [2], (ω is the angular frequency of the probing a.c.)

$$\frac{1}{C_{eff}^{I}} = \frac{1}{1 + (\omega R_{BL} C_{BL})^{-2}} \cdot \frac{1}{C_{BL}} + \frac{1}{C_{EL}} \quad [7]$$

$$\frac{1}{C_{eff}^{II}} = \frac{1}{1 + h(1 + C_{EL}/C_{BL})} \cdot \left(\frac{1}{C_{BL}} + \frac{1}{C_{EL}}\right) \quad [8]$$

The data of C_{eff}^{-1} with and without bilayer are shown in Fig. 4 for pH 6. The data of the uncovered electrode are fitted according to Eq. [2] with $V_{SC} = V - V_{FB}$, using the values $C_H^{-1} = 0.07$ cm²/μF, $V_{FB} = 0.28V_{SCE}$, and $N_D = 1 \times 10^{20}$ cm^{-3} as obtained from a C^{-2}/V plot.

C_{BL} is obtained from measurements with multibilayers on top of the electrode below flatband potential as shown in Fig. 5. C_{eff}^{-1} increases linearly with the number of the bilayers starting from C_H^{-1}. The capacitance per bilayer in the multibilayer system as derived from the slope in Fig. 5 is found to be $C_{BL} = 0.42$ μF/cm² in good agreement to data for dry multilayer systems (42, 43).

C_{eff}^{-1} of an electrode covered by one ideal multilayer-like bilayer ($R_{BL} = \infty$, $h = 0$) is obtained by addition of $C_{BL}^{-1} = 2.4$ cm²/μF to C_{EL}^{-1}. As shown in Fig. 4 the data approach this theoretical curve only at high potentials whereas a large discrepancy is found at low potentials. Fitting the data by Eq. [7] at low potentials with $R_{BL} = 3.8$ kΩ ($\omega = 1$ kHz) leads to a large disparity of theory and experiment at high potentials as shown in Fig. 4. Apparently the data cannot be fitted by model I, since Eq. [7] implies a constant increment to C_{eff}^{-1} for the bilayer. This disparity cannot be due to voltage drop in the bilayer. The d-c-resistance of the bilayer as estimated for cathodic polarization of the electrode is in the range of $10^5\Omega$, which is by two orders of magnitude lower than the blocking resistance of the electrode itself in anodic polarization.

The data, however, may be fitted by model II: The solid line in Fig. 4 is obtained from Eq. [8] with $h = 0.012$ and C_{EL} calculated from Eq. [2] with unchanged values of V_{FB} and C_H. The dotted line at low potentials is obtained when the measured C_{EL} is inserted into E . [8] still with $h = 0.012$. The agreement between theory and experiment is now very good over the whole voltage range: At low potentials the high capacitance of the blank regions of the electrode dominate such that large deviations occur as compared to the capacitance of an electrode covered by an ideal bilayer. At high potentials the low capacitance of the semiconductor reduces this contribution of the holes.

The value of the fraction of holes as assigned to the bilayer by fitting the capacitance according to Eq. [8] varies from 0.005 to 0.05 depending on the preparation of the semiconductor. Doping of the bilayer with

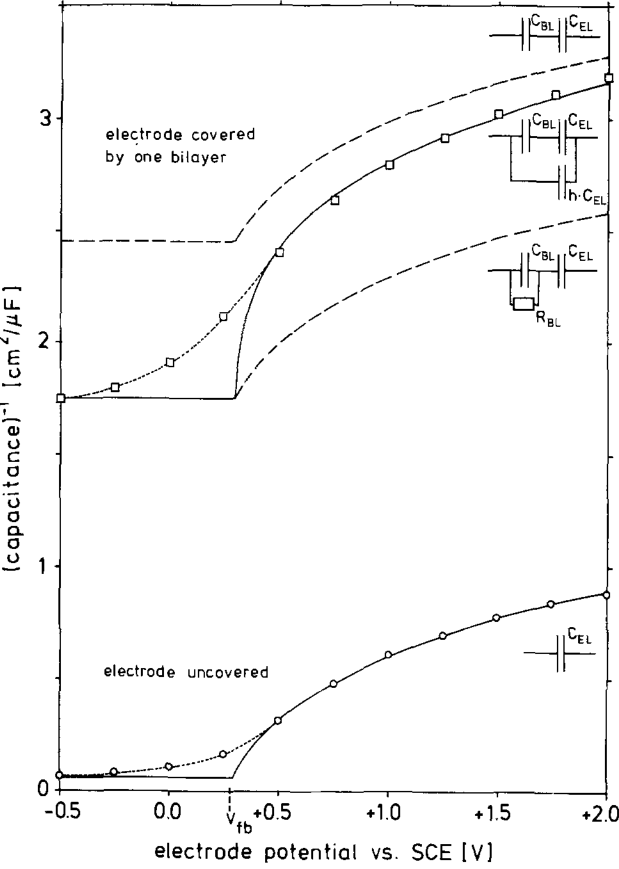


Fig. 4. Reciprocal capacitance *vs.* potential *V* at *p*H 6 for electrode uncovered and covered by one bilayer of Cd-arachidate. The solid and dotted curves represent theoretical *C-V* relations for the indicated equivalent circuits. Details in the text.

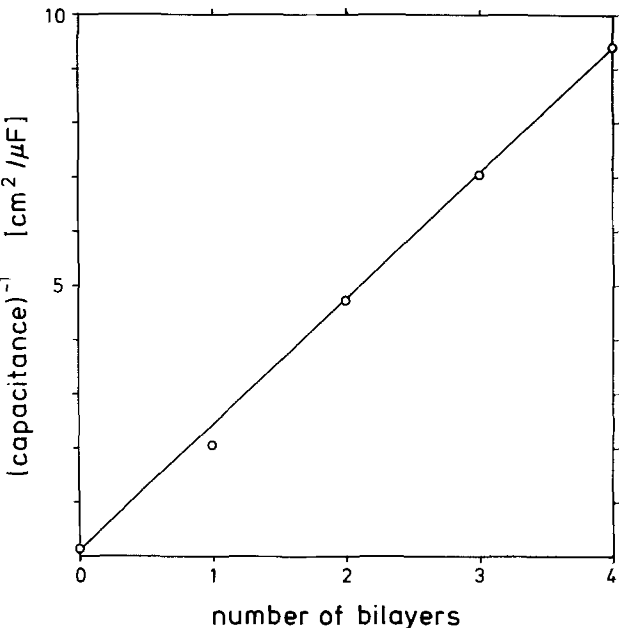

Fig. 5. Reciprocal capacitance of electrode as a function of the number of deposited bilayers at *p*H 6 and electrode potential $V = -0.5V_{SCE}$.

cyanine dye A does not change the hole fraction significantly. In any case the area of the bilayer equals the geometrical area at the air/water interface during coating (transfer ratio equals one). We attribute thus the free area h to roughness of the electrode. The rather small value of h indicates a very smooth nature of the surface. Bridging of roughness by the bilayer must be negligible, since chromophores incorporated at the bilayer/semiconductor interface reflect a direct contact of the bilayer with the surface by their features of optical absorption as discussed in the next section.

Mechanism of Photosensitization

Doping of the bilayer on top of the electrode by the cyanine dye A leads to an enhancement of photocurrent through the interface electrolyte/semiconductor. Structure and energy levels of the system are shown in Fig. 1.

The oxidation potential of the ground state S_0 of the dye is $E_{A/A^+}{}^{S_0} = 1.4V_{SCE}$ (44) (Table 1 and Fig. 2 in that reference). The oxidation energies of the first excited singlet and triplet state are constructed by subtracting the spectroscopic excitation energies. With an energy of optical absorption of 2.9 eV (*cf.* Fig. 7) the oxidation potential of S_1 is $E_{A/A^+}{}^{S_1} = -1.5V_{SCE}$. Considering a singlet-triplet splitting of 0.5 eV (45, 46) the oxidation potential of T_1 is $E_{A/A^+}{}^{T_1} = -1.0V_{SCE}$. The kinetic levels of electron donation for S_0, S_1, and T_1 and of electron acceptance for the oxidized doublet D^+ are assumed to be 0.4 eV higher and lower respectively than the corresponding equilibrium potentials as caused by reorganization (5).

It is apparent that the donor levels of both excited states $E_d{}^{S_1} = -1.1V_{SCE}$ and $E_d{}^{T_1} = -0.6V_{SCE}$ are well above the edge of the conduction band which is $E_C{}^i = -0.15V_{SCE}$ for indium-tin-oxide electrode at pH 10. The acceptor level of the oxidized state $E_a{}^{D^+} = +1.0V_{SCE}$ is on one hand far above the edge of the valence band at $E_V{}^i = +3.45V_{SCE}$ due to the large bandgap of 3.6 eV (29). On the other hand it is far below the surface states which are mainly distributed in the range of $0.0V_{SCE}$ according to the depth of 0.15 eV of their exponential distribution below $E_c{}^i$.

The sensitization of photocurrent by the cyanine dye A is characterized by seven observations as described below. These observations lead to a mechanism of sensitization as depicted in Fig. 6.

Absorption spectrum.—The absorption spectrum of dye A in the bilayer in contact to the indium-tin-oxide, as shown in Fig. 7, is characteristic for dye-monomers, with the 0-0 transition at 430 nm and a 0-1 vibronic transition at 410 nm (23). The typical absorption band of dimers at 410 nm, as observed usually in dye monolayers in contact to water (8, 47), is suppressed, although little contribution of dimer absorption to the shoulder at 410 nm cannot be excluded. Thus the interaction of the dye with the electrode breaks the stacking interaction of the chromophores without shifting the electronic transition of the monomers (Fig 7). This observation indicates close contact of the dye molecules with the semiconductor, presumably with flat orientation of the chromophores, without any significant modification of their electronic structure.

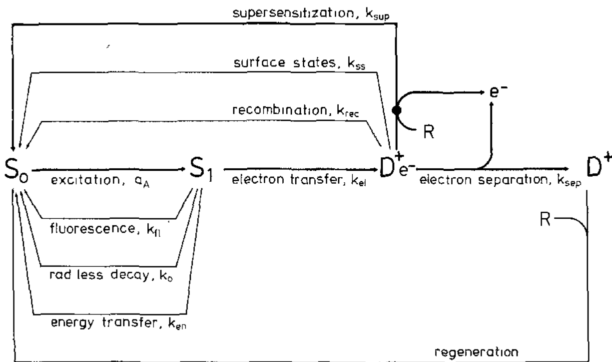

Fig. 6. Kinetic mechanism of photosensitization of indium-tin-oxide electrode by cyanine dye. Notations in the text.

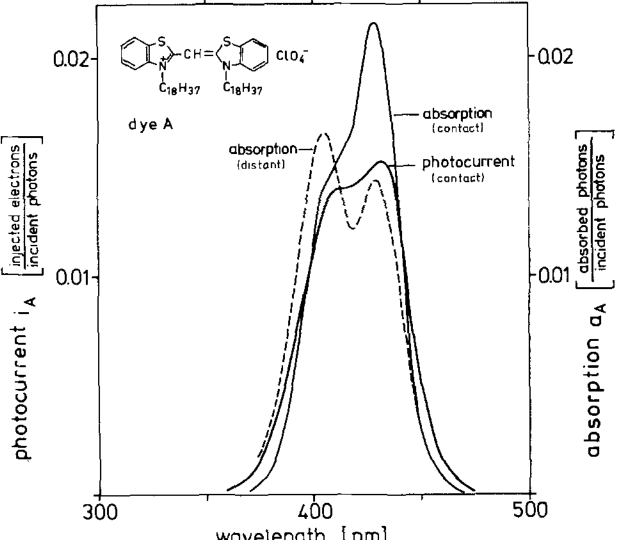

Fig. 7. Spectra of optical absorption and of photocurrent for thiacyanine dye A. The spectra refer to chromophores in direct contact to the electrode and on the aqueous side of the bilayer (*cf.* Fig. 1). The contribution of the electrode itself is subtracted [*cf.* Ref. (18)].

Photocurrent spectrum.—The photocurrent through an electrode coated with a dye-doped bilayer exhibits a component with a spectral maximum at 430 nm as shown in Fig. 7. Thus excitation of the dye monomer to its first excited singlet state S_1 induces charge transfer through the interface. Whether the shoulder at 410 nm, which is enhanced as compared to the absorption spectrum, has to be assigned to the action of the higher excited state of the monomer or to excited dimers cannot be decided at the present moment. The following experiments are all concerned with the maximum at 430 nm which can be assigned unequivocally to the $S_0 - S_1$, 0-0 transition of the monomer.

Chromophore variation.—Substitution of the monomethin-thiacyanine A by analogous dyes, a monomethin-oxacyanine, a trimethin-thiacyanine, and trimethin-carbocyanine (31), with absorption maximas from 360 nm up to 560 nm does not affect the efficiency of photocurrent, which is under optimal conditions (see below) about 0.7 (Fig. 7). The action spectrum of photocurrent of the free electrode extends up to 460 nm (18). Photosensitization by energy transfer from excited dyes to surface states of the electrode would be possible only for chromophores with some overlap of their emission spectrum with this action spectrum of the electrode. The constant efficiency for the homologous series of cyanine dyes up to an emission wavelength as long as 600 nm excludes this mechanism of sensitization. On the other hand the redox-potentials of the excited dyes are all far above the edge of the conduction band (Fig. 1) (44) such that sensitization by electron transfer from the excited dyes to the conduction band is consistent with the observations.

Bleaching.—Sensitization (without addition of thiourea) is connected with a fast reversible bleaching of the dye, as has been shown by fluorescence measurements in a previous paper (18). This result indicates the formation of an oxidized dye, the radical doublet D^+, having transferred an electron to the semiconductor (*cf.* Fig. 6).

