Such a stripper, if effective, would have a very substantial advantage over Caro's acid. The latter can only be produced by use of highly concentrated hydrogen peroxide. This material is potentially detonatable (upon admixture of only small amounts of organics) and can also present a serious fire hazard. For improperly clothed personnel, it can present further danger in the form of severe chemical burns.

Accordingly, the evaluation procedure used earlier for other strippers was carried out with a persulfate/sulfuric acid mixture as stripper. After some preliminary work, the composition and makeup described under Experimental was chosen. Results of this evaluation are shown in Table XIII. Note that all means for the 5 min strip are significantly larger (95% confidence) than the control, whereas the mean residues after 10 min are equivalent to, or lower than, the control. Thus, for normally processed and baked resist, the persulfate/H_2SO_4 combination gives results which are equivalent to those obtained previously with Caro's acid.

Evaluation with respect to highly cross-linked resist was made comparatively using only electron-beam as a cross-linking vehicle. Recall that previously stated results with Caro's acid showed that most of the elec-

Table XIII. Persulfate/H_2SO_4 stripping of normal AZ-1350J

Control	—	0	3.2	−7.2	3.3

tron dosages used produced far greater cross-linking effects than a typical ion-implant operation. Thus, use of such electron dosages will certainly provide a "worst-case" comparison of strippers.

In these experiments, a resist-coated sample was exposed by sweeping with the raster of an SEM using a different (but known) magnification for each sweep and keeping the exposure time constant. The process was then repeated (without turning off the beam or breaking vacuum) with a second sample having similar resist thickness. The result is two samples, each having an identical set of resist patches which have increasing cross-link density through the set. When these two pieces were subjected respectively to Caro's acid and to the persulfate/H_2SO_4 mixture, areas of lowest cross-link density were removed first, and higher density patches were removed as immersion time increased. The time necessary to remove a patch of given density is an indication of the relative effectiveness of the strippers.

Table XIV shows the lowest density patch remaining for each of the strippers as a function of stripping time. The numbers shown are only relative and are obtained by squaring the magnification factor. Two complete experiments were performed and the table shows the results of both. It is important to note that there is a steady decrease in residue as stripping time is increased. It is evident from the table that for a given stripping time the persulfate stripper is effective against only about half of the cross-link density that is stripped by Caro's acid. This must, however, be viewed against the virtual ineffectiveness of most organic strippers on this relatively huge level of cross-linking.

Conclusion

The data that have been presented here demonstrate the marked sensitivity of commonly used photoresists to processing, when one is concerned with extreme cleanliness of pattern exposed and stripped surfaces. Especially with regard to development, the occurrence of residues appears to be due to a very complex interaction of a number of parameters. (Consider, for example, the differences among the various resists studied and how this ranking changes when HMDS is used as an adhesion promoter).

It is of interest to note the effect, observed in most instances here, of higher residues with adhesion promoters. This appears to be especially true of HMDS when applied from vapor. The relative residue effects of the various adhesion promoters used cannot be simply tabulated. There would appear to be specific interactions with the various resists, leading, for example, to higher HMDS residues on AZ-111 but larger BSTFA residues with AZ-1350J. The choice of adhesion promoter must be made specifically for each specific resist.

We have also examined the effectiveness and suitability of a number of wet stripping processes to a variety of stripping situations. In general, we have seen that normally processed AZ-1350J resist, with proper control on bake cycles, offers no problem to almost any stripping system. If we consider "harder" resists, we find that ecologically acceptable organic stripping modes are essentially nonexistent. If we apply the further restriction that we wish our system to be universal for all substrate layers in general use, we find ourselves limited to essentially one class of strippers: that comprising Caro's acid and its related variations. As a direct and universal substitute for conventional Caro's acid, the persulfate modification cannot be claimed to be completely successful. Its area of deficiency is, of course, in the stripping of very highly cross-linked resist. It must be recalled that even Caro's acid is incapable of stripping resist with a high enough degree of cross-linking. The advantages of the persulfate system in ease of preparation would seem to more than make up for what may well be an irrelevant disadvantage in terms of speed of stripping highly cross-linked resist.

Finally, there remains the question of just what a permissible level of residue really is, both for development and for stripping. In the latter case, this would be determined by considerations involving the particular processing step which follows removal. However, unless the resist has been subjected to an extreme amount of high energy particle bombardment, it should be possible to reduce residues essentially to zero. For development, however, if we insist on a level which cannot statistically be distinguished from zero, then we cannot hope to achieve zero print bias in almost any of the resist/developer/promoter combinations studied. A practical process can then be achieved only by relaxing either the required residue level or the acceptable print bias. The trade-off between these two items must be carefully considered, along with the possible alternative of implementing an additional process step (*e.g.*, a brief O_2 plasma exposure) to remove trace residues without increasing resist image openings.

Table XIV. Persulfate/H_2SO_4 stripping of highly cross-linked AZ-1350J resist

Experiment	Strip time (min)	Lowest cross-link density remaining: Caro's acid	Persulfate/H_2SO_4

ABSTRACT

Dry oxygen pressure at 500 atm is used to grow SiO_2 films 10^3 nm thick on silicon at 800°C. The residual film stress, chemical etch rate, refractive index, and density of the pressure-oxide films is measured and compared with measurements of thermal oxide films prepared at 1 atm dry oxygen pressure. The high pressure/low temperature films exhibited higher refractive indexes, slower chemical etch rates, and higher measured densities compared to 1 atm thermal oxides prepared at 1000°C. These results are attributed to the lower oxidation temperature rather than the higher oxidation pressure of the pressure-oxide films. It is concluded that the formation of higher density SiO_2 films is a specific result of low temperature processing. The use of high pressure oxidation provides a convenient technique to prepare the low temperature high density SiO_2 films of sufficient thickness for further study.

Recently, Zeto *et al.* (1, 2) reported enhanced oxidation rates for single crystal silicon thermally oxidized in dry oxygen at elevated oxygen pressures up to 500 atm. It was shown (1) that the silicon oxidation rate obtained by using oxygen at 140 atm (*i.e.*, the pressure of oxygen in commercially available oxygen tanks) and 800°C was comparable to the rate obtained by using 1 atm oxygen at 1200°C. Therefore, the use of elevated oxygen pressures enables a reduction of the oxidation temperature and/or time for an oxidation step. This temperature/time reduction has great technological importance because of the need to maintain sharp dopant profiles and minimize the creation of thermally induced defects in modern small devices. The use of steam (3) and high pressure steam (4) for the thermal oxidation of silicon also offers considerable kinetic enhancement, however, the quality of the SiO_2 and Si may be degraded based on reports of increased electron trapping in SiO_2 due to H_2O (5) and increased Si defects resulting from exposure of the Si to steam oxidation (6).

Whether the MOS industry will accept a new process, such as the use of increased oxidant pressures, will depend both on the need for the lower temperature processing and the demonstration that the SiO_2 quality is not degraded by the new process. It is clear from the industry trend towards smaller devices that lower processing temperatures are required and therefore this study is aimed toward demonstrating that important aspects of the SiO_2 quality resulting from high pressure dry oxidation of silicon can be equivalent to the SiO_2 grown in the conventional 1 atm processes.

As with any new process, the dry high pressure oxidation process has problems associated with reproducibility and optimization. Notwithstanding these anticipated difficulties, Zeto *et al.* (2) reported that mobile and fixed charge levels were acceptably low (in the low 10^{10} charges/cm^2 range) on many samples. These promising results have provided the impetus to improve the process through equipment evolution and to obtain more physical properties data on the resulting SiO_2 films.

Key words: high pressure oxidation, silicon, silicon dioxide, density, film stress.

The present study reports the results of several physical properties measurements on SiO_2 grown by the high pressure dry oxidation of silicon: residual film stress, chemical etch rates, density, refractive index, and film morphology as obtained by transmission electron microscopy (TEM). Collectively, these measurements show that the films have increased density as compared with 1 atm films prepared at conventional oxidation temperatures of 1000°C. The higher refractive indexes, slower etch rates, and higher measured densities of the high pressure low temperature films are attributable to the lower processing temperatures rather than the higher oxygen pressures. Thus a specific advantage of high pressure oxidation methods is that these higher density low temperature SiO_2 films can be prepared in practical oxidation times.

Experimental Procedures

Sample preparation.—Four high pressure dry oxygen oxidation runs were performed as described below to grow oxides about 10^3 nm thick on six Si substrates. The Si slices were nominally 2 Ω-cm p-type, 2.54 cm diam, and 0.02 cm thick. Three each of <111> and <100> orientations were used and designated 111, 112, and 113 for the <111> samples and 012, 013, and 014 for the <100> samples. Control oxides were grown at 1 atm, 1000° or 800°C in pure dry O_2 on <100> silicon to similar thicknesses and were used in the film stress, etch measurements, and refractive index measurements to obtain meaningful comparisons with the high pressure grown samples. Prior to any oxidation all Si slices were thoroughly cleaned by a previously described procedure (7). The six samples for high pressure oxidation were initially oxidized at 1000°C in 1 atm ultradry O_2 to obtain 100 nm SiO_2. This was done to obtain a reproducible initial curvature in the Si substrates for the stress measurements.

Pressure oxidation.—The apparatus used for the high pressure dry oxidation was described previously (1) with the exception that a larger pressure vessel was used to accommodate the 2.54 cm diam Si slices noted above. For each of the experimental oxidations, the Si slices were heated to about 800°C while a vacuum was drawn on the vessel. Then, 500 atm dry oxygen pressure was applied within several minutes. After the de-

sired oxidation time the pressurized vessel was withdrawn from the furnace and cooled by radiation. All samples were oxidized at 800°C to yield about 10^3 nm SiO_2. The oxidation rates for the <100> samples were about 87 and 132 nm/hr for the <111> Si. The H_2O content of the pressurized gas was measured as less than 1 ppm.

Film stress.—The residual room temperature stress was calculated from a measurement of the curvature of a Si wafer before and after the SiO_2 film growth by dry pressure-oxidation. The change in Si curvature was measured by an optical interference technique. The apparatus, appropriate equations, and elastic constants used for the calculations as well as the procedures were previously described (8) for a study of Si_3N_4 film stress. Only a small difference (less than 10%) is anticipated in the residual stress for <100> for <111> orientations due to the difference of elastic constants for the different Si orientations and we ignored this difference in the present study. The pressure-oxide samples had about 5% thickness nonuniformity across the sample as compared with about 1% for the 1 atm SiO_2 oxides. The direct implication of this on the measured film stress has not been determined but it may contribute to the over-all scatter of the pressure-oxide stress data.

Chemical etch rates.—Chemical etch rates have been shown to be a very sensitive measure of SiO_2 film density (12). The temperature, composition, and extent of agitation of the etchant solution can all alter chemical etch rates. In order to preclude obscuring comparisons between high pressure oxides, controls, and low temperature oxides due to experimental difficulties, samples and controls for a given comparison were etched simultaneously in the same solution. For the comparison of high pressures oxides with 1 atm 1000°C standards, two samples of each were etched together in a commercially available 9/1: NH_4F/HF mixture at ~22°C. For this comparison (Fig. 1) more scatter was seen for the pressure oxides. The scatter was due to the larger nonuniformity of the SiO_2 thickness for these samples and the problem of returning to the same spot on the sample for ellipsometric thickness measurements after each exposure to etchant. However, the results to be reported are outside this scatter. Similarly, the comparison of etch rates for the 1 atm 800° and 1000°C grown SiO_2 was made on samples etched in a 9/1: NF_4/HF simultaneously and together at ~22°C. The differences in the 1000°C 1 atm controls are presumably due to the above-mentioned temperature, agitation, and etchant batch differences.

Density.—The SiO_2 film density, ρ was calculated from measured values for the mass change of the samples before and after removal of the film by etching and the volume of the film as obtained from the area of the Si wafer and the film thickness. Only the film on the polished side of the Si was used and a correction was made for the area lost as the Si wafer flat. The weighing accuracy was better than 3×10^{-6}g while the oxide mass was about 10^{-3}g. The average film thickness accuracy was estimated to be better than about 3% based on multiple ellipsometric measurements taken across the wafers and the surface area was known to better than 3%. Based on these values, the error in ρ, $\Delta\rho$, is calculated to be about 10^{-2}. Therefore, the higher density measured for the high pressure grown and the 800°C, 1 atm oxides as compared with 1000°C, 1 atm is a real difference but the absolute values are somewhat uncertain to better than several percent.

Film thickness and refractive indexes.—The SiO_2 thickness and refractive indexes were measured by ellipsometry. A description of the instrument with the various constants used was previously published (9). The reported measurements of refractive index were made near one-half of an ellipsometric period, *i.e.*, at odd multiples of ~140 nm for the 632.8 nm light and ~120 nm for 546.1 nm light. Near these thicknesses the ellipsometric measurement is most sensitive to different refractive indexes. The index measurements were made during the course of the etching experiments and the index values corresponding to half-period thicknesses were tabulated.

TEM.—Samples were prepared for microscopy by removal of the Si with an $HF\text{-}HNO_3$ etchant. Since the SiO_2 was too thick (~ 1 μm) for penetration by the 100 keV electrons, the etchant was also used to etch away most of the SiO_2 leaving about 100 nm for examination by TEM.

Experimental Results

Residual stress measurements.—A comparison of the SiO_2 film stress for the high pressure oxides, controls (1 atm O_2, 1000°C) and literature values are shown in Table I. All of the stresses shown in Table I both measured in this study and from the literature are compressive stresses. The high pressure oxides show more scatter in the stress values than the controls and this may be due to the greater thickness nonuniformity found for these films (about 5% across the wafers). Considering the scatter in the stress values, the film stress for the high pressure oxides is the same as for the controls. Optical microscopic examination revealed no evidence for Si slip due to stress on any of the substrates.

Chemical etch rates.—Figure 1 shows the combined etching results from two pressure-oxide and two control samples 1 atm O_2, 1000°C. Individually the etch rates were 50.0 and 48.2 nm/min for the pressure samples and 58.6 and 58.7 nm/min for the controls. The spread in the pressure-oxide samples was due to thickness nonuniformity which required returning to

the exact same spot on the SiO_2 film for the repeated thickness measurements. However, the difference in etch rate between pressure-oxides and controls was well outside the scatter and is therefore considered significant. Pliskin and Lehman (12) reported that a more dense SiO_2 can give rise to a slower etch rate in an HF-based etchant.

Index of refraction.—Table II shows that the high pressure grown samples have a significantly higher refractive index than the controls. This may be caused by pressure oxides having a higher density since it was reported that a higher SiO_2 film density will yield a measurably higher refractive index (12). The measurements associated with sample 013 are particularly interesting, since this sample has an initial oxide thickness near one-half an ellipsometric period. The initial oxide thickness is about 1000 nm, of which 100 nm is a 1 atm 1000°C SiO_2 and the remaining SiO_2 has been grown at 800°C with 500 atm oxygen. Since oxidation takes place at the Si-SiO_2 interface, the 1 atm SiO_2 is always on top of the high pressure SiO_2 and hence it would be removed after the first etching. However, before etching the composite index is larger than for 1 atm 1000°C SiO_2 but smaller than the high pressure SiO_2 while after the removal of this outer SiO_2 that has a lower index, the index returns to the pressure oxide value. This is a predictable result based on the fact that 1 atm, 1000°C SiO_2 has a lower index than the 500 atm 800°C films and this result demonstrates the sensitivity of the ellipsometric measurement.

Film density.—Since both the etch rate and index of refraction measurements showed the possibility that pressure-oxide SiO_2 samples have higher density, the direct measurement of density was performed. Table III shows that indeed the pressure-oxide films have a higher density than the 1 atm oxides.

TEM.—Figure 2 shows an area of a pressure-oxide film which had an unusually large amount of particulate. Diffraction showed the particulate to be amorphous and the electron contrast appeared to be about the same as for the 1 atm SiO_2. The pressure vessel used to prepare these samples contained a fused silica test tube liner to hold the silicon slices. We believe that the particulate is SiO_2 dust from the fused silica insert since procedures required that it be thermally cycled, physically handled, and mechanically vibrated in every experiment. Undoubtedly this particulate would contribute to various dielectric failure modes, therefore a second generation high pressure oxidation system has been designed to eliminate this problem.

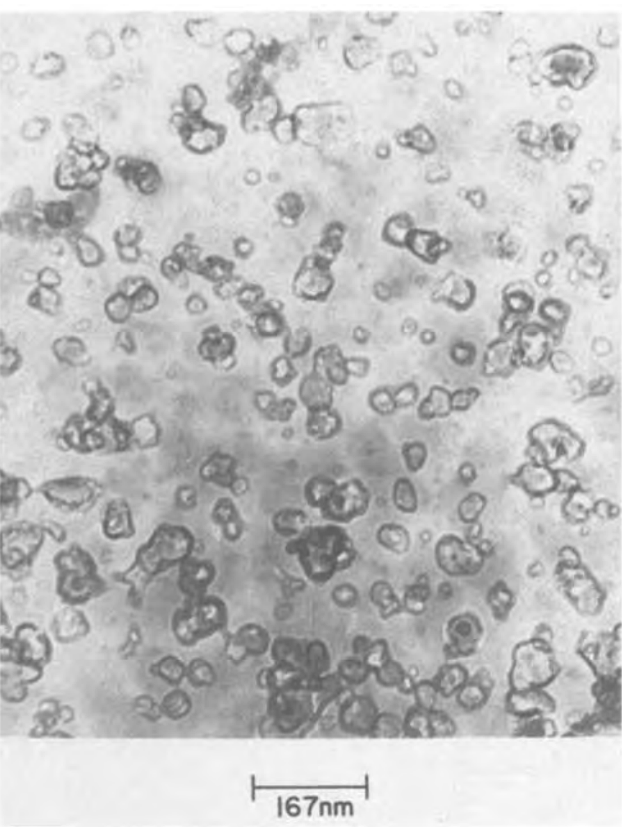

Fig. 2. TEM micrograph of pressure-oxide area which has a large number of amphorous SiO_2 inclusions.

800°C 1 atm SiO_2 film.—Up to this point the properties measurements on the high pressure oxides taken collectively indicate that these films have a higher density than the 1 atm 1000°C controls. However, in view of a recent study by Taft (13) which shows that a higher refractive index results from lower oxide growth temperatures, the higher density found for the high pressure oxides in this study may be due to the 800°C oxidation temperature and therefore independent of the higher oxidation pressure. To check this possibility, measurements of the refractive index, etch rates, and density using the same techniques described above were done on 800°C, 1 atm oxygen-grown SiO_2 films. The results shown in Table IV, while not extensive, clearly show that the lower temperatures produce a more dense oxide film. When an 800°C 1 atm SiO_2 film was heated in flowing N_2 at 1000°C for 2 hr, the refractive index returned to the 1000°C value. This suggests that higher defect concentrations produced at higher temperatures are responsible for the lower densities. Further work to clarify this situation is in progress.

Summary and Conclusions

It was previously demonstrated that a significant oxidation rate enhancement is obtained by using high dry O_2 pressures and that acceptable oxide charge and interface state levels could also be obtained. The present study extends the property measurements to include film stress, chemical etch rate, refractive index, density, and TEM morphology. These measurements show that: (*i*) there is no significant difference in the residual Si/SiO_2 film stress for high pressure and 1 atm thermal oxides, (*ii*) high-pressure/low-temperature thermal oxide SiO_2 films have a significantly higher density than films prepared at conventional oxidation temperatures such as 1000°C, and (*iii*) 1 atm thermal oxides prepared at 800°C have a higher density than films prepared at 1000°C.

The formation of high density SiO_2 films on silicon is therefore a specific merit of reduced oxide growth temperatures. The preparation of these higher density SiO_2 films is an advantage afforded by high pressure oxidation methods since higher pressures allow the oxides required in IC devices to be prepared at reduced temperatures in practical oxidation times. It remains to be determined whether or not the higher density material has other interesting properties, such as improved dielectric strength.

The Chemical Deposition of Boron-Nitrogen Films

A. C. Adams* and C. D. Capio

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Films containing boron, nitrogen, and hydrogen have been deposited at reduced pressure by reacting diborane and ammonia at 250°-600°C. Deposition rates as high as 15 nm/min (150 Å/min) have been achieved with thickness uniformities and reproducibilities better than ±3%. The films have been characterized by measuring infrared spectra, refractive index, optical absorption in the ultraviolet and visible, stress, chemical inertness, etch rates in a plasma, step coverage, and adhesion.

Boron nitride is a high resistivity semiconductor with a large bandgap. Several papers have been published describing the preparation of thin boron nitride films, the physical and chemical properties of these films, and potential applications to silicon integrated circuits (1-4). The possible applications include using the boron nitride film as a diffusion source (1-2), as a protective coating (1), as a sodium barrier (1), and as a dielectric (1). The previous films have been prepared by reacting diborane and ammonia at temperatures of 600°-1250°C (1, 2), by reacting these same gases in a plasma with substrate temperatures of 750°-1000°C (3), by reacting boron trichloride and ammonia at 600°-900°C (4), and by reactive sputtering at 250°-900°C (5). In this paper we describe the characterization of films containing boron, nitrogen, and hydrogen chemically deposited at low temperatures (250°-600°C).

Experimental

The deposition equipment is similar to other low pressure reactors that have been recently described (6,7), and is shown schematically in Fig. 1. The reaction takes place in a round quartz tube, 170 cm long, with an inside diameter of 11.5 cm. The tube is heated with a three-zone furnace (Lindberg Model 54677 with a Model 59754-A controller). All depositions are

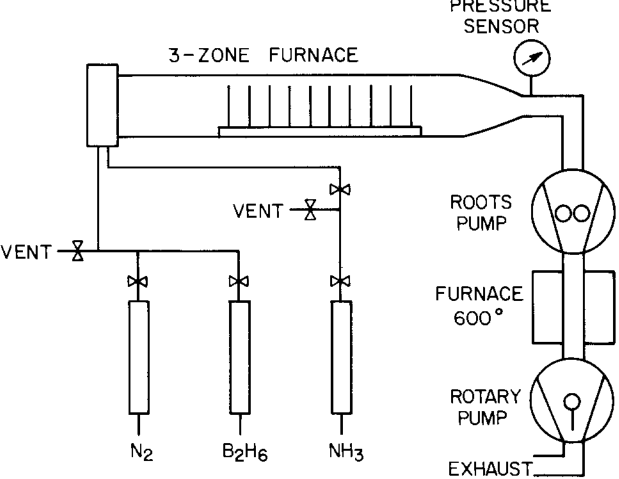

Fig. 1. Schematic diagram of the low pressure deposition reactor

* Electrochemical Society Active Member.
Key words: CVD, dielectrics, infrared, insulator.

made with a flat temperature profile, ±0.5°C, over the central 55 cm of the furnace. The ends of the quartz tube are sealed by O-rings in water-cooled flanges. Silicon wafers stand vertically, perpendicular to the gas flow, with a 5 mm spacing between adjacent wafers. The total capacity is 110 wafers. The samples are loaded and unloaded at the gas inlet end of the tube to avoid contamination from solid products that deposit at the exhaust. Diborane, ammonia, and nitrogen are individually metered through calibrated rotameters and introduced into the reaction tube. Separate lines are used for the diborane and the ammonia to prevent the formation of solid compounds in the gas lines. The reduced pressure is obtained with a Roots pump (Leybold-Heraeus, Model WS-250) backed by a mechanical pump (Sargent-Welch, Model 1397). The exhaust gases pass through a small furnace at 600°C to decompose any boron hydrides before they reach the mechanical pump. The pressure is measured with a capacitance manometer (MKS Baratron, Type 222) located at the exhaust end of the reaction tube. Valves are located at the inlet and exhaust of the reactor so gas samples can be taken to measure the reactant concentrations.

In a typical deposition, samples are loaded, the reactor tube sealed, and the system evacuated to 0.002 Torr. This pressure is maintained for 10 min while the samples reach thermal equilibrium. During this time, the gases are allowed to flow through the rotameters to a vent. The deposition is started at the end of the warm-up cycle by switching the gases from the vent to the reactor. Typical pressures during the deposition are 0.3-0.5 Torr. At the end of the deposition, the gases are switched from the reactor to the vent, the reaction tube evacuated to 0.002 Torr for 5 min, and then backfilled to atmospheric pressure with nitrogen.

For comparisons, some samples have been prepared at atmospheric pressure at 650°-775° using a radiantly heated reactor (A model AMN-715 Nitrox reactor manufactured by Applied Materials, Incorporated). The substrates are 75 mm diam silicon wafers, (100) orientation, phosphorus-doped, with a resistivity of 1-10 Ω-cm. Prior to deposition, the samples are cleaned by a sequence of acidic and basic hydrogen peroxide solutions (8). The gases used are 15% diborane in nitrogen or argon, electronic grade ammonia, both obtained from Matheson Gas Products, Incorporated, and nitrogen, obtained from a liquid nitrogen source.

Film thickness is measured by ellipsometry (9), reflectance spectroscopy (10), or prism coupling (11). The film refractive index is measured by ellipsometry at $\lambda = 0.5461$ μm (9), or by prism coupling at $\lambda = 0.6328$ μm (11). Film stress is measured by substrate bending using an optically levered laser beam to measure the radius of curvature. Infrared spectra are measured with a Perkin-Elmer Model 580 spectrophotometer using a bare silicon substrate in the reference beam.

Deposition

The films are formed by reacting diborane and ammonia. Attempts at determining the stoichiometry of the reaction by examining the composition of the gas leaving the reactor have not been successful. Infrared spectra of the exhaust gas shows the presence of unreacted diborane plus other species, probably higher boranes. These gases are not observed when the reaction temperature is above 550°C. Many chemical reactions appear to be taking place, and the complete system is very complex.

The deposition rate of the solid film depends on the square root of the diborane partial pressure (as shown in Fig. 2), is independent of the ammonia partial pressure (for ammonia partial pressures between 0 and 0.1 Torr), and is independent of the total pressure (at constant reactant partial pressures). This behavior differs from that observed for depositions at atmospheric pressure and at higher temperatures, where the rate

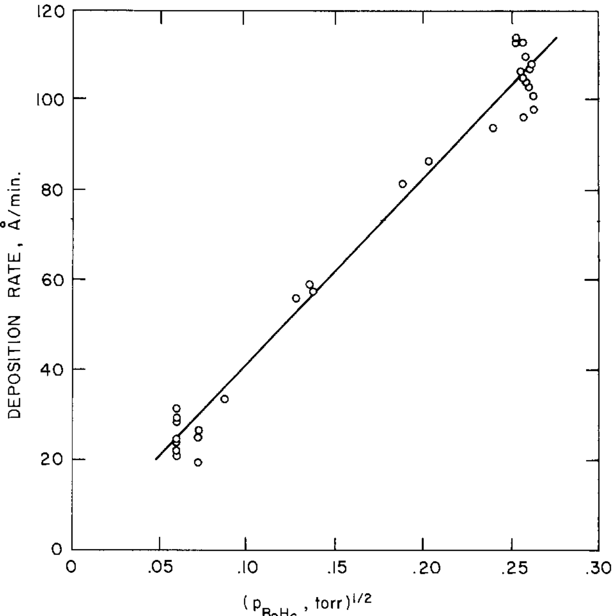

Fig. 2. Deposition rate vs. the square root of the diborane partial pressure for films deposited at 340°C; the ammonia partial pressure varies from 0.001 to 0.1 Torr; the total pressure is 0.5 Torr.

is higher (50-1000 Å/min), is proportional to the diborane concentration, and decreases with increasing ammonia concentration (1).

The deposition rate is shown as a function of temperature in Fig. 3. At low temperatures, the rate increases with increasing temperature and an Arrhenius behavior is observed. The rate reaches a maximum at about 430°C, and then decreases rapidly with additional increases in temperature. The decreasing rate results from depletion of reactants (caused by reactions on the hot walls at the front of the furnace) which also causes the thickness uniformity across a sample to degrade, as shown in Fig. 3.

An Arrhenius plot is given in Fig. 4 showing data obtained at four different diborane partial pressures. The activation energies range from 20 to 26 kcal/mole,

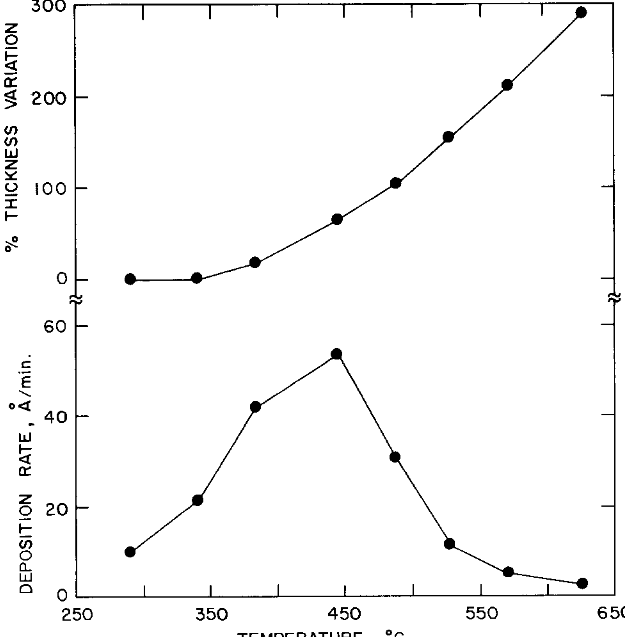

Fig. 3. Deposition rate and thickness uniformity vs. the deposition temperature. Pressures are: diborane, 0.005; ammonia, 0.006; total, 0.5 Torr.

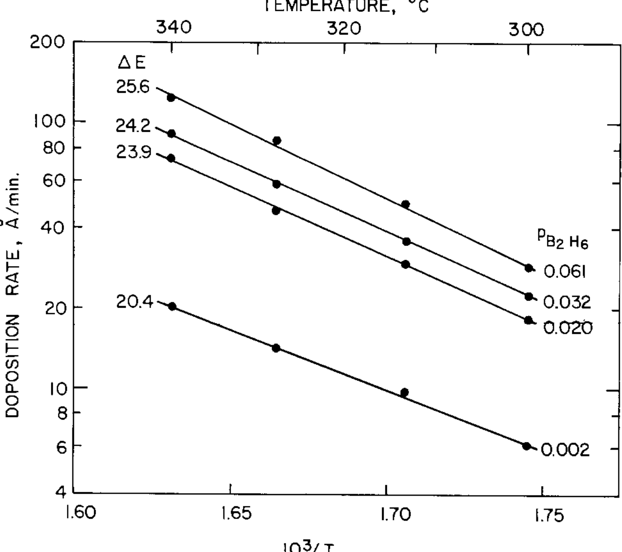

Fig. 4. Arrhenius plot; the total pressure is 0.5 Torr; the NH_3/B_2H_6 ratio is 2.

and a concentration dependence is suggested. Such a behavior is common for heterogeneous reactions, but further interpretation has not been attempted due to the lack of detailed kinetic information.

Film Properties

Infrared.—An infrared spectrum of a film deposited at 340°C is shown in Fig. 5. The assignments, which are tentative, are suggested by comparisons with spectra for cyclic boron-nitrogen compounds (12-16), in addition to comparisons with spectra for boron nitride (1-3, 17, 18). The infrared spectrum is insensitive to variations in the NH_3/B_2H_6 ratio in the reactant gas (for $0.5 < NH_3/B_2H_6 < 5$). This suggests that the film is a compound with a reasonably well-defined stoichiometry rather than a codeposited mixture. Films deposited at low temperatures (250°-400°C) have a strong B-N absorption at 1400-1415 cm^{-1}. This frequency is higher than the range reported for boron nitride (1315-1380 cm^{-1}) (1, 17, 18), and is similar to the frequencies reported for cyclic B-N compounds (1405-1440 cm^{-1}) (12, 13, 16). The B-H frequency (2510-2520 cm^{-1}) and the NH_2 frequencies (1540-1545 and 3210-3240 cm^{-1}) are similar to reported values (13-16). Thus the infrared spectra show that the deposited film contains boron and nitrogen, possibly bonded in a ring structure, and also contains hydrogen bonded to the boron (as BH) and bonded to the nitrogen (as NH_2). The weak absorption at 3400 cm^{-1} may be NH or may be an OH impurity.

The infrared spectrum is sensitive to the deposition temperature (Fig. 6). As the deposition temperature increases, the absorptions assigned to the NH_2 groups (at 3220 and 1540 cm^{-1}) quickly decrease in intensity and disappear. In addition, the BH absorption at 2500 cm^{-1} decreases in intensity and eventually disappears; the BN absorption at 1400 cm^{-1} shifts to lower frequencies; and, two well-defined absorptions appear at about 780 and 880 cm^{-1}. The spectrum in Fig. 6 for the material deposited at 600°C is essentially identical to that of boron nitride deposited at 600°C (1).

Structure and composition.—The films are amorphous as shown by electron diffraction and transmission electron microscopy. The maximum grain size, if grains exist, is estimated to be less than 25Å. Auger spectroscopy indicates a boron to nitrogen ratio of six for films deposited at 340°C with NH_3/B_2H_6 greater than 0.5. Quantitative measurements of the hydrogen content are not available. The films appear to have a composition of approximately B_6NH_x, where x is a strong function of the deposition temperature.

Refractive index.—The refractive index, as shown in Fig. 7 and 8, depends on the ratio of reactants and on the deposition temperature. The refractive index decreases rapidly from about 3.4 to 2.3 as the NH_3/B_2H_6 ratio increases from 0 to 0.5. Further increases in the NH_3/B_2H_6 ratio produce only small changes in the refractive index. This is another indication that the film composition is relatively constant for NH_3/B_2H_6 ratios greater than 0.5. The temperature dependence shown in Fig. 8 is more complex. The refractive index increases with increasing deposition temperature, goes through a broad maximum at about 400°C, and then decreases with further increases in temperature. For comparison, boron nitride deposited at atmospheric pressure at 600°-900°C has a refractive index between 1.7 and 1.8, and decreases with increasing deposition temperature (1). The high temperature data in Fig. 8 agree with this behavior. Polycrystalline boron nitride films deposited at 600°-900°C using boron trichloride

have a slightly higher refractive index, 1.9-2.0 (4), while cubic boron nitride has an index of 2.12 (19).

Absorption coefficient.—The optical absorption in the ultraviolet-visible region (190-900 nm) has been measured for samples deposited on fused silica disks. The maximum absorption occurs in the ultraviolet with a long tail extending throughout the visible (Fig. 9). Absorption coefficients have been calculated for a wavelength of 600 nm (considered as representative of the absorption in the visible region) and are plotted in Fig. 10 and 11. The absorption coefficient is high when the NH_3/B_2H_6 ratio is zero, is nearly constant when $NH_3/B_2H_6 > 0.5$, and increases with increasing deposition temperature. Plots of $\alpha^{1/2}$ *vs.* E or α^2E^2 *vs.* E, which have been used to measure the optical bandgap in boron nitride films (1, 4), cannot be used with the present films because the curves are not linear. The absorption coefficients in Fig. 10 and 11 appear to be larger than those found for boron nitride deposited at high temperatures (1), but are similar to those found for sputtered boron nitride films (5).

Stress.—The film stress has been measured for different reactant ratios and is shown in Fig. 12. The solid points are from films deposited at 340°C at reduced pressure; the open points are from films deposited at 700°C at atmospheric pressure. Films from both depositions have a tensile stress when the NH_3/B_2H_6 ratio is less than about 0.3. At higher ratios, the film stress is compressive. The films deposited at reduced pressure at 340°C have a lower stress at all NH_3/B_2H_6 ratios.

Etch rate.—The films deposited at 290°-450°C are insoluble in wet etchants. Solutions that have been investigated are: concentrated hydrofluoric acid, concentrated phosphoric acid (25° and 155°C), 5M potassium hydroxide, buffered hydrofluoric acid, boiling water, aqua regia, and a mixture of nitric, hydrofluoric,

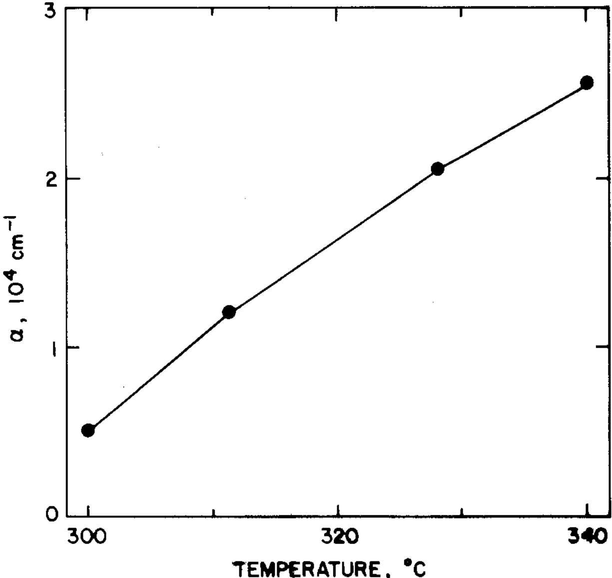

Fig. 11. Absorption coefficient at $\lambda = 0.6$ μm for films deposited with $NH_3/B_2H_6 = 1.3$.

and acetic acids (5:1:1). Etching is not observed in any of these solutions. The minimum detectable etch rate is about 0.2 Å/min. For comparison, the etch rate of boron nitride films is 80 Å/min in phosphoric acid at 130°C (2), and 150 Å/min in phosphoric acid at 180°C (1). Although the films are insoluble in etching solutions, they are easily etched in a CF_4-O_2 plasma with etch rates of approximately 3000 Å/min. This is the same rate as observed for boron nitride films (2).

Step coverage.—Step coverage has been evaluated by depositing over metal steps and examining with a scanning electron microscope. In addition, depositions have been made on wafers that have grooves 50 μm deep and 5 μm wide etched in the silicon. In all cases the depositions are conformal, as shown in Fig. 13, even in the case of the very deep grooves. Step coverage has been further investigated by depositing films over wafers metallized with aluminum or with titanium-platinum-gold, and then subjecting the samples to a metal etch (hydrofluoric acid for the aluminum, and aqua regia for the gold). Pinholes, cracks, or incomplete step coverage are revealed by attack of the metal. No regions of attack have been observed, showing that the step coverage is complete.

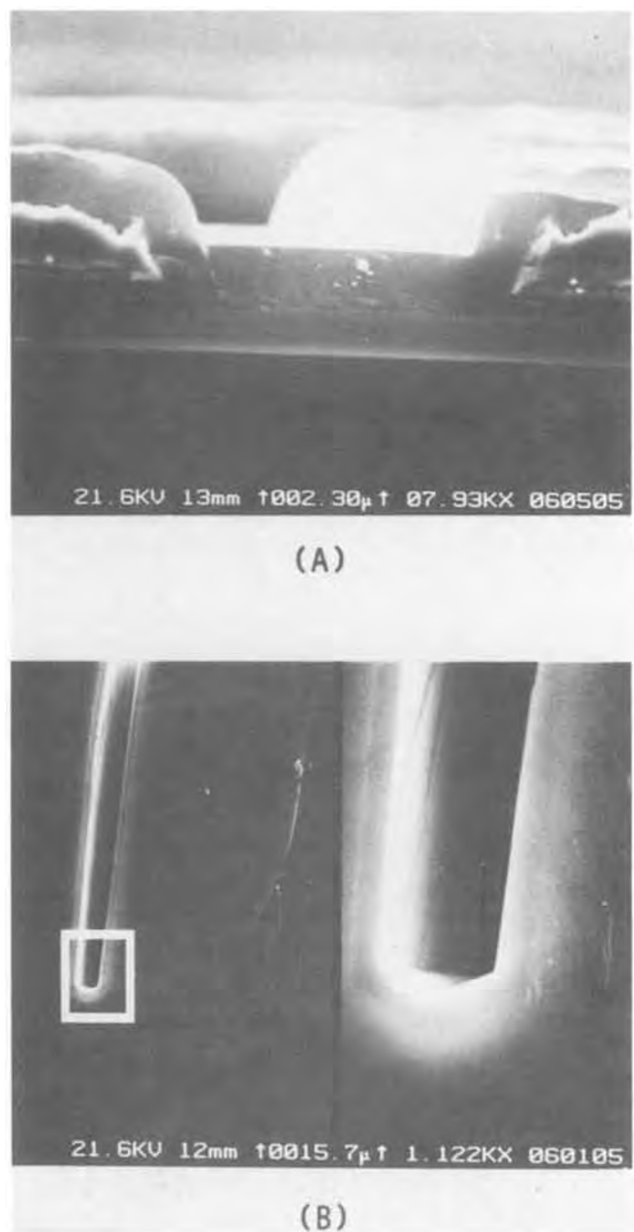

Fig. 13. Scanning electron micrographs showing step coverage of films deposited at 340°C; (A) over titanium-platinum-gold; (B) cross section showing deposition over very deep grooves etched in silicon.

Adhesion.—Quantitative measurements of the film adhesion have not been made. Generally the adhesion is satisfactory; peeling or cracking is not observed after etching patterns in a plasma, after various chemical treatments, or after standing in room ambient for several months. In addition, cracking of the film has not been observed for films over aluminum metallizations even after repeated temperature cycling between 25° and 450°C. Films deposited over gold metallizations show no signs of cracking after heating to 350°C. For both metallizations, cracking is evaluated by microscopic examination before and after decoration of any cracks with a metal etching solution.

However, there are a few exceptions to the generally good adhesion. Four samples (from more than

one hundred) have suffered adhesion loss after standing for 3-6 months. In one case, crystals (probably of boric acid) (1) have been observed on the film surface. Reasons for the adhesion loss on these four samples have not been determined. Auger analysis has detected oxygen in two of these films. This suggests that the adhesion loss may have been caused by a small leak in the reactor. Cracking and loss of adhesion also occur when the films on silicon substrates are annealed in steam at 2 atm pressure and 125°C. After 7 hr, cracking has started along the edge of the wafers. This cracking proceeds inward until the entire film is cracked after about 24 hr. The film thickness, refractive index, and infrared spectrum are unchanged by the steam anneal. It appears that the steam causes a reaction at the film-silicon interface leading to loss of adhesion and cracking, but the film itself does not react with the steam. Loss of adhesion is also observed after samples are annealed in vacuum at temperatures above 500°C. The annealing causes loss of hydrogen (determined from the decrease in intensity of the BH and NH_2 infrared absorptions) and causes changes in the BN bonds (the BN absorption shifts from 1400 to 1340 cm^{-1}). A few days after the anneal, the films start to crack. This phenomenon is not observed for films annealed at temperatures below 500°C.

Defects.—Films thicker than 0.1 μm are pinhole-free as shown by the inability of acids to attack metals (aluminum or gold) covered with the film. The major film defects are small round mounds or hillocks, which have been reported previously for films of boron nitride (1). The hillocks appear to have the same composition as the film and have a spherical shape (Fig. 14) ranging in size up to 1 μm in diam. The formation of the hillocks is independent of the substrate, independent of the NH_3/B_2H_6 ratio, and independent of the diborane partial pressure; however, the hillock density increases as the deposition temperature decreases. The cause of these hillocks and the mechanism of their formation are not understood.

Reproducibility.—An estimate of the deposition reproducibility has been obtained by measuring monitors from 13 consecutive depositions. The means and the standard deviations are: thickness, 0.582 and 0.014 μm; refractive index, 2.24 and 0.03; and stress, 0.05 $\times$ 10^9 and 0.38 $\times$ 10^9 dynes/cm^2. The reproducibility is very good.

Other Materials

During this work other materials have also been prepared and partially characterized. Depositions using diborane but no ammonia produce films containing boron and hydrogen, as shown by the BH infrared absorption at 2560 cm^{-1}. These films have a metallic appearance, have a refractive index of about 3.4, have a strong optical absorption near 200 nm, and have a high tensile stress, 3 $\times$ 10^9 dynes/cm^2. Addition of acetylene instead of ammonia gives films containing boron, carbon, and hydrogen. These films are not soluble in acid solutions, are easily etched in a CF_4-O_2 plasma, have a refractive index of 2.7, have infrared absorptions at 2555 cm^{-1} (BH) and 1105 cm^{-1}, and have a low tensile stress. Boron nitride films have been prepared by reacting boron trichloride and ammonia at reduced pressure at 700°-800°C. The films have a refractive index of 1.9-2.0 and have infrared absorptions at 3430, 1350, and 790 cm^{-1}. Crystals, probably of boric acid (1), form on the surface of these films within a few days.

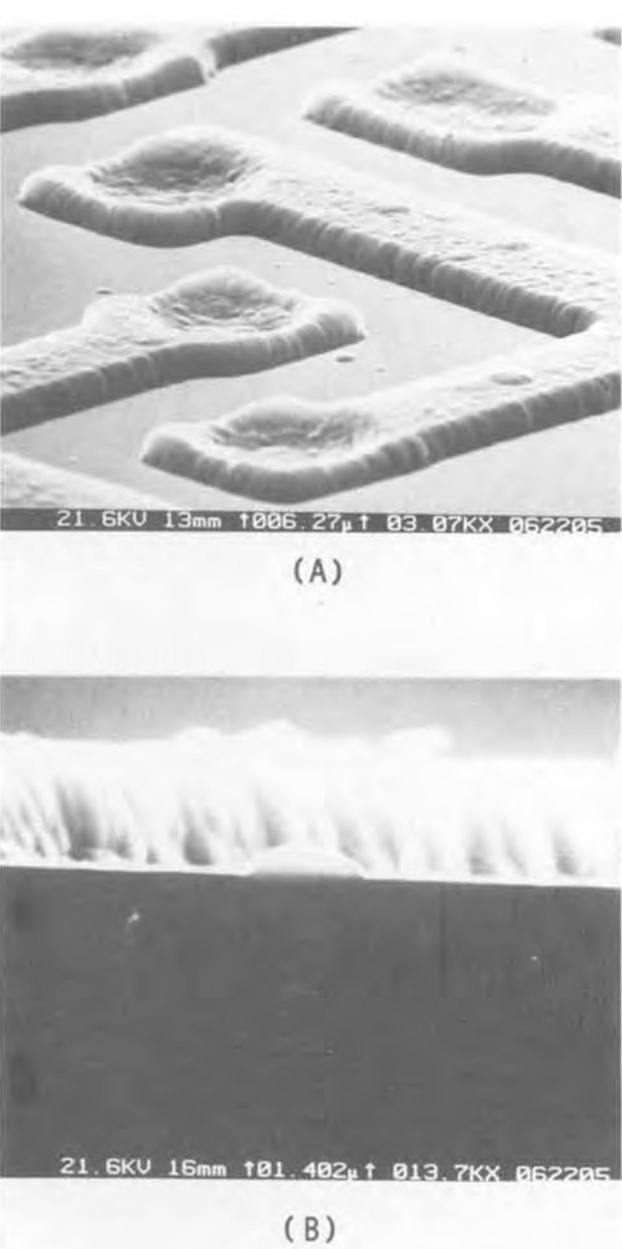

Fig. 14. Hillocks in films deposited at 340°C over aluminum metallization: (A) SEM of the surface; (B) SEM showing a cross section.

Summary

Films of a boron-nitrogen compound with a composition of approximately B_6NH_x have been deposited at reduced pressure by reacting diborane and ammonia at 250°-600°C. The thickness uniformity and reproducibility are within ±3% for films deposited at 340°C. Infrared spectra show that the films contain boron and nitrogen, possibly bonded in a ring structure, and hydrogen bonded as BH, NH_2, and possibly NH. The film properties are nearly independent of the ratio of reactants (for $0.5 < NH_3/B_2H_6 < 5$), but are affected by the deposition temperature. The film refractive index is about 2.2 for films deposited at 340°C. The films have an absorption maximum in the ultraviolet with a long tail extending throughout the visible region. At 600 nm, the absorption coefficient is about 2.5 $\times$ 10^4 cm^{-1} and increases with increasing deposition temperature. The films deposited in the reduced pressure reactor at 340°C have a lower stress than comparable films deposited at atmospheric pressure at 700°C. For NH_3/B_2H_6 ratios greater than 0.3, the films have a low compressive stress (0 to 1 $\times$ 10^9 dynes/cm^2). The films are in tension for lower values of the NH_3/B_2H_6 ratio and reach a maximum stress of about 3 $\times$ 10^9 dynes/cm^2 for $NH_3/B_2H_6 = 0$. The films are chemically inert, being insoluble in all etching solutions investigated. However, the films are easily etched in a CF_4-O_2 plasma with an etch rate of

3000 Å/min. The step coverage is conformal with no pinholes or cracks, and the adhesion is satisfactory; although, adhesion problems develop if samples are annealed at temperatures greater than 500°C or are heated in steam at 125°C for several hours. The major defects are spherical hillocks ranging in size up to 1 μm in diam. The hillock density decreases as the deposition temperature increases.

ABSTRACT

The ^{15}N hydrogen profiling technique is used to measure hydrogen concentration profiles in a variety of Al_2O_3 films including amorphous anodic barrier films grown in different electrolytes, pseudoboehmite, and composite oxide films grown by reaction with boiling water followed by anodic oxidation. Hydrogen profiles of the composite oxide films confirm that the "relaxation" which causes a large loss in field strength results from penetration of water deep into the oxide film. Comparison of our results with those obtained by SIMS is made where the SIMS data are available.

We have used a nuclear reaction technique to measure hydrogen concentration *vs.* depth in a representative group of aluminum oxide films including: amorphous barrier films grown in different electrolytes (phosphate, tartrate, glycol-borate), pseudoboehmite films formed by reaction of Al with boiling water, and composite oxides grown by reaction of Al with water followed by anodic oxidation. Composite oxides were examined both before and after a "relaxation" (1), which causes an order of magnitude loss of field strength. This "relaxation" seems to be associated with entry of water deep into the barrier oxide. Direct evidence for water within the barrier layer had not been available before the present study.

The presence of hydrogen in the form of protons or hydroxyl groups has been invoked by several investigators to explain the growth and properties of anodic aluminum oxide films. Hoar and Mott (2) suggested that porous Al_2O_3 growth involved transport of oxygen as OH^- to the metal interface coupled with a counterflow of H^+ to the solution; this idea was later expanded upon by Hoar and Yahalom (3). Heine and Pryor (4) proposed that an observed increase in the a-c conductivity of the outer portion of barrier Al_2O_3 films was due to OH^- in this part of the film. A-C resistivity profiles of anodic Al_2O_3 films were extensively measured by Brock and Wood (5) who ascribed all decreases in resistivity to the presence of protons or OH^-. No attempts to measure the hydrogen content had yet been reported and all these authors seemed to consider that any hydrogen in the oxide was present at low but unspecified concentrations. A radically different proposal came from Dorsey (6), who interpreted the infrared spectra of *in situ* anodic alumina films as showing that the barrier layer was an alumina trihydrate. It was later shown that his conclusion was the result of incorrect interpretation of the spectra and that anodic alumina films prepared in boric acid electrolyte contained no appreciable amount of hydroxyl group (7).

The introduction of secondary ion mass spectroscopy (SIMS) provided a new tool for the study of oxide

Key words: dielectrics, nuclear reactions, oxidation, water.

composition, one that could give information on composition *vs.* depth. Dorsey compared SIMS spectra of gibbsite, boehmite, and anodic alumina formed in 2M boric acid and again concluded that the anodic oxide was a trihydrate (8). Since it is known that this oxide is not a trihydrate, it appears that the interpretation of SIMS data for analysis of oxides and hydroxides must be done with great caution. More recently, SIMS has been used to measure hydrogen profiles of anodic Al_2O_3 films formed in tartrate electrolytes (9). Hydrogen was detected throughout the film, and the concentration depended upon the pH of the electrolyte.

Because of the potential difficulty in interpreting SIMS data, we have used the ^{15}N resonant nuclear reaction technique (10) to measure hydrogen concentration profiles in the anodic oxide films of the present study. While this is a relatively new technique, it has already been used to profile hydrogen in thin film insulators—silicon nitride (11), semiconductors—amorphous SiH_x (12), and superconductors—Nb_3Ge (13), as well as in a variety of hydrated glasses (14). This technique uses a nuclear reaction as a probe for hydrogen and, as a result, is inherently a more quantitative technique than those such as SIMS whose signal may be sensitive to poorly understood atomic or solid-state effects. Most importantly, in the ^{15}N hydrogen profiling technique the region of the sample being analyzed for hydrogen is not exposed to the atmosphere of the instrument chamber. Hence, the procedure is much less susceptible to experimental artifacts than is the SIMS technique (9). Because this method is relatively new and may not be familiar to many of the readers, we will briefly review it below. More detailed discussions of the method and its application are available in the literature (10-14).

The purpose of this study was to see what could be deduced about oxide film structure and composition from H profile measurements by nuclear reaction and to learn about the advantages and limitations of the technique. The intent was to survey a range of film types rather than study particular films in detail. Since the only reported H profiles are for films formed at several pH values in tartrate electrolyte (8), we put some emphasis on the analysis of similar films.

Experimental

Sample preparation.—99.99% Al foil was cut into 20 cm^2 coupons and chemically polished in a mixture of 15 parts 70% HNO_3 + 85 parts 85% H_3PO_4 for 2 min at 85°C. The foil specimen was then immersed in stirred 1M NaOH for 10 min at room temperature to remove the polishing film.

Anodic oxide films were formed on these foils in the following ways:

1. At 1 mA/cm^2, 95°C in 1.4 g/liter $NH_4H_2PO_4$ to 150V.
2. At 1 mA/cm^2, 25°C in ethylene glycol containing 17% ammonium pentaborate to 150V.
3. At 1 mA/cm^2, 25°C in 30 g/liter ammonium tartrate. Two sets of specimens were prepared. The first set was anodized to 60V at pH 4.26, 6.73, 9.08 and the second was anodized to 150V at pH 3.98, 6.27, 9.21.
4. By immersion of the specimen in boiling distilled water for 5 min to form a hydrous oxide film, followed by anodization ("formation") in 100 g/liter boric acid + 0.9 ml/liter 30% NH_4OH at 95°C. The formation was first at 1 mA/cm^2 to 220V and then at constant voltage until the current decayed to 25 $\mu A/cm^2$.

Procedure 4 gives a composite oxide film in which a largely crystalline barrier oxide layer forms between the Al substrate and the outer hydrous oxide (15). While there had been no direct evidence for water in these films, the barrier oxide layer contains voids and it has been suggested that these can become filled with water on open circuit in a nonaggressive electrolyte resulting in "relaxation" (1). To verify this, a composite oxide specimen was examined for hydrogen both before and after a relaxation in ~0.2M Na_2CO_3 at ~35°C for 10 min.

A second anodization (reformation) after a relaxation appears to fill the barrier layer voids with oxide (15). A foil which had been formed and relaxed was stabilized by a "reformation" at 25 $\mu A/cm^2$ to 220V in the boric acid electrolyte. This foil was also examined for hydrogen content.

Measurement of H content.—The ^{15}N hydrogen profiling technique (10) makes use of a narrow isolated resonance in the nuclear reaction $^{15}N + {}^1H \rightarrow {}^{12}C + {}^4He$ + 4.43 MeV gamma ray. The method is shown schematically in Fig. 1. Because this is a resonance reaction, there is a large probability for this reaction to take place only when the relative energy of the ^{15}N and ^1H is at the resonance energy. To use this reaction as a probe for hydrogen, the sample to be analyzed is bombarded with ^{15}N and the yield of the characteristic 4.43 MeV gamma rays is measured. If the ^{15}N is at the resonance energy, the yield of characteristic gamma rays is proportional to hydrogen on the surface of the sample. If the energy of the ^{15}N is raised above the resonance energy, there are essentially no reactions with hydrogen on the surface of the sample because the energy is too high. However, as the ^{15}N ions penetrate the sample, they lose energy and reach the resonance energy at some depth. Now the yield of gamma rays is proportional to hydrogen at this depth. Hence, by measuring the yield of 4.43 MeV gamma rays *vs.* ^{15}N energy, the hydrogen concentration *vs.* depth is determined. See Fig. 1. Further discussions of this technique and its application are available in the literature (10-14).

The sensitivity of the ^{15}N hydrogen profiling technique is determined by the amount of ^{15}N beam incident on the sample. In the present study, each data point required on the order of 100 sec of beam which resulted in a sensitivity limit of 1×10^{20} atoms cm^{-3}. The beam spot on the specimen was typically a few mm in diameter. The depth resolution near the surface of the sample is determined by the ratio of the width of the resonance over the rate of energy loss of the ^{15}N beam (dE/dx). For Al_2O_3 this depth resolution is 3 nm. However, as discussed below, the practical depth resolution for several of the films used in the present study is limited by the rather nonuniform outer layer of hydrous aluminum oxide.

The chamber used to measure the hydrogen profiles is shown schematically in Fig. 2. The samples to be analyzed were mounted on a "sample wheel" which could be remotely positioned and rotated to change samples. The ^{15}N beam is incident from the right and the gamma rays are detected by a sodium iodide detector placed directly behind the samples. No oil pumps are used in order to minimize hydrocarbon surface contaminations. Instead, the vacuum system is pumped only by ion pumps and liquid nitrogen cold

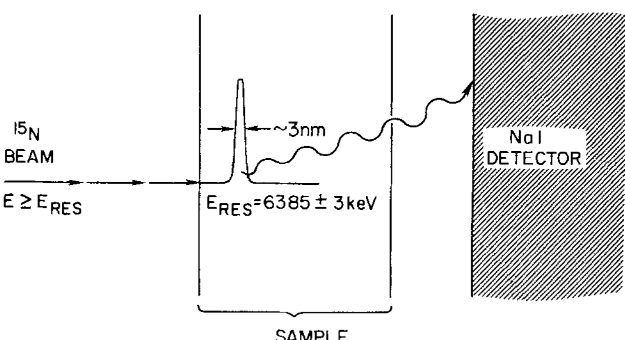

Fig. 1. A schematic representation of the ^{15}N hydrogen profiling method. Because of the narrow resonance at 6385 keV, the measured gamma ray yield is proportional to hydrogen content at a specific depth into the sample.

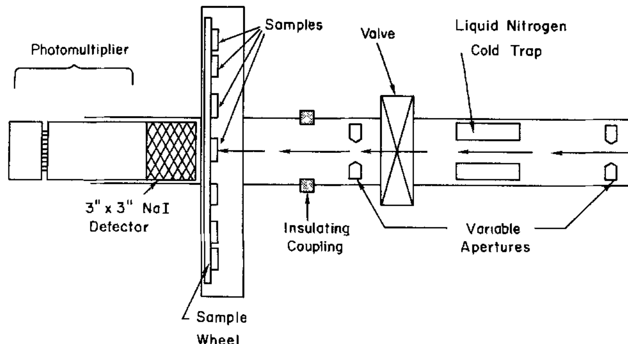

Fig. 2. A schematic representation of the experimental chamber used to measure hydrogen profiles.

traps. The vacuum is typically 10^{-6} Torr. The amount of ^{15}N beam incident on the samples is monitored by measuring the electrical current deposited on the target by the ^{15}N beam.

Determination of H profile.—The depth at which the ^{15}N reaches the resonance energy is given by

$$\text{depth} = (E - E_{res})/(dE/dx)$$

where E_{res} is the resonance energy, 6.385 MeV, and dE/dx is the gradient of energy loss of the ^{15}N ions. The latter quantity was calculated (16) from the Northcliffe and Schilling stopping powers corrected for "Z_2 oscillations." The stopping powers were 7.31 $MeV \cdot mg^{-1} \cdot cm^2$ for Al_2O_3 and 8.34 $MeV \cdot mg^{-1} \cdot cm^2$ for pseudoboehmite ($AlOOH \cdot \frac{1}{2} H_2O$). Table I(a) shows the energy loss rates in units of MeV μm^{-1} for the films used in this work. Each of the amorphous barrier films was assumed to have the same density as that found for glycol-borate films (17).

The hydrogen concentration (C_H) is given by

$$C_H = (\text{constant})\,(\text{gamma ray yield}/\mu C)\,(dE/dx)$$

where the constant depends only on the resonant cross section and detector efficiency. For our system

$$C_H(\text{atoms cm}^{-3}) = (3.8 \times 10^{19})\,(\text{counts per } 0.4\,\mu C)\,(dE/dx)$$

This calibration had been previously established and is accurate to better than 10% (10, 18).

Total film thickness was estimated from reported values for films formed under similar conditions. These values are listed in Table I(b).

Results and Discussion

Amorphous barrier layers.—Phosphate and glycol-borate films.—Hydrogen concentrations at several depths are shown in Table II; for comparison consider that the oxide consists of $\sim 2 \times 10^{22}$ Al_2O_3 units cm^{-3}. Both films have a surface region that is enriched in hydrogen and, to a depth of about 60 nm, the phosphate film contains more hydrogen than the G-B film. The highest H concentration in both films is about one H atom for every fifty Al_2O_3 units. These films were not examined for hydrogen at depths greater than 75 nm but from the results obtained it seems likely that the remainder of the films contained less than 1×10^{20} H atoms cm^{-3}. To offer another frame of reference, this concentration is equivalent to 0.04 weight percent (w/o) H_2O if the H were present as H_2O. Quite clearly, hydrogen is a trace constituent in these films.

Table I. Film properties

a. Density and energy loss	ρ (g cm^{-3})	Ref.	dE/dx (MeV μm^{-1})
Amorphous barrier Al_2O_3	3.17	(17)	2.32
Crystalline barrier Al_2O_3	3.65	(15)	2.67
Crystalline barrier Al_2O_3 (after reformation)	3.82	(15)	2.79
Pseudoboehmite	2.44	(19)	2.03

b. Total film thickness Film	Thickness (nm)	Ref.
150V phosphate	210	(20)
150V glycol-borate	170	(17)
60V tartrate	70	(5)
150V tartrate	175	(5)
220V composite barrier	220	(15)

Table II. H concentrations in phosphate and glycol-borate 150V films

Depth (nm)	C_H (10^{20} atoms cm^{-3}) Phosphate	Glycol-borate
17	4.3	4.5
37	2.6	<1
56	2.8	1.4
75	<1	<1

Randall and Bernard (21) have measured the phosphorous content of anodic Al_2O_3 films formed in phosphate electrolytes. In the outer $\sim$75% of the film there was a uniform concentration that depended only slightly on particular anodizing conditions and was independent of total film thickness. From their data for anodizations in $10^{-2}M$ NaH_2PO_4 at 98°C, we calculated a phosphorus concentration in the outer layer of 1.2×10^{21} atoms cm^{-3}. This is more than four times the hydrogen concentration we have observed in a similar film, so it is likely that the incorporation of hydrogen and phosphorus are independent processes and not the result of HPO_4^{2-} or $H_2PO_4^-$ incorporation.

Tartrate films.—These films formed at less than 100% current efficiency at all pH. Brock and Wood (5) estimated the current efficiency of film formation in 3% ammonium tartrate from dV/dt measurements. We made similar estimates, based on dV/dt for the G-B anodization which is 100% efficient. Their results at 0.1 and 10 mA/cm² compare in this way with our results at 1.0 mA/cm²:

pH	Current efficiency (%) 0.1	1.0 60V	1.0 150V	10
4-5	24	74	68	83
6-7	29	72	72	99
9	19	22	75	76

These figures are the percent of the total charge used for barrier oxide deposition. There was no significant gas evolution from the Al during anodization, so the balance of the charge presumably was used for Al dissolution.

Specimen capacitance was independent of pH. The 60V films had a capacitance in the range 2.16-2.22 μF and the 150V films were in the range 0.888-0.901 μF. From this we infer that the barrier layer thickness was independent of pH.

The hydrogen concentrations found in these films are summarized in Table III. The 150V pH 4 film was similar to the phosphate film. The high hydrogen concentration at a depth of 9 nm may not be a true measure of the concentration at that depth, but could be an artifact of surface contamination and surface roughness. Compared with the 150V pH 4 film, the 60V pH 4 and pH 7 films had 3-4 times higher hydrogen content throughout their thickness of about 70 nm. We do not know if the lower hydrogen content in the interior of the 150V pH 4 film as compared with the 60V pH 4 film is a true effect of film growth or merely due to specimen variation.

Table III. H concentrations in tartrate films

a. 60V films Depth (nm)	pH 4.3	C_H (10^{20} atoms cm^{-3}) pH 7.1	pH 9.1
17	7.1	4.2	115-132
37	—	—	36-100
56	9.9	6.7	28
75	<1	1.0	10
94	<1	<1	3.0
114	—	—	2.5

b. 150V films* Depth (nm)	pH 4.0	C_H (10^{20} atoms cm^{-3}) pH 6.3	pH 9.2
9	42	407-670	250-460
17	5.9	202-282	84-247
26	2.0	45-121	6-17
39	2.7	1.7-15.6	<1
83	2.4	3.8	1.7

* See Fig. 3.

The 60V pH 9 film had a surface layer greatly enriched in hydrogen. Repeated measurements at the same point in the film showed an apparent decrease of H with time indicating the ion beam was causing some of the hydrogen to be lost from the film. This behavior may be indicative of very weakly bound hydrogen, *e.g.*, as molecular water, which can be lost to the vacuum system. At greater beam penetration the H content fell to low values typical of the other amorphous barrier films, but this occurred at apparent film depths of 94-114 nm. Since the barrier layer thickness appears to be about 70 nm for all the 60V films (based on capacitance), it seems likely that the pH 9 film had a nonbarrier deposit on top of the barrier film.

Because of the ease with which hydrogen appeared to be lost from this surface, the 150V films were analyzed several times at each ^{15}N beam energy and repositioned for each increase in beam energy to expose a fresh area. The outer part of the pH 9 film had a very high H content that varied during the analysis in the same way as the 60V pH 9 film. The 150V pH 6 film exhibited the same behavior and it seems that both films can be described as having H-rich nonbarrier deposits on their outer surface. All the 150V film analyses are shown in Fig. 3.

The 150V films were stripped from the metal substrate and examined by transmission electron microscopy. The pH 9 film showed dark patches arranged in a linear pattern [Fig. 4(a)], and at high magnification a high density of fine pores was seen [Fig. 4(b)]. The pH 6 film had about the same density of linear patches but no porosity was evident. The pH 4 film had dark patches on some areas but much of the film was free of this feature. The patches may be $Al(OH)_3$ precipitated from solution onto barrier oxide. The patches and porous oxide are certainly not characteristic of barrier oxide and it seems likely that they are the H-rich outer regions. Other surface regions may also be H-rich but free of distinctive structural features.

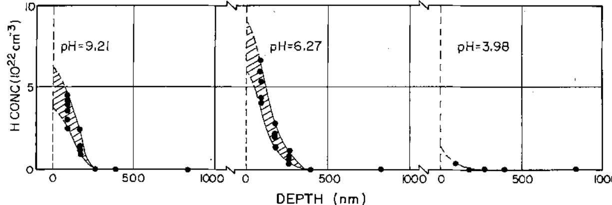

Fig. 3. Hydrogen profiles of 150V anodic Al_2O_3 films formed in tartrate electrolytes at different pH. The cross-hatched area indicates the range over which the hydrogen content decreased during the analysis at a given depth. See text.

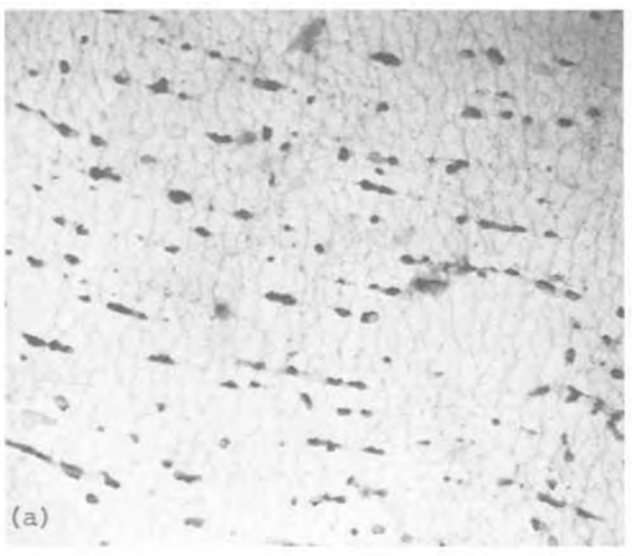

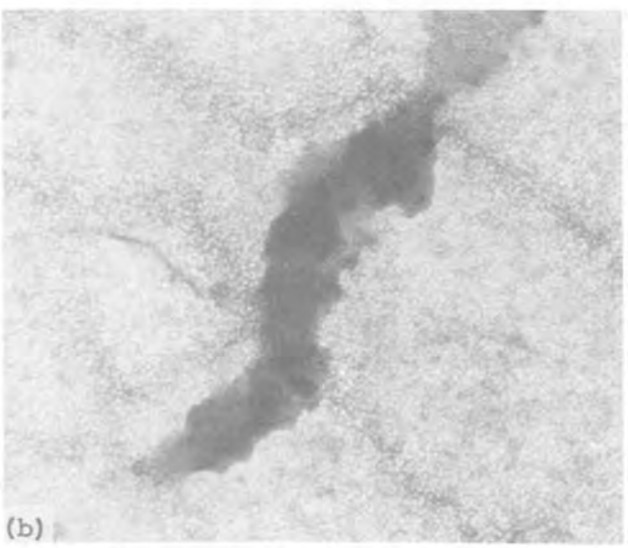

Fig. 4. Transmission electron micrographs of 150V pH 9 tartrate film at (a) 8,000× and (b) 75,000× magnification.

SIMS analysis of 60V tartrate films (8) also indicated an increase in film thickness at alkaline pH, but the profile of H-containing species was relatively flat across the layer formed at pH 9.9. Only at pH 10.6 was the outer film enriched in hydrogen, but the difference between surface and barrier oxide concentrations was no more than fivefold, far less than the hundredfold difference determined from nuclear resonance.

It is difficult to make a critical comparison of the two analytical techniques from these data because films formed in tartrate tend to be complex and perhaps difficult to reproduce. For example, Brock and Wood (5) observed $\sim 10^9$ pores cm^{-2} in films formed at pH 5, whereas we saw no pores in films formed at pH 4 or pH 6. Brock and Wood observed a decreased a-c resistivity in the surface region of films formed at pH 7, 10 mA/cm^2, but Richardson, Wood, and Breen (22) saw no unusual resistivity change with films formed and measured at presumably identical conditions. Finally, in this present work we have the example of a 60V pH 7 barrier film growing at 22% current efficiency whereas a 150V film grew at 75% efficiency. A suitable comparison of the two techniques could only be done by making the measurements on the same specimens.

Hydrous oxide films.—The reaction of aluminum with boiling water produces a film of pseudoboehmite, a poorly crystallized form of boehmite (γ-AlOOH) containing excess water. The film typically has a composition of $Al_2O_3 \cdot 2.1\ H_3O$, a specific density of 2.44 g cm^{-3} (19), and a duplex structure consisting of a dense inner layer and a porous fibrillar outer layer (23).

Al foil specimens were reacted with boiling water for either 5 or 30 min and, from the weight gain and previous thickness measurements on similar films (23), we estimated the structure to be the following:

Reaction time (min)	Avg film wt. ($\mu g/cm^2$)	Thickness (nm)	
		Inner	Outer
5	64.8	100	200-300
30	107.2	220	300

The H-profiles of these samples are shown in Fig. 5 and 6.

Before examining the profiles it will be helpful to first consider the effect of the film structure on the results. As the ^{15}N beam passes through the porous layer it loses energy only when in the solid phase, so it will always reach the resonance energy within the solid, and the correct value of dE/dx for calculating C_H is the local energy loss, which is the value shown for pseudoboehmite in Table I. Thus, the C_H values calculated for the porous layer will be specific concentrations for the solid phase in that layer and not bulk concentrations. Based on these same considerations, it can be seen that this profiling technique does not give the true thickness of the porous layer but will give a thickness equivalent to the weight and the specific density of pseudoboehmite. In other words, this technique does not distinguish between a porous structure and a dense structure if the solid phase in the two structures has the same composition and density.

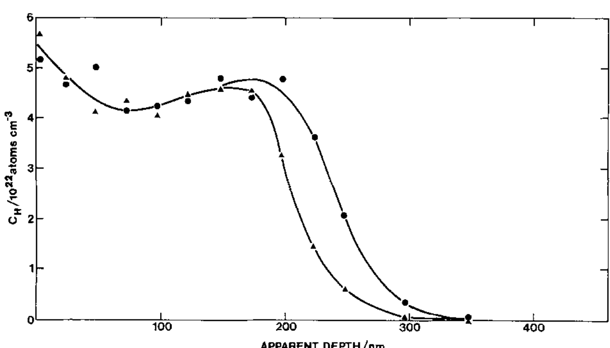

Fig. 5. The distribution of hydrogen in the surface film formed on Al during a 5 min reaction with boiling water. Results with two specimens are shown.

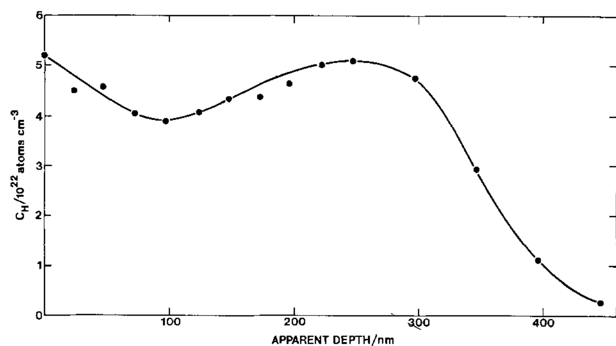

Fig. 6. The distribution of hydrogen in the surface film formed on Al during a 30 min reaction with boiling water.

Figures 5 and 6 show that the hydrogen content of the pseudoboehmite films was 4-5 $\times$ 10^{22} atoms cm^{-3}. This is in excellent agreement with the figure of 4.5 $\times$ 10^{22} calculated from the average film composition and a specific density of 2.44 g cm^{-3} (19).

The H-profiles show a gradual decrease towards the metal surface whereas micrographs of film cross sections show this interface to be quite sharp (23). We think this tail is due to the effect of the rough, uneven texture of the outer film surface. Surfaces of constant ^{15}N beam energy will approximately follow the contour of the outer surface. As the beam energy is increased so that the resonance reaction occurs deeper in the film, a point is reached where for part of the specimen surface the resonance energy level is within the metal rather than the film. This marks the beginning of the tail, and further increase in beam energy increases the fraction of metal at the resonance energy.

The half-height of the tail gives an estimate of the position of the oxide-metal interface. Since the corresponding film thickness is for a layer free of porosity, we can compare the weight of pseudoboehmite calculated from this thickness with the actual film weight. For the 5 min boil films the average apparent thickness is 226 nm, and for the 30 min film it is 358 nm. The corresponding film weights are 55 and 87 $\mu g/cm^2$, which are 15-20% lower than the measured values given earlier.

Thus, the rough porous nature of the outer film does not hinder an accurate measure of the H concentration of the film material, but it does effectively degrade the depth resolution for measurements inside the sample.

Composite oxide layers.—The H-profiles of 220V composite oxide films, before and after a relaxation, are shown in Fig. 7. The abscissa is presented as beam energy rather than a calculated depth.

For these films the pseudoboehmite tail extends into the barrier oxide and from the beam energy at half-height an apparent thickness of 167 nm was calculated for the hydrous oxide. This is about 60 nm less than the initial thickness because some of the hydrous oxide loses water and is converted to barrier Al_2O_3 (23, 24). From data reported for a 5 min boil + 175V composite oxide (24), it was calculated that 70 nm of pseudoboehmite was transformed, in reasonable agreement with these results.

No information can be obtained about H content in the barrier oxide close to the hydrous oxide. At greater depths C_H drops to a steady value in the range 2-3.5 $\times$ 10^{20} atoms cm^{-3} for the specimen that was not relaxed. This is the same concentration as in the amorphous barrier oxides (Tables II and III).

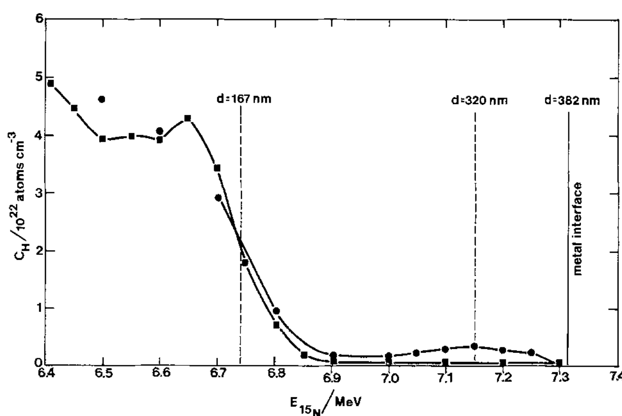

Fig. 7. The distribution of hydrogen in the composite films formed by 5 min reaction with boiling water and then anodizing to 220V. The hydrogen profiles are given both before (■) and after (●) inducing the "relaxation."

although the composite barrier layer is crystalline γ'-Al_2O_3.

After a relaxation there was a well-defined peak centered at 153 nm from the hydrous/barrier interface. (This depth was calculated using the dE/dx for crystalline barrier oxide shown in Table I and the half-height beam energy of 6.74 MeV as the reference plane.) The peak region is shown more clearly in Fig. 8. The peak width is broadened because of the spatial distribution of beam energy caused by outer surface roughness. The integrated area under the peak (which is not affected by the surface roughness) corresponds to $\sim 2.7 \times 10^{16}$ atoms cm^{-2}. A reformation removed the peak but left a residual hydrogen content slightly higher than in the film after formation. See Fig. 8.

The H-profile did not define the barrier oxide/metal interface because hydrogen was still detected at depths that must have been well within the metal. For example, ellipsometric measurements have shown this barrier layer thickness to be 215 nm (15) and this was used in Fig. 7 to delineate the oxide/metal interface. With the reformed specimen, C_H of 4.1 and 3.7×10^{20} atoms cm^{-3} were measured at beam energies of 7.43 and 7.65 MeV, and from the scale in Fig. 7 it can be seen that the resonance energy must have been within the metal. This situation did not arise with the amorphous barrier films where at beam penetrations greater than the oxide thickness the gamma ray yield dropped to the background level. This phenomenon may be due to preferential hydration along grain boundaries and at impurity sites during the boiling water reaction.

These results are in excellent agreement with a proposed model of Alwitt and Dyer (1) that explains the electrical instability that accompanies relaxation as the result of penetration of water into voids deep within the barrier oxide, while reformation subsequently fills the voids with anodic oxide and consumes the water. The H-profiles presented here are the first direct evidence for water penetration and accumulation in the barrier layer.

The area under the H peak corresponds to 0.4 μg cm^{-2} H_2O in the film, which compares with 0.6-1.5 μg cm^{-2} calculated from reformation charge with the assumption that the void volume occupied by the reformation oxide had been completely filled with water. Most of the reformation charge is consumed at low voltage, so it was inferred that the water accumulated near to the metal interface, in the lower $\sim 30\%$ of the barrier layer (1). This location of the voids is supported by the present results.

Summary

The ^{15}N nuclear resonance reaction can be used to measure H in Al_2O_3 at levels as low as 1×10^{20} atom cm^{-3}. The method easily gives quantitative results accurate to 10% and, because it measures H inside solids without the removal of the surface, it is free of ambient contamination effects.

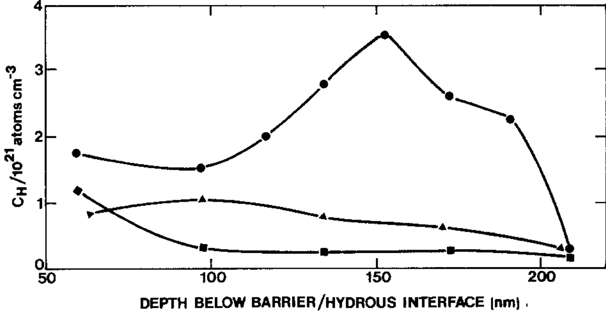

Fig. 8. Same specimen as in Fig. 7 but showing details of H-content in peak region; as formed (■), after inducing "relaxation" (●), and after reanodization (▲).

Ordinary amorphous anodic oxides, such as films formed in phosphate or glycol-borate electrolytes, contain only trace amounts of hydrogen. The G-B film had the lowest H content, but additional measurements would have to be made to test the significance of the connection between H content of the film and water content of the anodization electrolyte.

Films formed in tartrate electrolytes tended to have H-rich surface deposits, presumably containing precipitated $Al(OH)_3$. The deposits had no effect on the barrier layer and were not detected by electrical measurements. These solutions have been used by different investigators to produce anodic oxides whose properties are then studied and presented as perhaps being typical of the general class of anodic Al_2O_3 layers. The tendency to precipitation from solution and incipient porosity suggests that caution should be exercised in using these films, as only layers formed at 100% current efficiency can be free of these effects.

There is a problem with depth measurement in films that are not compact and of uniform thickness. This was illustrated by the pseudoboehmite film, where the rough outer layer introduced an energy dispersion that was present throughout the specimen thickness. Even so, it was possible to learn that there is only a small variation in composition throughout the film.

The H-profiles of the composite oxides gave detailed information on the composition of a very complex structure and provided the first direct experimental evidence verifying previous ideas about the cause of field strength instability of the barrier layer.

Nonsimultaneous Place Exchange: A Microscopic High Field Transport Mechanism in Solids

A. T. Fromhold, Jr.*

Department of Physics, Auburn University, Auburn, Alabama 36830

ABSTRACT

A nonsimultaneous place-exchange mechanism is postulated whereby ionic motion takes place by means of elemental excitations labeled "hopons." A hopon is defined to be the thermally activated electric field-modified motion of a localized place exchange between oppositely charged ionic constituents in a compound. The virtual defect associated with hopon motion is considered to be a highly localized disturbance which jumps statistically with time from place to place in the medium, although in certain cases it may be a somewhat more extended wavelike disturbance which propagates with a finite velocity through the medium. These two possibilities are referred to respectively as "noncollective" and "collective" hopon transport mechanisms. Some of the ramifications of hopons for the formation of anodic oxides on metals are examined, including consideration of where the new oxide layers are formed, the relative transport numbers for anions and cations through the oxide, the preservation of microscopic order in the anion and the cation sublattices in the oxide, and the energies and the kinetics for anodic oxide growth.

The classic mechanisms which have been proposed for ionic transport through insulators involve the concepts of lattice vacancies or ion interstitials (1-6). For metal oxides and similar compounds such as the alkali halides, the lattice vacancies or interstitials may involve either the cation species or the anion species, or both, depending on the system. As one example, in the superionic conductor α-AgI it has been concluded that ionic transport occurs primarily by the motion of silver ions in an essentially perfect anion lattice (7).

Other types of point defect motion have also been postulated in the literature. For example, Seitz (8) envisioned transport in metals by a lattice imperfection motion termed an interstitialcy that is the inverse counterpart of a lattice vacancy. Such motion occurs when an interstitial atom jumps into a normal lattice site while simultaneously forcing the atom which is there into a neighboring interstitial site. The activation energy for this type of motion was estimated to be less than that required for the simple hopping of interstitials between neighboring interstitial sites. Weber and Friauf (9) have interpreted their radioactive tracer data on the diffusion of Ag in single crystals of AgCl in terms of the interstitialcy motion of Ag.

Zener (10) also put forth a novel idea for diffusion in metals, namely, the simultaneous rotation of several metal atoms. This has been termed the "ring" mechanism.

For independent thermally activated motion of cation or anion species by any of the above mechanisms, a small difference in activation energies between possible mechanisms leads to the prediction of large differences in the mobilities. This leads to the conclusion that the relative transport numbers for cations and anions should be nearly 0 and 1, or else 1 and 0, as the case may be. (For example, activation energies of 1.0 and 1.1 eV lead to Boltzmann probability factors of 1.58×10^{-17} and 3.30×10^{-19} at a temperature of 300°K, so the corresponding diffusion coefficients will differ by a factor of 48.)

Although the independent motion of point defect species is, without doubt, a viable concept, there is experimental evidence that for particular systems some other mechanism may be more important. For example, transport numbers for cations and anions are sometimes found to be of the same order of magnitude, despite the high improbability that the vastly different sized and chemically unlike components would have essentially the same activation energy for motion through the medium. One example is the anodic growth of Ta_2O_5 on parent tantalum metal, for which Pringle (11) finds by means of marker experiments utilizing radioactive noble gases that the transport numbers of the cation species and the anion species are 0.24 and 0.76, respectively. One is forced by such experimental results to search for some mechanism involving a correlated motion of cations and anions through the lattice.

One concept of a correlated motion of cations and anions has been proposed by Sato and Cohen (12) to explain their experimental observations of logarithmic growth of anodic oxide films on iron. The Sato-Cohen mechanism is based on the earlier place-exchange concept of Lanyon and Trapnell (13) for a permutation of cation and anion positions in a dipolar surface layer as illustrated in Fig. 1. Sato and Cohen visualized simultaneous place exchanges of this type along an entire line of atoms extending through a three-dimensional layer. Their development involves the relative probability for the simultaneous flipping of all electric dipoles extending through the layer. The activation energy for individual place-exchange events de-

duced by comparison of this model with the experimental data was about 3.5 kcal/mole, or equivalently, 0.15 eV. Brusić (14) has pointed out that this is probably too low by about an order of magnitude.

It recently occurred to me (15) that there is an alternative to the simultaneous place-exchange mechanism of Sato and Cohen which leads to a more realistic value for the activation energy. This alternative is a nonsimultaneous place-exchange (or hopon) mechanism, in which individual place-exchange events occur sequentially in time (see Fig. 2) along a chain of dipoles extending through the medium (16).

To illustrate the mechanism we chose the specific system of an oxide overlayer on a metal (17, 18) and follow individual oxygen atoms from their initial chemisorbed state on the oxide surface until they become incorporated as part of the growing oxide layer and subsequently as the oxide continues to grow thicker on the metal. Alternatively, we could think of affixing appropriate ion exchange electrodes at the interfaces of a static ionic conducting layer and applying a voltage (19, 20). In fact, the presently considered mechanism will be most likely to occur in the case of applied voltages leading to very large electric fields, as for example, in the case of anodic oxidation (21-25) where fields in the 10^5-10^6 V/cm range are common.

One-Hopon Mechanism

The physical model.—Let us examine our problem by carrying out a gedankenexperiment in which we follow the time evolution of a sequence of correlated (but nonsimultaneous) place-exchange events in an oxide layer. Consider first of all a single place exchange to occur at the surface of a stoichiometric oxide covered with some adsorbed oxygen species at the oxide-oxygen (or oxide-solution) interface. That is, a cation exchanges position with an adsorbed oxygen thereby changing the physical picture from (a) to (b) in Fig. 2. It can be noted from (b) that, as a consequence of this place exchange, at least two negative charges are side-by-side. (In one dimension, there are two, but in three dimensions, the number will be greater.) This constitutes an increase in the Coulomb energy of the configuration of the order of $e^2/4\pi\epsilon d_o$, with d_o being the atom spacing.[1] A more accurate estimate would involve a consideration of the change in the Coulomb energies of interaction with all other ions in the solid, which for a crystalline lattice would involve a type of Madelung sum (26). The static dielectric constant ϵ in the Coulomb energy expression for nearest neighbor ions is not really appropriate because the side-by-side charges are not separated by a macroscopic region of oxide which can polarize and thus provide the necessary electrostatic screening. In addition, the increase in the energy of the system required for the place exchange will actually be different from this Coulomb value, because there will be a modified chemical bonding of the pair of oxygen and metal ions with the surrounding atoms in both the oxide and the adsorbed oxygen in the new configuration (3). The amount of this modification will depend to a large extent on the energy of formation and the degree of covalency of the oxide, but the value and even the sign of the contribution are difficult to ascertain because there are contributions of the opposite sign which are of the same order of magnitude. The amorphous state of some insulator compounds constitutes a further uncertainty in the defect energies. For a discussion of some of the various factors involved in the semiquantitative calculation of defect energies, see Kröger (27, 28). Actually a difficult quantum-mechanical calculation would be required to carry out this part of the problem properly.

In lieu of a quantum-mechanical calculation involving atomic and molecular wave functions and taking into account the disorder within the region, let us simply use the Coulomb energy expression given above as some reasonable estimate of the free energy increase U_H required for this initial place-exchange event. That is, U_H is the formation energy of a single place-exchanged pair (referred to as a hopon) in the oxide. A reasonable order-of-magnitude average value for the static dielectric constant ϵ is $10\epsilon_o$, where ϵ_o is the permittivity of free space. For $\epsilon \simeq 10\epsilon_o$, the Coulomb energy expression leads to an estimate of the order of 0.35 eV for U_H in a one-dimensional system; the values for two- and three-dimensional systems are larger because of the greater number of nearest neigh-

[1] The magnitude of the electronic charge is denoted by e; the charge on the electron is then $-e$. The ionic charge is denoted by Ze, where Z includes the sign of the ionic charge.

bor ions. An activation energy W_H will also be involved due to lateral interactions, but first of all let us consider the equilibrium number of such place-exchanged pairs per unit area of the oxide surface. Considering a submonolayer coverage of the oxide surface denoted by the fraction θ, then for $n_{cations}$ per unit surface area of the oxide we can expect the number $n_{pairs}^{(o)}$ of place-exchanged oxygens to be

$$n_{pairs}^{(o)} = \theta n_{cations} \exp(-U_H/k_B T) \quad [1]$$

For $n_{cations} = 6 \times 10^{15}/cm^2$, $\theta = 0.5$, $U_H \simeq 0.35$ eV, and $T = 300°K$, we find that $n_{pairs}^{(o)} \simeq 4 \times 10^8/cm^2$. Since $n_{pairs}^{(o)}/n_{cations} \simeq 7 \times 10^{-8}$, at least in this estimate, the mutual interaction between the place-exchanged pairs in the surface layer can be neglected in a first-order calculation.

At this point in our gedankenexperiment, let us consider a second place-exchange event which takes place within the oxide below one of the first place-exchanged pairs [see (c) in Fig. 2]. It is interesting to note that this second event involves neither member of the first pair. Although an activation energy W_H will be required for this second event, in the lowest order there will be no free energy change of the system. This is due to the fact that the Coulomb energy of the side-by-side (or nearest neighbor) charges of the same sign after the second flip (*i.e.*, place-exchange event) is the same as that of the corresponding configuration of charges of the same sign before the second flip, and likewise the modified bonding energy of the medium is essentially the same, though the position of the modified chemical bonds has been displaced in the medium (In higher order there will be some differences in the Madelung energy which may be neglected in view of the major uncertainties already discussed.)

Let us consider more closely the physical situation at this point in our gedankenexperiment. On balance, we have replaced one cation in the lattice by one anion, so we have a local nonstoichiometry, a local deviation from charge neutrality, and a localized density deviation. Any one of these three would constitute a "defect" in the amorphous (or crystalline) medium. Because the motion of this defect is not associated with any particular anion or cation, but instead, involves many such cations and anions in sequence along a path in the medium, such a defect is a "virtual defect" in the medium. We refer to this particular type of virtual defect as the "hopon." (The well-known lattice vacancy is likewise a virtual defect, since its motion similarly is unassociated with any particular ion, but instead, involves many different ions in sequence in its path through the medium.) The net charge deviation associated with the hopon is, at minimum, the charge on the anion; it can also be argued that the accompanying absence of a cation leads to an additional contribution to the effective charge having the same sign as that of the anion charge and having the magnitude of the cation charge. Let us denote the effective charge of this virtual defect by q_H. With an externally applied forward electric field E, there is an electric force $q_H E$ which acts on the virtual defect. The electric force tries to drive the virtual defect toward the metal interface.

From another viewpoint, the second place-exchange event described above leads to the movement of one cation through one atom distance d_o in the direction of the field, and simultaneously the event leads to the movement of one anion through one atom distance d_o in the opposite direction to that of the field. The change in electric potential energy $\Delta\mathcal{E}_P$ associated with the second place-exchange event is thus

$$\Delta\mathcal{E}_P = Z_c eEd_o + Z_a eE(-d_o) = (Z_c - Z_a)eEd_o \quad [2]$$

where $Z_c e$ is the charge of the cation and $Z_a e$ is the charge of the anion. Recognizing that this energy must be the same as that denoted by $q_H E d_o$, we again reach the conclusion that the charge magnitude of the hopon is the sum of the magnitudes of the charges $Z_c e$ and $Z_a e$, namely

$$q_H = (Z_c - Z_a)e = (|Z_c| + |Z_a|)e \quad [3]$$

The equality involving the magnitudes in Eq. [3] follows because the anion and the cation species are of opposite sign. If, on the other hand, one considered the possibility of an interchange of ions of the same type, as, for example, in the ring diffusion mechanism of Zener (10) for elemental metals, the charges of the two ions would be identical so that q_H would be zero. This clarifies the point that hopon motion in an ionic compound will be strongly promoted by an applied electric field even though there is no analogous effect of a field on the diffusion rate of cations in an elemental metal (6).

The conclusion reached by means of the above arguments leading to Eq. [3] is that the free energy is lowered by an amount $q_H E d_o$ by the second place-exchange event. The activation energy W_H is likewise lowered. For example, if the maximum in the activation barrier is presumed to occur when the exchange is half completed, as for example in the case of exchange by means of a simple 180° rotation of a dipolar molecule, then to first order the exchange barrier maximum is reached when each member of the pair has moved a distance $a = \frac{1}{2} d_o$. Considering the distance d_o to be parallel to the direction of the field, the activation energy barrier maximum W_H is lowered by an amount $\Delta W = q_H E a$ in the forward direction by the electric field. Thus the net barrier for forward motion of the virtual defect is

$$W^{(f)} = W_H - q_H E a \quad [4]$$

If the exchanged pair is at angle θ with respect to the field, as might be the case for a three-dimensional oxide, then from elementary physics it is easily seen that this energy takes the form

$$W^{(f)} = W_H - q_H E a \cos\theta = W_H - q_H \vec{E}\cdot\vec{a} \quad [5]$$

Motion in the reverse direction would be quite analogous, except the displacement would be $-d_o$ instead of d_o with respect to the field direction. To first order the activation barrier for reverse motion of the virtual defect will be raised by the amount $q_H E a \cos\theta$; the net barrier for reverse motion of the virtual defect is thus

$$W^{(r)} = W_H + q_H \vec{E}\cdot\vec{a} \quad [6]$$

Formal similarity to the hopping model.—One cannot help but note the striking formal similarity between the activation energy expressions given by Eq. [5] and [6] which have been deduced for the presently considered nonsimultaneous place-exchange event and the activation energy expression for the movement of a vacancy or an interstitial in the hopping model (17, 18, 21, 29). The present activation energy expression deduced for nonsimultaneous place exchange is, in contrast, markedly different from the activation energy for the simultaneous place-exchange model of Sato and Cohen (12). This difference can be shown to be particularly significant insofar as it leads to a different functional dependence on oxide thickness with an attendant markedly different kinetics for growth of the layer.

Although the motion of the hopon, as we have developed above, is mainly due to the electric field force, a gradient of hopons leads also to a net motion of hopons along the gradient. Thus the formal similarity between nonsimultaneous place exchange and the defect hopping picture can be carried quite far. In fact, the role of concentration gradients (17, 29), space-charge effects (18, 30), stress effects (31, 32), and electric field effects (17, 18) carry over *in toto*, as

indicated in Appendexes A through D. The concepts of interfacial equilibrium and transport-limited rates are also apropos under the proper conditions. The shape of the kinetic curves will therefore be similar to that deduced (15, 18) on the basis of the hopping model. Nevertheless, there remain two areas where great differences exist between the nonsimultaneous place-exchange and the hopping models. The first is that of the microscopic energies involved in the formation and movement of the defects: Place-exchange energies will be different from the corresponding energies for vacancies and interstitials, though a quantum calculation taking into full account the mechanistic differences would be quite involved from a calculational standpoint. Second, the microscopic reordering of individual tracer cations and anions in the already formed oxide during growth of new oxide is quite different for the two models.

Hopon chains.—It has already been pointed out that neither member of the pair of ions involved in the initial place-exchange event is involved in the second place-exchange event. Whereas a radioactive (or similarly tagged) oxygen ion moving a distance of two lattice spacings by interstitial motion in a direction perpendicular to the oxide-oxygen interface would be found a depth of $2d_0$ below this interface, the motion of the hopon through a distance $2d_0$, when it initiates with a radioactive oxygen ion at the oxide interface, would result in the displacement of the radioactive ion to a depth of only d_0 below the interface.

Continuing now with our gedankenexperiment described previously, a third place-exchange event occurring in line with, and immediately below, the first two place-exchanged pairs would involve essentially the same activation energy as the second pair, but it would lead to no further displacement of the tagged oxygen ion [see (c) and (d) in Fig. 2], even though the total distance of transport of the hopon in a direction perpendicular to the surface would then be greater by d_0.

In the present model of nonsimultaneous place exchange, each such place-exchange event is correlated in time and position with the preceding and succeeding place-exchange events; however, the place-exchange events do not occur simultaneously as they do in the case of the simultaneous place-exchange mechanism described by Sato and Cohen (12). Nevertheless, simultaneous and nonsimultaneous place exchanges both lead to the same microscopic arrangement of individual ions in the layer.

Continuing the above gedankenexperiment involving successive place-exchange events, one can visualize successive exchanges which follow a one-dimensional path of cations extending through the oxide to the metal interface. This leads us to the conclusion that the radioactive tracer oxygen ion would still have moved only a distance of d_0, even though the hopon would have moved all of the way through the oxide.

One result of this sequence of place-exchange events along a path of ions extending from the oxygen interface to the metal interface is the transport of one oxygen anion from the oxygen interface through the oxide to the metal interface, which anion can react with the metal to form more oxide. The sequence of events involving the creation of the hopon, the subsequent movement of the hopon through the medium, and the annihilation of the hopon at the end of its journey, will be referred to as a "hopon chain," or simply a "chain." This sequence of events (the chain) is depicted in Fig. 3. The last step, namely, the chemical reaction with the metal, can likewise be viewed as a place-exchange event, with the oxygen anion exchanging places with a metal cation in the metal surface. This latter event differs from the very first place-exchange event in that some free energy due to Coulomb forces is now liberated instead of absorbed. Interfacial equilibrium at the metal interface should therefore be a very good approximation even during rapid growth of the layer. In the interest of characterizing the last step quantitatively, we can designate the energy released as U_A, the subscript A indicating annihilation of the hopon which was created at the oxide-oxygen interface. The difference $U_A - U_H$ is a quantity related to the free energy U_{oxide} liberated in the formation of the oxide.

In the case of externally applied voltages, the question of charge balance during hopon motion is easily resolved, since charge can then be transported by electrons through the external circuit employed to set up the electric field in the oxide. This is, whatever charge is transported through the oxide due to motion of hopons can be equivalently transported through the external circuit by electrons to maintain a uniform steady-state loop current in the closed electrical circuit. Since any net mass current due to the motion of hopons is accompanied by an attendant charge current, hopon transport will in general require either such externally applied voltages, or else will require a corresponding electronic current through the oxide itself equivalent to that given by the coupled currents condition (17) in thermal oxidation.

Fig. 3. Chain of sequential place-exchange events labeled 1, 2. 3, . . . , N_1 which initiates at the oxygen interface and eventually leads to transport of one anion down a given row of ions in the compound extending from the oxygen interface to the metal interface. (This is an-on transport.)

Energies involved in bulk-limited place exchange.—To review the energies which have been introduced, there is first of all the formation energy U_H of the hopon, then there are the activation energies $W^{(f)}$ and $W^{(r)}$ for forward and reverse place exchange leading to forward and reverse motion of the hopon through the amorphous or crystalline medium, and last there is the annihilation energy U_A of the hopon. To the free energies U_H and U_A might be added the electrostatic potential energies $q_H E_0 d'$ and $q_H E_N d''$ due to the applied electric field, where d' and d'' represent in the present situation the atomic distances at the metal-oxide and the oxide-oxygen interfaces and the quantities E_0 and E_N represent, respectively, the electric fields at these interfaces. [Although d' and d'' may be the same as d_0, the lattice constant within the oxide, we allow for the possibility that these lattice parameters at the interfaces can be different because of the different number of chemical bonds at the interfaces. This has been treated by Young and Dignam (33).] However, such electric-field modifications in the interfacial free energies represent a higher order effect which frequently can be neglected. The above energies represent the ones of primary interest for a nonsimultaneous place-exchange transport mechanism which is rate limited within the bulk three-dimensional oxide, with near equilibrium conditions prevailing at the two interfaces.

Possibility of rate limitation by place exchange at the interfaces.—Let us consider, on the other hand, the possibility that the bulk oxide is near equilibrium, with the interfaces representing the rate-limiting step for transport. Then the electrostatic free energy differences $\Delta\mathcal{E}_P = q_H E d_0$ within the oxide (instead of the activation energy and the field modifications of such) become important. In addition, in this case the interfacial activation energy barriers and the field modifications $q_H E_0 a'$ and $q_H E_N a''$ of such (instead of the free energies of place exchange at the interfaces) become quite important. The parameters a' and a'' are related to the hopping distances d' and d'' at the interfaces; to first order, $a_0' = \frac{1}{2} d'$ and $a_0'' = \frac{1}{2} d''$.

Microscopic order in the cation and anion arrays.—Let us now continue our earlier gedankenexperiment and ask what happens when a new series of place-exchange events takes place along the same path which the first virtual defect followed to the metal interface. To recall the physical situation at the end of the first chain, refer to the event labeled N_1 in Fig. 3. The initiation step in the second chain is depicted by the event labeled 1 in the center of Fig. 4. The next step in the second chain is the second place-exchange event depicted in chain 2 in Fig. 4, and the third and fourth place-exchange events in the second chain are likewise depicted in Fig. 4. It is interesting to note that a tagged tracer oxygen ion would have now moved a distance $2d_0$, which thereafter remains unchanged throughout the course of the second chain. Analogously, a tagged tracer metal ion in the metal surface participating in the two chains considered above would move a distance d_0 in the direction of the oxide-oxygen interface at the end of the first chain, and would move an additional distance d_0 in the same direction near the end of the second chain. (This can be deduced by studying the sequence of events depicted in Fig. 5.) A different tracer oxygen which adsorbs on the oxide at the site of origination of the second chain would move one unit (namely, d_0) toward the metal interface if it becomes involved in the initiation of the second chain (see Fig. 4). A second tagged metal cation in the metal surface directly underneath the first tracer metal cation involved in the first chain will participate in the second chain, moving one unit in the direction of the oxide-oxygen interface at the end of the second chain (see Fig. 5).

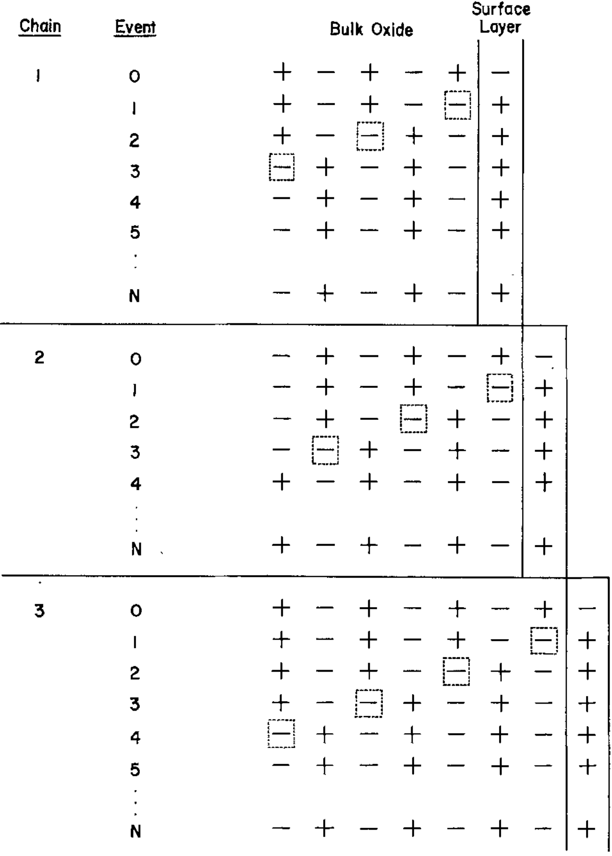

Fig. 4. Initiation of a series of sequential hopon chains (labeled 1, 2, 3) at the oxygen interface which lead to anion transport down a given row of ions in a compound, with the initiation of each chain leading to formation of new oxide at the oxygen interface.

Comparison of microscopic order for chains initiating at the gas interface with predictions of the hopping model.—Of very great interest is the order-preserving property of the nonsimultaneous place-exchange transport mechanism presently under consideration. Each successive chain initiating at the oxygen interface effectively marches each involved anion through one unit distance along the path toward the metal-oxide interface, and simultaneously marches each involved cation along the path through one unit distance toward the oxide-oxygen interface.

In contrast, consider the transport of other types of defect initiating at the oxygen interface in the hopping model. Each anion interstitial transported along a hopping path involves no individual movement of the ions in the already formed oxide; the new oxide formed as a consequence of transport to the metal interface is located at the metal interface, so it gradually shifts the layer of already formed oxide away from the metal interface. Each cation vacancy transported along a hopping path results in the shift of each cation on the path a distance of one unit toward the oxygen interface; the new oxide formed as a consequence of transport of the cation vacancy to the metal interface is formed at the oxygen interface. Thus, anion interstitial transport preserves the microscopic arrangements of both cations and anions within the already formed oxide, whereas cation vacancy transport preserves the microscopic arrangement of anions within the already formed oxide but shifts each cation along the path one unit nearer to the oxide-oxygen interface.

Initiation of chains at the metal interface and comparison of microscopic order with predictions of the hopping model.—Let us consider the alternate possi-

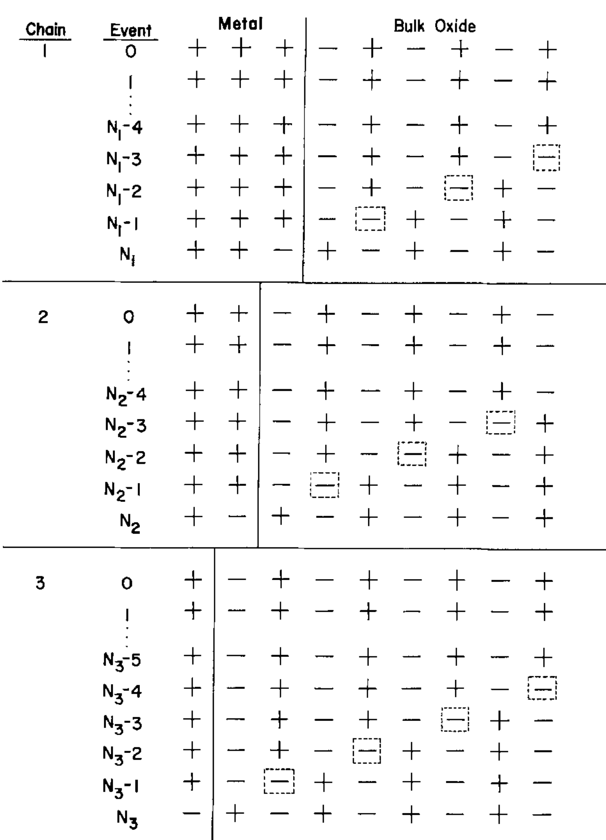

Fig. 5. Termination at the metal interface of the series of sequential hopon chains (labeled 1, 2, 3) which initiated on a given row of ions in the compound at the oxygen interface (Fig. 3), with each termination of a chain leading to formation of new oxide at the metal interface.

bilities of the movement of hopons and other point defect species originating at the parent metal interface and subsequently moving in the direction of the oxygen interface. An initial place-exchange event at the parent metal interface is depicted by event 1 in Fig. 6. The second, third, and other successive events in the chain are likewise depicted in Fig. 6.

It is interesting to note that the excess charge in the oxide is positive for the present case. This is opposite in sign to the excess charge produced in the oxide when a chain initiates at the oxygen interface. That is, when the chain initiates at the oxygen interface, a cation is thrust out of the oxide simultaneously while an adsorbed oxygen is thrust into the oxide as an excess anion, giving rise to an excess of negative charge within the oxide. However, when the chain initiates at the metal interface, a cation is thrust into the oxide simultaneously while an oxygen is thrust out of the oxide into the surface layer of metal ions, giving rise to an excess of positive charge within the oxide. The directions of motion of the two types of hopon are likewise opposite, since the hopon initiating at the oxygen interface moves toward the metal while the hopon initiating at the metal interface moves toward the oxygen. Because of the signs of the effective charges and the directions of motion, a hopon initiating at the oxygen interface will be referred to as an "an-on," in analogy with an excess anion, and a hopon initiating at the metal interface will be referred to as a "cat-on," in analogy with an excess cation.

The last event in the presently considered chain initiating at the metal interface is depicted as event N_1 in Fig. 6; this is the place-exchange event occurring at the oxide-oxygen interface. Thus a hopon chain originating at the metal interface (*viz.*, a cat-on) is merely the time-reversed version of a hopon chain originating at the oxygen interface (*viz.*, an an-on). (Compare, for example, Fig. 3 and Fig. 6.) In both situations, each cation in the path is marched one unit toward the oxide-oxygen interface, and each anion in the path is marched one unit toward the metal-oxide interface. One therefore cannot deduce the source interface for place exchange by an examination of the order within the ion arrays of the formed oxide. In other words, hopon chains initiating at either interface will lead to final results which are indistinguishable, namely, the formation of comparable amounts of new oxide at the two interfaces.

In the hopping model, on the other hand, each cation interstitial transported along a hopping path involves no individual movement of the ions in the already formed oxide; the new oxide which is formed at the oxide-oxygen interface as a consequence of transport of interstitial cations to that interface covers the layer of already formed oxide. Each anion vacancy transported along a hopping path results in the shift of each anion on the path a distance of one unit away from the oxide-oxygen interface; the new oxide is formed at the metal interface. Thus, cation interstitial

Fig. 6. Chain of sequential place-exchange events labeled 1, 2, 3, . . . , N_1 which initiates at the metal interface and eventually leads to transport of one cation down a given row of ions in the compound extending from the metal interface to the oxygen interface. (This is cat-on transport.)

transport preserves the microscopic arrangements of both cations and anions within the already formed oxide, whereas anion vacancy transport preserves the microscopic arrangement of cations within the already formed oxide but shifts each anion along the path one unit away from the oxide-oxygen interface.

Our conclusion is that hopon chains can initiate at either interface. The oxygen interface may be favored because the free surface allows the strain energy to be minimized. The initiation of hopons at opposite interfaces will be independent because of the relatively large separation distance of the interfaces.

Distinguishing between various possibilities by means of marker and tracer experiments.—To summarize the over-all picture, the simultaneous motion of the cation and anion arrays in opposite directions is characteristic of the place-exchange mechanism, the independent motion of the cation array toward the oxygen interface is characteristic of the cation vacancy transport mechanism, the independent motion of the anion array away from the oxygen interface is characteristic of the anion vacancy mechanism, and the preservation of both cation and anion arrays in the already formed oxide is characteristic of the interstitial transport mechanism. In the latter situation of transport by interstitials, the new oxide forms at the oxygen interface for cation motion, but it forms at the metal interface for anion motion. These predictions are summarized in Table I along with the effective charges of the various defects.

Experimentally, then, it should be possible to distinguish between the place-exchange model and the hopping model by studying the changes in microscopic ordering of the cations and anions in the already formed oxide taking place during new oxide growth. Experiments involving tracers (34-44) and markers (11, 45, 46) should be especially helpful. Markers indicate the relative amounts of new oxide formed on each side of a given position in the oxide film following marker placement. The positions of tracers of oxygen and the metal forming new oxide after incorporation into the oxide are characteristic of the transport mechanisms producing oxide growth. A given radioactive decay is a singular event for each excited nucleus, so that a given ion is not tagged by its radioactivity in the same way as if it could be painted red or yellow and thus located over and over again. That is, each radioactive atom cannot be viewed as measurable more than once. Sophisticated techniques are now used for the actual experiments, as for example, the use of O^{18} as tracer atoms and their subsequent activation by proton bombardment to enable the determination of their average location in the oxide films. In this way the over-all order of the ions can be deduced and the time evolution of such followed by measuring the distribution of radioactivity within the ensemble. The predictions listed in Table I for the hopon transport mechanism are in qualitative accord with the experimental tracer results of Pringle (34, 35), Amsel and Samuel (41), and also others (42). The quantitative agreement is discussed later in conjunction with relative ionic transport numbers predicted by the hopon model and the corresponding experimental results deduced by marker experiments (11).

Volume-preserving condition during oxide growth.—Another important aspect of the microscopic differences between the hopping and place-exchange models is the manner in which the new oxide volume-preserving condition is satisfied. A given chain in the place-exchange mechanism results in a cation being placed at the oxide-oxygen interface and an anion becoming buried within the first layer of metal at the metal-oxide interface. (See, for example, Fig. 4 and 5.) The associated chemical reaction of oxidation causes equal amounts of new oxide to be formed at both interfaces, assuming that the cations and anions have the same magnitude valence. This conclusion is independent of the source interface where the initial place-exchange event in the chain occurs. Already formed oxide thus becomes sandwiched between layers of new oxide which form subsequently by means of the place-exchange transport mechanism. There are some local strains at the metal interface as the new layer forms there, but these strains are gradually relieved as the monolayer of new oxide is completed. For equal magnitude valences, if the oxide molecular volume is greater than twice the volume of metal required for its formation, then the entire oxide layer will gradually be shifted sufficiently into the free region (containing only gaseous oxygen, or else the passivating or anodizing solution) to accommodate this extra volume; if the oxide molecular volume is less than twice the volume of metal required for its formation, then the entire oxide layer will gradually be shifted sufficiently toward the metal to accommodate this volume difference.

On the other hand, the volume-preserving condition is somewhat different in the case of vacancy or interstitial transport. For cation interstitial transport, the new oxide is formed at the oxygen interface. There need arise no large strains at that interface when the chemical reaction of new oxide formation occurs there, because it is a free (*i.e.*, an unconstrained) interface. However, the voids left behind at the metal interface by cation interstitial motion away from this interface must somehow be eradicated if the metal is to remain in physical contact with the oxide. The microscopic voids may simply diffuse into the metal and be annihilated at the dislocations. At the other extreme, the microscopic voids may coalesce until the oxide finally separates from the metal. Vermilyea (47) has addressed this question. He concluded that there is no problem with void formation if the cations from

Anion interstitial	$Z_{ai}e$	Metal interface	Metal interface	Metal interface	0	L
Anion vacancy	$Z_{av}e$	Metal interface	Metal interface	Oxygen interface	0	d_0
Hopon	$(\|Z_a\| + \|Z_c\|)e$	Both interfaces	Metal interface	Oxygen interface	d_0	d_0

* The charge is that which is acted on by the electric field E to produce the electric force $F = qE$. The Z values are derived from the valences, with subscripts c and a denoting some cation or some anion species, respectively; subscripts i and v denote specifically that the defect species is of the interstitial or vacancy type respectively.
† The oxide thickness is L, and d_0 is the oxide lattice parameter.

the metal enter the oxide at kinks in a lattice step on the metal surface, since the step can move continuously across the metal surface until a complete layer of atoms has been removed.

For anion interstitial transport, the local strains created in accommodating the new oxide formed at the metal interface are vastly larger than for the place-exchange mechanism, since there is no simultaneous removal of a cation. The Pilling-Bedworth ratio is relevant here: If the oxide molecular volume is greater than the volume of metal required for its formation (the Pilling-Bedworth ratio being the ratio of the two), then the entire oxide layer will gradually be shifted sufficiently into the free region (containing the gaseous oxygen or the solution) to accommodate this extra volume; if the oxide molecular volume is less than the volume of metal required for its formation, then the entire oxide layer will gradually be shifted sufficiently toward the metal to accommodate this volume difference.

For cation vacancy transport, the new oxide forms at the oxygen interface; the vacancy is annihilated at the metal interface, and the void so created in the metal must be somehow eliminated if adherence of the oxide to the metal is to be maintained. Surface diffusion within the metal to a dislocation or to a surface step is a likely mechanism since the corresponding activation energy is favorably low.

For anion vacancy transport, the new oxide forms at the metal interface; the vacancy is annihilated at the oxygen interface without difficulty. However, large local strains will be created within the oxide at the metal interface if the Pilling-Bedworth ratio exceeds unity, since the new oxide must somehow be accommodated until gradually a monolayer is formed and the entire oxide has shifted sufficiently into the free region to eliminate the volume difference.

For cases of hopon transport in which the valences of the anion and cation involved in the simple exchange process are unequal, there will be unequal volumes of oxide formed at the two interfaces. The relative amounts are deduced quantitatively in one of the following subsections (*viz.*, Ionic transport numbers). Consider ΔL_a to be the volume of oxide formed at the metal interface due to oxygen anion interstitial or vacancy transport, and consider ΔL_c to be the volume of oxide formed at the oxygen interface due to metal cation interstitial or vacancy transport. Then it follows that whenever the ratio of oxide molecular volume to the corresponding volume of metal containing the same number of metal atoms exceeds $(\Delta L_a + \Delta L_c)/\Delta L_a$, then the entire oxide layer will be shifted outwardly from the metal into the free oxygen region by a sufficient amount to accommodate this extra volume. On the other hand, whenever the ratio of oxide molecular volume to the corresponding volume of metal containing the same number of metal atoms is less than $(\Delta L_a + \Delta L_c)/\Delta L_a$, then the entire oxide layer will be shifted inwardly toward the metal by a sufficient amount to accommodate the volume difference. It is shown in the subsection entitled "Ionic transport numbers" that the ratio $\Delta L_a/(\Delta L_a + \Delta L_c)$ can be identified as the relative anion transport number t_a for the ionic portion of the electrical conductivity. Thus the critical ratio referred to above is the reciprocal of t_a.

Hopon recombination.—The question arises as to whether or not there can be a correlation (or a coupling) of hopon chains initiating at opposite interfaces, and whether or not hopons moving in opposite directions (*viz.* an-ons and cat-ons) can recombine similarly to the way electrons and electron holes recombine in a solid. First of all it is intuitive that chains originating at opposite interfaces of the oxide will initiate independently because the separation distance between the two hopons is initially the entire thickness of the oxide layer. The intuition is based on the fact that the molecular forces are simply not long range forces. Furthermore, it is intuitive that there will be no correlated motion (over long distances) of cat-ons and an-ons because the directions of motion are opposite. (This is to be carefully distinguished from the two-hopon transport process discussed in the section on Two-hopon processes.) On the other hand, if two hopons initiate independently at opposite interfaces but happen to travel down the same cation-anion line, then it is possible for them to annihilate at some intermediate point within the oxide. This is somewhat analogous to the way that an interstitial cation proceeding in one direction can annihilate a cation vacancy moving in the opposite direction. Thus cat-ons and an-ons can recombine within the oxide, quite analogous to the recombination of electrons and electron holes. The annihilation of two hopons can be visualized by considering the events depicted in Fig. 3 and 6 to occur simultaneously along the same line until the hopons meet at some point within the oxide layer. The hopon recombination process involves both a recombination of the virtual charges of opposite sign of the two hopons, as well as the uniform inversion of the cation-anion pairs along a continuous line through the oxide medium. The net result is a charge transport and a mass transport through the medium which is identical to that produced by single hopons of either type. The new oxide layers are located in the same places and have the same thicknesses as they would have for transport due to a single hopon process.

Ionic transport numbers.—Relative transport numbers for oppositely charged ionic species can be deduced in marker experiments such as those of Pringle (11). The relative quantities of new oxide formed at the two interfaces during a given time interval is measured; that oxide ΔL_a formed at the metal interface is attributed to anion transport (either interstitials or vacancies) and that oxide ΔL_c formed at the oxygen interface is attributed to cation transport (either interstitials or vacancies). Transport numbers traditionally provide a measure of relative charge transport, as opposed to relative mass transport or relative oxide volume formed at the two interfaces. However, in the usual situation in which the charge of a point defect during its motion through the oxide is the same as the product of its valence in the new oxide and the electronic charge magnitude, the quantities of oxide formed at the interfaces can be converted linearly to units related to the amounts Q_c and Q_a of the charge of the cations contained within each of the two respective quantities of new oxide ΔL_c and ΔL_a formed at the two interfaces (*i.e.*, $Q_c \propto \Delta L_c$ and $Q_a \propto \Delta L_a$). The ionic transport numbers t_c and t_a are then given by

$$t_a = Q_a/(Q_c + Q_a) = \Delta L_a/(\Delta L_c + \Delta L_a) \quad [7a]$$

$$t_c = Q_c/(Q_c + Q_a) = \Delta L_c/(\Delta L_c + \Delta L_a) \quad [7b]$$

The equations deduced in this section presume that the charges of the cation and anion during hopon transport are the same as their respective valences in the new oxide being formed. The alternate equations required whenever the charge of an ion during motion is different from that in the stoichiometric oxide are deduced in Appendix E.

The question which we now address is the following: What do we expect to obtain experimentally for t_c and t_a whenever transport occurs by hopons? First of all let us consider the simplest situation as depicted in Fig. 3 or Fig. 6, namely, individual place exchange events which involve a single anion and a single cation. (This is referred to as a "diatomic" hopon.) At the conclusion of a hopon chain originating at either interface, effectively one cation has been transported to the oxide-oxygen interface and one anion

has been transported to the metal-oxide interface. If Z_c represents the valence of the cation species and Z_a represents the valence of the anion species, the charge neutral oxide molecule composed of metal M and oxygen O can be characterized by the chemical formula $M_{|Z_a|}O_{|Z_c|}$. Thus one metal ion M is sufficient to form (on the average) a fraction $1/|Z_a|$ of a molecule of new oxide, and one oxygen ion O is sufficient (on the average) to form a fraction $1/|Z_c|$ of a molecule of new oxide. Therefore, considering that each transported oxygen ion is responsible for forming the new oxide at the metal interface and each transported metal ion is responsible for forming the new oxide at the oxygen interface, then in oxide growth resulting from place-exchange events involving single anion and cation pairs (*viz.*, the diatomic case), the relative amount of oxide formed at the metal interface to that formed at the oxygen interface will be in the ratio

$$\frac{1}{|Z_c|} \div \frac{1}{|Z_a|} = \left| \frac{Z_a}{Z_c} \right| \qquad [8]$$

The ratio of the oxide formed at the metal interface to the total oxide formed will be given by

$$\frac{\Delta L_a}{\Delta L_c + \Delta L_a} = \frac{1/|Z_c|}{(1/|Z_a|) + (1/|Z_c|)} = \frac{|Z_a|}{|Z_c| + |Z_a|} \qquad [9a]$$

and the ratio of the oxide formed at the oxygen interface to the total oxide formed will be given by

$$\frac{\Delta L_c}{\Delta L_c + \Delta L_a} = \frac{1/|Z_a|}{(1/|Z_a|) + (1/|Z_c|)} = \frac{|Z_c|}{|Z_c| + |Z_a|} \qquad [9b]$$

The transport numbers experimentally determined by measurements of the relative quantities of oxide formed at the two interfaces are given by comparison of Eq. [9a] and [9b] with Eq. [7a] and [7b]

$$t_a = \frac{\Delta L_a}{\Delta L_c + \Delta L_a} = \frac{|Z_a|}{|Z_c| + |Z_a|} \qquad [10a]$$

$$t_c = \frac{\Delta L_c}{\Delta L_c + \Delta L_a} = \frac{|Z_c|}{|Z_c| + |Z_a|} \qquad [10b]$$

These predictions are summarized in Table II. As an example, consider Ta_2O_5, for which $Z_c = +5$ and $Z_a = -2$. The preceding expressions yield $t_a = 2/7$ and $t_c = 5/7$, as compared to the experimental values $t_a = 0.76$ and $t_c = 0.24$ of Pringle (11). Assuming the correctness of the experimental values, the discrepancy may be due to the existence of a more complex type of hopon transport mechanism (as described in the following sections), or else the difference may reflect additional contributions to transport by individual anion interstitials or vacancies.

Next, let us consider more complicated situations in which individual place-exchange events involve more than two ions. If the stoichiometric oxide is represented by the chemical formula $M_{|Z_a|}O_{|Z_c|}$, then an equivalent representation insofar as relative numbers of metal atoms and oxygen atoms is MO_{p_0}, where p_0 is the rational number defined by $p_0 \equiv |Z_c/Z_a|$. If rotation of the stoichiometric unit MO_{p_0} by place exchange constituted the mode of hopon transport, then equal volumes of oxide would be formed at the two interfaces. This follows from the fact that at the completion of each chain, one stoichiometric rotational unit of oxide would have been formed at each interface. (A special case of this is an oxide composed of neutral diatomic molecules.) Suppose, on the other hand, that the individual place-exchange events each involve a group having composition MO_p, where p is a rational number but in general $p \neq p_0$. (For example, if a place-exchange event involves one cation and two anions, then $p = 2$; if a place-exchange event involves two cations and one anion, then $p = ½$.) If p is less than p_0, then for each molecule of stoichiometric oxide formed by the transport of one cation to the oxygen interface by a hopon chain, a lesser amount (namely, p/p_0 of a molecule, on the average) would be formed by place exchange of oxygen with atoms of the parent metal at the metal interface. If p exceeds p_0, then for each molecule of stoichiometric oxide formed by the transport of one cation to the oxygen interface by a hopon chain, a greater amount (namely, p/p_0 molecules, on the average) would be formed by place exchange of oxygen with atoms of the parent metal at the metal interface. Hopon motion would then lead to stoichiometric oxide layers having thicknesses in the ratio of 1 to p/p_0 to be formed at the oxygen and metal interfaces, respectively. The ratio p/p_0 for the amount of oxide formed at the metal interface to that formed at the oxygen interface in turn leads to the experimental transport numbers

Table II. Prediction of experimental ionic transport numbers and the minimum ratio for (oxide volume)/(corresponding volume of metal) which can give compressive stresses at the metal interface due to volume conservation*

	Type of defect	Relative ionic transport numbers t_c	t_a	Minimum ratio of oxide volume to metal volume for compressive stresses
Cation	Interstitial	$\left\lvert \frac{Z_{ci}J_{ci}}{J_{ionic}} \right\rvert$	—	∞
	Vacancy	$\left\lvert \frac{Z_{cv}J_{cv}}{J_{ionic}} \right\rvert$	—	∞
Anion	Interstitial	—	$\left\lvert \frac{Z_{ai}J_{ai}}{J_{ionic}} \right\rvert$	1
	Vacancy	—	$\left\lvert \frac{Z_{av}J_{av}}{J_{ionic}} \right\rvert$	1
Simple hopon	General diatomic case	$\frac{\lvert Z_c\rvert}{\lvert Z_c\rvert + \lvert Z_a\rvert}$	$\frac{\lvert Z_a\rvert}{\lvert Z_c\rvert + \lvert Z_a\rvert}$	$\frac{\lvert Z_a\rvert + \lvert Z_c\rvert}{Z_a}$
	Diatomic case for $\lvert Z_c\rvert = \lvert Z_a\rvert$	½	½	2
Complex hopon	General multi-atom case	$\frac{\lvert Z_c\rvert}{\lvert Z_c\rvert + \lvert Z_a\rvert p}$	$\frac{\lvert Z_a\rvert p}{\lvert Z_a\rvert p + \lvert Z_c\rvert}$	$\frac{\lvert Z_a\rvert p + \lvert Z_c\rvert}{\lvert Z_a\rvert p}$
	Multi-atom case with charge neutral rotational unit	½	½	2

* Notation is as follows: ci denotes cation interstitial; cv denotes cation vacancy; ai denotes anion interstitial; av denotes anion vacancy; J_{ionic} is the total ionic charge current in units of electrons-m^{-2}-sec^{-1}; p is the ratio of O to M ions in the place exchange unit (*e.g.*, MO_p), with $p = 1$ for the simple place exchange of an M with an O.

$$t_a = \frac{p/p_o}{(p/p_o)+1} = \frac{p}{p+p_o} = \frac{p}{p+|Z_c/Z_a|} = \frac{|Z_a|p}{|Z_a|p+|Z_c|} \quad [11a]$$

$$t_c = \frac{1}{(p/p_o)+1} = \frac{p_o}{p_o+p} = \frac{|Z_c/Z_a|}{|Z_c/Z_a|+p} = \frac{|Z_c|}{|Z_c|+|Z_a|p} \quad [11b]$$

For the simple place-exchange mechanism involving a single anion and a single cation, $p = 1$ and the above formulas reduce to the results [10a] and [10b] already derived. For $p = 2$, however, these formulas yield for Ta_2O_5 the values $t_c = 5/9$ and $t_a = 4/9$. For $p = 1/2$, on the other hand, these formulas yield for Ta_2O_5 the values $t_c = 5/6$ and $t_a = 1/6$. From another viewpoint, if we assume $t_c = 1/4$ for Ta_2O_5, in accordance with Pringle's results (11), then we have the relation

$$\frac{1}{4} = \frac{5}{5+2p} \quad [12]$$

which gives $p = 7\frac{1}{2}$. This would correspond (rightly or wrongly) to rotation of a group Ta_2O_{15} in each individual place exchange. In some respects this type of a rotation would be similar to the ring mechanism for diffusion in metals postulated by Zener (10), but as previously discussed, the hopon mechanism is promoted strongly by the electric field, whereas the ring mechanism is not influenced by the field.

Consider now the limiting case in which the value of p is the same as $p_o \equiv |Z_c/Z_a|$. Then the basic rotational unit is a neutral entity having the same composition as the stoichiometric oxide, and Eq. [11a] and [11b] yield straightaway $t_a = 1/2$ and $t_c = 1/2$. This result is in agreement with the above conclusions for this situation.

In Al_2O_3 and Nb_2O_5, the experimental transport numbers for the cations have been reported to have the values $t_c \simeq 0.37$ and 0.25, respectively (48). The value 0.37 for aluminum is within the range 0.33 to 0.41 (49, 50) obtained in the electrolyte aqueous ammonium dihydrogen citrate, but it is outside of the range 0.54-0.63 given for the electrolyte sodium tetraborate in ethylene glycol. The value of 0.25 for niobium is within the range of values 0.22-0.33 given by other experiments (49) using 0.1 molar aqueous Na_2SO_4 as the electrolyte. It is evident that the unit of rotation for Nb in Nb_2O_5 cannot be the neutral molecule, since the relative transport numbers do not have the value 0.5. It is quite interesting that $t_c \simeq 1/4$ in both Ta_2O_5 and Nb_2O_5, even though the chemical bonding of Ta and Nb is probably sufficiently different to yield significantly different values for the activation energy for cation motion. This lends credence to the place-exchange hypothesis that a molecular group is involved in some fundamental way in the transport mechanism. Since crystal structure is not such an important factor in amorphous oxides, one might expect an important factor to be the ratio of anions to cations in the neutral oxide molecule.

Applying the above formulas to Al_2O_3, utilizing $t_c = 1/3$ together with $Z_c = +3$ and $Z_a = -2$, leads to the result $p = 3$. This would correspond to the rotation of the molecular group AlO_3 in each place-exchange event, which indeed differs from the results for Ta_2O_5 and Nb_2O_5. (Using $t_c = 2/5$ leads to the result $p = 2.25$ for the aluminum oxide case, corresponding to the molecular group Al_4O_9.)

It is to be recognized that the specific numbers deduced in this way depend on the experimental measurements available at the present time. The results are nevertheless quite suggestive of the idea that transport under the presently considered conditions of high externally applied electric fields involves some type of cooperative motion between the cations and anions in the medium. In addition, it has been verified experimentally that the order of the oxygen ions is conserved (34, 39). [The oxygen atoms are fixed according to their order of arrival during the formation of amorphous compact layers on aluminum or tantalum, according to Cherki and Siejka (39), such that the oxygen atoms belonging to a new layer are located at the oxide-solution interface.] Likewise, in the case of Ta_2O_5 it has been found that the order of the tantalum ions is conserved (35, 42). For these reasons, the presently described hopon mechanism seems to provide the basis for a viable model of anodic oxidation.

Two-Hopon Processes for Transport in Three-Dimensional Systems

The Coulomb energy for hopon transport in a three-dimensional system (see Fig. 7 and 8) would increase continuously with successive place-exchange events because of the interaction between charges in the lateral directions. This undesirable feature can be essentially eliminated if a second hopon follows the first in a closely correlated manner down a single chain. (Possibly a mechanism involving laterally adjacent chains could also be envisioned.)

Consider, for example, the two-hopon process depicted in Fig. 9, and let us compare the Coulomb energy of this process with that of a one-hopon process for a three-dimensional system. It can be noted from Fig. 7 and 8 that the sequential reversal in the electric dipole orientation which can be accomplished without any additional energy input in a one-dimensional system (see Fig. 2) would require a linear increase in the energy due to lateral Coulomb interactions in the three-dimensional system, as mentioned above. This would quickly become prohibitive, so energetically it is favorable for the first place exchange to be closely followed spatially and temporally by a second place exchange which reinverts the orientation of the line of electric dipoles. The correlated motion of these two place exchanges through the oxide layer, as illustrated in Fig. 9, then requires no continuous input of energy, so in this respect the situation reverts energetically to that of the single place exchange moving down a line of atoms which is shown in Fig. 2.

Collective Hopon Transport

There are two closely related possibilities for the nonsimultaneous place exchange mechanism. First of all there is the situation already described in which it is implicit that each local place-exchange event has

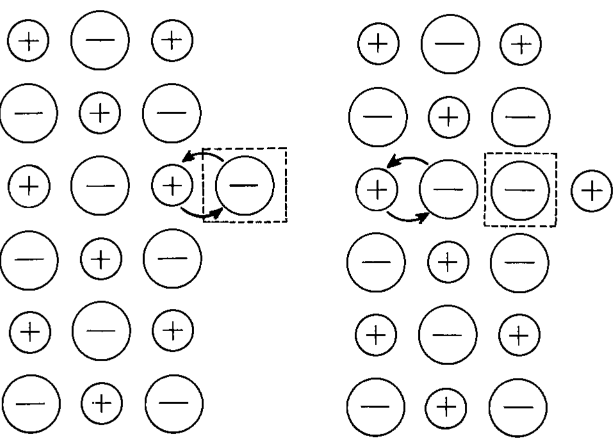

Fig. 7. Lateral Coulomb interactions produced by a one-hopon process down a row of ions extending through a three-dimensional oxide. (Left drawing: first place-exchange event; right drawing: second place-exchange event.)

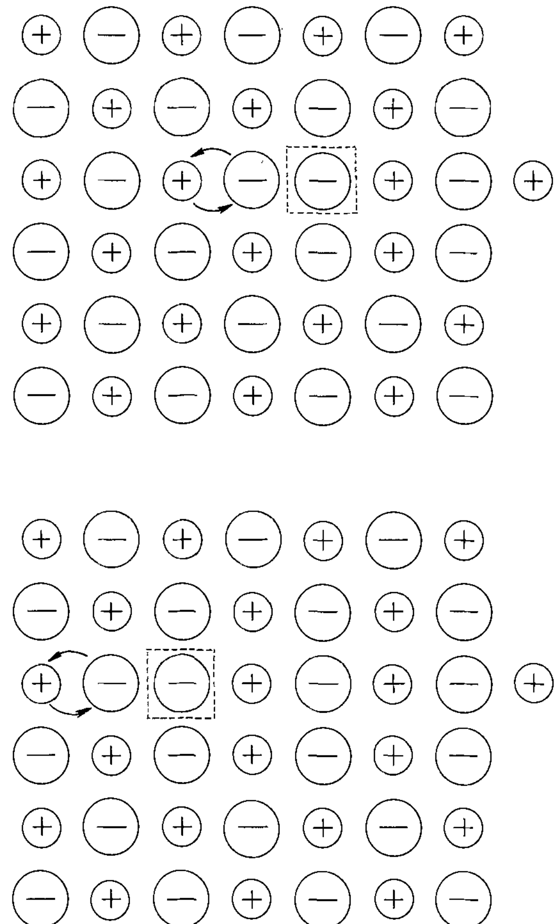

Fig. 8. Continuous Coulomb energy increase resulting from one-hopon transport down a row of ions extending through a three-dimensional oxide. (Upper drawing: third place-exchange event; lower drawing: fourth place-exchange event.)

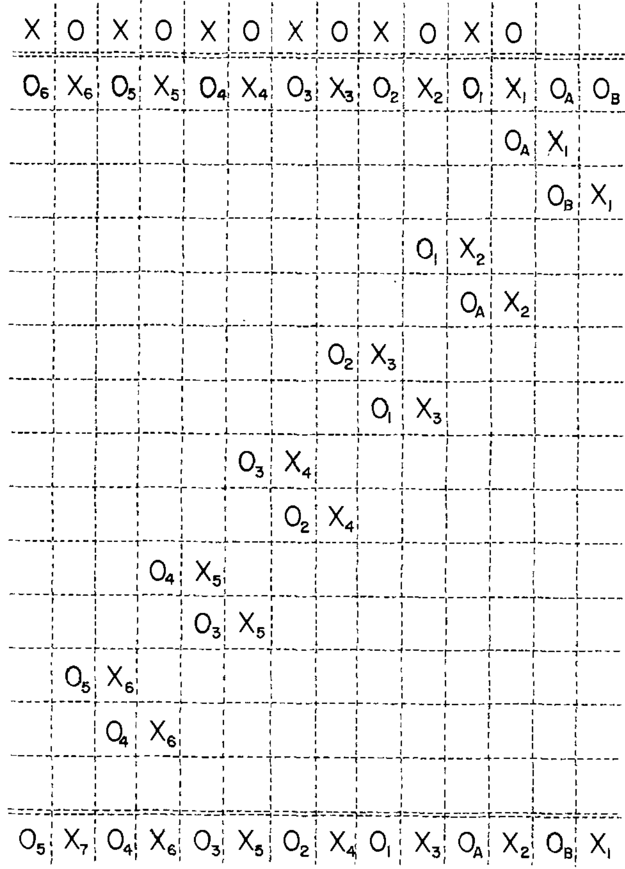

Fig. 9. Two-hopon transport process leading to temporal correlation of the transport of two anions (labeled O_A and O_B) through a compound made up of cations (labeled X_j, with $j = 1, 2, 3, \ldots$) and anions (labeled O_j, with $j = 1, 2, 3, \ldots$). [The top two rows indicate two lateral rows of ions in a compound, with adsorbed oxygens O_A and O_B at the end of one of the rows. Each successive row downward from the second in the configuration indicates the change in the preceding configuration produced by a single place-exchange event. A given row position thus indicates a given time. Each column indicates a given site in the lattice. At a given point in time (corresponding to a given row), the ion occupying any given column site is indicated by the nearest vertical entry upward in the column, beginning with the row in question. The second row indicates the starting configuration, and the bottom row indicates the final configuration. The important point to be noted is that the type of ion (cation or anion) occupying a given site is the same after completion of two-hopon transport down the row as it was initially. Furthermore, the Coulomb interaction energy remains constant during two-hopon transport once the two defect anions (O_A and O_B) enter the oxide.]

been completed before the adjacent place-exchange event along the chain begins. This situation represents a time and spatial sequence of individual (but correlated) place-exchange events occurring one at a time which eventually lead to completion of a hopon chain. There is a second possibility, however, in which each locally adjacent place-exchange event begins even before the first place-exchange event has been completed. This constitutes a collective behavior amounting to extension of the place-exchange event over distances larger than the atomic spacing in the medium (see Fig. 10). Perhaps the easiest way to understand this latter proposal is to consider the wavelike propagation of the disturbance associated with a falling row of dominos triggered by an initial push at one end of the row. Each domino begins to fall at a different point in time; the sequential tipping over of the various dominos in the row is collective but not simultaneous. In the same way, a single place-exchange event which occurs at one interface (*e.g.*, at the oxygen interface in an oxide film) may constitute the initiation of a time sequence of correlated partial place-exchange events which propagate at a finite speed down a chain.

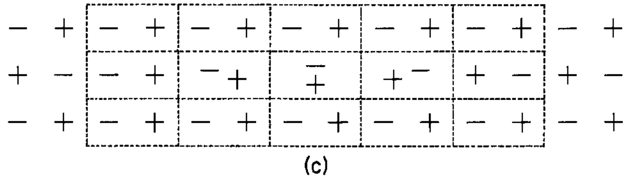
We refer to the above two possibilities as "noncollective" and "collective" hopon transport mechanisms, respectively. Noncollective hopon transport is characterized by a thermally activated electric field-modified motion of a highly localized place-exchange disturbance which jumps statistically in time from place to place in the medium. Collective hopon transport is characterized by a thermally activated electric field-driven motion of an extended wavelike place-exchange disturbance which propagates at a finite velocity through the medium. The limit in which the propagation velocity approaches infinity provides the closest approximation to the Sato-Cohen model (12). There are still some differences, namely, different activation energies and the dependence of these energies on oxide layer thickness.

It is evident that the two-hopon process can involve either the collective or the noncollective mechanism. Perhaps the a-c response and corresponding frequency dependence of the dielectric loss (51) within the film can be employed to distinguish between the various possibilities for any specific experimental system.

Discussion

The purpose of this paper has been to develop in some detail a microscopic picture for a specific high field transport mechanism, *viz.*, place exchange of oppositely charged ions in a solid. A quantitative basis is developed for deducing the transport rate due to this mechanism, which in turn can be applied to deduce the kinetics of anodic film formation on metals.

(a)



(b)

(c)

Fig. 10. Collective one-hopon transport [diagram (b)] contrasted with noncollective one-hopon transport [diagram (a)]. (In diagram (a), a single dipole consisting of a place-exchange pair is depicted in the process of flipping at some instant of time. In diagram (b) a group of adjacent dipoles are in various stages of flipping at a given instant of time. As time passes, the disturbance travels in one direction or the other with finite velocity. Diagrams (a) and (c) indicate the Coulomb interaction energy of the two types of disturbance with lateral rows of ions in the oxide.)

Although the basic idea that place exchange may give rise to transport through a three-dimensional layer dates back to the work of Sato and Cohen (12), it is only in the light of relatively more recent experimental results (11) indicating transport numbers of the same order of magnitude for oppositely charged ions that it seemed worthwhile to the present author to consider such a mechanism more seriously.

While it is relatively easy to compare the predictions of the presently considered hopon model with the predictions of other microscopic transport mechanisms (see Tables I and II, for example), it is more difficult to compare its predictions with phenomenological models which are not well defined from a microscopic viewpoint. One such model is the "network defect model" of Dignam (49) which was postulated to explain coupled cation and anion transport. Transport numbers, for example, are considered to be meaningless entities in the Dignam model, whereas these quantities are well defined in the hopon model. It is also difficult or impossible to estimate activation energies and the field modification of such in cases where the microscopic transport mechanism is unspecified. According to Dignam (49), the essence of the network defect model is a bond breaking and rearrangement, but this must indeed be characteristic of any transport mechanism because the motion of any defect involves a local modification in the chemical bonds of the surrounding atoms in the solid. Perhaps the unique features of Dignam's model are summarized in the following quotations:

> Within the framework of the random-network model of the vitreous state as proposed by Zachariasen [(52)] a defect can be imagined to form by rupture of one of the metal-oxygen bonds, followed by separation of these "dangling bonds" through a succession of processes each of which may be described as an exchange of partners.
>
> Such defects may be described alternatively as regions of local nonstoichiometry bearing a single charge, positive in the case of cation-network defects and negative in the case of anion-network defects, in order to satisfy valency requirements.
>
> . . . as the disturbance moves through a given region of the vitreous network, the atoms are displaced irreversibly; no single atom, however, is displaced as far as one interatomic distance.
>
> . . . ion transport by this mechanism maintains the order in both the anion and cation subnetworks, except for a small amount of reordering arising from the random nature of the transport process.
>
> . . . there can be no such thing as a unique marker that can be inserted into the vitreous film to define a position against which to measure unique transport numbers.

The Dignam model does not appear to be specific in the sense that it postulates any given microscopic transport mechanism. Apart from the fact that the hopon model is based on a specific microscopic mechanism, namely, place exchange, there are clearly a number of important differences between the Dignam network model and the hopon model. Among these are the distances traveled by any given ion in the oxide matrix per transported ion, the value of the defect charge, the relative amounts of oxide formed at the two interfaces, the relevance of the concept of transport numbers, and the general intuitive picture of how transport takes place.

Pringle (11) has listed five possibilities for the growth of new oxide, namely, the following: (*I*) The metal alone migrates, and the reaction to form new oxide occurs only at the oxide/oxygen interface. (*II*) The oxygen alone migrates, so that the new oxide is formed only at the metal/oxide interface. (*III*) When both metal and oxygen migrate, these two mechanisms could occur together, so that new oxide would be formed at both interfaces. (*IV*) When both the metal and oxygen migrate, however, the new oxide does not have to be formed at the interfaces; it could be formed within the existing oxide through the transport of material from each side. (*V*) Since mechanisms *III* and *IV* are not mutually exclusive, the new oxide could be formed both within the existing oxide and at the interfaces.

Although these possibilities in no way constitute microscopic transport mechanisms, they do more or less categorize the various possibilities to be considered when interpreting the marker and tracer experiments (11, 34). It can be noted that hopon transport leads to mode *III* in the above listing; this is also the category chosen by Pringle (11) as being the one most in accord with his radioactive noble gas marker experiments. Pringle makes the point that radioactive noble gas marker experiments can only determine how much of the new oxide is being formed by metal and/or oxygen migration; they cannot determine how the individual atoms migrate. A marker for oxygen itself is required to delineate more specifically how the oxygen moves. The conclusion was reached on the basis of the tracer experiments (34) that the oxygen atoms jump a distance corresponding to not much more than one interoxygen distance. This again is in accord with the predictions of the hopon mechanism. Likewise, recently reported measurements (35) of the motion of the tantalum ion during anodic oxidation are in accord with the hopon mechanism.

The intuitive picture which Pringle (11) put forth for the transport mechanism through anodic oxides formed on tantalum is perhaps best summarized by the following quotation:

> In this model . . . each moving atom carries a fraction of the charge a fraction of a "lattice spacing" in such a way that the total effect is equivalent to one charged atom jumping one "lattice spacing." Both tantalum and oxygen take part in this process, so that the lattice loses its rigidity during the charge transfer event.

To quote from the later experimental paper by Pringle (34) on the oxygen tracer work:

> The nature of the oxygen migration is thus rather obscure, but the present results are not inconsistent with the hypothesis put forward in a previous paper . . . that charge is transferred during the anodic oxidation of tantalum via the simultaneous movement of a group of atoms, both tantalum and oxygen.

It therefore seems apparent that Pringle did not have any specific microscopic transport mechanism in mind. It is not specified how the tantalum and oxygen are moving as a group, and it is not specified how the charges are distributed and how the net charge is carried through the medium. The above statements could be more or less consistent with a number of microscopic transport mechanisms.

Vermilyea (24) has speculated that in amorphous Ta_2O_5 the local configuration of ions surrounding each tantalum ion changes with the passage of current and thus depends on the conditions of formation (*i.e.*, the past history) of the oxide. This idea seems to be closely related to the intuitive picture underlying the network defect model (49) discussed earlier.

Young (53), in his paper on the steady-state kinetics of formation of anodic oxide films in sulfuric acid, pointed out the possible importance of the glassy structure (54) of the anodic oxide. This represented an early recognition of the relevance of the early work of Zachariasen (52) on glasses which others (55) since that time have cited as being relevant to metal oxidation.

Amsel and Samuel (41) discussed the possible transport mechanisms involved in anodic oxidation in the light of their experimental results using O^{18} isotopes. Because perfect conservation of order was observed for the oxygen in the oxide layer during growth, with the already formed oxide remaining at the metal interface and new oxygen being incorporated at the solution interface, it was concluded that the oxygen ions either did not move, or else that they move by highly correlated vacancy diffusion, the vacancies originating from the lattice plane in contact with the metal. From experiments using two metals simultaneously (Al and Ta), they concluded in addition that metal ions move by creation and subsequent annihilation of an atom or vacancy, with several possibilities discussed for this process. Cation vacancy diffusion coupled with exchange capture of cation interstitials were considered quite likely, the latter evidently being an interstitialcy mechanism (8).

Dewald (56) treated the effects of space charge on the ionic current. An extension of this single carrier model to include concentration gradients has been given by Fromhold and Kruger (57), and analytical results for the very high field limit have been deduced (58).

Fisher, Bean, and Vermilyea (59) have examined the role of the surface charge field in lowering the barriers for ionic hopping at the oxide interfaces, and Dignam (60) has examined the effects of asymmetry introduced into the potential energy barriers by the field. Dankov (61) has pointed out the role of stresses in thin oxide layers. Other creative ideas on transport mechanisms possibly relevant for anodic oxide formation have been summarized by Young (62).

The question of the experimental kinetics for anodic film formation is still being debated in the literature. Whereas Sato and Cohen (12) found a direct logarithmic growth law for the anodization of iron, Draper and Jacobs (63) found a space-charge modified growth law similar to that predicted by the work of Dewald (56). The latter would be in better accord with the theoretical predictions of the present model, which gives rise to the same kinetics as predicted by the space-charge gradient model (57, 58) for single carrier transport. Moshtev (64) found that even in the case of iron, the steady-state growth kinetics in the passive region using neutral solutions could be best described by a field-assisted single carrier transport equation of the same basic type as the space-charge gradient model. Thus the present model of anodic film formation by hopon transport is reasonably consistent with much of the published experimental data.

The central points which have been made in the present development of hopon motion are the following: (*a*) The postulated hopon transport is a new type of place exchange (nonsimultaneous) which leads to a different kinetics of growth from the simultaneous place-exchange mechanism of Sato and Cohen. (*b*) The structural ordering of the cation and anion lattices resulting from this specific microscopic transport mechanism of hopon motion has been carefully delineated and compared with the ordering expected for transport by cation and anion vacancies and interstitials. (*c*) An electric field represents an important driving force for hopon transport.

Conclusions

The nonsimultaneous place-exchange mechanism has certain features (primarily the microscopic ordering of cations and anions) which are very similar to the collective place-exchange model of Sato and Cohen; nevertheless, this mechanism has other features (primarily the kinetics) which are more closely related to the hopping model of Verwey. In fact, the reason that the picture of nonsimultaneous place exchange is so attractive is that it incorporates the best features of the hopping transport mechanism and the place-exchange transport mechanism. The energetically most favorable mechanism for any particular system will of course prevail. In some systems, this may be a hopon mechanism; in others, it will be the pure hopping of interstitials or vacancies. Since the microscopic order preservation is quite different for the various models, as summarized in Table I, radioactive tracer experiments can aid in differentiating between the possibilities for a given system.

The following interesting conclusions have been reached regarding oxide growth by means of the above-described hopon transport mechanism:

1. The new metal ions are incorporated at the metal interface and the new anions are incorporated at the oxygen interface; hopons can, in principle, initiate at either interface.
2. The microscopic order of the cations and anions within the line of atoms involved in a hopon chain are individually preserved during subsequent transport, since each cation is marched one unit cell distance away from the metal interface and each anion is marched one unit cell distance toward the metal interface with each successful termination of a hopon chain.
3. The transport numbers for the oppositely charged ionic species will be of the same order of magnitude.
4. Hopons result in the transport of a net charge through the medium; the rate of such transport will be markedly dependent on any applied or built-in electric field.
5. Space charge effects are much the same as for interstitials or vacancies.
6. A hopon gradient acts as a driving force for transport.
7. Many stress effects are quite analogous to those predicted for the hopping of vacancies or interstitials, though some of the quantities (*e.g.*, the Pilling-Bedworth ratio) must be replaced by different values.
8. The kinetics of oxide formation for hopon transport are quite analogous to those predicted by the lattice interstitial or vacancy hopping model.

Acknowledgments

The author enjoyed interesting discussions of hopon transport with Dr. J. S. L. Leach and Dr. N. Sato

while at the Passivity Symposium in Airlie, Virginia, and he wishes to thank Dr. R. P. Frankenthal and Dr. J. Kruger for giving him the opportunity to present the work at that conference. The author also enjoyed discussing the hopon mechanism with Dr. G. Amsel at the Anodic Films Symposium in Seattle, Washington.

Manuscript submitted Aug. 7, 1978; revised manuscript received July 29, 1979. This was Paper 198 presented at the Seattle, Washington, Meeting of the Society, May 21-26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Auburn University.

APPENDIX A

Transport due to a Gradient of Hopons

A gradient in the density of hopons can also act as a driving force for transport. In zero electric field, for example, the particle current of hopons at the position of the potential barrier labeled k is

$$J_k = \nu \exp(-W_H/k_BT)[n_{k-1} - n_k] \quad (k = 1, 2, \ldots, N) \qquad \text{[A-1]}$$

where n_k is the number of hopons per unit area located in the potential minimum following the potential barrier labeled k. In this one-dimensional labeling scheme, there are N barriers across the oxide film, so that in terms of an atomic separation distance d_o, the thickness of the oxide film is Nd_o.

APPENDIX B

Space Charge due to Hopons

The existence of space charge in the hopon model follows from the charges associated with the virtual defects. After the initial place exchange between two ions of opposite sign, we have a situation in which an ion of one sign in the lattice is replaced by an ion of opposite sign. Thus the excess charge, relative to a stoichiometric situation of local space charge neutrality, has the magnitude

$$|q_H| = (|Z_c| + |Z_a|)e \qquad \text{[B-1]}$$

The discrete form of Poisson's equation [Eq. (8.1) in Ref. (17)] then leads to a position-dependent electric field, which in SI units is

$$E_k = E_o + (q_H/\epsilon) \sum_{j=1}^{k} n_{j-1} \quad (k = 1, 2, \ldots, N) \qquad \text{[B-2]}$$

where E_o is the electric field at the source interface, E_k is the electric field at the potential barrier labeled k, and n_j is the number of hopons per unit area located in the potential minimum following the potential barrier labeled k.

APPENDIX C

Stress Effects due to an Electrochemical Potential Gradient of Hopons

An electrochemical potential difference for hopons can produce a stress somewhat analogous to the manner in which such a gradient for other types of point defects leads to such stresses (32). The general relation that the force is given by the gradient of the electrochemical potential $\tilde{u}$ leads to

$$F = -\frac{d\tilde{u}}{dx} \qquad \text{[C-1]}$$

for the force acting on each defect at position x in the oxide. For a bulk concentration C of hopons, a good approximation to the electrochemical potential $\tilde{u}$ is given by

$$\tilde{u} = k_BT \ln C + q_HV \qquad \text{[C-2]}$$

where V is the electrostatic potential determined in the usual way by a spatial integral of the electric field in accordance with Poisson's equation [see Sec. 4, Chap. 3 in Ref. (17)].

APPENDIX D

Fundamental Kinetics Equation for Oxide Growth by Hopon Transport

The kinetics of oxide formation are determined from the differential expression (17)

$$\frac{dL}{dt} = RJ_o \qquad \text{[D-1]}$$

where L is the oxide thickness, t is the time, J_o is the steady-state current of hopons, and R is the volume of oxide formed per hopon which traverses the oxide film from $x = 0$ to $x = L$. The local steady-state particle current J_k at the potential barrier labeled k is determined by the hopon gradient and the electrical force q_HE in accordance with the hopping expression

$$J_k = \nu \exp(-W_H/k_BT)[n_{k-1} \exp(q_H a_k^{(f)} E_k/k_BT) - n_k \exp(q_H a_k^{(r)} E_k/k_BT)] \quad (k = 1, 2, 3, \ldots, N) \qquad \text{[D-2]}$$

where $a_k^{(f)}$ is the forward hopping distance at barrier k, $a_k^{(r)}$ is the reverse hopping distance at barrier k, ν is an attempt frequency for place exchange, and all other parameters have been previously defined. The forward and reverse hopping distance $a_k^{(f)}$ and $a_k^{(r)}$ can differ because of the asymmetry introduced by superimposing the asymmetrical electrical potential energy on an otherwise symmetric potential energy barrier (29, 60). The integration of the above series of coupled difference equations can be carried out analytically or numerically in the limit of the steady state to obtain the hopon current density J_o required above for the kinetics. The results are the same as those obtained specifically for the case of one-species transport in the presence of space charge of the mobile species and a concentration gradient (57, 58).

APPENDIX E

Case of Transport by Ionic Defects Having a Variable Valence

Consider the situation in which new oxide having the stoichiometric composition MO_{p_o} is being formed, with the metal ion valence Z_c and the oxygen ion valence Z_a, with $p_o \equiv |Z_c/Z_a|$. Consider simultaneously the basic rotational unit to have a composition described by MO_p, with the metal ion charge during transport being $Z_c'e$, and the oxygen ion charge during transport being $Z_a'e$. The transport numbers based on relative charge transport would then be given by

$$t_a' = \frac{p|Z_a'|}{p|Z_a'| + |Z_c'|} \qquad \text{[E-1]}$$

$$t_c' = \frac{Z_c'}{p|Z_a'| + |Z_c'|} \qquad \text{[E-2]}$$

whereas the transport numbers computed from the relative amounts of oxide formed at the two interfaces would be given by

$$t_a = \frac{p/p_o}{(p/p_o) + 1} = \frac{p}{p + p_o} = \frac{p}{p + |Z_c/Z_a|} = \frac{p|Z_a|}{p|Z_a| + |Z_c|} \qquad \text{[E-3]}$$

$$t_c = \frac{1}{1 + (p/p_o)} = \frac{p_o}{p + p_o} = \frac{|Z_c/Z_a|}{p + |Z_c/Z_a|} = \frac{|Z_c|}{p|Z_a| + |Z_c|} \qquad \text{[E-4]}$$

It is to be noted by comparing Eq. [E-1] with Eq. [E-3], and also comparing Eq. [E-2] with Eq. [E-4], that the experimental values for the transport numbers deduced on the basis of relative amounts of oxide formed at the two interfaces are not in accord with the true transport numbers as determined on

the basis of charge transport. Although it might seem unlikely that Z_c' and Z_a' would differ from Z_c and Z_a in hopon transport, nevertheless one should keep an open mind as to various possibilities.

It is interesting that even in the case of transport by a single type of interstitial (or single type of vacancy) with some attendant electron transport, the ionic and electronic transport numbers obtained by a comparison of mass and charge transport will only be correct if the actual charge of the ionic defect during transport can be ascertained. Otherwise, the correct transport numbers are obtained only if the defect charge during transport is the same as that determined from the valence in the oxide being formed. As a specific example, consider the transport of cation interstitials and electrons. The meter current and the oxide growth rate will be given by

$$I_{\text{meter}} = Z_{ci}'eJ_{ci} + |(-e)J_e| \qquad \text{[E-5]}$$

$$\frac{dL}{dt} = R_{ci}J_{ci} \qquad \text{[E-6]}$$

where R_{ci} is the volume of new oxide formed per cation interstitial transported through the oxide film. The above constitute two equations and two unknowns. If $Z_{ci}'e$ is assumed to be equal to $Z_{ci}e$, then knowing the left-hand sides from measurements of the meter current and the oxide growth rate, together with the constant R_{ci} computed from the oxide density, then we can solve the two equations simultaneously to obtain the values of J_{ci} and J_e. Then the true transport numbers are given by

$$t_i' = Z_{ci}'eJ_{ci}/(Z_{ci}'eJ_{ci} + |eJ_e|) \qquad \text{[E-7]}$$

$$t_e' = |eJ_e|/(Z_{ci}'eJ_{ci} + |eJ_e|) \qquad \text{[E-8]}$$

Since, however, the determination involves presuming a value for Z_{ci}', which may in fact differ in certain cases from Z_{ci}, the determination of the relative charge transport numbers by employing the mass transport rate as indicated above can lead to error.

SiO_2 Particulates Dispersed in a CVD Reactor

II. Correlation with Film Characteristics

A. Shintani,* K. Suda, and M. Maki[1]

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

The concentrations of vitreous silicate particulates dispersed in the CVD reactor measured by a laser light scattering technique are related to the characteristics of the deposited film. The larger particulates, 0.3-0.5 μm in diam, decrease in number with increase of gas flow rate with constant reactant concentrations, but smaller particulates show no change in number. When the reactants are diluted, the smaller particulates increase in number but the large particulates decrease. This confirms that the large particulates are formed by coagulation of small particulates. The 0.3-0.5 μm diam particulates cause pinholes which can be detected by generation of hydrogen bubbles in an appropriate electrolyte. The smaller particulates, 0.1-0.3 μm in diam, and the film deposition rate do not affect the pinhole formation. The pinhole density (D) is expressed in terms of the electric field strength (E), where $D \propto E^n$ ($0 < n < 1.5$). The particulate contamination of the films varies with reactant concentration but does not correspond well to the variation of the particulates dispersed in the reactor. Hillock-like patterns on film surface are not particulates.

Formation of vitreous silicate and phosphosilicate glass (PSG) films has frequently been carried out at low temperatures (450°C) using chemical vapor deposition (CVD) with silane and oxygen as reactants. Film formation is the result of a complex heterogeneous free-radical branching-chain reaction involving a surface reaction of SiH_4 and O_2 (1). A SiO_2 fog is simultaneously produced in the gas phase. This fog possibly contributes to pinholes in the film and to particulate contamination.

Recently, an aerosol measuring technique was developed which makes it possible to evaluate particulate dispersion in the reactor (3, 4). In Part I of this study (3), the size, number, and relative distribution of SiO_2 particulates with submicron diameters were measured for various conditions.

In Part II of this study, the possible correlations of pinholes and particulate contamination in CVD SiO_2 films with SiO_2 particulates in the gas phase have been investigated.

Experimental

The CVD apparatus, laser particulate monitor (LPM), and the experimental setup have been described in detail in Part I (3) and elsewhere (2).

Methods for detecting and characterizing localized defects in dielectric films have been surveyed by Kern and Comizzoli (4), and the electrolysis method used in this work is similar to that described by these authors. The specimen is made the cathode in 0.1*N* NaCl aqueous solution with a platinum wire as anode. Pinholes are detected by observation of hydrogen bubbles. Electrically weak points in the film cannot be distinguished from pinholes in this technique.

Particulate contamination density was estimated from the average value of the particulate flakes on 40-50 square patterns of area 0.25 cm². In addition, He-Ne laser light scattered by particulates was detected using a photomultiplier.

Results and Discussion

The size distribution of SiO_2 particulates dispersed in the CVD reactor varies with reaction time (3). Larger particulates, greater than 0.3 μm in diam, decrease in number with time, whereas smaller particulates gradually increase. These trends can be attributed to particulate coagulation in the gas phase.

It can be easily understood that the particulate collisions in a CVD reactor are linearly proportional to gas contact time and particulate concentration. Contact time is defined by the reactor volume times the inverse of the total gas flow rate. The contact time decreases with the increase in the total gas flow rate admitted to the constant volume reactor. According to Eq. [3] in Part I

$$n = \frac{n_o}{1 + (cn_o V R^3) t}$$

the contact time is implicitly involved in the coagulation time defined by $1/(cn_o V R^3)$. The velocity gradient of the gas flow, $V = \partial V_x/\partial y$ included in the coagulation time, increases with total gas flow rate. This means that the decrease in coagulation time contributes to the particulate coagulation reduction trend. Therefore, large particulates decreased with the increase in gas volume when the reactant concentrations remained constant (Fig. 1). The figure shows the relation between particulate numbers and the inverse of total gas flow rate, $1/V$. While the number of large particulates increased with $1/V$, particulates smaller than 0.3 μm in diam showed no large change in number. The smallest measurable particulates, 0.1-0.2 μm, decreased in number with $1/V$.

Particulate collisions and hence coagulation is reduced when the reactant gas concentration is diluted. As shown in Fig. 2, 0.1-0.2 μm diam particulates increased in number with increased dilutions but 0.2-0.3 μm diam particulates decreased. The 0.1-0.2 μm diam particulates tended to saturate in number at dilution gas flow rates greater than 12 liters/min. The small particulate concentrations may indicate the nuclei or original particulate behavior.

The surfaces of deposited films show hillocks which increase in size with reaction time, as shown in Fig. 3. Hillock size and film thickness both rose linearly with reaction time. This result indicates that the particulates do not directly contribute to film growth. Although the behavior of particulates smaller than 0.1 μm in diam were not measured, these would be dispersed in a manner similar to the distribution of 0.1-0.2 μm diam particulates.

The particulates in the range of 0.1-0.5 μm in diam were observed because of the limitation of the LPM. On the other hand, the observed particulate flakes were larger than 1 μm in diam in both optical microscopic and laser light scattering technique measurements so that particulate contamination could not be directly

Key words: dielectric film, pinholes, particulate contamination, submicron particulates.

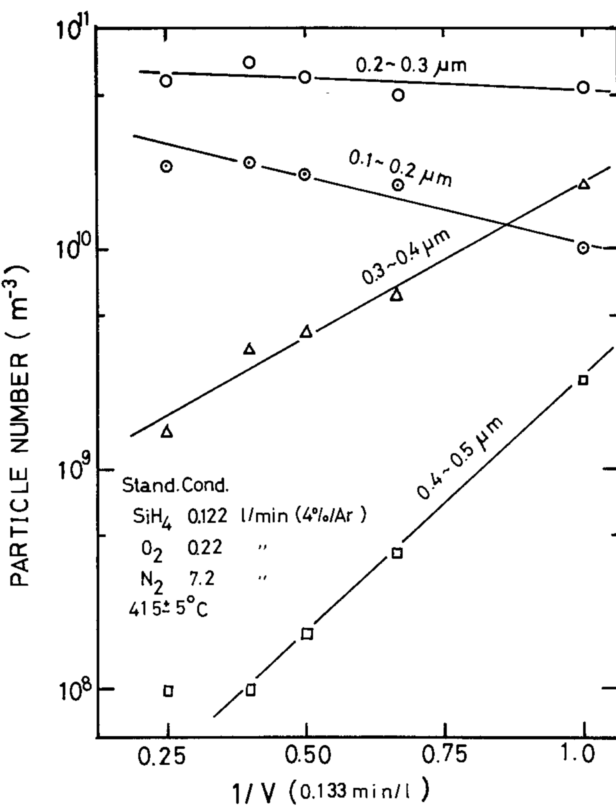

Fig. 1. Total gas flow rate dependences of individual particulate sizes at 5 min after reaction start. Basic gas flow rates were 0.122 liter/min for SiH_4 (4%/Ar), 0.22 liter/min for O_2, and 7.2 liters/min for N_2. Total gas flow rate was changed for the experimental conditions with these gas flow rate ratios remaining.

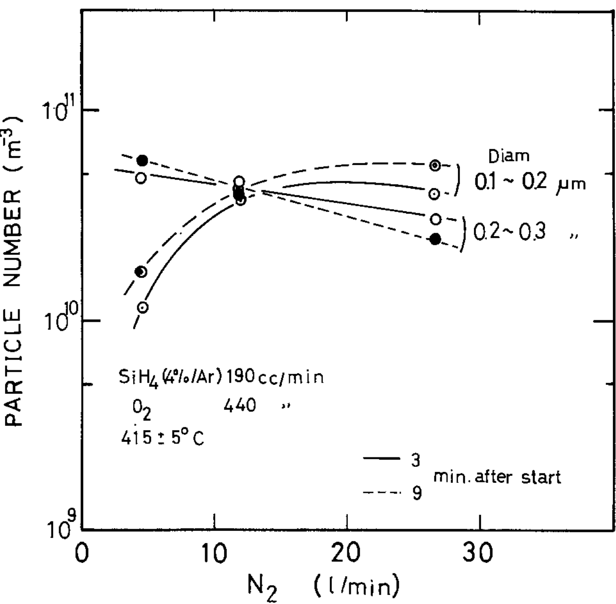

Fig. 2. Gas dilution effect on particulate distribution at 3 and 9 min after reaction start.

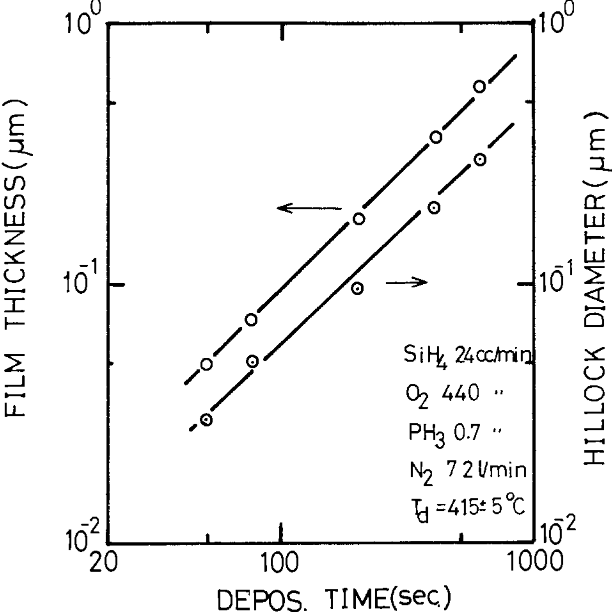

Fig. 3. Time dependences of film thickness and approximately largest hillock-like pattern sizes.

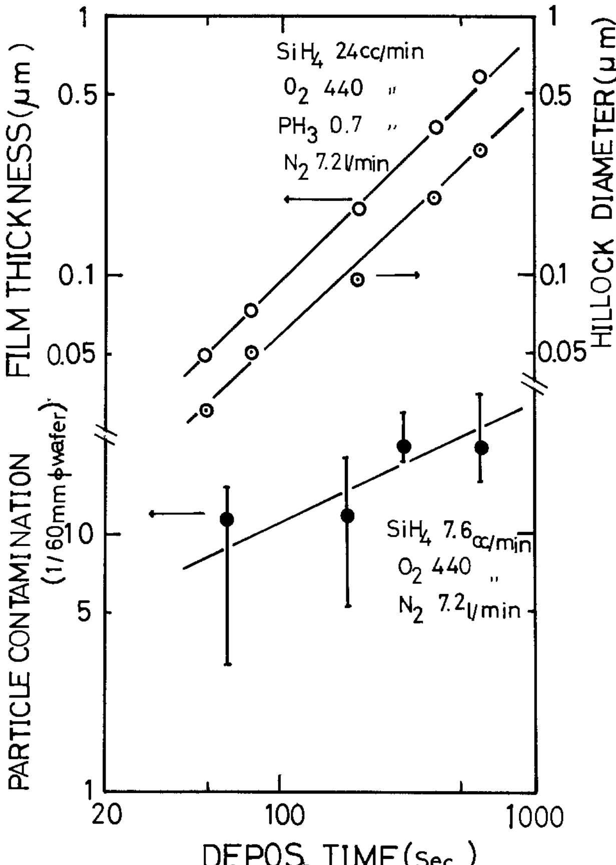

Fig. 4. Dependence of particulate contamination density on film formation time. The contamination was measured using the laser light technique.

compared with variations of dispersed particulates. However, the behavior of particulates larger than 0.5 μm in diam can be estimated from that for particulates larger than 0.3 μm in diam as reported in Part I. Particulates larger than 0.3 μm in diam tend to decrease in number with reaction time. Judging from this, particulates larger than 1 μm in diam should be reduced in number with reaction time. The number of these larger particulates would be less than that of particulates with diameters between 0.3 and 0.5 μm. If the particulates larger than 1 μm in diam contribute to the observed particulate contamination, the contamination density should increase with reaction time with a power lower than one. The results were apparently consistent with this (Fig. 4).

The addition of PH_3 to the reactants inhibits particulate coagulation (3). The contamination density tended to decrease monotonically with increase in PH_3 flow rate, as revealed in Fig. 5. Comparing with Fig. 8 shown later, particulate contamination does not correspond well to particulates dispersed in the reactor.

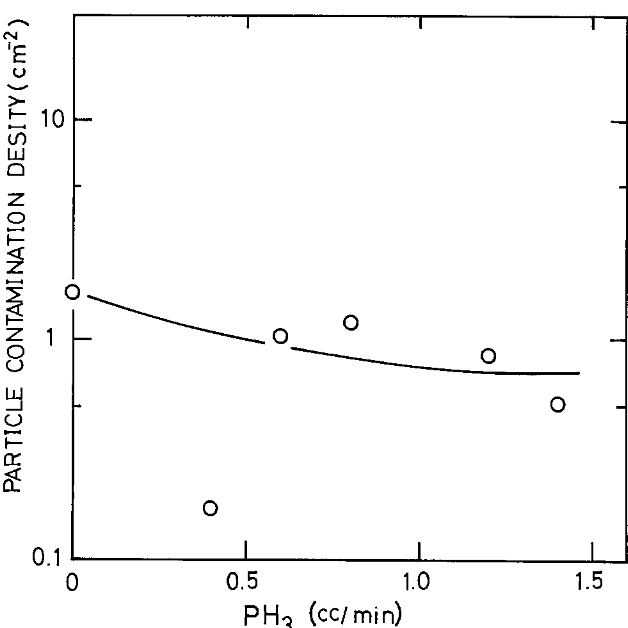

Fig. 5. PH_3 flow rate dependence of particulate contamination. The contamination was measured using a microscope.

Pinhole density measured by the electric technique depended on the strength of the electric field applied to the film, as shown in Fig. 6. Although each data point had large fluctuation, the mean pinhole density (D) can be experimentally expressed by

$$D \propto E^n \quad [1]$$

where E is the electric field strength applied to the film, and n is an appropriate constant. The figure shows that there is some difference in n between thermal and CVD oxide films.

Correlations between pinholes and film formation conditions are shown in Fig. 7 and 8. In a Si device, a vitreous silicate insulator sandwiched between evaporated Al layers is generally operated with an electric field of 10^6 V/cm. The densities plotted in the figures were obtained for films applied with electric fields of this magnitude. The number of 0.3-0.5 μm

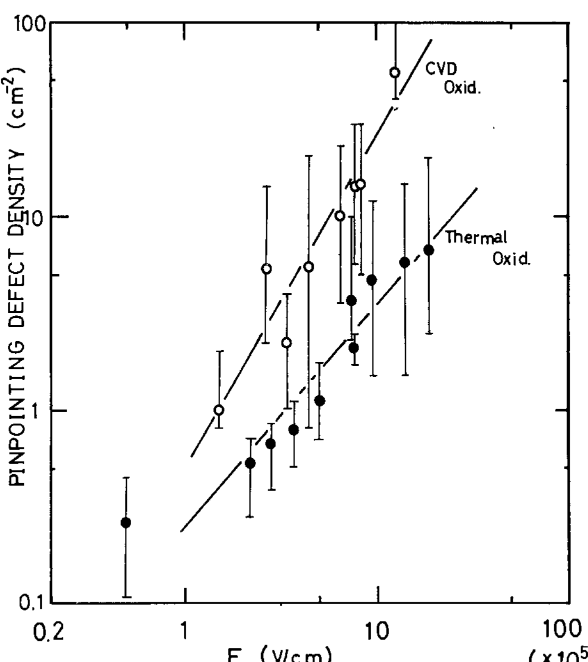

Fig. 6. Electric field strength dependences of pinholes in vitreous silicate films.

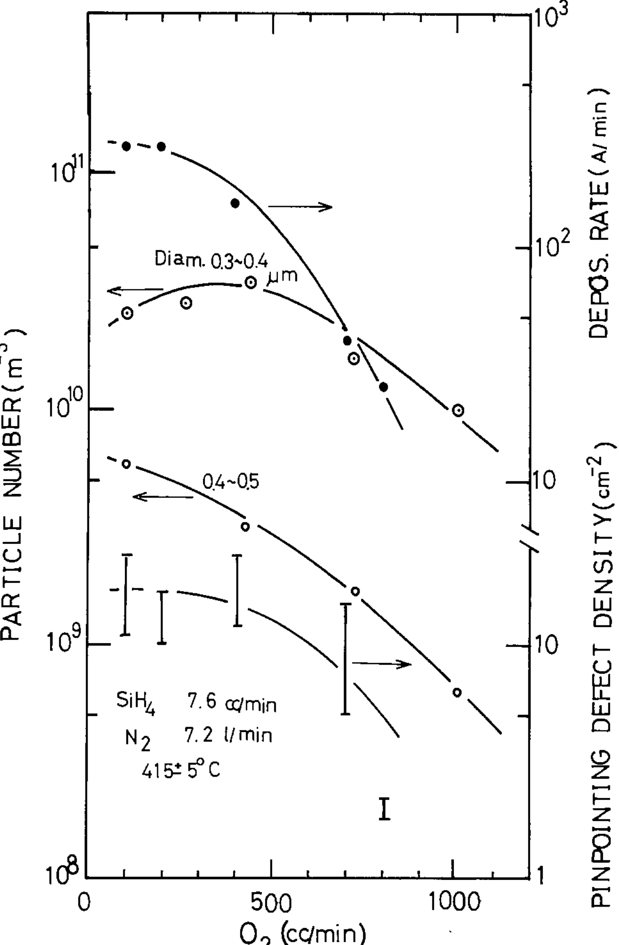

Fig. 7. O_2 flow rate dependences of 0.3-0.5 μm diam particulate number, pinhole density, and film deposition rate.

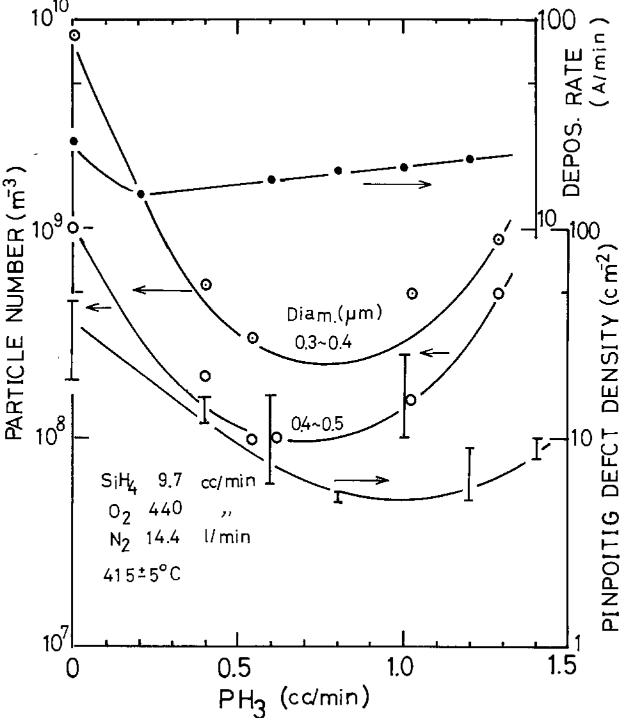

Fig. 8. PH_3 flow rate dependences of 0.3-0.5 μm diam particulate number, pinhole density, and film deposition rate.

diam particulates, the film deposition rate, and pinhole densities are illustrated. The variation in pinhole density with O_2 flow rate is in an approximate agreement

with the variations of both the film formation rate and number of particulates dispersed in the gas phase (Fig. 7). However, the variation of pinhole density with PH_3 flow rate follows that of particulate numbers, not that of film formation rate, as seen in Fig. 8. These results reveal that the pinholes and weak spots are extrinsically induced. If the local electrically weak characteristics were intrinsically generated during chemical vapor deposition, the pinhole density would undergo a major increase with the film deposition rate. When the plane formation of the film does not sufficiently develop, local irregularities in film thickness, which cause the electrically weak characteristics, occur. This can become extreme when the film surface consists of many hillock-like patterns and when the film deposition rate becomes fast. The dependence of pinhole density on PH_3 concentration is contrary to that of film deposition rate (Fig. 8).