Contacting.—The binding of the dye to the surface of the electrode leads to a quenching of fluorescence as compared to a dye incorporated at the aqueous side of the bilayer [Fig. 8(c)]. The quantum yield of the decay process of S_1 as induced by direct contact is 0.8. (The evaluation of this yield is discussed in the next section.) The induced decay of S_1 reflects the primary process of sensitization: The upper limit of the quantum yield of photocurrent, as observed at high potential and high supersensitization, is near 0.8 as well (Fig. 9 and 10). A significant induction of an unproductive decay has not been considered.

This primary process is not intersystem crossing as caused by a heavy atom effect followed by electron transfer (48): Contacting dye A in the bilayer to an evaporated thin layer of lanthanumfluoride breaks the dimers of the dye as in the case of indium-tin-oxide, but does not lead to any quenching of fluorescence. Lanthanum resembles indium and tin with respect to atomic number and ion radius such that the heavy atom effect of LaF_3 should be comparable to that of $In_2O_3|SnO_2$. However electron transfer from the dye is excluded in the case of LaF_3 due to the large bandgap of that insulator (6.7 eV) (49). These observations indicate that the primary process of sensitization is electron transfer directly from S_1 to the indium-tin-oxide.

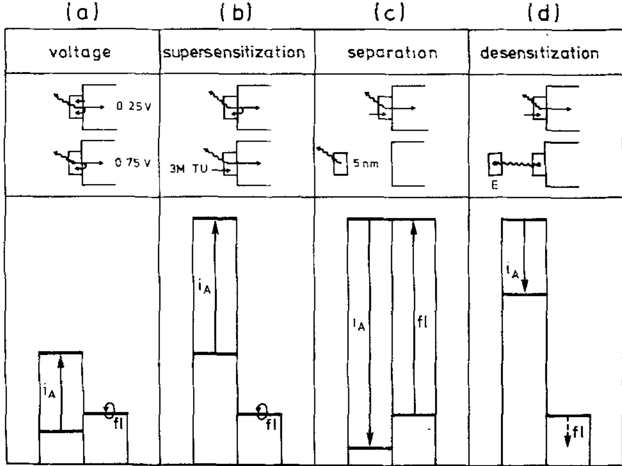

Fig. 8. Photocurrent and fluorescence as induced and emitted resp. by thiacyanine dye A in contact to electrode. (a) potential: $0.25V_{SCE}$ and $0.75V_{SCE}$, (b) thiourea *(TU)*: 0M and 3M, (c) dye location: direct contact and separation by one bilayer (5 nm) from electrode, (d) energy transfer: no acceptor and acceptor *E* at a distance of 5 nm. The schemes at the top of the figure illustrate the mechanistic effects as assigned in the text.

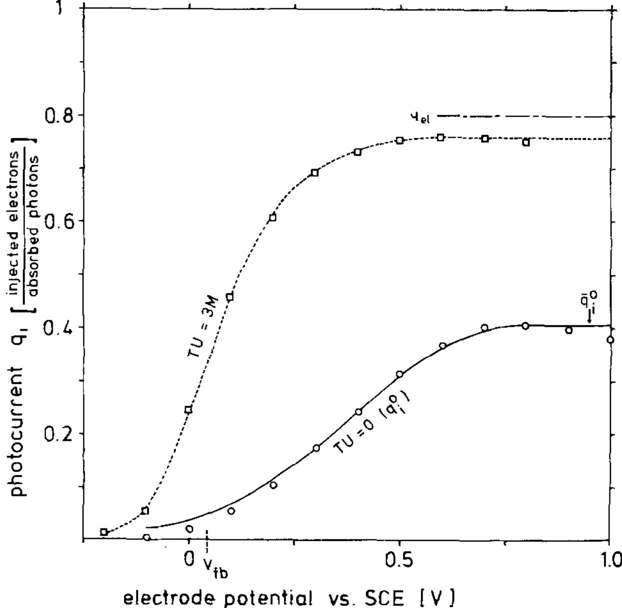

Fig. 9. Quantum yield q_i of sensitized photocurrent *vs.* potential *V* at *pH* 10 without and with 3M thiourea *(TU)*. The data without thiourea are fitted according to Eq. [10].

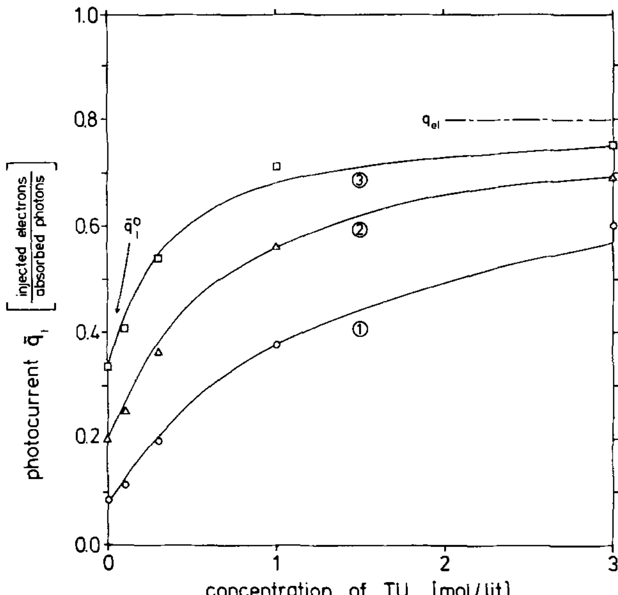

Fig. 10. Quantum yield $\bar{q}_i$ of sensitized photocurrent at saturating potential $V = 0.8V_{SCE}$ *vs.* concentration of thiourea (*pH* 10). The theoretical fit for the three samples is obtained according to Eq. [17].

Supersensitization.—Addition of thiourea to the electrolyte enhances the photocurrent [Fig. 8(b)]. This enhancement is observed from the very beginning of illumination. It is not only a suppression of bleaching during illumination. Thus the effect cannot be assigned to regeneration of the photo-oxidized D^+ (*cf.* Fig. 6). On the other hand the enhancement is not connected with any quenching of fluorescence [Fig. 8(b)]. Thus the supersensitization cannot be assigned to reduction of S_1 with subsequent induced electron transfer.

The observation indicates the existence of another intermediate formed by the primary process of electron transfer. This intermediate must consist of the photo-oxidized dye and the transferred electron at the surface of the electrode as symbolized by D^+e^- in Fig. 6: Supersensitization is due to reduction of the dye in the intermediate, as induced by thiourea, with subsequent removal of the electron to the bulk of the electrode as indicated in Fig. 6. This process competes with the unproductive recombination of D^+e^- back to S_0. Without supersensitization the photocurrent is caused by spontaneous separation of the electron in D^+e^- to the bulk of the electrode producing the bleached radical D^+ (Fig. 6).

Electrode potential.—Lowering the applied potential of the electrode leads to a lowering of photocurrent far above flatband potential [Fig. 8(a) and 9]. This inhibition as caused by lifting the Fermi potential may be due to electron donation from occupied surface states of the electrode back to the chromophore. Electron donation to S_1 is excluded, since no potential dependence of fluorescence is observed.

The drop of current is suppressed by supersensitization (Fig. 9). Thus the potential dependent inhibition is related to the intermediate D^+e^-. It reflects the antisensitizing reduction of the oxidized dye by occupied surface states with subsequent release of the electron (Fig. 6). This assignment is discussed in detail in the next section.

Quantum Yield of Photosensitization

The quantum yield of sensitized current q_i is the ratio i_A/a_A of sensitized photocurrent i_A per incident light intensity and the optical absorption (a_A) of the dye. Considering the reaction scheme of Fig. 6, q_i is determined by the quantum yield q_{el} of electron transfer leading to the intermediate D^+e^- and the quantum yields of release of the electron q_{sep} and q_{sup} corresponding to the spontaneous separation leading to the oxidized D^+ and to the supersensitization as induced by thiourea, according to Eq. [9]

$$q_i = i_A/a_A = (q_{sep} + q_{sup}) \cdot q_{el} \quad [9]$$

The present section considers the estimation of q_{el} and the evaluation of q_{sep} and q_{sup} as a function of electrode potential and thiourea concentration, respectively. All measurements refer to the very beginning of illumination, where bleaching of the dye by formation of D^+ has not to be considered, *i.e.*, the absorption a_A is always the absorption of the unperturbed dye layer.

Electron transfer.—Incorporation of an energy acceptor E at the interface bilayer/water perturbs the sensitizing process exclusively by the competition of energy transfer with electron transfer from S_1. Thus the ratio of current $i_A/i_A{}^E$ without and with acceptor equals the ratio of quantum yields $q_{el}/q_{el}{}^E$ without and with acceptor according to Eq. [9]. q_{el} and $q_{el}{}^E$ are defined by the rate constants of electron transfer k_{el}, of fluorescence k_{fl}, of radiationless deactivation k_o, and of energy transfer k_{en} according to Eq. [10a] and [10b]

$$q_{el} = \frac{k_{el}}{k_{el} + k_{fl} + k_o} \quad [10a]$$

$$q_{el}{}^E = \frac{k_{el}}{k_{el} + k_{fl} + k_o + k_{en}} \quad [10b]$$

By straightforward algebra the ratio $q_{el}/q_{el}{}^E$ may be expressed in terms of the unknown q_{el} and a parameter $k_{en}/(k_{fl} + k_o)$, which characterizes the energy transfer system, according to Eq. [11]

$$\frac{q_{el}}{q_{el}{}^E} = 1 + \frac{k_{en}}{k_{fl} + k_o}(1 - q_{el}) \quad [11]$$

The ratio $k_{en}/(k_{fl} + k_o)$ may be determined from fluorescence quenching in a bilayer arrangement without semiconductor. If the contact of the semiconductor does not affect the rate constants. q_{el} may be determined from Eq. [11]. This procedure has been used previously in the case of sensitization of silver bromide (25).

With dye A as an acceptor, using an analogous oxacyanine as a sensitizer, k_{en} is found to be two times faster than ($k_{fl} + k_o$) (18). With the quenching of current $q_{el}{}^E/q_{el} = 0.7$ [Fig. 8(d)] one obtains $q_{el} = 0.8$. The oxacyanine, used as a sensitizer in this experiment, behaves in all aspects as the original thiacyanine (18).

A similar result is obtained by evaluating the quenching of fluorescence as observed when the sensitizer is brought from the aqueous side of the bilayer to the semiconductor [Fig. 8(c)]. The ratio of fluorescence intensity of the dye in contact I_c and of the dye at a distance of 5 nm to the semiconductor I_d is related directly to q_{el} according to Eq. [12] as may be easily derived from a consideration of the rate constants

$$\frac{I_c}{I_d} = 1 - q_{el} \quad [12]$$

With $I_c/I_d = 0.2$ one obtains $q_{el} = 0.8$. This determination is less reliable than the previous one since the optical surroundings of the dye differ for the two different locations in front of the reflecting electrode.

The evaluation of q_{el} as considered is in fact an evaluation of the quantum yield of that decay process of S_1 which is induced by a semiconductor. Identification with the quantum yield of electron transfer implies that no other decay channels are opened by the electrode. This assumption is justified a posteriori by the fact that the quantum yield of current under optimal conditions of supersensitization approaches also the value of 0.8 (Fig. 10) and that no induced formation of the triplet state is observed. k_{el} may be expressed by k_{fl}: With the quantum yield of fluorescence without semiconductor $k_{fl}/(k_{fl} + k_o) = 0.2$ (18) and with $q_{el} = 0.8$ considering Eq. [10a] one obtains $k_{el} = 20 \cdot k_{fl}$. The radiative lifetime of the cyanine dye A is 3 nsec (50, 51). Electron transfer to the electrode from S_1 occurs thus with a rate constant of about $k_{el} = 7 \times 10^9$ sec^{-1}.

Inhibition by surface states.—The quantum yield of current without addition of thiourea. $q_i{}^o$, becomes significant only far above the flatband potential (Fig. 9). Such a characteristic has been reported previously for polycrystalline electrodes of SnO_2 (52). The removal of the transferred electron from the interface by the field in the space charge should lead, however, to a sharp increase of current at the flatband potential as reported for single crystalline electrodes of ZnO (5). In the present case such a characteristic is observed after addition of thiourea (Fig. 9). We attribute the depression of current in the absence of supersensitization to the action of occupied surface states of the semiconductor, donating an electron with rate constant k_{ss} to the intermediate D^+e^-, *i.e.*, reduction of D^+ to S_o with subsequent release of the electron (Fig. 6). Supersensitization inhibits this deactivation process by competition. Without supersensitization Eq. [9] becomes $q_i{}^o = q_{sep}{}^o q_{el}$, where $q_{sep}{}^o$ is defined by the rate constants of separation, recombination, and reduction by surface states, *i.e.*, k_{sep}, k_{rec}, and k_{ss}, respectively, according to Eq. [13] (see Fig. 6)

$$q_{sep}{}^o = \frac{k_{sep}}{k_{sep} + k_{rec} + k_{ss}} \quad [13]$$

The experimental results of Fig. 9 indicate a decrease of k_{ss} with increasing potential of the electrode. With $q_{el} = 0.8$ $q_{sep}{}^o$ in saturation ($k_{ss} = 0$) is $q_{sep}{}^o = 0.5$. This result means that the release of the electron to the bulk of the semiconductor with formation of D^+ occurs with a similar rate as the recombination to S_o. The value of $\overline{q}_{sep}{}^o$ varies considerably from sample to sample (*cf.* Fig. 10).

The voltage dependence of $q_i{}^o$ may be described in terms of $\overline{q}_{sep}{}^o$, q_{el}, and the parameter k_{ss}/k_{sep} characterizing the reduction by surface states according to Eq. [14] which is obtained from Eq. [9] and [13]

$$q_i{}^o = \frac{\overline{q}_{sep}{}^o}{1 + \overline{q}_{sep}{}^o \cdot k_{ss}/k_{sep}} \cdot q_{el} \quad [14]$$

Assuming k_{ss} to be proportional to the number of occupied surface states, the experimental data of Fig. 9 reflect the decrease of the number of states involved when the Fermi level is lowered. The smooth decrease of the current $q_i{}^o$ excludes electron donation only from a narrow range of surface states of energies, *e.g.*, near the acceptor energy of the dye, $E_a{}^{D+}$. This behavior is described, however, if one assumes that all occupied surface states above the acceptor level are involved considering the exponential distribution of states as determined above. Integrating over this distribution up to the Fermi e_oV and denoting the maximal rate of donation, when all states would contribute to reduction, by $k_{ss}{}^m$ one obtains k_{ss} as a function of the potential according to Eq. [15], which is analogous to Eq. [6]

$$k_{ss} = k_{ss}{}^m \exp\frac{E_C{}^I - e_oV}{\epsilon_s} \quad [15]$$

Best fit of the experimental data in Fig. 9 is obtained by Eq. 14 with $k_{ss}^m = 40 \cdot k_{sep}$. The other parameters are $\bar{q}_{sep}^o = 0.5$ and $q_{el} = 0.8$ as determined above. The values of $E_C^i = -0.15$ eV$_{SCE}$ and $\epsilon_s = 0.15$ eV are as in the case of intrinsic photocurrent.

Supersensitization induced by thiourea.—$\bar{q}_i$ is enhanced by thiourea as shown in Fig. 10. In order to act as a supersensitizer thiourea has to cross the bilayer in the intact regions or through the holes such that it reduces the D^+ in direct contact. The primary photochemical process may be followed by secondary dark reactions. According to Eq. [9] $\bar{q}_i$ depends on the sum $(\bar{q}_{sup} + \bar{q}_{sep})$ of quantum yields in saturation which is expressed by the rate constants according to Eq. [16] where k_{sup} is the rate constant of supersensitization (Fig. 6)

$$\bar{q}_{sep} + \bar{q}_{sup} = \frac{k_{sep} + k_{sup}}{k_{rec} + k_{sep} + k_{sup}} \qquad [16]$$

The data of Fig. 10 indicate an increase of k_{sup} with increasing concentration TU of thiourea, *i.e.*, an increase from $(\bar{q}_{sup} + \bar{q}_{sep}) = \bar{q}_{sep}^o$ for $TU = 0$ to $(\bar{q}_{sup} + \bar{q}_{sep}) = 1$ for $TU \to \infty$. Assuming a linear proportionality of supersensitization with the concentration of thiourea, *i.e.*, $k_{sup} = k_{sup}^M \cdot TU$ where k_{sup}^M is the rate constant for 1M thiourea, $\bar{q}_i$ is given by Eq. [17], which is obtained from Eq. [9] and [16] introducing $\bar{q}_{sep}^o$ as in the previous section

$$\bar{q}_i = \frac{\bar{q}_{sep}^o + \bar{q}_{sep}^o \cdot \dfrac{k_{sup}^M}{k_{sep}} TU}{1 + \bar{q}_{sep}^o \dfrac{k_{sup}^M}{k_{sep}} TU} \cdot q_{el} \qquad [17]$$

Supersensitization is characterized by the parameter k_{sup}^M/k_{sep}. The two summands of Eq. [17] reflect the enhanced contribution of supersensitization and the suppressed contribution of spontaneous separation when the concentration of thiourea is increased.

As shown in Fig. 10 the data of $\bar{q}_i$ scatter for different samples of the electrode. A fit of all data is obtained by Eq. [17] with $q_{el} = 0.8$ using a single parameter of supersensitization $k_{sup}^M/k_{sep} = 6.5M^{-1}$, if the samples are characterized by individual $\bar{q}_i^o = \bar{q}_{sep}^o q_{el}$. Accordingly, supersensitized injection with 3M thiourea is 20 times faster than spontaneous separation. The reduction of D^+e^- induced by thiourea may thus compete effectively with the reduction by surface states which is found to be up to 40 times faster than k_{sep}. This result is consistent with the modification of the potential dependence of current as induced by thiourea shown in Fig. 9. The variability of $\bar{q}_i^o$ ($0.05 < \bar{q}_i^o < 0.5$) is due to a variability of $\bar{q}_{sep}^o$ since q_{el} is found to be constant. In the expression $\bar{q}_{sep}^o = (1 + k_{rec}/k_{sep})^{-1}$ the variability has to be assigned to k_{rec}. A variation of k_{sep} such that the ratio k_{sup}^M/k_{sep} remains constant appears to be improbable. The recombination rate may depend on slight variations of the type and number of surface states which may be caused by irreproducible slight variations of the preparation conditions of the evaporated electrode.

Summary

The present paper includes the following results.

1. A lipid bilayer is deposited onto a semiconductor electrode rather homogeneously, but not without imperfections, where electrode and electrolyte are in direct contact. The fraction of free area is in the order of 0.01.

2. Electrons from an excited chromophore in a membrane structure are transferred to the semiconductor with a quantum yield of 0.8. The electron transfer from the first excited singlet state of the monomer of a thiacyanine dye occurs at a rate of about 10^{10} sec^{-1}. The rate does not depend on the electric field in the space charge.

3. Sensitization of photocurrent is connected with a kinetic intermediate consisting of the oxidized chromophore and the transferred electron at the surface of the electrode.

4. Supersensitization by thiourea is not due to reduction of the first excited singlet state but to reduction of the oxidized chromophore in the intermediate with subsequent release of the electron into the bulk of the semiconductor. This process competes with unproductive recombination.

5. The voltage dependence of sensitized current is due to reduction of the oxidized chromophore in the intermediate by occupied surface states in the electrode. All occupied states above the acceptor level of the dye, up to the Fermi potential, appear to be effective. The energetic distribution of the states corresponds to the distribution of surface states involved in surface recombination of holes in the case of intrinsic photocurrent.

Acknowledgments

We thank Prof. Th. Hehenkamp, Institut für Metallphysik der Universität Göttingen, for the determination of the composition of the electrode by an x-ray microprobe and Dr. E. E. Polymeropoulos for critical reading of the manuscript.

In Situ Measurement and Analysis of Plasma-Grown GaAs Oxides with Spectroscopic Ellipsometry

J. B. Theeten,[1] R. P. H. Chang,* D. E. Aspnes, and T. E. Adams[2]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A versatile ellipsometer with variable energy (1.5-5.6 eV) and angle of incidence (60°-75°) has been constructed for *in situ* thin film diagnostics on a linear plasma reactor. This instrument has been used to study the plasma oxidation of GaAs (100) surfaces. During oxidation the ellipsometer is set at a fixed wavelength and a fixed angle of incidence for monitoring the thickness of the oxide. Such information as the rate of oxidation, transient effects, uniformity, and optical absorption of the oxide layer are obtained during plasma processing. The oxidation process can be interrupted at any moment for examining the sample as a function of energy and angle of incidence. A multilayer analysis is presented to determine (*i*) the dielectric function and the thickness of the oxide layer, and (*ii*) the composition and the thickness of the interface region between the oxide and the GaAs substrate. The effect of the rate of plasma oxidation on the oxide properties is also discussed.

The use of plasma oxidation for obtaining oxide films with good electrical properties on a GaAs substrate has been actively investigated in the past few years (1). These oxide films have been analyzed by a variety of techniques (1-4). Of these, spectroscopic ellipsometry has proved to be suitable not only for determining the nature and the thickness of the oxide layer but also for nondestructively analyzing the interface region between the oxide and the substrate (2).

To investigate further the influence of plasma processing parameters on the characteristics of the oxide films during plasma exposure, we have constructed a versatile ellipsometer for *in situ* thin film diagnostics on a linear plasma reactor. The system not only will improve our knowledge of plasma-grown GaAs oxides, but also it will be applicable to films of more complex structure such as those involving both metallic aluminum and GaAs. In this paper we describe the system and various applications. The optical and the electronic aspects of the system are discussed. Kinetic measurements of the oxides and their interpretation are given and spectroscopic measurements with variation of the angle of incidence are illustrated. Both the modeling of our ellipsometry data and a complete multilayer analysis of two samples oxidized at very different rates are discussed. The analysis reveals marked differences between the two oxides, both in the oxide layer and at the interface with the GaAs substrate.

Description of the System

A simplified schematic diagram of the experimental configuration is shown in Fig. 1. It consists of a spectroscopic ellipsometer attached to a linear plasma reactor (5). The ellipsometer is a photometric type related to Fourier-transform rotating-analyzer ellipsometers described previously (6). The main difference in the present design is that the source and detector are interchanged. The sequence of optical elements is therefore lamp, rotating polarizer, sample, fixed analyzer, monochromator, and photomultiplier. The advantage of this configuration is that it places the monochromator between the reactor and the detector. Therefore, the light generated by the reactor is essentially

eliminated before reaching the detector, thus greatly improving the signal to noise ratio. An added feature with respect to previous systems is that the angle of incidence can be varied continuously.

In oxidation measurements, the sample is placed in a vacuum chamber such that its surface is nearly normal to the oxygen plasma column. The plasma is produced at an O_2 pressure of 10^{-3} Torr by a pair of rf electrodes. A typical rf power is 300W at 27 MHz. A magnetic field up to 1 kG confines the plasma along the axis of the vacuum chamber. The sample is biased positively at 50-100V with respect to the plasma. Typical currents collected during the oxidation process are a few 10 mA/cm^2.

The optical components are as follows. The light source is a feedback-stabilized high brightness 500W Xe arc lamp[3] which has an essentially line-free continuum over the accessible energy range of 1.5-5.6 eV that is ideally suited for this spectroscopic method. A quartz Rochon prism is used as the rotating polarizer to provide combined depolarizer/polarizer functions and thus greatly reduce the effects of any residual polarization in the lamp flux as well as providing approximately linearly polarized light to illuminate the sample. The shutter chops the incident beam to provide a background reference to eliminate effects of drift in electronic components and to isolate the fraction of light detected by the photomultiplier that originates by reflection from the sample. Strain-free fused-quartz windows mounted on standard 2¾ in. conflat flanges provide optical access to the plasma reaction chamber. To minimize oxide nonuniformity effects in optical data, as discussed later, the illuminated area on the sample is restricted to 0.3×0.6 mm^2 by an 0.3 mm diameter aperture.

A u.v. calcite Glan-Thompson prism is used as the fixed analyzer to reduce over-all system length. Absorption by this prism determined the 5.6 eV upper limit of the spectral range. Wavelength filtering is provided by a quarter-meter double grating monochromator[4] operated at a typical resolution of 1 nm. An S20 photomultiplier[5] is used as the detector and determines the low energy spectral limit of 1.5 eV.

The polarizer is mounted in a hollow-shaft d-c motor[6] that is feedback stabilized to operate at speeds typically near 25 rps. An attached hollow-shaft optical encoder[7] is used to trigger a 14-bit analog-to-digital converter (ADC) giving 1024 conversions per revolution. The entire lamp, polarizer, and shutter assembly is mounted on Teflon-supported rails designed to slide on the optical table to provide any angle of incidence from 60°-76°. The angle of incidence is determined geometrically by laser alignment and further checked by ellipsometric measurements on a reference SiO_2-Si sample.

The detector output voltage has a Fourier spectrum related to the optical configuration and sample properties as follows. If the complex reflectance ratio of the sample is

$$\rho = r_p/r_s = \tan \psi \, e^{i\Delta} \quad [1]$$

where r_p and r_s are the complex field reflectance coefficients for p- and s-polarized light, respectively, then the detector output is proportional to the intensity incident upon it, or

$$I(t) = I_{av} [\sin^2 P \sin^2 A + \cos^2 P \cos^2 A \tan^2 \psi + \tfrac{1}{2} \tan \psi \cos \Delta \sin 2P \sin 2A] \quad [2]$$

where I_{av} is the average intensity and the azimuth angles P and A are measured from the plane of incidence. In operation $A = A_0$ is fixed, and $P = \omega t$ where ω is the mechanical angular frequency. Under these conditions the harmonic spectrum of Eq. [2] can be written

$$I(t) = a \cos 2P + b \sin 2P + C \quad [3]$$

where the coefficients a, b, and c can be determined by Fourier analysis of the measured intensity. It follows from Eq. [2] that

$$\tan \psi = \tan A_0 \sqrt{\frac{c + a}{c - a}} \quad [4]$$

$$\cos \Delta = b/\sqrt{c^2 - a^2} \quad [5]$$

The angle of incidence dependence enters through P.

Fourier analysis of the data and over-all control of both plasma and optical systems are provided by the data processing and control system outlined in block form in Fig. 2. The system features two processors: (*i*) a fast acquisition and control interface for local control of peripherals, on-line data accumulation, and establishing the proper sequence of operations, and (*ii*) a central processing unit[8] to reduce and analyze the data and to interact with the control terminal and various input/output and long-term data storage devices. The interface frees the main CPU from operational details and with 1024 circulating locations accumulates on-line the output of the ADC to allow the main CPU to Fourier transform the previous set of data while the next data are being recorded.

A typical time sequence of operation is given in Table I. In this sequence, the plasma is turned on during the display and storage operation of the CPU by an interface-controlled bias change on a PIN-diode switch in the rf generator. A real-time clock accurately determines the time of exposure. The plasma is turned off during data and background acquisition. In this mode of operation data acquisition takes about 1 sec, corresponding to 24 turns of the polarizer, fol-

lowed by 1 sec of data processing and plasma exposure. In fact, chopping the plasma exposure allows the processing to be slowed down so that the ellipsometer can follow fast kinetic phenomena. For slow reactions such chopping is not necessary and measurements can be taken with uninterrupted plasma exposure. It is thus always possible to obtain spectroscopic ellipsometry data under quasi-equilibrium conditions.

Kinetics

A typical series of measurements during plasma oxidation are shown on Fig. 3. In this case, the wavelength of light and the angle of incidence were kept constant. The plasma exposure was stopped for spectroscopic measurements at various angles of incidence at times 1, 2, and 3. The cos Δ curve oscillates between −1 and +1 as the thickness of the oxide increases. For the 3000Å, 63.7° conditions of Fig. 3, the period in the cos Δ oscillations corresponds to approximately 800Å of oxide. The rate of growth is thus obtained directly from the cos Δ curve. Here, it is about 100 Å/min. We compare samples grown at 30 and 3000 Å/min in the next section. As seen in Fig. 3, the rate of growth decreases as the oxide thickness increases. The second oscillation takes about 570 sec to complete as to about 440 sec for the first one. This is due to the fact that the bias voltage of the sample is kept constant. The oxide growth behavior is in agreement with previously published kinetic curves (4).