Figures 7 and 8 show that particulates larger than 0.3 μm in diam are most likely to induce these defects. The distribution of particulates smaller than 0.3 μm in diam in the reactor contrast with those of large particulates, as mentioned previously [cf. Fig. 4, 5, and 7 in Ref. (4)]. These small particulates are accordingly not considered to be a primary cause of pinholes.

Film formation at 415°C is controlled by reactant diffusion through a stagnant gas layer over a substrate surface. Large particulates embedded on the substrate surface can act as a sink for adsorbed atoms moving on the surface and can perturb the gas phase boundary layer. Local thickness irregularities of the film, especially in the vicinity of very large particulates, is clearly visible even by eye as interference color variations. More drastic irregularities of the thickness can be seen with nondoped films than with PSG films. The addition of PH_3 to the reactants effectively inhibits the coagulation of small particulates, as discussed in Part I. The doped film surface is smoother than that of nondoped films.

Conclusions

Particulates, 0.3-0.5 μm in diam, decrease in number with increase of total gas flow rate with the reactant concentration constant but smaller particulates show no change. Small particulates increase in number when the reactant concentrations are diluted with the ratio of reactants (O_2/SiH_4) constant but the large particulates decrease in number. This confirms that large particulates are formed by coagulation of small particulates.

Pinholes and other electrically weak points can be detected by generation of H_2 bubbles in an appropriate electrolyte. The pinhole density (D) is expressed in terms of the electric field strength (E) applied to the film, where $D \propto E^n$. The value of n is a measure of the electrical characteristics of the film. The pinholes vary in density with PH_3 concentration similar to variations of 0.3-0.5 μm diam particulates, but not to variations of smaller particulates and film deposition rate.

The hillock patterns on the surface are not attributable to particulates in 0.1-0.5 μm diam region. The variations of particulate contamination densities of the films with reactant concentrations do not correlate well with the variations in the number of particulates dispersed in the reactor.

Luminescence of Doped and Undoped $Al_2(WO_4)_3$, $Sc_2(WO_4)_3$, and $Lu_2(WO_4)_3$

G. Blasse and M. Ouwerkerk

Physical Laboratory, State University, 3508 TA Utrecht, The Netherlands

ABSTRACT

The luminescence of doped (Eu^{3+}, Cr^{3+}) and undoped $Al_2(WO_4)_3$, $Sc_2(WO_4)_3$, and $Lu_2(WO_4)_3$ has been investigated. The tungstate luminescence is not very efficient for reasons closely related to the packing of the crystal structure, $Sc_2(WO_4)_3$ and $Lu_2(WO_4)_3$ are very hygroscopic. The Eu^{3+} emission can be used as a tracer for the moisture amount of these tungstates. At 4.2°K the Cr^{3+} emission consists of ^2E line emission (R and N lines). In the vibronic structure coupling with tungstate vibrational modes have been observed. At higher temperatures the $^4T_2$ emission takes over.

Vanadates, niobates, tungstates, and similar compounds are known as potential efficient luminescent materials: Examples are $Mg_3(VO_4)_2$ (1), $YNbO_4$ (2), and $CaWO_4$ (3). Surprisingly enough the aluminum analogs have never been studied before in this respect. The luminescence of $AlVO_4$ (4) and $AlNbO_4$ (5) has been reported elsewhere by us. None of these materials has a high luminescent efficiency. This was ascribed to structural pecularities.

Key words: tungstate, phosphors, crystal structure.

In this paper we report on the luminescence of doped and undoped $Al_2(WO_4)_3$, and extended our investigations to $Sc_2(WO_4)_3$ and $Lu_2(WO_4)_3$ because the three tungstates are isomorphous (6, 7). In this way we had available three host lattices in which the ionic radius of one of the constituents varies largely (Al^{3+} 0.535Å, Sc^{3+} 0.745Å, Lu^{3+} 0.861Å; radii according to Shannon and Prewitt (8) for six-coordination). As dopants we used Eu^{3+} and Cr^{3+} and, superficially, Bi^{3+} and U^{6+}

The crystal structure of these materials is rather complicated. The tungsten coordination is tetrahedral. There are two crystallographically different tungsten sites: W(1) has site symmetry C_2 and four equivalent positions in the orthorhombic unit cell, W(2) has C_1 and eight equivalent positions. The trivalent metal ion is in a distorted, octahedral coordination with site symmetry C_1.

Borchardt (9) has reported the luminescence of $Sc_2(WO_4)_3$ and $Lu_2(WO_4)_3$ at 77°K. Stork *et al.* (10) reported the 300°K emission spectrum of Cr^{3+} in $Al_2(MoO_4)_3$ during a study of the catalytic properties of the system Mo|γ-Al_2O_3. This molybdate is isomorphous with $Al_2(WO_4)_3$ as is $Cr_2(WO_4)_3$ (6). Our investigations are considerably broader without entering into every detail.

Experimental

Samples were prepared by firing intimate mixtures of the starting materials ($Al(OH)_3$, Sc_2O_3, Lu_2O_3, Eu_2O_3, Cr_2O_3, and WO_3) in corundum crucibles at 800°C and, after a milling procedure, at 1000°C for several hours in air. In a few cases samples were prepared in a completely dry atmosphere and mounted in the cryostat in a dry box. X-ray powder patterns were run on a Philips diffractometer using CuKα radiation. The performance of the optical measurements has been described before (1, 5).

Results and Discussion

Vibrational spectra.—The infrared and Raman spectra were measured for $Al_2(WO_4)_3$, $Sc_2(WO_4)_3$, and $Lu_2(WO_4)_3$. Figure 1 presents the Raman spectra in the region of the W-O stretching vibrations. Figure 2 gives the infrared spectrum of $Al_2(WO_4)_3$ in that region. Those of $Sc_2(WO_4)_3$ and especially $Lu_2(WO_4)_3$ show less subbands and are less broad. Figures 1 and 2 show two interesting facts, *viz.*, the number of lines or bands is large, and the spectral region which is covered by the W-O stretching vibrations is very large.

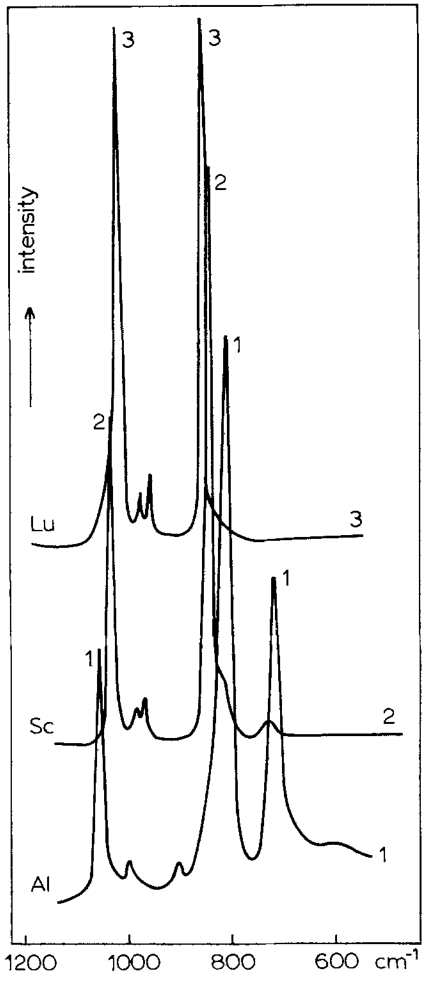

Fig. 1. Raman spectra of $Al_2(WO_4)_3$, $Sc_2(WO_4)_3$, and $Lu_2(WO_4)_3$ at room temperature in the W-O stretching region.

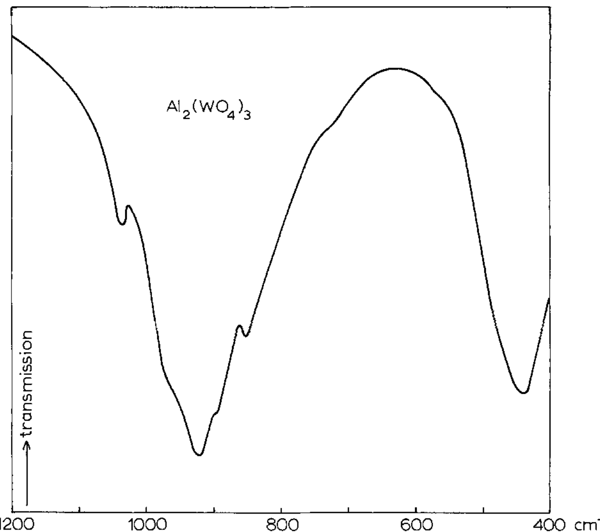

Fig. 2. Infrared spectrum of $Al_2(WO_4)_3$ at room temperature (KBr pellet).

This is especially clear after comparison with the spectra for a tungstate with a simple crystal structure, *e.g.*, Na_2WO_4, where the symmetric stretching mode (ν_1) is at 928 cm^{-1} and the asymmetric stretching mode (ν_3) at 811 cm^{-1} (11). The present complicated situation arises from the fact that the unit cell (with symmetry D_{2h}) contains four W(1) and eight W(2) ions. Under the low site symmetry of both ions the threefold degenerate ν_3 splits into components which, partly in the case of W(1) and completely in the case of W(2), have the same symmetry representation as ν_1. As a consequence the symmetric and asymmetric modes mix and it is no longer useful to make a distinction between them. A similar situation has been reported for Mg_2SiO_4 (12).

On the basis of the site symmetry alone (neglecting interaction between equivalent tungstate tetrahedra) we expect eight allowed peaks in the Raman as well as in the infrared spectra. We find fewer peaks, but the large difference between the Raman and infrared spectra suggests that the interaction (factor group analysis) should be taken into account. This yields 24 Raman peaks and 18 infrared bands which, due to the exclusion principle, should be different. It is clear that the experimental results cannot be analyzed on this basis. Two remarks can be made. (*i*) The interaction between equivalent tungstate groups is expected to be stronger in the aluminum compound than in the other two compounds in view of the shorter W-W distances. In fact the spectra of the aluminum compound extend over the widest range, (*ii*) The presence of relatively high vibrational frequencies (> 1000 cm^{-1}) may be related to the occurrence of relatively short W-O distances in the crystal structure [*e.g.*, 1.70Å for W(1)-O(4) in $Sc_2(WO_4)_3$ to be compared with the tetrahedral W-O distance in $CaWO_4$ of 1.78Å (6)]. However, the more important reason for reporting the vibrational spectra here is that they are of use in the interpretation of the Cr^{3+} emission spectrum of $Al_2(WO_4)_3$-Cr.

Diffuse reflection spectra.—The reflection spectra of the three tungstates resemble the reflection spectrum of $Sc_2(WO_4)_3$ reported by Borchardt (9). There is an optical bandgap in the short wavelength ultraviolet: at 230 nm for $Lu_2(WO_4)_3$, at 235 nm for $Sc_2(WO_4)_3$,

and 240 nm for $Al_3(WO_4)_3$. This part of the spectrum is independent of sample history. Excitation into this region will be called i-excitation below. This is the same absorption as observed, for example, for the alkaline earth tungstates MWO_4 (M = Ca, Sr, Ba) where the edge is also below some 250 nm and shifts to shorter wavelengths the larger the alkaline earth ion (13).

In addition, the reflection spectra show a tail which extends down to some 360 nm. The shape of the tail depends on sample history. The tail in the spectra of our samples has lower intensity than that reported in Ref. (9). We will call this part the e-part of the spectrum.

The absorption in these spectral regions is ascribed to charge-transfer transitions in the tungstate groups. A more detailed assignment will be given below in connection with the luminescence emission spectra.

Tungstate luminescence.—None of the undoped compounds under consideration show luminescence at room temperature; at liquid nitrogen temperature they show a weak, blue-green emission under ultraviolet excitation; the emission intensity increases upon cooling to liquid helium temperature. In Fig. 3 we have given some representative examples of emission spectra for the case of $Al_2(WO_4)_3$. For i-excitation the emission consists of a broad band with a maximum at about 460 nm, for e-excitation the emission depends on excitation wavelength and peaks in the range between 500 and 550 nm.

Excitation spectra do not yield much additional information because the broad emission bands cannot be separated. The excitation spectra can also be divided into what we have called an i and an e region. These spectra extend down to some 360 nm. The 460 nm emission band has a short wavelength limit at about 360 nm.

The i-region is assumed to be the intrinsic tungstate absorption region corresponding with the shorter wavelength emission band. This compares favorably with the situation in $CaWO_4$ (3, 13). One may wonder what is the reason for the relatively low quenching temperature of the luminescence and the absence of a really intense emission at very low temperatures. It cannot be excluded that this is partly due to the fact that the 460 nm emission band "touches" the e-region excitation band, so that energy transfer may have a reasonable probability. The emission spectrum for i-excitation, however, contains only a minor amount of the long-wavelength emission, so that this cannot be the real explanation for the low quenching temperature and luminescence intensity.

The sharp decrease of luminescence intensity and quenching temperature in the series of scheelites $CaWO_4$, $SrWO_4$, $BaWO_4$ has been ascribed to the increase of the ionic radius of the alkaline earth ion so that the parabola offset in the configurational coordinate diagram will be largest for the largest ion resulting in the lowest luminescence intensity and quenching temperature (14). In the scheelites the oxygen ion is surrounded by one tungsten ion and two alkaline earth ions in a roughly triangular way. If the W-O distance increases upon excitation, oxygen ion movement will be inhibited by the alkaline earth ions. In the crystal structure of the present tungstates the oxygen ion is coordinated by one tungsten ion and only one trivalent metal ion in a nonlinear arrangement. As a consequence the trivalent metal ion essentially does not oppose expansion of the W-O distance. This runs parallel with the influence of the large divalent ions in the ordered perovskite structure upon the quenching temperature of luminescence. This influence is practically nonexistent (15). This model explains why the parabola offset of the tungstate tetrahedra in the compounds $M_2(WO_4)_3$ under

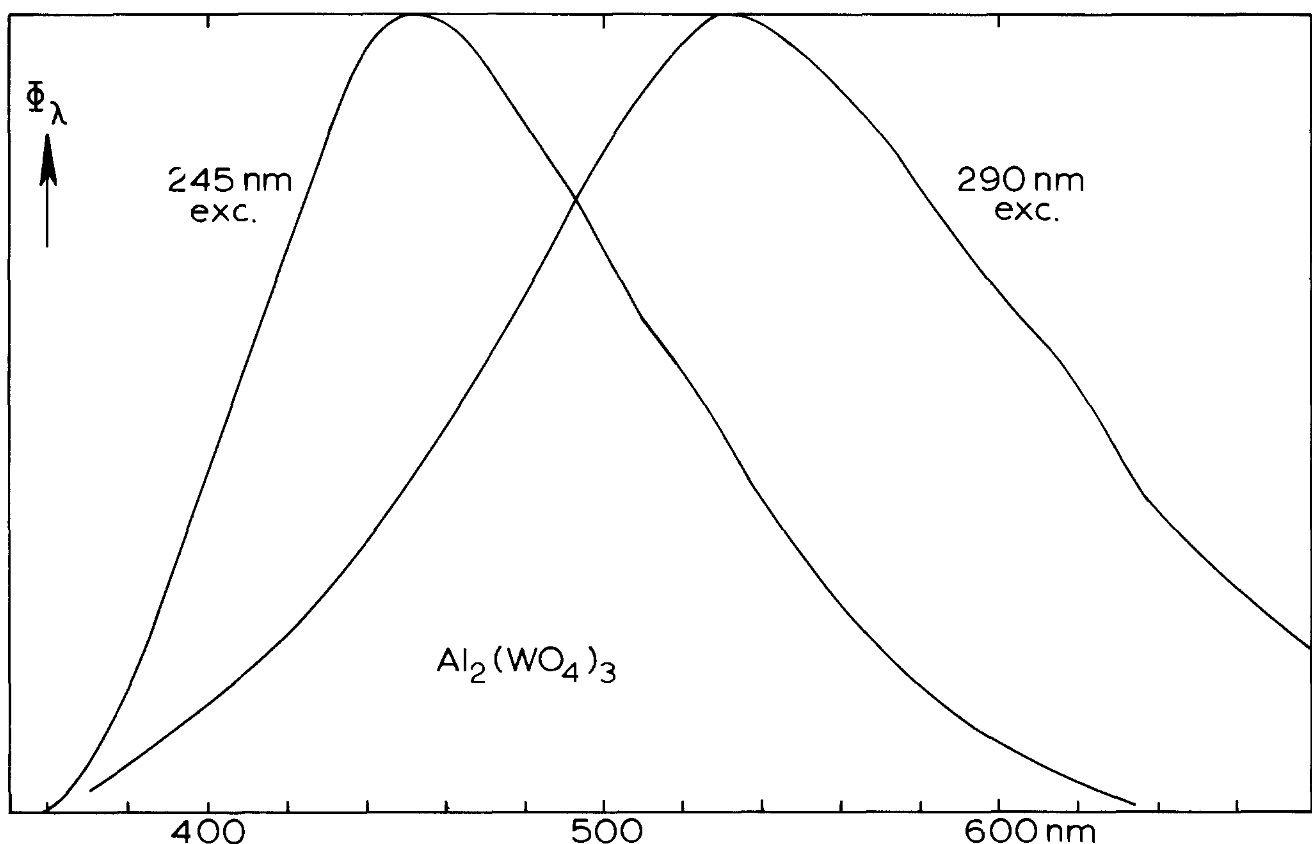

Fig. 3. Spectral energy distribution of the emission of $Al_2(WO_4)_3$ at 4.2°K. Φ_λ gives the spectral radiant power per unit wavelength interval in arbitrary units. Left-hand side: i-region excitation; right-hand side: e-region excitation (see also text).

consideration is large and, consequently, the luminescence intensity and quenching temperature low. The model has two implications. In the first place, the Stokes shift of the emission should be large. This is in fact observed. In the case of the efficient phosphor $CaWO_4$ the tungstate luminescence Stokes shift is some 16,000 cm^{-1} (3). In the present compounds it amounts to at least some 20,000 cm^{-1} (due to the short-wavelength limitation of our apparatus it is difficult to measure the i-excitation band maximum accurately). In the second place, the nature of the trivalent ion should not have a great influence on the quenching temperature. This also was observed.

Let us now turn to the e-excitation region with the longer wavelength emission band. Since the characteristics of this luminescence depends on sample history and on excitation wavelength, it is obvious to ascribe this luminescence to extrinsic tungstate groups, *i.e.*, groups which are located near to imperfections in the crystal lattice. It is now well known that many tungstates (and also titanates, niobates) show an additional long wavelength emission which is due to tungstate groups near defects (16). Energy transfer from intrinsic to extrinsic groups has also been shown to occur. What is different in the tungstates under consideration is the high concentration of the extrinsic groups as appears from the diffuse reflection spectra. It may be that the complicated character of the crystal structure favors a high concentration of imperfections. In addition it should be mentioned that especially $Sc_2(WO_4)_3$ and $Lu_2(WO_4)_3$ are hygroscopic. The hydrated samples can be excited most efficiently in the e-region (see below). Even samples prepared and handled in a completely dry atmosphere showed the e-region absorption, so that it cannot be solely due to the presence of hydration. It is general experience, and not unexpected, that the extrinsic groups have quenching temperatures and efficiencies which are about equal to and often even lower than those of the intrinsic groups (16). This agrees with the present results.

The complicated nature of the host lattice luminescence makes these compounds very unsuitable for a study of energy transfer. Nevertheless we investigated several doped samples. Only Eu^{3+} and Cr^{3+} activation seems to be worthwhile to be reported separately. The activation with U^{6+} yielded weak green luminescence with a uranyl-type character (17), and the activation with Bi^{3+} yielded new, broad emission bands at longer wavelengths upon excitation in the e-region as reported before for similar Bi^{3+}-activated compounds (18).

Eu^{3+} emission.—Eu^{3+}-activated tungstates $M_2(WO_4)_3$ (M = Al, Sc, Lu) show at room temperature a red luminescence of medium intensity. At lower temperatures the tungstate emission bands are also present. Figure 4 shows the Eu^{3+} emisison spectrum of $Al_2(WO_4)_3$:Eu upon excitation into the Eu^{3+} ions. Figure 5 presents the emission spectrum of dry $Lu_2(WO_4)_3$:Eu upon i-excitation, whereas Fig. 6 gives the emission spectrum of $Lu_2(WO_2)_3$:Eu upon e-excitation. The latter sample was prepared and handled in an undried atmosphere.

First we consider the Eu^{3+} emission spectrum. Formally the Eu^{3+} ion occupies a site without any symmetry element, so that all degeneracy should be lifted and every transition allowed. Figure 4 shows that this is only partially the case. The $^5D_0$-$^7F_1$ transition is not clearly split into three components in $Al_2(WO_4)_3$, but in dry $Lu_2(WO_4)_3$ it is not split at all (Fig. 5). This suggests that the coordination of the Eu^{3+} ion is not distorted too strongly from regular octehedral. Such coordination has been reported for Al, Sc and Lu (6, 7). The fact that the Eu^{3+} ion is much larger than the trivalent host lattice ions does not obviously change this situation, although it can be concluded that the distortion around Eu^{3+} on Al^{3+} sites must be

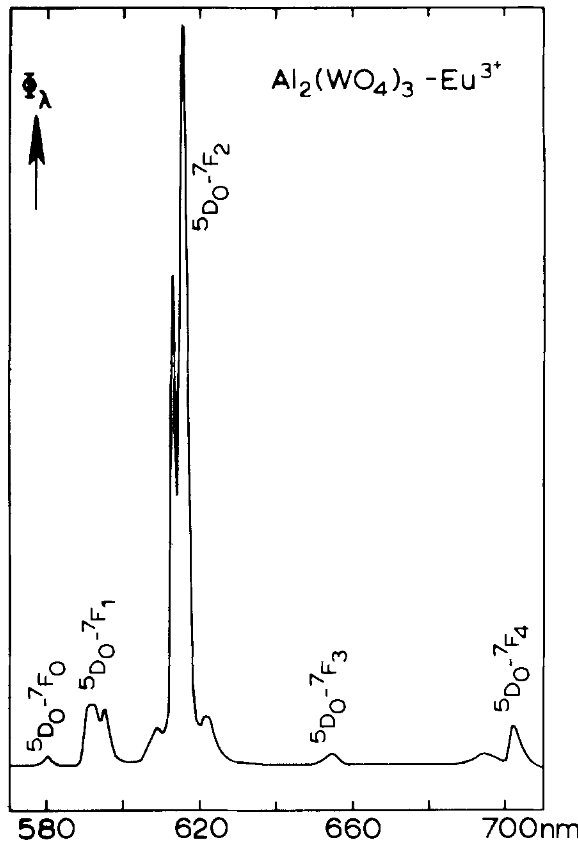

Fig. 4. Spectral energy distribution of the Eu^{3+} emission of $Al_{1.98}Eu_{0.02}(WO_4)_3$ at 4.2°K. Excitation into the Eu^{3+} ion at 395 nm.

larger than on the Sc^{3+} and Lu^{3+} sites. This is not too surprising. Note also that the Eu^{3+} emission is strongly concentrated in the red $^5D_0$-$^7F_2$ transition. This is another example of the influence of hypersensitivity on the $^5D_0$-$^7F_2$ transition (19-21). The small deviation from inversion symmetry (regular octahedron) is not enough to enforce the electric dipole transitions ($^5D_0$-$^7F_4$) considerably, but enforces strongly the hypersensitive $^5D_0$-$^7F_2$ transition.

Excitation into the host lattice yields emission spectra like those given in Fig. 5 and 6. For Eu^{3+} concentrations of 1 atomic percent (a/o) the ratio of Eu^{3+} to tungstate emission is of the order one-half to one-third. At first sight this indicates efficient transfer from the host lattice to the activator, but this is incorrect since the tungstate emission has already been partly quenched as argued above. There is no sense in studying energy transfer phenomena more quantitatively in these systems because the extrinsic tungstate groups compete with the Eu^{3+} ions in trapping the host lattice emission and also the quenching temperature of the tungstate luminescence is low.

The results for $Sc_2(WO_4)_3$:Eu^{3+} and $Lu_2(WO_4)_3$:Eu^{3+} depend on whether the samples have been kept completely dry or not. In Fig. 6 the emission spectrum of Eu^{3+} in the "wet" sample is different from that in the dry sample (Fig. 5). All lines are much broader in the wet sample; further, the $^5D_0$-$^7F_1$ transition is now split and the $^5D_0$-$^7F_0$ transition (at about 580 nm), although weak, has a higher intensity. Even in the dry sample the "wet" Eu^{3+} emission can be obtained by exciting selectively in the e-region, *viz.*, around 280 nm. The explanation of all this is that $Sc_2(WO_4)_3$ and $Lu_2(WO_4)_3$ are very hygroscopic [whereas $Al_2(WO_4)_3$ is not]. The hydrates are excited most efficiently at 280 nm. This is a very sensitive test for the humidity content of the samples. In fact not even our dry samples, prepared and mounted with great care, were completely water-free. The Eu^{3+} coordina-

tion in the hydrate is different from that in the dry compound.

Cr^{3+} emission.—The Cr^{3+} ion yields deep-red to infrared emission in the present host lattices. The character of this emission depends on the temperature. The 4.2°K emission of Cr^{3+} in $Al_2(WO_4)_3$ is shown in Fig. 7 and consists of two lines at 719 and 723.5 nm followed by some weak vibronic structure which has been tabulated in Table I. In view of the low Cr^{3+} concentration (0.5 a/o) and the fact that there is only one crystallographic site for the trivalent metal ions, the occurrence at low temperature of two lines is surprising. The lines are undoubtedly due to the $^2E \rightarrow {}^4A_2$ transition on the Cr^{3+} ion. The fact that there is more than one line can be ascribed to Cr^{3+} pair emission which has been studied intensively in other host lattices (22). The energy difference between the two lines, about 90 cm^{-1}, is well in line with such an interpretation. In Table I the 719 nm line is called the *R* line and the 723.5 nm pair line the *N* line following the literature convention. Table I shows that the *R* and the *N* line are followed by similar vibronic lines. There is coupling with a low frequency mode which probably has mainly Me^{3+}-O^{2-} character, but also with tungstate vibrational modes and especially with those which occur with high intensity in the infrared spectra. In view of the D_{2h} symmetry of the unit cell these have Ungerade symmetry as required for coupling to the parity-forbidden $^2E \rightarrow {}^4A_2$ transition. It is interesting that the transition on the Cr^{3+} ion couples with the tungstate vibrational modes.

The excitation spectrum of this emission contains, in addition to the tungstate excitation bands, the well-known $^4A_2 \rightarrow {}^4T_2$, $^4T_1(F)$, $^4T_1(P)$ transitions. These show also some vibrational structure in which the

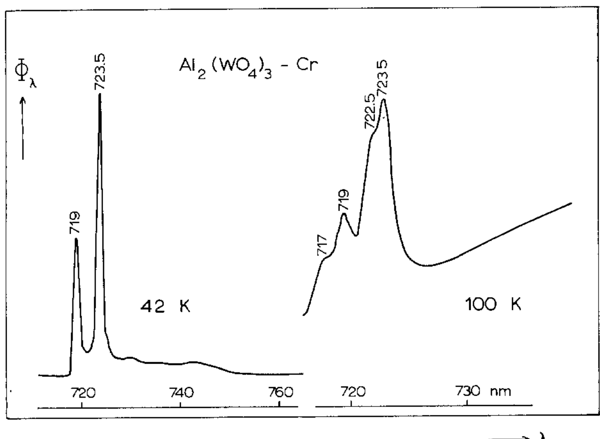

Fig. 7. Spectral energy distribution of the Cr^{3+} emission of $Al_{1.99}Cr_{0.01}(WO_4)_3$ at 4.2°K (left-hand side) and at 100°K (right-hand side) under 470 nm excitation [$^4A_2 \rightarrow {}^4T_1(F)$]. Note the change in wavelength scale. In the 100°K spectrum the highest energy part of the $^4T_2 \rightarrow {}^4A_2$ emission band (peaking at about 800 nm) is observable.

tungstate-vibrations can be recognized, but due to their vagueness the assignment cannot be made with much certainty.

The pair line (N) is much too strong for Cr^{3+} to be distributed at random among the aluminum lattice. Since our samples were made by solid-state reactions, we have to assume that the Cr^{3+} ions occur still in pairs in the lattice. This phenomena is well known for Cr^{3+} (23). In fact the samples mentioned in Ref. (10) were made from solution and show a higher R/N line intensity ratio than ours.

At higher temperatures the spectrum becomes rapidly more complex (see Fig. 7). The R as well as the N line are accompanied by a line at higher energy indicating the well-known splitting of the ^2E level (22). For the single ion this splitting amounts to some 40 cm^{-1} which is well in line with results on Cr^{3+} in other lattices (22). In addition, a broad-band emission develops peaking at roughly 800 nm. This is the $^4T_2 \rightarrow {}^4A_2$ emission from the thermally occupied $^4T_2$ level. The total emission intensity drops strongly from 4.2° to 300°K. This agrees with models proposed by Fonger and Struck (24) which state that the Cr^{3+} emission is quenched via the $^4T_2$ level. In ruby the $^4T_2$ level is high (2350 cm^{-1}) above the ^2E level, but in $Al_2(WO_4)_3$ the energy difference must be considerably smaller. From the position of the R line and the first peak in the vibrational structure of the $^4A_2 \rightarrow {}^4T_2(F)$ excitation band (which is then considered to be the zero-phonon line) the energy difference is estimated to be 500 cm^{-1}.

Table I. Vibronic side band frequencies of $Al_2(WO_4)_3$:Cr at 4.2°K

Vibronic side band frequency (±10 cm^{-1})[b]		Electronic origin[c]	Character	Vibrational spectrum (cm^{-1})[b]
195 cm^{-1}	(s)	R	Me^{3+}-O^{2-}	
195	(m)	N		
450	(m)	R	Tungstate deformation mode	440, IR, s
440	(m)	N		
870	(w)	R	Tungstate stretching mode	~920, IR, s
[a] 890	(w)	N		
[a] 980		R	Tungstate stretching mode	1050, Ra, s
1030	(w)	N		

[a] These vibronics coincide into a relatively broad peak.
[b] s: strong, m: medium, w: weak, Ra: Raman, IR: infrared.
[c] R: R line (single ion emission); N: N line (pair emission).

Concluding Remarks

The crystal structure of $Al_2(WO_4)_3$ is so complicated that it obviously allows a high concentration of defects which complicate the luminescence behavior. The thermal quenching temperature of the tungstate luminescence is low and composition independent which can be ascribed to a structural characteristic, *viz.*, the oxygen coordination.

Consequently, efficient energy transfer to activators does not occur. The emission of Eu^{3+} can easily be explained and is at the same time sensitive to the moisture content of the samples. The Cr^{3+} emission can be explained following well-known models. The Cr^{3+} emission couples with tungstate vibrational modes. The $^4T_2(F)$ level is rather close above the ^2E level resulting in broad-band emission and quenching at elevated temperatures.

U.V. Absorption Band in Ge-Doped Sodalite Powders

L. T. Todd, Jr. and F. M. Tranjan

Department of Electrical Engineering, University of Kentucky, Lexington, Kentucky 40506

ABSTRACT

A bright green luminescence, with an emission bandpeak at 5250Å and an excitation bandpeak at 3465Å, has been reported for germanium-doped sodalite powders. This article reports the results of an investigation of the properties of u.v. absorption band at 3450Å that is shown to be responsible for the luminescence. A settled slide technique was used to prepare samples so that small variations in the absorption band could be detected. Experimental results are presented that show the effect of the hydrogen annealing temperature, hydrogen annealing time, and F-center creation on the u.v. absorption band intensity. The results indicate a definite relationship between the u.v. absorption band and the luminescence. The results of the coloration experiments show that the luminescent centers are associated with thermally erasable F-centers while they are independent of photoerasable F-centers. The u.v. band was found to exist in sodalite: Cl, Br, and I. While the band intensities differ for those powders, the peak wavelengths are exactly the same. Possible models for both coloration and luminescence are discussed.

The luminescent properties of germanium-doped synthetic sodalite powders have been reported by Todd (1, 2). The luminescence is characterized by an emission bandpeak at 5250Å and an excitation bandpeak at 3465Å. Todd studied the effect of the hydrogen annealing temperature, the hydrogen annealing time, and F-center creation on the luminescent intensity. Information regarding the number of luminescent centers was obtained indirectly rather than by direct experimental observation. The intensity of the luminescence generated within the colored powders was calculated using data obtained from measurements of observed luminescence and diffuse reflectance spectra (2). That study found that F-center creation by electron beam coloration greatly reduces the observed luminescence. This reduction results partially from the absorption of generated luminescence by F-centers while further reduction results from actual quenching of luminescent centers. The quenching was shown to be associated with the creation of thermally erasable F-centers while the creation of optically erasable F-centers did not cause quenching.

This article reports the observation of a u.v. absorption band at 3450Å in germanium-doped sodalite powders. The purpose of this study was to determine if this band represents the absorption due to the luminescent centers reported earlier (2). If that were the case, one could directly observe the behavior of the luminescent centers under various experimental conditions rather than use indirect mathematical calculations to obtain the results. A technique for detecting small variations in the u.v. absorption spectra of sodalite powders is described. This technique is used to determine the effect of the hydrogen annealing temperature, hydrogen annealing time, and F-center creation on the u.v. absorption band intensity. The results of these experiments are compared to those reported by Todd (2).

Experimental

Material preparation and measurement techniques.—The materials used in this investigation were grown by a hydrothermal growth technique as described previously (2-4). The powders were annealed in a hydrogen atmosphere to sensitize them to permit both coloration and luminescence.

Samples for absorption measurements were made using a modified version of a technique described by Chang and Onton (5). Powders were settled onto glass slides (1 × 1/2 × 1/16 in.) using a conventional powder settling technique (6) rather than using the compressed powder technique used by Chang and Onton. The density of the settled powders was varied between 2.5-12.6 mg/cm^2. Samples were colored by electron beam exposure in a demountable CRT system using an accelerating voltage of 30 kV (7). Index matching liquid was added to the powder to reduce light scattering in order to permit transmission measurements. A second glass slide was placed over the powder surface to retain the index matching liquid.

Absorption spectra were obtained with a Cary-14 spectro-photometer. Two glass slides were placed in the path of the reference beam to nullify the absorption of the glass used for the sample holder. An index matching liquid with $n = 1.484$ was used for all experiments since it provided maximum light transmission. The absorption of this liquid is negligible in the wavelength region of interest (3100-8000Å).

Key words: sodalite, u.v. absorption, luminescence cathodochromism.

Results

The u.v. absorption band reported in this investigation is shown in Fig. 1 centered at 3450Å. This spectrum was obtained using a bromine sodalite sample with 1 atomic percent (a/o) germanium substituted for silicon, $Na_6Al_6(Si_{0.99}Ge_{0.01})_6O_{24} \cdot 2NaBr$. The powder was annealed in hydrogen at 750°C for 15 min and the sample density was 12.6 mg/cm^2. This powder emits a very bright green luminescence when excited by long wavelength u.v. radiation. The spectrum for an undoped bromine sodalite sample annealed under the same conditions is also shown in Fig. 1. This material does not luminesce under u.v. excitation and does not possess the u.v. absorption band at 3450Å. These spectra suggest that the u.v. band at 3450Å is then related to the luminescent centers.

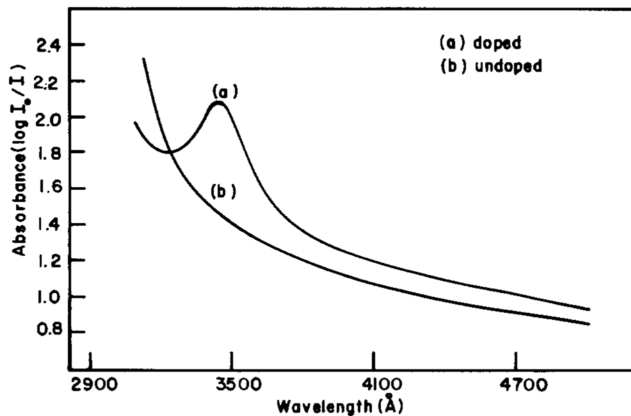

Fig. 1. Absorbance of Ge-doped (a) and undoped (b) bromine sodalite.

Effect of hydrogen annealing on the u.v. band intensity.—The effect of the hydrogen annealing temperature and time on the u.v. absorption band intensity was studied using a sample containing 1 a/o germanium. Figure 2 summarizes the results of an experiment in which samples were annealed at various temperatures for 15 min and their absorption bands measured. The absorption is negligible for anneal temperatures less than 650°C, but increases rapidly with increasing anneal temperature up to 750°C and then decreases sharply.

Figure 3 summarizes the results of an experiment in which samples were annealed at 750°C for various annealing times and their absorption bands were measured. The band intensity increases almost linearly with the annealing time between 0 and 15 min and then saturates for higher annealing temperatures.

The behavior of the u.v. band intensity as a function of hydrogen temperature and time is essentially identical to that reported by Todd (2) for the luminescent intensity as a function of the same parameters. The above results clearly indicate that the u.v. band is due to absorption by the luminescent centers.

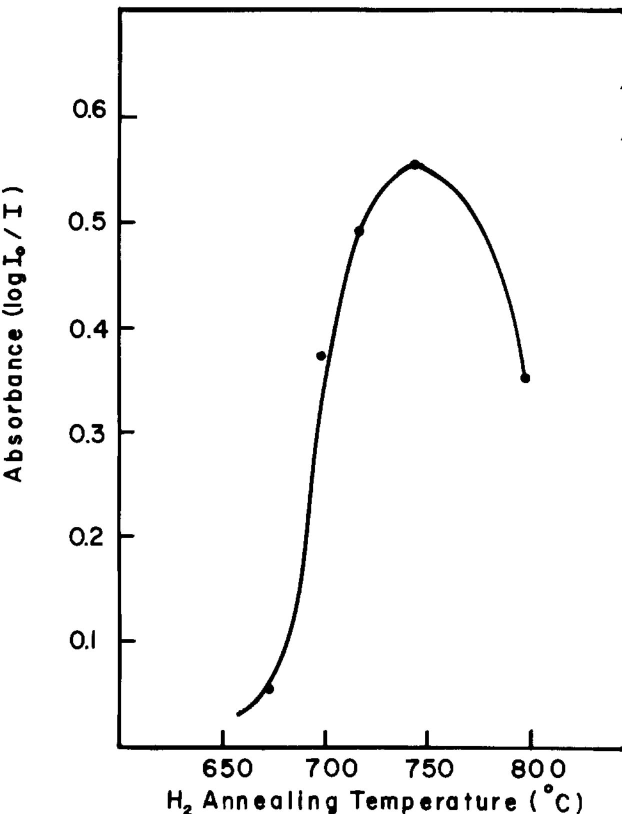

Fig. 2. Absorbance of the u.v. band as a function of H_2 annealing temperature.

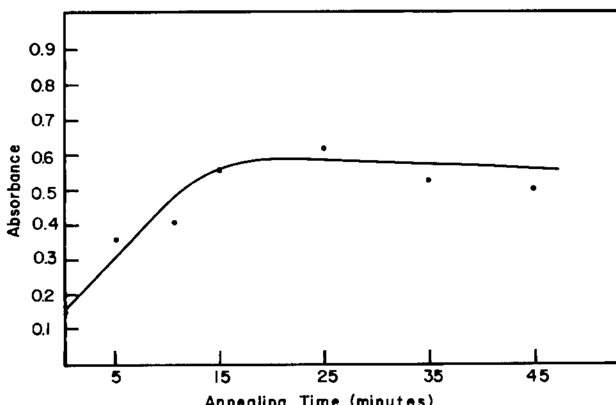

Fig. 3. Absorbance of the u.v. band as a function of H_2 annealing time at 750°C.

Effect of F-center creation on the u.v. band intensity.—It has been reported (2) that coloration of germanium-doped sodalite powders quenches the luminescent intensity. Therefore, an experiment was conducted to determine the effect of coloration on the u.v. band intensity. Samples of powder with the composition $Na_6Al_6(Si_{0.99}Ge_{0.01})_6O_{24} \cdot 2NaBr$ were settled with a density of 6.3 mg/cm^2. This density produced the optimum sample thickness for measuring small variations in the u.v. and F-band intensities. Thinner samples provided only small absorption bands while thicker samples could not be colored uniformly throughout the sample thickness.

The effect of photoerasable coloration on the u.v. band intensity was investigated. A sample was colored by electron beam exposure and its absorption spectrum was measured immediately after coloration. The sample was then optically bleached with white light for 1 hr and its spectrum remeasured. The resulting spectra, Fig. 4, show that the F-band intensity dropped considerably while the u.v. band intensity remained essentially unchanged. This result supports the earlier calculation (2) that indicated that photoerasable color centers were not involved in the quenching of luminescent centers.

The u.v. band intensity as a function of the formation of thermally erasable F-centers was also studied. In this experiment each colored slide was optically bleached before its spectrum was obtained. The absorption spectra, with backgrounds subtracted, of a colored and an uncolored sample are shown in Fig. 5. These spectra show that the u.v. band intensity does decrease upon coloration. Several samples were colored to different degrees of darkness and their spectra mea-

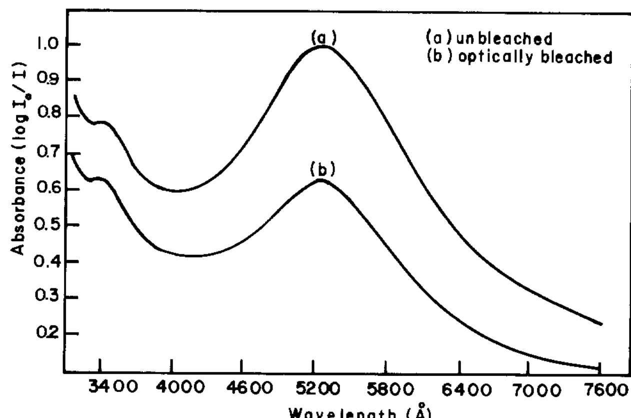

Fig. 4. Absorbance spectra of the u.v.- and F-bands for unbleached (a) and optically bleached (b) Ge-doped bromine sodalite.

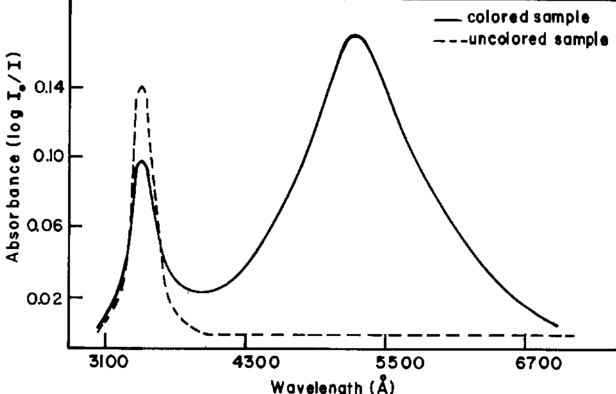

Fig. 5. Absorbance spectra, with background removed, of the u.v.- and F-bands for uncolored (- - -) and colored (——) Ge-doped bromine sodalite.

sured. The peak absorbance for both the F-band and the u.v. band were obtained. The absorbance is defined as $\log(I/I_0)$ where I is the sample beam intensity and I_0 is the reference beam intensity. The u.v. band fractional absorption $(1 - I/I_0)$ is plotted as a function of the F-band fractional absorption in Fig. 6. The graph shows that the u.v. band absorption decreases almost linearly with increasing F-band absorption. Also shown in Fig. 6 is a plot obtained by Todd (2) for the generated luminescent intensity as a function of the thermally erasable F-band fractional absorption. The generated luminescent intensities have been normalized to the same scale as the u.v. band fractional absorbance to permit an easier comparison. The slight difference in the slopes of the two plots is probably due to the constants assumed by Todd (2) to calculate the generated luminescence.

The results of the experiments discussed in this section clearly indicate that the u.v. band, and thus the luminescent center, is directly related to thermally erasable F-centers and is unaffected by the formation of optically erasable F-centers.

U.V. band intensity in sodalite: Cl, Br, and I.—Luminescent emission at 5250Å has been reported for Ge-doped sodalite: Cl, Br, and I (1). Hence the presence of the u.v. band in these sodalites was examined. The absorption bands for these three powders are shown in Fig. 7. The band intensity is most intense for sodalite: Cl and least for sodalite: I. The wavelength of the absorption bandpeak is unchanged by the halogen ion content.

Summary and Conclusions

Several experiments were conducted to show that the u.v. absorption band presented in this article is responsible for the luminescence reported for Ge-doped sodalite (2). It was found that the u.v. band exists in Ge-doped, luminescent powders but is not present in undoped sodalite samples that do not luminesce. The strong similarity in the behavior of the u.v. band intensity and the generated luminescent intensity (2), as a function of the hydrogen annealing temperature and time, indicates that the u.v. absorption band is directly related to the luminescent centers present in Ge-doped sodalite powders.

By directly observing the u.v. band intensity as a function of F-center creation, it is concluded that the creation of thermally erasable F-centers reduces the number of luminescent centers while the creation of optically erasable F-centers does not affect the luminescent center content. These experimental results support the mathematical calculations of generated luminescence as a function of F-center formation reported previously (2).

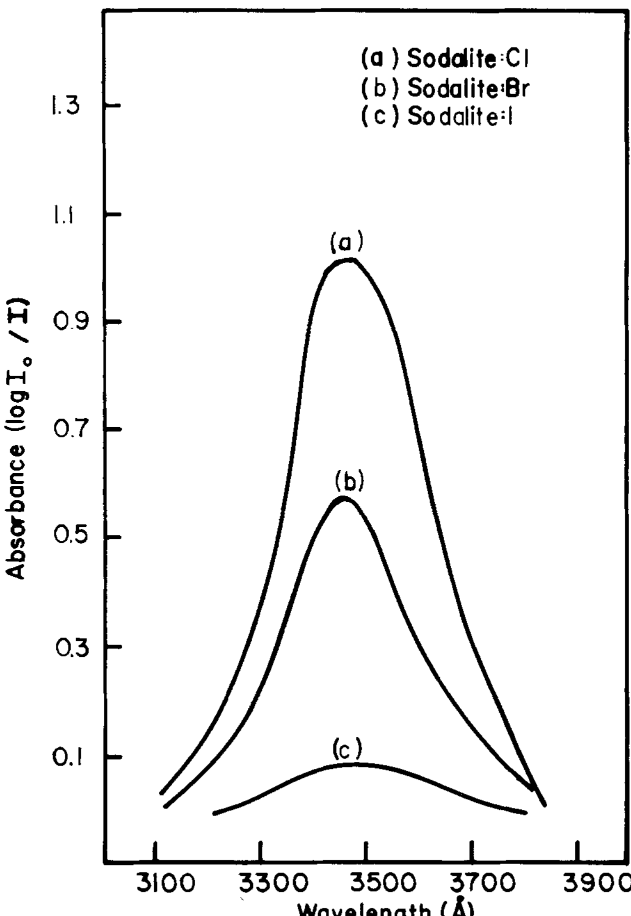

Fig. 7. Absorbance spectra of chlorine (a), bromine (b), and iodine (c) sodalite samples.

The above results may provide a key to determining the difference between the optical- and thermal-modes of coloration present in sodalite. While several models (8-10) have been proposed, none has adequately accounted for the two modes of coloration. It is generally accepted that both the optically and thermally erasable F-centers are created when electrons are trapped at halogen ion vacancies in the centers of sodalite cages (11-14). However, the origins of the electrons that become trapped have not yet been determined. It is possible that the origin of electrons that form thermally erasable F-centers is different from that of the electrons responsible for optically erasable coloration. Another possibility is that the electrons that are captured to form thermally erasable centers may originate far from the halogen vacancies they occupy while the electrons that are captured to form optically erasable centers may originate within or near the cage where the optically erasable center resides. Therefore, since a recombination site is readily accessible, the electrons of the optically erasable centers would have a high probability of recombination when optically pumped.

While both the "different origin" and the "proximity" models may be operative in a given material, the results reported here support the "different origin" explanation. One implication of these results is that the electrons responsible for thermally erasable F-centers are also involved with the transition which produces the observed luminescence. Electron beam exposure of the material may dislodge these electrons from the luminescent sites and they may become captured at a halogen vacancy to form an F-center. This sequence, extinction of a luminescent center at the expense of thermally erasable F-center formation, is consistent with our observations. The origin of those electrons

that result in optically erasable F-centers would then be somewhere other than a luminescent site since the formation of optically erasable centers does not affect the generated luminescence.

The exact location of the luminescent site is not known but a strong possibility is that the absorption and subsequent luminescence may be due to a hole located on a bonding oxygen atom. The hole could result from the removal of a nonbonding electron from an oxygen atom during the sensitizing process. This center is similar to the Al center or Al (III) e^+ center present in fused silica and quartz (15). Two of our observations support this possibility. First, an intershell transition localized on an oxygen atom would be well protected from variations in the lattice. We observe, in fact, that the wavelength of the peak of the u.v. absorption band is absolutely insensitive to changes in the halogen content which also causes significant alterations of the lattice parameter. The location of the emission band has also been reported to be insensitive to changes in the lattice size (1). Our second observation is that the efficiency of the luminescence increases greatly when small amounts of Ge are substituted for Si. Since Ge may be reduced much more easily than Si during the hydrogen annealing step, it is possible that a larger number of nonbonding electrons may be removed from oxygen atoms thus creating more luminescent centers. It has been reported (1, 3) that luminescence exactly like that described above also occurs in sodalite samples that contain no Ge. Therefore, Ge is not essential for luminescent emission but does improve the efficiency. This observation is also consistent with the above model since a hole could exist on the oxygen atom even in the absence of Ge. Quenching of the luminescence by F-center formation would be consistent with the above model if the removal of an additional electron from a luminescent site is sufficient to cause the luminescent transition to become forbidden. Additional experiments are being conducted to gather more information regarding the luminescent site and its relationship to the coloration mode.

Acknowledgments

The authors wish to thank Dr. E. B. Bradley for the use of his laboratory equipment during part of the experimental work, and Gary Grider and Debbie Shirley for their assistance in the preparation of the manuscript. This work was supported by the National Science Foundation under Grant No. DMR75-10620.

Manuscript submitted Feb. 1, 1979; revised manuscript received Sept. 5, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Fast Decay U.V. Phosphor—$YAlO_3$:Ce

Takeshi Takeda, Takeo Miyata, Fumio Muramatsu, and Tetsuhiko Tomiki[1]

Matsushita Research Institute Tokyo, Incorporated, Tamaku, Kawasaki 214, Japan

ABSTRACT

Samples prepared to obtain u.v.-emitting $YAlO_3$:Ce (YAP:Ce) by solid-state reactions up to 1600°C are never free of visible-emitting $Y_3Al_5O_{12}$:Ce (YAG:Ce). Furthermore, YAG cannot easily be removed from the products. By adding Ba compounds, the YAG content of the product can be minimized, and $BaAl_2O_4$ and other phases formed can be eliminated by HNO_3-treatment to yield "pure" YAP:Ce. The Ba compounds-fluxed YAP:Ce is moreover the most efficient of all trial samples. It has a radiant efficiency $\eta \sim 7\%$ and a decay time $\tau_{1/e} \sim 30$ nsec for CR excitation.

Ce^{3+}-activated phosphors show a very fast luminescence decay and are useful for flying-spot scanner tubes and beam-indexing tubes (1). Many hosts activated with Ce^{3+} (2-5) have been explored, *e.g.*, yttrium silicates and yttrium aluminates.

In the pseudobinary Y_2O_3-Al_2O_3 system, three compounds, $Y_3Al_5O_{12}$ [garnet: YAG (6)], $YAlO_3$ [perovskite: YAP (7)], and $Y_4Al_2O_9$ [monoclinic: YAM (8)], are known: YAG:Nd is a well-known laser material. YAG:Ce is the commercially available P46 phosphor with emission peak λ_{max} at 550 nm, radiant efficiency $\eta = 4\%$, and decay time $\tau_{1/e} = 70$ nsec for CR excitation (1). YAP:Ce single crystal is reported to show a luminescence with $\lambda_{max} \sim 370$ nm, $\tau_{1/e} = 16$ nsec, and efficiency near unity for u.v. excitation (9). However, YAP is described as metastable (10-14), because crushed single crystals (11, 12) or polycrystals from the melt (13, 14), both of which are single phase YAP initially, convert to YAG and an unidentified phase (11,

[1] Present address: The Department of Physics, University of the Ryukus, Naha, Okinawa, Japan.

Key words: ultraviolet, luminescence, tubes.

12) or to YAG and YAM (13, 14) when subjected to heat-treatment. Powder samples prepared through solid-state reactions below 1600°C contain YAG and YAM also (13, 14).

The purpose of this work is to prepare the u.v.-emitting YAP:Ce free of other phases, especially YAG phase. This is because YAG:Ce emits in the yellow, and moreover, it is not easily removed from the products. The preparation method is mainly through the use of Ba compounds as a flux which simultaneously produces an efficient YAP:Ce as the main product, and second phases, mainly $BaAl_2O_4$, which are mostly soluble in HNO_3.

YAP:Ce phosphors are described in patent documents (15) as having $\lambda_{max} \sim 370$ nm, $\eta = 2 \sim 3\%$, and $\tau_{1/e} \lesssim 40$ nsec for CR excitation. The properties of our phosphors are compared to these values below.

Phosphor Preparation

The starting materials were mainly Y_2O_3, Al_2O_3, and CeF_3 of 4*N* purity. Two kinds of attempts were carried out to investigate their influences on the solid-state reaction and luminescence properties. One was to add alkali or alkaline earth-compounds to the stoichiometric mixture and the other was to add excess Y_2O_3 to the stoichiometric mixture.

A designation x-y(CeF_3)-z(M) is used hereafter to specify the sample, which means that the sample is prepared from a mixture of $(1\text{-}0.01y)/2$ moles of Y_2O_3, $0.01y$ moles of CeF_3, $x/2$ moles of Al_2O_3, and $0.01z$ g-equiv. of M; M stands for the additive as flux. The starting materials were mixed by ballmilling for 20 hr in ethanol. After having been dried, the mixture was fired in a platinum crucible at temperatures in a range from 800° to 1600°C typically for 4 hr in air. Fired samples were ground slightly in an alumina bowl. Several samples were treated with HNO_3 solution (3*N*) and then washed with distilled water to remove the undesirable phases. The particle size of ground powders was about 1-10 μm with the maximum distribution at around 5 μm when the starting mixture contained fluorides, *e.g.*, CeF_3, BaF_2, YF_3. Samples prepared from the mixtures without fluorides were slightly sintered and had larger particle sizes.

The products were examined by powder x-ray diffraction using CuK_α radiation to identify the synthesized phases. To make a comparison easy of the relative amount of each phase in different samples, the operating parameters of the diffractometer were kept constant in all the measurements. The lines diffracted from the (121) plane of YAP, the (420) plane of YAG, the (221) plane of YAM, and the (222) plane of Y_2O_3 were marked.

Measurements

Emission spectra and intensities.—Measurements were made by employing a demountable CRT. The cathodoluminescent output emerging at 90° to the electron beam through a qualified fused silica window was focused by concave mirrors onto the entrance slit of a Leiss single-prism monochromator provided with a R666 photomultiplier (Hamamatsu TV Company, Limited). The correction factor for the instrumental response has been determined with the use of a D_2 arc lamp (Model UV-40, the Optronic Laboratory, Incorporated) and a tungsten lamp (EPI-1630, the Eppley Laboratory, Incorporated) which were both calibrated at NBS. Phosphors were settled on Al plates ($7 \times 13 \times 1$ mm^3) with an area density of 8 mg/cm^2. The emission spectra were taken under the irradiation of a 10 kV beam modulated at 430 Hz (duty 1/2). The beam current was set to ~0.3 $\mu A/cm^2$ and the spot size to 6 mm ϕ.

The emission intensity from YAP:Ce was estimated by using a u.v. bandpass filter (Hoya U360), and the relative intensity in different samples was measured under the same irradiation conditions by use of a turntable in a demountable CRT.

The radiant efficiency measurements were made by use of a thermopile (Hilger Schwarz FT 3·1, 2.3 μV/μW). Phosphors were excited by a beam modulated at 12.5 Hz. The relative radiant efficiency η of YAP:Ce phosphor was determined by using a number of NBS standard phosphors (NBS-1020 to -1028, and -1032) and η-values reported by Bril (16) and Ludwig and Kingsley (17).

Decay times.—The cathodoluminescence decay times were measured by employing a sealed off 6 in. CRT and a pulsed 10 kV electron beam with a repetition frequency of 1 kHz. The pulse width was usually set to 20 nsec and was enlarged up to 500 nsec in the estimation of the afterglow level in the decay curve. The emission from the sample was detected by the R666 photomultiplier combined with the U360 filter, and the decay curve was displayed on an X-Y recorder via a sampling oscilloscope (Sony-Tektronix 7S14). The time constant of the measuring system has been estimated as about 5 nsec (*i.e.*, pulse rise time ~ 1 nsec, photomultiplier transit time ~ 2 nsec, and RC-time constant ~ 2 nsec), and the 1/*e* decay time $\tau_{1/e}$ of P47 phosphor (Y_2SiO_5:Ce) measured here was about 4 nsec longer than the reported 30 nsec (1).

Results and Discussion

Solid-state reaction.—The formation profiles of various phases in the sample 1-1(CeF_3)-0 are shown against the firing temperature T_f in Fig. 1. The reaction is very sluggish and the product still contains YAG at $T_f = 1600$°C. By treating the samples with HNO_3, Y_2O_3 and YAM can easily be removed, but YAG cannot. Therefore, the suppression of YAG formation in the reaction process is important. As shown in Fig. 1, a remarkable dip occurs on the growth curve of YAP at $T_f = 1150$°C, corresponding to the growth curve peak of YAG. Since this unusual YAG growth at 1150°C is observed also in the sample 1-0-0 or 1-1(CeO_2)-0 when a part of Y_2O_3 or Al_2O_3 is replaced by YF_3 or AlF_3, it seems to have an intimate relation with the presence of fluorides in the starting mixture.

The addition of Ba compounds accelerates the formation of YAP and suppresses that of YAG. Figure 2 shows an example of the formation profiles of various phases in the sample 1-1(CeF_3)-1.5(BaF_2)-1.5($BaCO_3$). Other Ba compounds, *e.g.*, BaO, $Ba(NO_3)_2$, BaC_2O_4, affected the reaction similarly. Although the effect of Ba compounds on the YAP formation is less marked than that of KF (*cf.* Fig. 3), the Ba compound-fluxed sample is the most efficient phosphor of all the trial

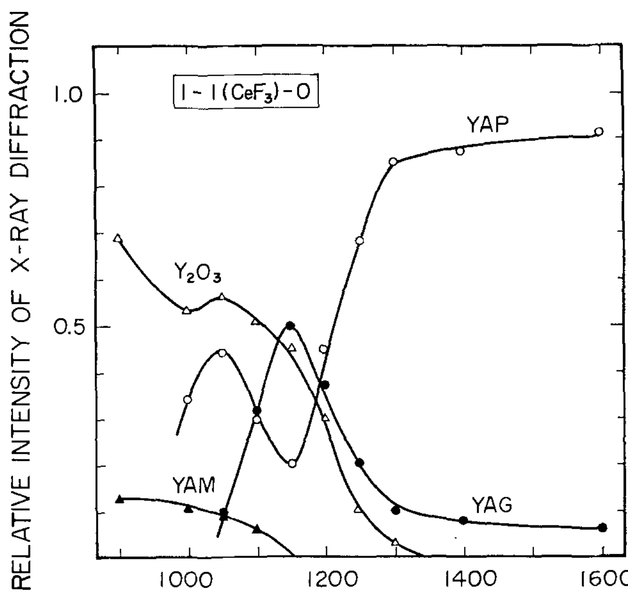

Fig. 1. Growth curves of YAP, YAG, and YAM in 1-1(CeF_3)-0

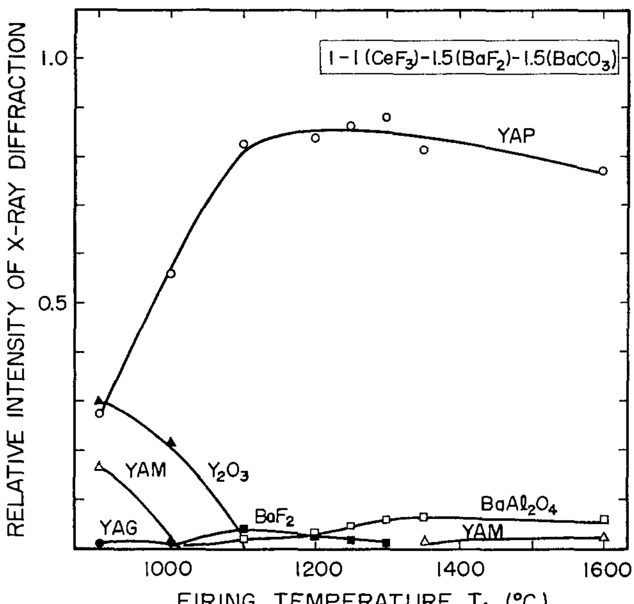

Fig. 2. Growth curves of YAP, YAG, YAM, and $BaAl_2O_4$ in 1-1 (CeF_3)-1.5(BaF_2)-1.5($BaCO_3$).

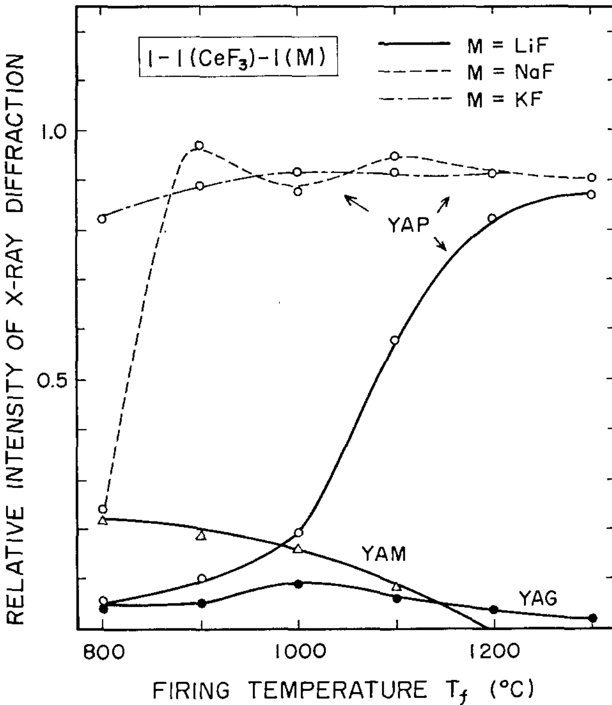

Fig. 3. Growth curves of YAP in 1-1(CeF_3)-1(M), M being LiF, NaF, or KF. Curves of YAG and YAM are shown only for 1-1(CeF_3)-1(LiF).

samples in this work. As is seen from Fig. 2, no YAG phase is detected in the samples fired at $T_f \geqq 1100°C$. $BaAl_2O_4$, BaF_2, and sometimes YAM are detected in these samples, but they can easily be removed by HNO_3-treatment to yield the x-ray diffraction pattern of "pure" YAP phase.

The above samples are prepared from the mixtures containing fluorides, *i.e.*, CeF_3 and BaF_2. In the fluoride-free mixtures the reaction proceeds similarly, but the products, *e.g.*, 1-1(CeO_2)-3($BaCO_3$), are slightly sintered and have larger particle sizes. Moreover, the products are less efficient phosphors than those from the mixtures with fluorides. Thus, the practical YAP: Ce phosphor is synthesized from the mixture containing both barium compound and fluoride. Fluorides may be CeF_3, BaF_2, YF_3, or AlF_3. The addition of Mg, Ca, Sr compounds hardly affected the reaction.

In Fig. 3 is shown the effect of LiF, NaF, or KF on the YAP formation; KF gives the most remarkable effect to accelerate the YAP formation and in the sample 1-1(CeF_3)-1(KF) the YAP content in the product shows a nearly saturated value even at $T_f = 800°C$. In these alkali compounds-fluxed samples, the YAG phase is almost equally suppressed and thus the growth curve of YAG phase is shown only for the case of LiF addition in Fig. 3.

The suppression of the YAG phase is observed also when excess Y_2O_3 is added to the mixture. According to Mizuno and Noguchi (13), the YAG phase is still detected in the sample prepared by firing a mixture with Y_2O_3:Al_2O_3 = 0.57 : 0.43 at 1600°C. This product is expressed as 0.754-0-0 in our designation. Figure 4(a) shows no YAG phase in the sample 0.78-1(CeF_3)-0 fired at $T_f \geqq 1300°C$. This difference might be caused by the presence of CeF_3 in the present mixture. The sample 0.5-1(CeF_3)-0 just corresponds to the product from the stoichiometric mixture for YAM. Figure 4(b) indicates that the formation of YAM is also sluggish. An attempt was made to obtain the single phase YAM by firing the mixture at 1600°C; this resulted in failure. Although a YAM:Ce phosphor is described (18) as having λ_{max} at 320 nm for the 254 nm excitation, we could not observe this emission. Only the YAP:Ce emission was detected in the sample 0.5-1(CeF_3)-0 fired at 1600°C for the 254 nm or the CR excitation.

X-ray diffraction lines which seem to be ascribed to CeO_2 or $Ce_2Y_2O_7$ are detected in the samples with $y \geqq 0.5$. These lines also disappear when the samples are treated by HNO_3. The Ce concentration was determined by means of a mass spectrometer and a spectrochemical analysis on the samples 1-y(CeF_3)-z(BaF_2)-(3 − z) ($BaCO_3$) with y = 0.1, 0.5, 1, and 2. Here, $3y + 2z = 6$ and $y \leqq 2$. The samples were fired at 1300°C for 2 hr and treated by HNO_3. The joint use of BaF_2 and $BaCO_3$ is for the sake of keeping the fluorine amount constant in the starting mixture when y is varied in the above formula. The detected Ce concentration was in good agreement with each of y-values [doped Ce

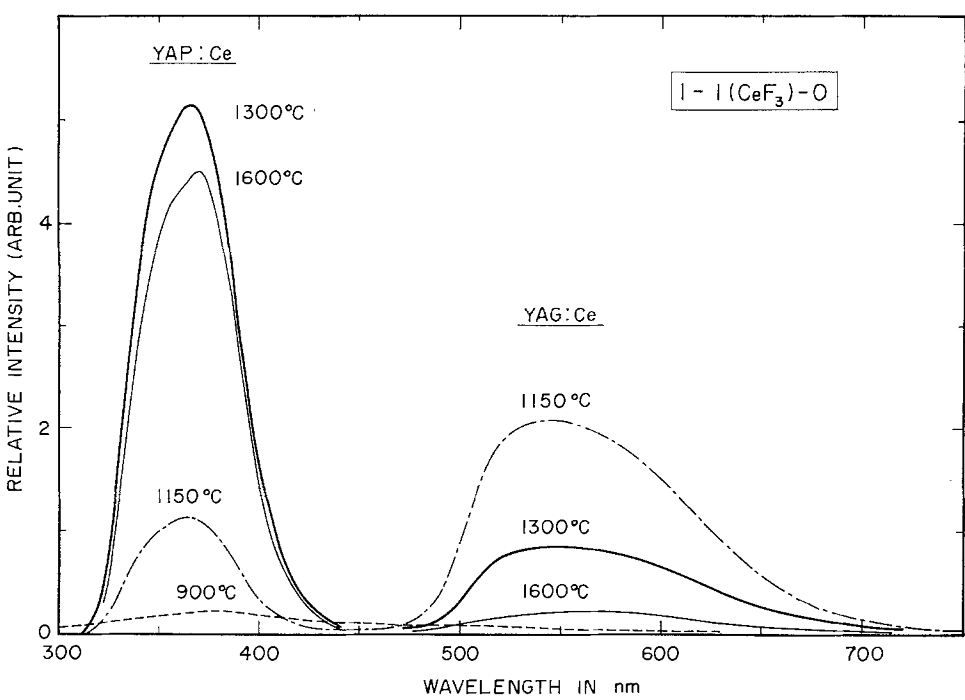

Fig. 5. Cathodoluminescence spectra in 1-1(CeF_3)-0 fired at 900°, 1150°, 1300°, and 1600°C.

concentration in atom percent (a/o)] for $y \leqq 0.5$ and tended to a saturated value of 0.5 $\sim$ 0.6 a/o for $y \geqq 1$. The agreement between the results obtained through the two methods was found to be sufficient. These results suggest that the solubility limit of Ce ions in YAP is around 0.5 a/o. This value is very close to the solubility limit of Ce ions in YAG (19).

Luminescence properties.—The emission spectra of the samples 1-1(CeF_3)-0 are shown in Fig. 5. Reflecting the unusual YAG growth in the 1150°C sample (*cf.* Fig. 1), the emission of YAG: Ce is much stronger than that of YAP: Ce in this sample. The emission color changes from yellow for T_f = 1150°C to white for 1300°C and further to whitish violet for 1600°C. As is seen from the figure, the apparent λ_{max} of YAP: Ce emission shifts to longer wavelengths as T_f increases, indicating an increase of absorption in the shorter wavelength region of the YAP: Ce emission spectrum.

The relative intensities of cathodoluminescence from samples with fluxes, 1-1(CeF_3)-1(M) and 1-1(CeF_3)-1.5(BaF_2)-1.5($BaCO_3$), are displayed against T_f in Fig. 6, where M stands for Li_2CO_3, NaF, KF, K_2CO_3, RbCl, CsCl, $MgCO_3$, $CaCO_3$, and $SrCO_3$. The data of samples without flux, 1-1(CeF_3)-0, are also included for comparison (a broken curve). Since the U360 filter is employed here, the emission from YAP: Ce is dominantly detected. The emission intensity of P47 phosphor [λ_{max} = 415 nm and η = 6% (1)] measured through this system is taken as unity in the figure. One sees in Fig. 6 that the emission intensity enhancement is most prominent in the (BaF_2 + $BaCO_3$)-fluxed samples. A similar enhancement is observed also when the samples are prepared with other Ba compounds, *e.g.*, BaO, $Ba(NO_3)_2$, BaC_2O_4. The 1100°C sample with Ba compounds is the most efficient of all the samples in Fig. 6 and has $\eta \sim 6\%$. The 1300°C sample without flux has $\eta \sim 3\%$; this value agrees well with the η-value of YAP: Ce in the patent documents (15b, 15c) where it is reported to be 0.8 $\sim$ 0.9 times the radiant efficiency of P16 phosphor [4% (4)].

As shown in Fig. 6, the emission intensity of Ba compounds-fluxed samples shows a pronounced decrease with T_f when it exceeds 1100°C; the intensity of the 1600°C sample is about one-half of that of the 1100°C sample. Decreases of the emission intensities are observed also in the samples with y = 0.5 and y = 0.1, as shown in Fig. 7. In the samples with $y \leqq$ 0.01, however, the emission intensity shows no decrease with increasing T_f. These results will be explained by taking into account the emission line shape and the decay time mentioned below.

The dependence on y of the YAP: Ce emission line shape is shown in Fig. 8. The spectra are normalized with respect to their maxima. The apparent λ_{max} shifts to longer wavelengths as y increases; from 355 nm for y = 0.01 to 365 nm for y = 1 at T_f = 1300°C.

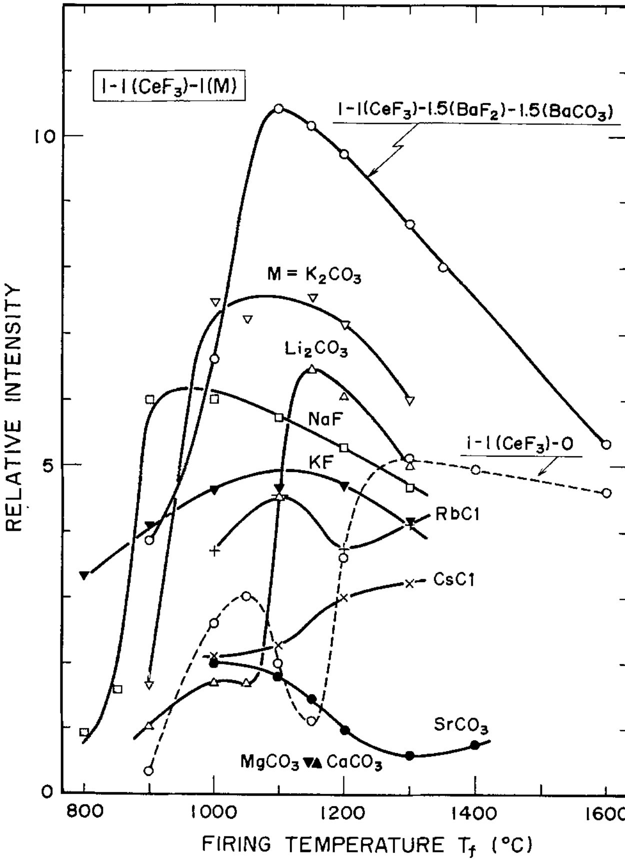

Fig. 6. Relative intensity of YAP:Ce cathodoluminescence in the samples 1-1(CeF_3)-0, 1-1(CeF_3)-1(M), and 1-1(CeF_3)-1.5(BaF_2)-1.5($BaCO_3$). M = Li_2CO_3, NaF, KF, K_2CO_3, RbCl, CsCl, $MgCO_3$, $CaCO_3$, or $SrCO_3$.

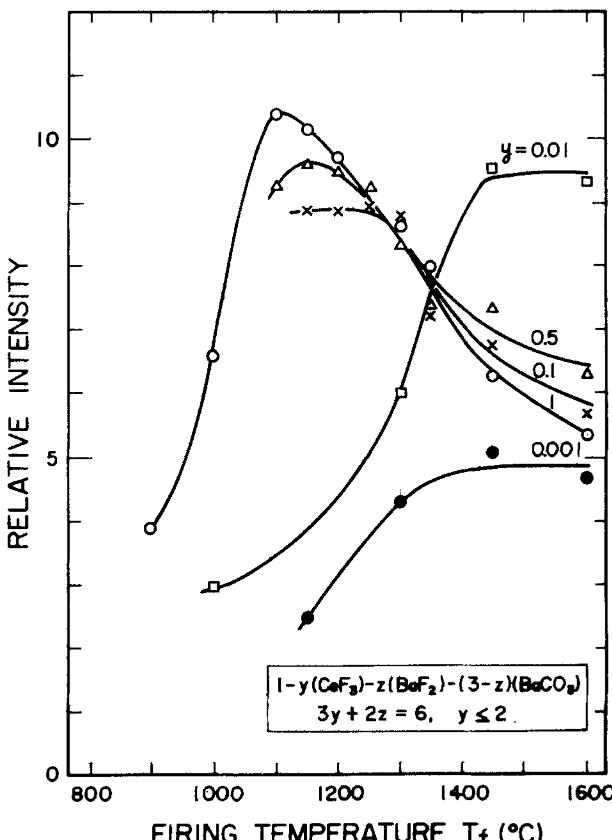

Fig. 7. Dependences on y and T_f of the relative intensity of YAP:Ce cathodoluminescence in Ba compounds-fluxed samples. Samples are treated with HNO_3.

Since Ce^{3+} in YAP has an absorption band extending to ~ 350 nm (9), a self-absorption would occur in the shorter wavelength region of the emission spectrum, and thus the increase of y would cause the apparent λ_{max}-shift to longer wavelength. In the samples with $y \geqq 0.1$, the apparent λ_{max}-shift to longer wavelength is observed also with the increase of T_f. On the contrary, it is observed in samples with $y \leqq 0.01$ that the emission line shape depends neither on y nor on T_f; this indicates that the self-absorption is negligibly small in these samples. The progressive increase of absorption with T_f in samples with $y \geqq 0.1$ will partly explain the decrease of the emission intensity in Fig. 7.

As shown in Fig. 8, the YAG:Ce emission becomes stronger with decreasing y. This means that not only barium ions, but also cerium ions play a role in suppressing the YAG formation.

The addition of Ba compounds is found not to cause an appreciable change in the YAP:Ce emission line shape.

The decay times are shown in Fig. 9. The data of the samples 1-1(CeF_3)-0 are included for comparison (a broken curve). As seen from this figure, $\tau_{1/e}$ for $y \geqq 0.1$, which shows a nearly constant value of 27 ~ 28 nsec for low T_f, becomes shorter with T_f when it exceeds a certain threshold value. This value is ~1150°C for $y = 0.5$ and $y = 1$, and is ~1350°C for $y = 0.1$. The $\tau_{1/e}$-values for $y < 0.1$ are greater than the above constant value, but tends to it as T_f increases. Since the $\tau_{1/e}$-values for $y = 1$ almost agree with each other for the samples with and without Ba compounds for $T_f \gtrsim 1150°C$, it seems that the addition of Ba compounds yields only a small influence in $\tau_{1/e}$.

The influences of LiF and NaF on $\tau_{1/e}$ are also small, but the addition of KF makes $\tau_{1/e}$ considerably long; for example, the sample 1-1(CeF_3)-1(KF) fired at 1300°C has $\tau_{1/e}$ of about 30 nsec.

In the samples x-1(CeF_3)-0 with $x < 1$, a broad maximum of the emission intensity is observed for x between 1 and 0.5, and $\tau_{1/e}$ shows a gradual increase with decreasing x. For example, in the sample 0.78-1(CeF_3)-0 fired at 1300°C, an emission intensity of 8 in unit of the ordinate of Fig. 6 and $\tau_{1/e}$ of 24 nsec are obtained; that is, the emission intensity and $\tau_{1/e}$ increase by 60 and 10%, respectively, in comparison with those in 1-1(CeF_3)-0.

The luminescence decay of Ce^{3+} in YAP is not expressed with a single exponential function and shows an afterglow which is usually more pronounced for lower T_f or smaller y. An example of the decay curve is shown for the sample 1-1(CeF_3)-3($BaCO_3$) fired at

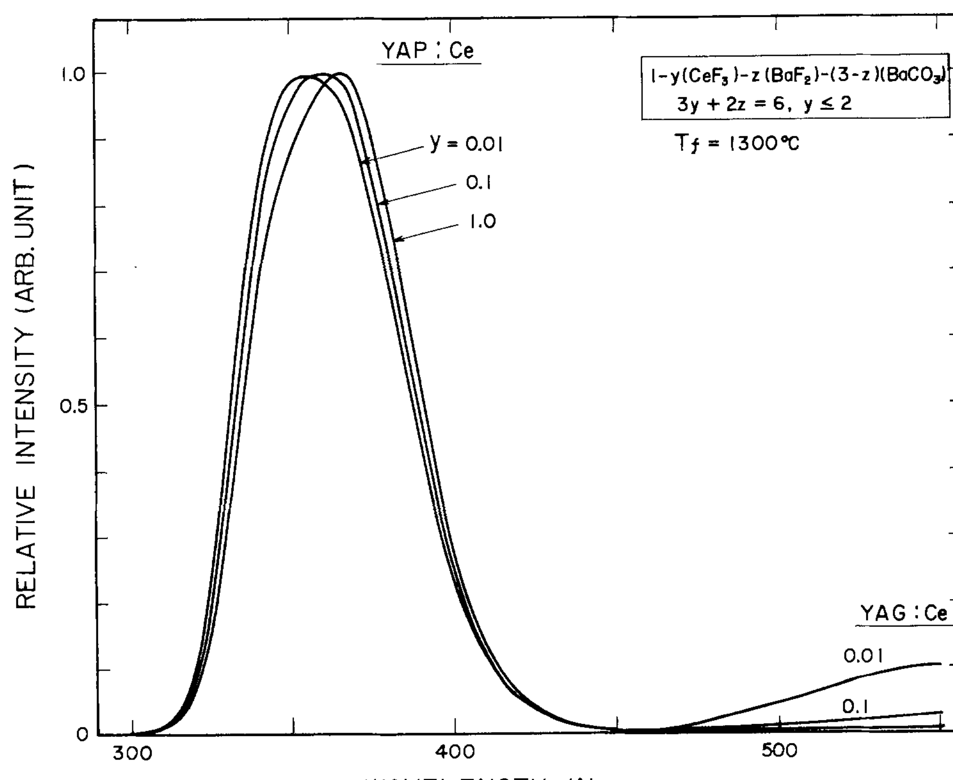

Fig. 8. Dependences on y of the cathodoluminescence spectrum in Ba compounds-fluxed samples. Samples are treated with HNO_3.

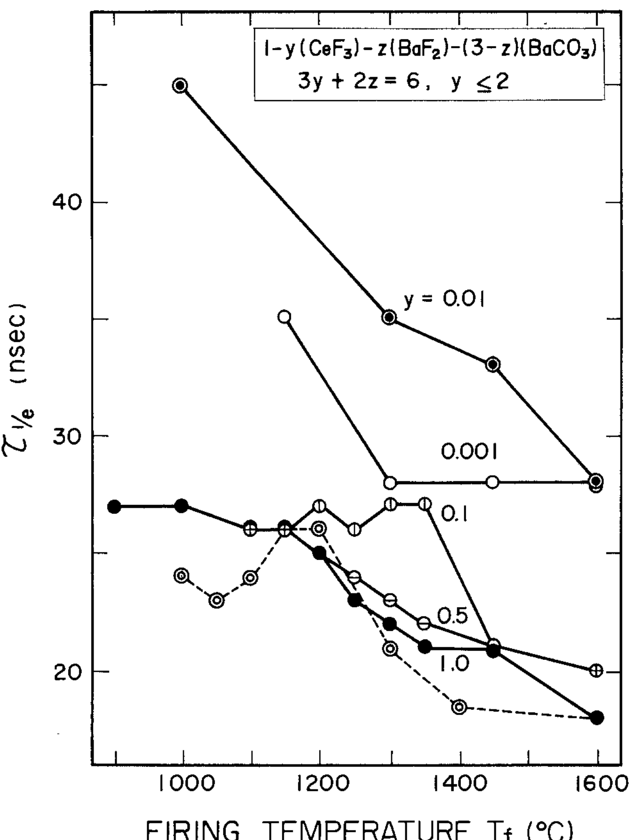

Fig. 9. Dependences on y and T_f of the cathodoluminescence decay time $\tau_{1/e}$ of YAP:Ce in the samples with and without Ba compounds as flux. Samples with Ba compounds are treated with HNO_3.

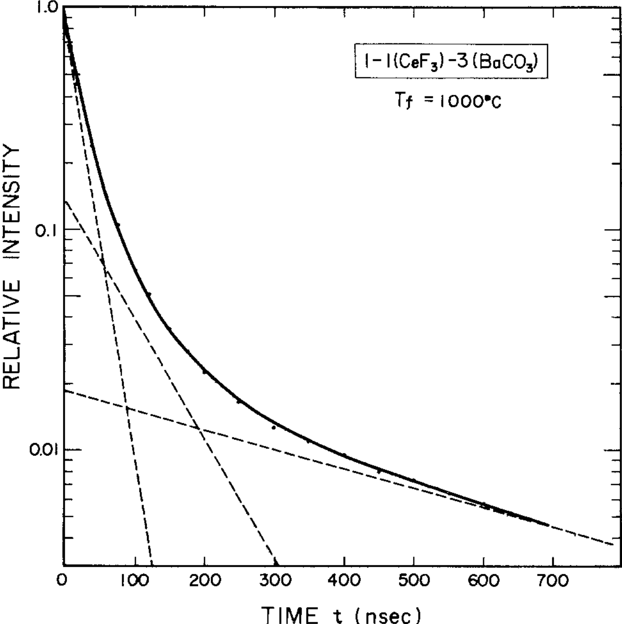

Fig. 10. An example of cathodoluminescence decay curve in 1-1(CeF_3)-3($BaCO_3$) fired at 1000°C.

1000°C in Fig. 10. Such decay curves have been observed in several Ce^{3+}-activated phosphors (20) and are explained in terms of energy traps which release their energy slowly to excite the emission center after the excitation pulse is turned off. As shown in the figure, the decay curve can be expressed by a sum of three different exponents (dashed lines) in a region of initial several hundreds nanoseconds. The decay function for this sample is

$$D(t) = \frac{\exp(-t/22) + 0.1590 \exp(-t/80) + 0.0217 \exp(-t/500)}{(1 + 0.1590 + 0.0217)} \quad [1]$$

Here, t is in nsec and the excitation pulse width (Δt) is 20 nsec. The full curve calculated by use of Eq. [1] is seen to fit the dots representing the experimental behavior. It will be reasonable to consider that the shortest decay constant (τ_1) corresponds to the lifetime of Ce^{3+} in the excited 5d level and that the longer ones represent the time constants of the process of energy release from energy traps. Since the greater number of energy traps are to be filled with the increase of Δt, the afterglow level would be more pronounced for longer Δt. Therefore, Eq. [1] is correct only for $\Delta t = 20$ nsec. To see the validity of Eq. [1], several decay behaviors with different values of Δt were analyzed. It was confirmed that each decay behavior observed could be well fitted only by changing the coefficients, *i.e.*, 0.1590 and 0.0217 in Eq. [1], without varying the time constants.

Figure 11 shows the values of τ_1 in several samples. From this figure, the following can be pointed out. First, for $y \leq 0.01$, τ_1 depends neither on y nor on T_f and shows a constant value of 22 ~ 23 nsec. Second, for $y \geq 0.1$, τ_1 which is initially equal to this constant value becomes shorter with increasing T_f above a certain threshold value. These results seem to indicate that the constant value corresponds to the radiative transition probability of the 5d-4f Ce^{3+} emission. Our measuring system has a time constant of about 5 nsec. So, by simply subtracting this from the constant value, we obtain 17 ~ 18 nsec. This is very close to 16 nsec obtained for the u.v. excitation (9).

The decrease of τ_1 in the samples with $y \geq 0.1$ and with higher T_f will be ascribed to a nonradiative transition. Energy sinks might be produced to cause a concentration quenching in these samples. These energy sinks will not affect τ_1 of the samples with $y \leq 0.01$, as the probability of energy transfer from Ce^{3+} to Ce^{3+} is negligibly small in these samples. The nonradiative transition causes the emission loss, and this as well as the absorption increase mentioned before will explain the decrease of emission intensity shown in Fig. 7.

As stated hitherto, Ce concentration, firing temperature, and combination of starting materials are interrelated in their effects on the emission intensity and the decay time. A partial replacement of Y_2O_3 or Al_2O_3 by YF_3 or AlF_3 is also effective. By optimizing

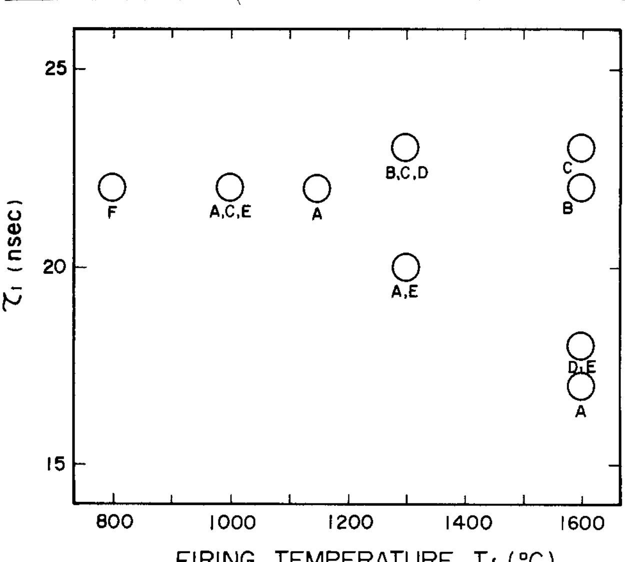

Fig. 11. Values of τ_1 in the samples 1-1(CeF_3)-0 (A), 1-y(CeF_3)-z(BaF_2)-(3 − z)($BaCO_3$) with y = 0.001 (B), 0.01 (C), 0.1 (D), 1 (E), and 1-1(CeF_3)-1(KF) (F). $3y + 2z = 6$ and $y \leq 2$. Samples except (A) are treated with HNO_3.

preparation conditions, the highest η of 7 ~ 7.5% is obtainable; however, this accompanies a longer $\tau_{1/e}$ of 30 ~ 32 nsec.

Finally, as for the deterioration against a continuous electron beam bombardment, the present phosphor is not serious and superior to P47 phosphor.

Acknowledgment

The authors are much indebted to Dr. J. Nishida and the members of his group for their cooperation in this work and information concerning YAP:Ce characteristics as beam-indexing phosphor in color TV applications.

The Interplay of Thermodynamics and Kinetics in Molecular Beam Epitaxy (MBE) of Doped Gallium Arsenide

R. Heckingbottom, C. J. Todd, and G. J. Davies

Post Office Research Centre, Martlesham Heath, Ipswich, IP5 7RE, Suffolk, England

ABSTRACT

Molecular beam epitaxy (MBE) is normally carried out with a substantial overpotential for growth. The generally accepted assumption, that as a consequence the thermodynamic framework describing chemical equilibrium is irrelevant, has been reexamined. The thermodynamic predictions for the behavior of the common dopants Si, Ge, Sn, Pb, Be, Mn, S, Se, Te, Zn, Cd, and Mg in GaAs under typical MBE conditions have been determined. Good agreement with observed behavior is found for all cases except Pb. Thus it is shown that when doping is unsuccessful it is because there is no overpotential for doping, even though the overpotential for growth of GaAs is maintained. The results show that there is no clear evidence for major kinetic barriers in MBE of GaAs, only the possibility of subtler effects of the kind found in VPE and LPE. The method should be predictive in the application of MBE to new systems.

It is generally assumed (1-3) that molecular beam epitaxy (MBE) of gallium arsenide is controlled by kinetic aspects of the crystal growth process. By this it is meant that the kinetic processes controlling the crystal growth are not those consistent with thermodynamic equilibrium being reached; rather that there are kinetic barriers which prevent equilibrium from being reached and which prevent thermodynamics being used to predict sensible approaches to MBE.[1] As a typical example it is often quoted that Zn cannot be used to dope GaAs successfully under MBE conditions because its sticking coefficient is too low, a fact which is regarded as a kinetic observation that could not be predicted from thermodynamics.

In this conventional view MBE is to be contrasted strongly with alternative methods of crystal growth, vapor phase epitaxy (VPE) and liquid phase epitaxy (LPE), where an important interplay between thermodynamic framework and kinetic detail is assumed

Key words: equilibrium, impurity concentration, vapor pressure.

[1] The authors would like to thank the referee for drawing a notable exception to these remarks to their attention. In their recent book (25) (not available in the U.K. at the time of writing) Casey and Panish outline an approach by Ilegems which starts from a similar standpoint to ours. The Ilegems approach accounts reasonably for the behavior of the low vapor pressure dopants but fails qualitatively for S, Se, and Te and quantitatively in the comparison of Zn and Mg.

Table I. Predicted and observed results of doping GaAs under MBE conditions

Dopant	Si	Ge	Sn	Pb	Be	Mg	Zn	Cd	S	Se	Te	Mn
Prediction	S	S	S	M	S	M	U	U	S	S	S	S
Observation	S	S	S	U	S	M	U	U	S	S	S	S

Where S = successful, M = moderately successful, U = unsuccessful.

(4, 5). It is pointed out here that it is layers grown by LPE and VPE that have proved suitable for semiconductor device fabrication. If MBE layers are to have a similar suitability, they must approach the equilibrium situation to a comparable extent and not contain large additional nonequilibrium concentrations of defects. In general MBE-grown layers of GaAs are proving suitable for device purposes with the implication that the approach to equilibrium is comparable in MBE, VPE, and LPE.

In this paper we examine closely what the predictions of the thermodynamic framework should be for MBE of GaAs, with particular emphasis on doping, and compare them with the experimental results. We have considered all the common dopants and the qualitative comparison is shown in Table I.

As can be seen from Table I, there is only one instance where the thermodynamic prediction is in error. In the first part of the paper we show, on a quantitative basis, how the qualitative summary in Table I is obtained. In the second part, the numerical results are compared with the experimental data and the implications of the close fit for the kinetics of doping in MBE of GaAs are outlined.

Theoretical Approach

The generally accepted approach to describing doping of GaAs under equilibrium conditions is illustrated by the following example of a donor impurity occupying a site on the arsenic sublattice

$$D_{gas} + V_{As} \rightleftharpoons D_{As} \qquad \Delta G_1 \qquad [1]$$

$$D_{As} \rightleftharpoons D_{As}^+ + e \qquad \Delta G_2 \qquad [2]$$

or overall

$$D_{gas} + V_{As} \rightleftharpoons D_{As}^+ + e \qquad \Delta G_3 \qquad [3]$$

where D_{gas} is a donor atom in the vapor phase, D_{As} and D_{As}^+ represent donor atoms and ions respectively substitutional on As lattice sites; V_{As} is a vacant arsenic lattice site, and e is an electron in the conduction band of GaAs. ΔG_1 etc. are the partial molal free energies of the respective reactions, thus

$$\Delta G_1 = -RT \ln K_1 \qquad [4]$$

where

$$K_1 = [D_{As}]/P_D[V_{As}] \qquad [5]$$

and [ ] represents concentration and P pressure in atmospheres, *i.e.*, assuming activity coefficients of unity. Similarly

$$K_2 = n[D_{As}^+]/[D_{As}] \qquad [6]$$

where $n = [e]$ and

$$K_3 = K_1K_2 = n[D_{As}^+]/P_D[V_{As}] \qquad [7]$$

If all the carriers in the bulk semiconductor originate from reaction [2] then

$$n = [D_{As}^+] = K_3^{1/2}P_D^{1/2}[V_{As}]^{1/2} \qquad [8]$$

Analogous treatments apply to donors on sites on the Ga sublattice and acceptors on both sublattices. In each case if we control the native defect concentration, *i.e.*, $[V_{As}]$ in the example illustrated by Eq. [8], via the arsenic pressure we may determine the carrier concentration in the GaAs (n in the above case) by the activity of the dopant outside the GaAs (P_D in the above case).

The basic problem therefore is to calculate what pressures of dopants are required to give useful concentrations of carriers under normal MBE conditions for growth of GaAs, and to see how these compare with the pressures needed in practice. First, if we require specific results we must define our growth conditions. We will choose $P_{Ga} = 10^{-6}$ Torr, $P_{As_4} = 2 \cdot 10^{-6}$ Torr and $T_{substrate} = 560°C$ ($\equiv$ 833°K) and calculate the dopant pressures required to give carrier concentrations of $2.2 \cdot 10^{19}$ cm^{-3} and $2.2 \cdot 10^{16}$ cm^{-3} (or 10^{-3} and 10^{-6} respectively when expressed as fractional concentrations of the relevant Ga or As sublattice sites). We can now consider the most effective way to make the quantitative estimates for the individual dopant elements.

Be, Si, Ge, and Sn.—It will be clear that we are concerned primarily with the interaction between the dopant atom and the GaAs lattice, *i.e.*, the enthalpies and entropies that contribute to ΔG_3. However this significant group of dopants permit a simplification which means it is sufficient to consider their elemental vapor pressures. Thus we note that if we apply any pressure in the typical MBE range (10^{-6}-10^{-10} Torr), these elements would condense at 560°C (6). In a nongrowth experiment we would have the condensed element with a surface concentration in the GaAs equal to the solubility limit at 560°C. To obtain sensible doping levels with no surface condensation some measure of ΔG_3 would be required. However we have specified a significant growth rate and based on the thermodynamic prediction of a unit sticking coefficient we calculate that a pressure of 10^{-9} Torr will give a dopant concentration of 10^{-3} (*i.e.*, P_D/P_{Ga}) and a pressure of 10^{-12} Torr will give a dopant concentration of 10^{-6}. It will be noted that the value of 10^{-12} Torr lies below the vapor pressures of Sn and Be at 560°C, technically invalidating the approximation near this lower limit. A fuller consideration based on LPE growth (7) of GaAs shows that even for the worse case, Sn, the correction is negligible.

S, Se, and Te.—In contrast to the previous group, all these important conventional dopants for GaAs have elemental vapor pressures P_D^o in excess of the MBE working range by several orders of magnitude at 560°C. Any MBE must be carried out therefore with dopant activities a_D ($\equiv P_D/P_D^o$) $<< 1$. A most convenient source of data for determining whether the values of a_D available in MBE will be high enough to provide useful doping is provided by LPE and VPE. Before carrying out any extrapolations however it is necessary to consider that the treatment given in Eq. [1] → [8] does not fit the experimental data. Thus the $n \alpha P_D^{1/2}$ relationship given in [8] is often replaced in practice by a linear relationship (8, 9) $n \alpha P_D$ or $n \alpha a_D$, which is more readily applicable to growth from solution.

One interpretation is that the thermodynamic treatment is inapplicable. However this seems most unlikely. The linear dependence has now been reported for group II, group IV, and group VI elements involving substitution on both sublattices and in both VPE and LPE (4, 5, 8, 9). It is unlikely that the crucial kinetics will be almost identical in all these dissimilar situations; rather that some overall thermodynamic framework does apply, and the model of the defect chemistry is wrong in detail. Linear dependence of $[n] = [D_{As}^+]$ at room temperature can be obtained by a simple amendment to the model. During growth we assume that n is not dominated by the incorporated [D] but is fixed at some higher value. In these circum-

stances n is constant and

$$[D_{As}^+] = K_3 P_D [V_{As}]/n = K_3' P_D [V_{As}] \quad [9]$$

showing the required linear dependence of dopant incorporation on P_D.

At least two important models for expecting n to be constant and $>[D_{As}^+]$ have already been described (5, 9). Casey and Panish (9) have proposed that a surface space-charge layer dominates the incorporation of S, Se, and Te while Hurle (5) has recently suggested that a high value of n may result from the ionization of a native defect, like V_{As}, at the growth temperature. For present purposes we do not need to adopt the details of either model, simply to adopt the observed linear dependence of $[D^+]$ on P_D or a_D for our extrapolations from VPE or LPE conditions to those in MBE.

We may now consider doping with sulfur. Under practical VPE conditions (10) a ratio of 10^{-7} for H_2S/H_2 is sufficient to give $[S_{As}^+] \simeq 10^{17}$ cm^{-3} at 750°C. If we assume that the $P_{H_2S}/[S_{As}^+]$ ratio is not particularly temperature sensitive, we may calculate the value of P_{S_2} at 560°C which is in equilibrium with $P_{H_2} = 1$ atm and $P_{H_2S} = 10^{-7}$ atm from standard free energy data (11). We then find that $[S_{As}^+] = 10^{17}$ cm^{-3} is equivalent to a P_{S_2} value of only $6.5 \cdot 10^{-21}$ atm. Using Eq. [9] for the case of D = S

$$[S_{As}^+] = K_3' P_S [V_{As}] = K_3'' P_{S_2}^{1/2} [V_{As}] \quad [10]$$

we may calculate the values of P_{S_2} necessary to give $[S_{As}^+]$ of $2.2 \cdot 10^{16}$ cm^{-3} and $2.2 \cdot 10^{19}$ cm^{-3} as being $1.98 \cdot 10^{-20}$ Torr and $1.98 \cdot 10^{-14}$ Torr respectively. Clearly the situation degenerates to that of the first group of elements during growth. Then allowing for the diatomic nature of S_2, the required pressures to obtain the upper and lower doping levels are $5 \cdot 10^{-10}$ Torr and $5 \cdot 10^{-13}$ Torr respectively. The assumption about the temperature dependence of the $P_{H_2S}/[S_{As}^+]$ ratio is unlikely to be poor enough to affect this conclusion.

For completeness we should also consider that there is a significant change in P_{As_4} in transferring from VPE to MBE conditions. From Ashen *et al* (12) we may set the value of P_{As_4} in a typical VPE kit at $1.5 \cdot 10^{-3}$ atm while we have chosen $2.6 \cdot 10^{-9}$ atm for our MBE system. The effect of P_{As_4} is conventionally described as follows

$$\tfrac{1}{4} As_4 + V_{As} \rightleftharpoons 0 \quad [11]$$

$$K_{11} = P_{As_4}^{-1/4} [V_{As}]^{-1} \quad [12]$$

$$[V_{As}] = K_{11}^{-1} P_{As_4}^{-1/4} \quad [13]$$

Substituting in Eq. [10] we have

$$[S_{As}^+] = K_3''' P_{S_2}^{1/2} P_{As_4}^{-1/4} \quad [14]$$

where $K_3''' = K_3'' K_{11}^{-1}$. Thus the reduction in P_{As_4} increases the level of $[S_{As}^+]$ corresponding to a given value of $P_{S_2}^{1/2}$. In the case above the increase is by a factor of 24.9. As a result our calculated values of P_{S_2} should fall by a factor of 620, making the prediction that the ratio of arrival rates will dominate even more secure. Alternative schemes (5) where V_{As} is ionized to give V_{As}^+ and a controlling value of n would by analogous treatment show a reduced dependence of $P_{As_4}^{-1/8}$ i.e., an increase of times 5 in $[S_{As}^+]$ due to the change of P_{As_4} between VPE and MBE conditions.

The only remaining doubt about the prediction for sulfur doping stems from a second reaction which is also thermodynamically possible. Ga_2S should not only be stable under the growth conditions but have a vapor pressure in excess of 10^{-6} Torr at 560°C. Thus the value of P_{S_2} needed in practice might differ from those shown in Table II due to a loss of both S and Ga due to the competing formation and reevaporation of Ga_2S molecules.

Tellurium is another member of the group where there is sufficient data, this time from LPE (13), to allow assessment of the likely position in MBE. Casey *et al.* (13) have shown that to obtain $[Te_{As}^+] = 10^{-6}$ at 1273°K one requires $[Te_{soln.}] = 2.85 \cdot 10^{-6}$, *i.e.*, the segregation coefficient is 0.35, in a typical LPE system. An estimation of the position at 833°K can be obtained by extrapolation of the data of Greene (14). The segregation coefficient is $\simeq 40$ indicating that the required value of $[Te_{soln.}]$ has fallen to $2 \cdot 10^{-8}$. The next task is to determine the vapor pressure of tellurium in equilibrium with the solution. We may write

$$Te_{soln.} \rightleftharpoons \tfrac{1}{2} Te_2 \quad [15]$$

$$K_{15} = P_{Te_2}^{1/2} / [Te_{soln.}] \quad [16]$$

To obtain an over estimate of K_{15} we may assume Raoult's law, *i.e.*, ignoring any stabilizing effect of Te-Ga interactions in the solution. Then for the limiting case of liquid Te we have at 560°C

$$K_{15} = [3.29 \cdot 10^{-3}]^{1/2}/[1] = 5.7 \cdot 10^{-2} \text{ atm}^{1/2}$$

Substituting for K_{15} and $[Te_{soln.}]$ in [16] we obtain

$$P_{Te_2}^{1/2} = 5.7 \cdot 10^{-2} \cdot 2 \cdot 10^{-8} \text{ and } 5.7 \cdot 10^{-2} \cdot 2 \cdot 10^{-5} \text{ atm}^{1/2}$$

for our required doping levels of $2.2 \cdot 10^{16}$ cm^{-3} and $2.2 \cdot 10^{19}$ cm^{-3}, respectively. The respective values of P_{Te_2} are thus $9.9 \cdot 10^{-16}$ and $9.9 \cdot 10^{-10}$ Torr. For our assumed growth conditions the lower value will again have to be increased to $5 \cdot 10^{-13}$ Torr. As with S doping there is the possibility of competing reactions giving Ga_2Te or similar volatile species, but in this case no firm data appear to be available.

Empirical data on the doping of GaAs with Se seem almost nonexistent. On general grounds its behavior is almost certain to be intermediate between that of S and Te. Comparison of the major enthalpy terms involving Se (heat of dissociation and heat of solution on V_{As}) in the incorporation equation

$$\tfrac{1}{2} Se_2 + V_{As} \rightleftharpoons Se_{As}^+ + e \quad [17]$$

can be made with analogous reactions for S and Te, using electronegativity differences as shown later in the Zn/Mg comparison. These estimates show that there is likely to be little difference between Se and Te, which is a sufficient prediction for our present requirements.

Zn, Cd, and Mg.—The final important class of dopants are the group II elements Zn, Cd, and Mg which normally give p-type doping. Again, the elemental vapor pressures of 5, 50, and 0.4 Torr, respectively, at 560°C

Table II. Predicted operating pressures (in Torr) of common dopants for GaAs under typical MBE conditions of $P_{Ga} = 10^{-6}$ Torr, $P_{As_4} = 2 \cdot 10^{-6}$ Torr, and $T_{substrate} = 833$°K (560°C)

Element	Si	Ge	Sn	Pb	Be	Mg	Zn	Cd	S*	Se*	Te*	Mn

* Assuming diatomic molecules in the gas-phase.

mean that only activities much less than unity can be used in MBE work and the problem is to determine whether these activities are high enough to give useful doping levels.

Most information is available for Zn, both from LPE and VPE growth of GaAs. Unfortunately it is not all in good agreement. A straightforward treatment of p-type doping invokes the reaction

$$Zn_{gas} + V_{Ga} \rightleftharpoons Zn_{Ga}^- + h \quad [18]$$

analogous to Eq. [3] with V_{Ga} representing a vacancy on the Ga sublattice of GaAs and h an electron hole. We may then write

$$p = [Zn_{Ga}^-] = K_{18}^{1/2} P_{Zn}^{1/2} [V_{Ga}]^{1/2} \quad [19]$$

with $p = [h]$ for the case where p is controlled by the addition of Zn. Further we may write

$$0 \rightleftharpoons V_{Ga} + V_{As} \quad [20]$$

so

$$K_{20} = [V_{Ga}][V_{As}] \quad [21]$$

and substituting for $[V_{Ga}]$ in [19] we have

$$p = K_{18}^{1/2} K_{20}^{1/2} P_{Zn}^{1/2} [V_{As}]^{-1/2} \quad [22]$$

Panish and Casey (15) have reported a hole concentration dependence on $X_{Zn(l)}^{1/2}$ where $X_{Zn(l)}$ is the atom fraction of Zn in the liquid phase. They also show that

$$P_{Zn} = P_{Zn}^{o} \gamma_{Zn(l)} X_{Zn(l)} \quad [23]$$

where $\gamma_{Zn(l)}$ is the activity coefficient of Zn and $\gamma_{Zn(l)} \simeq 1$ in Ga-rich conditions (despite the pressure ratio being in favor of arsenic species, the MBE conditions chosen represent a position close to the Ga-rich boundary of GaAs). Thus from Fig. 2 of Ref. (15) we obtain $P_{Zn}/P_{Zn}^{o} = 10^{-2}$ and 10^{-7} for doping levels of $2 \cdot 10^{19}$ and $2 \cdot 10^{16}$ cm^{-3}, respectively. With $P_{Zn}^{o} = 5$ Torr at 560°C the corresponding values of P_{Zn} are $5 \cdot 10^{-2}$ and $5 \cdot 10^{-7}$ Torr suggesting that the lower doping levels might be obtainable.

The above analysis assumes that the segregation coefficient between Zn in GaAs and in the melt remained constant in the temperature range 560° to 1000°C. This is likely to be reasonable assumption as there is experimental support for the range 650°-800°C from the work of Keller and Muench (16). However both this work (16) and the latest VPE work (17) show clearly that at these lower temperatures the hole concentration varies linearly with P_{Zn}. As with the n-type dopants the carrier concentration at the growth temperature becomes independent of the dopant concentration, and

$$[Zn_{Ga}^-] = K_{18} K_{20} P_{Zn} [V_{As}]^{-1} / p \quad [24]$$

analogous to Eq. [9]. Direct extrapolation of Sidorov's data (17) gives values of $4.8 \cdot 10^{-5}$ and $4.8 \cdot 10^{-2}$ Torr for the two doping limits required. These values need to be corrected for the reduction in P_{As_4} on changing from VPE to MBE conditions. The dependence of $[V_{As}]$ on P_{As_4} was given in Eq. [13]. For Zn incorporation the pressures given above need to be increased by factors of 25 or possibly 5, see S doping earlier. These values apply strictly to 770°C. If we assume as above (16) that the segregation coefficient varies little with temperature, then we must allow for the fact that a given value of P_{Zn} represents a much higher activity of zinc in the gas-phase at the lower temperature of 560°C. As a result the zinc pressure required to give a fixed value of $[Zn_{Ga}^-]$ is reduced by a factor of 32 at the lower temperature. The final values are shown in Table II confirming that Zn is not a suitable dopant for GaAs using MBE.

Cadmium is expected to be an even less suitable dopant. Using Sidorov's data (17) the extrapolated values are $3.8 \cdot 10^{-2}$ and 38 Torr for our two required doping concentrations. These values need correcting for the change in P_{As_4} as in the Zn analysis and the change in activity with temperature which in this instance gives a factor of 12.

Magnesium represents a more complex case as there appears to be no data on its use as a dopant for GaAs except in MBE experiments. However we may make a more approximate estimate of its behavior by the following comparison with Zn doping .We may assume Mg is incorporated onto the same sites as Zn so that the only significant change in comparison with Eq. [18] is in the enthalpy of solution to give Mg_{Ga}^- as compared with Zn_{Ga}^-. This difference we may estimate using Paulings method (18) to calculate the difference between Zn-As and Mg-As bond strengths. We have

$$\Delta H(\text{Zn-As}) = \tfrac{1}{2}\Delta H(\text{Zn-Zn}) + \tfrac{1}{2}\Delta H(\text{As-As}) + 23(X_{Zn}-X_{As})^{1/2}$$

and

$$\Delta H(\text{Mg-As}) = \tfrac{1}{2}\Delta H(\text{Mg-Mg}) + \tfrac{1}{2}\Delta H(\text{As-As}) + 23(X_{Mg}-X_{As})^{1/2}$$

where $X_{Zn} = 1.6$, $X_{Mg} = 1.2$, and $X_{As} = 2.10$ are the Pauling electronegativities of the elements. Now $\Delta H(\text{Zn-Zn}) \simeq \Delta H(\text{Mg-Mg})$ (19) so that the difference in bond strength depends only on the electronegativity term. The numerical value of 12.9 kcal/mole for $\Delta H(\text{Mg-As}) - \Delta H(\text{Zn-As})$ compares well with that of Naganuma and Takahashi (2) calculated by the same approach. The Pauling result only applies to the formation of a single bond, *i.e.*, to the distribution of the first electron involved in bonding. As both Zn and Mg contribute two electrons to the valence band in GaAs we can expect the difference due to the electronegativity difference to lie between 12.9 and 25.8 kcal/mole and a value of 20 kcal/mole will be taken as a sensible guide.

Now, at fixed p and $[V_{As}]$ Eq. [24] becomes

$$K_{25} = [Zn_{Ga}^-]/P_{Zn} \quad [25]$$

where $K_{25} = K_{18}K_{20}[V_{As}]^{-1}/p$. Also $K_{25} = 10^{-6}/3 \cdot 10^{-5} = 3.3 \cdot 10^{-2}$ Torr^{-1} under the chosen growth conditions, as indicated by the values in Table II. With the above assumptions the analogous constant $K_{Mg} = [Mg_{Ga}^-]/P_{Mg}$ is given by $K_{Mg} = \exp(+20{,}000/RT)\, K_{25}$.

At 833°K, $K_{Mg} = 1.85 \cdot 10^5 . 3.3 \cdot 10^{-2} = 6.105 \cdot 10^3$ Torr^{-1} so that for $[Mg_{Ga}^-] = 10^{-6}$, $P_{Mg} = 1.64 \cdot 10^{-10}$ Torr and for $[Mg_{Ga}^-] = 10^{-3}$ $P_{Mg} = 1.64 \cdot 10^{-7}$ Torr. If we consider reasonable limiting values of 16,000 and 24,000 cal/mole for the increase in enthalpy of solution for Mg we obtain values of P_{Mg} very close to one order of magnitude larger and one order of magnitude smaller, respectively. Thus Mg is clearly a possible dopant.

Mn and Pb.—The elements Mn and Pb have also been used as dopants for GaAs in MBE. These elements do not fit closely into any of the groups described so far and again there is little supporting data from other experiments. It is possible however to make some estimate of their expected behavior. Inspection of Pauling's equations (18) given for Zn and Mg in the previous section shows that the main variations between different substituents on the Ga sublattice derive from the metal-metal bond energy term and the electronegativity term. For metals forming monatomic vapors we may take the elemental vapor pressure as a measure of the bond energy term. The electronegativity term is then a measure of the additional stability conferred by the required incorporation in dilute solution in the GaAs lattice. We note (*i*) that for $[Zn_{Ga}^-] = 10^{-3}$ a value of $P_{Zn} \simeq 10^{-2} P_{Zn}^{o}$ was required and (*ii*) that $X_{Zn} \simeq X_{Mn} \simeq X_{Pb}$. Thus as a first estimate the pressures required to give our upper concentration value should be $\simeq$1% of the elemental vapor pressures, *i.e.*, $2 \cdot 10^{-10}$ Torr for Mn and $1.5 \cdot 10^{-6}$ for Pb. In prac-

tice therefore Mn should behave like the first group of elements (Si, etc.) and Pb should be less suitable but possible.

Results

The results are collected in Table II. In considering the results the following observations need to be kept clearly in mind. Most of the values are based directly or indirectly on results from VPE and LPE. They are not therefore indisputably thermodynamic values. In fact they incorporate any intrusion of kinetic limitations found in VPE and LPE. They are therefore the predictions based on the assumption that kinetic effects are comparable in MBE, VPE, and LPE. Kinetic effects showing doping concentration dependence on crystal growth rate and orientation are well documented (4) and factors ≥ 10 are typically reported—significant, but small compared with the extrapolations involved in this work.

A similar perspective is required when considering the possible errors due to the detail of the extrapolations, where estimates of temperature variation for several quantities had to be made for some elements. A more significant level of uncertainty is involved where recourse has to be made to basic data such as electronegativity coefficients. As indicated in the text for the case of Mg, a further uncertainty of about an order of magnitude is possible.

The predicted results may now be compared with experiment. The results for the first group of elements, Si, Ge, Sn, and Be, are very much as expected. The elemental vapor pressures are sufficiently low (and it has become established that the sticking coefficients are unity, as assumed in the thermodynamic treatment), that the thermodynamic background is obvious, and the doping problem degenerates to a simple ratio of dopant and gallium beam fluxes.

The second group of elements S, Se, and Te represents a striking success for the present approach. The elemental vapor pressures are high and specific attention to the chemical interaction of dopant and GaAs matrix is required. The earlier incorporation of Te (1) and the recent report of doping by S and Se (20) are seen as part of the predicted framework and not as intricate kinetic exceptions. The latter results (20) also show that in practice the competing reaction of evaporation of Ga_2S is of negligible importance. Additionally, the successful use of a compound source (PbS) argues strongly for facile surface kinetics which would allow the thermodynamically predicted situation to be reached. Finally it should be emphasized that because of the chemical interaction (primarily Ga-S) the thermodynamically predicted sticking coefficient for these three dopants is unity.

The third group of elements Zn, Cd, and Mg are equally successfully described by the thermodynamic approach even though the outcome is in such marked contrast with that for the second group. The underlying reason is that the chemical interaction, *e.g.*, Zn-As is much weaker than, *e.g.*, Ga-S. Thus Zn and Cd are unsuitable as dopants for GaAs under MBE conditions and the thermodynamically predicted sticking coefficients are extremely low at $3.3 \cdot 10^{-8}$ and $1.25 \cdot 10^{-11}$, respectively. The result for Zn is strikingly close to that estimated by Naganuma and Takahashi (2) using the same basic approach and also close to their single measured value of $5 \cdot 10^{-7}$. It should be noted that though these authors (2) stressed the kinetics of the reactions, the kinetics were those consistent with the thermodynamic framework outlined here. Turning to Mg, it is predicted to be usable as indeed it is. Our thermodynamic sticking coefficient is $6.25 \cdot 10^{-3}$, significantly higher than the earlier calculated value (2) of $1.8 \cdot 10^{-5}$. This arises because we feel that in the bulk Mg must form more than the single bond considered for the surface reaction in the earlier work (2). Our value does not agree well with any of the experimental values for the sticking coefficient of 10^{-5} (21) or 10^{-4} (2) based on electrical activity or unity (22) based on total chemical content. It is almost certain that the higher chemical figure (22) applies in general but that most of the Mg is not electrically active. This means most of it is not incorporated by the reaction considered here and so the prediction would not be expected to apply. One of the more likely competing reactions is the incorporation of Mg with O, as the CO and CO_2 pressures in a typical MBE system are thermodynamically sufficient to oxidize Mg at all the beam pressures explored.

Of the two remaining elements Mn is unexceptional, like the first group of elements, but Pb is the only example where the model prediction is wrong. Before concluding that Pb provides a clear case of kinetic dominance we must examine the grounds on which the prediction was made more closely. First we find that the data base was almost nonexistent in this case. A distribution coefficient of 10^{-1} was assumed based on the observed behavior of Zn. However there is some suggestion (7) that the true value for Pb is very low (at least like that for Sn) and in the region of 10^{-4}. In terms of our previous analysis the most likely term to have been ignored is a significant elastic term due to the large size of Pb which would reduce the enthalpy of solution of Pb in GaAs appreciably. With the lower segregation coefficient of 10^{-4} Table II would be amended to show $1.5 \cdot 10^{-3}$ and $1.5 \cdot 10^{-6}$ Torr. It is clear however that Wood (20) reports even less incorporation of Pb than this, suggesting that even with this revised thermodynamic framework there is evidence for additional kinetics barriers possibly also related to the large size of Pb atoms.

One final important aspect remains to be discussed. So far we have only considered the distribution of dopant atoms between gas-phase and bulk semiconductor. In any detailed treatment the surface must also be considered. In practical MBE this is particularly important as, in the growth of thin layers, the transient behavior at the start and finish of growth can determine the success or otherwise of the process. Thus in the cases of doping with Sn (23) and Te (1) and also Pb (20) high surface concentrations of the dopant have been established. In general these enhanced surface concentrations could arise from the thermodynamic basis or from kinetic barriers to further reaction. It should be stressed, however, that these complications do not invalidate the results of the bulk/gas-phase analysis described here. On the contrary these results can be used together with the experimental data to clarify the kinetic aspects of the doping reactions. The approach is described in more detail in the Appendix but the main conclusions are as follows. There is no evidence remaining for any kinetic barriers at the gas/surface interface. At the surface/bulk interface, the only cases where the experimental evidence suggests additional kinetic barriers may be important are for Pb doping, some of the transients observed in Sn doping, and for amphoteric doping by Ge.

Conclusions

The incorporation of all common dopants into GaAs under typical MBE conditions has been examined. It is found that in all cases except Pb the predictions based on the thermodynamic and chemical equilibrium framework fit the results observed in practice. The closeness of this fit indicates that any additional kinetic aspects of MBE growth are likely to be comparable to those found in VPE and LPE. In the light of these results it should be possible to obtain useful guidance in applying MBE to other systems by considering first the thermodynamic framework applying to them.

APPENDIX

The Interplay of Kinetics and Thermodynamics in MBE

In general, different concentrations of dopant in the surface and the bulk GaAs are to be expected, so that occurrence of surface enrichment is not necessarily evidence for kinetic delays in the bulk incorporation step. In fact, in the particular case of doping during growth a complete kinetic freeze at the surface/bulk incorporation step would give a disordered solid with the dopant buried in the bulk. Surface enrichment therefore like the growth of good crystalline material, gives evidence of considerable kinetic mobility on the surface. Thermodynamic data for dopant adsorption on the surface of GaAs is almost nonexistent, however we can learn something about the situation from the implications of the results in Tables I and II.

The main situations that are possible are shown schematically in Fig. A-1. The figure shows the free energies of the dopant in the gas phase, on the surface, and in the bulk. Obviously the free energy is a function of concentration and we illustrate the position for concentrations which are accessible and desirable in MBE.

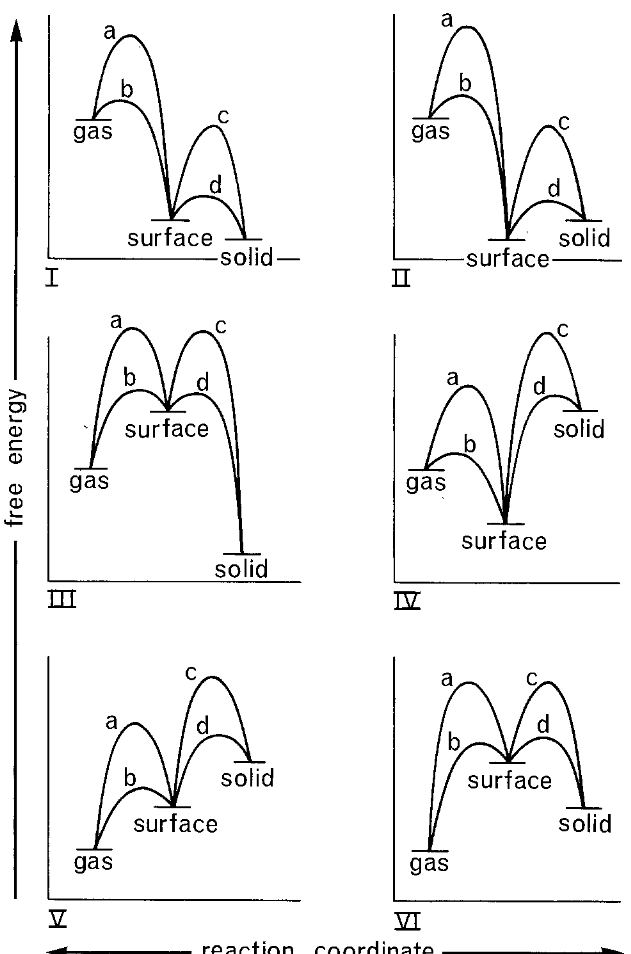

Fig. A-1. Dopant free energy vs. reaction coordinate diagrams for the important alternative possibilities in doping gallium arsenide from the gas-phase. Alternative reaction paths are shown as (a), (b), (c), and (d). The free energies refer to a pressure of 10^{-6} Torr in the gas-phase, a coverage of 10^{-3} on the surface, and a bulk concentration of $2.2 \cdot 10^{19}$ cm^{-3}.

Thus we have the maximum convenient gas-phase pressure of 10^{-16} Torr, a likely maximum bulk concentration of $2.2 \cdot 10^{19}$ cm^{-3}, and exactly the same surface concentration of 10^{-3} expressed as a fractional surface coverage.

The abscissa is the reaction coordinate for doping from the gas-phase.

In the more normal situation of doping during growth there is direct access from the gas-phase to both the surface and the bulk. The kinetic routes in the two main stages of reaction surface/gas interaction and surface/bulk interaction are shown by (a), (b), (c), and (d). Routes (a) and (c) represent routes with kinetic barriers which dominate the outcome of the process while (b) and (d) represent facile kinetic routes which allow the outcome to be predicted by the thermodynamic framework. Before considering specific dopants we can consider an example of the application of Fig. A-1, *e.g.*, case I. At 10^{-6} Torr there is a considerable gain in free energy if the dopant condenses on the surface to give a coverage of 10^{-3} and a further gain by incorporation at a bulk concentration of $2.2 \cdot 10^{19}$ cm^{-3}. If the kinetic paths are (b) and (d) then doping by MBE will work. In fact, to stop much higher doping concentrations than required from being obtained, the gas pressure will have to be reduced until either the free energy falls to that of the solid or simple considerations of arrival fluxes *vs.* the growth rate intervene. The concentration on the surface will then be lower than in the bulk. Alternatively, if path (a) applied, doping to the required level will not occur due to a low sticking coefficient due to kinetic factors. If route (b) (c) applies one is likely to get untidy incorporation of dopant, *e.g.*, leading to compensation or deep traps or conceivably, by a more complex mechanism, some surface enrichment. It is interesting to note that in the case (not shown) where free energies in all three states are equal, one would expect a sticking coefficient of 10^{-3} on thermodynamic grounds, *i.e.*, even though paths (b) and (c) were followed, and even lower values due to additional kinetic factors if path (a) was followed.

We may now consider the main groups of dopants in terms of Fig. A-1. Well-behaved dopants such as Si or Be clearly fit case I (b) (d) very well. Case II (b) (c) is conceivable if (c) gives direct burial of dopant, thus preventing surface segregation, but it must be considered unlikely. Dopants S and Se appear to be similar with the facile surface kinetics implied by I (b) (d) being even more likely, at least in Wood's experiments (20). Ge is also likely to fit I (b) (d). It is not clear whether the amphoteric doping by Ge is dominated by the thermodynamics of the stoichiometry variations in GaAs with P_{As_4} or by the dominance of path (c) at some values of P_{As_4}. Further study might increase our understanding of these factors considerably.

Turning to the usable but less satisfactory dopants, Sn and Te would appear to give a simple fit to II (b) (d). Possible alternatives are II (b) (c) or even I (b) (c) both of which would require sufficient mobility in the surface/bulk interaction to prevent burial of the dopant but insufficient to allow normal incorporation. This possiblity cannot be ruled out but it should be noted that it involves the same kind of sophisticated growth modelling required to explain LPE and VPE, not some simpler kinetic limitation peculiar to MBE. In so far as the highest doping levels cannot be obtained using Mn (24) case V or VI is suggested converting to I at lower doping levels. However the thermodynamic framework would predict I. The empirical results at lower doping levels suggest route (b) (d) but as suggested by Ilegems *et al.* (24) it is possible that at the higher concentrations the Mn on the surface interferes with the growth of the host crystal, causing unacceptable crystal morphology. As Mg incorporation is probably affected by impurities it will not be considered in this section.

Finally we consider the unsuccessful dopants Zn, Cd, and Pb. For Zn and Cd cases V or VI are predicted by thermodynamics. For Zn routes (b) and (d) are suggested by the single result of modified MBE (2). This result means that one cannot attribute the lack

of success in Zn doping simply to the occurrence of route (a) in any of the cases in Fig. A-1. There is no data on Cd but a parallel with Zn is to be expected. Pb is more complicated. The revised thermodynamic prediction suggests cases IV or V (the elastic term will have less effect on surface atoms) at the higher concentrations. In practice Wood's results favor case IV (with the beam on) and routes (b) and (d) are favored by the very completeness of the absence of Pb from the bulk. Here it seems likely that some kinetic barrier to incorporation also operates as discussed for Sn.

Properties of Sputtered Tungsten Silicide for MOS Integrated Circuit Applications

F. Mohammadi* and K. C. Saraswat**

Integrated Circuits Laboratory, Stanford University, Stanford, California 94305

ABSTRACT

Feasibility of the use of WSi_2 as gate electrode and electrical interconnecting material has been investigated. Properties of as-deposited and annealed thin films of WSi_2 have been studied to determine their compatibility with integrated circuit fabrication processes. Thin films of WSi_2 were deposited by sputtering on oxidized silicon, with and without a coating of poly-Si. As-deposited films were amorphous, with a resistivity of 6×10^{-4} Ω-cm. Upon annealing above 900°C in N_2, the films became polycrystalline. The resistivity decreased and the average grain size increased as a function of time and temperature. A minimum resistivity of 10^{-4} Ω-cm was obtained. Chemical reagents commonly used for cleaning and etching, when used with WSi_2, showed behavior similar to poly-Si. Al contacts to WSi_2 were stable up to 600°C for $WSi_2/SiO_2/Si$ structure and up to 550°C for WSi_2/poly-Si/SiO_2/Si structure. These are significantly higher than the temperatures commonly used for sintering Al contacts to Si. Thermal oxidation of WSi_2 films in steam in the temperature range of 1000°-1200°C was performed and good quality SiO_2 was grown. Finally WSi_2 gate MOS devices were fabricated and characterized.

With the advances in the integrated circuit technology as the device dimensions are continuously decreasing, severe requirements are being imposed upon the materials. In MOS integrated circuits, the requirements for the material used to form the gate electrodes and the electrical interconnections are low resistivity, ability to withstand various chemicals and high temperatures encountered during fabrication process, and the capability to be defined into fine patterns. Poly-Si is widely used for this application, however, its inadequate properties are beginning to limit the performance of the circuits. High resistivity of poly-Si causes degradation in the speed of the circuits because of *R-C* delay times. Although the grain size in as-deposited poly-Si can be very small, subsequent high temperature processing increases it markedly (1). This causes a problem in defining very fine lines. Refractory metals such as Mo and W can meet most of the above requirements, but they cannot withstand high temperature oxidizing ambients, because their oxides are generally volatile, and they cannot withstand chemical reagents commonly encountered during fabrication of integrated circuits. These two requirements can be met by the silicides of some of the refractory metals, such as $MoSi_2$ and WSi_2. Feasibility of the use

Key words: tungsten silicide, annealing, resistivity, oxidation.

of $MoSi_2$(2) and WSi_2(3) has been demonstrated. In order to use these materials routinely to fabricate integrated circuits, a much more detailed knowledge of their properties is required. This will allow not only the determination of the compatibility of silicides with fabrication processes, but also will allow optimization of the process involving the use of silicides.

In this work we have studied the properties of thin films of WSi_2 deposited by sputtering. WSi_2 was deposited on oxidized silicon with and without an interlayer of poly-Si. Properties of as-deposited films, effect of high temperature annealing in N_2 atmosphere on resistivity and structure, thermal oxidation in steam, and stability of Al contacts to these films has been studied. Finally, MOS devices fabricated using WSi_2 as the gate material have been characterized.

Sample Preparation

Intermetallic refractory metal silicides can be obtained by the deposition of the refractory metal on silicon and subsequent conversion of the refractory metal to the desired intermetallic by reaction of the refractory metal with silicon at elevated temperatures (4). Formation of silicides by chemical vapor deposition (5), coevaporation of metal and Si (3), sputtering from a target made of silicide (2), and laser irradiation of metal deposited on Si (6) have been investigated. In this work the deposition of WSi_2 was done by rf diode sputtering from a hot-pressed target made of the silicide.

Single crystal Si wafers with (100) and (111) orientation were thermally oxidized in dry O_2 to grow 1000Å SiO_2. The wafers were divided into two groups. On one group of wafers 4000Å thick undoped poly-Si was deposited by chemical vapor deposition. These wafers were further split into two subgroups by doping some of the poly-Si films with boron and phosphorus. The first set of poly-Si films was implanted with phosphorus, with dose varying from 10^{14} to 10^{16} ions/cm^2, at an energy of 100 keV. The samples were annealed for one hour at 1100°C, the first 15 min in dry O_2 and 45 min in dry N_2 atmosphere. The second set of poly-Si films was implanted with boron, with dose varying from 10^{14} to 5×10^{15} ions/cm^2, at an energy of 100 keV. The samples were thermally oxidized at 900°C wet oxygen for 30 min to grow a thin layer of SiO_2 and then annealed at 1100°C for 30 min in dry N_2 atmosphere. The oxide layer was grown at a lower temperature to minimize the loss of boron by leaching. The third set was doped with boron by thermal diffusion, using B_2H_6 as the source of impurity, and the fourth set was doped with phosphorus using $POCl_3$ as the source of impurity. Both sets were doped for 30 min at 1000°C. A 4000Å thick WSi_2 film was deposited on top of all of the samples, *i.e.*, SiO_2/Si and poly-Si/SiO_2/Si structures and single crystal Si, using a Perkin-Elmer, rf diode sputtering system. The ambient was argon at a pressure of 20μ, the substrate temperature was kept below 300°C and the rate of deposition was 360 Å/min with a peak voltage of 1.5 keV, and an rf power of 280W. The target was made of hot-pressed WSi_2. Prior to the deposition the samples were sputter-etched in order to obtain cleaner deposition interface and remove any residual SiO_2. For all of the subsequent studies the three basic structures, WSi_2/Si, WSi_2/SiO_2/Si, and WSi_2/poly-Si/SiO_2/Si, were used.

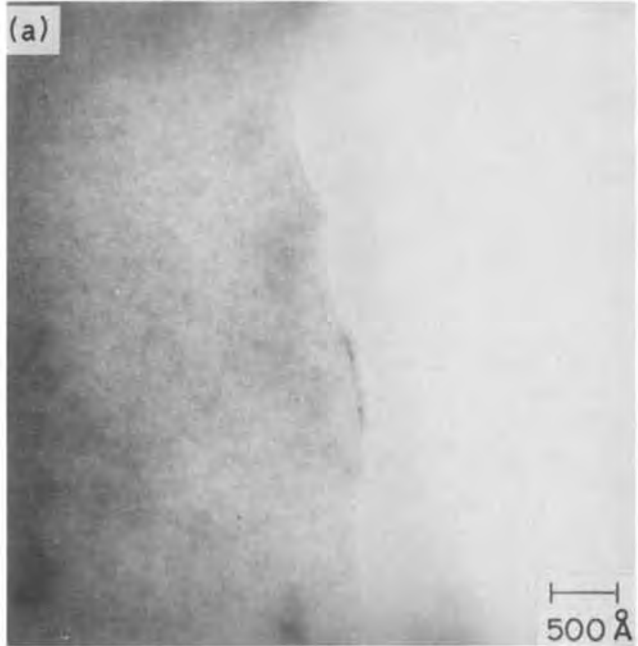
Properties of As-Deposited Films

Auger electron spectroscopy and electron microprobe measurements showed that in the as-deposited WSi_2 films the ratio between the number of Si atoms to the number of W atoms was approximately 2:1. Glancing angle x-ray diffraction analysis did not show any specific peak of WSi_2, indicating that the as-deposited films are amorphous. Figure 1(a) shows a transmission electron micrograph (TEM) of the films showing no specific grain structure, again strengthening the conclusion that the films are amorphous. An average resistivity of about 6×10^{-4} Ω-cm was measured for the films.

The films were not attacked by chemicals generally used in fabrication of IC's, *e.g.*, H_2SO_4, HNO_3, HCl, HF, and mixtures of $H_2SO_4 + H_2O_2$, HCl + H_2O_2, and $NH_4OH + H_2O_2$, the common cleaning reagents for Si. Therefore in all of the experiments described subsequently the samples were cleaned using cleaning procedures commonly used for Si.

Properties of Annealed WSi_2 Films

Since the as-deposited films were amorphous, a study was conducted to investigate the effect of high temperature annealing, on the properties of WSi_2 films. WSi_2/SiO_2/Si and WSi_2/poly-Si/SiO_2/Si samples were



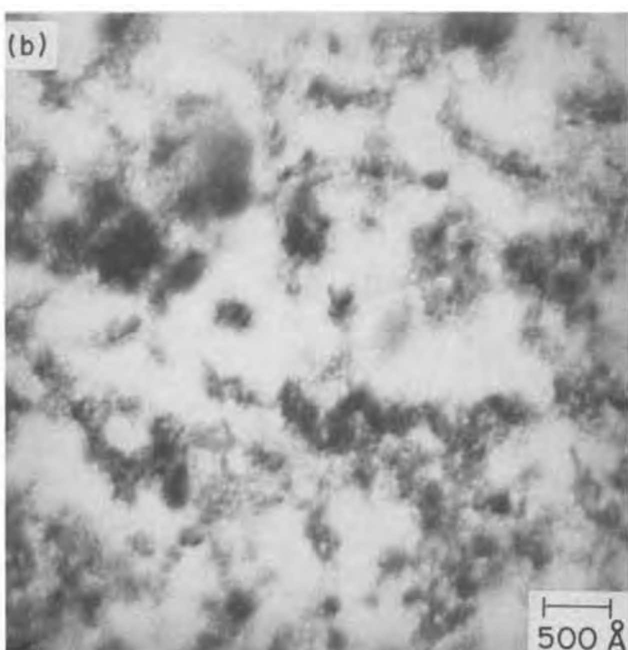


Fig. 1. TEM of WSi_2 films (a) as-deposited, (b) annealed at 1000°C for 120 min. In (a) the left side of the figure is the WSi_2 film and the right side is air.

annealed in N_2, in the temperature range of 975°-1200°C, for times ranging from 30 to 180 min. Poly-Si was kept undoped and a fresh sample was used for each annealing experiment. Figure 2 shows the change in resistivity of the samples annealed for 30 min at temperatures between 975°-1200°C. As the annealing temperature increased the resistivity decreased. The resistivity of the WSi_2 films deposited on poly-Si was slightly lower than the films deposited on SiO_2. Figure 3 shows the resistivity of the samples annealed at 975°C for times ranging from 30 to 180 min. Again the resistivity decreased as a function of time.

X-ray diffraction and TEM studies of the annealed samples showed that upon annealing the films became polycrystalline. Figure 1(b) shows the TEM of a WSi_2 film annealed for 120 min at 1000°C. There is a definite grain structure, with average grain size less than 500Å. Figure 4 shows results of x-ray diffraction of the same samples as used for TEM. Upon crystallization no specific preferred orientation of WSi_2 is observed. More x-ray diffraction studies showed that as the annealing temperature or time was increased the intensity of the diffraction peaks increased and the width decreased. This indicates that as the temperature or time of annealing is increased the degree of crystallization also increases.

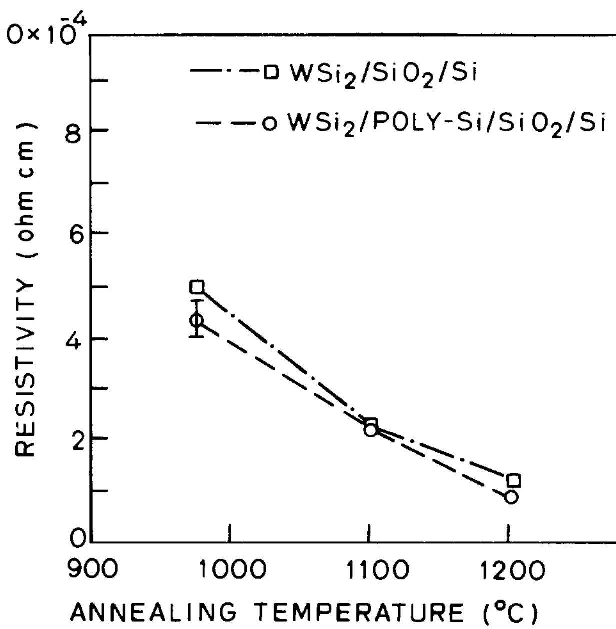

Fig. 2. Variation of resistivity as a function of annealing temperature for 30 min in N_2 ambient.

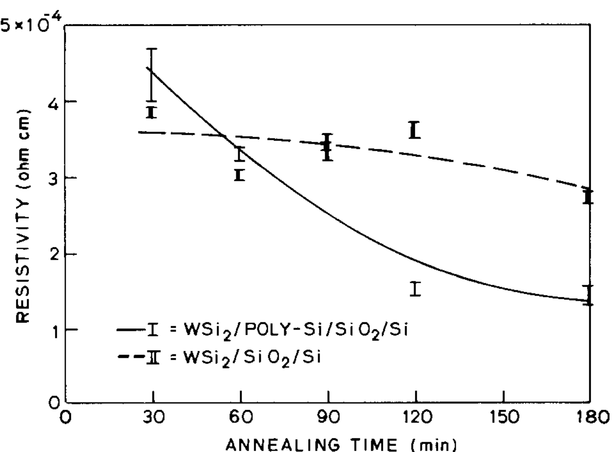

Fig. 3. Resistivity of WSi_2/poly-Si/SiO_2/Si and WSi_2/SiO_2/Si films as a function of annealing time for annealing temperature of 975°C in N_2 ambient.

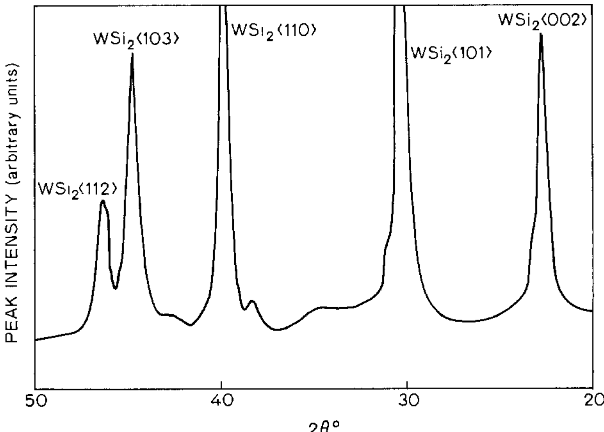

Fig. 4. X-ray diffraction pattern of the WSi_2 film annealed at 1000°C for 120 min. Cu-Kα_1 diffraction intensity is plotted as a function of twice the angle of incidence (2θ).

Finally compatibility of doped poly-Si with WSi_2 was investigated by studying the effect of annealing on WSi_2/doped poly-Si/SiO_2/Si structures. The poly-Si layers were doped with boron and phosphorus as described in "Sample Preparation." After depositing WSi_2 all samples were annealed for one hour in N_2 at 1000°C. Figure 5 shows the resistivity variation of the combined WSi_2 and poly-Si layers as a function of doping density in poly-Si. For comparison the resistivity of the poly-Si layers alone is also given. It is evident that the resistivity of WSi_2 dominates the total resistivity and the presence of the dopant does not have any adverse effect on the resistivity of WSi_2.

Thermal Oxidation

Formation of an insulator layer on top of the gate electrode and the interconnection layer is necessary so as to isolate it from subsequently deposited conducting layers. Vapor-deposited SiO_2 and Si_3N_4 can be used for this application. However, thermally grown

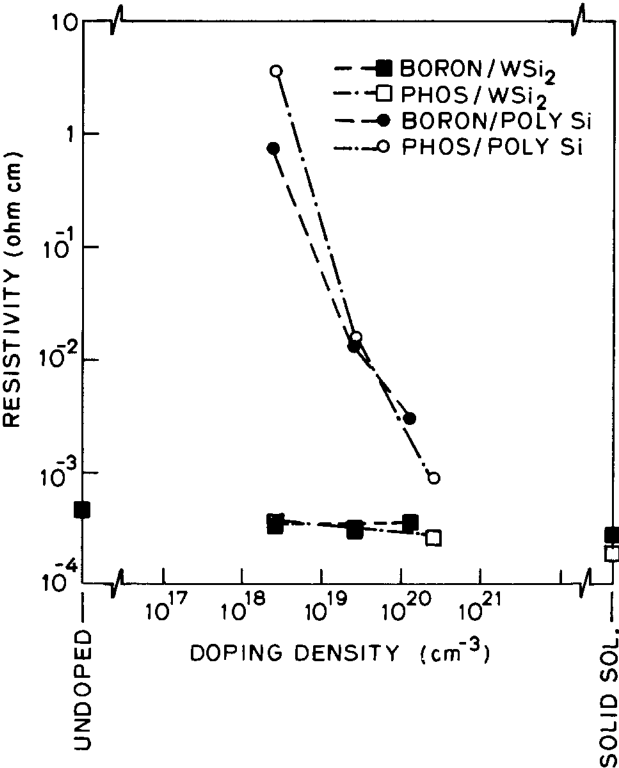

Fig. 5. Resistivity of WSi_2/doped poly-Si/SiO_2/Si and doped poly-Si/SiO_2/Si films as a function of dopant concentration.

SiO_2 is generally of superior quality. Therefore thermal growth of SiO_2 on WSi_2 is of extreme importance. The feasibility of thermal oxidation of WSi_2 was demonstrated by Zirinsky *et al.* (7) by oxidizing WSi_2/poly-Si/SiO_2/Si structure in steam at 1000°C. Their effort to oxidize WSi_2/SiO_2/Si structure was not as successful. In our work we have oxidized WSi_2 deposited on top of oxidized silicon as well as single crystal silicon(8). WSi_2/Si and WSi_2/SiO_2/Si samples were first annealed at 1000°C in N_2 for 60 min to crystallize the films. The annealed films were oxidized in steam with N_2 as the carrier gas, at 1000°, 1100°, and 1200°C, for periods of 5 to 30 min. After etching a step in the grown SiO_2, the thickness was measured with a Talystep. Figure 6 shows the thickness of SiO_2 as a function of time for the three temperatures of growth. It is seen that growth of SiO_2 is a stronger function of temperature for WSi_2 films deposited on Si. In order for SiO_2 to be used as an insulating layer in between conducting layers, it must have high electrical breakdown strength. For the oxides grown on WSi_2 the mean value of breakdown strength was about 4×10^6 V/cm, which is comparable to the oxides grown on poly-Si.

Stability of Aluminum Contacts

Aluminum is widely used as the last layer to provide electrical interconnections for multilayer structures. The last step in the Al metallization process generally is to anneal the wafers at 400°-500°C. This step improves the ohmic contact of Al to Si, removes the oxide damage caused during metal evaporation, and reduces the density of surface states at the oxide-silicon interface. It has been reported in the literature that at these temperatures Al can react with other silicide such as PtSi, $MoSi_2$, and $CoSi_2$ (9). In this reaction Al displaces Si from the silicide and forms compounds with metals, *e.g.*, $PtAl_2$, $MoAl_{12}$, and Co_2Al_9. In our work we have demonstrated the stability of the Al contacts to WSi_2 films.

After the deposition of 4000Å thick films of WSi_2, the WSi_2/SiO_2/Si and WSi_2/undoped poly-Si/SiO_2/Si samples were annealed at 1000°C for two hours in N_2 to crystallize the WSi_2 films. Following the anneal, 1.5 μm thick Al was deposited on top of the WSi_2 layers using an electron beam evaporation system. The resulting Al/WSi_2/SiO_2/Si and Al/WSi_2/poly-Si/SiO_2/Si structures were annealed for 30 min in dry N_2 at temperatures from 400° to 700°C. The quality of the annealing samples was examined by optical and scanning electron microscopes and x-ray diffraction.

The temperature up to which the Al/WSi_2 interface was stable was 600°C for the samples with WSi_2/SiO_2 interface and 550°C for the samples with WSi_2/Si interface. At and below these temperatures annealing did not affect the chemical and electrical properties of Al/WSi_2 layers. Average resistivity of the films was about 3×10^{-6} Ω-cm dominated by Al. X-ray diffraction on Al/WSi_2/SiO_2/Si samples showed that after annealing at temperatures up to 600°C, the intensity of the diffraction peaks of various orientations of WSi_2 and Al remained unchanged. Above 600°C the WSi_2 peaks did not change much, but the Al peaks completely vanished and new peaks of WAl_{12} and (111) Si appeared. This indicates a chemical reaction between Al and WSi_2 above 600°C

$$12Al + WSi_2 \rightarrow WAl_{12} + 2Si \quad [1]$$

Similar reactions have been observed for $MoSi_2$, $CoSi_2$, and PtSi at 550°, 425°, and 300°C, respectively (9). An optical photograph of the surface of the sample annealed above 600°C is shown in Fig. 7, clearly showing the damage to the surface of the sample.

The Al/WSi_2/poly-Si/SiO_2/Si samples annealed up to 550°C were found to be stable and the intensity of the x-ray diffraction peaks of various orientations of WSi_2, Al, and (110) Si [this is the predominant orientation of LPCVD poly-Si deposited at 620°C (1)] remained unchanged. No surface damage could be detected by SEM and optical microscope. However, the samples annealed at 600°C and above showed severe surface damage. Although the x-ray diffraction peaks of WSi_2 did not change significantly except for slight increase in the intensity of (101) and (002) orientations, the (110) Si peak reduced markedly and Al peaks almost disappeared. No WAl_{12} peak could be detected. This indicates that WSi_2 itself is not responsible for the instability; however, Al and poly-Si react above the eutectic temperature. It is known that diffusion of metals and Si can readily take place through a layer of silicide (9, 10). Therefore it is probable that upon annealing Al and Si diffuse through WSi_2 and at the eutectic temperature of 577°C cause the physical damage to the surface. The important point to be observed here is that both the structures were stable at the temperatures commonly used for sintering Al contacts to Si.

WSi_2 Gate MOS Devices

Using WSi_2 as the gate electrode, MOS capacitors of area 0.04 cm² were fabricated on (100)-oriented, n-type Si, with 5×10^{14} cm^{-3} doping density. Gate oxide of thickness 600Å was grown in dry O_2 at 1100°C. Following the WSi_2 deposition on the gate oxide, photolithography was done to define the gate electrodes and WSi_2 was etched in a HF-HNO_3 solution. The samples were annealed at 1000°C in N_2 for 30 min to crystallize WSi_2 and then annealed at 450°C in forming gas for 30 min to minimize surface states. Capaci-

tance was measured as a function of gate voltage at a frequency of 1 MHz. From the C-V plot, flatband voltage, and threshold voltage were measured to be 0 and −0.8V, respectively. From the C-V characteristics the work function of WSi_2 was calculated to be about 4.8 eV (11). Using this value of work function the fixed oxide charge density, Q_{ss} of 8×10^{10} cm^{-2} was calculated. By doing bias and stress C-V measurements the mobile charge density was found negligible.

Summary

Properties of WSi_2 to form gate electrode and electrical interconnecting material in silicon integrated circuits were examined. The conductivity of WSi_2 was found to be at least an order of magnitude higher than that of poly-Si. The higher conductivity can provide substantial improvement in the resistance of the electrical interconnecting lines used in VLSI structures. After long time annealing at high temperature the grain size of WSi_2 was found to be less than 500Å. This will facilitate etching of submicron lines which is essential for higher packing density. Other physical and chemical properties of WSi_2 are quite comparable to those of poly-Si from the point of view of compatibility with the fabrication technology. MOS devices fabricated with WSi_2 as the gate material showed excellent characteristics. Therefore, in conclusion, the use of WSi_2 as the gate and interconnecting material is feasible and should markedly improve the performance of the integrated circuits.

ABSTRACT

Anodic oxides on GaAs have been examined using x-ray photoelectron spectroscopy (ESCA) combined with Ar-ion etching. The ESCA spectra were analyzed using both analog, and in some cases digital techniques. Results showed the films to be composed of As_2O_3 and Ga_2O_3. The composition at the surface of the films was found to be electrolyte sensitive. At the oxide-semiconductor interface evidence was found suggesting a Ga_2O_3 rich oxide region and a layer adjacent to the semiconductor which appeared to contain elemental As. Anodically grown oxide films on GaAs incorporating Al were also studied and it appeared that the regions of GaAs native oxide above and below an Al_2O_3 region had differing compositions.

The anodic oxidation of GaAs (1) offers a very simple technique for producing barrier-type insulating films on this semiconductor. Such films are of great importance for the fabrication of MOS (metal-oxide-semiconductor) devices and success has already been achieved in producing transistors on GaAs (2, 3) using this technology. However, the oxide and interface properties obtained still show room for improvement and work in our laboratories is concerned with optimization of the anodization conditions in order to improve device behavior. To do this effectively, detailed structural information is required and of the methods available to obtain this data Auger electron spectroscopy (AES) (4) and x-ray photoelectron spectroscopy (ESCA) (5, 6) are probably the most useful, when combined with a suitable etching technique.

In this paper we present chemical depth profiles of anodically grown films on GaAs, obtained using ESCA combined with Ar-ion etching. We feel that ESCA

[1] Present address: Inorganic Chemistry Laboratory, Oxford, England.
[2] Present address: Institut fur Hoch Frequentztechnik, Fachbereich 18, Merckstrasse 25, Germany.

Key words: GaAs, anodic oxidation, ESCA, depth profiles.

offers advantages over AES due to the chemical shift data which is more easily obtained and interpreted with the former (6). However, AES does have the advantage of speed and of being able to examine different parts of a single sample, so that a combination of both techniques where available offers the best solution (5).

Experimental

GaAs samples (Monsanto n-type, carrier concentration 10^{18}) were cleaned in methanol and acetone and dried from acetone. Al (99.995% purity, M.R.C. Limited), where used, was deposited by evaporation under vacuum at about 10^{-6} Torr. GaAs samples were etched for 1 min in 1% HCl solution prior to anodization. Electrolytes were all made up from research grade reagents and deionized water. Two electrolytes were studied. These were: (*i*) 3% tartaric acid solution mixed in the volume ratio 1:2 with propan 1, 2 diol (AGW) (1) and (*ii*) 0.02M (NH_4) H_2PO_4 solution mixed in the volume ratio 1:2 with propan 1, 2 diol.

Anodization was carried out under constant current conditions using experimental apparatus and techniques described previously (1). After anodization the samples were rinsed in acetone. Typical sample size was 0.6 cm × 1.2 cm. The samples were attached to the copper spectrometer sample holder with ELECTRODAG 915 conducing paint (Acheson Colloids Company) to minimize sample charging. The sample holder itself was mounted on a UHV rotatable probe to ensure precise repositioning of the sample after rotation for etching.

ESCA spectra were recorded on an A.E.I. E.S. 200B spectrometer at typical chamber pressures of 2×10^{-8} Torr, utilizing Mg $K_{\alpha 1}$ $K_{\alpha 2}$ radiation at 1253.6 eV. They were recorded at 0.1 V sec^{-1} (Ga and As 3d peaks) and 0.05 V sec^{-1} (Al 2p and O 1s regions). Both analog and digital spectra were recorded simultaneously, the sampling rate for the latter being 50 times per minute.

Ar-ion milling was carried out using an ION-TECH saddle field ion source fitted with a scanning facility. The source has a beam of height 1 cm, and this was scanned along the length of the sample, at a mean angle of 45° to the sample surface. Argon was 99.996% purity (B.O.C.). The source was operated at either 8 kV 3 mA or 5 kV 2 mA. Approximate etch rates were 25Å/min in the former and 6Å/min in the latter case. These etch rates were estimated from depth profiles obtained from oxide films of known thickness. The anodic growth constants for oxidation of GaAs have been established previously (1). To obtain depth profiles the samples were etched in a stepwise fashion, spectra being recorded after each period of etching. Some idea of the reproducibility of the etching technique may be obtained from Fig. 6 where etching was continued into the substrate. As may be seen, in this region where constant composition is expected, fluctuations are less than ±5%.

Data Processing

Most depth profiles were obtained from the ESCA peak areas of the Ga and As 3d peaks, the Al 2p peak and the O 1s peak in the analog spectra. To calculate these areas a triangular approximation was assumed so that

peak area = peak height × width at half height

The intensity of photoelectrons of a given energy observed in a homogeneous material of path length x is given by (7)

$$I = \frac{F\alpha Dk}{\sigma}[1 - \exp(-x\sigma)] \qquad [1]$$

if elastic scattering is neglected. I = intensity of photoelectrons emitted; F = x-ray flux; α = cross section for photoionization in a given energy level of a given atom for a given x-ray energy; D = density of the given atom in the material; k = a spectrometer constant; $\sigma = 1/\lambda$, where λ is the mean escape depth of photoelectrons of given kinetic energy.

For two separate core energy levels A and B in the same sample measured under identical conditions [1] may be written

$$\frac{N_A}{N_B} = \frac{D_A}{D_B} = \frac{I_A\,\alpha_B}{I_B\,\alpha_A} \qquad [2]$$

where N_A and N_B are the number of atoms per unit volume of A and B, if it is assumed that $\lambda_A \simeq \lambda_B$. In our case this is true for the Ga and As 3d levels and the Al 2p level to within 3% since $\lambda \propto \sqrt{\text{kinetic energy}}$ (8) and the above-mentioned levels are of very similar kinetic energies. We have used Eq. [2] to give depth profiles that show the relative numbers of atoms per unit volume. The results have been plotted relative to the Ga 3d intensity I_{Ga} by plotting I_{Ga}, $I_{As}\frac{\alpha_{Ga}}{\alpha_{As}}$ and $I_{AL}\frac{\alpha_{Ga}}{\alpha_{AL}}$ giving the relative number of atoms per unit volume in arbitrary units of $\frac{N_A}{N_{Ga}} I_{Ga}$ for atom A. The cross sections (α) were taken from those calculated by Scofield (9). The O 1s region showed a strong oxide oxygen peak, the intensity of which was only used to obtain interface widths, so no corrections were applied.

Where the Ga 3d peaks due to Ga_2O_3 and GaAs were not clearly resolved the position of the composite peak center at half-height relative to the two extreme positions was used to estimate the amount of each component present, *i.e.*, percentage of peak due to Ga_2O_3

$$\frac{\text{BE(Ga 3d)} - \text{BE(GaAs 3d)}}{\text{BE}(Ga_2O_3\text{ 3d}) - \text{BE(GaAs 3d)}} \times 100\%$$

In the presence of As_2O_3, elemental As was always observed after Ar-ion etching. On etching through the oxide film to the GaAs substrate the elemental As peak disappeared. An experiment using a sample of powdered As_2O_3 mounted on double-sided sellotape indicated that some of the oxide was reduced to elemental As by the ion beam. This is illustrated in Fig. 1. A similar experiment showed that Ga_2O_3 was stable towards reduction under the same conditions. It was therefore assumed that the origin of the elemental As peak in the anodic oxide film was from reduction of As_2O_3. When constructing depth profiles the intensities of the As_2O_3 and elemental As 3d peaks were summed to give the total amount of As originally present as oxide. (Making the approximation that the cross sections and escape depths are the same for the two materials.) Where the elemental As 3d peak was obscured by that due to As in gallium arsenide its peak height was assumed to be one-third of that of the As_2O_3 peak for etching at 8 kV and one-quarter for ion etching at 5 kV. These were the ratios observed experimentally in the bulk of the oxide. Under these circumstances the assumed elemental As intensity was also subtracted from the measured As 3d intensity of GaAs.

In order to assess the errors involved in the above approximations an attempt was made to analyze one complete set of digital spectra by employing a nonlinear least squares fitting program which uses a Gaussian Lorentzian product function (10).

In order to obtain meaningful results it was necessary to fix the linewidths of the various 3d peaks of Ga and As in the interface region. The fixed values used were obtained from fits of spectra from the oxide, or from the GaAs substrate. The results are illustrated in Fig. 2, which also includes the profile obtained from the analog spectra. (The dips in the analog profiles after 13 min etching are where the sample was left over night in the spectrometer after having etched for 10 min.)

As a further check of the validity of the approximation used to resolve the Ga 3d peaks of Ga_2O_3 and

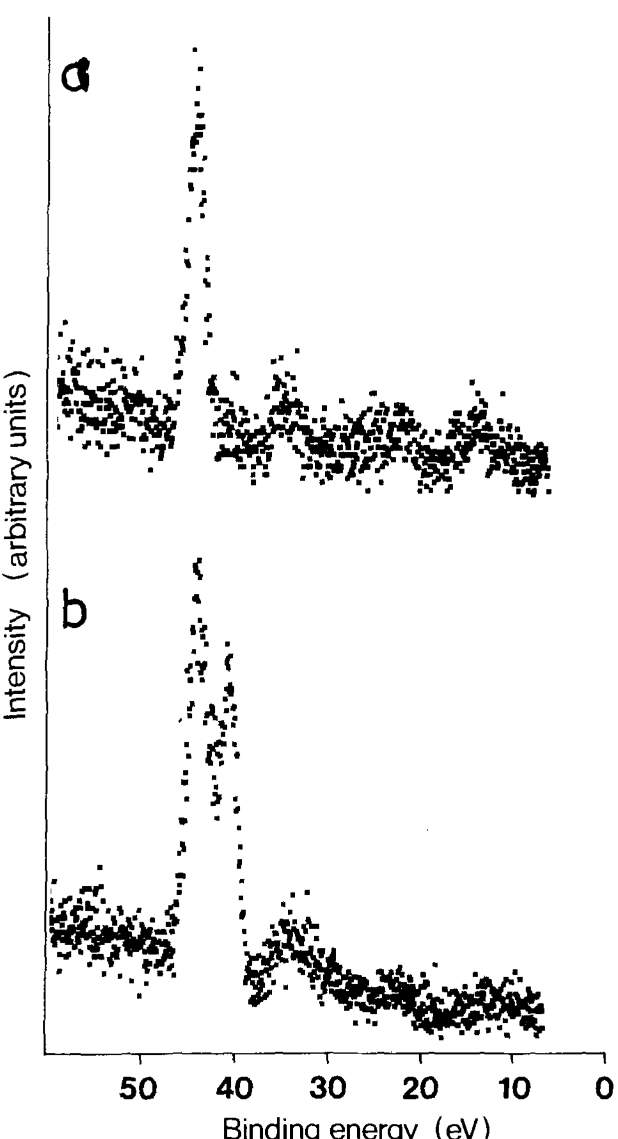

Fig. 1. ESCA spectra of the As 3d peaks for an As_2O_3 powder sample (a) before and (b) Ar-ion etching at 5 kV.

GaAs in the analog spectra the values of the expression

$$\frac{BE(Ga\ 3d) - BE(GaAs\ 3d)}{BE(Ga_2O_3\ 3d) - BE(GaAs\ 3d)}$$

were compared with values of the expression

$$\frac{I(Ga_2O_3)}{I(Ga_2O_3) + I(GaAs)}$$

where $I(Ga_2O_3)$ is the intensity of the Ga 3d peak of Ga_2O_3 obtained from the digital analysis and similarly $I(GaAs)$ represents the Ga 3d intensity of GaAs. Since both expressions represent the fraction of the Ga 3d peak due to Ga_2O_3 they should be identical. The values agree well ($\pm5\%$) when the component peaks were of similar intensities but discrepancies appeared where the intensity ratio of the two components was estimated as greater than about 5:1 from the analog data. In these cases the weaker peak appeared relatively stronger from the digital analysis. However only in one case, point 14 in Fig. 2(b), did the difference exceed the $\pm95\%$ confidence limits (equal to 2 standard deviations) of the digital analysis.

These differences probably arise for two main reasons. First, the approximation used to resolve the analog spectra is not entirely valid under the conditions where the discrepancies occur. Second, the 3d peak shapes are not perfectly fitted to a single peak

(a) Profiles from analogue spectra, (b) profiles from digital spectra, and (c) profile of elemental As from digital spectra. For (a) and (b), ○, Ga in Ga_2O_3; ●, Ga in GaAs; ■, As in As_2O_3; □, As in GaAs.

(they are in fact closely overlapping doublets comprising the 3d 5/2 and 3d 3/2 peaks) and so the fitting program may obtain a better statistical fit by modifying the intensity of the weaker peak present. However the good agreement obtained in most cases is encouraging and indicates that the approximation used is a useful one in cases where no other method is available.

The region where the accuracy of the profile becomes most critical is at the interface because here the greatest compositional variations occur. In particular there is the question of whether or not there is any elemental As present at this interface.

In the case of the analog spectra, elemental As could not be resolved out in the presence of gallium arsenide As (*i.e.*, at the interface); rather, a constant ratio of As_2O_3:As was assured in these cases and only this amount subtracted from the overlapping peak of gallium arsenide (see above). Any additional elemental As over and above this amount will still be included with the gallium arsenide As. Hence, if there were excess elemental As present we might expect to see a profile such as that in Fig. 2(a) where the gallium arsenide As appears before, and is initially more intense than the Ga. (Note that within the substrate the As appears less intense than the Ga due to selective etching. This effect is discussed later.)

From the digital spectra, the computer analysis made it possible to resolve out the As 3d peaks due to As_2O_3, As, and GaAs as shown in Fig. 3. The As_2O_3 and As intensities have not been summed in Fig. 2(b) but the elemental As plotted separately in Fig. 2(c). (The error bars in the latter figure represent the 95% confidence limits of the digital curve fitting analysis and do not include any other experimental errors.) As may be seen the amount of elemental As appears to increase at the interface even though the amount of As_2O_3 is decreasing. This also suggests the presence of excess elemental As at the interface. However in the digital profile of Fig. 2(b) the gallium arsenide Ga appears earlier than in Fig. 2(a), leading to some

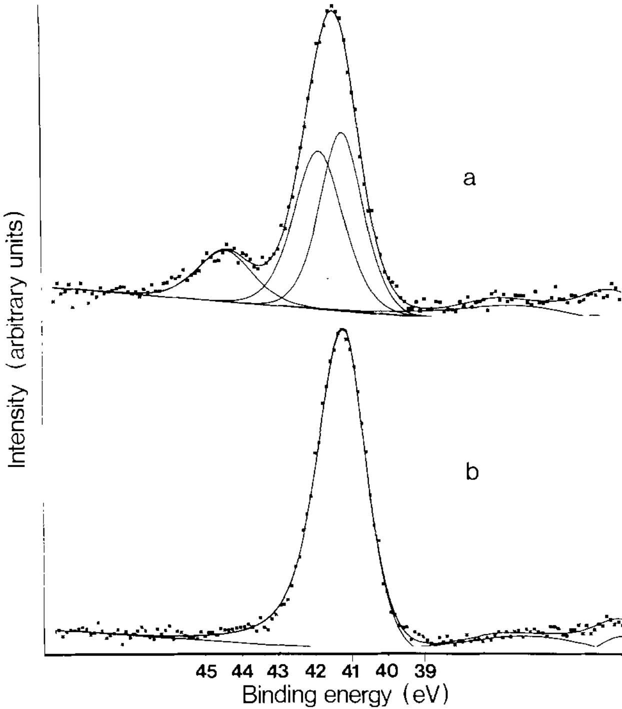

Fig. 3. Expanded spectrum of the As 3d region (a) at the interface showing the digital resolution of the 3d peaks due to As_2O_3, As, and GaAs; (b) in the GaAs substrate.

uncertainty as to whether the feature in the analog profile can definitely be identified as being due to elemental As and is not merely an artifact of the method of data analysis. Two points should be mentioned in conjunction with this. First, although the Ga profiles do deviate in the interface region the difference between these in Fig. 2(a) and (b) only exceeds the 95% confidence limits of the digital analysis at point 14 (indicated on the figure). Second, the Ga profile of gallium arsenide is iterated to zero arbitrarily at the point shown in Fig. 2(b) since here none was observed. However the profile could be more abrupt than shown.

However better resolution was required in order to clarify this issue. This was achieved for the ESCA spectra by going to the narrowest slit width available. Figure 5 shows spectra at the interface of a sample grown at 10 $\mu A\ cm^{-2}$ using this maximum resolution. The analog profile for the same sample is shown in Fig. 6. The spectra in Fig. 5 clearly show that significant changes occur in the As 3d spectrum before similar changes occur in the Ga 3d region and we believe that this is due to the pressure of elemental As. Subsequently (for the profiles shown in Fig. 7 and 8) improved depth resolution was achieved by using lower Ar-ion etch rates.

With this improved resolution, and since reasonable overall agreement was obtained between the profiles obtained by analog and digital analysis of the same set of data the authors decided to rely exclusively on the analog treatment of the results.

Results

The binding energies of the various 3d peaks of Ga and As and of the Al 2p peak observed in these experiments are listed in Table I and compared with previously reported binding energies. The comparison indicates that the major peaks observed in the anodically grown films on GaAs correspond in position with those of Ga_2O_3, As_2O_3, and As within experimental error. In the film incorporating aluminum the Al 2p peak corresponds in position with that of Al_2O_3. The ClS peak at 284.6 eV (which is the value obtained in this laboratory for a hydrocarbon contamination layer based in Au $4f_{7/2}$ at 84.0 eV) was generally used for

[a] Referred to ClS at 284.6 eV.
[b] Referred to Ga 3d position of Ga_2O_3 at 20.5 eV.
[c] Obtained from the best computer fitted spectra of the anodic oxide.
[d] Referred to ClS at 285.0 eV.
[e] Obtained from digital spectra.

calibration if possible but in many cases this did not prove reliable. (This may be due to the presence of a carbon-containing species in the anodic films but more work is required to definitely establish this.) Under these circumstances internal calibration against the Ga 3d peak of Ga_2O_3 was used. In all experiments the internal calibration was consistent with the above assignment. Typical ESCA spectra of the Ga and As 3d region for an anodic oxide and the GaAs substrate are illustrated in Fig. 4.

In addition to the ESCA peaks discussed above, several other weaker peaks were also observed in the

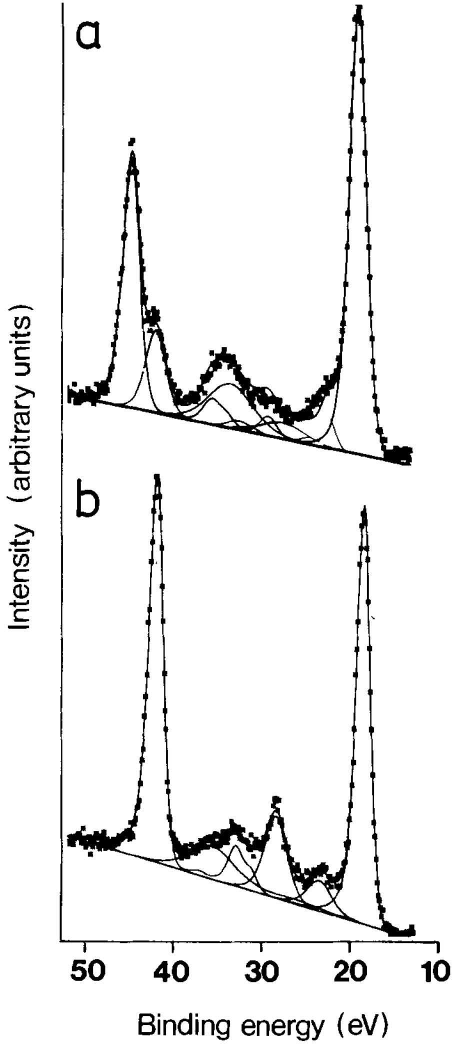

Fig. 4. ESCA spectra of the Ga and As 3d region with computer fit peaks of (a) GaAs native oxide and (b) GaAs substrate after removal of the native oxide by Ar-ion etching at 8 kV.

10-60 eV binding energy region (see Fig. 4). Two pairs of peaks occurred in the anodic oxide spectra between about 26 and 35 eV. These were assigned to the As $L_3M_{45}M_{45}$ Auger transitions (11), there being one pair associated with As_2O_3 and another with elemental As. When GaAs started appearing a third pair of Auger peaks were seen to slightly lower binding energies. Other peaks are the satellite peaks from the nonmonochromated x-radiation used in the spectrometer. Their position and intensity are well known and are taken from x-ray spectroscopy results (13). A broad peak was identified in the computer-analyzed spectra of the anodic oxide at about 39 eV. A similar peak was seen in the GaAs substrate at around 35 eV. The latter peak is a plasmon loss peak associated with GaAs (4, 14) and the lower peak probably has a similar origin. Finally, a new peak was seen at 27.5 ($\pm$1) eV which disappeared on etching through to the substrate. This is probably the oxygen 2s peak (15), the assignment being supported by the fact that the peak correlates quite well with the oxygen 1s intensity which was monitored in most of these experiments.

Oxides grown in the (NH_4) H_2PO_4/glycol electrolyte. —The depth profiles shown in Fig. 2 were obtained from a 1000Å thick native oxide film on GaAs, grown in the (NH_4) H_2PO_4/glycol electrolyte at 50 μA cm^{-2}. As seen in the figure the surface of the oxide grown in this electrolyte is As deficient as compared to the bulk. For a similar sample grown at 500 μA cm^{-2} the ESCA spectrum showed no As present at the surface. The bulk oxide region is fairly uniform and shows a constant As/Ga ratio of atoms per unit volume of between 0.5 and 0.6, this value appearing to be independent of growth current density over the range 10 μA-500 μA cm^{-2}. To what extent this ratio is affected by selective etching has not been established. However it is clear from the Ga and As profiles of gallium arsenide, where the As/Ga ratio is 0.6 instead of unity, that selective etching of As from the substrate definitely occurs.

At the oxide-semiconductor interface the As_2O_3 intensity generally starts to drop before that of Ga_2O_3. Indeed, in some cases the Ga_2O_3 intensity increases first before dropping off. This leads to a Ga_2O_3 rich oxide next to the substrate. The effect seems to be more pronounced at higher and lower growth current densities than it is at 50 μA cm^{-2}. See for example Fig. 6 for a sample grown at 10 μA cm^{-2}. Similar behavior has been observed for samples grown at 500 μA cm^{-2}.

From the profile in Fig. 2(c) it can be seen that the amount of elemental As observed increases at the oxide-semiconductor interface even though the As_2O_3 intensity is decreasing. This suggests that there is a region adjacent to the GaAs substrate where elemental As was present prior to Ar-ion etching. Alternatively it is possible that very thin films of As_2O_3 may be more readily reduced, leading to a smaller As_2O_3/As ratio than that observed in the bulk of the film. However, it has been suggested previously (4) that there is an As rich region adjacent to the substrate in anodic films on GaAs. In view of this it seems very probable that what we are seeing here is confirmation of the presence of elemental As at the oxide/semiconductor interface. Figure 5 shows spectra obtained on etching through the interface of a sample grown at 10 μA cm^{-2}. It can be seen that the changes in As 3d spectrum occur earlier than those in the Ga 3d region. The profile from the sample is shown in Fig. 6 and shows a similar region to Fig. 2(c) although in this case the elemental As intensity is included in the As profile of gallium arsenide as discussed earlier. Similar results were also observed for samples grown at 500 μA cm^{-2}.

Interface widths, measured from these profiles, were defined as the distance over which the intensity of the component being measured changed from 20 to 80% of its steady-state value (6). Interface widths

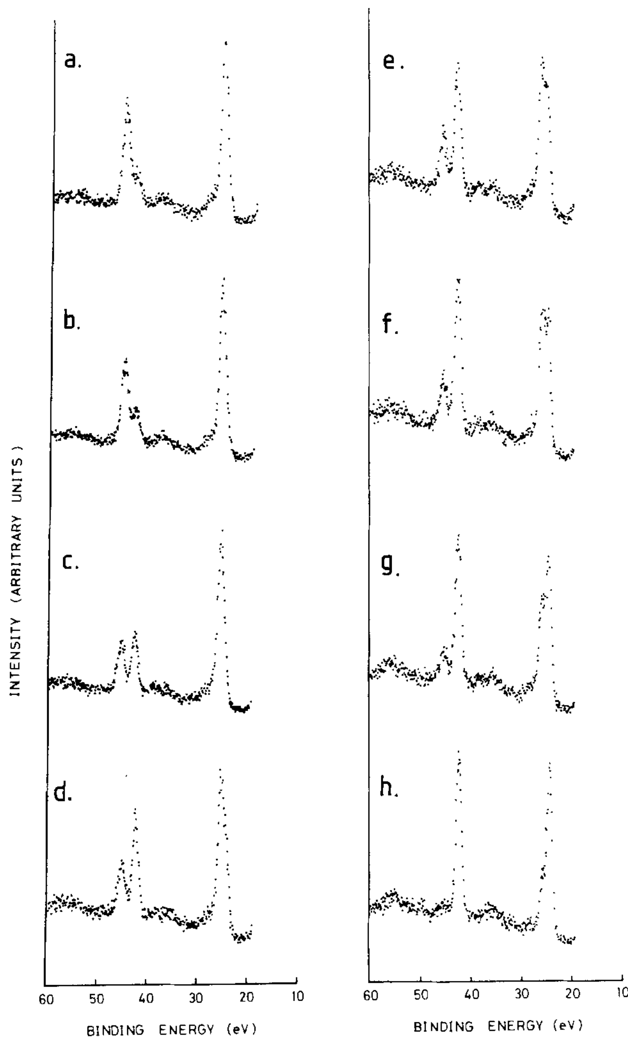

Fig. 5. ESCA spectra of As and Ga 3 d region of sample grown at 10 μA cm^{-2} after Ar-ion etching at 8 kV for (a) 25 min, (b) 28 min, (c) 31 min, (d) 32 min, (e) 33 min, (f) 34 min, (g) 36 min, (h) 39 min.

were measured on both Ga, As, and oxygen profiles. It was found that those measured from the oxygen

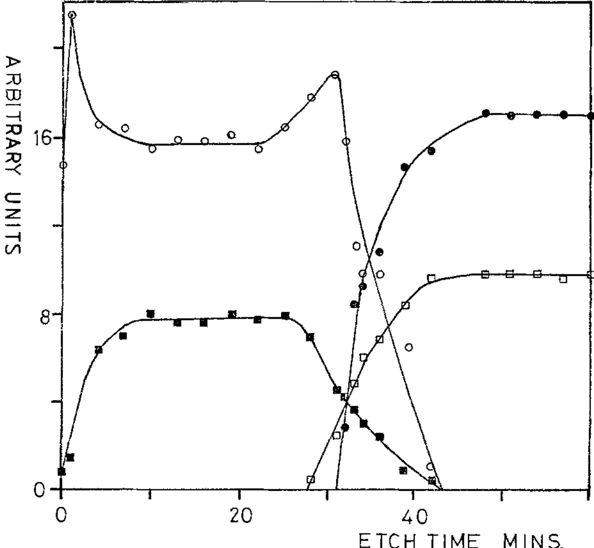

Fig. 6. Depth profiles of Ga and As 3d ESCA intensities from 800Å oxide film grown on GaAs in $(NH_4)H_2PO_4$/glycol electrolyte at 10 μA cm^{-2}. Ar-ion etching at 8 kV. ○, Ga in Ga_2O_3; ●, Ga in GaAs; ■, As in As_2O_3; □, As in GaAs.

profiles gave the largest widths, as would be expected since they reflect the change in both As_2O_3 and Ga_2O_3 at the interface. The widths from the oxygen profiles are therefore used in discussing the interfaces.

Significantly smaller interface widths were observed when etching at 5 rather than 8 kV. For example the interface width measured for a 1000Å film grown at 500 μA cm^{-2} and etched at 8 kV was 210Å whereas the width measured for a similar film etched at 5 kV was about 90Å. This is due to knock-on effects occurring during ion etching which make the interface appear broader than it actually is. The effect is greater for higher energy bombarding ions. Another effect which has not been investigated in a systematic way here is uneven etching. This makes the observed interface width depend on what film thickness has previously been etched away, the broadening increasing for thicker films (6). Because of these effects the measured interface widths represent an upper limit and the actual widths may be expected to be significantly smaller than the measured values.

Oxides grown in the tartaric acid/glycol electrolyte.—Figure 7 shows the profiles obtained from a 500Å native oxide film grown on GaAs in the AGW electrolyte at 200 μA cm^{-2}. In contrast to oxides grown in the previous electrolyte the surface region is As rich as compared to the bulk. (The first point in all these profiles is unrepresentative due to surface contamination and should be ignored.) The other features of these profiles are very similar to those already discussed. The bulk of the film is uniform with an As/Ga ratio of about 0.5. There is a slightly Ga_2O_3 rich region adjacent to the substrate and the As profile of the GaAs substrate indicates the probable presence of elemental As at the interface. The interface width obtained from the oxygen profile was 60Å. (The sample was etched at 5 kV.)