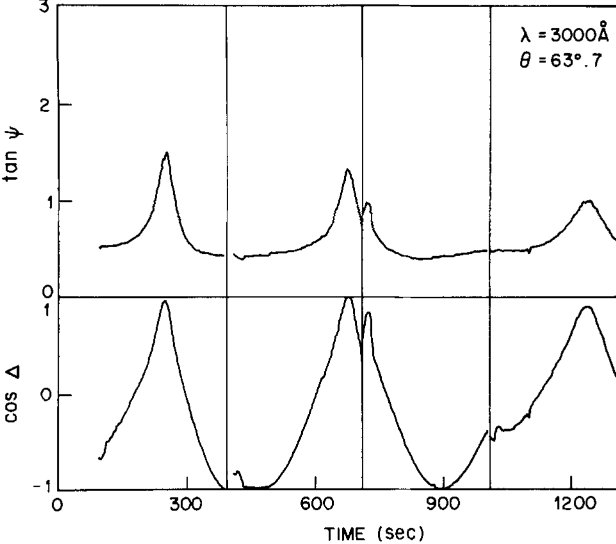

Fig. 3. Typical real-time kinetic measurements. The tan Ψ and cos Δ values were recorded at a fixed wavelength (3000Å) and a fixed angle (63.7°) as a function of the time of plasma exposure. The plasma exposure was interrupted at 1, 2, and 3 for spectroscopic and angular analysis.

The tan ψ curve exhibits a series of peaks associated with each cos Δ oscillation. The interesting fact is that the heights of these peaks are not constant but decrease as the oxide thickness increases. As illustrated schematically in Fig. 4, the decrease indicates that the oxide is optically absorbing at 3000Å. If the plasma oxide were like the anodic oxide, which does not absorb below 4.8 eV (7), then both tan ψ and cos Δ curves would be cyclic with a repeat thickness of about 800Å as shown in Fig. 4a. In particular, the height of the tan ψ peaks would be constant. If one now assumes that the plasma-grown oxide is equivalent to an anodic oxide but containing 2% unoxidized As, then the tan ψ peak heights decrease as shown in Fig. 4b. To obtain Fig. 4b, we calculated the dielectric function of a 98% oxide-2% amorphous As (aAs) mixture in the Bruggeman effective-medium approximation (EMA) (8) using reported data (9) for aAs. Here, the effective dielectric function $\langle\epsilon\rangle$ of the mixture is given by

$$\sum_i v_i \frac{\epsilon_i - \langle\epsilon\rangle}{\epsilon_i + 2\langle\epsilon\rangle} = 0 \quad [6]$$

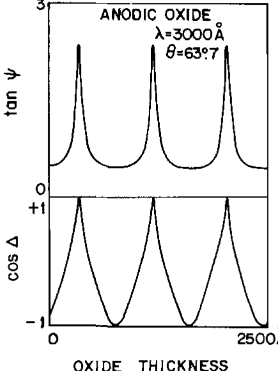
where ϵ_i represents the (complex) dielectric function of the ith constituent and v_i the relative volume fraction, where

$$\sum_i v_i = 1 \quad [7]$$

The calculated tan ψ curve shows a decrease in the peak heights because the oxide layer is absorbent, so the constructive interference regimes that give rise to the tan ψ maxima are less and less effective as the light has to propagate further and further into the layer. A comparison between Fig. 3 and 4 indicates that 2% aAs incorporated into the oxide is a reasonable estimate. The dielectric function of the plasma-grown oxide is discussed more extensively later. The tan ψ kinetic curve can thus be used as an indication of the oxide layer composition.

Inspection shows that (cos Δ) does not exactly reach +1 in its third oscillation in Fig. 3. This is a much smaller effect than the decrease in the tan ψ and is related to the nonuniformity of the oxide layer thickness within the area probed by the beam. It is seen most clearly in the very narrow positive extrema of cos Δ and is discussed in the next section. Kinetic measurements thus can also be used to estimate the uniformity of the deposit without changing either the wavelength or the angle of incidence or the position of the sample.

Another interesting feature in Fig. 3 is the anomalous behavior of tan ψ and cos Δ when plasma oxidation is restarted at 1, 2, and 3. Generally speaking, when the plasma is restarted after a sufficiently long shutdown (typically 15 min), the oxide thickness tends



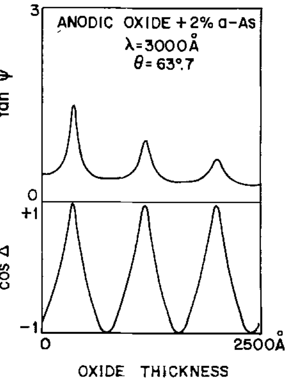


Fig. 4. Simulated kinetic data for (a, left) an anodic oxide and (b, right) a mixture of 98% anodic oxide and 2% amorphous arsenic.

to decrease before increasing again. A more detailed example of this phenomenon is shown in Fig. 5. At the onset of the plasma, cos Δ decreases before increasing. We speculate that when the plasma is on, the oxide layer has to charge up before a breakdown voltage is reached, enabling O^- ions to migrate toward the oxide-substrate interface (or the Ga^+ and As^+ ions to migrate from the substrate toward the oxide-vacuum interface) before oxidation will start. Thus before breakdown occurs, the bombardment of the oxide-vacuum interface by the plasma ions tends to sputter off some of the oxide. A detailed study of this effect will be reported later.

Spectroscopy and Angular Variation

The capability of varying both angle and energy continuously is a very important improvement with respect to conventional ellipsometry. If the dielectric functions of the constituents of a complex multilayer structure are known or can be measured independently, then the only unknowns in a modeling of the ellipsometric data for the structure are the thicknesses of the various layers and the composition of each layer. We assume here that a multilayer description is reasonable (that is, the boundaries between layers are sharp, and in the case of heterogeneous layers, the Bruggeman EMA is valid). By contrast to the conventional ellipsometer, which gives only two independent data tan ψ and cos Δ at the operating energy and angle, our system gives a very large number of independent data. This allows a very refined model to be fitted to the experiment. We have achieved fits up to 5 parameters, as will be shown in the next section. A qualitative discussion of optimizing sensitivity to interfaces or nonuniformities is given below.

In general at a fixed angle of incidence our spectroscopic ellipsometer yields tan ψ and cos Δ curves exhibiting a series of resonances if the overlayers are transparent and at least 1000Å thick. A detailed study of the nature of these resonances has been reported previously (10). In short, for energies at tan ψ peaks, the s-polarized component of the incident light is transmitted through the top layer and into substrate with maximum efficiency (minimum reflected intensity) for a given configuration. The top layer(s) therefore develop an interference condition to impedance match the s-polarized light from the ambient to the substrate. The height of the tan ψ peak is a measure of the minimum of r_s at the "resonance," because when $r_s \rightarrow 0$, $|r_p/r_s| = \tan\psi \rightarrow \infty$. Under these conditions a possible thin interface layer between substrate and overlayer(s) can modify the multiple interference regime established in the top layer(s) and can be detected with great sensitivity. It is clear that the sensitivity to interfaces is greatest when the "resonance" is sharpest, *i.e.*, when the height of the tan ψ peak is greatest. Since r_s is a rapidly varying function of the angle of incidence, it is possible by varying this angle to "tune" or "detune" the s-wave antireflection condition and thus increase or decrease the sensitivity to the interface region. The sensitivity can be enhanced by a judicious choice of energy. For example, Fig. 6 shows spectroscopic data for a 2100Å thick plasma-grown oxide for various angles of incidence. The peak in tan ψ near 2.7 eV increases when the angle of incidence is decreased from 72° to 61°. At the same time, the cos Δ curve narrows. The other peaks near 4.1 and 5 eV show less variation because the oxide here is more absorbent in these regions. Thus the multiple interference regime is most effective, or the sensitivity to an interface layer the greatest, at 2.7 eV and 61.5°. The height of the tan ψ peaks can thus be used to monitor in a very sensitive way the presence and the nature of an interface layer. However, another effect has to be considered which may also affect the apparent "quality" of the s-wave matching. If the top layer is not uniform in thickness, resonances for beams coming from different areas will not occur at the same angle or energy, causing an apparent broadening or lowering of the resonance.

To demonstrate this effect experimentally, we have examined the Si-SiO_2 system where the interface region is known to be extremely sharp (11) and therefore have eliminated any possible strong influence of an interface layer. An 8900Å thick SiO_2 layer thermally grown on a single crystal Si substrate was nonuniformly etched with CF_4 in our plasma reactor to a thickness of about 6000Å. By probing the various regions of the sample with a 0.3 mm diameter beam, a nonuniformity in thickness of about 175 Å/min is estimated. The tan ψ and cos Δ curves obtained for various beam diameters on the same spot are given in Fig. 7. If the thickness were constant over the sample, then a calculation shows that the tan ψ peak should be about 4.7 and the cos Δ cusp should reach −1 at about 2.3 eV. For our smallest beam diameter of 0.3 mm the illuminated sample area is an ellipse of 0.3 × 0.7 mm at 67°. The thickness of the oxide therefore varies by

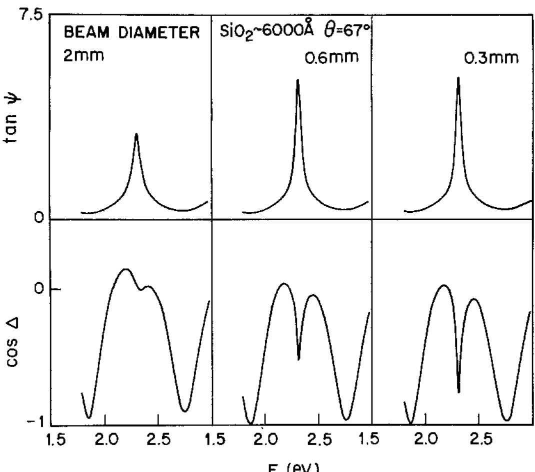

Fig. 7. The effect of nonuniformity of oxide thickness on tan Ψ and cos Δ. The sample is a 6000Å SiO_2 layer on a crystalline Si substrate. The nonuniformity is about 175 A/mm.

about 120Å, or 2%, over the beam spot. Although the tan ψ peak height is close to its calculated value, Δ only reaches −0.8. For a 0.6 mm diameter beam, corresponding to about 4% thickness variation over the beam spot, tan ψ is still acceptable while cos Δ only reaches −0.5. For a 2 mm aperture that includes about a 14% thickness variation, both tan ψ and cos Δ are affected. These measurements show that a few percent of nonuniformity in the top layer can be detected. As also discussed in connection with Fig. 4, the effect of the nonuniformity is more pronounced on cos Δ than on tan ψ.

Modeling

In this section we treat the analysis of raw data such as those shown in Fig. 6. Everything is based on the assumption that films can be represented as a superposition of distinct, uniform layers. The validity of this assumption should be tested where possible by an independent technique such as depth profile Auger spectroscopy. The AES studies reported earlier (12) on these plasma-grown oxides indicate that Ga, As, and O concentrations are uniform to within a few percent throughout the entire oxide layer. A narrow interface, less than 100Å wide, is generally detected between the oxide and the substrate. Describing this interface region as a single layer of uniform composition is obviously an approximation, but if its thickness is much less than the wavelength the optical effect of the actual interface will be similar to that of a unique layer. Therefore, in the subsequent discussion a four-phase system consisting of air, a top layer, an interface layer, and a substrate is considered. We also show that this simple four-phase structure fails when the interface region is sufficiently wide.

The four-phase model requires for its complete definition the complex dielectric functions $\epsilon_S(E)$, $\epsilon_I(E)$, $\epsilon_L(E)$, and $\epsilon_a = 1 + i0$ of the substrate, interface, top layer, and (air) ambient, respectively, the thicknesses d_I and d_L of the interface and top layer, and the angle of incidence, θ_0. From these parameters a complex reflectance ratio

$$\rho = \rho(\epsilon_S, \epsilon_I, d_I, \epsilon_L, d_L, \theta_0, |E) \quad [8]$$

can be calculated using standard equations (13). At any given energy and angle of incidence, an experimental value of ρ can be determined to be compared with the calculated value. This provides two constraints on the eight variables in Eq. [8] [we assume E and θ_0, like ρ, are input data].

Taken at face value, the parameters in Eq. [8] are still highly underdetermined. However, it is always possible to measure the substrate dielectric function ϵ_S independently, either before film growth or by stripping after the oxide has been grown. [We note that the plasma reactor is ideally suited for this purpose.] Because ϵ_S is usually much more rapidly varying in energy than ϵ_I and ϵ_L, it is more difficult to determine in a multilayer system and hence more important to know *a priori* and to be able to treat as data. We therefore assume that ϵ_S is known.

Further constraints can be obtained from the energy dependence of ρ, using the fact that d_I and d_L are independent of energy, and that ϵ_I and ϵ_L are usually slowly varying. If the film is known to be transparent in a certain region of the spectrum, then at least $\mathrm{Im}(\epsilon_L) = 0$. If also $d_I = 0$, then the only remaining unknowns are d_L and $\mathrm{Re}(\epsilon_L)$ and Eq. [8] can be solved exactly for these quantities. Having d_L, it is now possible under this restriction to calculate ϵ_L at all energies. This approach was used in fact with two sets of ellipsometric data, taken on samples with very thin natural and very thick anodically grown oxides, which were reduced simultaneously to obtain both ϵ_S and ϵ_L for GaP, GaAs, and GaSb (7).