Using the data shown in Fig. 7 an attempt was made to estimate the amount of elemental As present at the interface over and above that expected due to reduction of As_2O_3 by the ion beam. The gallium arsenide As peak intensities were all corrected for selective etching using the observed Ga/As ratio of the substrate, which is 0.65 instead of unity, and assuming that the effect becomes operative as soon as the substrate appears. Using the corrected values the difference in areas beneath the Ga and As profiles of the gallium arsenide was obtained. From the known etch rate and the known density of As atoms in GaAs the area could be converted into a number of atoms per square centimeter, giving the value 2×10^{15} atoms per cm^2. It was not possible to assign a realistic value to the errors involved in this estimate.

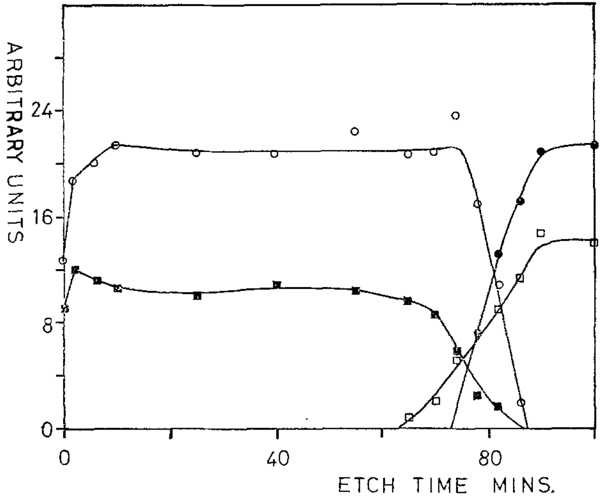

Fig. 7. Depth profiles of Ga and As 3d ESCA intensities from a 500Å oxide film grown on GaAs in tartaric acid/glycol electrolyte at 200 μA cm^{-2}. Ar-ion etching at 5 kV. ○, Ga in Ga_2O_3; ●, Ga in GaAs; ■, As in As_2O_3; □, As in GaAs.

Anodic films incorporating aluminum.—Figure 8 shows the profile obtained from an anodic oxide film grown in the AGW electrolyte on a GaAs sample with 200Å of Al deposited onto its surface. ESCA spectra of the Ga and As 3d region taken at points A, B, and C in Fig. 8 are shown in Fig. 9. The total oxide film thickness here is approximately 900Å. As already noted, the Al 2p peak can be assigned to that of Al_2O_3, (see Table I). This peak was observed all the way through the oxide film and significant amounts were seen at the surface.

From Fig. 8(a) it can be seen that there are two GaAs native oxide regions, one above and one below the Al_2O_3 layer. The native oxide beneath the Al_2O_3 layer is similar in all respects to that observed on GaAs in the absence of Al [compare Fig. 4(a) and Fig. 9(c)] and at the oxide semiconductor interface the probable presence of elemental As is indicated. However the native oxide at the surface of the film [see Fig. 9(a)] shows marked differences when compared to the normal GaAs native oxides grown without Al. First the oxide is very As deficient as compared to the normal anodic oxide. The As/Ga ratio of atoms per unit volume here is about 0.3 rather than 0.5. Second the As_2O_3:As ratio in this region is almost 1:1, not the 4:1 ratio expected from reduction of As_2O_3 by Ar ions at 5 kV. This situation persists right through the predominantly Al_2O_3 region until the oxide region underneath is reached when the normal ratio is again observed. This seems to suggest that there is some difference between the As_2O_3 in the two regions such that that nearer the surface is more readily reduced. An alternative possibility which cannot be ruled out from the data available here is that there was originally some unoxidized Al present in the film which reacted with As_2O_3 during Ar-ion etching to produce As + Al_2O_3, since Al_2O_3 is the thermodynamically more stable oxide.

Discussion

The foregoing results indicate that anodic native oxide films on GaAs may be divided into three regions;

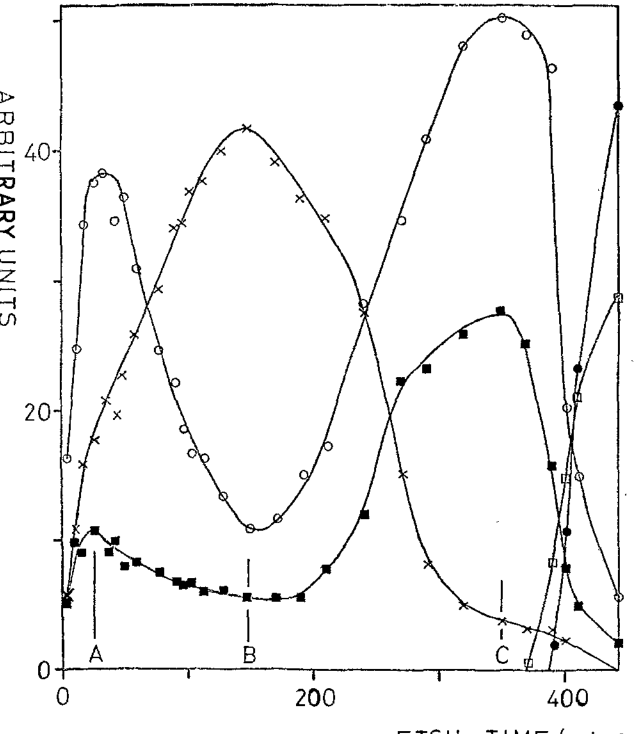

Fig. 8. Depth profiles of Ga and As 3d and Al 2p ESCA intensities from an anodic oxide grown on GaAs + 200Å Al in tartaric acid/glycol electrolyte at 100 A cm^{-2}. Ar-ion etching at 5 kV. ○, Ga in Ga_2O_3; ●, Ga in GaAs; ■, As in As_2O_3; □, As in GaAs; ×, ½ of Al 2p intensity in Al_2O_3.

the surface, the oxide bulk, and the oxide/GaAs interface region. In terms of chemical composition the surface region is extensively influenced by the electrolyte whereas the other two regions are not. The factors which control the surface composition are not known but the adsorption behavior of the electrolyte is probably important.

Due to the limited number of samples studied here no definite conclusions have been drawn concerning the influence of growth current density on film structure. However no overall systematic changes were observed over nearly two orders of magnitude (10-500 μA cm^{-2}). The most obvious variation seen was in the extent to which there was a Ga_2O_3 rich region in the oxide near the oxide/semiconductor interface. This seemed much less pronounced for samples grown at 50 μA cm^{-2} than for those grown at the extremes of the range studied. It is conceivable that the observed variation was simply an experimental artifact. However a previous report (16) of oriented β-Ga_2O_3 observed at this interface for samples grown at very high current densities (>2 mA cm^{-2}) may also suggest a more Ga_2O_3 rich oxide at the interface, since As_2O_3 is a primary glass former and its absence could lead to polycrystalline Ga_2O_3 being formed. [Wilmsen and Kee also reported a Ga_2O_3 rich oxide near the interface in anodic oxides grown in both tartaric acid/glycol and H_3PO_4 solutions (5).] There was also some evidence that the surface depletion of As was less severe for samples grown at low current densities in the $(NH_4)H_2PO_4$ electrolyte. Similar results have been reported by Croset *et al.* (17) for samples grown in a Na_3PO_4/glycol electrolyte.

As noted above it is possible that the as-grown anodic oxide films contain elemental As at the oxide/semiconductor interface. The origin of this elemental As is not known, but we have previously suggested (18) that the growth mechanism may be responsible. Whatever the reason for this accumulation, its presence must influence the interface properties and hence device behavior where this technology is employed. Because of this it would be advantageous to be able to control and hopefully eliminate this elemental As buildup. However, at present there is no obvious way in which this might be accomplished.

One further observation of relevance in connection with the oxide film growth mechanism is that in Fig. 8(a) Al_2O_3 is seen throughout the film. Its occurrence deep in the film, below the expected Al_2O_3 region, may be due to knock-on effects during ion etching. However, the spreading towards the oxide surface cannot be explained as an experimental artifact. It may mean that the previously suggested interstitial mechanism for metal ion drift (18) is an oversimplification and that "lattice" and "interstitial" ions can interchange within the film. Further experimental work is required here.

Finally, it is important to consider the effects of ion etching on the sample and how this influences the results. We have observed in these experiments that the Ar-ion beam reduces As_2O_3. No similar effect was seen with Ga_2O_3. We have also seen selective etching in the GaAs substrate where the observed Ga:As ratio was not unity. However, we have not yet been able to estimate the extent to which selective etching effects the observed Ga:As ratio in the oxide. Until the extent of this effect is known we cannot make any reliable quantitative measurements from results such as these. Also we have noted that the measured interface width is significantly influenced by the etching conditions, a factor which should be taken into account when using such measurements.

Conclusions

The results presented in this paper illustrate the application of ESCA to the study of anodic oxide films. Using this technique we have been able to obtain chemical depth profiles which provide considerable insight into the structure of such films. They indicate that the oxide/semiconductor interface region is very complex with variations in the Ga_2O_3/As_2O_3 ratio as well as the probable presence of elemental As. Some variation was noted between films grown in two different electrolytes.

Results from an anodic film grown on a GaAs substrate plus 200Å of aluminum also showed complex behavior. Two different native oxide regions were identified, one at the film surface which was relatively As_2O_3 deficient and one below the Al_2O_3, adjacent to the substrate, which resembled the anodic native oxides seen in the absence of Al.

Much more work is still required, both on anodic native oxides of GaAs and also on multilayer anodic films. It is hoped that progress will be assisted by further applications of ESCA to take advantage of the insight which it allows.

Arsenic Ion-Implanted Shallow Junction

Yasuo Wada* and Norikazu Hashimoto

Hitachi, Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Shallow junction formation technology by arsenic ion implantation is evaluated from the viewpoint of practical application to the coming VLSI's. Carrier profile, residual defect profile, and electrical characteristics are examined as functions of acceleration energy, dose, annealing conditions, and surface oxide thickness. The carrier profile is determined mainly by both arsenic ion amount in the substrate layer and annealing conditions. The residual defect profile is determined by implantation energy and surface oxide thickness. It is necessary to implant arsenic ions shallower than the resulting carrier profile, to obtain arsenic ion-implanted junctions with acceptable electrical characteristics. A junction diode, with junction depth as shallow as 0.16 μm is fabricated according to this principle, and is ascertained to have acceptable electrical characteristics.

The increasing demand for higher packing density MOS LSI's has accelerated progress for larger and more densely integrated devices. The integration density has almost tripled every two years, along the trend curve for higher integration (1).

This progress has been achieved mainly through the scale-down theory (2), in which the physical dimensions of the unit device, MOS FET, are reduced $1/k$ times that of original values. This factor k is called the scale-down factor. The resulting circuit speed becomes k times faster, and the resulting power dissipation of the circuit also becomes $1/k^2$ times smaller. According to the scale-down theory, heavily doped shallow junction formation technology is indispensable in addition to fine pattern lithographic technology.

In line with this, heavy arsenic ion implantation technology has attracted attention recently as a means of fabricating shallow and low resistivity MOS LSI source and drain regions (3). The main reasons for this trend are the precise controllability and high flexibility that ion implantation technology provides. The in-process monitoring of ion implantation energy and dose facilitates high accuracy in fabricating very shallow junctions. Moreover, ion implantation technology makes it possible to reduce the lateral spread of impurity as compared with conventional thermal diffusion technology (3). Arsenic ion-implanted emitters of bipolar transistors/LSI's also provide acceptable device characteristics (4).

* Electrochemical Society Active Member.

Key words: ion implantation, leakage current, oxygen knock-on, p-n junction.

There, arsenic ion implantation technology will inevitably be used for the formation of shallow and low resistivity source and drain regions of high density MOS LSI's as well as emitters of bipolar devices. However, there still remains the problem of the high density residual defect even after prolonged annealing at high temperatures (5), which might affect the electrical characteristics of junctions.

This paper reports the residual defect penetration depth as well as carrier profile of shallow arsenic ion-implanted layers as functions of implantation energy, dose, annealing conditions, and surface oxide thickness. It also provides information on the electrical characteristics of the shallow junction in relation to carrier and residual defect profile results.

Experimental Procedures

Ion implantation and annealing.—Arsenic ions were implanted through oxide layers into p-type, (100) oriented silicon wafers. The oxide layers were thermally grown to thicknesses of between 0 and 50 nm. The acceleration energy and dose were in the range 40-120 keV and 1×10^{15} cm^{-2}-2×10^{16} cm^{-2}, respectively. Annealing in a dry nitrogen atmosphere at between 900° and 1100°C for 20-120 min was carried out to activate the implanted ions.

Carrier and defect profile measurements.—Carrier profiles of arsenic ion-implanted layers were measured by the incremental sheet resistivity method (6). Measurement accuracy was better than 20% for carrier number, and better than 5% for depth. Carrier num-

ber was derived using Irvin's ρ-N relationship (7). Therefore, the clustering effect of heavily arsenic-doped layers (8) was not taken into consideration. Carrier number in the implanted layer was also measured by Hall effect measurements.

The residual defect penetration depth of the arsenic ion-implanted layers was measured using a combination of the layer removal method and thin film transmission electron microscope (TEM) observation technique (9).

Junction diode fabrication and leakage current measurements.—An n^+-p junction diode with 1 mm^2 area was fabricated by conventional silicon gate MOS LSI processing technologies (14). A 1 μm thick oxide layer was thermally grown on a p-type, (100) oriented 10 Ω-cm silicon wafer. Then, the diode region was delineated by photolithography, followed by thin (20-50 nm thick) thermal oxide growth and arsenic ion implantation. A phosphosilicate glass layer was deposited by the CVD method. Annealing in a dry nitrogen atmosphere was carried out, followed by aluminum metallization and low temperature hydrogen annealing. Phosphorus atoms in the PSG layer do not diffuse into the silicon substrate, because of the thin thermal oxide layers underneath the PSG layer.

Leakage current of the diode was measured using a combination of constant voltage source and picoammeter. Leakage current as low as 10^{-13}A (10^{-11} A/cm^2) could be detected.

Results and Discussion

Dose dependence of carrier profile.—The carrier profiles of arsenic ion-implanted annealed layers were measured as functions of dose, energy, surface oxide thickness, and annealing conditions. Typical results of dose dependence between 1×10^{15} cm^{-2} and 1×10^{16} cm^{-2} are shown in Fig. 1. The heavier the ion dose, the deeper the carrier profile becomes. The dose dependence of carrier profile can be explained in terms of concentration dependent arsenic diffusion coefficient in silicon (14). The peak carrier concentration remained at about 2×10^{20} cm^{-3}, regardless of ion dose. Total carrier number measured by Hall effect was less than 50% in the 1×10^{16} cm^{-2} implanted case, whereas it was about 100% in the 3×10^{15} cm^{-2} implanted case. These carrier saturation phenomena have been explained in the light of clustering effect in the heavily arsenic ion implanted layers (8). Therefore, in order to form shallow and low resistivity junction, it is better to control the peak arsenic concentration at about 2×10^{20} cm^{-3}, so as to avoid the unnecessary clustering phenomena.

However, it was found that there is a practical limitation for the shallow and low resistivity junction formation. The sheet resistivity and junction depth relationship of the arsenic ion-implanted annealed layer was measured, and the typical results are shown in Fig. 2. In the figure, the low resistivity and shallow junction is on the lower left-hand side, and vice versa. These results clearly show that a practical limitation exists in forming shallow and low resistivity junctions. Taking a 0.2 μm depth junction for example, the lowest resistivity achievable by arsenic ion implantation and high temperature annealing is around 35 $\Omega/\square$. These limitations are determined by the contribution of temperature dependent solid solubility (8), as well as the concentration dependent arsenic diffusion coefficient in silicon (14).

The influence of initial arsenic profile on the resulting carrier profile was estimated. Typical calculated results assuming Gaussian distribution (12) are shown in Fig. 3, in which the acceleration energy was between 40 and 120 keV. Although the initial profile differed markedly according to the implantation conditions, as shown in Fig. 4 (12), the resulting carrier profiles after high temperature annealing are almost identical. In

comparison with the dose dependence of carrier profile results shown in Fig. 1, it can be concluded that the arsenic ion amounts in the silicon substrate, as well as annealing conditions, almost completely determine the resulting carrier profile in silicon.

Therefore, the resulting carrier profiles after thermal annealing do not depend on the initial arsenic profiles in silicon. It is essential to control the annealing conditions, as well as the arsenic amount in silicon to obtain a suitable carrier profile in the arsenic-implanted layers.

Residual defect penetration depth.—Residual defect penetration depth was measured as functions of acceleration energy and surface oxide thickness. Arsenic ion dose was 1×10^{16} cm^{-2}. The samples were annealed in a dry nitrogen atmosphere at 1000°C for 30 min. Residual defect differences observed by TEM are depicted in Fig. 5. The result for a 40 keV implanted sample is markedly different from the other TEM micrograph results. The residual defects did not grow to dislocation loops, possibly due to the very shallow residual defect profile. On the other hand, the defects grew to dislocation loops in higher implantation energy cases. If the dose amount was doubled, the residual defect shape changed from dislocation loop to small scattered dislocations. However, prolonged annealing of up to 120 min did not change the residual defect structures. This phenomenon originated from the dislocation pinning effect of knock-on oxygen (3).

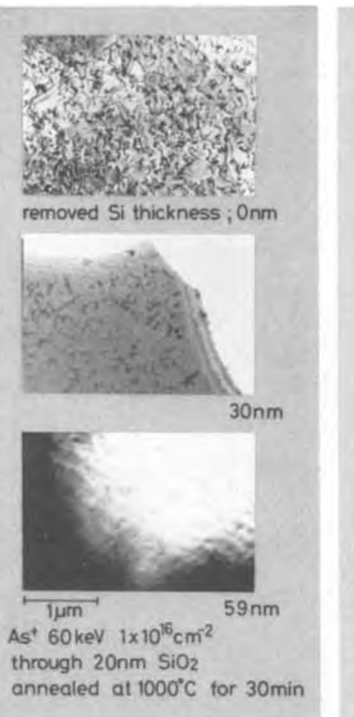

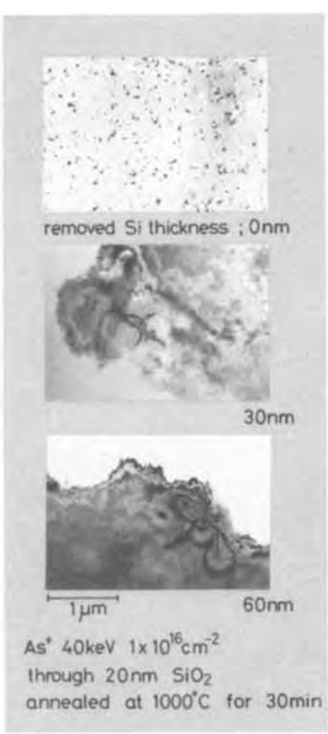

Fig. 6. TEM micrographs showing residual defect penetration depth measured by layer removal method: acceleration energy, as a parameter; (a, left) 120 keV, (b, center) 60 keV, (c, right) 40 keV.

The defect penetration depths for samples shown in Fig. 5 were measured by the layer removal method, and typical TEM micrographs are shown in Fig. 6(a), (b), and (c). Taking the 40 keV implantation case for example, residual defects remained only within 30 nm of the surface, while the residual defects in samples implanted with a 120 keV acceleration energy penetrated to a depth of around 0.11 μm. Therefore, it can be concluded that the higher the implantation energy, the deeper the residual defect penetration depth becomes in the silicon-silicon dioxide (Si-SiO_2) system.

Defect profile analysis.—The acceleration energy dependence of residual defect penetration depth is analyzed in terms of oxygen knock-on phenomenon (15). A typical knock-on oxygen profile in silicon, measured by secondary ion microanalysis (SIMS) is shown in Fig. 7 by open circles (11). Arsenic ions were implanted through a 102 nm thick surface oxide layer, to a 1×10^{16} cm^{-2} dose at a 180 keV acceleration energy. In the figure, the calculated arsenic profile in the silicon-silicon dioxide system (Si-SiO_2) is also depicted by a solid line (12).

The distance between the Si-SiO_2 interface and the oxygen profile, normalized by arsenic ion projected range (R_p) in silicon dioxide is derived as a function of surface oxide thickness, that is also normalized by R_p. Typical results are shown in Fig. 8, in which the oxygen concentrations were chosen as 10^{19} and 10^{20} cm^{-3}. The results clearly show that between a normalized surface oxide thickness of 0.5 and 3.0 (*e.g.*, 50-300 nm thick), the thinner the oxide thickness, the deeper the knock-on oxygen profile becomes. If surface oxide thickness is half of R_p, the depth where knock-on oxygen concentration is 10^{20} cm^{-3} becomes about 1.2 times deeper than R_p from the Si-SiO_2 interface, while the depth where the oxygen concentration is 10^{19} cm^{-3} becomes about three times deeper.

The acceleration energy dependence of residual defect penetration depth, shown in Fig. 6, can be analyzed on the basis of normalized knock-on oxygen penetration depth shown in Fig. 7 and 8. Assuming that the residual defect remains in the region where the knock-on oxygen concentration is above 8×10^{19} cm^{-3}, the experimentally obtained residual defect penetration depth and the calculated penetration depth coincide well, as shown in Fig. 9. In the figure, it is shown that the results for acceleration energy of between 40 and 120 keV fell almost on the same line.

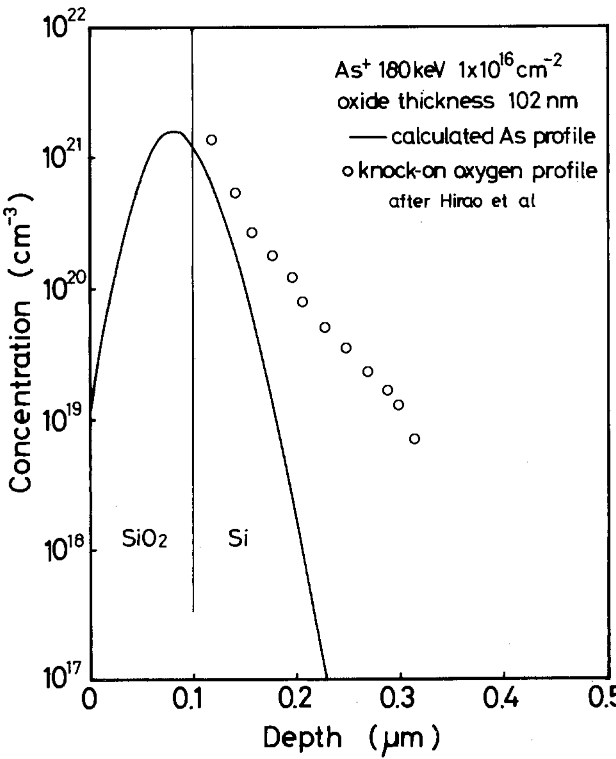

Fig. 7. Knock-on oxygen profile in silicon [after Hirao (10)]

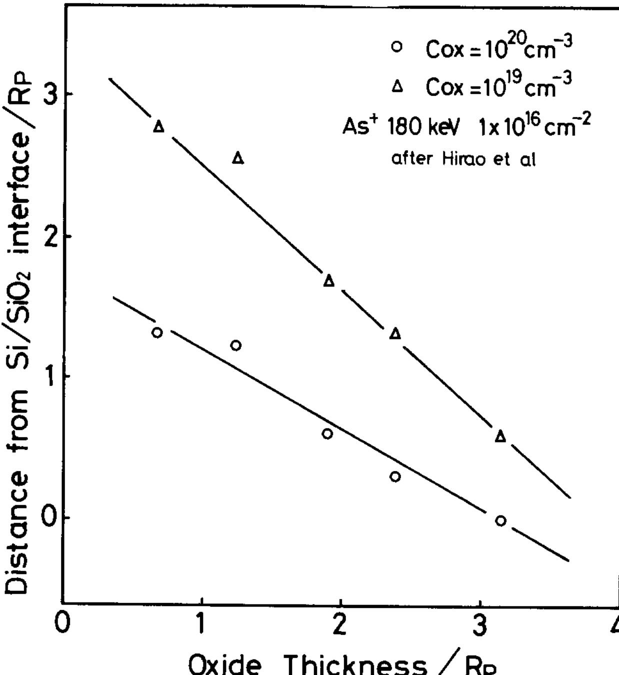

Fig. 8. Normalized relationship between knock-on oxygen penetration depth and surface oxide thickness.

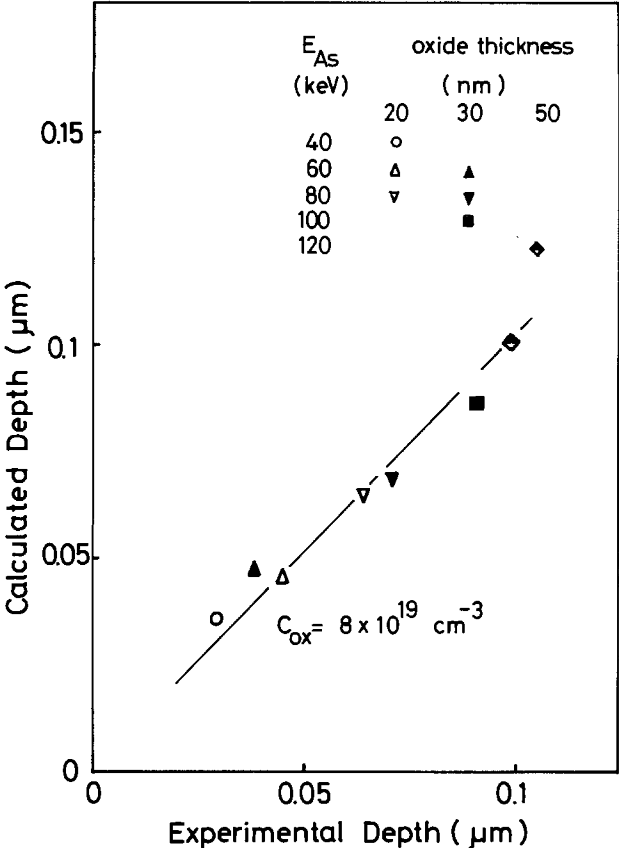

Fig. 9. Comparison of experimental and calculated residual defect penetration depth. Oxygen concentration, $C_{ox} = 8 \times 10^{19}$ cm^{-3}.

The normalized residual defect penetration depth (X_{defect}/R_p) is expressed as a function of normalized oxide thickness (t_{oxide}/R_p) as follows

$$X_{defect}/R_p = -2/3\ (t_{oxide}/R_p) + 2 \qquad [1]$$

Therefore, residual defect penetration depth can be predicted from the normalized knock-on oxygen penetration depth and normalized surface oxide thickness relationship shown in Fig. 8. In other words, residual defect penetration depth can be controlled by the suitable choice of implantation energy and surface oxide thickness. These results suggest that low energy ion implantation through thin silicon dioxide layers is recommendable for shallow arsenic ion-implanted junction formation, from the viewpoint of residual defect penetration depth.

Electrical characteristics of junction diode.—If residual defect penetration depth exceeds the junction, the generation-recombination center concentration of the junction would increase markedly. In other words, if arsenic ions were implanted at a high acceleration energy and annealed at low temperature, so that the carrier profile would not move, or would not exceed the residual defect penetration depth, the electrical characteristics of the diodes would become poor. Therefore, practical limitations of shallow junction formation technology were evaluated from the standpoint of diode leakage current characteristics.

The junction leakage current of diodes fabricated by shallow arsenic ion implantation was measured as functions of residual defect penetration depth and carrier profile. The results are shown in Fig. 10. In the figure, junction depths were measured by the bevel-etch staining method (10), as well as by the incremental sheet resistivity method (6). The residual defect penetration depth was derived from the results shown in Fig. 9. As long as the residual defect penetration depth does not exceed the junction depth, the leakage current level is low enough to apply to practical device fabrication (3). Junctions as shallow as 0.16 μm depth were shown to have acceptable electrical characteristics.

Annealing temperature dependent leakage current results (13) were also analyzed in view of this defect penetration depth analysis. The relationship of annealing temperature and calculated residual defect penetration depth, as well as junction depth, are shown in Fig. 11. In the figure, arsenic ions were implanted at 100 keV through a 54 nm thick SiO_2 layer to a dose of 4×10^{15} cm^{-2} (13). The residual defect penetra-

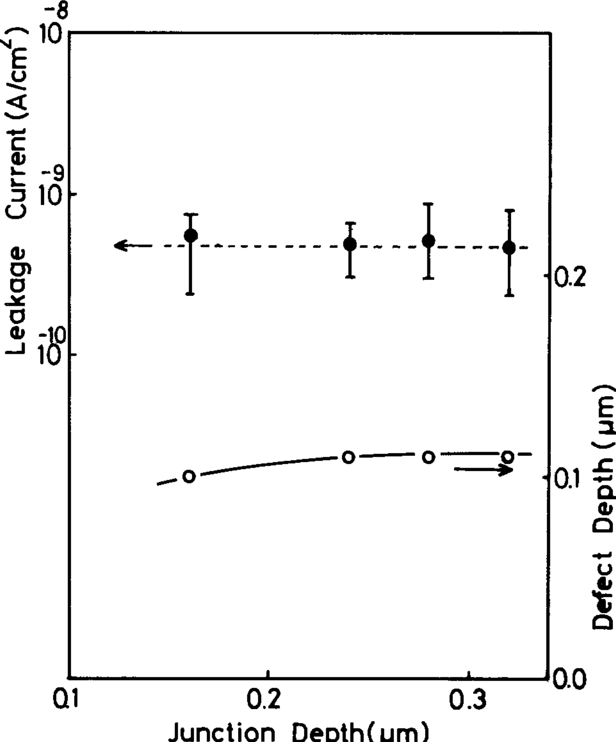

Fig. 10. Junction leakage current of shallow junction diodes fabricated by shallow arsenic ion implantation. Residual defect penetration depth and junction depth, as parameters.

tion depth should be around 0.09 μm according to the analysis previously shown. On the other hand, the junction depth increases with annealing temperature. Corresponding leakage current results are also shown in Fig. 11. Leakage current is too high for practical applications, when the difference between junction and defect depth is around 0.02 μm. These results clearly indicate that junction leakage current is higher when the residual defects penetrate deeper or at least 0.02 μm shallower than the carrier profile. Therefore, the guiding principle, *i.e.*, "Junction depth should be deeper than residual defect penetration depth by at least 0.02 μm," can be derived.

Conclusions

The residual defect penetration depth and the carrier profile of arsenic ion-implanted layers after high temperature annealing were measured as functions of implantation conditions and annealing conditions. The results obtained in this study are summarized as follows.

1. Residual defect penetration depth can be predicted by arsenic ion implantation conditions and surface oxide thickness.
2. Resulting carrier profile after high temperature annealing is determined mostly by arsenic ion amounts in the substrate region as well as by annealing conditions.
3. Guiding principle, "Junction depth should be deeper than the residual defect penetration depth by at least 0.02 μm" can be derived from the device application viewpoint.
4. Shallow arsenic ion implantation technology will be a key tool for the coming VLSI fabrication.

The Alloying of Gold and Gold Alloy Ohmic Contact Metallizations with Gallium Arsenide

D. C. Miller

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The alloying of gallium arsenide with thin films of pure gold and the gold 12% germanium-silver-gold ohmic contact metallization used for a GaAs FET, has been investigated using optical and scanning electron microscopy. The heating rate and maximum temperature attained during heat-treatment was found to govern the morphology of the pure gold films, and to a lesser extent the ohmic contact metallizations. The alloying cycle commences with decomposition of the underlying GaAs and diffusion of gallium into the metal at about 260°C. Melting commences above about 480°C with pure gold and 360°C with the contact metallization. The final gallium content of the metal increases as the temperature is increased and the solidification temperature of both a pure gold and multicomponent contact heated to 525°C is 343° ± 2°C. The GaAs-metal interface is very irregular consisting of approximately rectangular depressions, often over 1 μm deep, filled with metal.

Gold is used extensively in the fabrication of gallium arsenide devices, both as a component of an alloy in ohmic contacts and as a final metal or conductor. In order to make ohmic contacts of low resistance, the metallization is fused at temperatures often as high as 500°C. This is the temperature at which GaAs itself begins to decompose (1). Furthermore, gold forms low melting point alloys with gallium, so it is not surprising that considerable dissolution of the underlying GaAs takes place during the alloying cycle. The result is a contact with good electrical properties but one which is morphologically very irregular and difficult to reproduce. Even though the contact resistance itself was found not to be directly related to the morphology, morphology may play a significant role in performance and reliability.

Evidence has accumulated which indicates that decomposition of the GaAs accompanies the alloying cycle (2-6). This is confirmed here and further details of the alloying reaction are presented. Some of the parameters which govern the contact morphology are discussed for both pure gold and the alloys used in device manufacturing. Burnout and device performance are specifically not discussed in this paper.

Experimental Details

Transistors in various stages of completion as well as semi-insulating substrates coated with vapor-deposited pure gold were used for the studies reported here. The manufacturing details of the transistors have been presented elsewhere (7), and only certain relevant aspects will be outlined below.

The 0.4μ thick active layers are deposited by CVD on chromium-doped semi-insulating substrates oriented about 6° off the (100). Some samples had a semi-insulating CVD layer under the active layer, but this did not affect the alloying or morphology. The standard ohmic contact metallization consists of 400 or 500Å of Au 12 weight percent (w/o) Ge, 1000Å of Ag, and 1000Å of pure Au. It is made by vacuum deposition after 300Å of the GaAs is etched away by an H_2O_2, NH_4OH solution (8). The samples coated with just pure gold were not etched before deposition, but this did not appear to have any effect on the results. Alloying was accomplished by heating the samples on a resistance heated carbon plate in an H_2 ambient. Alloying was also performed using a hot stage in both an optical microscope and an SEM. In the optical microscope either a vacuum or various gas ambients could be used. Temperature measurement in all cases was by means of a thermocouple in intimate contact with the underside of the heating strip under the sample, and was accurate to within ±2°C except for very fast heating rates. Calibration was checked by observing the melting points of various metals such as lead, zinc, etc.

Key words: alloy, films, diffusion.

Alloying of Pure Gold

Because gold is the major component of the contact metallization, it was decided that the behavior of pure gold on GaAs during heating should first be established as a reference. Consequently, a number of samples of semi-insulating GaAs were coated with 1000Å of Au. A sample given an alloy cycle which can be used to make ohmic contacts is shown in Fig. 1. This cycle consists of raising the temperature at 400°C/min to 490°C then shutting the power off thereby quenching the sample, which cools to below 100°C in a few seconds. This treat-

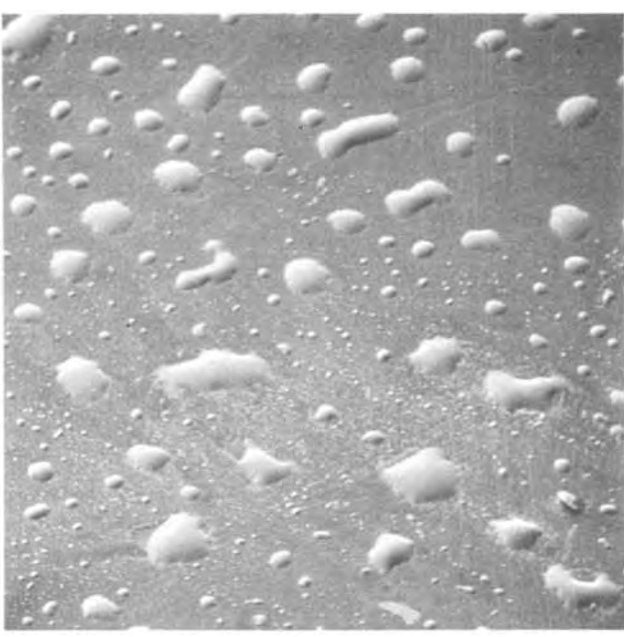

Fig. 1. Pure gold film heated to 500°C at a rate of 400°C/min. 135×.

ment has clearly caused the metal to "ball up" severely.

In an attempt to alter this morphology a number of samples were alloyed under a range of ambients and using various heating rates. The type of gas ambient, or vacuum, had no effect whatever on either the surface or interface morphology, in agreement with the work of Zee and Munir (9). Hence, all subsequent experiments were performed under 1 atm of H_2, except where otherwise noted. In contrast, the heating sequence used had a significant effect on surface morphology. By reducing the heating rate to below about 100°C/min a nonballed, silver colored film of Au-Ga was obtained, with the gallium content increasing as the ultimate temperature attained was increased. This was determined using an energy dispersive x-ray analyzer on the SEM calibrated using various bulk Au-Ga alloys and various thicknesses of unalloyed pure gold to measure the substrate contribution to the Ga signal. The excess As vaporized as evidenced by the presence of an arsenic film on the inside of the cover glass of the heating stage. Heating to 525°C over 10 min produced a mirror-like, silver colored film which could not be distinguished from pure Ag by the unaided eye. Its appearance in the SEM is shown in Fig. 2.

During heating, a slight texture change occurred between 260° and 280°C, but the dramatic color transition from gold to silver began between 480° and 515°C, normally at the edge of the sample or at an imperfection. As the heating rate was increased, the temperature required to initiate the reaction also increased. Attempts were made to initiate the reaction below 480°C by waiting but they were unsuccessful due to equipment overheating problems which developed after about 5 min. This was not sufficient time to initiate the reaction below 480°C. It was obvious in the microscope that the gold to silver color transition was accompanied by, and probably the result of, the metallization melting. This melting temperature is probably also a function of the thickness of the Au, since the source of Ga is the GaAs decomposition reaction which is temperature-dependent and probably diffusion-limited until the first liquid forms. Once initiated, the rate of advance of the silver colored phase can be controlled by adjusting the temperature of the hot stage and started or stopped by adjusting the temperature above or below 343° ± 2°C, respectively. This is very near the

Fig. 2. Pure gold given a reduced heating rate of about 50°C/min. 135×.

eutectic temperature as indicated by the AuGa phase diagram shown in Fig. 3 (10). This phase front on one of the specimens removed to the SEM is shown in Fig. 4. The unmelted gold is to the left and the silver colored gallium alloy is to the right. The small voids in the gold were not quite visible in the optical microscope, but they apparently occur without melting and are not present in the as-deposited gold. The intermediate region between the two regimes puffs up like a soufflé then collapses to form the morphology on the

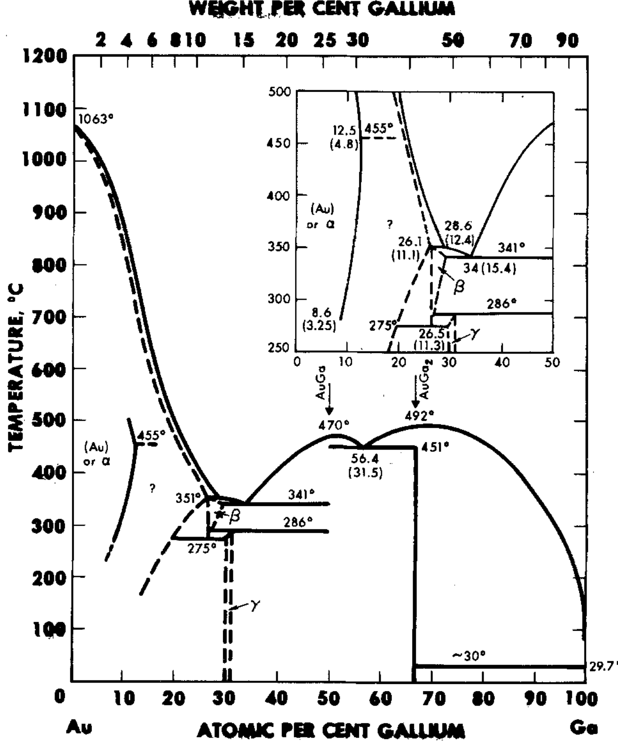

Fig. 3. The gold-gallium phase diagram from Hansen (10)

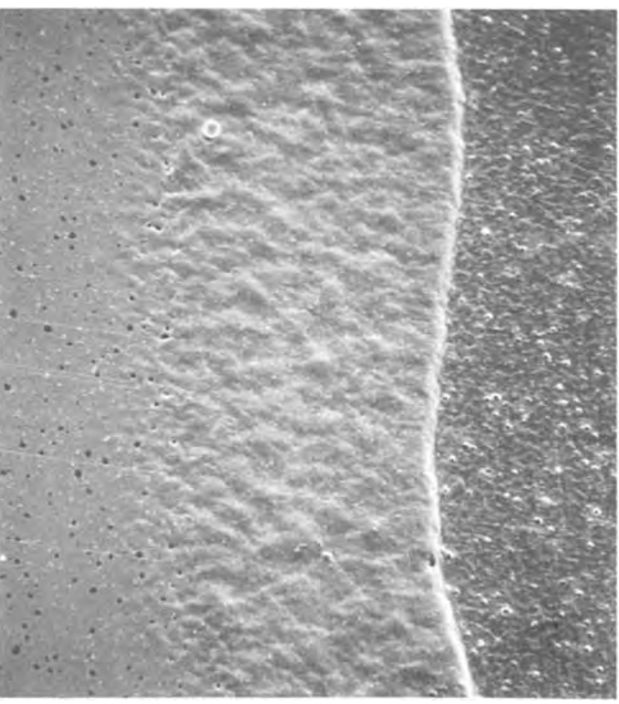

Fig. 4. Gold to silver colored phase boundary. The gold colored region is on the left and the silver colored region is on the right. 1200×.

right as the color changes. Arsenic vapor combined with other absorbed gases may cause the puffing up because the Au-GaAs reaction has begun without the topmost layers of the gold having yet melted.

To explore this reaction further, Au-Cr thermocouples were prepared by depositing 2 mm wide stripes 3000Å thick, first of gold then of chromium, orthogonally on semi-insulating GaAs. A Chromel-Alumel thermocouple with 0.002 in. diam. wire was glued to the substrate with silver paste near the thin film thermocouple. The substrate was then heated to 400°C at 36°C/min in a small oven in an N_2 ambient. The potentials of both thermocouples were recorded simultaneously so that the potential of the thin film thermocouple could be determined as a function of temperature and this is shown in Fig. 5. The change in potential at 260°C indicates that at this temperature decomposition of the GaAs has begun and that diffusion of gallium is very rapid at quite low temperatures. The large dip at 340°C correlates well with the Au-Ga eutectic at 341°C. Similar thermocouples made on SiO_2 substrates did not show these changes during similar heating sequences. Upon cooling and subsequent reheating the voltage *vs.* temperature curves of the thin film thermocouple were smooth and approximately linear, just lower in voltage than before heat-treatment. This experiment indicates that as the alloying sequence is initiated, decomposition of the gallium arsenide and diffusion of gallium into the gold has already begun at low temperatures, and when the first liquid is nucleated significant amounts of gallium are already present in the metal.

Ohmic Contact Metallization

The sequence of events occurring during heating of the ohmic contact metallization should differ markedly from the case of pure gold just discussed. There is the 500Å layer of AuGe of eutectic composition which melts at 356°C, and the 1000Å of Ag between the AuGe and final 1000Å of Au. However, they behave in a remarkably similar fashion except that each event occurs at a somewhat lower temperature with the multicomponent contact. The first sign of change occurs at 240°, a modest grain growth resulting in a less yellow appearance. Melting of the AuGe layer begins at about 360° and is accompanied by the development of holes in the metallization without the whole contact melting. This presumably occurs by a diffusion and grain growth process. At 380°C, the gold to silver color transition occurs indicating that the top layer of Au contains enough gallium to almost form the eutectic composition. This was confirmed bv physically removing the metallization and measuring the Ga content.

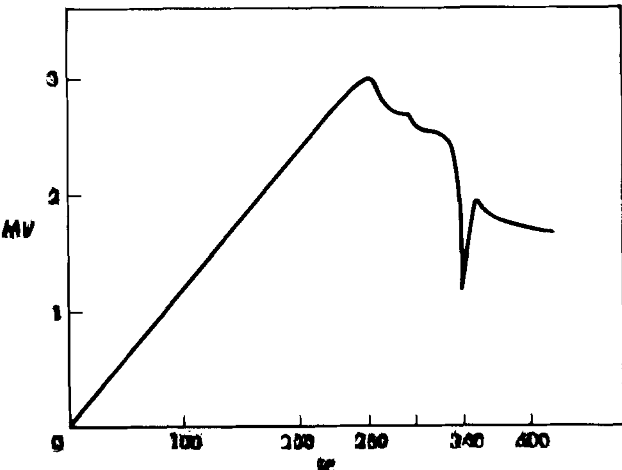

Fig. 5. The mV output *vs.* temperature of an Au-Cr thin film thermocouple vapor-deposited on semi-insulating GaAs.

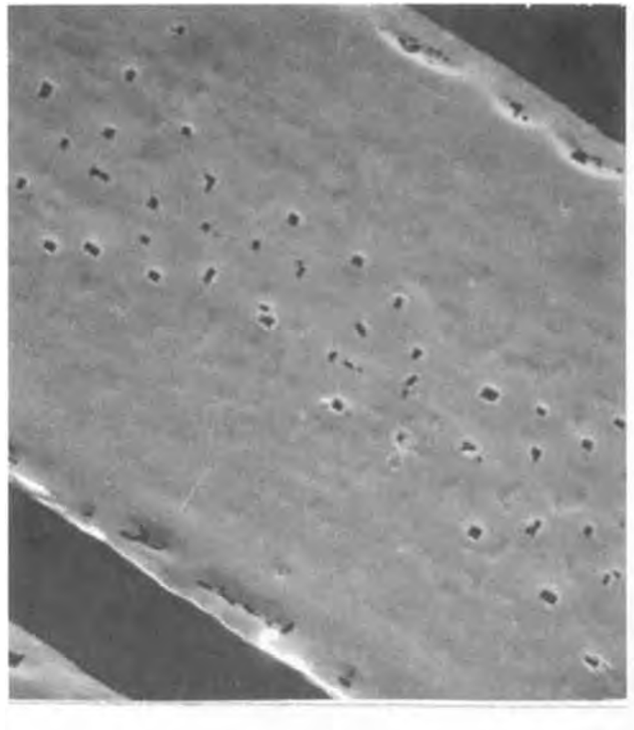
This occurs without the Ag layer dissolving. At about 480°C, for reasonable heating times (50-400°C/min), the Ag finally appears to go into solution since the whole contact appears to be liquid. It was, however, not possible to determine reproducibly exactly when or at what temperature this occurs. Melting is clearly complete when balling up begins, but with the lower heating rates there is not enough apparent structural change when the silver dissolves to be obvious in either the optical microscope or SEM when employing hot stages. The gold-silver color transition need involve only gallium, as was indicated by the pure gold results, and the silver does not have to go into solution for the top 1000Å of Au to saturate with Ga and melt. The appearance of a contact during heating is shown in Fig. 6(a-c). Once the contact has melted, it will solidify and remelt at 343° ± 2°C, almost identical to the case of pure Au. Hence, the Au must dominate the AuGeGaAg quaternary (plus whatever As may be present) or else it is just a coincidence that the melting points of the alloyed pure gold and multilayer metallization are so similar. In all cases the total amount of gallium in the metal, whether Au or the contact, increases with an increasing final temperature (see Fig. 7). This was calculated by subtracting the known signal contributed by the gallium in the underlying GaAs from the measured signal using an energy dispersive analyzer in the SEM and by analyzing Au-Ga alloys of known composition.

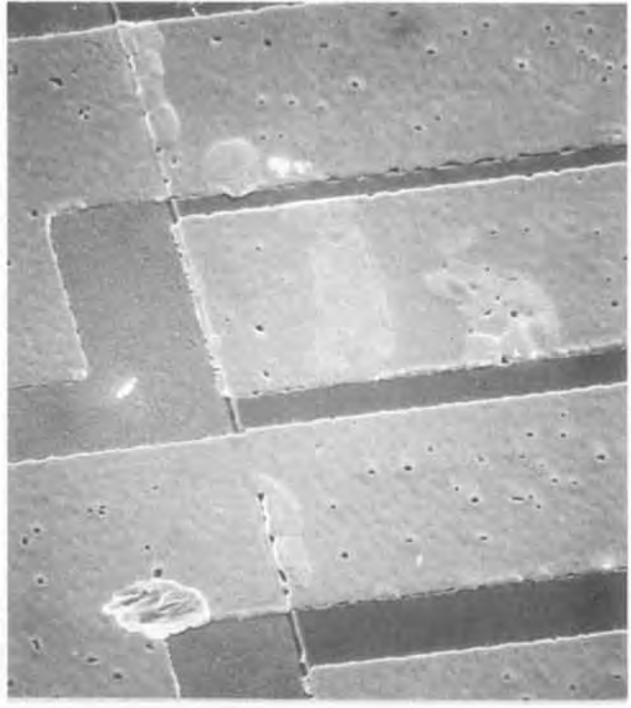
A typical ohmic contact alloying procedure is to increase the temperature at a rate of 400°C/min to about 500°C. Contacts alloyed to temperatures between 480° and 525°C all had adequate contact resistances of about 1×10^{-5} Ω cm² as measured using standard techniques (7), with 490°C appearing to result in the minimum resistance of about 1-2 $\times 10^{-6}$ Ω-cm². Two contacts heated to 480° and 525°C are shown in Fig. 8a and 8b, respectively. Contacts heated to 490° showed considerable variation in morphology, varying between that shown in Fig. 8a and b, some times even on the same specimen, despite careful control of the temperature. Apparently, the conversion from the morphology of 8a to b is extremely sensitive to the precise temperature, time, and film thickness combination used. The contact resistance was, however, independent of the morphology in this temperature range. Even heating to 525°C for 40 min or to only 425°C in a minute still resulted in only a factor of four or five higher contact resistances.

Interface Morphology

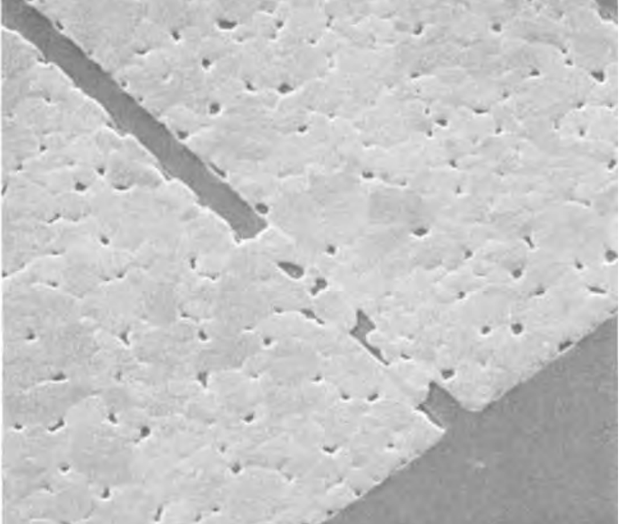
During alloying, a pattern of rectangular depressions forms at the interface which is filled with metal to roughly the level of the GaAs surface. This is true for both pure Au and the metallization, but the metallization is both easier to remove and of greater technical importance so most of the work was performed on the contacts. An example of the interface morphology is shown in Fig. 8b and Fig. 9. The size of the metal patches increases and their density decreases as the maximum temperature attained is increased. The contacts shown in Fig. 9a-d were alloyed at 450°, 480°, 525°, and 560°C, respectively. No patches developed below about 350°C, but none would be expected to develop below 341°C, the Au-Ga eutectic temperature, unless there was some lower melting Au-Ge-Ga ternary. There was no evidence to support this, however. These samples were subjected to a 400°C/min alloying cycle and development of the patches may simply require more time in the 340°-350°C range. If this structure does not form, the contact is not ohmic. However, even at temperatures below 341°C, the GaAs decomposes and gallium transport into the still solid metallization has begun. This is evidenced by the



a



b



c

Fig. 6. A contact at room temperature alloyed on the microscope hot stage, just before (a), stopped in transition (b) and just after (c) the silver has gone into solution. (a) 2600×; (b) 700×; (c) 1600×.

thermocouple experiment described earlier, and by the difference in contrast (secondary emission efficiency), apparent under the contact shown in Fig. 10 which was heated to only 280°C. Analysis in the SEM revealed that arsenic was deficient in the region under the contacts.

From the data presented it may safely be concluded that the pattern of rectangular metal patches is the result of melting at the interface. One mechanism of formation may be that GaAs dissolves to saturation in the molten metal mass, which is uniform in composition down to some depth in the GaAs. Then, upon freezing, two phases form; metal with a little As in solution, and GaAs with a little Au, Ge, and possibly Ag, in solution. Analyses in the SEM do reveal trace concentrations of As in the metal and Au in the GaAs, but the signals could well be generated from the surrounding areas due to scatter, etc. This view is supported by a previous study which indicates that little Au is in the GaAs near the interface (11), and little As could be in solution in alloys in this temperature range (12). Significant amounts of As also vaporize and escape through holes in the layer or from around the edges of the metal.

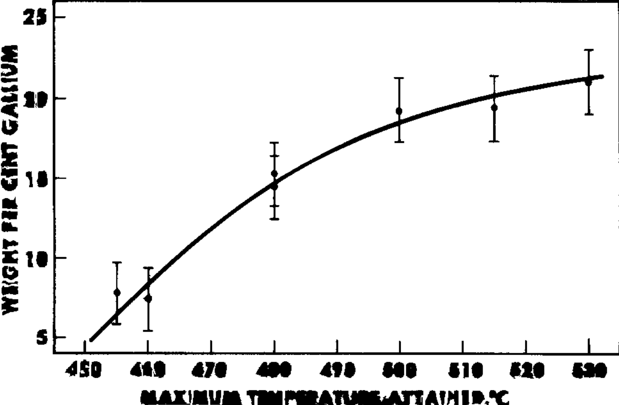


Fig. 7. Relative gallium content of alloyed device contacts vs. final or maximum temperature attained during alloying. This was calculated by subtracting the known signal contributed by the gallium in the underlying GaAs from the measured signal using an energy dispersive analyzer in the SEM.

Another explanation for the reaction is that as heating commences and the GaAs decomposes the gallium permeates the metallization, which is very porous (14), by surface and grain boundary diffusion, and the excess arsenic simply vaporizes. Then the liquid phase "nucleates" in certain spots and these areas expand in a negative crystal growth process which proceeds as long as gallium is required to saturate the metal as the temperature increases. When the temperature is lowered the metal in the rectangular depressions freezes, and a very thin degenerate layer of GaAs grows by LPE between the metal and unaffected GaAs making the contact ohmic. In order to test this hypothesis, a sample was prepared in which a 500Å, sputter-deposited tungsten layer was added between the original 500Å of Au-12% Ge and the silver. Previous evidence suggested that the sputtered tungsten layer was not a gallium diffusion barrier but would prevent liquid flow (13). The results are shown in Fig. 11. The rectangular depressions are

clearly visible under the tungsten and are far too large to have been the result of gallium dissolution in only the 500Å of Au-12% Ge under the W, which has adhered to the underside of the W. Furthermore, the SEM x-ray analysis revealed that the balled metal on top of the tungsten contained as much gallium as when no tungsten was present. Even though this experiment supports the negative crystal growth hypotheses, the mechanism of pattern formation is still not completely clear because the rectangles contain less than 1-2% gallium. This was determined by observing the color of a series of Au-Ga alloys of known composition and then matching their color to that of the rectangular patches. In another experiment, very lightly alloyed contacts (400°C/min heating rate, 425°C final temperature) were analyzed in the SEM. The GaAs was dissolved away with $4H_2SO_4$, $2H_2O$, $1H_2O_2$, leaving only the contact. The GaAs-AuGe interface side of the contact was then analyzed in the SEM and only a trace Ga signal was observed in the protruding

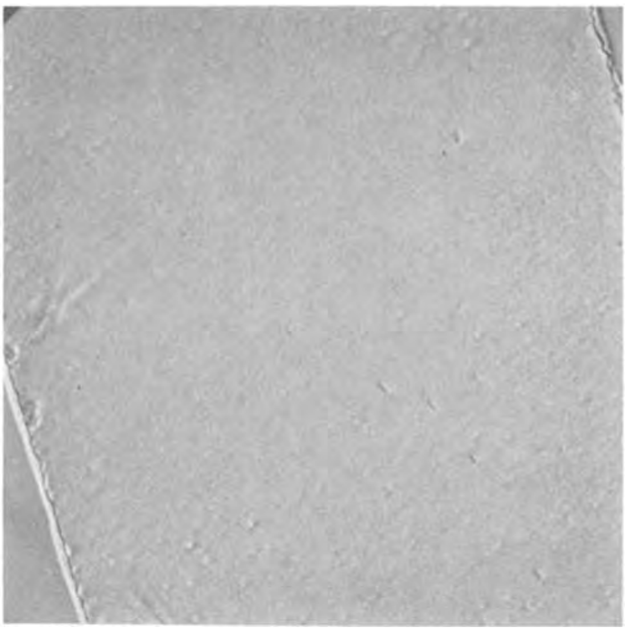

Fig. 12. Device contact heated to 525°C over 65 min in the SEM. 3000×.

metal patches, also indicating that if gallium is present in the contact it is near the detection limits of the energy dispersive analyzer, or about 1%. An alloy this low in Ga has a melting point above 700°C! Yet, liquid must have been present to form the islands. The most likely explanation for this paradox is that the second sequence outlined above does occur and the concentration of gallium was high in the thin liquid layer present during alloying and patch formation. Then, upon cooling, or even during alloying, the gallium quickly diffused throughout the remainder of the contact thereby reducing its concentration at

the GaAs-contact interface. Further attempts will be made to detect this gallium.

In spite of the inconsistencies discussed above, the results do indicate clearly that the decomposition of the GaAs is controlled by the Au-Ga reaction. The Ge appears only to change the surface tension and allow the Au-Ga reaction to progress further at lower temperatures because the Au-Ge eutectic melts at 356°C and the liquid metal helps initiate the reaction. The role of Ag is to allow the alloy to melt next to the GaAs without the whole contact melting.

Effect of Different Alloy Cycles

In order to improve both the surface and interface morphology of the contacts, a number of different alloying sequences were tried. Because the slowly alloyed pure gold layer did not "ball," a contact was alloyed to 535°C in the SEM over 65 min and is shown in Fig. 12. It clearly has a superior surface morphology, but contact resistance was up to about 1×10^{-4} Ω-cm. The 8°C/min heating rate could not be duplicated in the microscope hot stage under H_2 because of overheating problems. However, samples heated to 540°C at 350° and 30°C/min are shown in Fig. 13a and d, respectively, and with the contact metal etched away (13b, c, and e). Substantial improvements in surface morphology were achieved, but the metal-GaAs interface remains rough. The depths of the rectangular pits are 1.1 and 1.4μ, respectively, though with the slower rate they are somewhat more uniform. Modest improvements in surface and interface morphology were achieved with a very fast heating rate of ~1000°C/min to about 525°C shown before and after contact removal in Fig. 14a and b, respectively. In this case, the Ag layer probably did not have time to melt. Reducing the AuGe layer thickness from 500 to 400Å also helped (Fig. 15). It has not changed the morphology but may have reduced slightly the amount of GaAs which decomposes and the penetration depth. The deepest penetration measured was 0.45μ, or about the epi thickness (Fig. 16). This is a modest improvement, but the contact between metal and epi remains very irregular and the contact may still penetrate to the substrate or buffer layer. As has been shown, this is true even if the contact looks smooth from the top. Hence, an irregular channel width as well as sharp projections of the contact metal into the substrate or buffer layer may still result during alloying. It is important to recognize further that gallium diffusion and further decomposition of the GaAs can proceed involving the final conductor metal if temperatures approach the 250°C range during final processing or operation.

One further test was made. Several samples were annealed in arsenic gas at about 2 atm. Conditions were not the same as reported earlier (15), in that the samples were heated to 500° ± 10°C over 12 min and some O_2 contamination could also have been present. No improvement in contact resistance or surface morphology was observed. One sample previously alloyed in the normal way was subsequently subjected to the arsenic anneal and the Ga content of the metallization reverted to near its prealloy value suggesting GaAs regrowth had occurred.

Conclusions

From all of the observations and results presented above it must be concluded that gallium arsenide in contact with gold will decompose readily at temperatures as low as 260°C resulting eventually in void formation at the GaAs-metal interface and rapid diffusion of gallium throughout the metallization. This fact should be considered with regard to both the fabrication and long term operation of GaAs devices.

The surface morphology of the alloyed metal can be controlled by adjusting the heating rate. Reducing the AuGe thickness, using faster heating rates, and alloying to lower temperatures improves the interface morphology somewhat without severely increasing contact resistances. However, the rough interface morphology can be modified only in degree, not in its basic character, by changes in the heating cycle. Perhaps a process with better control of the applied heat such as laser alloying (16) is needed to achieve a major improvement.

Variations in the irregular morphology of the GaAs-metallization interface do not appear to affect the ohmic properties of the contact, but may play an important role in the reliability of devices using this contact especially in view of the fact that the contact metal may regularly penetrate to the substrate. More work is required to fully understand the mechanism of formation of the rectangular metal patches.

Acknowledgments

The author is indebted to W. C. Niehaus and B. S. Hewitt for generously providing the ohmic contact samples and for many helpful discussions. The aid of J. C. Irvin and B. S. Hewitt in obtaining the metal depositions is gratefully acknowledged. The author also wishes to thank J. W. Nielsen for reviewing the manuscript, helpful discussions, and support.

Manuscript submitted May 3, 1979; revised manuscript received Aug. 28, 1979. This was Paper 315 presented at the Seattle, Washington, Meeting of the Society, May 21-26, 1978.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Bell Laboratories.

Formation Mechanism of Porous Silicon Layer by Anodization in HF Solution

Takashi Unagami

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino-shi, Tokyo, 180, Japan

ABSTRACT

The mechanism of formation of porous silicon layer (PSL) has been studied according to the following experimental results. PSL is formed by the local dissolution of silicon which occurs only at the base of the pores. The HF concentration of the electrolyte in the pores of PSL is constant during anodization and the anodic reaction in the pores proceeds uniformly in the thickness direction. The dissolution of silicon in the pores is the results of the divalent and the tetravalent reactions of silicon with HF, without the disproportionation reaction. The insoluble surface porous film (SPF) exists at the surface of PSL and the silicic acid is formed in PSL. A model of forming PSL is proposed, with emphasis being placed on the anodic reaction and the local dissolution of silicon which is initiated by SPF and is promoted by the hindrance layers composed of the silicic acid.

The anodization of silicon in hydrofluoric acid solution has been studied by many investigators. These investigations are almost always related to the electropolishing of silicon to process silicon wafers for the electronic device fabrication. On the other hand, Uhlir (1) found in 1936 that anodic film is formed on a silicon wafer by the anodization under certain conditions. This anodic film is the porous silicon layer (PSL) which consists mainly of silicon (2). PSL is oxidized very rapidly at low temperature, so thick oxide layers can be formed by short time oxidation. These thick oxide layers can be applied in the fabrication of integrated circuits (3).

Turner (4), and subsequently Memming and Schwandt (5), investigated the formation condition of PSL and proposed that PSL is formed by the disproportionation reaction of silicon difluoride. On the other hand, in an investigation of the structure of PSL, Arita and Sunohara (6), and Unagami and Seki (7), postulated that the anodic dissolution of silicon occurs at local points on atomic scale to form PSL from the observation that PSL has a single crystal structure. No detailed investigations have been reported with respect to the formation mechanism of PSL, particularly with respect to the mechanism of the progress of the local silicon dissolution.

In this paper the author studied the anode potential-current characteristics for various HF concentration, the HF concentration of the electrolyte in PSL, the dissolution of silicon by the anodization, the structure of PSL, the infrared spectra of PSL, and the electric resistivity of PSL. Based on these results, the formation mechanism of PSL is discussed.

Experimental Procedures

Wafer preparations.—Silicon wafers were (111) p-type single crystals (boron-doped) made by the Czochralski method. Before the anodization, wafers were cleaned by boiling in the solution (1 NH_4OH + 1 H_2O_2 + 4 H_2O). After that, the thin oxide layer was removed in dilute HF solution and the wafers were rinsed in deionized water.

PSL formation.—The electrolytic cell for PSL formation by the anodization has been given in a previous paper (7). In the case of high resistivity silicon wafers, aluminum alloy layers were formed before the anodization on the back surface of the silicon wafers in order to make the anodic current distribution uniform. The silicon wafers were covered with acid-proof wax (Apiezon wax) to perform the anodic reaction selectively in the wafer. Gas bubbles break out from the silicon wafer surface during anodizing, so the ultrasonic oscillator was used to prevent gas bubbles from sticking on the surface. A constant current source was supplied as the electric power.

The measurement of the anode potential-current characteristics.—The anode potential was measured against a saturated calomel electrode (SCE). The anode potential-current characteristics were recorded with a X-Y recorder. The SCE capillary tip end was dipped in HF solution positioned near the silicon wafer surface and the opposite electrode was connected with the anode electrode.

The measurement of weight change.—The weight change was measured with an electric microbalance made by Mettler. After the anodization and immersion in HF solution, the samples were dried by blowing dry N_2 gas on them without rinsing in water.

Infrared spectra measurement.—Infrared transmission spectra were measured with a double beam type infrared spectrometer (a Model IR-27G) made by Shimadzu Seisakusho, Limited. The wafers were 4 $\sim$ 7 Ω-cm in resistivity. In order to prevent the influence of the absorption of a substrate, a wafer which has the same thickness and the same resistivity was prepared as the reference. The transmission spectra were measured in the wavelength range from 2.5 to 25 μm.

Experimental Results

The anode potential-current characteristics.—The characteristics of the anodization in various HF concentration solution were measured. The results are shown in Fig. 1. The potentials, obtained at the end of a 30 sec period of supplying the constant anodic current, are plotted. In the region of the low anodic current density, the characteristics obey Tafel's law and the dependence on HF concentration does not appear. On the other hand, in the high current density region, Tafel's law is not satisfied and the characteristics depend strongly on HF concentration. The anode potential becomes high with decreasing HF concentration at the same anodic current density.

The anode potential is shown in Fig. 2 under the condition of the constant current density anodization. HF concentration is 50% in weight percent (w/o). The growth rate of PSL is 8.45 μm/min, 4.50 μm/min, and 0.95 μm/min at 100 mA/cm^2, 50 mA/cm^2, and 10

Key words: porous silicon layer, anodization, formation mechanism.

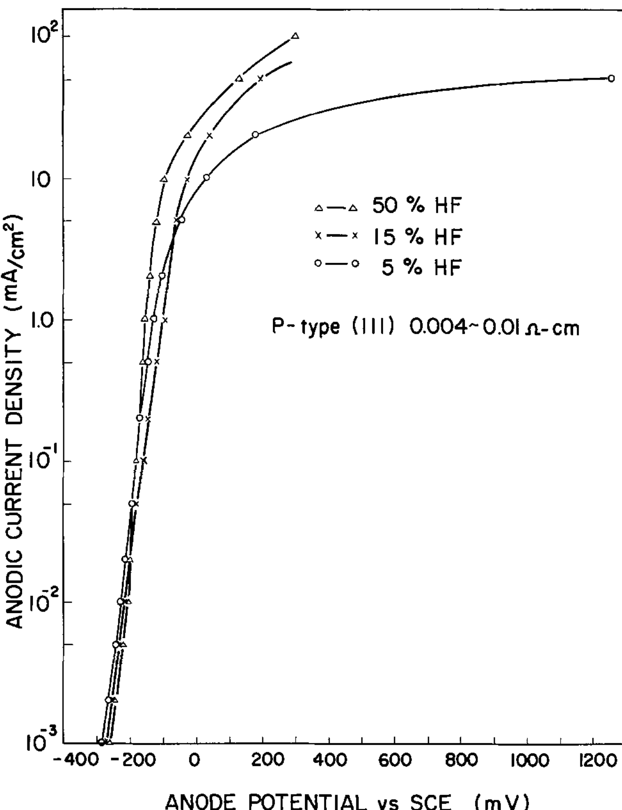

Fig. 1. Anode potential-current characteristics under various HF concentrations.

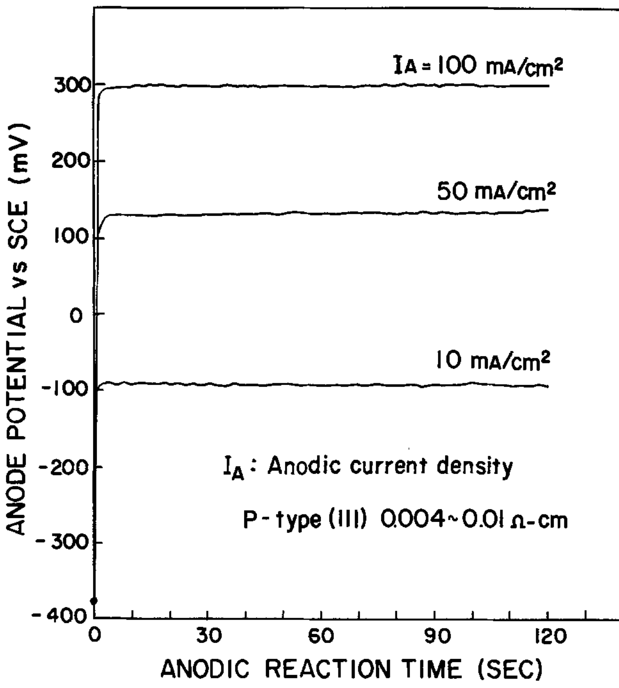

Fig. 2. Relationship between anode potential and anodic reaction time. HF concentration is 50 w/o.

mA/cm² in the anodic current density, respectively. At all anodic current density, the anode potential shows no change, that is, the anode potential is constant in spite of forming thick PSL. From these results, the HF concentration of the electrolyte in PSL is presumed to be constant during the anodization.

Figure 3 shows the relationship between the anode potential and the anodic reaction time under the various HF concentration. The anodic current density is 10 mA/cm². In a highly concentrated HF solution, the anode potential is constant. However, in a low concentrated (5%, 10%) HF solution, some increase (a few mV) in the anode potential appears after two minutes. When the HF concentration is low, a change in electrolyte concentration appears to occur.

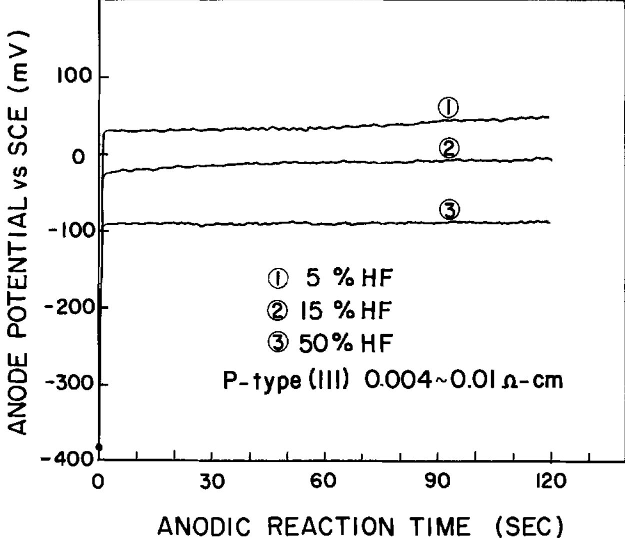

Fig. 3. Relationship between anode potential and anodic reaction time under various HF concentrations. Anodic current density is 10 mA/cm².

The analysis of the electrolyte in the pores.—The weight and the HF concentration of the electrolyte in the pores were examined by the measurements of the weight change and fluoride ions concentration. The weight was measured before the anodization, just after the anodization, and after the heat-treatment. The weight and fluoride ions concentration just after the anodization were measured without removing the wax, in order to prevent the electrolyte in the pores from coming out into a solvent (trichloroethylene). The heat-treatment was done in dried N_2 gas or a vacuum at 100° ~ 150°C for two hours. The result of the weight change is shown in Fig. 4. ΔW_1 is the change between the weight before and that after the anodization. On the other hand, ΔW_2 is the change between the weight before the anodization and that after the heat-treatment. So, the weight change between these two values, W_E, is the amount of the electrolyte in the pores. The electrolyte in the pores can be released by the heat-treatment. Figure 5 shows this effect. The weight changes, caused by immersing the heat-treated PSL in 50% HF solution and by the heat-treatment of immersed PSL, are shown. The sample has the same weight after the heat-treatment as before immersion in 50% HF solution. That is, the heat-treatment can release all the solution in the pores. From the result shown in Fig. 4, W_E is given in Fig. 6. W_E increases linearly with the anodic reaction time. W_s, given in Fig. 6, is the weight corresponding to the solution with which the volume of the pores in PSL are filled. The total volume of the pores in PSL is calculated from ΔW_2 and the specific gravity of 50% HF solution is 1.12 g/cm³ at the room temperature. As shown in Fig. 6, W_E corresponds to about 57% weight of W_s. That is, about 57% of the pore volume in PSL seems to be filled with HF solution at the time of the anodization. Because of the gas generation at the time of the anodization, the pores are partially filled with the generated gas.

The HF concentration of the electrolyte in the pores was measured with a fluoride electrode. The samples of PSL formed in 50% HF solution were immediately immerged in 10 cm³ deionized water. These experimental solutions were measured after PSL had soaked for two hours. A *p*H meter was used to measure the

potential of the fluoride electrode with respect to SCE connected to the experimental solution in the Teflon beaker. PSL was formed in a p-type silicon substrate (0.02 ~ 0.035 Ω-cm). The potential of fluoride electrode as a function of HF weight percent is shown in Fig. 7. The HF weight percent of the experimental

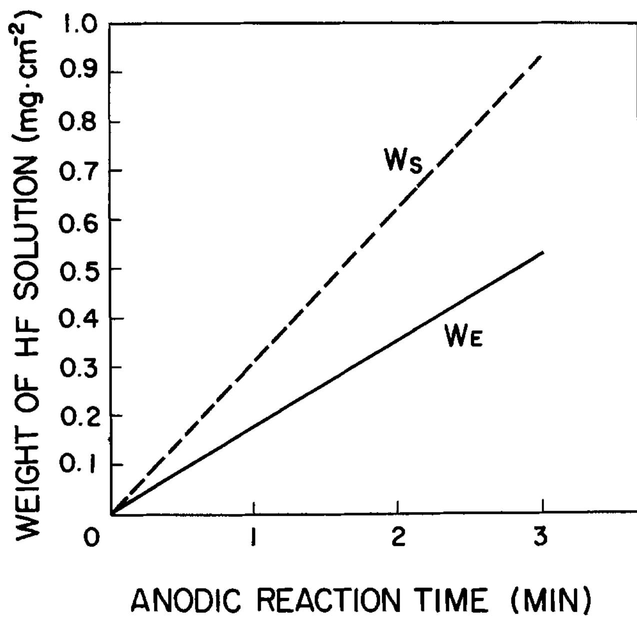

Fig. 6. Relationship between weight of HF solution and anodic reaction time.

solutions is determined according to the result shown in Fig. 7. The results are shown in Table I. The HF weight percent of the electrolyte in the pores is Wt which is obtained from $Wt' \times 10/W_E$. As a result, the HF concentration of the electrolyte in pores is considered to be constant and the same as that of the outer HF solution of the pores. This result is consistent with the result that the anode potential is constant during the constant current anodization, as shown in Fig. 2. Figure 8 shows the weight of HF solution penetrated into the pores when the immersion time in 50% HF solution is changed. The pores in PSL were emptied beforehand by the heat-treatment. It is obvious that HF solution of 50 ~ 60% of W_E can penetrate into the pores within a few seconds. From the results that HF concentration of the electrolyte in the pores is constant and HF solution can penetrate into the pores rapidly, it can be thought that the reactants and the products of the anodic reaction can be supplied and released rapidly in the pores, respectively.

Dissolution of silicon by anodization.—Uhlir (1) and Turner (2) have reported that silicon dissolution is

Wt --- Weight % of HF solution in PSL

divalent in the condition of forming PSL while tetravalent in the condition of electropolishing. In order to study the mechanism of silicon dissolution, the results of the detailed investigation are reported. The substrates of 0.02 Ω-cm in resistivity were used. Figure 9 shows the relationship between the anodic reaction time and both the PSL thickness (T_p) and the amount of dissolved silicon (ΔW). The amount of dissolved silicon per unit area is derived from ΔW_2 as shown in Fig. 4. PSL was formed in 50% HF solution and the anodic current density was 100 mA/cm². T_p and ΔW increase with increasing the anodic reaction time. The silicon density of PSL (ρ) is denoted as the equation

$$\rho = \rho_0 - \frac{\Delta W}{T_p} \quad [1]$$

where ρ_0 is the silicon density of a bulk silicon wafer (2.329 g/cm³). As the values of ΔW and T_p, which are obtained from Fig. 9, are substituted into Eq. [1], ρ is constant to be about 1.5 g/cm³. That is, PSL, which has a uniform silicon density in the thickness direction, is formed. So, it is clear that the dissolution of silicon by the anodization is uniform in the thickness direction.

On the other hand, the effective dissolution valence (Zi) is given as $Zi = Ne/N_{Si}$ where N_{Si} is the number of dissolved silicons which is obtained from ΔW and Ne is the number of flowed elementary charges. That is, Zi corresponds to an average number of elementary charges which is needed for dissolving one atom of silicon. Figure 10 shows the relationship between Zi and the anodic current density as the HF concentration is varied. Zi is charged between 2-4 according to the condition of the anodization. It is clear that Zi has the value from 2 to about 2.8 under the condition of forming PSL.

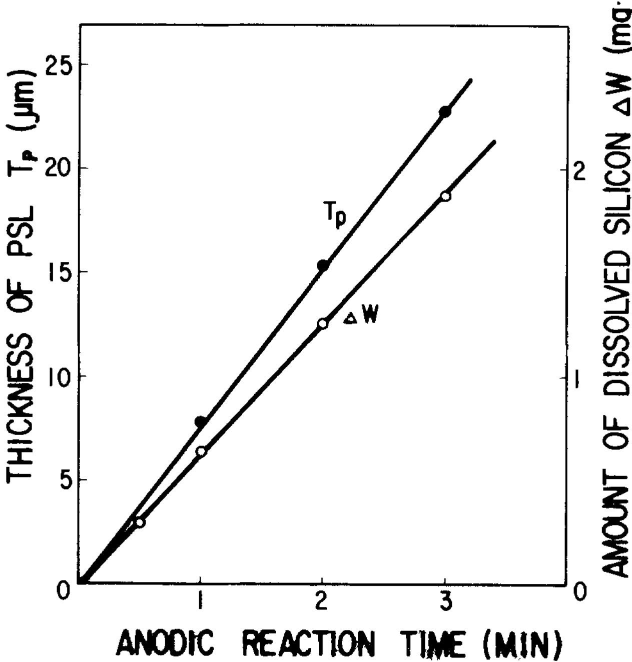

Fig. 9. Thickness of PSL and amount of dissolved silicon *vs.* anodic reaction time for p-type (0.02 Ω-cm) silicon substrate.

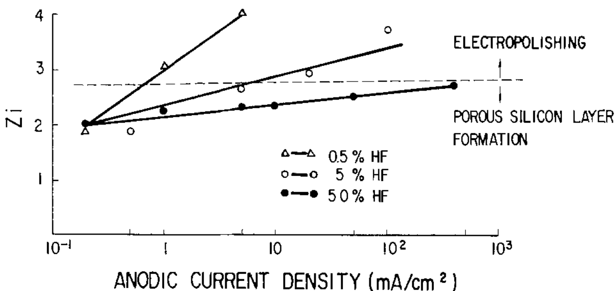

Fig. 10. Relationship between *Zi* and anodic current density

Structure of PSL.—PSL is a single crystal according to the analysis of x-ray diffraction, but only on the surface of PSL, polycrystalline silicon can be seen by electron diffraction (3, 6, 7). The pores of PSL distribute at random, and the pore diameter at the surface is smaller than some 10Å and that of the inner part of PSL is some 10 ~ 300Å (3). Moreover, the pores are not formed straight; that is, the pores are formed zigzag in the thickness direction of PSL (7).

On the other hand, an insoluble thin porous film in HF solution is formed at the surface of PSL (8). This insoluble thin porous film is left even after PSL is soaked in HF solution for a month while the majority of PSL except this insoluble thin film is active and has dissolved already in HF solution. This insoluble thin film is named as surface porous film (SPF) and is distinguished from the active PSL formed under SPF. That is, PSL can be divided into two layers of SPF and the active PSL, as shown in Fig. 11.

Figure 12 shows the thickness of both SPF (T_s) and PSL (T_p) *vs.* the anodic reaction time. Substrates of 0.02 Ω-cm in resistivity and 50% HF solution were used to form PSL. T_s is saturated within one minute while T_p increases with increasing the anodic reaction time and grows to be thick (some 10 μm). SPF is formed from the beginning when forming PSL, so the growth of PSL, that is, the dissolution of silicon in a silicon substrate, is done through SPF.

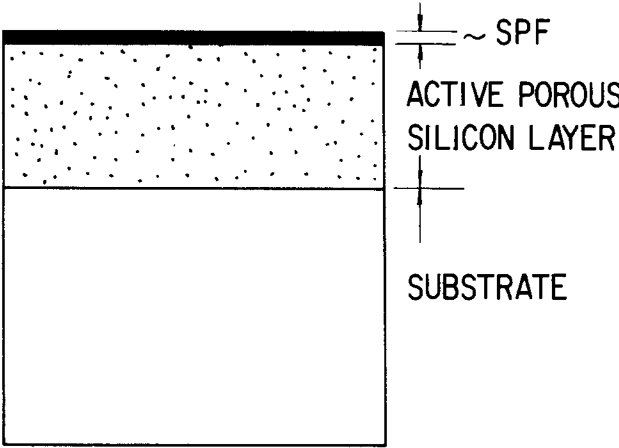

Fig. 11. Structure of PSL

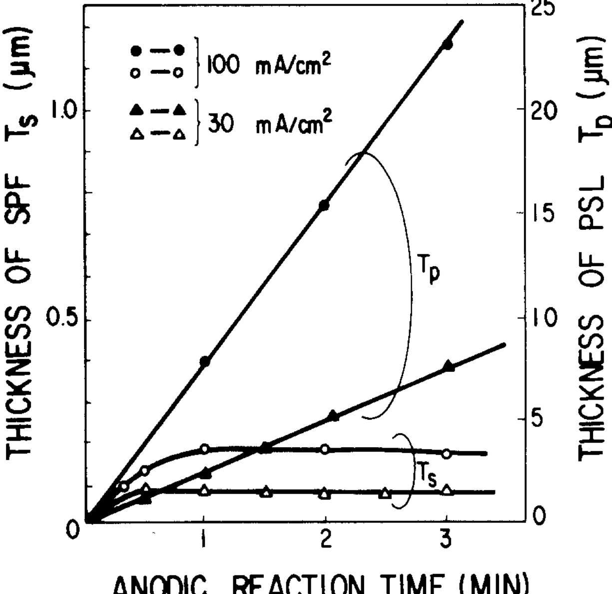

Fig. 12. Thickness of SPF and PSL vs. anodic reaction time, as a function of anodic current density.

The dependence of T_s and T_p on substrate resistivity is shown in Fig. 13. The anodization was performed for two minutes in 50% HF solution and the anodic current density was 100 mA/cm². The amount of dissolved silicon was constant for the various resistivity of substrates. T_s is strongly dependent on substrate resistivity and the maximum of T_s appears at about 0.02 Ω-cm in resistivity. T_s has the same dependence on substrate resistivity as the thickness of the stain film formed in HNO_3-HF solution (9). But the dependence of T_p on substrate resistivity differs from that of T_s and that of the stain film. According to the observation of the PSL surface with electron beam diffraction, there are polycrystalline silicon as well as single-crystalline silicon at the surface of PSL (7). Therefore, SPF consists of polycrystalline and single-crystalline silicon. That is, the crystalline structure of SPF agrees with that of the stain film. Moreover, SPF is insoluble in HF solution but is rapidly dissolved by silicon etches. These chemical properties of SPF agree precisely with those of the stain film.

Considering many similar points between SPF and the stain film, SPF can be thought to be formed by the same anodic reaction as the stain film. As Archer has reported in his paper (9), the disproportionation reaction proposed by Turner occurs at the surface of a substrate. That is

$$Si + 2HF + (2 - n)e^+ \rightarrow SiF_2 + 2H^+ + ne^- \quad [2]$$

$$2\,SiF_2 \rightarrow Si^\circ + SiF_4 \xrightarrow{+\,2HF} H_2SiF_6 \quad [3]$$

where $n < 2$, e^+ and e^- represent hole and electron. SPF is formed by the deposition of elementary silicons (Si°) produced by the disproportionation reaction [3] on the surface of a substrate. Considering that the growth of SPF can occur only at first as shown in Fig. 12, the disproportionation reaction [3] seems to occur only at the early step of forming PSL and at the surface of PSL. So no disproportionation reaction takes place after the growth of SPF is stopped. The reaction of forming thick PSL under SPF can be thought to differ from that of forming SPF, because of the differences in reactivity to HF solution, the growth progress (Fig. 12) and the dependence on substrate resistivity (Fig. 13).

Infrared spectra of PSL.—The dependence of the absorbance on PSL thickness was examined by infrared spectroscopy. The absorption bands appear at 4.7 μm (ν_1), 9.5 μm (ν_2), 11.1 μm (ν_3), 12.2 μm (ν_4), 16 μm (ν_5), and 21 μm (ν_6) (10). ν_1 and ν_3 are due to the Si-H bond. ν_5 is due to the Si-Si bond, ν_2, ν_4, and ν_6 are due to the antisymmetric stretching, symmetric stretching, and bending of the Si-O bond, respectively. The relationship between the absorbance ($\alpha \cdot t$) of these bonds and PSL thickness is shown in Fig. 14. α and t are the extinction coefficient and PSL thickness, respectively. The anodization was done in 50% HF solution at a constant current density of 100 mA/cm². The absorbance increases with increasing PSL thickness. When PSL is etched in a Freon (CF_4) gas plasma, $\alpha \cdot t$ decreases as the PSL thickness decreases. This shows that the Si-H, Si-Si, and Si-O bonds are

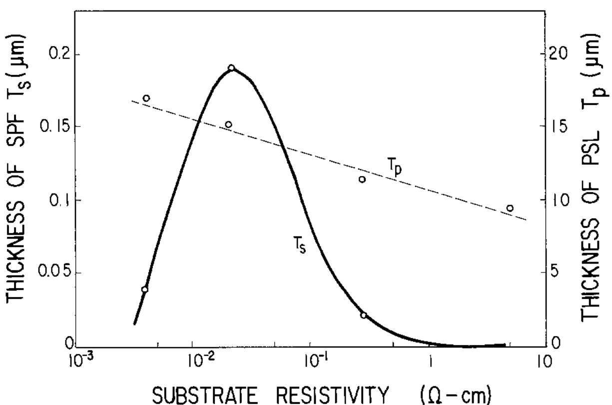

Fig. 13. Dependence of thickness of SPF and PSL on substrate resistivity.

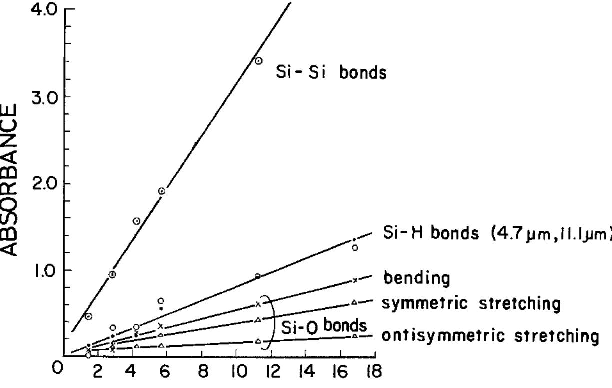

Fig. 14. Relationship between absorbance and thickness of PSL. Resistivity of p-type substrate is 4 ~ 7 Ω-cm.

distributed uniformly in the thickness direction of PSL.

The changes of infrared absorption spectra caused by immersion in 50% HF solution are shown in Fig. 15. The absorption strength of Si-O bonds decreases with increasing the time of immersion. After immersion for about 20 hr, the absorption due to Si-O bonds is still observable. This result means that the product, which is observed as Si-O bonds at 9.5, 12.2, and 21 μm has a small dissolution rate into HF solution. This insoluble product is changed by the heat-treatment above about 300°C in a vacuum as shown in Fig. 16. The absorption at 10.2 μm due to SiO (11), is increased by the heat-treatment. The weight is not increased by the heat-treatment, so oxidation of PSL has not occurred. The increased amount of the absorption at 10.2 μm has vanished immediately by immersion in HF solution. The insoluble product is changed to silicon oxide soluble in HF solution by the heat-treatment. As results, it is clear that the insoluble product formed during anodization has the following three characteristics. (*i*) The absorbance $(\alpha \cdot t)_{\nu 2}$, $(\alpha \cdot t)_{\nu 4}$, and $(\alpha \cdot t)_{\nu 6}$ at ν_2, ν_4, and ν_6, respectively, are ranked as $(\alpha \cdot t)_{\nu 4} > (\alpha \cdot t)_{\nu 6} > (\alpha \cdot t)_{\nu 2}$ in order of magnitude. This order is different from that of silicon dioxide layers formed by high temperature oxidation of bulk silicon. In the case of silicon dioxide layer of bulk silicon, the order is $(\alpha \cdot t)_{\nu 2} > (\alpha \cdot t)_{\nu 6} > (\alpha \cdot t)_{\nu 4}$. (*ii*) Insolubility in HF solution. (*iii*) The conversion into SiO occurs by heat-treatment.

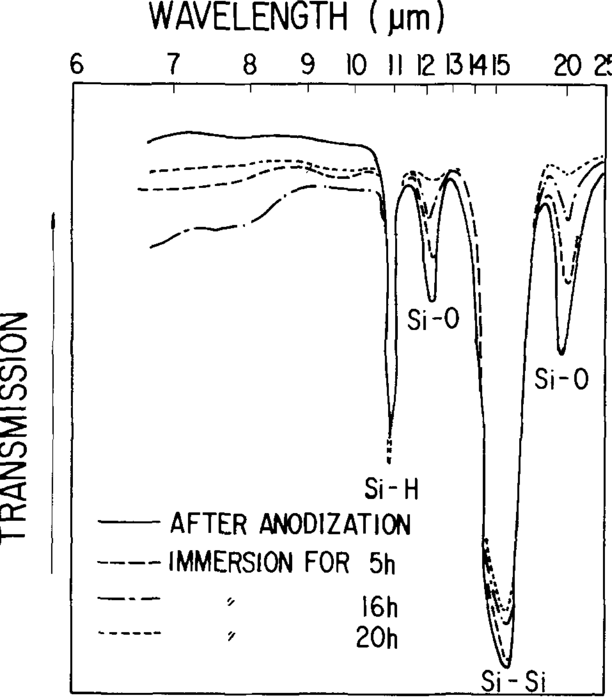

Fig. 15. Change of absorption spectra of PSL by immersion in 50% HF solution.

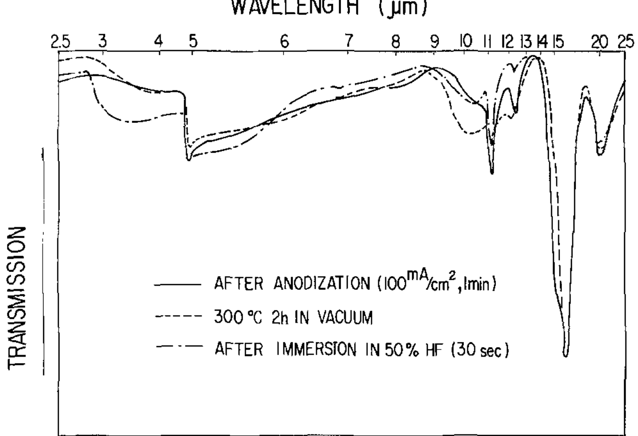

Fig. 16. Absorption spectra of PSL after anodization, heat-treatment at 300°C in a vacuum, and immersion in 50% HF solution.

On the other hand, SiF_2 or SiF_4 is produced by the anodic reaction, as mentioned later in detail. So it is possible that SiF_2 and SiF_4 react with H_2O in HF solution. When SiF_2 or SiF_4 reacts with H_2O, silicic acid (12) or fluorodisiloxane (13) is considered to be produced. In the infrared spectra of fluorodisiloxane, the strong absorption due to Si-F bonds appears (13). But no absorption due to Si-F bonds appears in the infrared absorption spectra of PSL, so the product observed as Si-O bonds seems to be silicic acid.

The resistivity of PSL.—The resistivity of PSL in the thickness direction was measured by forming an aluminum electrode on the surface of PSL. Aluminum was evaporated in a vacuum. The voltage-current characteristics were measured with a curve tracer without any heat-treatment after forming PSL. A Schottky junction is formed on the surface of PSL. The *i-V* characteristic gives essentially a straight line in the high current region in the forward direction. The resistivity of PSL in the thickness direction is obtained from the slope of the *i-V* characteristic. Figure 17 shows the resistivity of PSL formed in the silicon substrates with the various resistivity. PSL was formed in 50% HF solution and the anodic current density was 100 mA/cm². It is clear that the resistivity of PSL has the high resistivity of $10^4 \sim 10^5$ Ω-cm.

As shown in Fig. 2, the anode potential is not increased as PSL thickness increases. This means that the anodic current is passed not through the residual silicon layer in PSL but through the pores in PSL. That is, the anodic reaction (the dissolution of silicon) takes place only at the base of the pores in PSL.

Discussion

As already mentioned above, the insoluble surface porous film (SPF) exists at the surface of PSL and is formed by the disproportionation reaction. That is, elementary silicons, which are produced by the disproportionation reaction, deposit on the surface and form SPF. This disproportionation reaction takes place only at the early step of the anodization, because the growth of SPF becomes saturated. Considering that SPF is formed at the surface of PSL from the beginning of the anodization and SPF is insoluble

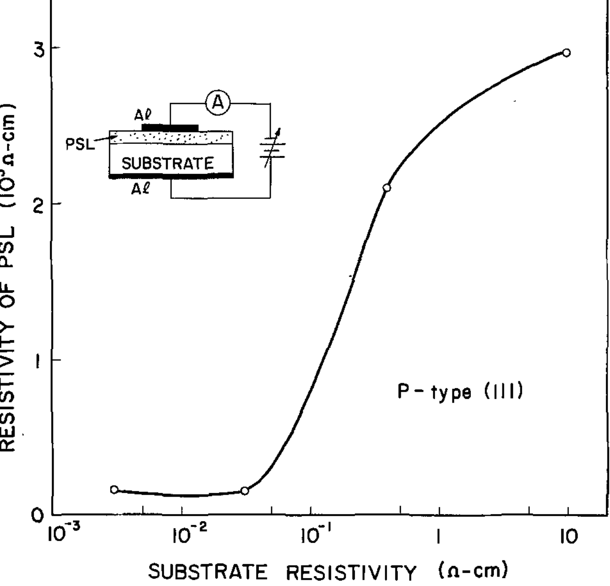

Fig. 17. Resistivity of PSL formed in various resistivity substrates

in HF solution, it can be thought that the place of dissolving silicon in the substrate is restricted by SPF, so that local corrosion occurs.

The anodic reaction of forming thick PSL under SPF differs from that of forming SPF, as discussed above. Therefore, another anodic reaction which does not consist of the disproportionation reaction must be considered in the case of forming PSL under SPF. As for the reaction of dissolving silicon difluoride in HF solution without the disproportionation reaction, two possibilities proposed by Memming and Schwadt are replaced by the disproportionation reaction as follows

$$\begin{array}{l} SiF_2 + 2HF \rightarrow SiF_4 + H_2 \\ \qquad\qquad\qquad \lfloor + 2HF \\ \qquad\qquad\qquad \rightarrow H_2SiF_6 \end{array} \quad [4]$$

or

$$\begin{array}{l} SiF_2 + 2H_2O \rightarrow SiO_2 + 2HF + H_2 \\ \qquad\qquad\qquad \lfloor + 6HF \\ \qquad\qquad\qquad \rightarrow H_2SiF_6 + 2H_2O \end{array} \quad [5]$$

The remarkable difference between reaction [4] and [5] is that SiO_2 is formed and dissolved in HF solution in the case of reaction [5], but not in the case of reaction [4]. For the formation of PSL, the dissolution of silicon difluoride is performed by reaction [4] from the following result. As shown in Fig. 10, the growth rate of PSL is 7.5 μm/min at an anodic current density of 100 mA/cm^2 in 50% HF solution. On the other hand, the dissolution rate of SiO_2 in 50% HF solution is 1.4 μm/min. Therefore, in the case of reaction [5], the reaction rate is equal to or smaller than 1.4 μm/cm^2. That is, the reaction rate of reaction [5] is much smaller than the growth rate of PSL. Consequently, as the reaction of dissolving silicon difluoride in HF solution occurs, reaction [4] can take place.

According to investigation about the effective dissolution valence (see Fig. 10), the valence has the value between 2 to about 2.8 under the condition of forming PSL. Silicon is thought to be dissolved by the anodization in the divalent state or in the tetravalent state (1, 2, 5), so the effective dissolution valence more than 2 means that the dissolution in the tetravalent state as well as divalent state occurs. From the same reason about the reaction rate as the divalent reaction, the tetravalent dissolution reaction which consists of neither the formation nor the dissolution of SiO_2 must be considered. That is, the reaction between silicon and HF can occur, but that between silicon and H_2O cannot. The following anodic reaction seems to be the most probable for the tetravalent dissolution reaction of silicon

$$\begin{array}{l} Si + 4HF + (4 - \lambda)e^+ \rightarrow SiF_4 + 4H^+ + \lambda e^- \\ \qquad\qquad\qquad\qquad\quad \lfloor + 2HF \\ \qquad\qquad\qquad\qquad\quad \rightarrow H_2SiF_6 \end{array} \quad [6]$$

$$(\text{where } \lambda < 4)$$

At the larger value of the effective dissolution valence, the tetravalent reaction [6] seems to increase in ratio between the divalent reaction and the tetravalent reaction.

PSL is formed by the local anodization of generating pores. During anodization, the HF concentration of the electrolyte in the pores is constant and the same as that of the outer HF solution of the pores. HF solution can penetrate into the pores rapidly. Therefore, it can be thought that the reactants and the products of the anodic reaction can be supplied and released rapidly in the pores, respectively. On the other hand, during anodization, the anodic potential is constant in a high concentrated HF solution as shown in Fig. 2. These results show that the anodic reactions in the pores (reaction [2], [4], and [6]) proceed uniformly in the thickness direction of PSL. This agrees with the result of infrared spectra measurement that Si-H, Si-O, and Si-Si bonds formed by the anodization are distributed uniformly in the thickness direction of PSL.

The resistivity of PSL is very high. So if the anodic current passes through the residual silicon layer in PSL during anodization, the anode potential must increase significantly with increasing PSL thickness. From the fact that the anode potential is constant during the constant current density anodization, it can be considered that the anodic reaction occurs only at the base of pores in PSL.

According to infrared spectra measurement, silicic acid is formed in the process of PSL formation. Moreover, this silicic acid has a small dissolution rate in concentrated HF solution. The silicic acid is thought to be produced by the reaction of H_2O with a part of Si, SiF_2, or SiF_4. SiF_2 and SiF_4 are produced by reaction [2],]4[, and [6]. The silicic acid is left in PSL during anodization and seems to act as a hindrance layer to the following anodization. That is, the anodization of dissolving silicon can progress only at places where the silicic acid is not formed, and not at places where the silicic acid is formed. It can be said that the local dissolution is promoted by the hindrance layers composed by the silicic acid.

Proposed Formation Mechanism of PSL

The mechanism proposed to form PSL is required to initiate and sustain the local dissolution of silicon in a silicon substrate. At the surface of PSL, the insoluble surface porous film (SPF) is formed from the beginning of the anodization. SPF restricts the place of dissolving silicon, so that the local anodization can be initiated. The following anodic reaction takes place only at the base of the pores in PSL. The silicic acid is produced in PSL during anodization. The local dissolution of silicon is promoted by the hindrance layers composed of the silicic acid. The anodic reaction in the pores is uniform in the thickness direction of PSL and contains no disproportionation reaction. From these results, the mechanism of formation of PSL is proposed as shown in Fig. 18.

Conclusions

From the result of experimental investigations and discussions, the following are obtained.

1. The insoluble surface porous film (SPF) exists at the surface of PSL and is formed by the deposition of elementary silicon. The deposition of elementary silicon takes place only at the early step of the anodization.

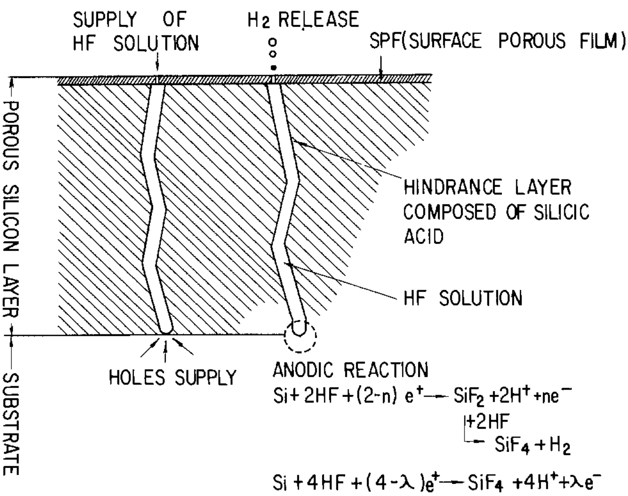

Fig. 18. Proposed formation mechanism of PSL

2. In the pores of PSL, the dissolution of silicon is the result of the divalent and the tetravalent reactions without the disproportionation reaction. The divalent anodic reaction is given as

$$Si + 2HF + (2 - n)e^+ \rightarrow SiF_2 + 2H^+ + ne^-$$

$$SiF_2 + 2HF \rightarrow SiF_4 + H_2$$

$$\xrightarrow{+2HF} H_2SiF_6$$

($n < 2$, e^+ and e^- are hole and electron, respectively). The tetravalent anodic reaction is given as

$$Si + 4HF + (4 - \lambda)e^+ \rightarrow SiF_4 + 4H^+ + \lambda e^-$$

$$\xrightarrow{+2HF} H_2SiF_6$$

$$(\lambda < 4)$$

3. The electrolyte in the pores of PSL has the constant HF concentration during anodization in concentrated HF solution.

4. The anodic reaction in the pores proceeds uniformly in the thickness direction and takes place only at the base of the pores.

5. PSL is formed by the local dissolution of silicon. The local dissolution of silicon is initiated by SPF and is promoted by the hindrance layers composed of the silicic acid.

ABSTRACT

Implantation of As and P into preannealed n-type CdTe crystals produced conversion from n- to p-type for the whole range of Cd pressures used for postimplantation annealing. Since Ar-implanted samples showed type conversion only for the lower Cd pressures, it is concluded that As and P cause chemical doping in CdTe. Defect equilibrium behavior and diffusion in the implanted samples as a function of the postimplantation Cd pressure used for annealing were investigated by chemical stripping of the implanted surface. The defect equilibrium behavior is consistent with a model proposed by Selim and Kröger on the basis of their investigation of P impurity in CdTe, in which the shallow acceptors introduced by implantation are compensated by interstitial Cd for higher postimplantation annealing Cd pressures, and by As or P at Cd sites at lower Cd pressures. Two fast diffusion mechanisms were observed in As-implanted samples, but only one of these in P-implanted samples.

Only a few implantation investigations have been carried out with CdTe. Kachurin *et al.* (1) first investigated the implantation of Ag and Ga in CdTe thin films, but the doping effects were unclear. Donnelly (2) implanted As^+ ions into n-type CdTe crystals and reported conversion to p-type after postimplantation annealing; similar results were reported by Agrinskaya *et al.* (3), who compared the results of implanting Ne and As ions in CdTe and concluded that As chemically dopes the CdTe. Doping efficiency has been increased by coimplantation of As^+ and Cd^+, as well as P^+ and Cd^+, to produce p-type CdTe (4).

Gettings and Stephens (5) reported conversion of a p-type CdTe substrate to n-type under implantation of n-type dopants such as Bi and In. An implantation efficiency of 30% was measured for a dose of 10^{14} cm^{-2} In ions. Although more activity was generated by Bi ions, Te and Ar ions produced no measurable electrical changes. An observed increase in lattice

Key words: implantation, p-n junctions, defects, diffusion.

disorder and sample resistivities for annealing temperatures above 400°C was attributed to thermally generated active defects and to loss of the implanted ion species.

More recently Bean *et al.* (6) have investigated implantation of As, Kr, and Cs in CdTe and suggested that doping due to As implantation appeared to be caused by implantation-induced defects whereas doping due to Cs implantation appeared to be actual chemical doping. The present authors have previously reported successful production of CdTe p-n photovoltaic junctions by As implantation followed by Cd-pressure controlled postimplantation annealing (7).

Although efforts have been made to improve the doping efficiency in CdTe, the understanding of implantation effects in this material is still quite limited. The factor of defect equilibrium chemistry has been largely neglected during the postimplantation annealing. Figure 1 summarizes the defect equilibrium behavior of CdTe doped with Cu, In, Au, or P, as reported by de Nobel (8) and by Selim and Kröger (9). The conductivity type and the carrier concentration of CdTe are strongly affected by the Cd pressure used in annealing. It is therefore to be expected that the postimplantation annealing Cd pressure can play an important role in controlling the implantation efficiency.

In the research described in this paper, CdTe single crystal samples were implanted with As, P, or Ar. After postimplantation annealing with controlled Cd pressures, these samples were chemically stripped and the experimental results are compared with those of Selim and Kröger (9).

Experimental Procedure

CdTe single crystals without intentional doping were grown by the unidirectional solidification method[1] in Cd and 0.5 atomic percent excess Te solution. The crystal growth conditions and the details of sample preparation procedure have been previously reported (7). The samples used here had dimensions of $5 \times 5 \times 1\ mm^3$.

[1] Crystals were grown by R. Raymakers and Dr. R. S. Feigelson in the Crystal Growth Laboratory of the Center for Materials Research at Stanford University.

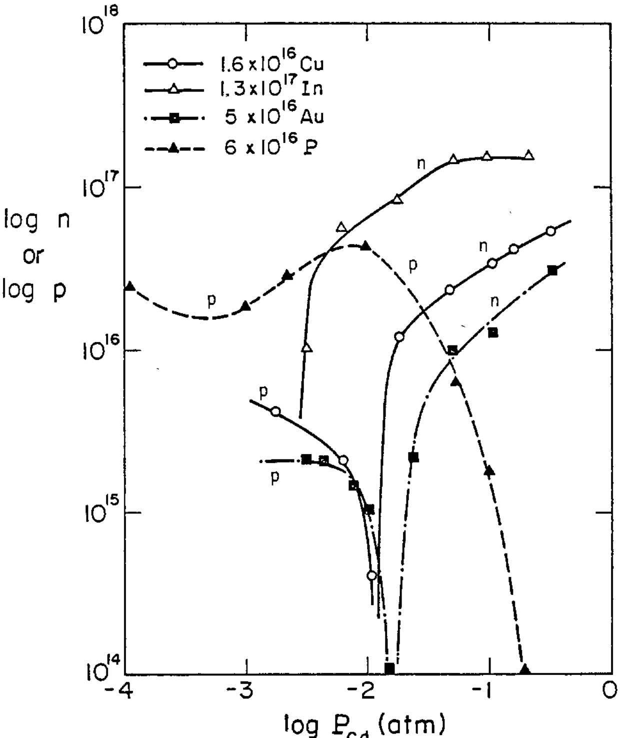

Fig. 1. Carrier concentration of CdTe samples doped with Cu, In, Au, or P as a function of the annealing Cd pressure after the samples were quenched from an annealing temperature of 700°C. P data from Selim and Kröger (9), all other data from de Nobel (8).

Preimplantation annealing.—The as-grown CdTe crystals were p-type with a hole concentration of $10^{13}\ cm^{-3}$ and a hole mobility of 80 cm^2/Vsec, as expected due to the generation of Cd vacancies and/or Te interstitials by the growth in excess Te. To obtain n-type substrates for implantation, these crystals were converted to n-type by annealing in a two-zone furnace under Cd pressure for 36 hr in evacuated clean quartz tubes containing Cd. The first zone was used to control the substrate temperature at either 500° or 600°C, and the second zone was used to control the Cd temperature, which determines the Cd pressure in the tube, between 320° and 600°C. After annealing, samples were quickly cooled by quenching the ampul in water.

Implantation.—After preimplantation annealing, samples were etched with bromine-methanol to remove Cd precipitates from the surface. After etching, As, P, or Ar ions were implanted into CdTe substrates held at either 25° or 300°C.

Postimplantation annealing.—The procedure for postimplantation annealing was similar to that for preimplantation annealing except that the annealing time was just 1 hr. The purpose of this annealing was to decrease the crystal damage caused by the implantation and to make the dopant electrically active.

As Implantation

Table I summarizes the seven series of experiments that were carried out in the present investigation of As implantation in n-type CdTe.

Preliminary investigation and reproducibility (series As-1 and control).—Series As-1 was implanted with As for the investigation of type conversion, annealing effects as a function of Cd pressure, and reproducibility of the results. The control samples were processed through all the same procedures as As-1, except that they were not implanted.

After preannealing, all the samples in these two series were n-type with a mobility of 670 cm^2/Vsec and an electron density as shown in Fig. 2. For high Cd pressures, the electron density varied as the 0.36 power of the Cd pressure; this value is close to 0.33 which corresponds to determination of the n-type conductivity by doubly ionized native defects, either doubly ionized interstitial Cd or Te vacancies (10-13).

After heating in the implantation system at 300°C, with or without As implantation, the surface of all samples converted to p-type, probably associated with Cd vacancies formed by out-diffusion of Cd, which have a shallow acceptor level with ionization energy of 0.05 eV.

After postimplantation annealing, the control samples were again n-type with identical electrical properties as before processing in the implantation system, provided that the 300°C heating in the implanter was not longer than 1 hr. This indicates that the 500°C postannealing under Cd pressure annihilated the Cd vacancies formed by the 300°C heating in the implanter, unless the 300°C heating was long enough to generate vacancy clusters.

The As-implanted samples, however, showed quite different properties after postimplantation annealing. The substrates of these samples were indeed n-type with the same electrical properties as the control samples, but the As-implanted surfaces were p-type with the sheet hole concentrations shown in Fig. 3 as a function of Cd pressure. Reproducibility for these samples was excellent.

These preliminary experiments confirm that type conversion upon As implantation is due to the As implantation itself, and not to any extraneous processing effects.

Table I. Summary of samples and treatments

Sample series	Preimplantation annealing	Implantation temperature, °C	Dopant and dose, cm^{-2}	Ion energy, keV	Postimplantation annealing
As-1	500°C, p_{Cd} varied	300	As, 10^{15}	60	Same as preimplantation annealing
Control	500°C, p_{Cd} varied	300	None	None	Same as preimplantation annealing
Ar	500°C, max p_{Cd}	300	Ar, 10^{15}	60	500° or 600°C
As-2	500°C, max p_{Cd}	300	As, 10^{15}	100	500° or 600°C
As-3	500°C, max p_{Cd}	25	As, 10^{15}	100	600°C
As-4	600°C, max p_{Cd}	25	As, 10^{15}	100	500° or 600°C
As-5	600°C, max p_{Cd}	25	As, 5×10^{13}	100	600°C
P-2	500°C, max p_{Cd}	300	P, 10^{15}	100	500° or 600°C
P-3	500°C, max p_{Cd}	25	P, 10^{15}	100	500°C
P-4	600°C, max p_{Cd}	25	P, 10^{15}	100	500° or 600°C

Implantation damage (Ar series).—Twelve samples comprise the Ar series; these were preannealed, implanted with Ar, and postannealed as described in Table I. After implantation half the samples were annealed at 600°C under different Cd pressures, and half the samples were annealed at 500°C under different Cd pressures.

For a whole range of Cd pressures from 10^{-3} to 10^{-1} atm at 600°C, and for all Cd pressures greater than 2.5×10^{-3} atm at 500°C, no conductivity type conversion is caused by Ar implantation. Only for Cd pressures less than 2.5×10^{-3} atm and for annealing at 500°C is conversion to p-type observed, as indicated on Fig. 4. This p-type behavior can be associated with implantation damage (Cd vacancies, Te interstitials, or defect clusters) which is annealed away for all Cd pressures at 600°C, and for all but the lowest Cd pressures at 500°C. These results show that the Cd pressure is an important parameter in annealing the implantation damage, as well as the annealing temperature.

As implantation and electrical properties (series As-2, As-3, As-4, and As-5).—Four series of experiments were carried out to investigate the effects of implantation substrate temperature, preannealing temperature, and postannealing temperature on the electrical properties of As-implanted samples.

Twelve As-2 samples were treated similarly to the Ar samples, except that they were implanted with 100 keV As ions. The implanted surfaces of all samples were converted to p-type, while the substrate remained n-type. The variation of sheet hole concentration measured on the implanted surface as a function of postannealing Cd pressure and annealing temperature is given in Fig. 4. The hole mobilities range from 30 to 60 cm^2/Vsec for the whole range of pressures and temperatures used. All of these samples were remeasured two months after the initial preparation to check their stability. Only the samples annealed under maximum Cd pressure showed any changes; for them the sheet hole concentration had decreased to half of its initial value.

Six As-3 samples were treated similarly to the As-2 samples, except that they were implanted at 25°C and were postimplantation annealed at 600°C only, to test the effect of implantation substrate temperature. Conductivity type conversion was observed on all these samples with the sheet hole concentration results shown in Fig. 5. The mobilities of these samples decreased from 50 cm^2/Vsec at low Cd pressure to 10 cm^2/Vsec at maximum Cd pressure. Arkad'eva *et al.* (4) did 25°C-implantation, annealed their samples under maximum Cd pressure, and reported hole mobilities between 9 and 30 cm^2/Vsec. Remeasuring these samples after two months again showed no changes ex-

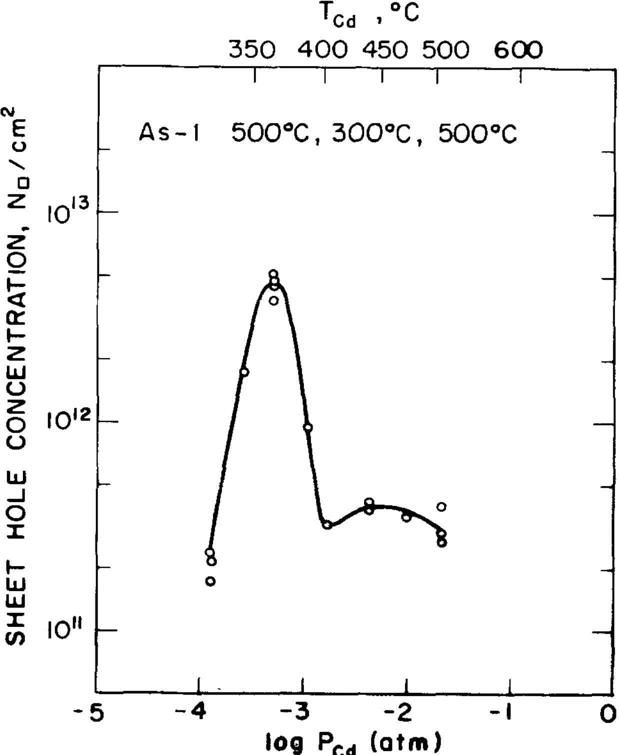

Fig. 3. Sheet hole concentration for As-1 samples as a function of postimplantation Cd pressure. The temperatures given indicate preimplantation annealing, implantation, and postimplantation annealing temperatures.

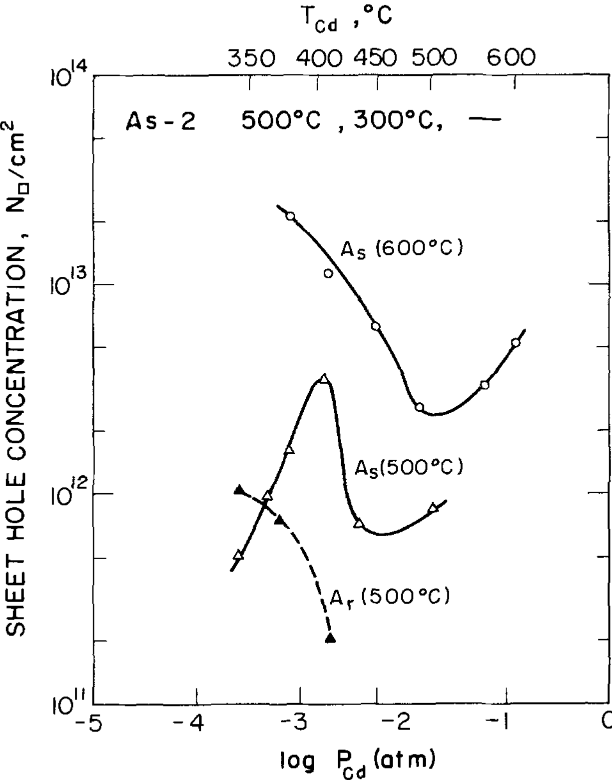

Fig. 4. Sheet hole concentration for As-2 samples as a function of postimplantation Cd pressure at 500° and at 600°C (preimplantation annealing at 500°C and implantation at 300°C), and for Ar samples postimplantation annealed at 500°C. Ar-implanted samples postimplantation annealed at 600°C did not show conductivity type conversion.

cept for the samples annealed under maximum Cd pressure, for which the sheet hole concentration had decreased to half of its initial value.

Ten As-4 samples were used to check the effects of changing the preannealing temperature from 500° to 600°C. The sheet hole concentrations are shown in Fig. 5. Hole mobilities were similar to those found for As-3 samples.

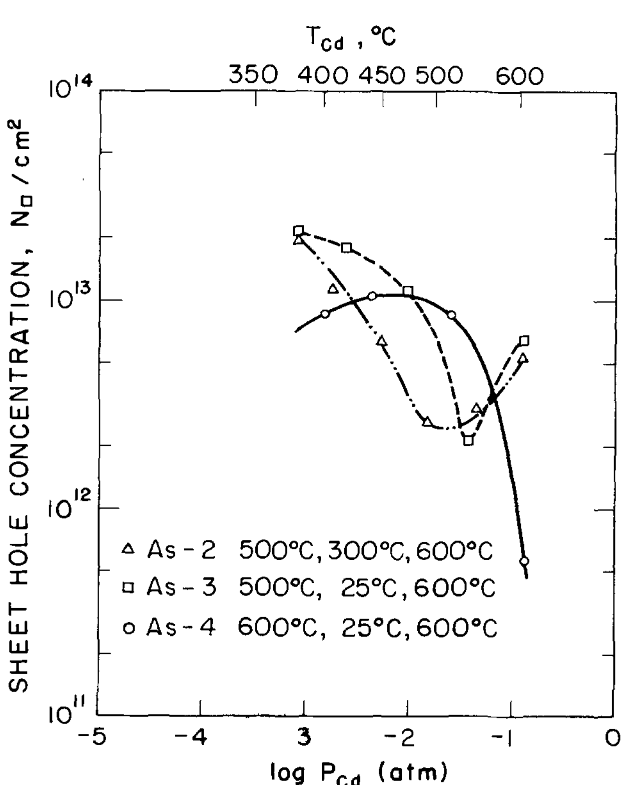
Four As-5 samples were used to check the effects of dose on implantation results. The sheet hole concentrations are also shown in Fig. 5. A decrease in dose by a factor of 20 was accompanied by an increase in the maximum implantation efficiency from 1 to 3%.

Diffusion and defect equilibrium behavior.—Sheet concentrations cannot be used for direct analysis of the detailed doping process because the sheet concentrations are the product of two variables: (*i*) the hole concentration per unit volume, and (*ii*) the diffusion distance of As atoms after annealing. These two variables were separated by chemical stripping experiments.

An etching solution was used to etch away a thin layer of the implanted samples. By measuring the sheet hole concentrations before and after etching, and dividing the difference between these two concentrations by the thickness of the etched layer, the hole concentration per unit volume of that layer can be calculated. By a series of such experiments, the profile of the hole density can be obtained for each sample. We used a 0.01% by volume bromine in methanol etchant, which has an etching rate of 2 A/sec. The profiles of hole density in our samples were calculated by assuming a constant mobility as measured on the surface.[2]

The hole density profiles for As-2 600°C postimplantation annealed samples are shown in Fig. 6. The theoretical ion distribution in As-implanted samples is also shown in this figure, which was approximated by the following Gaussian distribution (14)

[2] The difference of the sheet hole concentration between two consecutive measurements was less than 5% of the total sheet hole concentration. Since a 5% error was observed during Hall effect measurements, we did not make Hall measurements after each stripping, but instead assumed an essentially constant mobility and restricted ourselves to conductivity measurement only.



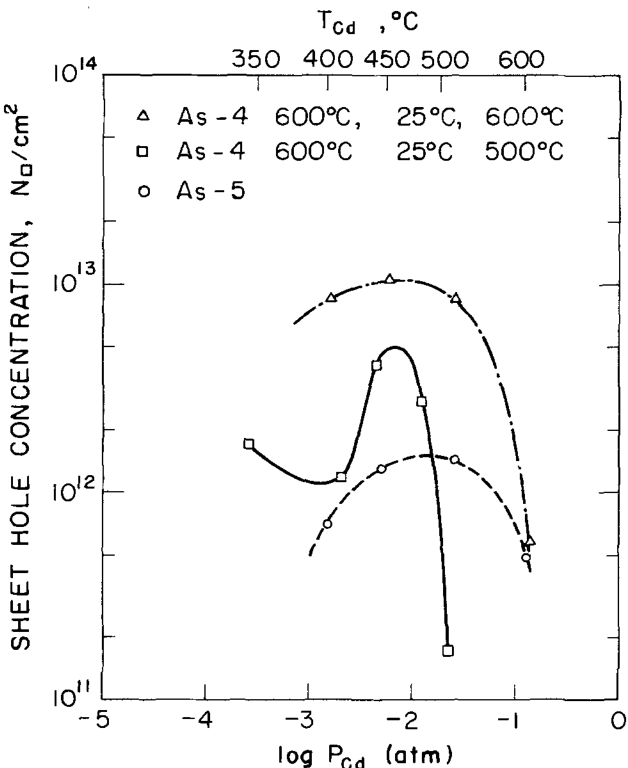


Fig. 5. (a, left) Comparison of the dependence of sheet hole concentration on postimplantation Cd pressure for samples As-2, As-3, and As-4. Temperatures indicated are preimplantation anneal, implantation, and postimplantation anneal. (b, right) Comparison of the dependence of sheet hole concentration on postimplantation Cd pressure for samples As-4 and As-5.

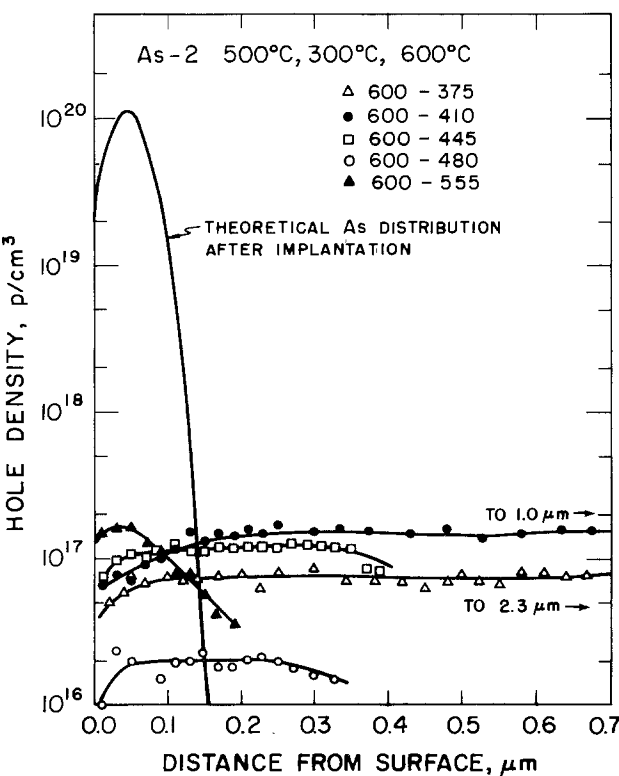

Fig. 6. Hole density profiles in 600°C postimplantation annealed As-2 samples. Each curve is designated with two temperatures; the first, 600, represents the temperature in °C of the postimplantation anneal, while the second gives the temperature in °C of the Cd during the anneal.

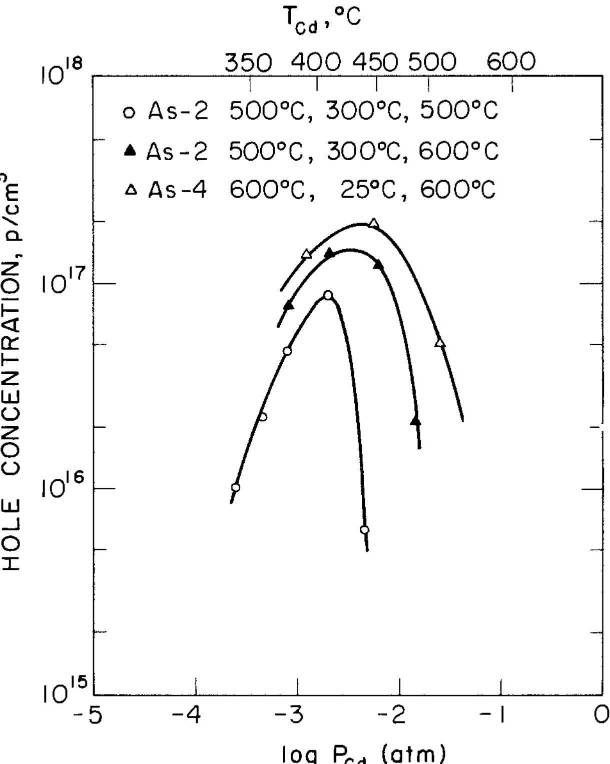

Fig. 7. Hole concentration as a function of postimplantation annealing Cd pressure for As-2 and As-4 samples. Temperatures given correspond to preimplantation annealing, implantation, and postimplantation annealing.

$$N(x) = \frac{N_i}{(2\pi)^{2/3}(\Delta R_p)} \exp\{-(x - R_p)^2/2(\Delta R_p)^2\} \quad [1]$$

where R_p is the projected range, ΔR_p is the standard deviation, x is the perpendicular distance into the substrate, and N_i is the ion dose. For 100 keV As in CdTe, $R_p = 439\text{Å}$ and $\Delta R_p = 258\text{Å}$ (15). The hole density profiles of the As-2 500°C-annealed samples and the As-4 600°C-annealed samples have also been measured, but are not presented here in the interest of brevity (16).

The curves of Fig. 6 show the dependence of hole density and the effective diffusion distance on annealing Cd pressure. The hole density profiles of most samples, except for two As-2 samples annealed under maximum Cd pressure, were very flat and extended into the samples, indicating that the diffusion of As-associated acceptors was very fast.

The hole densities of these samples (except for those annealed under maximum Cd pressure) are given in Fig. 7 as a function of Cd pressure. There is a close similarity between these curves and those given by Selim and Kröger (9) in Fig. 1.

By using the approximation

$$L \simeq (4D_{eff}t_d)^{1/2} \quad [2]$$

the effective diffusion coefficients of the samples can be estimated and are plotted in Fig. 8. In Eq. [2], L is the effective diffusion distance, D_{eff} is the electrically active dopant diffusion coefficient, and t_d is the diffusion time (1 hr for our samples).

Shallow acceptor level associated with As implantation.—Low temperature Van der Pauw measurements (a four-point probe measurement) were made on As-implanted samples to determine the energy level of the shallow acceptor levels generated by As implantation. An energy level lying 0.08 eV above the valence band is indicated, which may be associated with As substituted for Te.

P Implantation

The behavior of P in CdTe has been investigated to a certain extent, providing additional guides for our interpretation of implantation effects. Doping and compensation phenomena of P in CdTe were reported by Lorenz and Segall (17), Morehead and Mandel (18), and Arkad'eva *et al.* (19). Diffusion of P in CdTe at 900° and 950°C has been investigated by Hall and Woodbury (20). We have already mentioned the defect equilibrium chemistry investigation of P-doped CdTe by Selim and Kröger (9).

The procedures used for implanting P in CdTe were similar to those used for implanting As. Three series of experiments were carried out to investigate the effects of implantation substrate temperature, preimplantation conditions, and postimplantation annealing conditions. The samples are summarized in Table I.

Electrical properties (series P-2, P-3, and P-4).—The implanted surfaces of all twelve P-2 samples were converted to p-type while the substrates remained n-type after implantation and postimplantation annealing. Figure 9 shows the sheet hole concentrations of these samples as a function of postimplantation annealing Cd pressure, including also the Ar implantation data for comparison. Although differences in detail are evident, the general behavior after P implantation is quite similar to that after As implantation. Chemical doping by implanted P impurities seems to have occurred.

The hole mobilities in these samples were also measured. An average mobility of 45 cm²/Vsec was found for samples annealed at 500°C, independent of Cd pressure. The mobilities for samples annealed at 600°C decrease from 70 to 33 cm²/Vsec with increasing Cd pressure.

Four P-3 samples were treated similar to P-2 samples except that the implantation was at 25°C. All implanted surfaces were converted to p-type, but van der Pauw measurements in conjunction with chemical stripping experiments showed these samples to be inhomogeneous.

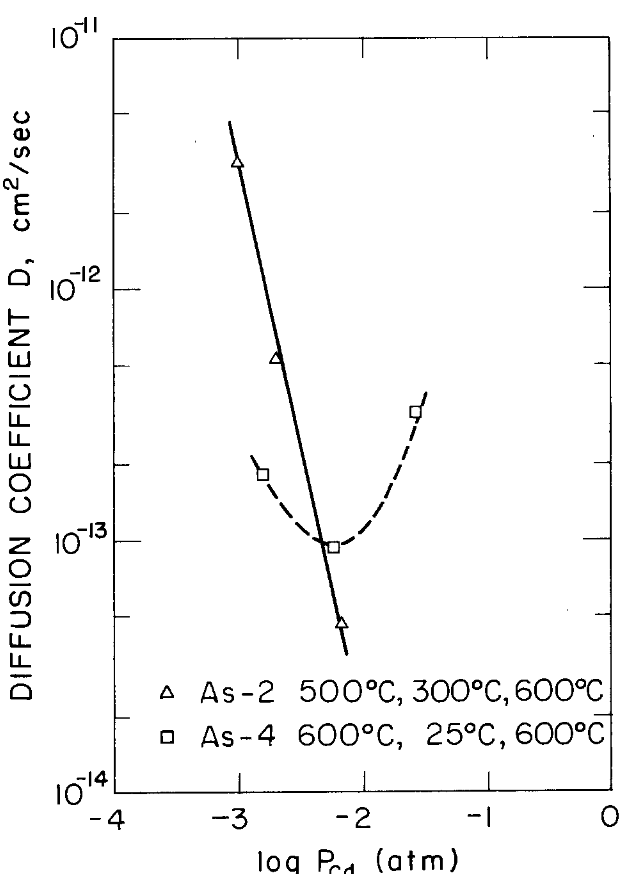

Fig. 8. Effective diffusion coefficients as a function of postimplantation annealing Cd pressure for As-2 and As-4 samples. Temperatures given correspond to preimplantation annealing, implantation, and postimplantation annealing.

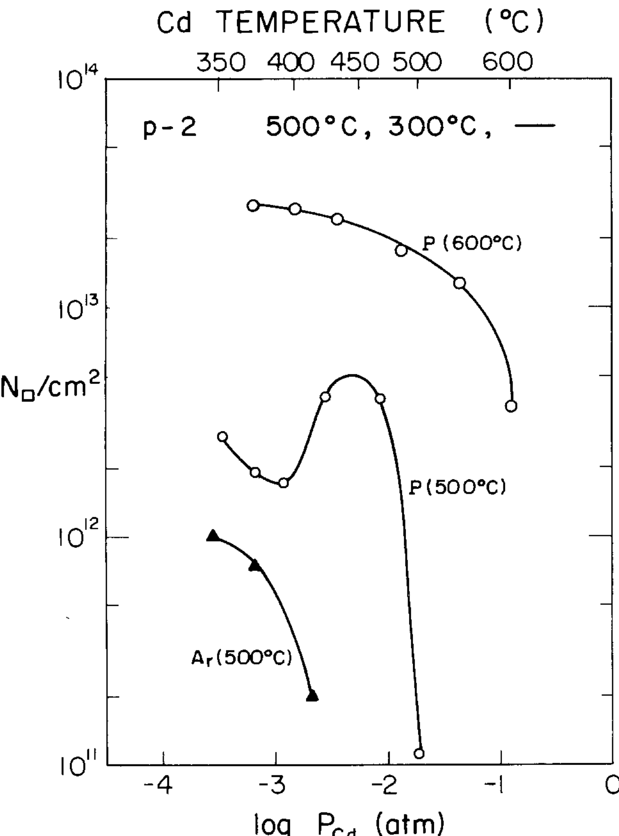

Fig. 9. Sheet hole concentration as a function of postimplantation annealing Cd pressure for P-2 samples compared to Ar samples. P-2 samples were preimplantation annealed at 500°C and implanted at 300°C; postimplantation annealing was carried out at 500°C and at 600°C, yielding the two curves shown.

Eight P-4 samples were preannealed at 600°C under maximum Cd pressure. All samples showed conversion to p-type on the implanted surface. Those postimplantation annealed at 500°C were again inhomogeneous. The electrical properties of samples annealed at 600°C were measured; the sheet hole concentrations were considerably smaller than those of P-2 samples, while the hole mobilities were comparable to those found for P-2 samples.

Diffusion and defect equilibrium behavior.—Stripping experiments, as described previously for As-implanted samples, were carried out for P-2 samples postimplantation annealed at 500° and 600°C, and for P-4 samples annealed at 600°C. The results for 600°C-annealed P-2 samples are given in Fig. 10, which show that the diffusion coefficient and hole concentrations are a function of the annealing Cd pressure. Figure 10 also includes the theoretical P distribution after implantation calculated using Eq. [1] where $R_p = 875Å$ and $\Delta R_p = 571Å$ for a P ion energy of 100 keV (15). The hole concentrations as a function of Cd pressure for the P-2 samples are given in Fig. 11, which includes Selim and Kröger's (9) results for their 600° and 900°C annealed P-doped samples. In their work the P was incorporated during crystal growth and the P concentration was 5×10^{19} cm^{-3}. Higher hole concentrations are apparently achievable by ion implantation.

Stripping experiments also show that P does not have appreciable diffusion in 500°C-annealed P-2 samples or in 600°C-annealed P-4 samples.

Estimates of the diffusion coefficients involved for the 600°C-annealed P-2 samples, according to Eq. [2], are given in Fig. 12.

Shallow acceptor level associated with P implantation.—Low temperature Hall effect measurements were made on P-2 samples to determine the properties of the shallow acceptor level caused by P implantation. An ionization energy of 0.037 eV was found that is in agreement with the published data (9).

Ohmic contacts.—The preparation of ohmic contacts to p-type CdTe is a difficult one. No metal exists with workfunction larger than that of p-type CdTe. Although ohmic contacts to p-type CdTe have been reported (21), the contact resistivities have not been reported. By evaporation of Au on slightly bromine-methanol etched P-implanted p-type CdTe (*e.g.*, a sample of P-2 with postimplantation substrate temperature of 600°C and Cd temperature of 370°C) ohmic contacts were achieved with a contact resistivity of 0.2 Ω-cm².

Discussion: As Implantation

Limitations on quantitative analysis.—Detailed quantitative analysis of our results is limited by two major problems: (*i*) the effects of implanted As on chemical diffusion in CdTe are unknown, and (*ii*) the As-related species formed by implantation is unknown.

Since the preimplantation and postimplantation annealing conditions of most samples are not the same (except for the As-1 samples) because of practical limitations on the number of samples to be investigated, there was chemical diffusion in CdTe even without implanted As. This chemical diffusion process has been studied by Zanio (22), Rud' and Sanin (23), and Whelan and Shaw (11). Zanio's experiments covered the temperature range from 500° to 800°C, and he found that the chemical diffusion coefficient could be written as

$$\tilde{D}_{CdTe} = 4 \exp(-1.15\ eV/kT) \quad cm^2\,sec^{-1} \quad [3]$$

and was independent of the annealing Cd pressure. This result was explained by Chern and Kröger (24) by attributing the chemical diffusion to a combination

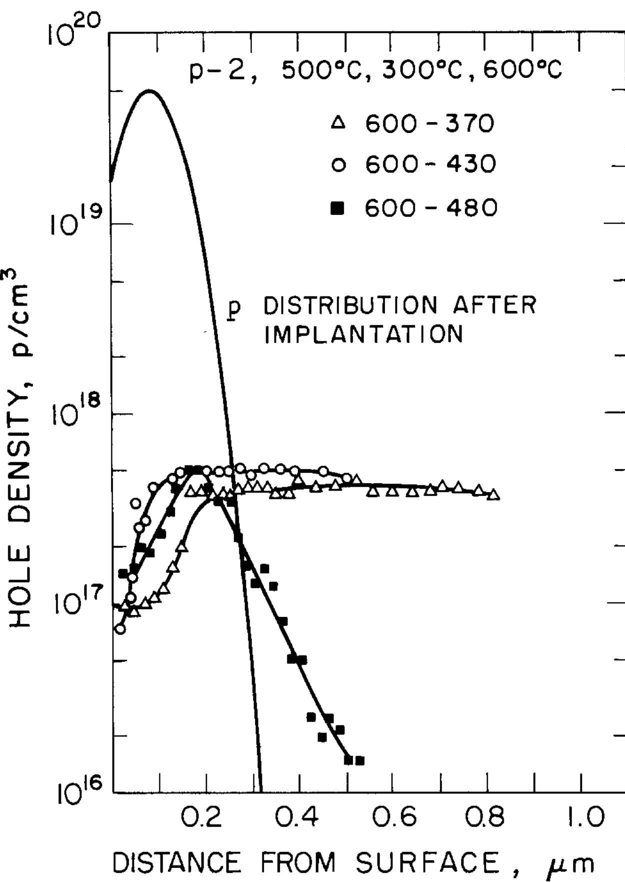

Fig. 10. Hole density profiles for P-2 samples after 600°C postimplantation annealing under Cd pressure. For each curve two figures are given: the first, 600, is the postimplantation annealing temperature in °C, and the second is the Cd temperature during this annealing in °C.

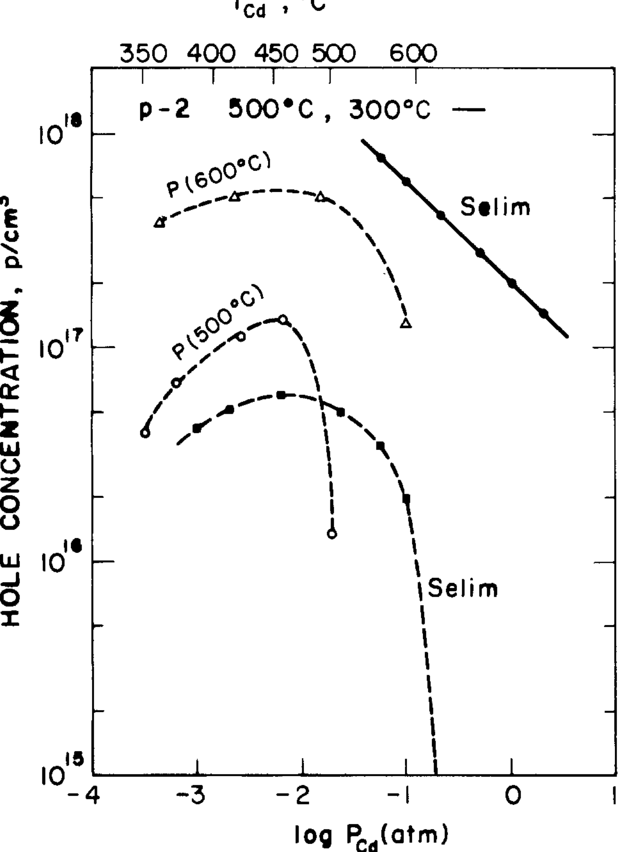

Fig. 11. Hole concentration as a function of postimplantation annealing Cd pressure for P-2 samples, which were preimplantation annealed at 500°C and implanted at 300°C; postimplantation annealing was carried out at 500° and 600°C, yielding the two curves shown. Also shown for comparison are data from Selim and Kröger (9); the lower curve is for 600°C annealing, and the upper curve is for 900°C annealing.

of diffusions of different native defects. In our experiments it is not clear how many diffusion mechanisms the As atoms will have in CdTe, and the interaction between the chemical diffusion of native point defects in CdTe and As is unknown.

In Lidow and Gibbons' work on ion implantation in GaAs (25) they found that Se_{As}-V_{Ga} complexes formed during implantation above 150°C. Although measurements of photoluminescence that we performed on our samples indicate different photoluminescence responses associated with different As-related species, it is not clear whether these species were formed during implantation or during postimplantation annealing.

In spite of these difficulties, some conclusions can be tentatively drawn from the experimental results described above.

Defect equilibrium chemistry.—Figure 7 is the defect equilibrium diagram for the As-implanted CdTe samples, which is quite similar to the results reported by Selim and Kröger (9) for P-doped CdTe as shown in Fig. 1. Our low temperature Hall measurements indicated only a single acceptor associated with As implantation, which we assigned to As on Te sites. The observed decrease of the hole concentration from the maximum concentration as a function of Cd pressure is apparently caused by compensation; likely defects for such compensation are interstitial Cd at higher Cd pressures, and As on Cd sites at lower Cd pressures. According to Selim and Kröger (9), P can occupy Cd sites and behave as a triple donor during annealing under low Cd pressure; it might be expected that the concentration of As_{Cd}, a triple donor, would be even higher than that of P_{Cd} under the same conditions because the size and electronegativity of As are closer to those of Cd than are those of P. Comparison of Fig. 7 with Fig. 11 does indicate that compensation in As-implanted CdTe is stronger than in P-implanted CdTe for low Cd pressures, in agreement with this argument.

Differences indicated in Fig. 7 between the hole concentrations of 600°C-annealed As-2 and As-4 samples might be interpreted as follows. The As-4 samples had a higher density of Te vacancies after higher temperature preimplantation annealing, and since there was no supply of Te atoms during postimplantation annealing, the probability of As going to Te sites and behaving as acceptors was enhanced for the P-4 samples.

Diffusion.—Detailed analysis of the self-diffusion of defects has been carried out by Chern and Kröger (24) who expressed the tracer diffusion coefficients as

$$D^* = D_o^* p_{Cd}^b \exp(-H^*/kT) \quad \text{cm}^2\,\text{sec}^{-1} \quad [4]$$

where b is a number, D_o^* is a constant, and H^* is the activation energy for diffusion. The factor b describes the pressure dependence of the diffusion coefficients for defects and has a different sign for different types of defects; b is positive in CdTe for $D_{Cd_i^{\cdot\cdot}}^*$ and for $D_{V_{Te}^{\cdot\cdot}}^*$, but b is negative for $D_{V_{Cd}'}^*$, $D_{V_{Cd}''}^*$, and $D_{Te_i^{\times}}^*$.

Figure 8 shows that the diffusion coefficients of As-2 samples have a negative b, which indicates that As diffusion is through a mechanism involving Cd vacancy and/or Cd interstitial sites. That As diffusion in Cd interstitial sites should have a negative b follows from the fact that $D_{Cd_i^{\cdot\cdot}}^*$ is positive, but an increase in the Cd_i concentration means a decrease in the diffusion rate through interstitial sites.

Figure 8 also suggests that the diffusion coefficients of As-4 samples have components with both positive

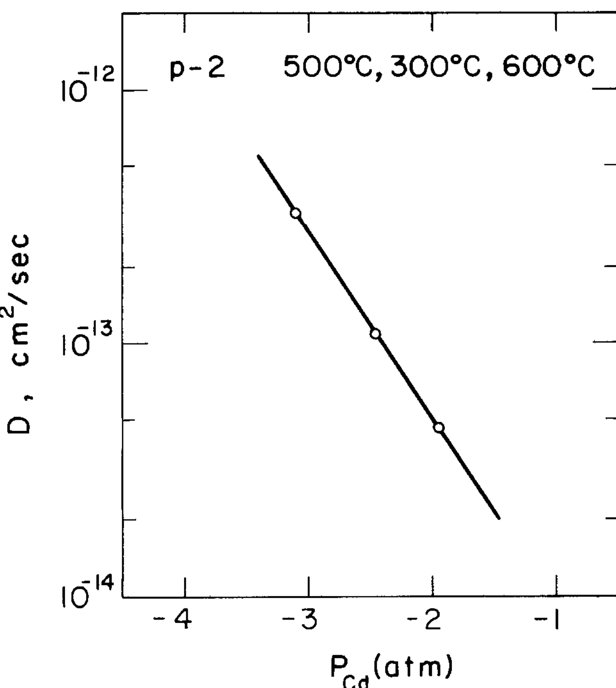

Fig. 12. Effective diffusion coefficients as a function of postimplantation annealing Cd pressure or P-2 samples. The temperatures given correspond to preimplantation annealing, implantation, and postimplantation annealing.

and negative b. Since these samples were preimplantation annealed at a higher temperature than the As-2 samples, under maximum Cd pressure, they will have higher concentrations of Cd_i and V_{Te} and lower concentrations of V_{Cd} than the As-2 samples. The expected result is that the diffusion mechanism with negative b will be suppressed, while that with positive b will be enhanced. This is consistent with the trend of the observations.

Our measurements on the photoluminescence response of these samples support these suggestions. As-2 and As-4 samples with different diffusion characteristics had different photoluminescence responses. In As-2 samples at least one As-associated species is indicated with a photoluminescence peak at 0.77 eV; in As-4 samples, at least three As-associated species are indicated with peaks at 0.77, 0.90, and 1.10 eV, although the intensity of the 0.77 eV peak is much less than that of the other two. Since the preimplantation annealing and implantation conditions for As-2 samples caused many Cd vacancies and a low concentration of Cd interstitials, an identification is reasonable between the 0.77 eV peak and either single As or As complexes, with As at either Cd sites or Cd interstitial sites. The preimplantation annealing of As-4 samples indicates that the concentration of Te vacancies should be greater than in the As-2 samples, and that the concentration of Te interstitials should be less than in As-2 samples. Hence, we might attribute peaks at 0.90 and 1.10 eV to As at Te substitutional or interstitial sites. Although certainly not a tight argument, these assignments are at least consistent with the diffusion data.

Discussion: P Implantation

Defect equilibrium chemistry.—Most of the results of P implantation are quite similar to those of As implantation and can be interpreted within the framework of the interpretation of Selim and Kröger (9). Under higher Cd pressures (Fig. 11) the compensation of P_{Te} acceptors is by interstitial Cd, while at lower Cd pressures, the compensation of P_{Te} is by P_{Cd}, a triple donor. The observation that the hole concentrations reported by Selim and Kröger for 600°C annealing are about ten times smaller than those produced by P implantation in spite of the high P concentration (5×10^{19} cm^{-3}) in their samples, cannot be explained without further investigation.

Diffusion.—The effective diffusion coefficients for P-2 samples shown in Fig. 12 are smaller than those of As in As-2 samples treated in a similar way. Only a negative b factor in Eq. [4] is indicated by the results, indicating that electrically active P in these samples diffuses through a mechanism involving P at Cd substitutional or interstitial sites.

The 600°C annealed P-4 samples showed no appreciable diffusion. This result indicates that (*i*) diffusion through the mechanism involving a negative b factor is suppressed, and (*ii*) P does not diffuse through a mechanism with a positive b factor.

The inhomogeneity of the 500°C-annealed samples can be attributed to the low P diffusion coefficients.

Summary

A Cd-pressure controlled postimplantation annealing was shown to be a useful method for controlling impurity doping and impurity diffusion. This annealing method is expected to be useful for the studies of ion implantation in a variety of compounds, including II-VI, III-V, and ternaries.

The fact that conductivity-type conversion from n- to p-type was obtained for the whole range of postimplantation annealing Cd pressures after As or P implantation, but only at low annealing temperatures and low Cd pressures after Ar implantation, leads to the interpretation that As and P cause chemical doping in CdTe.

Defect equilibrium behavior is similar in both As- and P-implanted CdTe and can be described in terms of a model proposed by Selim and Kröger (9) on the basis of their investigation of P impurity in CdTe. Under higher postimplantation annealing Cd pressures, the shallow acceptors, (probably As_{Te} or P_{Te}) are compensated by Cd_i, whereas at lower Cd pressures the shallow acceptors are compensated by As_{Cd} or P_{Cd}. The shallow acceptors in As-implanted CdTe have an energy level 0.08 eV above the valence band, and the shallow acceptors in P-implanted CdTe have an energy level 0.037 eV above the valence band.

Two fast diffusion mechanisms were observed in As-implanted samples with different dependence on the annealing Cd pressure: the first is tentatively described in terms of As at Cd or Cd_i sites, and the second in terms of As at Te or Te_i sites. In P-implanted samples, only one fast diffusion mechanism was observed, tentatively, assigned to P at Cd or Cd_i sites.

Ohmic contacts with low resistivity of 0.2 Ω-cm^2 were made on As- and P-implanted CdTe samples.

Additives That Improve Positive Resist Durability for Plasma Etching

Katsuhiro Harada

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki, 319-11, Japan

ABSTRACT

Additive effects on plasma etching durability for positive resist have been studied. The radical scavenger and plastics antioxidant increase the plasma etching durability of positive resists by reducing thickness loss and pattern deformation after plasma etching (thickness loss decreases about 2 times for 10% additive). The sensitivity, contrast, and development of additive-containing resists, showing slight difference from original resists, are investigated by electron beam exposure.

Dry etching, which has been foreseen as a technique enabling the LSI and other devices manufacture having fine pattern and high accuracy, is performed by the process using active species such as accelerated ion, reactive ion, and radical, which are called sputter etching, reactive ion etching, and plasma etching (1), respectively.

A resist used for the dry etching process requires a dry etching durability in order to achieve the highly accurate process addition to high sensitivity and high resolution which are required mainly by a resist for conventional chemical etching process. The dry etching durability for a resist is defined practically as a minimum of thickness loss and pattern deformation, which are induced by resist decomposition and denaturation as a result of the etching process. However, the resist decomposition and denaturation, under a dry etching atmosphere, have rarely been studied in detail.

The difference between positive and negative resist is apparently an approach to designing high dry etching durability having high sensitivity. Chloromethylated polystyrene (CMS) (2), as a negative resist, makes it possible to have these functions in a homopolymer, owing to designing a polymer which has a benzene-ring as a dry etching durable group and chloromethyl groups as a cross-linking highly sensitive functional group. However, it is not possible to possess these two functions in positive resist, because the main chain decomposition must accelerate for high sensitivity, but it must be inhibited for dry etching durability. Therefore, positive resist has been a conflicting property between dry etching durability and high sensitivity, *e.g.*, polystyrene sulfone has excellent durability for ion milling, but it has a low sensitivity of 1×10^{-5} C/cm^2, compared with polyolefin sulfone, which has a high sensitivity of $1 \sim 3 \times 10^{-6}$ C/cm^2 and low dry etching durability (3, 4). AZ-1350, as a positive photoresist, has high dry etching durability but a low sensitivity of 1.5×10^{-4} C/cm^2 (4).

Additives, which are expected to have selective reaction with active species and to inhibit positive resist decomposition and denaturation under dry etching atmosphere, have been studied using the plasma etching process in order to avoid this conflicting property on the positive resist.

Key words: resist additive, positive resist durability, plasma etching.

Experimental

Sample preparation.—Positive resists used in current work are polymethylmethacrylate (PMMA, Elvacite 2041, du Pont), polyhexafluorobutylmethacrylate (FBM, Daikin Kogyo) (5), and polydimethyltetrafluoropropylmethacrylate (FPM) (6). The additives used were commercially available 1,1-diphenyl-2-picrylhydrazyl (DPPH), galvinoxyl (GAL), 2,2-methylene bis (4-methyl-6-tert-butylphenol) (MBP), 2,4,6-tritert-butylphenol (TBP), and 2-mercaptobenzothiazole (MBT).

The about 1 μm thick resist film samples were prepared on a surface-oxidized silicon wafer using the standard spin-coating technique from the solution which dissolved resist or resist and additive. They were baked in air for 30 min before plasma etching

or electron beam exposure. The baking temperature, considering the glass transition temperature of the resist and the melting point of the additive, was 140°C for original FBM, additive-containing FBM and DPPH, MBP and TBP-containing resist, and 170°C for other resists and additive-containing resists.

Plasma etching.—Plasma etching durability of resists and additive-containing resists were evaluated by thickness loss and pattern deformation after the etching process. Thickness loss is represented with normalized plasma etching selectivity ratio S, defined by

$$S = d_S/d_R$$

where d_S is the etching depth for the SiO_2 substrate and d_R is the thickness loss of the resist after plasma etching. The determination of S is illustrated in Fig. 1. Step heights (a, b, and c) were measured by Talystep (Taylor-Hobson).

The pattern deformation was observed by a scanning electron microscope (SEM).

Plasma etching process was performed by commercially available apparatus (IPC-2005, International Plasma Corporation). Etching gas was tetrafluoromethane, involving 4.2% oxygen. Gas flow rate was 100 cm^3/min and gas pressure was 0.8 ~ 1.1 Torr. Impressed rf power was 200W. All etching processes in the current work were carried out over a 28 min period using an etching tunnel, in which the substrate (SiO_2) was finally etched about 5000Å in depth. The etching atmosphere temperature, measured by a mercury thermometer inserted into the etching chamber, was elevated from room temperature (18° ~ 20°C) to below 100°C.

Electron beam exposure and development.—Thickness-dose curves and pattern delineation for resists and additive-containing resists were obtained by electron beam exposure (accelerating voltage, 20 kV).

The developer used was a solvent mixture consisting of methylisobutylketone (MiBK) and isopropylalcohol (IPA). The mixing ratio was MiBK/IPA = 1/1 for original and additive-containing PMMA, MiBK/IPA = 19/81 for original and additive-containing FPM, and MiBK/IPA = 1/150 for original and additive-containing FBM. The development temperature was controlled at 22.5°C and the development time was 2 min for all resists and additive-containing resists.

Radiation G-value determination and plasma decomposition analysis.—Radiation G-value for resists and additive-containing resists were determined from the inverse number-average molecular weight $1/M_n$ *vs.* γ-radiation dosage (7). The film samples were irradiated with γ-rays (Co^{60}) in air at room temperature for 40 days at dosages ranging from 1.5 to 7.1 megarad. The film samples were prepared at first to remove the solvent which dissolved resist or resist and additive, then baked in air for 30 min at 170°C for original and additive-containing PMMA, and at 170°C for original and additive-containing FBM before γ-irradiation.

M_n for radiation G-value and the resist molecular weight variation by plasma etching were measured by gel permeation chromatography (GPC) (HLC-802UR, Toyo Soda Kogyo). The samples for the latter was prepared by dissolving the film on the wafer after plasma etching, which was performed under standard conditions described above.

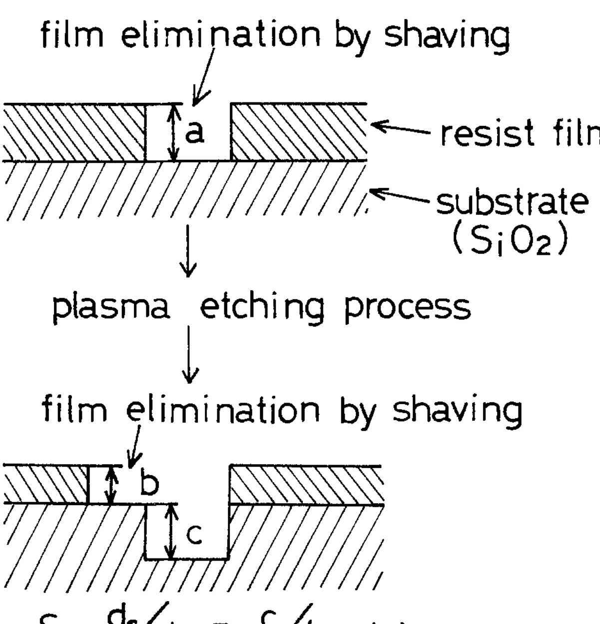

Fig. 1. Determination of plasma etching selectivity ratio S

Results and Discussion

Additive effects on plasma etching durability.—Table I shows plasma etching selectivity ratio S for each resist containing the same amount of additives under the same etching condition. It was recognized that S-value increased by two kinds of additives. One of them was a radical scavenger or free radical, such as DPPH and GAL. The other was a plastics antioxidant such as MBP, TBP, and MBT. S-value also increased according to increasing the additive concentration, as shown in Fig. 2. This behavior was similarly observed in other additives in Table I and additive-containing FPM's and FBM's.

Both radical scavenger and plastics antioxidant have abilities to deactivate an active radical and to decompose a peroxide. Many transient intermediates, such as polymer radical and polymer peroxide, which generate during the polymer decomposition process, are well known in pertinent literature (8). The polymer radicals, indicated as follows, have been proposed for PMMA photolysis (9) and radiolysis (10) as the transient intermediates before main chain scission occurs

$$\sim CH_2-\overset{CH_3\ (9)}{\underset{\bullet C=O}{C}} \sim , \quad \sim CH_2-\overset{CH_3\ (9)}{\underset{\bullet}{C}} \sim ,$$

$$\sim \overset{CH_3\ (10)}{\underset{COOCH_2}{C}} - \overset{\bullet}{C}H \sim$$

Hence, it is considered that the decomposition of the positive resist under plasma etching atmosphere is inhibited by the reaction of the active resist intermediate with the radical scavenger or plastics antioxidant.

Figure 3 shows molecular weight variations resulting from plasma etching. Original PMMA ($M_n = 2.5 \times 10^5$) was highly decomposed and became $M_n = 1.2 \times 10^5$, compared with additive-containing PMMA ($M_n = 2.0 \sim 1.5 \times 10^5$). These results indicate the

effect inhibiting the polymer decomposition by the additive. Two inhibition mechanisms are considered, one of them is a reaction of the additive with the polymer radical described above, the other is a reaction of the additive with active species, such as CF_3, CF_2, F, etc. being induced by CF_4 plasma and invading into resist layers.

On the other hand, the additive also inhibited thermal decomposition of the resist. Figure 4 shows a TGA thermogram for original and additive-containing PMMA. The decomposition temperature was heightened about 50° ~ 60°C by the addition. Therefore, this is considered as one of the effects to increase plasma etching durability. It has been proposed that

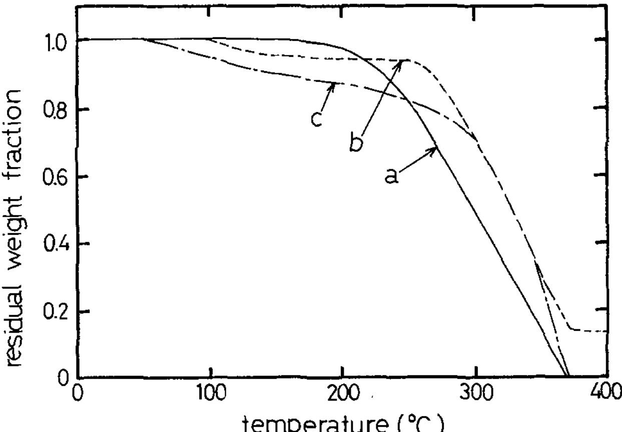

Fig. 4. PMMA TGA thermograms. Atmosphere, N_2; heating rate, 5 °C/min. Curve a, original PMMA; curve b, 9.1% DPPH-containing PMMA; curve c, 9.1% MBP-containing PMMA.

the plasma gas temperature is estimated at several hundred degrees centigrade (11), and resist decomposition is possible in such temperature.

Thickness-dose curve and development of an additive-containing resist.—It is presumed that radical scavenger or plastics antioxidant addition to positive resist causes a change in reactivity for high energy rays and physical properties which influence the resist properties. Therefore, several properties of additive-containing resists have been studied.

Fundamental important parameters, which influence the properties of positive resists, are radiation G-value and solubility behavior to the developer.

Table II shows radiation G-value for PMMA and FBM with respect to several DPPH concentrations. G-value decreased markedly by DPPH addition and concentration effect was observed on DPPH-containing PMMA.

The representative resist properties are sensitivity and contrast, which are evaluated from the thickness-dose curve. Two behaviors on sensitivity were observed from the thickness-dose curve, with respect to additive addition. One of them was the sensitivity de-

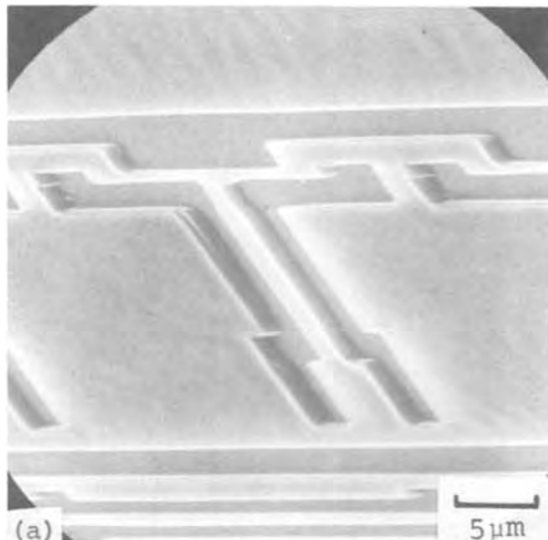
crease, as shown in Fig. 5. The other was the behavior in which the sensitivity did not change or increased, as shown in Fig. 6. Those behaviors depend on the kind of additive. DPPH and GAL belong to the former and MBP and TBP belong to the latter.

Figure 7 shows the sensitivity ratio with respect to additive concentrations. A similar tendency was observed on sensitivity ratio for DPPH and MBP addi-



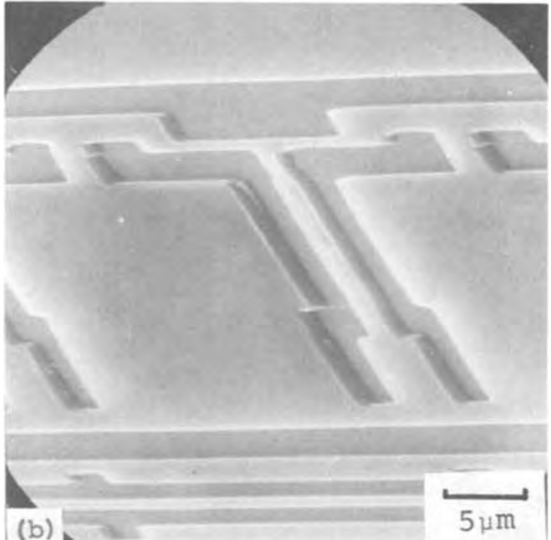


Fig. 11. PMMA patterns after development. Development conditions: MiBK/IPA = 1/1, 22.5°C, 2 min, (a) original PMMA, dosage = 1.2 × 10^{-4} C/cm^2; (b) 16.7% DPPH-containing PMMA, dosage = 1.4 × 10^{-4} C/cm^2.

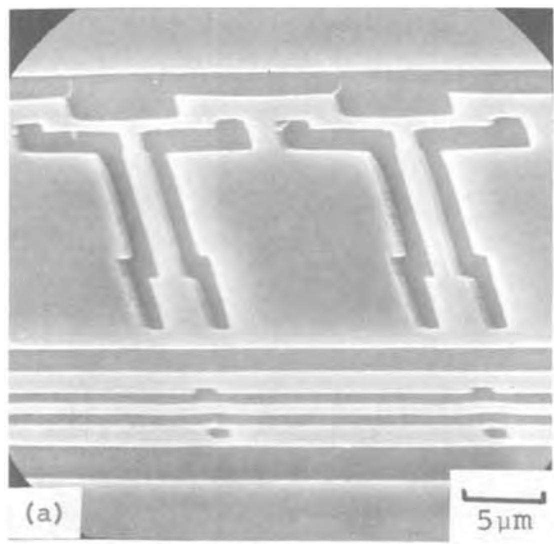
tion. Sensitivity-decreasing magnitudes for DPPH addition are different from resists, in order of PMMA, FPM, and FBM. These results suggest that the most dominant factor for positive resist sensitivity is not radiation G-value. It is considered that one reason for sensitivity decreasing depends on the DPPH solubility to the developer, because DPPH is soluble in MiBK but scarcely in IPA. The MiBK volume percents in the developer are 50, 19, and 0.7 for PMMA, FPM, and FBM, respectively. MBP-containing resist sensitivity did not change, or increase. The reason is also considered to be the MBP solubility to the developer, because MBP is liable to dissolve in both MiBK and IPA.

Figures 8, 9, and 10 show thickness-dose curves for original resists and the same amount of additive-containing resists in order to compare the contrast. The contrasts of additive-containing resists were scarcely changed, compared with that of original resist. However, the contrast of DPPH-containing PMMA decreased somewhat. Figure 11 shows resist patterns for 16.7% DPPH-containing PMMA, compared with original PMMA, after electron beam exposure and development. No difference in pattern accuracy and surface condition could be detected. This was same as for other additive-containing PMMA's and additive-containing FPM's. On the whole, it is recognized that the contrast of additive-containing positive resists is hardly different from that of original resist in the region of additive concentration, studied in the current work. These facts indicate that an additive in the unexposed resist scarcely effuses to the developer. The reason is considered as being that the additives have a very bulky structure, compared with the side chain of the resist. Therefore, an additive cannot shift among the main chain to effuse.

FBM pattern is obtained under very strict development conditions (5) because FBM solubility changes markedly by little deviation in development conditions. No FBM pattern deformation, containing more than 4.8% additive, was observed. However, FBM's, containing over 9.1% additive, were required to reduce the development time in order to obtain the nondeformed pattern, as shown in Fig. 12.

Resist pattern deformation after plasma etching.—Figure 13 shows sectional views of resist and substrate after plasma etching, with respect to additives and its concentrations. The pattern deformation, uneven



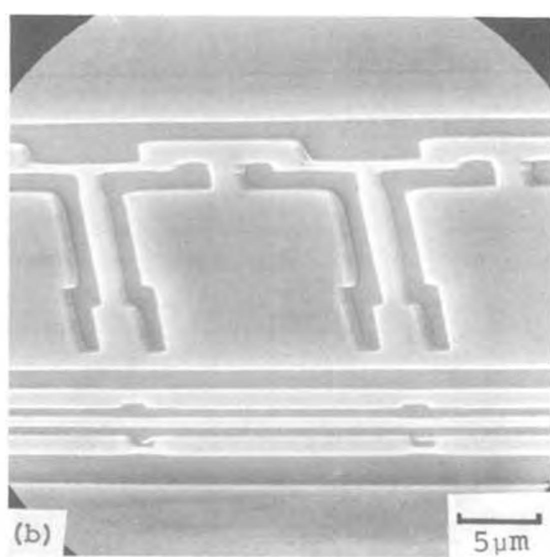


Fig. 12. FBM patterns after development. Development conditions: MiBK/IPA = 1/150, 22.5°C, (a) original FBM, dosage = 2.3 × 10^{-6} C/cm^2, development time, 2 min; (b) 9.1% MBP-containing FBM, dosage = 2.5 × 10^{-6} C/cm^2, development time, 30 sec.

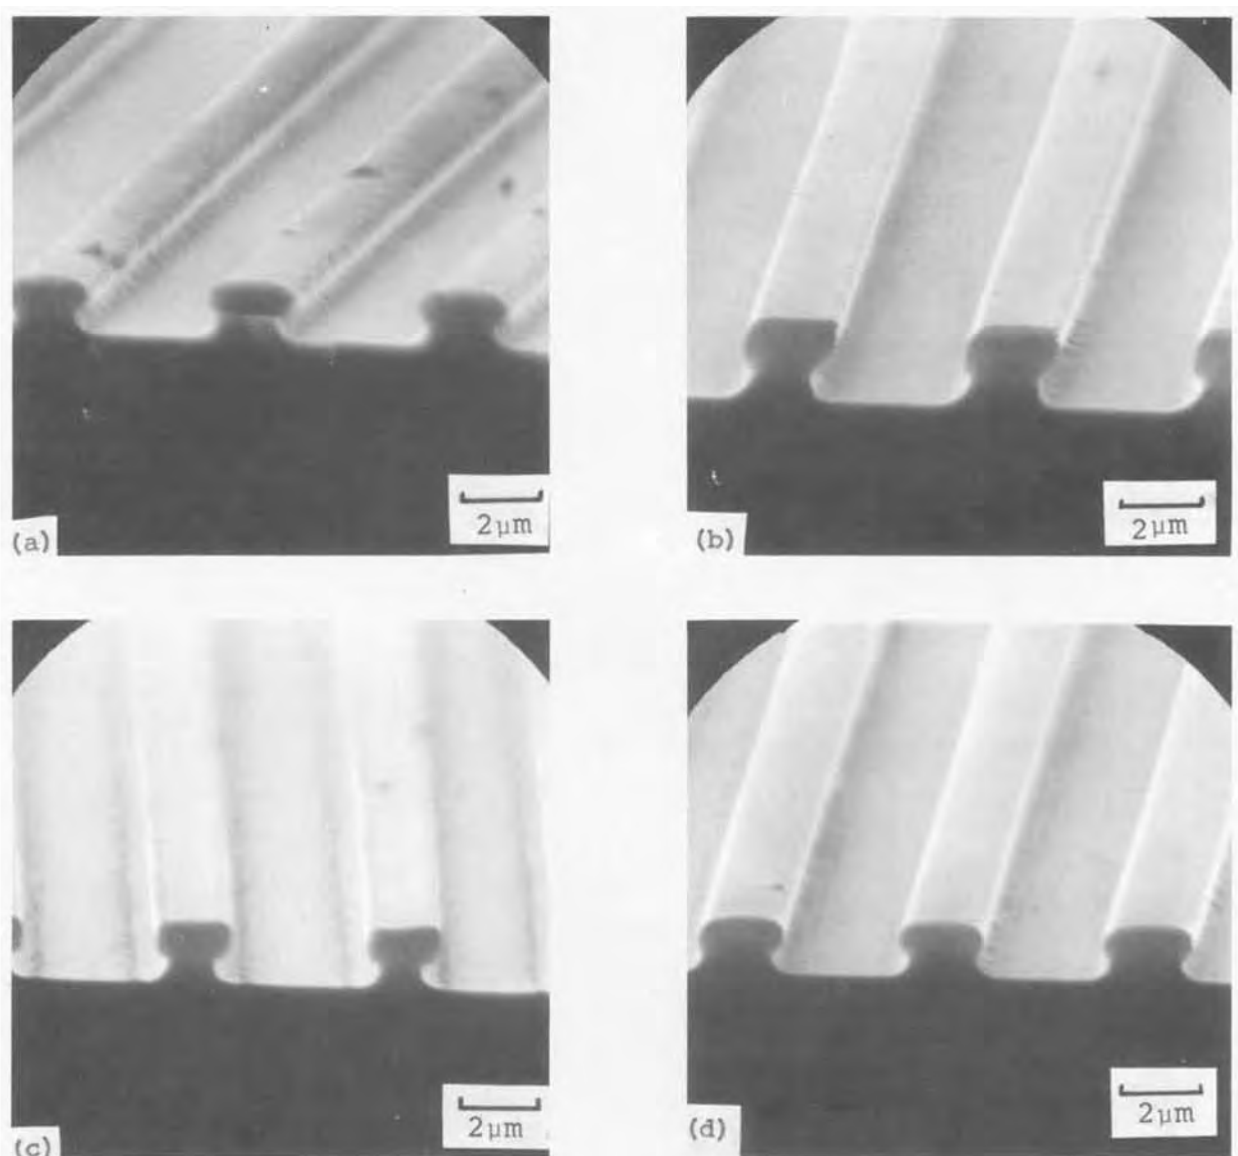

Fig. 13. Sectional views of PMMA pattern and substrate after plasma etching. Plasma etching conditions: gas, $CF_4 + 4.2\% O_2$; gas flow rate, 100 cm^3/min; rf-power, 200W; etching time, 28 min, substrate (SiO_2) etching depth, about 5000Å, initial resist thickness, 8000Å, (a) original PMMA, (b) 9.1% MBP-containing PMMA, (c) 16.7% MBP-containing PMMA, (d) 9.1% DPPH-containing PMMA.

surface, and thickness loss for the resist are observed for original PMMA. But, MBP-containing PMMA indicates the sharp resist pattern and less thickness loss. DPPH-containing PMMA also shows less thickness loss but resist pattern edge rounded slightly. It is revealed that both MBP and DPPH-containing PMMA showed almost the same plasma decomposition behavior (Fig. 3), the same TGA thermograph (Fig. 4), and similar curves for differential scanning calorimeter (DSC). The reason for the difference between plasma etched MBP and DPPH-containing PMMA pattern, in spite of those results, has not been determined experimentally.

FBM has relatively low plasma etching durability. Remarkable pattern deformation and thickness loss were observed on original FBM and even on additive-containing FBM, as shown in Fig. 14(a) and (b). However, when plasma etching was performed at low atmosphere temperature, the pattern deformation decreased and additive effect appeared, as shown in Fig. 14(c) and (d).

Conclusions

It is found that the plasma etching durability of positive resists is increased by addition of additives such as radical scavenger and plastics antioxidant. This effect contributes to the decrease in thickness loss and pattern deformation after plasma etching.

These additives also decrease the radiation G-value of the resist. However, it should be realized that the sensitivity of additive-containing resists is remarkably affected by the solubility of the additive into the developer, rather than the radiation G-value. Consequently, MBP and TBP which do not cause a decrease in sensitivity are obtained. The contrast for additive-containing resists scarcely changes and no pattern deformation occurred after development.

Additives, especially MBP-containing positive resists, show excellent plasma etching durability. These additive effects for plasma etching are to be expected for other dry etching, such as sputter etching and reactive ion etching.

Chronopotentiometric Investigation of the Anodic Reaction in Cryolite Melts

Influence of Dissolved Metal Traces

Frédéric Lantelme, Damianos Damianacos, and Marius Chemla*

Laboratoire d'Electrochimie, E.R.A. 310, Université Pierre et Marie Curie, 75230 Paris Cedex 05, France

ABSTRACT

The mechanism of the anodic reaction in cryolite melt is studied in presence and in absence of a layer of aluminum metal in the cell. These two experimental conditions give rise to large differences which are interpreted on the basis of changes in the interfacial properties at the electrode. The chronopotentiometric technique is used to obtain a better insight into these surface variations and on the gas evolution on the graphite anode. The dissolved metal reacts with the graphite to form at its surface aluminum or sodium carbides and gives a better contact between the electrolyte and the electrode. The analysis presented here is illustrated by the generation of three types of anode effects: By depletion of dissolved metal near the electrode which very much changes the wetting properties; by decrease of the pressure in the cell which, in absence of liquid metal, increases the dimension of retained gas bubbles; and by rapid repetition of the galvanostatic pulses which indicates that the gas evolution is a slow process. These observations have the same origin, *i.e.*, the gas covering of the electrode which markedly depends on the presence of dissolved metal.

The industrial preparation of aluminum by electrolysis of alumina dissolved in fused cryolite involves complex electrochemical reactions, especially on the anodic side. In order to improve the working conditions of the electrolytic cells, much research is devoted to the study of these reactions (1); the nature of the ionic associations present in the bath has been studied (2), the diffusion coefficients (3), and the transport numbers of the constituent elements are known (4). From these data different hypotheses have been built up to obtain a better insight into the mechanism of the electrolysis.

However, it has been recently (5, 6) shown that an important part of the observed overvoltage arises from the gas formation on the graphite anode. The kinetic parameters of the electrochemical reaction depend on the pressure in the cell, and the properties of the electrolyte-graphite interface (wetting angle θ and interfacial tension γ) have a considerable influence on the electrode process.

We plan to give here the results of the chronopotentiometric study of these phenomena. Special attention will be paid to the presence of dissolved aluminum in the bath (7) for it has been observed that, when molten cryolite is in contact with liquid aluminum metal, a very large change of the surface tension occurs (8). As a consequence, the results of chronopotentiometry are quite different to those obtained in pure ionic melts.

In industrial cells the electrolyte is in contact with a layer of liquid aluminum; a part of the faradaic loss can be attributed to the oxidation of the dissolved metal (9). Our research indicates also that this presence induces a large change in the interfacial tension at the electrode and influences the gas coverage of the electrode surface.

Experimental

The experiments with liquid aluminum in the bath are carried out in the cell represented in Fig. 1. The graphite crucible is coated with a boron nitride shield; indeed the carbon is unstable in the presence of cryolite saturated with aluminum. The electrical contact between the liquid metal which acts as cathode and the crucible is realized through a disk of titanium boride. The densities of liquid aluminum and molten cryolite are quite close; to avoid any disturbance we

have used a liquid alloy 40% Al-60% Cu, the activity of which is known (10).

Some experiments were carried out in the absence of liquid aluminum. In this case the bath was directly introduced into a vitreous carbon crucible (11).

Graphite rods (6 mm diam) with a conical extremity (angle: 30°) constitute the working electrodes; the area in contact with the electrolyte (about 1 cm^2) is determined from the immersed length. In some experiments the area is determined by shielding the electrode in boron nitride. In general no significant difference appears; however our procedure is more reliable, as it has been observed that when the shield got old penetration of cryolite occurs which leads to random results (12). Different types of graphite supplied by the company "Le Carbone Lorraine" have been used. A reference electrode is formed by electrodeposition of a thin layer of aluminum on a rod of titanium boride (3 mm diam).

The crucible is covered by a disk of boron nitride which also guides the electrode. This assembly is placed in a stainless steel (QA2) container on the top of which is placed a Pyrex cover with torion joints for the electrical conductors. The assembly is vacuum tight, and so a very pure argon atmosphere may be used at different pressures varying from 0.1 to 1 atm.

The melt is prepared from natural cryolite. Definite amounts of alumina are introduced through the tube to study the influence of the alumina content. The nature of the alumina is an important factor in the chronopotentiometric response. Normally α alumina (Patinal Merck) is used; however different tests were also performed with γ alumina.

Procedure for the Galvanostatic Method

Conventional circuitry was used for the chronopotentiometric measurements with pulses delivered by a power galvanostat (I_{max} = 60A; rise time 10 μsec) built in the laboratory by J. Chevalet. The potential response is recorded on a digital waveform recorder (Biomation, Model 805) and the curve $V(t)$ is drawn on an X-Y plotter. This curve is characterized by a sudden change of potential after a time τ; this effect corresponds to the complete depletion of the electroactive species at the surface of the electrode. When the transport process is diffusion-controlled, the following expression has been established by Sand (13): $i\tau^{1/2}c^{-1} = 0.5\ nF(\pi D)^{1/2}$ where i is the current density, c the concentration, and D the diffusion coefficient of the electroactive species.