We are concerned here with interface layers, so we cannot assume that d_I is zero. Two possibilities now exist. First, we may make "educated guesses" about the probable composition of interface and layer, and then model ϵ_I and ϵ_L in the EMA. By so doing, the number of free parameters is substantially reduced if the dielectric functions of all constituents are known over the available spectrum. This follows because the energy dependence of ϵ_I and ϵ_L is now determined by the data for their constituents, and the model parameters remaining are layer thicknesses and constituent volume fractions, all of which are independent of energy. The validity of the model must be inferred by how well it fits the entire experimental spectrum. This approach was used recently to investigate effective-medium representations of surface roughness on aSi samples grown by CVD (14).

The second approach is to assume $d_I = 0$ and solve for d_L and ϵ_L as if the interface did not exist. The question then arises as to how ϵ_L and d_L will differ from their correct values. Remembering that the effect of the interface is greatest at energies where tan ψ is maximum, it may be expected that ϵ_L will be fairly close to its correct value away from the tan ψ peaks, particularly if $d_I << d_L$, and that d_L will be too large by approximately d_I. Rapid, unphysical variations or discontinuities in ϵ_I may appear near peaks of tan ψ where the interface cannot be ignored.

To examime these points, we use the simulated spectra given in Fig. 8a. Here, we plot the tan ψ and cos Δ energy dependence calculated from the following

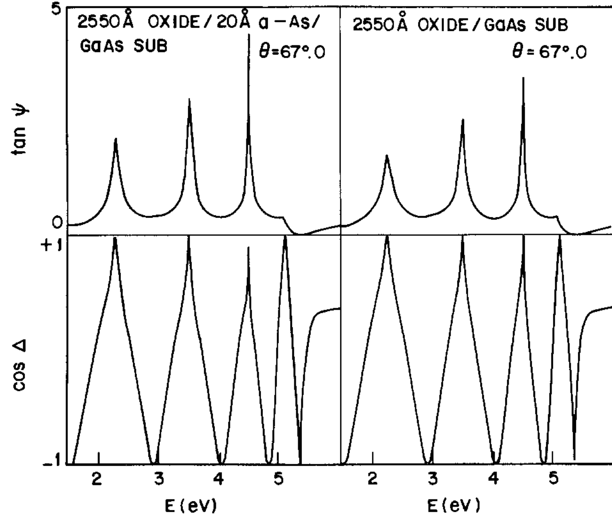

Fig. 8. Calculated tan Ψ and cos Δ curves as a function of energy: (a, top) for a 2550Å anodic GaAs oxide on a GaAs substrate with a 20Å interface layer of aAs, and (b, bottom) same as (a) but without the aAs interface layer. The angle of incidence is 67°.

data: top layer, 2550Å of anodic oxide on GaAs with $\epsilon_L(E)$ taken from Ref. (7); transition layer, 20Å of aAs with $\epsilon_I(E)$ taken from Ref. (9); substrate, cGaAs with $\epsilon_S(E)$ taken from Ref. (15). The angle of incidence is 67°. For comparison, the curves with no transition layer, but otherwise unchanged, are given in Fig. 8b. Note that the presence or the absence of the transition layer can only be seen in the height of the tan ψ peaks, as we have previously emphasized. We consider now reducing the simulated data of Fig. 8a, calculated in a four-phase system, by means of a three-phase model.

Using the constraint that $\text{Im}(\epsilon_I)$ must be nearly zero in the long wavelength region (specifically at 1.5 eV) gives $d_L = 2540$Å and the ϵ_I spectrum as curves 1 in Fig. 9a. Curves 2 give the true values used for generating the data of Fig. 8a. The value of d_L obtained in this model is not the actual one since the assumed absence of the transition layer has to be compensated by a modification of the top layer. Comparing curves 1 and 2 of Fig. 9a indicates that the real part of ϵ_L obtained in this three-phase model is very close to the actual value. In fact, the deficiency of this model can be only seen in the oscillations of $\text{Im}(\epsilon_L)$ and its negative value in the region where it should be zero. The fact that the calculated $\text{Im}(\epsilon_L)$ becomes negative comes from the assumed absence of a rejecting interface layer. Thus, the top layer has to "generate" light to compensate for this absence.

Apart from the small deviations of $\text{Im}(\epsilon_L)$ the agreement between curves 1 and 2 in Fig. 9a is satisfactory. We therefore conclude that a three-phase analysis of the experimental data is a reasonable way to obtain the dielectric function of the top layer.

Having determined ϵ_L, it is now tempting to try to determine ϵ_I as well. In this case Eq. [8] contains 4 unknowns: ϵ_I, d_I, and d_L. As already noted, d_L as deduced from the three-phase model is not valid and it also must be varied for the contribution of the transition layer to be determined. Since the interface region represents the transition from an absorbing substrate to a dielectric it is not likely to be a dielectric and that $\text{Im}(\epsilon_I)$ might be small is not valid. To obtain ϵ_I from Eq. [8], one must guess the values of d_L and d_I. Unfortunately, as illustrated in Fig. 9b, the calculated ϵ_I is too strongly dependent on these parameters, especially d_L. In Fig. 9b we have plotted the results of inverting Eq. [8] for ϵ_I with an improper guess of $d_L = 2570$Å and $d_I = 20$Å as curves 1. Curves 2 give the proper result for $d_L = 2550$Å and $d_I = 20$Å, which is of course the dielectric function of aAs. The disagreement between curves 1 and 2 indicates that a minor error in d_L totally modifies the calculated ϵ_I. In fact, this result was expected by comparing Fig. 8a and 8b, because the interface layer only influences the resonance regions. Outside these energy regions, a small error in the top layer parameters requires a large change in the parameters of the interface layer to compensate it.

It therefore appears very difficult to obtain ϵ_I from the experiment, at least when d_I is small compared to d_L. We must limit ourselves to the less general model discussed, making some further assumptions on the nature of this interface and modeling its dielectric function appropriately. Since the various possible constituents of this layer are cGaAs, aGaAs, aAs, aGa, and oxide, an EMA mixture of these constituents is assumed. Then, only a limited number of energy-independent parameters need be determined. As already mentioned, we used a five-parameter model for this purpose. Although this procedure is less general than desired, the examples discussed in the next section show that it gives a good qualitative picture of the nature of this interface layer, which allows us to investigate films grown by different rates of oxidation.

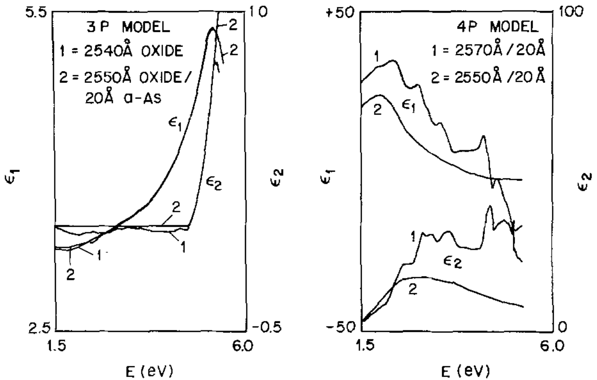

Fig. 9. (a, left) Real (ϵ_1) and imaginary (ϵ_2) parts of the dielectric function ϵ of the top layer as calculated in a three-phase model reduction of the calculated four-phase spectra of Fig. 8a. The results are given as curves 1. The true dielectric function of the anodic GaAs oxide is given as curves 2. (b, right) Real (ϵ_1) and imaginary (ϵ_2) parts of the dielectric function ϵ_I of the interface layer, obtained in a four-phase data reduction of Fig. 8a but using the incorrect thickness. The calculated values, shown as curves 1, are compared to the actual dielectric function of aAs shown as curves 2.

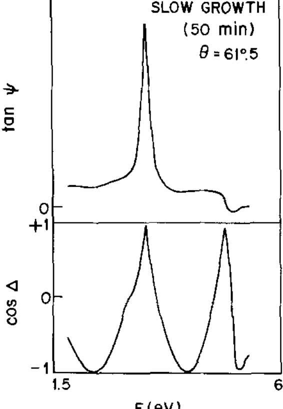
Results and Discussion

The capabilities of our system for a multilayer analysis are now demonstrated by studying the effect of the rate of growth on the characteristics of the oxide layer. The tan ψ and cos Δ spectroscopic curves given in Fig. 10 represent data from two samples of comparable thickness (~1600Å) but grown at very different rates. The first was oxidized in about 30 sec, while the second, in a lower density plasma, was oxidized in 50 min.

A three-phase model reduction of the data of Fig. 10 yields the dielectric function ϵ_L shown in Fig. 11a and 11b. As already mentioned, d_L is adjusted to minimize the imaginary part of ϵ_L. For the slow grown oxide, Fig. 11a, the oscillations in the $\text{Im}(\epsilon_L)$ curve are more pronounced, indicating as discussed above the inadequacy of a three-phase description. If we now consider the fast-grown oxide results of Fig. 11b, the oscillations are much smaller, indicating that the interface region is much thinner. In both cases, we note the striking feature that the $\text{Im}(\epsilon_L)$ curve is greater than zero even at low energies. Since the anodic oxide film is totally transparent below 4.8 eV (7) the long absorption tails in Fig. 11 are a clear indication of unoxidized material in the plasma-grown oxide. To obtain a quantitative estimate of the amount of absorbing material, we use the anodic GaAs oxide as a reference and insert via an EMA calculation a small fraction of aAs. The result for 98% anodic oxide and 2% aAs is also plotted in Fig. 11. Interestingly, the agreement between ϵ_L and the composite dielectric function



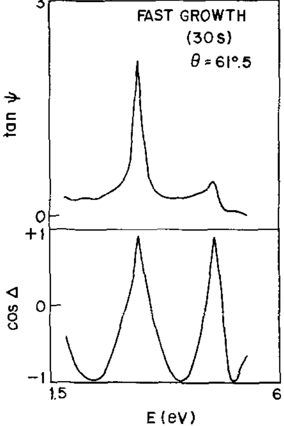


Fig. 10. Experimental tan Ψ and cos Δ spectra for two plasma-grown oxides with very different rates of growth. The angle of incidence is 60.5°.

is satisfactory to 4.8 eV. Above 4.8 eV, deviations occur indicating that the plasma-grown oxide and the anodic oxide are different materials. To choose one as a reference for the other is no longer justified. However, below 4.5 eV the description of the plasma-grown oxide as a mixture of anodic oxide and aAs is a good approximation and can be used to estimate the amount of absorbing material.

The effect of aAs in Fig. 11 is not unique. A similar effect would be obtained by mixing the anodic oxide with aGaAs or aGa, and the amount of absorbing material will differ slightly from one mixture to the other. On chemical grounds aGa is unlikely, but the existence of aGaAs cannot be ruled out by our analysis in the 1.5-4.5 eV region. Nevertheless, the use of aAs appears more reasonable from the greater stability of Ga_2O_3 compared to As_2O_3 (16). Furthermore, the presence of aAs in these oxides has recently been observed via Raman scattering (17).

To obtain a complete five-parameter representation, we will therefore use as adjustable parameters d_I, d_L, the percentage of aAs in the top layer, the percentage of aAs in the interface layer, and the angle of incidence. We use the angle of incidence because the actual value might differ slightly from earlier alignment measurements.

To give an estimate of the relative effect of the various parameters, Table II gives the least squares deviations between experiment and the four-phase model calculations when only the thicknesses are allowed to vary and the compositions are changed by finite increments. From Table II, it is seen that the agreement is significantly improved by incorporating aAs into the top layer and including a transition layer. The fit is very sensitive to the composition of the top layer and to a lesser extent to the composition of the interface layer. The best fit in Table II occurs for a 1558Å top layer of 98% anodic oxide and 2% aAs, a 32Å interface layer of 75% anodic oxide and 25% aAs, and an angle of incidence of 61°. The least squares residual is 0.67. If all five parameters are allowed to vary independently, the statistical analysis gives the following results: the angle of incidence is 60.50° ± 0.02°, the top layer thickness is 151 ± 2Å with a composition of anodic oxide with (1.5 ± 3.6%) aAs, the unbiased estimater δ of the mean squares deviation (18) for this fit is $\delta = 7.06\ 10^{-2}$. The comparison between this model and the data is shown in Fig. 12. As expected, the curves differ above 4.5 eV, indicating that the mixture assumption is no longer valid.

A similar five-parameter fit to the slow-growth data is given in Fig. 13. In this case, the fit is less satisfactory. The unbiased estimator is now $\delta = 16.5\ 10^{-2}$. The following structure is obtained: the angle of incidence is 60.45° ± 0.02°, the top layer thickness is 1502 ± 210Å with a composition of anodic oxide with (1.9 ± 0.2%) aAs, the interface layer thickness is 400 ± 210Å with a composition of pure aAs. The fact that the tan ψ data are not reproduced very well even below 4.5 eV, in the energy region where the mixture approximation was found reasonable for the fast-grown sample, indicates that a four-phase model is not correct. In fact, the thickness and the composition obtained for the transition layer indicate that this region is broad and very absorbent. A gradual variation of its composition from the top layer to the substrate is therefore more likely, in which case a multilayer analysis is improper. Also, the top layer itself is

Table II. Least squares analysis of the data of Fig. 10 for a fast-grown plasma oxide. To illustrate the relative influence of the various parameters, only the thicknesses are varied for this table while compositions (percentage of aAs) of the layers are incremented. The minimum deviations as well as the best thicknesses for each set of compositions are given.