As pointed out by Dewing (14) the heterogeneous nature of the graphite creates some difficulties in obtaining reproducible responses. In general the first pulses on a fresh electrode are abnormally long; however with repeated pulses a stationary state is reached. Moreover it is important to avoid the fluoride discharge which strongly perturbs the surface properties of the anode; a special electronic device is used to switch off the current when the potential reaches a predetermined value. The repetition interval between the pulses has to be first determined in order that a change of this time does not affect the value of τ. The influence of this interval depends on the intensity of the current. For short pulses less than 0.1 msec (high current density) a very rapid repetition (5 sec) does not alter τ. In our working conditions we have used repetition intervals ranging from 1 to 3 min in order to obtain reproducible chronopotentiograms.

The results are examined in the frame of Sand's law. The influence of the current density on the product $i\tau^{1/2}$ is first examined and next we try to determine the effect of alumina concentration on this product.

Influence of the Current Density

In general the product $i\tau^{1/2}$ decreases as i increases, but for high values of i a plateau is obtained (Fig. 2). In fact, we have undertaken two sets of determinations according to the experimental conditions.

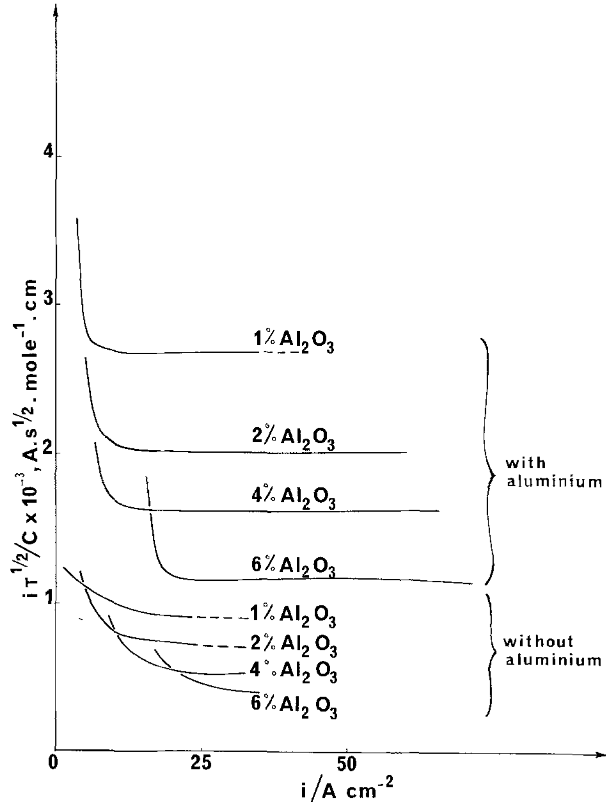

Fig. 2. Plot of $i\tau^{1/2}/c$ vs. i; graphite electrode (GR 208) at 1036°C.

1. In the absence of aluminum metal in the bath (lower curves on Fig. 2) a continuous change of the quantity $i\tau^{1/2}$ is observed as i is varied; this change becomes important as soon as the transition time is longer than 2 or 3 msec. This effect is attributed to the influence of a convection process (15). The thickness of the diffusion layer corresponds in this case to the mean path $\sqrt{2D\tau}$ of the electroactive species which is about 3 μm. This result is very different from the behavior normally observed in fused salts where the predictions drawn from a diffusion-controlled mechanism are verified up to transition times as long as 5 sec (16). The important contribution of the convection process near the electrode is probably the consequence of the gas evolution. However, as pointed out by Ibl (17), this perturbation depends on the interfacial tension electrolyte-electrode; here, in absence of aluminum, the cryolite does not wet the graphite; the gas bubbles are retained on the electrode surface which is partly covered and their departure induces large turbulences near the surface. The gas evolution seems to be a slow process; indeed for a rapid repetition of the pulse an anode effect is obtained (Fig. 3) which is induced by the total covering of the electrode by the gas phase. A model has been recently proposed to take account of the considerable influence of the retained gases in the aluminum electrolysis (12).

2. In the presence of aluminum metal a strong increase of the duration of the transition time is observed; this duration being amplified by a factor of about 8 as shown in Fig. 2. Using the same working conditions, Grjotheim *et al.* (18) observed the formation of aluminum carbide at the graphite-cryolite interface. During the anodic pulse, this compound contributes to the oxidation current; on the other hand, in the case of a porous electrode (graphite) the removal of the material could look like a diffusion process (19). However, in our procedure where galvanostatic pulses are repeated at short time intervals, these mechanisms seem to be of little importance, as confirmed by the following two remarks: the oxidation potential is not affected by dissolved metal, and the same be-

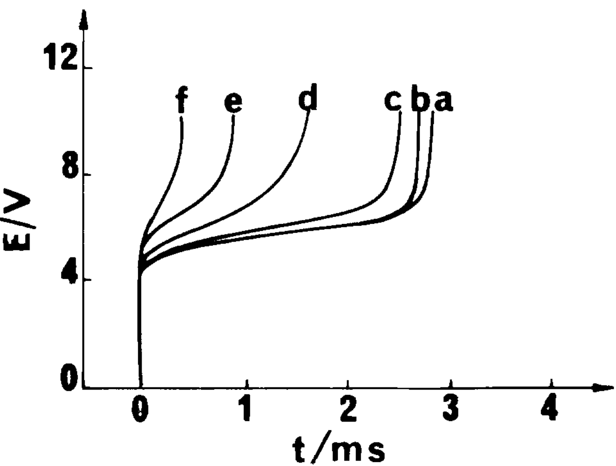

Fig. 3. Chronopotentiograms on a graphite electrode (GR 208). Stationary state; repetition interval: a, 3 mm; b, 1 mm; c, 30 sec; d, 10 sec; e, 5 sec; f, 2 sec. Cryolite bath without dissolved aluminum at 1036°C. $i = 9.0$ A-cm^{-2}.

havior is also observed on a nonporous vitreous carbon electrode.

Moreover, when alumina is introduced in the melt, a corresponding increase of the transition time is observed, which proves the reliability of our method since we do not observe the decrease of carbide pointed out by Grjotheim *et al.* (18). Finally our results lead to the evidence that the main effect of dissolved metal is to change strongly the interfacial properties of the electrode. The presence of aluminum metal in the bath enhances the wetting properties of the electrolyte (8); then the adherence of the gas bubble is less important. As a consequence the active surface of the electrode becomes greater (upper curves on Fig. 2) and the thickness of the diffusion layer increases. The two regions of the curves $i = f(t)$ are more apparent; the plateau corresponding to a constant product $i\tau^{1/2}$ is now well defined. The intervention of the convective regime appears for longer τ (about 40 msec). Moreover, total coverage of the electrode by the gaseous compounds is not obtained, even for very rapidly repeated pulses.

Influence of the Alumina Content

Nature of the alumina.—It must be emphasized that preliminary experiments show a marked effect of the structure of added alumina. As an example when γ alumina (containing about 1.5% of moisture) is introduced in the bath it takes a long time (up to 90 min) to reach a stable value of τ. This is attributed to the chemical desorption of the gases on the electrode. A visual observation shows indeed the presence of numerous small gas bubbles on the graphite. Probably these gases are mainly carbon monoxide and hydrogen, and it is known (20) that they are strongly adsorbed on the graphite. Finally we studied the influence of Al_2O_3 content obtained by successive additions of α alumina (Patinal Merck) which is anhydrous.

Determination of the alumina concentration.—Different attempts have already been made to determine electrochemically the alumina concentration c in the electrolytic cell (21). If the anodic reaction of the oxygenated species was diffusion-controlled the transition time should be proportional to the square of the concentration. In general this relation is not obeyed, except for low values of c, and often a saturation occurs for high c values.

A similar observation has been described by Dewing (22) when noble metals are used as anode; the value of the product $i\tau^{1/2}$ is diffusion-controlled up to 1.6% of Al_2O_3 on platinum electrode and up to 0.7% of Al_2O_3 on gold electrode. This limitation is attributed to the formation of an oxide film on the electrode. With graphite electrode an analogous phenomenon occurs, but now the covering arises from the gases retained at the electrode surface. This is particularly clear when the influence of the pressure in the cell is studied (12).

1. In the absence of aluminum in the bath a sensible decrease of the transition time is observed when the pressure is lowered (Fig. 4). In some cases (for low current densities) a complete passivation of this electrode is obtained at low pressure; this corresponds to the generation of an anode effect by variation of pressure.

2. In the presence of aluminum this behavior is not observed; a balance occurs between the growing of the gas bubbles at the electrode surface and the improvement of the evolution process which is now possible since the adhesion energy $W_A = \gamma_{LV}(1 + \cos\theta_G)$ is weaker, the angle θ_G being greater than 90° (Fig. 5). This observation may be compared to the process indicated by Jansen at a gas-evolving electrode (23).

Even in this favorable case no linear dependence of $i\tau^{1/2}$ on c is obtained. This may be first attributed to the variation of D *vs.* c; as indicated by Desclaux and Rolin (24) a decrease of 25% is observed when c varies from 0 to 6%. This effect is almost sufficient to explain the variation of $i\tau^{1/2}$ when a medium porosity graphite (No. 208 Carbone Lorraine) is used as anode in a cryolite bath in the presence of aluminum. However a partial covering of the electrode surface remains as indicated on the curve of Fig. 6, the higher the

alumina concentration the greater this effect. As indicated in a previous paper (5) the chronopotentiometric response may be qualitatively improved by use of an ultrasonic vibration of the electrode.

Hollow-anode.—In the absence of aluminum an efficient method of obtaining a correct chronopotentiometric response is to use a hollow graphite anode [thickness of the wall: 1 mm (11)]. When a depression is created in the central part of the electrode the gas bubbles completely disappear. As a consequence Sand's law is quite well obeyed and chronopotentiometry may be used to determine the variations of alumina concentration with good accuracy (5). However this technique does not work when aluminum metal is present in the bath. As already pointed out the electrolyte wets the graphite and flows through the wall of the electrode.

Influence of dissolved metal.—It appears that the dissolved metal plays an important role in the electrolysis of alumina: (*i*) it changes the wetting properties of the electrolyte. The preceding study shows (Table I) that this phenomenon very much affects the gas covering of the electrode and the local current density; (*ii*) it has also a direct influence on the faradaic yield of the cell; the metal may be oxidized either by the carbon dioxide (9) or directly on the anode (25). This last contribution is studied hereafter.

Influence of a Small Oxidation Current

The galvanostatic pulses are now performed on an electrode submitted to a small direct anodic current i_p, the applied voltage is always less than 1V (*vs.* the Al^{+++}/Al electrode). As indicated in Fig. 7 and Table II, the presence of this current induces shorter transition times. This effect is in agreement with the prediction of the gas wetting model described above; the dissolved metal has a favorable influence on the gas evolution and improves the area of the active surface of the electrode. Since the anodic current i_p creates a depletion of the metal concentration near the electrode its influence vanishes progressively. The adhesion energy of the gas bubbles becomes greater, the covering of the electrode increases and thus, for a given galvanostatic pulse i, the transition time is shorter. It happens that for a critical value of this small anodic current $i_{p,c}$ = 39 mA cm^{-2} the electrode becomes completely inactive as shown on the curves of Fig. 7. This phenomenon corresponds to an anode effect obtained by variation of the wetting properties, in agreement with the extensive studies of Mazza, Pedeferri, and Re (26).

As a first approximation we consider the preceding critical current density as being equal to the limiting

Table I. Coefficient $\nu = S_a/S$ for different experimental conditions: Graphite anode (quality No. 208), T = 1036°C, c = 1% Al_2O_3, $D = 2.42 \times 10^{-5}$ cm^2/sec (24), S_a = active surface; S = geometric surface of the electrode

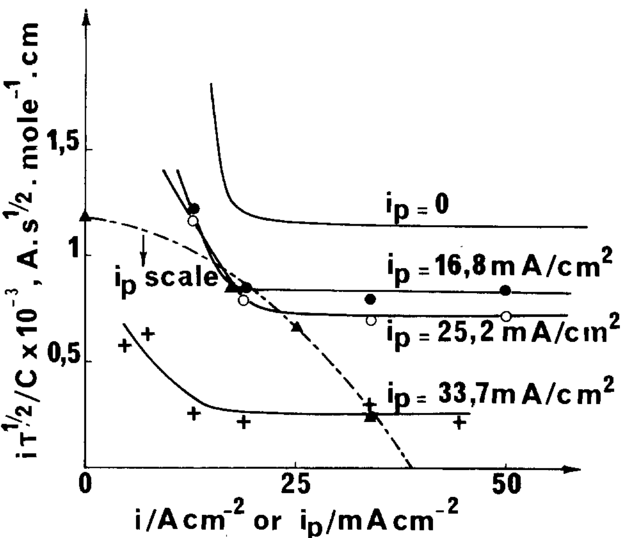

Fig. 7. The effect of the continuous galvanostatic current i_p on the plots $i\tau^{1/2}$ c^{-1} vs. i. Dashed line: evolution of the plateau value of the preceding curves when i_p is varied. Electrode: graphite 208; cryolite bath with dissolved aluminum at 1036°C.

diffusion current of the dissolved metal. According to Vetyukov and Dyblin (27) the aluminum solubility is $C_s = 2.56 \times 10^{-4}$ g-equiv. cm^{-3} at 1036°C; the same order of magnitude is also given by Yoshida and Dewing (28). The activity a_{Al} of aluminum in the aluminum-copper alloy being known [$a_{Al} = 0.48$ in the alloy 40% Al-60% Cu (10)], the concentration of dissolved aluminum is proportional to $a_{Al}{}^x$ (27), with $1/3 < x < 2/3$. The introduction of the x exponent, which is equal to $x = 0.483$, is due to existence of the reactions (27)

$$Al + 3Na\,F \rightleftarrows Al\,F_3 + 3\,Na$$

$$2Al + Al\,F_3 \rightleftarrows 3\,Al\,F$$

In our working conditions, the concentration of dissolved aluminum is then equal to

$$C_{Al} = C_s \cdot a_{Al}{}^x = 6 \times 10^{-5} \text{g at cm}^{-3}$$

Now, for a thickness of the diffusion layer estimated at 100 μm (29) we find for the diffusion coefficient of the dissolved metal $D_{Al} \simeq 2.3 \times 10^{-5}$ cm^2 sec^{-1}. This result agrees quite well with voltamperometric measurements of Saget *et al.* (9) who found $D_{Al} = 2.10 \times 10^{-5}$ cm^2 sec^{-1}. These values are of the same order of magnitude as the diffusion coefficients of the other components of the melt (3); moreover the observed limiting diffusion current is in good agreement with the value indicated by Thonstad (30). However larger values of D_{Al} have been recently reported by Vetyukov and Dyblin (27), $D_{Al} = 61.8 \times 10^{-5}$ cm^2 sec^{-1} as well as by Dewing and Yoshida (31), $D_{Al} = 28 \times 10^{-5}$ cm^2 sec^{-1}. New investigations are still needed for the precise determination of the content and diffusion constant of dissolved metal in cryolite.

Conclusion

The study of the anodic reaction of alumina in a cryolite bath indicates the considerable influence of the dissolved aluminum metal which changes markedly the interfacial properties of the melt. Indeed the metal may form an aluminum carbide (32) at the surface of the electrode. A detailed study of this reaction has recently been carried out by Grjotheim, Naeumann, and Øye (18), it is shown that the carbide formation is highly dependent on the surface properties of the carbon material.

Moreover, the graphite acts also as a depolarizer for the sodium deposit which forms interstitial compounds (33). In a cryolite bath the aluminum metal reduces the sodium ion in presence of carbon. As an illustration of this process we have observed that in our cell, under a dry argon atmosphere, when aluminum is introduced in the cryolite bath directly placed in a graphite (or vitreous carbon) crucible, drops of sodium metal rapidly appear on the cold parts of the cover of the cell. This may be compared to the primary sodium deposit on graphite which is observed during the starting period of the industrial cell (34). This surface reaction strongly affects the wetting properties of the graphite; in the presence of aluminum the penetration of the electrolyte in the graphite pores becomes important. The chronopotentiometric measurements illustrate this surface variation; they establish also a useful connection between the electrochemical behavior of the system and the important problem of the gas retention at the electrode surface.

Technical Note

Cathodoluminescence of $(Zn + Mg)_3(PO_4)_2:Mn^{2+}$

W. Lehmann*

Westinghouse Research and Development Center, Pittsburgh, Pennsylvania 15235

Cathodoluminescent zinc-magnesium phosphate phosphors activated by Mn^{2+} are well-known (1-3). $Zn_3(PO_4)_2:Mn^{2+}$ had been used as red phosphor component in the early days of color television and is still available as P-27. The latter is reported to show, after excitation by short electron beam pulses, near-exponential afterglow requiring approximately 27 msec to 1/10 of the original (4). We observed a substantially longer decay time, also near-exponential, in Mn-activated intermediate zinc-magnesium phosphate of the approximate composition $ZnMgPO_{4.5}$. According to a published phase diagram (3), a chemical compound of this composition does not exist. A brief investigation was initiated to determine the origin of the long decay time.

The phosphors were prepared by standard techniques. The starting materials (ZnO, MgO, $MnCO_3$, and H_3PO_4-solution) were mixed in aqueous slurries which were then dried and pulverized in a mortar. These powders were fired in open quartz containers in stagnant air for one to several hours. The firing temperatures depended on the material and were in the 900°-1150°C range. Emission spectra were measured under steady excitation by 8 kV electrons of low intensity (about 1 $\mu A/cm^2$). The spectra given in Fig. 1 are corrected for monochromator transmission and photomultiplier response. Efficiencies were compared, also under 8 kV excitation of low intensity, against NBS-1025 which is a $Zn_3(PO_4)_2:Mn^{2+}$ phosphor reported to have an efficiency of about 6% (5). Decay curves were determined by exciting the phosphors with 1/10 sec e-beam pulses and by using the photocurrent for vertical deflection of the beam of an oscilloscope with constant horizontal sweep rate. The curves so traced were photographed and evaluated afterwards.

Starting from the original observation on a material of the mole ratio Zn:Mg:P = 1:1:1, a series of phosphors was prepared with constant 1:1 ratio of Zn:Mg but with different P_2O_5 concentrations. The emission colors of the resulting samples were reddish-orange for the 1:1:1 ratio (that is. $ZnMgPO_{4.5}$) and less P_2O_5, and red for 3:3:4 (that is, the *ortho*-phosphate) and higher amounts of P_2O_5. Typical spectra are shown in Fig. 1. Powder diffraction x-ray spectra of the 1:1:1 and of the 3:3:4 materials both revealed only the *ortho*-phosphate structure with no indication of any undissolved ZnO or MgO. Some decay curves are shown in Fig. 2, and decay times (to 1/10 of the original) and efficiencies in Fig. 3. There is little or no dependence (exceeding the unavoidable scatter) of the added P_2O_5-concentration on the decay but there is a distinct peak of the efficiency close to the composition of the *ortho*-phosphate. We conclude that the compound responsible for the long decay is the *ortho*-phosphate.

A second series of phosphors, all *ortho*-phosphates, was prepared with varied Zn:Mg ratio. Decay curves of these phosphors are shown in Fig. 4. X-ray powder diffraction spectra indicated the sample corresponding to the top curve in Fig. 4 to be β-$Zn_3(PO_4)_2$, all others had $Mg_3(PO_4)_2$-structure. It is seen that the long decay is restricted to the $Mg_3(PO_4)_2$ crystal structure.

A third series was prepared of the 3:3:4 composition ratio (*ortho*-phosphates) with varied Mn-concentrations, the Mn^{2+} substituting for the Zn^{2+} ion. Some

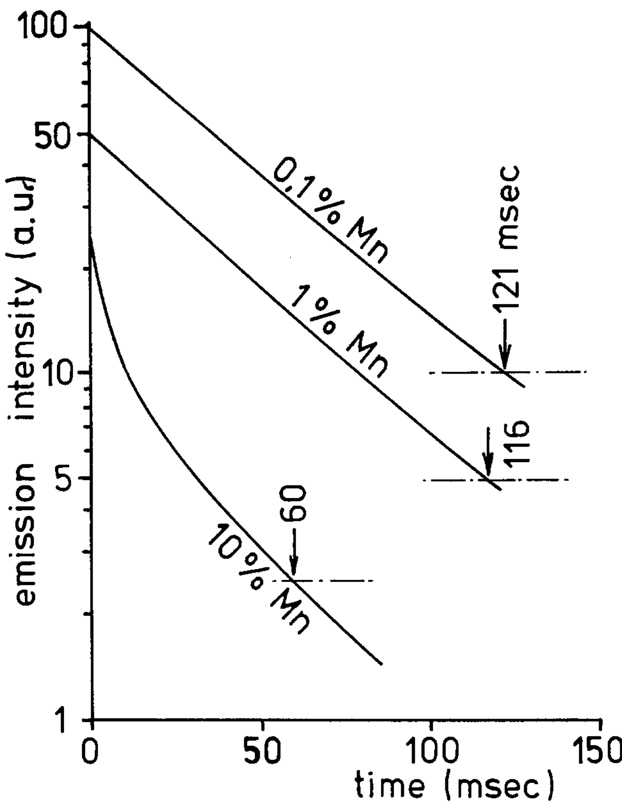

Fig. 5. Decay curves of $(Zn_{1/2} + Mg_{1/2})_3(PO_4)_2$:Mn. The Mn-concentrations are in % of the Zn. Curves are arbitrarily shifted vertically to provide clarity. Arrows indicate decay times to 1/10 of original.

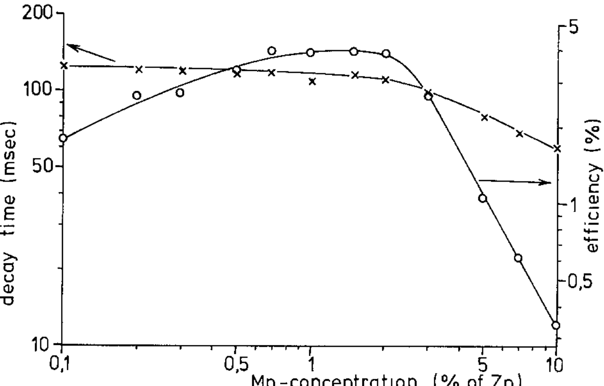

Fig. 6. Efficiency of cathodoluminescence and decay times (to 1/10 of original) of $(Zn_{1/2} + Mg_{1/2})_3(PO_4)_2$:Mn as functions of the Mn-concentration.

decay curves are shown in Fig. 5, and decay times and efficiencies in Fig. 6. The decay is near-exponential at low Mn-concentrations requiring slightly more than 100 msec to go to 1/10 of the original. The deviation from the exponential at high Mn-concentrations may be due to a Mn-Mn interaction which also causes the rapidly decreasing efficiency in this range.

While intermediate $(Zn + Mg)_3(PO_4)_2:Mn^{2+}$ phosphors per se are fairly well-known, it seems that their peculiar long times of near-exponential afterglow have not been recognized before. We cannot offer an explanation why these materials do show this long decay while the related $Zn_3(PO_4)_2:Mn^{2+}$ does not. However, we suggest that orange-to-red emitting $(Zn + Mg)_3(PO_4)_2:Mn^{2+}$ phosphors may be valuable for use in CR-tubes where long decay is desired but where fluoride phosphors (P-12, P-19, P-33, P-38) cannot be tolerated because of their stong tendency to electron burn. Although we have no quantitative data yet on the burn resistance of the phosphates, qualitative observations in this laboratory have shown that they are very much more stable than the fluorides. The decay times of the phosphates (~100-120 msec to 1/10) are shorter than those of the fluorides (~200 msec in P-33) but this appears to be compensated by the higher efficiencies of the phosphates (~4% so far) over the fluorides (~2%). How much the phosphates can still be improved in long decay and efficiency is not known, but it appears unlikely that the optimum has already been reached.

A Correlation Between Etch Characteristics of GaAs Etch Solutions Containing H_2O_2 and Surface Film Characteristics

E. Kohn

AEG-TELEFUNKEN Serienprodukte AG, Semiconductor Division, D-7100 Heilbronn, West Germany

Several authors have investigated surface contamination of GaAs after chemical treatments (1-5), and surface layers of various compositions and thicknesses have been found, as well as a change in the interfacial stoichiometry of GaAs.

In this note we discuss the influence of such surface layers in respect to the etching behavior of a number of commonly used GaAs etch solutions containing H_2O_2 as listed in Table I. Recently, most attention has been given to very slowly etching solutions, which give a highly polished and flat surface, mainly because such a solution is needed in many device fabrication process steps. However, no systematic investigation has previously been carried out on the influence of a possible surface layer on the etching characteristics of these solutions. These layers being present during the etching process may afterwards be very disadvantageous when the etching step is followed by a Schottky-metal evaporation or ion implantation. In solutions of low H_2O_2 content and high H_2O content, two types of etching behavior are observed apart from preferential anisotropic etching (9): (*i*) an H_2O_2-diffusion limited type giving enhanced etching at the mask edge, because additional H_2O_2 is provided from the protected area; and (*ii*) a surface reaction limited type resulting in the desired flat bottomed profile.

Experimental

The etching solutions selected, together with the composition ranges, are listed in Table I. Emphasis is on slow etching rates below 1 μm/min and on solutions leaving a mirror-like surface on polished substrates. The etching experiments were generally carried out in unstirred solutions at a temperature of $\theta = 21° \pm 1°C$. For the H_3PO_4 solution (F) the temperature was lowered to 15°C because the etched surface may turn rough at higher temperatures (8).

The substrates were (100) oriented and of horizontal boat-grown material with an n-doping concentration in the range of 10^{16}-10^{18} cm^{-3}. In some cases Cr-doped semi-insulating material was additionally tested and no difference was observed in the etching behavior or surface layer characteristics within the typical spread of the data. For GaAs, it is well-known that etching characteristics depend strongly on the surface orientation. Thus, etching speed is dependent on the crystal orientation and under certain conditions surface roughening can be expected. However, the etch solutions used here all produced smooth surfaces on the (100) oriented samples at least up to an etched depth of approximately 1 μm, with some just noticeable roughening, especially due to dislocations, for longer etching times. The protected areas were covered with Pizein wax (Pizein 105 produced by the New York Hamburger Gummi-Waren Compagnie). Starting condition was always a surface cleaned by etching with H_2SO_4-solution C of 8:1:1 composition at 60°C for 3 min followed by a 3 min treatment in HCl, giving a surface layer of 10-15Å. After etching, the samples were rinsed for 3 min in deionized water and then flushed with hot chloroform.

Key words: semiconductor topography, contamination, ellipsometry.

The etched profiles were measured with a Dektak profiler (manufactured by the Sloan Corporation). The surface layer was characterized by ellipsometry at $\lambda = 5461$Å and measured immediately after etching. For the calculations of film thickness and refractive index (which was assumed to have no imaginary component), a GaAs reference index of $n_{GaAs} = 4.065 - j\,0.304$ was taken (5).

Results

The results are listed in Fig. 1-5. Figure 1 gives two examples to illustrate the surface smoothness and the two types of etching profiles considered here by a depth profile trace. Figure 2a and b shows the surface layer thickness and refractive index *vs.* rate after 2 min etching time for the various etching solutions. The etching rate Δ_∞ is determined from an etching depth at an appropriate distance from the mask edge to

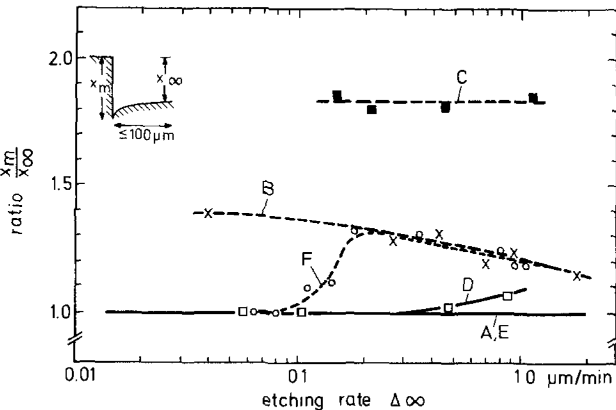

Fig. 3. Effect of enhanced etching at the mask edge vs. etching rates.

exclude the H_2O_2 diffusion effects from the protected area. For each point, at least two independent measurements were taken and the lowest film thickness listed. The spread of the data is typically within 20% for rates $\Delta_\infty > 0.1$ μm/min, but much higher for lower rates. The corresponding profile topology, *i.e.*, the H_2O_2 diffusion effect is characterized in Fig. 3 by taking the ratio of the enhanced depth at the mask edge to the depth at an appropriate distance from the edge as indicated. Further, the development of the film thickness with increasing etching time is shown in Fig. 4. Figure 4a summarizes the behavior of solutions A, B, E, and F: Fig. 4b shows the behavior for the H_2SO_4 solution D and the influence of an additional HCl treatment. The etching rates are thereby correlated to the H_2O_2 concentration as seen in Fig. 5, all results at 21° ± 1°C.

Taking the various parameters considered as surface contamination, etching rates, etched profiles, and H_2O_2 concentration, it is possible to list a number of general tendencies:

1. A thin surface layer is connected to a pronounced H_2O_2 diffusion effect.
2. No etchant with surface reaction limited behavior is found with a surface layer thickness below 40Å.
3. It takes a few minutes time until the dynamic equilibrium between etching rate and surface layer thickness is established. In most cases the surface layer is built up slowly.
4. In all solutions with low H_2O_2 and high H_2O content the etching rate is roughly proportional to the mole percentage of H_2O_2 content and thus determined by the H_2O_2-GaAs reaction.
5. The overall refractive index stays between that of GaAs (5) and that of native oxide (6), decreasing for thicker films. The high values indicate metal-rich compounds.

The change from the diffusion-limited case to the flat-bottomed profile case corresponding to the build-up of a surface layer can be observed with the H_3PO_4 solution F. The transition occurs at an etching rate of around 0.1 μm/min, and no reproducible etching rates were measured in this region. The same tendency is seen for the H_2SO_4 solution when changing from composition C to D. In the case of composition C, the reaction is determined by the H_2SO_4 part, which is bivalent, and the H_2O_2 diffusion in the solution. This gives a subsquare behavior in the etching rate *vs.* the H_2O_2 concentration relationship. Therefore, the enhanced etching at the mask edge is very pronounced. In contrast to this, changing to the weak H_2O_2 concentration

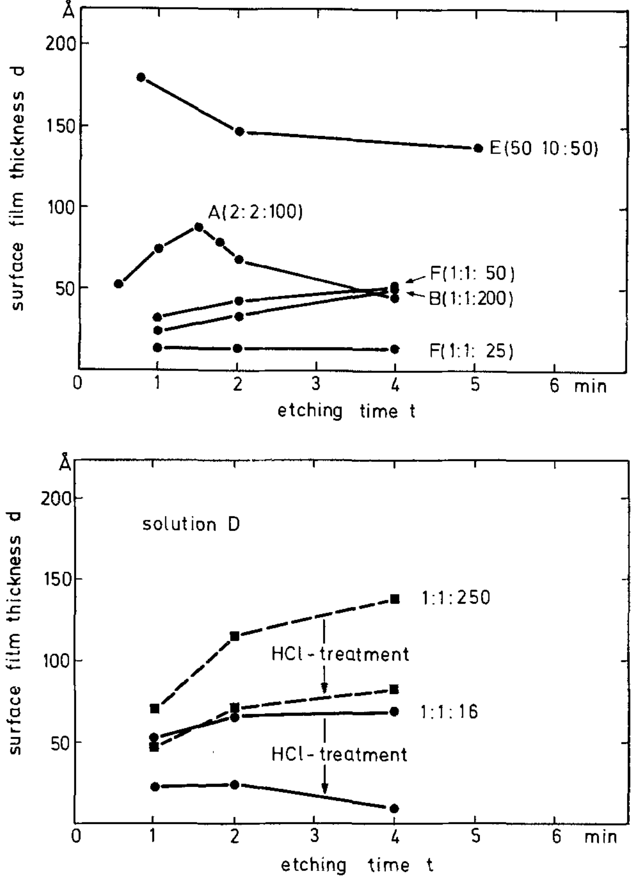

Fig. 4. (a) Evaluation of the film thickness with etching time and (b) the additional influence of an HCl treatment after etching by the H_2SO_4 solution D.

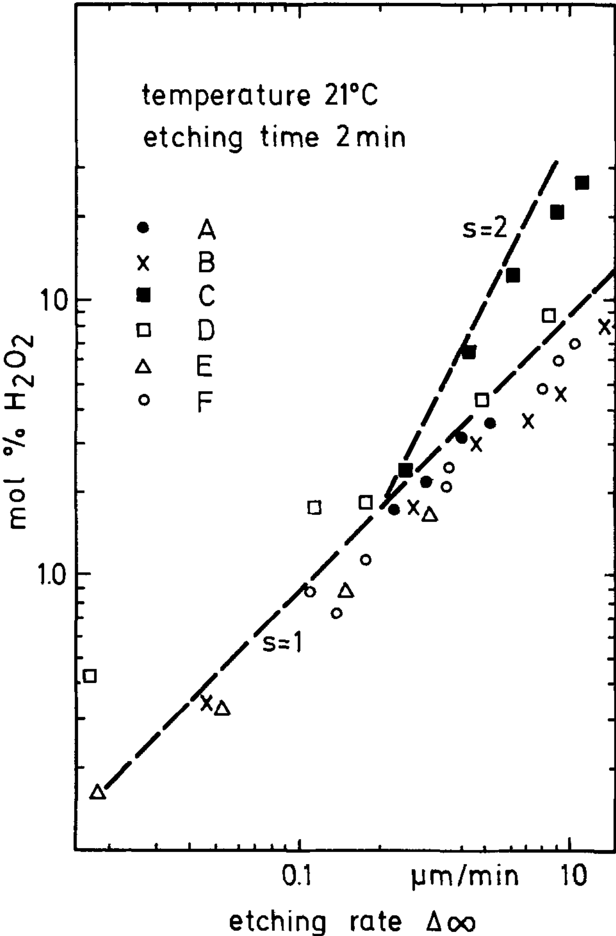

Fig. 5. Correlation between H_2O_2 content and etching rates for the various solutions.

causes the enhanced etching at the mask edge to disappear but at the same time creates a surface layer. The etching rate is now determined by H_2O_2 concentration and diffusion in the surface film.

Etch solution E (citric acid) shows an unusual behavior: the surface film thickness increases with etching rate, but decreases with etching time. However, the film is very porous, and weakly bonded to the surface, and can even be wiped off by a cotton bud.

It was further found that additional treatment in hot HCl, which removes native oxide rapidly, generally does not reduce the film thickness by more than 20% except for the film left by the H_2SO_4 etchant D. This case is additionally indicated in Fig. 3b.

Discussion

In Ref. (8) a general model is given for the etching process of GaAs for mixed solutions containing H_2O_2 and H_2O. The various reaction steps are listed and, for the case of low H_2O_2 and high H_2O contents, the H_2O_2 adsorption to the active centers of the GaAs surface was proposed to be the rate-determining factor.

However, this picture seems to be oversimplified. The etching rate is indeed roughly proportional to the H_2O_2 concentration for all solutions. But by plotting the data carefully, a more or less pronounced sublinearity can be observed [see also Ref. (4)], certainly due to the H_2O_2 diffusion effect, either in the etch solution or in the surface layer. For flat-bottomed profiles, it seems necessary to have a diffusion barrier between etch solution and GaAs surface. Most likely, GaAs is oxidized by the H_2O_2 to form a native oxide, which is highly soluble in the etch solution (all solutions used can etch anodic oxides very quickly). In contrast, the surface layer found cannot be dissolved in HCl or HF. Possibly this layer is formed by a preferential and complex reaction also involving the acidic part of the solution. In some cases, the layer seems to be very porous and unstable. Clearly, a constant etching rate, especially for the first minutes, cannot be expected for these cases, even when starting with a clean surface. This may explain the spread of the data in Fig. 4.

The usefulness of such surfaces for device applications, as for instance Schottky-metal deposition, seems mainly to depend on the composition of this layer and whether or not it can be consumed in an annealing process. Indeed, best Schottky-barrier characteristics are achieved after short forming processes. Further investigations in this direction are being undertaken.

Post Field Recombination in the Pulsed Electroluminescence of Zinc Sulfide

M. S. Waite* and A. E. Thomas**

Division of Materials Science, Thames Polytechnic, London, SE18 England

Direct current electroluminescence in ZnS:Mn powder panels (i.e. "Vecht-type") is now an established display technique(1-3). In contrast to the bright yellow-orange luminescence of the Mn doped phosphors, undoped zinc sulphide powder phosphors when prepared as electroluminescent panels in exactly the same way give a very weak, but spectrally broad, emission (Fig. 1, spectrum a-b) (4). The bands stretch from ca. 330nm, the cut-off point of the conducting glass substrate on which the powders are deposited, to ca. 700nm. During the examination of the decay characteristics of undoped zinc sulphide, an additional radiative recombination process was observed, with characteristics as discussed below.

The material used for the preparation of the phosphors was luminescent grade ZnS, from Levy West Ltd., muffle-fired to 950°C and washed with acetic acid before use. The powder was washed in cupric chloride solution, deposited in conducting glass strips, and an Al back electrode was evaporated on exactly as published for ZnS:Mn phosphors (1). The thickness of the powder layer was about 200 microns and the phosphor was formed to 100 V dc before examination of the response to pulsed excitation. The phosphor was not deliberately doped, but contains chlorine and sub ppm traces of Mn.

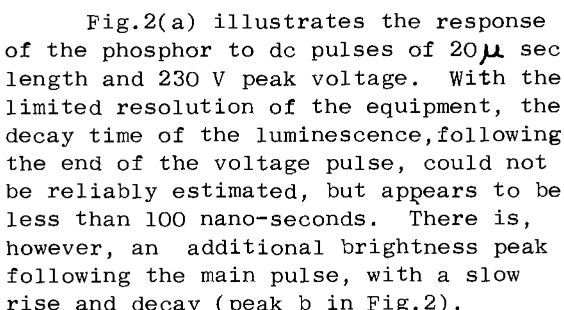

Fig.2(a) illustrates the response of the phosphor to dc pulses of 20μ sec. length and 230 V peak voltage. With the limited resolution of the equipment, the decay time of the luminescence, following the end of the voltage pulse, could not be reliably estimated, but appears to be less than 100 nano-seconds. There is, however, an additional brightness peak following the main pulse, with a slow rise and decay (peak b in Fig.2).

The rise time, or the delay time between the peak maximum and the end of the voltage pulse is from 5 to 45μ secs., varying with different samples, and the decay time to 1/10 of peak brightness is at least 300μ secs. The ratio of the height of the secondary peak to that of the main peak varies with specimen, voltage and the age of the panel. The longer the panel runs, the less prominent the secondary peak, whilst the primary peak increases with voltage at a greater rate than the secondary peak. The ratio of secondary to primary peak heights is also dependent on the length of the excitation pulse. It is difficult to assess for pulse lengths $<$ 40μ secs., but rises gradually as the pulse length increases (Fig.3). Furthermore, the secondary brightness peak builds up slowly, when the pulsed field is first applied.

By choosing a long pulse length, 200μ sec., a high duty cycle and a low applied voltage, 80 V, it is possible to obtain emission predominately from the secondary peak (see Fig.2(b). Thus, the spectral distribution of this secondary emission could be recorded free from interference by the "in-field" emission. It appears as a band with a maximum at 467nm (curve C, Fig. 1) and is identical to the CL spectrum of the original ZnS phosphor. This corresponds to the well-known S-A emission of ZnS, due to

electron-hole recombination at a zinc vacancy-chlorine complex, Fig. 4(5,6). It seems, therefore, that the post-field emission from undoped zinc sulphide arises from the recombination of an electron with a hole bound to a V_{Zn} - Cl site in the lattice. The slow rise in appearance of this emission following the end of the main pulse, may be due to the slow diffusion of electrons as the space charge created by the voltage pulse decays, or the thermal release of electrons from other traps in the phosphor. The secondary emission disappeared when the pulsed field is applied at 77°K and was not observed in ZnS refired in H_2S and lacking the S-A photo or cathodo luminescence. We suggest, therefore, that the self-activated centre is ionised by the field in the formed layer or by collision ionisation, leaving a hole bound to the V_{Zn}-CL complex and an electron which is trapped elsewhere. The slow rise in appearance, over several minutes, of the secondary peak after the pulsed field is initially applied may be due to the slow creation of trapping centres for the electrons.

By measuring the intensity of the emission in the secondary peak, and assuming each recombination is radiative, with negligible self-absorption, an approximate estimate of the number of ionised centres can be made. For a sample operated at 105 V with a 140μsec. pulse width and a frequency of 200 Hz, a recombination rate of 10^{12} sec^{-1} out of phase with the field was estimated, or 5 x 10^9 recombinations per cycle. The thickness of the formed layer was determined as 3μ from capacitance measurements, compared with 2 μ found in ZnS / Mn panels (1). This would give an estimated density of ionised centres of ca. 5 x $10^{19} m^{-3}$ in the formed layer following each voltage pulse.

Similar explanations have been proposed for the brightness peak observed during square wave excitation of copper doped zinc sulphide phosphors as the field is turned off, for example Zallen et al(7). In that case, however, the spectral distribution of the"post-field" peak was the same as that of the brightness observed at the start of the pulse. In these undoped zinc sulphide phosphors, the fast decay of the primary emission observed during the pulse and the quenching of the secondary emission as the field is re-applied (see Fig. 2b) suggests that the recombination process represented by the secondary peak does not also occur whilst the field is on. Thus, doubt is cast on models for dc electroluminescence which involve energy transfer to Mn^{2+} from electron-hole recombination at defect centres, such as the S-A centre. In addition, the difference between the emission spectra arising from continuous dc excitation and the spectra of the recombination process is further evidence that the broad bands, or "avalanche spectra observed during dc excitation of the undoped ZnS have an intra-band or intervalley origin (8).

Silicon Dioxide as Masking Film in Alkaline Etching

Irene Barycka and Helena Teterycz

Instytut Technologii Elektronowej, Politechniki Wroclawskiej, Wroclaw, Poland

Anisotropic etching of selected areas of silicon surfaces in alkaline solutions is often applied in technology of silicon semiconductor devices, for example for making grooves, dividing structures, or in production of thin silicon membranes (1-5). In the two last examples, when a large etch depth *ca.* 200 μm is needed, the etch resistance of the masking film is of special importance. The use of SiO_2 films made by silicon wafer oxidation as masking material is well justified for technical reasons. Selected areas of the surface are exposed to etching solution by simple photolithography. It should be emphasized that the shape of hole or groove, especially in the case of deep etching, depends much more on the crystal strucutre than on the precision of lithography.

The etch resistance of SiO_2 to organic bases is reported by Finne and Klein (6). The rate of this etching is as low as $3.5 \cdot 10^{-4}$ μm/min.

This communication presents the results of investigations on SiO_2 etch resistance to 30 w/o NaOH. Since NaOH is much cheaper and easily handled, its use is fully justified as a substitute for organic bases.

SiO_2 films of 0.5 and 1.3 μm thickness were produced by oxidation of silicon wafers in wet oxygen at 1373°K. It appears that films prepared on smooth, polished, or rough silicon surfaces did not differ in their masking ability.

The wafers under study were mounted on rotating disk (250 rpm) and etched in 30 w/o NaOH in the temperature range 350°-373°K. Etching rate *vs.* reciprocal temperature is plotted in Fig. 1. The calculated activation energy obtained in this same way for silicon is 62-64 kJ/mol. Another interesting result obtained is the ratio of etching rates for slowly etching <111> and SiO_2. This is shown in Fig. 2. The results obtained allow one to choose an optimal safe thickness of masking film for silicon etching to the required depth. In the conditions reported, the ratio of Si <111> to Si <100> etching rate is 1:6.6.

The examined SiO_2 films were successfully used as masking material in thin silicon membranes production (7) and in other similar operations

Abstract

We have found that reactive neutral fragments, generated by multiple infrared photon dissociation of various molecules with a CO_2 laser, are capable of etching silicon oxide or nitride surfaces. The laser-generated radical etching process has a potential for major commercial impact, by eliminating ion-bombardment damage in the resulting semiconductor device and by permitting more efficient and selective etching to be performed. In addition, this provides an investigative tool for learning the precise identity of the active species, the extent of their interaction with the substrate surface, and the rates of the key steps in the reactions resulting in net removal of silicon.

Introduction

In the reactive ion etching process, which is in wide current use for processing of semiconductor devices[1,2] an etch gas such as CF_4 or CHF_3 is dissociated by an rf plasma in a chamber containing the wafers or other workpieces. The resulting fragments then react with the exposed surface of the material. One problem associated with this process is that the charged particles present in the plasma induce radiation damage in the material being etched[3]; eliminating this damage often requires an additional annealing step in the manufacturing process. Also, the presence of a large number of species in the reactive plasma makes it difficult to establish the mechanism of the etching reactions in any detail[4].

We have found that etching of SiO_2 surfaces can be accomplished by dissociating a suitable etch gas with a high-power infrared laser, when the beam is focussed near but not directly on the surface. This differs from the usual type of laser-annealing process[5], in which the sample surface is directly heated by the laser radiation. CF_3Br was chosen as the etch gas, since it is easily dissociated by using a CO_2 laser[6].

Experimental Results

Initial irradiation was carried out with a Tachisto 215-G TEA CO_2 laser (line-tunable, 0.2-1.5 J/pulse, 45-nsec pulse width, 1 Hz pulse repetition rate). The surface of the substrate in the test chamber was positioned $\sim$ 1 mm away from the focal volume of the laser beam. In a typical result, a sample of silicon dioxide (deposited on a silicon substrate by reaction of SiH_4 + N_2O at 900°C) was etched in an atmosphere of 5.5 Torr CF_3Br. 1200 pulses of the CO_2 laser [R(28), 00°1-02°0 line at 9.23 μm, 0.4 J/pulse] produced an etch depth of 350 Å, as determined by a scanning stylus-probe step-height technique. Silicon nitride samples were also tested, and other etch gases (CF_2Cl_2, CDF_3) were employed; positive evidence of etching was obtained in most cases. Additional surface diagnostics on these samples are being carried out at the present time.

Discussion

The 1200 pulses necessary to achieve an etch depth of 350 Å required 20 minutes irradiation time with a 1-Hz laser. While in absolute terms this appears to be a slow etch rate, some analysis is required to understand the true significance of this result. The 1200 x 45-nsec laser pulses correspond to only 54 μsec of laser "on"-time. A more pertinent time scale is the exposure of the substrate surface to the active species, CF_3. Benson[7] gives the bimolecular recombination rate for CF_3 radicals as $k = 1.7 \times 10^{10}$ liter mole^{-1} sec^{-1} at 300°K. Since about 10% of the total CF_3Br (5.5 Torr) was dissociated by each pulse, the mean CF_3 lifetime can be estimated as $t_{1/2}[CF_3] = 1/[CF_3]_0 \times k_{recomb} \approx 1.5 \times 10^{-6}$ seconds; thus, the total exposure time is 1200 x 1.5 μsec ≈ 1.8 msec. Thus, the true "etch rate" is on the order of 350Å/1.8 x 10^{-3} sec ≈ 200,000 Å/sec ≈ 12,000,000 Å/min. This is spectacularly greater than the customary plasma etch rate, which at best is about 2000 Å/min.

In practical terms, the 1200 laser pulses could be delivered by a 200 Hz TEA CO_2 laser(8) in 6 seconds, giving an overall etch rate of 3500 Å/min. This is already quite comparable with current technology in this area, and points up the importance of using a high-repetition-rate laser for further studies of these phenomena. The reaction volume associated with the focussed laser beam can be expanded by suitable optics(9) to permit exposure of a standard 3-4" wafer to the reactive species, although the extent to which this is feasible will be limited by the threshhold fluence requirements for the multiphoton dissociation.

Further development of this laser-generated radical etching technique should lead to a new "dry" processing method which will eliminate compromise of device performance resulting from radiation damage, and also lead to more rapid and selective etching. A possible limitation to this process, which requires further investigation, is the degree of etch anisotropy which can be produced by neutral instead charged species bombarding the surface of the material. Since the laser produces only a single reactive species (e.g., CF_3, CF_2, F, or the like), at a high concentration and also highly localized in time and in proximity to the surface, a detailed mechanistic study of the surface reactions leading to etching can be carried out.

A Different View of the Tafel Equation in Electrode Processes

Akira Doi

Department of Inorganic Materials, Nagoya Institute of Technology, Nagoya 466, Japan

At not too low overvoltages ($|\eta| > RT/zF$), any electrode process satisfies the Tafel equation (1)

$$\eta = a - b \log_{10} i \qquad [1]$$

where i is the current density, a and b the Tafel constants, R the universal gas constant, z the valency, and F the Faraday's constant. Although a number of papers deal with Eq. [1] (2), many of them presuppose thermal excitation processes for charge transfer to occur. Even a quantum-mechanical interpretation in terms of electron-tunneling requires thermal rearrangement of solute molecules in the vicinity of relevant electrode (3,4). The purpose of the present note is to suggest an alternative that the Tafel equation can be obtained without reference to thermal equilibrium of the form

$$O + ze \rightleftharpoons R \qquad [2]$$

where O and R are two oxidation states. For convenience sake, only cathodic polarization ($\eta < 0$) is considered.

Recently, it is inferred (5) that the neutralization process of alkalis in alkali silicate glass is due to tunneling of electrons through the potential barrier in the space charge-cathode double layer, and that the neutralization probability comes close to unity with increasing i, although it depends strongly on the work function of the cathode and perhaps on what the charge carriers are. In alkali silicate glass a potential drop appears in the alkali-depletion layer near the anode (5), whereas in liquid electrolyte having two mobile carriers of the opposite sign, large potential drops are developed on both electrodes and overwhelm a potential drop across the electrolyte. If the neutralization probability of negative charge carriers on the anode is unity as positive charge carriers on the cathode do, that is, if no space charges are left unneutralized on both electrodes, the polarization potential at the cathode is about $-V/2$, so

$$\eta \approx -\frac{V}{2} + E_e \qquad [3]$$

where V is an applied voltage, and E_e is the equilibrium electrode potential. Therefore, for cathodic polarization, η may be equal to an effective potential drop near the cathode. Such a potential drop across the space charge-cathode double layer of an effective thickness d gives an electric field $-\eta/d$ which is sufficient for easy tunneling of electrons to occur.

In these circumstances, since dynamic motion of charge carriers in liquid electrolyte resembles diffusion of constituent ions in solid (6), a theory of ionic conduction in glass (7) can be employed to give the current density as a function of overvoltage, as

$$i = \frac{ne\lambda p}{3} \exp\left[e\left(-\frac{\eta}{d}\right)\frac{\lambda}{2kT} \right] \qquad [4]$$

where

$$p = \nu \exp[-H/kT] \qquad [5]$$

is the jumping probability of charge carriers over an energy barrier H, ν the jumping frequency, n the carrier density, and λ the average jumping distance. Rewriting Eq. [4], we obtain the Tafel equation

$$\eta = \frac{2kTd}{e\lambda} \log_e \frac{ne\lambda p}{3} - \frac{2kTd}{e\lambda} \log_e i \qquad [6]$$

The Tafel slope b is then

Key words: Tafel equation, charge transfer, tunneling.

$$b = 2.30 \frac{2kTd}{e\lambda}$$

$$(= 0.119 \frac{d}{\lambda} \text{ at room temperature}) \quad [7]$$

If $d \approx \lambda$, the value of b is in good agreement with the experimental results for e.g. the hydrogen electrode(2). With decreasing η , the polarization curve deviates from Eq. [1] and i becomes proportional to η , in further coincidence with the theory of ionic conduction in solid.

Semiconductor Electrodes

XXIX. High Efficiency Photoelectrochemical Solar Cells with n-WSe_2 Electrodes in an Aqueous Iodide Medium

Fu-Ren F. Fan, Henry S. White, Bob Wheeler, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

A number of photoelectrochemical (PEC) photovoltaic (or regenerative) cells based on semiconductor electrodes in aqueous and nonaqueous media have been described; see (1-7) and references therein. High solar energy conversion efficiencies in such cells require a semiconductor band gap energy (E_g) which matches well with the solar spectrum, a semiconductor flat-band potential (V_{fb}) and solution redox couple potential (V_{redox}) which maximizes the output voltage, and conditions which minimize recombination processes in the semiconductor and solution and at the interface. The solution redox couple and solvent are selected to stabilize the semiconductor from photoinduced corrosion processes (8,9). The highest published power efficiency for such cells is the 12% reported for a single crystal n-GaAs electrode in a selenide medium (10). We describe here a PEC cell based on single crystal n-WSe_2 which shows comparable efficiencies.

The applicability of the layer-type compounds based on molybdenum and tungsten dichalcogenides (e.g. MoS_2 and $MoSe_2$) as semiconductor electrodes was first described and investigated by Tributsch and co-workers (11-15). In more recent work cells based on p-WSe_2 (16,17) and the dependence of the photopotential on the solution redox couple for n-WSe_2 has been described. These materials appear promising as candidates for practical PEC solar cells because their excitation involves d-d transitions which may provide good stability (12) and because they are relatively cheap and abundant materials. However the performance of cells reported to date have been rather modest. We report here an n-type WSe_2 with a high efficiency.

The n-WSe_2 crystals, grown by chemical vapor transport, were generously donated by Drs. Barry Miller and Frank DiSalvo of Bell Laboratories. They were connected to a copper wire with silver epoxy cement (Allied Products Corp., New Haven, Conn.). Before mounting the crystal, a clean, new crystal surface (⊥ c-axis or van-der-Waals surface) was prepared by sticking adhesive tape on the surface, and then pulling it, along with the surface layer of the crystal, off. The crystal was mounted in 7 mm-diameter glass tubing with all sides insulated with silicone rubber sealant (Dow Corning Corp., Midland, Mich.) leaving exposed the van-der-Waals surface with an area of about 0.017 cm^2. Before use, the electrode surface was etched with 12 M HCl for 5-10 seconds followed by a thorough rinsing with water. The electrochemical measurements followed previous practice (7). The PEC cell consisted of the n-WSe_2 electrode and a Pt foil counter electrode (40 cm^2) immersed in a solution of 0.5 M H_2SO_4, 0.5 M Na_2SO_4, 1.0 M NaI and 0.025 M I_2. The path length from the Pyrex window of the cell to the n-WSe_2 electrode was about 1 cm. The n-WSe_2 electrode was irradiated with light from a 450 W xenon lamp which was passed through a 590-nm cut-on and an infrared (water) filter (i.e., only light of wave length longer than 590 nm irradiated the cell). The intensity at the cell window was 150 mW/cm^2 (which is somewhat higher than the maximum terrestrial solar intensity). Under these conditions I^- is photo-oxidized to I_3^- at the WSe_2 and I_3^- is reduced to I^- at the Pt counter electrode with the passage of an external current. The short circuit photocurrent was about 65 mA/cm^2 and the open-circuit photovoltage was about 0.71 V. The i-V curve for this cell, shown in Figure 1, yields a fill factor of 0.46. The maximum power conversion efficiency under these conditions, without corrections

*Electrochemical Society Active Member. Key words: photovoltaic, energy conversion.

for solution absorbance and electrode and window reflectivities, is about 14%. The short circuit photocurrent was linear with light intensity up to at least 150 mW/cm^2 (Figure 2). Moreover the open circuit photovoltage closely approached its saturation value of 0.7 V at light intensities $\geq$ 10 mW/cm^2. This latter finding and the high fill factor suggests that recombination processes are relatively unimportant for this material. The cell was operated under roughly maximum power conditions for 8 hours. At this time the current and cell voltage were essentially the same as the initial values and the electrode surface showed no apparent change or signs of degradation. (The total amount of electricity passed in this 8-hour trial, about 32 coulombs, would represent on the order of 113 mg of WSe_2 lost, assuming a one-electron process, if a photodissolution process occurred.)

While the results here are of a preliminary nature and we have found some sample-to-sampel variability with WSe_2, they appear to confirm the earlier predictions of Tributsch, et. al. on the potential usefulness of layer-type semiconductors in PEC cells. The nature of the semiconductor surface is also probably of major importance in the attainment of high efficiencies. The investigation of surface pretreatment effects and the application of oriented polycrystalline materials or epitaxial layers of n-WSe_2 in iodide media is currently under investigation.

Acknowledgment.--This work was supported in part by the Office of Naval Research and by the Solar Energy Research Institute (in a cooperative project with SumX Corporation).

Anodic Behavior of Lithium in Aqueous Electrolytes

IV. Influence of Temperature

E. L. Littauer* and K. C. Tsai*

Lockheed Palo Alto Research Laboratory,
Lockheed Missiles and Space Company, Incorporated, Palo Alto, California 94304

ABSTRACT

The influence of temperature on the anodic behavior of lithium in LiOH was studied at constant electrolyte flow velocity, concentration, and contact pressure. It was found that the thickness of oxide film decreases significantly with increasing temperature and the active surface area decreases gradually with increase in temperature. A rate equation for the H_2 e.r. at an anodically polarized Li surface serves to predict the current efficiency at various temperatures. By polarizing the anode, the hydrogen evolution reaction is inhibited and this, coupled with a significant decrease of the surface active area with increasing temperature, explains the stability of the lithium electrode in aqueous alkaline electrolytes. Data on the conductivity of 4.5M LiOH at temperatures from 17° to 64°C are reported.

The rapid dissolution of Li in alkaline aqueous solutions can be utilized electrochemically to produce very high rate batteries. In the Li-H_2O system, the rate-limiting process is the oxidation of lithium rather than the reduction of H_2O at the cathode. A critical examination of the corrosion processes has revealed that the H_2 e.r. at the Li surface is rate-determining, not the Li dissolution reaction (1). Thus, unlike conventional battery systems, in Li-H_2O cells the current efficiency is governed by the ratio of two competing processes, namely, the anodic dissolution reaction and the parasitic self-corrosion reaction (2). The current efficiency increases as the electrode is polarized from its OCV, and it decreases at elevated temperatures where the corrosion reaction is stimulated. One of the most important features of the system is the fact that the maximum current (or limiting current) obtained during anodic polarization never exceeds the OCV corrosion rate. This unusual behavior and the impact of elevated temperature on the faradaic efficiency of the cell are examined in this paper.

Experimental

Details of the electrochemical cell and support equipment have been given previously (1). In summary, the test cell housed a circular 11.4-cm^2 area anode support to which were bonded lithium test specimens. The cathode comprised a wire screen spotwelded to a ribbed iron back plate. Anode-cathode contact pressure was controlled by an air pressure cylinder linked to the anode pushrod. Elimination of the hydraulic pressure component was accomplished by a thrust balance cylinder connected to the inlet and outlet lines of the cell. Electrolyte hydraulic pressure could be varied by a control valve on top of the test cell. A needle point penetrometer was mounted on the cathode compartment such that on activation the platinum-plated steel needle could pass through the matrix and penetrate the anode surface. The penetrometer was instrumented with an impedance meter and linear motion transducer (2). Accuracy of the probe position was within $\pm 10^{-3}$ cm.

Electrolyte flow through the cathode matrix and across the anode face was provided by a micropump and was monitored with a rotameter. Electrolyte temperature was controlled to ±0.1°C by passing it from a reservoir to a constant temperature heat exchanger, and into the cell.

Real time hydrogen rate measurements were obtained using a wet test meter which was modified with an optical encoder connected to a digital/analog converter.

Lithium hydroxide solutions were prepared using reagent grade chemical and deionized water.

The experimental conditions for the sequence of tests reported here were: LiOH concentration: 4.5M, electrolyte flow rate: 30 cm/sec, anode-cathode contact pressure: 6.2×10^4 Pa, and electrolyte temperature: 18°, 25°, 35°, 45°, 55°C.

Polarizations were performed potentiostatically, using a custom-designed 0-10A, 0-10V instrument. Response time was 60 μsec (from no load), input impedance was 1.5×10^{12} Ω, and voltage stability was ±2.5%. The duration of each polarization run was less than one minute. Steady-state conditions were actually achieved within a fraction of a second. Runs were repeated three times for each temperature, reproducibility was within ±5%. Film thickness measurements were repeated six times by rotating the anode through 60° segments.

Anode potentials were monitored with a cadmium (cadmium hydroxide) reference electrode (E° = −0.809V *vs.* NHE).

Electrolyte conductivities were measured at 28°, 38°, 45°, 51°, 55°, and 64°C using a conventional conductivity cell of constant 1.07 obtained by reference to 0.1*N* KCl solution.

Results

The influence of temperature on the anodic polarization of Li in 4.5M LiOH at a constant anode-cathode contact pressure, $P = 6.2 \times 10^4$ Pa and electrolyte flow velocity, $v = 30$ cm/sec is shown in Fig. 1. The OCV values measured here at various temperatures are essentially the same (*i.e.*, within 5 mV) of those obtained in an earlier investigation (1). The polarization curves possess two distinct regions, typified by the curve at 55°C. The initial portion of the curve depicted as a-c is linear. It represents *IR* drop across an essentially invariant protective oxide film layer. The highly polarized curved portion c-l has a configuration which is often characteristic of a limiting current. Over the entire span, a-c-l, it is assumed that the anodic film formation rate is balanced by the film dissolution rate because, as has previously been observed (2), the film thickness is independent of the extent of polarization. Under the experimental conditions specified herein, it was noted that increasing temperature decreased the film's resistance and the maximum current increased markedly with increasing temperature.

From the slopes of the resistive polarization sections of the curves of Fig. 1, a plot of film resistance *vs.* temperature may be obtained as shown in Fig. 2. Temperature dependence of the limiting current density, i_l, derived from Fig. 1, and of the measured corrosion rate at OCV, i_{cor}, are displayed in Fig. 3. i_{cor} increases significantly at elevated temperatures (*i.e.*, > 35°C) while i_l maintains a linear relationship with temperature over the range of this study.

Figure 4 shows that the relationship between anode film thickness and temperature is nonlinear. The decrease of film thickness x_0 with increasing temperature may be associated with the fact that the solubility of LiOH, which comprises the major portion of the oxide film, increases with increasing temperature (3).

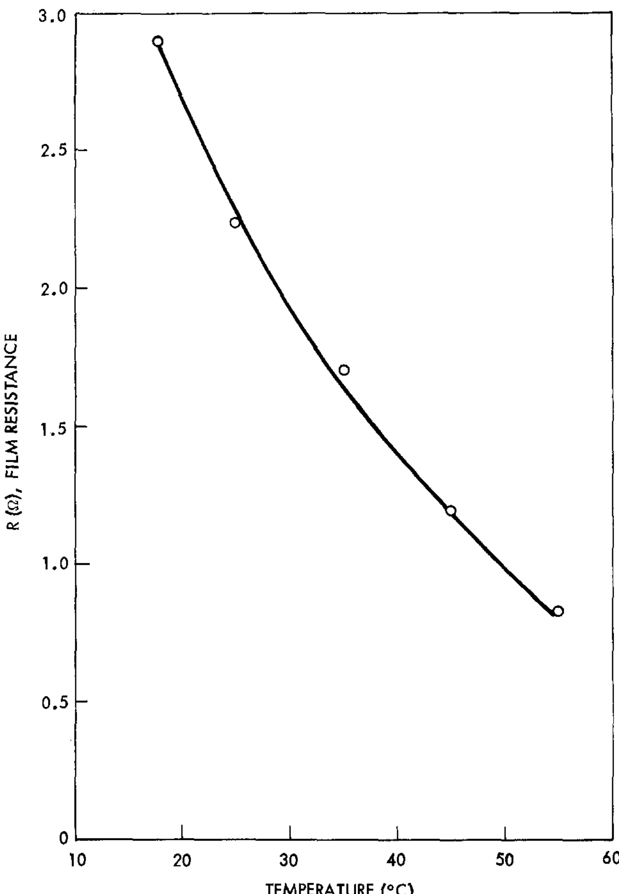

Fig. 2. Influence of electrolyte temperature on anode film resistance in 4.5M LiOH. $P = 6.2 \times 10^4$ Pa, $v = 30$ cm/sec.

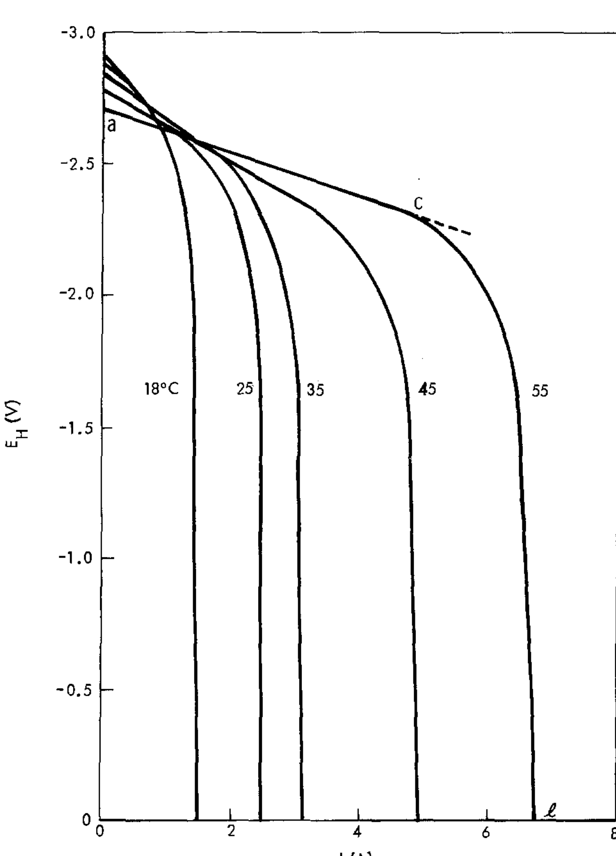

Fig. 1. Anodic polarization of Li in 4.5M LiOH at various temperatures. Anode-cathode contact pressure $P = 6.2 \times 10^4$ Pa, electrolyte flow rate $v = 30$ cm/sec.

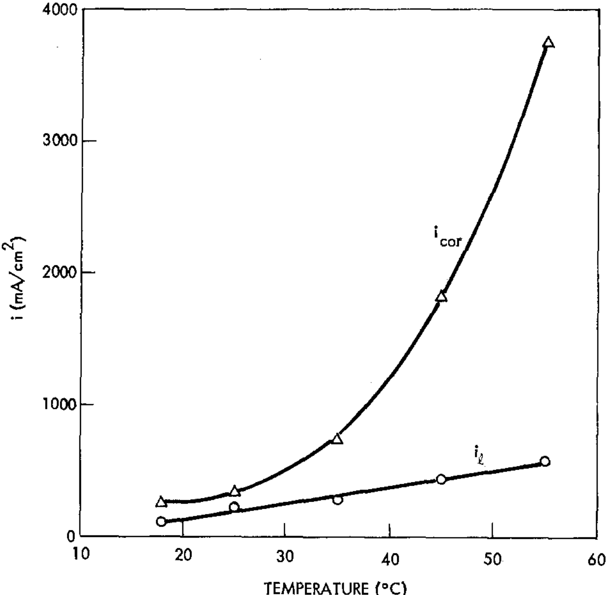

Fig. 3. Li corrosion rate at OCV i_{cor}, and anode limiting current density i_l as function of electrolyte temperature in 4.5M LiOH. $P = 6.2 \times 10^4$ Pa, $v = 30$ cm/sec.

It was found that the variation in film thickness from one 60° segment to the next was somewhat greater at the lower temperatures. Since the film thickness does not change with polarization, it seems reasonable to assume that the solubility of LiOH at various temperatures plays the predominant role in determining the film thickness.

Information on the conductivity of the electrolyte as a function of temperature is required for analysis

of the experimental data. This data is presented in Fig. 5.

Discussion

In strongly alkaline solution, the dissolution of Li, even when under anodic polarization, consists of two competing processes—an electron-producing electrochemical reaction as described by Eq. [1]

$$Li + OH^- \rightleftarrows LiOH + e^- \quad [1]$$

and a direct corrosion (parasitic) reaction as depicted by Eq. [2]

$$Li + H_2O \rightleftarrows LiOH + \tfrac{1}{2} H_2 \quad [2]$$

Strictly speaking, the overall corrosion reaction [2] is a coupling of [1] with the cathodic reduction of H_2O at adjacent sites on the anode surface.

Since the competing reactions [1] and [2] can occur at any polarization level at anode sites, one cannot assume that temperature has identical impact on each. Indeed, Fig. 3 clearly illustrates the difference. On one hand, at OCV where there is no external electron-producing reaction, the corrosion rate i_{cor} follows an Arrhenius exponential dependence (1). On the other hand, when the corrosion reaction is suppressed to a negligible amount by polarizing the electrode, the rate of the electron-producing process, i_l, increases linearly with increasing temperature. Taking a typical polarization curve, such as that at 55°C in Fig. 1, i_{cor} and i_l represent the rates of Li dissolution at points a and l respectively. During normal operation of the Li-H_2O cell, the Li anode is polarized to a level between a-l and the current efficiency of the anodic reaction is always somewhat less than 100%. In an earlier paper, a rate equation for the general case of parasitic hydrogen evolution reaction at a polarized electrode was derived

$$i_{H_2} = i_{cor} \exp\left(\frac{-n\alpha F(E - E_c)}{RT}\right) \quad [3]$$

where E_c is the OCV of the Li at a given temperature; α, the transfer coefficient of H_2 e.r. on the Li surface = 0.14 (1), and the other terms have their usual meaning. The current efficiency for the polarized Li anode is defined as (4)

$$\epsilon(\%) = \frac{i}{i + i_{H_2}} \quad [4]$$

where i represents the rate of anodic reaction. Using Eq. [3] and the data of Table I, and Fig. 1, $\epsilon(\%)$ at different temperatures have been calculated and are shown in Fig. 6. Figure 6 also includes experimental results obtained from the H_2 rate measurements. Although the two curves are not exactly identical, the similarity in their shapes seems to support the validity of the model which holds that the H_2 e.r. is the rate-determining step in the corrosion reactions of Li. It

55	0.623	591	3760	0.018	0.082	0.03

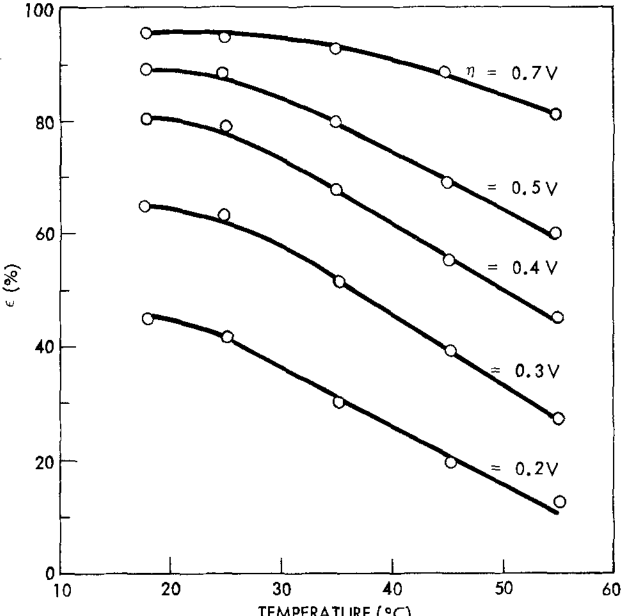

Fig. 7. Effect of anodic polarization on the current efficiency of a Li anode at various temperatures.

should be mentioned that the differences in the curves between the experimental and the calculated results can, with the exception of the 35° data, be eliminated if the value of α is increased from 0.14 to 0.143. In other words, the discrepancy is probably ascribable to errors in the calculation of the H_2 evolution rate using Eq. [3]. It may also be seen from Fig. 6 that by imposing significant polarization, near to 100% current efficiency is obtained. To illustrate the temperature dependence of $\epsilon(\%)$ at various polarization levels, Fig. 7 has been constructed. At elevated temperatures, i.e., $T \geqq 55°C$, $\epsilon(\%)$ is generally degraded due to the very high parasitic reaction rate. Thus, in order to operate the Li-H_2O system efficiently at elevated temperatures, a trade-off has to be taken in the form of additional polarization of the anode to achieve acceptable faradaic efficiency.

Over the span of the active polarization region (curve a-c-l in Fig. 1), steady-state conditions are observed. It is conceivable that in this region a quasi-equilibrium state exists between active and inactive sites. A simplified model of the system indicates that the fraction of active sites, $1 - \Theta_o$, may be related to the film thickness (x_o), the average conductivity of the electrolyte (k), film resistance (R), and the projected surface area (A) by the equation

$$1 - \Theta_o = \frac{x_o}{kAR} \quad [5]$$

where Θ_o is the surface coverage by the oxide film. Coupling this equation with data of Table I enables calculation of $(1 - \Theta_o)$ at various temperatures. The results are listed in the last column of Table I. The decreasing trend of $(1 - \Theta_o)$ with increasing temperature is an intriguing observation, because earlier investigation on the influence of LiOH concentration on the fraction of the active sites revealed that $(1 - \Theta_o)$ decreases markedly with increase in M LiOH, *e.g.*, at 25°C, $(1 - \Theta_o)$ ranged from 0.34 at 2.96M to 0.05 at 4.84M. However, it should be pointed out that the fraction of active sites calculated in this way only serves to compare changes of the active surface areas as a function of temperature. In the present work, the tortuosity factor has been arbitrarily taken as unity and the bulk electrolyte conductivity has been used directly, the basis for this simplification has been discussed previously (2).

Under steady-state conditions, the solubility of LiOH governs the dynamic balance between oxide film formation and dissolution. There is little doubt that the rapid increase in the dissolution rate of Li (see Fig. 3), and its subsequent crystallization as LiOH on the electrode surface at elevated temperatures, far exceeds the rate of increase of solubility of the salt as the temperature increases (3). This then results in a higher rate of film formation than dissolution. A parallel effect of this imbalance of rates is an increase in surface coverage at higher temperature, and this is reflected by a decrease in $(1 - \Theta_o)$. The implication of these observations is the realization that the Li-H_2O system is inherently stable even at elevated temperatures provided sufficient polarization is imposed on the anode.

Conclusions

This study has shed further light on the observation that polarization of the H_2 evolution reaction at the Li surface is the rate-limiting process rather than the anodic dissolution reaction. The rate equation which has not previously been tested for the H_2 e.r. at an anodically polarized Li surface serves successfully to predict the current efficiency at various temperatures. The investigation has also shown that, despite the fact that Li reacts rapidly with H_2O at elevated temperatures, this reaction can be controlled in an electrochemical cell where the H_2 e.r. can be inhibited sufficiently at the anode to permit good current efficiency to be obtained. The decreasing area of surface active sites with increasing temperatures reaffirms the stability of the Li-H_2O system in aqueous alkaline electrolytes.

Bifunctional Air Electrode for Metal-Air Batteries

Lars Carlsson and Lars Öjefors*

Swedish National Development Company,
Department for Energy and Environmental Technology, 184 00 Akersberga, Sweden

ABSTRACT

In order to fulfill volume and cost requirements on metal-air batteries it is necessary to use bifunctional air electrodes which also serve as counter-electrodes during charge. This twofold duty puts a very high demand on the electrode, especially the structure and catalyst. In the iron-air battery program of SNDC a 0.6 mm porous Ni-electrode with Ag catalyst has been developed for this purpose with a life of more than 1000 charge/discharge cycles. In this paper design, performance, structural changes, mode of failure etc. are discussed.

Secondary metal-air batteries are very attractive from the point of view of energy density because the positive electrochemical reactant, oxygen is supplied from outside the battery. Work on this type of power source started in the middle 1960's in the United States, Japan, and Europe. In most cases these activities were based on know-how from fuel cell development. A short review on these activities is given in Ref. (1).

Swedish National Development Company (SNDC) has been working with an iron-air battery system since 1968. These activities have resulted in full scale batteries tested in vehicles. In 1974 a second generation prototype was tested in a 15 kW-hr-battery in a mine vehicle. Based on experience obtained during these tests a third generation was designed and a 30 kW-hr-battery built and tested during 1974 and 1975. This battery system including auxiliaries is described in Ref. (1).

For primary and mechanically rechargeable metal-air batteries, where zinc dominates the field as negative active electrode material, comparatively simple designs of air electrodes can be used since they only work in discharge mode. Consequently designs used in fuel cells are suitable for these applications. For a secondary metal-air battery the application of the air electrode differs somewhat from its use in fuel cells unless a third auxiliary electrode is used during charge. Since volume is a very critical parameter in a metal-air battery it is necessary to use rechargeable air electrodes which can be used as counterelectrodes during the charge process. This twofold duty puts a very high demand on the electrode, especially the structure and catalyst. The air electrode used in the prototype battery is of a double layer 0.6 mm thick with nickel as the supporting material. In this paper the structure, limiting factors, as well as different possibilities to improve performance and life will be discussed.

Very little has been published on bifunctional air electrodes (2-4). The electrode developed by Siemens is composed of two layers, one of which is a hydrophilic porous nickel sheet adjacent to the electrolyte. The other one bordering the gas phase consists of a hydrophobic carbon layer. During oxygen reduction the carbon layer plays the active part, while the nickel layer catalyzes the electrode process in liberating oxygen. The activity of the carbon powder is increased by addition of silver (> 9.6 mg/cm^2). These electrodes have a life of slightly more than 100 cycles. Efforts to increase life by providing an additional hydrophobic layer on the gas side were not successful.

Design of the SNDC Air Electrode

The SNDC bifunctional air electrode is built up of a double layer sintered nickel structure where the raw materials are INCO Ni-287-powder and silver for catalyst. In the production of the electrode, spacer and hydrophobic additives are used. The spacer is mainly used to build up the coarse layer (thickness 0.4 mm) in order to obtain a uniform porosity and pore size. The use of spacers and the technology to vary its form and grain size developed by SNDC (5) has proved to give advantages regarding the utilization of both nickel and silver as well as the adaption of structure to low differential pressure. This technology is based on mixing the prepared spacer, generally a water soluble inorganic salt, with a metal powder and cold pressing it to an electrode. After sintering the electrode plaque the spacer is removed by dissolving it in water, thus forming a porous body. It is also possible to make electrodes consisting of layers with different porosities.

Figure 1, which is a SEM micrograph cross section of an uncycled air-electrode, shows the fine and coarse layer. This electrode has during several years been optimized to fulfill the requirements regarding critical parameters for a full scale metal-air battery. Figure 2 gives the air electrode performance during life test at 40°C and 5M KOH. Each cycle includes 2 hr charge and 1 hr discharge.

Key words: battery, electrode, air.

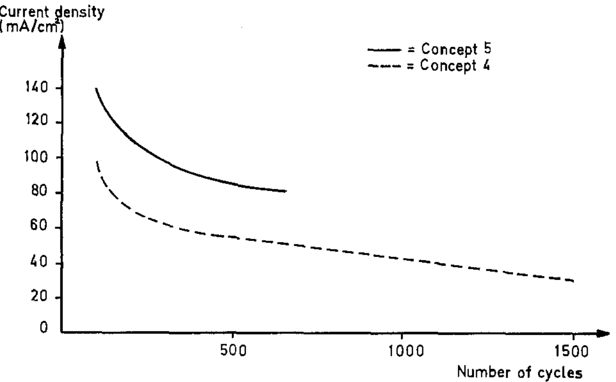

Fig. 2. Air electrode performance during life test. 1 cycle—2 hr charge and 1 hr discharge at 40°C, 5M KOH. Normally 25 mA/cm² is used during the tests.

For a metal-air battery, especially when used in vehicles, the five parameters thickness, differential pressure, working temperature, catalyst contents, and life of the air-electrode are of interest. The thickness is critical since in a metal-air battery the number of air-electrodes is normally twice that of the negatives. This fact together with the fact that volume of the battery stack is more critical than the weight of the battery makes it necessary to develop very thin electrodes. The air-electrodes used in the prototype battery is only 0.6 mm thick.

It is also important to have a low differential pressure in order to minimize the power to pump air through the system as well as the demand on strength and stability on stack design and electrodes. These electrodes are optimized to work at a $\Delta P = 0.02$ bar, a level necessary to keep a steady flow through the system.

Owing to the heat evolved, mainly in the air electrodes, it is necessary to cool the battery. In order to achieve long life for both electrodes and cell stack it is necessary to keep the temperature below 50°C. The electrodes are designed to work at 40°C.

The silver used as catalyst has a tendency to leave its original site in the electrode during cycling and go out into the electrolyte. This phenomenon, which causes decrease in activity and sometimes short-circuiting, depends on the fact that oxygen evolution occurs in the corrosion region of Ag (6). It is important, for economical reasons, to keep the catalyst content at a low level and shield it from dissolving into the electrolyte bulk.

Hydrophobic Treatment

By combining the spacing agent with treatment of hydrophobic agents the active surface of the electrode is increased at the same time as the thickness of the electrolyte layer within the electrode is minimized. This improves the performance of the electrode considerably.

Treatment with hydrophobic agents also decreases the dissolution of silver when going from charge to discharge and vice vèrsa. This depends probably on a thinner electrolyte layer which decreases the possibility for migration of silver ions out into the electrolyte bulk. This effect is shown in Fig. 3 where the silver dissolution is about 10 times lower after treatment with hydrophobic agents. It is evident that hydrophobic additives have a positive influence on the performance and life of the bifunctional air electrode. By optimizing the structure and hydrophobic treatments the performance of the electrode has gradually been improved at the same time as the number of cycles has been increased and the differential pressure has been decreased.

Catalyst Contents

By placing the silver in the active coarse layer zone of the electrode the level can be kept on 2.5 mg/cm² without negative influence on life and performance (Fig. 4).

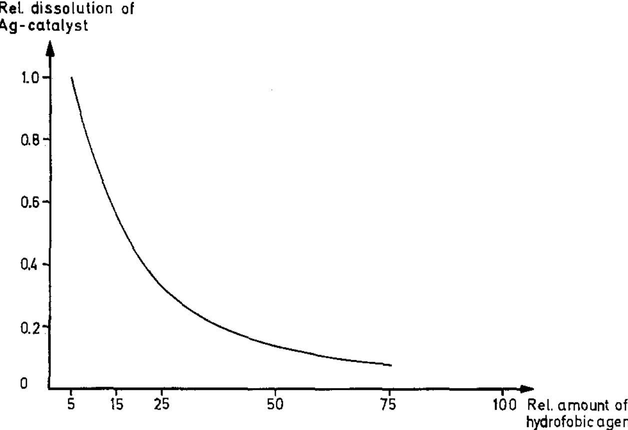

Fig. 3. Influence of hydrophobic treatment on dissolution of Ag-catalyst in SNDC-air electrode. 40°C, 100 cycles.

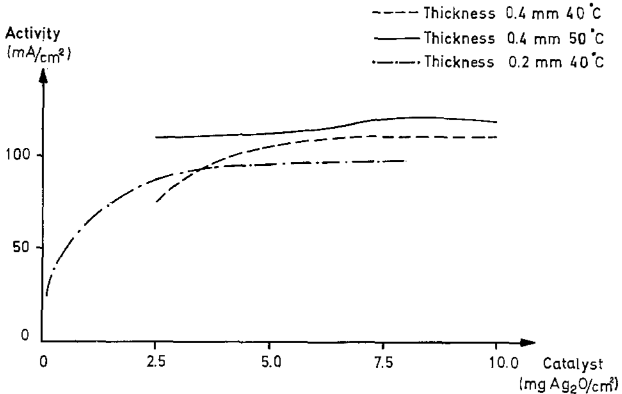

Fig. 4. Influence of catalyst level on air electrode performance. Current density at −300 mV vs. Hg/HgO.

In this figure results of tests are shown where the catalyst contents have been varied in the interval 10-2.5 mg/cm². It is evident that at 50°C the activity of the electrode is not influenced by the variations in catalyst loading. At 40°C and a coarse layer thickness of 0.4 mm, however, the activity decreases below 5 mg Ag/cm². By decreasing the coarse layer thickness to 0.2 mm the overall activity of the electrode will be lower but with a better utilization of the catalyst. This shows that not only the amount of catalyst is of interest but also the relationship Ni/Ag in the coarse layer. The dissolution of Ag into the electrolyte appears during the first 200 cycles after which the level is almost constant (Fig. 5). The initial loss of Ag is apparently connected to the improvement in capacity during the first 40 cycles (Fig. 6), which also has been observed by Cnobloch *et al.* (4). This depends probably on a redistribution of the catalyst and an increase in the electrochemically active surface of the electrode. The low dissolution rate after 200 cycles de-

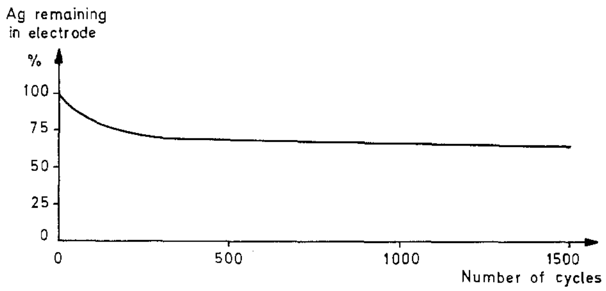

Fig. 5. Dissolution of Ag as a function of cycles

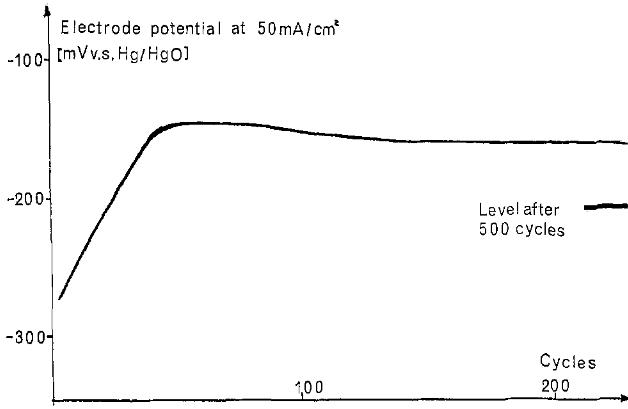

Fig. 6. Performance of air electrodes during cycling. Full cycle 2 hr charge and 1 hr discharge.

pends probably on a decrease in availability of the catalyst partly caused by corrosion products in the Ni-structure.

The relation between catalyst contents and thickness of the coarse layer has also been studied. The tests show that the activity of the electrodes increases from 80 mA/cm^2 at 0.1 mm coarse layer to the level of 140 mA/cm^2 at 0.6 mm coarse layer. The catalyst contents were constant as per mg/cm^2 projected electrode area which means that the highest concentrations of catalyst per volume active material in the thinner layers have not been compensated for the decrease of the specific active surface (Fig. 7).

Life Limiting Factors

After about 150 cycles the performance steadily decreases (Fig. 6). By analyzing electrodes at different stages it has been proved that the main reason for decrease in performance is plugging of the porous structure from corrosion products, mainly $Ni(OH)_2$. Figure 8 shows how the contents of oxygen which is

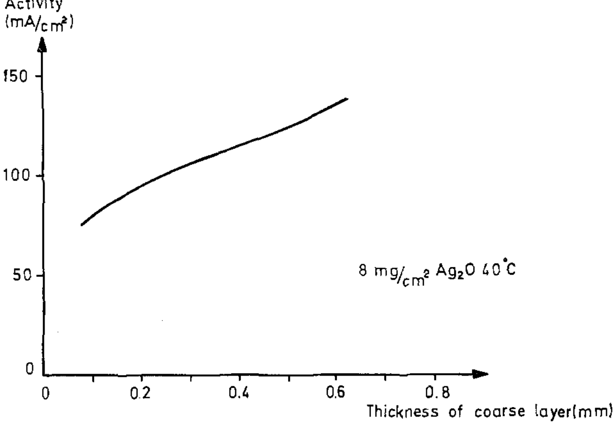

Fig. 7. Influence of coarse layer thickness on air electrode performance. Current density at —300 mV vs. Hg/HgO.

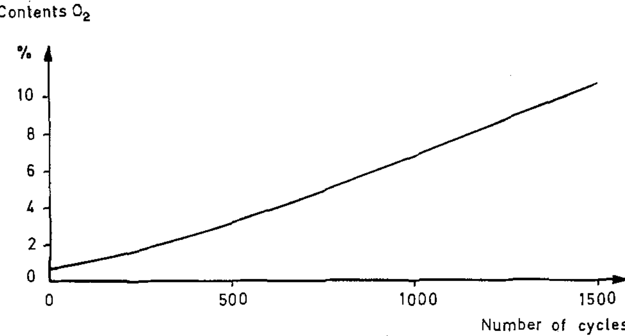

Fig. 8. Development of corrosion products within the air electrode

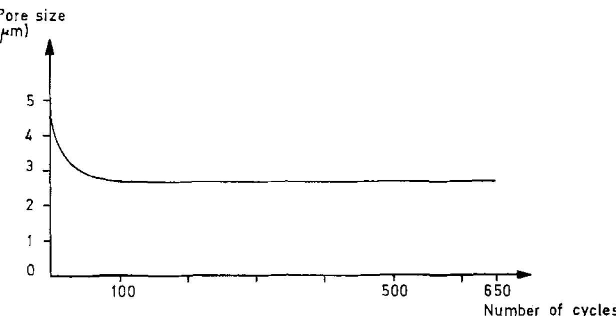

Fig. 9. Mean pore size distribution as a function of cycles

equivalent to corrosion products increase almost linearly when cycling the electrode. This results in a decrease of average pore size according to Fig. 9. The average pore size has been obtained by bubbling air through the electrode. This method is mostly sensitive to changes in the fine pore layer.

The pore size distribution can be determined by mercury porosimetry. Figure 10 gives the distribution for a new electrode, after 650 cycles and after the corrosion products have been dissolved by a special treatment. It is evident that the pore size distribution changes considerably during cycling due to corrosion. The performance of the electrodes at these three stages is given in Fig. 11. After dissolving the corrosion products initial electrode performance is retained. This depends probably not only on the sudden increase in porosity but also on an increase in active catalytic surface. On continued cycling the corrosion process proceeds and performance decreases.

Corrosion of Ni shall normally not occur in the normal working region of a bifunctional air electrode with 5M KOH as electrolyte (7). The corrosion proc-

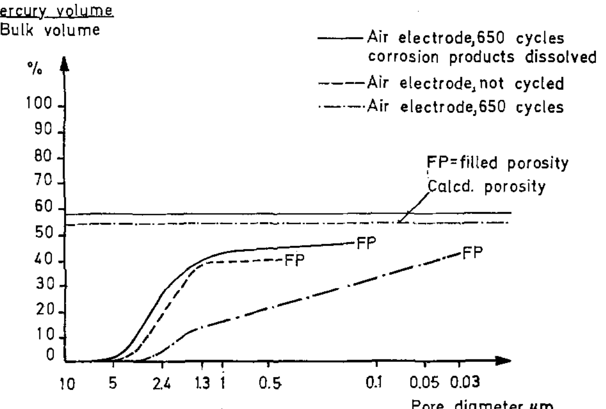

Fig. 10. Pore size distribution of electrodes after different treatments.

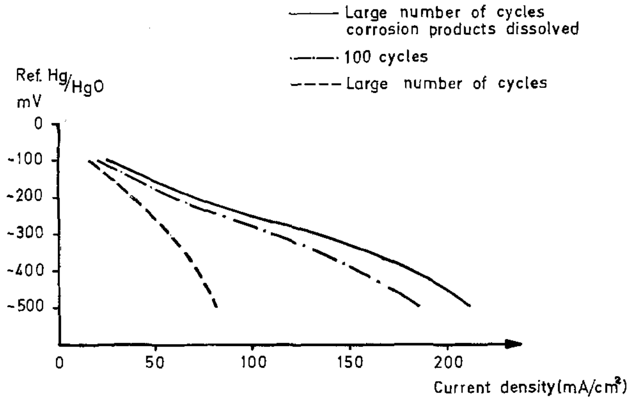

Fig. 11. Polarization curves for air electrodes after different treatments. 40°C $\Delta P = 0.02$ bar.

ess may, however, be catalyzed by traces of chlorine or sulfur which are introduced to the electrode during cycling. Chlorine may emerge from NaCl which is used as spacer and K_2S is sometimes added to the electrolyte to improve the performance of the iron negative electrode. Also the silver catalyst, which is oxidized and reduced during cycling, may have a positive influence on the corrosion process. In order to reduce this life limiting process spacing agents not containing elements with catalytic effect on corrosion of Ni have to be used. Another possibility is to reactivate the electrodes after substantial cycling by dissolving the corrosion products.

Summary

The investigations show that during the first 40-50 cycles of the air electrode an improvement in performance occurs after which the activity is quite stable for about 100 cycles. This means that the electrodes are giving their best performance between 50-150 cycles. This depends probably on an increase in active surface of the nickel electrode at the same time as the catalyst is redistributed. This latter effect means that the dissolution process is comparatively high during this stage of life for the electrode. On continued cycling the catalyst will become less exposed which depends on plugging of the porous electrode by corrosion of the nickel structure. This process presently limits the life of the electrode. The life of the electrodes can be extended by dissolving the corrosion products. In order to avoid this, spacer materials will be tested not containing elements having catalytic effect on the corrosion.

Bromine Complexation in Zinc-Bromine Circulating Batteries

Daniel J. Eustace*

Advanced Energy Systems Laboratory, Corporate Applied Research Laboratory, Exxon Research and Engineering Company, Linden, New Jersey 07036

ABSTRACT

Upon electrolysis of aqueous zinc bromide solutions containing unsymmetrically substituted, cyclic quaternary ammonium bromides, both zinc metal and a bromine-rich liquid are produced. Data, reported for N-ethyl, N-methylmorpholinium (1), N-methoxymethyl, N-methylpiperidinium (2), and N-chloromethyl, N-methylpyrrolidinium (3) bromides suggest that the bromine-rich liquid is a fused salt and separates from the aqueous solution because of insolubility and density differences. The separation process of the bromine fused salt from the aqueous solution is represented as a partitioning of bromine between two phases and is dependent upon electrolysis state-of-charge, quaternary ammonium bromide, bromide ion concentration, and temperature. The bromine-fused salts have properties dependent on composition. Selected examples of densities, specific resistances, viscosities, and polarization are given. Bromine, in the form of a dense, stable, conductive liquid, is useful in circulating zinc-bromine batteries.

The development of zinc-bromine secondary batteries has been impeded by self-discharge, associated with high Br_2 solubility in the aqueous electrolyte, and cell shorting, from dendritic zinc deposition, that limit turn-around efficiency and life.

Recent papers (1) offer a solution to these phenomena by suggesting circulating electrolyte batteries and ion-selective separators that isolate the Br_2-rich stream from the zinc deposit.

An alternative approach is to complex the Br_2 in a form which lowers its activity in the aqueous phase. The present paper discusses this latter approach and details some of the properties of bromine complexes useful in circulating Zn/Br_2 batteries. A model for the chemical system where Br_2 is sequestered as an electrochemically active and chemically stable liquid is presented.

Several chemical methods that decrease the solubility of bromine in Zn/Br_2 aqueous solutions have been reported in context with efforts to reduce the self-discharge of Zn/Br_2 cells.

The reaction between low molecular weight tetraalkylammonium halides and perchlorates with bromine-containing aqueous solutions to form sparingly soluble polyhalides has been used to reduce bromine solubility in Zn/Br_2 batteries (2, 3).

Schemes employing bromine extraction as a second liquid phase, coupled with external storage of the cathode-active material, have been employed in circulating electrolyte systems. Bromine extraction that used a miscible organic cosolvent and a quaternary

* Electrochemical Society Active Member.

ammonium bromide was demonstrated by Walsh and co-workers (4). Br_2 separated from the aqueous electrolyte as a dense liquid, which comprised both the cosolvent and quaternary ammonium polybromide.

We found that symmetrical quaternary ammonium bromides used as single bromine-separating agents, formed solid polybromide species that were insoluble in aqueous $ZnBr_2$ solutions. These solids were resistive and formed liquids at higher levels of bromination. Similar results have been reported (2).

A recent paper (5) discusses circulating electrolyte Zn/Br_2 batteries that operated at high turn-around efficiencies (~75%) and to high states-of-charge (>70%). In operation, while Zn is plated, Br_2 is produced, complexed as a dense liquid, and stored in external reservoirs. This paper discusses the chemistry in $ZnBr_2$ solutions of liquid bromine complexation by unsymmetrically substituted, cyclic quaternary ammonium bromides (QBr).

The nature of the liquid bromine complexes, reported here, is ionic, based on specific resistance measurements. Differential scanning coulorimetry indicates that no distinct liquid-solid transitions are observed, yet the product at low temperature is a viscous glass. Spectroscopic and quantitative analyses reveal two major components: the QBr and bromine. Since it is well known that halides and halogens readily combine to form polyhalide species, it is viewed that the liquid complexes are bromine-fused salts.

Experimental

Materials.—The unsymmetrically substituted (*i.e.*, no axis of symmetry) quaternary ammonium salts were synthesized by known synthetic methods. N-ethyl, N-methylmorpholinium bromide **1**, N-methoxymethyl, N-methylpiperidinium bromide **2**, and N-chloromethyl, N-methylpyrrolidinium bromide **3** gave expected elemental and spectroscopic (ir, NMR) analyses.

1	**2**	**3**
O, N^+, CH_3, CH_2CH_3, Br^-	N^+, CH_3, CH_2OCH_3, Br^-	N^+, CH_3, CH_2Cl, Br^-

Commercial zinc bromide was obtained from American Hoechst Corporation (analysis >98.6%). Fisher Certified ACS grade zinc sulfate, ammonium chloride, ammonium bromide, and potassium chloride were used. Solutions were prepared with doubly distilled water.

Methods of study.—Bromine determinations were made by the indirect iodometric titration method. Zinc ion concentration was measured by EDTA titration with Eriochrome Black T indicator. Quaternary ammonium salt characterization was accomplished on an A-60 NMR spectrometer. ^1H NMR signal integration was used to quantify mixtures containing the quaternary ammonium salts. Solution conductances were measured on a Beckman Instruments RC-18A Conductivity Bridge and viscosities were measured with Cannon-Fenske viscosimeters.

Electrochemical studies were carried out at constant-current conditions in laboratory cells containing Pt foil electrodes for bromine production and consumption. Spectroscopic carbon rods were the substrates for zinc, and approximately 2.0-4.0 cm^3 of electrolyte were used at 23°C, unless otherwise indicated. Constant current electrolysis experiments were terminated at definite intervals and the zinc electrodes removed within 0.25 hr to study the characteristics of the remaining components.

Results

Physical properties of electrolytes.—$ZnBr_2$ electrolytes can be prepared over a considerable composition range, since the solubility is $>10M$ (1.6×10^3 W-hr/liter) at ambient temperature. The maximum $ZnBr_2$ concentration is lower in many multicomponent solutions. Typical compositions and solution physical properties are shown in Table I.

State-of-charge electrolysis studies.—The solutions reported in Table I were studied in constant current electrolysis cells. Passage of current produced zinc metal and a two-phased electrolyte, the composition of which was shown to be dependent upon the initial solution composition, state-of-charge (*i.e.*, percent of $ZnBr_2$ electrolyzed), temperature, and the presence of supporting electrolytes. The efficiency of Br_2 separation is revealed by the Br_2 concentration of the upper, aqueous phase. The effect of these variables on the Br_2 content of the aqueous phase is shown in Fig. 1-3.

In a similar way, Br_2 can be said to be partitioned between the two phases as expressed by the distribution coefficient, K

$$K = \frac{\text{Total Br}_2\text{ content of Br}_2\text{-rich phase}}{\text{Total Br}_2\text{ content of aqueous phase}}$$

This parameter is described for the three quaternary salts in Fig. 4, 5, and 6.

The composition of the Br_2-rich phase varies with the state-of-charge of the electrolyte. ^1H NMR integration,[1] and iodometric titration analyses revealed the phase to be exclusively Br_2 and QBr and the Br_2 was greater at higher states-of-charge, as shown in Fig. 7 for **1**.

[1] The ^1H NMR spectrum integration results are reliable with ~5-10% error. Thus, the results in Fig. 7 do not add up to 100% in each case. Also, each experiment produced two phases.

Table I. Compositions and specific resistances of zinc bromine solutions containing quaternary ammonium bromides and supporting electrolytes (23°C)

Solute*	Supporting electrolyte	$[ZnBr_2]$ (M)	[Solute] (M)	[Supporting electrolyte] (M)	Density (g/cm^3)	Specific resistance ($\Omega \cdot cm$)

Properties of Br$_2$-rich phase.—Liquid mixtures of Br$_2$ and QBr produced by electrolysis of ZnBr$_2$ solutions were in the composition range of 30-80 weight percent (w/o) (x = weight fraction of Br$_2$). These mixtures are characterized at 23°C by their densities ($\rho \approx 2.0x + 1.1$), specific resistances (for example, Br$_2$ mixtures with **1** are represented in Fig. 8), and viscosity (for example, for Br$_2$ complexes of **1**, $x = 0.61$, 10.9 c stokes, 25 cp.).

Br$_2$ liquids of **1** and **3** are stable over the temperature range from 0° to 60°C and for 15 months, as shown by proton NMR. They remain liquids for the same conditions when kept in contact with an aqueous electrolyte. Br$_2$ complexes of **2** were observed to react at the α-carbon position to the oxygen on stand.

The oxidation-reduction properties of a typical Br$_2$ complex is shown for **1** ($x = 0.61$) at a Pt electrode in Fig. 9.

Discussion

System model.—The formation of the bromine-rich phase upon electrolysis of ZnBr$_2$ solutions containing quaternary ammonium bromides is hypothesized to be a micellar-like separation process where pseudomicrophases coalesce and separate from the aqueous electrolyte by density differences. Parametric studies indicate that the critical

$$Br_2(aq) \leftrightarrows Br_2 \text{ (fused salt)}$$

equilibrium is responsive to the bromide ion concen-

tration, temperature, and quaternary ammonium salt. This equilibrium is influenced by the multiple ionic equilibria for Br_2 in the aqueous phase of $ZnBr_2$ solutions, principally polyhalide anion formation; for example

$$Br_2\ (aq) + Br^-\ (aq) \rightleftharpoons Br_3^-(aq)$$

$$Br_3^-(aq) + Br_2\ (aq) \rightleftharpoons Br_5^-(aq)$$

$$Br_5^-(aq) + Br_2\ (aq) \rightleftharpoons Br_7^-(aq)$$

and polyhalide ion pair formation, for example

$$Q^+Br^- + Br_7^-(aq) \rightleftharpoons Q^+Br_7^-(aq) + Br^-(aq)$$

The second phase is exclusively QBr and Br_2 in a series of polyhalide ion pair mixtures; for example

$$Q^+Br_3^- + Br_2 \rightleftharpoons Q^+Br_5^-$$

$$Q^+Br_5^- + Br_2 \rightleftharpoons Q^+Br_7^-$$

which is analyzed as a nonstoichiometric mix described simply as a bromine fused salt.

Increasing the concentration of bromide ion is seen to influence the position of the aqueous phase equilibria and, thus, the partitioning of bromine between the aqueous and fused salt phase

$$Q^+Br_n(aq) \rightleftharpoons Q^+Br_n^-\ (\text{fused salt})\ n = 3, 5, 7$$

Figure 1 shows the incremental increase of the aqueous phase Br_2 concentration found with incremental increases in the $ZnBr_2$ concentrations for N-methoxymethyl, N-methylpyrrolidinium bromide **2** solutions. Higher solubility of bromine is shown in Fig. 3 for the 3.0*M* $ZnBr_2$ and 1.0*M* N-methyl, N-methylmorpholinium bromide **1** solution containing 4.0*M* NH_4Br when compared to the similar $ZnBr_2$-**1** solution with 0.2*M* $ZnSO_4$. Indeed, the 0.2*M* $ZnSO_4$ has the effect of lowering the aqueous phase bromine concentration by approximately 10% over the similar system without supporting electrolyte.

Increasing the temperature shifts the partitioning equilibria, allowing more bromine to be soluble in the aqueous phase. Although bromine loss by reaction with zinc metal and evaporation affect the values obtained at higher temperatures, 85-90% of the bromine produced in each experiment was accounted for in the analyses. The loss in precision this gives does not affect the trend seen in Fig. 2. Indeed, it is noted that the energy of activation for the partitioning of bromine obtained from the results of the N-ethyl, N-methylmorpholinium bromide system are in the range of −0.6 to −1.4 kcal·mole^{-1}. This activation energy is lower than typical activation energies of ionic diffusion (for example, 3.8-4.6 kcal·mole^{-1}), suggesting a solution ordering effect similar to micellar systems (6).

Differences between the bromine partitioning abilities of the three quaternary salts is obtained by comparing their Br_2 partition coefficients for similar composition solutions. The distribution coefficients are in the decreasing order: **3** $\sim$ **2** $>$ **1**.

System analogies.—Systems that are similar to the Br_2-fused salts have been described previously in another context. Kraus and co-workers (7) studied quaternary and tertiary ammonium solutes in the solvent bromine. Typical physical properties for $(CH_3)_3NH^+Br^-$ in bromine, shown in Table II, are quite similar to **1** in bromine at a similar composition.

Br_2 complexation that is used in circulating Zn/Br_2 batteries can also be compared with phase transfer

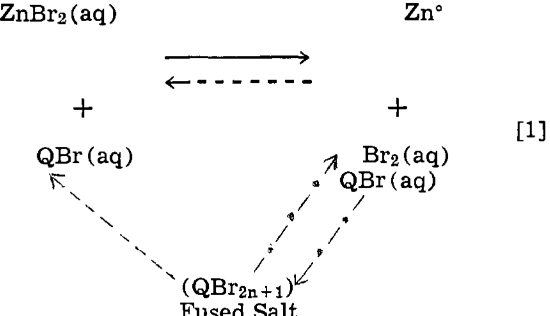
Nature of second phase	Stable (0°-60°C) conductive	Promote selected reactions with a turnover of agent

catalysis by quaternary ammonium salts (8) (Table III). Both processes employ monovalent cations that are active ion pair extraction agents. The extraction coefficients for Br_2 separation are typically 1 to 10^2 and dependent on QBr. Similar distribution coefficients for phase transfer catalysis are from 1 to 10^4 and both agent- and second-solvent-dependent. Added salts have similar effects on the distribution coefficients. The two systems differ in the fact that a second immiscible phase is required for the catalysis, and that the bromine-fused salt (at least for **1** and **3**) is stable and conductive. Also, the catalytic systems promote specific reactions.

System application.—The electrolytic properties of a typical bromine-fused salt are given in Fig. 8 and 9 for compositions generated from 3.0*M* $ZnBr_2$ and 1.0*M* **1**. The composition-dependent specific resistance is obtained by using the results shown in Fig. 7 with Fig. 8. In the range where the bromine weight percent falls between 32 and at least 61, the fused salt specific resistances are less the 100 Ω·cm. Taking one composition as an example, Fig. 9 shows that the bromine-fused salt with 61 w/o Br_2 can be charged and discharged with little activation polarization at currents up to approximately 50 $mA \cdot cm^{-2}$.

The Zn/Br_2 electrochemical couple can employ the bromine-fused salt in a flowing electrolyte system. Equation [1] schematically represents the chemical processes in the circulating electrolyte Zn/Br_2 battery. On battery charge, $ZnBr_2$ is electrolyzed to Zn° and Br_2 (→). The Br_2 is consumed by polybromide equilibria partitioning it mostly into a separate bromine-fused salt phase (-·-·-·→)



[1]

Zinc is oxidized and Br_2, both in the fused salt and the aqueous phase, is reduced when the battery is discharged (- - -→).

System optimization with respect to the quaternary ammonium bromide aims at improving the energy density (increasing the starting $ZnBr_2$ concentration) without increasing bromine-related self-discharge for batteries operating at ambient temperature and practical rates.

Summary

The chemistry associated with Br_2 separation in Zn/Br_2 circulating electrolyte batteries has been described. The Br_2-rich liquid phases normally formed in battery operation (Br_2 weight percents are ~30-~80) have been studied and characterized as a bromine-fused salt.

The electrolytic formation of the bromine-fused salt is modeled as a micelle-like process, where the dominant phase separation process is controlled by the polyhalide ion activity in each phase.

This method of Br_2 complexation is useful in energy storage, since it renders Br_2 into a controllable, condensed fluid which is conductive and chemically stable on standing.

Studies on Pollutants

IV. Electrolytical Recovery of Lead from Battery Scrap

S. Das Gupta, Shahid Abbas Abbasi,[1] R. Raman, and D. L. Roy

Department of Metallurgical Engineering, IIT, Powai, Bombay, India

ABSTRACT

Recovery of lead from waste battery paste has been carried out by an electrolytic method employing paste suspended in sodium hydroxide as electrolyte. Effect of several parameters, viz., current density, temperature, time, lead ion concentration, sodium hydroxide concentration, agitated bath and cathode material on the cathode potential, current efficiency, and nature of deposits, has been studied and possible reasons for the observed effects have been discussed. A mechanism for lead deposition has been elucidated. It is observed that cathodic reaction takes place after the dissolution of lead or lead compounds in sodium hydroxide and the ion responsible for lead deposition is biplumbite ($HPbO_2^-$) ion. The optimum conditions for conducting the electrolysis are: temperature 60°C, current density 7 A/dm^2, concentration of sodium hydroxide 600 g/liter, time 120 min.

Used lead acid batteries form an important secondary source of lead, especially in countries which are not otherwise rich in lead resources (1). The treatment of used acid batteries for recovering lead is important from the point of view of lead production as well as pollution abatement as otherwise the battery scrap may lead to disposal problems. The lead in used batteries is in the form of grid plates and pole bridges made up of lead-antimony alloy (5-12% antimony) and paste consisting mainly of antimony-free lead, lead oxide, and lead sulfate.

In an earlier communication (2), a pyrometallurgical method was reported for the recovery of lead from battery scrap using carbon with calcium carbide or calcium carbonate as reducing agents. It was observed that the recovery was not satisfactory because lead sulfate, a constituent of the battery paste, required high temperatures for the reduction causing fume and slag losses. It appeared that the recovery of metal values from the battery scrap will be economical if the battery plates (consisting of antimonial lead) and battery paste (consisting of lead compounds including lead sulfate) are treated separately. An electrochemical method was conceived for the treatment of battery paste in the hope of obtaining high purity lead; detailed studies of which are presented here.

Among the reported electrolytic methods of purification of lead, the conventional type (3-5) makes use of anodes made up of impure lead with suitable leachants for lead as electrolytes. Waheed *et al.* (6) have reported two processes for recovery of lead from battery waste employing a sodium hydroxide bath as electrolyte. The work is confined to feasibility studies and development of process parameters for recovering one pound of lead per hour. In the present work detailed studies have been carried out on the mechanism of lead deposition, and on the cause-effect relationship of several parameters with the lead recovery, nature of deposits, and cathode potential. From the generated data, optimum conditions for lead recovery have been worked out.

Experimental

The electrolytic cell was a 1000 ml glass vessel (Fig. 1) with a cylindrical mild steel rod as cathode. The rod was 12 mm in diameter with an effective length of 7 cm. It was rotated for some experiments by means of a fractional horsepower motor. To investigate the effect of lower temperatures on the nature of deposits, a chilled cathode was used which was a lower-end-closed cylindrical nickel-plated tube, 2.7 cm diameter by 5 cm long. The cathode was cooled by pouring in ice while water was removed from inside the cathode at regular intervals of 3 min. The anode consisted of two strips of stainless steel 1.2 cm wide by 12 cm long. To investigate the effect of cathode material on cathode potential and current efficiency lead, stainless steel, graphite, and mild steel were used successively as cathodes.

The different baths used for investigations were comprised of sodium hydroxide and one of the following: waste battery paste, lead sulfate, lead monoxide, or powdered lead. The electrolysis in each experiment was conducted with 1000 ml of electrolyte, keeping anode to cathode distance 4.4 cm and anode to anode distance 10 cm. A multispeed stirrer was used to ensure efficient stirring near the cathode. For heating the electrolyte to desired temperatures, an immersion heater, connected to a Variac, was employed.

The cathode and anode were connected to a rectifier through a voltmeter, an ammeter, and a rheostat (to obtain the desired current in the cell).

For measurement of the cathode potential a standard mercury-mercuric oxide (Hg-HgO) electrode was used as a reference electrode. The Luggin tip of the connecting bridge was made to touch the cathode. To record the potential the reference electrode was connected to the positive terminal and the cathode was connected to the negative terminal of a high impedance vacuum tube voltmeter (Heathkit, Model V-7A).

Waste battery paste was analyzed by standard methods (7). Average analysis of battery waste active material was as follows

Lead monoxide:	27.77%
Lead sulfate:	63.08%
Free lead:	7.44%
Total lead:	75.42%
Antimony:	2.55%

All the experiments were carried out after stirring the solute (lead sulfate, lead monoxide, lead waste battery paste) in sodium hydroxide at the temperature of 70°-80°C for half an hour. Before each experiment the cathode was cleaned thoroughly with hydrochloric acid and washed.

The lead deposits obtained after each experiment were washed well with water, then with 2% acetic

Key words: mechanism, lead deposition, current efficiency.

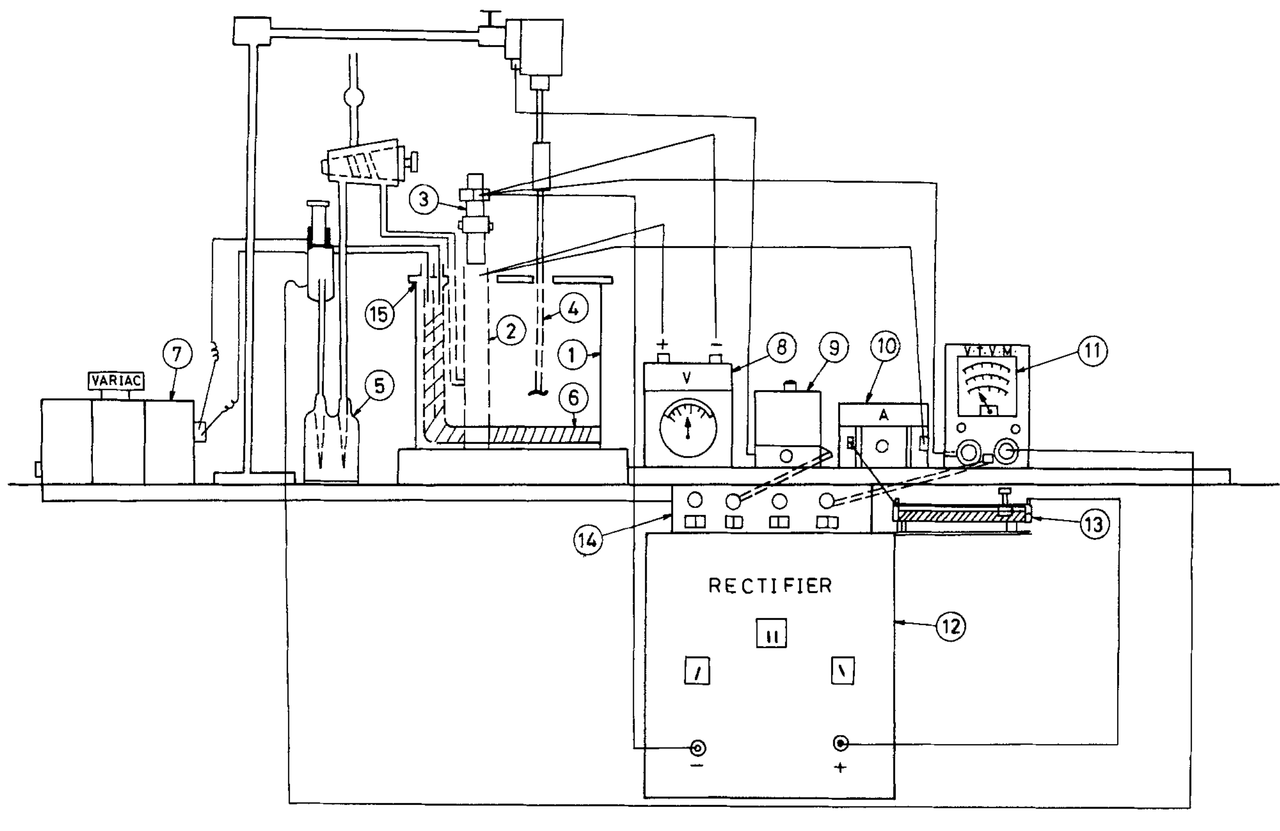

Fig. 1. Experimental setup for the electrolysis studies

acid, washed again with water, and dried in a vacuum furnace at 100°C for 1 hr.

Results and Discussion

The results of studies on the effects of various parameters, *viz.*, temperature, sodium hydroxide concentration, current density, cathode material, concentration of lead ions, time, etc., on cathode potential, current efficiency, and nature of lead deposits are presented in Tables 1-XI. The results of experiments which were carried out with lead sulfate, lead monoxide, or lead powder to elucidate the mechanism of lead deposition are presented in Tables I-IV while results of the experiments carried out with waste battery paste are presented in Tables V-XI.

Reaction mechanism of lead deposition.—The cathodic reaction taking place during electrolysis may involve lead or lead compounds in the solid (suspended) state, or it may proceed after the dissolution of lead or lead compounds.

Results (Tables I-IV) show that the nature of lead deposits changed with the variation of such parameters, *viz.*, sodium hydroxide concentration and temperature, which influenced the dissolution of lead bearing material. This indicates that cathodic reactions were taking place after the dissolution of lead or its compounds in sodium hydroxide. The probable chemical reactions are

$$PbSO_4 + 4NaOH = Na_2SO_4 + Na_2PbO_2 + 2H_2O \quad [1]$$

$$PbO + 2NaOH = Na_2PbO_2 + H_2O \quad [2]$$

$$Pb + 2NaOH = Na_2PbO_2 + H_2 \quad [3]$$

All three reactions generate sodium plumbite. The ionization of sodium plumbite during electrolysis may lead to plumbous ion (Pb^{2+}), biplumbite ion ($HPbO_2^-$), plumbite ion (PbO_2^{2-}), plumbic ion (Pb^{4+}), acid metaplumbite ion ($HPbO_3^-$), metaplumbite ion (PbO_3^{2-}), and orthoplumbite ion (PbO_4^{4-}). The potential-pH diagram for the system lead-water (8) indicates that under the highly alkaline condition of the bath ([NaOH] > 2M, pH $\simeq$ 14), the predominant lead-containing ion is biplumbite ion ($HPbO_2^-$), the concentration of other lead containing ions being insignificant.

The diffusion and hydrodynamic flow force the anions ($HPbO_2^-$) to move towards the cathode where

these ions are reduced. High percentage recovery with stirred baths (Table IX) compared to static baths also indicates the importance of convective flow. The probable reaction is

$$HPbO_2^- + 3H^+ + 2e = Pb + 2H_2O \quad [4]$$

$$E_o = 0.702 - 0.0886\,pH + 0.0295 \log [HPbO_2^-] \quad [5]$$

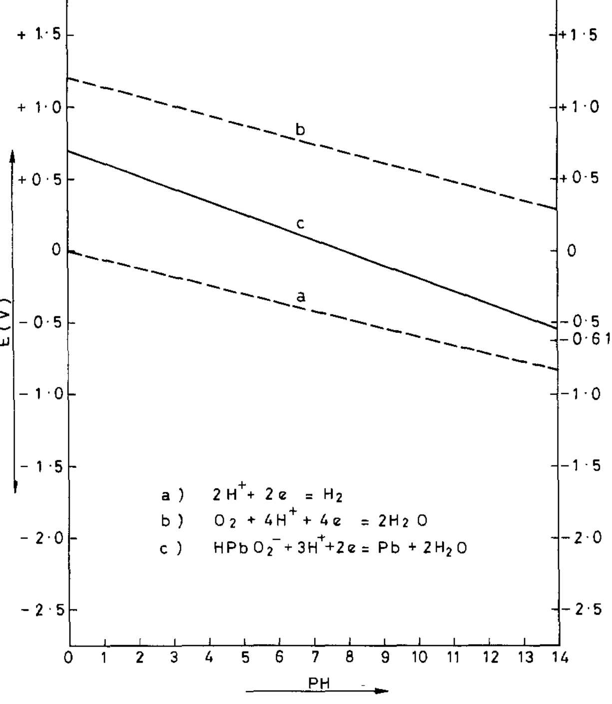

Fig. 2. Proposed potential-pH diagram for the lead-water system, at 298°K.

Assuming activity of biplumbite ion as unity, the above equation has been represented in the E/pH diagram (Fig. 2). At pH = 14 the above reaction is feasible when the cathode potential value is more negative than −0.530. The observed cathode potential values (−0.61 to −1.70V) distinctively show the likelihood of the above reaction.

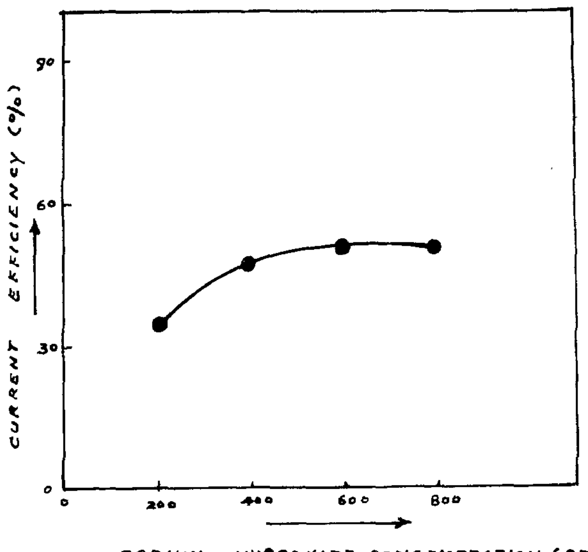

Fig. 3. The effect of sodium hydroxide concentration on the current efficiency. (Waste battery paste 20 g/liter; current density 25 A/dm^2; temperature 35°C; time 60 min.)

Effect of various parameters on the electrolysis of waste battery paste.—Effect of current density.—The effects of current density on current efficiency, cathode potential, and nature of lead deposits are represented in Table V (Fig. 3).

The current efficiency did not vary much in the current density range of 2.5-10 A/dm^2. Above 10 A/dm^2 the current efficiency decreased rapidly with the increase in current density. With the increase in current density the effective metal ion concentrations in the vicinity of the cathode reduce and hydrogen evolution increases leading to reduced current efficiency. Similar influence of lead-containing ions on current efficiency is observed in the results shown in Table IV. The experiments were carried out keeping the waste battery paste in suspension in the sodium hydroxide solutions and in all likelihood, as detailed during discussion on the mechanism of lead deposition, the electrolysis was preceded by dissolution of paste. The decrease of current efficiency may also be due to the fact that the rate of dissolution of lead compounds and free lead in sodium hydroxide becomes the rate-controlling factor.

The purity of lead obtained was about 90%. This low purity may be due to the presence of lead oxide in the deposits owing to the following reasons:

1. Lead oxide may occur in the lead deposits because of decomposition of mechanically held sodium plumbite (in the deposits) during drying. The likely reaction is

$$Na_2PbO_2 + H_2O \rightleftarrows PbO + 2NaOH \qquad [6]$$

The observed value of current efficiency higher than 100% for current density of 7 A/dm^2 is also probably due to the above mentioned phenomena, *i.e.*, mechanical inclusion.

2. The reactivity of electrolytic powders are in general greater than that of powders prepared by thermal processes. The particles in electrolytic powder consist of clusters of very small crystals (about 0.07 μm in diameter) which are under strained condition (9). This leads to higher reactivity causing oxidation. In the present investigation the oxidation was minimized by using a vacuum furnace during drying.

The nature of deposits was black spongy throughout the current density range studied. The analysis of deposits showed that it contained arsenic (0.056%), antimony (0.55%), copper (0.016%), and iron (0.001%) besides lead oxide.

The effect of temperature.—The effects of temperature on cathode potential, current efficiency, nature of deposits, and purity of lead are represented in Table VI.

With the increase in temperature the cathode potential is seen to decrease (become less negative). It is known that, for overpotential (η)

$$\eta = \eta_c + \eta_a + \eta_R$$

As a rule with the increase in temperature, η_c, the concentration overpotential, η_a, the activation overpotential, and η_R, the resistance overpotential, are all reduced. This may be the reason for the observed lower cathode potential values at higher temperature in the present investigation.

The current efficiency increased with the increase in temperature up to 60°C but beyond this temperature it decreased. This may be due to lower hydrogen overvoltage and higher rate of dissolution of deposited lead at higher temperatures.

At room temperature the nature of deposits was black spongy. In the temperature range 60°-100°C the deposits were black spongy near the cathode while the outer portions were bright and flaky. The bright flaky portion may be due to lower activation polarization and higher concentration polarization. With time of electrolysis the concentration of lead ions in the electrolyte becomes less causing an increase in concentration polarization. The activation polarization is lower with higher temperatures. When concentration polarization dominates over activation polarization, the flakes grow more or less perpendicularly from the electrode surface into the solution.

The effect of sodium hydroxide concentration.—The results are presented in Table VII (Fig. 4). The change in sodium hydroxide concentration from 200 to 800 g/liter showed an increase in current efficiency from 34.2 to 50.2%. Black spongy deposits were obtained in all cases and the purity of lead was about 90%.

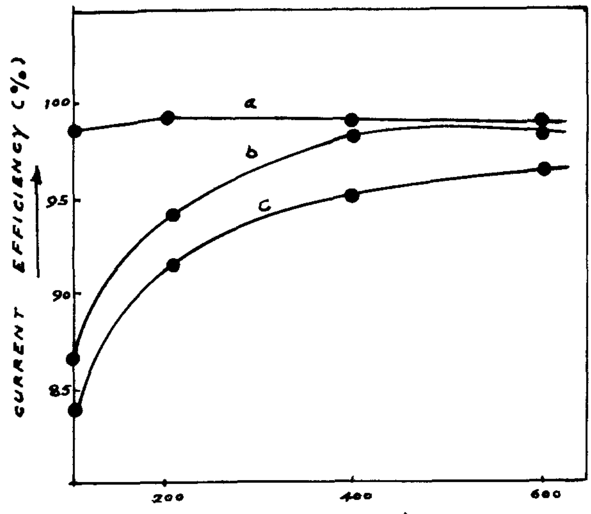

Fig. 4. Variation of current efficiency with the concentration of sodium hydroxide for the different constituents of the battery paste: (a) lead sulfate (b) lead oxide (c) lead. (Current density 5 A/dm²; temperature 60°C; time 30 min.)

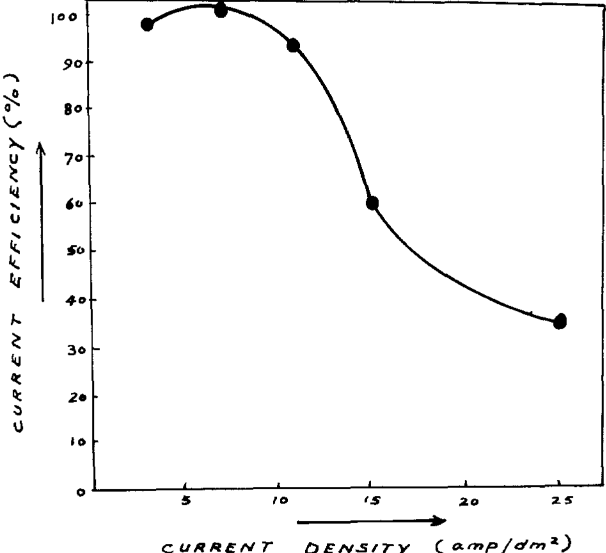

Fig. 5. The effect of current density on current efficiency. (Waste battery paste 20 g/liter; sodium hydroxide 200 g/liter; temperature 35°C; time 60 min.)

The increase in current efficiency with the concentration of sodium hydroxide is possibly due to the increase in solubility of lead and its compounds. Experiments on different constituents of the paste (Table II Fig. 5) reveal that the current efficiency remained practically constant in case of lead sulfate while it increased with increase in sodium hydroxide concentration when lead or lead monoxide were electrolyzed. The reason for this observation is that the solubility of lead sulfate in sodium hydroxide is high even at low alkali concentrations and the increase in solubility with increase in alkali concentration is not substantial. The dissolution of lead or lead monoxide, on the other hand, increases markedly with the increase in alkali concentrations resulting in a similar trend for current efficiency.

The current efficiency-sodium hydroxide concentration curves level off at, and beyond, the sodium hydroxide concentration of 600 g/liter, and this value is taken as the optimum concentration of sodium hydroxide.

The effect of time.—The results (Table VIII) show that the current efficiency remained practically constant up to 120 min and then decreased slowly up to 210 min. After 210 min the current efficiency fell steeply, probably due to unavailability of lead-containing ions for deposition. The cathode potential increased after 210 min as concentration polarization probably

arose from insufficient number of lead-containing ions. The weight percent recovery of lead was 91.9%.

Effect of static bath, agitated bath, and rotated cathode.—The results are shown in Table IX.

The deposit of lead on the stationary cathode in the static bath was nonadherent and spongy. It readily peeled off even while the cathode was taken out of the cell. On the other hand the lead deposit in the agitated bath and on the rotating cathode was adherent, spongy, compact, and could be handled easily. It may be due to the fact that rotation of cathode and stirring of the bath reduces the thickness of the electrical double layer, leading to compact and adherent deposits.

The cathode potential in case of the rotated cathode was less than in the case of the static cathode. This unexpected observation may be explained on the basis of contact resistance (electrical contact to the rotating electrode) and/or improper contact of Luggin tip (of reference electrode) with the rotating cathode, which might have developed.

The current efficiency of the static bath-static cathode system (91.5%) was found to be between that of agitated bath-static cathode system (98.1%) and agitated bath-rotated cathode system (83.7%). The higher efficiency in the case of agitated bath-static cathode system compared to that of static bath-static cathode system is expected, but the low value of current

Current efficiency: 93%

Purity of lead: 96%

efficiency in the case of the rotating cathode was probably due to the loss of deposited lead by dissolution and/or peeling off during rotation of the cathode.

Effect of cathode material.—The experiments (Table X) were carried out under similar conditions of electrolysis for all the cathodes. The value of current efficiency for nickel, stainless steel, graphite, and mild steel cathodes were close to each other, about 99%, but the value for the lead cathode was 85.87%. This low value is likely to be due to passivation of the lead cathode.

Effect of chilled cathode.—When the cathode was chilled during electrolysis (Table XI), the lead deposit consisted of fine powder and granules. Electrolytic deposition is a nucleation and growth process. As the cathode is chilled, the growth of the crystals at the cathode surface is hastened resulting in fine powder. Since the heat conductivity of lead is not high, the cooling of the deposited powder is not efficient after a few layers have been deposited. Subsequent deposits are thus granular.

The purity of lead was 96% which was higher than the purity of spongy deposits obtained in earlier experiments. The granular and powdery deposits were easier to wash which possibly reduced the formation of lead oxide during drying and favorably effected the purity of lead.

Conclusion

As discussed earlier (2), the pyrometallurgical method for the recovery of lead from lead battery waste suffers from the drawback that while lead oxide can be efficiently reduced to metallic lead by carbon,

the reduction of lead sulfate requires high temperature, causing fume and slag losses and reducing the efficiency of lead recovery. If the battery plates, which contain antimonial lead and battery paste, which contains lead compounds including lead sulfate, can be treated separately, the former by pyrometallurgical method and the latter by electrolytic method, the combined "duplex" process may be an economical proposition. In the duplex process the waste paste on the grid plates would be washed thoroughly with a concentrated sodium hydroxide solution, dissolving away all the paste. The grid plates would be then treated pyrometallurgically (2) to recover antimonial lead. The sodium hydroxide solution containing the paste would be electrolyzed to recover pure lead. The present studies prove the feasibility of the electrolytic process though further work is required to evaluate the economics of the process.

The following important conclusions can be drawn from the present work:

1. The deposition of lead takes place at the cathode after the dissolution of lead or lead compounds in sodium hydroxide and the ion responsible for lead deposition is the biplumbite ($HPbO_2^-$) ion.

2. The optimum values for the various parameters are: current density 7 A/dm^2, concentration of sodium hydroxide 600 g/liter, temperature 60°C, time of electrolysis 120 min.

3. A current efficiency of 97% is achieved when the electrolysis is carried out under near-optimum conditions (current density 5 A/dm^2, concentration of sodium hydroxide 400 g/liter, temperature 60°C, time of electrolysis 120 min).

High Rate Discharge Characteristics of Li/SOCl$_2$ Cells

K. A. Klinedinst* and M. J. Domeniconi*

GTE Laboratories, Incorporated, Waltham, Massachusetts 02154

ABSTRACT

The performance characteristics of the Li/$SOCl_2$ cell have been determined as a function of discharge rate, electrolyte composition, cathode thickness, and cell temperature. Cells have been discharged at rates ranging from about 3 to nearly 300 mA/cm^2. Cathodes with electrolyte solutions have contained either $LiAlCl_4$ or $AlCl_3$, with the most efficient discharge characteristics being realized with 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ solutions. The use of pure $AlCl_3$ dissolved in $SOCl_2$ as the electrolyte results in substantially higher average discharge voltages and discharge capacities than can be achieved with cells containing the conventional $LiAlCl_4$ electrolyte. With both electrolytes, however, the discharge capacity per unit cathode volume (the effective cathode utilization) decreases with increasing cathode thickness, the rate of decrease being greater the higher the discharge current density. Increasing cell temperature results in an improvement in cathode utilization and a decrease in overvoltage, again with both $LiAlCl_4$ and $AlCl_3$ electrolyte solutions.

The performance characteristics of the lithium/thionyl chloride primary battery system at relatively low rates of discharge ($I \lesssim 10$ mA/cm^2) have been frequently described (1-5). However, the characteristics of the battery at high rates of discharge ($I \gtrsim 10$ mA/cm^2) are not well known. It has thus been the purpose of this investigation to determine the performance characteristics of the Li/$SOCl_2$ cell as a function of discharge rate, particularly with respect to current densities greater than about 10 mA/cm^2. In addition to the discharge rate, the experimental variables explored have included the electrolyte composition, the cathode thickness, and the cell temperature.

In the design of any high rate cell, the anode/cathode interfacial area should be as large as possible to reduce current density and thus to minimize losses due to polarization or reduced electrode capacity. Since the total cell volume is generally fixed, this usually requires that the electrode thickness be reduced by an amount proportional to the increase in electrode area. For this reason, the cathodes employed in this work were all thinner than 1.0 mm with most being less than 0.1 mm in thickness.

The conventional Li/$SOCl_2$ cell electrolyte consists of a solution of $LiAlCl_4$ in $SOCl_2$. This solution is commonly prepared by first dissolving the required amount of $AlCl_3$ in purified $SOCl_2$ followed by the addition of a stoichiometric amount of LiCl (1). On the other hand, we have previously reported that, if the electrolyte solution contains less than the stoichiometric amount of LiCl or even in the complete absence of LiCl, the average discharge voltage and discharge capacity (at a given rate of discharge) assume substantially greater

* Electrochemical Society Active Member.

Key words: battery, cathode, electrolyte, polarization.

values than when the $SOCl_2$ contains only $LiAlCl_4$ (6, 7). However, because the excess $AlCl_3$ will readily remove the passivating film of LiCl which normally is present on the surface of lithium which is in direct contact with $SOCl_2$, the Li will continue to be attacked by the $SOCl_2$ until one of the three reactants (Li, $SOCl_2$, or $AlCl_3$) is exhausted. Thus, Li/$SOCl_2$ cells containing excess $AlCl_3$ must be operated as reserve cells in which the electrolyte is allowed to contact the electrodes shortly before the beginning of discharge. Both $LiAlCl_4$ and $AlCl_3$ electrolyte solutions have been used in this work.

Experimental

A schematic diagram of the experimental cell is shown in Fig. 1. The anode was a 0.75 mm thick sheet of lithium pressed onto a nickel metal current collector. The cathode was a layer of carbon black containing 5-10% PTFE (polytetrafluoroethylene) also supported upon a nickel current collector. The cathode was 1 cm^2 in area and ranged in thickness from 0.025 to 1.0 mm. (Cathode thicknesses were measured by the use of a precision micrometer.) The two electrodes were separated by a 0.13 mm thick sheet of porous glass paper. A PTFE-coated or glass-coated metal weight was used to maintain good interfacial contact between the cell components. Nickel wire current leads were used, and the cell was positioned within an evacuable Pyrex glass container with glass-to-metal seals at the points where the current leads passed through the container.

The cell was assembled in a dry room (relative humidity $<2\%$), and the electrolyte (a solution of either $LiAlCl_4$ or $AlCl_3$ in $SOCl_2$) was placed within the electrolyte reservoir. The sealed Pyrex container was then transferred to the test stand where it was usually allowed to equilibrate at room temperature. In some cases, the glass container was placed within a thermostatically controlled oil bath to equilibrate at either 45° or 65°C. The Pyrex container was evacuated for 30 min. Then, the electrolyte was allowed to enter the evacuated container (through a Teflon stopcock), completely submerging the electrodes. Dry air was added to bring the container to atmospheric pressure, and the constant load or constant current discharge was begun after no more than a ten minute stand on open circuit.

A Fluke datalogger was used to record the cell voltage as a function of time. The average discharge plateau voltages and currents were determined from the resulting discharge curves, and the capacities were calculated by the integration of each discharge curve to a cutoff voltage which was in every case 10% below the average plateau voltage.

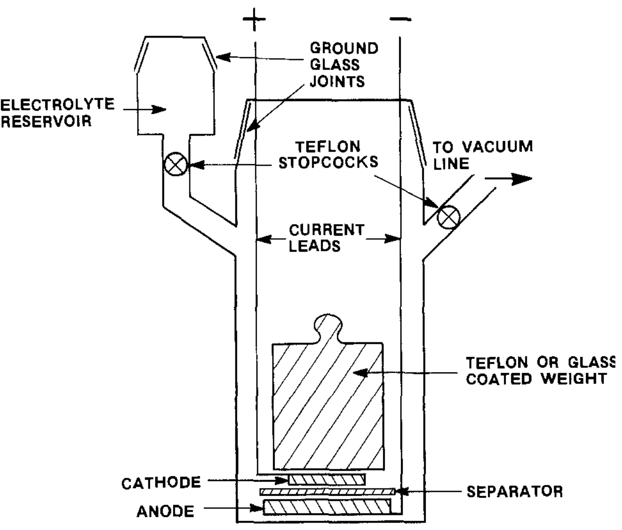

Fig. 1. Schematic diagram of the experimental test cell

The carbon black used in this work was 50% compressed Shawinigan acetylene black, and the PTFE was supplied by du Pont as an aqueous dispersion (TFE-30). The lithium was supplied by Foote Mineral Company. The LiCl was obtained from J. T. Baker and was vacuum dried for 16 hr at 350°C prior to use. The Fluka $AlCl_3$ (puriss) was obtained from Tridom Chemical Company, and the $SOCl_2$ from Hooker Chemical Company. Before use, the $SOCl_2$ was twice distilled over Li. To prepare the electrolyte, an adduct of $AlCl_3$ and $SOCl_2$ was first formed. [The preparation of such adducts are described in Ref. (8) and (9)]. Distilled $SOCl_2$ was added to the adduct to form an $AlCl_3$ solution of the desired concentration. In order to form the $LiAlCl_4$ electrolyte, an excess of LiCl was added to the $AlCl_3$ solution. The undissolved LiCl was subsequently removed by filtration. The extent to which the electrolyte was contaminated by water was determined by infrared spectroscopy (10). The electrolyte was found to be contaminated by less than 0.5 ppm of water, the limit of detection of the infrared spectroscopic method.

Results

In the initial experiments, the concentrations of $LiAlCl_4$ and $AlCl_3$ in the electrolyte solutions were varied in order to determine the effect upon discharge capacity. A moderately high discharge current density of about 30 mA/cm^2 was chosen for these initial experiments. Two cathode thicknesses, 37 and 950 μm, were employed.

The data obtained with the $LiAlCl_4$ solutions are plotted in Fig. 2. With the 37 μm cathodes, the capacity maximized at a $LiAlCl_4$ concentration of about 1.5M. However, with the 950 μm cathodes, the capacity maximized at a $LiAlCl_4$ concentration of about 4.0M. Since most of the succeeding experiments were to be performed with cathodes which were about as thick as the 37 μm cathodes, 1.5M was chosen as the concentration to be used in most of the experiments in which $LiAlCl_4$ electrolyte solutions were employed.

The data obtained with the $AlCl_3$ solutions are shown in Fig. 3. With the 37 μm cathodes, the capacity maximized at an $AlCl_3$ concentration of about 4.5M. With the 950 μm cathodes, on the other hand, the capacity maximized at an $AlCl_3$ concentration of about 3.0M. As before, since most of the succeeding experiments were to be performed with cathodes which were about as thick as the 37 μm cathodes, 4.5M was chosen as the concentration to be used in most of the experiments in which $AlCl_3$ electrolyte solutions were employed.

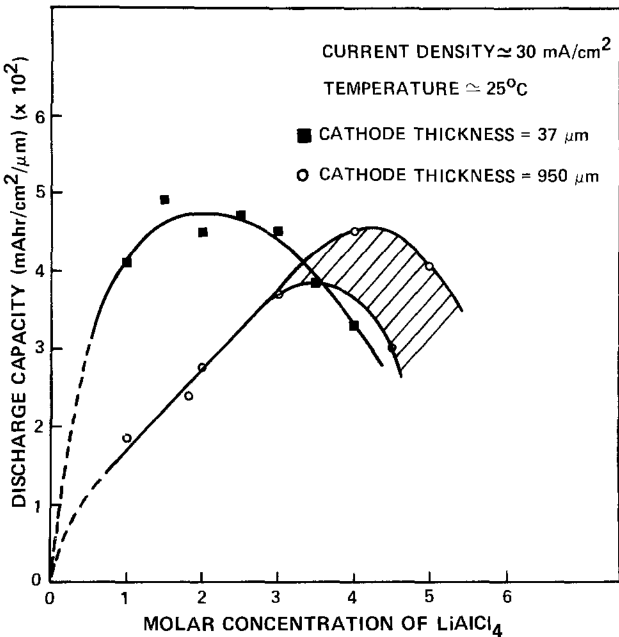

Fig. 2. Discharge capacity vs. $LiAlCl_4$ concentration

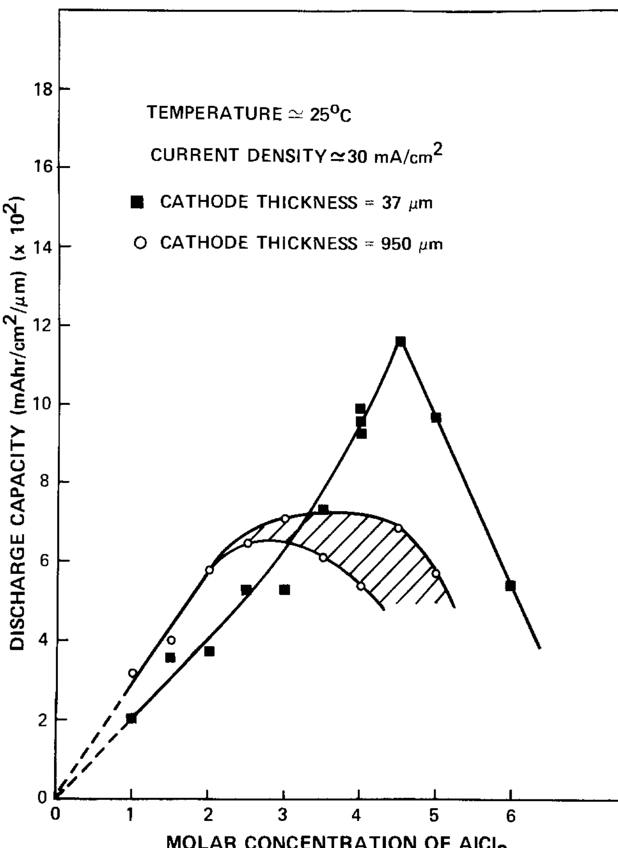

Fig. 3. Discharge capacity *vs.* $AlCl_3$ concentration

Typical discharge curves obtained at a current density of 30 mA/cm^2 with 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ electrolyte solutions are compared in Fig. 4. In these experiments, the cathodes were 55 μm thick, and the $Li/SOCl_2$ cells were discharged at room temperature. The increases in both operating voltage and discharge capacity associated with the use of the $AlCl_3$-containing electrolyte are apparent.

As shown in Fig. 1 and 2, the discharge capacity (per unit cathode thickness) of the high rate $Li/SOCl_2$ cell is a function of both electrolyte composition and cathode thickness. Further, with both $LiAlCl_4$ and $AlCl_3$ electrolyte solutions, the capacity per unit cathode volume decreases with increasing thickness. This effect is clearly demonstrated by the data in Fig. 5 where the $Li/SOCl_2$ cell discharge capacity is plotted as a function of thickness for thicknesses ranging from about 20 μm to about 950 μm. Cells were discharged with both 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ electrolyte solutions. (The $Li/SOCl_2$ cells were all discharged at about 30 mA/cm^2 current density.) It can be seen that, particularly with the 4.5M $AlCl_3$ solution, the effective cathode utilization increases very significantly as the cathode thickness is decreased below about 150 μm.

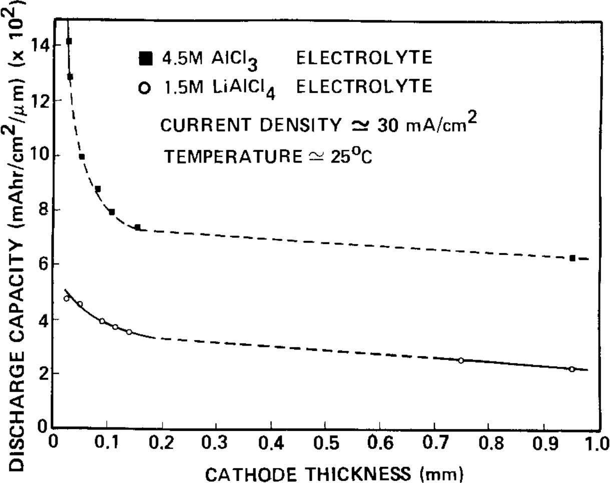

Fig. 5. Discharge capacity *vs.* cathode thickness.

The combined effects of discharge rate, cathode thickness, and electrolyte composition upon the discharge capacities of $Li/SOCl_2$ cells are shown graphically in Fig. 6 where the average current density is plotted *vs.* the discharge duration per unit cathode thickness on a log-log scale. Data are shown for both 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ electrolyte solutions and for cathode thicknesses of 55 and 950 μm. As expected, the discharge capacities obtained with the $AlCl_3$ electrolyte solution are uniformly larger than those obtained with the $LiAlCl_4$ electrolyte over the entire range of discharge rates. It can also be seen that, at low current densities, the capacity per unit cathode thickness is approximately independent of thickness. However, at higher discharge rates, the capacity per unit cathode thickness (the apparent cathode utilization) decreases with increasing thickness, the rate of decrease being greater the higher the average current density.

All of the above results were obtained with cells discharged at room temperature. In order to determine what gains in performance might be realized at higher temperatures, $Li/SOCl_2$ cells were also discharged at 45° and 65°C. The effects of temperature variation are exemplified by the discharge curves shown in Fig. 7 for cells discharged at both room temperature and 65°C. These cells contained 50 μm thick cathodes and 1.5M $LiAlCl_4$ electrolyte solutions and were discharged

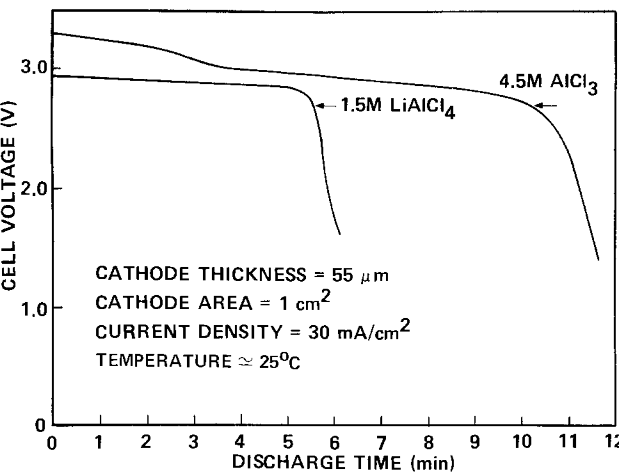

Fig. 4. Discharge curves comparing 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ electrolyte solutions.

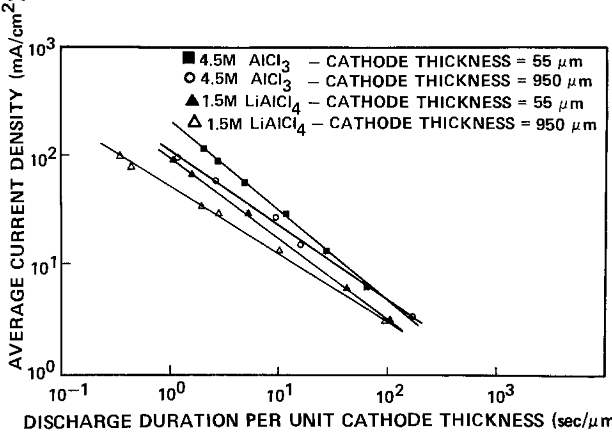

Fig. 6. Average discharge current density *vs.* discharge duration per unit cathode thickness.

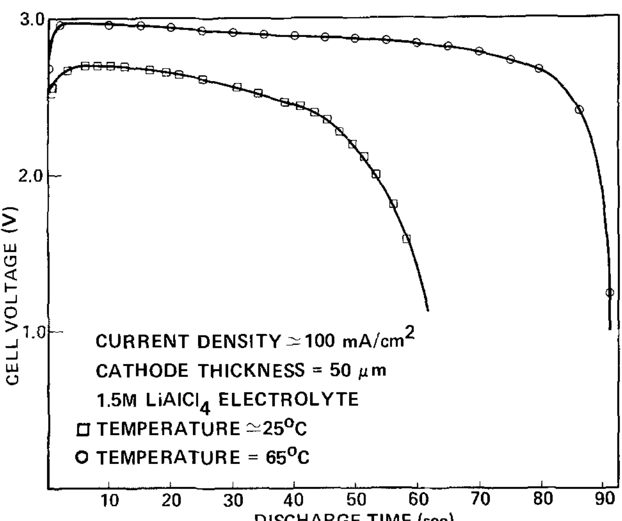

Fig. 7. Discharge curves at room temperature and 65°C

at a current density of about 100 mA/cm². As the figure shows, an increase in temperature causes the cell to discharge for a longer time at a higher operating voltage and with a flatter discharge curve. Thus, operating high rate $Li/SOCl_2$ cells at elevated temperatures increases cathode utilization and decreases cell polarization.

The current-potential curves (plotted on a semilog scale) derived from the discharge of $Li/SOCl_2$ cells containing 50 μm cathodes and 1.5M $LiAlCl_4$ in $SOCl_2$ as the electrolyte at room temperature, 45°C, and 65°C are compared in Fig. 8. (Each point is determined by the average voltage and average current-density obtained from the plateau portion of the discharge curve of an individual $Li/SOCl_2$ cell.) The decrease in polarization with increasing temperature is apparent over the entire range of discharge rates.

The discharge duration per unit cathode thickness is plotted as a function of current density on the log-log plot shown in Fig. 9. (Each point corresponds to one of the points in the current-potential curves shown in Fig. 8.) As expected, the discharge capacity increases with increasing temperature and with decreasing discharge rate.

The current-potential curves obtained from the discharge of $Li/SOCl_2$ cells containing 50 μm cathodes with both 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ electrolyte solutions and at both room temperature and 65°C are compared in Fig. 10. The corresponding discharge rate *vs.* duration data are plotted in Fig. 11. With 4.5M $AlCl_3$, as with the 1.5M $LiAlCl_4$ electrolyte, the voltage characteristics improve with increasing temperature, and the discharge capacity increases with increasing temperature and with decreasing discharge rate. As expected, over the entire range of discharge rates and at both temperatures, the use of the 4.5M $AlCl_3$ electrolyte results in higher voltages on load and larger discharge capacities than are obtained with the conventional 1.5M $LiAlCl_4$ electrolyte.

Discussion

Perhaps the first question to be answered is how a $SOCl_2$ solution containing only $AlCl_3$ with no deliberately introduced LiCl can function as a very good electrolyte in $Li/SOCl_2$ cells, since the room temperature

conductivity of a 3.0M solution of $AlCl_3$ in $SOCl_2$ is only about $3 \times 10^{-4}\ \Omega^{-1}\ cm^{-1}$ (11). In such a system, two parallel chemical reactions will be occurring. The Li will be reacting with the $SOCl_2$ in a direct oxidation-reduction reaction, depositing a protective insoluble LiCl film on the surface of the Li; simultaneously, the $AlCl_3$ in solution will react with the LiCl film to produce soluble $LiAlCl_4$. As this LiCl film is removed from the surface of the Li, more LiCl forms which again reacts with the $AlCl_3$. By the continuation of this process, enough $LiAlCl_4$ is produced to make the solution sufficiently conductive to support the discharge of the cell. The fact that this system is stable to any degree is evidence that the rate of film formation is much more rapid than that of its removal. However as previously noted, if such a cell was allowed to stand indefinitely on open circuit, the Li would continue to be oxidized by the $SOCl_2$ until one of the three reactants (Li, $SOCl_2$, or $AlCl_3$) was exhausted. Thus, $Li/SOCl_2$ cells containing excess $AlCl_3$ must be discharged soon after the $SOCl_2$ solution is allowed to contact the electrodes.

The normal overall discharge reaction of the $Li/SOCl_2$ cell can be written as (12, 13)

$$4Li + 2SOCl_2 \rightarrow 4LiCl + S + SO_2 \quad [1]$$

Sulfur crystallizes from the electrolyte once its solubility has been exceeded. The Cl^- produced by the reduction of $SOCl_2$ reacts with the Li^+ contained within the $LiAlCl_4$ electrolyte solution to form insoluble LiCl which immediately precipitates within the cathode pores, leading to eventual discharge termination (12, 13). However, if excess $AlCl_3$ is present, the Cl^- produced during discharge reacts preferentially with the $AlCl_3$ to produce $AlCl_4^-$, and the overall discharge reaction now becomes

$$4Li + 2SOCl_2 \xrightarrow{AlCl_3} 4LiAlCl_4 + S + SO_2 \quad [2]$$

Since the ΔG for this reaction is greater than that corresponding to Eq. [1], the cell voltages before and during discharge are greater in the presence of excess $AlCl_3$ than they are in its absence. (The open-circuit voltages of $Li/SOCl_2$ cells containing 4.5M $AlCl_3$ and 1.5M $LiAlCl_4$ electrolyte solutions are about 4.0V and about 3.6V, respectively.) Later, as the excess $AlCl_3$ is consumed by reaction with the Cl^-, the primary cell reaction shifts from reaction [2] to reaction [1], giving rise to two distinct discharge plateaus as shown in Fig. 4. Because the discharge of the $Li/SOCl_2$ cell terminates when the cathode pores become choked by the precipitating LiCl, such a cell will have a greater discharge capacity when its electrolyte contains excess $AlCl_3$ than when it does not.

Except for the two-step discharge curve characteristic of the presence of excess $AlCl_3$, the general performance characteristics of $Li/SOCl_2$ cells with and without excess $AlCl_3$ are very similar. As shown in Fig. 2 and 3, in both cases the discharge capacity per unit cathode volume maximizes as the $AlCl_3$ or $LiAlCl_3$ concentration is increased. The fact that the conductivity of the electrolyte generally increases with increasing $AlCl_3$ or $LiAlCl_4$ concentration presumably leads to an increase in capacity with concentration. The subsequent capacity decrease with a further increase in $AlCl_3$ or $LiAlCl_4$ concentration is probably the result of the increasing viscosity of the $SOCl_2$ solution, making it less able to function as an efficient mass and charge transfer medium.

In order to investigate these effects further, the conductivities of a number of solutions containing both $AlCl_3$ and $LiAlCl_4$ were measured over the temperature range $-20°$ to $+65°C$. The introduction of $AlCl_3$ into the $LiAlCl_4$ electrolyte was usually found to increase the conductivity at higher temperatures but reduce the conductivity at lower temperatures. For the particular case of a $LiAlCl_4$ concentration of 0.5M,

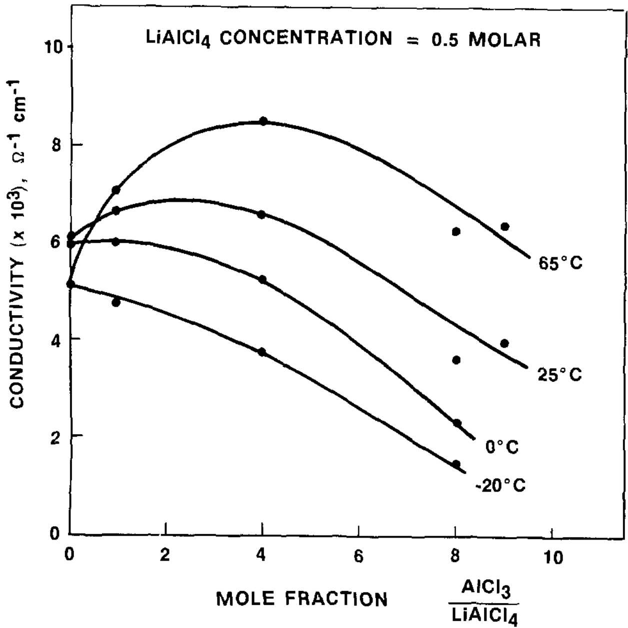

Fig. 12. Conductivity vs. mole fraction $AlCl_3$:$LiAlCl_4$ for a $LiAlCl_4$ concentration of 0.5M.

Fig. 12 shows the conductivity as a function of the mole ratio $AlCl_3/LiAlCl_4$ in solution at four temperatures.

The data suggest that an interaction such as

$$AlCl_3 + AlCl_4^- \rightleftarrows Al_2Cl_7^- \quad [3]$$

or perhaps higher complexing is occurring. At low temperatures and at high $AlCl_3/AlCl_4^-$ ratios, the equilibrium is displaced to the right, resulting in the formation of the less mobile $Al_2Cl_7^-$ species. Conversely, at high temperatures and low concentrations, the equilibrium is displaced to the left, and the conductivity of the solution is the sum of independent contributions from $AlCl_3$ and $AlCl_4^-$.

As shown in Fig. 5, the capacity per unit cathode volume decreases with increasing cathode thickness at constant discharge rate. The depth of discharge in each increment of thickness into the cathode (proportional to the amount of deposited LiCl in that increment) decreases due to the limitations upon mass transport through the rapidly narrowing cathode pores (5). As shown in Fig. 6, the steepness of the cathode utilization *vs.* thickness curve rapidly increases with increasing discharge rate. The fact that this effect is much more pronounced with the $AlCl_3$ solution than with the standard $LiAlCl_4$ electrolyte is a result of the ability of the excess $AlCl_3$ (contained within the separator as well as within the cathode itself) to act as an effective getter or sink for the LiCl product, thus tripling the effective capacity of the thinnest cathodes.

Finally, as shown by the data in Fig. 7-11, the discharge efficiency of the high rate $Li/SOCl_2$ cell can be greatly increased by increasing the cell temperature. There are a number of factors which may combine to result in improved cathode utilization with increasing temperature. The solubilities of the solid reaction products and of the $LiAlCl_4$ all increase with temperature. Quite probably, the efficiency with which the LiCl is deposited within the porous cathode is also improved at elevated temperatures. The increasing conductivity of the electrolyte with increasing temperature also probably contributes to improved cathode utilization. Which factor may predominate as a function of discharge rate and temperature is, of course, still a matter of conjecture.

Similarly, there are a number of factors which may contribute to a decrease in overvoltage with increasing temperature. In view of the fact that it is not known what physical process primarily determines the over-

voltage of the $Li/SOCl_2$ cell at room temperature and at relatively low discharge rates, to suggest what factors may result in decreased overvoltage at elevated temperatures and at higher discharge rates is clearly not yet possible. In any case, reduced cell polarization is generally found to accompany an increase in operating temperature.

Summary and Conclusions

The performance characteristics of the $Li/SOCl_2$ cell have been determined as a function of discharge rate, electrolyte composition, cathode thickness, and cell temperature. Cells have been discharged at rates ranging from about 3 to nearly 300 mA/cm^2. The $SOCl_2$ electrolyte solutions have contained either $LiAlCl_4$ or $AlCl_3$, with the most efficient discharge characteristics being realized with 1.5M $LiAlCl_4$ and 4.5M $AlCl_3$ solutions. Cathodes with thicknesses between 0.025 and 1.0 mm have been utilized.

The discharge curve of a $Li/SOCl_2$ cell with an electrolyte containing excess $AlCl_3$ is characterized by two distinct voltage plateaus, resulting from the ability of the $AlCl_3$ to complex with the Cl^- produced by the reduction of the $SOCl_2$. Moreover, the use of pure $AlCl_3$ dissolved in $SOCl_2$ as the electrolyte results in substantially higher average discharge voltages and discharge capacities than can be achieved with cells containing the conventional $LiAlCl_4$ electrolyte.

With both $LiAlCl_4$ and $AlCl_3$ electrolyte solutions, the capacity per unit cathode volume (the effective cathode utilization) decreases with increasing cathode thickness, the rate of decrease being greater the higher the discharge current density. Finally, it has been found that an increase in operating temperature results in an increase in cathode utilization and a decrease in overvoltage, again with both $LiAlCl_4$ and $AlCl_3$ electrolyte solutions.

ABSTRACT

Porous electrocatalytic electrodes for the polysulfide redox system, containing one of various metallic sulfides (especially of Co, Cu, Pb) are described. Emphasis is placed on their use as counterelectrodes in photoelectrochemical cells employing polysulfide electrolytes. Their activity is measured as a function of electrolyte temperature and composition. The ratio of S to S^{2-}, and through it the local redox potential of the solution, is shown to be an important factor controlling electrode activity. The short and long term stability of the electrodes, as cathodes, is discussed, and it is shown that, when used in conjunction with photoanodes, Cu_2S and CoS may poison the photoelectrode surface, thereby reducing total cell efficiency.

Since the discovery that polysulfide electrolytes can stabilize various photoelectrodes against photocorrosion (1-3), in particular CdS and CdSe, the need for an efficient counterelectrode has arisen, since electrodes of carbon and platinum, usually used for this purpose, are not very active for the polysulfide redox system [Ref. (4), Fig. 1].

The importance of the counterelectrode in a photoelectrochemical cell (PEC) can be illustrated by Fig.

* Electrochemical Society Active Member.

Key words: electrodeposition, sulfidation, photoelectrochemistry, energy conversion.

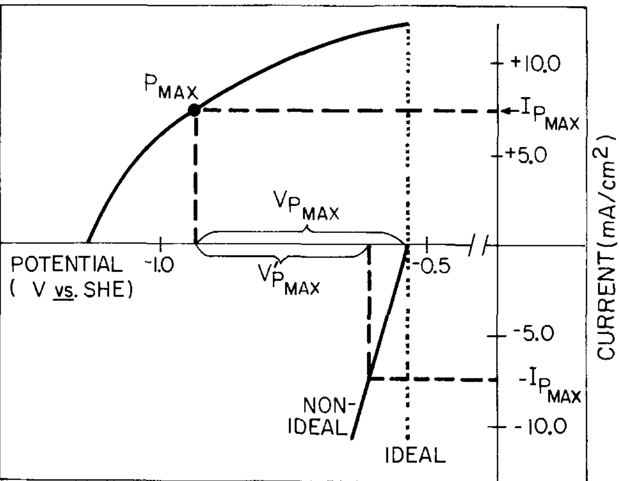

Fig. 1. Potentiostatic current-voltage curve of n-CdSe photoanode together with an ideal and nonideal (polarizable) countercathode. P_{max} represents the maximum power point on the illuminated CdSe *I-V* curve. The cathodic curves are for an ideal (no polarization broken line) and nonideal counterelectrode.

1, which shows potentiostatic current-voltage curves of both the photo and counterelectrodes. For the purpose of the illustration, the upper curve is that of a typical CdSe electrode [prepared by electroplating (1)] while the lower plot is that of a counterelectrode which is assumed to polarize 100 mV at a cathodic current of 10 mA (solid line) or an ideal counterelectrode which maintains the redox potential of the electrolyte at all current densities (dotted line). Looking first at the CdSe electrode against the ideal counterelectrode, we see that at maximum power the combined system delivers 7.4 mA (I_{Pmax}) at 400 mV (V_{Pmax}), *i.e.*, 2.96 mW. If the counterelectrode is the polarizable one, then at I_{Pmax}, the voltage output of the cell falls to 327 mV (V'_{Pmax}), and the power delivered is now 2.42 mW. (In fact, the maximum power point will shift slightly, but this will make only a small difference, and will be ignored here.) This represents an 18% drop in power, which is manifested by a drop in fill factor from 0.41 to about 0.34 for the overall cell.

It should be noted that this kind of loss often goes unnoticed or is overlooked when power output of a PEC is derived from potentiostatic *I-V* plots. Therefore, any influence of the counterelectrode is neutralized and too optimistic a picture of cell performance is obtained.

We reported previously that electrodes of CoS, NiS (4), Cu_2S, and PbS (5) are active for polysulfide reduction (required for n-type photoelectrodes; (poly)sulfide oxidation for p-type photoelectrodes). The purpose of this work is to compare the properties of such electrodes especially those that can be prepared simply (an important consideration for possible practical PEC's), and to find the optimum working conditions for their use, mainly in terms of electrolyte composition.

Experimental

We consider three basic types of electrodes: Cu_2S, CoS, and PbS.

1. Cu_2S electrodes are prepared by immersing a brass gauze (70% Cu, 30% Zn) in a (poly)sulfide solution. The gauze gradually blackens, forming Cu_2S. This process of sulfidization can be accelerated by anodizing the gauze in the (poly)sulfide solution. The presence of zinc in the alloy imparts mechanical coherence to the electrode; copper alone in sulfide solution rapidly disintegrates as Cu_2S forms throughout the bulk of the copper, while sulfidization of zinc is relatively limited to the surface, thereby holding the Cu_2S in a matrix, the bulk of which is zinc metal.

2. Co electrodes are prepared by first electroplating $Co(OH)_2$ onto a stainless steel cathode. The electroplating solution consists of an aqueous solution of 20g $CoSO_4$/liter with a potassium biphthalate buffer to maintain the pH between 3 and 6. The anodes are cobalt plates or rods, one on each side of the cathode for an even current distribution. Electrolysis is carried out at room temperature and without stirring. The current density used varies between ~20-60 mA/cm². (In this study, 1 cm² means an electrode of 1 cm² geometric area. Since both sides of all electrodes are exploited, this is really 2 cm². However, assuming a counterelectrode will be, at least, identical in size to the photoelectrode in a PEC, then both sides of the counterelectrode will be available for reaction, unless the counterelectrode is also the back wall of the cell. Since we wish to evaluate a counterelectrode as it will be used in a practical cell, this system of measurement is chosen.) The optimal current density depends mainly on the *p*H of the electrolyte, the current density increasing as the *p*H decreases. Thus at a *p*H of 5, the optimal current density is 30-40 mA/cm². The plating time varies from 3 to 6 min. If plating continues for longer, the layer becomes dendritic, and mechanically unstable. Under these conditions, a black coating is obtained which dries to a blue-green color, and which consists mainly of $Co(OH)_2$. When immersed in (poly)sulfide solution, this is converted to cobalt sulfide, mainly CoS. A reduction treatment at ~ −1200 mV (*vs.* SCE) in a (poly)sulfide solution for several minutes improves the electrode performance somewhat.

3. PbS electrodes are prepared by electroplating PbO_2 onto a stainless steel anode using a Pt cathode and an aqueous electrolyte of lead nitrate. The conditions for plating (electrolyte composition, current density, plating time) were found to be noncritical; typically the plating was carried out from a 0.3M solution of lead nitrate (or acetate) at a current density of ~50 mA/cm² for 5 min. This layer is then reduced electrolytically in (poly)sulfide solution under the same conditions as those used for CoS. This reduction treatment is essential to obtain active electrodes.

In addition to these three types of electrodes, several other electrode materials were tested, largely for comparison purposes: Platinized platinum (platinum black electroplated on platinum metal); high surface-area carbon in the form of plates ~ 1 mm thick; electroplated brass on steel with a Cu:Zn ratio of 95:5; and RuS_2 prepared by cathodic treatment of a stainless steel substrate in an aqueous solution of 0.5g $RuCl_3$/liter and subsequent reduction in polysulfide solution as described above for CoS and PbS electrodes.

Potentiostatic current-voltage curves were obtained using either an Elscint CHP-1 or Wenking LT 73 potentiostat. The polysulfide electrolytes contained KOH and S (Frutarom), $Na_2S \cdot 9H_2O$ (BDH), and deionized water. A water-jacketed cell, connected to a thermostat was used. Argon was continually passed over the electrolyte to prevent oxidation, but no stirring was employed (unless specifically mentioned). A saturated calomel electrode was used as reference in most cases, though a Pt wire, which takes the potential of the solution, was used in some experiments. The counterelectrode was a 10 cm² Pt gauze.

Results and Discussion

Electrocatalytic activity.—The electrocatalytic activity of the electrodes studied is given directly by the current-potential plots in Fig. 2. Seven types of electrodes are shown here. The three main electrodes studied, CoS, PbS, and sulfided brass (30% Zn), are shown by one plot, since the activities of all three are almost identical, within experimental variations. From Fig. 2, it can be seen that these electrodes outperform all others with the exception of the 95% Cu electrode, which however is not very stable (see under long-term stability of electrodes, below). Platinized Pt, the

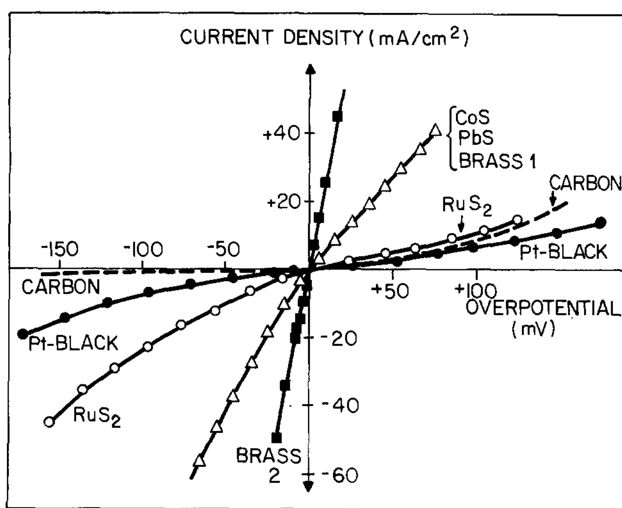

Fig. 2. Anodic and cathodic polarization curves of various electrode materials in 1M[OH], 1M[S^{2-}], and 1M[S] electrolyte at 30°C. Brass (1) contains 70% Cu, 30% Zn. Brass (2) contains 95% Cu, 5% Zn; Pt-black is platinized Pt.

most active electrode studied by Allen and Hickling (6), is much less active, and carbon, even less so. (Smooth Pt is similar, or less active, than carbon.)

The results obtained suggest that other sulfides which are good electrical conductors, *i.e.*, metallic or degenerate semiconductors, may be good electrocatalysts for this system. Preliminary experiments with RuS_2 support this, as can be seen in Fig. 2. These electrodes are intermediate in activity between platinized Pt and the active sulfides in the cathodic direction. At present, we have succeeded in making only very thin layers of RuS_2 by electroplating, much less than the several microns usually plated of the other sulfide electrodes. From this, we may reasonably infer that RuS_2 is intrinsically as active as the other sulfides, and the measured lesser activity is due only to a lower active surface area.

Dependence of activity on electrolyte composition.—The composition of the electrolyte in a photoelectrochemical cell is of crucial importance for cell operation. Even for a redox system which is known to be able to stabilize a certain semiconductor, such as polysulfide/CdSe, the absolute concentrations of the oxidized and reduced forms of the electrolyte can affect such properties as stability of photoelectrode (7, 8), magnitude of photocurrent (9), light absorption in electrolyte, and polarization of the counterelectrode. Since it is the last of these properties which interests us here, we have investigated the effect of the composition of the polysulfide solution on the electrocatalytic activity of the sulfide electrodes.

Normally we would expect an increase in concentration of the electroactive species (for an n-type photoelectrode, the electroactive species at the counterelectrode is the oxidized form) to decrease the polarization at an electrode. If we look at Fig. 3(a), where polarization curves are shown for a CoS electrode in solutions of fixed [OH^-] and [S^{2-}], and varying [S], we see that indeed when [S] $\leq$ 1M, this is true for the relevant cathodic direction. The trend to limiting current densities apparent at low [S] concentrations can be explained by normal concentration polarization, where the current is determined by the rate of diffusion of oxidized species to the electrode surface. However, when [S] > [S^{2-}] (1/1/2 and 1/1/3 in Fig. 3), we obtain the unexpected result that the activity again decreases as [S] increases. That the determining factor here is the ratio between [S] and [S^{2-}], rather than the absolute value of [S], is clear from Fig. 3(b), where, for different absolute values of [OH^-] and

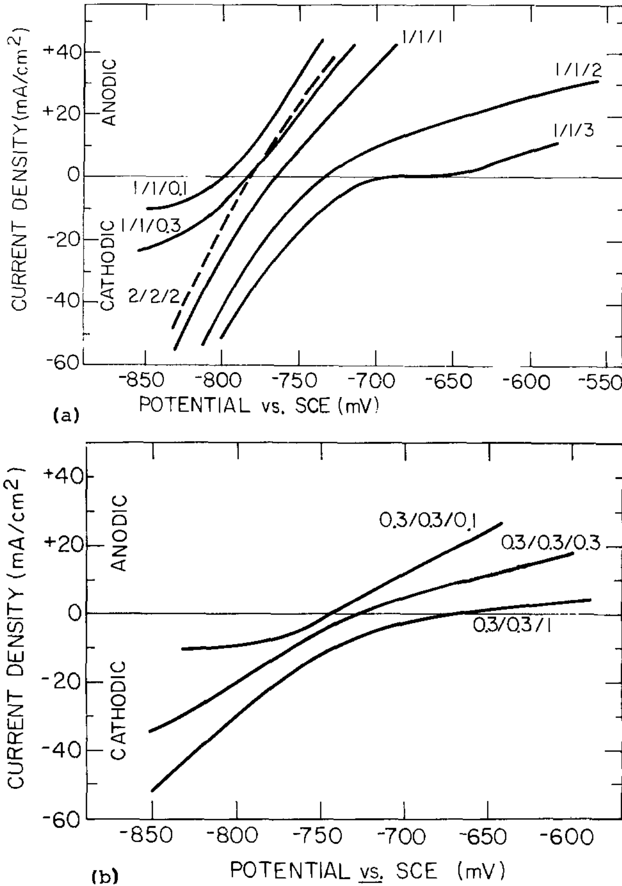

Fig. 3.(a) Polarization curves of a CoS electrode in various polysulfide electrolytes at 30°C. The number for each curve represent the molar concentrations of [OH^-], [S^{2-}], and [S], respectively. Except for the 2/2/2 electrolyte (broken line), the curves represent a variation of [S] with fixed [OH^-] and [S^{2-}]. (b) As Fig. 3(a), but with lower [OH^-] and [S^{2-}] (0.3M each) than in Fig. 3(a).

[S^{2-}], the maximum activity is again obtained when [S] = [S^{2-}], and decreases when [S]/[S^{2-}] $\neq$ 1.

This behavior can be rationalized, if we consider the effect of electrolyte composition on the redox potential (potential of zero current in Fig. 3). Figure 4 shows E_{redox} as a function of [S] and the anomalous behavior for [S] > 1, which means in this case [S]/[S^{2-}] > 1, is obvious. The underlying reason for this steep change in E_{redox} can be found in the rather complicated equilibria involving various higher polysulfides, that enter into the picture under these conditions [as has been explained by Allen and Hickling (10)].

Using Fig. 4 we can now understand the fact that the anodic parts of the curves for 1/1/2 and 1/1/3 [Fig. 3(a)] and 0.3/0.3/1 [Fig. 3(b)] are much flatter than expected. When oxidizing these sulfur-rich solutions more sulfur is formed in and around the pores of the electrode and because of this, the redox potential changes to less negative values, approaching the point of zero current. This is especially obvious in the curve for 1/1/3, where between the voltages −700 and −650 mV *vs.* SCE the electrode passes practically no current. Because this effect is dependent on the rate by which the S formed is removed from the electrode, one would expect such a phenomena to be strongly influenced by either stirring or temperature. The temperature effect is clearly illustrated in Fig. 5 and the effect of stirring is very similar.

The same reasoning explains the cathodic part of the curve. As long as the polarization is insufficient to shift the electrolyte potential near the electrode out of the non-Nernstian region (where [S] >[S^{2-}]) into

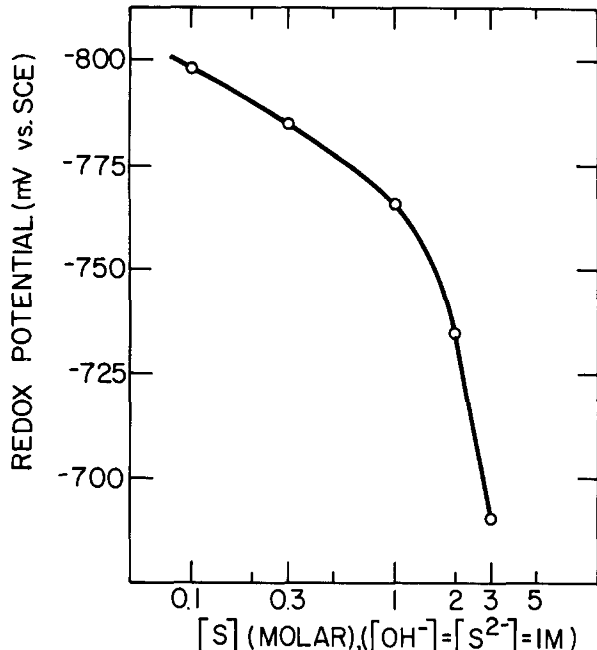

Fig. 4. Effect of [S] on the redox potential of a polysulfide electrolyte at 30°C; $[OH^-]$ and $[S^{2-}]$ fixed at 1M each.