INTERFACE LAYER \ TOP LAYER	PURE ANODIC OXIDE	1% a As	2% a As	3% a As

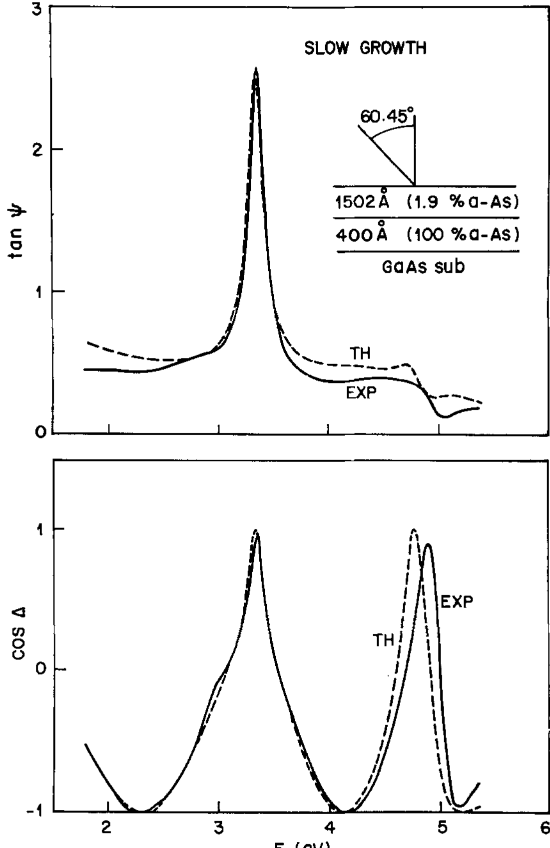

Fig. 13. Best five-parameter fit for the slow-grown sample

more absorbent than for the fast-grown oxide, making an analysis of the interface more difficult.

Although a four-phase model is not completely satisfactory, the values of the parameters obtained in the analysis of the two samples give some insight into the mechanism of plasma oxidation of GaAs. Whatever the rate of growth, some unoxidized material is present in the oxide, and it tends to accumulate at the interface between the oxide layer and the substrate. As already mentioned, the relative instability of As_2O_3 with respect to Ga_2O_3 can be invoked to speculate that unoxidized arsenic is left in the oxide during the plasma oxidation.

If the process is very fast, the dynamics tend to favor a stoichiometric oxide. However, if the rate of oxidation is slow, more As atoms will be left unoxidized. More quantitatively, the total amount of unoxidized As in the fast-grown sample is equivalent to a layer of 42Å of aAs, while the same thickness for the slow-grown sample would be 410Å. The fact that unoxidized material is mainly located at the oxide-substrate interface is probably due to segregation. To obtain a good quality oxide, the above analysis stresses the importance of a fast rate of oxidation.

Conclusion

In situ analysis of plasma-grown oxides with spectroscopic ellipsometry has been demonstrated. The present system is capable of evaluating the rate of oxidation during plasma processing, the uniformity of the oxide, as well as the composition of the oxide through a multilayer analysis. One of the unique features of our system is the ability to monitor the amount of unoxidized aAs in the oxide during processing.

We have also shown that the technique for the multilayer film analysis is quite powerful in assessing the interface structure of the oxide films. This technique can certainly be extended to study the oxidation mechanism of layered films (*e.g.*, Al on GaAs). The present study on the oxidation of GaAs is by no means conclusive. There are still many facets (such as the transient effect at the onset of the oxidation) that remain to be understood.

Manuscript received Feb. 26, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Bell Laboratories.

Residues from Wet Processing of Positive Resists

L. H. Kaplan and B. K. Bergin

IBM Data Systems Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

An ellipsometric study has been made of the residues left from the development and stripping of several positive resists as a function of surface treatment, development, and stripping variables. Residues of up to nearly 5 nm have been ellipsometrically observed in the development of AZ-1350J and AZ-111, using commonly employed developer solutions under conditions which yield positive print biases. The use of adhesion promoters HMDS, BSA, and BSTFA generally appeared to increase the amount of residue. The stripping effectiveness of organic solvents such as acetone was found to be extremely sensitive to postbaking, with temperatures as low as 130°C causing detectable residues after stripping. The use of a postdevelopment exposure helps prevent this problem. High temperature inorganic strippers, such as sulfuric/nitric acid mixtures, are highly effective, but unexplained "negative residues" are observed. Also, for resist that is cross-linked by ion bombardment, considerable residue is observed at patterned edges and can be removed only by a 400°C bake before stripping. Caro's acid, evaluated as a room temperature inorganic stripper, is fully equivalent to the high temperature acids. In addition, it shows superior stripping properties for cross-linked resists and minimal attack on Cu-Al-Si metallization. A persulfate-based stripper, similar in composition and properties to Caro's acid but whose makeup does not involve the handling of concentrated hydrogen peroxide, was also evaluated. This type of stripper appears best suited to commonly used process technology, from considerations of safety, effectiveness, and pollution control.

Modern semiconductor technology makes use of positive-type resists for the definition of patterns that are subsequently etched or otherwise defined into the substrate material. The pattern definition involves the formation of a resist film, exposure of the film in a pattern by energetic radiation, and the dissolution of the exposed regions by a suitable "developer" liquid. After defining the pattern in the substrate, the resist must be completely removed to avoid adversely affecting subsequent processing steps.

The most commonly used positive resists consist of mixtures of novolak resins with napthodiazoquinone sulfonic acid esters, generally referred to as the photoactive compound (PAC). The two-component mixture in a cast film has aqueous basic solution dissolution rates less than those of the films of the novolak resin alone. Exposure to suitable radiation decomposes the diazo groups and results in a basic aqueous solution dissolution which is faster than for the novolak resin alone. It is known that, as a result of exposure to radiation, the PAC is transformed into a carboxylic acid which contributes to increasing the dissolution rate of the resist film (1). After immersion in a basic aqueous solution (developer), the remaining patterned material is generally baked to enhance its resistance to subsequent processing. It can then be used as a mask for performing various chemical (generally etching) and physical operations on the exposed portions of the underlying substrate material.

A basic premise of the photolithographic process is that the photoresist will be evenly and completely removed from all areas defined as open by the patterned light distribution. These areas must be fully etchable in a uniform manner. Even a partial blockage of an area to be etched by resist residue would require extra etching time, during which some feature dimensions could be unacceptably widened. On the other hand. if the etch is terminated on dimensional criteria, the random resist residues will give rise to random residues of the material being etched. This could adversely affect the contact resistance in via holes or could cause shorts between adjacent metal lines. In the case of FET gates, resist residues can introduce undesirable surface states and charge.

Key words: photoresist, residue, stripper, develop, ellipsometry.

After being used to protect delineated areas of the substrate material from a particular operation, the resist must be removed to allow further processing. This is often accomplished by immersion of the working piece in a "stripping solution." [The use of oxygen plasma, or "ashing," is also a well-known means of removing resist but has not been evaluated in the present work. It has, however, been adequately covered elsewhere (2, 3).]

Four general requirements are associated with performance of resist stripping solutions. First, the stripper must be effective in completely removing all resist films of interest, including those which have been subjected to conditions that dramatically change their chemical properties. This removal should be complete, down to the limits of detectability. Second, the stripping liquid must not attack anything other than the resist. For example, it should be inert to reactive metallurgies. Third, preparation and handling of the stripper should be as safe as possible. It is generally accepted. in this connection, that room temperature is more desirable than elevated temperatures. Consideration must also be given here to the hazard potential of the materials used in preparation of the stripper, if it is prepared *in situ*. Finally, there is the matter of pot-life and the subsequent method of disposal required. Clearly, the most ideal disposal technique is the ability to flush the spent stripper down the industrial waste drain, if this is feasible from an ecological viewpoint.

Probably the most popular type of stripper for unmodified positive resists is also the most ecologically undesirable. This is the phenol-based hot stripper. Strippers such as this must generally be used at about 100°C or higher. At this temperature, their pot-life is short and the disposal becomes a problem. This is especially true because "clean water" environmental standards for phenol content are extremely rigorous (4). The use of phenol-type strippers is rapidly becoming untenable and, consequently, this class of stripper was ignored in the present work.

The most widely used room-temperature organic stripper is acetone, which. because of its very active solvent action, is quite efficient in visually removing normal photoresist. Unfortunately, it is quite volatile

and flammable, leading to safety as well as air contamination problems. Further, as will be seen later, it has limitations in its stripping abilities.

Most inorganic strippers are mixtures of sulfuric acid with certain other ingredients. The two most popular mixtures are those containing some form of oxidized chromium and those containing nitric acid. The former type has been suspected of causing electrical defects in circuits. The sulfuric/nitric acid mixtures now appear to be the most widely used inorganic strippers. This type of mixture is effective only at elevated temperatures (*e.g.*, 100°C) and, under these conditions, it is capable of ruining metallurgy by its severe chemical attack. Hot acid strippers, then, can only be used in situations where metal is absent (*e.g.*, after oxidation, diffusion, CVD, etc.).

There exist very few examples of a fourth type of stripper, the room temperature inorganic solution. The two evaluated in this work are "Caro's acid," as defined herein (5), and a related stripper using $K_2S_2O_8$ in H_2SO_4. Aside from temperature, these systems have the advantages of low metal attack and simple disposability. On the other hand, there have been some objections raised regarding the safety aspects of their formulation.

In the present work, we were concerned with the effectiveness of the develop and strip processes, in terms of how well the original surface was regenerated. The characterization of any surface has ambiguity. When we ask how well a given stripper or developer cleans a surface, we must become involved, not only with residual resist which remains, but also with changes to the original surface which the resist application and/or removal might have made. This may not be too important if we are willing to neglect everything below, say, the 10 nm range. If, however, we are interested in monolayers and submonolayers, we are forced to become involved with questions of surface state, bound water, etc., and the effects of these on our measurement method.

For the thickness range (*e.g.*, up to 10 nm) indicated, there are actually only three types of quantitative measurement methods available: ellipsometry, plasma chromatography, and high energy spectroscopy. The last, consisting mainly of ESCA and ISS, is useful for carbonaceous materials only when coupled with ultrahigh vacuum, oil-free pumping systems which only recently became available in commercial equipment. Plasma chromatography is an extremely sensitive method (6) for detection of volatile residues on surfaces. At this point, however, its quantitative capabilities are undemonstrated for applications such as we have here and chemical identification requires generation of a library of reference spectra. In addition, mention should be made here of a more qualitative residue test, commonly known as the "breath test." This is highly sensitive to very thin surface layers but generally requires these layers to be spatially nonuniform in order to form visible breath figures.

For the purposes of this study, ellipsometry was most heavily employed, with some use being made of plasma chromatography. Classically, if an ellipsometric measurement (*e.g.*, of a resist residue) is to be made on a reflecting surface, such as Si or Al, a knowledge of the optical constants of the surface is necessary, as well as a knowledge of at least one optical constant of the residue. This is not always available, and a technique involving residue on a transparent surface, such as thermally grown SiO_2, is much more amenable to approximating the thickness of the residue. In this case, the procedure is to make a preliminary measurement of the oxide thickness before resist is applied and remeasure the apparent "oxide" thickness after stripping. Naturally, the location of the measurement site must be extremely accurate. The method described yields an "equivalent oxide" thickness of the residue. That is, it gives the thickness which the residue layer would have if it were thermal oxide. Since calculations by So (7) have shown that the computed thickness is a very weak function of refractive index, this method gives a very good approximation of the true residue thickness, although it admittedly says nothing about the chemical identity of the residue or its physical/optical characteristics (other than approximate thickness).

Experimental

Several resists were investigated in this study. Single lots of each of two commercially available resists, AZ-1350J[1] and AZ-111[1], were evaluated.

The photoresists were applied and processed as follows.

AZ-1350J: (1000 nm). 4 parts resist: 1 part AZ thinner[1] (by volume); spin 30 sec at 3600 rpm; bake 15 min at 85° ± 5°C (hot plate).

AZ-111: (1250 nm). Neat; spin 30 sec at 3300 rpm; bake 20 min at 85° ± 5°C (hot plate).

Exposure times were established in preliminary testing to yield zero print bias (2500 nm line) in 60 sec (180 sec for AZ-111) of development. Resist layers were blanket-exposed for these times and developed for various periods of time in the following developers.

AZ-1350J: AZ developer[1] (undiluted), or AZ developer (1:1 dilution with water), or tetramethyl ammonium hydroxide (5% in water).

AZ-111: AZ-303 developer[1] (1:5 with water).

All studies were done using thermally oxidized (nominal 80 nm SiO_2) 57 mm silicon substrates. Where utilized, adhesion promoter precoats were applied in one of the following ways.

Hexamethyldisilazane (HMDS):

HMDS, vapor: Immerse wafer (in carrier) for desired time in vapor over boiling mixture of HMDS/Freon TF.[2] Withdraw slowly. Preliminary experimentation suggested the following optimum parameters for each of the resists used: AZ-1350J: 4 min, 10% HMDS (b.v.); AZ-111: 10 min, 4% HMDS (b.v.).

HMDS, puddle: statically apply HMDS (neat); spin 15 sec at 3600 rpm; dynamically apply Freon TF during first 10 sec of a 90-sec spin at 3600 rpm.

Bis-N,-O-(trimethylsilyl)acetamide (BSA):

BSA, puddle: statically apply (0.1% in Freon TF); spin 30 sec at 3600 rpm; bake 45 min at 130°C (hot plate).

Bis-N,O(trimethylsilyl)trifluoroacetamide(BSTFA):

BSTFA, puddle: statically apply (neat); spin 30 sec at 3600 or 6000 rpm; A-1100 silane primer,[3] 0.1% in H_2O, dip; DI water rinse, 15 sec; spin dry.

Four stripping processes were characterized in this work. The procedures are as follows.

Acetone: Immerse in ultrasonically agitated acetone at room temperature for 5 min. Repeat two additional times with fresh acetone. Rinse in DI water for minimum of 5 min. Blow dry with filtered N_2.

H_2SO_4/HNO_3: Immerse in 12% HNO_3/88% H_2SO_4 (b.v.) for 5 min at 100°C. Rinse in DI water (5 min). Blow dry with filtered N_2.

Caro's acid:

Preparation: Measure 85 p.b.v. of 90% H_2O_2 into a Teflon[2] tank. Add 5 p.b.v. of DI water. Quickly add 1900 p.b.v. H_2SO_4 with stirring. Monitor temperature and keep peak $T < 50$°C. After cooling to room temperature, do functional cotton swab test. Cotton swab test: Dip a cotton swab into the solution, start timer. Place cotton swab immediately into a clean dry beaker. Observe time for cotton swab to suddenly blacken and smoke violently. This time should be < 12 sec for satisfactory stripping.