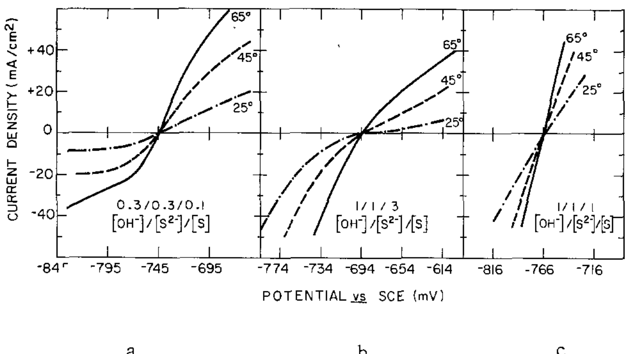

Fig. 5(a). Effect of temperature on the polarization curves of a CoS electrode in a 0.3/0.3/0.1 polysulfide electrolyte. (b) As Fig. 5(a), but for a 1/1/3 electrolyte. (c) As Fig. 5(a), but for a 1/1/1 electrolyte.

the Nernstian region (where $[S] \leq [S^{2-}]$), a small change in electrolyte composition at the electrode (caused by a small current density) can shift the potential strongly in the cathodic direction (*i.e.*, a large overpotential). When the electrolyte composition near the electrode approaches $[S] = [S^{2-}]$, it now shows normal Nernstian behavior, and the shift in potential with increasing $[S^{2-}]$ (*i.e.*, increasing current density) becomes less. At the potential where $[S] = [S^{2-}]$ [−750 mV in Fig. 3(a)], and 1/1/1, 1/1/2, and 1/1/3 curves all become more or less parallel as is to be expected. This behavior is in contrast with that of a normal concentration overpotential, where the change in overpotential increases with increasing current density, as occurs for example in the cathodic branch of the 1/1/0.1 and 1/1/0.3 curves of Fig. 3(a).

Galvanostatic pulse measurements in the S-rich solutions show that the decay of the overpotential after the pulse (and the buildup at the start of the pulse) can take minutes. However, this decay can be shortened considerably by stirring the solution vigorously. Specifically, experiments in a 1/1/1 electrolyte show that the instantaneous part of the decay (representing a minimum value for *IR*-losses) accounts for about one third of the measured overpotential. The greater part of the remainder can be eliminated by stirring and therefore any activation overpotential present contributes in a minor way only to the total overpotential. The diffusion (or concentration) part of the overpotential, which thus makes the largest contribution to the whole, arises in the same way as that described above for electrolytes with $[S]/[S^{2-}] > 1$.

Figure 3(a) also shows the curve obtained in a 2/2/2 electrolyte. As expected, since the concentration of electroactive species is higher, yet $[S] = [S^{2-}]$, this electrolyte gives a somewhat better performance than does the 1/1/1 electrolyte.

Changing the hydroxide concentration shows no marked effect on the performance of the electrode. Its main effect is to shift E_{redox} to somewhat more negative values with increasing $[OH^-]$.

Although the results above are illustrated with CoS electrodes, they hold for Cu_2S and PbS electrodes as well.

Temperature dependence of electrolytic activity.—Since the operating temperature of a photoelectrochemical cell may vary over a wide range, from near 0°C to as much as 60°C, the effect of temperature on its operation is of particular importance. Here we are concerned with the effect of temperature on the functioning of the counterelectrode.

Figures 5(a), (b), and (c) show the effect of temperature on the activity of a CoS electrode in three different electrolyte compositions; low concentrations of [S] and $[S^{2-}]$ (0.3/0.3/0.1); high $[S]/[S^{2-}]$ ratio (1/1/3), and the standard electrolyte 1/1/1. Variation of temperature has a small effect on the redox potential, and for clarity of comparison, it has been neglected here. Since we know from the results described above that a large part of the overpotential is due generally to a diffusion-controlled component, we expect a substantial increase in activity due to increased diffusion at higher temperatures, and this is indeed observed. Of particular interest are the results obtained in Fig. 5(b), where $[S] > [S^{2-}]$. In the cathodic direction, the polarization in this electrolyte drops from 45 mV at 25°C to 10 mV at 65°C for a current density of 10 mA/cm². Even more striking is the change in the anodic direction, where, for a current density of 5 mA/cm², the polarization varies from 70 mV at 25°C to 8 mV at 65°C. The results from Fig. 5 may be used directly, as shown previously (in Fig. 1) to calculate the losses in a photoelectrochemical cell due to counterelectrode polarization over a certain temperature range. We have found the effect of stirring on electrode activity to be qualitatively similar to that of temperature, as expected from a diffusion-controlled overpotential. Because of the desirability of lack of external stirring in practical PEC's due to external power source and space considerations, we have not given much attention to this effect. However, it may be of importance in combined cells with heat transfer, where the electrolyte is in motion (11).

Stability consideration of the sulfide electrodes.—The most important single characteristic of a counterelectrode for use in a photoelectrochemical cell is, as for the photoelectrode, the long-term stability of the electrode. For the electrodes mainly under consideration in this study, PbS, Cu_2S, and CoS, the stabilities are quite different.

PbS.—PbS is by far the least stable of these three, and therefore it will be dealt with briefly. The activity of a PbS electrode drops slowly to about 10% of its initial activity, over a period of a couple of weeks when used in a cell under normal (day-night) working conditions, and remains constant thereafter. The initial activity may be regenerated by cathodic reduction. Presumably, the deactivation is caused by a surface alteration of the PbS, which itself is probably a surface layer on a substrate of porous PbO_2.

Cu_2S.—The stability of Cu_2S (in the form of sulfided brass) can be separated into three distinct parts. First of these is the mechanical stability, which we have mentioned briefly already. Pure Cu disintegrates in

polysulfide solutions within a short time. By adding increasing amounts of Zn to the Cu (as brass), the mechanical stability improves. For a 5% Zn, 95% Cu electrode as in Fig. 2, the electrode is stable for a period ranging from hours to a few days. Thus, in spite of the very high activity of such electrodes, they are not practical due to lack of stability. For a brass gauze with a Cu-Zn ratio of ~70:30 (normal or α-brass) the mechanical disintegration is slowed to such an extent that we have found no visible change in form of the gauze after 1 year in polysulfide solution, although black Cu_2S powder does fall from the electrode very slowly; this is noticeable even after short periods of a few weeks as the Cu_2S settles at the bottom of the cell. This very slow disintegration is open to further reduction by increasing further the Zn content of the brass (which will decrease the electrochemical activity), or possibly by using an alloy metal other than Zn, which itself is not completely stable in these solutions.

The second consideration is the stability of electrochemical activity of the Cu_2S electrode. We have found no change in activity over months of use. This is not unexpected, since the surface of the electrode is subject to a very slow, but continuous, renewal due to the mechanical disintegration.

The third, and less obvious, type of instability to be considered is the effect of the Cu_2S electrode on the photoelectrode. We have noticed during accelerated lifetime experiments (high illumination intensity), using CdSe single crystal photoelectrodes and Cu_2S counterelectrodes, that on some occasions, a bluish-black deposit forms on parts of the surface of the CdSe. Figure 6 shows a scanning electron micrograph of such a deposit, which takes the form of hexagonal platelets of dimensions of several microns, which tend to bunch together into flower petal-like aggregates. Electron microprobe composition measurements, as well as the hexagonal form of the crystallites, show the deposit to be CuS (covellite). Since the composition of the counterelectrode itself has been shown, by x-ray diffraction, to be $Cu_{>1.75}S$, it seems that the CuS is formed by photooxidation of Cu_2S at the illuminated CdSe surface. It is unclear whether the copper arrives at the CdSe as Cu^+ ions (although Cu_2S has a very low solubility product, there will be some Cu^+-containing ions

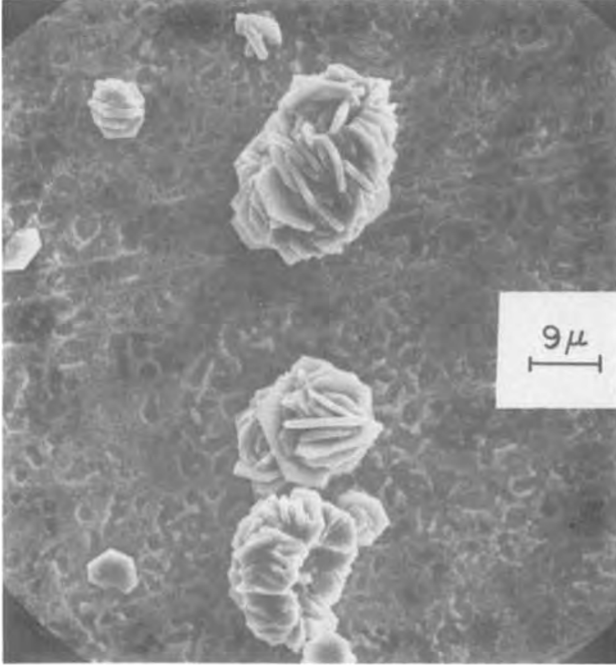

Fig. 6. SEM picture of CuS (covellite) formation on a single crystal n-CdSe photoanode after accelerated test using Cu_2S as a counterelectrode in a photoelectrochemical cell.

in solution) or as Cu_2S particles (colloidal or larger) from the slow disintegration of the sulfided brass. We have carried out some experiments with a Cu_2S and a gold electrode in polysulfide solution. The gold is connected to the negative terminal of a power-supply, to simulate an n-type photoelectrode, and the Cu_2S to the positive terminal. At a voltage between the two electrodes $\geqq$0.47V, a black deposit is clearly visible on the gold within 24 hr of the start of electrolysis, while at a voltage lower than this, no deposit was visible after two days of electrolysis. This suggests that a field assisted migration, as well as simple diffusion, may be occurring.

The presence of CuS on the surface of the CdSe can lead to several undesirable effects. One is blocking of the light, incident on the CdSe. Another is a possible local cell action (back-reaction) leading to reduction of polysulfide at the CuS, and loss of current. This is not expected to be serious, as CuS, unlike Cu_2S, is not a very good electrical conductor. A third effect is diffusion of Cu^+ into the CdSe leading to Cu-compensated CdSe. This could lead to a serious deactivation of the CdSe, since CdSe:Cu as used in photoconductors, is a very poor photovoltaic material. We notice some deactivation; in the worst cases ~20% loss in power output for single crystal electrodes. Washing such deactivated electrodes in aqueous KCN (which dissolves CuS) results in a partial restoration of the original activity.

If the Cu_xS deposition is largely due to a field-assisted migration, then use of a Cu_2 electrode with a p-type semiconductor electrode should not be susceptible to this deposition, as the electric field is now in the opposite direction. Furthermore, the mechanical stability of the Cu_2S electrode may conceivably be improved, as Cu^+ which originally came from the electrode may be redeposited on the Cu_2S, which is negative with respect to the photoelectrode.

CoS.—As long as the layer of CoS is not too thick, the electroplated CoS electrode, does not suffer from either mechanical or electrochemical instability over a period of more than four months, which is the longest period over which these electrodes have been tested at present. However, while there is no visible effect on a CdSe photoelectrode, the open-circuit voltage of the cell drops typically from 600-650 mV initially to 500-550 mV within some minutes, which translates to ~15% loss in power conversion efficiency. The photocurrent is not much affected. This suggests that, in a manner, analogous to that observed for Cu_2S, CoS is deposited on the CdSe surface. Since CoS is a good conductor of electricity, we may expect a local cell reaction on the deposited CoS. Due to the shape of the photocurrent-voltage curve of these cells (poor near the open-circuit voltage and good near the short-circuit current), such a local cell action may make a fairly large difference to the open-circuit voltage while the short-circuit current is much less affected, as is indeed observed.

The approximately 100 mV loss in open-circuit voltage due to the CoS does not increase with time, suggesting a limiting layer on the CdSe. If the CdSe is removed from the electrolyte, and placed, without washing, in a new electrolyte with a non-CoS counterelectrode, the drop in photovoltage remains. If, however, the CdSe is washed with water in-between, the original photovoltage is obtained, suggesting a very loose CoS layer is formed on the CdSe. Furthermore, over a period of months, there is often a tendency for the open-circuit voltage to increase somewhat. In analogy with CuS formation on illuminated CdSe, this may be due to oxidation of CoS to a higher, less conducting sulfide.

While we have found this degradation of photovoltage due to the CoS electrode to be a quite general effect, we have noted some cases where such degradation did not occur, while the counterelectrode activity remained high. We have been unable to reproduce

these conditions at will, and do not as yet understand the reason for this effect. However, such exceptions show that the photovoltage deactivation due to the CoS electrode can be overcome. This is an important point for eventual practical use of such electrodes. Clearly, further investigations, especially surface analytical ones, are called for to gain a full understanding of such processes, which, ultimately may play an important role in determining the future of a practical PEC.

Summary

Several metal sulfides have been shown to act as good electrocatalysts for the polysulfide redox reactions. As practical electrodes, only two show sufficient stability for possible practical use—Cu_2S (as sulfided brass) and CoS. The former has the disadvantage that, as presently fabricated, the lifetime will probably be limited to a few years due to mechanical instability, while the latter, due to deactivation of the photoelectrodes lowers the power output of a photoelectrochemical cell in which it is used by 15-20%. Thus, for routine and relatively short-term experiments, Cu_2S is the preferable counterelectrode while for long-term use, CoS becomes preferable.

The effect of electrolyte composition and temperature on the activity of these electrodes has been measured, enabling a choice of electrolyte for polychalcogenide electrochemical cells to be made on the basis of the counterelectrode. In short, for the cathodic direction (which, at the present time, is the more important one), the electrode activity increases as [S] increases, with the important condition that $[S] \leq [S^{2-}]$. Thus, since the maximum solubility of Na_2S in water at normal temperatures is 2-3M, the optimum electrolyte is ~2M S and 2M S^{2-}. The concentration of OH^- is of secondary importance for the counterelectrode, although there is a slight improvement in performance with higher $[OH^-]$, particularly at low total ionic concentrations.

At higher temperatures, the necessity for the $[S]/[S^{2-}]$ ratio to be <1 becomes less important.

After seven months operation in a PEC, a CoS counterelectrode which did not poison the photoelectrode (CdSe) remained stable, both in electrocatalytic activity and physically, and did not have any adverse effect on the CdSe during the seven months in operation.

ABSTRACT

An experimental and theoretical study has been made to determine the feasibility of a hydrogen-bromine cell for energy storage applications. The laboratory data were collected for the cell performance and the membrane characteristics during the charge and the discharge operations. An unsteady-state heat balance was used to predict the temperature change and the overall electric-to-electric efficiency. The results indicate that the hydrogen-bromine system can achieve an efficiency greater than 70% when the operating cell current density is less than 160 mA/cm².

Electrochemically regenerative hydrogen-halogen cells have been recently proposed for large scale energy storage in weekly cycle load-leveling applications (1-4). The cells can also be coupled with variable and interruptible primary energy sources, such as solar and wind energy, because the cells can be operated at high current densities and the reactants are stored external to the cell. The system can be independently sized for various energy and power requirements. The operating conditions, and the cell and membrane characteristics of a hydrogen-chlorine system have been previously reported (4, 5). This paper is concerned with the use of a hydrogen-bromine cell for energy storage applications. The laboratory data were collected for the cell performance and membrane characteristics during the charge and discharge operations, and an unsteady-

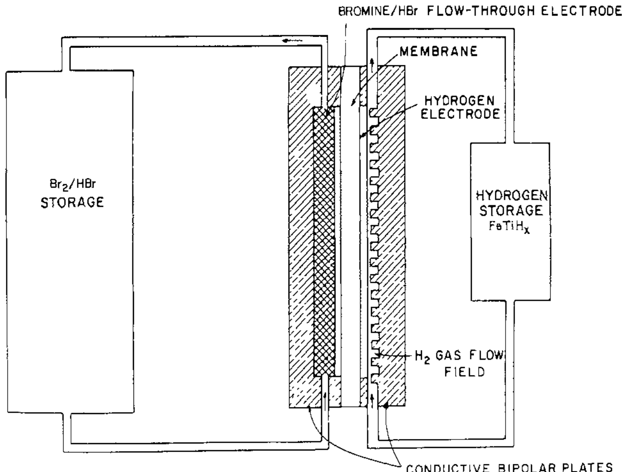

Fig. 1. Schematic of the hydrogen-bromine energy storage system

state mass and heat balance was used to predict the temperature change and the overall electric-to-electric efficiency of the system.

The concept of the hydrogen-bromine system is illustrated schematicallly in Fig. 1. Off-peak electric energy is used to electrolyze concentrated hydrobromic acid. Cells based on solid polymer electrolyte (SPE) technology can be used (3, 6). The hydrogen and bromine produced are stored external to the cell. During discharge the hydrogen and bromine are fed back to the cell to generate electricity. The overall reaction is

$$\text{HBr (aq.)} \underset{\text{discharge}}{\overset{\text{charge}}{\rightleftharpoons}} \frac{1}{2} H_2(g) + \frac{1}{2} Br_2(l) \quad [1]$$

The hydrogen-bromine cell has several advantages: (*i*) the system has a high electric-to-electric efficiency because of fast electrode kinetics; (*ii*) the same electrochemical cell can be used for both charge and discharge operations; (*iii*) it can be operated with shallow discharges, and can tolerate both over charge and over discharge; (*iv*) the use of the SPE technology allows the anode and the cathode to be operated at different pressures, thus hydrogen can be produced at a pressure high enough for storage as a metal hydride or as compressed gas without further compression; (*v*) the cell has a high coulombic efficiency because of low self-discharge rate; (*vi*) there is no mass transfer limitation in the cell operation because of the high solubility of bromine in the hydrobromic acid electrolyte; (*vii*) the bromine storage unit and the bromine electrode can be operated near the ambient pressure because of the low vapor pressure of bromine; and (*viii*) since the reactants and products are fluids, the problem of intercell imbalances does not arise.

The General Electric SPE cells use a perfluoro sulfonic acid (Nafion) membrane as the cell separator. The cell usually consists of a bipolar configuration with electrocatalysts bonded on each side of the membrane as shown in Fig. 1. The Nafion membrane possesses excellent corrosion resistance and thermal stability; it is suitable for use in the hydrogen-bromine cell.

Experimental

Nafion membranes.—Unless otherwise specified, all the membrane measurements were performed with a sample having an equivalent weight of 1200. The sample was 0.25 mm thick and was boiled in distilled water for one hour before each experiment.

Laboratory HBr electrolyzer.—The cell components are shown in Fig. 2. A Nafion-115 (equivalent weight of 1100 and thickness of 0.13 mm) was used as the cell separator. Both hydrogen and bromine electrodes were located next to the membrane so that the interelectrode distance was equal to the thickness of the membrane.

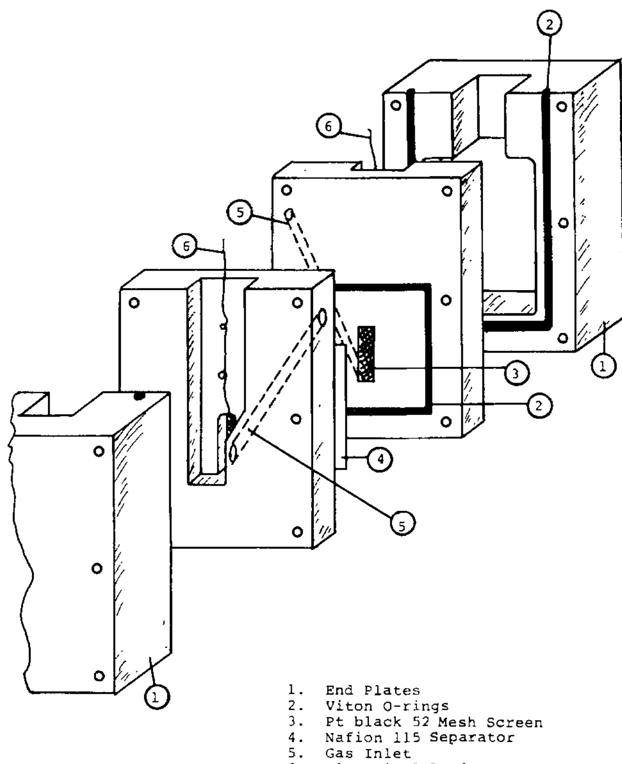

Fig. 2. Construction of a BNL experimental cell

Membrane conductivity studies.—The conductivity measurements were made using the d-c method of Lander and Weaver (7) in a cell described in an earlier report (5). Prior to each measurement, the membrane was boiled in H_2O and then soaked in the HBr electrolyte at 25°C for at least three days.

Electrolyte content in membranes.—The equilibrium electrolyte content of the membrane was determined by a method previously described (8).

Acid concentration in membranes.—The membrane, being on reaching equilibrium in the electrolyte, was removed, surface dried, and then thoroughly leached with water; the extract was titrated for hydrobromic acid. The HBr concentration in the membrane was calculated from the electrolyte content and the amount of acid leached out from the membrane.

Experimental Results

Cell performance.—The experimental cell, shown in Fig. 2, was used to determine the open-circuit cell voltage and the cell polarization for charge at ambient temperature and pressure. The results for the cell voltage *vs.* charge current densities is shown in Fig. 3. For comparison, the results with the General Electric SPE cells and the results obtained by other investigators (9-11) are also shown in the figure. Figure 4

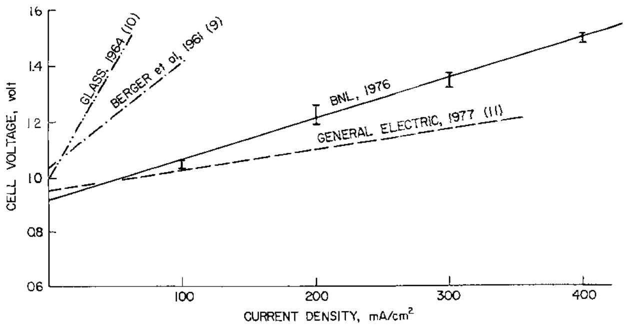

Fig. 3. Charge cell voltage *vs.* current density for various hydrogen-bromine cells.

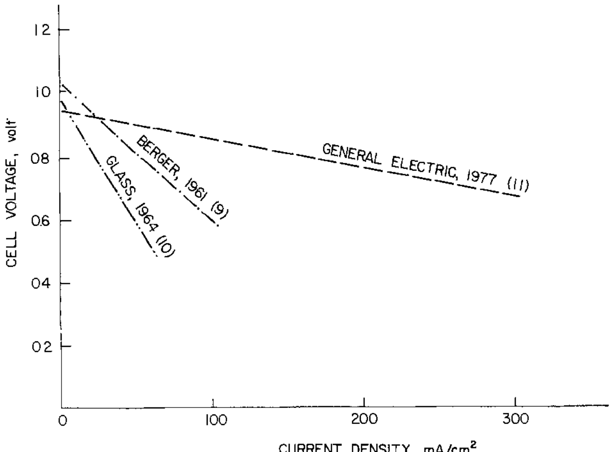

Fig. 4. Discharge cell voltage vs. current density for various hydrogen-bromine cells.

presents the discharge performance of various H_2-Br_2 cells. It is seen that the General Electric SPE cell and the present cell had very low polarizations; the overvoltage was primarily caused by *IR* drop across the cell membrane. The results of various HBr concentration and cell temperatures can be summarized by the following empirical equations: For charge

$$E = E_o - 0.681i \quad [2]$$

For discharge

$$E = E_o - 0.589i \exp(2.19X) \quad [3]$$

where i is the charge and discharge current density in A/cm^2 and X is the weight fraction of HBr in the electrolyte. E_o is the open-circuit cell voltage and may be expressed as

$$E_o = \pm \left\{ \phi - (T - 298)\left(4.3 + 1.86 \ln \frac{12.36X}{1-X}\right) \times 10^{-4} + 4.31 \times 10^{-5} T (\ln f_{H_2} + \ln a_{Br_2}) \right\} \quad [4]$$

where

$$\phi = \begin{cases} 1.073 - 0.0567 \ln \dfrac{12.36X}{1-X} & (0.016 < X < 0.11) \\ 1.095 - 0.1042 \ln \dfrac{12.36X}{1-X} & (0.11 < X < 0.28) \\ 1.336 - 0.2581 \ln \dfrac{12.36X}{1-X} & (0.28 < X < 0.58) \end{cases} \quad [5]$$

T = temperature in °K

f_{H_2} = fugacity of hydrogen gas

a_{Br_2} = activity of Br_2 in the electrolyte, equal to 1.0 for bromine present as a liquid phase.

Equation [4] was obtained for the fuel cell reaction. Consequently, according to the thermodynamical conventions, E_o will have a positive value for discharge and a negative value for charge. These results demonstrate that the General Electric SPE cell can be operated up to 0.3 A/cm^2 with relatively low overvoltages.

Characterization of membrane.—It was found (5) that the transport properties of the membrane were strongly related to the electrolyte content of the membrane. Figure 5 shows the electrolyte content and the HBr concentration in Nafion membrane as a function of HBr concentration in the electrolyte. It should be mentioned that the membrane was boiled in water for more than two hours before each test. It is seen that the electrolyte content in the membrane decreased with increasing HBr concentration. The relationship can be represented by the following empirical equation

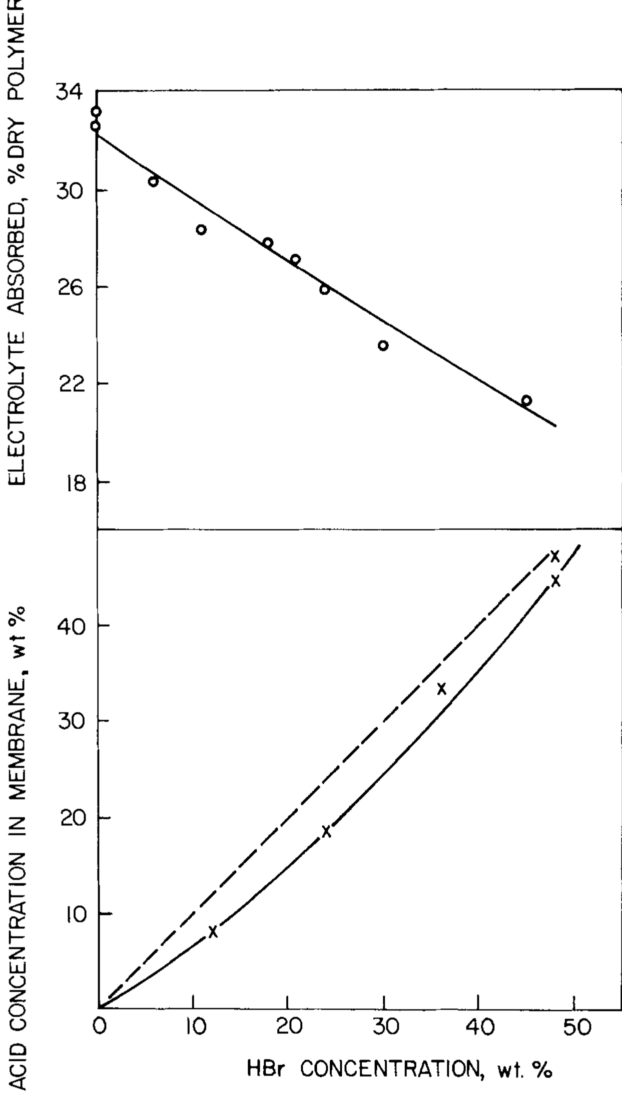

Fig. 5. Electrolyte content and acid concentration in Nafion membrane vs. HBr concentration.

$$W = \frac{0.323}{1 + 0.068M} \quad [6]$$

where W is the electrolyte content in the membrane and M is the molarity of HBr in the electrolyte. Equation [6] is similar to the one previously reported (12), except that the numerical factors are different. The deviation was probably due to the difference in experimental conditions. The HBr concentration in the membrane was less than the acid concentration outside the membrane; however, the difference was not large. When HCl is used as the electrolyte, and the membrane without pretreatment, it has been found that the concentration of HCl in the membrane is only equal to one-half of the acid concentration outside the membrane (13).

Figure 6 presents the membrane conductivity as a function of HBr concentration. The membrane conductivity in H_2O (14) and the conductivity of HBr electrolyte (15) at 25°C are also included for the sake of comparison. The membrane conductivity is about one order of magnitude less than that of the free electrolyte. The result is similar to those obtained with HCl (5), $ZnBr_2$ (16), and NaBr (16) electrolytes. The solid curve in Fig. 6 can be represented by the following semiempirical equation

$$\sigma = 1.4\sigma_{ex}(1 - V_1)^{2.3} \quad [7]$$

where σ and σ_{ex} are the membrane and the free acid conductivities, respectively, and V_1 is the volume frac-

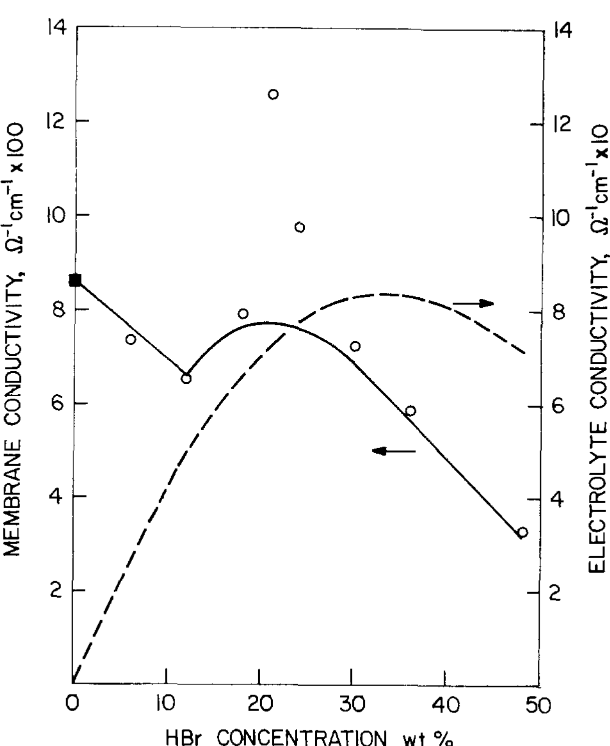

Fig. 6. Membrane and free acid conductivity as a function of HBr concentration. (■) H_2O, after Ref. (14); (○) HBr, present study, (– –) free acid conductivity; (——) calculated by Eq. [7].

tion of the polymer matrix in the membrane. V_1 can be calculated from the density of the polymer (2.1 g/cm^3) and the electrolyte content estimated by Eq. [6]. For the acid concentrations of less than 12% HBr, $\sigma_{ex} = 0.49\Omega^{-1}$ cm^{-1} should be used for calculations because of the intrinsic conductivity of the membrane.

Table I shows the membrane conductivity under different membrane pretreatments. The membrane conductivity increases with increasing electrolyte content.

Unsteady Heat Balance

For energy storage applications, the operation of the hydrogen-bromine system is of an unsteady nature. Reaction [1] has a large entropy change of 4.4 kcal/g-mole-HBr. This results in a cooling of the electrolyte during charge and an additional heating effect during discharge. The unsteady heat balance can be used to predict the changes in the electrolyte concentration and temperature, and the maximal electric-to-electric efficiency allowed by the thermodynamics and electrokinetics of the cell reactions (4).

A material and energy balance between the time t_o and t results in the following equations for the system shown in Fig. 1

$$-0.8605 \int_{t_o}^{t} EIdt + Q_{Acid}$$
$$= \int_{T_o}^{298} \{W_{HBr,o}C_{P,HBr}(X_o,T) + W_{Br2,o}C_{P,Br2(l)}(T)\}dT$$
$$+ \Delta n_{HBr}H^{\circ}_{f,HBr}(X_o)$$
$$+ \frac{W_{HBr}X}{80.917}\{H^{\circ}_{f,HBr}(X) - H^{\circ}_{f,HBr}(X_o)\}$$
$$+ \int_{298}^{T} \{W_{HBr}C_{P,HBr}(X,T)$$
$$+ (W_{Br2,o} - 79.91\Delta n_{HBr})C_{P,Br2(l)}$$
$$- 1.008\Delta n_{HBr}C_{P,H2(g)}\}dT \quad [8]$$

$$\Delta n_{HBr} = \mp 3.7307 \times 10^{-5} \int_{t_o}^{t} Idt \quad [9]$$

Table I. Effect of thermal history on membrane conductivity

Treatment	Electrolyte content, w/o of dry polymer	Conductivity in 24% HBr, Ω^{-1} cm^{-1}
Standard treatment	25.9	0.098
Untreated	17.8	0.076
Dried in vac. at 140°C	11.4	0.035

$$W_{HBr} = W_{HBr,o} + 80.917\Delta n_{HBr} \quad [10]$$

$$X = \frac{W_oX_o + 80.917\Delta n_{HBr}}{W_o + 80.917\Delta n_{HBr}} \quad [11]$$

$$Q_{Acid} = 0 \quad \text{for } T_{min} < T < T_{max} \quad [12]$$

The symbols in the foregoing equations are explained at the end of the text. The quantities with subscript o are the variables and the physical and thermodynamical properties at the time t_o; those without subscript o are the instantaneous values at the time t. The convention used here is that Δn_{HBr} has a negative value when HBr is consumed for electrolysis during charge and a positive value when HBr is produced during discharge. It has been assumed that the temperature of electrolyte in the cell is the same as that in the acid storage tank. This condition is approximately true if the electrolyte is circulating at a high rate. The function of Q_{Acid} is to maintain the electrolyte temperature within a limit specified by T_{min} and T_{max}. At T_{min}, external heat will be needed to maintain the electrolyte temperature, and the values of Q_{Acid} is positive. At T_{max}, cooling will be required and Q_{Acid} will have a negative value. The details of the mathematical modeling have been illustrated elsewhere (4) and will not be discussed here.

Equations [8] and [9] together with the cell voltage data given by Eq. [2]-[5] have been solved numerically on a digital computer for the concentration and the temperature of electrolyte as a function of time at various operating cell current densities. The calculation was made for a 2 MW energy storage module being operated at 10 hr charge and 10 hr discharge cycles. To account for the concentration and temperature variation of the thermodynamical properties, the values of $C_{P,Br2(l)}$, $C_{P,H2(g)}$, and $H^{\circ}_{f,HBr}$ published in the literature (18) were used in the computation. Unless otherwise noted, the concentration of HBr electrolyte varied from 7 to 35 weight percent (w/o), and the operating temperature was limited to a maximum of 50°C and a minimum of 15°C. The cell pressure was kept at 10 atm.

Figure 7 shows the change of electrolyte concentration during the charge and the discharge cycles. The change in electrolyte temperature is shown in Fig. 8 for a range of operating current densities from 0 to 350 mA/cm^2. It is seen that the temperature decreases during charge; the rate of temperature drop decreases with increasing current densities. During discharge, the temperature rises rapidly, and cooling is necessary to maintain the electrolyte at 50°C. This phenomenon is similar to the hydrogen-chlorine cell; however the extent of temperature changes is smaller with the hydrogen-bromine system. Figure 9 shows the magnitude of calculated cell voltages during the charge and the discharge cycles.

The overall electric-to-electric efficiency can be evaluated from the cell voltage changes according to the equation

$$\epsilon\% = -\frac{\left(\int_0^{10} EIdt\right) \text{discharge}}{\left(\int_0^{10} EIdt\right) \text{charge}} \times 100 \quad [13]$$

Figure 10 presents the overall electric-to-electric efficiency as a function of cell current densities. To ex-

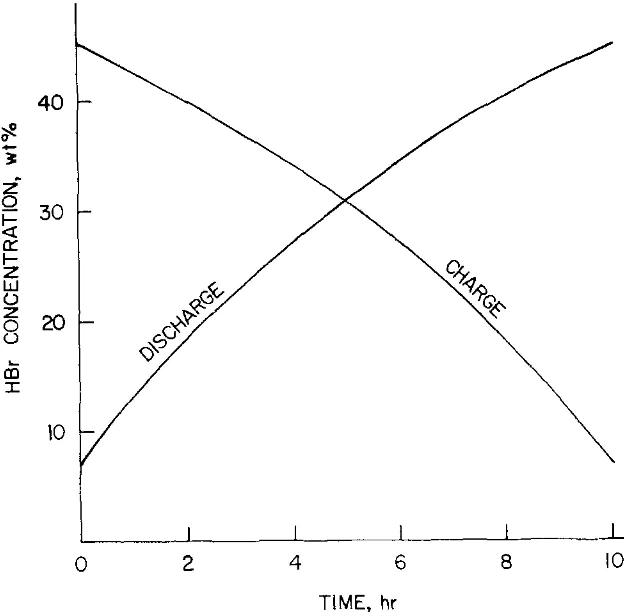

Fig. 7. Changes in HBr concentration during the charge and discharge cycles.

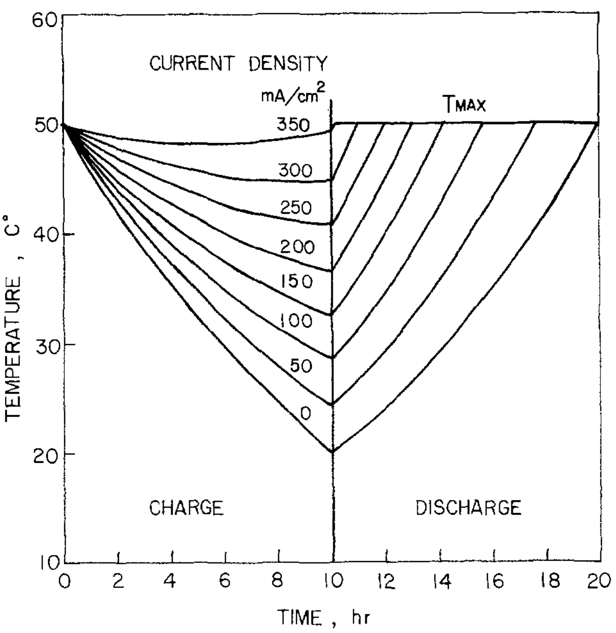

Fig. 8. Changes in the electrolyte temperature during the charge and discharge cycles for various operating cell current densities. The curves were calculated for a range of HBr concentration varying from 7 to 35 w/o during the operation.

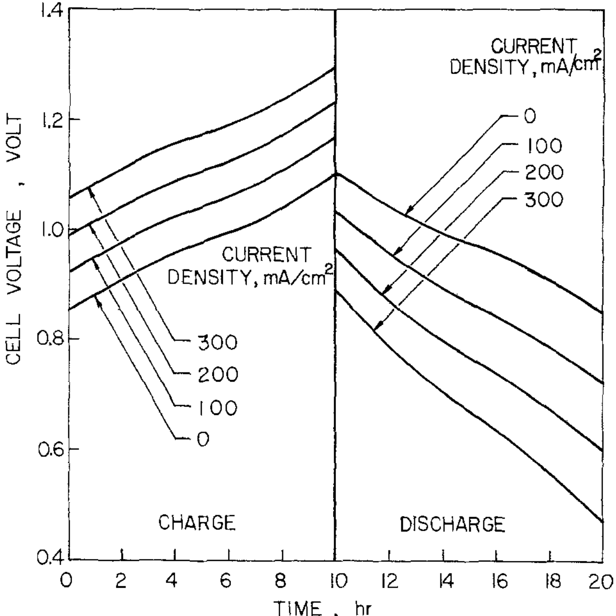

Fig. 9. Charge and discharge cell voltage as a function of time for current densities of 0 mA/cm², 100 mA/cm², 200 mA/cm², and 300 mA/cm². The curves were obtained with 7-35 w/o HBr and a maximum operating temperature of 50°C.

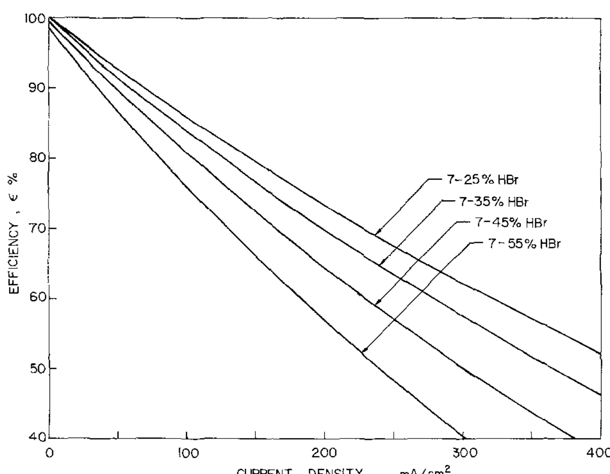

Fig. 10. The electric-to-electric efficiency as a function of cell current density for various acid concentration ranges. The maximum operating temperature was 50°C.

amine the effect of electrolyte concentration on the overall efficiency, the unsteady heat balance was also performed for the HBr electrolyte concentration other than 7-35 w/o as shown in the figure. It is seen that the overall efficiency decreases with (*i*) increasing current densities; and (*ii*) increasing electrolyte concentration at the onset of charge. These curves were calculated for a cell pressure of 10 atm and a range of operating temperatures between a minimum of 15°C and a maximum of 50°C. Results for different pressures (1 ~ 40 atm) and temperatures (T_{max} between 30°-90°C) indicate that the temperature and the pressure have insignificant effect on the overall efficiency.

Discussion

Efficiency of energy conversion.—The polarization performance of the General Electric SPE cell strongly demonstrates the reversibility of the hydrogen and bromine electrode reactions. Since the electrode kinetics is fast, the voltage and coulombic efficiencies are largely determined by the membrane conductivity and the reactant permeation across the membrane. It has been found that because of the formation of negatively charged bromine complex ions (Br_3^- and Br_5^-), the coulombic loss in the hydrogen-bromine cell is less than 2% (5). This suggests that the overall cell efficiency can be simply represented by the voltage efficiency. In the light of this, the improvement in membrane conductivity is vital in the design of efficient cells. The membrane conductivity is strongly related to the electrolyte content of the membrane as well as the method of pretreatment as shown in Table I. There is no doubt that good conductivity can be achieved by boiling the membrane in water to fully swell the polymer matrix prior to installation in the cell. However, the effect of this pretreatment would be destroyed if the membrane is dried, especially at elevated temperatures (12).

Figure 10 demonstrates that the hydrogen-bromine system has an energy conversion efficiency comparable to the hydrogen chlorine system. However, the hydrogen-bromine cell has the advantage of a smaller electrolyte temperature variation during the charge and

discharge cycles. Consequently it can be operated at a lower temperature and pressure to increase the cost effectiveness in the system construction and operation. The space required for the electrolyte storage is comparable to the hydrogen chlorine system because a 45 w/o HBr can be used at the onset of charge. With this concentration, the General Electric SPE cell can be operated up to 160 mA/cm^2 and yet achieve an electric-to-electric efficiency greater than 70%. The large operating current density also makes the system feasible for use with variable and interruptible loads, such as solar and wind energy generators.

Effect of membrane hysteresis.—The operation of the hydrogen-bromine energy storage system is a time-dependent nonsteady-state process. The electrolyte concentration continuously changes with time as seen in Fig. 7. Accordingly, the electrolyte content of the membrane will decrease with time during discharge and increase during charge. Figure 11 shows the electrolyte content as a function of time. It is clear that the electrolyte content will not reach the equilibrium state. The electrolyte content in the membrane is less than the equilibrium value when the cell is initially started with 45% HBr and then charged to 7% HBr in 10 hr. On the other hand, the membrane would absorb more electrolyte than the equilibrium value if the cell is started with 7% HBr and discharged to 45% HBr in 10 hr. Furthermore, soaking the membrane in H_2O before charge/discharge will result in additional electrolyte uptake, especially during the initial period of charge/discharge operation. Thus, there is a strong hysteresis effect on the cell performance because of the slow diffusion of the electrolyte in the membrane which is about one order of magnitude less than that in the free acid (17). There is the added effect that the diffusion of electrolyte in membrane decreases greatly with increasing electrolyte concentration (13) whereas the diffusion rate in free acid is rather constant (related to the viscosity of the acid) at a given temperature.

The hysteresis is expected to decrease with longer charge/discharge times and with smaller acid concentration range and higher cell temperature. This result indicates that if the cell will become idle for a relatively long period of time, the cell should be filled with water or dilute HBr acid. Also the cell will have a higher efficiency if the plant is started with the discharge rather than the charge cycle.

Acknowledgment

Special thanks are due to Mr. K. L. Hsueh of Clarkson College of Technology for his help in the computer work and to Dr. P. Wong of BNL for technical contributions. The authors are also grateful to Drs. J. McBreen and S. Srinivasan, of BNL, and Mr. J. F. McElroy of GE for their helpful discussions. The Nafion membrane samples were kindly supplied by du Pont Company.

This study was carried out under the auspices of the U.S. Department of Energy.

Mössbauer Study of the Passive Oxide Film on Iron

William E. O'Grady*

Brookhaven National Laboratory, Department of Energy and Environment, Upton, New York 11973

ABSTRACT

Mössbauer spectroscopy has been used to study the structures of both the *in situ* and dried states of well-passivated iron surfaces. The parameters found in this study correlate only with the parameters found in the literature for iron in amorphous iron (III) oxides and in polymeric chains. The same parameters determined for dried passive films correlate only with those of γ-Fe_2O_3. The effects of drying the film give indications of the important role played by water in the passivation phenomenon.

The role and importance that passive layers play in the protection and strengthening of metals is well documented (1) in the recent Proceedings of the Fourth International Symposium on Passivity. It is interesting to note that one of the main points of discussion was the nature and structure of the protective films formed in aqueous environments on iron surfaces. It appears that the problem of the structure of the passive film is one of the most important problems for corrosion scientists.

In the particular case of the passivation of iron, an extensive effort has been made to work out the structure of the passive film (1, 2). In addition to the many applications of electrochemical techniques (2), ellipsometry (3-6) and electromodulated reflectance spectroscopy (7, 8) have also been utilized in an effort to determine the *in situ* structure of the passive film on iron. *Ex situ* investigations have included the use of electron diffraction (9), Auger electron spectroscopy (1, 10, 11), and photoelectron spectroscopy (12). Despite these efforts, the complete structure of the passive film on iron remains unsolved.

The passivating layer on iron is known to be of the order of 5 nm thick (13). For this layer to make a significant contribution to the Mössbauer spectrum, the volume of the layer must contain a large proportion of the total Mössbauer active iron available. Previously, this has been accomplished by using very small oxidized particles (14) or by supporting the Mössbauer nuclei on high surface-area substrates (15). These two techniques cannot be used in the present study where the iron substrate plays a significant role. Thick oxide films on the surface of nonenriched iron foils have been studied (16) by electroplating enriched ^{57}Fe on the surface and completely oxidizing the ^{57}Fe layer to give a Mössbauer signal which would be large compared to that of the supporting foil. Emission Mössbauer has also been used to study passivated steel and cobalt surfaces (17, 18), but this method is compromised by the possibility of the occurrence of unstable oxidation states especially in the presence of water (19). A preliminary report of our *in situ* study of passivated iron has appeared previously (20).

In this investigation we have applied Mössbauer spectroscopy to determine *in situ* the structure of the passive film on iron. Three types of experiments were run in this study. First, the passivated iron was examined *in situ* while the potential was maintained in the passive region. Second, hydration effects in the film were studied by dehydrating and aging the passivation film in dry nitrogen for varying lengths of time. The subsequent rehydration of these same dried samples was also attempted. Third, the temperature dependence of the Mössbauer spectra of both wet and dry samples was obtained.

Experimental Procedures

The electrochemical cell used in this work was designed to allow a 2 mm thick film of solution to lie in the γ-ray beam. The solution causes very little attenuation of the beam as the half thickness at 14 keV is ~5 mm (13). The cell consists of two parts as shown in Fig. 1. Both of these parts are machined from Plexiglas, and the cell window is 1.5 mm Plexiglas

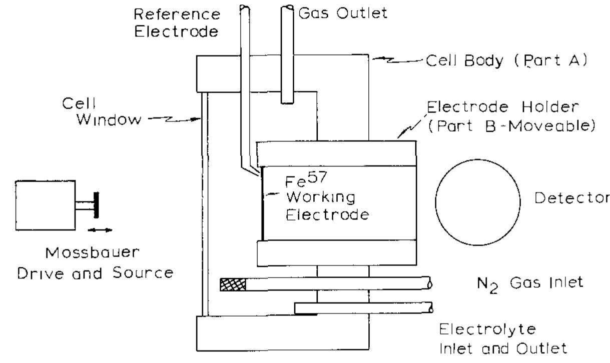

Fig. 1. Schematic diagram of the electrochemical cell used for *in situ* studies of iron passivation.

* Electrochemical Society Active Member.

Key words: oxides, oxy-hydroxides, water passivation.

sheet. The thickness of the solution between the iron working electrode and the window is adjusted to the 2 mm value after the electroplating and washing operations by moving the working electrode holder (B) into the cell body (A) until it contacts the cell window. The radiation passes through the hole in the center of the electrode holder into the shielded detector.

The Mössbauer spectra were recorded with an Elscint AME-30 Mössbauer spectrometer using a 25m Ci ^{57}Co-Cu source (New England Nuclear Corporation). All isomer shift values are reported with respect to a sodium nitroprusside absorber obtained from the National Bureau of Standards. The zero velocity is defined to be half the distance between its two quadrupole split peaks (23). The internal magnetic field was calibrated using a 1 mil iron foil obtained from New England Nuclear Corporation. The minimum line width obtained with the spectrometer was 0.25 mm/sec as determined with an electrochemically plated iron sample containing 2.1×10^{17} atoms of ^{57}Fe/cm^2. The spectrometer was operated at constant acceleration and was driven by a sawtooth function in a flyback mode such that only one spectrum was accumulated in the Victoreen Pip 400A multichannel analyzer (MCA). A Reuter Stokes RSG-61-M, proportional counter tube equipped with aluminized mylar windows was used as the detector to avoid any contribution to the spectrum arising from iron impurities which might be present in beryllium windows. To insure reproducible geometry, the source drive, electrochemical cell, and shielded detector were all centered and aligned on an optical bench.

An Oxford Instrument's continuous flow cryostat (CF-100) was used in the variable temperature experiments. Temperatures were monitored with a calibrated linear resistance thermistor coupled with a bridge. The measured temperatures are believed to be accurate within ±1°K.

The Mössbauer spectra were analyzed by computer, fitting the experimental data to a theoretical curve composed of Lorentzian peak shapes superimposed on a parabolic baseline using a least squares fit. The program also evaluated the isomer shift, quadrupole splitting, magnetic hyperfine splitting, and the integrated intensities of the spectrum. The inverse-square-law intensity and background corrections were determined by running a blank sample for the same length of time (24).

Samples were prepared by passivating a thin layer of 90% enriched ^{57}Fe such that the passive layer composed 10-20% of the total available ^{57}Fe, thus giving rise to an easily detectable Mössbauer effect. A layer of ^{57}Fe 25-30 nm thick was electrodeposited (21) onto a 25 nm thick vacuum-deposited gold film supported on 0.04 mm mylar. At the completion of the electrodeposition, the potential of the iron electrode was maintained in the cathodic protection region at −0.740V with respect to the normal hydrogen electrode (NHE), while the plating solution was drained and the electrode and cell washed and filled with 0.15*N* boric acid-sodium borate buffer solution (*p*H = 8.4) (22). The sample was then passivated at a potential of 0.6V (NHE) and the *in situ* Mössbauer spectrum was taken. The potential 0.6V (NHE) was chosen because it is well into the passive region and should produce a uniform film.

Dried samples were prepared by passivating as previously described. The solution was then drained from the cell, and the cell and electrode were washed twice with distilled water. The wash solution was drained and dry-purified nitrogen was circulated through the cell at 0.2 liters/min for varying lengths of time. After a prescribed amount of time, circulation of the nitrogen was stopped and the Mössbauer spectrum was taken. After taking the spectrum, circulation of the nitrogen was continued until a total of eight hours of circulation time had accumulated for a given sample. Several samples were stored for six months in a nitrogen-filled vac-

uum dessicator to observe if any further changes occurred in the film after the initial drying treatment. Rehydration of a series of these dried samples was attempted. After the sample was dried for a prescribed period, the cell was refilled with fresh borate solution, the electrode potential was held at 0.6V, and the Mössbauer spectrum was taken.

For the cryostatic measurements the samples were prepared by passivating them as described above, but the cell was placed in a nitrogen purged dry box. After the current in the cell reached a value of 0.1 A/cm^2 the iron electrode was quick frozen with liquid nitrogen, removed from the cell, sealed in a polyethylene sheath, and placed in the precooled (77°K) sample holder of the cryostat. Three individual samples were sandwiched together for each run. The polyethylene sheath was used to prevent dehydration of the samples. The temperature of the cryostat could be brought from 200°K to room temperature in 5 min by flowing dry nitrogen through the Dewar. This technique was used to bring the samples, which were frozen with electrolyte, to room temperature quickly so a spectrum could be run and compared to that obtained from the *in situ* samples. The Mössbauer parameters for these two types of samples are compared in Table I. On the basis of this data it is concluded that quick freezing the passive film does not perturb the structure of the film. Hence, the low temperature spectra are characteristic of the *in situ* passive film.

Experimental Results

The characteristic steady-state current potential behavior for bulk iron (3, 22) is shown in Fig. 2. Superimposed on the bulk iron curves are the points determined for the steady-state behavior of electrodeposited ^{57}Fe. As can be seen in Fig. 2, passivation of the electrodeposited ^{57}Fe closely parallels the characteristic curve for the electrochemical passivation of bulk iron. Also, the value of +0.6V (NHE) at which the samples were passivated for this study can be seen to be well into the passive region.

The Mössbauer spectrum for a 25 nm ^{57}Fe film held at −0.75V (NHE) in the oxide-free cathodic protection

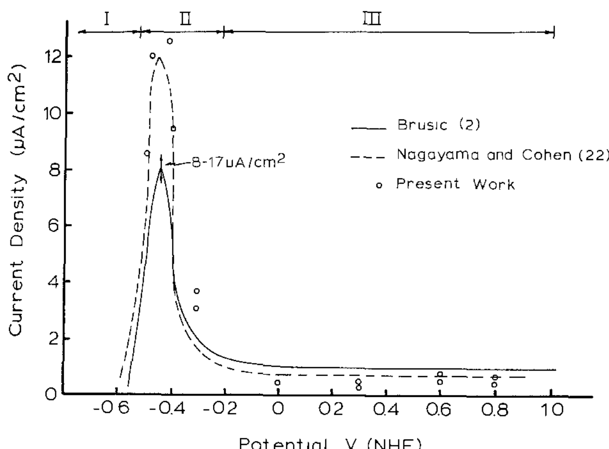

Fig. 2. Current-voltage behavior of electroplated iron films compared to the behavior found in the literature for bulk iron.

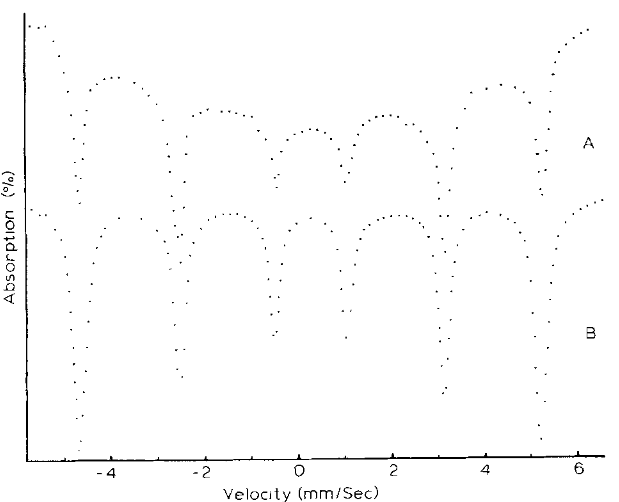

Fig. 3. Mössbauer spectra: A. Electroplated ^{57}Fe film approximately 50 nm in thickness; B. Standard iron foil.

region is shown in Fig. 3A. The spectrum shows the six-line pattern expected for iron. However, the intensity ratios of the electroplated sample lie very near to 3:4:1:1:4:3 whereas the intensity ratios normally found for bulk iron are 3:2:1:1:2:3 as shown in Fig. 3B. The relative intensities of the six-line pattern of iron are a function of the angle θ between the direction of the internal magnetic field and the γ-ray beam. The relative intensities as a $f(\theta)$ can be written $3:\beta:1:1:\beta:3$ where β is given by $4/(1 + 2 \cot^2\theta)$ (25). In the case of a bulk iron sample, the internal magnetic field is randomly oriented, and an average must be taken over all values of θ which gives rise to the 3:2:1:1:2:3 intensity ratio normally observed. In the case of thin iron films, the internal field is found to be constrained in the plane of the film (26). Therefore $\theta = \pi/2$ and the 3:4:1:1:4:3 intensity ratio is found. This ordering arises in the case of thin films because the particles making up the film are of the same order of size as single domains and the anisotropy constant for the magnetic vector of the particles forces the magnetic vector to lie in the plane of the film. Theoretical calculations (27) indicate that this energetically preferred magnetic domain configuration for thin films breaks down for thicknesses greater than 300 nm and experimental results seem to verify this prediction (28). The isomer shift of the electroplated iron film was 0.00 ± 0.03 mm/sec *vs.* the standard iron foil. The linewidths, full width at half maximum (Γ), for the outer lines at room temperature were 0.25 and 0.32 mm/sec for the electroplated iron film and the standard iron foil, respectively. Thus, it is concluded that these electroplated iron films behave like bulk iron and will be generally representative of the behavior of iron.

In situ studies.—In Fig. 4 is shown a characteristic spectrum of a passivated iron sample. The spectrum includes the six-line pattern of iron and two new peaks in the center arising from the passive film on the surface of the iron. The center of the spectrum is expanded in Fig. 5 and shows only the contribution of the two inner lines of the iron pattern and the two new peaks which appear with passivation of the iron film and are attributed to the passive oxide film. The computer fitting of the data is shown in Fig. 5; the contributions from both the iron and the oxide film are shown. The analysis in this case was based on the fact that the oxide peaks are a quadrupole split pair. The Mössbauer parameters determined from this analysis with their mean square deviations are 0.70 ± 0.01 mm/sec for the isomer shift, 1.02 ± 0.07 mm/sec for the quadrupole splitting, and 0.86 ± 0.08 mm/sec for the linewidths. These values are the result of the examination of six separate samples. Efforts were also made to fit two quadrupole split sets of peaks to this experimental

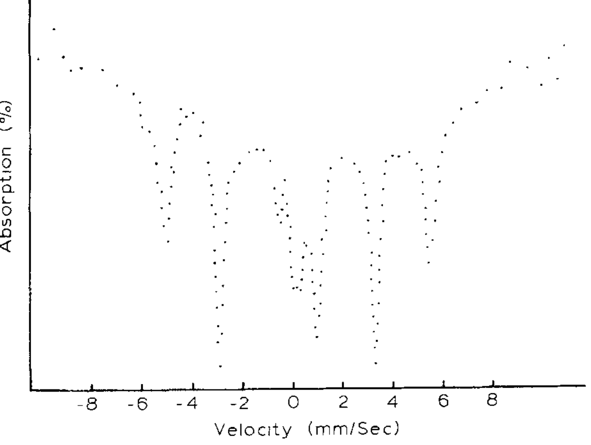

Fig. 4. Mössbauer spectrum of ^{57}Fe film passivated at 0.6V (NHE) showing the characteristic iron spectrum and two new peaks in the center of the spectrum due to the passive film.

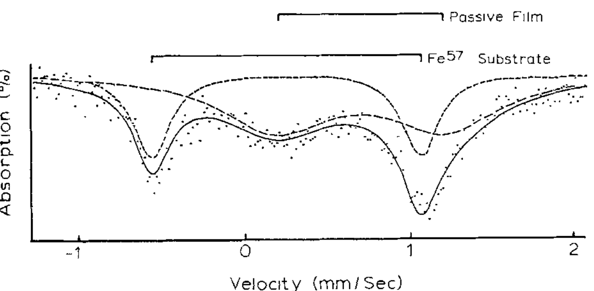

Fig. 5. Expanded Mössbauer spectrum encompassing the two inner lines of the iron spectrum and the two new lines due to the passive oxide film. The dots are the experimental points, the solid line is the computer calculated best fit to the experimental data, the short dashed line is the contribution of the iron substrate, and the long dashed line the contribution of the passive film.

data. However, a much higher χ^2 value was obtained for this fit, and hence the single quadrupole split pair was accepted as the best description of the data.

Dehydration studies.—The dehydration of the passive film gave results which can be divided into two groups. The samples dried for durations of up to five hours gave the values: IS, 0.66 ± 0.01 mm/sec, QS, 1.0 ± 0.1 mm/sec, and Γ, 0.9 ± 0.1 mm/sec. The second group of samples was dried over periods of time between five hours and six months and gave the following values: IS, 0.61 ± 0.01 mm/sec, QS, 0.8 ± 0.1 mm/sec, and Γ, $0.8 + 0.1$ mm/sec. Each group consisted of three separate samples.

Efforts were made to repassivate several samples after they were dehydrated in order to determine the reversibility of the hydration-dehydration process. The results for repassivating the samples dried for times less than five hours are given in Table II. The samples which were dried for longer times could not be successfully repassivated. When the samples dried for longer times were reimmersed in fresh electrolyte the entire sample would curl up and peel off the supporting mylar substrate. This curling suggests that there were strong tensional forces in the film.

Table II. Mössbauer parameters for the repassivated film

Sample	Area	IS (mm/sec)	QS (mm/sec)	Γ (mm/sec)
1—*in situ*	Film 0.65	0.70	0.99	0.83
1—dried	Film 1.0	0.64	1.03	1.00
1—repassivated	Film 0.64	0.70	0.96	0.86
2—*in situ*	Film 0.80	0.70	1.03	0.85
2—dried	Film 1.00	0.65	0.96	1.01
2—repassivated	Film 0.75	0.69	1.00	0.82

Low temperature studies.—A series of spectra were run at temperatures down to 3°K in order to further elucidate the structure of the passive film. Many of the iron oxides show magnetic hyperfine splitting resulting from the coupling of the magnetic moment of the nucleus with an external magnetic field usually arising from unpaired d-electrons on the iron atom. This magnetic hyperfine splitting is one of the characteristic features describing a particular oxide material (29).

Figures 6A and 7A show the following spectra: one for a sample that was dried for a period of greater than five hours (Fig. 6A) and one for a sample which was quick frozen in the cell (wet sample) and transferred into the Dewar at 77°K (Fig. 7A). Both spectra exhibit a hyperfine splitting but the dried sample shows much sharper lines than those of the wet sample. A value of ~470 kOe is found for the internal magnetic field of both the samples.

The temperature dependence of the hyperfine splitting of a dried sample is shown in Fig. 6. The 4°K spectrum shows hyperfine splitting with a small contribution of unsplit paramagnetic species still remaining in the center of the spectrum. As the temperature is raised, the paramagnetic contribution grows and reaches its maximum at about 45°K.

In the case of the quick frozen samples the temperature dependence is much more complex. At 3°-4°K as seen in Fig. 7 a magnetically split spectrum is observed. The measured internal field is 470 ± 10 kOe and the linewidth (Γ) is 0.96 mm/sec. When the temperature is raised from 4° to 10°K, the outer lines broadened to 1.8 mm/sec (see Fig. 7B). By 15°K no perceptible structure is visible, only a broad adsorption across the entire spectrum as seen in Fig. 7C. As the temperature is raised, no significant structure appears in the spectrum until a temperature of ~100°K is reached, Fig. 8A. In the temperature range of 100°-160°K two paramagnetic peaks continue to grow until about 70% of the total area under the curve for the passive film is achieved (Fig. 8B). In the temperature range of 160°-170°K, the remaining 30% of the total area for the passive film is obtained under the curve in Fig. 8C.

Discussion

Structure of the in situ passive film.—The characteristic parameters which have been derived from the computer fitting of the Mössbauer spectra of the *in situ* passive film are compared with the Mössbauer parameters available in the literature for the well-defined iron oxides and oxy-hydroxides in Table III. Considering only the isomer shift, there are two candidates for the passive film, α-FeOOH and δ-FeOOH. In the case of α-FeOOH no quadrupole splitting is observed while that of the passive film is 1.02 mm/sec. The HFS of α-FeOOH, 515 kOe (77°K) is larger than the 470 kOe (4°K) value of the passive film. For δ-FeOOH the QS is 0.01 mm/sec and the HFS is 505 kOe (80°K) which are also significantly different.

There are no obvious correlations of the Mössbauer parameters determined for the *in situ* passive film with those values collected in Table III. Hence, it is concluded on this basis that the passive film is not any of the well-defined stoichiometric crystalline oxides for oxy-hydroxides.

The isomer shift (0.70 mm/sec) and quadrupole splitting (1.02 mm/sec) found for the passive film tend to be higher than most of those found for the oxides in Table III. However, both values lie well within the range of values found for octahedral high spin ferric iron (30). The HFS value (470 kOe), al-

though on the low side for an iron oxide, also indicates the iron in the film is in an octahedral high spin ferric state (30). The values of the HFS for octahedral iron tend to be lower whenever one or more of the coordination sites of the iron is occupied by a hydroxyl ion or by water as seen from the HFS values in Table III for $Fe(OH)_3$, $Fe_2O_3 \cdot nH_2O$. However, these species in the coordination sphere do not seem to have any appreciable effect on the isomer shift and quadrupole splitting values found for these compounds.

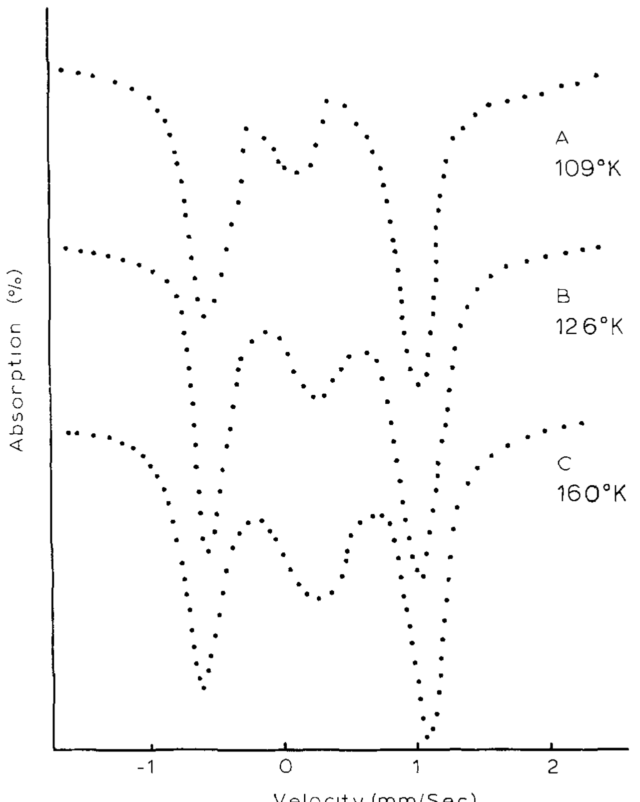

Fig. 8. Temperature dependence of the expanded Mössbauer spectra of a wet passive film.

Considering the amorphous iron (III) oxide also included in Table III, an extremely good correlation of the IS, QS, and HFS with the values found for the passive oxide film is observed. The higher values of the IS and QS are characteristic of amorphous oxides and indicate that the films are composed of FeO_6 octahedra each of which has a different local bonding character. The number of neighboring octahedra may be different as well as the type of bonding to the neighbors, *i.e.*, sharing of corners, edges, or faces. The value of the HFS is also characteristic of the amorphous oxide and this will be discussed in detail later.

Further correlations can be made with literature values of the isomer shift and quadrupole splitting of inorganic compounds of well-defined structure. An extremely good correlation is found with a series of binuclear oxo-bridged iron (III) compounds, as the values in Table IV show (31, 32). Of course no HFS is observed because these dimeric ferric compounds have a dimagnetic ground state, which arises from strong antiferromagnetic coupling.

Also shown in Table IV are a set of values for a trimer of iron atoms connected by dihydroxy-bridge bonds (33, 60). Here again an extremely good correlation is found with the IS and QS values of the passive film. No HFS is seen here due to a very rapid spin-spin relaxation.

$(C_9H_{19}NH_3)_2FeOH(SO_4)_2$ (trimer)	0.75	0.89	(33)
Iron dimer	0.77	1.57	(60)
$FePO_3$ (glass)	0.75	0.88	(34)

[a] Isomer shift relative to SNP.

Another comparison can be made with glassy $FePO_3$, and the values for its IS and QS (34) are also included in Table IV. The match up of these values with those of the passive film is extremely good. A comparison of crystalline and glassy $FePO_3$ gives some additional insight into the passive film structure. The IS values 0.77 mm/sec for the crystal and 0.76 mm/sec for the glass indicate that the local environment, coordination number, and type of bonding are essentially the same. The QS values on the other hand, 0.37 mm/sec for the crystal and 0.88 mm/sec for the glass, indicate that the distortion of the sites in the glass is considerably larger than in the crystalline material. The linewidths, 0.53 mm/sec for the crystal and 0.64 mm/sec for the glass, indicate that the distribution of sites is much larger in the glassy material. The structure of the glassy phosphates is generally long chain polymers (35), and this would tend to give rise to the distortions at the iron as seen in the higher QS values.

The low temperature behavior of the samples frozen *in situ* gives further insight into the structure of the passive film. As was demonstrated earlier, this data is characteristic of the hydrated *in situ* passive film. The spectra between 300° and 177°K are essentially equivalent. At temperatures between 170° and 160°K the contribution to the quadrupole split portion of the spectrum decreases by about 30% without developing a magnetically split spectrum. Between 160° and 100°K the remainder of the quadrupole split contribution is lost still without the development of a magnetic split spectrum. Only an increase in the background area is observed. When the temperature reaches values in the region of 10°-15°K, an extremely broad magnetic hyperfine spectrum is observed which sharpens up at 4°K. Behavior of the type demonstrated by the Mössbauer spectra of the passive film at temperatures of 20°K and lower has been observed recently (61-65) in the case of amorphous iron (III) oxides and hydroxides and is the result of a new type of magnetic ordering called sperimagnetism (61). This state is described as a magnetically ordered system at low temperatures with the atomic magnetic moments in a particle randomly oriented and a total moment which does not vanish.

Sperimagnetism is characterized by a very low magnetic ordering temperature 20°-100°K, a large IS (0.5-0.7 mm/sec), and a large QS (0.8-1.2 mm/sec) at room temperature which disappears below the transition temperature. The QS disappears because at low temperatures it is coupled to the hyperfine field which for this type of sample is randomly oriented and hence it is smeared out. A further consequence of this smearing out is the much larger linewidths observed at low temperatures as compared to those at room temperature (64). At 4°K the passive film is magnetically split with the same value for the HFS as is shown by the amorphous oxide materials in Table I. The linewidth of the passive film at 4°K is $\Gamma = 0.96$ mm/sec, while at 300°K $\Gamma = 0.86$ mm/sec. As the temperature increases to 10°K, Γ increases to 1.8 mm/sec, all in agreement with sperimagnetic character observed for the amorphous iron (III) oxides (61-65).

Although the collapse of the magnetic hyperfine splitting at 15°K leads to the unblocking of the superparamagnetic fine particles, the true magnetic ordering temperature is higher, about 100°K. The behavior between 15° and 100°K is undoubtedly due to relaxation effects. This behavior may be accounted for by several explanations, one of which is spin-lattice relaxation. Here, the ions see the fields arising from the splitting of the Kramer's doublets, and the contributions due to the magnetic fields arising from the $+5/2$, $+3/2$, $+1/2$ spin states are unresolved. Thus, the spectrum appears as a continuous broad adsorption. It has been shown (37, 38) that when one of the coordinating ligands is water the spin-lattice relaxation is slower. A second explanation suggests that the FeO_6 octahedra making up the film are more and less strongly bonded to the neighboring octahedra leading to stronger and weaker magnetic interactions, respectively. The distribution of magnetic moments arising from such an ensemble would lead to a general broadening of the entire spectrum. This latter explanation is the more likely one (64).

Above 100°K the Mössbauer spectra show the characteristic behavior of a paramagnetic specie.

The structure of the *in situ* passive film which emerges from this discussion is one which is not highly structured but is amorphous and polymeric in nature. It consists of FeO_6 octahedrons in a chainlike structure bonded together by di-oxy and di-hydroxy bridging bonds, and these chains are further linked together by water to form a continuous film covering the iron surface and leading to its protection.

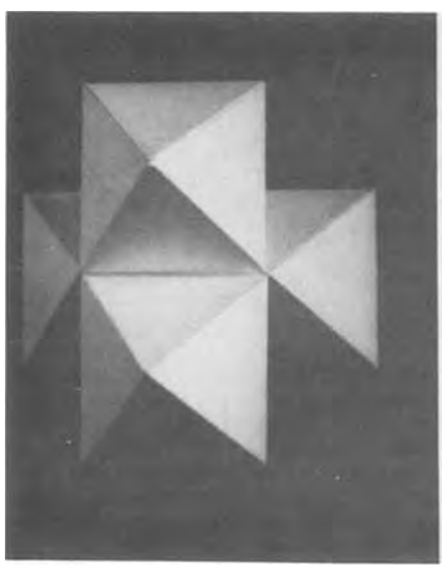
Hydration and dehydration of the in situ passive film.—This set of experiments shows, for the first time, that the passive film undergoes very definite changes when it is removed from the solution, and it demonstrates the necessity to study these films *in situ*.

The reversibility of the hydration of the film as well as the amount of water contained in the film is extremely important information for further understanding the structure of the *in situ* passive film. The samples which were dried for times longer than five hours and which showed irreversible hydration characteristics will be discussed in the next section. The samples, however, that were dried for less than five hours showed reversible hydration behavior. An estimate of the amount of hydration water can be obtained by utilizing the partial isomer shift concept (39). The contribution to the isomer shift due to water is 0.03 mm/sec/H_2O/Fe atom (40). The isomer shift has changed from 0.70 to 0.64 mm/sec, a total of 0.06 mm/sec. This change in the film is reversible and hence it can be assumed that it arises only from changes in the water content of the film. This results in a loss of two water molecules by each iron atom in the film which agrees with the value obtained from tritium studies (41).

The reversibility of the hydration of the film imposes severe restrictions on the structure of the film. The structure required to allow the water to move in and out of the film must be quite simple to avoid giving rise to condensation reactions or other types of reactions leading to structures prohibiting the reversible exchange of water. It is proposed here that the structure of the passive film is built up of the fundamental units recently suggested for hydrolyzed iron sols (42). This fundamental unit is composed of four octahedrally coordinated iron atoms bonded together by oxy-bridging forming the structure shown in Fig. 9. The passive film would be composed of these tetramer units linked together by water and di-hydroxy bridging bonds forming a continuous film. The water which shows the reversible behavior is the water which links these units together. Furthermore, these units may edge bond to one another as shown in Fig. 10 leading to a face-centered cubic oxygen lattice which is the basis of the iron oxides (35).

The process of dehydration of this structure would involve only those oxygen-containing species which are not involved in the tetramer bonding. With the removal of two water molecules from each unit the final structure will be more compact than the original one, thus leading to the increase in the area found for the dehydrated samples (area values in Table I). This indicates that in the hydrated sample the iron is behaving as though it were solubilized and hence is not as strongly bonded as in the dehydrated case.

Other experimental evidence which supports this model is found in the recent nuclear reaction microanalysis of Agius *et al.* (50). The data presented in this paper gives a value of 1.38 oxygen atoms in the film per electron required to reduce the film. None of



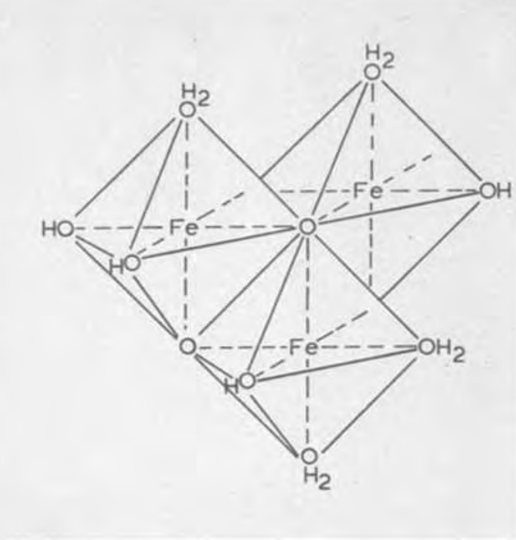


Fig. 9. Model of the basic building unit, the tetramer, suggested for a possible arrangement of the combination of two di-oxy or di-hydroxy chain species to form a tetramer. Inset shows a possible distribution of the oxygen atoms, hydroxyl groups, and water molecules around the iron atoms.

the theoretical values derived for stoichiometric oxides agree with this quantity. However, using the tetramer model suggested here, a value of 1.4 is obtained. This information, combined with the dehydration data obtained in this work, together with the tetramer model leads to a stoichiometry of $Fe_4O_4 \cdot (OH)_4 \cdot (H_2O)_8$. The dehydration of this species would give rise to an unstable form of FeOOH as the intermediate state. The isomer shift (0.66 $\pm$ 0.01 mm/sec) value of the intermediate state correlates well with the values given in Table III for several forms of FeOOH. However, the value of the quadrupole splitting (1.0 $\pm$ 0.1 mm/sec) and Γ (0.9 $\pm$ 0.1 mm/sec) indicate that the structure is highly distorted.

Structure of the dried passive film.—The samples which were shown in Table II to have been dried for periods of longer than five hours will be referred to as the dried film. The Mössbauer parameters, IS, 0.62 mm/sec; QS, 0.88 mm/sec; and HFS, 470 kOe (4°K) match up with those of γ-Fe_2O_3 found in Table III, hence we conclude that the dehydrated film is γ-Fe_2O_3.

Simmons *et al.* (44) made a study of the dried passive film in which they obtained values of 0.62 mm/sec for IS and 0.88 mm/sec for QS in good agreement with this study. Their interpretation of the data is that the film is a hydrated superparamagnetic γ-Fe_2O_3. It is not clear in this reference what the evidence was for considering the sample to be hydrated. In order for the passive film to make the transition from the hydrated to the dried state, two steps are observed. The first step is the reversible dehydration of the film which lowers the IS from 0.7 to 0.64 mm/sec. The second step is irreversible and involves a change in the bonding in the film. One of the primary steps in the growth of iron oxide from basic solutions has been shown to be the de-oxalation or de-hydroxalation of the di-oxy or di-hydroxy bridging bonds (43, 45). There are several mechanisms whereby this breaking of the bridging bond can occur. One (45) is by a condensation type reaction

$$\mathrm{Fe}\begin{matrix}\diagup \mathrm{OH} \diagdown \\ \diagdown \mathrm{OH} \diagup\end{matrix}\mathrm{Fe} \longrightarrow \mathrm{Fe{-}O{-}Fe} + H_2O$$

with a decrease in the coordination number of the iron. A second (45) is the condensation of two different complexes

$$2\left[\begin{matrix}\mathrm{Fe} & & \mathrm{Fe} \\ & \diagdown \mathrm{OH} \diagup & \end{matrix}\right] \longrightarrow \begin{matrix}\mathrm{Fe} & & \mathrm{Fe} \\ & \mathrm{O} & \\ \mathrm{Fe} & & \mathrm{Fe}\end{matrix} + H_2O$$

with the iron coordination number being conserved.

If it is assumed that the film which has the reversible water removed from it undergoes both of the above condensation reactions resulting in the final distribution of iron atoms being that of γ-Fe_2O_3, it is possible to calculate the final value of the isomer shift. In γ-Fe_2O_3, 61% of the iron atoms occupy octahedral sites (35). The isomer shift for tetrahedral iron in γ-Fe_2O_3 is 0.53 mm/sec and that for octahedral iron is 0.66 mm/sec (46). Using the additivity concept of the isomer shift and calculating the average isomer shift, assuming 61% have a value of 0.66 mm/sec and 39% have a value of 0.53 mm/sec, results in a value of 0.61 mm/sec for the IS. This is in good agreement with the value of 0.62 mm/sec found for the dried passive film.

The mechanism proposed for the growth of the oxide should lead to oxide particles having a characteristic temperature dependence. At 4°K the six-line magnetic hyperfine spectrum is observed (Fig. 7). As the temperature is raised, the hyperfine spectrum is gradually replaced by a paramagnetic quadrupole split doublet. This behavior is quite different from that observed at the Neel point (magnetic ordering temperature) which is very sharp. The behavior observed here for the dried passive film is characteristic of very finely divided particles of magnetic materials and is referred to as superparamagnetism (47). The superparamagnetic state can be represented as a collection of single domain particles, each particle having a simple uniaxial anisotropic energy given by KV where K is the anisotropy energy and V is the volume of the particle.

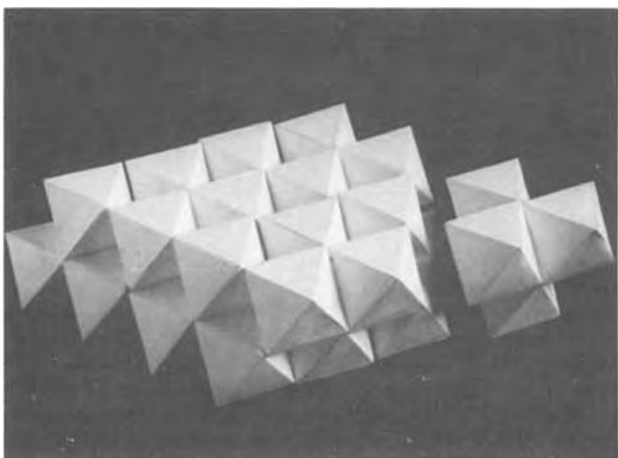

Fig. 10. Condensation of tetramers to form an FCC oxygen lattice.

There is a finite probability that the net magnetization can change its direction due to thermal fluctuations, and this is proportional to exp (KV/kT). Hence the net magnetization can fluctuate with a relaxation given by

$$\tau^{-1} = f \exp(-KV/kT)$$

where f is the frequency factor and τ is the rate at which the magnetic vector flips between the easy magnetization directions separated by the energy barrier KV.

The particle size V can be calculated from the prior equation. Substituting the Larmor precession time 2.5×10^{-8} sec for τ and the frequency factor given by Kundig (36) leads to the following equation $\ln (2 \times 10^{-4}K) = KV/kT$, where K is the anisotropy constant, V the volume, k Boltzmann's constant, and T the temperature. The value for the anisotropy constant of γ-Fe_2O_3 given in the literature (48) is 1×10^6 erg/cm³.

The fact that the magnetic transition takes place over a wide temperature span (25°-45°K) indicates that there is a distribution of particle sizes. The temperature at which both states coexist equally is 35°K and this is taken to be the average particle size (36). The particle size which results from this calculation is a sphere with a diameter of 3.6 mm. This latter value correlates well with the value obtained by Sewell (49) in an electron microscopy study of the growth of oxides on iron single crystals in oxygen.

Summary

In this study the structure of the *in situ* passive film has been determined for the first time using Mössbauer spectroscopy.

The results found here for the *in situ* passive film are not those of any of the stoichiometric, crystalline oxides including γ-Fe_2O_3, Fe_3O_4, and $Fe_2O_3 \cdot H_2O$. All of the Mössbauer parameters match those of amorphous iron (III) oxides, iron containing polymers, and bi-nuclear iron compounds containing di-oxy and di-hydroxy bridging bonds between the iron atoms. The low temperature studies of the *in situ* frozen samples also show that the film is not highly structured but is amorphous and polymeric in nature. It consists of chains of iron atoms bonded together by di-oxy and di-hydroxy bridging bonds, and these chains are further linked together by water to form a continuous film covering the iron surface and leading to its protection.

Furthermore, it has been shown that γ-Fe_2O_3 results only when extensive drying of the *in situ* passive film has caused irreversible changes.

Acknowledgments

I would like to thank Professor J. O'M. Bockris for the encouragement and direction which he provided during the experimental portion of this work. Also, I would like to thank Professors D. Drazic and R. W. Hoffman for many valuable discussions and Dr. C. R. Anderson for pointing out the papers on sperimagnetism. This work was performed under the auspices of the U.S. Department of Energy.

Manuscript submitted March 7, 1979; revised manuscript received Sept. 12, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Brookhaven National Laboratory.

Atmospheric Corrosion of Nickel

D. W. Rice,* P. B. P. Phipps, and R. Tremoureux

IBM Corporation, General Products Division, San Jose, California 95193

ABSTRACT

Nickel atmospheric corrosion is discussed, ranging from moisture adsorption isotherms to measured indoor corrosion rates. Significant quantities of water are adsorbed on nickel surfaces with a heat of adsorption equal to 10.7 kcal/mole. Corrosion kinetics are linear and exponentially dependent on relative humidity. The partial pressures of SO_2, Cl_2, NO_2, and NH_3 significantly influence nickel corrosion while H_2S and O_3 have little influence. Nickel corrodes in indoor environments at rates significantly less than outdoors and follows log normal statistics over the field site population studied.

The resistance of nickel to atmospheric corrosion is of broad interest because it is a component of many structural materials, as well as an alloying additive in magnetic materials. Nickel is thermodynamically unstable with respect to most practical operating environments. Its stability is therefore controlled by diffusion processes through surface corrosion products and corrosion product dissolution kinetics. Faraday recognized this over a century ago, yet models do not exist today that explain quantitatively the atmospheric behavior of nickel over a broad range of conditions (1).

The mechanism of atmospheric corrosion is a complex combination of dry oxidation and aqueous electrochemistry that depends on temperature, pollutant concentrations, relative humidity, and the material (2, 3). In dry high temperature oxidation, the predominate corrosion product is NiO formed in a multistage oxidation mechanism that can be explained by Wagner's defect diffusion theory (4-10). The aqueous electrode kinetics of nickel have been extensively studied (11-24). The dissolution of NiO to form a complex product via a rate-controlling $NiOH^+$ step is considered the important mechanism of decay.

Evans states that the main controlling factor in atmospheric corrosion is the moisture content of the air (25). The complexity of the corrosion process on nickel was demonstrated by Vernon four decades ago (26). He showed that the corrosion product on nickel in outdoor industrial atmospheres was not a simple nonstoichiometric oxide but a basic nickel sulfate. Hudson has shown that nickel sheltered from rain corrodes more rapidly than nonsheltered nickel. He attributed this to the hygroscopic nature of the corrosion products and their ability to accelerate corrosion when left on the surface (27). Campbell and Thomas showed a marked seasonal dependence for nickel indoor corrosion (28).

In this paper we present the results of a study designed to focus attention on the complex process of nickel atmospheric corrosion from water adsorption to observed corrosion in indoor business environments. The quantitative importance of relative humidity and pollutant concentration is presented followed by a discussion of the comparative indoor corrosion of nickel and associated corrosion products. A similar study has been reported for cobalt (2).

Experiment

Materials used in the study were 100 nm (1000Å) nickel films and 12 μm nickel foils. The films were prepared by electron beam evaporation from a 99.99+ purity nickel ingot on AT cut quartz or glass substates at 0.4 nm/sec. The background pressure during evaporation was less than 10^{-6} Torr and the substrate temperature was 200°C. The nickel foils were 99.99+ purity. Both films and foils were cleaned prior to use by a sequence of hot toluene, isopropanol, and DI water immersions.

The cleaned surfaces as measured by XPS (x-ray photoelectron spectroscopy) and Auger electron spectroscopy consisted of significant quantities of hydrocarbon in addition to nickel and oxygen. Traces of sulfur and chlorine were present. The oxide thickness was approximately 0.6 nm. These observations are

* Electrochemical Society Active Member.

Key words: atmosphere, corrosion, nickel.

characteristic of most cleaned air exposed transition metal surfaces. The nonmetallic impurities were easily sputtered away, indicating they were surface not bulk contaminants.

The atmospheric test environments were synthesized from high purity dilute gases, purified air, and water vapor. The reaction chamber and associated gas-handling system was made of Pyrex glass to minimize adsorptive losses. Considerable care was required to purify the air before introducing pollutants. Without this precaution the levels of NO_2 and O_3 were found to fluctuate with the ambient outdoor NO_2 and O_3 levels characteristic of urban California environments. The purified air had concentrations of pollutants equal to or less than 0.1 $\mu g/m^3$ for NO_2, 0.05 $\mu g/m^3$ for Cl^-, 0.006 $\mu g/m^3$ for H_2S, 0.1 $\mu g/m^3$ for NH_3, 1 $\mu g/m^3$ for O_3, and 0.9 $\mu g/m^3$ for SO_2.

The influence of SO_2, NO_2, O_3, H_2S, Cl_2, and NH_3 concentrations on the corrosion rate of nickel was studied in a special plexiglass chamber with five reaction regions. Each reaction region was doped with a higher concentration of the pollutant being studied, while the remaining pollutants were held at a fixed reference concentration.

The reference environmental concentrations of the above pollutants, used as the background for the majority of the experiments, the rationale for selection, and the associated analytic procedures are given in Table I. The pollutant levels in the test are estimated to represent the upper 1% of the cumulative distribution function of indoor concentrations, a severe condition for indoor corrosion, but not particularly severe for outdoor urban center. NH_3 was not part of the reference environment, but was evaluated in the kinetic studies because of its "basic" chemical behavior and as a potential indoor pollutant coming from copiers and cleaning agents. The analytic equipment was calibrated using permeation tubes primarily.

The corrosion kinetics of the nickel foils were measured using a microbalance to monitor weight gain. These weighings were not made *in situ* because of the large number of samples tested. The procedure was to place enough 2.54 × 2.54 cm samples in the chamber to be equivalent to the number of test-time intervals required. Each sample was removed at its appropriate time and weighed, but not returned to the chamber.

The piezoelectric technique was used to measure the H_2O adsorption isotherms. These isotherms were measured in a humidified pure air system on nickel surfaces that had been air exposed (2, 29).

Finally, nickel foils (2.54 × 2.54 cm) and 100 nm films were placed in eight different indoor environments throughout the United States and the weight gain and reflectivity, respectively, were measured after 6, 12, and 18 months. Benzene soluble organic material was removed before the final weight and reflectivity were measured. The samples were held in a configuration such that the environment flow velocity was 250 cm/sec across the surface. The surface compositions of these returned samples were measured by Auger electron spectroscopy. The resistance increase of the nickel thin films due to corrosion in the field was measured by the four-point probe technique.

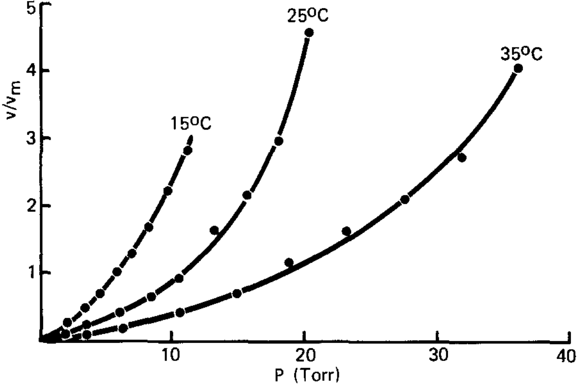

Fig. 1. Nickel thin film (100 nm) moisture adsorption results. Ratio of adsorbed water volume to monolayer volume (v/v_m) vs. water partial pressure (*P*).

Results and Discussion

H_2O adsorption.—The air-formed films on both the evaporated and foil nickel samples showed the presence of hydroxide, oxide, and traces of sulfate and chloride as measured by XPS. This is similar to cobalt surfaces (2) and has been reported by others for nickel (30-32). The adsorption of H_2O on these complex hydroxylated nickel surfaces is characterized by the isotherms measured at three temperatures shown in Fig. 1. These isotherms are typical of those seen on hydroxylated Fe_2O_3 particles (33) and cobalt (2). Figure 2 shows the isotherms plotted *vs.* p/p_o, the relative humidity. The isotherms exhibited no hysteresis, suggesting no chemisorption during the H_2O exposures. The surfaces had previously been exposed to enough H_2O, as the surface studies demonstrated, to preclude any further chemisorption during the period of measurements. The amount of adsorbed H_2O could be described by the BET isotherm up to a relative humidity p/p_o of approximately 0.80 (34). This is characteristic of gas-solid interactions and shown in Fig. 3. The isotherms also show that on nickel many apparent monolayers of water are present at higher RH's. It is not surprising that corrosion should proceed readily via these relatively thick layers of water on the hydroxy surfaces.

Table II summarizes the heat of adsorption (ΔH_{ad}), monolayer volume, and relative humidity at apparent monolayer coverage obtained by fitting the data to a BET isotherm over the interval p/p_o = 0-0.5. The heat of vaporization (ΔH_v) of water was taken as 10.5 kcal/mole in these calculations. The isoteric heat of adsorption was similar to that obtained from the BET isotherm. It was 10.9 kcal/mole at 0.5 monolayer coverage and 8.4 kcal/mole at 3 monolayers coverage.

Table I. Test reference environment (temperature = 25.0°C, gas velocity = 10 cm/sec)

Gas	Concentration ($\mu g/m^3$)	Rational for selection and sources	Analytic method
H_2O	70% RH	Known accelerator of galvanic corrosion and present at relatively large P/P_0	Dew point on cooled Au surface (continuous)
SO_2	786	Major pollutant, known to attack iron, nickel, cobalt. Forms acid on metal surface. Fossil fuel source.	Flame photometric (continuous)
NO_2	940	Major pollutant, known to attack Co, Ni, and Fe. Photochemical source.	Chemiluminescence (continuous)
O_3	334	Major pollutant, degrades polymers and accelerates oxidative decay of H_2S, NO_2, and SO_2. Photochemical source.	Chemiluminescence (continuous)
H_2S	21	Stress corrosion accelerator. Fossil fuel source.	Pb acetate densitometry (periodic)
Cl_2	8.6	Destabilizes otherwise passive films by lattice impregnation and acid dissolution. Fossil fuel and PVC incineration source.	o-toluidine densitometry (periodic)
NH_3	—	Forms chemically basic surface. Cleaning agent and copier source.	Chemiluminescence (continuous)

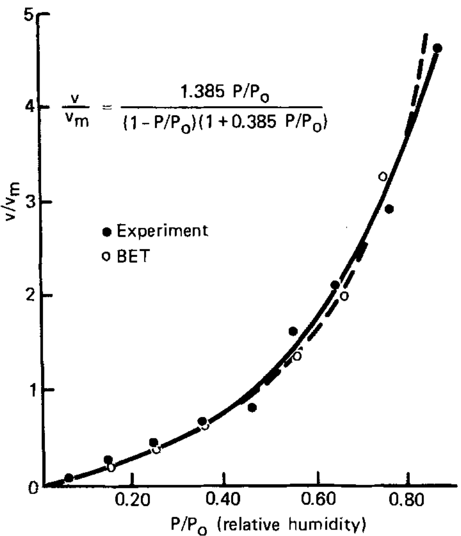

Fig. 3. Nickel thin film (100 nm) moisture adsorption isotherm comparison of experiment and theory ($T = 25°C$).

The similarity between the ΔH_{ad} and ΔH_v implies that the H_2O molecule shows no great preference for the surface as compared to liquid water. It could just as well combine with a neighboring H_2O molecule to form a local H_2O cluster. The ΔH_{ad} measured in the study of Ni is slightly less than that reported on Fe_2O_3 particles (33), Cu surfaces (35), and Au surfaces (36), but in general agreement. Klier *et al.* have demonstrated that water clusters on surfaces well below apparent monolayer coverage (37). In fact, they found via infrared spectroscopy that silica surfaces at monolayer H_2O coverage consisted of equivalent amounts of clustered and surface adsorbed water. These results suggest that the apparent monolayer coverage, as measured in the isotherms for nickel, may significantly underestimate the local surface volume of H_2O due to clustering.

Table II. Heats of adsorption (ΔH_{ad}), relative humidity at monolayer coverage, monolayer volume, and C in the BET isotherm for H_2O on air exposed Ni surface

T (°C)	ΔH_{ad} (kcal/mole)	RH ($v/v_m = 1$)	v_m (cm³/cm²)	C
15	10.8	0.45	3.1×10^{-8}	1.71
25	10.7	0.46	3.1×10^{-8}	1.39
35	10.8	0.44	3.1×10^{-8}	1.50

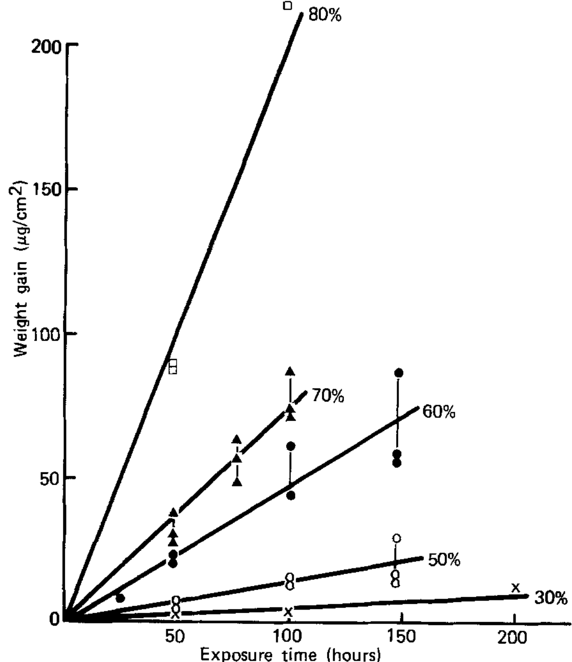

Fig. 4. Weight gain *vs.* reference environment exposure time for nickel foils at various relative humidities (%).

Relative humidity.—Figure 4 shows representative weight gain *vs.* reference environment exposure time curves for various relative humidities. The corrosion kinetics of nickel in the reference test atmosphere is seen to be linear, exhibiting no tendency to passivate further. Table III summarizes the linear rate constants for the five relative humidities studied at four different SO_2 concentrations with the other pollutants held at the reference test conditions. Figure 5 is a representation of this data. The rate constants were fit to an equation of the form $r = Ae^{bRH}$. The table summarizes the constants obtained from the fit and the correlation coefficient (CC). Relative humidity has a profound influence on nickel corrosion in these atmospheres. No evidence for a critical humidity is seen. In the absence of SO_2 the same influence is observed with a slightly larger dependence of rate on relative humidity.

Cobalt shows similar behavior in these complex environments (2). Nickel in high SO_2 environments has been reported to have a critical humidity at approximately 68% RH determined by the H_2O in equilibrium with hydrated nickel sulfate. Above this relative humidity marked rate increases have been measured (38).

Table III. Nickel corrosion rate (μg/cm²hr) vs. relative humidity (RH) at various SO_2 concentrations (μg/m³)

* Exponent n in rate expression $r = AP_x^n$ where P_x is pollutant concentration.

Pollutants.—The atmospheric corrosion of nickel is dependent on the integrated effects of water vapor, temperature, and pollutants. The simplest form of this dependence is

$$\text{corrosion rate} = A \int_0^1 \int_0^\infty \int_0^\infty P(C_x)\,[C_x]^{n-1}\, P(T)\, e^{-\frac{\Delta H^{**}}{RT}}\, P(\text{RH})\, e^{b\text{RH}} dC_x dT d\text{RH}$$

where C_x is the pollutant concentration, n and b are constants, ΔH^{**} is the activation energy associated with the atmospheric corrosion mechanism, $P(\text{RH})$, $P(C_x)$, and $P(T)$ are the relative humidity, pollutant, and temperature distribution functions, respectively, and RH is the relative humidity.

The object of this section of the work was to assess the important pollutants from a nickel corrosion point of view and evaluate the constant n for six different pollutants at a fixed RH equal to 70% and at a fixed temperature equal to 25°C. Table IV summarizes the rate data *vs.* concentration for each pollutant. Recall that all other pollutants were held at the fixed reference level. Figure 6 is a graphical presentation of the results. The range of concentrations is typical of urban environments and considerably lower than most reported laboratory studies.

Four of the pollutants, SO_2, Cl_2, NO_2, and O_3, increased the rate of nickel corrosion with increased concentration, one pollutant, H_2S, showed no marked influence, and NH_3, significantly inhibited nickel corrosion. This is similar to the behavior of cobalt reported earlier (2) except that ammonia did not inhibit cobalt corrosion.

If we assume that the water adsorbed on the corroding metal is similar to bulk water we can provide a qualitative framework for discussing the effect of the various gases. We calculate the concentration of the species derived from the gases from the solubility (39) and ionization constants and the partial pressures of gases in our test atmosphere. Since bisulfite is the dominant anion we can solve for the pH and arrive at the concentrations given in Table V. Direct measurements of the pH of the condensate give values approximately equal to 3.5. A similar value is calculated.

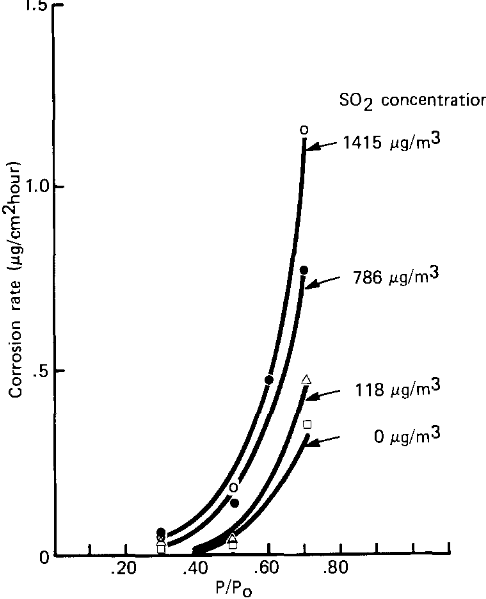

Fig. 5. Nickel corrosion rate *vs.* relative humidity (P/P_0) for various SO_2 concentrations.

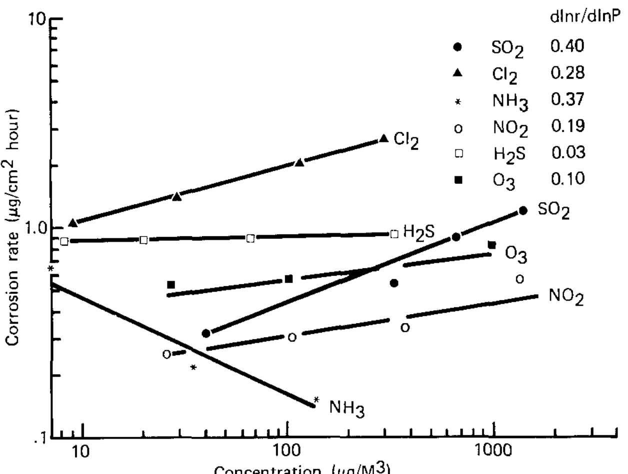

Fig. 6. Nickel corrosion rate *vs.* pollutant concentration

If we assume a corrosion rate proportional to $[H^+]$, as has been reported for stainless steel (40-42), we would predict that the corrosion rate of nickel should vary as $(P_{SO_2})^{0.5}$ from

$$SO_2 + H_2O \rightleftharpoons H_2SO_3 \rightleftharpoons H^+ + HSO_3^-$$

$$[H^+] \simeq [HSO_3^-] \text{ (charge neutrality)}$$

Therefore, the corrosion rate $r = k[H^+] = k(P_{SO_2})^{0.5}$. The observed dependence is given in Table IV

$$r = A(P_{SO_2})^{0.4}$$

Similarly, the effect of chlorine on the rate of corrosion might be attributed to

Table V. Species in the gaseous and aqueous phases

Gas	*	CO_2	NH_3	NO_x	H_2S	SO_2	O_2	HCl
p atm		3×10^{-4}	2×10^{-8}	5×10^{-7}	10^{-8}	3×10^{-7}	10^{-1}	3×10^{-9}
Product	H^+	H_2CO_3, HCO_3^-	NH_4OH, NH_4^+	HNO_2, NO_2^-	H_2S, HS^-	H_2SO_3, HSO_3^-	O_2	Cl^-
log [ ] moles	−4	−5, −7.5	−6, −0.5	−9, −8.5	−8.8, −12	−6.4, −4.5	−0.36	1

* H^+ estimate was from pH measurement of the atmosphere chamber condensate as well from these calculations.

$$Cl_2 + H_2O \rightleftharpoons HCl + HOCl$$
$$HCl \rightleftharpoons H^+ + Cl^-$$
$$HOCl \rightleftharpoons H^+ + OCl^- \quad p_K = 7.5$$

If the pH is less than 8, as predicted from the SO_2 pressure, the HOCl is fully ionized and we could predict $[Cl^-] = \frac{1}{2}[H^+] \propto (P_{Cl_2})^{0.25}$. If the pH is greater than 8, then

$$[Cl^-] = [H^+] \propto (P_{Cl_2})^{0.5}$$

Table IV shows that the corrosion rate is proportional to $(P_{Cl_2})^{0.28}$. Nickel corrosion has been reported to vary as $[Cl^-]^{0.28}$ in $0.1N$ $HClO_4$ (14). More detailed data is required to discuss this further.

The small effect of NO_2 despite its high concentration can be attributed to its low solubility and the weakness of HNO_2. Nitrates are not found in our corrosion products from field exposure. The weakness of H_2CO_3 suggests that it too will have very little effect on the surface pH despite the high concentration and solubility of CO_2.

The sulfide concentration is sufficient to precipitate NiS whose solubility product, K_{sp}, is 10^{-24} mole^2 liter^{-2}. The sulfur found is in the form of sulfate. Clearly, the effects of oxidation should be introduced into the simple model.

The effect of NH_3 might be connected with its effect of raising the pH. We would predict

$$[H^+] \propto (P_{NH_3})^{-0.5}$$

The corrosion rate reported in Table IV is

$$r \propto (P_{NH_3})^{-0.37}$$

The reason for the effect on nickel corrosion and not on cobalt corrosion is unknown (2). This simple observation dramatically highlights the complexity of atmospheric corrosion. Metals as similar as nickel and cobalt behave so differently.

Indoor corrosion.—The nickel foils sent to the indoor business environment testing sites showed corrosion rates that ranged from approximately 0-1.18 $\times$ 10^{-2} μg/cm^2 hr. Table VI summarizes the data by location and external environmental class. The distribution function for nickel corrosion rates is approximately log normal over the site population as shown on the log probability paper of Fig. 7. The indoor corrosion of nickel measured in this study was slightly

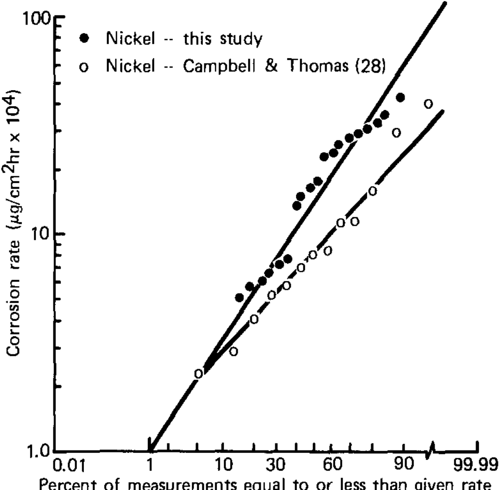

Fig. 7. Nickel corrosion rate distribution in indoor environments

greater than the values measured by Campbell and Thomas (28). Their data is shown for comparison in Fig. 7. Also, Sharma measured the film thickness formed on nickel in a central office in Cleveland (43). This site showed comparatively low rates, 0.6 $\times$ 10^{-4} μg/cm^2 hr, and exhibited parabolic kinetics.

These measured indoor rates are considerably less than values measured by others in outdoor sites. Table VII compares our measured indoor rates with outdoor industrial, sea coast, and rural rates (44). Outdoor industrial environments corrode nickel 600 times greater than indoor urban environments. This is due in large part to the pollutant adsorption losses on internal surface in buildings, coupled with less extreme humidity conditions.

Neither the resistance change nor the surface reflectivity of the thin nickel films correlated well with the weight gain measurements, however, there is a general trend for the more severe corrosion rate sites to show higher reflectivity changes (surface roughening) and resistance increases than the more prestine sites (Fig. 8).

Finally, Auger electron peak-to-peak (P/P) intensities were measured for thin films returned from six of the eight sites after 18 months. The ratio of Cl, S, and O P/P intensities compared to Ni is shown in Fig. 8. No clear picture emerges pointing to one element as the most important indicator of corrosion severity. All samples had varying amounts of S, O, Cl, N, Ni, and C. Limited XPS work showed the oxygen to be associated with hydroxide or more complex anions. The sulfur was present as sulfate, and carbon as hydrocarbon not carbonate. Nitrogen was too low in concentration to make reasonable XPS bonding estimates. The samples returned from Los Angeles showed traces of lead conjectured to result from tetraethyl lead in the urban Los Angeles environment.

Table VI. Nickel corrosion rate, surface reflectivity, and resistance change ($\Delta R/R_o$) in indoor environments

Summary

The air-formed surfaces of exposed nickel adsorb significant quantities of water that can be approximated by a BET isotherm. The corrosion rate of nickel in a complex polluted environment is strongly de-

Table VII. Comparison of nickel corrosion rates in indoor and outdoor environments

	Average rate (μg/cm^2 hr)
Indoor urban	0.0013
Indoor industrial	0.0038
Outdoor rural	0.0274
Outdoor sea coast	0.0893
Outdoor industrial	0.7975

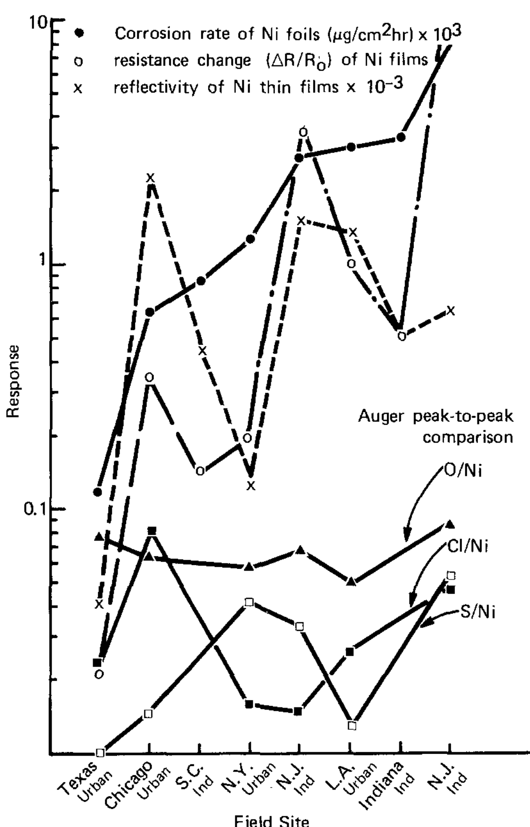

Fig. 8. Comparison of different measurement techniques for samples returned from indoor field locations (Table VI).

pendent on relative humidity. Sulfur dioxide and chlorine both significantly increase the corrosion rate of nickel while ammonia inhibits it. The observed indoor corrosion rates of nickel follow log normal statistics over the site population in this study and are much less than the observed outdoor rates.

Acknowledgments

We thank I. Rodriquez and J. Fazio for taking the rate data, Dr. V. I. Gupta for some of the adsorption data, F. Wagner for his tactical support of the field study, and Dr. H. Anderson for his continued support.

The Sulfidation of Iron by Carbonyl Sulfide: An Example of Kinetics Involving Parallel Sequences

P. Hadjisavas, M. Caillet, A. Galerie, and J. Besson*

Laboratoire d'Adsorption et Réaction de Gaz sur Solides, Ecole Nationale Supérieure d'Electrochimie et d'Electrométallurgie, Domaine Universitaire—BP 44—38401 Saint Martin d'Hères, France

ABSTRACT

The sulfidation of iron by carbonyl sulfide obeys a paralinear rate law in the temperature range from 300° to 700°C, with a linear influence of pressure on the linear rate constant. The morphology of the sulfide scale is complex. Several observations lead to the conclusion that the equilibrium is not reached in the gaseous phase. The proposed mechanism accounting for the kinetic results involves two parallel processes: the decomposition of COS in the gaseous phase and in the adsorbed phase.

The sulfidation of iron by sulfur vapor or by other sulfur-containing gases (H_2S, SO_2, CS_2) has been extensively studied (1-12), but only few papers describe the behavior of iron in a COS atmosphere (13-14).

Hayen and Steiten (13) showed that COS-CO-CO_2 mixtures react with iron and give only the iron (II) sulfide FeS between 750° and 900°C. The COS partial pressure and the duration of the reaction both influence the form of the rate law: for low pressures and short times, the rate law is linear. According to the same authors, there are two limiting processes: the sorption and the decomposition of COS in the adsorbed phase. When the COS pressure increases, the rate law becomes parabolic.

Rahmel (14) studied the same system but observed the formation of FeO and FeS, the disappearance of one of these products corresponding to a change in the mechanism of the corrosion.

Experimental Procedure

All experiments were carried out with N17 carbonyl sulfide from the Matheson Gas Company. The iron sheets (Ferholtzer S, 2N5, from Creusot-Loire) were machined into parallelepiped samples (15 × 10 × 1 mm). The kinetic experiments were performed with a quartz spring thermobalance in a static COS atmosphere. After evacuating the apparatus down to 10^{-5} Torr ($1.3 \cdot 10^{-3}$ Pa) the iron sample was heated under vacuum in an electric furnace up to the required temperature. The initial time of the reaction corresponds to the introduction of COS in the reaction chamber. The weight gain of the sample was then electronically recorded with an accuracy of about 50 μg. After cooling in the COS atmosphere, the sample was analyzed by x-ray diffraction and observed by scanning electron microscopy.

Results

Product of the reaction.—For all temperatures and COS initial pressures, the x-ray patterns showed only FeS in the corrosion layer.

Influence of the temperature.—For a COS pressure of 100 Torr in the temperature range 300°-700°C, the rate law was paralinear as shown in Fig. 1 and 2. The linear rate constant obeyed the Arrhenius law; the measured activation energy was 76 kJ · $mole^{-1}$ (Fig. 3).

Influence of the gas pressure.—The influence of the COS pressure was studied only at 414°C, from 5 to 250 Torr (Fig. 4). The linear rate constant varies with P_{COS} according to a linear law as long as the pressure exceeds 10 Torr (Fig. 5).

Morphological observations.—The cross section of the sulfide scale was studied by scanning electron microscopy. The observed morphology was not different from that of scales prepared by reaction of iron with hydrogen sulfide or sulfur vapor. On the micrographs, three different layers could be identified (Fig. 6a and b): (*i*) an outer porous layer, often foliated for low values of the temperature or pressure, coarsely crystallized for higher values. Such an observation was already made in the case of the sulfidation of copper by carbonyl sulfide (15): (*ii*) an intermediate layer, obviously porous, often reduced to scarce iron sulfide bridges; and (*iii*) an inner layer, finely crystalline the compactness of which is difficult to ascertain. According to many authors we assume that at least a thin layer adjacent to metal is compact.

Composition of the Gas Phase

Thermochemical calculations.—The calculation of the equilibrium partial pressures of the species resulting

from the decomposition of COS was carried out in our laboratory by minimizing the total Gibbs free energy of the ternary system C-O-S using the Direct Search Method developed by Hooke and Jeeves (16). In this system, twenty-one different species were considered. Figure 7 shows the results obtained for a COS initial

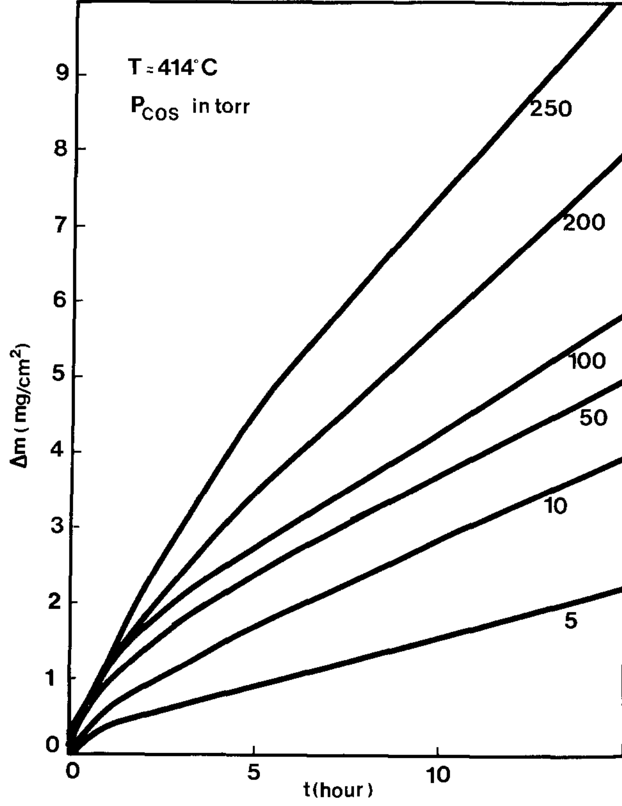

Fig. 4. Influence of pressure

pressure of 100 Torr. From this diagram, it can be seen that: (*a*) Only eight gaseous species are present in significant amounts at equilibrium between 500° and 1300°K; (*b*) at equilibrium, the COS pressure never exceeds one-half of its initial value; (*c*) at high temperatures, the decomposition of this compound is rather complete. As reported in the literature it may be represented approximately by the equation: $COS \leftrightarrows CO + \frac{1}{2} S_2$; and (*d*) at low temperatures ($T < 800°K$) the equation reported in the literature ($2\ COS \leftrightarrows CO_2 + CS_2$) does not agree with our results. In this temperature range, the calculation shows that solid carbon is formed. At 600°K, for example, 45% of the initial carbon is present in the solid phase at equilibrium.

Kinetic observations.—In our experiments, only a small part of the gas is heated. Under such conditions, if sulfur vapor is present in the hot gas phase, solid sulfur is expected to condense on the colder inner wall of the apparatus above the furnace.

In a previous work using carbon disulfide as the sulfidizing agent (11), we have shown that the sulfur condensation takes place wih a significant rate for sulfur pressures greater than about 10^{-1} Torr. For lower values, no visible deposit was observed in our apparatus even after 20 hr or more.

In the present case no solid sulfur appeared in the temperature range 300°-700°C. Its partial pressure in the gas phase was therefore very low ($<10^{-1}$ Torr) so that this phase could not possibly have reached an equilibrium state. The decomposition process of COS in the gas phase is consequently slow and its rate must be taken into account in any interpretation of the kinetics of the overall reaction.

Discussion of the Results

According to Rahmel (14), a linear rate law highly dependent on temperature is an indication of a rate-determining reaction at the scale/gas phase boundary. In this case, FeS and Fe oxides must be formed simultaneously if sulfur and oxygen pressures are greater than the Fe/FeS and Fe/Fe oxide equilibrium pressures.

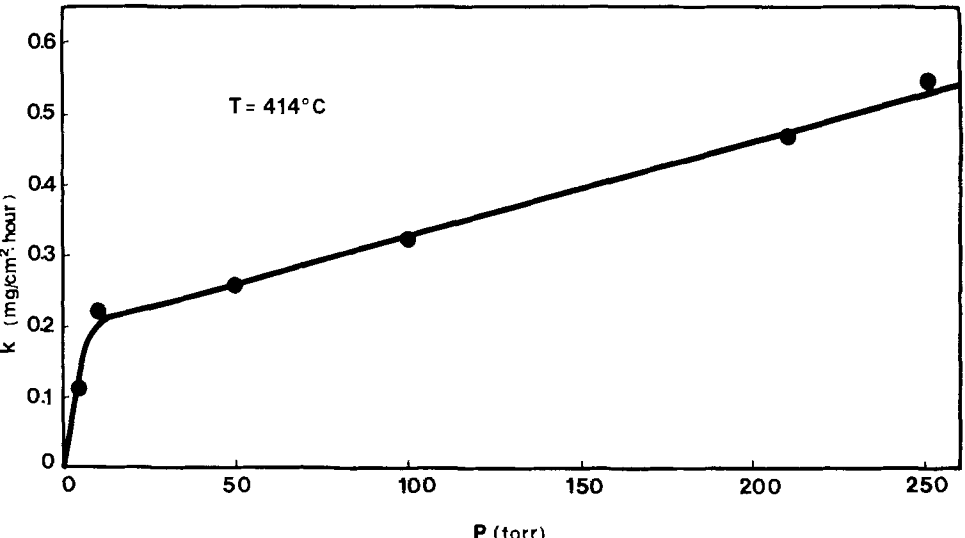

Fig. 5. Influence of pressure

In our experiments, despite the fact that both FeS and FeO (or Fe_3O_4 at lower temperatures) were thermodynamically stable, we never observed any iron oxide. This is another indication of the nonequilibrium state of the gas phase.

In such conditions, it is possible to describe more precisely the elementary steps involved in the gas phase and at the scale/gas phase boundary and to propose a model which can account for our experimental results: linear rate law with linear but nonproportional influence of pressure. This model rests on the following observations: (*i*) Contrary to the sulfidation of iron by carbon disulfide (11, 12), the reaction of carbonyl sulfide does not liberate carbon. It can therefore be assumed that CS_2 formed by thermal decomposition of COS does not interfere in the reaction. (*ii*) As the reaction product is pure iron sulfide, the only adsorbed species to be considered are COS and S_2. The species $S_x (2 \leq x \leq 8)$ exist also but, due to the observed nonequilibrium state of the gas phase, the partial pressure of sulfur must be very low, thus promoting the diatomic species S_2. (*iii*) The existence of two different sulfidizing agents in the gas phase (COS and sulfur vapor) makes it necessary to consider two parallel sequences of elementary steps, both leading to the formation of adsorbed sulfur. (*iv*) The FeS inner layer (or part of it) is compact so that diffusion through this layer must take place.

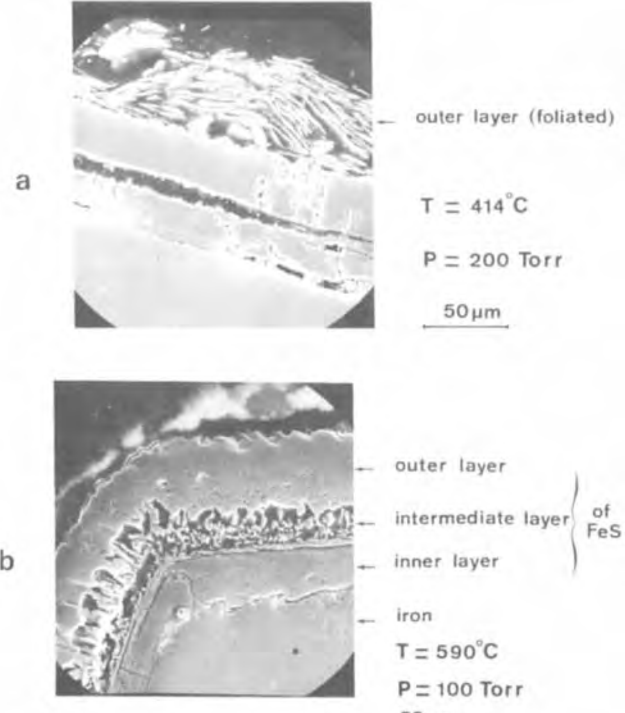

Fig. 6 (a and b). Cross sections of the FeS layer

In agreement with these remarks, the successive steps of the reaction can be represented as in Fig. 8. According to this model, the reacting species, consisting of adsorbed S_2 molecules, are formed by two parallel sequences called A and B and two cases are to be distinguished: (*a*) At least one of the two sequences A and B is fast and consequently these two sequences have no influence on the rate of the overall reaction. Here the limiting step would be either one of the two interfacial half-reactions or the diffusion in the FeS layer, but these processes lead to parabolic or linear rate laws with a nonlinear influence of pressure and must be discarded. (*b*) The two sequences A and B are slow, therefore not at equilibrium. In this case, the reaction rate is the sum of the rates of each sequence. The overall reaction will obey a simple rate law if only one step of each sequence is slow. If the two steps of at least one sequence are slow, the rate law will be complex.

Considering only simple rate laws, four combinations of rate-determining steps are possible: (*i*) adsorption of COS/decomposition of COS in the gas phase, (*ii*) adsorption of COS/adsorption of S_2, (*iii*) decomposition of COS in the adsorbed phase/decomposition of COS in the gas phase, and (*iv*) decomposition of COS in the adsorbed phase/adsorption of S_2.

The combinations (*ii*) and (*iv*) imply that the decomposition of COS in the gaseous phase reaches its equilibrium state, which is not supported by experiments, so that these combinations may also be discarded.

From the remaining two combinations the first one, already described in the case of the sulfidation of copper (15), leads to a proportionality between the rate constant and the COS pressure and is also in contradiction with experimental evidence (Fig. 5).

There is therefore only one possible combination, (*iii*)

$$\text{sequence A} \begin{cases} [[COS]] + s \rightleftarrows (s - COS) & \text{(fast step)} \\ 2(s - COS) \rightarrow 2[[CO]] & \\ \quad + (s - S_2) + s & \text{(slow step)} \end{cases}$$

$$\text{sequence B} \begin{cases} [[COS]] \rightarrow [[CO]] + \tfrac{1}{2}[[S_2]] & \text{(slow step)} \\ [[S_2]] + s \rightleftarrows s - S_2 & \text{(fast step)} \end{cases}$$

s is an adsorption site at the surface of the compact part of the FeS layer.

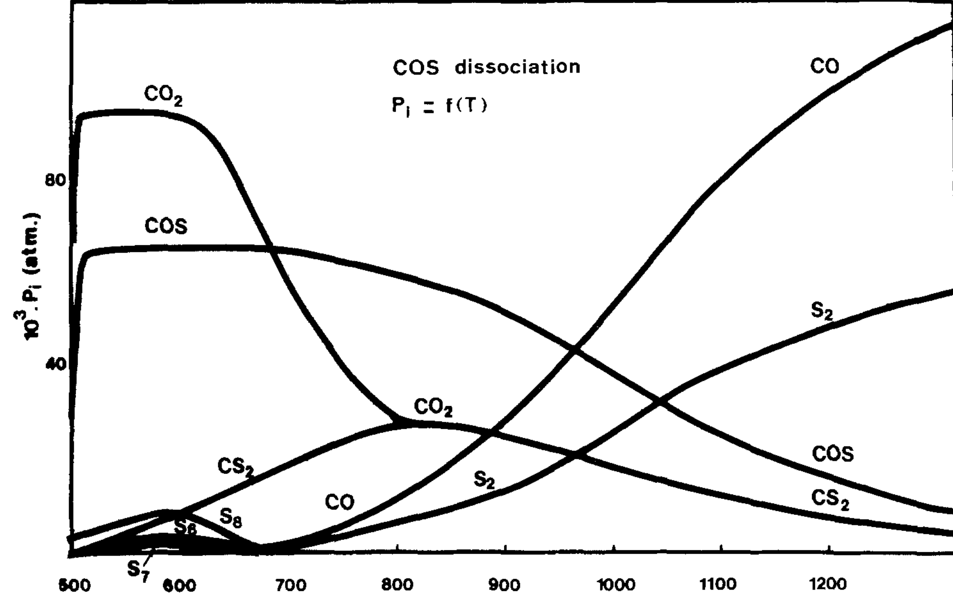

Fig. 7. Equilibrium partial pressures resulting from the thermal decomposition of carbonyl sulfide.

The next steps involve the external and internal half-reactions and are supposed to be fast enough to reach the equilibrium. They can be written

external reaction (equilibrated):

$$(s - S_2) \rightleftarrows S_S + V_{Fe}'' + 2h^{\cdot} + \frac{1}{2}[[S_2]] + s$$

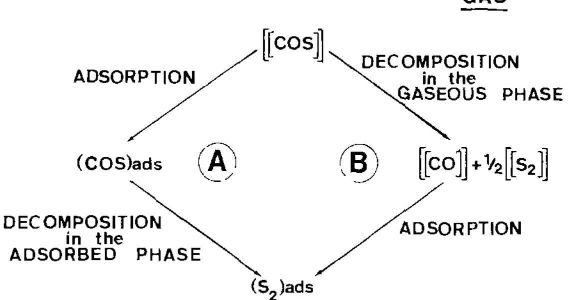
internal reaction (equilibrated):

$$\langle Fe \rangle + V_{Fe}'' + 2h^{\cdot} \rightleftarrows Fe_{Fe}$$

Let k_{Ad}, k_{Bd} be the elementary rate constants of the slow processes for sequences A and B, respectively and K_{As}, K_{Bs}, the equilibrium constants of the equilibrated processes of sequences A and B. The indexes "s" or "d" refer to the nature of the considered reaction: adsorption or decomposition. P, θ, P_2, θ_2 are the pressure and the coverage ratio of COS and S_2, respectively.

If the rate-limiting steps are very far from equilibrium, their rates are given by

$$\begin{cases} v_{Ad} = k_{Ad}\theta^2 \\ \quad \text{(decomposition of COS in the adsorbed phase)} \quad [1] \\ v_{Bd} = k_{Bd}P \\ \quad \text{(decomposition of COS in the gas phase)} \quad [2] \end{cases}$$



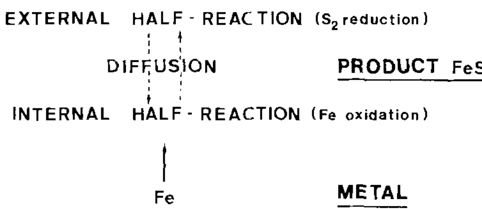


Fig. 8. Schematic diagram illustrating the whole mechanism with parallel sequences.

The coverage ratio θ can be derived from the law of mass action

$$K_{A_S} = \frac{\theta}{(1 - \theta - \theta_2)P} \quad \text{and} \quad K_{B_S} = \frac{\theta_2}{(1 - \theta - \theta_2)P_2}$$

Therefore

$$\theta = \frac{K_{A_S}P}{1 + K_{A_S}P + K_{B_S}P_2} \quad [3]$$

The rate of the overall reaction in $mg \cdot cm^{-2} \cdot hr^{-1}$ is then

$$\frac{d\Delta m/s}{dt} = \frac{M_{COS}k_{A_d}K_{A_S}{}^2P^2}{(1 + K_{A_S}P + K_{B_S}P_2)^2} + M_{COS}k_{B_d}P \quad [4]$$

This equation may account for the observed rate law. As soon as the carbonyl sulfide is introduced into the reaction chamber, a slow dissociation takes place and the sulfur pressure P_2 increases, leading to the observed decreasing speed. After a few hours, a stationary value of P_2 is reached,[1] and the rate law becomes linear. During this second stage of reaction the influence of COS pressure P on the linear rate constant is represented, according to Eq. [4], by

$$k_1 = \frac{aP^2}{(1 + P)^2} + bP$$

where a and b are constants. The corresponding curve agrees with our experimental results (Fig. 5).

Thin Zinc Films on Aluminum

David Lashmore

Chemical Stability and Corrosion Division, National Bureau of Standards, Washington, D.C. 20234

ABSTRACT

As part of a study of plating on aluminum, the deposition of thin zinc films on aluminum substrates was investigated by transmission electron microscopy and by electron diffraction. Zinc coatings on 99.999% aluminum were formed by immersion in aqueous solutions of sodium zincate. It was found that zinc initially forms epitaxial semicontinuous films on all aluminum principal planes. Subsequent zinc growth continued in the form of separate crystallites (2000Å diam) which grew upon the initial film while continuing to maintain the epitaxial relationship. Using dark field transmission electron microscopy in combination with electron diffraction, it was found that Zn: (0001) $<10\bar{1}0>$//Al (100) $<010>$, Zn: (0001) $<11\bar{2}0>$//Al $(1\bar{1}0)$ $<111>$, and Zn: (0001) $<11\bar{2}0>$// Al (111) $<1\bar{1}0>$.

The literature covering epitaxial deposits on aluminum is rather limited presumably due to the difficulty in obtaining an oxide-free aluminum surface. Dorey, however, has reported (1) that in high vacuum ($\sim 5 \times 10^{-7}$ Pa), nickel evaporated onto (111) aluminum held at 40°C forms epitaxial islands of AlNi. As the temperature was raised to 250°C, a continuous layer of Al_3Ni was formed with no preferred orientation. At 330°C unstable elongated regions showing a (110) preferred orientation were observed. These regions tended to form spheres, presumably to minimize their surface area. The aluminum substrate used by Dorey was formed by evaporation of the aluminum onto rock salt, again at high vacuum. Jona (2) has reported good autoepitaxy of aluminum at room temperature. His specimens were prepared by evaporation of aluminum at similar vacuums onto single crystal aluminum substrates which had undergone elaborate cleaning steps. Substrates of (100), (110), and (111) orientations

were considered. In all cases epitaxy was found, and on the (110) surfaces Jona found that there were indications of (111) facets present.

In spite of many studies of zinc-coated aluminum (3-9), there have been no reports of zinc epitaxy on aluminum substrates. In an investigation of the zincate process, Bullough and Gardam (4) speculated that adhesion between zinc and aluminum might very well depend on the degree of epitaxy between the deposit

Fig. 3. A dark field micrograph of a (110) zincated specimen taken with a (220) reflection, illustrating the initial growth of a rectangular crystallite. Note the bend contours within the transparent zinc crystallites of hexagonal morphology.

and the substrate, and they gave several examples of orientations of zinc which would be expected on the aluminum principal planes; however, no experimental evidence was presented to support their theory. Bailey (8) published an x-ray and electron diffraction study of zincated aluminum, concluding that the zinc film was covered with separated small single crystallites of zinc. He also offered evidence to support the existence of small amounts of zinc hydroxide on the surface. However, no information on the substrate orientation was presented nor was the morphology described.

The zinc immersion process is used extensively as the first step in electroplating on aluminum (10). Essentially, the process is simply the immersion of a very clean aluminum substrate into an aqueous solution at 23°C of sodium hydroxide and zinc oxide. The aluminum oxide is dissolved in solution and a displacement reaction takes place, where ideally two aluminum atoms pass into solution for every three zinc atoms deposited on the surface. It has been shown (11), however, that the reaction which takes place in solutions containing ferric chloride and Rochelle salt (standard additions) is more complex.

Procedure

Specimens of 99.999% aluminum were electropolished to electron transparency using a twin jet technique. The electrolyte used was a solution of 15% perchloric acid in methanol cooled to 250°K. In most cases it was possible to stop the polishing before the specimens were perforated. After appropriate rinsing, the specimens were zincated for 60 sec on one side using either of two solutions. Solution I consisted of 525 g/dm^3 sodium hydroxide and 100 g/dm^3 zinc oxide in distilled water. Solution II had, in addition to the above, 1.0 g/dm^3 ferric chloride and 10 g/dm^3 Rochelle salt. The specimens were examined in transmission electron microscopes at 100 or 200 kV. Both microscopes used in this investigation were equipped with anticontamination stages and double tilt specimen holders.

Results

A dark field micrograph of a single crystallite of threefold symmetry is shown in Fig. 1(a) along with its associated selected area diffraction pattern in 1(b). This micrograph of (100) aluminum was taken with the (002) reflection and, as will be discussed below, indi-

cates that this zinc crystallite is epitaxial on the (100) substrate.

On substrates of the (110) orientation, similar results are observed. A single hexagonal crystallite with its selected area diffraction pattern superimposed upon it is shown in Fig. 2(a). Note that hexagonal crystallites are observed on both (100) and (110) substrates, indicating that (0001) zinc can grow on either orientation. A dark field micrograph taken with a $(\bar{1}\bar{1}1)$ reflection as shown in Fig. 2(b) indicates that a number of crystallites maintain an epitaxial relationship to the substrate. In Fig. 3 one sees another dark field micrograph of a (110) substrate, taken this time with the (220) reflection which illustrates the initial stages of growth of a rectangular crystallite as well as the general morphology of the zinc on substrates of this orientation (solution I).

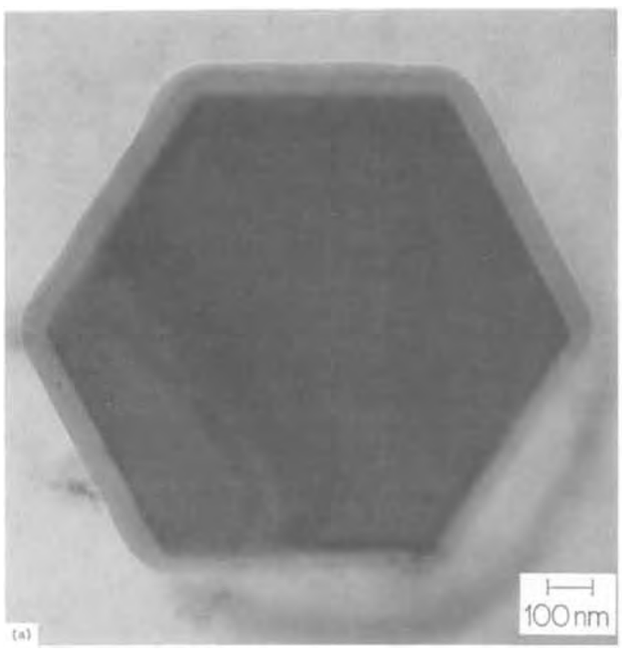
Zinc films deposited from solution II show similar epitaxial relationships to the substrate as those formed from solution I. For example, a single hexagonal crystallite is shown in the bright field TEM micrograph of Fig. 4(a) with its corresponding selected area diffraction pattern in Fig. 4(b). A dark field micrograph taken with the (220) reflection shows the same crystallite in bright contrast in Fig. 4(c).

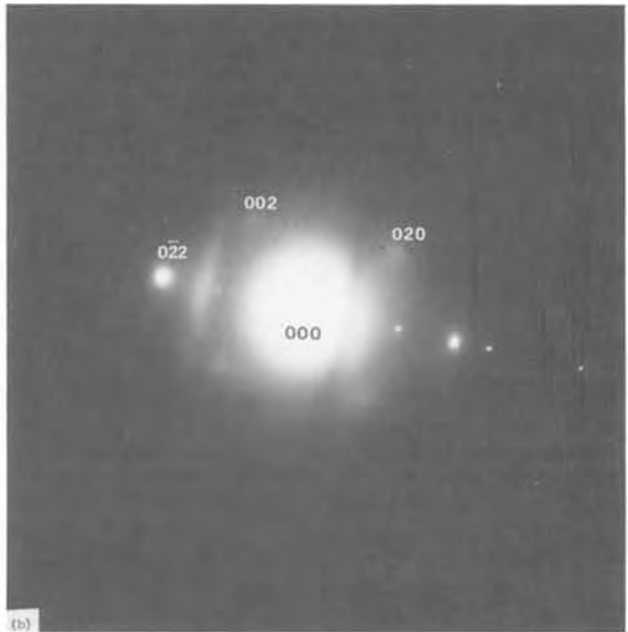
On {111} grains, the epitaxy between the zinc and the aluminum manifests itself in Moiré fringes, as shown in the bright field-dark field pair in Fig. 5(a) and (b) with the corresponding selected area diffraction pattern in 5(c).

A more or less continuous thin film of zinc formed from the growth and coalescence of numerous nuclei is seen in the bright field micrograph of Fig. 6 of deposits produced from solution II. Note the contrast change from bright to dark across the bend contour. The zinc seems to have been nucleated in discrete areas and eventually grows into connecting regions, many of which exhibit threefold symmetry. Coatings formed from solution I also seem to form noncontinuous zinc films as shown in the bright field TEM micrograph of Fig. 7.

Discussion

Zinc deposits formed from both kinds of solutions considered here can give rise to epitaxial films. Consider first the (100) aluminum plane whose atomic positions are shown in Fig. 8 and upon which the zinc





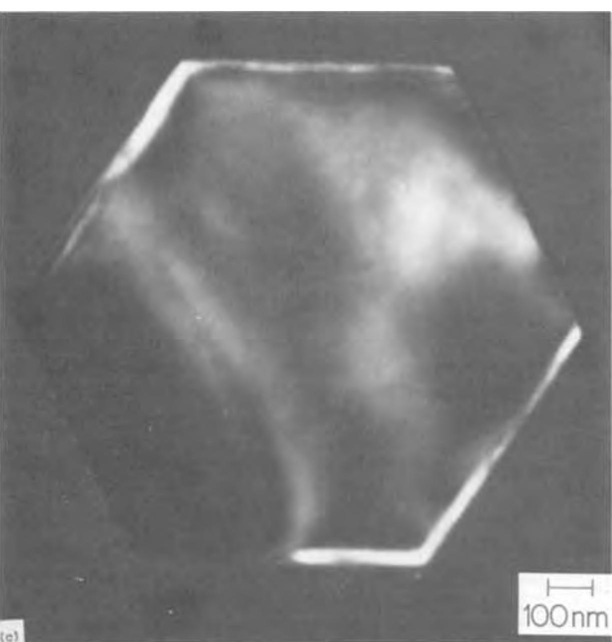


Fig. 4. (a) A single hexagonal crystallite (solution II). (b) The corresponding selected area diffraction pattern. (c) A dark field micrograph of the same crystal taken with a zinc $\langle 1010 \rangle$ reflection.

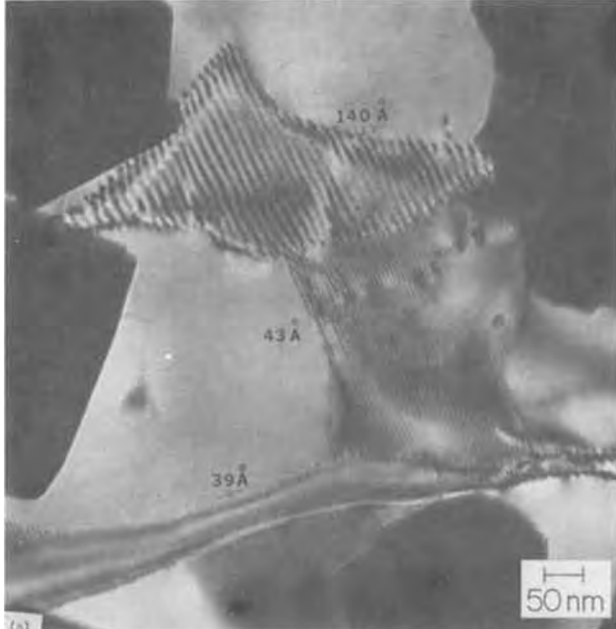

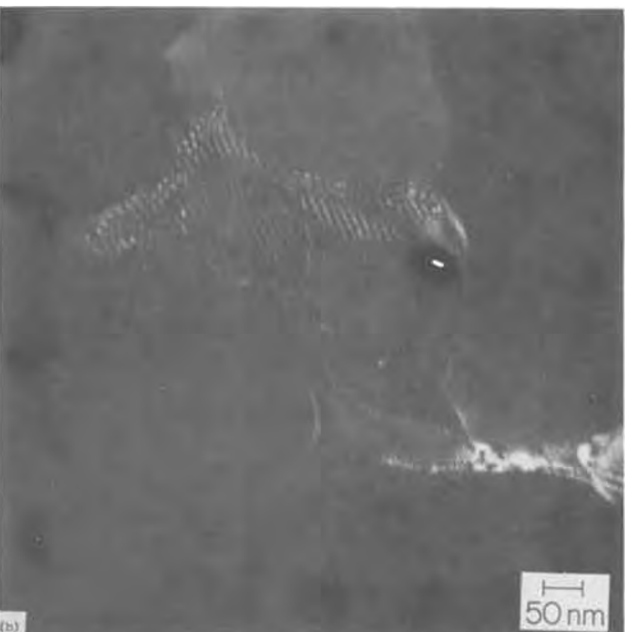

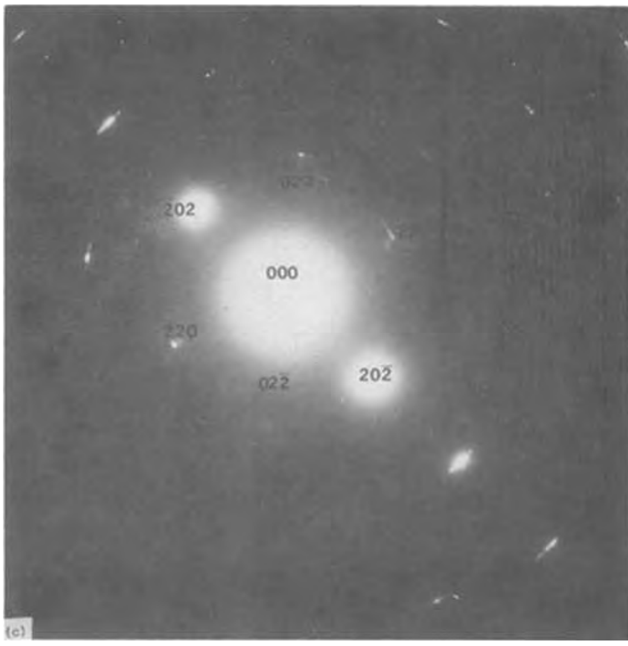

Fig. 5. (a) A bright field micrograph of a polycrystalline aluminum specimen. The (111) grains exhibit Moiré fringes due to (0001) zinc epitaxy. (b) Corresponding dark field micrograph taken with a (220) reflection. (c) Corresponding selected area diffraction pattern.

(0001) plane has been fitted in such a way that the aluminum [010] direction lines up with the $[1\bar{1}00]$ directions in the zinc, only one of which is shown in Fig. 8. The zinc misfit in the <100> direction is given by the zinc spacing ~2.308Å minus the aluminum spacing ~2.024Å, divided by the zinc spacing, or about 12.3%, which is within the Royer rule of epitaxy (~15%) (12). A diffraction pattern from such an atomic arrangement would be expected to show a distorted pattern in one direction superimposed upon a normal aluminum pattern. The (002) and (002) aluminum spots should coincide approximately with the zinc $(\bar{1}100)$ and $(1\bar{1}00)$ spots. One might, in addition, observe extra spots due to double diffraction. The diffraction pattern seems to correspond quite well with that expected with exception that the $(\bar{1}010)$ and $(10\bar{1}0)$ spots are absent. This is thought to be due to a substrate slightly tilted out of the diffraction condition for these planes. The double diffraction spots are indicated on Fig. 1(b). It can, therefore, be concluded that the (0001) zinc is epitaxial on (100) aluminum.

Consider now (110) aluminum planes. At least three possibilities exist for zinc to be epitaxial on a substrate of this orientation. The first shown in Fig. 9 is a match between the zinc $(01\bar{1}0)$ plane and the aluminum so that the [100] aluminum direction aligns with the zinc [0001] direction. In this situation, for every aluminum atom there exactly corresponds a zinc atom. The misfit between atoms in Al: [100] is about 7.5% while in the other direction, Al [110], the misfit is about 18%. The symmetry of crystallites growing with this orientation would, of course, be twofold. The second possibility for an epitaxial arrangement of the zinc on aluminum is given by a $(01\bar{1}0)$ zinc plane; however, this time consider a rotation of the zinc in such a way that the <111> aluminum direction is parallel to the zinc [0001] direction. In this case the misfit in the [001] aluminum direction is essentially 0% and in the [110] aluminum direction about 1.5%. This reduction in misfit comes at the expense of two unpaired atoms of the zinc as shown in Fig. 9(b). Lastly, consider the case of the zinc (0001) or basal plane oriented on the (110) aluminum in such a way that the $[11\bar{2}0]$ direction in the zinc coincides with one of the aluminum <111> directions. In this case, the misfit in the [100] aluminum direction is 12% and

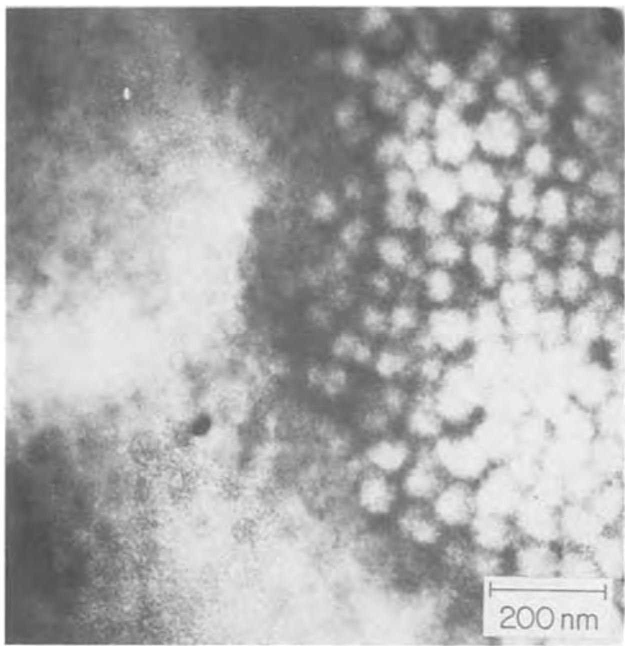

Fig. 6. Bright field micrograph of initial stage of zinc growth from solution I.

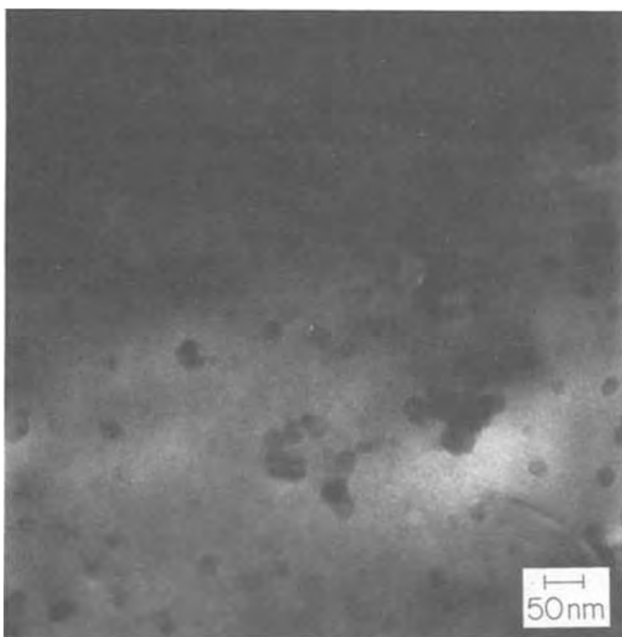

Fig. 7. Bright field micrograph of initial stage of zinc growth from solution II.

in the [110] direction 7.5%. Unpaired zinc atoms do exist as shown in Fig. 9; however, these unpaired zinc atoms would line up with very little misfit with the aluminum atoms on the plane immediately below the surface. In addition, crystallites growing with this orientation would have threefold symmetry. The spots associated with the (01$\bar{1}$0) zinc orientation have not been observed; see, for example, Fig. 4(b). As the zinc on this orientation has been observed to have both two, three, and sixfold symmetry, and because the diffraction patterns from (0001) zinc would about coincide with that of (110) aluminum, and because the zinc shows up in bright contrast in dark field when one of the aluminum spots is used to form the image, it can be concluded that it is the (0001) zinc orientation, as described in Fig. 9(c), which is epitaxial on the (110) aluminum.

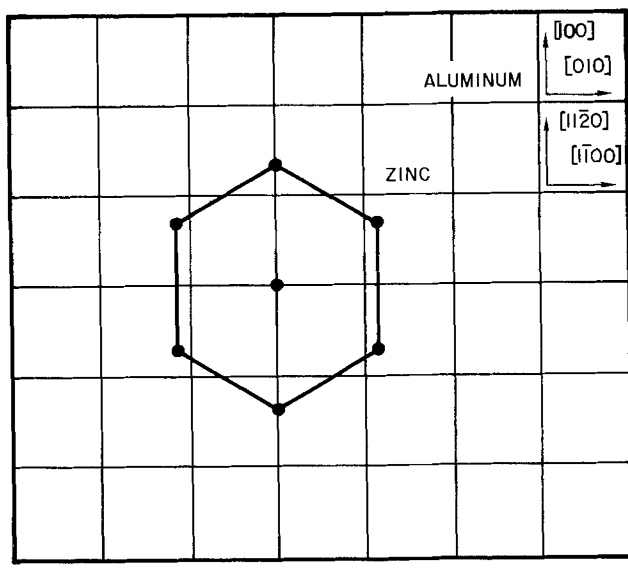

Fig. 8. The atomic positions in the (100) aluminum plane with (0001) zinc oriented such that $\langle 1010 \rangle // \langle 100 \rangle$.

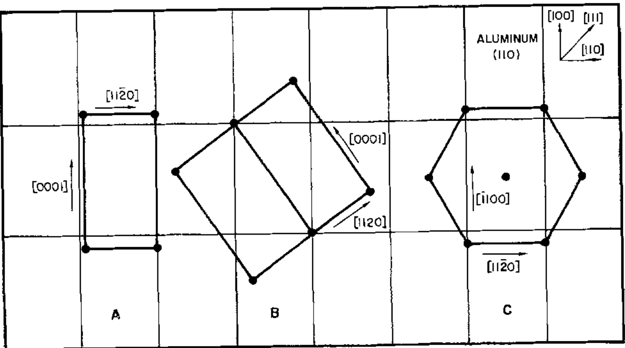

Fig. 9. (a) A (110) aluminum substrate on which a (01$\bar{1}$0) zinc (prism) plane has been fitted so that the zinc [0001] is parallel to the [011] direction in aluminum. (b) A (110) aluminum substrate on which a (01$\bar{1}$0) zinc (prism) plane has been fitted so that the zinc [0001] direction is parallel to the aluminum [111] direction. (c) A (111) aluminum substrate on which a (0001) zinc plane has been fitted so that the [11$\bar{2}$0] direction in zinc aligns with the [111] aluminum direction.

The last aluminum principal plane to consider is the (111). As shown in Fig. 10, the (0001) zinc plane is quite a good fit. The mismatch of 7.4% is symmetrical.

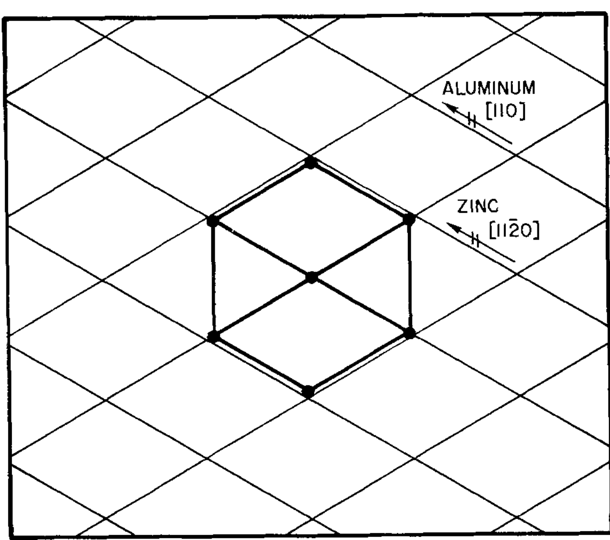

Fig. 10. The atomic positions in the (111) plane with (0001) zinc orientated such that $\langle 11\bar{2}0 \rangle // \langle 110 \rangle$.

Because of this symmetrical mismatch, the Moiré fringes shown in Fig. 5 are not unreasonable. If the fringes are due only to a translational mismatch, the spacing between them is given by

$$D \text{ (fringes spacing in Å)} = \frac{d_1 d_2}{d_1 d_2} = \frac{(2.8662)\cdot(2.665)}{2.8662 - 2.665} \cong 38\text{Å} \qquad [1]$$

As seen in Fig. 5, for the most part the fringe spacing is rather close to this number with the exception of one grain where the spacing is 140Å. Again, because of the symmetry of deposits on grains of this orientation in combination with the above arguments, it seems reasonable that on $(11\bar{1})$ aluminum that zinc (0001) is epitaxial on the aluminum, and, moreover, zinc on this orientation can be continuous.

The importance of this finding of epitaxy of zinc on aluminum can be understood in terms of the relationship of epitaxy to adhesion of two metals. The adhesion between two surfaces in contact can broadly be understood in terms of their respective surface energies, γ, and the energy of their mutual interface, γ_i. Bonding between these two materials can be characterized by an associated energy of adhesion, E_{Ad}. This energy of adhesion is that energy necessary to take an atom from a distance of approximately one lattice distance to infinity and can be expressed (13) in terms of the surface free energy γ_s for two materials a and b as

$$E_{Ad} = \gamma_{s,a} + \gamma_{s,b} - \gamma_{i,ab} \qquad [2]$$

where $\gamma_{i,ab}$ is the interfacial energy of the two metals in contact. If, for example, the two metals are identical then

$$E_{ad} = 2\gamma_s - \gamma_i \qquad [3]$$

The adhesion between two materials therefore depends on the interfacial energy. In the case of perfect epitaxy, the adhesive energy reaches a maximum value given by

$$E_{ad} = 2\gamma_a \qquad [4]$$

The value of γ_i therefore varies with the nature of the boundary. The lowest values generally are epitaxial interfaces, increasing with twins, stacking faults, low angle boundaries, and grain boundaries.

It has been shown experimentally (14) that the adhesive energy E_{ad} between two dissimilar metals increases with not only the degree of epitaxy but also with the surface energy. This finding is consistent with Eq. [2].

Conclusions

It has been demonstrated that zinc deposited from room temperature (300°K) solutions of sodium zincate forms thin epitaxial films on all the principal planes of aluminum. The morphology of the zinc deposits has been characterized for the first time as a thin semicontinuous film upon which larger epitaxial crystallites grow in such a way that Zn: (0001) $\langle 10\bar{1}0\rangle$//Al: (100) $\langle 010\rangle$, Zn: (0001) $\langle 11\bar{2}0\rangle$//Al $(1\bar{1}0)$ $\langle 111\rangle$, and Zn: (0001) $\langle 11\bar{2}0\rangle$//Al: (111) $\langle 1\bar{1}0\rangle$. The adhesion of zinc to aluminum is thought to be aided by the low energy epitaxial boundaries between the zinc and the aluminum.

The Anodic Sectioning of Beryllium

M. T. Shehata*,[1] and Roger Kelly**,[2]

Institute for Materials Research, McMaster University, Hamilton, Ontario, L8S 4M1 Canada

ABSTRACT

The anodic sectioning of a metal permits successive atomically thin layers (2.6-17 nm in the case of Be) to be removed from the surface of macroscopic specimens. The procedure with Be is based on forming an amorphous anodic film in an ethylene-glycol based electrolyte containing sulfate and phosphate ions, followed by dissolving the film in 10% KOH. The inorganic ions replace part of the O^{2-} in the anodic film, the empirical result of this being that P-containing ions reduce the dissolution rate during anodizing whereas S-containing ions increase the dissolution rate of already-grown films in KOH. Thickness calibrations, based on a combination of measuring weight changes and analyzing depth-distribution curves for implanted radioactive ions, may be expressed as follows

$$\text{metal-removal thickness} = -0.18 + 0.066 \times \text{volts } \mu g/cm^2$$

$$\text{anodic-film thickness} = -0.7 + 0.23 \times \text{volts } \mu g/cm^2$$

The logic used for arriving at the results is developed so that it can in principle be used as a guide for establishing anodic-sectioning procedures with still unstudied systems. Examples of depth distributions of 5, 15, and 30 keV Kr^+ in both Be and the anodic film on Be are given.

Over the past 20 years, various approaches for the microsectioning of solids have been developed. These include chemical dissolution (1-3), anodic sectioning (4-15), formation and dissolution of films other than oxides (16), vibratory polishing (17), bombardment-induced solubility of surface layers (18, 19), and sputtering (20-22). These techniques have their main applications in measuring depth distributions of implanted ions and radiation damage, and in determining diffusion coefficients at low temperatures (23).

While anodic sectioning is probably the most effective microsectioning technique of all, there is a severe problem in that it is not universally applicable. Not only is it relevant only with metals, but for some time procedures were available only for Al (4), W (5), Si (6-8), Au (9), and, to some extent, Nb and Ta (10). More recently, programs undertaken in our laboratory (11-13) and elsewhere (14, 15) have made possible the anodic sectioning of Mo (11), V (12), Nb, Ta (13), Ag (14), and Cu (15), and have extended the accessible voltages with W from 75 (5) to 140V (13). It is now possible to microsection elements having masses ranging from 27 to 197.

We will consider here the anodic sectioning of Be, which is the lowest mass target that can be conveniently worked with in the field of atomic collisions. The difficulty in the anodic sectioning of Be appeared at first sight to lie in establishing conditions under which a barrier-type, stable, amorphous film could be formed. We showed previously (24), however, that such films were easily obtained by the use of electrolytes based on ethylene glycol which is saturated with Na_2HPO_4 or KH_2PO_4 or both Na_2HPO_4 and Na_2SO_4. As will be seen, these films are readily soluble in KOH and thus permit uniform layers 2.6-17 nm thick to be removed from Be.

An important aspect of what follows is that an attempt will be made to establish a "logic," in so far as one exists, for anodic sectioning. We will, for example, show why in the particular case of Be the electrolyte must contain both sulfate and phosphate ions, and not just one or the other. We will also emphasize that the electrolyte chosen for Be has a *p*H which corresponds to a passive region in the Pourbaix diagram (25), the same being true for most other anodizable systems (26).

Key words: films, electrolyte, anode, oxidation.

Experimental

The Be specimens, obtained from Ventron Corporation (Alpha Products), were polycrystalline foils which were 0.25 mm thick and had a purity claimed to be 99.5%. Most of the experiments involved specimens with dimensions 25 × 12.5 mm. The surfaces were prepared by an initial polishing with SiC papers, further polishing with 6 μm diamond paste using kerosene as a lubricant, and five anodic sectionings at 50V. All polishings were carried out in a special fume hood reserved for this project owing to the toxicity of Be.

Anodizings were carried out at room temperature (~22°C) using a power supply such that limits to both the current and potential could be preset (Hewlett-Packard Model 6186B). The specimens were half submerged in the electrolytes, with the relevant areas determined in hindsight from the interference colors. The electrolytes were neither stirred nor protected from air, and, in view of the possibility of decomposition, were discarded after five anodizings or one hour, whichever came first. For the 25 × 12.5 mm specimens, the cathode consisted of Pt gauze in the form of a cylinder with an inside diameter of 25 mm. Larger specimens were sandwiched between a cathode consisting of two sheets of Pt.

The detection and profiling of impurities in the anodic films was carried out with a secondary-photon spectrometer. This consisted of a mass-separated ion beam (12 keV Kr^+) striking a target with the target surface viewed, via a quartz lens, by a 0.25m Jarrell-Ash Model 82-410 monochromator. A refrigerated photomultiplier tube (EMI Model 6256 QB) served to detect the photons from atoms sputtered in excited states. Surface oxygen was detected from the enhancement of the Be signal at 235 nm [a similar effect occurs with Al (27)], and S and P were detected from the weak emissions at, respectively, 393 and 215 nm (28). As the beam profile was quite irregular, the results must be regarded as somewhat approximate.

Anodic Sectioning of Be

Choice of electrolyte.—The main requirements of an electrolyte to be used for anodic sectioning are that it should lead to films which are simultaneously barrier-type, stable, and amorphous. Being barrier-type normally assures that a uniform, voltage-dependent, limiting film thickness exists (3); stability assures, in a general sense, that the film does not dissolve extensively in the electrolyte during formation; while amorphicity often plays a role in enabling films to be

chemically stripped without the metal substrate being attacked. We showed previously (24) that the most interesting electrolytes for Be are those consisting of ethylene glycol saturated with Na_2SO_4, Na_2CO_3, $Na_2B_4O_7$, Na_2HPO_4, KH_2PO_4, or a mixture of Na_2HPO_4 and Na_2SO_4, the last being designated "electrolyte A."

They were all inferred to lead to barrier-type films, thence uniform, voltage-dependent, limiting film thicknesses, on the basis of the *V-t* and *I-t* characteristics [Fig. 5 of Ref. (24)].

Film stability was evaluated in two ways. Approximate current efficiencies were estimated by comparing $\int Idt$, *i.e.*, the area under the *I-t* curves, with the film weight as determined using electrolyte A and assuming a composition BeO. The results, shown in column 4 of Table I, are subject to the uncertainties that the films were lightly doped with S and P, and that the weights for electrolyte A are not necessarily fully correct. In spite of this, there is little doubt that the phosphate-containing electrolytes yield the highest efficiencies, thence the most stable films.

Stability was also examined in terms of the extent of Be metal dissolution during a full anodizing cycle. Be specimens were implanted with 30 keV ^{85}Kr (beta-active) to a dose of 2×10^{15} ions/cm², and the radioactivity was noted before and after 2 or 4 min anodizings with presettings of 50V and 3.0 mA/cm² (column 5 of Table I). If the activity profile is approximated as exponential

$$\text{integral concentration} = \exp(-[x\ln 2]/R_m) \quad [1]$$

where the median range R_m can be taken from Fig. 7 (to follow) as 25 nm, inferred Be losses are obtained as in column 6 of Table I. Minimum losses clearly occurred with the phosphate-containing electrolytes. It is readily seen from Fig. 7 (to follow) that the assumption of exponential profiles underestimates thicknesses in the range 90-100% activity. Specimens which were sectioned to about 50% activity and which should be accurately exponential with $R_m = 25$ nm were therefore used in conjunction with electrolyte A and the Be loss was redetermined to be 2 ± 0.5 nm. Even with this approach there is a major uncertainty in that the inert-gas marker would tend to be buried to an extent which cannot be determined owing to film being formed in part by the outward migration of Be. This causes the Be losses to be underestimated and they are therefore indicated as being lower limits in Table I.

It is worth noting that, however imperfect is the information in Table I, the two approaches as embodied in columns 4 and 6 lead to similar conclusions.

Table I. Approximate current efficiencies and metal losses in ethylene-glycol based electrolytes for 2 or 4 min anodizings of Be with presettings of 50V and 3 mA/cm² [a]

Electrolyte (ethylene glycol saturated with indicated compound)	pH	Total anodizing time (min)	Current efficiency[b]	Fraction of Kr implanted which is retained	Inferred loss of Be[c] (nm)
1. Na_2SO_4	6	4	0.18 ± 0.03	0.73 ± 0.04	≥ 11
2. Na_2CO_3	10	4	0.23 ± 0.03	0.88 ± 0.04	≥ 5
3. $Na_2B_4O_7 \cdot 10H_2O$	6	4	—	0.92 ± 0.04	≥ 3
4. Na_2HPO_4	8.5	2	0.90 ± 0.04	0.994 ± 0.008	$\sim\geq 0$
5. KH_2PO_4	—	2	0.89 ± 0.04	0.994 ± 0.008	$\sim\geq 0$
6. 1:1 mixture of (1) and (4) ("electrolyte A")	7.5	2	0.67 ± 0.04	0.986 ± 0.006	$\sim\geq 1$

[a] With presettings of (for example) 50V and 3 mA/cm², the anodization proceeds at 3 mA/cm² until 50V is reached and then with decreasing current until the process is terminated.
[b] Deduced by comparing $\int Idt$ with the film weight as determined using electrolyte A and assuming a composition BeO: see Eq. [3]. The errors do not take into account any associated with the composition of the anodic film.
[c] Deduced by substituting the values of Kr retention from preceding column into Eq. [1].

This is that the ordering of the electrolytes in terms of the stability of the films is 1-2-3-6-4/5. (Electrolytes 4 and 5 are equivalent.) Also, the approaches are amenable to a high degree of repeatability and are rapid.

The question of the amorphicity of the films was dealt with previously (24). The films formed with electrolyte A were amorphous in the sense that the reflection electron-diffraction pattern showed halos.

It is interesting to note that the pH's of the electrolytes in Table I range from 6 to 10, for according to the Pourbaix diagram (25) reproduced in Fig. 1 such values all lie within the "passive" region. A similar correlation is also found for other anodizable systems (26). The following electrolytes had pH's lying outside of 6-10 and all showed unacceptably high extents of metal dissolution with Be, the latter being given in the second bracket in nm: a CrO_3-HNO_3 mixture (29, 30) ($\geq$ 40 nm), 1% H_2SO_4 ($\geq$ 120 nm), 1% HNO_3 ($\geq$ 50 nm), 1% KOH ($\geq$ 60 nm), 0.5M Na_2CO_3 (31) ($\geq$ 50 nm), an acetic-acid based mixture (11, 12) ($\geq$ 60 nm), a $(C_2H_5)_2SO_4$-H_2SO_4 mixture (13) ($\geq$ 90 nm), $(C_2H_5)_2HPO_4$ ($\geq$ 90 nm). It is possible that Pourbaix diagrams, although normally used only in low-voltage work, may be an important guide to electrolyte choice in high-voltage applications, as here or in Ref. (26).

Feasibility of doping.—In cases such as Ag, Au, Cu, Mo, Si, V, and W, the anodic films have naturally a high chemical reactivity and are therefore easily dissolved for the purpose of anodic sectioning. In other cases, such as Hf, Nb, Ta, and Zr, the converse is true and one seeks to alter the film chemistry by incorporating ions from the electrolyte. To accomplish this it is essential either that a significant part of the film form by the outward motion of cations, or that the dopant be mobile.

Explicit information on the occurrence of incorporated ions is obtained by sputter profiling. To this end we have anodized Be for 2 min in electrolyte A and have then bombarded the specimens with 12 keV Kr^+ while measuring the secondary-photon emission from Be, S, and P. Results as in Fig. 2 and 3 were obtained. Oxygen was not detected directly but rather was inferred from the enhancement (27) of the Be signal.

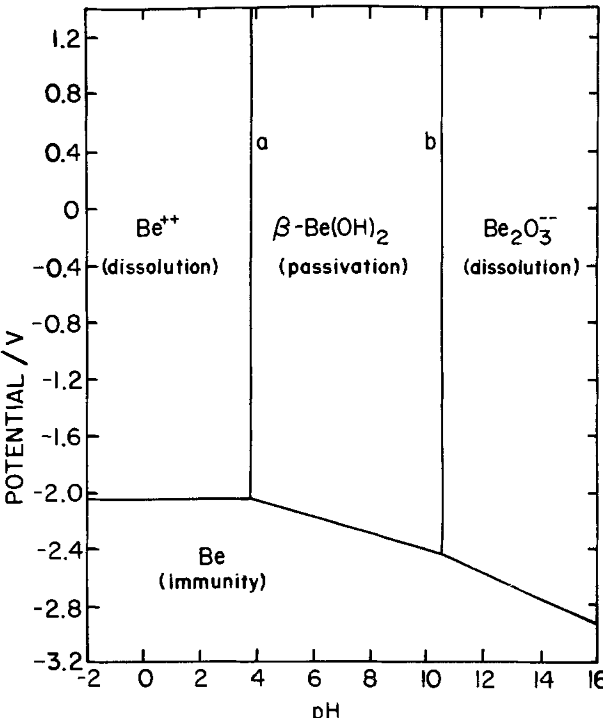

Fig. 1. Potential-pH diagram for the system beryllium-water at 25°C in simplified form after Pourbaix (25). Line a is drawn for $[Be^{2+}] = 10^{-6}M$ and line b for $[Be_2O_3^{2-}] = 10^{-6}M$.

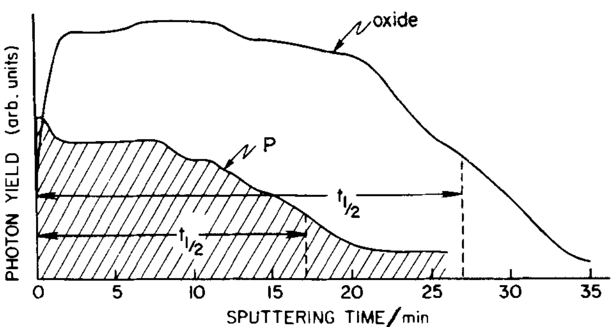

Fig. 2. Composition-depth profiles obtained by measuring secondary-photon yields for P and for Be in the anodic film. Sputtering was undertaken with 15 $\mu A/cm^2$ of 12 keV Kr^+, P was detected at $\lambda = 215$ nm, and Be in the anodic film was inferred from the oxygen-induced enhancement of the Be signal at $\lambda = 235$ nm.

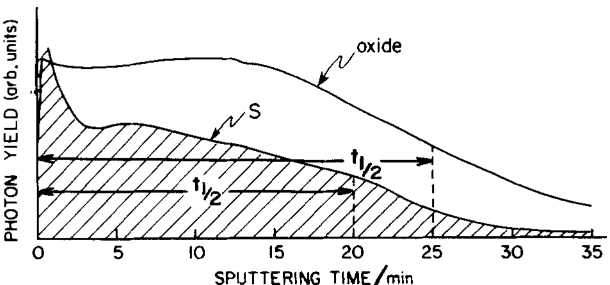

Fig. 3. Like Fig. 2 but for S, which was detected at $\lambda = 393$ nm

It is clearly feasible to dope anodic BeO, with the films, in fact, being chemically altered throughout most of their thickness.

The ratio of the half-time, $t_{1/2}$, for S or P to that for oxide, which can be deduced although not with high precision from Fig. 2 and 3, is 0.75 ± 0.07 (total of 8 specimens). If we postulate that S and P are incorporated only at the outer surface and are subsequently immobile, it would follow that the cation transport number (the fraction of the ionic current carried by cations) is also 0.75 ± 0.07. Given that the cation transport number for Al is 0.33-0.72, for Nb or Ta is 0.28 ± 0.03, and for Zr or Hf is 0.05 (32, 33), Be would appear to have the highest value amongst systems presently studied. If the S and P were mobile [as with Ta_2O_5 (34)], the cation transport number would be <0.75. We would suggest that it is unrealistic to try to obtain transport numbers from information as in the present work owing to the problem of whether the supposed marker is mobile.

Stripping step.—The search for a solvent for an anodic film is largely empirical, though is simplified if the film is labelled with a radioactive tracer. Be specimens were accordingly implanted with 30 keV ^{85}Kr, anodized for 2 or 4 min with presettings of 50V and 3.0 mA/cm^2 in each of the six electrolytes of Table I, and exposed to a solvent. By considering the residual activity as in Fig. 4 it was found that 10% KOH had an optimum behavior provided the electrolyte contained Na_2SO_4. Results are summarized in Table II. Other solvents considered were sulfuric acid, which attacked the metal, and solutions of Be salts, which were too slow. It had been hoped that solutions containing Be^{2+} would remove the anodic film by the formation of complex ions (35).

Since phosphate incorporation minimized the dissolution losses during anodizing and sulfate incorporation optimized the stripping behavior of already-grown films, it follows that a mixture might combine the behavior. The results were favorable (Tables I and II).

The dissolution "end point," *e.g.*, as marked on Fig. 4, was checked from the point of view of its actual representation of complete film stripping. In one series

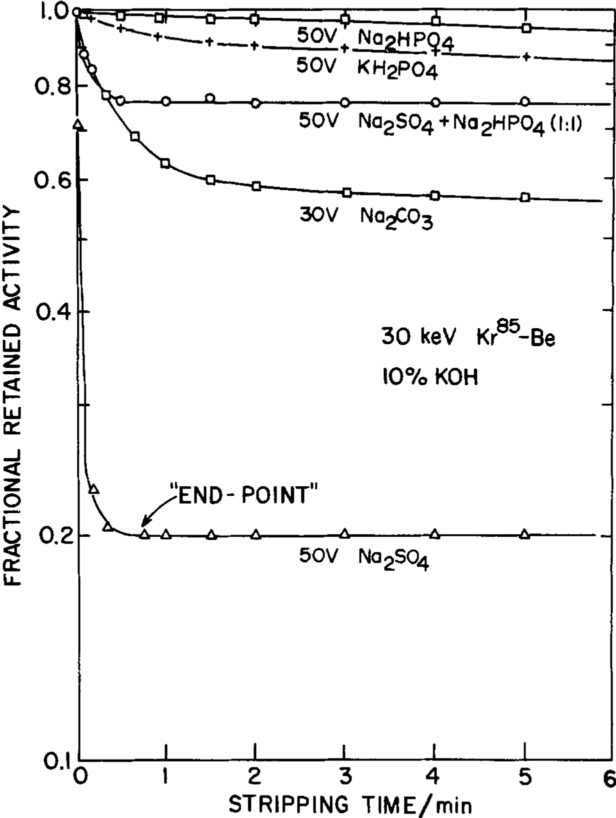

Fig. 4. Dissolution of anodic films on Be as inferred by the loss of radioactivity that was introduced prior to anodization as 2×10^{15} ions/cm^2 of 30 keV ^{85}Kr. Films were formed for 2 or 4 min and with a preset current density of 3 mA/cm^2 at the voltages indicated in ethylene glycol saturated with the indicated compounds. Solvent: 10% KOH at ~20°C.

of experiments, specimens were anodically sectioned in electrolyte A at 50V 10-12 times. There was no evidence for accumulated film and the *V-t* curves were fully reproducible. The second check was done by noting the value of the initial voltage rise in the anodizing cell while applying a very small current density of 30 $\mu A/cm^2$. The initial voltage rise always lay in the region < 1V, corresponding to roughly <2 nm if one assumes the approximate relation, valid for virtually all anodizable metals, (thickness in nm) ≈ (2.0 ± 1.0) × V.

Summary of anodic-sectioning procedure.—In summary, the films formed by anodizing Be for 2 min with a preset current density of 3 mA/cm^2 in electrolyte A at up to 50V could be completely stripped within 2 min in 10% KOH solution. Electrolyte A, consisting of a 1:1 mixture of ethylene glycol saturated with Na_2SO_4 and ethylene glycol saturated with Na_2HPO_4, is chosen as leading to films having simultaneously

Table II. Rates of dissolution of anodic films on Be and of Be metal in aqueous KOH at ~20°C. The films were formed as in Table I and the thicknesses are contingent on the film densities being 3.01 g/cm^3

Electrolyte (ethylene glycol saturated with indicated compound)	Solvent	Rate of anodic-film dissolution (nm/sec)	Rate of Be metal dissolution (nm/sec)
1. Na_2SO_4	10% KOH	2	0.05
2. Na_2CO_3	10% KOH	0.1	0.05
3. Na_2HPO_4	10% KOH	0.05	0.05
4. 1:1 mixture of (1) and (3) ("electrolyte A")	Sat. KOH	Very rapid	2.0
	10% KOH	1.0	0.05
	1% KOH	0.1	0.007

low dissolution losses during anodization and optimum stripping behavior of already-grown films.

Thickness Calibrations

Metal-removal thicknesses.—Two methods were employed to determine metal-removal thicknesses. For larger formation voltages (25-50V), weight-loss was used directly while for smaller voltages (10-20V) the depth-distribution method (12) served to estimate the ratio (thickness)/(thickness at 50V). In the weight-loss method Be specimens were weighed, anodized and stripped 5 to 12 times, and then reweighed. In the depth-distribution method, specimens were bombarded with 30 keV ^{85}Kr to a dose of 2×10^{15} ions/cm^2 and the residual radioactivities were noted after repeated sectionings at a given low voltage. For example, the residual activity in three specimens after 20 sectionings at 10V was found to be 0.16 ± 0.03. According to a 30 keV depth-distribution curve constructed from sectionings at higher voltages (Fig. 7, to follow), this activity corresponds to a thickness removed of 9.2 ± 0.4 μg/cm^2. The metal removed in a single sectioning at 10V follows as being 0.46 ± 0.08 μg/cm^2.

Overall results, summarized in Table III and Fig. 5, can be represented to within 10% as follows

$$\text{metal-removal thickness} = -0.18 + 0.066 \times \text{volts } \mu\text{g/cm}^2 \approx -1.0 + 0.36 \times \text{volts nm} \quad [2]$$

the nm form being contingent on the density of Be being 1.85 g/cm^3. Figure 6 compares metal-removal thicknesses for 8 systems permitting anodic sectioning.

Anodic-film thicknesses.—Anodic-film thicknesses for 20-50V were determined by weight gain, using extra large specimens having a surface area of 20 cm^2. Thicknesses for 10-15V could, if desired, have been obtained with a modified depth-distribution method (12). The results, included in Table III and Fig. 5, can be represented to within 10% as follows

$$\text{anodic-film thickness} = -0.7 + 0.23 \times \text{volts } \mu\text{g/cm}^2 \approx -2.3 + 0.76 \times \text{volts nm} \quad [3]$$

the nm form being contingent on the density of the film being that of BeO, 3.01 g/cm^3. The real density would be different as the films are neither crystalline nor pure.

It will be noted that the observed film weights (solid line in Fig. 5) are greater than would be expected for pure BeO based on the metal weights (dashed line). The discrepancy is consistent with the evidence already given in the section "Feasibility of doping" for S and P incorporation and can be understood quantitatively if part of the O^{2-} in the film is replaced by (for example) SO_4^{2-} or HPO_4^{2-} to yield a stoichiometry between $BeO_{0.92}(SO_4, HPO_4)_{0.08}$ and $BeO_{0.93}(SO_4, HPO_4)_{0.07}$. Whether this incorporation arises by the literal replacement of O^{2-} to yield a phase $Be(O, SO_4, HPO_4)$, or by the physical trapping of Na_2SO_4 or Na_2HPO_4, cannot be decided. For example, the fact that Na profiles (26) are much nearer the surface than S or P profiles (Fig. 2 and 3) conveys little information owing to the likelihood that the Na could migrate outwards (36, 37). We also see no significance in the result that the films crystallized to a product having the diffraction pattern of BeO alone (24).

Table III. Metal-removal and anodic-film thicknesses for Be anodized in electroyte A for 2 min with a preset current density of 3 mA/cm^2

Preset potential (V)	Average metal-removal thickness (μg/cm^2)	Corresponding thickness from Eq. [2] (μg/cm^2)	Average anodic-film thickness (μg/cm^2)	Corresponding thickness from Eq. [3] (μg/cm^2)
10	0.46 ± 0.08	0.48	—	—
15	0.95 ± 0.15	0.81	—	—
20	1.11 ± 0.15	1.14	3.92 ± 0.5	3.90
25	1.42 ± 0.15	1.47	5.06 ± 0.5	5.05
30	1.83 ± 0.26	1.80	6.12 ± 0.5	6.20
35	2.05 ± 0.24	2.13	6.88 ± 0.5	7.35
40	2.56 ± 0.35	2.46	8.14 ± 0.5	8.50
45	2.85 ± 0.25	2.79	10.3 ± 0.5	9.65
50	3.33 ± 0.41	3.12	10.85 ± 0.5	10.8

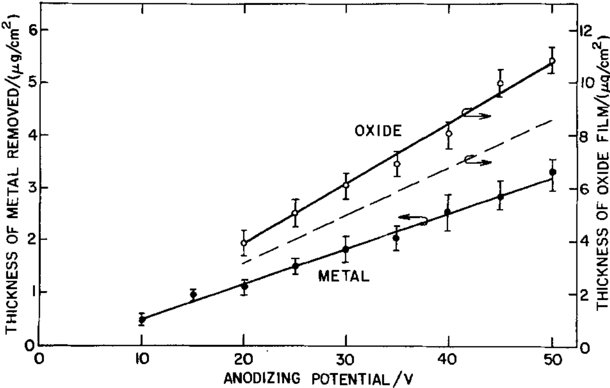

Fig. 5. Calibrations for metal-removal thicknesses (scale at left) and for anodic-film thicknesses (scale at right). The dashed line is calculated for an anodic-film consisting of pure BeO based on the metal-removal results.

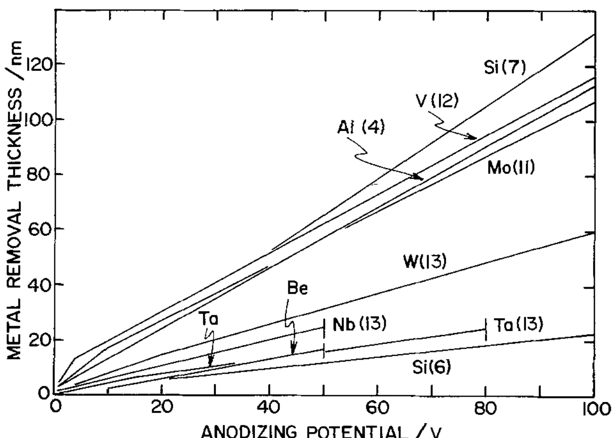

Fig. 6. Comparison of metal-removal thicknesses for 8 systems permitting anodic sectioning. The references are indicated after each symbol. The current-density presettings were as follows: Al (none), Be (3 mA/cm^2), Mo, V, and W (2 mA/cm^2), Nb and Ta (5 mA/cm^2). Si of Ref. (6) (6 mA/cm^2), Si of Ref. (7) (19-41 mA/cm^2). Si of Ref. (8) was very similar to that of Ref. (6). Ag(14), Au(9), and Cu(15) are not included as the anodic films are not protective, so that the proper representation is rate of metal removal vs. current density.

Depth Distributions in Be and the Anodic Film on Be

In view of the fact that, as already pointed out, Be is the lowest mass target that can be conveniently worked with in the field of atomic collisions, a limited number of experiments were carried out to determine the integral depth distributions of implanted 5, 15, and 30 keV Kr^+ ions in Be and the anodic film on Be.

With Be, sectioning was accomplished as in the section "Summary of anodic-sectioning procedure," with an anodizing voltage of 20V for 5 keV and 50V for 30 keV. Results based on a total of 48 experimental points are shown in Fig. 7 (solid lines). The reproducibility was such that the median ranges, *i.e.*, depths at 50% activity, could be specified to within about 10% as follows: 1.9 μg/cm^2 for 5 keV and 4.7 μg/cm^2 for 30 keV.

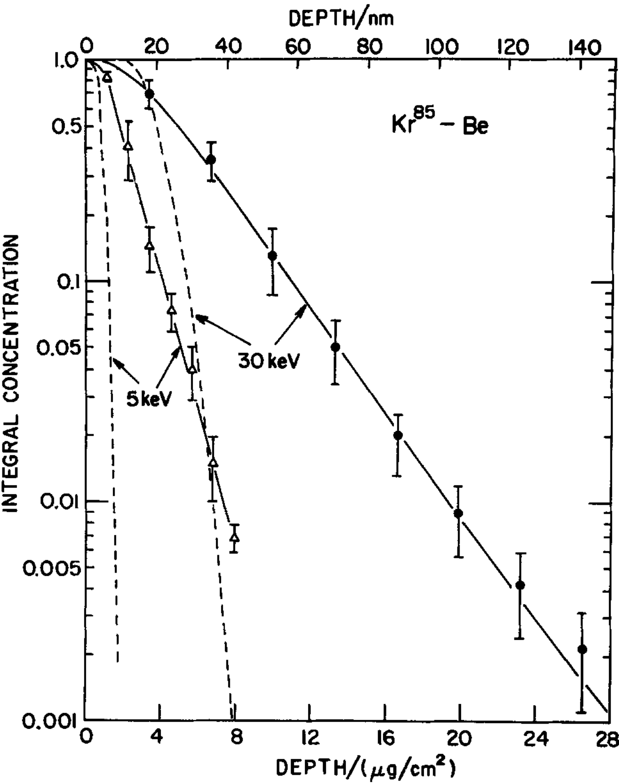

Fig. 7. Integral depth-distribution curves for 5 and 30 keV ^{85}Kr in polycrystalline Be. Dose: 2×10^{15} ions/cm². The dashed lines are the theoretical curves for amorphous Be calculated using Eq. [4] with ranges appropriate to carbon.

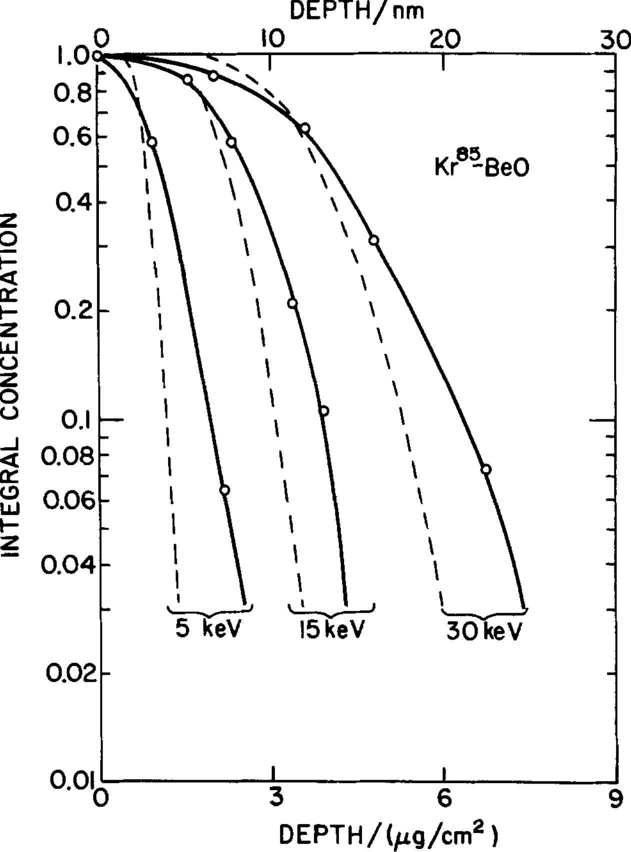

Fig. 8. Integral depth-distribution curves for 5, 15, and 30 keV ^{85}Kr in the anodic film on Be. Dose: 4×10^{14} ions/cm². The dashed lines are the theoretical curves for amorphous BeO calculated using Eq. [4] with ranges appropriate to carbon.

With the anodic film on Be the equivalent of sectioning was accomplished with the transmission technique (38). This consisted of forming anodic films, implanting ^{85}Kr ions and counting the radioactivity, stripping the films, and then determining the residual activity in the metal substrate. The results are shown in Fig. 8 (solid lines), with median ranges to within 10% as follows: 1.1 μg/cm² for 5 keV, 2.6 μg/cm² for 15 keV, and 4.1 μg/cm² for 30 keV.

Also shown in Fig. 7 and 8 (dashed lines) are theoretical distributions constructed using an Edgeworth expansion in integral form (39) with the fourth moment ratio β_2 taken as (40)

$$\beta_2 = 3 + \frac{5}{3}\beta_1$$

where β_1 is the third-moment ratio. This expansion is as follows

$$C^{\text{int.}} = \frac{1}{2}\,\text{erfc}\,(\zeta/2^{1/2}) - (2\pi)^{-1/2}\exp(-\xi^2/2)\,g(\xi) \quad [4]$$

where ζ stands for $(x - \langle x \rangle)/\Delta x$ and $g(\zeta)$ stands for

$$\frac{\beta_1^{1/2}}{6}(1-\zeta^2) + \frac{\beta_1}{72}(5\zeta^3 - \zeta^5) + \ldots$$

The various ranges and moments were assigned values appropriate to carbon (40).

The results were in all respects as expected, with Be showing the usual mixture of random and channeled stopping and the anodic film on Be showing stopping in fair agreement with theory, thence mainly random. These results constitute an independent proof that the anodic film is amorphous, the previous evidence being based on electron diffraction (24). The excessive skewness found with the anodic film, confirmed also with WO_3 (19), is possibly due to inadequacies in either the Edgeworth expansion of Eq. [4] or the Thomas-Fermi potential underlying the theoretical ranges and moments. We regard it as being unlikely that it is due to experimental deficiencies.

Powers and Whaling (41) have given experimental values for the range of Kr in Be using the momentum analysis of elastically scattered protons to accomplish the profiling. Their values for incident energies of 46 to 500 keV may be extrapolated to give 4.6 ± 0.8 μg/cm² at 30 keV, the present value being 4.7 ± 0.3 μg/cm².

Summary

Electrolytes consisting of ethylene glycol saturated with inorganic salts and having a pH of 6-10 enable protective anodic films to be grown on Be at 10-50V. Those formed in the presence of phosphate showed the least dissolution during anodizing, those formed in the presence of sulfate showed (once grown) the most rapid rate of dissolution in aqueous 10% KOH, while those formed in the presence of both had the expected combined properties.

The pH range 6-10 referred to above lies within the "passive" region of the Pourbaix diagram for Be (Fig. 1). A similar correlation is also found for other anodizable systems (26), suggesting that Pourbaix diagrams may be an important guide to electrolyte choice in high-voltage applications.

Sputter profiling combined with secondary-photon measurement showed that S and P were incorporated into the outer 0.75 ± 0.07 of the anodic films. The films were thus chemically altered throughout most of their thickness, a fact which helps to explain why the composition of the electrolyte referred to above affected the dissolution properties so strongly.

The metal-removal and anodic-film thicknesses were shown to have values as given by Eq. [2] and [3]. The film "thicknesses," in reality weights, were about 20-25% higher than expected from the metal-removal thicknesses. This is understandable in view of the S and P incorporation referred to above.

Depth distributions in Be showed the expected mixture of random and channelled stopping, whereas those in the anodic film on Be were in fair agreement with theory, as if the stopping was mainly random. The latter is of interest in constituting an independent proof that the anodic film is amorphous.

The experiments undertaken here on the anodic sectioning of Be have been described in such a way as to emphasize a "logic," in so far as one exists. For example, a systematic effort was made to establish conditions under which an anodic film could be formed which was simultaneously barrier-type, stable, and amorphous. The Pourbaix diagram turned out to be a useful guide for choosing the pH. The possibility of incorporating foreign atoms into the anodic film in order to alter the film chemistry was confirmed by sputter profiling. Appropriate adjustment of the chemistry then yielded the final film, namely one which was stable enough to be grown (due to P incorporation in the case of Be) but still preserved a high reactivity towards KOH (due to S incorporation in the case of Be).

The Behavior of Implanted Xenon When Used as a Marker during the Anodic Oxidation of Aluminum

Evidence for an Explanation of a Dose-Dependant Splitting Effect

ABSTRACT

Using 2 MeV lithium ions backscattering and transmission electron microscopy techniques, some of the xenon atoms introduced by implantation in aluminum metal under the initial oxide layer are shown to be transported by the moving metal-oxide interface during anodic oxidation. For specific anodization conditions (V^{ct}, $T = 90°C$) this splitting of the initial xenon distribution is interpreted in terms of bubble formation and growth above a given local concentration threshold. A schematic model for this behavior evolution is proposed. This dose dependance is of practical interest in the determination of transport numbers. Although unambiguously measured they may be subject to significant systematic uncertainties which are discussed.

The determination of cationic or anionic transport numbers in the anodic oxidation of metals has widely used implantation of noble gases near the surface of the material. Locating the final position of the marker after anodization and thus extracting transport numbers can be achieved either by using radio emitters (1, 2) or stable isotopes (3). The first case which is often associated with chemical sectioning has the advantage of requiring low implantation doses (typically 10^{13} atoms/cm^2) while the second, which is based on Rutherford backscattering analysis (RBS), needs at least a ten times larger value. Neither in the previous work of Brown *et al.* (3) on aluminum, using RBS, nor in the investigations of Pringle (4) on tantalum, using radiotracers, has "anomalous" behavior of the implanted rare gases on anodization been reported. The final location of the marker is unambiguous whatever the transport number values may be. Most of the foregoing investigations dealt with implantation into preformed oxide layers sufficiently thick to contain all the implanted atoms. However, we have observed an anomalous behavior when xenon was implanted into samples covered with only a thin layer of oxide so that some of the Xe atoms were located in the oxide and some in the underlying metal. The amount of xenon implanted was $\sim 10^{15}$ atoms/cm^2, the energy was 30 keV. After anodization of such samples the distribution of the marker atoms was no longer coherent but split into two distinct agglomerations. This observation was the result of earlier investigations of the possible roles of the initial oxide layers in industrial anodization processes [V constant, high current density (200 mA/cm^2) at the start of operation, $T = 90°C$] (5). In these, the oxide films had been formed during metallurgical elaboration (hardening) annealing or polishing treatments. All were less than 3-4 μg/cm^2 thick.

We report here on the systematic investigations of the parameters responsible for such an unexpected behavior. In addition to the RBS analysis with 2 MeV lithium ions, transmission electron microscopy (TEM) experiments on ultramicrotomed sections have been performed for such a purpose.

Experimental Procedure

In accordance with our interest in the possible effects of the initial oxide layers on the transport, we used refined aluminum (99.99%) in a sheet form of 90 μm thick, the nature of the oxide layers being determined by the metallurgical treatment (rolling and rough cleaning) for the hardened material or by the thermal treatment for the annealed material. In addition, a chemical polishing treatment identical to the one described by Brown *et al.* (3), has been applied to the hardened material in order to remove the initial layer and to have a more defined air-formed one. In a few cases, we also performed electropolishing of the hardened material and passivation in phosphoric acid (30 g/liter) of the annealed material. A few samples kindly supplied by Mackintosh [disk form, 0.5 mm thick, see Ref (3)] were also used. ^{131}Xe implantations were performed with the isotope separator of the Institut de Physique Nucléaire de Lyon at various energies but most often at 30 keV and 5 keV for doses ranging from 10^{14} to 10^{16} atoms/cm^2. Mackintosh's samples were implanted with the isotope separator of Chalk River Nuclear Laboratories at 20 keV for 2×10^{14} and 10^{15} atoms/cm^2.

Following the industrial procedure of the manufacturer, the samples were anodized after implantation in the following electrolytes: adipic (ammonium adipate) at $pH = 5.5$, phosphoric (acid) $pH = 2.7$, boric (ammonium borate) $pH = 4.5$. The voltage was preset at 100V and the typical decrease of the current density was from 200 mA/cm^2 to 1 mA/cm^2 after 25 sec, 5 min being allowed for reaching a constant value of the order of 0.04 mA/cm^2. The temperature was kept at 90°C. For comparison purposes, several samples were treated at a constant current density of 2 mA/cm^2 in a saturated solution ($\sim$5%) of ammonium pentaborate in water at room temperature, and one other in an adipic electrolyte solution.

Rutherford backscattering has been performed with lithium ions instead of alpha particles because of the better depth resolution (about 4.5 μg/cm^2 for aluminum in aluminum oxide) achievable (6) at an incident energy of 2 MeV. Xenon relative displacement can then be followed easily over small thicknesses (typically $\sim$50 μg/cm^2 in the present experiments). High yield and consequently good counting statistics can be achieved in about 20 min with the use of a specifically designed pile-up rejection system (5) associated with conventional electronics. In this manner the analyzing beam current can be adjusted for an optimum count rate.

Key words: metals, films, gas, interfaces.

The small thickness of the initial oxide layers was determined by measuring the total oxygen content of these layers with the ^{16}O (d, p) nuclear reaction at 850 keV incident energy (7). For the aluminum matrix the sensitivity of about 0.1 $\mu g/cm^2$ far exceeds our requirement (the lowest measured concentration is $\sim$ 1 $\mu g/cm^2$). One must of course assume an Al_2O_3 stoichiometry to determine the oxide thickness. In view of the shallow depth of Xe implantation (the maximum of the distribution is close to 100Å) and the need to determine the respective distributions in the initial oxide and in the metal, a grazing angle geometry was used in RBS experiments. Practical considerations such as the roughness and flatness of the samples restricted the detection angle to 177° and the angle between the sample surface and the beam direction (tilt angle) to only 15°. The resulting spectra are shown in the Fig. 1 for two typical samples implanted at $\sim 10^{15}$ atoms/cm².

Using a technique similar to those of Bethune *et al.* (8) to obtain ultramicrotomed sections of about 1000Å thick, TEM analysis was performed with the Philips E.M. 300 microscope of the Centre de Recherches de Voreppe (P.U.K. Company). From these measurements structure and linear thickness of the layers as well as marker agglomeration into bubbles were so investigated and confronted to the microanalysis results.

Results and Discussion

For an annealed sample implanted at a preset fluence of 10^{15} atoms/cm² (later determined to be 1.3×10^{15} atoms/cm²) the anodization produces a splitting of the initial xenon distribution. This clearly appears in the backscattering spectra of Fig. 2 taken from an anodic layer about 50 $\mu g/cm^2$ thick (adipic electrolyte — V^{ct} = 100V). Of course it cannot be stated which peak indicates the transport. On the other hand, no changes in thickness and stoichiometry were detectable from the spectra of the implanted and unimplanted face of the anodized foil. The various surface impurities seen are characteristic of the material and their significance have been discussed elsewhere (9).

The splitting effect cannot be attributed to sample preparation or to the analyzing procedure since most of their possible combinations lead to the same qualitative result (Table I). On the other hand it must be remembered that, as illustrated in Fig. 1, the xenon atoms are in all cases partly located in the initial oxide and partly in the metal. If the implantation is restricted to the oxide layer (*i.e.*, into a preformed oxide film such as at 40V $\simeq$ 20 $\mu g/cm^2$) only the peak located near the middle of the oxide layer remains. This is in agreement with the results of Brown *et al.* (3). Moreover the xenon fraction introduced in the initial layer depends on its thickness or, for a given layer, can be increased by lowering the implantation

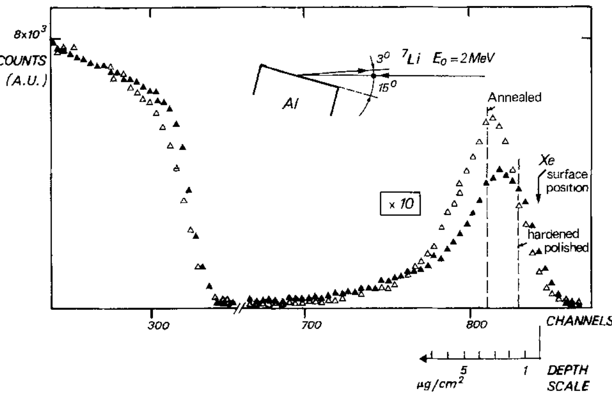

Fig. 1. Grazing angle backscattering spectrum from $\sim 10^{15}$ atoms/cm² Xe atoms implanted in hardened polished ▲▲▲ and annealed △△△ samples. Respective initial oxide thicknesses are indicated.

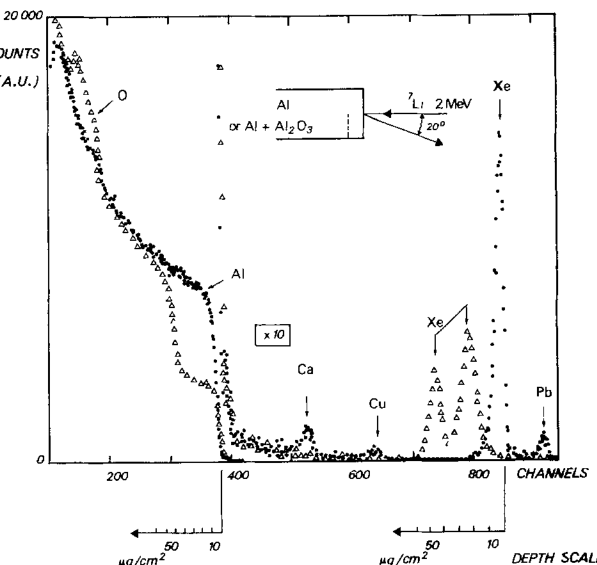

Fig. 2. Backscattering spectrum from 1.3 10^{15} atoms/cm² Xe atoms implanted in annealed sample before . . . and after anodization △△△△.

energy (5 keV). As shown in Table I, there is a similar variation of the xenon fraction found near the middle of the anodic oxide layer. Nevertheless the agreement is only qualitative which will be explained later on.

The splitting effect is dose-dependant as evidenced in Fig. 3 which shows the evolution of the xenon peaks after anodization of the most representative samples: annealed and hardened polished. From 10^{14} to 10^{16} atoms/cm² the relative value of the low energy peak increases above a given threshold up to a maximum and then decreases (Fig. 4). Such results point out a "snowplow" effect of the xenon implanted in the metal beneath the initial oxide layer by the moving metal interface during the anodization. The dose dependance can be interpreted in terms of xenon bubbles formation in a two-step process. For a given concentration in the implantation profile, the xenon atoms begin to form bubbles large enough to be trapped at the oxide metal interface and be transported by this moving interface through the defects of the polycrystalline material. When the local concentration increases a critical bubble size is reached. The largest bubbles can no longer be dragged along and are absorbed into the growing oxide layer (see sketches of Fig. 4). The fraction of xenon atoms found near the interface then

Table I. Xenon fraction found near the middle of the layer after 100V anodization. Total fluence 10^{15} atoms/cm² for samples of different initial layer. Layers are obtained for V_{ct} and $T = 90°C$ except for (*) where $I = C^t$ and $T = 25°C$

Samples of initial layer thickness range	Implantation energy	Electrolyte: Adipic	Phosphoric	Boric	Ammonium pentaborate
Annealed (3.2 → 4.4 $\mu g/cm^2$)	30 keV 5 keV	0.68-0.64 0.87	0.61 0.82	0.77 0.87	
Hardened (2.7 → 3.5 $\mu g/cm^2$)	30 keV 5 keV	0.34-0.52 0.54	0.36 0.7	0.36 0.44	
Annealed Passivated (phosphoric) (1.2 → 1.6 $\mu g/cm^2$)	30 keV	0.26			
Hardened electropolished (1.2 → 1.7 $\mu g/cm^2$)	30 keV	0.27-0.24*			0.17*
Hardened polished (1 → 1.5 $\mu g/cm^2$)	30 keV	0.22			
Polished**	20 keV	0.39			

** Samples supplied by W. D. Mackintosh, A.E.C. Ltd., Chalk River Nuclear Laboratories, Chalk River, Ont., Canada.

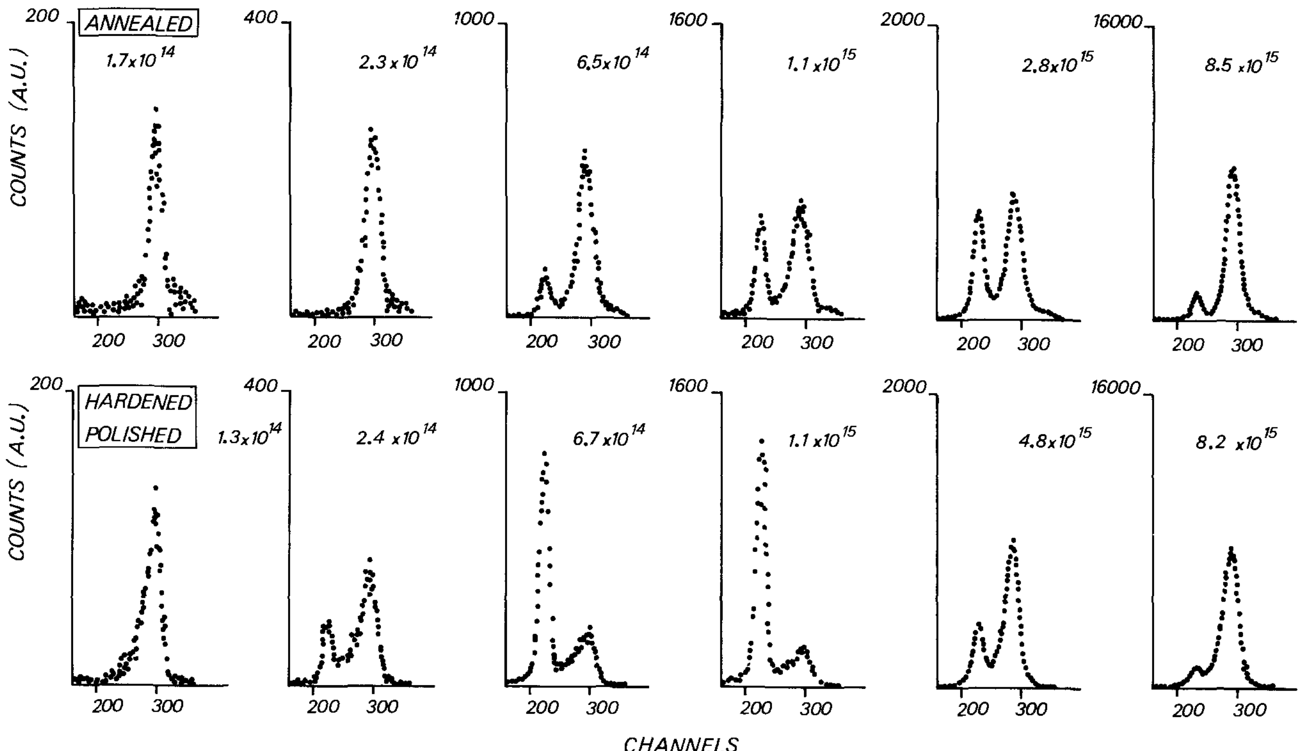

Fig. 3. Evolution of the backscattered xenon peaks after anodization of the hardened polished and annealed samples for doses from 10^{14} to 10^{16} atoms/cm^2.

decreases. But even at doses as high as 10^{16} atoms/cm^2 there still remains a large amount of transported bubbles.

Comparison of the number of transported xenon atoms with the number of implanted atoms in the metal beneath the surface layer should provide additional information. As mentioned earlier the fraction of xenon in the metal can be measured but with an uncertainty governed by the oxide thickness determination and the degree with which the interface can be defined. Even with these uncertainties the results shown in Fig. 5 point out some interesting features. First of all, for these two different samples, extrapolated thresholds are very close to each other (between 1 and 1.5 $\times$ 10^{14} for the hardened polished and between 1.5 and 2 $\times$ 10^{14} for the annealed). Next, the increase above the threshold is nearly linear with a slope close to 1 as long as the concentration does not exceed $\sim$ 10^{15} atoms/cm^2. Further on there is a marked deviation for the two samples which merge again at the higher doses. Thus in the first step, corresponding to the linear rise, all the newly incorporated atoms seem to contribute to the growth of the already formed bubbles more than to create new ones. When a critical size is reached the annealed material seems more impermeable to the transport than the hardened polished one. This is consistent with the former's lower defect density.

A support for the bubble development and growth model can also be found in the evolution of the xenon peak width corresponding to the "immobile" fraction (Table II). The initial broadening of the peak which appears more clearly in the hardened polished case is due to partial drag towards the interface. When larger bubbles become incorporated into the oxide layer, the peak width decreases significantly due to the variation of the stopping power for the analyzing particles (for a given linear thickness the particles are slowed down into gaseous xenon rather than into aluminum oxide). This is in agreement with the results and interpretation of Liau and Sheng (10) who observed such effects when progressively increasing argon doses were injected into Pt Si.

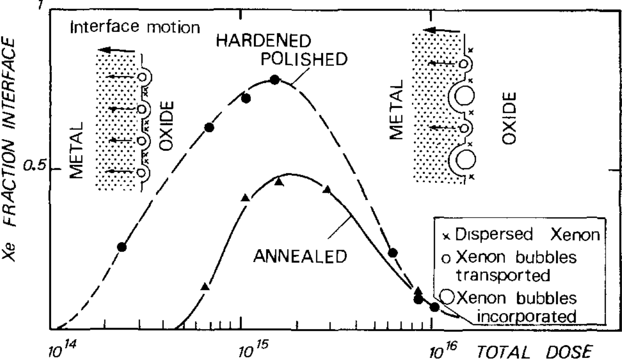

Fig. 4. Variation of the implanted xenon atoms fraction found near the interface vs. the total dose. Inserted are the sketches illustrating the two dominating effects due to the bubble growth.

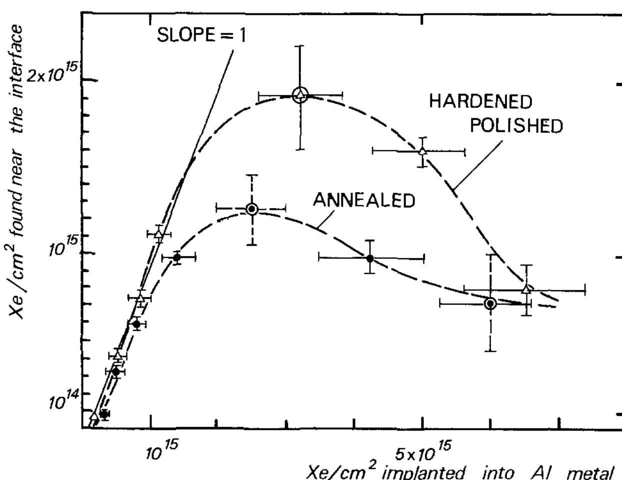

Fig. 5. Number of xenon atoms transported at the interface as a function of the number of xenon atoms implanted in the metal under the initial oxide layer. Circles points have been interpolated from Fig. 4.

Table II. Evolution of the xenon peak width (keV) corresponding to the "immobile" fraction, as a function of the initial total dose at 30 keV (atoms/cm^2)

Initial dose	Hardened polished	Annealed
1.5×10^{14}	53	47
2.3×10^{14}	51	43
6.6×10^{14}	60	50
1×10^{15}	58	51
1.5×10^{15}	55	55
2.8×10^{15}		43
6.3×10^{15}	41	
8.3×10^{15}	48	43
1×10^{16}	46	

Such a general evolution must occur for all types of sample preparation but with some quantitative differences arising from the structure of the metal and the definition of the initial oxide layer (for example stoichiometry and structure). This can explain some discrepancies among the values given in Table I for samples of comparable initial oxide layer thickness. Regarding the implantation conditions and especially the energy, a significant parameter for the bubble formation is certainly the xenon distribution. This formation occurs most probably at a given depth corresponding to the maximum of the distribution profile (maximum local concentration of xenon) and, if it is so, on both side of this maximum there still remains dispersed xenon. Accordingly, only the fraction agglomerated into bubbles will be dragged. Evidence of such a behavior is given in Fig. 6(a) and (b) for implantation at higher energy (150 and 300 keV) into annealed aluminum, showing wider distributions with maximum concentrations deeper in the metal. The interpretation of the peak deformation illustrated by the corresponding sketches is consistent with the previous picture: a large amount of xenon atoms in the metal is not transported because the local concentration is not sufficient for bubbles formation.

The experiments performed with TEM on ultramicrotomed sections were intended to visualize this bubble formation and growth. The micrograph of Fig. 7, taken from an unimplanted face of an annealed sample, clearly shows that the oxide layer is amorphous and has a very well-defined interface. The bubbles agglomeration after implantation and anodization becomes visible for a total dose of 2.8×10^{15} Xe atoms/cm^2, the distribution being split into $\sim 1.8 \times 10^{15}$ atoms/cm^2 near the middle of the layer and $\sim 10^{15}$ atoms/cm^2 at the interface. From Fig. 8 the maximum bubble size appears to be $\sim$ 30Å in the central part while there is only a significant shadowing at the interface for attesting to the presence of transported material, compared to the interface of the unimplanted surface. Higher implantation doses reveal more clearly the bubble growth. For 8.5×10^{15} Xe/cm^2 (split into 7.5×10^{15} and 1×10^{15}), the mean bubble size appears

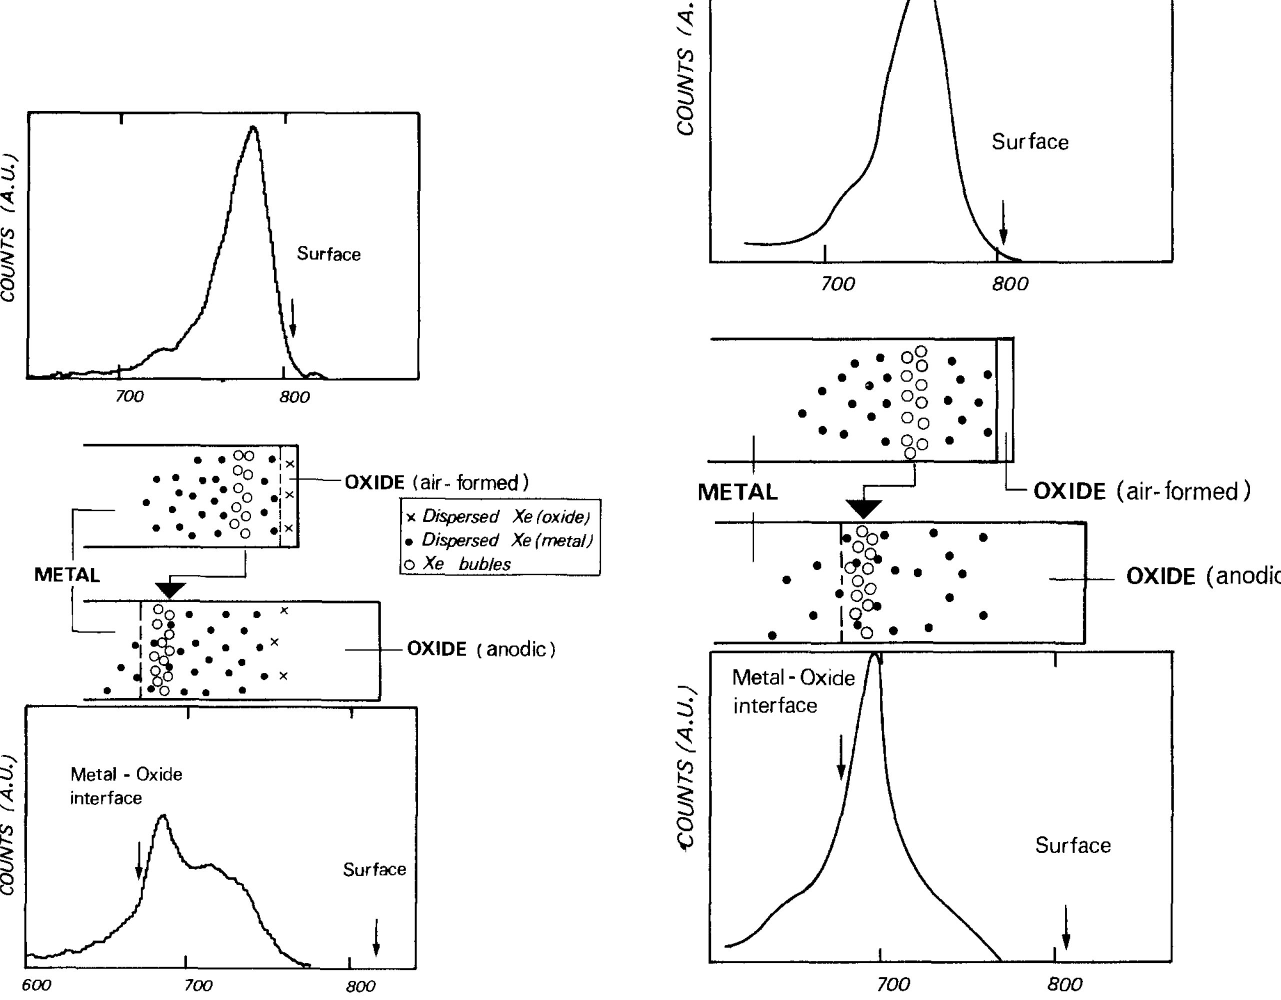

Fig. 6. Backscattered xenon peaks for a 10^{15} atoms/cm^2 implantation dose at 150 keV (a, left) and 300 keV (b, right) with corresponding model sketches: before (top) and after (bottom) anodization.

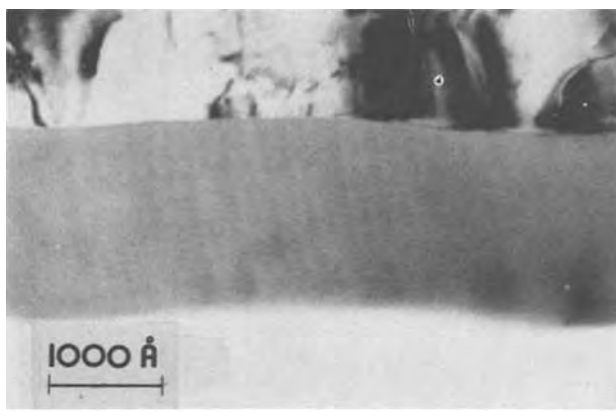

Fig. 7. Ultramicrotomed section of oxide film formed at 100V into adipic electrolyte at 90°C from annealed aluminum (unimplanted face).

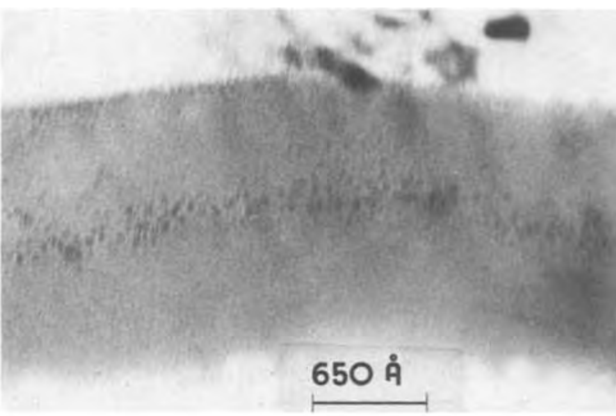

Fig. 8. Ultramicrotomed section of oxide film identically formed as in Fig. 7 but implantation performed at 2.8 10^{15} atoms/cm^2.

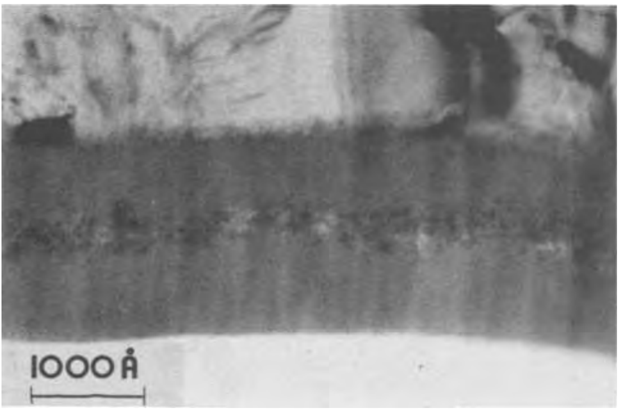

Fig. 9. Ultramicrotomed section of oxide film identically formed as in Fig. 7 but implantation performed at 1.1 10^{16} atoms/cm^2.

to be ~ 50Å and on Fig. 9 for 1.1×10^{16} Xe/cm^2 (split into 9.8×10^{15} and 1.2×10^{15}) it reaches about 100Å. Near the interface, the xenon atom density remains too low for a significant determination of the bubble size, but is still sufficient for attesting, in all cases, to the bubble agglomeration. As additional information these micrographs show that the xenon does not affect the oxidation process since the thickness and the amorphous structure are identical for both implanted and unimplanted side of the foil. The visual determination of the transport number is in very good agreement with the backscattering results (± 5%).

One important question remains concerning the confidence one can have on the value of the "right" transport number t_m. We have only done at this time a systematic study for a particular electrolyte (adipic) in very specific anodization conditions (V^{ct}, $T = 90°C$ see details in experimental procedure). In no case has the maximum deviation exceeded 0.05 for a mean value of 0.49. On the other hand, from the more limited experiments we performed on preanodized samples formed at constant current density in ammonium pentaborate, a significant difference is pointed out ($t_m \leq 0.4$). Such a difference has also been recently reported by Mackintosh *et al.* (11) but using only one anodizing condition. Since the broadening of the marker peak is always very large one cannot exclude a partial transport of the xenon atoms supposed immobile. The xenon part laying in the aluminum phase is the most probable suspect (5 keV implantation gives slightly lower transport numbers) but without further characterization of the initial oxide layer, its role cannot be clarified.

Conclusion

Xenon atoms implanted into aluminum samples beneath their initial oxide layer agglomerate into bubbles when a critical concentration is reached, leading to a "snowplow" effect by the moving oxide-metal interface during anodic oxidation. We found no exceptions to this general behavior for fluences of about 10^{15} atoms/cm^2 at typical energies of 30 keV. From a more specific study of two differently prepared materials we have pointed out a two-step mechanism by which the growing of the bubbles lead them to be first transported and finally reincorporated into the anodic layer. The first step process has been found to be not only dependant on the total number of implanted atoms into the metal but on the distribution of the species, *i.e.*, of their local concentration.

Although the agglomeration of implanted xenon atoms into bubbles has been recognized in various materials like silicon (12) and its metallic compounds (10, 13) for comparable fluences, such a splitting effect seems to be characteristic of the anodic oxidation of aluminum. Such a behavior is not observed for thermal (13) or anodic (14) oxidation of silicon and for anodic oxidation of tantalum (4). Moreover, in the last case, even higher doses (10^{16} atoms/cm^2) do not induce this phenomenon.

In summary we note that partial results have been recently reported by Mackintosh *et al.* (11) confirming the general picture but with some quantitative differences. Our particular conditions may explain the more pronounced splitting effect due to the fast displacement of the moving interface at the beginning of the anodization. Finally there still remains the possibility of partial transport of the xenon atoms which are supposed to be immobile because they are found incorporated into the anodic layer. The remaining discrepancies in the transport numbers determined from implantation into preformed and nonpreformed oxide layers deserves more investigations particularly concerning the role of the initial layer in the whole process.

Acknowledgments

We are very grateful to A. Plantier for his assistance in mass separator operation, B. Payerne and L. Vidal for anodic oxidation, and all the staff of the Van de Graaff accelerators for irradiations. It is a pleasure to acknowledge the help of W. D. Mackintosh for kindly providing samples and unpublished results, and of N. Cue for critical reading of the manuscript. This work was supported by the D.G.R.S.T. (Contracts No. 777 1091 and 1092).

Manuscript submitted April 16, 1979; revised manuscript received Oct. 17, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Studies on Electrodeposition of Nickel-Cobalt-Tungsten Alloys

V. B. Singh, L. C. Singh,[1] and P. K. Tikoo

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

ABSTRACT

Electrodeposition of nickel-cobalt-tungsten alloys containing 2-51% Ni, 18-79% Co, 5-62% W has been carried out from a citrate bath under different conditions of concentration of electrolyte, current density, pH, and temperature. Tungsten content in the deposit was found to increase with an increase in its content in the bath and also with an increase in pH, temperature, and current density. Surface morphology of the deposits was examined by scanning electron microscopy and crystal structure by x-rays. Microhardness of the deposits increased with an increase in tungsten content in the alloy.

Electrodeposition of tungsten from an aqueous bath has large commercial potentialities. There are, however, many peculiarities observed during the electrodeposition which have attracted the attention of many workers. It would appear that tungsten can only be electrolytically deposited from an aqueous electrolyte as an alloy of metals, the alloying metals being preferably the iron group metals. Electrodeposition of binary alloys of tungsten with iron group metals have been reported by many workers (1-9). The chemical composition of the deposits, their properties, and structures have been studied under different conditions by these investigators. However, work done on the electrodeposition of its ternary alloys with the iron group metals is rather limited. Therefore, it was of interest to study the electrodeposition in such systems.

Preliminary investigations on the electrodeposition of some of its ternary alloys with the iron group metals have been reported earlier (10-12). The present investigation relates to the electrodeposition of ternary nickel-cobalt-tungsten alloys under varied conditions and to some studies on the structure and hardness of the deposits obtained.

Experimental

Experimental setup and working procedures are the same as in the earlier communications (10, 13). Cylindrical platinum electrodes were employed but for qualitative studies copper cathodes were used. Each experiment was carried out in a fresh solution without agitation. The deposits were dissolved in two volumes of fuming nitric acid and one volume of hydrofluoric acid in a polyethylene beaker and evaporated to dryness for chemical analysis. The metal contents in the deposits were determined polarographically (14) using a mixture of ammonia and ammonium oxalate as supporting electrolyte.

[1] Present address: Udai Pratap Postgraduate College, Varanasi, India.

Key words: electrodeposition, cathode potential, scanning electron microscopy, x-rays, microhardness.

Microstructure of the deposits was examined on Phillips 500 scanning electron microscope, and hardness was measured on a microhardness tester (πMT-3).

Results and Discussion

The influence of different variables on composition of the deposit, cathode current efficiency (CCE), structure, and appearance of the deposits is described below.

Concentration of electrolyte.—Variation in composition of the bath by changing the concentration of electrolytes was done as per the guidelines of Brenner (15) and was carried out in three steps. When the concentration of either metal in the bath is increased, the metal content of the respective metal in the deposit also increased [Fig. 1(a), (b), (c)]. Cobalt content in the deposit was found to increase while tungsten content decreased and attained a constant value when citric acid concentration was increased [Fig. 1(d)]. The cathode current efficiency decreased when the metal percentage of tungsten in the bath was kept constant or with increasing concentration of citric acid in the bath [Fig. 1(d)], but it almost attained a constant value or increased after decreasing to some extent in the case when cobalt or nickel percentage in the bath was held constant [Fig. 1(a), (b), (c)]. When the concentration of tungsten in the bath was increased, its content in the deposit was found to be higher than in the bath particularly at low concentrations [Fig. 1(b)], but the curve for tungsten became horizontal towards the right which indicates that tungsten content approaches a limiting value in the deposit [Fig. 1(b)]. At the high tungsten end of the series the deposits tended to flake off the cathode. In most of the cases the deposits were bright and uniform when nickel was added but turned gray by cobalt additions to the bath. Hydrogen evolution was enhanced by increase in tungsten content in the bath. The tungsten content in the deposit which was higher than in the bath particularly in the low concentration range showed preferential deposition of tungsten. The variation in composition of

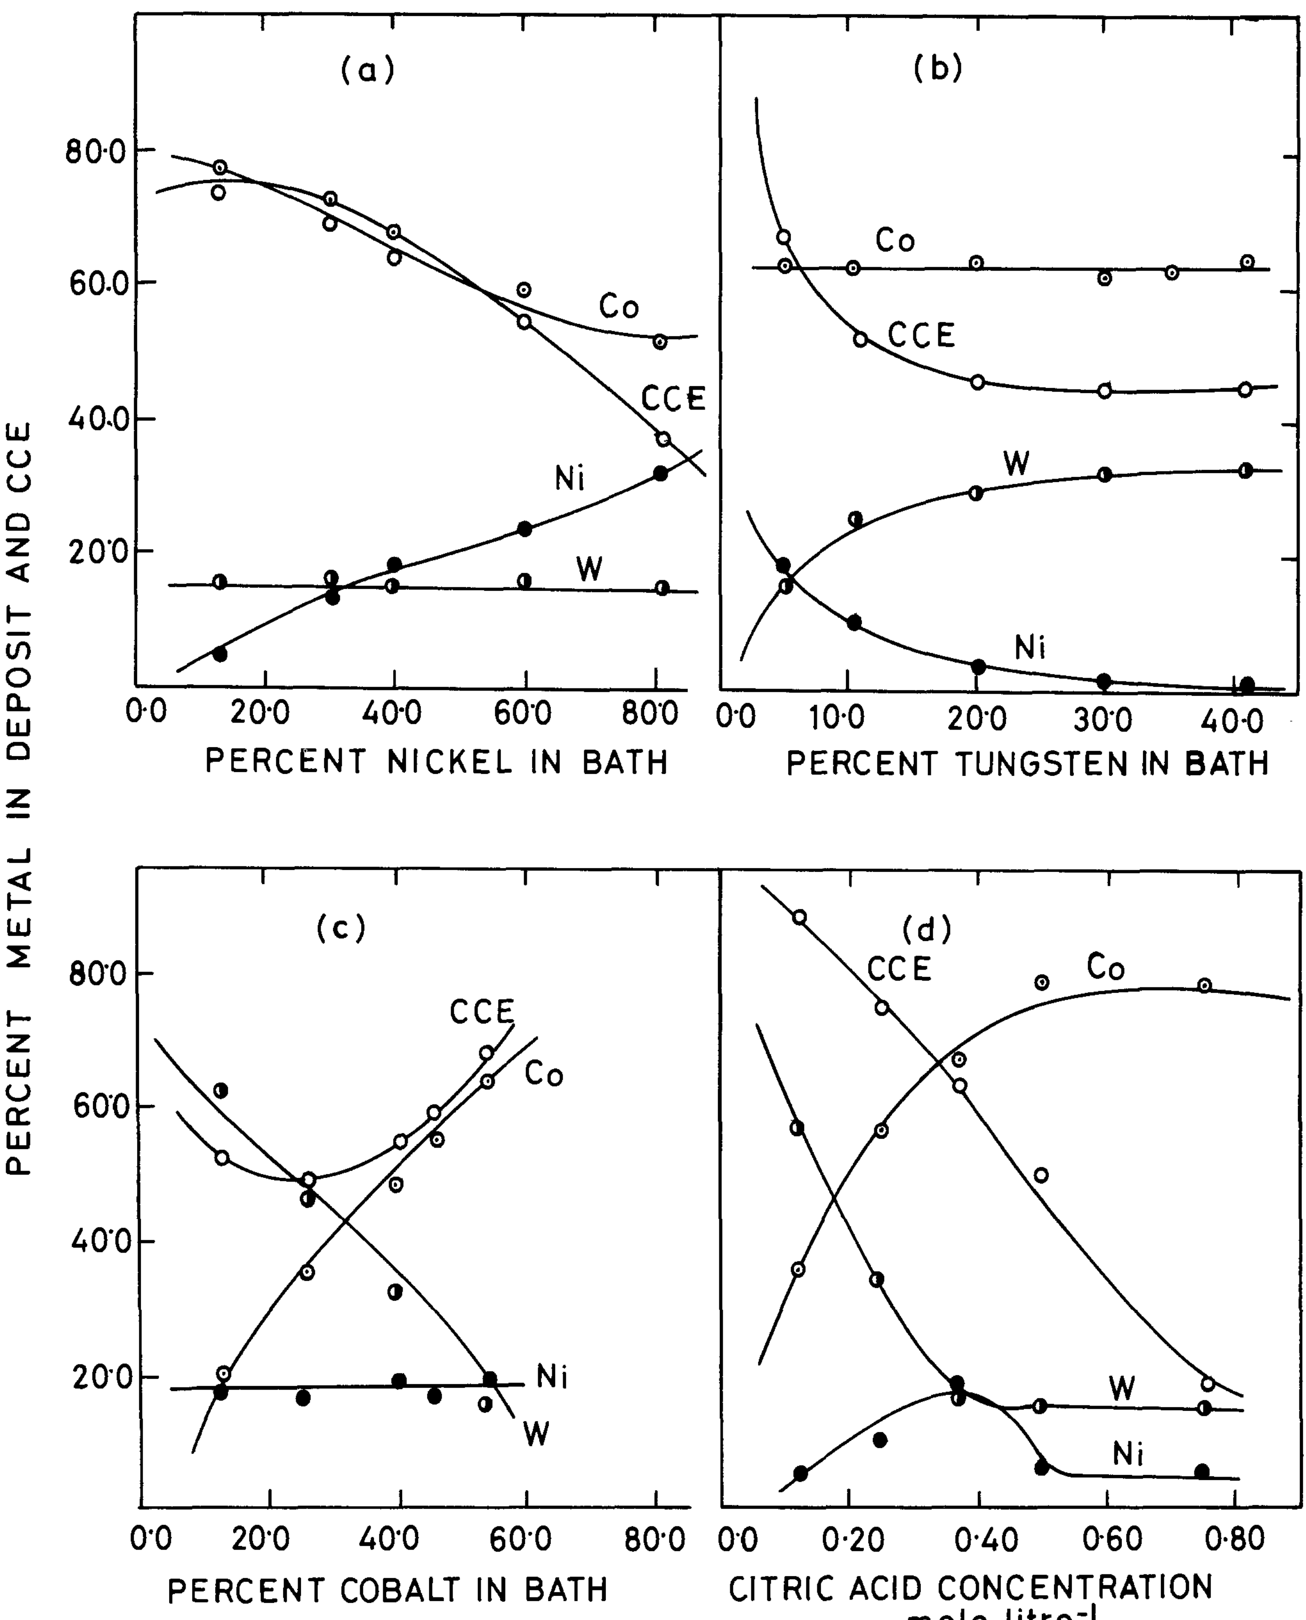

Fig. 1. Represents the effect of bath composition on CCE, and composition of the Ni-Co-W deposits when total metal content (0.2529N) and one of the metal percentages are held constant in the bath (CD 1.0 A/dm^2, pH 5.2, temp. 35°C). (a), When metal percentage of tungsten (5.1%) is held constant; (b), when metal percentage of cobalt (54.3%) is held constant; (c), when metal percentage of nickel (40.6%) is held constant; and (d), effect of citric acid concentration on CCE and composition of the Ni-Co-W deposit under otherwise optimum conditions.

the deposit and cathode current efficiency with electrolyte concentration is in excellent agreement with that of other workers (11, 16).

The optimum bath composition arrived at by the experiments is as follows: nickel sulfate 0.108M, cobalt sulfate 0.142M, sodium tungstate 0.0045M, citric acid 0.333M, sodium chloride 0.170M.

Current density (CD).—Using a bath of optimum composition, the influence of current density was studied between 0.2-4.0 A/dm^2. In the lower region of current density the deposits were dull and coarsely cystalline, but with an increase in current density up to 1.5 A/dm^2 fine grained, bright, and adherent deposits were obtained. As the current density was increased

beyond 1.5 A/dm², it resulted in the formation of relatively inferior deposits which were less bright, cracked, and nodular.

Tungsten content in the deposit initially decreased but increased after 1.5 A/dm². Variation in cobalt content in the deposit with respect to the current density is different from the nature of the tungsten curve. The cathode current efficiency decreased up to 2 A/dm² and became constant afterwards [Fig. 2(a)]. Such variation in the composition of the deposit with respect to current density has also been reported by Holt *et al.* (11, 17).

pH.—The pH of the bath solution was varied from *p*H 2-9 and studies were made at optimum current density (1 A/dm²). Unsatisfactory deposits were obtained below *p*H 4 but bright and adherent deposits were obtained between *p*H 4.5 and 6. Deposits obtained at lower *p*H tended to be dull and rough and

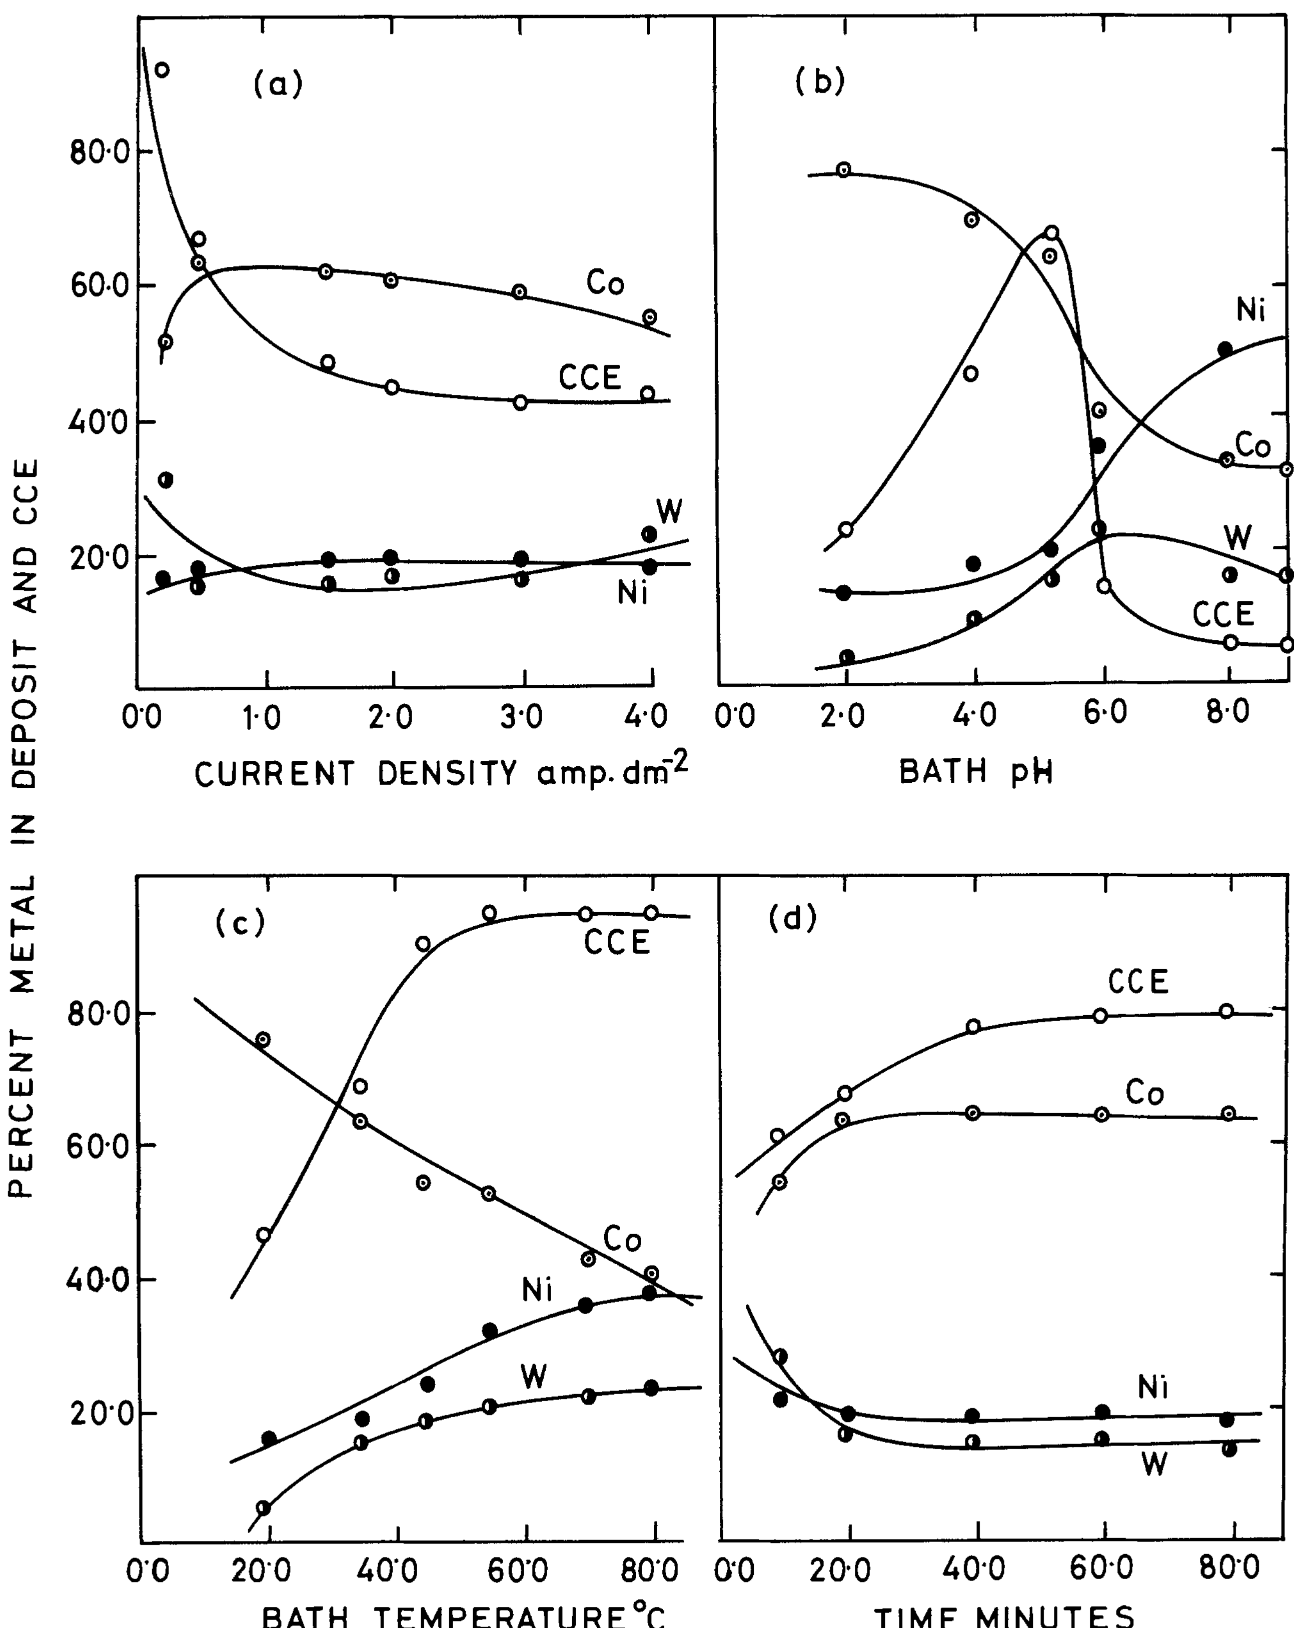

Fig. 2. (a)-(d) represent, respectively, the effect of current density, bath *p*H, and temperature, and duration of electrolysis on CCE and composition of Ni-Co-W electrodeposits. Bath composition and other conditions at optimum.

ultimately darkened. Tungsten and nickel content in the deposit increased with pH but above pH 6 tungsten content decreased. Cobalt content in the deposit decreased with an increase in pH of the bath. The CCE increased and then decreased after attaining a maximum value at pH 5 [Fig. 2(b)]. However, such a maximum value for tungsten content in the deposit with respect to pH is inconsistent with other findings where a regular increase in tungsten content has been observed (10, 18, 19).

Temperature.—The bath was operated between temperature range 20°-80°C under otherwise optimum conditions (at pH 5.2). Bright, fine grained, and adherent deposits were obtained up to 35°C but the deposit tended to become coarse, rough, and nonuniform beyond this temperature. Deposits at higher temperatures (>55°C) were bright but nodular and contained some dull spots on the surface. Tungsten and nickel content in the deposit increased while cobalt content decreased with an increase in the temperature of the bath. The cathode current efficiency (CCE) improved with temperature and became constant at higher temperatures [Fig. 2(c)]. Such variation in tungsten content in the deposit with respect to the temperature has also been reported by other workers during its codeposition with the iron group metals (4-6, 19-21).

This increase in tungsten content in the deposit and fair improvement in the CCE with temperature of the bath reflects that polarization factor (largely activation type) appears to be predominant.

Electrolysis was carried out (under optimum conditions and for every time in a fresh solution) for varying durations of 10-80 min. The composition of the deposit remained almost unchanged with respect to the different durations of time [Fig. 2(d)] except in the early runs. Sound deposits were obtained up to 20 min, but prolonged duration (>40 min) resulted in dull, nodular, and highly cracked deposits.

Table I. Effect of addition agents on metal content and CCE of Ni-Co-W electrodeposit under optimum conditions

Addition agent	Amount (g/liter)	Deposit composition (%) Ni	Co	W	CCE (%)
Tetra-n-butyl ammonium iodide (TnBAI)	0.250	9.3	70.4	19.8	74.0
Tetraethylammonium iodide (TEAI)	0.250	13.9	60.1	25.1	86.2
Tetraethyl ammonium bromide (TEABr)	0.200	23.6	59.1	15.6	58.1
p-Chloraniline	0.300	12.8	65.1	21.6	40.0

Some addition agents listed in Table I were separately and singly added to the bath under the optimum conditions. Except tetraethylammonium bromide, other agents used improved the deposits in respect to brightness and grain refinement. These also helped in suppressing the cracks and peeling off to some extent which are seen at higher current densities or during prolonged operation of the bath. The composition of the deposits and CCE also varied to some extent in their presence.

Cathode potential.—Current density *vs.* cathode potential studies for the metals and alloy (Fig. 3) show that the curve for Ni-Co-W alloy lay at a more noble potential than the curve for nickel and cobalt (curves 4, 1, 2). Curve 3 for tungsten appears due to primarily cathodic hydrogen discharge. The more noble potential for the alloy deposition may be due to the decrease in free energy that occurs in the formation of solid solution; x-ray studies confirmed the formation of solid

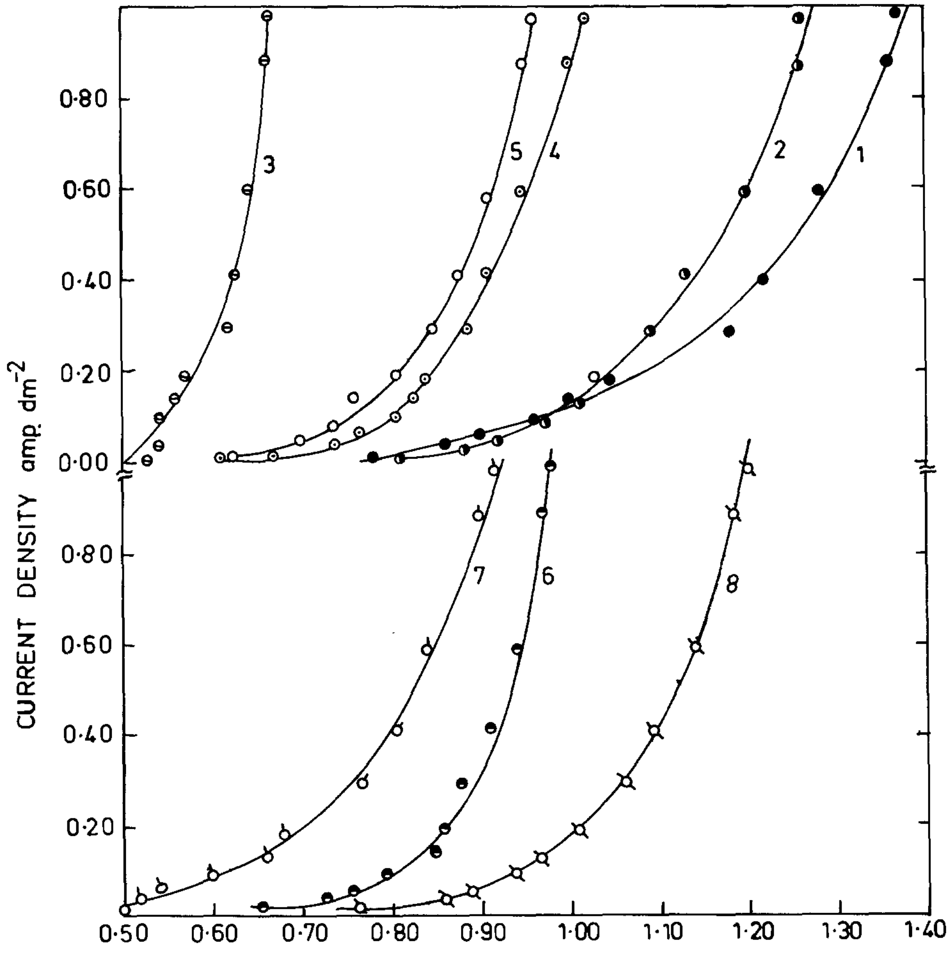

Fig. 3. Current density *vs.* cathode potential curves for the electrodeposition of Ni-Co-W alloy. Optimum concentration of each electrolyte and citric acid 0.333M has been taken at 35°C. Curve 1, nickel alone; curve 2, cobalt alone; curve 3, tungsten; curve 4, Ni-Co-W alloy; each at *pH* 5.2. solution of tungsten with the alloying metals (Table II).

Similar behavior was observed by Golt'z and Kharlamov (22). The alloy curve is nearly identical in nature to the curves of pure codepositing metals, Ni and Co.

Tetraethylammonium iodide lowered the polarization of the deposition (Fig. 3, curve 5), while tetra-n butylammonium iodide increased the cathodic polarization (curve 6).

Several attempts have been made to explain the mechanism and characteristics of induced codeposition of tungsten. The hypotheses advanced by various investigators and their shortcomings have been discussed in detail by Brenner (23). It emerges from the results of the present investigation that certain trends observed during the electrodeposition of the ternary nickel-cobalt-tungsten alloys can be explained by the hypothesis of transfer of polarization (23). A large polarization of the activation type, a discharge potential in the vicinity of the equilibrium potential of the reluctant element, and ability to form solid solutions are known to be the effective factors which are mainly responsible for codeposition of the reluctant metal with other metals.

In light of the above discussions, the preferential deposition of tungsten particularly from a bath having a low concentration of tungsten, the increases in tungsten content in the deposit and cathode current efficiency with bath temperature, and the occurrence of alloys as solid solutions (Table II) well agree with the hypothesis of transfer of polarization.

Structure of the deposits.—The alloy deposits were generally bright and silvery to gray in appearance. The low tungsten content alloy deposits were bright, uniform, and adherent while those having high tungsten content contained a few cracks and nometallic inclusions and were noncoherent.

An inspection of the deposits by scanning electron microscope showed that deposition was uniform, though some pits and cracks on the surface were also present. The deposits were laminated but also possessed columnar structure with polyhedral grains [Fig. 4(a), (b)]. Polyhedral laminated grains were also present in ternary nickel-iron-tungsten alloys (10), but the deposits were not so adherent and satisfactory as those of nickel-cobalt-tungsten alloys. Hydrogen which evolved during the process of electrodeposition, had a marked effect on the alloy deposits. Possibly it initiated the cracks on the surface which propagated parallel to the surface. Sometimes these cracks initiated from the pits and sometimes terminated at the pits [Fig. 4(c), (d)]. The hydrogen bubbles which might get entrapped in the pits or holes may enlarge them and form a cavity through which the gas diffuses giving rise to multiple minor cracks [Fig. 4(e), (f)]. Such diffusion of hydrogen results in poor internal strength of the deposits leading to embrittlement. Highly cracked and poorly adherent deposits, shown in Fig. 4(g) obtained at high current densities or on prolonged operation of the bath, appear to be due to the adsorbed hydrogen which has caused stress in the deposit. The deposition appears to be in layer form. The alloy coating was examined after bending it and then bringing to the original state; it was still adherent to the base metal but cleavage facets were seen in the ruptured part of the coating [Fig. 4(h)].

X-ray diffraction studies of the deposits (in as-deposited conditions) containing up to 25% of tungsten showed that the alloy deposits were single phase with expanded lattice of cobalt only (hcp), Table II. Electrodeposited binary alloys of tungsten with the iron group metals (4, 18, 24) have been reported to form solid solutions containing up to 40% of tungsten and the lattice was similar to the codepositing metal but with some expansion.

Microhardness of the deposit was measured at 20g load, the line of application of the load was perpendicular to the surface. The hardness of the deposit was found to increase with tungsten content in the deposit (Table II).

Conclusions

Ternary alloys of nickel-cobalt-tungsten of wide composition range were electrodeposited successfully from a citrate bath. The alloy deposits were sound and satisfactory under most conditions. An explanation has been offered for the various trends observed during the investigation, in light of transfer of polarization hypothesis.

Preparation and Properties of Bismuth Ruthenate Thin Film Electrodes for Chlorine Evolution

P. F. Carcia,* R. B. Flippen, and P. E. Bierstedt

E. I. du Pont de Nemours and Compnay,
Central Research and Development Department, Wilmington, Delaware 19898

ABSTRACT

We have prepared thin film electrodes in a compositional range about $Bi_2O_3 \cdot 2RuO_2$ by rf sputtering directly onto heated titanium substrates. Specifically we prepared $Bi_2Ru_2O_7$ with the pyrochlore structure, $Bi_3Ru_3O_{11}$, and noncrystalline bismuth ruthenate films. The resistivity of all films at 300°K was $<10^{-2}$ Ω-cm. Electrochemical measurements on well-characterized anodes of $Bi_2Ru_2O_7$, and $Bi_3Ru_3O_{11}$ show high activity for chlorine evolution. Examination of the stability of the $Bi_2Ru_2O_7$ electrode shows that some Bi is lost from the surface.

The use of RuO_2 anodes in Cl_2 production is one of the most significant achievements of electrocatalysis. The energy savings to that industry is estimated at several billion kW-hr/yr (1). Appropriately, a number of papers (2-10) have examined the preparation and electrochemical properties of these electrodes. Therefore, the investigation of other Ru oxides as Cl_2 anodes is of great practical interest.

In this paper, we describe the preparation and electrochemical properties of conducting oxides in the compositional range about $Bi_2O_3 \cdot RuO_2$. We prepared electrodes as thin film coatings on heated Ti substrates by rf sputtering (11). Well-characterized electrodes were tested as anodes for Cl_2 evolution from brine. Several had high electrocatalytic activity.

Experimental

Thin films were prepared by rf sputtering in a commercial system (Materials Research Corporation, Model SEM-8620). The target was a 2 in. diam (~¼ in. thick) disk of $Bi_2Ru_2O_7$, fabricated by solid-state sintering of the constituent oxides at 950°C in air overnight.

Substrates were ceramic Al_2O_3 (Alsimag 614, 3M Company) and Ti sheet (Ti-50A obtained from Timet Corporation), degreased and cleaned by standard vacuum cleaning techniques. These substrates could be heated to ~1000°C in the vacuum chamber during deposition. The elevated temperatures were achieved by electrically heating a supporting tungsten ribbon. Temperatures were measured by a Chromel-Alumel thermocouple clamped to the ribbon underside. These are the "substrate temperatures" reported in this paper, and no correction is attempted for actual substrate surface temperature which may differ by as much as 150°C (12).

The sputtering atmosphere was usually 10^{-2} Torr of Ar and 10^{-3} Torr O_2, established after initial pumpdown of the chamber to $\sim 10^{-6}$ Torr. In some experiments the Ar was gettered by passing it over heated Zr and Ti metal filings.

The thin films were routinely characterized by x-ray diffraction. Some were also examined by scanning electron microscopy (SEM) and analyzed for relative chemical composition and valence state by x-ray photoelectron spectroscopy (XPS). Electrical resistivity measurements were made by the standard four-probe method.

Electrochemical measurements were made in a three-compartment glass cell. The cathode (~20 cm²) was a Pt screen. The cathode compartment was separated from the main anode reservoir by a fine glass frit or a Nafion® perfluorosulfonic acid membrane. The electrolyte was an aqueous solution of 20 weight percent (w/o) Fisher reagent grade NaCl. The *p*H remained in the range 3-4 during experiments of several hours duration. All electrode potentials were measured *vs.* saturated calomel (SCE), at a distance of 2 mm from the electrode surface by a fine capillary tube filled with electrolyte. The entire cell was heated on a standard laboratory hot plate. Temperature control was typically ±3°C, determined by measuring temperature before and after an experiment.

The bismuth ruthenate-coated Ti anodes were contacted electrically to a brass screw with silver paste (Dupont 4922). A Cu wire threaded through a glass sleeve was soldered to the screw and the entire configuration potted with a fast-drying epoxy (Adhesive A-36, Armstrong Products Company). Only the bismuth ruthenate surface was exposed to the electrolyte.

Electrochemical measurements were made with a Princeton Applied Research Model 173 Potentiostat/Galvanostat. This unit could be programmed with triangular or pulse waveforms from a PAR Model 175 Universal Programmer. Current densities quoted in this paper were obtained by dividing the measured current by the geometric area of the Ti substrate (typically ~1 cm²).

Results and Discussion

Thin films.— Table I summarizes preparation conditions and cubic cell dimensions for bismuth ruthen-

* Electrochemical Society Active Member.
Key words: chloralkali anodes, thin film, pyrochlore, electrodes, electrocatalysis.

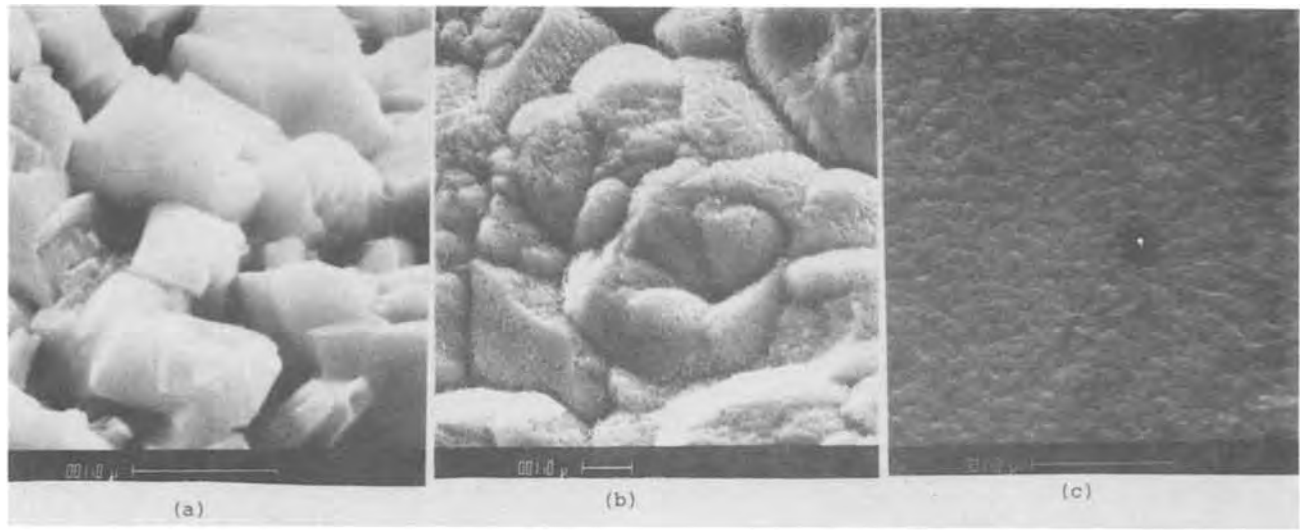

Fig. 1. Scanning electron micrographs of (a) $Bi_2Ru_2O_7$, (b) $Bi_3Ru_3O_{11}$, and (c) amorphous thin films. Scale is 1 μm

ate thin films. Films sputtered onto unheated substrates are amorphous to x-rays. At a substrate temperature (T_s) ~725°C, the pyrochlore-type $Bi_2Ru_2O_7$ (13) is formed. The $KSbO_3$-related $Bi_3Ru_3O_{11}$ (14) crystallizes at T_s ~525°C. It could also be prepared by annealing amorphous films on Al_2O_3 substrates in air at ~550°C. Film thicknesses were 1-4 μm.

For the pyrochlore-type films on Ti substrates the lattice parameter ranges from 10.35 to 10.43Å, or 0.5% to 1.0% larger than air-fired polycrystalline $Bi_2Ru_2O_7$ (13), a_o = 10.294Å. Some of this difference (~0.5%) may be accounted for by differential thermal expansion of the Ti ($\alpha \sim 8 \times 10^{-6}$°$C^{-1}$) substrate and the $Bi_2Ru_2O_7$ thin films ($\alpha \sim$ 11-12 $\times 10^{-6}$°C^{-1}), putting the film in tension. In fact, the thin film with the smallest measured lattice was slowly cooled to 25°C over two hours to minimize thermal strain.

Another possible explanation for the large lattice parameter is that the pyrochlore-type structure (13) can exist over a wide range of composition and stoichiometry. If one-third of the Ru^{4+} ions are substituted by larger Ru^{3+} ions, the new lattice is calculated to be larger by ~1% (15), *i.e.*, for $Bi_2{}^{3+}Ru_2{}^{4+}O_7$, a_o = 10.30Å and for $Bi_2{}^{3+}Ru_{1.33}{}^{4+}Ru_{0.67}{}^{3+}O_{6.67}$, $a_o \sim$ 10.40Å. This is reasonable, since the films are prepared in a low O_2 partial pressure. It is also consistent with the observation that the lattice parameter contracts after the film is tested electrochemically under oxidizing conditions as an anode for chlorine evolution.

We characterized surface chemical composition and valence states of one $Bi_2Ru_2O_7$ electrode by XPS. The valence states of the metallic elements were Bi^{3+} and Ru^{+4}. The Ru 3p1/2 photoelectron peak was used for ruthenium and the Bi 4f7/2 peak was used for bismuth. The charge corrected binding energies, referenced to the O 1s peak, were 160.8 eV for Bi and 488.4 eV for Ru. The O/Ru ratio was 3.6, close to the ideal 3.5 for pyrochlore. We concluded, therefore, that at the surface, the chemical composition of this thin film was close to $Bi_2{}^{3+}Ru_2{}^{4+}O_7$.

Table I

Film No.	Substrate temperature T_s (°C)	Gas pressures (× 10^{-3} Torr) P_{O_2}	P_{Ar}	Phase	Lattice parameter a_o (A)
−75	725	1	10	$Bi_2Ru_2O_7$	10.36
−86	525	0.5	10	$Bi_3Ru_3O_{11}$	9.45
−89	725	1	10	$Bi_2Ru_2O_7$	10.43
−15	725	1	10	$Bi_2Ru_2O_7$	10.35
−17	550 (Annealed)	0.5	10	$Bi_3Ru_3O_{11}$	9.31
−87	725	1	10	$Bi_2Ru_2O_7$	10.40
−66	15	1	10	Amorphous	

The lattice parameter for thin films of $Bi_3Ru_3O_{11}$, prepared in the sputtering chamber, is also large, a_o = 9.45Å compared to the air-fired polycrystalline value, a_o = 9.30Å (14). However, when this phase was prepared by annealing amorphous thin films in air at T = 550°-600°C for 15 to 30 min the lattice parameter was 9.31Å. Again, by analogy with the pyrochlore-related bismuth ruthenate films, annealing may relieve strain or decrease an oxygen deficiency.

In Fig. 1 the surface morphologies of $Bi_3Ru_3O_{11}$, $Bi_2Ru_2O_7$, and amorphous thin films are contrasted by SEM. The $Bi_2Ru_2O_7$ surface has sharp, angular crystalline features resembling the octahedral habit of mm-size crystals of $Bi_2Ru_2O_7$ grown in this laboratory. Amorphous and $Bi_3Ru_3O_{11}$ films are less distinctive. $Bi_3Ru_3O_{11}$ films have large (>1 μm) textured grains with a variety of shapes. The amorphous film has a "pebbled" structure with very fine 0.1-0.2 μm grains. The electrical resistivity of all films at 300°K was $<10^{-2}$ Ω-cm.

Electrochemical properties.—Figures 2 and 3 show equilibrium current density for Cl_2 evolution *vs.* potential for $Bi_2Ru_2O_7$ and $Bi_3Ru_3O_{11}$ thin film electrodes. Figure 4 shows the polarization behavior of a $Bi_2Ru_2O_7$ electrode obtained by sweeping potential at 20 mV/sec between 0.7 to 1.2 V/SCE. At 23°C, the current density is 2 mA/cm² at 1.10 V/SCE, the same for both electrodes. Above 80°C, this current density increases to nearly 100 mA/cm² on a $Bi_2Ru_2O_7$ electrode. This corresponds to an apparent overpotential [measured from the equilibrium potential (16), E_o = 1.0285 V/SCE] of only 75 mV, an activity comparable to that for RuO_2/TiO_2 coated Ti anodes (2). The $Bi_2Ru_2O_7$ and $Bi_2Ru_3O_{11}$ thin films are excellent electrocatalysts for

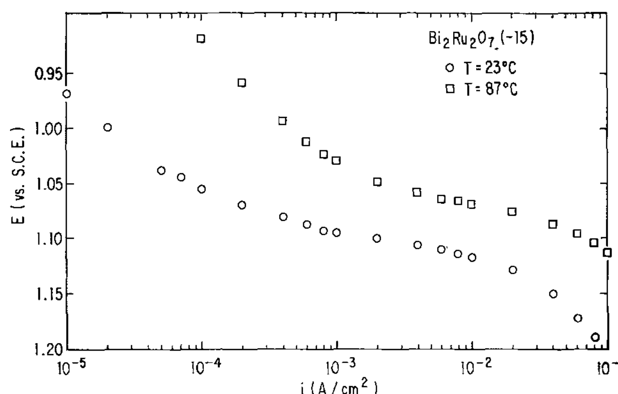

Fig. 2. Anodic polarization behavior of $Bi_2Ru_2O_7$ thin film in 20 w/o NaCl solution.

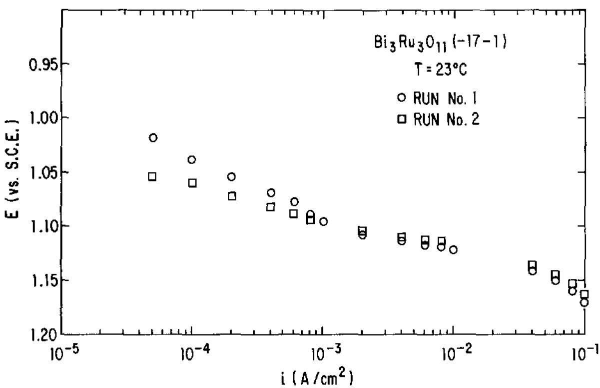

Fig. 3. Anodic polarization behavior of $Bi_3Ru_3O_{11}$ thin film in 20 w/o NaCl solution.

Cl_2 evolution. Of course, as for RuO_2 electrodes, the surface roughness of the bismuth ruthenate electrodes also likely contributes to their low overpotential.

From the linear portion of the $E/\log i$ polarization characteristics (between 10^{-2} and 10^{-3} A/cm²) in Fig. 2 and 3, we estimate a slope of 30 mV/decade. This is different from the 40 mV/decade Tafel slope (2, 3) observed for RuO_2/TiO_2 electrodes, perhaps suggesting a different rate-determining step for chlorine evolution on bismuth ruthenate electrodes. However, further detailed investigation is needed to confirm this.

In addition to determining electrocatalytic activity, we have examined the corrosion resistance of a $Bi_2Ru_2O_7$ electrode. Our tests monitored the change in electrode potential *vs.* the time of Cl_2 evolution. Subsequently, we characterized the electrode by SEM, XPS, and x-ray diffraction.

Only a 1% change in potential (E = 1.10 V/SCE) occurred in 6 hr for a $Bi_2Ru_2O_7$ electrode evolving Cl_2 at 90 mA/cm² in an aqueous NaCl solution at 85°C. (Much larger changes did occur on $Bi_3Ru_3O_{11}$ and amorphous electrodes.) Scanning electron micrographs in Fig. 5 contrast the surface before and after Cl_2 evolution. The original angular, crystalline features have been replaced by an abraded, less dense surface. Much of the change in morphology is probably caused

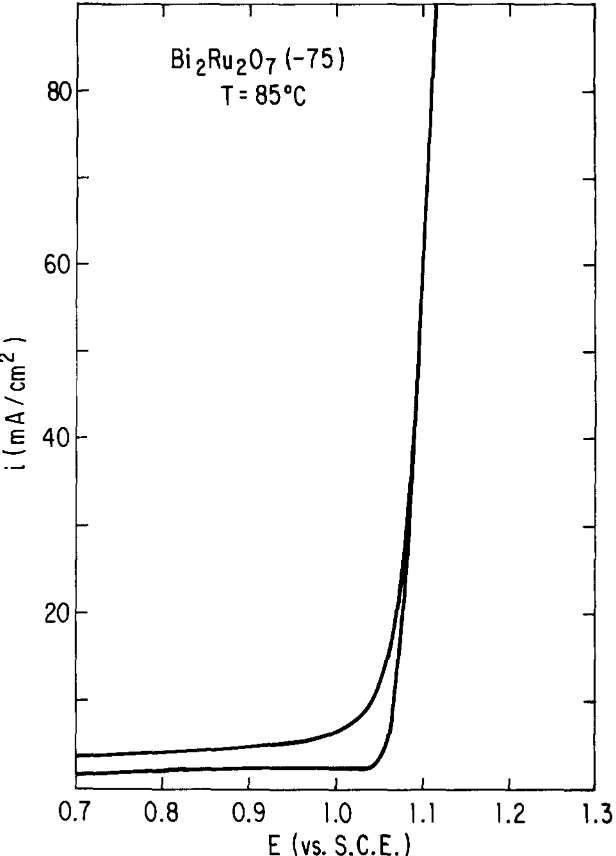

Fig. 4. Polarization characteristic of $Bi_2Ru_2O_7$ thin film obtained by a potential sweep method at 20 mV/sec.

by the frictional forces of Cl_2 gas evolution. Measurement of the surface chemical composition by XPS showed that appreciable (~50%) Bi was lost. X-ray diffraction indicated the presence of some RuO_2 not previously detected. The fact that the activity was not affected indicates that RuO_2 and $Bi_2Ru_2O_7$ have about the same activity. Although these data do suggest some

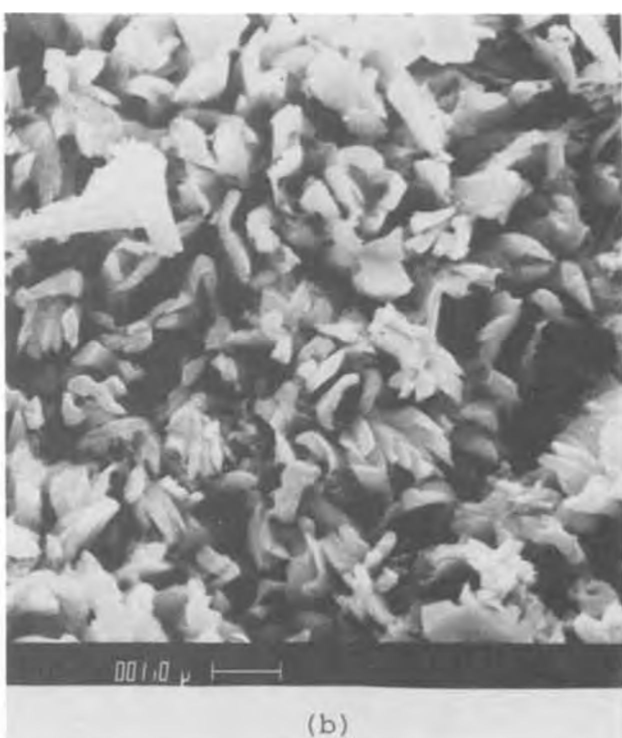

Fig. 5. Scanning electron micrographs of $Bi_2Ru_2O_7$ electrode (a) before Cl_2 evolution and (b) after Cl_2 evolution. Scale is 1 μm

dissolution of the $Bi_2Ru_2O_7$ electrode, the high activity is encouraging, particularly since no attempt was made to optimize mechanical and chemical characteristics of the electrode, as done by other investigators (2).

In summary, we have prepared bismuth ruthenate electrodes by rf sputtering directly onto heated Ti substrates. These electrodes showed high electrocatalytic activity for Cl_2 evolution. Further studies are required to determine whether these electrodes could be improved by chemical or other modifications.

Chlorine Saturation Levels in the Electrolyte Adjacent to the Anode Surface

Relationship to the Polarization Curves

I. V. Kadija*

Olin Chemicals, Charleston, Tennessee 37310

ABSTRACT

Using a rotating ring electrode, we have simulated chlor-alkali and chlorate anode operation. We have detected considerable supersaturation of molecular chlorine in the electrolyte adjacent to the anode. We have also detected supersaturation in the solution bulk when simulating a chlor-alkali cell. Parts of polarization curves for the anode can be explained in terms of concentration polarization under various operating conditions.

In our earlier work (1-4) with H_2 and O_2 evolution, we used a rotating ring electrode as the operating electrode. The hydrodynamics of the rotating disk and the hydrophobic nature of Teflon (5) caused bubbles to appear at the Teflon insulator adjacent to the outer edge of the ring. Nucleation was not observed at the ring surface and consequently the surface hydrodynamics were undisturbed.

In a rotating double ring electrode combination, the outer ring electrode can be used as the analytical electrode for the species present in the solution near the operating surface. We detected in our previous work (1-4) considerable supersaturation levels of gaseous species (like H_2 and O_2) in the solution adjacent to the operating ring electrode.

The objective of this work was the measurement of steady-state gaseous chlorine concentrations in the electrolyte adjacent to the anode in chlor-alkali cells. From these measurements some reaction characteristics of chlor-alkali cells were deduced.

* Electrochemical Society Active Member.

Key words: electrolyte, anode, polarization.

Experimental Methods

The apparatus is presented in Fig. 1. The ring dimensions are shown in the figure. The rotational speed ranged from 518 to 5525 rpm, with most of our experimental conducted at 2320 rpm.

The two independent electric circuits for two ring electrodes and the rest of the apparatus were previously described (2). In addition, we had air, N_2, and Cl_2 cylinders for purging the electrolyte as required. Platinizing the platinum ring electrodes has been described elsewhere (1). Electrolytes were made with reagent grade NaCl and the pH was adjusted with HCl and NaOH solutions. The operating temperature was 25°C.

The measurement was conducted in the following manner. The thermostated electrolyte was saturated with one of the gases for several hours while disk rotated at 2320 rpm. After saturation, the limiting current at the outer ring was measured by obtaining a steady-state *i-V* curve by galvanostatic method. We have used the limiting current at the outer ring at zero current of the operating ring as a measure of the bulk

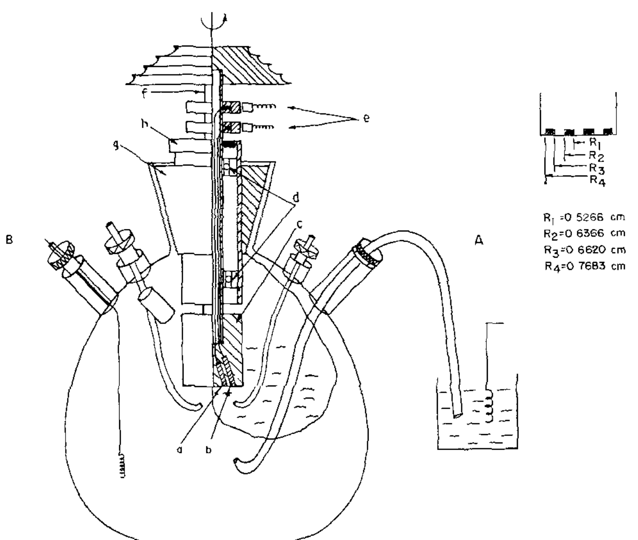

Fig. 1. Experimental cell. A, chlor-alkali cell simulation; B, chlorate cell simulation, a—inner ring, b—outer ring, c—Teflon disk body, d—ball bearings, e—sliding electrical contacts, f—titanium shaft, g—Teflon stopper, h—graphitized asbestos sealing.

saturation level with respective gas. With nitrogen atmosphere only traces of Cl_2 gave a very small limiting current. With Cl_2 we obtained 22 millimoles Cl_2/liter as chlorine solubility in our solution quite in agreement with literature (6). After establishing the bulk solution limiting current as a reference level for chlorine saturation, we have proceeded with measuring the limiting current at the outer ring at various operating current densities at the inner ring.

Hence, while the inner ring operated with a certain current density G (the range was 0.24-2.76 kA/m²) we have plotted the i-V curve at the outer ring. In-between each operating current density at the inner ring, we have rechecked the level of chlorine saturation in the bulk by repeating the limiting current measurement $G = 0$ level. In estimating the collecting efficiency of the double ring system we have used previously developed mathematical interpretations (7, 8). For each operating current G we have compared the collecting efficiency at the outer ring with the theoretically predicted value.

We simulated a chlor-alkali cell and a chlorate cell in our experiments. The chlor-alkali cell was simulated by separating the cathode from the anode (inner ring) with an electrolytic bridge (Scheme A, Fig. 1). Thus, the whole content of the reaction flask could be considered as anolyte. The chlorate cell was simulated by operating the cathode and anode in the same reaction flask. Hence, the electrolyte was considered to be chlorate cell liquor (Scheme B, Fig. 1).

Results

Chlor-alkali cell simulation.—In the cell saturated with air and without operation of the inner ring (curve $G = 0$ of Fig. 2) the detection current obtained at the outer ring was very small. As the inner ring started to operate at certain finite anodic currents, the outer ring limiting current increased correspondingly (curves $G = 0.24$ to $G = 2.64$ kA/m² of Fig. 2).

In the cell saturated with chlorine from the cylinder the limiting current obtained with the outer ring represented the saturation of chlorine in the bulk. This limiting current (curve $G = 0$ of Fig. 3) depended on the history of the cell. The $G = 0$ curve presented in Fig. 3 was obtained after the shutdown of the inner ring operation at currents higher than 0.2 kA/m².

Figure 4 shows the limiting currents plotted against operating currents for the inner ring in both of the above cases. The lower curve is for the air-purged cell. This curve followed the theoretical prediction until

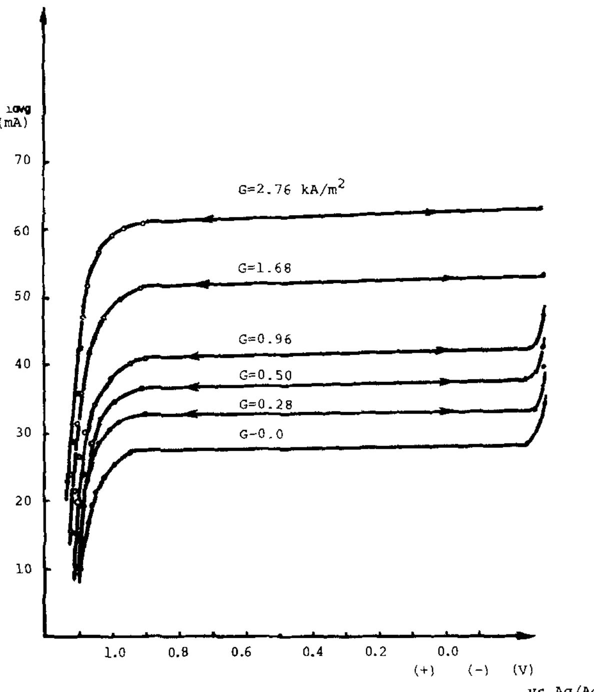

Fig. 3. Outer ring polarograms for Cl_2 reduction, pH = 0.5, 300 g/liter NaCl, 25°C. Cell saturated with Cl_2 under operating conditions.

medium current densities were reached. At current densities above 1 kA/m² there was a deviation from the theoretical prediction and the observed limiting current was lower by 20-25%.

A similar shape (upper curve on Fig. 4) was obtained with Cl_2-saturated solution. At currents lower than 0.2 kA/m², the detection level is considerably smaller than one would predict by extrapolation from the higher current densities. As shown in Fig. 5 and 8, at lower current densities or no current from the inner ring the steady-state $G = 0$ level dropped considerably.

Figure 5 shows the change in Cl_2 concentration after the anode is shutdown with continued stirring. A few seconds after the shutdown at operating currents higher than 0.2 kA/m², the Cl_2 concentration level was much higher and corresponded to a Cl_2 saturation of

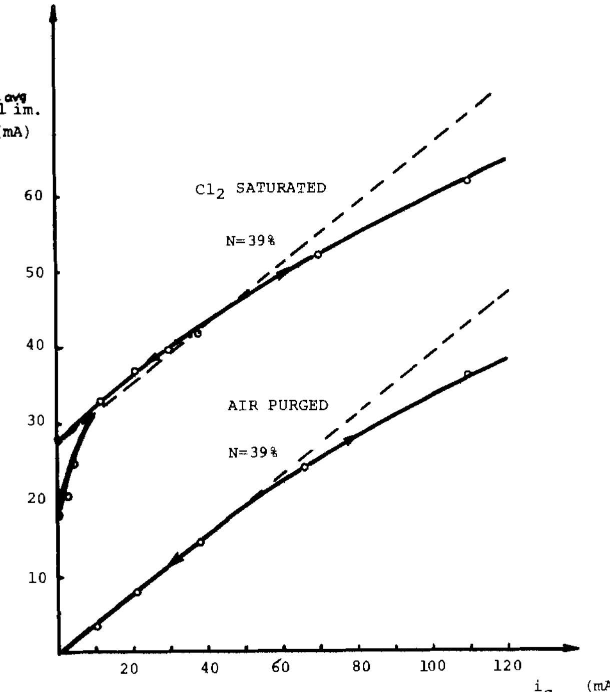

Fig. 4. Outer ring limiting current *vs.* operating current *G* on inner ring. pH = 0.45 and 0.50, 300 g/liter NaCl, 25°C.

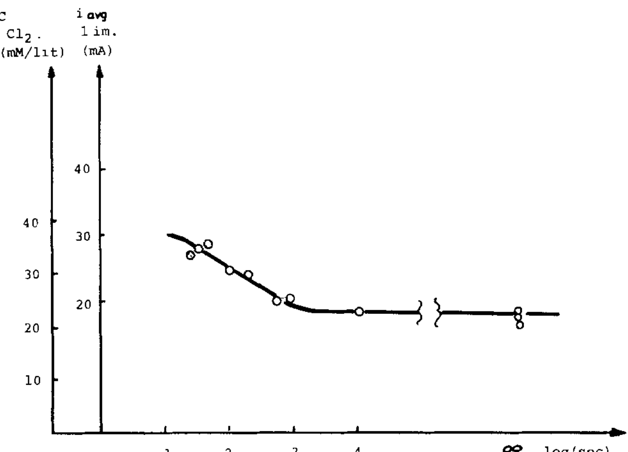

Fig. 5. Bulk Cl_2 reduction limiting current and concentration as a function of time after the anode shutdown.

170-190% compared to equilibrium with a pressure of 1 atm over the solution. The level of Cl_2 in the bulk after a few hours of stirring without current was the same as that obtained by Cl_2 bubbling at 1 atm.

Chlorate cell simulation.—Figure 6 shows the outer ring polarograms obtained at different operating current densities at the inner ring. Four identifiable waves were reproducibly obtained with the outer ring. The first wave from the open circuit corresponds to the chlorine reduction reaction. We suspect that the other three waves correspond to reactions involving ClO^-, ClO_2 radical, or ClO_2^-. We are continuing our investigation in order to positively identify the species as well as the possible interference of platinum oxides reduction.

In order to measure the bulk chlorine saturation we operated our cell for 16 hr at 2.4 kA/m², and immediately after the shutdown obtained the curve $G = 0$ with the outer ring. We could not identify any chlorine in the bulk. The two species identified were probably due to minute amounts of ClO^- and some platinum oxide reduction.

We present the limiting current for chlorine reduction in Fig. 7 as a function of operating current. We

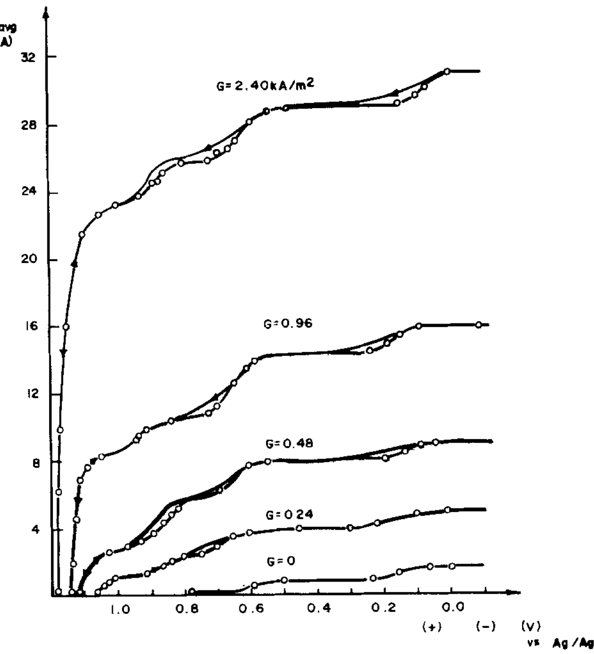

Fig. 6. Reduction polarograms obtained on the outer ring during chlorate cell simulation at different current densities. pH = 6.5-7.3, 200 g/liter NaCl, 25°C. Same hydrodynamic conditions and surface quality as in chlor-alkali cell simulation.

also compare the collection levels for molecular chlorine in two cases: chlor-alkali simulation purged with air, and chlorate cell simulation, both at 2320 rpm. The numbers beside each data point indicate the percentage of detection in the chlorate cell compared to detection at the same operating current in the chlor-alkali cell. The asymptotic approach to the 60-70% detection level is shown in the bottom right graph.

Figure 8 shows the polarization curves for the same anode at the same rotation speed in the three solutions tested above: B_1 = chlor-alkali cell saturated with Cl_2, B_2 = chlor-alkali cell purged with nitrogen (the air replaced with nitrogen to avoid any influence of

O_2 on potential at low current densities), and B_3 = chlorate cell.

Discussion

Chlor-alkali cell.—The dashed lines in Fig. 4 indicate the limiting currents one should obtain at the outer ring if the species formed on the inner ring is dissolved and can be reduced or oxidized on the outer ring with the same number of electrons per molecule as required for its formation on the inner ring. Since our experimental evidence agrees with the theoretically predicted lines, we can assume that most of the chlorine generated at the inner ring crosses the electrode-liquid interface as a dissolved species.

Some deviations are noticeable at higher current densities. We attribute this to the so-called "bubble gate" effect [see Ref. (4)]. At less than 15 mV polarization the bubbles wetting angle is 90°-110°. Bubbles are attached to the Teflon insulator and penetrate deeper into the solution bulk. As polarization increases, the bubbles wetting angle becomes smaller and so the necks become shorter and bubbles bodies start to interfere with the mass transfer between the two rings. This results in a 20-25% decrease in collecting efficiency at polarizations of 60-80 mV.

The upper curve in Fig. 4 also shows deviations from the predicted line at very low currents but only if the Cl_2 is depleted in the bulk (see Fig. 5). Otherwise, at higher current densities, this curve follows the theoretical predictions, indicating that most of chlorine is produced as dissolved species.

Hence, we suggest the following chlorine production mechanism at the anode surface, regardless of the electrode kinetics phenomena

$$2Cl^- = Cl_2 + 2e^- \text{ (electrode surface)} \quad [1]$$

$$Cl_2 \text{ (electrode surface)} \rightarrow Cl_2 \text{ (diffusion layer)} \quad [2]$$

$$Cl_2 \text{ (diffusion layer)} \rightarrow Cl_2 \text{ (bulk)} \quad [3]$$

or

$$F_{Cl_2(\text{Surface/liquid interface})} \approx F_{Cl_2(\text{bulk})} \quad [4]$$

where F_{Cl_2} are the respective fluxes of molecular chlorine.

One finds that it is frequently assumed that the liquid adjacent to the electrode surface can be saturated with gaseous products up to the extent which corresponds to 1 atm pressure of the respective gas. This conclusion is usually based on visual observation of the electrode surface. However, the evidence of extensive bubbling from the electrode surface does not necessarily indicate that saturation stays close or equivalent to 1 atm pressure regardless of the current density. It was already indicated in literature that the saturation can reach far in excess to the one corresponding to 1 atm pressure (9-12). Our findings with O_2 and H_2 have confirmed that also (4). Due to the nature of operation of a ring electrode, we have been able to measure the actual saturation levels at the operating surface which was not covered with bubbles.

The following is our calculation of the surface liquid saturation level as a function of current density and diffusion layer thickness. For a more accurate saturation and equivalent pressure distribution, we have developed the analysis shown in the Appendix of this paper.

In the first approximation for surface concentration calculation one can use the Nernst equation

$$C_{Cl_2(\text{surface})} = C_{Cl_2(\text{bulk})} + \frac{\delta_{avg} i_{avg}}{zFD_{Cl_2}} \quad [5]$$

where δ_{avg} is diffusion layer thickness.

For a ring type electrode δ_{avg} is an average diffusion layer thickness as calculated by the Levich equation

$$\delta_{avg} = 1.61\, D_{Cl_2}^{1/3} \nu^{1/6} \omega^{-1/2} \left(1 - \frac{r_0^3}{r_1^3}\right)^{1/3} \quad [6]$$

where $D_{Cl_2} = 1.22 \times 10^{-5}$ cm/sec^2, $\nu = 1.75 \times 10^{-2}$ poises, $\omega = 2320$ rpm, $r_0 = 0.5266$ cm, and $r_1 = 0.6398$ cm.

Introducing numerical values in Eq. [5] we obtain the following equation that can be used to estimate the surface Cl_2 concentration in millimole/liter as a function of current density and diffusion layer thickness

$$C_{Cl_2 \text{ avg (surface)}} = 40 + 4.3 \cdot i_{avg} \cdot \delta_{avg} \quad [7]$$

where δ_{avg} is in microns and i_{avg} is in kA/m^2.

The Cl_2 solubility at 1 atm and 25°C is 22 millimoles/liter atm. Hence, through Henry's constant, one can calculate the equivalent average pressure of gas saturation in the solution adjacent to the operating surface

$$P_{Cl_2 \text{ (surface)}} = 1.82 + 0.2 \cdot i_{avg} \cdot \delta_{avg} \quad [8]$$

where i_{avg} and δ_{avg} have same units as in Eq. [7].

Chlorate cell.—In a chlorate cell, chlorine hydrolyzes into hypochlorous ions which in turn disproportionate to form chlorate

$$Cl_2 + H_2O \rightarrow HClO + Cl^- + H^+ \quad [9]$$

$$HClO = ClO^- + H^+ \quad [9a]$$

and

$$2HClO + ClO^- \rightarrow ClO_3^- + 2Cl^- + 2H^+ \quad [10]$$

Hence, molecular chlorine present in the anode-surface electrolyte converts into chlorate at a certain overall rate. The rate of the reaction, [10] and [11], is a function of pH. The optimum condition for the conversion is pH 6.5-7.5.

During the anode operation chlorate may form electrochemically

$$6ClO^- + 3H_2O \rightarrow 2ClO_3 + 4Cl^- + 6H^+ + 3/2\, O_2 + 6e^- \quad [11]$$

This reaction becomes diffusionally limited if the ClO^- concentration in the bulk is too small. Also, reaction [9] causes slightly acidic conditions at the anode

surface; this acidity considerably reduces the rate of the electrochemical reaction (11). We performed our experiments with a dilute hypochlorous ion concentration. Figure 6 shows the $G = 0$ detection curve which indicates only traces of hypochlorous ion or other intermediates in the solution bulk. Under such operating conditions, and especially at higher current densities, one can assume that anode chlorine production efficiency is close to 100%.

The solution layer adjacent to the anode surface became more concentrated with Cl_2 as current increased. The concentration should follow the current density in a manner similar to that observed in the chlor-alkali cells. Our results in Fig. 6 and 7 indicate that the chlorine saturation at the surface increases with the operating current density. However, there appears to be an asymptotic approach to the level of 66% compared to the chlor-alkali cell. Ibl *et al.* [Ref. (13) and (15)], Jakšić (14), and others have indicated that the reaction may occur apart from the electrode surface but still within the limits of the diffusion layer. Our experimental evidence seems to confirm this. A part of the reaction must also take place in the transition region from the inner to the outer ring for the time necessary for transfer of the species from the inner to the outer ring.

In spite of these speculations, there is clear evidence of surface saturation with chlorine. Assuming that transfer and diffusional conditions are similar to a chlor-alkali cell, one can write the following equation

$$C_{Cl_2\ avg(millimole/liter)} = 66\ i_{avg} \qquad [12]$$

where i_{avg} is in kA/m^2 and δ_{avg} is taken as 23 μm for the 2320 rpm.

In the early 1960's T. Beck proposed the following equation to describe the chlorine concentration at the anode surface as a function of the current density in chlorate cell

$$C_{Cl_2\ avg} = \frac{\left(\frac{D_2}{k}\right)^{1/2} \cdot i_{avg}}{2 \cdot F \cdot D_2} \qquad [13]$$

The rate constant k for the reaction is proposed to be about 0.2 sec^{-1} (14).

Instead of 23 μm in production, one can have diffusion layer thicknesses of 100-120 μm as proposed and measured by Ibl (13). With this value for δ_{avg} our empirical equation will give concentration levels similar to those predicted by Eq. [13].

Concentration polarization.—We have calculated the equivalent average pressure (8) of molecular chlorine at the anode surface at several polarization data points. These are presented in the graphs in Fig. 8.

Curve B_1.—The anode operating in a chlorine saturated solution did not experience polarization at current densities below 0.05-0.07 kA/m^2. There was no polarization since the surface chlorine concentration and corresponding pressure was only slightly higher than in the bulk. In addition, the surface was catalytically active (exchange current was higher than operating current at low current densities). At higher current densities, however, both concentration and activation polarization were evident.

Curve B_2.—In nitrogen atmosphere the major source for chlorine at the surface is the Cl^- oxidation current. Hence, as the current increased the chlorine concentration at the surface increased. The dependence was linear and consequently for an order of magnitude of current change we obtained 30 mV of polarization due to a tenfold increase in chlorine saturation at the surface.

At higher current densities the activation polarization adds to the overall polarization and, therefore, curves B_1 and B_2 coincide. However, one has to bear in mind that the 30 mV/dm concentration polarization is present also at higher current densities. We measured the chlorine saturation gradual increase with current density and this is shown by higher equivalent pressure.

Curve B_3.—The behavior was similar to that observed in the chlor-alkali cell purged with nitrogen (B_2). In the chlorate cell the chlorine concentration in the bulk was very low. Here, Cl_2 was consumed in the hydrolysis reaction. However, the resulting species OCl^- is also electrochemically active at the platinized platinum surface. Therefore, at low current densities and at open circuit, the polarization curve shows potentials which are a result of a mixed reaction where hypochlorous ions were oxidized and chlorine evolved simultaneously.

In the presence of low ClO^- content at moderately low currents 0.02 kA/m^2 or higher) the hypochlorous reaction became diffusion-limited. As the potentials increased, the current generated chlorine under surface conditions similar to that in the nitrogen purged chlor-alkali cell. Consequently, the shapes of the curves became very similar.

The coincidence of the three curves at higher current densities indicates that the surface electrochemical discharge and the chlorine saturation are practically independent of the conditions in the bulk at high reaction rates.

As a hypothetical result, we have plotted Curve A (Fig. 8) assuming no concentration polarization. This allows the initially low Cl_2 concentration in the bulk to be taken as a reference Cl_2 concentration. The resulting curve obviously contradicts the experimental findings. Hence, small bulk concentration of Cl_2 has little bearing on the polarization curves and cannot be used as reference level for the polarization curve.

Conclusions

1. In chlor-alkali simulation, rotating ring electrode operates with considerable supersaturation of molecular chlorine in the adjacent electrolyte. The supersaturation is a linear function of current density.
2. At current densities lower than 0.03 kA/m^2 in chlorate cell simulation, there is no evidence of surface chlorine saturation. At higher current densities, the saturation follows the current density but to a lesser degree than experienced in the chlor-alkali cell.
3. The bulk solution in a chlor-alkali cell can experience chlorine concentrations saturated to the level of 170-190% under operating conditions.
4. Part of the anode polarization curve can be interpreted in terms of concentration polarization in chlor-alkali as well as in chlorate cell operation.
5. We believe that the uneven reactant concentration distribution at the ring surface (see Appendix) has little bearing on our finding. Under our operating conditions, molecular chlorine is primarily produced as dissolved species.
6. Although these findings could be a more general nature, one cannot safely apply our empirical equations on other experimental apparatus without careful study.

Considering the nature of the steady state of gas-producing reactions, we believe that one might obtain similar results with plane electrodes as suggested by Landolt, Mueller, and Tobias (20). However, it appears that ring electrodes are more feasible to build and operate.

Manuscript submitted June 4, 1979; revised manuscript received Sept. 24, 1979. This was Paper 283 presented at the Boston, Massachusetts, Meeting of the Society, May 6-11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

APPENDIX

Current Distribution for Chloride Oxidation

It is generally accepted that a rotating disk electrode is a uniformly accessible surface. This assumption allows the investigation without any particular consideration of possible uneven distribution of reaction rate across its surface. However, one must bear in mind that the so-called uniformity of the rotating disk operation applies only to limiting current conditions as indicated by Newman (16).

Ring electrodes are not uniformly accessible even under limiting current operation. This is true predominantly because of the flow pattern of the solution across the ring surface. Solution flows from the inner towards the outer edge of the ring. This pattern creates considerable differences between the two edges. The inner edge is influenced more by the bulk solution while the outer edge operates in the solution saturated with electrochemical reaction products accumulated in the surface solution. These mechanics of operation require a thorough analysis of the operating conditions to estimate the possible influence on the experimental data.

The recent publications of Pierrini, Parrish, and Newman (17, 18) probably best describe the present understanding of the phenomena involved.

The article (17) which deals with ring electrodes current distribution plots several parameters important for the characterization of the investigated reaction. We have used these parameters to characterize the feasibility of our ring electrode system.

Dimensionless exchange current density (J).—J is described by Eq. [9] of the article (17)

$$J = \frac{i_0 r_1 \mathbf{F}}{RT\kappa} = 5 \quad \text{[A-1]}$$

where (i) is the characteristic exchange current density assumed to be 50 mA/cm^2, and conductivity of the bulk solution $\kappa = 0.25\ cm^{-1}$. J values are indications of the reaction reversibility. $J = 1$ or close are considered medium rate reversibility reaction and, consequently, $J = 0$ or close are rather irreversible reactions. J values above one are considered as fast reactions and above 100 are very fast reactions.

Dimensionless stirring rate (N).—N is described by Eq. [10] of the above article

$$N = \frac{r_1{}^2\omega^{1/2}}{\nu}\left(\frac{0.51}{3D_{Cl^-}}\right)^{1/3}\frac{\mathbf{F}^2 D_{Cl^-} C_{Cl^-}}{RT} = 200 \quad \text{[A-2]}$$

where (ω) is 38.67 sec^{-1}, 1.75×10^{-2} poise, and $D_{Cl^-} = 1.6 \times 10^{-5}\ cm/sec^2$. N defines the influence of the mass transport on the reaction rate. For finite N values there is always a certain influence of the mass transport phenomena on reaction rate and concentration distribution at the surface. For infinite values of N, the surface concentration is same as in the bulk.

Our value of 200 indicates that at the 2320 rpm there was still some influence of mass transport on the surface concentration and operating conditions. With our RDRE system, N could be varied between 100-300.

Ring radii ratio (r_0/r_1).—The ratio of the ring radii is an important parameter when defining operating conditions for the ring electrode. The values of 0.5-0.7 are considered to be ratios that indicate the ring electrode behavior typical for ring type surfaces. That is, they do not simulate the disk or a plane type electrode. Smaller values indicate that a behavior similar to disk electrode can be expected. Larger values (thin ring electrodes) tend to simulate the current and concentration distributions typical for plane electrodes (18).

Our ratio is

$$\frac{r_0}{r_1} = 0.823 \quad \text{[A-3]}$$

Hence, a typical or close to plane electrode current distribution can be expected when operating with such electrode.

Operating vs. limiting current.—By means of the Levich (19) equation for limiting current, we can estimate the limiting current for chloride oxidation from the brine

$$i_{\text{avg LIM}} = (0.62\mathbf{F}C_{Cl^-}D_{Cl^-}{}^{2/3}\nu^{-1/6}\omega^{1/2}) \Big/ \left(1 - \frac{r_0{}^3}{r_1{}^3}\right)^{1/3} \quad \text{[A-4]}$$

$$i_{\text{avg LIM}} = 2.5\ A/cm^2$$

In this work, we operated with current densities 1-200 mA/cm^2. Hence, our operating current *vs.* limiting current ratio is

$$\frac{i_{\text{avg}}}{i_{\text{avg LIM}}} = 4 \times 10^{-4} - 0.12 \quad \text{[A-5]}$$

Keeping this parameter in mind, we analyzed the information presented by Newman and others (17, 18). It appears that the closest current distribution description is given in Fig. 8 of Ref. (17). We do have a redox couple Cl^-/Cl_2 with a relatively large exchange current. We are also operating at small $i_{\text{avg}}/i_{\text{avg LIM}}$ ratios. Thus, the curves for ratio = 0.2 best represent our current distribution across the ring electrode width.

Using this information, we plotted our current distribution curve (see on Fig. 9, curve a) and obtained a rather uniform distribution over most of the ring width. However, at the edges, we obtained values equal to 2 to 2.5 times greater than i_{avg}.

Molecular Chlorine Concentration Distribution Across the Ring Electrode Width

Our electrochemical reaction product diffuses into solution. Hence, there is always a concentration gradient between the surface and the bulk. This condition requires the analysis of diffusion layer thickness *vs.* the ring width and it is described by Levich (19).

Figure 9 (curve b) shows the relative change of diffusion layer thickness against the ring width. At the inner edge it is about 40% of the δ_{avg} and at the outer edge it is about 40% thicker.

By means of curves a and b one can obtain the resulting concentration distribution across the ring width. We used the numerical solutions for several r values using Eq. [7] of this manuscript and obtained curve c, assuming $C_{Cl_2\,(\text{bulk})} = 0$.

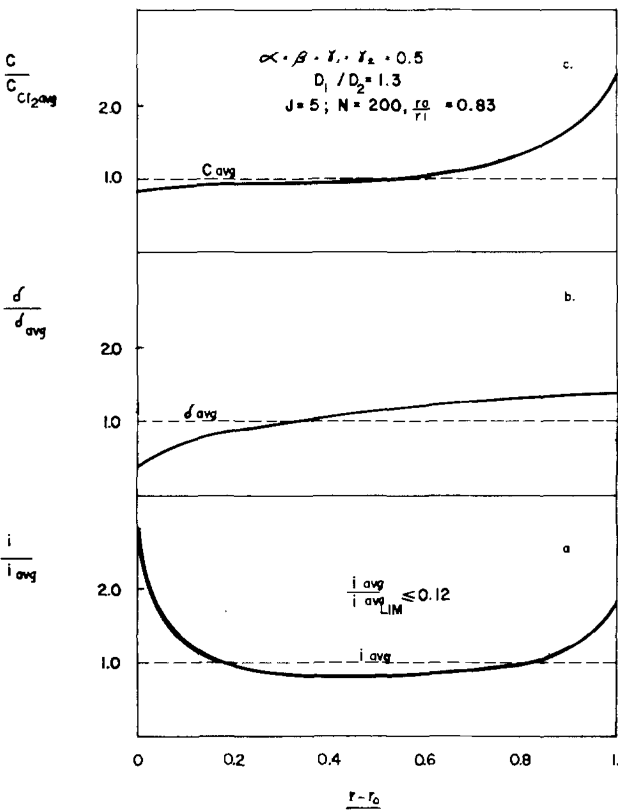

Fig. 9. Distribution of: a, current, b, diffusion layer thickness, and c, molecular chlorine concentration across the operating ring.

One can see that the surface concentration of molecular chlorine appears quite uniform for most of the operating surface. It is interesting, however, that the outer edge of the ring electrode operates with concentrations 2-2.5 times higher than average.

LIST OF SYMBOLS

$C_{Cl_2\,avg}$ average concentration of molecular chlorine on the operating electrode surface
$C_{Cl_2\,bulk}$ concentration of molecular chlorine in solution bulk
$D_{1,2}$ chloride ion and molecular chlorine diffusion coefficients, cm^2/sec

An Engineering Model for Electro-Organic Synthesis in Continuous Flow-Through Porous Electrodes

Richard C. Alkire* and Ronald M. Gould*[,1]

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Under controlled experimental conditions, 9-10 diphenylanthracene (DPA) was oxidized in a sectioned flow-through porous electrode in order to study the relation between operating conditions and product yield. The DPA solution contained 0.2*N* tetraethylammonium perchlorate in acetonitrile. The electrode was fabricated from 100-mesh platinum screens. The reaction rate distribution within the sectioned electrode was measured directly, and the reactor effluent was analyzed to obtain the concentrations of DPA and its cation radical (DPA^+). Experimental data were compared with calculations based on flow-through porous electrode theory with consideration of the multiple reaction sequence (EEC) under study. Literature values, where available, were used without adjustment in making theoretical calculations with use of a mathematical model of the reactor system. The model calculations predicted total currents which were within 4% of experimental data, and gave good agreement with current distribution data at various flow velocities and applied potentials.

Synthesis of organic compounds by electrolysis can usually be carried out with high selectivity provided that the potential along the electrode surface is essentially uniform. In order to achieve large reaction rates per unit volume, a necessary conjunct of large-scale processes, porous electrodes are often used since they possess large internal surfaces on which heterogeneous charge-transfer reactions may occur. One consequence of using such electrodes is that interior mass transfer and ohmic resistance effects may lead to a nonuniform potential distribution, thereby affecting adversely the selectivity which might otherwise be achieved. Defining the optimal trade-off between high selectivity and high reaction rate is clearly an important engineering design consideration.

The relation between design parameters and reactor performance is particularly complex in the case of most electro-organic processes owing to the interaction

Key words: electro-organic, porous electrode, flow, mathematical model.

of multiple reactions which invariably occur. Therefore, it seems reasonable that mathematical models would find use in engineering design, optimization, and scale-up of high rate electro-organic synthesis reactors. In this investigation, the reaction distribution within a flow-through porous electrode was measured experimentally and compared with predictions based on a mathematical model of the electro-organic reaction system.

MacMullin (1) provided a classic discussion of important engineering considerations involved in scale-up of electro-organic processes. Recent vigorous industrial activity has been described in a symposium on electro-organic synthesis technology (2). An indexed bibliography of electro-organic synthesis literature (3) has recently been compiled and utilized as a data base in the evaluation of possible candidates for electrochemical synthesis of high tonnage organic chemicals (4). A variety of high rate electrochemical reactor designs has been critically reviewed by Houghton and Kuhn (5). In particular, past literature on fixed-bed flow-through porous electrode systems has recently been collected and discussed (6).

Electrochemical behavior in the presence of multiple reactions has received considerable attention during recent years. Early electroanalytical investigations successfully analyzed data on EC and ECE sequences by assuming that chemical reaction occurred primarily in the bulk of the solution (7-9). Branching mechanisms in electro-organic systems have been treated in an analogous manner (9, 10). The foregoing analyses generally assumed that the primary reaction occurred under mass transfer control and that the secondary reaction proceeded at a rate characterized by its half-wave potential. Analyses have also been presented for multiple reactions in flow systems in which the presence of a mass transfer boundary layer along a solid electrode was included in the model (8, 11-14); of these theoretical papers, one included experimental verification (12).

Extension of the foregoing principles to porous electrode applications has taken place only recently. The first theoretical treatment (15) evaluated several types of reaction mechanisms, including an electro-organic ECE sequence, and has been the basis for experimental investigations (16), including that reported in the present publication. Other recent studies on two-step reactions evaluated the interaction of convection, axial diffusion, and ohmic resistance (17). Theoretical models have been developed for parasitic reactions where the secondary reaction occurs at a rate characterized either by its half-wave potential (18) or by a linear approximation to the surface polarization equation (19). The importance of feeder plate and counterelectrode placement in minimizing current loss by secondary reactions has also been emphasized (20).

The purpose of the present investigation was to relate the synthesis performance of a flow-through porous electrode reactor to the design parameters which characterized the electrode. The oxidation of 9-10 diphenylanthracene, a reaction sequence which exhibits two successive electrochemical steps followed by a homogeneous chemical reaction, was studied in a porous electrode which was designed to permit measurement of local reaction rates within the cell. Electrolyte flow occurred parallel to the flow of electrical current in the solution phase; the counterelectrode was in the downstream position. A mathematical model of the porous electrode was developed for comparison with the experimental data.

Experimental Apparatus and Procedures

Specific details of cell and electrode design, flow system, and electronic measurements are available elsewhere (21). Therefore, only a brief summary is provided here. The cylindrical anode chamber shown schematically in Fig. 1 was fabricated by drilling out a solid piece of Teflon. The flow-through sectioned anode consisted of a stack of 100-mesh platinum screens, 13 mm diam. Electrical contact to each electrode section was made with thin gauge Pt wire fed through the side wall; electrode sections were insulated from each other with Teflon gauze. The counterelectrode (consisting of 80-mesh nickel screen) was positioned in the flow loop downstream from the anode. An aqueous saturated calomel reference electrode (A. H. Thomas Company, No. 4092-F15) was used following procedures recommended elsewhere (22); contamination of the flow system with water was avoided by forming the liquid junction external to the flow circuit. Samples of electrolytic solution were withdrawn through Teflon tubing. A potentiostatic power supply was used to control anode potential with respect to the reference electrode. A multichannel zero-resistance operational amplifier circuit was used to measure individual section currents while maintaining all sections at the same potential.

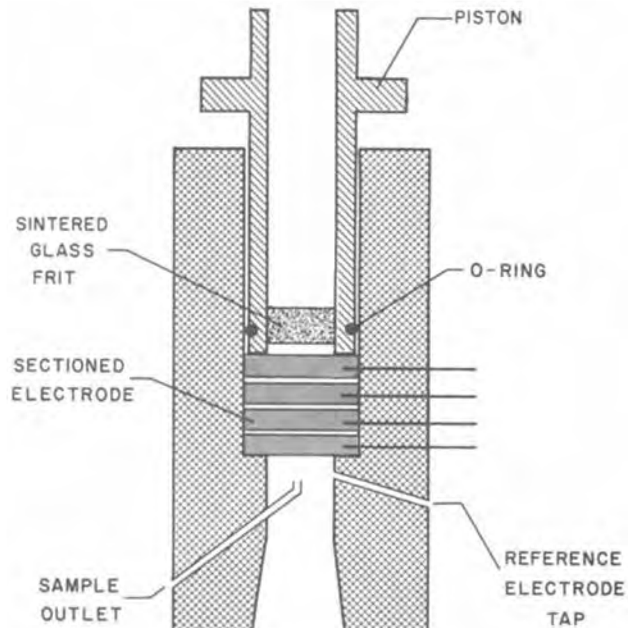

Fig. 1. Cross-sectional diagram of the assembled experimental cell.

Electrolyte was freshly prepared under dry nitrogen with the composition 0.0015M 9-10 diphenylanthracene (Aldrich Chemical Company, "Gold Label" No. D20,500-1), 0.2*N* tetraethylammonium perchlorate (G. F. Smith Chemical Company, polarographic grade) in acetonitrile (Aldrich Chemical Company, "Gold Label" spectrograde No. 15,460-1). Chemicals were used without further purification; the supplier specifications indicated a maximum of 0.03% water in the solvent. The refractive index, viscosity, and conductivity of the acetonitrile solvent were measured and found to be in agreement with literature data (23). Because absorption of atmospheric moisture affects oxidation of the 9-10 diphenylanthracene cation radical (24), the enclosed flow system was purged with copious quantities of dry nitrogen prior to introduction of electrolyte and was maintained under nitrogen atmosphere throughout the course of experimentation.

Prior to conduct of electrolysis, a sample of solution was withdrawn through the upstream sample port. After establishing flow in the system, an anodic potential sweep was carried out at 1 mV/sec over the range 0-2500 mV with respect to SCE. The background current at 900 mV *vs.* SCE was typically less than 1% of the measured value. The potential was then set to various constant values; at each value, the system was allowed to reach steady state, at which time a 1 ml downstream (outlet) sample of electrolyte was withdrawn. In a like manner, data and solution samples were obtained at various flow rates.

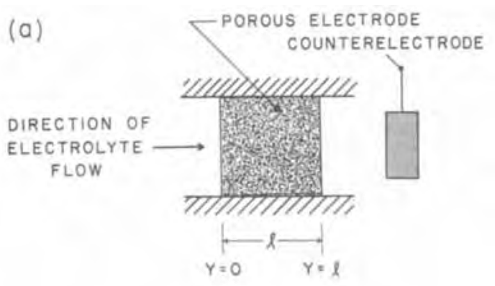
The solution samples were investigated by u.v. absorbance spectrophotometry to measure concentrations of 9-10 diphenylanthracene (DPA) and the cation radical (DPA^{+}). Each electrolyte sample was diluted to 10 ml with pure acetonitrile; the blank was pure acetonitrile. Absorbances at 321 and 372.5 nm were recorded and concentrations were calculated based on molar absorptivities as reported elsewhere (25). Analysis of inlet samples was accurate to within ±1.5%. Analysis of downstream samples was less certain owing to the half-regeneration reaction of the cation radical with residual water (24, 25). The error inherent in determination of DPA and DPA^{+} in the effluent is ±10%.

Since instability of the dication (27) prevented direct quantitative analysis, the DPA^{+2} concentration was estimated by a mass balance about the cell with assumption of 100% current efficiency; the error inherent in this procedure is therefore also on the order of 10%.

Theoretical Model

Since the model developed here parallels general procedures that have been outlined previously (15), the following paragraphs are intended only for the purpose of brief description. The geometry of the porous electrode is depicted in Fig. 2(a). Electrolyte flow is in the direction of the y-coordinate, the electrode is of thickness l, and the counterelectrode is downstream from the porous electrode. Other details of cell construction are not taken into account in development of the model. Electrolyte percolates through the porous matrix, supplying reactants to the interior solid surface where electrochemical reaction occurs. The local reaction rate varies with position since the potential and species concentration vary within the electrode owing to ohmic and transport limitations. The following model equations were used to compute the reaction rate distribution throughout the porous electrode and, thereby, to predict the product spectrum in the effluent stream.

Steady-state operation under isothermal conditions is treated. The electrode phase is isopotential, is of uniform porosity, and has pore dimensions which are large with respect to the double layer thickness. The solid surface of the interior region may be of arbitrary configuration since it is accounted for in the following model by a specific area term. Hydrodynamic and mass transport processes occurring within the pore structure are illustrated in Fig. 2(b). Convection through the electrode is assumed to occur by plug flow. Mass transport of reactant species from the central region of the pores to the surface is assumed to occur across a mass transfer diffusion layer which occupies a negligible fraction of the pore volume. By this view, homogeneous chemical reactions would occur primarily in the well-mixed core region. Conduction in the solution phase obeys Ohm's law and migration effects are negligible owing to the presence of supporting electrolyte. The foregoing constraints allow the model equations to be written in a one-dimensional form in which the heterogeneous electrochemical reactions appear as pseudohomogeneous source terms.



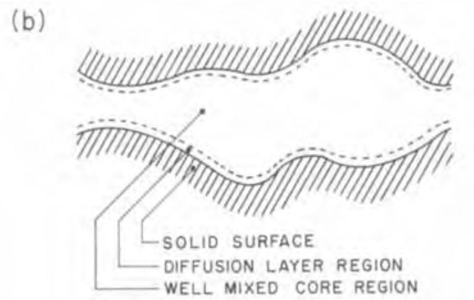


Fig. 2. Schematic diagram of porous electrode

In the electrolyte there are i reactive solute species which take part in a total of j reactions, which may be either heterogeneous or homogeneous. The stoichiometry of the reactions is defined by

$$\sum_i \nu_{ij} M_i^{+z_i} = n_j e^- \qquad [1]$$

In addition to the i reactive solute species, there may be additional inert species which do not take part in the reactions and which are not taken into account in the analysis.

The steady-state one-dimensional species conservation equations are

$$D_i \frac{d^2}{dy^2}[c_i(y)] - v\frac{d}{dy}[c_i(y)] = \sum_j \nu_{ij} S_{ij} \qquad [2]$$

Any particular reaction involving species i will be either heterogeneous (electrochemical) or homogeneous (chemical). Heterogeneous reactions take place on the interior surface and obey a rate equation in which the surface concentration appears

$$S_{ij} = \frac{a}{n_j \mathbf{F}} f_j^e [c_i^s(y), \phi(y)] \qquad [3]$$

Homogeneous reactions take place in the "core" of the flowing electrolyte within the porous electrode and obey rate equations in which the core concentrations appear

$$S_{ij} = f_j^h [c_i(y)] \qquad [4]$$

The specific form of the rate equations f_j^e and f_j^h will of course depend on the particular reactions as is illustrated below.

The local concentration difference between surface and core are related to the heterogeneous reaction rate through the mass transfer coefficient

$$f_j^e[c_i^s(y), \phi(y)] = \nu_{ij} n_j k_i \mathbf{F}[c_i^s(y) - c_i(y)] \qquad [5]$$

The one-dimensional charge balance equation is

$$\frac{d^2}{dy^2}[\phi(y)] = \frac{a}{\kappa}\sum_j f_j^e [c_i^s(y), \phi(y)] \qquad [6]$$

Equations [2], [5], and [6] comprise a set of (2i + 1) relations which are sufficient in number to determine the (2i + 1) unknown functions: $c_i(y)$, $c_i^s(y)$, and $\phi(y)$. Whereas Eq. [5] is algebraic, [2] and [6] are differential equations and therefore require boundary conditions.

When the counterelectrode is downstream

at $y = 0$

$$c = c_i^o$$

$$\frac{d\phi}{dy} = 0$$

at $y = 1$

$$\frac{dc_i}{dy} = 0 \qquad [7]$$

$$\phi = \phi^o$$

The following general reaction notation will be used to characterize the anodic E-E-C sequence studied in this investigation

$$M_1 \rightarrow M_2 + e^- \text{ (electrochemical)} \quad [8]$$

$$M_2 \rightarrow M_3 + e^- \text{ (electrochemical)} \quad [9]$$

$$M_3 + M_4 \rightarrow M_5 \text{ (chemical)} \quad [10]$$

It will be assumed that the two electrochemical reactions proceed with reversible Butler-Volmer rate expressions, while the chemical reaction is first order in each reactant and is irreversible. That is

$$f_1^e = i_{o1}\left\{\frac{c_1^s}{c_1^o}\exp\left[\frac{\alpha_1 n_1 \mathbf{F}\phi}{RT}\right] - \frac{c_2^s}{c_2^o}\exp\left[\frac{-\beta_1 n_1 \mathbf{F}\phi}{RT}\right]\right\} \quad [11]$$

$$f_2^e = i_{o2}\left\{\frac{c_2^s}{c_2^o}\exp\left[\frac{\alpha_2 n_2 \mathbf{F}}{RT}(\phi+\phi_r)\right] - \frac{c_3^s}{c_3^o}\exp\left[\frac{-\beta_2 n_2 \mathbf{F}}{RT}(\phi+\phi_r)\right]\right\} \quad [12]$$

$$f_3^h = k_c c_3 c_4 \quad [13]$$

In these equations, ϕ is the potential with respect to the rest potential of reaction [8], while ϕ_r is the thermodynamic rest potential of reaction [8] with respect to reaction [9]. The rest potential difference is computed by consideration of the ionic concentration of reactants as they enter the porous electrode. Note that the electrochemical reaction rate depends on the concentration at the surface, c_i^s, while the homogeneous reaction rate depends on the concentrations in the well-mixed core, c_i.

By defining the dimensionless variables

$$C_i = \frac{c_i}{c_i^o}, \quad Y = \frac{y}{l}, \quad \Phi = \frac{\mathbf{F}\phi}{RT}, \quad \Phi_r = \frac{\mathbf{F}\phi_r}{RT} \quad [14]$$

and by following the manipulations described previously (15), the equations for this coupled system are found to be

$$\begin{aligned} C''_1 - \zeta_1 C'_1 &= + \chi_1 F_1 \\ C''_2 - \zeta_2 C'_2 &= + \chi_2[F_2 - F_1] \\ C''_3 - \zeta_3 C'_3 &= - \chi_3 F_2 + \Lambda_1 C_3 C_4 \\ C''_4 - \zeta_4 C'_4 &= \Lambda_2 C_3 C_4 \\ C''_5 - \zeta_5 C'_5 &= - \Lambda_3 C_3 C_4 \\ \Phi'' &= \xi_1 F_1 + \xi_2 F_2 \end{aligned} \quad [15]$$

where

$$F_1 = \frac{C_1 \exp[\alpha_1 n_1 \Phi] - C_2 \exp[-\beta_1 n_1 \Phi]}{1 + \frac{\xi_1}{\Gamma_1}[\exp[\alpha_1 n_1 \Phi] + \lambda_1 \exp[-\beta_1 n_1 \Phi]]}$$

$$F_2 = \frac{C_2 \exp[\alpha_2 n_2(\Phi+\Phi_r)] - C_3 \exp[-\beta_2 n_2(\Phi+\Phi_r)]}{1 + \frac{\xi_2}{\Gamma_2}[\exp[\alpha_2 n_2(\Phi+\Phi_r)] + \lambda_2 \exp[-\beta_2 n_2(\Phi+\Phi_r)]]}$$

$$\zeta_i = \frac{vl}{D_i}$$

$$\Gamma_i = \frac{a k_i n_i \mathbf{F}^2 l^2 c_i^o}{\kappa RT}$$

$$\xi_i = \frac{i_{oi} a l^2 \mathbf{F}}{\kappa RT}$$

$$\chi_i = \frac{i_{oi} a l^2}{n_i \mathbf{F} D_i c_i^o}$$

$$\Lambda_1 = \frac{k_c l^2 c_4^o}{D_3}$$

$$\Lambda_2 = \frac{k_c l^2 c_3^o}{D_4}$$

$$\Lambda_3 = \frac{k_c l^2 c_3^o c_4^o}{D_5 c_5^o}$$

$$\lambda_1 = \frac{c_1^o}{c_2^o}$$

$$\lambda_2 = \frac{c_2^o}{c_3^o}$$

The dimensionless boundary conditions are

at $Y = 0$ $\quad C_i = 1, \quad \Phi' = 0$

at $Y = 1$ $\quad C'_i = 0, \quad \Phi = \Phi^o \quad [16]$

The dimensionless parameters which arise here are closely related to parameters which arise in other electrochemical analyses and in engineering analyses of chemical reactors. Each of these dimensionless parameters indicates the relative importance of two effects. Usually, however, more than two effects are important in controlling electrode behavior. However, the relative magnitude of the parameters with respect to each other can be employed to estimate intuitively which particular effects would be important for any specific electrode system. Detailed examples of interpretation were given elsewhere describing flow-through porous electrodes with a single electrode reaction and no homogeneous reactions (28), as well as for multiple electrode and homogeneous reactions (15).

The model equations were first linearized about a trial solution, then recast into finite difference form by employing central difference operators. The resulting set of tri-diagonal matrices was inverted by a modified Gauss-Jordan elimination method (29) with the use of a CDC/CYBER-175 computer. Solution of the nonlinear coupled equations was obtained by successive approximation until a convergence of 0.01% was achieved. The number of iterations required for convergence was dependent on the system being modeled, but was usually less than ten. The choice of 101 mesh points gave results which were accurate to within the line width used in graphical representation of the results. At the limiting current, numerical calculations were found to give results which were identical to analytical calculations.

Results and Discussion

In "dry" acetonitrile, the mechanism of the oxidation of 9-10 diphenylanthracene consists of two successive electrochemical reactions followed by a rapid, irreversible reaction of the dication with a nucleophilic species, usually water present in trace amounts in the electrolyte (24)

$$\begin{aligned} DPA &\rightarrow DPA^+ + e^- \\ DPA^+ &\rightarrow DPA^{+2} + e^- \\ DPA^{+2} + Nu &\rightarrow \text{Product} \end{aligned} \quad [17]$$

By comparison of sequence [17] with reactions [8]-[10], it is seen that species 1 through 5 would denote DPA, DPA^+, DPA^{+2}, nucleophile, and final product, respectively. Although other reaction paths are available to DPA^+ when sufficient quantity of nucleophile (such as H_2O) is present (36), the above reaction sequence was used on a tentative basis for the analysis of data. The extent of agreement between theory and data then becomes in part a test of correctness of the assumed reaction sequence.

Table I. Physical properties of 9-10 diphenylanthracene (DPA) solutions

Property	Units	Value	Reference
κ	$(\Omega\text{-cm})^{-1}$	2.06×10^{-2}*	
μ	g/(cm sec)	$3.67 \pm 0.05 \times 10^{-3}$*

* Measured in the laboratory.
† Estimated.

Values of the properties of the DPA system are listed in Table I. The effective electrolyte conductivity used in model calculations was calculated according to Bruggemann (30)

$$\kappa_{eff} = \kappa\epsilon^{1.5} \quad [18]$$

Rate constants for oxidation of the cation radical intermediate (DPA^+) to the dication (DPA^{+2}) were neither available in the literature nor readily obtainable by experimental measurement. In order to perform the model calculations in the absence of reliable kinetic and physical property data, the following assumptions were made: (*i*) the molecular configurational and electronic charge density differences between DPA^+ and DPA^{+2} were accounted for by the (experimentally measured) thermodynamic rest potential between the two species in solution; (*ii*) the exchange current densities, i_{oi}, of the two reactions were directly proportional to the respective inlet concentrations of the anodic reactants; and (*iii*) the relative values of the inlet concentrations of DPA, DPA^+, and DPA^{+2} were 1000:1:1. Thus, by the first assumption, the anodic and cathodic transfer coefficients of the second oxidation step are equal to those of the first reaction. The third assumption, although unrealistic, was necessary to avoid computational singularities. Finally, the irreversible nature of the second electrochemical reaction was modeled by equating the cathodic back-reaction to zero.

Electrode geometric properties are listed in Table II. The electrode porosity was found by weighing the electrode and measuring the volume occupied after assembly in the cell. It was found by microscope observation that the wire surface was not smooth, as assumed in correlations of specific surface area (35). Based on auxiliary limiting current data in a single reaction system (16, 21), it was concluded that the value obtained by Ref. (35) should be increased by 15% to account for surface roughness effects. With this procedure, it was found that (*a*) the adjusted specific surface area was essentially identical to those best values found by Alkire and Gracon (28) who used a different procedure of determination; (*b*) current distribution data agreed well with model predictions as illustrated in this work and elsewhere (16); and (*c*) the total current agreed to within 3% of model predictions.

Table II. Electrode properties and experimental conditions: 9,10 diphenylanthracene system

Electrode cross-sectional area	$0.95\ cm^2$
Electrode length*	5.4 mm
Number of screens in electrode	30
Number of sections in electrode	5
Electrode porosity	0.731
Specific surface area†	$153\ cm^2/cm^3$
Electrolyte flow rate	0.98-16.7 ml/min

* Includes separator material.
† Based on total length and Ref. (35).

Polarization data.—Figure 3 compares the theoretical predictions based on the above parameters to the polarization behavior of the flow-through porous electrode for an electrolyte flow rate of 1.65 ml/min. The experimental curve has not been corrected for the *IR* drop exterior to the working electrode. Considering the approximations that were made for the kinetic parameters, the agreement is reasonable. The model accurately predicts the limiting current but underestimates the kinetically controlled current attributable to the second electrochemical reaction by about 15%.

Yield data.—Reactant and product conversions defined by the relations

$$\theta_{DPA} = 1 - \frac{c_{DPA}^1}{c_{DPA}^0}$$

$$\theta_{DPA+} = \frac{c_{DPA+}^1 - c_{DPA+}^0}{c_{DPA}^0 + c_{DPA+}^0}$$

$$\theta_{DPA+2} = \frac{c_{DPA+2}^1 - c_{DPA+2}^0}{c_{DPA}^0 + c_{DPA+}^0\, c_{DPA+2}^0}$$

Figure 4 depicts the influence of electrolyte flow rate on the collection efficiency of the porous electrode at the higher of the applied potentials employed during

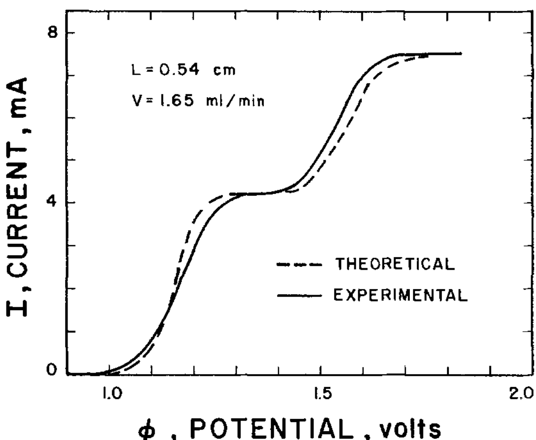

Fig. 3. Comparison of experimental and predicted polarization behavior of 9-10 diphenylanthracene system.

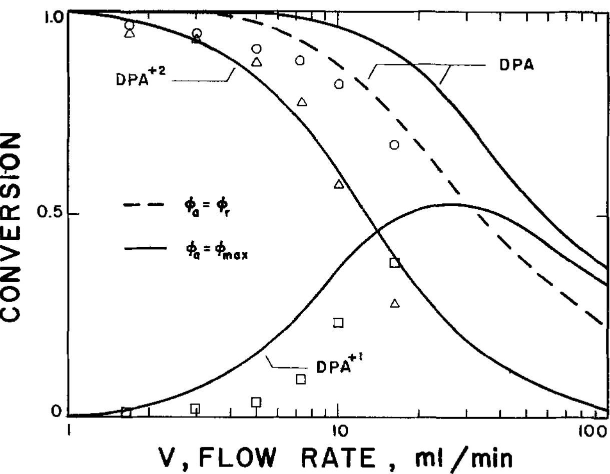

Fig. 4. Collection of efficiency vs. flow rate for 9-10 diphenylanthracene system.

each run. All reported applied potentials are *vs.* the downstream SCE and have been corrected for *IR* drop external to the porous electrode. The DPA conversion efficiency at the lower applied potential value can be determined within experimental error from the DPA conversion curve in Fig. 4. At the lower flow rates, the residence time is sufficiently long to permit nearly quantitative formation of the dication. Decreasing the residence time improves the relative conversion to the radical intermediate since the formation of the final product (DPA^{+2}) is affected more adversely by flow rate increases than is the conversion efficiency of DPA to total product.

As mentioned previously, the conversion efficiency of DPA to total product was identical, within experimental error, at both levels of the applied potential employed in this study. The theoretical results for the conversion of DPA to DPA^+ at an applied potential of $\phi_a = \phi_r$ are indicated by the dotted curve in Fig. 4. The solid lines represent the theoretical calculations for the higher of the two experimentally applied potentials, $\phi_a = \phi_{a,max}$. A summary of the collection efficiencies for the three chemical species is given in Table III. Qualitative agreement with the data is achieved by the model, although the fractional conversion of DPA to DPA^+ has been underestimated. The predicted total currents are within 3.4% of the observed current levels.

Although experimental limitations prevented investigation of electrode behavior at flow rates in excess of about 20 ml/min, it is apparent from Fig. 4 that the fractional conversion to DPA^+ for large ϕ_a should eventually reach a maximum value owing to the unabated decrease in the conversion of the starting material to total product as a function of electrolyte flow rate. The anticipated maximum in the outlet concentration of the cation radical supports the contention that a low, single pass conversion at high flow rate is required to maximize the formation of a reaction intermediate (26) for large values of the applied potential. The theoretical calculations indicate that the maximum should occur at 25 ml/min and have a value of 0.53. Therefore, in order to maximize the production efficiency of the reaction intermediate, a low applied potential would be required for flow rates less than 30 ml/min. At higher flow rates, a larger applied potential would result in enhanced DPA^+ yields at the expense of increased ohmic loss within the electrode and, hence, greater power consumption by the electrochemical reactor.

Current distribution data.—Figures 5 through 10 compare experimental current distribution data with theoretical calculations. All reported applied potentials are *vs.* the downstream SCE and have been corrected for *IR* drop external to the porous electrode. For the lower of the applied potentials, the multiple reaction sequence is equivalent to a single-electron redox reaction. At the higher of the applied potentials, electrode operation is more complex since the partial current distribution for the second reaction depended on upstream production of DPA^+ as well as operational parameters, such as flow rate and electrode length.

Table III. Collection efficiency measurements: 9-10 diphenylanthracene system

V, ml/min	I_{total}, mA*		θ_{expt}			θ_{calc}

* Total current efficiency is 99% + for each flow rate.

The normalized total current distributions for a flow rate of 1.65 ml/min at the two levels of applied potential are shown in Fig. 5. At 1425 mV *vs.* SCE, the oxidation of DPA proceeds at the limiting current throughout the electrode; conversion is quantitative within experimental error. The observed increase in the local current near the electrode outlet is a consequence of fluid channeling along the cell block wall. At 1900 mV *vs.* SCE, reactor performance is also characterized by a highly nonuniform current distribution but with quantitative production of the dication and its nucleophilic addition analog. In Fig. 5, the combination of low flow rate and a uniform potential distribution within the electrode allows both reactions to proceed at their respective mass transfer limited rates.

As the convective supply rate is increased, the second reaction becomes kinetically controlled in the upstream regions of the electrode and the total current distribution becomes more uniform as shown in Fig. 6 and 7. The agreement between theory and experiment indicated by the figures is good.

Figure 8 compares the experimental and theoretical current distributions at two values of the applied potential for a flow rate of 7.25 ml/min. For a low value of the applied potential, ohmic resistance in the solution phase precludes mass transfer control of the initial oxidation step in the upstream region of the electrode. The reaction rate distribution is uniform and the collection efficiency of the cation radical is approximately 87%. The larger ohmic voltage losses

preclude oxidation of DPA^+ in the upstream third of the reactor. At the higher applied potential, the model indicates the DPA consumption occurs at the limiting current in upstream regions and so leads to the observed exponential decrease in total current. As the fluid approaches the counterelectrode, it encounters larger values of the local potential which serve to increase the rate of the second oxidation reaction. The total current proceeds through a maximum owing to reactant depletion in the downstream region. Collection efficiencies for DPA and DPA^+ are 88% and 11%, respectively. Compared to experimental data, the predicted partial current distribution for the second reaction exhibits a greater degree of nonuniformity and is shifted toward the downstream region of the reactor.

Figure 9 shows that, for a large value of the applied potential, an increase in the electrolyte feed rate to 9.96 ml/min yields a more uniform total current distribution and causes a downstream shift in the local maximum owing to the second electrochemical reaction in the sequence. The model tracks the reaction rate distribution with reasonable accuracy and indicates that the oxidation of DPA is kinetically limited for values of the dimensionless distance less than 0.4.

For the highest flow rate investigated, the model predicts a potential drop across the reactor of approximately 1.2V. The large ohmic resistance within the electrolyte is responsible for the local maximum in the partial current distribution of the first oxidation step as illustrated in Fig. 10. In addition, the highly nonuniform potential distribution has restricted the second reaction in the sequence to the downstream half of the electrode. The quantitative agreement between theory and experiment at the higher flow rates is an indication that the EEC model can be used to obtain reasonably good estimates of detailed electrode behavior.

Conclusions

In this study, experimental conditions were selected to insure a high level of certainty with respect to reaction chemistry, cell configuration, and theoretical principles for predicting cell behavior. The agreement between experimental data and theoretical calculations reported in this study was particularly noteworthy since it was obtained with use of literature values of system parameters, where known. While still better agreement could have been obtained by further adjustment of parameter values, the purpose of the investigation was to demonstrate the value of engineering models of cell processes in predicting behavior, not to provide an improved data base.

Over the range of conditions studied, a mathematical model of the DPA oxidation reaction was found to provide accurate predictions of cell behavior, even when behavior depends on complex interaction of mass transfer, ohmic, kinetic, and thermodynamic effects. It seems clear that efforts to demonstrate technical feasibility of other electro-organic syntheses might benefit by incorporating mathematical models in the assessment of cell designs. In particular, such models can be used to predict cell behavior and thereby would guide scale-up and optimal specification of design trade-offs. The accuracy of any model is

closely tied to the use of appropriate assumptions and accurate parameter values.

The model used in this study required knowledge of a variety of system characteristics. Included among these were reaction sequence, kinetic rate constants, half-wave potentials, conductivity, mass transfer coefficient, specific surface area, etc. Such detailed knowledge is often not available in practice. Under typical industrial constraints, the act of developing a mathematical model is itself subject to optimal considerations since excessive uncertainty of parameter values can foreshorten the value of any model, no matter how fundamentally sound. Consequently, development of models for specific applications should be guided largely by the availability of information about the process. Improved strategies are needed for constructing engineering models of practical electrochemical systems.

Complications in using mathematical models may be anticipated when cell processes are not understood or easily characterized. Examples which occur frequently in electro-organic syntheses include multiphase flow as with gaseous feedstock, gas evolution reactions, and use of immiscible liquid phases. Additional engineering studies are needed if such processes are to be designed with confidence on a large scale.

Determination of Some Physical Properties of N-Type Semiconductor Alloys ($0 \leq x \leq 1$) by Photoelectrochemistry

ABSTRACT

Some physical properties (the bandgap energy, the electronic transition mode, and the diffusion length) are determined on n-type $Ga_xIn_{1-x}P$ alloys with ($0 \leq x \leq 1$), using photoelectrochemical techniques. Studies were made in acidic solution (KCl 0.5M + HCl pH ~ 1), since the photocurrent is only stable at this pH. The values obtained are in very good agreement with the results of electroreflectance piezotransmission and transmission measurements.

It is well established that the theoretical optimum bandgap energy (E_g) of semiconductors for photovoltaic conversion of solar energy is about 1.6 eV (1) (Fig. 1). The collecting structure can be a Schottky diode, a p-n junction, or a photoelectrochemical cell (2, 3). Among the different possible materials the $Ga_xIn_{1-x}P$ alloys are attractive for this purpose, because for $0 \leq x \leq 0.64$, they have a direct bandgap energy in the range 1.3-2.00 eV.

Due to the direct nature of the electronic transition mode, the absorption coefficient of photons with energy $h\nu > E_g$ is high compared with that for indirect bandgap materials, and the absorption length for such photons is typically a few microns.

In this paper, we study a $Ga_xIn_{1-x}P$ photoelectrochemical cell with $0 \leq x \leq 1$, and from the analysis of the photocurrent behavior we deduce several optical and electrical properties of these alloys. All the experiments are made without redox systems. The nature of the photocurrent in this case is developed in this paper. In the future it will clearly be of interest to study these compounds in the presence of redox systems with the aim of improving the quantum yield.

Theoretical Analysis of the Photocurrent

This measurement technique uses the photoeffect across an electrolyte-semiconductor junction. The presence of an electrolyte at the surface of a semiconductor can create either an accumulation or a depletion layer at the surface depending on the nature of the charge distribution of the electrolyte-semiconductor interface. For an n-type semiconductor with a concentration of majority carriers $N_D - N_A \approx 10^{17}$ cm^{-3} and an electrolyte concentration 0.5M, a depletion layer is created at the interface. When the semiconductor is illuminated, a photocurrent due to the generation of electron-hole pairs is produced. These pairs are separated by the electric field produced in the space charge region. So, for n-type electrodes, the holes are attracted by the counterelectrode, via the electrolyte, so photoelectrolysis of the water is produced, or anodic dissolution of the electrode depending on the relative position of the free energy of these two reactions, but also, both reactions may take place simultaneously.

If the surface of the cathode is sufficiently large, then the photoresponse of the cell is determined by the oxygen reaction or anodic photodecomposition kinetics, or by the generation-recombination-diffusion processes of the electron hole pairs generated in the semiconductor. If the variation of the photocurrent is linear with the light intensity, then the carrier generation is the rate-limiting step. So, if the junction electrolyte-semiconductor is considered to be equivalent to a Schottky barrier and if the electron hole recombination at the surface is neglected, as it is possible for polycrystals with large band bending, when there is a linear variation of the photocurrent *vs.* the incident light energy, it is easy to describe the photocurrent by the theory of Gärtner (4)

$$J = q\Phi[1 - e^{-\alpha W}/(1 + \alpha L_p)] + qp_oD_p/L_p \quad [1]$$

α is the optical absorption coefficient determined with an absorption spectrometer, q is the charge transfer per unit electrochemical reaction, Φ the photon flux density, L_p the diffusion length, D_p the diffusion constant, and p_o the concentration of holes at equilibrium,

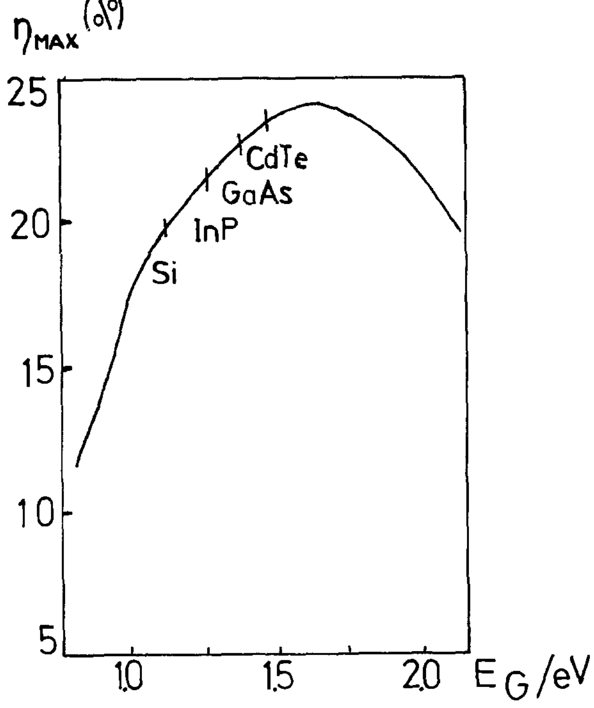

Fig. 1. Theoretical maximum efficiency for solar batteries as a function of the energy gap of the semiconductor (1).

* Electrochemical Society Active Member.

Key words: semiconductors, alloys, photoelectrochemistry, energy conversion.

without illumination. W is the depletion layer width given by the following expression

$$W = K_o(V - V_{fb})^{1/2} \quad [2]$$

V is the applied voltage relative to the reference electrode, V_{fb} the flatband potential measured relatively to the same reference. K_o is a constant which depends on the permittivities of free space ϵ_o on the dielectric relative constant in the depletion layer of the semiconductor ϵ_r and on the number of majority carriers $(N_D - N_A)$

$$K_o = \left(\frac{2\epsilon_r\epsilon_o}{q(N_D - N_A)} \right)^{1/2} \quad [3]$$

The term $qp_o\, D_p/L_p$ can be neglected as corresponding to the dark current.

This expression of the current density is also good if the light is chopped with frequencies $\omega < 1/t_o$, t_o being the carrier transit time through the depletion layer (4). So the quantum efficiency is given by

$$\eta = \frac{J}{q\Phi} = 1 - e^{-\alpha W}/(1 + \alpha L_p) \quad [4]$$

If the potential of the electrode is near the flatband potential so that $\alpha W << 1$, then, Eq. [4] can be approximated to

$$\eta = \frac{\alpha}{1 + \alpha L_p} [L_p + K_o(V - V_{fb})^{1/2}] \quad [5]$$

This theory was developed further by Wilson (5) in the case where there is a surface recombination.

Experimental Techniques

For photoelectric measurements, we used a 150W Xenon lamp (Schoeffel) as the light source and a Jobin-Yvon HRS 2 monochromator with a 500 nm blazed grating. The monochromatic light illuminates the electrode through a quartz window situated in the bottom of the electrochemical cell. In order to avoid the dark current contribution, the light is modulated by a chopper (PAR 125 A) and the photocurrent is detected by a lock-in amplifier (PAR Model 121), so that the dark current is eliminated at the detection. However for samples investigated in this work, the dark currents are negligible in front of the photocurrents.

The electrochemical cell is inserted on a plate which can be rotated around three axis and displaced in any of these directions. So, it is easy to position the electrodes very accurately always at the same place and then to compare their efficiencies. The intensity of the light has been determined by a photodiode located behind the cell, so that the contribution of the light absorption in the solution is taken into account.

For linear sweep voltammetry (LSV) measurements, a classical experimental set is used.

Samples and Experimental Conditions

Samples.—The semiconductor electrodes used are polycrystalline $Ga_xIn_{1-x}P$ alloys ($0 \leq x \leq 1$). They were doped with sulfur and the free electron concentration is $(N_D - N_A) \approx 10^{17}/cm^3$ at 300°K for all the alloys. To collect the current, the contact between the semiconductor and the metal must be perfectly ohmic. The decrease of the barrier of the contact is obtained by tin diffusion. The composition of these polycrystals was determined by electron microprobe analysis, and the surface area was measured for all samples by a photographic technique with a precision of about 5%. These polycrystals are mechanically polished. Before studying them the first time, they were etched for a few seconds in a 2% bromine solution in methanol. This etching was not repeated before all experiments, because the photocurrents observed for the compositions with high percentage of In, both in the dark and under the light are unstable. Probably some bromine remains absorbed on the electrode and can be removed after numerous sweeps, because the I-V curves then become stable.

Experimental Conditions and Stability of the Electrodes

The photocurrents observed are stable only in acidic solutions. In solutions of neutral or basic pH, they slowly decrease with the time, except for $x = 0$. This was also observed by Vervaet *et al.* (6) on InP electrodes, and by Gautron and Lemasson (7), on ZnSe. On InP, this result can be explained by the formation of $In(OH)_3$ film which remains on the surface of the electrode in neutral or basic solutions for it is insoluble at this pH (8). In the case of GaP, $Ga(OH)_3$ is formed, which is soluble at all pH because the photocurrent remains always stable. For this reason, all the experiments were done in acidic pH (pH ≈ 1) in 0.5M KCl + HCl electrolyte.

The different decomposition reactions which can be involved are recalled here: for GaP, the anodic dissolution process involves six holes (9-11)

$$GaP + 6H_2O + 6p^+ \rightleftarrows Ga(OH)_3 + H_3PO_3 + 6H^+ \quad [6]$$

As we have also the following reaction at the counterelectrode

$$6H^+ + 6e^- \rightarrow 3H_2 \quad [7]$$

The total reaction is

$$GaP + 6H_2O \rightleftarrows Ga(OH)_3 + H_3PO_3 + 3H_2 \quad [8]$$

The calculation of the free energy of this reaction gives, with the free enthalpy of dissociation of GaP: $\Delta G_{GaP} = -24.4$ kcal/mole (12), $E°_{1dp\ GaP} = -\Delta G/n\mathbf{F} = -0.29$ eV/NHE at pH $= 0$ (13). (n is the number of holes ($n = 6$) in the reaction, $\mathbf{F}$ is the Faraday constant). As these electrodes have a Nernstian behavior

$$E_{1dp\ GaP} = -0.35 \text{ V/NHE at } pH = 1$$

Another reaction of dissolution should be taken into account; the cathodic reaction of dissolution involving hydrogen (14)

$$GaP + 3/2\, H_2 \rightleftarrows Ga + PH_3 \quad [9]$$

that gives as redox potential for this anodic decomposition of GaP $E°_{dn} = -0.40$V at pH $= 0$ or $E_{dn} = -0.46$V at pH $= 1$.

The reactions involved are of the same type for InP, and the free energy of the reactions falls also in the middle of the bandgap. With $\Delta G_{InP} = -11.55$ kcal (15), $E°_{1dp\ InP} = -0.253$V/NHE at pH $= 0$ or $E°_{1dp\ InP} = -0.31$V/NHE at pH $= 1$. For the cathodic decomposition, $E°_{dn} = -0.23$V/NHE at pH $= 0$, or $E_{dn} = -0.29$V/NHE at pH $= 1$.

Other reactions can be involved in this electrolyte as

$$GaP + 3HCl + 3H_2O \rightleftarrows GaCl_3 + H_3PO_3 + 3H_2$$

The free energy of this reaction is $E°_{2dp\ GaP} = -0.50$V at pH $= 0$, or $E_{2dp\ GaP} = -0.44$V at pH $= 1$.
With the InP, the reaction involved is

$$InP + 3HCl + 3H_2O \rightleftarrows InCl_3 + H_3PO_3 + 3H_2$$

and the free energies are $E_{2dp\ InP} = -0.576$V at pH $= 0$, or $E_{2dp\ InP} = -0.516$V at pH $= 1$.

Quantum Efficiency of This Photocell Determination of the Bandgap and the Transition Mode of the $Ga_xIn_{1-x}P$ ($0 \leq x \leq 1$)

The main purpose of this work is to obtain the bandgap energy and the electronic transition mode of these compounds by means of a photoelectrochemical technique. With electroreflectance, cathodoluminescence, and transmission measurements, these studies were previously made (Fig. 2-3) (16-18) so the results obtained in this work can be easily compared.

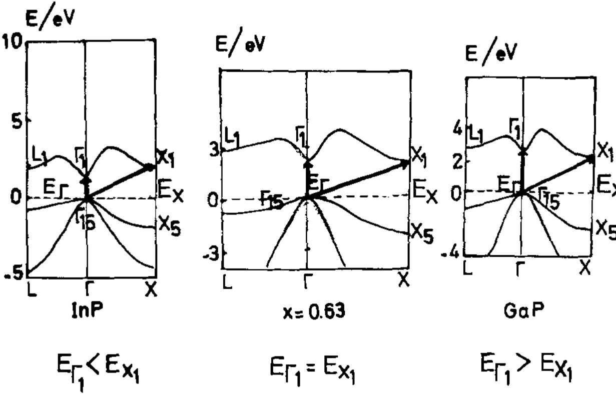

Fig. 2. Band structure for $x = 0$ (InP), $x = 0.63$ ($Ga_{0.63}In_{0.37}P$), $x = 1$ (GaP) (17).

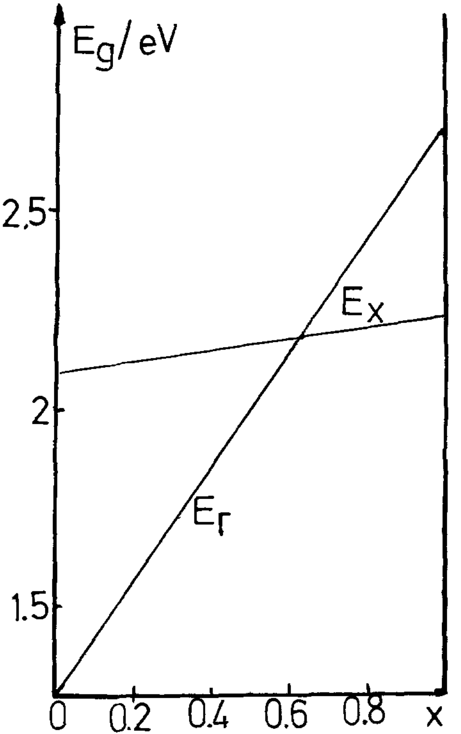

Fig. 3. Variation of the bandgap width as a function of the composition of the alloy (16).

Quantum efficiency vs. the composition of the alloys and the polarization of the electrode.—Determination of L_p.—The electrodes are illuminated and positioned always at the same place corresponding to the maximum of photocurrent. All the intensities are converted to unit area, and the quantum efficiencies are determined and compared for several compositions. Figure 4 shows the quantum efficiency variation obtained with this compound *vs.* the wavelength of the incident light.

The stationary LSV curves were obtained for different compositions (Fig. 5). The behavior is different, depending on the composition x. This can be easily understood by the difference of diffusion length L_p (Eq. [5]).

After verifying the linearity of the photocurrent *vs.* the intensity of the incident light so that the limiting rate is the creation of hole pairs, we can estimate the diffusion length L_p of minority carriers using the approximation of Eq. [5], that is to say in the case where $\alpha W << 1$. The comparison of our results to those obtained classically using D_p, diffusion constant, and τ_p time recombination of minority carriers, shows that the theory of Gärtner is valid for our compounds.

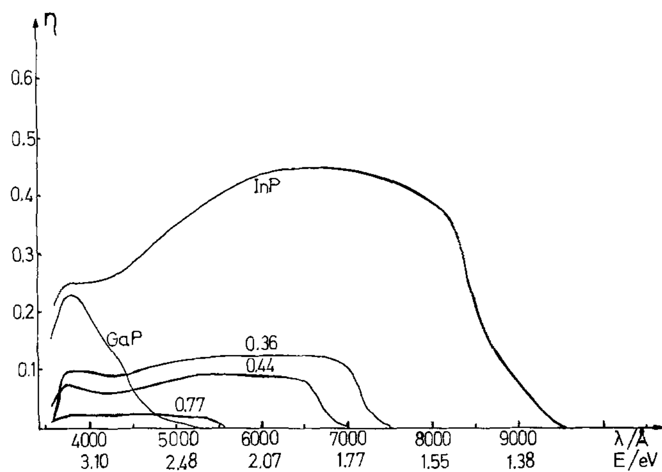

Fig. 4. Variation of the quantum efficiency for the different compositions x of the alloys $Ga_xIn_{1-x}P$ vs. the incident photon energy. All the results are corrected from the surface of the sample and the response of the photodiode. Electrolyte, KCl 0.5M + HCl (pH ≈ 1). Bias voltage $V = -0.25$ V/NHE.

In the case of GaP, the different constants are $\mu_p = 100$ cm²/Vsec (mobility of minority carriers), $\tau_p \simeq 30$ nsec (time recombination of minority carriers) (19), $\epsilon_r = 11$, $N_D - N_A \approx 10^{23}/m^3$ and $D_p \approx 2.5$ cm²/sec. So, as

$$L_p = \sqrt{D_p \tau_p} \quad [10]$$

then the diffusion length is $L_p \approx 2.7$ μm. Studying the photocurrent, as $\alpha \sim 2.25 \; 10^2$ cm^{-1} (Fig. 6) for $h\nu = 2.4$ eV, and as $\eta = 0.049$ for the same energy (Fig. 4), with a polarization $V = 1.65$ V/NHE, with $V_{fb} = -1$ V/NHE (pH = 1) (Fig. 11), then the diffusion length obtained is $L_p \approx 2.5$ μm.

For InP compounds, $\mu_p \approx 100$ cm²/Vsec, $\tau_p \approx 3$ nsec, $\epsilon_r = 12.37$, $N_D - N_A \approx 10^{23}/m^3$, so that $L_p \approx 0.9$ μm. As $\eta = 0.54$ for $h\nu = 1.35$ eV and $V = 0.7$ V/NHE (Fig. 4), with $\alpha \approx 10^4$ cm^{-1} (Fig. 7) (20), with $V_{fb} = -0.2$ V/NHE (pH = 1) (Fig. 11), the diffusion length of minority carriers obtained is $L_p = 0.9$ μm.

The values obtained are in good agreement.

Determination of the bandgap width and the transition mode.—The absorption coefficient α, directly depends on the photon energy following the expression (21)

$$\alpha = A \frac{(h\nu - E_x)^2}{h\nu} \quad [11]$$

for indirect interband transitions, and

$$\alpha = A \frac{(h\nu - E_\Gamma)^{1/2}}{h\nu} \quad [12]$$

for allowed direct transition.

The quantum efficiency η, in the case of $\alpha L_p << 1$ is proportional to α, so, it is easy to determine the bandgap plotting the different values of η^2 or $\eta^{1/2}$ *vs.* the incident energy $h\nu$, near the bandgap where the variation $h\nu$ is large compared with the difference $(h\nu - E_g)$ (with $E_g = E_\Gamma$ or E_X). Then, E_Γ and E_X being known, the transition mode can be studied plotting log $(\eta h\nu)$ *vs.* $(h\nu - E_g)$. So, if the slope is 2, the transition is indirect and if the slope is ½, the transition allowed is direct.

On Fig. 8, the variation of $\sqrt{\eta}$ deduced from Fig. 4, for $x = 0.77$, $x = 0.905$, $x = 1$ is plotted *vs.* the incident energy $h\nu$. The low energy portion is characteristic of the incident electronic transition, and its extrapolation towards $\eta = 0$ gives the value of the bandgap energy E_X. At higher energy, the dominant absorption comes from the direct electronic transition which arises approximately when the slopes change.