Strip: Immerse for 5 min. Without rinsing, immerse in a second bath of the same material for 5 min.

[1] Product of Shipley Corporation, Newton, Massachusetts.
[2] Product of E. I. du Pont de Nemours & Company, Incorporated, Wilmington, Delaware.
[3] Product of Ohio Valley Specialty Chemicals, Incorporated, Marietta, Ohio.

Rinse in DI water for 5 min. Blow dry in filtered N_2.

Potassium persulfate stripper:

Preparation: Add 700g $K_2S_2O_8$ to 2000 ml H_2SO_4. Stir (magnetic stirrer) for several hours or until dissolved.

Strip: Immerse 5 min in a first bath. Immerse 5 min in a second bath of the same solution. Rinse in DI water. Blow dry.

Residues from both development and stripping were measured using ETA, an automated ellipsometer which has been previously described elsewhere (8). The thicknesses of the nominal 80 nm oxide films were measured before and after the complete resist process, at 10 premapped 3 mm spots on each wafer. The differences were corrected for instrumental drift via a control wafer and were then averaged. For most of the work reported, each thickness measurement was repeated 5 times to reduce measurement error.

Development Residues

AZ-1350J development.—The characterization of the residues from this resist covered the areas of developer type, concentration, exposure time, and adhesion promotion. Five exposure levels (in addition to no exposure) were used. In the case of optimum exposure (arbitrarily chosen as that yielding zero print bias on a 2.5 micron line in 60 sec development time), wafers were run with 2 modes of HMDS precoat, as well as without precoat. For the optimum exposure and for zero exposure, additional wafers were run with the 2 HMDS modes but without overlying resist. Two developers were used: AZ developer and a 5% solution of tetramethyl ammonium hydroxide (TMAH). The AZ developer was used both neat and in dilution with an equal volume of water (1:1).

Figure 1 shows the variation of residue thickness with development time for the three developer solutions investigated. The curves shown are for the case of optimum exposure with no adhesion promoter, but analogous curves for other conditions are similar. The general trend of residue thickness *vs.* development time is predictably down. However, the slope of the curves is strongly influenced by the specific developer solution, the TMAH developer showing much faster residue decay than the AZ developer. The diluted AZ developer shows especially tenacious residues, which remain at significant levels even after long development times.

Figure 2 illustrates the variation of residue thickness with exposure time for AZ developer and TMAH. The particular curves shown are for 45 sec development time without an adhesion promoter, but are typical of other situations. The exposure time is shown as a percent of the optimum exposure. As with development, the residues are seen to decrease with exposure time, with the AZ developer showing significantly higher residues than TMAH.

The effect of the use of adhesion promoters on the residues left by neat AZ developer is shown in Fig. 3. The residues shown by the HMDS (vapor) case are significantly higher than those shown by the HMDS (puddle) case, which is statistically indistinguishable (at 90% confidence) from the no-promoter case. The corresponding plot for TMAH, shown in Fig. 4, indicates the same relative positions for the two HMDS cases but a distinguishably lower residue for no promoter.

To further study the difference between puddle and vapor processes with AZ developer, residues for the two processes were measured without applying a photoresist layer after HMDS treatment. In this way, the effect of liquid resist solubility of the HMDS would be eliminated. Interestingly enough, in this case, the two processes yielded substantially equivalent residues, as shown in Table I. Thus, the larger residue shown by the resist using the vapor process cannot be explained by postulating a larger initial HMDS layer. Rather, it would appear that the HMDS layer deposited by the vapor process is capable of bonding the lowest resist layers more effectively. Such bonding is indicated by the fact that, regardless of the precoat process, more residue is left (after any given development time) by the resist-coated samples than by samples coated with HMDS only. This is shown in Tables II and III for the vapor and puddle processes, respectively.

After selected development steps, the various wafers were analyzed by plasma chromatography in an attempt to gain insight into the chemical nature of the residues. Figures 5 and 6 show several plasmagrams for the various residues. System blanks are included in each figure as references. Note, from Fig. 5, that the plasmagrams for vapor and puddle HMDS alone (no resist) are almost identical for AZ developer. Reference to the figures indicates that the HMDS, with or without resist, produces a pair of peaks at 7.1 and 9.5 msec of drift time. For situations involving resist, additional peaks at 6.4 and 8.6 msec are evident. A distinct difference seems to exist between residues from "HMDS only" situations and those from cases without promoters. In the case of HMDS (puddle) with resist, the only peaks in evidence are the same peaks (7.1 and 9.5 msec) seen for HMDS alone. But, for HMDS (vapor) these peaks are accompanied by residual peaks at 6.4 and 8.6 msec, thus indicating the presence of resist-related components in the larger residue found with vapor HMDS.

Another material used for adhesion promotion is BSTFA. Figure 7 presents the results of examining this material as a function of development time in neat AZ developer. Also shown for reference is the curve of Fig. 1, corresponding to no adhesion promoter. Note that, with AZ-1350J, BSTFA yields a significant residue, which does not reduce with further development.

AZ-111 development.—This resist showed rather interesting results in terms of the individual lots of developer used. Figure 8 shows data for this resist, using two different lots of developer designated "good" and "bad" to reflect the residue situation. Without the use of HMDS, the developer lot used has no effect. A single curve may be drawn through the experimental points for both curves. For the cases involving HMDS

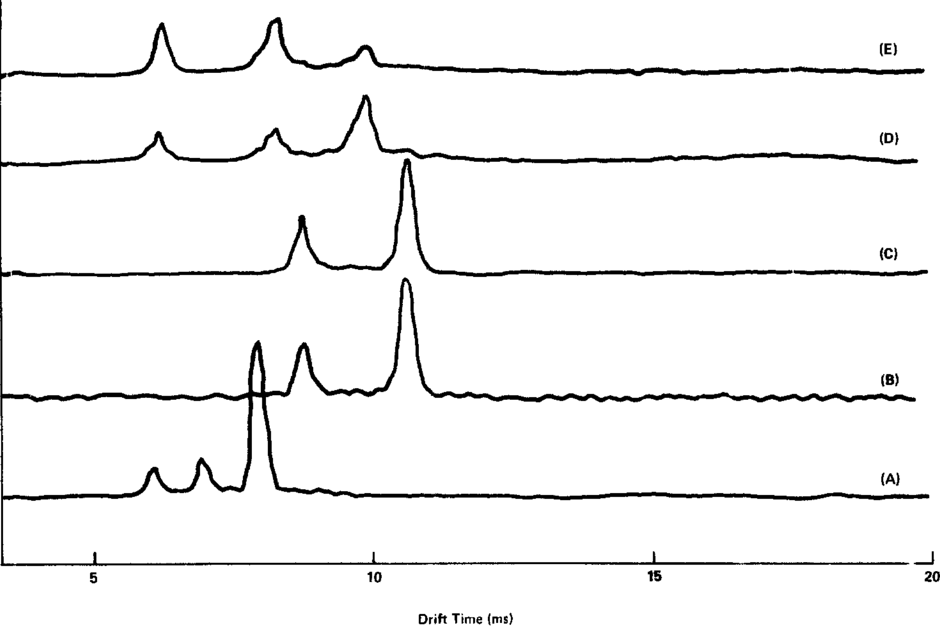

Fig. 5. Plasmagrams. (A) System blank; (B) HMDS (vapor), no resist, 30 sec dev.; (C) HMDS (puddle), no resist, 30 sec dev.; (D) AZ-1350J, no promoter, 30 sec dev., opt. exp.; (E) AZ-1350J, no promoter, 30 sec dev. underexp.

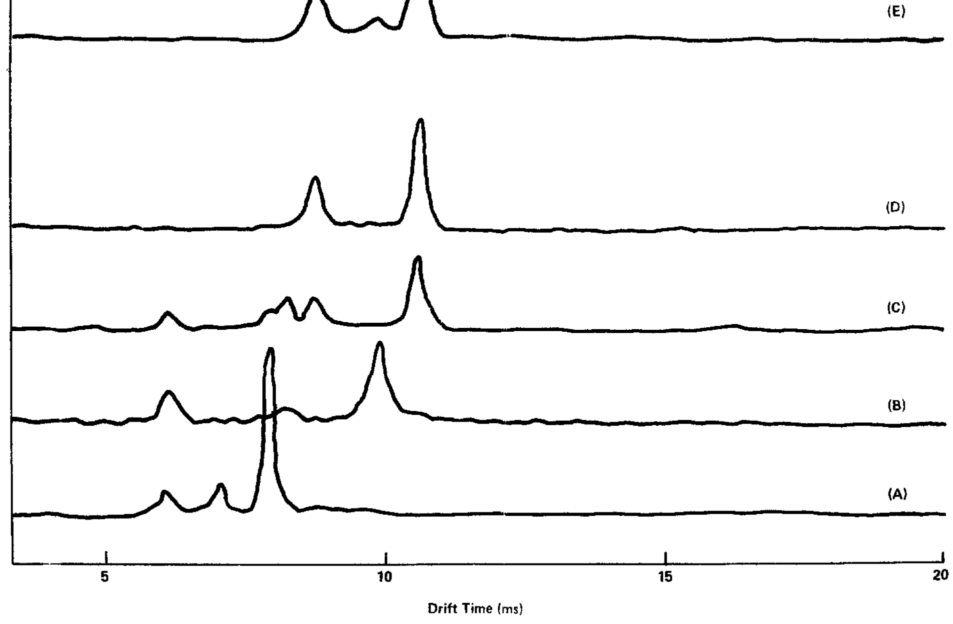

Fig. 6. Plasmagrams. (A) System blank; (B) AZ-1350J, no promoter, opt. exp.; (C) AZ-1350J, HMDS (vapor), opt. exp.; (D) AZ-1350J, HMDS (puddle), opt. exp.; (E) AZ-1350J, no promoter, overexposed.

precoating, however, a substantial difference exists between the lots of developer. Thus, it would appear that residues formed by the interaction of the HMDS with components of the resist are particularly sensitive to small changes in developer.

Stripping Residues

Acetone.—The behavior of acetone in stripping normally processed AZ-1350J resist is shown in Table IV. Here, several processes were used, including BSA and HMDS adhesion promotion as well as no adhesion promoter at all. The mean values and standard deviations for the effective oxide thicknesses of the residues are shown along with the statistical evidence that they are different from the control wafer. Note that in many cases the residue was so thick that it could not be measured by ETA in the configuration utilized (*i.e.*, combined thickness > 140 nm).

The origin of these catastrophic residues is strongly suggested by our knowledge of the resist process and mechanism. In the above work, a postbake of 30 min at 130°C has been used. It is well known that exposure to elevated temperatures, especially in the presence of reactive compounds such as diazo, can cause polymers to cross-link (9). Such cross-linking can result in more difficult removal of the resist after postbake. Further, a normal laboratory hotplate, such as is commonly utilized for postbakes, has a relatively unstable temperature, with excursions of $\pm$ 20° about the mean being common.

The mechanism just proposed for the occurrence of catastrophic residue failure suggests its own cure. It was indicated previously that cross-linking is favored by thermal treatment in the presence of free-radical initiators, such as the diazo containing molecules of the photoactive compound. A simple approach toward alleviating the residue difficulty would then be to eliminate the diazo groups once the pattern has been formed. This could be accomplished easily by a post-development exposure thorough enough to harmlessly convert all diazo groups into carboxyl groupings so that no initiating groups remain to cause cross-linking during the postbake. It has been previously shown (10) that such exposed resist does not begin to in-

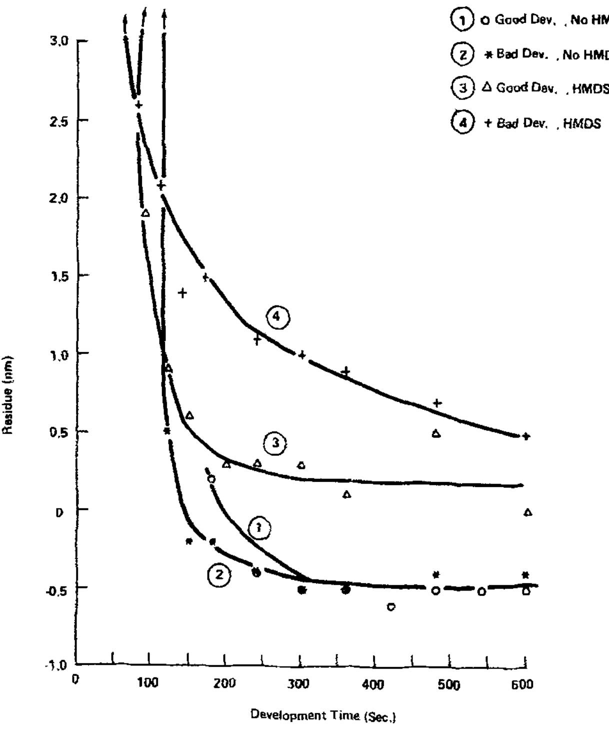

Fig. 8. Development curves for AZ-111

solubilize until temperatures in excess of 170°C are reached. Therefore, use of a postdevelopment exposure should eliminate the necessity of precise control and limitation of postbake temperature.

Accordingly, an experiment was carried out in which several wafers, having each of the three adhesion promotion treatments used previously, were either exposed or not exposed to u.v. after development.

After postbaking, stripping was carried out with acetone, but, unlike the previous work, the films were measured after time increments of 5, 10, and 40 min (total) in ultrasonically agitated acetone. The mean and standard deviations for the apparent residue thicknesses are shown in Table V. Note that, as before, in some cases the residue was too thick to measure. Where the residue was reduced to approximately zero by a given acetone treatment, of course, no further processing was done. The efficacy of the exposure treatment appears to be a function of the adhesion promoter used. The method appears to give best results with no adhesion promotor and worst results with BSA-promoted resist.

Since it was suspected that the catastrophic residues reported for acetone were caused by excessive temperature excursions during postbake, an experiment was carried out in which the occurrence of residue was studied as a function of carefully controlled (±1°C) postbake temperature from 130° to 138°C. All 130°C samples appeared clean to the naked eye, as did all control samples (no processing) for each temperature. All experimental samples baked at 138°C showed residues over the entire substrate. Wafers baked at

intermediate temperatures showed varying residue coverage, depending on the adhesion promoter used.

Ellipsometric measurements confirmed these observations. Wherever a visible residue existed, the ETA indicated residue thicknesses in excess of 50 nm, *i.e.*, out of range of the normal mode for the instrument. Spot checks of such sites with interference measurements, however, often showed residue thickness ranges of several hundred nanometers.

The amount of residue after acetone stripping is plotted in Fig. 9 against the postbake temperature. It is evident that residue is a very strong function of temperature, rising from barely above detectable limits at 130°C to visible thicknesses at 138°C. It will be noted from Table VI that the controls in all cases indicate "residues" of less than 5 nm, indicating minimal ambient contamination to the samples. For the processed substrates, statistically significant residues were found even for the 130°C postbake. Since such residue levels might eventually prove to be process-compatible, however, it is more important to consider results for the higher temperatures. For the 138°C postbake, all processed sample residues were unmeasurably high using ETA. Even at 135°C, catastrophic failure still results in cases involving either BSA or HMDS. Thus, for postbakes in the range of 130°C, acetone must be looked upon as a marginal stripper, requiring very precise control of postbake temperature.

Table VI. Ellipsometric measurements of residues (mean/σ in nm × 10)

	Postbake temperature (°C)				
	130	132	133	135	138 ± 1

Evaluation of a High Temperature Inorganic Stripper

As previously mentioned, 12% HNO_3 in H_2SO_4 at 100°C was chosen as representative of this stripping category. Table VII shows the results observed on a particular set of processed wafers using this stripping technique. Each wafer here is statistically compared with the group control. These results indicate the occurrence of negative "residue" for certain cases. That is, the measured oxide thickness is smaller after processing than it was originally. The origins of these "negative residues" can be sought in two directions. First, of course, is the possibility that the hot acid stripper is active enough to remove surface layers from the oxide film, or at least to change the surface optically (*e.g.*, Si-O-Si to Si-OH) in a way which would be interpreted as lower oxide thickness. On the other hand, another explanation would be that an original impurity layer was measured as the initial oxide thickness and that this layer was removed by the application and spinning of the adhesion promoter or resist.

In order to test this last hypothesis, a separate experiment was run, in which HMDS and BSA, respectively, were applied to separate wafers, with measurements being made before and after application. The above hypothesis suggests that the "oxide" thickness should diminish as a result of this process. However, as shown by Table VIII, the adhesion promoters each leave a very real residue. This does not, of course, preclude the possibility that an original impurity layer is solubilized by the promoter layer and is removed during subsequent stripping.

A further evaluation of the hot acid technique involved removal of the highly cross-linked resist formed when AZ-1350J is used as a mask for ion implant operations. In typical situations (*e.g.*, 50-80 kV, 7.5 × 10^{15} As ions/cm^2, 1 mA), a 15 min immersion in the hot H_2SO_4/HNO_3 stripper produced rather poor stripping, with much of the resist remaining intact (see Fig. 10). Use of a bake in air for 1 hr at 400°C prior to stripping improved the results markedly. However, residue still tended to remain at the edges of resist openings, where (because of the resist profile) the full ion flux impinged on the resist/oxide interface (see Fig. 10b). The effect of this high temperature bake probably is to oxidize and crack the resist structure,

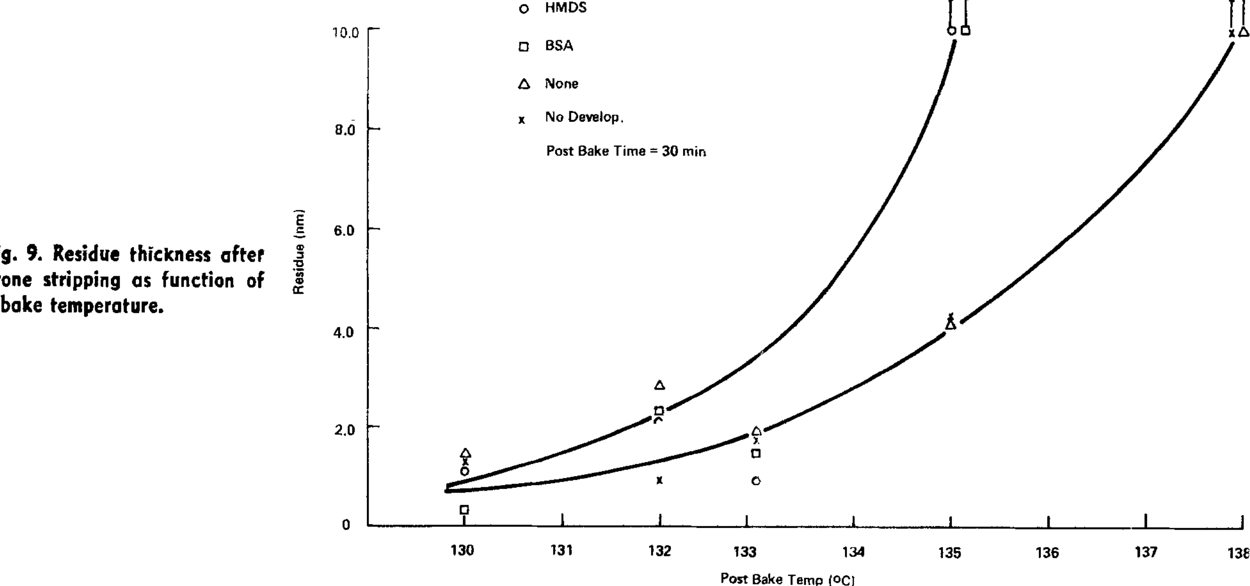

Fig. 9. Residue thickness after acetone stripping as function of postbake temperature.

Table VIII. Effect of adhesion promoter application on "oxide thickness"

	Mean (nm × 10)	σ	N
HMDS*	+16.3	2.3	10
BSA*	+22.7	3.8	10
Control	−1.3	2.2	10

* Applied as in processing resist. See Experimental.

rendering it more easily removable by the acid. However, the resist cross-linked in the immediate vicinity of the oxide surface apparently is firmly bound and not removed.

Evaluation of Caro's Acid

"Caro's acid," a solution of peroxymonosulfuric acid in concentrated sulfuric acid, was first seriously proposed as a resist stripper by Beck *et al.* (5). The stripping solution is created by a mixture of concentrated H_2SO_4 with highly concentrated (85-90%) hydrogen peroxide. The reaction is said to proceed as follows

$$H_2O_2 + H_2SO_4 = HO—(SO_2)—O—OH + H_2O$$

While the reaction itself is not highly exothermic, substantial heat can be developed by dilution of the sulfuric acid medium with water contained in the peroxide, as well as that formed by the reaction. Since the H_2SO_5 species is not particularly heat-stable, excessive amounts of water in the peroxide can lead to thermal decomposition of the H_2SO_5. This makes it necessary to use the peroxide in highly concentrated form. Use of the usual laboratory "concentrated" H_2O_2 will lead to an overheated solution on mixing and little or no H_2SO_5 concentration. An additional deleterious effect of excess water is, of course, its potential for shifting the equilibrium in the above reaction, since water is a by-product.

Caro's acid has several major advantages as a stripper. First, it is used at room temperature. Its mode of action is understood to be dehydration coupled with oxidation. In general, organic materials such as photoresist are oxidized to CO_2 and H_2O, thus avoiding a buildup of intermediate products. This leads to a potlife of the order of 3 weeks or more and ecologically acceptable disposal may be made by aspirating into an industrial waste drain, since only sulfate remains.

The residues left by AZ-1350J as a function of immersion time in Caro's acid are shown for several sets of process parameters in Table IX. It is obvious that normally processed resist is completely stripped by a total of 10 min in Caro's acid.

Table IX. Thermal SiO_2-AZ-1350J-Caro's acid. Effect of multiple cycles (ten sites/wafer, all wafers developed).

Adhesion promoter	Number of cycles*	Residue (nm × 10) Mean	σ
HMDS	1	11.4	1.1
	2	−3.8	2.3
BSA	1	14.2	3.4
	2	−0.7	1.4
	3	−3.1	15.5
None	1	5.0	2.2
	2	−0.9	1.9

* Each cycle consisting of 5 min dip into Caro's acid which had not been disturbed for previous 5 min.

Table X. Comparative stripping of various positive resists by Caro's acid

Resist*	Time for visual cleanliness (min)
AZ-1350J	5
AZ-111	20
PR 102	15

* Applied to obtain approximately 1000 nm thickness in each case.

In addition to evaluation of AZ-1350J resist, some observations were also made on the ability of Caro's acid to strip several other positive resists. Table X gives comparative results in terms of stripping time necessary to obtain visually clean surfaces, using AZ-111, and Microline PR 102[4] resists.

As in the case of hot acid stripping, the capability of Caro's acid with respect to highly cross-linked resist was evaluated. Three types of cross-linking were used. In the first, the resist film over thermal oxide was subjected to a CF_4 plasma (simulated dry etch of SiO_2) for sufficient time to strip about one-half the thickness of resist, and the remaining film was then stripped in Caro's acid. The experiment was repeated two times, inserting a 130°C bake once before the plasma, and once after the plasma. Ellipsometric re-

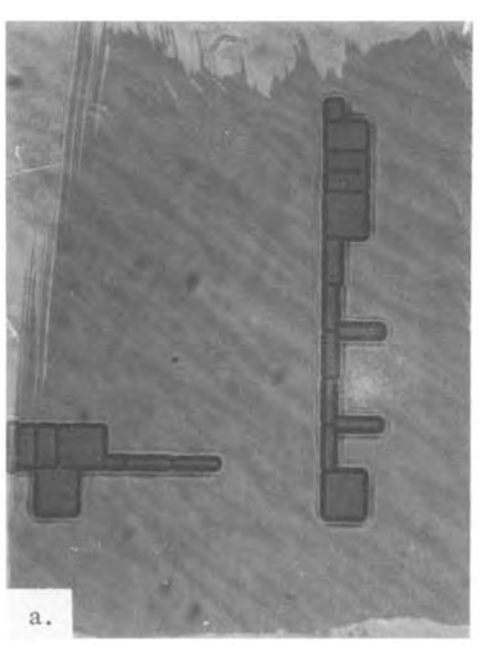

Fig. 10. Micrographs of acid-stripped ion implant patterns. (A) After 15 min strip; (B) 1 hr at 400°C followed by 15 min strip.

sults on this experiment, given in Table XI, show that no significant residue remains after a 10 min strip.

In the second cross-linking procedure, AZ-1350J with an added thermal-free radical initiator (Lupersol 101,[5] an organic peroxide) was applied to a premeasured oxidized Si wafer and then subjected to an arsenic ion bombardment (80 kV, 5×10^{15} ions/cm^2). The results of Caro's acid stripping of this wafer are also shown in Table XI, and here we see that a 10 min immersion proved insufficient to produce a clean surface. Table XII presents residue data for further immersions in Caro's acid. Extrapolation of these results suggests that the ion implant process forms an approximately 15 nm residual film, which is not removable by Caro's acid treatment alone. Inclusion of a high temperature bake prior to stripping, however, renders the residue removable in Caro's acid, although not without difficulty (see Table XII). It was desired to isolate the cause of this residue and, to this end, two additional samples (for which the actual ion bombardment was removed from the process) were characterized. The first sample consisted of the postbaked, peroxide-modified resist, while the other was postbaked (see Experimental section) but contained no peroxide. The results clearly indicate that the ion bombardment is necessary for formation of the previously mentioned 15 nm residue.

As a final attempt at cross-linking, a film of AZ-1350J (applied by the standard process through 130°C postbake) was bombarded with 15 kV electrons for various periods of time in raster patterns by "looking" at it with an SEM at various magnifications. After stripping, an interference contrast microscope was used to search for residual patterns, using scribed marks as locating aids. The results here are necessarily qualitative since we cannot calculate with any accuracy

either the cross-linking efficiency or the flux density of the SEM primary electrons. Table XI summarizes the results obtained in terms of relative electron exposures. These results indicate that increasing electron beam exposure rapidly insolubilizes AZ resist so that, after some degree of exposure, even 1.5 hr of Caro's acid immersion will not remove it, nor will any other wet strip process we have studied. Although it is likely that such exposures would never be experienced by resist in any reasonable process, the data gives us insight into the action of Caro's acid on organic materials, *i.e.*, the solubilizing action does not arise from simple oxidation alone but requires that the carbon atoms be relatively free.

Persulfate Stripper

Caro's acid stripper has as its active ingredient peroxymonosulfuric acid, H_2SO_5. This rendition of the formula is somewhat misleading in that it appears to indicate a higher oxidation number for sulfur than the maximum of six allowed by its electronic structure. The proper rendition, HO—(SO_2)—O—OH, indicates correctly that the molecule retains the sulfur in its +6 state but has incorporated an atom of oxygen in a peroxide configuration. Thus, the oxidizing ability of this species rests with its (extra) active oxygen.

With this in mind, the question might well be asked as to why a molecule with a similar configuration on the opposite side of the sulfur (*i.e.*, persulfuric acid, or HO—O—(SO_2)—(SO_2)—O—OH) would not be equally or more effective. Although the acid itself is not readily available, its potassium salt, $K_2S_2O_8$, is a commonly used analytical compound. Admixture of this salt with sulfuric acid should produce substantial quantities of the acid species. Although it is difficult to predict the change in activity of the active oxygen due to the dimeric molecule (*e.g.*, resonances, inductive effects), it is certainly reasonable to assume that there will be some similarity in activity of such a persulfate solution to the Caro's acid system with which we have been working.