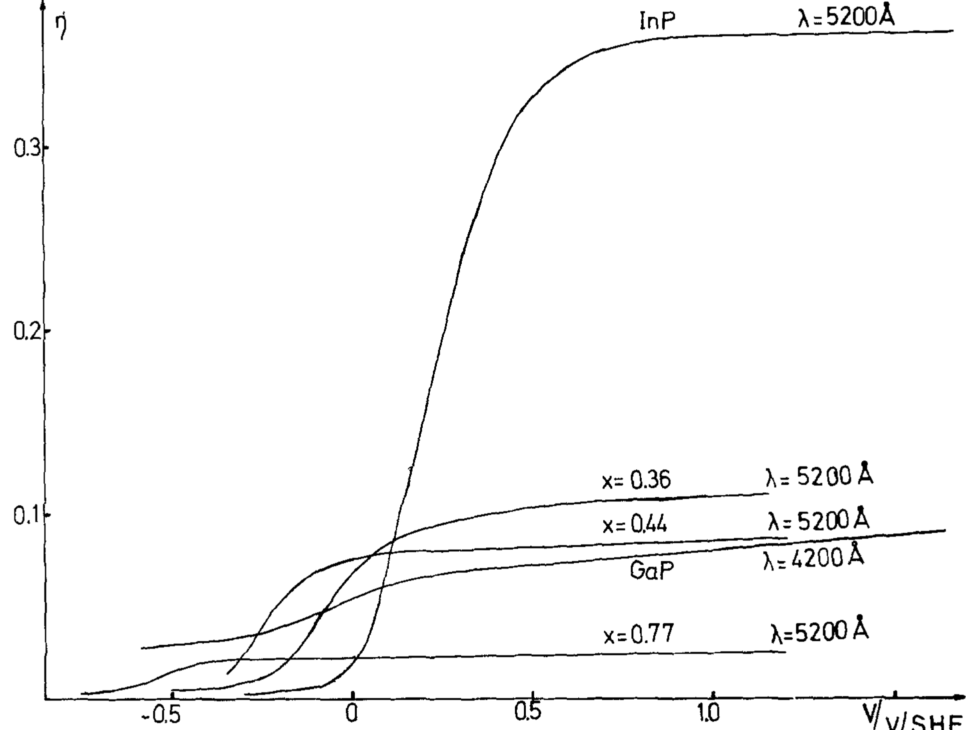

Fig. 5. Quantum efficiency for different compositions x of the alloys $Ga_xIn_{1-x}P$ vs. the polarization of the electrode. Incident light λ = 5200Å for x = 0, 0.36, 0.77 and λ = 4200Å for GaP. Speed of the sweep v = 10 mV/sec.

For $0 \leq x \leq 0.64$, the transition mode is direct, so that η^2 is drawn *vs.* $h\nu$ (Fig. 9).

These results are also in very good agreement with the results obtained by electroreflectance measurements (17).

Then, drawing log ($\eta h\nu$) *vs.* ($h\nu - E_X$) or ($h\nu - E_\Gamma$), the optical transition mode can be determined (Fig. 10). The results are also in accordance with the previous works, obtained by transmission, electroreflectance, and piezotransmission (22). For $x = 0$, 0.36, 0.44, the transition is direct, as for $x = 0.77$, 0.905, 1, the transition is indirect.

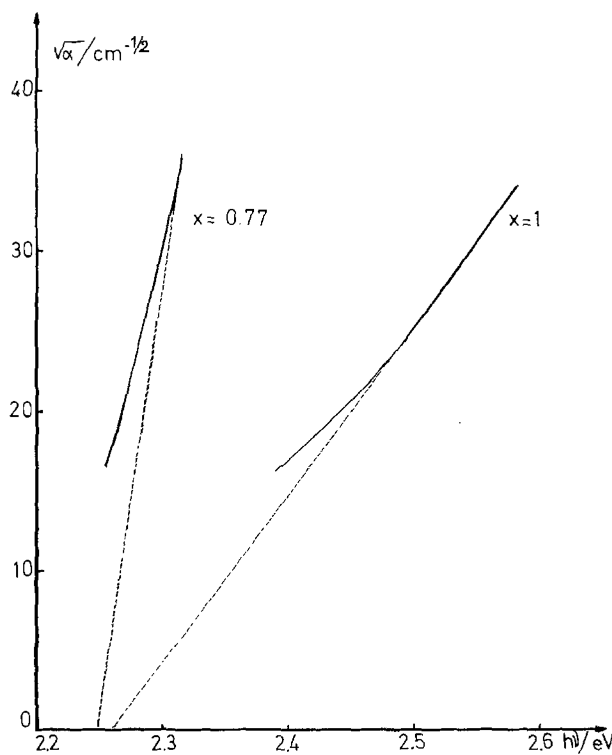

Fig. 6. Variation of the absorption coefficient α for the compositions x = 0.77 and x = 1 vs. the incident photon energy.

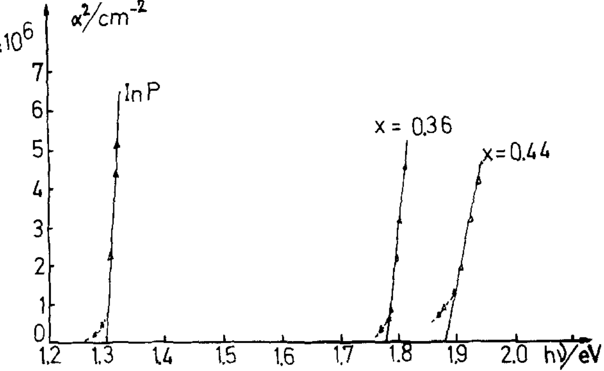

Fig. 7. Variation of the absorption coefficient α for the compositions $0 \leq x \leq 0.64$ vs. the incident photon energy.

Knowing the bandgap energy and the Fermi level from impedance measurement (23, 24), the position of the energy levels are deduced in our experimental conditions (pH = 1) (Fig. 11).

The flatband potential can also be determined studying the variation of the square root of the photocurrent *vs.* the electrode potential. This study was made by Butler on WO_3 electrodes (25), and by Gautron and Lemasson (7) on ZnSe. If $L_p << W$, then Eq. [5] can be approximated by the relation

Table I.

Composition	E_X (eV)	E_Γ (eV)
GaP ($x = 1$)	2.26	2.7
$x = 0.905$	2.24	2.42
$x = 0.77$	2.22	

Table II.

Composition	E_Γ (eV)
$x = 0.44$	1.8
$x = 0.36$	1.72
$x = 1$	1.3

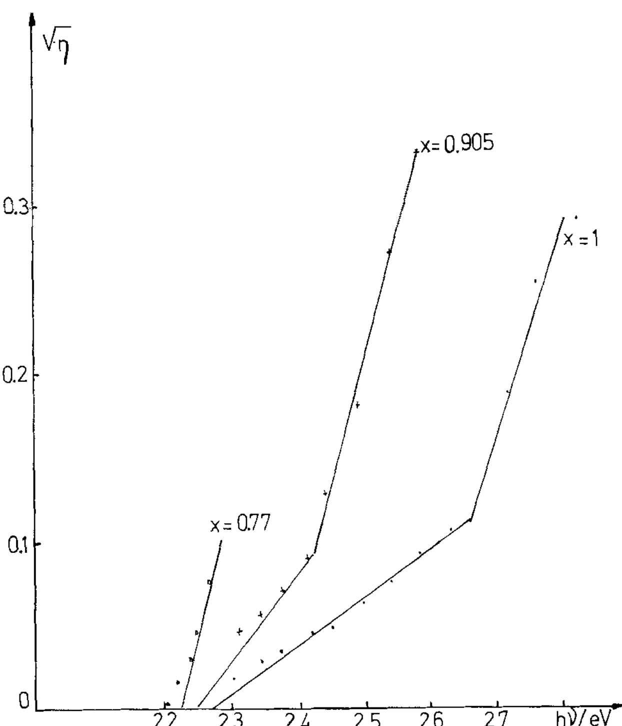

Fig. 8. Variation of $\eta^{1/2}$ for the compositions $0.64 \leq x \leq 1$ vs. the incident photon flux in KCl 0.5M + HCl (pH = 1). Bias voltage $V = -0.25$ V/NHE.

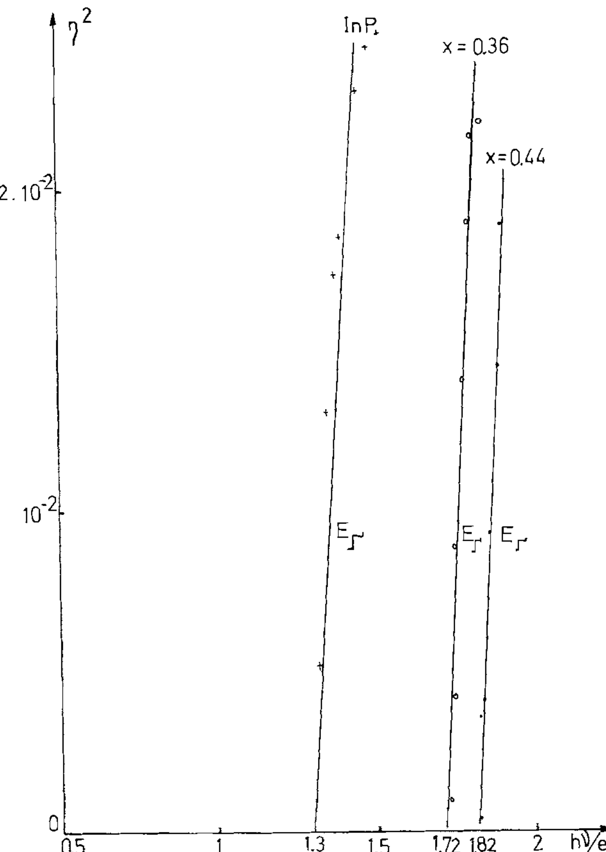

Fig. 9. Variation of η^2 for the compositions $0 \leq x \leq 0.64$ vs. the incident photon flux in KCl 0.5M + HCl (pH = 1). Bias voltage $V = -0.25$ V/NHE.

$$V - V_{fb} = \eta^2(1 + \alpha L_p)/\alpha K_o \quad [13]$$

The results obtained are approximately the same as those found from impedance measurements (Fig. 11).

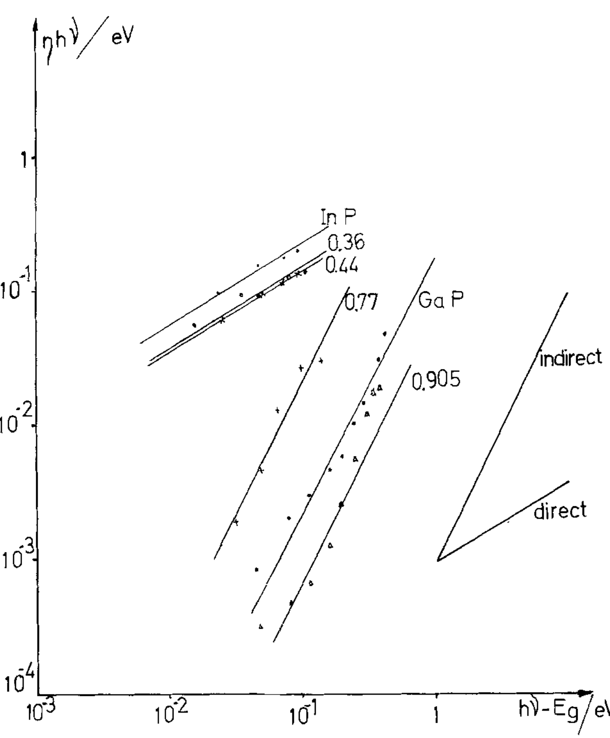

Fig. 10. Behavior of quantum efficiency with incident photon energy for the determination of the electronic transition mode.

Conclusion

The $Ga_xIn_{1-x}P$ alloys ($0 \leq x \leq 1$) are very interesting compounds as for compositions $0 \leq x \leq 0.64$, the transition is direct and the bandgap is included in the range 1.35-2.00 eV the theoretical maximum efficiency being 1.6 eV (1).

By photoelectrochemical measurements, it is easy to determine the bandgap energy, the electronic transition mode, and the diffusion length for new materials, as shown in this work.

But an important disadvantage remains the anodic dissolution of the electrode. First the dark current increases at anodic potentials for compositions with low x probably due to a dissolution. The potential where the current begins is increasing when x increases. Second, the photocurrents obtained for low x compositions are more important than the photocurrents of $x \approx 1$. As the energy of anodic decomposition is greater than the energy of O_2 formation by photoelectrolysis of the water (E_{1dp}), then this photocurrent, in this experimental condition is due to the reaction of decomposition with the solvent (25). This photodecomposition is also more important for low x values (Fig. 11). We are working now on the possibility of blocking this dissolution with a suitable redox reaction.

Acknowledgments

The authors wish to thank Dr. Parsons for his helpful discussions, Dr. Ph. Lemasson, Dr. A. M. Baticle, and Dr. J. L. Sculfort for their constant help in the execution of this work. The alloys were made by J. Bourneix and mounted on their support by Mme. de Mende. The construction of the apparatus was executed with aid of a D.G.R.S.T. Contract No. 650.1617.

Manuscript submitted May 24, 1979; revised manuscript received Sept. 24, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

On the Kinetics of the Thermal Oxidation of Silicon

I. A Theoretical Perspective

William A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

This paper provides a perspective overview of the partitioning of the total driving force for the oxidation process into the key parallel subprocesses and delineates the boundary value problems needed to quantitatively connect these components. An over-all framework is given for viewing all aspects of this process. This constitutes a new and generalized description of oxidation with specific attention to the oxidation of Si. The free volume supply condition required to sustain such a transformation is explicitly given so that attention is focused on vacancy and interstitial formation in the substrate as well as viscous flow in the oxide. An atomistic level model for the oxidation process is given which appears consistent with much of the earlier data; also five possible paths for influencing the rate and character of the oxidation process are described.

For the past 10-15 years a great debate has occurred over whether or not the Si oxidation process is controlled by the diffusion of charged or neutral species. Jorgensen (1) finds that (*i*) an applied electric field enhances oxidation when the Si is made positive with respect to the oxide/gas interface and retards it when the Si is made negative, (*ii*) oxidation under a retarding field ceases when the voltage across the oxide is equivalent to the free energy driving force for the oxidation reaction, and (*iii*) the dependence of oxidation rate on field indicates that oxygen ions are the predominant diffusing species (otherwise the oxidation reaction could not be completely stopped). Jorgensen and Norton (2) find similar field effects of permeation through SiO_2. On the other hand, Doremus (3) finds that (*i*) the calculated value of the parabolic rate constant, B, for molecular oxygen in fused silica is within a few percent of that found experimentally for the oxidation of silicon, (*ii*) the pressure dependence of B is linear with oxygen pressure in the gas which also agrees with experiments for silicon oxidation, and (*iii*) the activation energy for diffusion of molecular oxygen through fused silica is within 5% of the experimentally determined activation energy for silicon oxidation.

Rayleigh (4) went on to show that, when an electric field is applied to the oxidizing silicon in the manner of Jorgensen, an electrolytic process is superimposed on the normal oxidation process. If an external circuit is provided for the flow of electrons, diffusive transport of oxygen ions requires only ionic conduction through the bulk of the oxide. However, with no such external circuit present, polarization fields would develop to inhibit ionic transport. Collins and Nakayama (5) support Rayleigh's conclusions and suggest that the neutral oxygen species may be in thermodynamic equilibrium with various ionized species. They suggested several possible anodic and cathodic reactions.

More recently, Mills and Kröger (6) measured the electrical conductivity of SiO_2 in the temperature range 0°-700°C and proposed that the species responsible for ionic conduction at elevated temperatures is the doubly negative oxygen ion, $O_=$, in interstitial positions. The activation energy, derived from their high temperature data (673°-873°K), for combined defect creation and defect motion is within a few percent of that found for neutral oxygen self-diffusion in silica. Thus, at this point it appears that there is support for both neutral and ionized species diffusion during thermal oxidation.

Key words: thermodynamic model, atomistic model, phase transformation.

Cabrera and Mott (7) showed that it was possible to treat the diffusion of ions in oxides by using an effective diffusion coefficient, $D_{eff} = 2D_i$, and by neglecting any electric field effects in the analysis of ionic transport during oxidation, provided that the oxide layer thickness was large compared to the space charge thickness. Deal and Grove (8) utilized this approach to provide a simple expression for the oxide layer thickness as a function of time in substantial agreement with oxidation data obtained over a wide range of temperature, partial pressure, and oxide thickness for both oxygen and water oxidants.

The thermal oxidation of heavily doped Si substrates shows that the oxidation rate is substantially faster than that observed on lightly and moderately doped substrates (9). In addition, the incorporation of HCl into the oxidizing ambient substantially influences the oxidation rate (10, 11).

The foregoing seemingly conflicting data on the charged nature of the diffusing oxygen species, plus the need to explain the foreign species effects on the oxidation rate, suggest that perhaps a more basic look at this particular oxidation process may be of value at this point in time. The purpose of this paper is to provide a beginning assessment and it is devoted to both a perspective overview and to a model that qualitatively seems to restore harmony to what might appear to be opposing views.

Review of Unconstrained Crystal Growth from a Melt (12, 13)

In practice, we can distinguish two unique modes of crystallization, constrained and unconstrained. In the unconstrained mode, which occurs in isothermal cooling, crystals nucleate and grow freely in a large bath of liquid of constant temperature which is below the melting temperature of the crystal. Here, the total driving force for the phase change, ΔG, is larger in the liquid far from the interface than it is in the liquid right at the interface because the temperature is lower in the far field than at the interface. In the constrained mode, which occurs in normal crystal pulling, the crystals are grown from a bath of liquid held at a temperature above the melting temperature of the crystal. Here, the total driving force for the phase change, ΔG, is smaller in the liquid far from the interface than it is in the liquid right at the interface.

Let us consider the unconstrained growth of a crystal from a dilute binary alloy melt that is supercooled an amount ΔT ($\Delta G = \Delta S \Delta T$, where ΔS is the entropy of fusion), as illustrated in Fig. 1. Here, $T_L(C_\infty)$ is the equilibrium freezing temperature of the bulk liquid

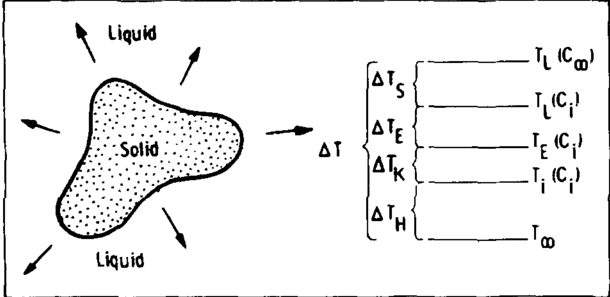

Fig. 1. (Left) A crystal growth from a supercooled binary alloy liquid; (right) the important temperatures in such a growth process. The magnitudes of the temperature differences indicate the degree of solute diffusion, capillarity, attachment kinetics, and heat-transport control.

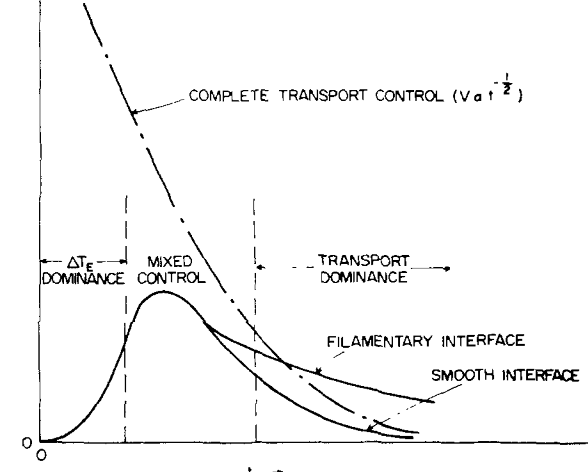

Fig. 2. Schematic representation of a crystal's growth velocity, *V*, vs. time, *t*, illustrating the regions where various mechanisms are dominant.

(the liquidus temperature), and T_∞ is the actual temperature of the liquid far from the growing crystal. Due to the presence of solute atoms in the melt, a partitioning of solute occurs at the moving interface and, because of the slow diffusion of these atoms, the solute concentration changes at the interface from C_∞ to C_i, where C_i depends on the freezing velocity, particle shape, and other factors. This change lowers the liquidus temperature of the crystal surface by ΔT_S to $T_L(C_i)$.

Since the growing crystal is curved, a pressure due to capillarity is imposed on the solid. In addition, the growing crystal may contain nonequilibrium defects. These two effects lower the equilibrium melting temperature of the solid by ΔT_E from $T_L(C_i)$ to $T_E(C_i)$. Further, since the crystal is growing, a certain departure from the equilibrium temperature, ΔT_K, must exist at the interface to drive the molecular transfer from liquid to solid so that the actual interface temperature T_i is below T_E by an amount ΔT_K. Finally, the crystal must be evolving latent heat as it grows and thus T_i must be enough above T_∞ (by the amount ΔT_H) to allow the dissipation of latent heat into the bath.

The foregoing describes the subdivision of the total driving force, ΔG, or the total supercooling, ΔT into its component parts, ΔT_S, ΔT_E, ΔT_K, and ΔT_H, in a simple crystal growth situation wherein no electric fields are applied to the system. All four components are involved in every such growth problem; however, certain ones dominate in different materials. In the growth of large crystals from a relatively pure melt, ΔT_H is approximately equal to ΔT, so this growth is largely controlled by heat flow. During the growth of an oxide crystal from a melt of steel, for example, ΔT_S is approximately equal to ΔT, so the growth is largely matter-transport controlled. During the growth of a polymer crystal from a melt, ΔT_K may be approximately equal to ΔT, and the growth is largely controlled by the kinetics of interface attachment. Finally, during the growth of many lamellar eutectic crystals, ΔT is divided between ΔT_S and ΔT_E and these two factors largely control the growth.

The interplay of these four factors can be simply illustrated by considering the growth velocity of any crystal as a function of time (see Fig. 2). We find that at small times, ΔG_E (or $\Delta T_E = \Delta G_E/\Delta S$) dominates the crystal growth and thus plays an overriding role in its morphology. At zero time, during the nucleation stage, $\Delta G = \Delta G_E$. At large times, ΔG_S and ΔG_H dominate the crystal's growth, which becomes transport limited, and lead to very different morphologies. At intermediate times, all four factors play significant roles in the growth velocity and shape adopted by the crystals.

For these simple cases where the transformation occurs through the variation of one scalar parameter only, the total driving force for crystal growth is given by

melt-solid

$$\Delta G = \Delta S \Delta T \approx H_f[(T - T_o)/T_o]; \quad |\Delta T|/T_o << 1 \quad [1a]$$

solution-solid

$$\Delta G = RT \ln (C/C_o) \approx RT[(C - C_o)/C_o]; \quad |\Delta C|/C_o << 1 \quad [1b]$$

where T_o and C_o are the equilibrium transformation temperature and concentration, respectively, H_f is the heat of fusion, and ΔS is the average entropy of fusion. For the more general case where several scalar parameters vary at the same time, we must use the following relationship

$$\Delta G = A \sum_j [X_j^C \eta_j^C - X_j^N \eta_j^N] \quad [2a]$$

where A is Avogadro's number, C and N refer to crystal and nutrient, respectively, the mole fractions X_j of the j constituents are related by

$$\sum_j X_j^\beta = 1; \quad \beta = C, N \quad [2b]$$

and where the electrochemical potential, η_j, is given by

$$\eta_j = \mu_{jo} + RT \ln a_j + q_j \phi + \sum_n E_n \quad [2c]$$

Here, μ_{jo} is the standard state chemical potential, a_j is the chemical activity, q_j is the charge, ϕ is the electrostatic potential, and E_n is the interaction energy between some additional field n and the species j.

The particular partitioning of the total driving force ΔG into its component parts (ΔG_S, ΔG_K, ΔG_E, and ΔG_H) for the four concurrent interface processes is illustrated in Fig. 3 for a binary alloy system. Here, since we are going from a bulk liquid at point a (C_∞, T_∞) to an interface liquid at point b (C_i, T_i), the sum of ΔG_S and ΔG_H is given by

$$\Delta G_{SH} = G_L(a) - G_L(b) \quad [3a]$$

in Fig. 3. The maximum available driving force for crystal formation from a liquid of interface concentration C_i occurs for solid of the same chemical potential at point c of concentration C_S and, thus, the sum of ΔG_E and ΔG_K is given by

$$\Delta G_E + \Delta G_K = G_S(c) - G(f) \quad [3b]$$

Since ΔG_E is due purely to an internal energy excess

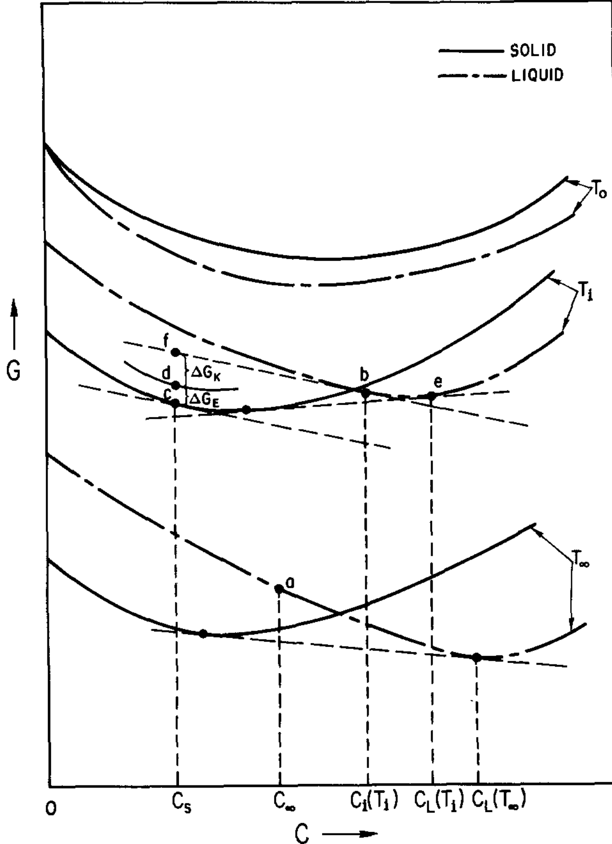

Fig. 3. Free energy, G, curves for solid and liquid as a function of composition, C, of element B for three different temperatures, T_0 (melting temperature of A), T_i (interface temperature), and T_∞ (far-field temperature) needed to evaluate the component ΔG's in the crystallization process.

of the solid, it can be simply represented as a uniform shift of the G_S curve from point c to point d.

A "coupling" equation can be written for the system in the form

$$\Delta G = \Delta G_{SH} + \Delta G_E + \Delta G_K \quad [4a]$$

It is often operationally much more useful to use a description relation to the subdivision of the total bath undercooling, $\Delta T = \Delta G/\Delta S$, into its four component parts since it is conserved during the growth process; *i.e.*

$$\Delta T = \Delta T_S + \Delta T_E + \Delta T_K + \Delta T_H \quad [4b]$$

For those who grow crystals mostly from solution and who do not feel comfortable working with a ΔT-coupling equation, one can easily generate a ΔC-coupling equation (or a ΔP-coupling equation for growth from the vapor) since concentration is conserved during the growth process; *e.g.*, for growth from solution

$$\Delta C = \Delta C_H + \Delta C_E + \Delta C_K + \Delta C_S \quad [4c]$$

Both ΔT-partitioning and ΔC-partitioning are illustrated in Fig. 4, where we note that the phase diagram is being used as our standard reference state. In Eq. [4c], ΔC_H can be readily obtained as $\Delta C_H = (T_i - T_\infty)/m_L$, where m_L is the liquidus slope, ΔC_E is readily obtained as $\Delta G_E/m_L\Delta S$, ΔC_K comes directly from the applicable interface attachment kinetic law, and ΔC_S comes from the solution to the transport equations. As can be readily understood, the only operational temperature and concentration measurements are T_i, T_∞ and C_i, C_∞, respectively.

If one is growing a crystal from solution containing minor chemical constituents, j, as well as the major host constituent, M, these will be partitioned at the interface and require Eq. [4c] to be altered to become

$$\Delta C = \Delta C_H + \Delta C_E + \Delta C_K + \Delta C_S{}^M + \Delta C_S{}^m \quad [4d]$$

where

$$\Delta C_S{}^m = \sum_j \Delta C_S{}^j \quad [4e]$$

In addition, it should be recognized that some of these j constituents may strongly interface-adsorb and may either poison or catalyze many of the specific interface sites needed for attachment of the major constituent, M, to the crystal surface. Thus, ΔC_K in Eq. [4d] may be greatly increased or decreased by the presence of the $C_\infty{}^j$ in the bulk solution.

General Overview of Unconstrained Crystallization

When considering the formation of a new crystal from a nutrient phase, the most information we generally have available to us is the bulk free energy driving force, ΔG_∞. If we are fortunate, we know this function in terms of the important state variables for the reaction; *i.e.*

$$\Delta G_\infty = G_{N_\infty}(C_\infty, T_\infty, P_\infty, \phi_\infty) - G_{C_\infty}(C_\infty, T_\infty, P_\infty, \phi_\infty) \quad [5a]$$

for the state variables of chemical constitution, temperature, pressure, and electrostatic potential where the subscripts N and C refer to nutrient and crystal, respectively. What we need, to understand the growth process in a fundamental way, is the value of ΔG_i operating at the interface between the two phases; *i.e.*

$$\Delta G_i = G_{N_i}(C_i, T_i, P_i, \phi_i) - G_{C_i}(C_i, T_i, P_i, \phi_i) \quad [5b]$$

For this, we must obviously gain solutions to the boundary value problems connecting the far-field variables with the interface variables; *i.e.*, we need to evaluate C_i/C_∞, T_i/T_∞, P_i/P_∞, and ϕ_i/ϕ_∞. Formally, we can express the change in free energy ΔG_{SV} due to the state variable changes in terms of the activity changes at the two locations

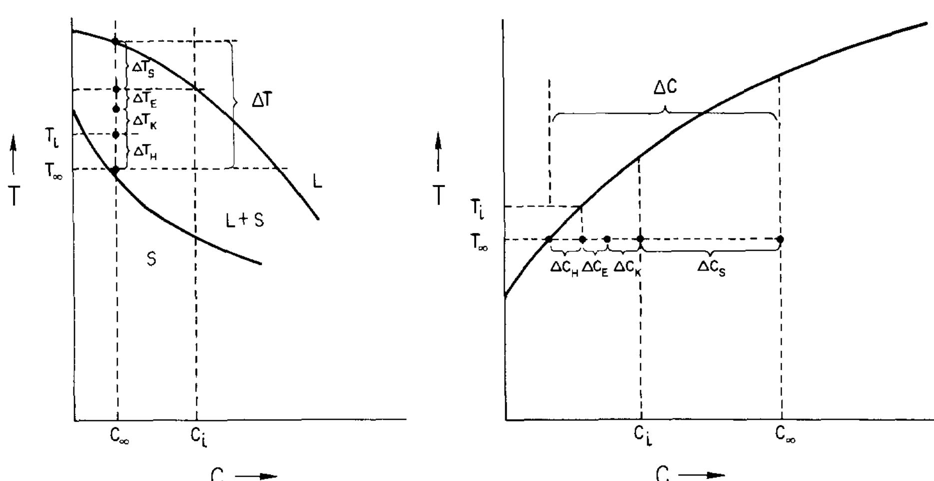

Fig. 4. Phase diagram illustrations of the coupling equations for ΔT and for ΔC during crystal growth from alloy melts. Case a (left) is typical of solvent growth at low alloy concentration while case b (right) is typical of solute crystal growth.

$$\Delta G_{SV} = \Delta G_{\infty} - \Delta G_{i}$$
$$= RT[\ln(a_{\infty}^{SiO_2}/a_{i}^{SiO_2}) - \ln(a_{\infty}^{Si}/a_{i}^{Si}) - \ln(a_{\infty}^{O_2}/a_{i}^{O_2})] \quad [6]$$

for the reaction example

$$Si + O_2 \rightleftarrows SiO_2$$

The driving force, ΔG_i, available at the interface for the transformation, is consumed by two parallel processes. One involves the excess free energy, ΔG_E, generated as a result of the transformation process and stored in both phases as discrete defects and/or strain fields. The other involves the departure from equilibrium, ΔG_K, needed for the molecular transition from the nutrient phase to incorporation in the crystal phase; *i.e.*

$$\Delta G_i = \Delta G_K + \Delta G_E \quad [7]$$

From crystal growth theory, with V = crystallization velocity and μ_i = a material coefficient (i = 1 to 4), we find that

$$V = \mu_1 \Delta G_K \quad [8a]$$

$$V = \mu_2 \Delta G_K^2 \quad [8b]$$

or

$$V = \mu_3 \exp(-\mu_4/\Delta G_K) \quad [8c]$$

for either (*i*) layer edge attachment and uniform attachment limited kinetics (Eq. [8a]), (*ii*) dislocation source limited kinetics (Eq. [8b], or (*iii*) two-dimensional nucleation source limited kinetics (Eq. [8c]), respectively. At low driving forces, layer generation or layer edge attachment operates while at high driving forces, uniform attachment operates. The greater is the difference in binding energy or enthalpy between the two phases, for constant growth temperature, the greater is the value of ΔG_K needed to reach the uniform attachment domain and the smaller are μ_1, μ_2, and μ_3. Likewise, for constant binding energy difference, the lower is the growth temperature, the greater must ΔG_K be to reach the uniform attachment domain and the smaller are μ_1, μ_2, and μ_3.

To obtain the values of C_i, T_i, P_i, and ϕ_i, one must solve some rather complex and coupled boundary value problems in general, so it is best to continue with the specific example of present interest; *i.e.*, the thermal oxidation of Si. For this system, we can assume $T_i/T_{\infty} = 1$ and the matter transport constraint yields for the oxidation rate

$$V = \Omega^{SiO_2}[J_{O_2} + \tfrac{1}{2} J_{O^=}] \quad [9a]$$

where J is flux per square centimeter and Ω is the molecular volume. Since

$$J^j = -\frac{D^j C^j}{kT}\frac{\partial \eta^j}{\partial x} \quad [9b]$$

Eq. [9a] becomes

$$V = \Omega_{SiO_2} \sum_j \left\{ -\frac{D^j}{n_j}(\nabla C^j)_i - \left[\frac{D^j}{kT} C^j \nabla(\Delta G^\circ)\right]_i \right\} \quad [9c]$$

where the interface field effect, ΔG°, is given by

$$\Delta G^\circ = Z^j e\phi + \frac{\partial}{\partial C^j}\left[\frac{\epsilon}{2}(\nabla\phi)^2 + \frac{\sigma^2}{2E}\right] + \Delta\mu_{H.M.} + \ldots \quad [9d]$$

In Eq. [9], the two diffusing species of greatest interest are j = O_2 (n_j = 1) and j = $O^=$ (n_j = 2); D^j is the diffusion coefficient of the j species, Z^j is the valence, ϵ is the permittivity of Si and SiO_2, which may vary somewhat with position, σ is the stress distribution, E is the modulus, $\Delta\mu_{H.M.}$ is a chemical potential change relating to different bonding energies for solute and solvent species in the interface region, and neglected contributions include activity coefficient effects, etc. To obtain the electrostatic potential in Eq. [9], as a function of position, we must solve Poisson's equation

$$\nabla^2\phi = -\frac{4\pi\rho}{\epsilon} \quad [10a]$$

$$= -\frac{4\pi e}{\epsilon}\left\{(n_p - n_e) + \sum_i (Z_D^i N_D^i - Z_A^i N_A^i) + \sum_l Z_l N_l + \sum_q Z_{O_q} N_{O_q}\right\} \quad [10b]$$

and

$$\epsilon_{Si}(\nabla\phi)_{Si} - \epsilon_{SiO_2}(\nabla\phi)_{SiO_2} = \rho_{Si/SiO_2} \quad [10c]$$

In Eq. [10], ρ is the total charge density, n_p and n_e are the density of holes and electrons, respectively, N_D and N_A refer to the densities of donor and acceptor species of un-ionized or ionized variety, respectively, N_l refers to the density of l-type physical defects of valence Z_l created by mechanical or other stress (here, l refers to charged vacancies and charged Si interstitials, etc.), and N_{O_q} refers to the density of oxygen species of un-ionized or ionized nature.

The third group of equations needed to complete Eq. [9] and [10] involves the local pressure and stress distribution created in the interface region as a result of the oxidation process. For the moment, because of the complexity of these equations, we shall content ourselves with a simple functional representation of the interface situation; *i.e.*

$$\frac{P_i}{P_{\infty}} = f(\Delta\lambda, E, \sigma, \sigma_Y, V, \rho_i, \eta^*, \ldots) \quad [11]$$

Equation [11] is meant to represent that the molecular size mismatch, $\Delta\lambda$, existing at the Si/SiO_2 interface produces a strain which connects to a stress σ through the modulus E. When σ exceeds the yield stress, σ_Y, for the Si and SiO_2, flow begins to occur in these two phases which creates point and line defects of density ρ_i which may be charged. Since the degree of flow depends on the viscosity, η^*, of the materials and the time available, the process also depends on the oxidation rate, V. Eernisse (14) has clearly demonstrated the viability and importance of the viscous flow process during Si oxidation. We shall deal with this complex process at greater length in Part II (15). Here, we are primarily interested in illustrating the coupled nature of the three state variables, C_i, P_i, and ϕ_i.

From the foregoing, we can set up an excess free energy balance for the system and can see that ΔG_E from Eq. [7] is given by

$$\Delta G_E = \frac{1}{V}\frac{\partial}{\partial t}\left[\mathcal{E}_D + \frac{1}{2E}\int \sigma^2 dv\right] \quad [12]$$

where $\mathcal{E}_d$ is the energy stored in defects (planar, line, and nonequilibrium concentrations of point defects) relative to the standard state structure of the Si and the SiO_2 (the equilibrium structures involved in the thermochemical balance under consideration) and the second term in the bracket represents the stored elastic strain energy in the two materials. The final general constraint equation that one wishes to delineate fulfills the requirement that, for the satisfaction of Eq. [9], there must be sufficient free volume available in the interface region for the various incoming oxygen species to occupy and react with the local silicon species. From Rutherford backscattering studies (16), we know that Si does not diffuse to the outer surface of the oxide but that the oxygen diffuses inward. However, a type of viscous flow could occur due to interface stresses wherein SiO_2 units flowed out and free volume flowed in. In addition, the condition might also be satisfied by vacancy influx or interstitial egress from the Si phase. We call this the "free volume supply condition" and express it as

$$V \propto J_v^{Si} + J_v^{SiO_2} \quad [13a]$$

where $J_v{}^i$ is the flux of free volume from phase i to the interface per unit interfacial area. For example, since the relaxed spacing between the Si atoms in the SiO_2 units is about 1.3 times the Si-Si spacing in the Si lattice, if the Si/SiO_2 interface moves into Si at V cm/sec, the oxide must thicken at 2.25 V cm/sec and this requires that free volume flow in at a rate of 1.25 V cm/sec to produce an unstrained condition with no Si interstitial flow.

To be more precise, if the Si/SiO_2 interface moves into the Si phase at a velocity V, the number of Si atoms per unit area of interface to be oxidized per unit time, N^*, is equal to the number of SiO_2 molecules formed per unit area per unit time where

$$N^* = \frac{V}{\Omega^{Si}} - (J_I{}^{Si} - J_{V^*}{}^{Si}) \quad [13b]$$

Here, Ω is the atomic volume and the bracketed term gives the rate of flow of the Si atoms away from the interface and into the Si via interstitials, I, leaving the interface and vacancies, V*, approaching the interface. This assumes that those interstitials flowing into the SiO_2 from the interface will all become oxidized to SiO_2, which may not be completely correct. If we assume that either a condition of zero strain exists in the SiO_2 at the interface region or a stationary state strained layer has developed in the SiO_2 at the interface, then the total free volume supply condition becomes

$$N^*(\Omega^{SiO_2} - \Omega^{Si}) = \Omega^{Si}(J_I{}^{Si} - J_V{}^{Si}) + \bar{v}_f{}^{SiO_2} J_{\bar{v}}{}^{SiO_2} \quad [13c]$$

Here, $\bar{v}_f{}^{SiO_2}$ is the average free volume element size for the SiO_2 flow process. If, instead, we assume that an isotropic strain, δ', develops in the SiO_2 film at the interface, then the free volume supply needed at the interface per unit area time, $\Delta v_f{}^*$, is given by

$$v_f{}^* \rightleftharpoons N^*[(\Omega^{SiO_2} - \Omega^{Si}) - (\delta'\lambda^{SiO_2})^3] \quad [13d]$$

where λ is the average SiO_2-SiO_2 distance of equilibrium.

The realistic situation to be considered is the thermal oxidation of Si in the presence of impurities or intentional dopants. The appropriate representation of the driving force is then via the supersaturation, ΔC, so that Eq. [4d] should be used as the governing coupling equation for the SiO_2 as the nutrient phase. This situation is represented pictorially in Fig. 5 where that portion of the driving force needed to maintain the major constituent concentration at the interface, $C_I{}^M$, is illustrated as a small portion of the total driving force; *i.e.*, $\Delta C_S{}^M/\Delta C_\infty << 1$. We shall see in Part II (15) that this is probably an appropriate representation of the true state of this system. The component $\Delta C_S{}^m$ may itself be quite small; however, if the j constituents refer to hydrogen or carbon (17), etc., they may either poison or catalyze a sufficiently large fraction of active interface sites for oxygen attachment that $\Delta C_K{}^M$ must be either greatly increased or decreased for the same V. We shall see in Part II that ΔC_E will be very large for a state of completely coherent strain applying at the interface and very small for the state of a completely incoherent interface. Next, $C_R{}^M$ is the equilibrium concentration of oxygen at the Si/SiO_2 interface and is given in terms of the activities for SiO_2 and Si at the interface and the equilibrium constant for the reaction. Finally, a supersaturation $\Delta C_g{}^M$ is needed to maintain the bulk SiO_2 at an oxygen concentration of $C_\infty{}^M$. Using the gas as our reference nutrient phase, the applicable coupling equation is

$$\Delta C_\infty = \Delta C_g{}^M + \Delta C_S{}^M + \Delta C_K{}^M + \Delta C_S{}^m + \Delta C_E \quad [4f]$$

Proposed Oxidation Model for Si

At the initial stages of the oxidation process illustrated in Fig. 6, electrons are thought to transfer from the Si to the SiO_2 in order to equalize the electrochemical potential of the electrons, η_e, throughout both phases. Since the electrons are the most mobile species in the system, they will quickly equilibrate via tunneling and conduction. This charge transfer leads to a positive potential on the Si side and a negative potential on the SiO_2 side of the interface. Electron transfer continues until equilibrium is established for the electrons and a Galvani potential difference $\Delta\phi$ is developed across the three-phase system Si/SiO_2/gas. The magnitude of $e\Delta\phi$ will be given by ΔE_F, the difference in Fermi levels for the Si and the SiO_2 relative to the zero energy state of vacuum. The relative fraction of $\Delta\phi$ developed across each phase requires a solution to Eq. [10] (Poisson's equation).

In the SiO_2 near the gas interface, the following ionization reaction is expected to occur

$$O_2 + 4e^- \rightleftharpoons 2\,O_= \quad [14]$$

These $O_=$ interstitial ions are formed in the presence of the Si/SiO_2 electrostatic field which attracts them to the interface region. Of course, this loss of negative charge from the SiO_2/gas interface region invites more electron transfer from the Si so that η_e stays constant. At the Si/SiO_2 interface, the $O_=$ becomes involved in the reaction

$$v_f + Si + 2\,O_= + 4p^+ \rightleftharpoons SiO_2 \quad [15]$$

which tends to make the Si more negative so more electron transfer is needed from Si to SiO_2 to restore η_e to a constant value throughout (v_f stands for free

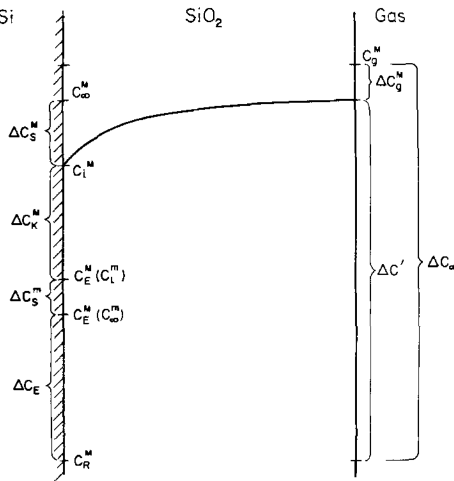

Fig. 5. Schematic representation of the supersaturation coupling equation involved in the thermal oxidation of silicon.

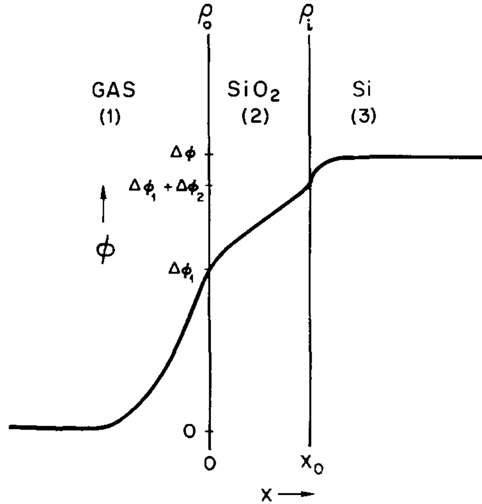

Fig. 6. Illustration of the electrostatic potential variation across the three-phase system, Gas/SiO2/Si, during the oxidation process.

volume). The O_2 continues to decompose and to pump $O^=$ to the interface region in order to oxidize the Si. The electron transfer in the reverse direction to equalize η_e completes the electrical circuit and sustains the pumping action so that the interface field, $\nabla\phi_i \approx \Delta\phi_2/X_o$ in Fig. 6, is maintained.

With this model, one can readily see why Jorgensen (1) was able to stop the oxidation of Si by imposing a sufficiently large negative potential on the Si even if neutral oxygen species were present. One can see that, even with a flow of neutral oxygen toward the Si, if the electric field drives the $O^=$ away from the Si/SiO_2 interface region, then Eq. [14] will produce ionization of the incoming neutral oxygen to maintain the equilibrium level of $O^=$ and $\nabla\phi_i$ will move it toward the SiO_2/gas interface. Thus, a conversion of O to $O^=$ occurs in the interface region and the reverse reaction occurs in the SiO_2/gas region so that no oxygen is available at the interface to react with the Si to form SiO_2.

One can also see why Doremus (3) holds to his viewpoint. The need to satisfy the free volume supply condition of Eq. [13] generally requires either viscous flow, diffusion of oxygen vacancies in the SiO_2, or diffusion of vacancies and interstitials in the Si. The latter of these two SiO_2 processes has an activation energy associated with neutral oxygen diffusion since substitutional oxygen must diffuse outward to the SiO_2/gas interface in order for vacancies to diffuse inward to the Si/SiO_2 interface. However, such a process, already proposed by Fowkes *et al.* (18), does not seem likely to sustain the oxidation reaction. The former SiO_2 process, that of viscous flow, is the more likely one for SiO_2 and, since it involves the breaking of bridging oxygen bonds, the activation energy for the flow process should be similar to that for neutral oxygen transport in SiO_2. By inserting Eq. [14] into Eq. [15], one can also see that the $2\,O^=$ reaction species is equivalent to the O_2 reaction species so that one expects the driving force for oxidation to be proportional to $[O_2]$ when the system stays close to equilibrium; *i.e.*, to vary linearly with oxygen gas pressure. This may resolve the Doremus objections to $O^=$ as an oxidizing species.

Specific Pathways for Influencing the Oxidation Velocity

From the two preceding sections, one should realize that any experimental process variation that produces a change in the oxidation rate can do so only via a change in Eq. [4]-[15]. It is via scrutiny of these equations that one may illuminate the factors controlling the oxidation rate in general, and whereby one may discover the possible mechanisms whereby high silicon doping levels can influence V in particular. Let us now consider some of these specific pathways.

1. As mentioned in the text adjoining Eq. [11], and to be discussed more fully in the Part II (15), the strain generated by the molecular size mismatch at the oxidizing interface influences the defect production in the interface region during oxidation. This influences V via the ΔG_E term in Eq. [7] which controls the available ΔG_K, for fixed ΔG_i, and also via the interface charge states to alter $\nabla\phi_i$ in Eq. [9].

2. At sufficiently high doping levels, the Si becomes extrinsic even at the oxidation temperature and the Fermi level shifts from midband. Thus, the electron transfer from the Si to the SiO_2 to produce η_e equal to a constant is shifted. This alters $\nabla\phi_i$ and thus V via Eq. [9]. In addition, the Fermi level shift increases the equilibrium charged vacancy and interstitial concentration in the Si so that J_v^{Si} in Eq. [13] may be greatly increased and thus V increased without an increase in ΔG_E. This process path will be discussed at length elsewhere (19).

3. The dopant redistribution at the interface during oxidation will produce a pileup of phosphorus or a depletion of boron at the Si side of the interface because of solute partitioning at the moving interface. This changes the activities of the key species Si and SiO_2 at the interface altering the magnitude of ΔG_i in Eq. [6] and thus altering V via Eq. [7] and [8]. Calculations, to be published elsewhere (20), indicate that the field-determined segregation is much more significant than the segregation due to interface partitioning.

4. The interface pileup of P or depletion of B alters the strength of the Si-Si bonds at the interface. This changes the degree of roughness and interface vacancy states on a molecular scale so that the molecular attachment coefficients μ_j in Eq. [8] are altered. Thus, the oxidation rate will be altered via this change in μ_j. The magnitude of this effect will be assessed at a later date.

5. For completeness, one needs to recognize that, at heavy doping levels, the basic diffusion coefficients D^j in Eq. [9] may be altered as may the thermodynamic activity coefficients entering the complete equation. These would also influence V.

Acknowledgments

Dr. B. E. Deal, Dr. J. D. Plummer, Mr. C. P. Ho, and Mr. H. Z. Massoud provided many helpful discussions of the available thermal oxidation data and of the processes involved. This work was supported by the Defense Advanced Research Projects Agency under Contract No. DAAB07-77-C-2684.

Manuscript submitted Oct. 2, 1978; revised manuscript received Sept. 11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug 1, 1980.

Publication costs of this article were assisted by Stanford University.

On the Kinetics of the Thermal Oxidation of Silicon

II. Some Theoretical Evaluations

William A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A steady-state transport analysis, including electric field effects, leads to orientation-dependent linear and parabolic rate constants. A free energy budget accounting indicates that neutral oxygen diffusion in the SiO_2 cannot alone account for the oxidation reaction. An analysis of the system relaxation associated with the Si/SiO_2 interface disregistry indicates that a network of extra half-planes forms at the interface to reduce the stored strain energy and that movement of the interface requires the influx of vacancies from the Si, egress of Si interstitials from the interface back into the bulk Si, or free volume influx from the SiO_2 to remove the extra half-plane segments. This tends to become a dominant feature of the kinetics of oxidation. An analysis of the proportioning of the total driving force into its component contributions and their relative magnitudes is given. The coordination of a variety of diverse oxidation studies is indicated.

In Part I of this series (1), both a theoretical perspective and a new model of thermal oxidation with specific application to silicon were presented which qualitatively seems to restore harmony to what might appear to be opposing views of the oxidation process. In addition, the various possible process paths available for changes in oxidation rate have been delineated. In the present paper, theoretical consideration is given to (*i*) a steady-state transport analysis which explicitly delineates interface-field effects, (*ii*) an analysis of the system relaxation associated with the Si/SiO_2 interface disregistry, and (*iii*) an analysis of the relative magnitudes of the various parallel driving forces ΔG_{SV}, ΔG_E, and ΔG_K in comparison with ΔG_∞ for the oxidation process (1). From these considerations, one finds orientation-dependent linear and parabolic rate constants for the oxidation process plus a clear indication that neutral oxygen diffusion alone in the SiO_2 cannot account for the oxidation reaction. In addition, unless the interface relaxes to become partially incoherent, large amounts of strain energy are stored in the SiO_2 and this greatly retards the oxidation process. The relaxation process leaves a network of extra half-plane segments on the Si side with associated dangling bands at the interface. Movement of the interface requires the generation of interstitials and the influx of vacancies to remove these half-plane segments and this becomes a dominant feature in the kinetics of oxidation. From these analyses, the coordination of a variety of diverse Si oxidation studies becomes possible and a number of new experiments are suggested.

Modified Deal-Grove Transport Analysis

Since we cannot unambiguously prove that only one chemical species is migrating in the SiO_2, it seems more useful to consider the presence of two diffusing species, O_2 and $O_=$, in any transport analysis. Si transport is neglected for the reasons outlined in Part I (1). Even though the concentration ratio of $O_=/O_2$ may be quite small, the interface field effect may generate comparable fluxes of the two species so that neither should be neglected in the oxidation process. The analysis to follow is carried out in two phases. The first phase deals solely with charged species transport and completely neglects the neutral species diffusion so that we can compare the results with those found by Deal and Grove (2) using the D_{eff} approach (1). The second phase deals with mixed diffusion of the two species, which is the general case.

Key words: field effects, point defects, pseudo-dislocation array.

Some Deal and Grove analysis results.—The steady-state flux, J_2, of oxygen across an oxide film of thickness X_o and having an SiO_2/gas concentration of C_o and an SiO_2/Si concentration of C_i is given by (2)

$$J_2 = \frac{D_{eff}}{X_o}(C_o - C_i) \quad \text{[1a]}$$

$$\frac{C_i}{C^*} = 1 \bigg/ \left[1 + \frac{k^*}{h^*} + \frac{k^* X_o}{D_{eff}}\right] \quad \text{[1b]}$$

and

$$\frac{C_o}{C_i} = 1 + \frac{k^* X_o}{D_{eff}} \quad \text{[1c]}$$

In Eq. [1], C^* is the equilibrium concentration of the oxidant in the oxide, k^* and h^* are the rate constants for O_2 transfer applying at the SiO_2/Si and the SiO_2/gas interfaces, respectively, and $D_{eff} \approx 2D_i$ if the transport species is ionic. The solution for X_o is found to be

$$X_o^2 + AX_o = B(t + \tau) \quad \text{[2a]}$$

where

$$A = 2D_{eff}\left(\frac{1}{k^*} + \frac{1}{h^*}\right) \quad \text{[2b]}$$

$$B = 2\frac{D_{eff}C^*}{N_1} \quad \text{[2c]}$$

and

$$\tau = \frac{X_i^2 + AX_i}{B} \quad \text{[2d]}$$

In Eq. [2], N_1 is the number of oxidant molecules incorporated into a unit volume of the oxide layer, X_i is the initial layer thickness at $t = 0$, B is the parabolic rate constant for the oxidation regime

$$X_o^2 \approx B(t + \tau) \qquad \text{for } t + \tau >> A^2/4B \quad \text{[3a]}$$

while B/A is the linear rate constant for the oxidation regime

$$X_o \approx \frac{B}{A}(t + \tau) \qquad \text{for } t + \tau << A^2/4B \quad \text{[3b]}$$

Modified Deal-Grove analysis for $O_=$ and a constant field.—We consider the case where the fraction α, of the total macropotential difference, $\Delta\phi$, developed from the gas to Si, is located across the SiO_2 (see Fig. 6 of Part I). We will consider the field to have an approximately constant value $\alpha\Delta\phi/X_o$. Then, equating the ion fluxes at the gas/SiO_2 and the Si/SiO_2 interfaces with J_2, we find

$$J_2 = D_i \left[\frac{C_o - C_i}{X_o} + \alpha \left(\frac{2e}{kT} \right) \frac{|\Delta\phi|}{X_o} \left(\frac{C_o + C_i}{2} \right) \right] \quad [4a]$$

$$= \frac{1}{X_o} [C_o a - C_i b] \quad [4b]$$

where

$$a = D_i \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right); \quad b = D_i \left(1 - \frac{\alpha e |\Delta\phi|}{kT} \right) \quad [4c]$$

The solution for the film thickness, X_o is the same as Eq. [2] but with A, B, and τ replaced by A', B', and τ', where

$$A' = 2 \left(\frac{b}{k^*} + \frac{a}{h^*} \right) = 2D_i \left[\left(1 - \frac{\alpha e |\Delta\phi|}{kT} \right) \frac{1}{k^*} + \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right) \frac{1}{h^*} \right] \quad [5a]$$

$$B' = \frac{2aC^*}{N_1} = 2D_i \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right) \frac{C^*}{N_1} \quad [5b]$$

$$\tau' = (X_i^2 + A'X_i)/B' \quad [5c]$$

$$\frac{B''}{A''} = \frac{C^*}{N_1} \left[\frac{k^* h^*}{k^* + h^* \frac{b}{a}} \right] = \frac{(C^*/N_1)(k^* h^*)}{k^* + h^* \left\{ \dfrac{1 + (D_{O=}/2D_{O_2}) \left(1 - \frac{\alpha e |\Delta\phi|}{kT} \right) [p]_i^{-2} \left(\frac{K_1}{K^*} \right)^{1/2} C_i^{-1/2}}{1 + (D_{O=}/2D_{O_2}) \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right) [e]_o^2 K_o^{1/2} C_o^{-1/2}} \right\}}$$

$$\alpha = f \left(X_i, \frac{\epsilon_{Si}}{\epsilon_{SiO_2}}, \rho_S \right) \quad [5d]$$

In Eq. [5], ϵ refers to the permittivity, ρ_S to the surface charge density, and $N_1' = 2N_1$. The exact value of α is yet to be determined and it is merely represented here as the function f of the variables involved.

Perhaps the most interesting feature to note about these results is that the electric field effect, which enhances the ionic transport, enters the formal solution as modified kinetic coefficients

$$k^{*\prime} = D_i k^*/b; \quad h^{*\prime} = D_i h^*/a \quad [6]$$

as well as an altered parabolic rate constant. Thus, changing the Si doping level, such that the Fermi energy moves away from midband at the oxidizing temperature, should alter the magnitude of α and thus both the linear and the parabolic rate constants. In addition, since $\alpha\Delta\phi$ is expected to depend on the orientation of the Si substrate, both B' and B'/A' will be orientation dependent.

Combined $O_=$ and O_2 transport with constant field.—We shall define the interface concentrations, C_o and C_i as

$$C_o = C_{oO_2} + C_{oO=} \approx C_{oO_2} \quad [7a]$$

$$C_i = C_{iO_2} + C_{iO=} \approx C_{iO_2} \quad [7b]$$

where we have from Eq. [14] and [15] of Part I (1) for the unconstrained case (neglecting v_f)

$$C_{oO=} = K_o^{1/2} [e]_o^2 C_{oO_2}^{1/2} \quad [8a]$$

$$C_{iO=} = \frac{K_i^{1/2}}{K^{*1/2}} [p]_i^{-2} C_{iO_2}^{1/2} \quad [8b]$$

and

$$K^* = [O_2][Si]/[SiO_2] \quad [8c]$$

Following our standard procedure, we obtain

$$J_2 = \frac{D_{O_2}}{X_o} (C_{oO_2} - C_{iO_2}) + \frac{D_{O=}}{2X_o} \left\{ (C_{oO=} - C_{iO=}) + \frac{\alpha e |\Delta\phi|}{kT} (C_{oO=} - C_{iO=}) \right\}$$

$$= \frac{1}{X_o} [C_o a - C_i b] \quad [9a]$$

where

$$a = D_{O_2} + \frac{D_{O=}}{2} \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right) [e]_o^2 K_o^{1/2} C_o^{-1/2} \quad [9b]$$

$$b = D_{O_2} + \frac{D_{O=}}{2} \left(1 - \frac{\alpha e |\Delta\phi|}{kT} \right) [p]_i^{-2} \left(\frac{K_1}{K^*} \right)^{1/2} C_i^{-1/2} \quad [9c]$$

Thus, our solution for X_o is again of the same form as Eq. [2a] with altered A, B, and τ by using Eq. [9b] and [9c] instead of Eq. [4c] in Eq. [5]. In this general case, the modified kinetic coefficients (Eq. [6]) depend on both the Fermi level effect via α and the partial pressure of oxygen in the gas phase.

The parabolic and linear rate constants are given by

$$B'' = \frac{2D_{O_2}C^*}{N_1} \left\{ 1 + \frac{D_{O=}}{2D_{O_2}} \left(1 + \frac{\alpha e |\Delta\phi|}{kT} \right) [e]_o^2 K_o^{1/2} C_o^{-1/2} \right\} \quad [10a]$$

Although the orientation dependence of these quantities is clearly displayed, the oxygen pressure dependence is not because we do not yet know how α, $[e]_o$, and $[p]_i$ depend on p_{O_2}. For similar reasons, we cannot fully evaluate the heavy doping effects (3) on enhancing the oxide growth velocity, V, even though one expects $\Delta\phi$ to increase for n-type and decrease for p-type dopants.

Consequences of Interface Disregistry

It is relatively easy to discuss the consequences of atomic disregistry at an interface for two crystalline materials but it is much more difficult to do so for a crystalline/amorphous combination. In the latter case, the prevailing opinion is that distorted interface bonds do not produce much strain energy in amorphous material and this is a fair approximation for changes at constant volume. However, for oxidation processes, like that of Si, where large molecular volume differences exist between the two phases, this approximation does not hold. One must visualize extra half-planes in the nutrient crystal phase (Si) terminating at a moving oxide interface where the product phase (SiO_2) has a greater specific volume. The ends of these extra half-planes may not have the same excess energy as they would have if the amorphous phase were crystalline; however, the basic ideas involved should be qualitatively similar. Thus, let us first consider the consequences of disregistry between two crystalline materials and then extend the ideas to the Si/SiO_2 interface.

In the crystal/crystal disregistry case, it is well known that, for thick crystals, a dislocation net of edge-screw type forms at the interface to satisfy the coherency strains (4). This leads to a predictable spacing between the dislocations with the softer crystal predominantly determining the shear stress level at the interface. For one of the crystals being very thin, the system may adopt a coherent rather than a dislocated interface in order to minimize the free energy of the system and, at some critical film thickness, the system relaxes to provide an interface dislocation net of lower total free energy. Thus, the transition is from a distributed strain energy throughout the film to a localized defect energy at the interface. This same effect is observed as a result of the constitutional strains developed as a result of the diffusion of n-type

or p-type dopant into Si from the surface layer (5, 6). At low doping levels, the strain is not sufficient to cause the transition to dislocation net formation; whereas, above a predictable condition (6), the dislocation net appears.

To illustrate the interface relaxation process more fully, consider taking a single crystal which is sliced along a low index plane and then one-half is rotated with respect to the other by some angle. On the interface, regions will exist where adjacent atoms in the two pieces are within 10-20% of a coincident position. Other regions will exist where adjacent atoms are out of coincidence by more than 20% of a lattice distance. At a temperature suitable for atomic relaxation, those regions wherein only small displacements are needed for coincidence become completely coherent and the adjacent regions become completely incoherent. This situation is illustrated in Fig. 1 for the (110) plane of the body-centered lattice wherein a hexagonal network of dislocations forms at the interface.

Carrying the coincidence net idea a little further, suppose one considered the (111) plane of Si as one surface net of molecules and a random network at the average spacing of SiO_2 as the other surface net of molecules. Placing these two nets in contact would lead to irregular regions of near coincidence separated by domains out of coincidence by a large amount. Thus, relaxation at the interface should lead to irregularly shaped domains of coherence and incoherence at the interface. The relative proportions of these two should be a function of the orientation of the interface. In the incoherent regions, loci of Si surface atoms will exist that do not have a matching SiO_2 molecule associated with them across the interface. This will lead to dangling Si bonds distributed irregularly at the interface. The density of these bonds will be called N_θ^b to represent that it will vary with the Si surface orientation, θ.

The importance of these bonds, besides the obvious surface-state connotation, is that they represent the exposed portion of extra half-plane segments of the Si that must be removed by the influx of vacancies or by the egress of interstitials so that the Si/SiO_2 interface can continue to propagate into the Si during the oxidation process. Thus, N_θ^b indirectly controls the oxidation rate in that it determines what the vacancy and interstitial flux must be for a given oxidation velocity V or, assuming a limited and fixed interstitial and vacancy flux, V is determined (see Eq. [19]).

No one has observed a net of dislocations at the Si/SiO_2 interface, which is not too surprising. Even if the extra half-plane segments were aligned to form a rectangular or triangular grid of macroscopic extent, diffraction would not reveal them as a dislocation net. This is because diffraction contrast is effective only when dealing with small departures from a perfectly regular lattice and, here, one side of the interface represents only small departures from a perfectly random lattice. Thus, we cannot expect to find the large constructive interference effects against which a dislocation is delineated as a consequence of a line of destructive interference. Although the extra half-plane segments at the Si/SiO_2 interface might be thought of as dislocation segments, they do not have either the normal strain field associated with a dislocation or the same line energy. In the present case, the line energy of these pseudo-dislocations will be much lower than that for regular dislocations in the Si lattice.

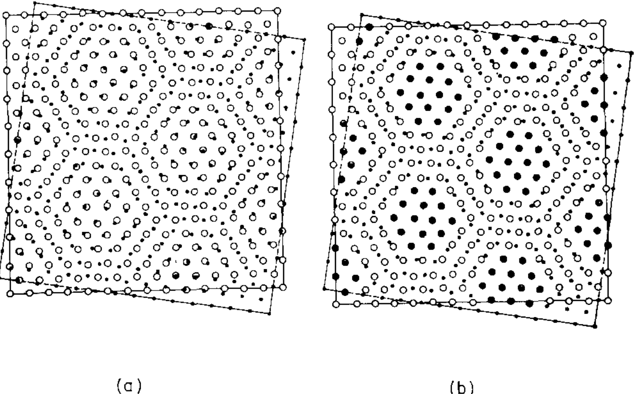

Fig. 1. Formation of a hexagonal network in the (110) plane of the body-centered lattice: (a) after rotation of the two nets of atoms and (b) after relaxation of the atoms.

Although it is possible to construct an abrupt transition from a regular Si lattice to a random network of SiO_2 by distortion of interface bonds with a relatively small calculated excess energy storage at the interface for distortions at constant volume, the real distortion condition which involves volume changes should be reflected macroscopically in the modulus of elasticity of the SiO_2. Thus, the strain energy determined by the use of macroscopic elasticity parameters should specify the excess energy of the interface region. In terms of structural effects in the SiO_2, one might also expect that, since a regular Si lattice is the starting point for oxidation, some tendency toward a crystalline ordering related to a form of SiO_2 might appear in a narrow transition zone at the interface. The film thickness at which relaxation occurs to the equilibrium configuration of SiO_2 would be of real interest.

If we approximate the situation with the two-crystal analogy where one is a thin film, the minimum free energy of the system will be a compromise between pseudo-dislocation energy, $\mathcal{E}_d$, and stored strain energy, $\mathcal{E}_S$. The total energy, $\mathcal{E}_T$, of the film can be minimized with respect to the degree of strain, δ', existing at the interface. In the initial stages of oxidation, the oxygen atoms are expected to force themselves between the silicon atoms to form SiO bonds which are highly strained. The initial thin film may be coherent and highly structured in spite of the $\sim$30% compressive strain located in the film. Using $E = 6.6 \times 10^{11}$ dynes/cm^2 for SiO_2 at 1200°C (7) and $\nu \sim 0.33$, this leads to $\mathcal{E}_S \approx 10^{11}\omega$ dynes/cm^2 for an SiO_2 film thickness of ω. This reduces to a value of about 60 kcal/mole SiO_2, which is a very significant energy storage when it is recalled that the free energy of formation, ΔG_o, for SiO_2 from Si and oxygen (1 atm) is -154 kcal/mole at 1000°C ($\Delta G_o = -\Delta G_\infty$). If we compare this with an interface pseudo-dislocation net of average spacing $\sim$3-4 Si distances and energy $\mathcal{E}_d \sim 500$-1000 ergs/cm^2, we find that $\mathcal{E}_S > \mathcal{E}_d$ even when $\omega = 1$ lattice spacing thick. Thus, if it is possible for it to do so, a monolayer of SiO_2 on Si will relax to form a pseudo-dislocation net at the interface. Of course, for such a two-dimensional SiO_2 structure, the equilibrium intermolecular spacing will be somewhat different than for a three-dimensional structure. However, it should be clear that, if the system can rearrange itself to introduce these pseudo-dislocations, it will be energetically favorable to do so and the excess stored energy, ΔG_E, will be reduced to small values characteristic of the residual stored strain energy in the film.

At present, good theoretical and experimental evidence exists for flow via dislocations in glass (8, 9). Silicate glasses tend to flow in a viscous manner, while metallic glasses tend to be plastic, and amorphous polymers fall somewhere in between. In the silicate case, the glass is an open covalently bonded network and the passage of dislocations through it leaves broken bonds (free radicals) in their wake. In addition, density fluctuations, as well as dislocation loops, may be part of the debris left in the wake of a moving dislocation in such a system (9). The shear modulus of amorphous SiO_2 is less than that of crystalline SiO_2 by about 14% (10) and the elastic energy of a dislocated random network is lower than that of the dislocated crystal by the same factor. If the plastic deformation of a glass is not absolutely uniform, dislocation-like defects with

long-range stress fields separate regions that have suffered different shears. Given sufficient time, the long-range stress field will relax by a kinematic process involving the uncorrelated motion of pairs, or small groups, of atoms, a process not possible in a crystal because its translational symmetry permits only correlated motion. These relaxed defects have been named "disjunctions" and they, rather than dislocations, will be found in well-annealed glass (10).

Disjunctions are expected to influence electrical and optical properties by introducing new electronic energy levels into the network. They will also act as high diffusivity paths for mass-transport in network glasses. Because they have low energy (roughly equal to the core energy of a dislocation) and do not interact strongly, it may be possible to introduce a very high density of disjunctions into a glass.

For the total energy associated with the film-forming process, we must include the nonequilibrium vacancy and interstitial effects in the silicon; *i.e.,* we must use, per unit area of interface

$$E_T = \mathcal{E}_d + \mathcal{E}_S + \int_0^\infty [(C_V - C_{V\,\mathrm{equil.}})\eta_V + (C_I - C_{I\,\mathrm{equil.}})\eta_I]dx \quad [11]$$

where $\mathcal{E}_d$ is the pseudo-dislocation net energy and $\mathcal{E}_S$ is the stored strain energy, while the equilibrium concentrations, $C_{j\,\mathrm{equil.}}$, and the electrochemical potentials, η_j, for the vacancies and interstitials will be a function of the Fermi energy, the local electrostatic potential, and the state of stress. For the moment, we shall neglect the V and I effects and will return to them later. Let us first consider the macroscopic flow of the SiO_2 to determine how easily that process can influence pseudo-dislocation network formation and propagation at the Si/SiO_2 interface.

The viscoelastic process.—Ernisse (11) has clearly demonstrated the viability and importance of the viscous flow process during Si oxidation at high temperatures, so let us consider the kinetics of this flow at normal oxidation temperatures. The general viscoelastic expression relating applied stress, τ, to strain rate, $\dot{\gamma}$, is

$$\dot{\gamma} = A\left(\frac{\tau}{\tau_y}\right)^n \quad [12]$$

where τ_y is the yield stress, A is a constant, and $n = 1$ for linear elasticity, $1 < n < 10$ for nonlinear elasticity, and $n > 10$ for ideal plasticity. Let us first consider the simple approximation that our SiO_2 film yields in the same fashion as the simple "Maxwell element" shown in Fig. 2. For this case, $n = 1$ and the load τ acting on the spring leads to an initial strain γ_{sp} given by

$$\gamma_{sp} = 3\tau/E \quad [13a]$$

and the dashpot begins to relax at a strain rate $\dot{\gamma}_{dp}$ given by

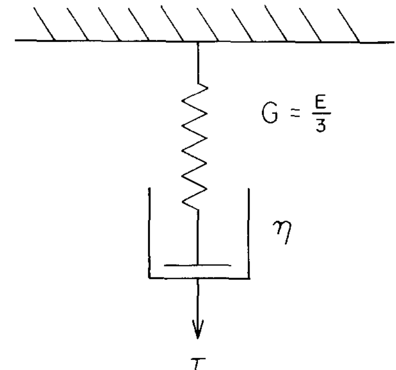

Fig. 2. A simple Maxwell viscoelastic element as a mechanical analogue to the SiO_2 stress relaxation.

$$\dot{\gamma}_{dp} = \tau/\eta^* \quad [13b]$$

Solving the differential equation for the stress as a function of time, utilizing the condition $\dot{\gamma}_{sp} + \dot{\gamma}_{dp} = 0$, leads to

$$\tau(t) = \tau_o \exp\left(-\frac{Et}{3\eta^*}\right) \quad [14]$$

Thus, the stress relaxation rate depends on the viscosity of the material. Using Eq. [14], we can ask how far into the oxide, $m^*\lambda_o$, where m^* is a number and λ_o is the intermolecular distance, we must go before the stress has relaxed by an order of magnitude. This distance would give us the effective size of a nonequilibrium structured layer of SiO_2 at the Si interface. Allowing $t^* = m^*\lambda_o/\overline{V}$, where $\overline{V}$ is the average oxidation velocity, the width of the structured layer, $m^*\lambda_o$, is given by

$$m^*\lambda_o \approx 9\eta^*\overline{V}/E \quad [15]$$

Using $T = 1000°C$, $\overline{V} \sim 10^{-9}$ cm/sec, $E \sim 10^{12}$ dynes/cm^2, $\eta_{\mathrm{equil.}}^* = 6.3 \times 10^{16}$ poise for dry O_2 (I.R. Vitreosil) (11), and $\eta_{\mathrm{equil.}}^* = 5.6 \times 10^{14}$ poise for wet O_2 (O.G. Vitreosil + 0.4% OH) (11), we find $m^*\lambda_o \sim 5 \times 10^{-4}$ cm and 5×10^{-6} cm, respectively, for dry O_2 and wet O_2. This number seems to be a factor $\sim 10^3$ too large which suggests that the value of n to be used in Eq. [12] should be at least 2. Thus, although we cannot proceed effectively to evaluate the application of Eq. [12] with higher values of n because of uncertainties with respect to A and τ_Y, we can see that (*i*) the flow process does not readily generate the minimum free energy condition and (*ii*) the flow process will yield a nonequilibrium structured SiO_2 layer of some thickness X^* at the Si/SiO_2 interface, X^* for dry oxygen will be greater than X^* for wet oxygen, and X^* for each will increase as the temperature is decreased. If we had used $\tau_Y = \beta\eta^{*1/p}$ in Eq. [12], where β and p are fitting parameters for a given material, we would have found for $n/p = 2/3$, that $m^*\lambda_o \sim 55$Å for dry O_2 at 1000°C when $m^*\lambda_o \sim 3.5$Å for wet O_2 at the same temperature.

Investigators working in the area of the mechanical properties of crystalline materials (12, 13) have shown how many of these properties may be explained in terms of dislocation dynamical modeling. One usually invokes the Taylor-Orowan equation as the basic description for plastic flow; *i.e.*

$$\dot{\gamma} = \alpha'\rho_m\tilde{V}b \quad [16]$$

where $\dot{\gamma}$ is the plastic strain rate, α' is a geometrical constant, ρ_m is the mobile dislocation density, $\tilde{V}$ is the average dislocation velocity, and b is the Burger's vector. In addition, one uses an equation analogous to Eq. [12] to represent the strain rate sensitivity n as

$$n^{-1} = \frac{d\ln\tau}{d\ln\dot{\gamma}} \quad [17]$$

and assumes a power law stress-velocity relationship of the form

$$V = (\tau/\tau_o)^m \quad [18]$$

where τ_o and m are constants. Such a relationship has been experimentally verified for many fcc and bcc metals (14-16). Recently (17) it has been shown that, if proper account is taken of the fraction of mobile dislocations and the internal back stresses due to work hardening, the dislocation dynamical modeling which worked so well for bcc metals can be extended to fcc metals.

The application of this approach to the SiO_2 flow problem at the Si/SiO_2 interface is beyond the scope of this paper. However, it has been introduced here both to set the stage for further work and to reveal the importance of the dislocation velocity to the overall process. The reason for introducing this latter aspect is to indicate another important electrical feature that

will enter the SiO_2 flow considerations. It has been shown (18) that the dislocation mobility in the vicinity of a surface is strongly dependent on the charged nature of the surface. If the surface is at its isoelectric point (uncharged), the dislocation mobility is least. If the surface is strongly charged, either positively or negatively, the dislocation mobility is highest. Such a change in basic dislocation mobility for crystals, glasses, polymers, rocks, etc., transforms a basically brittle material into a plastic one as ϕ_i increases to large positive or negative values and vice versa as ϕ_i decreases toward a zero value.

Interface pseudo-dislocation grid propagation.—Since the formation of the interface pseudo-dislocation grid lower the free energy of the system quite significantly and, since the flow properties of the SiO_2 do not easily allow the grid to form, the maintenance and propagation of the grid is likely to be a key consideration in the oxidation process. Thus, how is it to propagate at the oxidation rate V? If the edge pseudo-dislocation forming the array were lying on the {111} planes making an angle to the Si/SiO_2 interface, then the film stress might possibly cause dislocation glide in the proper direction and at the proper rate to move the entire grid at velocity V perpendicular to the interface. A more likely alternative is that the pseudo-dislocations could climb in a direction toward the Si at the necessary rate to allow the grid to move at velocity V. If only climb could operate (see Fig. 3), at low temperatures (no viscous flow in SiO_2), the average spacing, D, of the propagating pseudo-dislocation grid would assume that value allowed by the vacancy plus interstitial flux in the Si and the remainder of the molecular mismatch would be retained as stress in the film; *i.e.*, the oxidation reaction requires an interface front velocity of V but the vacancy influx process and the interstitial outflux process may only allow a grid of spacing $D > D^*$ to propagate at V (D^* is the optimum spacing for minimum free energy).

To gain a deeper perspective of the low temperature situation, let us assume that the interface contains a perpendicularly crossed grid of pseudo-dislocations, of spacing D, so that the interface can only advance by pure climb driven by the free volume flux from the Si. For this case, the number of vacant sites needed per unit area of interface per second is $2V/D\lambda_{Si}^2$ where λ_{Si} is the unit cell spacing at the interface. Since the supply is just $J_I^{Si} - J_V^{Si}$, we have the allowed spacing, D, given by

$$D = 2V/\lambda_{Si}^2(J_I^{Si} - J_V^{Si}) \quad [19]$$

The vacancy and interstitial distributions are illustrated in Fig. 4. Since C_{Ii} and C_{Vi} are functions of the level of strain, δ', existing at the interface, Eq. [19] is coupled to Eq. [11] via the film strain level δ'. Thus, the allowable dislocation grid spacing, and thus the film stored energy, is determined by the point defect flux. For an alloyed system where impurity-vacancy and impurity-interstitial complexes must be considered, the description of the equilibrium distributions of various species is beyond the scope of this paper. However, for a relatively pure system where such complexes can be neglected, we find

$$C_{I\text{equil.}}(x) = \sqrt{2}\,N \exp\left\{-\left[\frac{(\Delta G_I + \Delta G_V) + 2Z_I e(\phi(x) - \phi_\infty)}{2kT}\right]\right\} \quad [20a]$$

$$C_{V\text{equil.}}(x) = \sqrt{2}\,N \exp\left\{-\left[\frac{(\Delta G_I + \Delta G_V) + 2Z_V e(\phi(x) - \phi_\infty)}{2kT}\right]\right\} \quad [20b]$$

where N is the number of lattice sites per unit volume and Z_I and Z_V are the valencies of the interstitials and vacancies, respectively.

Relative Magnitude of the Component Driving Forces

A perspective can be gained on the relative importance of the previous sections to the oxidation process by considering a free energy balance equation for the overall process; *i.e.*

$$\Delta G = \Delta G_{SV} + \Delta G_E + \Delta G_K \quad [21]$$

We know that $\Delta G_\infty = 154$ kcal/mole at 1000°C and that $\Delta G_E \gtrsim 60$ kcal/mole (it may be higher if our chosen modulus value is too small). We have not yet explored ΔG_K in this paper but will estimate its order of magnitude from other work. However, let us first consider the magnitude of ΔG_{SV}.

First, if we consider the work of Deal and Grove (2) and use the D_{eff} approach, so that the electric field dependence is neglected, and also assume that we have primarily neutral O_2 diffusion so that ΔG_{SV} arises only from the difference between C_o and C_i, then we have

$$\Delta G_{SV} = \Delta G_S = RT \ln C_o/C_i \quad [22]$$

This can be evaluated by equating the transport flux through the oxide, F_2, with the interface flux at the Si/SiO_2 interface, F_3; *i.e.*

$$F_3 = kC_i = \frac{D_{eff}}{X_o} C_i \left(\frac{C_o}{C_i} - 1\right) = F_2 \quad [23]$$

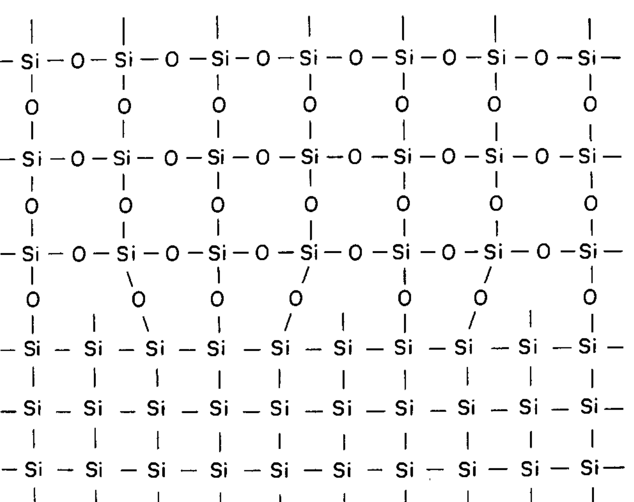

Fig. 3. Representation of pseudo-dislocation net (extra half-planes) and dangling bonds at the Si/SiO_2 interface for an idealized ordered SiO_2.

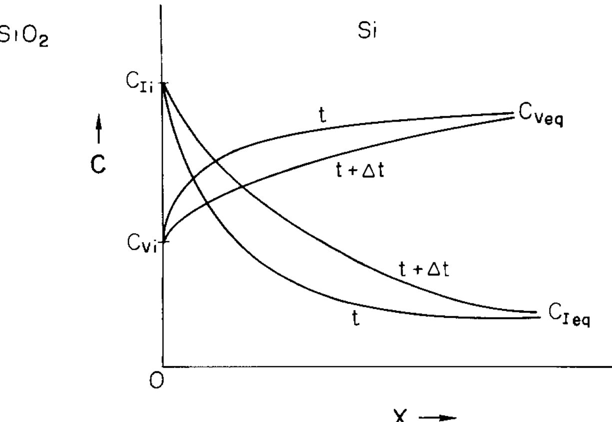

Fig. 4. Schematic illustration of interstitial and vacancy distributions on the Si side of the Si/SiO_2 interface for times t and $t + \Delta t$.

Using $k = 3.6 \times 10^4$ μm/hr for dry O_2 at 1000°C (2) and $D_{eff} \approx 2.8 \times 10^3$ μm²/hr for oxygen in fused silica at 1000°C (19), we find that $C_o/C_i \approx 1.26$-13.9 for X_o from 0.2 to 1.0 μm. Thus, in this range of X_o, ΔG_S is 0.58-6.6 kcal/mole. These are very small values indeed and the range is so small compared to ΔG_∞ that one begins to question the meaning of a "transport limited" reaction for this case.

Next, if we consider $O_=$ transport as being the prime diffusing species in the process, then we have

$$\Delta G_{SV} = \Delta G_{S,\phi} = RT \ln \frac{C_o}{C_i} - 2\mathbf{F}(\phi_o - \phi_i) \quad [24]$$

where **F** is the Faraday (96,484C). Thus, for $(\phi_o - \phi_i) \sim -1V$, the electrostatic term would be ~46 kcal/mole, a much more respectable range for a process that has a transport-controlling regime as the Si oxidation reaction appears to have. To more fully evaluate $\Delta G_{S,\phi}$, let us look at the linear rate constant B'/A' from Eq. [5]; *i.e.*

$$B'/A' = \left(\frac{C^*}{N_i}\right) \frac{k^*h^*}{k^* + h^* \frac{1 - \alpha e|\Delta\phi|/kT}{1 + \alpha e|\Delta\phi|/kT}} \quad [25]$$

From Eq. [25], if $\alpha e|\Delta\phi|/kT << 1$, then B'/A' equals B/A from Eq. [2] and $\Delta G_{S,\phi} \approx \Delta G_S \lesssim 7$ kcal/mole. If $\alpha e|\Delta\phi|/kT >> 1$, then B'/A' becomes negative and $k^* = 3.6 \times 10^4$ μm/hr from the Deal and Grove analysis. If $\alpha e|\Delta\phi|/kT \approx 1$, then k^* can be larger by several orders of magnitude and it can be positive or negative. This would increase C_o/C_i in proportion so that ΔG_S might increase to ~20 kcal/mole but the electrostatic contribution would decrease to about 5 kcal/mole leading to $\Delta G_{S,\phi} \sim 25$ kcal/mole, which is of respectable magnitude.

To estimate ΔG_K, we can slightly modify the simple rate theory as applied to the liquid/crystal transformation (20). There, a molecule in the liquid at the interface must transcend an activation barrier and join the crystal lattice at selected sites on the interface so that μ_1 in Eq. [8a] of Part I (1) is given by

$$\mu_1 = \frac{\beta^*\alpha^*D}{\lambda RT} \quad [26]$$

where D is the diffusion coefficient for transport across the interface (generally assumed to be the same as diffusion in the liquid), α^* is the fraction of interface sites available for molecular attachment (generally only those at layer edges and sometimes only a fraction of them), and β^* is the number of liquid molecular sites within one jump distance of an attachment site ($\beta^* \sim 3$-4). When one is dealing with a network liquid so that intermolecular bonds must be broken before the interface attachment jump can occur, another factor must be included in D to account for the probability that the bond-breaking event will occur.

In our case, the situation is not too dissimilar. We can think of the oxygen species as diffusing interstitially in the SiO_2 up to the Si/SiO_2 interface. The critical activation barrier at the interface involves both a normal diffusion-type jump plus the breaking of Si-Si bonds. Thus, Eq. [26] should be altered to

$$\mu_1 = \frac{\beta^*\alpha^*D_{O_2}}{\lambda RT} e^{-\Delta G^*/RT} \quad [27]$$

where ΔG^* is the energy required to break a Si-Si bond (~42 kcal/mole when the silicon is unstrained). Evaluating Eq. [27] leads to $\mu_1 \sim 2.5 \times 10^{-8} \alpha^*$ cm/sec/kcal/mole. For a (111) interface, one would expect $10^{-4} < \alpha^* < 10^{-2}$ and, picking the intermediate value, we predict that $\Delta G_K \sim 40$ kcal/mole for $V \sim 10^{-9}$ cm/sec. Since the value of α^* will depend on the source of layer edges (dislocations or two-dimensional nucleation), it will vary with interface temperature and interface supersaturation so that ΔG_K will vary accordingly. In addition, α^* may be sensitively dependent on the presence of certain impurities like H or C, etc. (21).

From the foregoing, we have found that $\Delta G_E \lesssim 60$ kcal/mole, $\Delta G_{S,\phi} \sim 25$ kcal/mole, and $\Delta G_K \sim 40$ kcal/mole. Since an error of a factor of 2 could reasonably be ascribed to any or all of these, we may allow that all of the ΔG_∞ has been accounted for. It is interesting to note that the recent modeling of Blanc (22) focuses totally on the ΔG_K contribution, that of Svensson (23) is involved with the structural aspects of the ΔG_E contribution, while that of Fowkes *et al.* (24) brings to light the importance of possible defect equilibria such as enter the $\Delta G_{S,\phi}$ contribution. It should also be noted that no real attention has been given to the magnitude of the driving force, ΔC_g^M, needed for the transfer of gaseous species across the gas/SiO_2 interface. This is expected to be small (2) but, for completeness, it needs to be considered more carefully in the future.

Discussion

From the use of Eq. [22] and [23], it is clearly seen that the diffusion of neutral oxygen through SiO_2 to oxidize the Si cannot be responsible for the parabolic rate constant represented by Eq. [2c]. This would indicate that the position held by Doremus (25) is untenable, provided that the data on k^* generated from the Deal and Grove analysis (2) is correct. The diffusion of ionized oxygen is a more likely candidate for the oxidation process based on the use of Eq. [24] and [25]. However, it is difficult to see how it could become totally rate controlling and lead to a diffusion-limited regime where the parabolic rate constant B' dominates the process because this would require that ΔG_{SV} approach ΔG_∞ in magnitude. Such a situation would require a large value of $\phi_i - \phi_o$ in Eq. [24], which would lead to a negative value for k^* unless the assumption that $h^* >> k^*$ (2) is in error (if ΔC_g^M is not negligible in magnitude). Perhaps it is necessary to look elsewhere for the source of the diffusion-limited regime.

One heretofore overlooked possibility is that the parabolic term arises as a consequence of vacancy and interstitial transport in the Si as a response to the free volume supply condition (see Part I (1), Eq. [13]). Certainly, from Eq. [19], the average grid spacing of the pseudo-dislocation net at the interface is determined by the flux of interstitials and vacancies in the Si. From Eq. [11], ΔG_E may be strongly determined by the nonequilibrium vacancy and interstitial concentration levels needed to provide this flux of Si atoms away from the interface. The ΔG_E contribution is of sufficient magnitude to completely dominate the oxidation process; thus, if the pseudo-dislocation net forms and the residual strain stored in the film is negligible, as much as −50 kcal/mole could be pumped into the Si vacancy-interstitial diffusion mechanism, which would definitely yield a significant parabolic term in the thermal oxidation process. This possibility certainly shifts the focus of one's attention to a new direction.

From Eq. [27], the molecular attachment kinetic coefficient μ_1 will be a strong function of temperature through ΔH^* and the activation energy for D_{O_2}. However, for the vacancy flux mechanism, the term exp $(-\Delta H^*/RT)$ will be replaced by a term proportional to the vacancy concentration at the interface and this will very likely be a nonequilibrium value. Some support for this possibility comes from the work of Ho and Plummer (26) who have provided a quantitative explanation of the enhanced oxidation rate via heavy doping of Si with n-type or p-type solutes.

In Eq. [27], α^* is a key parameter and it may be reduced or increased by the presence of specific interface impurities. Both Revesz (21) and Gunthaner and Maserjian (27) have shown that the presence of H and C in an initial surface film prior to oxidation reduces the oxidation rate and that these impurities migrate with the interface. Thus, these impurities appear to reduce the fraction of active sites for oxidation, α^*, at the interface. Perhaps this is the reason for the initially rapid oxidation rate in dry O_2 which results in a value of $X_i \sim 200Å$ for Eq. [2]. We might speculate that it takes a short time of oxidation until the interface builds up to a stationary state hydrogen concentration with α^* reduced to some stationary state value. On the other hand, oxidation with wet O_2 is faster than with dry O_2 and $X_i \approx 0$ in this case. This would seem to require that either α^* is increased or that the reduced viscosity of the SiO_2, with the H_2O content, allows flow to occur in the film to provide the excess free volume needed for the interface process to proceed. To resolve these issues, a close look at the geometrical aspects of the oxidation process will be needed. In addition, the value of n in Eq. [12] needs to be determined experimentally for SiO_2 in both dry and wet O_2 for the temperature ranges of interest.

Such a strain rate experiment would apply to bulk vitreous SiO_2 but might not completely apply to the interfacial SiO_2 which may have some crystalline characteristics added to it and which may really be of stoichiometry SiO_x. In this regard, it is of interest to note that the lattice parameters of low temperature cristobalite are a $\approx$ 5.1Å and c $\approx$ 7.4Å if extrapolated to $\approx$1000°C (28). Further, the volume change from high cristobalite to low cristobalite at 218°C is a decrease of 3.7% (29). Thus, the a-plane of low cristobalite has a size registration that is close to that of the Si so that a trace of this type of ordering might be found in the Si/SiO_2 interface layer material. Such an ordering would undoubtedly influence the flow properties.

From the foregoing, one can project a variety of processing alterations that should lead to enhanced oxidation rates:

1. Apply a negative surface charge to the SiO_2/gas interface to enhance the oxide electric field and thus V (similar to plasma anodization if just O_2 used).

2. Produce dissociation in the gas phase so that the surface sees O rather than O_2 which should lead to a higher population of $O_=$ in the oxide if there is a kinetic barrier to its formation from O_2.

3. Irradiate the growing oxide with u.v. at a photon energy beyond the bandgap to break Si/Si bonds at the interfaces and thus reduce ΔG_K (in addition, Fermi energy changes occur which should be beneficial for highly doped p-type Si).

4. Enhance the available vacancy source strength in the Si by annealing Si slices at very high temperatures prior to oxidation and quenching to the oxidation temperature.

5. Enhance the available vacancy source strength in the Si at the oxidizing interface by the application of an electric field to the Si prior to oxidation so that excess vacancies migrate to the appropriate side of the slice.

6. Use heavy doping of the Si and anneal at a high temperature prior to oxidation so that excess vacancies will be generated due to the Fermi level shift away from midband.

7. Add network terminators to the oxidizing gas so that the SiO_2 will have a lower viscosity and less strain energy will be stored in the SiO_2 film and ΔG_E will be reduced.

It is very likely that the oxidation studies of Ligenza (28) utilizing a microwave excited oxygen plasma is an example of 1 and 2 combined from the above list. The O_- ion is generated in large populations, which will both charge the surface and enhance the ion flux to the interface. The work of Oren and Ghandhi (30) is an example of item 3 above. The work of Ho *et al.* (3) is an example of item 6 and Cl additions to the gas stream (31) may be beneficial in part via item 7 above.

A final comment should perhaps be made concerning the accuracy of using the Cabrera and Mott (32) D_{eff} procedure. In their treatment, they neglected any displacement current effects associated with moving space charges and this is not appropriate for the type of moving interface situation we are dealing with here. A much more accurate procedure is to deal with the electric field directly, as was done in the section on Modified Deal-Grove Transport Analysis. As one goes toward treating much thinner films, or when one wants to say something about surface charge and volume charge which relates to detailed solute distributions, and when one wants to deal with more subtle film properties like interface instability and solute redistribution, one should not use the D_{eff} approximation.

Acknowledgments

Dr. B. E. Deal, Dr. J. D. Plummer, Mr. C. P. Ho, and Mr. H. Z. Massoud provided many helpful discussions of the available thermal oxidation data and of the processes involved. Discussions with Dr. E. Eernisse on viscous flow of SiO_2 were also helpful. This work was supported by the Defense Advanced Research Projects Agency under Contract No. DAAB07-77-C-2684.

Manuscript submitted Oct. 2, 1978; revised manuscript received Sept. 11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Stanford University.

The Rotating Cylinder-Collector Electrode (RCCE)

Michael C. H. McKubre* and Digby D. Macdonald*,[1]

SRI International, Materials Research Laboratory, Menlo Park, California 94025

ABSTRACT

A rotating cylinder-collector electrode (RCCE) for the study of electrochemical processes that involve electroactive intermediates and/or products is described. Calibrations of the collector efficiencies (N) for both major and minor sectors have been performed using the ferri/ferrocyanide redox couple over a wide range of rotational velocity (225-3060 rpm). With the minor sector as the collector, a collection efficiency of ~7.2% was observed, and N was found to be independent of rotational velocity over the range considered. However, the collection efficiency increased to ~67% when the major sector was used as the collector, thereby indicating that the RCCE is a sensitive device for the detection of dissolved electroactive species. The utility of this electrode is illustrated by investigating the anodic behavior of copper and nickel in hydroxide solution at various temperatures between 0° and 80°C.

The rotating disk (RDE) and rotating ring-disk electrodes (RRDE) have proved to be powerful tools in the study of electrochemical process (1-5). In the latter case, electroactive intermediates formed at the disk electrode are detected at the ring by oxidation or reduction under potentiostatic or potentiodynamic control. Thus, the ratio of the ring to disk currents for the removal and generation of the active species, respectively, defines the collection efficiency (N) for the electrode. Ideally, the collection efficiency is a function of geometry only; in practice, however, it is found to depend on the state of the collector surface and the hydrodynamic properties of the system (5). Typically, N varies between 0.1 and 0.5 depending on the relative dimensions of the disk and the ring (5). It is important to note, however, that the theories developed to date apply only to the case of complete mass transfer control.

In spite of its popularity, the rotating disk and rotating ring-disk electrodes suffer a number of disadvantages when not operating under complete mass transfer control or when being used for the study of surface controlled processes. Thus, in the absence of complete mass transfer control, the current density is not uniform across the disk radius due to the ohmic potential drop in solution. Newman (6) and Nanis (7) have elaborated on this problem and Newman (6) has shown that the current density at the center can vary between 50 and 100% of the average current density. The distribution in current density under these conditions implies a distribution in potential across the disk radius, and consequently a distribution in electrochemical state. While this property does not pose a limitation on the validity of the RDE or the RRDE for most of the application reported so far (mass transfer controlled systems), it does so for the study of technologically important phenomena, such as corrosion, where frequently complete mass transfer control is not observed.

A second problem with both the RDE and the RRDE is that a distribution in Reynolds number

$$Re_r = r^2\omega/\upsilon \quad [1]$$

where υ is the kinematic viscosity and ω is the rotational velocity (rad/sec) also exists across the surface. This Re varies from zero at the rotation axis to a maximum at the outer edge of the disk. Since the shear stress at the interface increases with the velocity gradient (and hence with Re), it is clear that the mechanical stresses to which surface films are subjected are dependent on the distance from the axis of rotation. It is expected that this property could have an important effect on film growth processes occurring at the surface of RDE.

In this paper we describe a rotating cylinder-collector electrode (RCCE) that exhibits certain characteristics that we believe are superior to those for the RRDE. For example, the roles of both the "source" and "collector" are interchangeable which can result in an advantageously large change in the collection efficiency. Also, the system is characterized by a single value for Re, and the distribution in current density across the surface is thought to be more uniform than that for a RDE or RRDE operating below the mass transfer limit. It is worth mentioning, however, that the observation of a steady-state current clearly demonstrates the existence of a flow pattern that is not a property of a perfect rotating cylinder. The existence of such a flow may well impose a considerable degree of nonuniformity under mass transport controlled conditions.

The collection efficiency for the system is evaluated empirically and the application of the RCCE to the study of electrochemical processes is illustrated by considering the anodic behavior of copper and nickel in hydroxide solution.

Experimental

Construction of electrode.—The RCCE was fabricated from 99.999% Cu rod machined to produce two approximately hemi-cylindrical sections of the desired length, and from 99.998% Ni sheet 1 mm thick. These three components plus two Mylar insulating spacers 0.011 cm thick are shown in Fig. 1. Machining of the parts does not present any practical difficulties, provided these are made oversized and the electrode turned, once final assembly is completed, to a circular cross section of the desired radius.

Key words: electrochemistry, corrosion, rotating cylinder electrode, collection electrode.

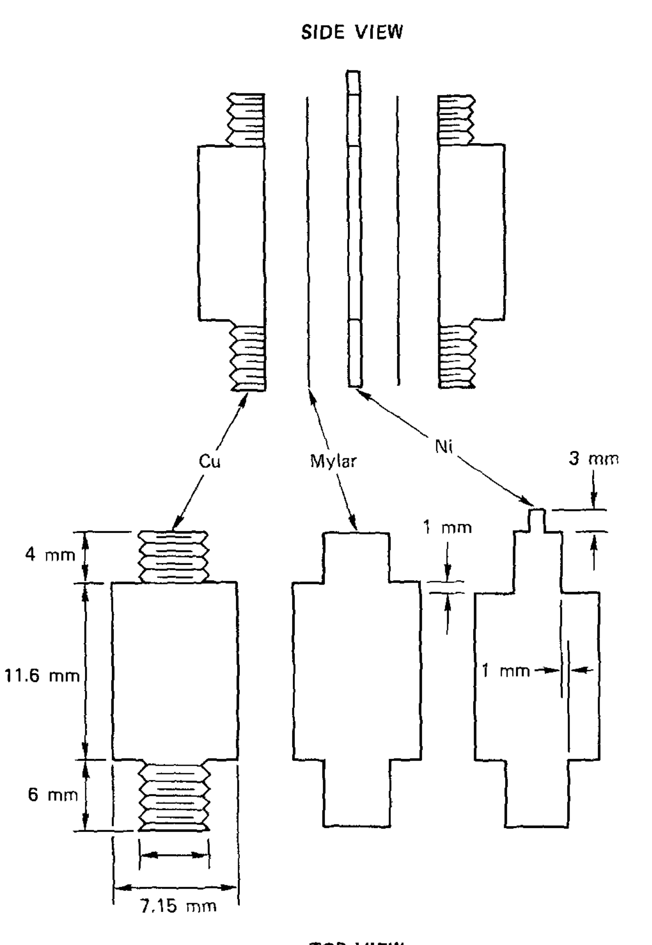

Fig. 1. Exploded view of RCC electrode components

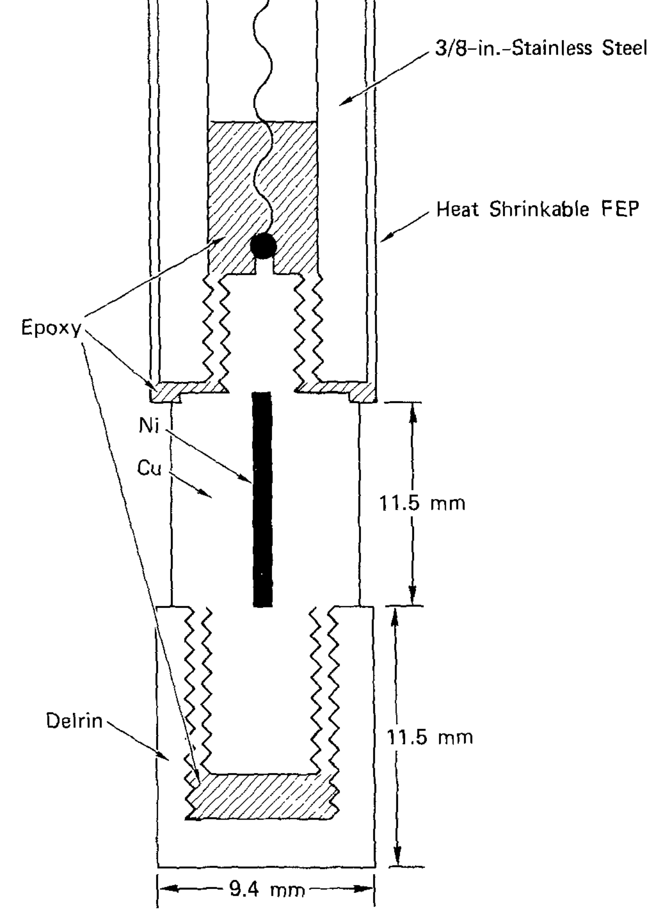

Fig. 2. Mounted RCC electrode

The electrode and supporting shaft are shown in Fig. 2. After loose assembly the electrode was screwed into a threaded Delrin[2] end cap previously filled with unset epoxy which ensures that there are no voids for electrolyte penetration, and provides mechanical strength upon setting. The top of the electrode assembly was screwed into an internally threaded 0.953 cm (⅜ in.) stainless steel tube which makes electrical contact to and between the two hemi-cylindrical Cu electrode sections. Electrical contract to the Ni key was accomplished by an insulated Cu wire soft soldered to the protruding key shown in Fig. 1.

Electrolyte contact with the supporting stainless steel cylinder was prevented by the use of heat shrinkable FEP tubing (8).

The cell was constructed entirely of Teflon (both FEP and PTFE) incorporating an internal 0.5 mm diam Pt wire counterelectrode and having the form of a circle coaxial with the RCCE assembly, and coplanar with the midpoint of the working electrode and the tip of the Luggin probe (see Fig. 3).

Variable rotation speed was accomplished using a side mounted d-c motor and pulley assembly with a variable voltage supply. Conventional bearings were employed and quadrature mounted amalgamated copper brushes were used to make reliable electrical contact with the Cu and Ni section of the RCCE.

The completed electrode assembly had the following dimensions. Overall electrode length 1.150 cm, electrode diameter 0.775 cm, working electrode area 2.800 cm^2, thickness of Mylar 0.011 cm, thickness of Ni 0.095 cm, exposed area of Ni 0.219 cm^2, exposed area of Cu 2.556 cm^2. The area ratio Cu:Ni was 11.69:1.

Electrode surface preparation.—Before experimentation the RCCE was polished with various grades of emery paper, finishing with 600 grit (25 micron particle size) while rotating the assembly in air. This technique was found to produce a good polished finish, and reproducible electrochemical properties.

For some experiments utilizing the copper electrode as a collector (see later), the surface was previously amalgamated to reduce cathodic competition from the reductive evolution of H_2 gas. Such amalgamation must necessarily be accomplished without contamination of the exposed Ni surface with Hg metal, since the electrode cannot subsequently be polished. A very simple procedure proved to be effective. A freshly polished RCCE was wet with dilute HCl to remove the surface copper oxide and a very small drop of mercury transferred to the surface with a copper wire. The contact angle is very small and the mercury immediately wetted one hemi-cylindrical copper electrode section, up to the insulating Mylar spacer, which is not wetted by mercury. This process was repeated for the remaining copper hemi-cylinder, and a lustrous silver colored amalgamated surface was achieved.

Reagents.—Electrolytes were prepared from AnalaR reagents using doubly distilled deionized water, with the second distillation under N_2 to exclude CO_2. High purity (99.999%) nitrogen was used to sparge the cell.

Electronics.—Two potentiostatic circuits with common reference (SCE or Hg/HgO) and counterelectrodes were used to control the Ni and Cu electrodes in a variety of experiments. During initial experiments a PAR Model 173 potentiostat was used to control the working electrode, and a specially con-

[2] Trade name.

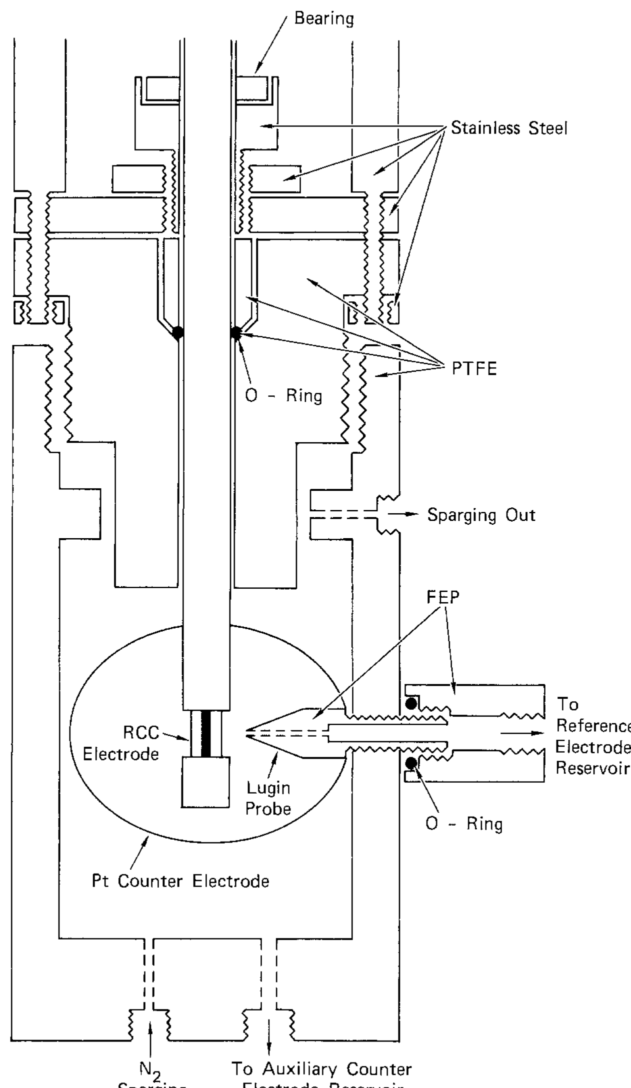

Fig. 3. RCC electrode and cell assembly

structed (9) fast potentiostat with a high degree of electrical isolation was used to control the collector. In subsequent experiments two PAR 173's were used; one connected to mains ground, and the other isolated at a high resistance from ground using an isolating transformer. Leakage across this transformer did not appear to result in spurious collector currents, and this latter combination allowed greater flexibility of current and voltage output.

All experiments described in this paper were performed under potentiostatic control and in a temperature controlled bath thermostated to within ± 0.1K.

Results and Discussion

Collection efficiency.—Experiments were designed to reproduce those of Miller (10) for the calibration of a ring disk electrode in 0.1M $K_3Fe(CN)_6$ with 1.0M NaOH supporting electrolyte, at 20°C.

Collection efficiency is defined here as the percentage of the mobile dissolved species produced at the working electrode, that react electrochemically at the collector. Since there almost always exists a background current on both electrodes, this definition requires some elucidation.

As mentioned in above, unlike rotating ring disk systems, the RCC sections are complementary, and either may be used as the working or collector electrodes. Consequently, the electrode was calibrated in both configurations; first with the copper functioning as the working electrode reducing $Fe(CN)_6^{3-}$ to $Fe(CN)_6^{4-}$, and the nickel electrode as the collector, performing the converse reaction, and secondly vice versa.

Before the results of these calibrations are presented, it is necessary to comment on the use of a swept potential for this purpose, and the separation of collection currents from the observed and unobserved background currents.

It is certainly not necessary, here, to propound the advantages of potentiodynamic experiments, but for ring disk, RCC, and other electrodes with collectors, it is possible to sweep either the working or the collector electrodes separately, or both simultaneously. While the latter course has certain theoretical advantages, these are complex, and the practical difficulties are extreme, and this alternative will not be discussed further in this paper.

Figure 4 shows the observed potentiodynamic response for the Cu and Ni sections of the stationary RCCE separately swept at 100 mV sec^{-1}, in the calibrating electrolyte. Potentials are with respect to a saturated calomel electrode, and the current density scales are identical but are displaced for clarity.

From Fig. 4 it is clear that peaks associated with the formation and reduction of higher nickel oxides occur at potentials similar to those of the ferri/ferro-cyanide couple. Thus, it is not possible to sweep the nickel electrode either as a working or collector electrode without incurring serious errors in the measured collection efficiency. For Cu however, the only significant potentiodynamic features between hydrogen evolution and oxygen evolution occur well cathodic of the ferri/ferro-cyanide peaks. Thus, this electrode can be swept either as a working or collector electrode, and having a stable and reproducible base current, the collection efficiency can be measured accurately.

A considerable source of error in the calculated collection efficiency for a system having either the working of collector electrode reactions not completely under mass transport control, can be introduced by an apparent coupling of the working and collector electrode currents in their shared *IR* drop. This has been separately treated by the present authors (11) and will be invoked to explain some of the results in this work. However, for a swept electrode system it is usually sufficient to observe the collected current in the presence and absence of rotation, or as a function of rotation, in order to eliminate the effects of coupled *IR* drops. Dissolved working electrode reaction products cannot reasonably be expected to be transported to the collector electrode in short times in a quiescent system. Thus, the collector current observed (as a function of voltage sweep) can be considered as a base

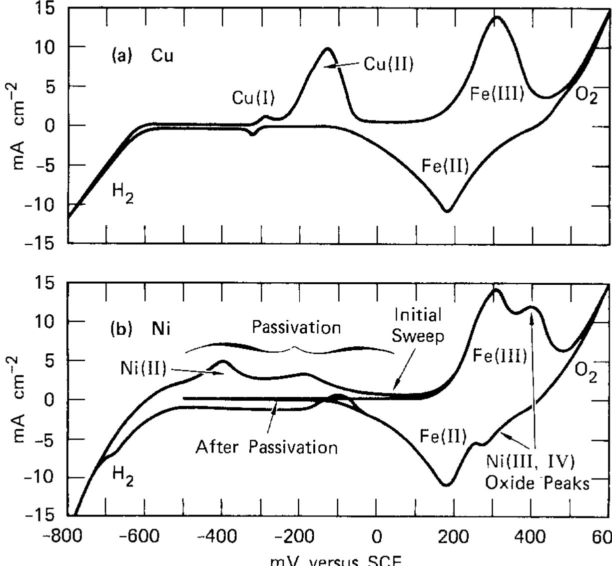

Fig. 4. Typical cyclic voltamograms for Cu and Ni electrodes in 0.1M $K_3Fe(CN)_6$/1.0M NaOH.

line, and be subtracted from the current observed at the rotating electrode, in order to calculate the electrode collection efficiency.

Calibration case 1: Ni collector.—Figure 5 shows the influence of electrode rotation on the working (Cu) and collector (Ni) electrode currents. The collector was held at +500 mV *vs.* SCE to oxidize Fe(II), and the working electrode was swept from −700 to +600 mV *vs.* SCE at 100 mV sec^{-1}. Assuming that at −500 mV (for example) all the working electrode current goes to produce Fe(II), and that the collector oxidation of this species may be equated with the difference between the rotating and quiescent Ni electrode currents, then the collection efficiency may be calculated as

$$N = 100 \times \frac{(7.05 - 0.7)}{69} = 9.20\%$$

A better estimate of the collection efficiency can be obtained by holding the working and collector electrodes at constant potentials, and measuring the two reaction currents as a function of electrode rotation speed, ω.

Figure 6 shows the results of three separate experiments with the working electrode (Cu) potentiostated at −500 mV and the collector electrode at +500 mV vs. SCE. From Fig. 6a we see that the working electrode current I_w varies with the square root of rotation velocity, with the regression line for all data given by

$$I_w = -13.3 + 2.98\,\omega^{-1/2}$$

and having a regression coefficient (12)

$$r^2 = 0.993$$

Figure 6b shows values of collector current, I_c, plotted against I_w for all data between 225 and 3060 rpm. These data were transcribed from X-Y recorder plots of the two currents, and show a clear linearity, the slope of which being the collection efficiency. The regression line for the data in Fig. 6 is

$$I_c = 0.763 + 0.072\,I_w$$

with a regression coefficient

$$r^2 = 0.994$$

A linear dependence of I_c on I_w is thus well obeyed, and the measured collection efficiency is 7.2%.

The upper limit of rotation speed was imposed by the motor, but at speeds lower than 225 rpm, significant

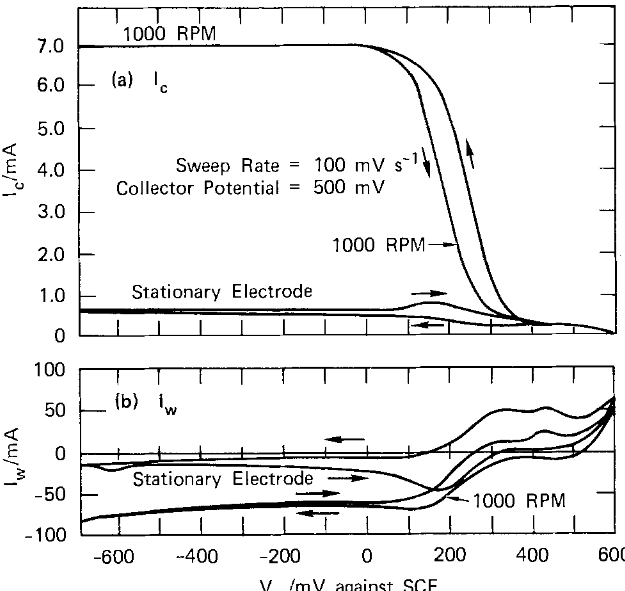

Fig. 5. Copper working and nickel collector electrode currents at 20°C in 0.1M $K_3Fe(CN)_6$/1.0M NaOH.

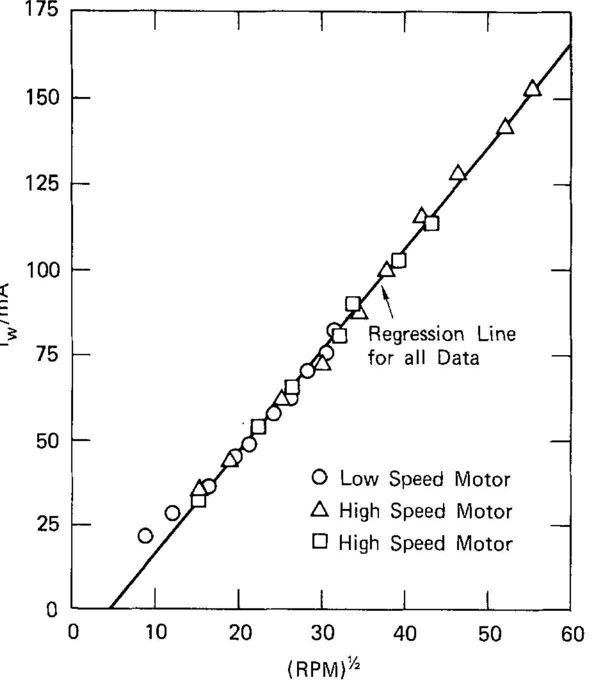

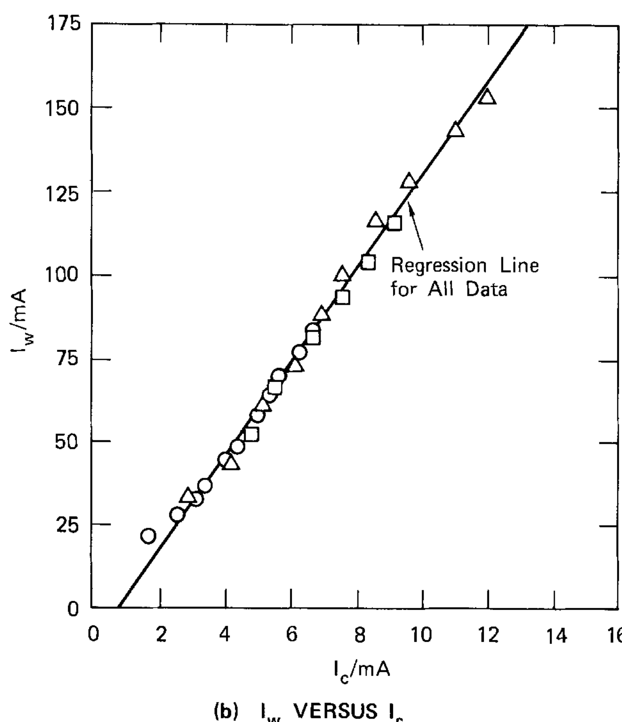

Fig. 6. Calibration of Cu working, Ni collector, RCC electrode in 0.1M $K_3Fe(CN)_6$/1.0M NaOH.

curvature was observed in a plot of I_c *vs.* I_w, presumably due to the increasing influence of radial diffusion with decreasing rotation speed.

At this point it is worth noting that while a collection efficiency of 7.2% represents a rather small value compared with those possible for a rotating ring-disk system, (5, 10, 13-15), the working electrode in a RCCE may have a relatively much greater area for this particular configuration. The collector currents may thus be very large compared with likely ring currents. Since the cylinder collector area is not significantly larger than the collector ring in a ring disk assembly, the RCCE affords the advantage of a larger collected current without a substantial increase in collector background current.

Calibration case 2: Cu collector.—A significant improvement in collection efficiency at the expense of decreased collector current and increased background current, can be achieved by using the smaller area nickel electrode as the working electrode, and the larger area copper electrode as the collector.

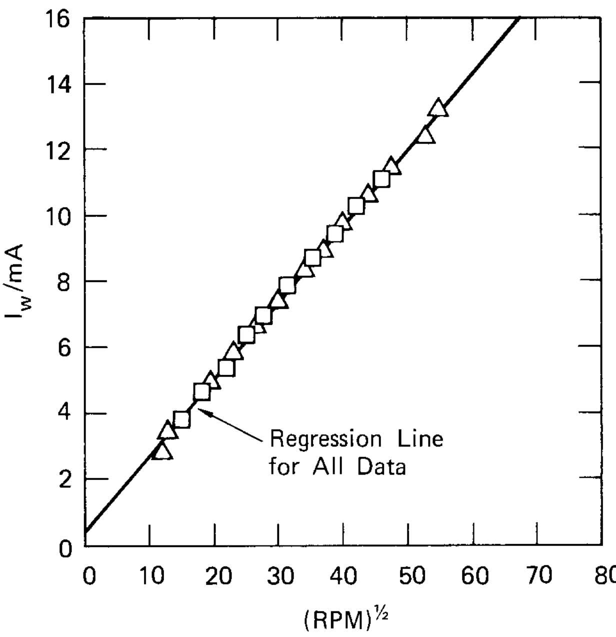
Calibration was accomplished precisely as described in the previous section, but with the Ni electrode potentiostated at −500 mV to reduce Fe (III), and the Cu collector held at +500 mV *vs.* SCE to reoxidize Fe (II) to Fe (III).

Figure 7a shows the influence of rotation speed on I_w, and Fig. 7b is a plot of I_c *vs.* I_w for rotation speeds up to 3140 rpm. The regression line for I_w *vs.* $\omega^{-1/2}$ is

$$I_w = 0.418 + 0.228\,\omega^{-1/2}$$

with the regression coefficient

$$r^2 = 0.998$$



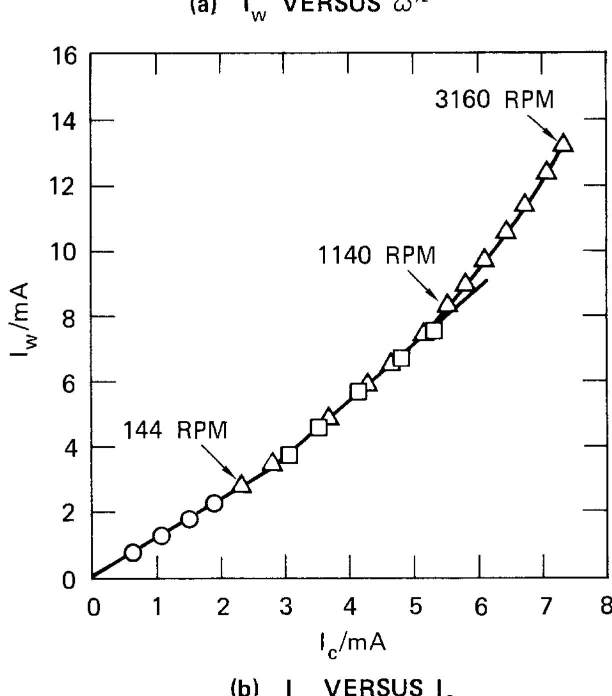


Fig. 7. Calibration of Ni working, Cu collector, RCC electrode in 0.1M $K_3Fe(CN)_6$/0.1M NaOH.

Figure 7b shows three distinct regions of collection efficiency. For the uncalibrated rotation speeds below 100 rpm (the rotation speed is not an explicit parameter in this plot), the slope of I_c *vs.* I_w approaches unity, and thus the collection efficiency approaches 100%. Between 100 and 1000 rpm, I_c *vs.* I_w has a well-behaved linear form, with regression line

$$I_c = 0.623 + 0.670\,I_w$$

and

$$r^2 = 0.999$$

indicating a collection efficiency of 67.0%. The large collector background current of 0.623 mA (= 0.243 mA · cm^{-2}) is due either to the dissolution of the incompletely passivated Cu electrode surface, or to background oxygen evolution. Both processes are effectively uninfluenced by electrode rotation.

At rotation speeds greater than 1000 rpm, the I_w *vs.* I_c correlation Fig. 7b shows some curvature, and the collection efficiency (dI_c/dI_w) declines to below 50% at 3140 rpm. The reason for this decline is not immediately apparent but may be due to the occurrence of stable hydrodynamic vortices with radial components of convection (16).

These results indicate that, provided a relatively high background current can be tolerated, a substantial rotation "window" exists for this electrode configuration, having a constant and large (67%) collection efficiency.

The anodic dissolution of Cu in alkaline solution.—Having calibrated the RCCE collection frequency, two further experiments were planned to demonstrate the utility of this system in each configuration of working and collector electrodes.

In the first, an attempt was made to reproduce and extend the elegant experiments of Miller (17) in which evidence from a split ring disk study was used to infer the presence of Cu (I), Cu (II), and Cu (III) dissolved species.

With the exception that an RCCE was used with Cu working and Ni collector electrodes, experimental conditions were as far as possible identical with those described by Miller (17). Briefly, experiments were performed in sparged 1M NaOH thermostated at three temperatures, 0°, 25°, and 50°C. An Hg/HgO reference electrode was used instead of the SCE employed by Miller.

Experiments were performed in the following manner. Prior to measurement, the Cu electrode was held in hydrogen evolution and the system sparged for at least 5 min to ensure a reproducible and oxide-free surface. With the Ni potentiostated at the desired value, the Cu electrode was subjected to a single potentiodynamic sweep well into oxygen evolution and back into hydrogen evolution. Since some of the chosen collector (Ni) electrode potentials coincided with those of nickel oxide growth or reduction, this electrode was held at constant potential prior to a measurement for a sufficient time such that I_c in the quiescent system declined to a steady value. I_w and I_c were recorded simultaneously against working electrode potential, first with the RCCE electrodes rotating (at 1000 rpm), then the experiment was repeated with a stationary electrode. Values of I_c presented in Fig. 9 represent the difference between the rotating and stationary collector currents. I_w was not significantly influenced by electrode rotation. A constant potentiodynamic sweep rate of 20 mV sec^{-1} was used.

25°C.—Figure 8 shows the results of potentiodynamic sweeps for a stationary and rotating Cu working electrode at 25°C. The three transitions of interest are labeled I, II, and III and are associated by Miller (17) with these Cu species.

Direct evidence for a Cu (II)/Cu (III) transition is difficult to obtain from Fig. 8. Any oxidation peak is overwhelmed by oxygen evolution and the reductive

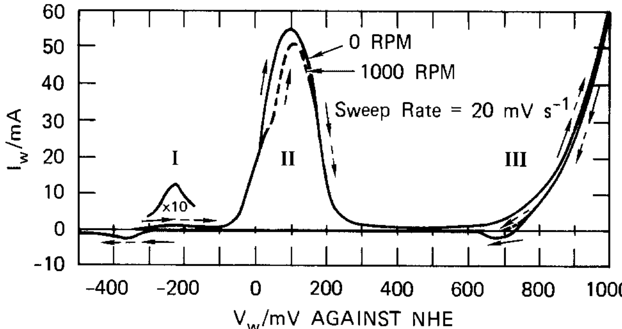

Fig. 8. Single potentiodynamic sweeps of copper electrode at 25°C for stationary and rotating electrode.

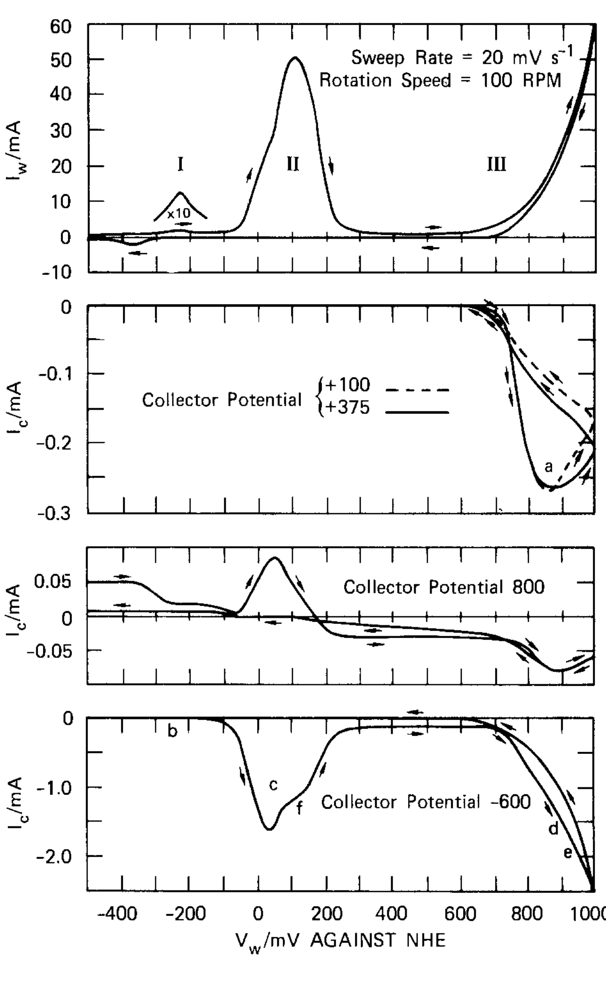
peak is not well defined for the stationary electrode, and apparently absent at a rotating electrode. However, by holding the collector electrode at appropriate potentials we can reduce any dissolved Cu (III) species and possibly oxidize or reduce dissolved Cu (I) and Cu (II), in order to demonstrate the existence of these species.

Figure 9a shows the results of experiments at 25°C with collector held at four different potentials. The top trace shows a typical working (Cu) electrode current trace to define the potential scale. The second trace shows collector currents with the collector held at +100 and +375 mV against an NHE. In contrast with the observations of Miller (17), no oxidative collector processes (specifically, associated with Cu (I) → Cu(II)) were observed, but the appearance of a reductive collector peak at 660 mV is strong evidence for the presence of a dissolved Cu (III) species.

The potential at which this collector peak occurs is well into the region of oxygen evolution on the working electrode. Figure 9b shows the magnitude of Cu dissolution current required to cause the observed collector peak, calculated using the measured value of collection efficiency, and compared to the observed total current from this, it is possible to deconvolve the measured working electrode current into currents associated with oxygen evolution and Cu dissolution.

Despite the considerable extent of oxygen evolution on the working electrode, it is unlikely that a significant component of the observed collector current can be ascribed to the presence of dissolved oxygen since, (*i*) a potential of +375 mV is barely sufficient to reduce oxygen to hydroxyl ions $E^{o}_{O_2/OH^-} = 0.40V$ for $O_2 = 1$ atm at 25°C in 1M NaOH), and (*ii*) the rate of oxygen evolution on the working electrode must increase exponentially with anodic potential (18). Collector reduction current associated with the presence of dissolved O_2 may be expected to parallel this, attaining a limiting value, but not passing through a maximum.

The third trace in Fig. 9a shows the current observed with the collector held at + 800 mV, a potential assumed to be sufficient to oxidize any dissolved species. This is similar to the comparable trace observed by Miller (17). However, we do not believe that this current profile provides unequivocal proof of the existence of dissolved Cu (I) or Cu (II) species. For this case alone, the background collector current at the stationary electrode showed considerable "coloration" with swept working electrode potential. Figure 10 shows the collector current at +800 mV, *vs.* working electrode potential for the electrode rotating at 1000 rpm and stationary, together with the collected current defined as the difference between these. The major features of the rotating and stationary current traces are similar, and conform almost exactly with the shape of the derivative of the working electrode cyclic voltammogram. The current determined as the difference between these is probably associated more with a small change in the reference potential than a real collected current.



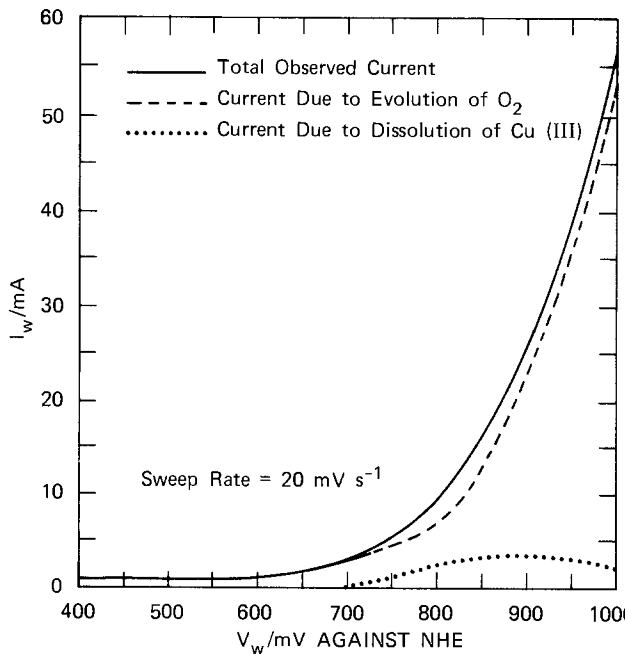


Fig. 9. Copper dissolution data at 25°C. (a, top) Copper working and nickel collector electrode currents for a single potentiodynamic sweep at 25°C. (b, bottom) Measured copper working electrode current for a single anodic potentiodynamic sweep, deconvolved into its component currents at high potentials.

The features described above conform precisely with those predicted and observed to be associated with a coupling of the *IR* drops due to working and collector electrode currents (11).

For the bottom trace in Fig. 9a, the collector was held at − 600 mV. This potential is sufficient to reduce

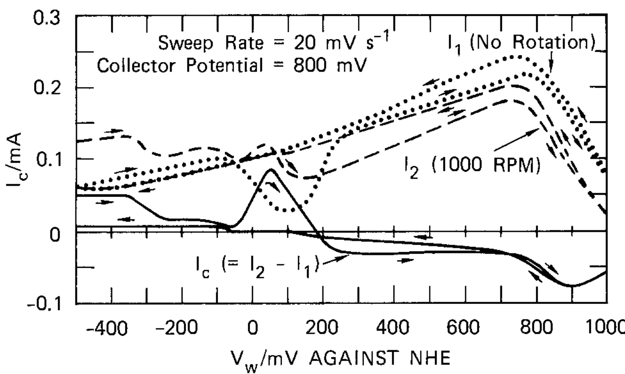

Fig. 10. Collector current at 800 mV at stationary and rotating electrode.

all copper ions back to metal, and oxygen to hydroxyl ions (17). For this case our observations and interpretation conform exactly with those of Miller (17). In conformation of this previous work, the processes we believe to be associated with the labeled features of the collector currents are as follows.

a. Cu (III) → Cu (II)
b. Cu (I) → Cu (O)
c. Cu (II) → Cu (O)
d. Cu (III) → Cu (O)
e. O_2 → OH^-

Using the measured collection efficiency of 7.2%, we calculate that the charge associated with dissolved Cu (I) accounts for approximately ¼ of the total charge in peak I. The remainder of the charge presumably goes to form a passivating Cu (I) oxide on the electrode.

Interestingly, the features of the working electrode current in peak II are reflected more strongly in collector current peak c, with the order of peak and shoulder reversed. We can speculate that these peaks indeed disguise two surface reactions and different dissolved species.

The shoulder labeled f, associated with the reduction of Cu (II), was apparently not observed by Miller.

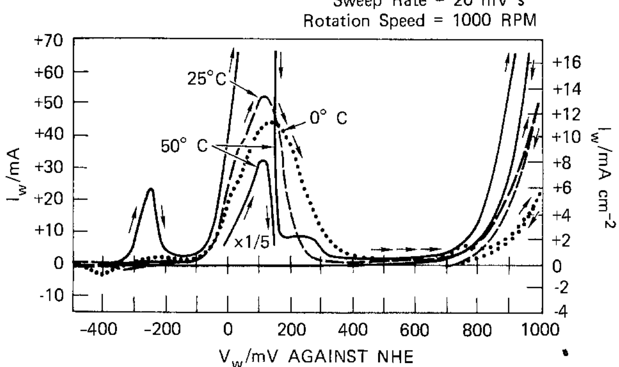
0° and 50°C.—Figure 11 shows the results of potentiodynamic sweeps of the Cu electrode as a function of temperature. At 0°C, the reduction of oxygen evolution at potentials greater than +700 mV *vs.* NHE, resolves a peak, presumably associated with Cu (II) → Cu (III), in Fig. 11a. Figure 11b shows the current collected at a potential of +375 mV increases abruptly at a working electrode potential coinciding with this observed I_w peak (approximately +750 mV).

The combined observation of a working electrode oxidation current peak associated with a dissolved species reducible at +375 mV leaves little room for doubt that a Cu (III) species is indeed involved.

Because of the increased rate of oxygen evolution at 50°C and the apparently negligible shift in the Cu (II)/Cu(III) redox potential with temperature, there is no direct evidence for such a transition at 50°C in Fig. 11a. However, Fig. 11b shows that an appreciable dissolution of Cu (III) occurs at working electrode potentials more positive than +700 mV *vs.* NHE.

Unlike the data at 25°C, the dissolution currents at 0° and 50°C do not display a maximum, but appear to approach a plateau; suggesting that no surface Cu(III) oxide, or an imperfectly passivating oxide film is formed.

Dissolution of Ni in concentrated alkali.—Over a limited potential range in highly concentrated alkali solutions, the thermodynamically most stable nickel species (19, 20) is in the monovalent ion $HNiO_2^-$ or possibly NiO_2^{2-}. To our knowledge this ion has not



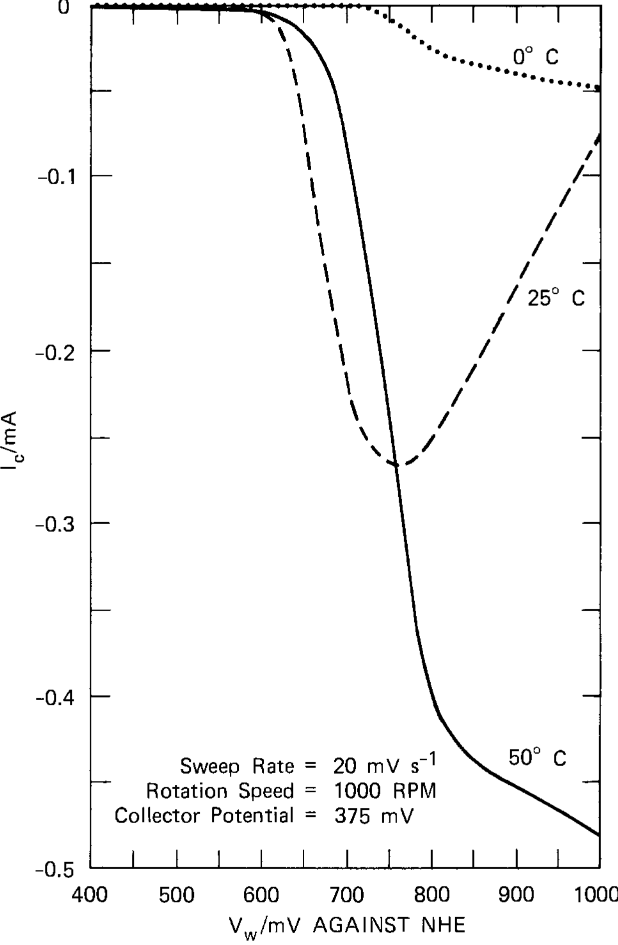


Fig. 11. (a, top) Potentiodynamic response of copper electrode in 1M NaOH, as a function of temperature. (b, bottom) Cu(III) dissolution current as a function of temperature.

been observed directly, but the possibility of Ni dissolution products at high potentials has serious implications for many industrial processes, particularly those involving Ni battery electrodes.

We have attempted to observe this species employing a conventional rotating Pt ring/Ni disk electrode and for a variety of reasons (20), have failed to identify it unambiguously.

By using the Ni as a working electrode and the copper (amalgamated as described in the section Electrode surface preparation) as a collector, the RCCE described here offers a number of advantages over a rotation ring-disk electrode. Paramount amongst these are the advantages of a defined potential distribution described in the introduction, and the very large (approximately 70%) collection efficiencies that can be attained.

Experiments were performed at 40° and 80°C in 6M NaOH. With the amalgamated Cu collector held

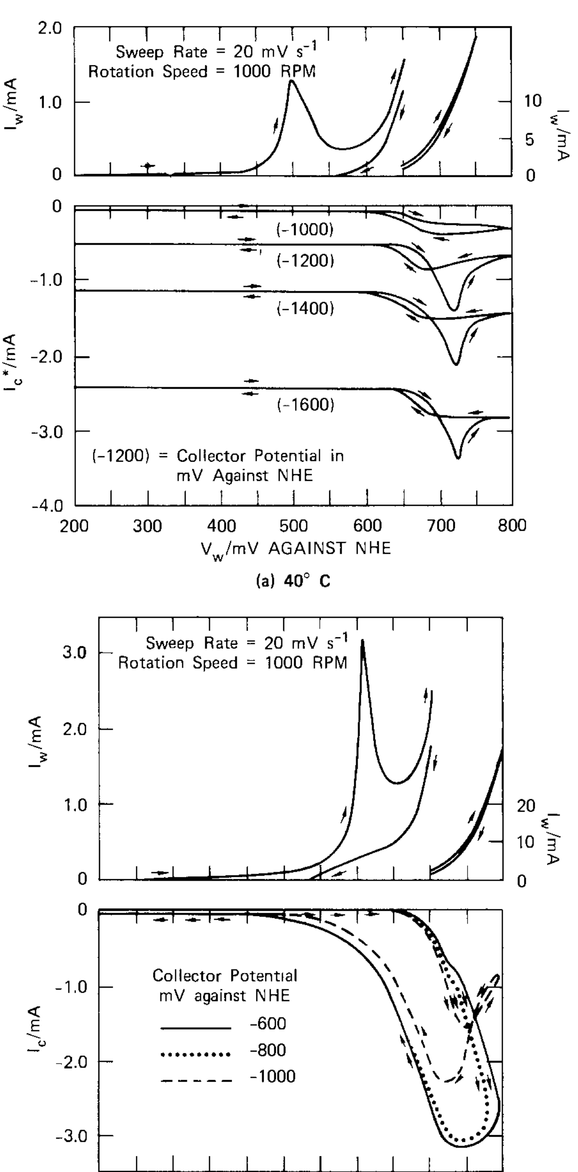
at the desired potential, the Ni electrode was subjected to a single potentiodynamic sweep at 20 mV sec^{-1}, well into oxygen evolution and back. I_w and I_c were recorded simultaneously against V_w with the electrode rotating and in a quiescent system. Working electrode currents were insignificantly influenced by electrode rotation, and values of I_c are reported as the difference between the measured rotating and stationary electrode currents.

The only features observable at the collector appear with the collector at large negative potentials and with the Ni working electrode well into oxygen evolution. This has two important experimental consequences: (*i*) the reduction of a dissolved species at the collector occurs at such a large negative potential that it is necessary to amalgamate the collector in order to increase the hydrogen evolution overvoltage sufficiently to resolve the collector current, and (*ii*) with substantial oxygen evolution at the working electrode and the collector at a potential sufficiently cathodic to reduce O_2 it is necessary to distinguish between collector current due to dissolved Ni ions, and dissolved oxygen.

Figure 12a shows working and collector electrode currents against working electrode potential, for different values of collector potential. At 40°C the forward sweep shows a well-defined peak in I_c at collector potentials more negative than −1100 mV *vs.* NHE. Beyond this peak and on the retrace, the collector current increases again marginally, and then returns to the background at +1100 mV. This peak we associate with dissolution of nickel. The second process, and the collector current at collection potentials more anodic than −1100 mV, we attribute to the presence of dissolved oxygen.

At 80°C the collector current peak on the forward sweep increases roughly by a factor of two. However, the current due to reduction of oxygen on the collector increases markedly, consistent with the greatly increased working electrode oxygen evolution current.

The collector current goes through a peak on the cathodic sweep. This peak appears over a wide range of collector potentials and regardless of whether a peak appears on the forward anodic sweep, and presumably signifies that the near surface O_2 concentration goes through a maximum shortly after reversal of potential.



*These data are presented without the subtraction of the collector background current to emphasize the extent of Hydrogen evolution.

Fig. 12. Nickel dissolution current in 5M NaOH

Summary and Conclusions

1. The RCCE is an effective device for the detection of electroactive dissolved intermediates. This system has the advantage over the rotating ring-disk electrode (RRDE) that the working and collector electrodes are complementary. Thus, interchanging the roles of the two electrodes affords a wide range of collection efficiency. Calibration of the RCCE using the ferri-ferrocyanide redox couple demonstrates that, for the electrode used in this study, collection efficiencies of 7.2 and 67% are attainable.

2. The RCCE system has an additional advantage over the RRDE in that the current distribution due to uncompensated resistance is significantly reduced, and there is no distribution of Reynolds number over the working electrode surface.

3. Experiments on the anodization of copper in 1M sodium hydroxide solution at 0°, 25°, and 50°C provides confirmatory evidence for the formation of soluble Cu (III) species at potentials close to oxygen evolution as previously reported by Miller (17).

4. Using a RCCE we have also detected the formation of soluble species on anodization of nickel in 6M NaOH at 40°C at potentials close to massive oxygen evolution. We were unable to detect these dissolved species using a RDDE, partly because of the lower collector current and collector efficiencies. The formation of soluble species on the nickel anode in strong alkaline systems possibly has important implications for the performance of nickel-based alkaline battery systems.

Factors Affecting the Electrochemical Responses of Metal Complexes at Pyrolytic Graphite Electrodes Coated with Films of Poly(4-Vinylpyridine)

Noboru Oyama* and Fred C. Anson*

Arthur Amos Noyes Laboratory, California Institute of Technology, Pasadena, California 91125

ABSTRACT

Electrochemical responses from the reduction of Ru^{III} (edta) coordinated to films of high molecular weight poly(4-vinylpyridine) on pyrolytic graphite electrodes were studied as functions of film thickness, temperature, supporting electrolyte composition, and solvent. Responses at filmed electrodes from metal complexes that do not coordinate to the films were also examined. With films thicker than *ca.* 1000Å, the current responses are limited by the rates of molecular motions within the films. Penetration of counterions, segmental motion of sections of the polymer chains, and juxtapositioning of pairs of attached metal complexes to facilitate intercomplex electron transfer within the film or combinations of the three are suggested as likely current limiting processes.

There has been considerable current interest in the preparation and properties of polymer-coated electrode surfaces (1-12). Examples of polymer coatings that have been described include nonelectroactive polymers (1, 6), polymers bearing repeating electroactive groups (2, 3, 7, 8, 11), and electroinactive polymeric coatings that become electroactive when metal complexes are attached to them (4, 5, 7, 9). Among the questions that await definitive answers for such coatings is how electron transfer is accomplished between the electrode surface and electroactive sites present in the polymeric films.

Kaufman and Engler (8) have recently proposed that electrons are conducted through rather thick films of a polymeric pyrazoline by electron transfer between the electroactive groups within the polymer. They proposed that such transfer required that the sites of electroactivity be mobile enough to achieve appropriate juxtapositions of neighboring sites in order for electron transfer to occur. In addition, the polymer film must be porous enough to allow penetration by ions of the supporting electrolyte to maintain electroneutrality within the film.

In the present report we address this and related issues for films of poly(4-vinylpyridine) (PVP) attached to pyrolytic graphite electrodes. The versatility of this polymeric ligand in anchoring transition metal complexes to electrode surfaces was described recently (9) and it seemed desirable to obtain more information on the electron transfer properties of these films which have electroactive groups (metal complexes) introduced into them after they have been attached to the graphite surface.

Experimental

Pyrolytic graphite electrodes with the graphitic basal planes exposed to the solutions were prepared and treated as previously described (9). Glassy carbon electrodes were prepared by cutting disks from cylindrical stock (Tokai Electrode Manufacturing Company, Limited, Tokyo). The disks were sealed to the ends of glass tubing with heat-shrinkable polyolefin tubing (Alfa Wire Company) to produce an electrode area of 0.2 cm. The glassy carbon surface was polished with silicon carbide paper of successively finer grain and finally with 0.3μ alumina. The polished surface was washed with excess water and methanol.

Poly(4-vinylpyridine) (Borden Incorporated, Philadelphia, Pennsylvania) was recrystallized twice from methanol-diethyl ether. Its average molecular weight was determined viscometrically (13) to be 7.4×10^5. This was the polymer utilized in all experiments except those associated with Fig. 2. Aquoethylenediaminetetraacetatoruthenium (III) was prepared and purified as previously described (9). Other chemicals were reagent grade and were used as received. Aqueous solutions were prepared with triply distilled water. The supporting electrolyte for most electrochemical measurements in aqueous media was 0.2M CF_3COONa adjusted to the desired *p*H with CF_3COOH. Potentials are quoted with respect to a sodium chloride saturated calomel reference electrode (SSCE).

The electrochemical instrumentation and procedures utilized have been described previously (9). With electrodes bearing heavy coatings of PVP and Ru^{III} (edta) the quantity of electrochemically active attached complex could not be determined reliably by electronic integration of voltammograms. Figure 1 shows an example of a voltammogram for a coated electrode and its area as measured by electronic integration of the current during the potential scan. Note that the slope of the integrated current curve does not drop to background levels even at potentials well negative of the peak potential. Significant contributions to the current integral continue to accumulate at potentials far removed from the peak. For this reason the quantities of reactants attached to polymer layers were evaluated by integration of the current that passed when the electrode potential was stepped and held at a value well beyond the voltammetric

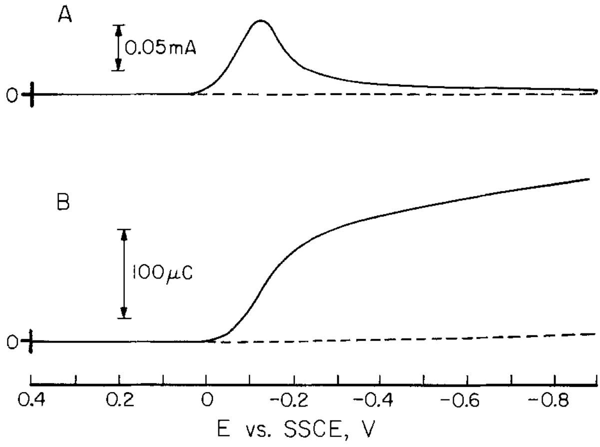

Fig. 1. A, voltammogram for the reduction of Ru^{III} (edta) attached to a coating of 2.3×10^{-7} moles cm^{-2} of pyridine as PVP on a pyrolytic graphite electrode. Ru^{III} (edta) attachment was that resulting when the PVP-coated electrode was exposed to a 5 mmole solution of Ru^{III} (edta) at pH 3.9 for 15 min. Supporting electrolyte: 0.2M CF_3COONa (pH = 2.85). Scan rate: 100 mV sec^{-1}. B, area under the voltammogram in A obtained by electronic integration of the current as the voltammogram was recorded. Background current and its integral are shown by the dashed lines.

peak potential until the rate of charge accumulation decreased to background levels.

To provide electrode surfaces containing known quantities of attached PVP, measured aliquots of a stock solution of the polymer in methanol were carefully transferred to the surface of a horizontally mounted electrode with a microliter syringe. 1-4 microliters of the solution spread uniformly on pyrolytic graphite and well-polished glassy carbon surfaces without overflowing, to produce a visibly uniform film upon evaporation of the solvent. To introduce Ru^{III} (edta) onto the electrode surfaces the resulting polymer-coated electrodes were immersed in a 5 mmole aqueous solution of Ru^{III} (edta) at pH 3.9 for 15 min. After attachment of the complex by coordination to the pendant pyridine ligands in the polymer coating (9), the electrodes were washed repeatedly with water, dried, and stored. This procedure is not well calculated to ensure a uniform distribution of coordinated Ru^{III} (edta) throughout the PVP layer. None of the electrochemical experiments performed with these coatings of PVP-Ru(edta) gave indications of highly anisotropic film compositions but it would not be surprising to find that more of the attached complex resided near the electrolyte/film interface than the electrode/film interface.

Scanning electron micrographs were obtained with an ETEC Corporation Autoscan U-1 (Hayward, California) instrument. Electrodes were coated by the procedure just described. Cross-sectional views of coatings applied to polished glassy carbon electrodes were obtained by appropriate mounting of the electrode specimens in the microscope. In this way the thickness of the polymeric layers could be estimated.

Results and Discussion

Effects of molecular weight on the adsorption of PVP on graphite.—To assess the dependence of the molecular weight of the PVP on the extent of its attachment to pyrolytic graphite, a set of PVP samples fractionated by successive crystallization from methanol solutions to which increasing amounts of diethyl ether were added was prepared and the average molecular weight of each fraction was determined viscometrically (13). Freshly cleaved pyrolytic graphite electrodes were exposed to 0.5% solutions of each fraction in methanol for 15 min followed by washing with methanol (for 15 min) and exposure of the resulting PVP coated electrodes to a 5 mmole solution of Ru^{III} (edta) for 15 min. The amount of Ru^{III} (edta) that coordinated to the PVP coating was then determined electrochemically in 0.2M CF_3COONa (pH 2.7) supporting electrolyte by the methods described in the Experimental section. The extent of Ru^{III} (edta) coordination depended on the average molecular weight of the PVP used to coat the electrode as shown in Fig. 2. The first two points correspond to the use of 4-ethylpyridine and 1,2-bis(4-pyridyl)-ethane to coat the electrode. Neither produced a surface with measurable affinity for Ru^{III} (edta). With polymers of higher average molecular weight the extent of binding of Ru^{III} (edta) is assumed to reflect an increase in the quantity of PVP that is present on the graphite surface. PVP samples with average molecular weights in excess of 2×10^5 are clearly the most potent for preparing electrode coatings that accept the largest quantities of Ru^{III} (edta).

Film morphology.—Scanning electron micrographs of films of PVP on glassy carbon show the polymer to be distributed somewhat unevenly with islands of polymer surrounded by bare or lightly covered areas. The uneveness appears to increase when Ru^{III} (edta) is coordinated to the polymer. A cross-sectional view of the layer produced when a methanolic solution containing 6×10^{-7} moles cm^{-2} of monomeric pyridine units was allowed to evaporate on a glassy carbon surface is shown in Fig. 3. The apparent thickness of the layer is $(8 \pm 2) \times 10^4$Å which corresponds to an effective density of only *ca.* 0.08 g/cm^{-3}. Since the density of bulk poly(4-vinylpyridine) is 1.1 this could indicate that the polypyridine layer is quite porous. However, the apparent film thickness observed in the SEM may not be an accurate reflection of that prevailing on the electrodes used in the electrochemical experiments. For example, several of the experiments to be described in what follows indicate clearly that PVP films deposited on graphite under some conditions behave electrochemically as if they presented a dense, impervious domain to reactants seeking the electrode surface. Thus, exposure of films deposited from methanol to the low pressures within the SEM may cause a large expansion of the film as residual trapped solvent escapes from the film, causing them to appear less dense. For this reason we do not regard the film densities estimated from SEM measurements as representative of electrode surfaces that are never exposed to high vacuum.

Coatings of PVP on glassy carbon that exceed *ca.* 5×10^{-8} moles cm^{-2} (expressed as monomeric pyridine units) are clearly visible without magnification. The originally black surface becomes gray and the glassy carbon loses its luster. When Ru^{III} (edta) is coordinated to such heavy PVP coatings, a distinct and persistent golden color develops on the electrode surface when the Ru(III) is reduced to Ru(II). The electrode can be cycled repeatedly between potentials that cause reduction and oxidation of the ruthenium

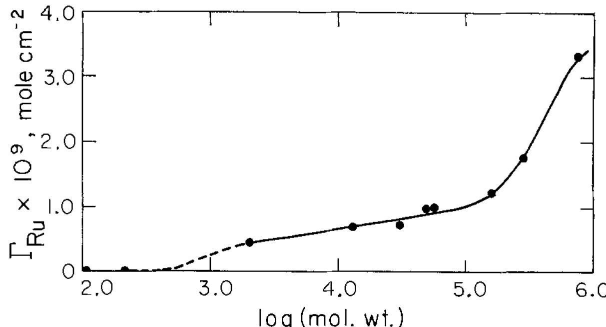

Fig. 2. Effect of the average molecular weight of PVP on its attachment to graphite electrodes as reflected in the coordination of Ru^{III} (edta) to the polymer coatings under standard conditions (see text for details).

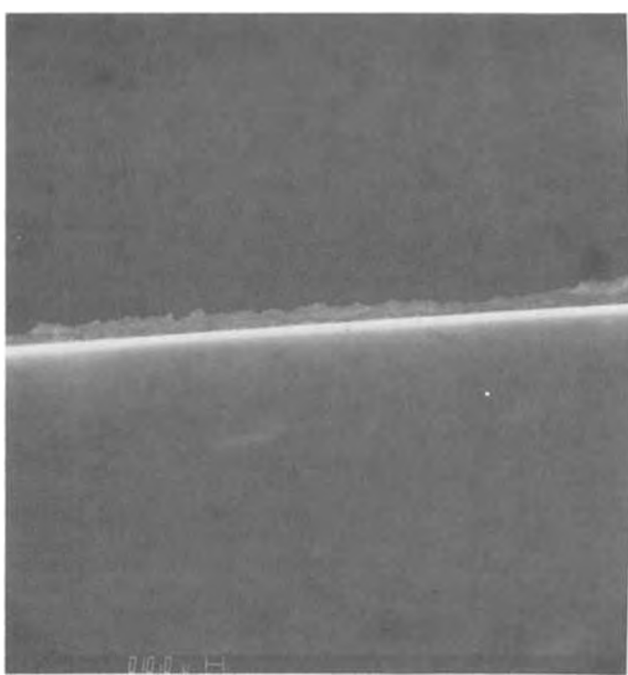

Fig. 3. Scanning electron micrograph of a PVP coating on a glassy carbon electrode. 6 × 10^{-7} moles cm^{-2} of pyridine as PVP was placed on the surface by evaporation of an aliquot of a methanolic solution. The calibration mark at the bottom of the micrograph corresponds to 10 microns.

centers and the golden color fades and reappears correspondingly. Similar observations have been made with polypyrazoline films (8).

Cyclic voltammetry and chronocoulometry.—Cyclic voltammograms obtained with electrodes coated with PVP to the extent of no more than *ca.* 10^{-8} moles cm^{-2} (of pyridine units) and then with Ru^{III} (edta), by exposure to a 5 mmole solution for 15 min, exhibit the symmetrical shapes and linear dependence of peak currents on scan rate expected for reactants that are attached to electrode surfaces (14). In addition, the area under voltammograms for such coatings shows almost no dependence on scan rate. However, as shown in Fig. 4, increasing the quantity of PVP applied to the electrode surface causes the shapes and peak currents of the resulting voltammograms to change: at first, increasing the quantity of PVP on the electrode surface causes the peak current to increase but still heavier coatings produce diminished peak currents. At the same time the shape of the voltammograms becomes less symmetric and they come to resemble voltammograms for unattached reactants that diffuse to the electrode surface. There is a corresponding change in the scan rate-dependence of the peak currents. With light polymer coatings the peak currents are proportional to the scan rate (Fig. 5) as expected for attached reactants (14) but with sufficiently heavy coatings, the peak currents exhibit the proportionality to the square root of scan rate typical of diffusing reactants (Fig. 5). The apparent areas under the voltammograms obtained with heavy polymer coatings show a strong inverse dependence on scan rate and the integral of the current that passes in response to a potential step from 0.7 to −0.7V grows rapidly at first and then continues to increase slowly for periods as long as 30 or 40 min. Figure 6 compares the charge consumed one minute after a potential step was applied with the charge required to reduce all of the attached complex. With sufficiently heavy coatings of PVP the charge consumed in a fixed time interval is smaller than with lighter coatings even though the actual quantity of Ru^{III} (edta) coordinated to the coating continues to increase as heavier PVP coatings are applied. [This assertion was

confirmed by spectroelectrochemical measurements using optically transparent graphite electrodes (15, 16).]

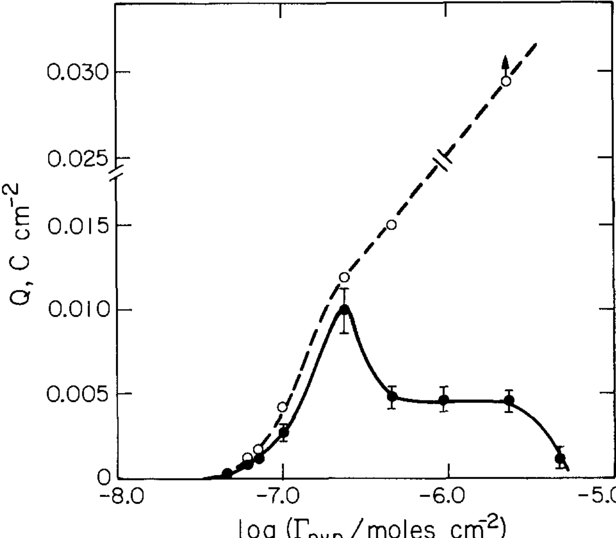

Fig. 6. Charge consumed by the reduction of Ru^{III} (edta) attached to PVP-coated electrodes. (Ɪ) Charge consumed during the first 60 sec following the application of a potential step from +0.7 to −0.7V. (○) Charge required for complete reduction of the attached complex at −0.7V. Supporting electrolyte: 0.2M CF_3COONa (pH = 4.2). Ru^{III} (edta) attachment procedure as in Fig. 1. The charges required for complete reduction were obtained by continuing the current integration until the rate of increase of of charge matched background levels.

Straight lines were obtained for chronocoulometric plots of the charge passed in response to the potential step against the square root of time. This behavior suggests diffusive transport as the current-limiting factor. In line with the proposals of Kaufman and Engler (8), both the motions of the anchored metal complexes to achieve the proper juxtaposition for inter-complex electron transfer as well as diffusive supply of counterions to the sites where the attached complex is to be reduced could be responsible for the observed behavior. Both the attached Ru^{III} (edta) and Ru^{II} (edta) complexes are likely to be anionic at the pH of the supporting electrolyte, 4.2 (17). Upon reduction, the negative charge on the complex doubles so that a cation must be supplied to each attachment site before the reduction of the attached Ru^{III} (edta) can occur. The current may be limited by the rate at which segments of the polymer chains within the attached layer can move out of the pathway of counterions entering the film (18). (Note that such motion is required even if the polymer layer contains an abundance of supporting electrolyte because an additional counterion must still be transported from the bulk of the solution to each site where an additional charge is generated.)

Temperature dependence of the electrochemical response.—The diffusion of small molecules (and ions) through polymeric matrices has received considerable study (19-21). Apparent diffusion coefficients that have been measured typically exhibit an Arrhenius type of temperature dependence and the corresponding activation process has been identified with segmental motions within the polymer (20). To evaluate diffusional activation energies for the reduction of the Ru^{III} (edta) complex attached to the polymeric layer the temperature dependence of cyclic voltammetric peak currents and chronocoulometric slopes were measured. Figure 7B shows the cyclic voltammograms for Ru^{III} (edta) coordinated to a PVP layer on the electrode surface at 5° and 45°C. The temperature dependence of the peak currents is comparable to that observed with freely diffusing Ru^{III} (edta). However, since significant quantities of the attached complex can remain unreduced under cyclic voltammetric conditions (Fig. 4), the magnitude of the peak current does not provide a reliable measure of the apparent diffusion coefficient. For this reason we used the slopes of the linear chronocoulometric charge-(time)$^{1/2}$ plots shown in Fig. 7A as measures of the product of the (square root of the) apparent diffusion coefficient and the concentration of the diffusing species. It is not straightforward to obtain numerical values of the apparent diffusion coefficients from the slopes of the plots such as those in Fig. 5C and 7A because the concentration of the "diffusing" species is not known. The concentration of counterions in the bulk of the solution is not the appropriate concentration to use because we observed no change in the magnitude of voltammetric peak currents when the concentration of the supporting electrolyte was varied between 0.02 and 2.0M at constant pH.

Figure 8 shows the Arrhenius plot of the slopes of the chronocoulometric plots in Fig. 6A from which an apparent diffusional activation energy of 4.6 kcal per

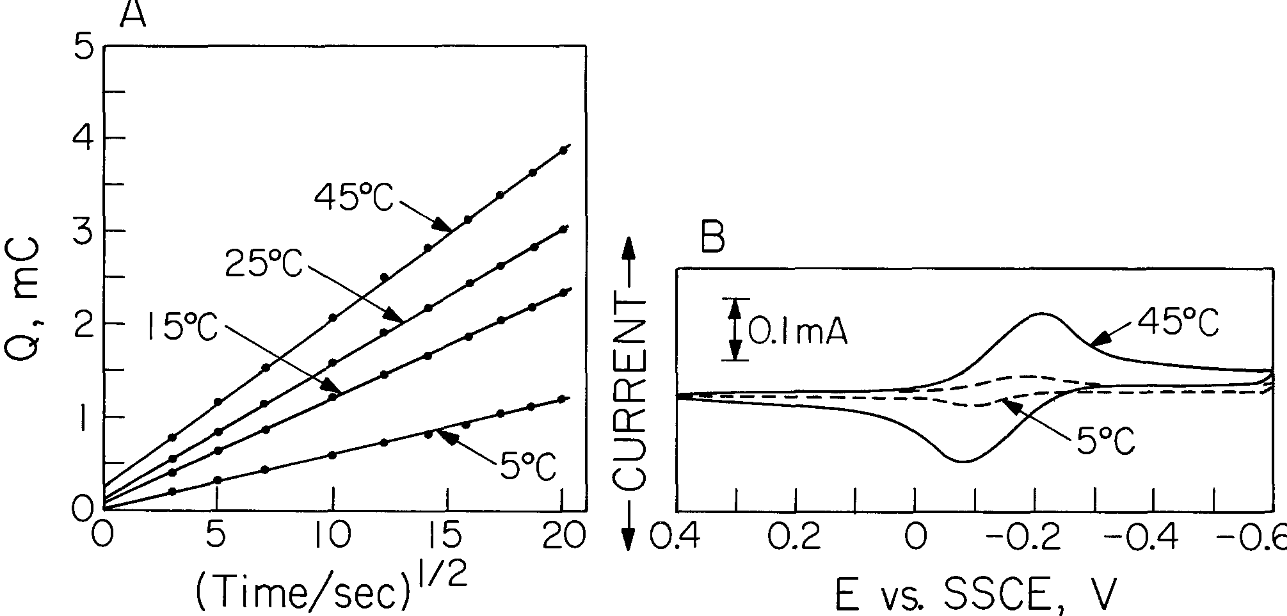

Fig. 7. Temperature dependence of (A), charge-(time)$^{1/2}$ plots and (B), cyclic voltammograms (scan rate: 200 mV sec^{-1}) for Ru^{III} (edta) attached to electrodes coated with 2.3×10^{-6} moles cm^{-2} of pyridine as PVP. Ru^{III} (edta) attachment procedure and supporting electrolyte as in Fig. 2 except pH was 3.4.

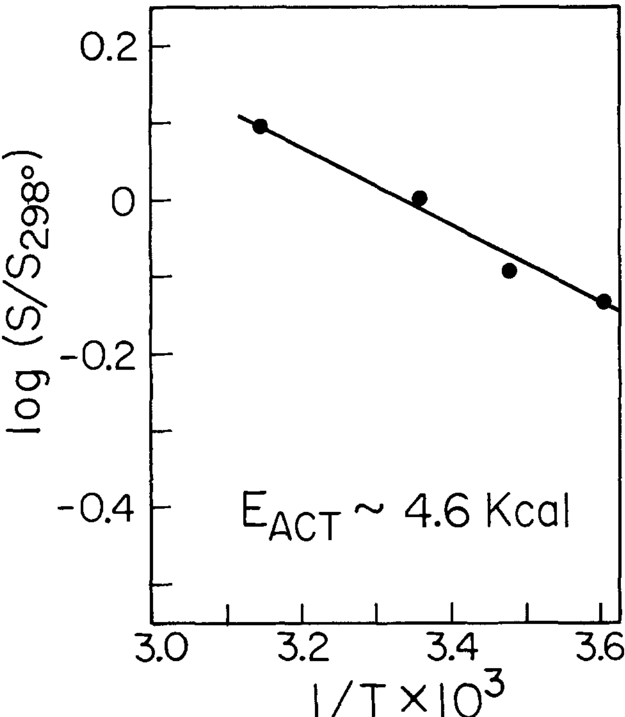

Fig. 8. Arrhenius plot of the slopes of the charge-(time)$^{1/2}$ lines in Fig. 7 relative to the slope at 298°K.

mole was calculated. This is a somewhat smaller value than those reported for the diffusion of small molecules within solid polymer films (20) but it is similar to values observed for such films in the presence of plasticizing agents that facilitate segmental motions of molecular chains within polymeric matrices (20). It does not seem unreasonable that acidic, aqueous solutions could serve to "plasticize" the coatings of PVP on graphite surfaces. The activation energy evaluated in Fig. 8 could then be regarded as a measure of the barrier faced by small segments of the PVP chains as they reorient to juxtapose pairs of anchored Ru(edta) complexes and to permit counterions to reach (or depart form) the sites where the electrode reaction causes an increase (or decrease) in ionic charge.

Effect of solvent on the electrochemical response.—Changes in the solvent employed to conduct electrochemical measurements on Ru^{III} (edta) coordinated to PVP coatings can produce dramatic differences in the responses obtained. Figure 8 shows the responses obtained from the same coating in five different solvents. The Ru^{III} (edta) is rendered virtually electroinactive in acetonitrile and dimethyl sulfoxide. The effect is not the result of removal of the complex from the surface because transfer of electrodes that give very small responses to an aqueous electrolyte immediately restores the electrochemical activity of the attached complex.

In separate experiments with optically transparent graphite electrodes (15) we have found that essentially all of the Ru^{III} (edta) attached to PVP coatings is electroactive in aqueous supporting electrolytes with polymer coatings similar to those employed in Fig. 9. Thus, these results show that changes in solvent can cause a fully electroactive film to become largely inactive.

Solvents that diminish the electroactivity of complexes attached to polymer coatings produce similar effects on electrode process involving unattached reactants: Fig. 10A shows a cyclic voltammogram for ferrocene at an uncoated pyrolyte graphite electrode in acetonitrile. Coating the electrode with a moderately heavy layer of PVP (10^{-7} to 10^{-6} moles cm^{-2} of pyridine) somewhat inhibits the ferrocene wave. If

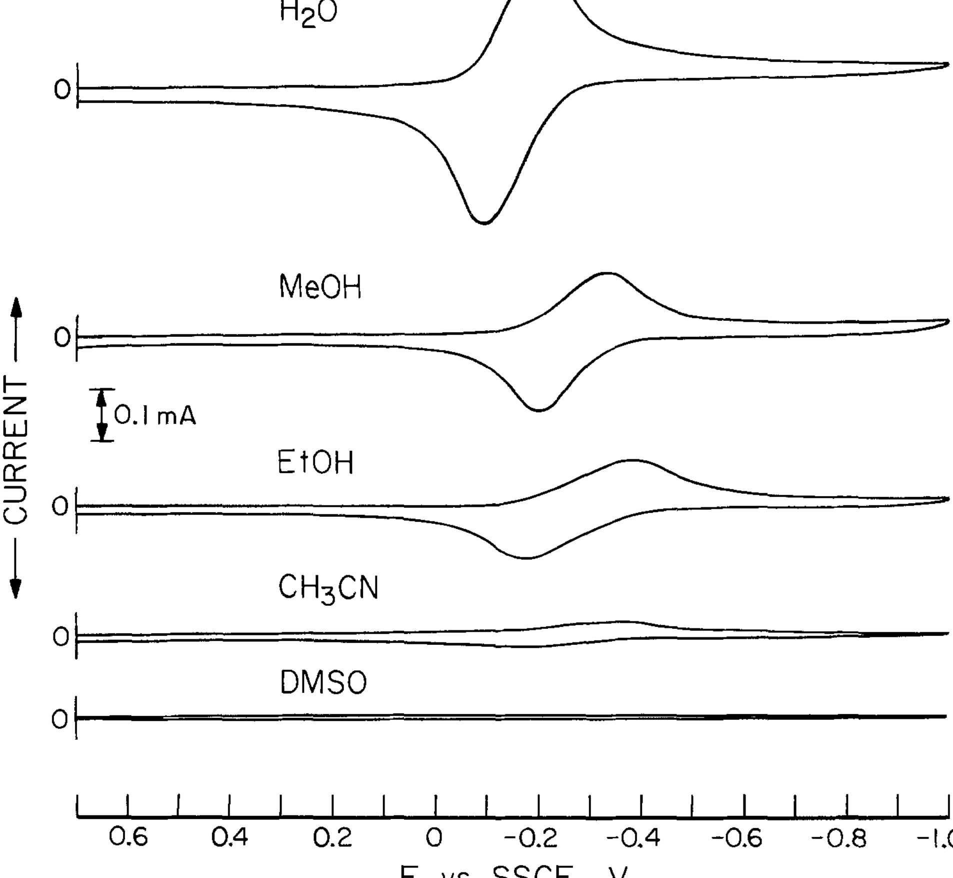

Fig. 9. Solvent dependence of steady-state cyclic voltammograms for Ru^{III} (edta) attached to electrodes coated with 4.6 × 10^{-7} moles cm^{-2} of pyridine as PVP. Supporting electrolytes: H_2O, 0.2M CF_3COONa (pH = 4.2); other solvents, 0.2M $NaClO_4$. Scan rate: 200 mV sec^{-1}. Ru^{III} (edta) attachment procedure as in Fig. 2. A freshly coated electrode was used in each solvent.

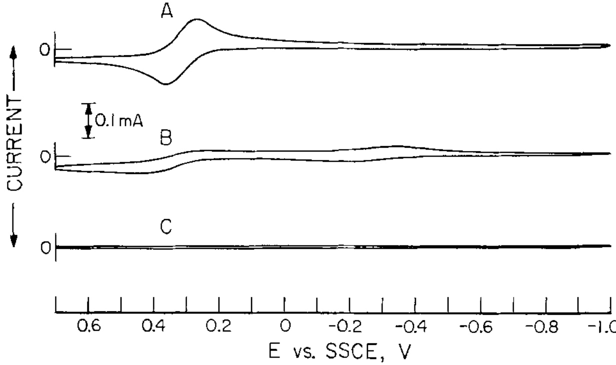

Fig. 10. Steady-state cyclic voltammograms for 1.3 mmole ferrocene at pyrolytic graphite electrodes in acetonitrile. Electrode pretreatments: A, freshly cleaved; B, coated with 4.6 $\times$ 10^{-7} moles cm^{-2} of pyridine as PVP, soaked in 5 mmole Ru^{III} (edta) for 15 min, washed with H_2O and acetonitrile. C, coated with 2.3 $\times$ 10^{-6} moles cm^{-2} of pyridine as PVP then as in B. Scan rate: 200 mV sec^{-1}. Supporting electrolyte: 0.2M $NaClO_4$.

Ru^{III} (edta) is attached to the coating, inhibited responses are observed for both the attached complex and ferrocene in the solution (Fig. 10B). With heavier coatings of PVP, the responses from both the attached and the dissolved reactant are severely inhibited (Fig. 10C). That the wave for the dissolved ferrocene can be almost eliminated with sufficiently heavy coatings of PVP indicates that the PVP films produced by exposure to this solvent are relatively free of holes or other defects that would allow the ferrocene to reach the graphite surface. Since the supporting electrolyte would presumably also be unable to penetrate the film, it is not surprising that reactants attached to such films should also exhibit little or no electroactivity. Structures of polymeric films that are compact enough to impede the motion of supporting electrolytes through them might also lack adequate flexibility for the needed positioning of the redox centers to accomplish electron transfer through the film.

The swelling of polymeric matrices bearing ionic groups, *e.g.*, ion exchange resins, by exposure to aqueous media (22) provides a familiar example of the ability of solvents to influence the density and texture of polymeric materials (20). It seems likely that the differences among the voltammograms in Fig. 9 can be attributed in large measure to variations in the swelling tendencies among the solvents tested.

Effects of changes in supporting electrolyte.—Change in the nature of the aqueous supporting electrolytes in which the electrochemistry of attached Ru^{III} (edta) is observed produce quantitative differences in the responses obtained rather than the qualitative differences arising from changes in the solvent. Figure 11

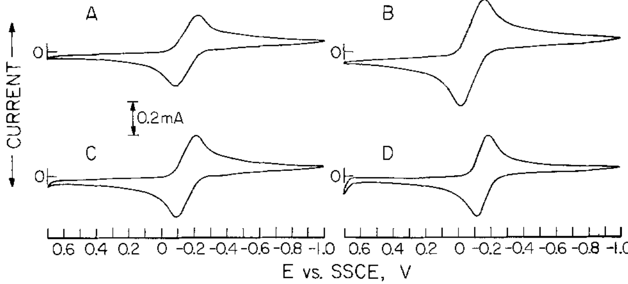

Fig. 11. Effects of supporting electrolyte on steady-state cyclic voltammograms for Ru^{III} (edta) attached to electrodes coated with 2.3 $\times$ 10^{-6} moles cm^{-2} of pyridine as PVP. A, 0.2M CF_3COONa (*p*H = 4.2). B, 0.2M CF_3COONa plus 0.025M CF_3COOH (*p*H = 1.6). C, 0.2M NaBr (*p*H = 4.2). D, 0.2M $(CH_3)_4NBr$ (*p*H = 4.2). Scan rate: 200 mV sec^{-1}. Ru^{III} (edta) attachment procedure as in Fig. 2.

compares cyclic voltammograms recorded in four different supporting electrolytes with identically prepared electrode surfaces. The peak current in the electrolyte at *p*H 1.6 (curve B) is about twice as large as those in the other electrolytes indicating that charge transfer through the film is facilitated by protonation of the pyridine groups. Protonated PVP chains no doubt tend to stretch apart to minimize coulombic repulsions (23) and this would lead to a film through which ions could move more readily. As a result, segmental motions within the polymer layer may also be facilitated because the penetration of macromolecular solids by low molecular weight species is known to produce such effects (24).

Curves A and C in Fig. 11 have rather similar shapes indicating that changing the anion of the supporting electrolyte from trifluoroacetate to bromide produces only small effects. The change of supporting electrolyte cation from sodium to tetramethylammonium (curves C and D) yields a more symmetrical voltammogram. This might be the result of less hydration of the latter cation with a corresponding decrease in the extent of segmental motion within the polymer required for its penetration.

The suggestion that the current enhancement in curve B of Fig. 11 results from an "opening up" of the polymeric structure because of repulsive interactions among protonated sites along the polymer chains receives added support from the voltammograms in Fig. 12. Curve A in Fig. 12 is a cyclic voltammogram for Fe^{III} (edta) at an uncoated electrode. Curve B results when the electrode is coated with PVP and used in the solution of Fe^{III} (edta) at a *p*H where the PVP is not significantly protonated (25). The polymer layer apparently cannot be penetrated by the Fe^{III} (edta) complex. However, when the *p*H is lowered to a value where the PVP layer is protonated, the electroreduction of Fe^{III} (edta) is immediately restored (curve C). When $Ru(NH_3)_6{}^{3+}$ is substituted for the anionic Fe^{III} (edta) complex and the experiments repeated, curves D, E, and F in Fig. 12 are obtained. Protonation of the PVP film restores only partially the electrochemical response from the reduction of $Ru(NH_3)_6{}^{3+}$ (curve F). Protonation of the polymer produces a more porous film but it is also highly positively charged so that the tri-positive reactant evidently can traverse it only with difficulty. This would account for the drawn-out shape of voltammogram F compared with that for the anionic Fe^{III} (edta) complex in voltammogram C.

An additional factor that could influence the ionic conductivity of PVP layers is the increase in the quantity of counterions within the polymeric matrix that must accompany the introduction of charged sites. Thus, the quantity of anions that are electrostatically held within a protonated PVP layer will be relatively insensitive to the ionic strength of the supporting electrolyte but highly sensitive to its *p*H. The magnitudes of voltammetric peak currents and chronocoulometric slopes for anchored reactants exhibit similar sensitivities which might be an indication that the counterionic content of the polymer coatings controls the magnitude of the currents that can traverse them.

One is left with two possible rationalizations for the increased currents that result when charged sites are introduced into PVP films: increased permeability arising from stretching of the polymer chains by repulsive electrostatic interactions among sites and/or increased conductivity within the polymeric matrix resulting from a higher salt content. The data presently available do not allow a clear choice to be made between these two rationalizations or rule out the possibility that both mechanisms are operative.

If protonation of PVP films produces a more open texture the introduction of other charged ions into the polymer might be expected to produce similar effects. Figure 13 demonstrates that the attachment of Ru^{III} (edta) to a PVP film does indeed convert a

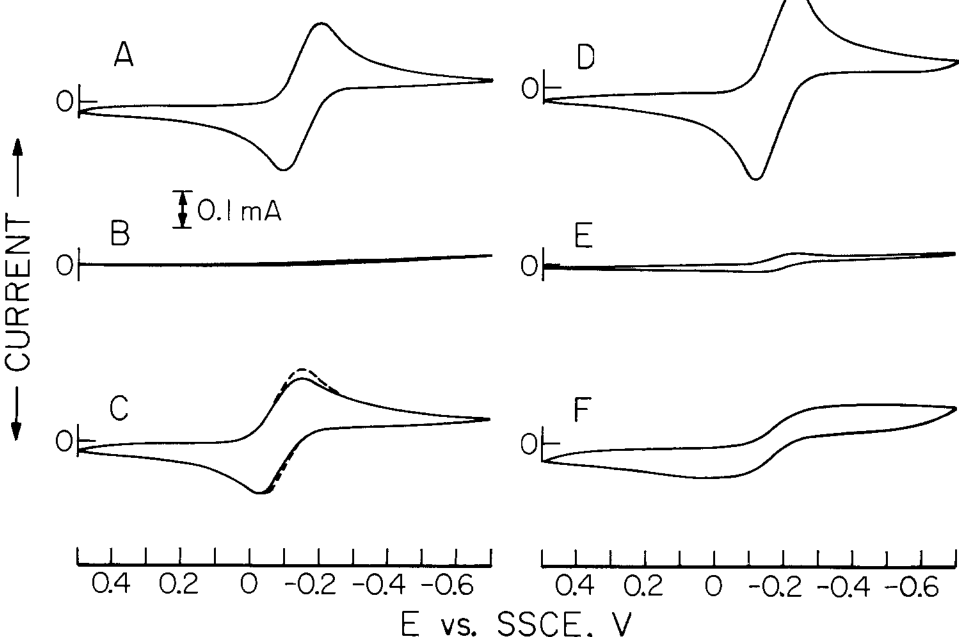

Fig. 12. Steady-state cyclic voltammograms for 5 mmole solutions of Fe^{III} (edta) or $Ru(NH_3)_6^{3+}$ at pyrolytic graphite electrodes under following conditions: A, D, freshly cleaved electrode; supporting electrolyte, 0.2M CF_3COONa at pH 5.4 (Fe) or 6.0 (Ru). B, E, coated with 4.6×10^{-7} moles of pyridine as PVP; supporting electrolyte as in A, D. C, F, supporting electrolyte adjusted to pH 2.2 with CF_3COOH. The dashed line in curve C is the response at a freshly cleaved electrode at pH 2.2. The response for $Ru(NH_3)_6^{3+}$ showed no significant pH dependence. Scan rate: 200 mV sec^{-1}.

blocking layer into one at which the $Fe(CN)_6^{3-/4-}$ redox reaction can proceed. The cyclic voltammogram obtained at an uncoated electrode (curve A) is annihilated by the presence of an unprotonated PVP coating (curve B) but it reappears, in a slightly distorted form, when Ru^{III} (edta) [a monoanion at pH 5.4 (17)] is coordinated to the polymer (curve C). In this case the density of bound (anionic) charge is not as high as that resulting from protonation of the polymer at low pH but the restored response is almost as great as that obtained at the uncoated electrode. The coated electrode can also be unblocked by protonation, as in Fig. 12.

The response observed for the $Fe(CN)_6^{3-/4-}$ couple in curve C of Fig. 13 can be understood simply in terms of an increase in the porosity of the film which allows the reactant to pass into the film much more readily than was true under the conditions of curve B. However, a second possible origin of the increased film conductance in this case (as contrasted with curves C and F in Fig. 12) is the transmission of electrons through the film via the attached Ru^{III} (edta) centers. That is, electron transfer from the graphite to the $Fe(CN)_6^{3-/4-}$ couple may be mediated by electron transfer among the anchored redox centers in the film. Distinguishing between these two mechanisms of

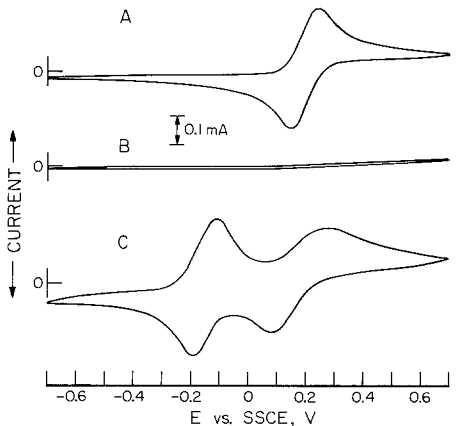

Fig. 13. Steady-state cyclic voltammograms for a 5 mmole solution of $Fe(CN)_6^{4-}$ in 0.2M CF_3COONa at pH 6.0. Pyrolytic graphite electrode pretreatments: A, freshly cleaved; B, coated with 4.6×10^{-7} moles cm^{-2} of pyridine as PVP; C, after the electrode used to record curve B was soaked for 15 min in 5 mmole Ru^{III} (edta) and rinsed. Scan rate: 200 mV sec^{-1}.

charge transfer may be possible by suitable manipulation of mass transfer and charge transfer rates and we have such experiments underway. However, it may be worth emphasizing two points in conclusion. (*i*) The presence of electroactive redox centers within polymer films is no assurance that the films will support charge transfer either to the attached redox centers or to reactants dissolved in solution: PVP coatings containing large quantities of coordinated Ru^{III} (edta) nevertheless behave as insulating layers in certain nonaqueous solvents (Fig. 10). (*ii*) Charge transfer between dissolved reactants and electrode surfaces covered with thick (1-10 μm) PVP films can occur rapidly even when the films do not have redox centers attached to them: protonation converts an insulating PVP film to one that does not impede the reduction of dissolved reactants (Fig. 12).

Acknowledgments

The assistance of Prof. J. P. Revel and Pat Cohen in obtaining electron micrographs is acknowledged gratefully. Drs. Alan Rembaum and Roger Williams kindly provided the samples of fractionated PVP that were used to obtain the data for Fig. 2. Several perceptive comments and criticisms by the reviewers of an earlier version of this manuscript helped us to formulate our speculations more clearly.

ABSTRACT

Current-potential (i-E) curves for the electrochromic process at WO_3 electrodes were calculated with a digital simulation model which assigns the rate of charge transfer at the oxide/solution interface and the rate of diffusion of hydrogen into the bulk of the film as major variables. The simulated i-E curves agreed well with experimental ones for different types of WO_3 films and predicted the observed dependency of current on scan rate. The simulation required knowledge of the form of the electrochemical isotherm, which was obtained experimentally, and adjustment of a charge transfer rate constant, k_f, and the hydrogen atom diffusion coefficient within the film, D_H. The best fit was obtained with $k_f = 9 \times 10^{-3}$ sec^{-1} (mole/cm^3)$^{-2}$ and $D_H = 1 \times 10^{-9}$ to 2×10^{-10} cm^2/sec for the WO_3 films prepared by vacuum evaporation and $k_f = 7.2$ sec^{-1} (mole/cm^3)$^{-2}$ and $D_H = 5 \times 10^{-8}$ cm^2/sec for WO_3 anodic films. Simulated potential step results, which are similar to the experimental curves at longer times but show some discrepancy in the short time region, and concentration profiles are also reported.

Recently a great effort has been made to understand the electrochromic process which occurs at WO_3 electrodes during reduction and reoxidation and to construct display devices based on this process (1-5). While it appears clear that the process involves formation and oxidation of hydrogen tungsten bronzes, the detailed mechanism and a quantitative model of the electrochromic process and the steps which govern the rate of the color-bleach (CB) process have not been resolved. Different WO_3 films produced by vacuum evaporation exhibit different response times for coloring and bleaching, even when they are prepared by similar techniques (5). Moreover different types of WO_3 electrodes (*e.g.*, anodic *vs.* evaporated films) show significant differences in response time and electrochemical characteristics in the electrochromic region (6-8). The existence of water in the WO_3 film (7-9) and film porosity (7-8) appear to play important roles in determining the response time of the WO_3 electrodes. Crandall and Faughnan (10) discussed the factors entering into the dynamics of the CB process at WO_3 and compared values for the composition of the film with time, obtained during potential-step experiments, with calculated values. Their model assumed that mass transfer within the film was very large and that the rate-limiting steps involved proton transfer at the WO_3/liquid interface and the buildup of a "back emf" as the hydrogen bronze formed. Good agreement between the experimental and calculated values was obtained in the short time region after the start of the coloring step or when the coloring step was made at low potentials within the electrochromic region. With this model (5) the bleaching process is limited by the "space charge" which is created by accumulation of H^+ in the film. Arnoldussen (11) measured exchange currents and transfer coefficients for

* Electrochemical Society Active Member.
Key words: electrode, interfaces, films.

the electrochromic process but did not relate these values to any particular mechanism for the process. In the model previously suggested for the coloration process (10), diffusion of hydrogen atoms within the WO_3 film was not taken into consideration nor were fits to potential sweeps for different films attempted. These were thus restricted to descriptions of processes occurring at very short times after the start of the coloration process, at low coloration levels, or for very thin WO_3 films.

In this paper we present a digital simulation model of the WO_3 systems and report calculated current-potential (i-E) and current-time (i-t) curves which compare well to those obtained with WO_3 evaporated and anodic film electrodes in the electrochromic region (7, 8). This model includes the effects of charge-transfer from the electrode to the hydrogen ion in solution and diffusion of hydrogen atoms in the film. The differences in the electrochromic behavior between the evaporated and anodic film electrodes, which was attributed (7, 8) to a significant difference in the charge transfer rate constants and the diffusion coefficient of the hydrogen atom in both these films is demonstrated by the simulation. The model proposed here may also be relevant to the thin layer behavior found in electrodes prepared by coating with films of polymers or other electrodes with multilayer surface modification.

Models

Theoretical model.—The model we propose for the CB process at the WO_3 electrode is shown in Fig. 1. We assume that mass transfer of protons in solution and transport of electrons through the semiconducting films are not rate-limiting and that there is no barrier to electron injection at the metal/WO_3 contact (10). The rate-determining processes are then (*i*) charge transfer to protons at the WO_3/solution interface to form hydrogen atoms (H); (*ii*) diffusion of H-atoms within the film; (*iii*) build up of the H-atom concentration within the film towards the saturation level, y, determined by the ultimate film composition, H_yWO_3. This is represented by the equation

$$H^+ + e \underset{k_b}{\overset{k_f}{\rightleftharpoons}} H_i \xrightarrow{\text{diffusion}} H_b \qquad [1]$$

where H_i and H_b represent H-atoms at the interface and in the bulk film, and k_f and k_b are charge transfer rate constants. The concentration of H-atoms within the film, which is a function of x and t, is represented as [H] and the relative saturation or occupancy of H-atoms, θ, is given by

$$\theta = [H]/C_{max} \qquad [2]$$

where C_{max} represents the maximum concentration of hydrogen within the film. At the interface $[H] = [H]_i$ and $\theta = \theta_i$. The rate of formation of H-atoms at the interface can be related to the current density, j, and the potential drop across the interface, V, by the following equation

$$\frac{d[H]_i}{dt} = \frac{j}{n\mathbf{F}} - D\left(\frac{\partial^2[H]_i}{\partial x^2}\right) = k_f[H^+]C_{max}{}^q(1-\theta_i)^q \exp\left[\frac{-\beta n\mathbf{F}}{RT}V\right] - k_rC_{max}{}^m\theta_i{}^m \exp\left[\frac{(1-\beta)n\mathbf{F}}{RT}V\right]\exp[-r\theta_i] - D\left(\frac{\partial^2[H]_i}{\partial x^2}\right) \qquad [3]$$

This equation is of the usual form for interfacial charge transfer with a transfer coefficient, β. The empirical coefficients, q, m, and r, which must be determined experimentally, take account of the fact that: (*i*) the forward reaction is attenuated by a factor representing the availability of free sites on the WO_3 for H-atoms, $(1 - \theta_i)$; (*ii*) the backward reaction is governed by the activity of the dissolved hydrogen, rather than by its concentration [expressed by the term exp $(-r\theta_i)$, which is equivalent to the interaction term in the Frumkin isotherm (12), where r is the factor expressing the extent of interaction between the absorbed hydrogen atoms, with a negative value of r implying a repulsive interaction].

We assume that the motion of hydrogen atoms in the film is governed by diffusion processes, governed by Fick's law (Eq. [4]), and that at the

$$\partial[H]/\partial t = D_H(\partial^2[H]/\partial x^2) \qquad [4]$$

boundaries of the film $x = 0$ (the oxide-electrolyte interface) and $x = l$ (the oxide-conductor interface) the conditions are always

$$\frac{j}{n\mathbf{F}} = D_H(\partial[H]/\partial x)_{x=0} \qquad (x = 0) \qquad [5]$$

$$D_H(\partial[H]/\partial x) = 0 \qquad (x = l) \qquad [6]$$

where D_H is the diffusion coefficient of hydrogen atom in the film. These boundary conditions express the assumptions that there is no accumulation of H-atoms at the oxide-electrolyte interface, and that there is no transfer of hydrogen across the oxide-conductor

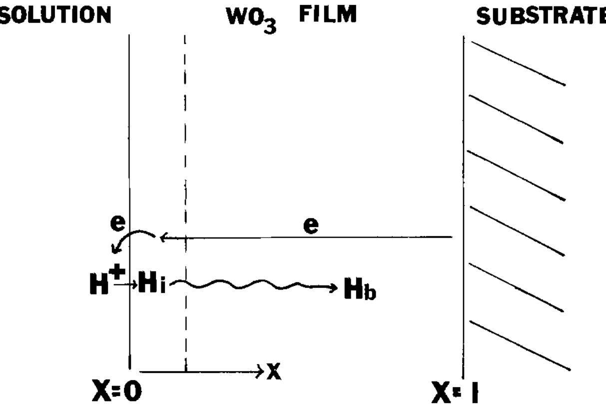

Fig. 1. Model for the electrochromic process at WO_3 electrodes

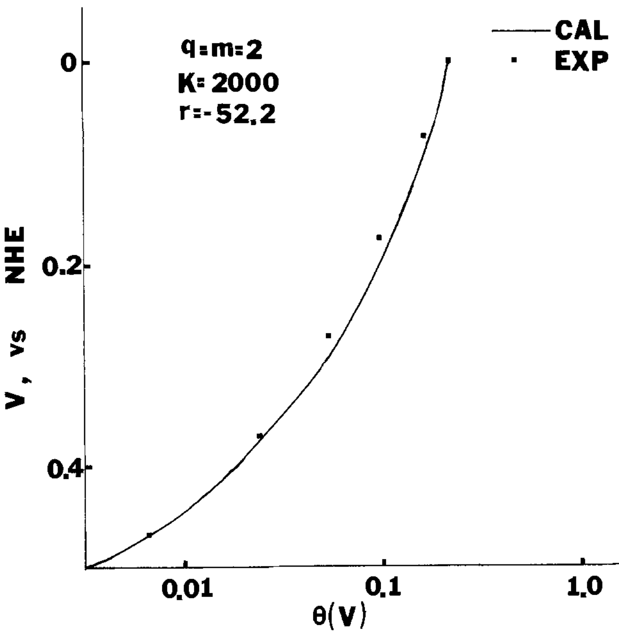

Fig. 2. Electrochemical isotherm for hydrogen in WO_3 electrodes. The line represents Eq. [9] with $q = m = 2$, $r = -52.2$, and $k = 2000$. The points are experimental data.

interface. The initial condition is

$$[H] = 0 \quad (t = 0, \quad \text{at all } x) \qquad [7]$$

Digital simulation model.—The digital simulation followed the usual finite difference approach to the solution of electrochemical problems (13-16), where the film was divided into increments of thickness, Δx, and [H] and θ are calculated for different times, divided into increments, Δt. The [H] (and θ) in the first space element (*i.e.*, at the surface) is obtained from its rate of production, Eq. [3], corrected for the loss into the film by diffusion. Within the film, [H] and θ are controlled only by diffusion, subject to the constraints of finite thickness and saturation of [H] at its maximum value at a given potential.

Results and Discussion

Hydrogen isotherm.—To carry out the simulation, values of the parameters q, m, and r must be obtained. These are available from the equilibrium isotherm. At a given potential, V, equilibrium is achieved when the distribution of H throughout the film is uniform (*i.e.*, $\partial\theta/\partial x = 0$) and θ attains its maximum value for that potential, $\theta_{eq}(V)$. At equilibrium, $j = 0$, so from Eq. [3]

$$k_f[H^+][1 - \theta_{eq}(V)]^q \exp[(-\beta n\mathbf{F}/RT)V] = k_r\theta_{eq}(V)^m \exp[(1-\beta)n\mathbf{F}V/RT]C_{max}^{m-q}e^{-r\theta_{eq}(V)} \qquad [8]$$

$$\frac{\theta_{eq}(V)^m}{[1-\theta_{eq}(V)]^q} e^{-r\theta_{eq}(V)} = K[H^+]\, e^{-(n\mathbf{F}/RT)V}\, C_{max}^{m-q} \qquad [9]$$

where $K = k_f/k_r$. C_{max} was evaluated by assuming a formula of HWO_3, for the oxide saturated with hydrogen (17). The parameters q, m, and r were estimated by fitting Eq. [9] to the experimental electrochromic isotherm. The isotherm was determined

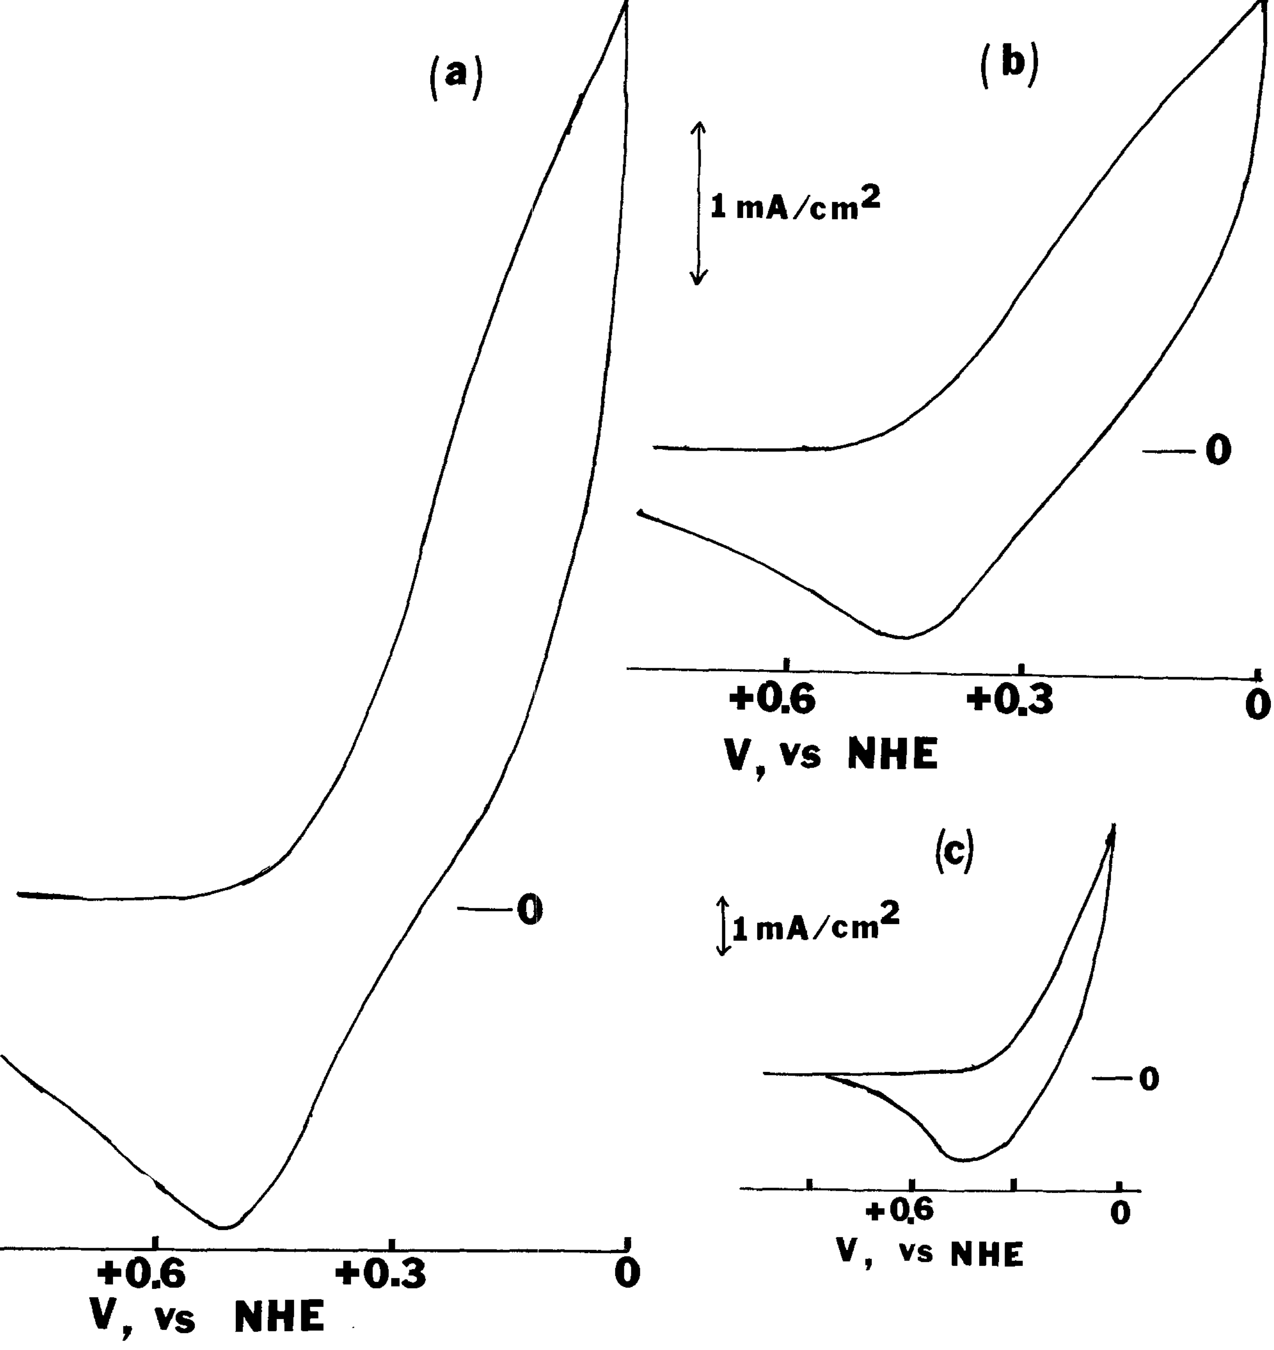

Fig. 3. Simulated current-potential curves for the electrochromic process at WO_3. Film thickness, 1.8 μm; scan rate, 100 mV/sec; k_f, 9×10^{-3} sec^{-1} $(mole/cm^3)^{-2}$; and (a) $D_H = 1 \times 10^{-9}$ cm^2/sec, (b) $D_H = 2 \times 10^{-10}$ cm^2/sec. (c) Typical experimental current-potential curve for WO_3 evaporated film electrode 1.8 μm thick at scan rate of 100 mV/sec.

by stepping the WO_3 electrode potential to a certain value, V, with respect to the reference electrode ($Hg/Hg_2SO_4/1M\ H_2SO_4$), within the electrochromic region. After stepping the potential, the amount of charge involved in coloration was determined coulometrically by integrating the current until it decayed to zero and equilibrium was attained. This procedure was repeated with various potentials within the coloration region. A similar isotherm was obtained by Faughnan *et al.* (17). The experimental isotherm and the calculated one are shown in Fig. 2. The best fit was obtained with $q = m = 2$, $K = 2000$ cm^3/mole, and $r = -52.2$. A similar conclusion regarding the values of q and m was reached by Faughnan *et al.* (17). Since $K = k_f/k_r$, the assignment of a numerical value to K requires that only the magnitude of either k_f or k_r is needed in the simulation.

Evaporated film electrodes.—The digital simulation was carried out by taking $\beta = 0.5$ and assuming different values for k_f and D_H. Typical simulated curves (illustrated with a 1 cm^2 electrode area, 1.8 μm thick film, and scan rate, v, of 100 mV/sec) with $k_f = 9 \times 10^{-3}$ sec^{-1} (mole/cm^3)$^{-2}$ and D_H of (a) 1×10^{-9} and (b) 2×10^{-10} cm^2/sec are shown in Fig. 3. These are of the same shape as experimental i-E curves found for evaporated film WO_3 electrodes (7) [Fig. 3(c)]. Thus the cathodic current, which begins at ~0.5V, increases monotonically upon scanning to more negative potentials and upon reversal of the scan direction, the current remains cathodic only becoming anodic at potentials 0.2-0.3V more positive than the reversal potential for 1.8 μm films. The anodic current peak is typically 2-3 times smaller than the cathodic current at 0V. The magnitudes of currents shown in the simulated curves are also similar to those obtained experimentally. The dependence of the simulated electrochromic i-E curves on scan rate is shown in Fig. 4. The simulation shows that the coloration current at more negative potentials is linearly dependent on $v^{1/2}$ as observed experimentally with the evaporated WO_3 film electrodes (7) [see Fig. 4(c)].

The k_f and D_H values both affect the rate of the electrochromic process, the shape of the i-E curves, and the scan rate dependence. For a film with a given thickness, l, the potential at which the simulated electrochromic current changes its sign from cathodic to anodic following the change in the direction of the potential scan, is very sensitive to the charge transfer rate constant, k_f. This is illustrated in Fig. 5. Typically the experiments with 1.8 μm WO_3 evaporated film electrodes produced i-V curves which crossed the X-axis about 200-300 mV after the potential of scan reversal. This behavior, shown in Fig. 3, puts k_f at a value of $\sim 9 \times 10^{-3}$ sec^{-1} (mole/cm^3)$^{-2}$. For a typical evaporated WO_3 film, this choice of k_f value produces a ratio of the cathodic to the anodic peak current similar to the experimental values. For some evaporated films the experimental anodic current started to appear at more positive potentials. The simulation results suggest that in these cases k_f was smaller, perhaps because of some change in the nature of the surface of the film. In other extreme cases the experimental anodic current started to appear at a more negative potential, indicating a larger k_f value for these. The value of D_H also affects the potential at which the anodic current begins on scan reversal but its effect on this value is smaller than that of k_f. However the magnitude of D_H strongly affects the size of the electrochromic current, as shown in Fig. 3. For two films with the same k_f an increase in D_H by a factor of five causes an increase

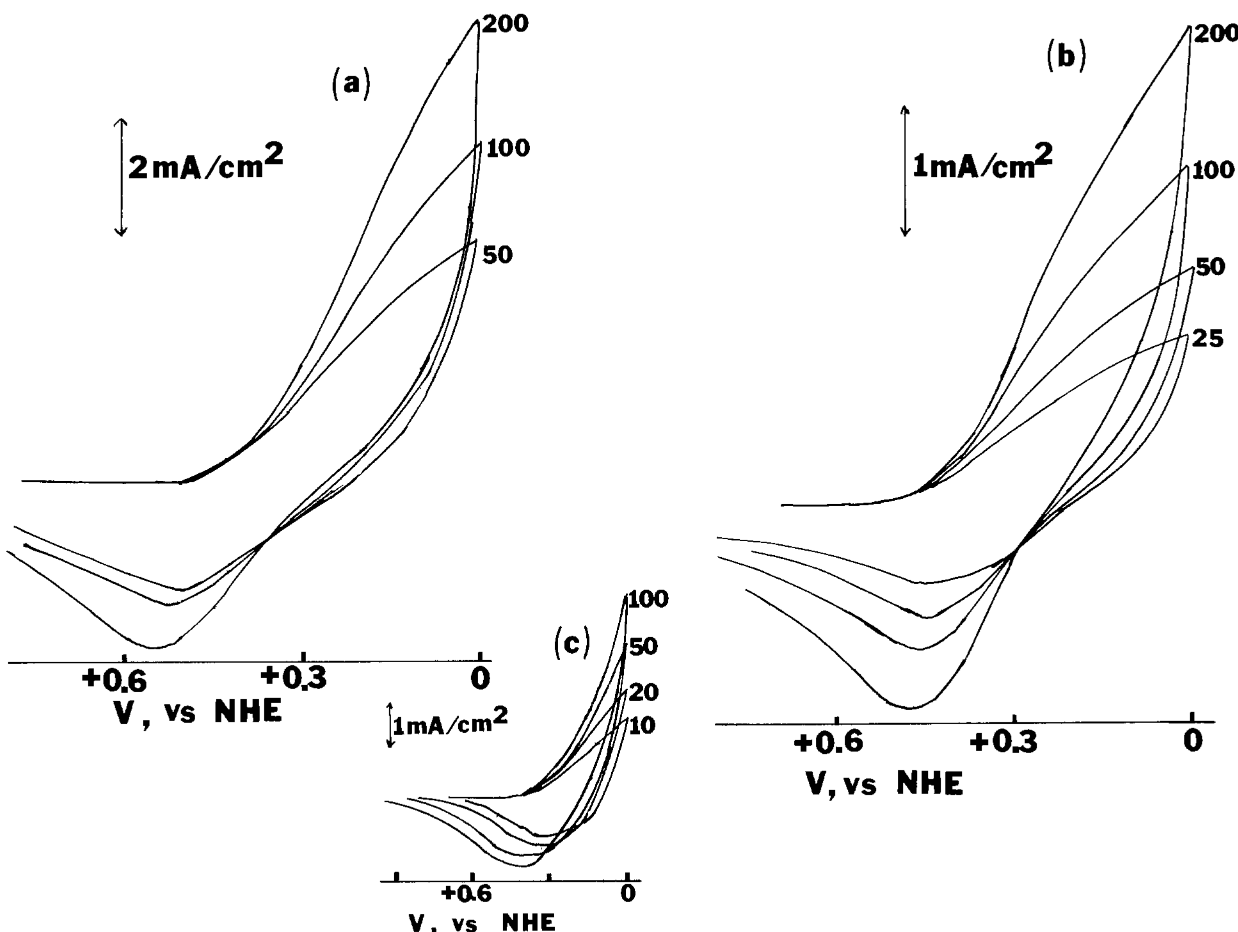

Fig. 4. (a), (b) Simulated electrochromic current-potential curves, as in Fig. 3, for different scan rates. (c) Experimental current-potential curve of the evaporated film shown in Fig. 3(c) at different scan rates. The numbers are the scan rates in mV/sec.

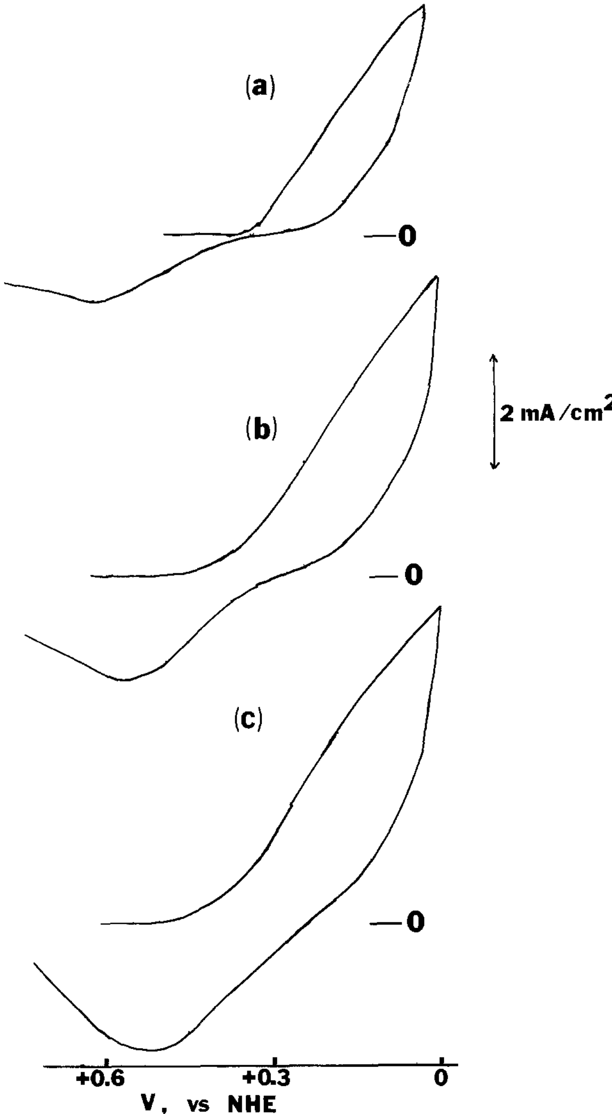

Fig. 5. Simulated current-potential curves for the electrochromic process at a WO_3 film, 1.8 μm thick with $D_H = 1 \times 10^{-9}$ cm²/sec and with k_f values of (a) 1.8×10^{-3}, (b) 4.5×10^{-3}, (c) 9×10^{-3} sec^{-1} $(mole/cm^3)^{-2}$.

in the electrochromic current by a factor of about 2. The values of D_H which produced simulated i-E curves with currents similar in magnitude to typical experimental ones with evaporated WO_3 films were 1×10^{-9}-2×10^{-10} cm²/sec. Mainly l and D_H determine the dependence of the current on the scan rate. The calculated concentration profile of the hydrogen atom within the evaporated film at the negative potential limit (0V *vs.* NHE) is shown in Fig. 6(a) and (b) for different scan rates and two different film thicknesses. As expected the concentration profile shows a sharp slope at the surface, which is caused by slow diffusion into the film. It is this behavior which results in the $v^{1/2}$ dependence observed in the i-E curves. We have observed similar i-E curves and scan rate dependences for WO_3 layers obtained by thermal oxidation of W (18), which suggests that these films have k_f and D_H values similar to those of the evaporated film electrodes.

Anodic film electrodes.—The shape of the i-E curves and the scan rate dependence were different for the WO_3 anodic film electrodes (7, 8) [Fig. 7(a) and (b)]. These i-E curves appear more reversible than those for the WO_3 evaporated film electrodes discussed above. Thus, the electrochromic current changes sign from cathodic (coloring) to anodic (bleaching) almost immediately after the direction of the potential scan is reversed. The anodic current magnitude is similar to that of the cathodic current and generally the curves look more symmetrical. Moreover, the electrochromic current in this case depends directly on v [Fig. 7(b)] as opposed to the $v^{1/2}$ dependence found with the evaporated or thermally oxidized films. This difference in behavior can be ascribed to large differences in k_f and D_H. Indeed to obtain simulated i-E curves which resembled those obtained experimentally with the WO_3 anodic film electrodes, much larger values of k_f and D_H had to be used [Fig. 7(c) and (d)]. To obtain an i-E curve of this shape, k_f must be taken as about 7.2 sec^{-1} $(mole/cm^3)^{-2}$. D_H values of about 5×10^{-8} cm²/sec then yield current magnitudes in the simulated i-E curves similar to those obtained experimentally. With these k_f and D_H values, the current in the simulated i-E curves is linearly dependent on v [compare curves (b) and (d) in Fig. 7]. The H-concentration profile within the film, calculated for E = 0V *vs.* NHE, with the same thickness (l), k_f, and D_H values as in Fig. 7 is shown for several scan rates in Fig. 6(c). These concentration profiles are almost flat, so that the concentration of hydrogen atoms is essentially uniform throughout the film. This concentration is also near the equilibrium value at this potential (compare with the data in Fig. 2). This type of response is typical of "thin film" behavior as found for thin electrochemical cells (19) and as well as for adsorbed layers, modified electrodes, etc., and results in a dependency of current directly on v.

Current-time curves.—Simulated current-time (i-t) curves for the electrochromic process can be calculated with the same digital simulation model and parameters. Simulated i-t curves for the coloration process at two different potentials are compared to an experimental one obtained with the WO_3 evaporated films in Fig. 8. The values of k_f and D_H used for the calculation of the simulated curves are those which were used for calculated i-E curves of Fig. 3. While these values give simulated i-t curves which are similar to the experimental ones, there is some discrepancy between the simulated and the experimental curves in the shorter time region. In general the experimental i-t curves show a bump or irregularity in the short time region, while the simulated curves are smooth at all times. The source of this irregularity in the short time region has not yet been established, and we could not simulate it by any minor variations in the model (such as attempts to incorporate a proton source, like water, within the film). The H-concentration profiles during a coloration potential step, which are directly related to the intensity, were calculated for several times (Fig. 9). Such curves are useful for predicting what degree of coloration will be obtained at a given time after the onset of a potential step into the coloration region. For the evaporated film electrodes, 1.8 μm thick, 50% of the maximum coloration occurs at about 15 sec. This is similar to what is found experimentally.

Conclusions

The model suggested here describes in a satisfactory way the experimental results obtained for the electrochromic processes at different types of WO_3 electrodes. The model proposes as major factors both the rate of diffusion of hydrogen atoms within the WO_3 films and the rate of charge transfer at the WO_3/solution interface along with the saturation effect which occurs as the hydrogen tungsten bronze forms. The scan rate dependence of the current and rate of coloration of the films is mainly a function of D_H and l and the behavior can be roughly classified according to the dimensionless parameter $S = (RT/\mathbf{F})D_H/vl^2$. When S is greater than ~1, i varies with v and "thin layer" behavior is observed. For S less than ~0.1, a $v^{1/2}$ dependency is found. This model also describes in a generally satisfactory

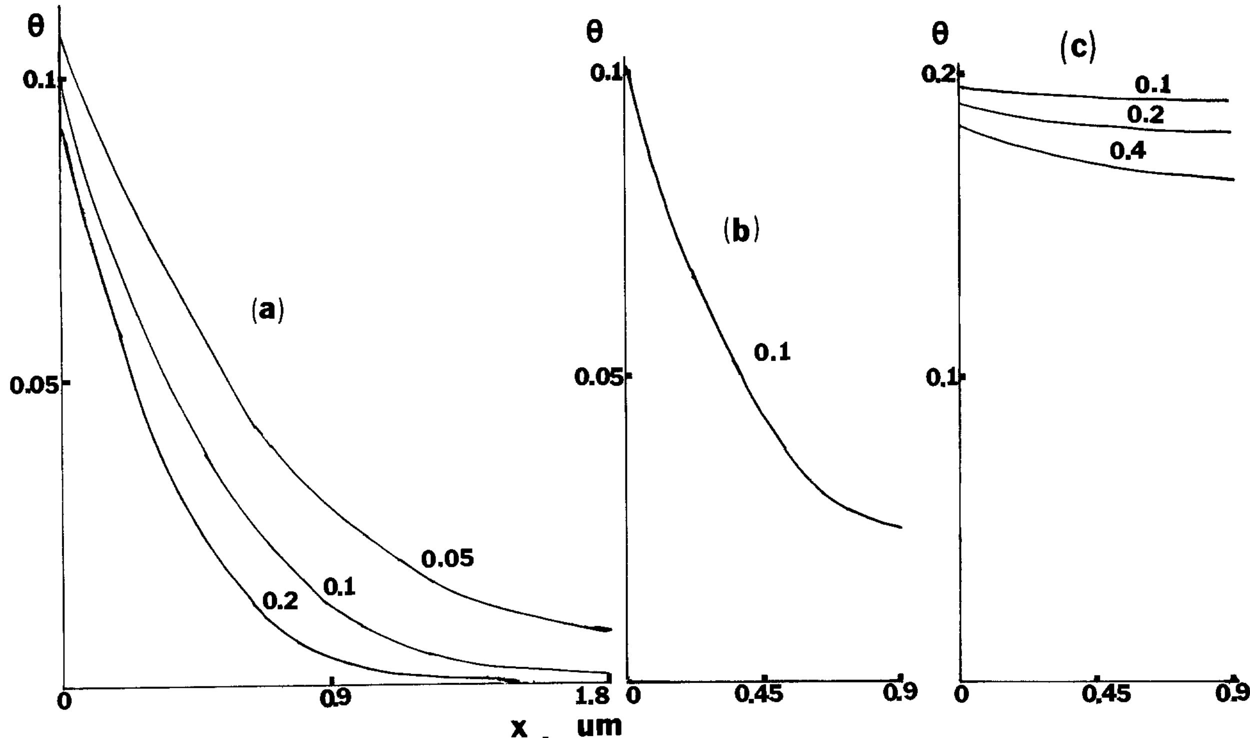

Fig. 6. Simulated concentration profiles of hydrogen atoms within the WO_3 evaporated film. (a) $k_f = 9 \times 10^{-3}$ sec^{-1} (mole/cm^3)$^{-2}$, $D_H = 1 \times 10^{-9}$ cm^2/sec, $l = 1.8$ μm; (b) as (a) with $l = 0.9$ μm; (c) $k_f = 7.2$ sec^{-1} (mole/cm^3)$^{-2}$, $D_H = 5 \times 10^{-8}$ cm^2/sec, $l = 0.9$ μm. All curves are for an electrode potential of 0V, at the scan rates indicated on the curves (mV/sec).

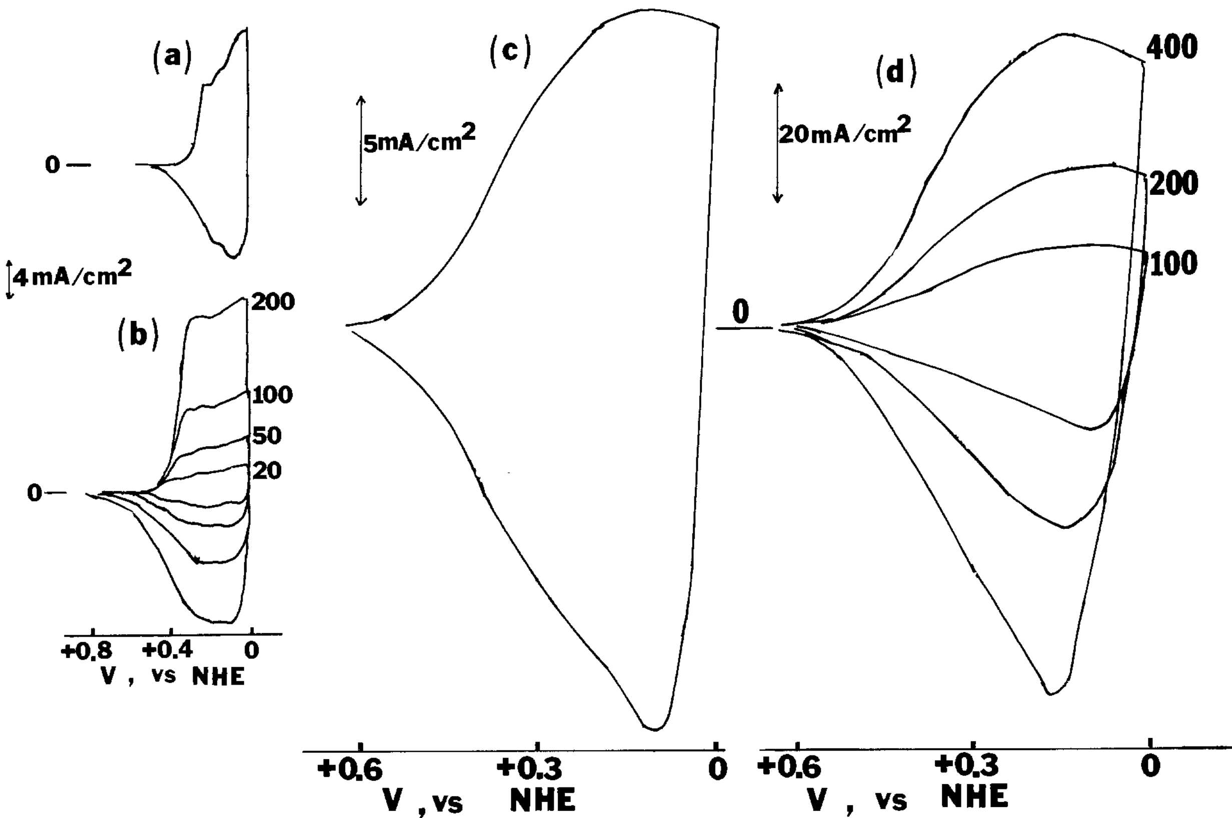

Fig. 7. (a) Experimental current-potential curves recorded at 100 mV/sec for 0.9 μm thick anodic film electrodes in 1M H_2SO_4 solution; (b) as (a) for different scan rates indicated on the curves (mV/sec); (c) simulated current-potential curve with $l = 0.9$ μm, $k_f = 7.2$ sec^{-1} (mole/cm^3)$^{-2}$, $D_H = 5 \times 10^{-8}$ cm^2/sec, scan rate = 100 mV/sec; (d) simulated current-potential curve as in (c), for different scan rates.

way the i-E behavior of WO_3 electrodes as well as i-t transients at longer times. The discrepancies between the experimental data and the simulated i-t curves in the short time region remain to be explained and modifications of the model which can simulate this behavior may lead to further insight into the nature of the electrochromic process and changes which occur in the films during coloration and bleaching.

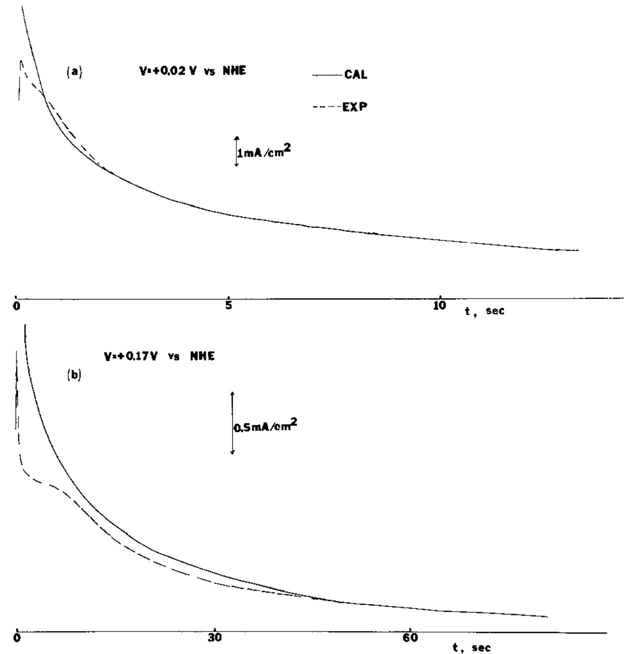

Fig. 8. Simulated (——) and experimental (- - -) current-time curves during the coloration process at WO_3 evaporated film electrode, 1.8 μm thick at two different potentials (a) +0.02V, (b) +0.17V vs. NHE. The values of k_f and D_H used for the calculation were the same as those which were used to calculate the current-potential curves of Fig. 3(a).

The Thionine-Coated Electrode for Photogalvanic Cells

W. John Albery, Andrew W. Foulds, Keith J. Hall, and A. Robert Hillman

Department of Chemistry, Imperial College, London SW7 2AY, England

ABSTRACT

The successful operation of a photogalvanic cell for solar energy conversion requires that the illuminated electrode should discriminate between the two redox couples in solution. In the case of the iron-thionine system the electrode must oxidize photogenerated leucothionine but not reduce the photogenerated Fe(III). Modified electrodes with coatings of thionine of up to 20 monolayers can be prepared on Pt and SnO_2. These electrodes have been investigated using ring disk, cyclic voltammetry, XPES, and spectroelectrochemical measurements. Results for the modified electrode kinetics are presented for the following systems: thionine, disulfonated thionine, Fe(III), $Fe(CN)_6^{4-}$, $Ru(bpy)_3^{3+}$, Ce(IV), quinone, and N,N,N′,N′-tetramethyl-p-phenylenediamine. The results for the Fe(III) and thionine systems show that this modified electrode is suitable for the iron-thionine photogalvanic cell.

A typical photogalvanic cell for solar energy conversion is shown in Fig. 1. The iron-thionine system for such a cell works according to the following reaction scheme (1-3)

$$\text{Th} \xrightarrow{h\nu} \text{Th}^*$$

$$\text{Th}^* + \text{Fe(II)} \xrightarrow{\text{H}^+} \text{S}^\cdot + \text{Fe(III)}$$

$$\text{S}^\cdot + \text{S}^\cdot \xrightarrow{\text{H}^+} \text{Th} + \text{L}$$

Illuminated electrode

$$\text{L} \longrightarrow \text{Th} + 2e + 3\text{H}^+$$

Dark electrode

$$2\text{Fe(III)} + 2e \longrightarrow 2\text{Fe(II)}$$

where Th is

N
H_2N S^+ NH_2

L is

H
N
H_3N^+ S NH_3^+

and $S^\cdot$ is the semithionine radical.

In order to obtain power from the cell it is essential that the illuminated electrode should discriminate between the photogenerated leucothionine (L) and Fe(III) (4). If the electrode does not so discriminate, then addition of the electrode reactions in the reaction scheme shows that the electrode merely catalyzes the back-reaction of photogenerated products into the original reactants

$$\text{L} + 2\text{Fe(III)} \rightarrow \text{Th} + 2\text{Fe(II)}$$

The illuminated electrode must remove one of the photogenerated products, in this case L, and force the other, Fe(III), to diffuse across the cell and react on

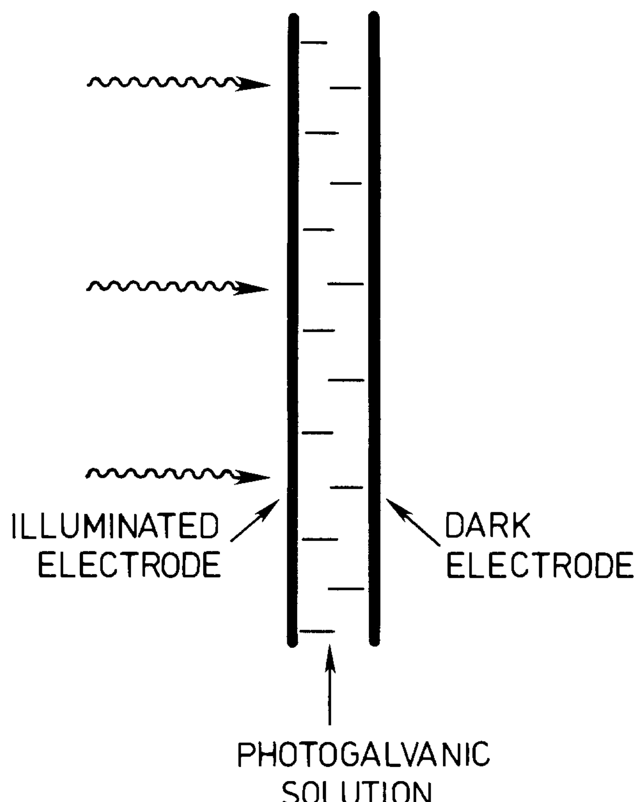

Fig. 1. Typical photogalvanic cell

Key words: photogalvanic cells, modified electrodes, thionine.

the dark electrode. It should be noted that for an efficient photogalvanic cell the electrode kinetics of the two electrodes must be different (5). If the Fe(III) reaction is blocked on the dark electrode as well as the illuminated electrode then the cell operates only as a concentration cell and produces insufficient voltage of $\sim RT/\mathbf{F}$ (6). In this paper we describe how to modify the illuminated electrode by coating it with thionine itself. The modified electrode then discriminates between the photogenerated L and Fe(III). A photogalvanic cell with a modified and an unmodified SnO_2 electrode will then possess the necessary differential electrode kinetics (7).

Theory

The kinetics of the electrode processes were measured on the rotating disk electrode. For the reaction

$$O + ne \rightleftarrows R$$

we can derive the general equation

$$\ln \left\{ \frac{i_O}{i} - 1 + \left(\frac{i_R}{i} + 1\right)\left(\frac{D_O}{D_R}\right)^{2/3} \exp\left[\frac{n(E-E')\mathbf{F}}{RT}\right]\right\} = y = \ln\left(\frac{k_{D,O}'}{k_o'}\right) + \frac{\alpha(E-E')\mathbf{F}}{RT} \quad [1]$$

where i_O and i_R are the limiting currents for the reduction of O and oxidation of R, respectively, E' is the formal potential for the O, R couple in the particular medium, $k_{D,O}'$ is the mass transfer rate constant for O, and k_o' is the standard electrochemical rate constant for the O, R couple at $E = E'$.

At a rotating disk electrode (11, 12)

$$k_{D,O}' = 1.55 D_O^{2/3} \nu^{-1/6} W^{1/2} \quad [2]$$

$$i_O = nA\mathbf{F}k_{D,O}'[O] \quad [3]$$

ν is the kinematic viscosity and W is the rotation speed in Hz.

For the irreversible reduction of O the current voltage curve is observed when $(E - E')$ is fairly negative and hence the exponential term in [1] may be neglected leading to the usual Tafel equation corrected for mass transport

$$\ln\left(\frac{i_O}{i} - 1\right) = y = \ln\left(\frac{k_{D,O}'}{k_o'}\right) + \alpha\frac{(E-E')\mathbf{F}}{RT} \quad [4]$$

In this work we observe limiting currents that are not entirely transport controlled. There is a two-step reaction at the electrode where the rate constant, $k_?'$, of one of the steps does not depend on potential. For such a scheme with two consecutive steps we replaced $k_{D,O}'$ in [1] or [3] with

$$k_{D,?}'^{-1} = k_{D,O}'^{-1} + k_?'^{-1} \quad [5]$$

where $k_{D,?}'$ will be determined by the smaller of the two rate constants $k_{D,O}'$ and $k_?'$. At reducing potentials we then obtain from [3] and [2] the usual Koutecky Levich equation (13) for the limiting current

$$\frac{nA\mathbf{F}[O]}{i_O} = \frac{1}{k_{D,O}'} + \frac{1}{k_?'} = \frac{0.65 D_O^{-2/3}\nu^{1/6}}{W^{1/2}} + \frac{1}{k_?'} \quad [6]$$

Experimental

All the electrochemical experiments were carried out at 25°C and all potentials reported with respect to the saturated calomel electrode. Rotating disk and ring disk studies were performed using an Oxford Electrodes motor controller, rotating assembly, and control electronics. Antimony-doped SnO_2 electrodes were prepared by spraying a solution of 10 ml $SnCl_4$ and 0.6 ml $SbCl_5$ added to 20 ml ethyl acetate for 3 sec onto the end of a quartz rod heated to 1000°C and rotating at 5 Hz. Spectra were recorded on a Unicam SP 600 recording spectrophotometer. XPES spectra were measured on an AEI ES 200 B photoelectron spectrometer using Mg Kα exciting radiation; the base pressure was $\sim 10^{-9}$ Torr. The conductance of the thionine coating was measured in the d-c mode after vapor deposition of an Au contact.

Results and Discussion

Preparation and properties of modified electrodes.—Both Pt and SnO_2 electrodes can be coated with a stable layer of thionine by holding the electrode at 1.1-1.5V for a period of several minutes in a solution containing thionine. Figure 2 shows a ring disk experiment which monitors the consumption of thionine during the coating process. From the decrease in the transport limited current for thionine at the ring electrode we can calculate from $N^{-1}\int \Delta i_R dt$ the amount of thionine consumed on the disk where N is the collection efficiency (8, 9). When the modified electrode is removed from the thionine solution, washed and placed in background electrolyte (*e.g.*, 50 mmole H_2SO_4) containing no thionine, cyclic voltammograms as shown in Fig. 3 are

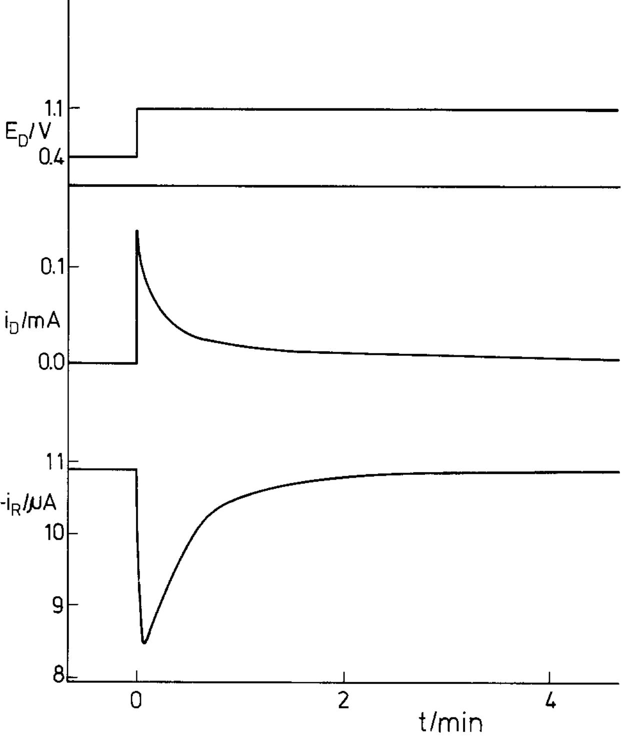

Fig. 2. Ring disk study of coating process; E_D, disk potential; i_D, disk current; i_R ring current. Amount of thionine coated on disk found from $N^{-1}\int \Delta i_R\, dt$.

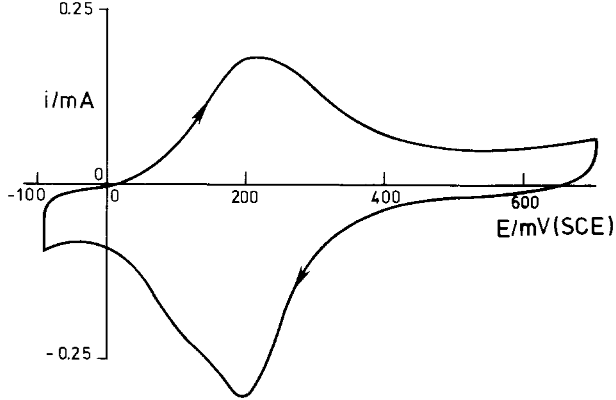

Fig. 3. Cyclic voltammogram of thionine-coated Pt electrode in 0.05M H_2SO_4 containing no thionine.

obtained. The peak height of these voltammograms varies linearly with sweep rate as expected for surface bound species. From the charge passed per cycle we can also calculate the amount of thionine in the layer. The coverages found from cyclic voltammetry agree with those from the ring disk experiment but are usually about 20% lower. Coatings of up to 20 monolayers can be obtained and these coatings are stable in background electrolyte for at least several months. XPES studies, see Fig. 4, of a coated electrode show identical peaks to those of thionine and the Pt 4f peak is complely absent (10).

The cyclic voltammograms before and after the XPES experiment show that exposure to high vacuum for several hours only reduces the coverage by about 10%.

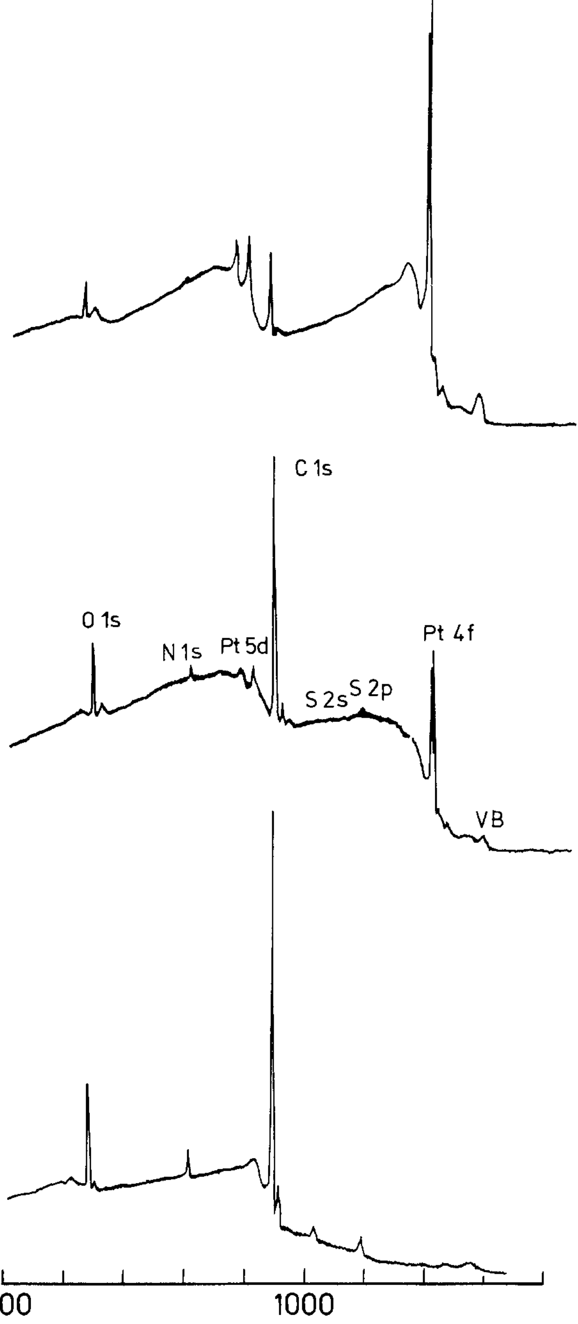

Fig. 4. Typical XPE spectra. The top trace shows a Pt electrode that has been exposed to thionine solution at 0.4V. The principal feature is the Pt 4f signal. The second and third traces show Pt electrodes coated at 1.0 and 1.1V, respectively. The Pt signal becomes progressively suppressed; C, N, and S peaks corresponding to thionine are found. x-axis, KE/eV.

Compared to thionine in solution the visible spectrum of a coated SnO_2 electrode on a quartz plate shows a broadened peak at much the same wavelength ($\lambda_{max}/nm \simeq 600$) (10). At reducing potentials this peak disappears. As shown in Fig. 5 the proportion of thionine, f, and leucothionine in the layer obeys the Nernst equation

$$\frac{RT}{n\mathbf{F}} \ln \left(\frac{f}{1-f} \right) = E - E_c' \qquad [7]$$

We find $n = 2$ and $E_c'/mV = 180$. This value is similar to that of thionine in our solution ($E'/mV = 208$). The resistance of 1 cm^2 of a layer coated at 1.1V containing 6 nmole cm^{-2} was found to be 60Ω. From these results we conclude firstly that the layer consists of thionine or leucothionine depending on the electrode potential. Secondly, the layer is remarkably stable and coherent; it cannot be washed off and the disappearance of the Pt signal in the XPE spectrum is particularly noteworthy. Thirdly, for current densities less than 150 μA cm^{-2} the voltage drop across the layer is less than 10 mV and can be neglected.

Thionine.—We now examine the electrode kinetics of various redox couples on the thionine-coated electrode starting with thionine itself. Figure 6 shows typical current voltage curves for the reduction of thionine on a clean and a thionine-coated Pt electrode. On the clean electrode the system is reversible. On the coated electrode the system is nearly reversible. Figure 7 shows the current voltage data plotted according to [1]. Kinetic parameters for different electrodes are collected in Table I. We conclude firstly that on the coated electrode there is little difference between Pt and SnO_2 as the substrate surface. Secondly the electrochemical rate constant is decreased for electrodes coated at higher voltages and for longer times. In particular there is a significant reduction in rate constant for electrodes coated at 1.4V or above for periods longer than one hour. It should be noted from Fig. 2 that after the initial coating process lasting two min-

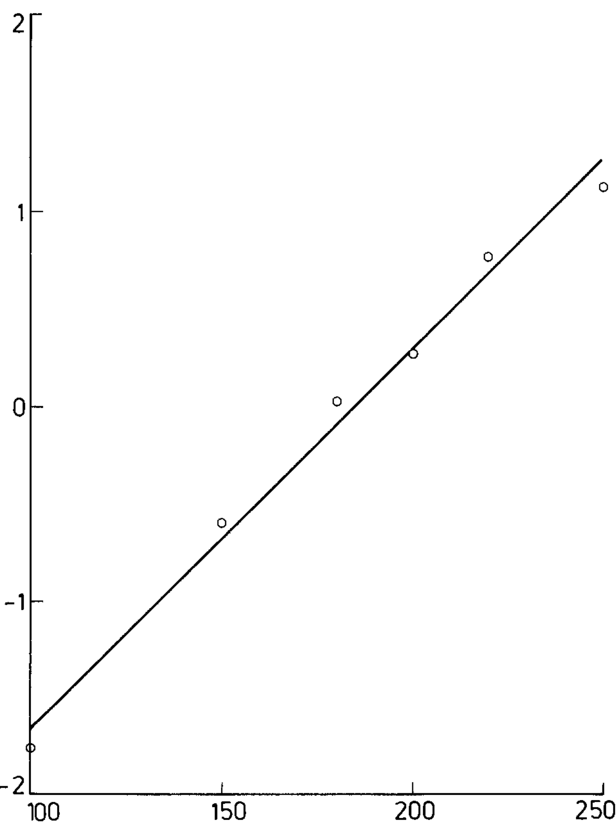

Fig. 5. Plot of Nernst Eq. [7] describing the bleaching of the thionine layer. x-axis, E/mV(SCE); y-axis, ln(f/1 − f).

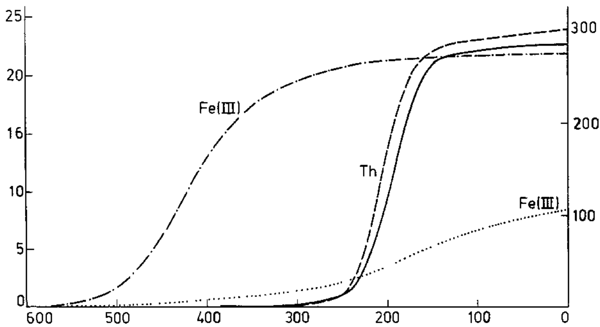

Fig. 6. Typical current voltage curves for thionine (Th) and Fe(III) on an uncoated (- - - and —·—·) and thionine-coated Pt electrode (——— and . . . .). x-axis, E/mV(SCE); left-hand y-axis, $i_{Th}/\mu A$; right-hand y-axis, $i_{Fe(III)}/\mu A$.

utes, the ring electrode does not detect any further consumption of thionine on the disk electrode. From cyclic voltammetry (see Fig. 3) the amount of adsorbed thionine does not change significantly after the initial coating process.

The value of $\alpha \simeq 1.0$ is interesting It suggests that the rate-determining step in the reduction of thionine involves a reaction of a semithionine species which is in equilibrium with the thionine. On a clean Pt electrode as the pH is increased the value of k_o' decreases. Preliminary results are consistent with the following scheme of squares (14, 15) mechanism

$$
\begin{array}{l}
Th^{+} \\
H^{+} \downarrow\uparrow \\
HTh^{2+} \overset{e}{\rightleftharpoons} HS^{\cdot +} \\
\qquad\qquad H^{+} \downarrow \text{R.D.S.} \\
\qquad\qquad H_2S^{\cdot 2+} \overset{e}{\rightarrow} H_2L^{+} \\
\qquad\qquad\qquad\qquad \downarrow \\
\qquad\qquad\qquad\qquad H_3L^{2+}
\end{array}
$$

In this scheme we have included the added protons explicitly. We have estimated the pK's of the transition states from the pK's of the thionine, semithionine, and leucothionine species (16-20). In order to explain the variation of k_o' with coating conditions (see Table I) the thionine species must be adsorbed on the electrode.

Disulfonated thionine.—Photogalvanic cells have so far been extremely inefficient for the conversion of solar energy (21) because thionine is not sufficiently soluble to absorb the solar radiation close enough to the illuminated electrode (3). We have recently synthesized disulfonated thionine. The solubility is increased so that solutions $\sim 10^{-2}$M can be prepared and furthermore from the visible spectrum there is no evidence for dimer formation. The disulfonated thionine cannot be coated onto the electrode in the same way as thionine. However the electrode kinetics of disulfonated thionine are very similar to those of thionine. Results are given in Table II.

Table I. Kinetic parameters for the reduction of thionine

Quinone.—Results for the reduction of quinone are given in Table III. In these experiments a Pt electrode was used throughout and the coating time was ¼ hr. The reduction was carried out in 0.1M H_2SO_4. It can be seen that the thionine coating has practically no effect on the electrode kinetics of the quinone reduction.

N,N,N',N'-tetramethyl-p-phenylenediamine.—The normal reaction scheme for the oxidation of N,N,N',N'-tetramethyl-p-phenylenediamine is as follows

NMe$_2$ NMe$_2$ NMe$_2$

$\xrightarrow{-e}$ $\xrightarrow{-e}$

NMe$_2$ NMe$_2$ NMe$_2$

Wurster's Blue +

Coating voltage, V	α	k_o', cm ksec^{-1}
Clean	0.6	0.18
1.1	0.6	0.24
1.4	0.6	0.20
1.5	0.7	0.15

reaction are observed. On an electrode coated with thionine at 1.1V for ¼ hr while the rate constant for the first wave is somewhat reduced, the second electron transfer is completely blocked. At present we can offer no explanation for this complete blocking. It is true that Wurster's blue is positively charged but then the positively charged thionine reacts rapidly as shown in Fig. 6.

Apart from the complication of Wurster's blue and the small variations in Table I, we find that for these organic species the thionine coating does not produce a drastic change in the electrode kinetics. This is to be contrasted with the inorganic systems that we now consider.

Fe(III).—Typical current voltage curves for the reduction of Fe(III) are shown in Fig. 6. It can be seen at once that the coating produces firstly a shift of some 200 mV in the half-wave potential and secondly that the limiting current of the shifted wave is very much less than that on the untreated electrode. The variation of the limiting currents of the shifted waves with rotation speed are plotted in Fig. 9 according to the Koutecky Levich equation Eq. [6]. From the intercept, which corresponds to infinite rotation speed, we can find values of $k_?'$. For the rising part of the current voltage curve we can use the simple irreversible Eq. [4] with i_0 being the observed limiting current. A typical plot is shown in Fig. 10. Results for the Fe(III) system are collected in Table IV. Instead of extrapolating the results for k_o' for the coated electrodes a long way to the E' for the Fe(III)/Fe(II) couple, we have reported the results at E' for thionine.

The first point to note is that for this reaction α is close to 0.5. This suggests that the potential dependent rate constant is still describing an electron transfer, even though the rate is much slower on a coated electrode compared to a clean electrode. The conductivity of the thionine film means that there cannot be large potential differences within the film and hence the main potential drop occurs at the thionine/water interface. The second point to note is that, like thionine, although Fe(III) has different electrode kinetics on clean Pt and clean SnO_2, there is not much difference once the electrodes are coated. Thirdly, the existence of $k_?'$ means that there must be a second step in the mechanism, the rate constant of which is not greatly affected by potential. These results will be further discussed below.

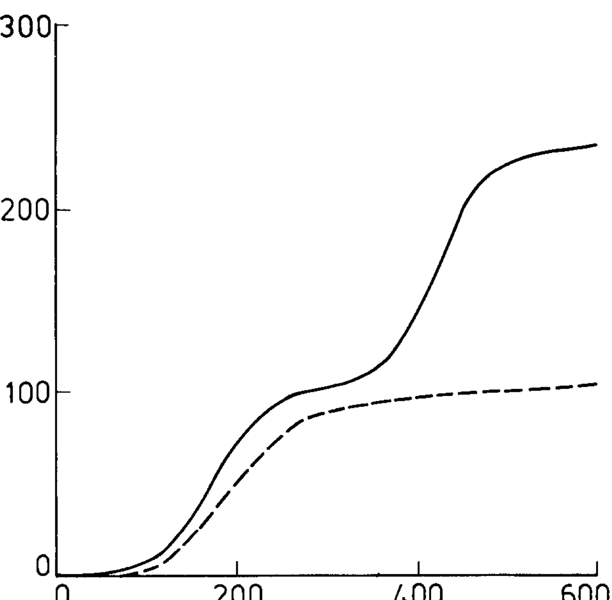

Fig. 8. Current voltage curves for oxidation of N,N,N',N'-tetramethyl-p-phenylenediamine on a clean (———) and coated (- - -) Pt electrode. x-axis, E/mV(SCE); y-axis, $i/\mu A$.

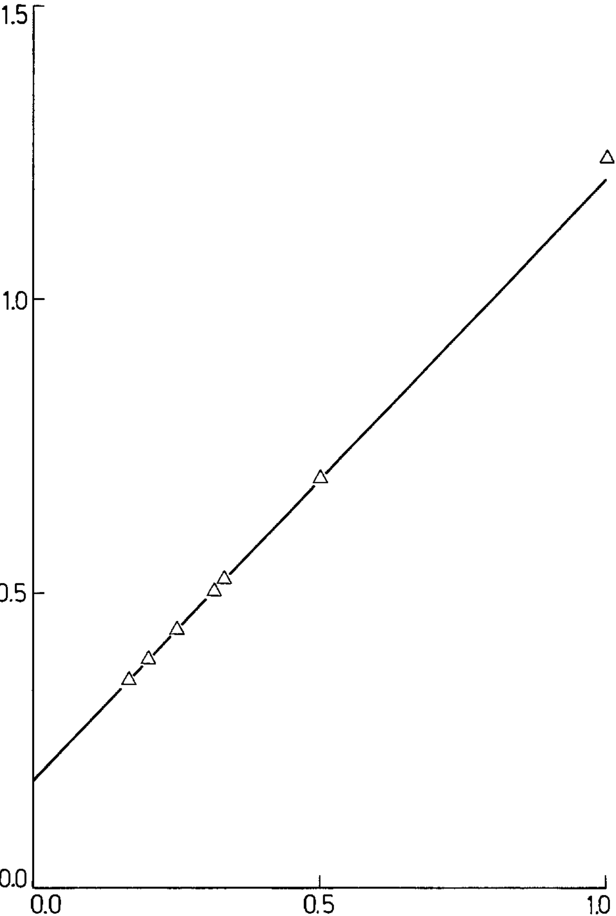

Fig. 9. Koutecky Levich plot, Eq. [6], for reduction of Fe(III) on a coated Pt electrode. x-axis, $(W/Hz)^{-1/2}$; y-axis, $(i_L/mA)^{-1}$.

$Fe(CN)_6^{4-}$.—Results for the oxidation of $Fe(CN)_6^{4-}$ in 0.4M K_2SO_4 at *p*H 7 are similar to those for Fe(III). Typical results are shown in Fig. 11. On a clean Pt electrode as expected the couple is reversible but on a coated electrode the wave is irreversible and again there is a second step. For an electrode coated at 1.1V for ¼ hr we find k_o'/cm ksec^{-1} $\simeq$ 0.6 and $k_?'$/cm ksec^{-1} $\simeq$ 2.2. It is very striking how the thionine coat has blocked this normally rapid electron transfer.

Ru(bpy)$_3^{3+}$.—Even more dramatic are the results for the reduction of $Ru(bpy)_3^{3+}$ in 0.5M H_2SO_4 where *bpy* is 2,2′ bipyridine. Results on a coated electrode are shown in Fig. 12. On a clean electrode $Ru(bpy)_3^{3+}$ is reduced at potentials less than 1.0V, in a reversible wave. The thermodynamics for the reduction are favorable and the kinetics are rapid. However on the coated electrode the transport limited current is not

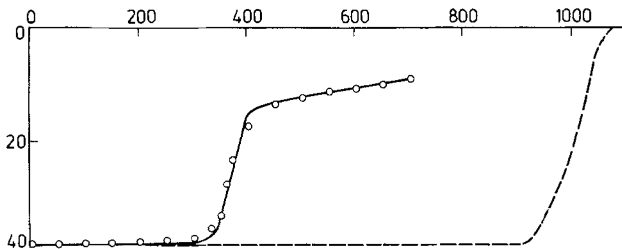

Fig. 12. Current voltage curves for reduction of $Ru(bpy)_3^{3+}$ on a clean (- - - -) and a coated (○) Pt electrode. The solid line is the calculated curve for the two parallel processes discussed in the text. Label x-axis, E/mV(SCE); y-axis, i/μA.

reached until 0.30V. Inspection of the current voltage curve shows that there are two parallel processes. For potentials greater than 0.40V we find a small current which increases gradually as the potential decreases. Figure 13 shows a Tafel plot of this current according to Eq. [4]. A reasonable straight line is obtained with a low value of $\alpha = 0.05$. At 0.4V a second process takes over and the current rises rapidly to its transport limited value. To allow for the two parallel processes we use a modified form of [4]

$$\ln y = \ln\left(\frac{i_0 - i}{i - i_1}\cdot\frac{i_0 - i_1}{i_0}\right) = \ln\frac{k_{D,O}'}{k_2'} + \alpha\frac{(E - E_{Ru}')\mathbf{F}}{RT} \quad [8]$$

where i_1 is the current due to the process plotted in Fig. 13 at $E \simeq 0.4$V. When $i_1 = 0$, [8] reduced to [4]. The data for the steep part of the wave are plotted in Fig. 14. A reasonable straight line is found with α close to 2. This high value of α cannot be caused by driving the electron transfer for the reduction of Ru(III). For that reaction we would expect [as was found for Fe(III)] that $\alpha \simeq$ ½, and in any case α must be less than unity. Returning to the data in Fig. 5 where $n = 2$ we propose that the second process is the reaction of Ru(III) with L formed on the outside of the layer

$$\underset{\mathbf{f}}{3H^+ + Th} + 2e \rightleftharpoons \underset{1-\mathbf{f}}{L}$$

$$\underset{1-\mathbf{f}}{L} + Ru(bpy)_3^{3+} \rightarrow S^{\cdot} + Ru(bpy)_3^{2+} + 2H^+$$

The very small fraction of L($\sim 2 \times 10^{-3}$) present when the second process takes over can be estimated from the Nernst Eq. [7] and the value of E_c' for 0.5M H_2SO_4 where $E_c'/V = 0.270$. Combining [7] and [8] we obtain

$$k_2' \exp\left[\frac{-2(E - E_{Ru}')\mathbf{F}}{RT}\right] = k'(1 - \mathbf{f}) \simeq k' \exp\left[\frac{-2(E - E_c')\mathbf{F}}{RT}\right]$$

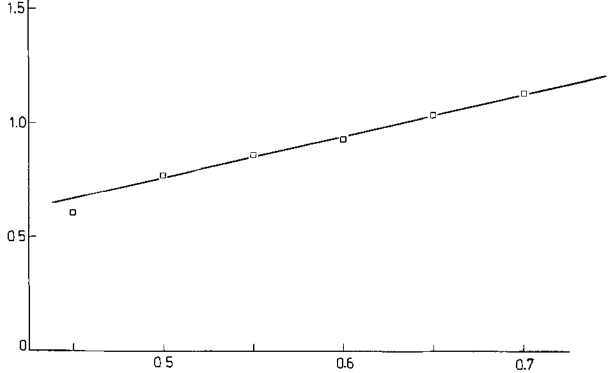

Fig. 13. Tafel plot [4] for points in Fig. 12 for E/mV > 400. Label x-axis, E/V(SCE); y-axis, y.

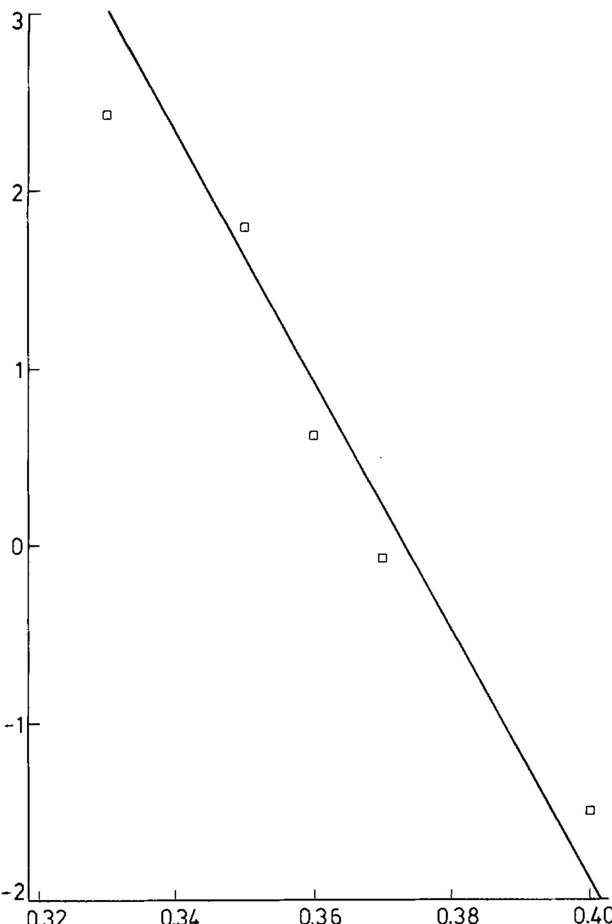

Fig. 14. Plot of Eq. [8] for steep part of current voltage curve for reduction of $Ru(bpy)_3^{3+}$ shown in Fig. 12. Label x-axis, E/V(SCE); y-axis, y.

From the data for k_2' in Fig. 13 we find

$$k'/\text{cm sec}^{-1} = 9 \quad [9]$$

It is interesting that this fast rate constant can be measured in the steady state by the dilution of the active species on the surface of the electrode; Fig. 5 shows that the oxidation state of the thionine layer obeys the Nernst equation.

We have also measured the homogeneous rate constant, k_2, for the reaction between $Ru(bpy)_3^{3+}$ and leucothionine in 0.5M H_2SO_4 using stopped flow. We find

$$k_2/M^{-1}\,\text{sec}^{-1} = 1 \times 10^8$$

This rate constant and the heterogeneous rate constant in [9] are each some two to three orders of magnitude below the respective encounter rates (22) for neutral species. This may be because of the coulombic interaction between $Ru(bpy)_3^{3+}$ and the doubly charged leucothionine, or there may be a small free energy barrier of much the same size in both processes.

Finally we return to Fig. 12 and calculate the current voltage curve using the parameters derived from the analysis in Fig. 13 and 14. A good fit is found. The fact that in this treatment we use $\alpha = 2$ confirms the conclusion from the conductance measurements the *IR* losses in the coat are negligible.

While our model for the second process fits the data very well, we do not as yet have a detailed model for the slow process occurring at potentials greater than 0.4V. The very low value of α means that the process is not a straightforward electron transfer. It may be that this process is similar to the $k_?'$ step in the reduction of Fe(III). The potential range over which we can observe the $k_?'$ process for Fe(III) is too restricted to be certain if $k_?'$ depends slighly on potential or not.

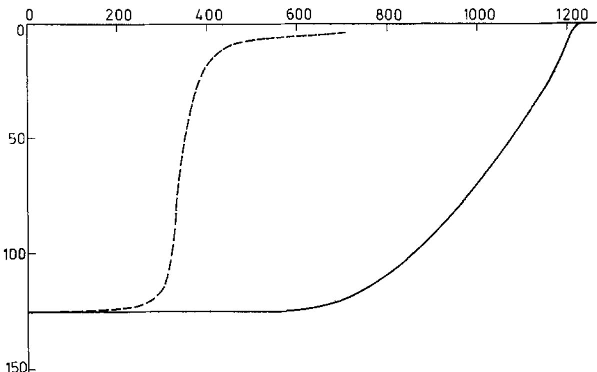

Fig. 15. Current voltage curves for reduction of Ce(IV) on a clean (———) and a coated (- - - -) Pt electrode. Label x-axis, E/mV(SCE); y-axis, i/μA.

Ce(IV).—The reduction of Ce(IV) resembles that of $Ru(bpy)_3^{3+}$. A typical current voltage curve is shown in Fig. 15. Again two processes are evident. Following the same analysis as for $Ru(bpy)_3^{3+}$ we find that the steep part gives a somewhat curved Tafel plot with α varying between 1.4 and 2.0. The fact that these values are greater than unity suggests that we must again be seeing a reaction between L in the coat and Ce(IV).

Effects of coating voltages and coating times.—Because of our interest in photogalvanic cells we have investigated the thionine and Fe(III) systems in more detail. For these systems we find that there is some reduction in the kinetic parameters the higher the coating voltage and the longer the coating time. This effect can be seen in k_o' in Table I and k_o' and $k_?'$ in Table IV. In Fig. 16 and 17 we show that there is a correlation between the different sets of rate constants; there is a particularly good correlation with a gradient of unity between k_o' and $k_?'$ for the Fe(III) system. Since these rate constants describe different processes we assume that the correlations arise through a general effect of the higher voltage or coating time on the coat itself. This affects all three processes, the reduction of thionine, the electrochemical step, and the $k_?'$ step in the reduction of Fe(III), to much the same extent. The higher coating voltages and coating times may cause this, for instance, by blocking off active sites on the surface.

Inorganic electron transfers.—While as discussed above the coat seems to have no drastic effect on the reduction of thionines or of quinone, single electron transfers to inorganic ions which normally proceed by outer sphere mechanisms are in all cases blocked by the coat. This is probably because the thickness of the

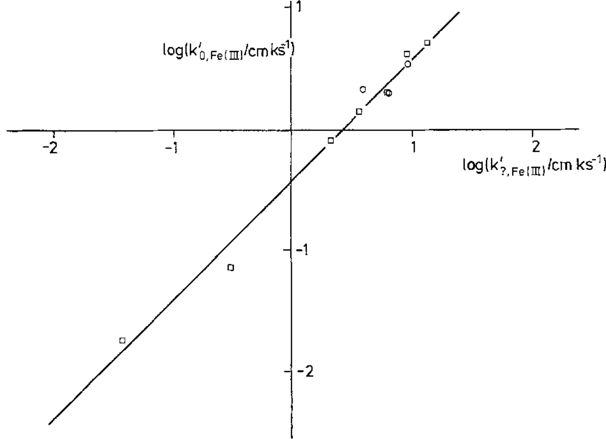

Fig. 16. Correlation between k_o' and $k_?'$ from Table IV for reduction of Fe (III) at coated electrodes: Pt, ○; SnO_2 □.

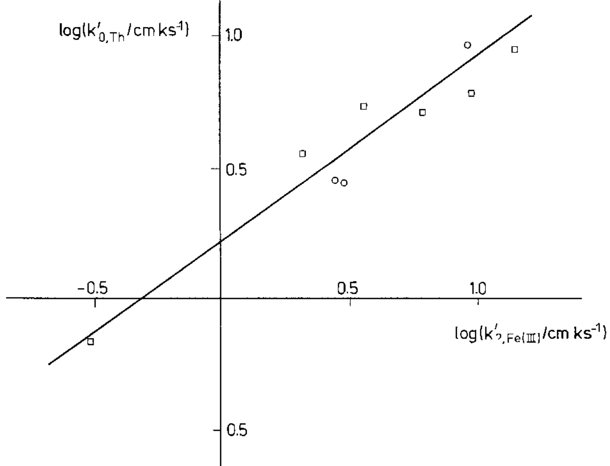

Fig. 17. Correlation between k_o' for thionine from Table I and $k_?'$ for Fe(III) from Table IV at coated electrodes: Pt, ○; SnO_2 □.

coat prevents the direct tunnelling of electrons from the metal or SnO_2 to the solvated inorganic ion. For strong oxidizing agents like Ru(III) and Ce(IV) it appears that the main path for reaction is the oxidation of leucothionine on the outside of the coat. For Fe(III), because there is not such a strong thermodynamic driving force, the reaction between Fe(III) and L is 7 orders of magnitude slower than diffusion control. Hence it appears that we have a two-step mechanism of which one step is an electron transfer and we suggest that the other is the formation of a "complex" between Fe(III) and leucothionine at the surface. Such complexes have been found in homogeneous reactions between Fe(III) and L (23). It is interesting that the half-wave potential for the reduction of Fe(III) is close to that of E' for thionine suggesting that the conversion of thionine to leucothionine in the coat may well be necessary for the reaction.

Implications for photogalvanic cells.—Finally we return to the question of the selectivity of these electrodes for use in photogalvanic cells. Inspection of Fig. 6 shows that the thionine-coated electrode does have the required selectivity. The coating leaves the electrode kinetics of the thionine couple sufficiently rapid to handle the photogenerated thionine (3) but it blocks the reduction of Fe(III). Thus an illuminated electrode working at a potential where it is oxidizing leucothionine will only have a small current caused by the simultaneous reduction of Fe(III). Hence we conclude that the thionine coated electrode is an ideal illuminated electrode for the iron-thionine photogalvanic cell. The fact that it can be made so easily and that it is relatively stable are added advantages.

Acknowledgments

We thank Mr. A. F. Orchard and Dr. R. G. Egdell for making the XPES measurements reported in this paper. We thank Dr. R. Whiteside for making the disulfonated thionine. We thank the SRC for equipment grants and for studentships for ARH and AWF. This is a contribution from the Oxford Imperial Energy Group.

Manuscript received Aug. 13, 1979. This was Paper 331 presented at the Boston, Massachusetts, Meeting of the Society, May 6-11, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Technical Notes

The Effect of Anion Activity on Electrochemical Equilibria: Three-Dimensional Potential-pH Diagram for $Pb/H_2SO_4/H_2O$ System

Kathryn R. Bullock*

Globe-Union Incorporated, Corporate Applied Research Group, Milwaukee, Wisconsin 53201

Potential-pH diagrams have been widely applied to electrochemical problems in corrosion, electrodeposition, and batteries. They summarize a large volume of data in a single graph and thereby provide a quick visual means of identifying the influence of potential and pH on the principal products of the reaction (1, 2).

One disadvantage of such a representation is that it is necessary to assume either that the metal ion does not complex with anions in the solution or that the activity of the anion remains fixed as the pH varies. Frequently, neither assumption is valid. A well-known example is the lead-acid battery in which the positive lead grid corrodes to form $PbSO_4$, basic lead-sulfates, and lead oxides (3). The relative predominance of these species is dependent on both the hydrogen ion activity and the sulfate ion activity, and these values vary as the battery charges and discharges. Furthermore, the $PbSO_4$ film produced when the grid corrodes inhibits diffusion of hydrogen and sulfate ions to the corroding lead interface, creating a concentration gradient across the corrosion film (4).

Potential-pH diagrams have been published assuming the log of the total sulfate ion activity to be 0 (5, 6), −4 (7), or −7 (6). Such assumptions are unnecessary if modern computer graphics methods are used to plot potential-pH diagrams in which the anion activity is represented as a third dimension. DISSPLA software (Integrated Software Systems Corporation), a Honeywell 6640 computer, and a Tektronix 4014 terminal were used to plot the three-dimensional diagram shown in Fig. 1 for the $Pb/H_2SO_4/H_2O$ system. The pH is plotted on the x-axis, the negative log of the sulfate ion activity, pS, is plotted on the y-axis, and the standard hydrogen potential, E_h, is plotted on the z-axis. The stability region of each species is separately depicted as a solid figure in the three-dimensional box. By fitting these solid figures together much like the pieces in a three-dimensional puzzle, the complete diagram (Fig. 1g) is formed.

The electrochemical equilibria among all the compounds shown in Table I were considered. The diagram was then simplified by determining which compound forms at the lowest potential under each set of conditions and at what potential this compound oxidizes further. Table II shows the equations used to generate the lines in the simplified diagram. Below $p\text{H} = 1.9$, the equilibria involving HSO_4^- were used and above this pH the equilibria involving $SO_4^=$ were used.

In all potential-pH diagrams, a region of immunity exists at low potentials where the metal does not corrode. The immunity region for Pb, defined by Eq. [1]-[5], is shown in Fig. 1h.

Above this region, the lead (II) species, $Pb(OH)_2$, $3PbO \cdot PbSO_4 \cdot H_2O$, $PbO \cdot PbSO_4$, and $PbSO_4$, can form (Fig. 1c, 1d, 1e, 1f, respectively). The tetrabasic lead sulfate, $4PbO \cdot PbSO_4$, is not stable with respect to the lead oxides at room temperature. Experimental uncertainties in the free energies of formation of the lead (II) oxides have produced conflicting opinions as to which is actually the most stable species [see for example Ref. (2), (5), and (8)]. $Pb(OH)_2$, which is most stable according to the equations in Table II, was chosen to represent all three lead (II) oxides shown in Table I.

Two lead (II) species, $Pb(OH)_2$ and $3PbO \cdot PbSO_4 \cdot H_2O$ will oxidize under basic conditions to Pb_3O_4 at a

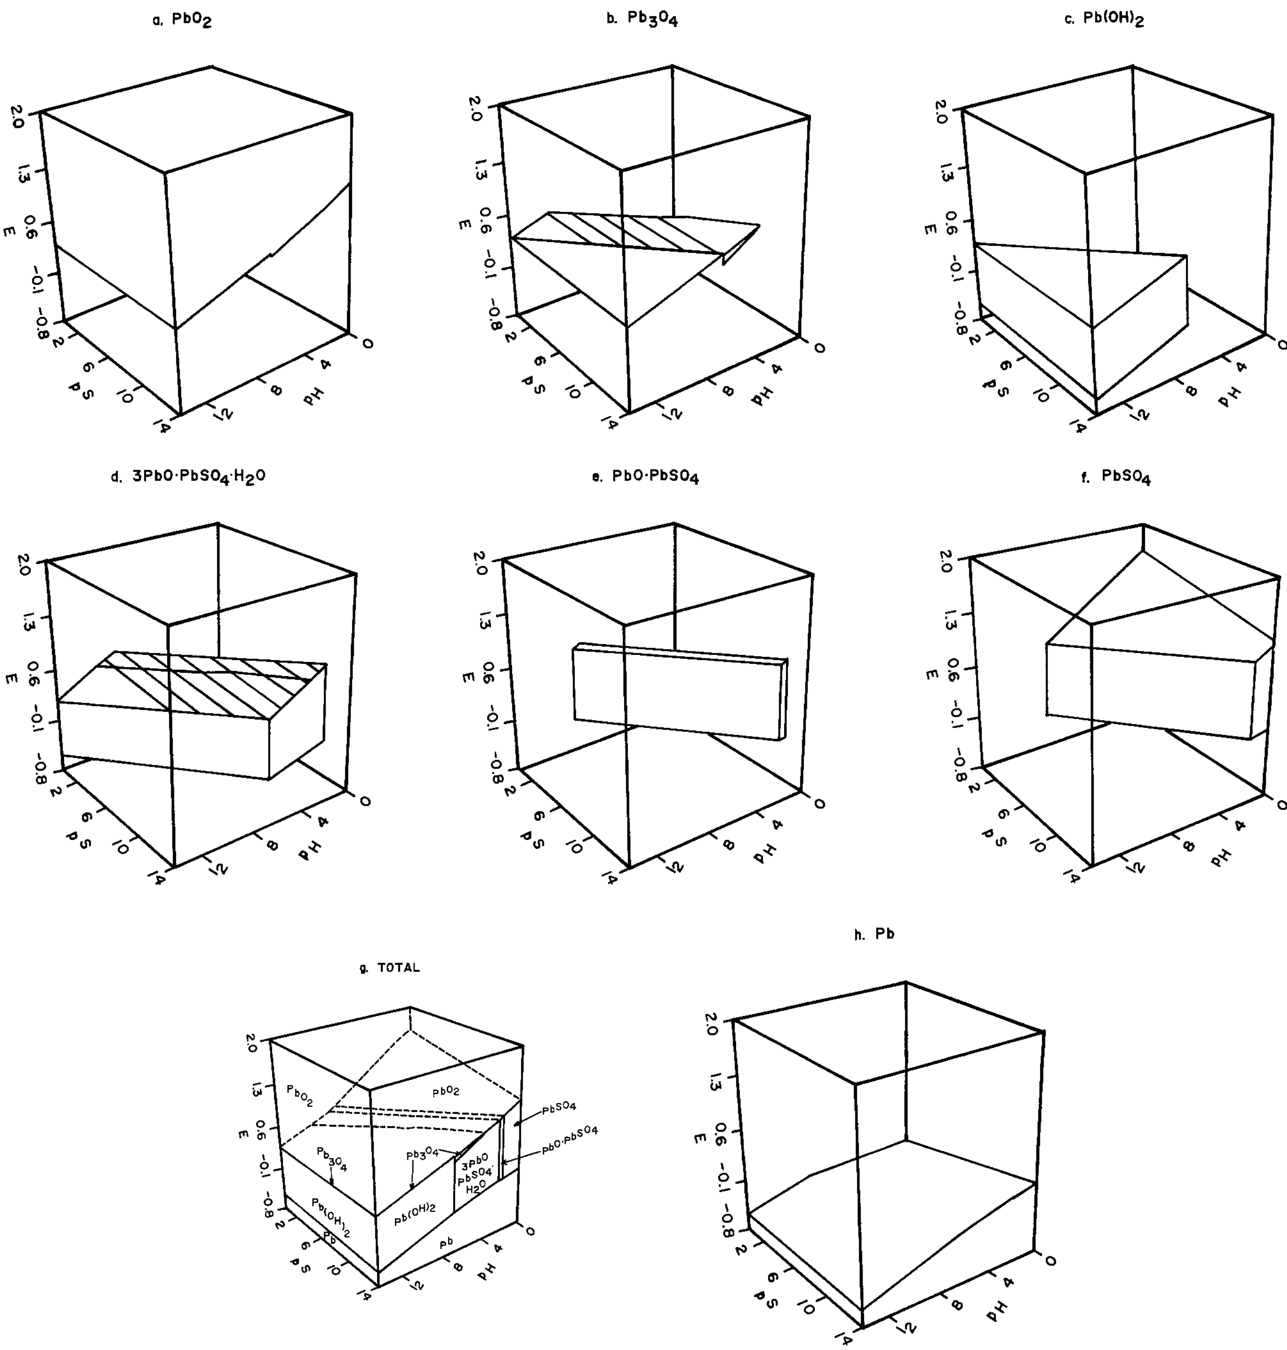

Fig. 1. Three-Dimensional diagram of $Pb/H_2SO_4/H_2O$ system with observer viewpoint at $pH = +19$, $pS = +25$, $E = +15$

slightly lower potential than they will oxidize to PbO_2. This leads to the thin stability region for Pb_3O_4 shown in Fig. 1b, which is defined by Eq. [6], [7], [11], and [12]. The uncertainties in Eq. [6], [7], and [11] are larger than in the other equations in Table II and give rise to slight mismatches of the lines. This occurs because the experimental errors in the determination of the free energies of formation are multiplied by 3 for $3PbO \cdot PbSO_4 \cdot H_2O$ and by 4 for Pb_3O_4 in deriving Eq. [6], by 3 for $Pb(OH)_2$ in deriving Eq. [7], and by 4 for PbO_2 in deriving Eq. [11]. The most obvious mismatch in the Pb_3O_4 diagram is between Eq. [6] and [7], evidenced by the sudden increase in the thickness of the figure at pS of 14 and pH of about 7. At higher pH values the figure is so thin that the bottom line (from Eq. [7]) and the top line (from Eq. [12]) are nearly indistinguishable.

Pb_2O_3 has a very small stability region within the Pb_3O_4 region. This is not shown in the figure because the equilibrium properties of Pb_2O_3 are not well known (5) and the uncertainties in the data are larger than the calculated stability region.

The PbO_2 stability region occurs at the top of the box (Fig. 1a) where the potentials are highest. No attempt has been made to differentiate between α- and β-PbO_2, since at 25°C the free energies of these two polymorphs differ by only 4 kcal/mole (9). α-PbO_2 will form under basic conditions and β-PbO_2 under acidic conditions (6).

The competition among lead (II) species is strongly influenced by both the hydrogen and the sulfate ion activities. At low values of pS and pH, $PbSO_4$ predominates. As pS and pH increase, first $PbO \cdot PbSO_4$, then $3PbO \cdot PbSO_4 \cdot H_2O$, and finally $Pb(OH)_2$ and PbO will form. In a lead-acid battery, the corrosion film consists of successive layers of these compounds as the pH and pS increase from the film/solution interface to the grid/film interface (6). This same conclusion can be reached by considering the effect of sulfate and hydrogen ion activities on the solubilities of the lead (II) compounds and assuming that the least soluble compound is the most stable in the corrosion film (10).

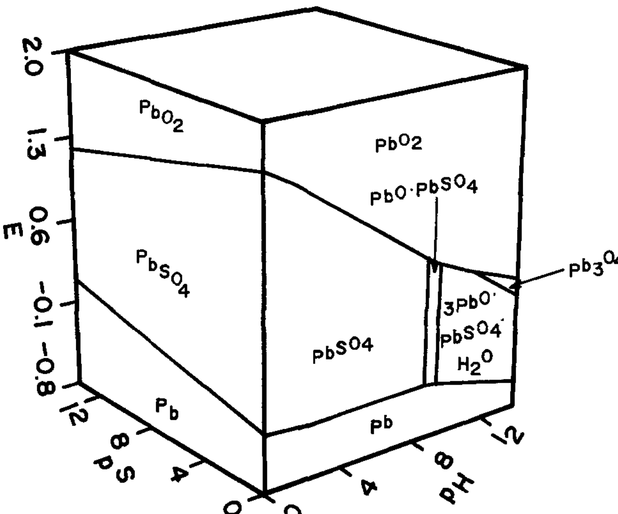

Fig. 2. Three-dimensional diagram of $Pb/H_2SO_4/H_2O$ system with observer viewpoint at $pH = -19$, $pS = -25$, $E = +15$.

Figure 1g shows the stability regions from a viewpoint which emphasizes the conditions at the grid/film interface (high pH and pS). The left front wall, which is a potential-pS diagram at a pH of 14, shows that oxidation of lead will give $Pb(OH)_2$ and PbO at the grid/film interface. Further oxidation will give Pb_3O_4 and then α-PbO_2. These processes are independent of sulfate ion activity.

The right front wall is a conventional potential-pH diagram at a pS of 14. It is similar to previously published diagrams (5, 6) with pS values of 0 and 7. The principal effect of decreasing sulfate ion activity (increasing pS) is to shift the regions of predominance to lower pH values, thus favoring formation of the basic lead sulfates and lead oxides. For example, the pH at which $Pb(OH)_2$ can form changes from 14 when $pS = 0$ to 6.9 when $pS = 14$.

One advantage of computer graphics is that the viewpoint from which a three-dimensional diagram is observed can easily be changed. Thus, Fig. 2 shows the complete diagram turned around so that the conditions at the film/solution interface are emphasized. In this figure the potential-pH diagram for pS of 0 can be seen on the right front wall and compared to previously published results (5, 6). The potential-pS diagram on the left front wall shows that at the corrosion film/solution interface at pH of 0, only Pb, $PbSO_4$, and PbO_2 can form and the product will depend on the potential. This is in agreement with the double sulfate mechanism for charge and discharge in a lead-acid battery (3, 7). The battery potential will decrease as pS increases.

No additional experimental data are required to derive a three-dimensional diagram of this type from a conventional potential-pH diagram. The computer programs used to plot these diagrams are short and easily understood. Thus the effect of the anion concentration on electrochemical equilibria need not be ignored.

Pore Volumes and Densities of Lead Dioxide of Lead Acid Positive Plates

C. W. Fleischmann*

Eltra Corporation, C&D Batteries Division, Plymouth Meeting, Pennsylvania 19462

Previous reports (1, 2) discussed the porosity and density of unformed active material of positive plates for use in lead-acid batteries. The type of positive plate which had been studied used flat, cast, lead-alloy grids, into which the active material precursor was pressed as a paste. The pastes were made from acidified lead oxides (1, 3-5), or from tetrabasic lead sulfate (2, 6-7). After a curing step, the precursor was electrochemically oxidized to lead dioxide, the positive active material, according to Eq. [1]

$$Pb(II) + 2H_2O = PbO_2 + 4H^+ + 2e \qquad [1]$$

* Electrochemical Society Active Member.

Key words: battery plates, electrode porosity, electrode density, lead-acid battery.

The porosity of the positive active material ultimately affects the battery performance (3, 5, 6, 8), and, therefore, is an important parameter of battery production. In the previous studies (1, 2), the pore volumes and dry paste densities were measured for unformed, cured pastes by a simple method. In the present study, the same experimental method was used to obtain values of the porosity and apparent densities of formed plates and of cycled plates.

Experimental

Acidified lead oxide plates were prepared variously from three commercial oxides and cured by different methods. The characteristics of the precursor oxides

(1, 9) and the compositions of the pastes after various cures (9) were given in earlier reports for duplicate plates of this same series. The apparent densities of the dry, unformed pastes varied from 3.4 to 4.8 g/cm^3, and the specific void volumes ranged from 0.08 to 0.15 cm^3/g. The symbol "D" will be used for the apparent density of the formed active material and the symbol "v" for the specific void volume. Percentage porosity is given by 100 Dv. The measured density of the active material (PbO_2) in the plate is represented by "d."

The plates were electrochemically formed to lead dioxide overnight at a sufficient charging rate to provide 80% more coulombs than required by Eq. [1]. After formation, the plates were cycled. Some plates were removed after formation and some after different numbers of cycles up to and including ten. Individual positive plates were cycled against two negatives in excess acid of 1.210 specific gravity. No separators were employed. Each positive was discharged to a polarization of 250 mV from the open-circuit value, measured using a positive lead-acid reference electrode (10, 11). Since the plates employed were of four different thicknesses, 0.18, 0.41, 0.68, and 0.79 cm, and since a range of paste densities were used, different currents were required to provide for discharge in approximately five hours. The plates were recharged at a constant current for 16-18 hr at a rate sufficient to provide a nominal 10% overcharge. The data are not identified in this report according to variations in plate thickness, cure, oxide type, or number of cycles, because correlations to these parameters could not be identified. On the other hand, the data are discussed in terms of apparent density of the active material and the void volumes as these parameters were found to be relevant.

Pore volumes were determined for all plates by the amount of water the plate absorbed under vacuum. The water absorbed was determined gravimetrically. The apparent density of the soaked plates was then determined by weighing in air and then submerged in water and applying Archimedes' Principle. The process was repeated after removing a determined mass of active material from the plate. From the measured values for the mass and volume of the material removed, it was possible to determine the apparent density of that active material. [The procedure was similar to that previously used to determine the pore volumes and densities of unformed positive material (1, 2).] Measurements were made on 63 plates including 11 of 0.18 cm thickness, 24 of 0.41 cm thickness, 9 of 0.68 cm thickness, and 19 of 0.79 cm thickness.

The active materials of four of the thinnest (automotive type) plates and of three of each of the plates of the other thicknesses were subsequently evaluated for density of the solids by the method of gas (helium) pycnometry using a Quantachrome Model PY-5. Eight of these samples were subsequently purified to remove sulfates and then reexamined by gas pycnometry. Sulfates were removed by boiling for 20 min in a solution 4.4M in ammonium acetate and 2.5M in acetic acid. The active material was analyzed for PbO_2 using an iodine titration. The pycnometry determinations and the PbO_2 analyses were performed as services by the Materials Testing Laboratory of C&D Batteries of Eltra Corporation.

Identification of the crystal form of PbO_2 by x-ray analysis was a service from the Materials Laboratory of the Prestolite Electrical Division of Eltra Corporation.

Evaluation of the data of Fig. 1 for a linear fit was developed by a curve-fitting program in the Standard Pac of the Hewlett Packard HP-97 desk calculator.

Results and Discussion

The apparent density, D, of the active material of each plate is plotted in Fig. 1 against the specific void volume, v. The curve drawn through the data points

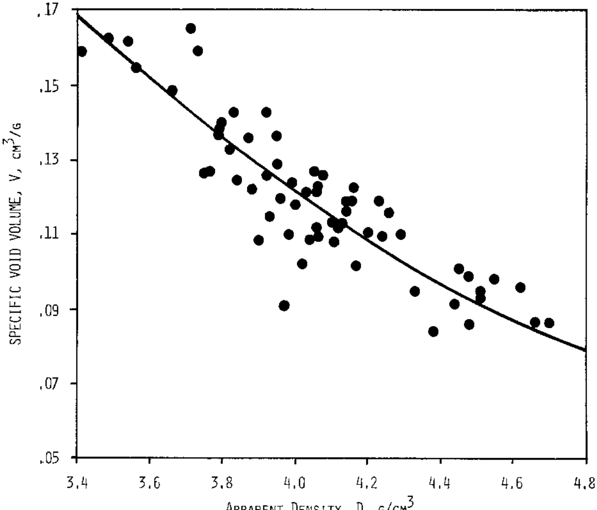

Fig. 1. The specific pore volumes of various formed or formed and cycled plates plotted against the apparent densities of the active material of the plates.

corresponds to a visual fit of these data to the curve obeying a constant value of 7.8 g/cm^3 for the density, d, of the active material (PbO_2) of the positive plate. For a constant value of d, the values of D and v are fixed according to Eq. [2], which simply states that the total plate volume, D^{-1}, is the sum of the volume of the active material, d^{-1}, and the void volume, v

$$D^{-1} = d^{-1} + v \quad [2]$$

The standard deviation of v for a given D was estimated to be ± 0.01 cm^3/g which corresponds to a deviation of ± 0.6 g/cm^3 for d.

Analyses of these and other plates in the same series always showed that the PbO_2 was of the β-PbO_2 (rutile) structure and that the active material contained at most 10%, usually about 5%, of lead compounds in the lower oxidation state.

The literature gives a value of 9.63 g/cm^3 for the density of β-PbO_2 (12). The most probable, and least dense, impurity found in cycled positive active material is the unconverted discharge product, $PbSO_4$, with a density of 6.323 g/cm^3 (12). The expected density range for the PbO_2 in the plate, considering up to 10% $PbSO_4$ as an impurity, would be 9.30-9.63 g/cm^3.

The evaluation of the solids' density of the 13 plates examined by gas pycnometry gave an independent and direct value of the active material density of 8.5 $\pm$ 0.4 g/cm^3 (standard deviation). This value is in fair agreement with the value 7.8 $\pm$ 0.6 g/cm^3 that conforms to the data of Fig. 1. Furthermore, when eight of the thirteen samples were subsequently chemically leached to remove sulfates, the mean density for these samples was essentially unchanged (8.6 $\pm$ 0.4 g/cm^3). This result suggests that the estimate of sulfation by chemical analysis was, if anything, too high.

Since the low experimental values for the solids' density compared to the theoretical value could not be attributed to sulfate impurities, it is assumed that the PbO_2 in the electrochemically charged plates was of sufficiently poor crystalline perfection to provide the measured values.

Acknowledgments

This work was supported, in part, by Eltra Corporation's Prestolite Battery Division. Most of the experimental work was conducted by T. A. Bavaria, a co-op student from Drexel University, and by D. K. Bauman. K. Centrella is also acknowledged for the services of the C&D Materials Testing Laboratory.

Manuscript received March 23, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Eltra Corporation.

LIST OF SYMBOLS

- D apparent density of formed, or formed and cycled positive active material, in g/cm^3
- d measured density for the solids' portion of the positive active material, essentially PbO_2, in g/cm^3
- v specific void volume of the positive active material, in cm^3/g

A Technique for the Study of Flow Patterns in Electrolysis

M. S. Quraishi and T. Z. Fahidy*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada

Flow patterns in liquid media have been widely studied by indirect methods, *e.g.*, by suspended particles, interferometry, and Schlieren photographs; these methods have certain advantages but their major drawback, two-dimensional and/or abstract nature, renders the visualization of three-dimensional flow patterns rather difficult. For electrolysis, where three-dimensional flow patterns are usual, the electrolytic visualization technique, presented in this communication, is better suited for the study of flow-profile development and for the understanding of the dynamics of electrolytic flow phenomena. The proposed technique is illustrated by the specific case of natural convection in magnetically enhanced electrolysis where it has been found (1) that flow patterns differ appreciably from those observed in the absence of a magnetic field. Notably, some velocity components of electrolyte flow have a major effect on the dynamics of an electrolytic system (2) while in conventional electrolysis the effect of such components may be negligible. Proper understanding of flow behavior both in the bulk and in the vicinity of the electrodes, required for the study of the dynamics of the governing transport phenomena, makes the utilization of a nonabstract three-dimensional flow visualization technique imperative.

The essential advantage of the presented technique is that clear visual contrast due to color change is obtained via the passage of the same electric current used for electrolysis; moreover, the change in color is accompanied by a change in darkness and opaqueness. The bulk fluid is clear-light-yellow and the marked fluid flowing away from the cathode in the cell is opaque-dark-blue; thus, the boundary between the two fluid phases is continuously well defined. The color contrast is caused by strongly different local hydronium ion concentrations (the pH range for the Thymol-blue indicator is 1.2-2.8; pK_{in} = 1.6). The approach is a modification of the method of Baker (3) which has more than fifty different applications in heat transfer and fluid mechanics. The authors are not aware of any major previous modification of the electrolyte solution used originally by Baker except for the alteration proposed by Gerrard (4) via the addition of a minute amount of NaCl to increase the intensity of the electrolytically produced dye. The color change due to locally different hydronium-ion concentrations has apparently

not been employed for the study of fluid motion generated by electrolysis until the current investigation, although electrolytically induced color changes in voltammetric studies (5) have been observed.

Amongst various *a priori* possibilities considered, aqueous solutions containing Thymol blue, NaCl, and HCl were found best suited for this study, where high electric conductivity and low *p*H must simultaneously be maintained. Adding a small amount of concentrated Thymol-blue solution to a large volume of NaCl-HCl solution avoids difficulties during the preparation of electrolyte, such as precipitation due to low *p*H and common ion effects.

Figure 1 shows a schematic diagram of the experimental setup. The electrolytic cell is a five-sided rectangular box with an open top in which two vertical copper electrodes are fitted in parallel position against opposite walls. The cell assembly is placed inside a frame on whose top a mirror inclined at 45° toward the electrolyte surface is mounted. The entire assembly is placed between the pole faces of a regulated d-c electromagnet. Diffused photo-floodlight is provided from the back and photographic filters are used to match the exposure required for the top view through the mirror and for the direct front view of the electrolyte in the cell. Photographs were taken in a predetermined time sequence throughout each experiment, where the voltage drop across the cell and the magnetic field strength imposed transversely to the electric field are set to desired values. Figures 2-4, chosen out of about 2500 photographs, illustrate typical flow patterns in natural convection at vertical plates. At zero time a voltage drop of 2.5V was set between the pure copper electrodes. The electrolyte solution was made up of 0.1 g dm^{-3} Thymol blue, 0.998 mole dm^{-3} NaCl, and 0.0025 mole dm^{-3} HCl. The photographs show instantaneous flow patterns existing at 5, 30, and 120 sec, after start of electrolysis; each time instant is illustrated by one figure showing the effect of the imposed magnetic field at the flux density of 0.004, 0.100, 0.285, and 0.540 Tesla. The upper part of each photograph gives the view of the electrolyte surface (top view) as seen through the mirror, and the lower part gives the front view of the electrolyte in the cell.

Since it is rather difficult to represent three-dimensional flow by two-dimensional images, the best recording via photographic means is by taking at the same time instantaneous pictures of the flow pattern at mutually perpendicular directions. In this manner three-dimensional structure may be visualized.

In discussing the complex nature of the flow pattern of the marked fluid leaving the cathode, reference is made to Fig. 5. The coordinate system is defined in the following manner: x-direction from cathode towards anode, z-direction from free surface toward bottom, and y-direction mutually perpendicular to both x and z.

Due to the physical nature of the cathode process under these operating conditions (current density at 5 sec about 120 $A \cdot m^{-2}$) the marked fluid rises at the cathode ($V_z < 0$) and reaches the free surface as seen in Fig. 2. At very low magnetic flux densities (residual field of 0.04T) the marked fluid travels on the free surface (xy plane) toward the cathode but with a V_y velocity component in the direction pointing away from the cell wall, thus creating two flows at the surface whose momentum exchange generates a flow in the z-direction (xz plane) as shown by the dark line in the upper view in Fig. 3a. The xz plane corresponding to this line may be denoted as the central plane. In this flow pattern V_z near the central plane is positive and near the walls negative. Motion in the y-direction extends from walls to the central plane near the free surface, and from central plane to walls in the vicinity of the cell bottom. V_x reaches a positive maximum at the free surface, then becomes progressively smaller as z increases; it finally becomes negative in the neighborhood of the bottom. As time progresses, this

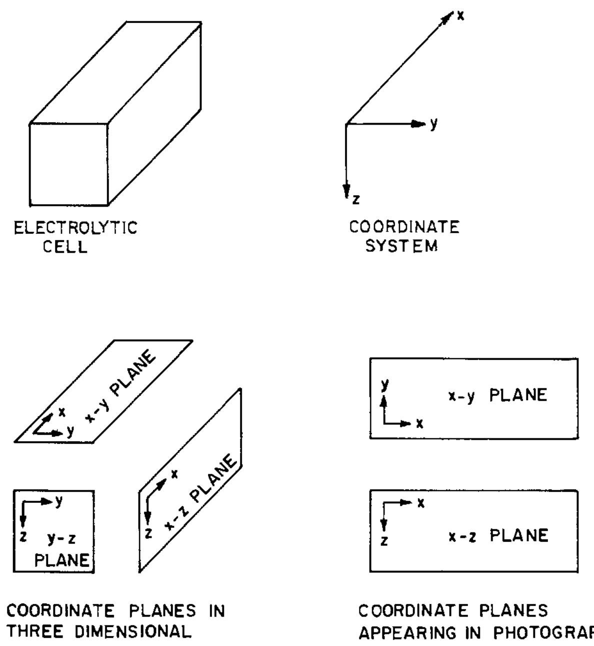

Fig. 5. Definition of the coordinate system and coordinate planes

development results in a typical pattern shown in Fig. 4a; the freshly marked fluid is confined to the cathode area. In the meantime, the "old" marked fluid becomes very faint and finally disappears due to diffusion of H ions from the bulk.

The imposition of a magnetic field will increase V_y in one direction and decrease it in the opposite direction, the net result being the displacement of the central plane towards one of the walls. Even at as weak a field as 0.1T, this distortion of V_y can be strong enough to suppress this velocity component in the opposite direction and the central plane essentially coincides with one wall. The stronger the magnetic field, the larger the magnitude of V_y as clearly seen in Fig. 2. The marked fluid no longer covers the entire free surface but it is confined to a triangle whose outer edge is defined by the marked fluid leaving the opposite edge of the cathode. As the magnetic field strength is increased this triangle is formed increasingly faster but its size becomes smaller. The flow developed in this case is similar to the flow observed in very weak magnetic fields, with one cell wall virtually "replaced" by the central plane. Magnetohydrodynamic forces, due to combined electric/magnetic fields, generate faster motion and result in the expansion of the marked fluid confined to the cathode areas, as shown in Fig. 4.

The potential usefulness of this flow visualization technique is by no means restricted to magnetically enhanced natural convection, although this particular example is a very good illustration of its value. Fresh marking of the fluid is done continuously by the electrolytic process at the cathode and the coexistence of marked and unmarked fluids, and their travelling boundary can easily be observed. No "abstract" visualization is required and the possibility of motion misjudgment is minimized. The technique is equally promising for the study of flow patterns generated by different shapes and orientations of two-dimensional and three-dimensional electrodes and, in general, for various investigations of transport phenomena where the surface under study can be made cathodic for continuous marking of the fluid leaving the surface.

The Effect of Zirconium on the Isothermal Oxidation of Nominal Ni-14Cr-24Al Alloys

A. S. Kahn,[1] C. E. Lowell, and C. A. Barrett

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

The isothermal oxidation of Ni-14Cr-24Al-xZr, typical $\gamma/\gamma' + \beta$ alloys, was performed in still air at 1100°, 1150°, and 1200°C for times up to 200 hr. The zirconium content of the alloys varied from 0-0.63 atom percent (a/o). The oxidized surfaces were studied by optical microscopy, x-ray diffraction, and scanning electron microscopy. The base alloy was an alumina former with the zirconium-containing alloys also developing some ZrO_2. The addition of zirconium above 0.066 a/o increased the rate of weight gain relative to the base alloy. Due to oxide penetration, the weight gain increased with Zr content, however, the scale thickness did not increase. The Zr did increase the adherence of the oxide, particularly at 1200°C. The $\Delta W/A$ *vs.* time data fit the parabolic model of oxidation. The specific diffusion mechanism operative could not be identified by analysis of the calculated activation energies. Measurements of the Al_2O_3 scale lattice constants yielded the same values for all alloys.

The extent of adhesion of oxide scales to a substrate is one of the most important indicators of high temperature cyclic oxidation resistance of an alloy. Poor adhesion may result in spalling of the oxide to bare metal on cooling to room temperature. Good adhesion does not necessarily eliminate spalling, but restricts it to within the oxide layer and, in general, results in substantially lower metal consumption rates in cyclic tests.

A small addition of rare earth elements or reactive elements such as Si (1-6) has often resulted in a significant improvement of the cyclic oxidation resistance of alloys primarily by increasing scale adhesion. The mechanism(s) by which these tramp elements can improve oxide adhesion is not clearly understood. Several mechanisms have been proposed. In the mechanical pegging model (2, 4, 6) it has been proposed that oxide pegs are developed at the oxide-alloy interface which prevent oxide spallation during cycling. On the other hand, in the vacancy sink model (7) it has been proposed that formation of voids at the oxide-alloy interface leads to poor oxide adhesion. The added tramp elements are purported to prevent void formation and, therefore, enhance oxide adhesion. It has also been suggested that the added element might form stronger chemical bonds across the alloy-oxide interface (8). The subject of oxide adhesion has been treated by Wright (9) and by Giggins and Pettit (10) who included references up to 1975.

Recently Golightly *et al.* (11) proposed that in the absence of rare earth additions, oxide growth occurs within the existing layer and the lateral stresses resulting from this growth cause oxide detachment at the oxidation temperature which results in extensive spalling during cooling. Oxide growth within the existing layer was also assumed to be responsible for the observed convoluted oxide configuration. Additions of yttrium may prevent oxide formation within the layer and thus cause the oxide growth to occur at the alloy-oxide interface. This would result in an adherent scale. Despite various models proposed to explain the enhanced oxide adhesion by tramp additions, it has not been possible as yet to rationalize all the observed oxidation characteristics of tramp-element containing alloys by any of these models.

Previous publications from NASA Lewis Research Center on the oxidation of Ni-Cr-Al alloys (12, 13) indicated that alloys melted in zirconia crucibles have significantly improved cyclic oxidation and hot corrosion resistance compared to comparable alloys with no significant zirconium. In view of these results it was decided to critically examine the role of zirconium in the high temperature oxidation resistance of Ni-Cr-Al alloys. As a first step, this paper describes the effect of small amounts of zirconium on the isothermal oxidation on a Ni-Cr-Al alloy. This composition was chosen as representative of a wide range of alumina-forming alloys with good cyclic oxidation resistances as was demonstrated in Ref. (12). In this paper the effects of zirconium on the isothermal oxidation of these alloys is described in terms of scale growth and adhesion. A detailed cyclic oxidation study is in preparation.

Materials

Chemical compositions and thermal histories of the alloys prepared for this investigation are presented in Table I. Compositions of the alloys were determined both by standard wet chemical methods and by atomic absorption spectroscopy. In Table I, compositions are expressed in both weight percent (w/o) and atom percent (a/o). The concentration of chromium varied from 12-19 a/o while that of aluminum varied from 22-26 a/o. The concentration of zirconium varied between 0 and 0.63 a/o. For the sake of simplicity in identification in this report and also to emphasize the

variation of oxidation properties with zirconium content, the alloys studied have been represented by a general composition, Ni-14Cr-24Al-xZr, while the actual compositions are shown in Table I. The alloys will be referred to by the Roman numerals from Table I with the zirconium atom percent in parentheses. The Zr-free alloys were machined directly from vacuum induction melted master heat ingots or from these master ingots induction remelted in alumina crucibles. The alloys III-(0.038), IV-(0.066), and VI-(0.63) were vacuum induction melted using individual elements in zirconia crucibles and poured into zirconia leaf molds. These three alloys picked up Zr from the zirconia crucible. Alloy VI-(0.63) was held molten in the crucible for a longer time than usual which accounts for the higher pickup. An additional alloy V-(0.33) was induction vacuum remelted from a master ingot in an alumina crucible with 0.33 a/o Zr added to the melt and poured into a zirconia leaf mold. The phase diagram of the Ni-Cr-Al system is presented in Fig. 1 (14). The alloys tested are plotted on this ternary at their specific Cr and Al levels. The Zr composition is also listed.

Metallographic analysis on the alloys showed that they have similar structures. A typical photomicrograph is presented in Fig. 2. The structure is characterized by γ (nickel solid solution), γ' (Ni_3Al type), and β (NiAl) phases with small particles of αCr (chromium solid solution) in the β phase. The presence of α, β, γ, and γ' and a possible segregation of zirconium in the matrix were investigated by SEM, EDS, and elemental x-ray scan. These procedures were performed on the alloy with the maximum Zr content in the series, *i.e.*, VI-(0.63). The SEM micrograph of the alloy VI-(0.63) presented in Fig. 3 shows the cubic γ' phase in the matrix of γ and that αCr is randomly distributed in the β phase. The EDS spectra shown in Fig. 3 give the peak intensity for the wave lengths of the elements. These peaks are qualitative indication of relative abundance only. The elemental x-ray micrograph for zirconium did not show any zirconium enriched area (Fig. 3), although the spectrum trace showed that zirconium was present. It is therefore concluded that the tramp zirconium in the alloys studied is uniformly distributed and the solubility of zirconium in this class of alloys is in excess of 0.63 a/o.

Procedure

The isothermal oxidation of the Ni-14Cr-24Al-xZr type alloys was performed in static air. Oxidation coupons were 22 × 10 × 2 mm with a hole drilled in one end for suspension in the ceramic tube furnace. Prior to testing, specimens were ultrasonically cleaned in alcohol. Isothermal oxidation experiments were carried out at several temperatures in the range 1000°-1200°C for periods of up to 200 hr. The specimens were suspended with a platinum hanger from a Mettler H-2

recording balance. At the start of the test the furnace was heated to the test temperature and oxidation was initiated by raising the furnace. The temperature of the furnace was controlled to within ±2°C. At various time intervals, the weights of the specimens were obtained as a digital millivolt (mV) printout. The weight data were also recorded continuously on a strip chart recorder. Data were simultaneously printed on two channels and the weights obtained were generally within ±0.1 mg of each other, but occasional variation of as much as 0.5 mg in the weight was observed between them. The maximum scatter in $\Delta W/A$ was about ±0.1 mg/cm^2. In addition to this, there was a loss of platinum from the hanger due to volatilization at temperature. It was necessary to correct each weight change value for this loss. Blank experiments were performed with Pt-13Rh suspension rod at 1100°, 1150°, and 1200°C for 200 hr. The weight loss of the hanger was found to be nearly linear. The total weight loss of the hanger for 200 hr at 1100° and 1150°C was below 5 mg, but at 1200°C the weight loss was close to 10 mg. The loss of the suspension rod will depend on the quantity of material, test temperature, the temperature gradient to which it is exposed, and the subsequent condensation of the vaporizing species on the cooler part of the suspension rod. Therefore, the weight of the hanger rod was recorded at the beginning and at the end of every experiment and with correction for the weight loss applied assuming a linear weight loss. From such corrected data, the parabolic scaling constants were calculated for 30.5 hr oxidation times. Weights at $t = 0$ hr were determined by back extrapolation.

At the completion of the test the furnace was rapidly lowered and the sample was surrounded by a Pyrex beaker to catch any spall as the sample cooled. This spall was subsequently analyzed by x-ray diffraction. To retain the scale formed at temperature, several samples were potted in a low melting point alloy (Cerrobend). These oxidized specimens were rapidly removed from the furnace and held in a cavity made from an aluminum block and potted by pouring molten metal around the hot sample. After cooling, the alloy mount was removed from the aluminum block and sectioned for examination.

Treatment of Data

Kinetic data obtained for the isothermal oxidation of the nominal Ni-14Cr-24Al-Zr alloys at 1100°, 1150°, and 1200°C were fitted to a parabolic model of oxidation. This model assumes the oxidation to be diffusion controlled. Mathematically, the expression is given by $\Delta W/A = k_p^{1/2}t^{1/2}$, where ΔW is the weight change at any time, t; A is the area of the specimen; and k_p is

the parabolic constant. The $\Delta W/A$ *vs.* time data were treated by a regression analysis which yielded $k_p^{1/2}$; standard error of estimate, σ; and the coefficient of determination, R^2. The regression equations and the computer programs for the calculation have been described by Barrett *et al.* (15). In most cases the fit was excellent with R^2 values over 0.90. At all temperatures the $k_p^{1/2}$ (and therefore k_p) values were evaluated using all the data up to 30.5 hr.

The $k_p^{1/2}$ estimates derived from the shorter time data were used to compute the expected $\Delta W/A$ values at both 30.5 and 200 hr. These values ($\Delta W/A_{calc.}$) are listed along with the actual observed values ($\Delta W/A_{obs.}$) where available for comparison.

Results and Discussion

Metallographic and x-ray analyses.—The surface and the spalled oxides were analyzed by x-ray diffraction (XRD). Oxidized surfaces were also characterized by metallography and SEM. The results of XRD are shown in Table II, from which it is seen that alumina was the primary oxide formed in the temperature range 1100°-1200°C. In addition to Al_2O_3, some ZrO_2 (cubic and monoclinic) and the spinel $NiAl_2O_4$ (a_o = 8.10Å) were also formed on the alloys containing Zr. Photomicrographs obtained from alloys IV-(0.066) and V-(0.33) tested at 1150°C, and which were cooled in air, are shown in Fig. 4. The structure shown in Fig. 4 is characterized by the presence of oxide penetration and is typical of the alloys containing Zr. Oxide penetration increased considerably with the Zr content of the alloy and with temperature. The zero zirconium alloy did not show any oxide penetration. Metallography to obtain the total oxide scale along with oxide penetration was difficult due to external scale spalling during cooling. In order to observe the total scale, certain samples containing 0, 0.066, and 0.63 a/o Zr were potted in a low melting point alloy (Cerrobend) which prevented the scale from spalling during cooling. A cross section of the scales in the Cerrobend mount is shown in Fig. 5 for alloys containing 0, 0.036, and 0.63 a/o Zr. An examination of Fig. 5 shows that the oxide scales of all the alloys appeared to have been retained by this procedure. It may also be seen that the alloys exhibit an oxide penetration which increases with Zr content, while the outer scale thickness was nearly independent of Zr content. This would indicate that the increase in oxidation kinetics (see below) is due primarily to increases in oxide penetration rather than scale growth.

SEM and elemental x-ray micrographs of the V-(0.33) alloy at 1200°C are presented in Fig. 6. An examination of Fig. 6 reveals that no Zr is concentrated near the surface. Al_2O_3 penetrates from the surface to a depth of about 50 μm. Zr concentration away from the surface appears to be associated with the alumina penetration. This microstructure is typical of all Zr-containing alloys.

Kinetic data.—The specific weight change ($\Delta W/A$) data are plotted in Fig. 7. The test temperatures represented are 1100°, 1150°, and 1200°C and times are to 200 hr. Duplicate runs were plotted in several cases

Immediately after oxidation, samples were dropped into low melting point alloy to retain the surface oxide.

to allow an evaluation of over-all variability. The derived parabolic kinetic constants are listed in Table III and the average k_p's are plotted in Fig. 8. At 1150° and 1200°C, k_p became slightly smaller as Zr increased to 0.038 a/o. Further increases in Zr content resulted in large increases in the calculated k_p. As noted above, this increase in weight gain is primarily associated with increasing oxide penetration rather than with an increased scale growth. Since such oxide penetration represents a major portion of the total change in weight, the parabolic scaling constants derived from alloys with substantial oxide penetration cannot be used to calculate scale thickness. However, they can be used to determine total metal consumption.

Fig. 6. Distribution of Al and Zr on Ni-14Cr-24Al cross section after 200 hr at 1200°C (0.33 a/o Zr); 1500×

In an attempt to evaluate the temperature dependence of the short time (30.5 hr) k_p values in light of the diffusion of Al and O in Al_2O_3, the data were plotted as k_p *vs.* $1/T$ in Fig. 9 and activation energies computed. For comparison, diffusion data of Paladino and Kingery (16, 17) and Oishi and Kingery (18) are also plotted on Fig. 9. In addition, data up to 48 hr for the oxidation of a pure NiCrAl alloy reported by Giggins and Pettit (19) are plotted. Except for alloy IV-(0.066) the activation energies derived from the present study are remarkably consistent (see Table IV). The activation energies range from −114 to −123 kcal/mole [except for alloy IV-(0.066)] and are consistent with the data of Giggins and Pettit (19). Unfortunately, little insight can be gained from these data in regard to which diffusing species is controlling oxidation as the activation energies calculated are similar to those for both Al and O in polycrystalline

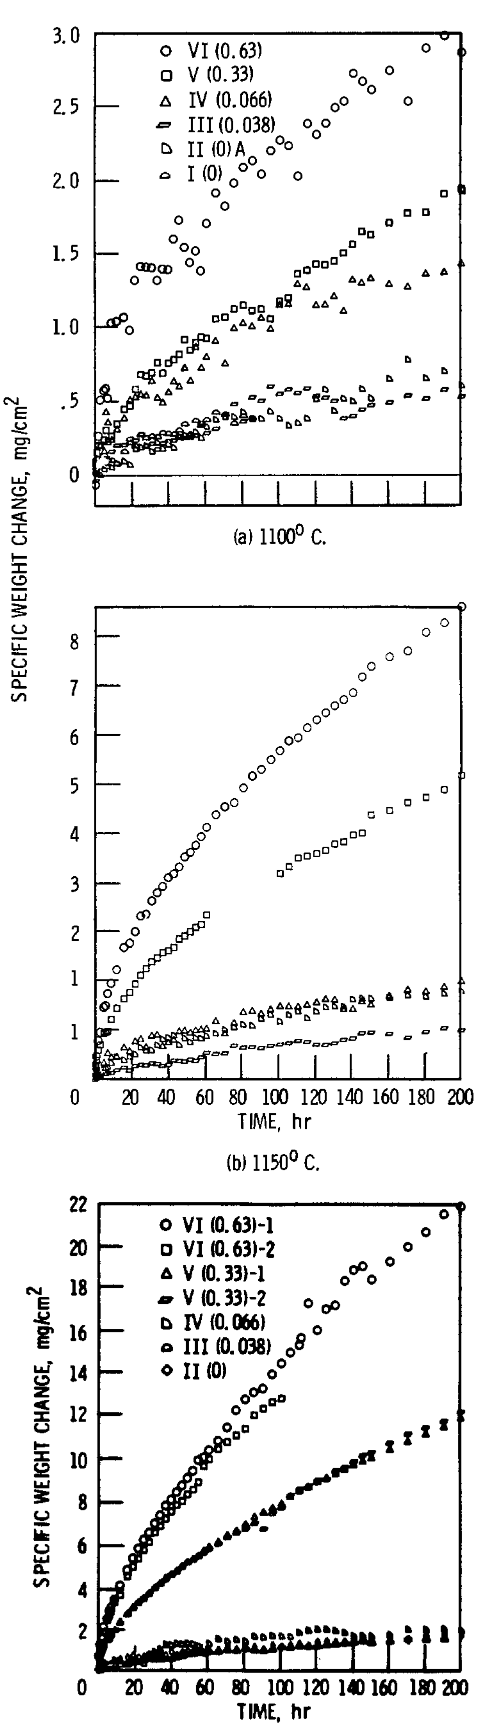

Fig. 7. Selected specific weight change vs. time plots for Ni-14Cr-24Al alloys with various Zr levels at (a) 1100°C, (b) 1150°C, and (c) 1200°C in still air.

Al_2O_3 at high temperatures (17, 18). The data for alloy IV-(0.066) are anomalous. The k_p is nearly independent of temperature which could indicate a change in oxidation or diffusion mechanism. However, at this Zr concentration, the oxides formed were essentially the same based on the analyses performed for all temperatures. In addition, microstructural examination of this alloy revealed substantially the same oxide penetration regardless of temperature (see Fig. 10). This effect deserves further attention.

oxide adhesion and spalling. While these tests were not aimed specifically at the latter phenomena, the changes in oxide adhesion with zirconium were dramatic. Figures 11(a) through (f) show SEM photographs of the surface of I-(9), IV-(0.066), and V-(0.33) after 200 hr in air at 1200°C. The I-(0) sample shows spalling to bare metal over major portions of the surface. The remaining oxide is convoluted and is only in partial contact with the metal. This Al_2O_3 scale morphology is quite similar to that found by Golightly (11) and perhaps is an indication of his lateral growth stress mechanism.

The SEM photographs of IV-(0.066) and V-(0.33) show that what spalling has taken place is all within the oxide, *i.e.*, no bare metal spalling. These two alloys appear to spall as small platelets of sheets of oxide resembling mica. This behavior is most strikingly observed on the surface of the V-(0.33). Of all

the alloy levels of Zr tested, the minimum amount of spall collected was for the alloys III-(0.038) and IV-(0.066) where not enough could be collected after any temperature test to run a diffraction pattern. These results are consistent with those found by Allam *et al.* (20) in their examination of the effects of hafnium additions on the oxidation of cobalt-chromium-aluminum. They demonstrated that hafnium increased oxide adhesion and prevented spalling to bare metal. They also found that hafnium additions led to Al_2O_3 oxide penetration and attributed the increased scale adhesion to such penetrations or "pegs."

The pegging explanation is consistent with the microstructural observations both in Ref. (20) and the current work. However, it does not account for either the elimination of oxide-metal interface voids or the evident reduction of lateral growth stresses in the oxide which are present in the pure alloys. It appears, therefore, that the hafnium effect on cobalt-chromium-aluminum alloys is the same as that of zirconium on nickel-chromium-aluminum, but the mechanism remains unclear.

It seems likely that Zr is present in the oxide and is the cause for the increased diffusion of oxygen through the scale which is evidenced by the increases in k_p and the formation of oxide penetration. However, no direct evidence for Zr solution in the Al_2O_3 scale was found. Lattice constant measurements of the Al_2O_3 formed during selected tests were made. These data are tabulated in Table V along with lattice constants from a pure Al_2O_3 powder. No significant differences were found. Therefore, any solutioning effects which occur must be quite small, *i.e.*, below the levels of x-ray detectability. More detailed investigations of the structure of adherent and nonadherent Al_2O_3 must be made to clarify the situation.

Conclusions

As a result of the isothermal oxidation of nominal Ni-14Cr-24Al-xZr alloys, containing from 0 to 0.63 a/o Zr, at 1100°, 1150°, and 1200°C, the following conclusions were reached:

1. Up to some critical, but low value near 0.06 a/o, small additions of zirconium lead to increased scale adhesion on cooling and to minimal oxide spalling. The spalling that does take place occurs within the scale while the absence of Zr leads to much poorer adherence and localized oxide spalling to bare metal on cooling.
2. Over the range studied, increased Zr does not lead to measurably increased Zr solution in the Al_2O_3 lattice, nor does it lead to any significant change in the rate of external scale growth. The controlling oxide is still αAl_2O_3.
3. The Zr does tend to increase the rate of oxygen uptake after an initial drop at very low Zr concentrations, thereby increasing the amount of Al_2O_3 oxide penetration. Scale growth is still nearly parabolic.

Diffusional Analysis for Growth of the Monosulfide Scale on Cobalt-Iron Alloys

D. J. Young,*[,1] T. Narita,*[,2] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

A ternary diffusion model is invoked to interpret growth of the (CoFe)S scale on Co-Fe alloys containing greater than 40 atomic percent (a/o) Fe in H_2S-H_2 atmospheres, $3.4 \times 10^{-7} \leq P_{S_2} \leq 1 \times 10^{-5}$ atm, at temperatures 533°-980°C. Concentration profiles in the solid phases were determined from electron probe microanalyses; the iron concentration across a scale continuously decreased from its highest value at the scale/alloy interface. Computations demonstrated that the relative self-diffusivity of cobalt to iron in (CoFe)S was dependent on concentration increasing asymptotically from a value of 1.3 in essentially pure FeS to a value of 2.4 at 60 a/o FeS. A numerical computing method capable of determining sulfidation rates of a binary alloy from diffusional and thermodynamic data was used to demonstrate that calculated metal composition profiles in the (CoFe)S scales and values of the parabolic sulfidation rate constants were in good agreement with the experimental determinations.

Kinetics and morphological development of sulfide scales formed on Co-Fe alloys (1, 2) and iron (3, 4) in H_2S-H_2 atmospheres of various sulfur activities at temperatures 533°-980°C were determined in earlier investigations. A reaction mechanism based on metal diffusion through the scales was advanced to account for the parabolic sulfidation kinetics. Ternary diffusion theory has been recently applied to interpret high temperature sulfidation kinetics and cation profiles in monosulfide scales formed on several iron-base binary alloys (5, 6). The purpose of this investigation is to interpret by diffusion theory measurements of metal concentration profiles in (CoFe)S scales formed on Co-Fe alloys and to obtain the most reliable computing method for predicting sulfidation rates of these alloys when scaling data are not available.

Experimental

Co-Fe alloys containing 38.6, 49.9, 60.0, 80.1, and 90.0 weight percent Fe were sulfidized in H_2S-H_2 atmospheres, $3.4 \times 10^{-7} \leq P_{S_2} \leq 1 \times 10^{-5}$ atm, at 533°, 600°, and 700°C. Methods, materials, and the scaling kinetics were presented previously (1, 2). Linear regression fit of the parabolic rate constant values for growth of (CoFe)S scales on the alloys at 700°C to the relationship

$$\log k_p = \frac{1}{n} \log P_{S_2} + \text{constant} \quad [1]$$

yielded $n = 5.6 \pm 0.5$.

Key words: sulfidation, Co-Fe alloys, diffusion model, alloy.

Sulfidized specimens were cross sectioned and metallographically polished finishing with 0.25 μm diamond paste. The large columnar grained scales were compact and adherent to the metal substrate. Electron probe microanalysis (EPMA) was used to measure compositions as a function of position in these scales. Identical results were obtained using two different instruments with different take-off angles for the emergent x-rays when Co, Fe, and S were measured simultaneously to negate any instrumental drift. X-ray counts were converted to composition by comparison to standards of FeS_2, a Fe-FeS two-phase mixture, and a series of Co-Fe alloys. Results were corrected for atomic number and absorption effects; fluorescence corrections were negligible and they were ignored. An example of the columnar (CoFe)S scale and its compositional profile determined by EPMA is illustrated in Fig. 1.

Compositions at several positions in each scale normalized to $y = x/x_s$, where x_s is scale thickness, were evaluated as FeS mole fraction knowing atom fractions of Co, Fe, and S and by considering $(CoFe)_{1-\delta}S$ as a pseudo-binary solution of the pure metal sulfides. Compositions were often determined over two and three different regions of a scale cross section. Concentration profiles in the scales formed on the series of alloys at 700°C and $P_{S_2} = 2 \times 10^{-6}$ atm are shown in Fig. 2. Figure 3 shows these profiles in scales formed on Co-60 Fe at 700°C and sulfur pressures in range 1×10^{-5}-3.4×10^{-7} atm while Fig. 4 shows these scale profiles for $P_{S_2} = 2 \times 10^{-6}$ atm and temperatures of 700°, 600°, and 533°C. In all scales, iron contents of (CoFe)S were largest at the alloy/scale interface and continuously decreased to smaller values at the scale/gas interface. Values are given in

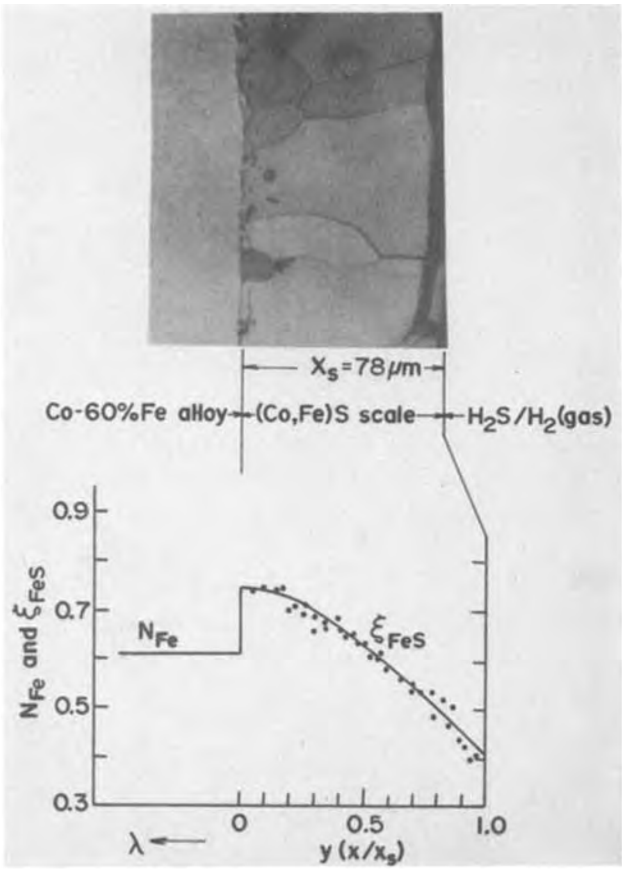

Fig. 1. (CoFe)S scale formed on Co-60% Fe alloy at 600°C and $P_{S_2} = 2 \times 10^{-6}$ atm in 1 hr. Compositions of the solid phases were determined from EPMA of Co, Fe, and S concentrations.

Table I of the FeS content in (CoFe)S at the alloy and gas interfaces, ξ' and ξ'', respectively, and its average composition in scales formed on the various alloys at 700°C and $P_{S_2} = 2 \times 10^{-6}$ atm.

Diffusion Model for Growth of (CoFe)S Scales

Wagner (7) has presented a theory for binary alloy oxidation and sulfidation which applies to growth by ambipolar metal diffusion of a solid solution scale. Before considering this diffusion model, it is necessary to establish features of the defect structure and cation diffusivities of the metal sulfides. $Fe_{1-\delta}S$ exhibits a broad range of nonstoichiometry arising from the presence of iron vacancies; the iron self-diffusion coefficient D_{Fe} is related to the chemical diffusivity $\tilde{D}$ and nonstoichiometry δ by the following expression (3)

$$D_{Fe} = \frac{\tilde{D}_o\delta}{1 + \left[\frac{8}{R}\delta(1-\delta)\right]\left[\frac{7900}{T} + 4\right]} \exp - \tilde{E}/RT \qquad [2]$$

where $\tilde{D}_o = (6.7 \pm 2) \times 10^{-2}$ cm²/sec, $\tilde{E} = 20{,}900 \pm 600$ cal/g atom, R is the gas constant, and T is the absolute temperature. D_{Fe} can be regarded as linearly related to δ only at extremely low sulfur pressures. At sulfur pressures of scale growth in this investigation, D_{Fe} is related to sulfur activity $a_s = (P_{S_2})^{1/2}$ as a good first approximation (3) by

$$D_{Fe} = D^o_{Fe} a_s^{2/n} \qquad [3]$$

where $n = 5$ and D^o_{Fe} at $P_{S_2} = 2 \times 10^{-6}$ atm is taken as the standard reference value at each temperature (3, 8). Cobalt diffusivity D_{Co} in $Co_{1-\delta}S$ is not known.

Cobalt and iron monosulfides exhibit similar defect structures. The ratio of cation vacancy concentrations in CoS and FeS is estimated to be 0.60 at 700°C and $P_{S_2} = 2 \times 10^{-6}$ atm (9, 10). We therefore express cation self-diffusivities of (CoFe)S in the manner used for describing diffusional properties of (CoNi)O (11). That is

$$D_{Fe} = D^o_{Fe}\beta^{1-\xi} a_s^{2/n} \qquad [4a]$$

$$D_{Co} = D^o_{Co}\beta^{1-\xi} a_s^{2/n} \qquad [4b]$$

where ξ is the FeS mole fraction in (CoFe)S and β signifies the ratio of vacancy concentrations for the pure binary sulfides. For example, $\beta = 0.60$ at 700°C and $n = 5$.

Equations [11] and [19] from Wagner's original paper (7), which describe the metal flux in a (CoFe)S scale normalized to fractional thickness y in terms of the parabolic rate constant k and the metal gradient in the scale, can be expressed as follows

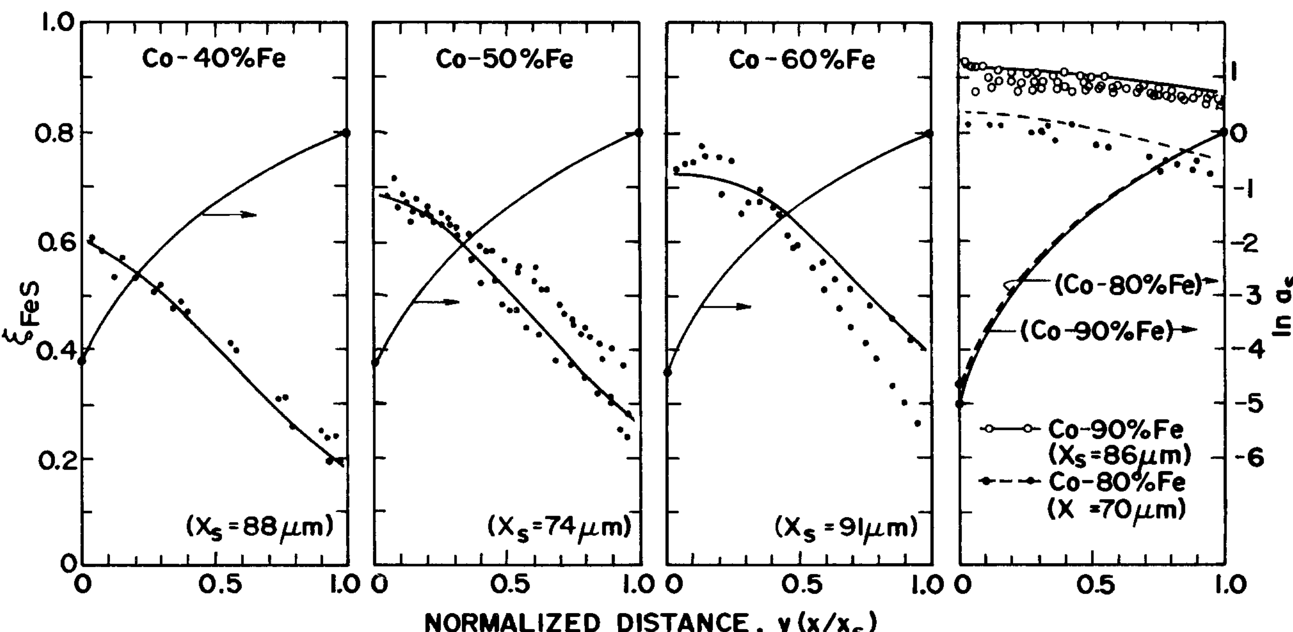

Fig. 2. FeS composition of (CoFe)S scales grown on Co-Fe alloys at 700°C and $P_{S_2} = 2 \times 10^{-6}$ atm. The plots represent calculated FeS composition and sulfur activity profiles.

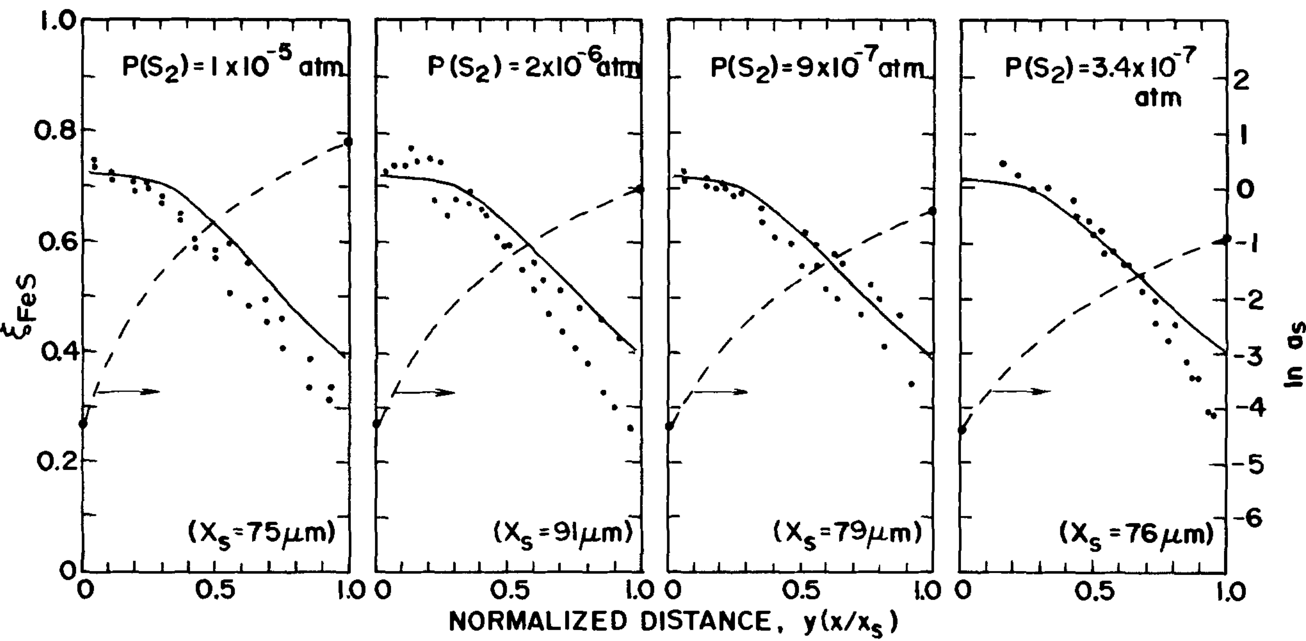

Fig. 3. FeS compositions of (CoFe)S scales grown on Co-60% Fe alloy at 700°C and $3.4 \times 10^{-7} \leq P_{S_2} \leq 1 \times 10^{-5}$ atm. The plots represent calculated profiles.

$$D_{Co}(1-\xi)\left(\frac{-d\ln a_{CoS}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Co}}{Z_s}\frac{d\ln a_s}{dy}\right)$$
$$+D_{Fe}\xi\left(\frac{-d\ln a_{FeS}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Fe}}{Z_s}\frac{d\ln a_s}{dy}\right)=k \quad [5]$$

$$yk\frac{d\xi}{dy}=\frac{-d}{dy}\left[D_{Fe}\xi\left(\frac{d\ln a_{FeS}}{d\xi}\frac{d\xi}{dy}-\frac{d\ln a_s}{dy}\right)\right] \quad [6]$$

The symbols D, a, and ξ refer to the appropriate metal self-diffusion coefficient, activity, and iron composition, respectively. These two equations are placed in the following forms for computational purposes assuming ideal solution of the binary sulfides and $Z_{Co} = Z_{Fe} = |Z_s| = 2$

$$\frac{d\ln a_s}{dy}=\left[\frac{k}{D_{Fe}}-(p-1)\frac{d\xi}{dy}\right]\Big/W \quad [5a]$$

$$\frac{D_{Fe}p}{W}\frac{d^2\xi}{dy^2}+\left[\frac{d\xi}{dy}-\xi\frac{d\ln a_s}{dy}+\frac{k\xi}{D_{Fe}W}\right]\frac{d}{dy}(D_{Fe})$$
$$+\left\{\left[\frac{k\xi}{W^2}-D_{Fe}\frac{(p-1)\xi}{W^2}\frac{d\xi}{dy}\right](1-\xi)\right.$$
$$\left.+D_{Fe}\frac{\xi}{W}\frac{d\xi}{dy}\right\}\frac{d}{dy}(p)+\left\{yk-D_{Fe}\frac{d\ln a_s}{dy}\right.$$
$$\left.-\left[k-(p-1)\frac{d\xi}{dy}\right]\frac{(P-1)\xi}{W^2}\right\}\frac{d\xi}{dy}=0 \quad [6a]$$

where $p = D_{Co}/D_{Fe}$, $W = p - (p-1)\xi$, and

$$\frac{d}{dy}(D_{Fe})=D_{Fe}\left(\frac{2}{n}\frac{d\ln a_s}{dy}-\ln\beta\frac{d\xi}{dy}\right)$$

The parabolic rate constant k (cm²/sec) in these equations is related to the experimental k_p (g²/cm⁴/sec) by

$$k=\frac{1}{2}\left(\frac{M_{(CoFe)S}}{\rho_{(CoFe)S}M_s}\right)^2 k_p \quad [7]$$

where M_s is the atomic weight of sulfur, $M_{(CoFe)S}$ is the average molecular weight of (CoFe)S of metal ratio equal to that in the specific alloy, and $\rho_{(CoFe)S}$ is the (CoFe)S density (g/cm³) calculated from room temperature densities of pure metal sulfides assuming a linear dependence between these sulfides with composition and a temperature expansion coefficient of 2×10^{-5}/°C equal to that for FeS (3).

Several auxiliary equations may be used in this numerical analysis. Values for $(d\xi/dy)_{y=1}$ are estimated from a mass balance at the scale/gas interface (Eq. [39] in Ref. (7))

$$\left(\frac{d\xi}{dy}\right)_{y=1}=-\frac{k^*}{\beta^{(1-\xi'')}(a''_s)^{2/n}}\cdot\frac{(p''-1)(1-\xi'')\xi''}{p''} \quad [8]$$

where $k^* = k/D^o_{Fe}$ and double primes refer to this interface. Also, the ratio of cobalt to iron flux into a scale at its inner interface is equivalent to metal ratio in bulk alloy. Equation [35] in Ref. (7) gives

$$\left(\frac{d\xi}{dy}\right)_{y=0}=-\frac{k^*}{\beta^{(1-\xi')}(a'_s)^{2/n}}\left\{\frac{N^o_{Fe}[p'-(p'-1)\xi']-\xi'}{p'}\right\} \quad [9]$$

where N^o_{Fe} is iron mole fraction in bulk alloy and a single prime refers to metal interface. This latter expression is applicable when significant depletion of the alloying element does not exist in the metal substrate.

Sulfur activity, a''_s, at a scale surface is established by its atmospheric activity. The displacement reaction

between pure sulfides and alloy components defines the sulfur activity at inner interface, a'_s, as a function of interfacial composition ξ'

$$a'_s = [\gamma - (\gamma - 1)\xi'] \exp \Delta G^o_{FeS}/RT \qquad [10]$$

where $\gamma = \exp[(\Delta G^o_{CoS} - \Delta G^o_{FeS})/RT]$ and ΔG^o is a standard free energy change for formation of a pure binary sulfide.

Computer Simulation of (CoFe)S Scale Growth

Preliminary calculations.—Equations [5a] and [6a], which are simultaneous nonlinear differential equations in dependent variables ξ and a_s, were numerically solved using the modified predictor-corrector Hamming method containing automatic changes of step width (12). Four boundary values ξ', a'_s, ξ'', and a''_s and also the first derivative of concentration at the scale/gas interface $(d\xi/dy)_{y=1}$ were used for numerical integration of the above equations from this interface to its inner interface.

$(d\xi/dy)_{y=1}$ is obtained in terms of k^* and p'' from Eq. [8] and in preliminary calculation methods p was assumed to be constant independent of composition for the scale formed on a specific alloy. In the first method, k was chosen equal to the experimental value and values of n and p obtained by computation to obtain best fit to the FeS concentration profile using Eq. [5a] and [6a] with maximum and minimum boundary estimates of ξ'' and ξ', respectively. This method was discarded as the fits were not good and the value of $n = 3.2$ was not in agreement with $n = 5.6 \pm 0.5$ determined from the experimental sulfur dependence on k. This type of fit to the concentration profile in a scale formed on the Co-60 Fe alloy involving $p = 2.15$ and $n = 3.16$ is shown in Fig. 5. The second method involved selecting a value $n = 5$; values of p and k were obtained by numerically integrating Eq. [5a] and [6a] to obtain best fit to a concentration profile commencing with the outer minimum or maximum estimated ξ'' and ending with inner maximum or minimum estimated ξ', respectively. These two types of fit are also illustrated for the concentration profile in Fig. 5. It was apparent from these preliminary calculations that assumption of a constant value of p was unwarranted because best fits for concentration profiles in scales on the various alloys demonstrated that p actually exhibited a compositional

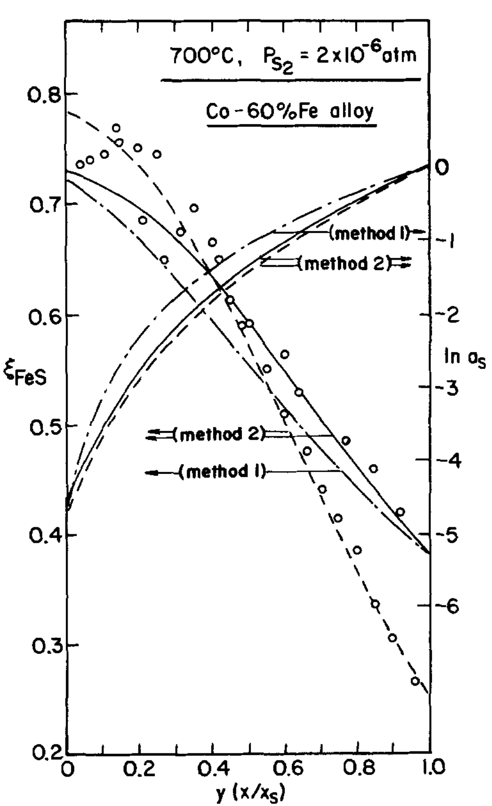

Fig. 5. Fits of calculated profiles to determinations of FeS compositions in the (CoFe)S scale formed on Co-60% Fe alloy. Computation methods given in text. Method 1: $k_p^* = 1.66$, $\xi' = 0.72$, $\xi'' = 0.38$. Method 2: $n = 5$, for $\xi' = 0.73$ and $\xi'' = 0.38$, and for $\xi' = 0.79$ and $\xi'' = 0.25$.

variation and the values of p calculated by the second method are shown in Fig. 6. There is also included here minimum and maximum estimates of p obtained from Eq. [9] by assuming $(d\xi/dy)_{y=0} = 0$ (Fig. 2-4) which arises if the metal diffusivities are much less in the alloy than in the reaction product scale. This condition applied because $\tilde{D}_{alloy}$ (13) $\sim 10^{-5}$ D_{Fe} in FeS (3, 8).

Complete calculations.—Since preliminary calculations demonstrated that the ratio of metal diffusivities in a sulfide scale exhibited a compositional variation, a complete computer simulation program was established to gain a description for parabolic growth of the scale using only diffusional and thermodynamic data for the alloy and scale compound. In principle, it is necessary in the general case for growth of a solid solution scale on a binary alloy to solve the flux and continuity equations for the scale and alloy using metal diffusivities and appropriate boundary conditions at the gas/scale and scale/alloy interfaces knowing the original alloy composition, ambient sulfur pressure, and temperature. The input data, therefore, are the self-diffusivity of iron and $p = D_{Co}/D_{Fe}$ for the sulfide scale, the interdiffusion coefficient $\tilde{D}_{all}$ for the alloy, and the free energy change ΔG for the displacement reaction between the pure metal sulfides with the alloy components. Sulfur activities at the gas/scale and scale/alloy interfaces are defined by the atmospheric sulfur pressure and the thermodynamic relationship given by Eq. [10], respectively. Auxiliary equations [8] and [9], which include the parabolic scale growth parameter $k^* = k/D_{Fe}$, were derived from interfacial mass balances to obtain expressions for the metal concentrations and gradients at the inner and outer scale interfaces.

A flowchart for the computer simulation is given in Fig. 7. D_{Fe} in (CoFe)S is related to the self-diffusivity of iron in pure FeS (3, 8), scale composition, and sulfur activity by Eq. [4a]. Since $p = D_{Co}/D_{Fe}$ was previously shown to be dependent on the scale composition, the preliminary calculated values of this parameter were empirically represented by functions representing linear, probability, and asymptotic type compositional dependences using the average FeS content of a (CoFe)S scale. The appropriate equations

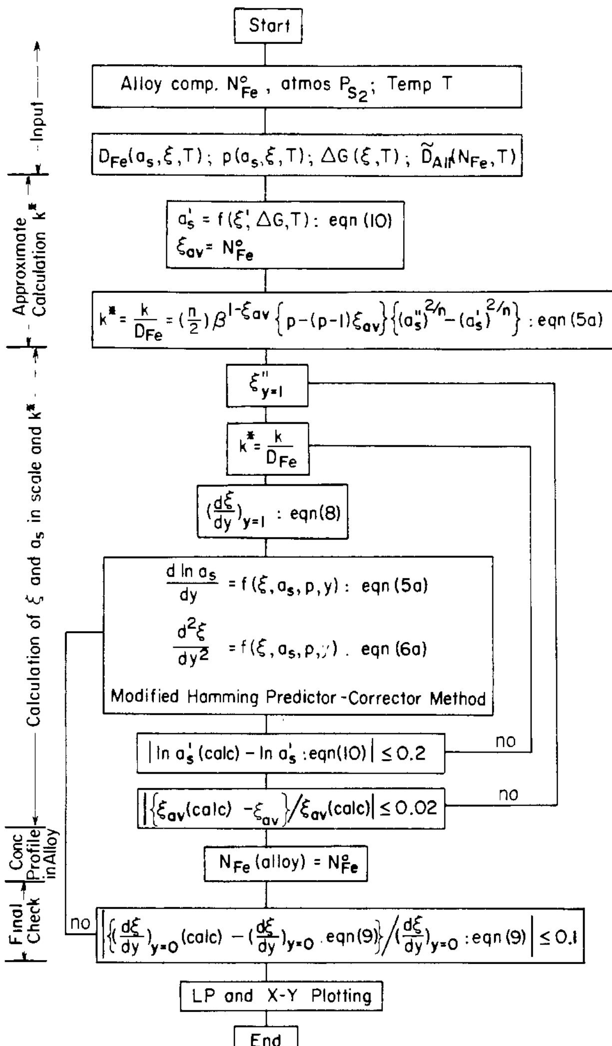

Fig. 7. Flowchart for computer simulation of the sulfidation of Co-Fe alloys to (CoFe)S scales.

were

$$p = 3.7 - 2.7\xi \quad [11]$$

$$p = 1.0 + 2.0 \exp - \{(\xi - 0.55)/0.25\}^2 \quad [12]$$

$$p = 2.4 \text{ for } \xi \leq 0.65 \quad [13]$$

$$= 1.3 + 1.1 \exp - \{(\xi - 0.65)/0.07\}^2 \text{ for } \xi \geq 0.65$$

These three dependences were chosen because no results are available of diffusion in (CoFe)S and each equation represented the preliminary evaluations of p as shown by the plots in Fig. 6.

It was not necessary to consider diffusion in the alloy in the calculations because $D_M(\text{CoFe})\text{S}/\tilde{D}_{all} >> 1$; hence, the iron alloy concentration was equal to the average FeS content of a (CoFe)S scale (7). As illustrated in the flow sheet, a first estimate of $k^* = k/D_{Fe}$ was made by solving Eq. [5a] under the approximation that $d\xi/dy = 0$ and $\xi = \xi_{av} = N^o{}_{Fe}$. This value of k^*, an arbitrarily chosen value of $\xi''_{y=1}$, $(d\xi/dy)_{y=1}$ given by Eq. [8], was then utilized to initiate integration of Eq. [5a] and [6a] from the outer to inner scale interface using the modified Hamming predictor-corrector method (12) to obtain values of ξ and a_s across a scale and the most reliable value of k^*. Two do loops were employed with prescribed absolute error limits to a_s and ξ_{av} and integration step intervals were adjusted automatically to satisfy $< 10^{-8}$ truncation error. A final check of the calculations was carried out by comparing the calculated $(d\xi/dy)_{y=0}$ to that given by Eq. [9] assuming

that the alloy composition remained equal to its initial value.

Calculations were first carried out to determine which equation for p (Eq. [11], [12], or [13]) led to best representation of the measured iron contents of the (CoFe)S scales. A comparison of the fits obtained for the composition profiles in scales formed on the 40% and 60% Fe alloys at $T = 700°C$ and $P_{S_2} = 2 \times 10^{-6}$ atm is shown in Fig. 8 for illustrative purposes. Best fits were obtained using Eq. [13] which describes p as asymptotically approaching a high from low value with decreasing iron content of (CoFe)S as shown in Fig. 6. The calculated ξ and a_s profiles across scales formed on exposing the alloys at several temperatures and sulfur pressures using Eq. [13] for p, Eq. [4a] for D_{Fe}, and Eq. [10] for ΔG as input data into the computer program are depicted by the plots in Fig. 2-4.

A comparison of values for the sulfidation rate constants obtained by computation to those determined experimentally for alloys containing $\geq$ 40% Fe at $T = 533°$ and 700°C and $P_{S_2} = 2 \times 10^{-6}$ atm is given in Fig. 9. Predicted and experimental values agree within the uncertainty of the determinations. The variation of the parabolic rate constant with sulfur pressure is also accurately predicted as illustrated in Fig. 10. At $P_{S_2} \geq 10^{-7}$ atm, the pressure dependence approaches k vs. $P_{S_2}{}^{1/5}$ as given by the model. Calculations for the temperature dependence of the rate constant gave an interesting prediction in that this coefficient attained a maximum at intermediate temperature (14). The plots in Fig. 11 illustrate this behavior for the calculated rate constants of alloys containing 99% and 60% Fe sulfidized at $P_{S_2} = 2 \times 10^{-6}$ and $533° \leq T \leq 980°C$: maxima are obtained at ~900° and 850°C, respectively. A maximum value of the parabolic sulfidation rate constant at an intermediate temperature is determined by two factors: First, the temperature coefficients of the metal diffusivities (plot of D^*_{Fe} vs. $1/T$ in Fig. 11) increase less significantly with increasing temperature due to a regular Arrhenius-type increase in the mobility of cation vacancies but with a decreasing vacancy concentration at constant sulfur pressure (4); and, second, the sulfur activity gradient across a scale decreased with increasing temperature due to larger sulfur activities given by Eq. [10] governing equilibria at the scale/alloy interface.

The computation program using the above estimated relations for D_{Fe}, p, and ΔG was used to evaluate master plots of the FeS composition and sulfur activity profiles across the scales formed on Co-60% Fe at 700°C and sulfur pressures $1 \times 10^{-9} \leq P_{S_2} \leq$

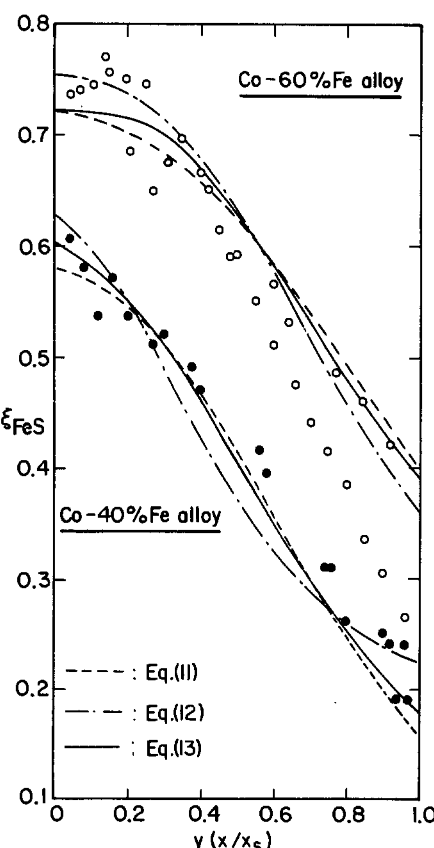

Fig. 8. Calculated fits to composition profiles in (CoFe)S scales on Co-40% and 60% Fe alloys at $T = 700°C$ and $P_{S_2} = 2 \times 10^{-6}$ atm as discussed in text.

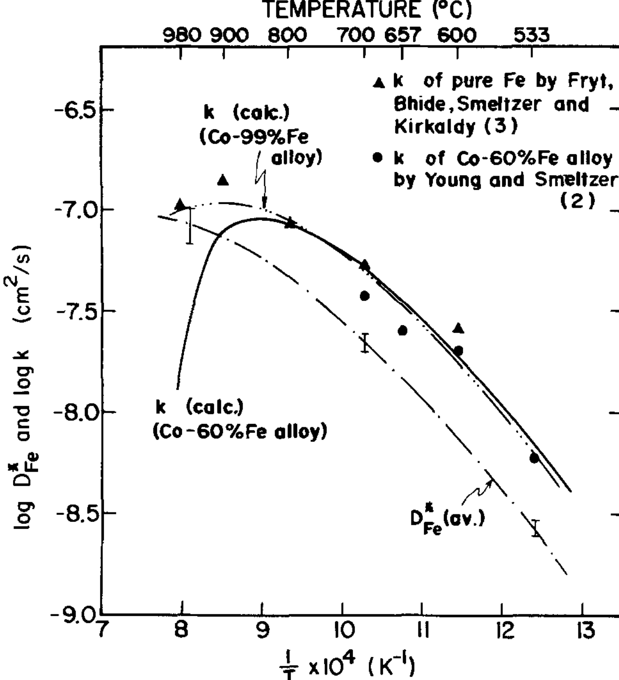

Fig. 11. Temperature dependences of calculated and experimentally determined parabolic sulfidation rate constants.

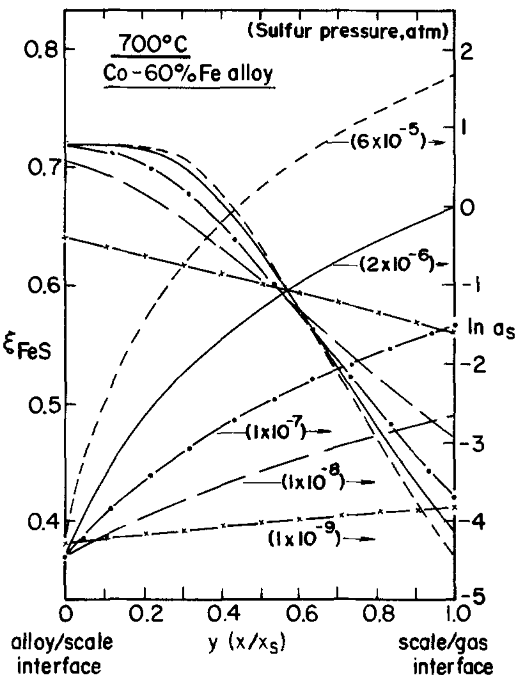

Fig. 12. Master plots of the FeS composition of (CoFe)S scale on Co-60% Fe alloy at $T = 700°C$ and $1 \times 10^{-9} \leq P_{S_2} \leq 6 \times 10^{-5}$ atm.

6×10^{-5} atm, Fig. 12, and at various temperatures $600° \leq T \leq 980°C$ and $P_{S_2} = 2 \times 10^{-6}$ atm as shown in Fig. 13. The corresponding calculated parabolic rate constants under these conditions are those given in Fig. 10 and 11. It is seen that the FeS profiles in the scales formed isothermally become flatter and approach the average composition equal to N^o_{Fe} because of the decrease in sulfidation rate with decreasing sulfur pressure. A similar effect on the composition profile is shown by increasing temperature especially above 900°C at constant sulfur pressure because the parabolic rate constant attained a maximum at this temperature due to the influence of temperature

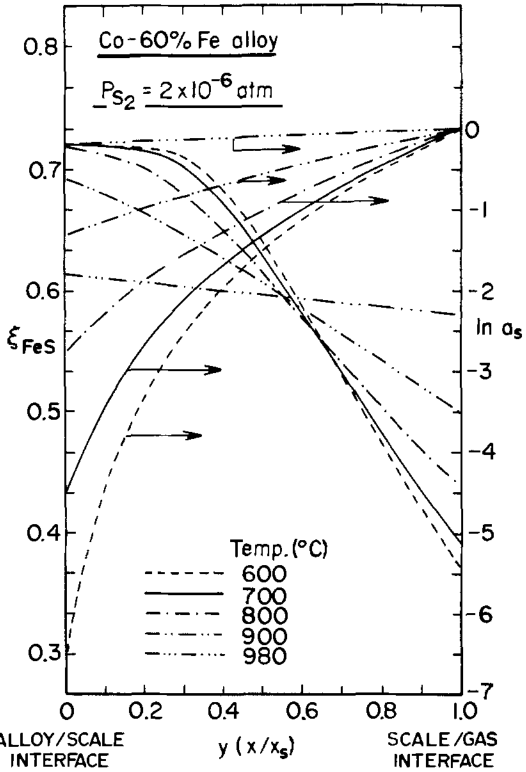

Fig. 13. Master plots of the FeS composition of (CoFe)S scale on Co-60% Fe alloy at $P_{S_2} = 2 \times 10^{-6}$ atm and $600° \leq T \leq 980°C$.

on the metal diffusivities and on the sulfur activity gradient across the scale as previously discussed.

This analysis has demonstrated that a reliable computation method was obtained for predicting parabolic sulfidation rates and concentration profiles in the solid phases when scale growth is controlled by metal diffusion. Scaling data are not required in these calculations since the problem is defined knowing the influence of the dependent variables, composition, and sulfur activity on the diffusivities and thermodynamic equilibria. These latter properties are not completely known for any binary alloy-sulfur system. A dearth of such information is exemplified by the present analysis which demonstrated that calculations had to be carried out assuming relationships for the diffusivities and thermodynamics of (CoFe)S using sulfidation scaling data to define the dependence of the metal diffusivities on composition and sulfur activity.

Structure and Properties of LPCVD Silicon Films

T. I. Kamins*

Hewlett-Packard Laboratories, Palo Alto, California 94304

ABSTRACT

Silicon films deposited by low pressure chemical-vapor deposition over the temperature range from 525° to 725°C were investigated. It was found that polycrystalline films are formed above 600°C and are more stable than the amorphous films deposited at lower temperatures. Their crystal structure is a strong function of the deposition temperature and a weaker function of the deposition rate. Either the {110} or the {100} texture may dominate the structure, depending primarily on the deposition temperature. The electrical resistance obtained on doping the LPCVD films that are polycrystalline as deposited is maximum for films deposited at the lower temperatures (near 600°C), although this dependence on deposition temperature decreases after annealing at higher temperatures. Dopant atoms reversibly segregate to the grain boundaries during lower temperature heat-treatments subsequent to doping and are dispersed at higher temperatures, with corresponding changes in resistivity. The oxidation rate is only a weak function of the deposition temperature, although the initially amorphous films may oxidize somewhat more rapidly. The index of refraction of amorphous films is significantly higher than that of polycrystalline films.

The deposition of polycrystalline silicon at reduced pressures has recently become widespread throughout the semiconductor industry, primarily because of its compatibility with high volume wafer fabrication (1). Since this type of polysilicon is replacing material deposited at atmospheric pressure and several hundred degrees higher temperature, an understanding of its properties and their sensitivity to variations in the deposition conditions is needed.

A previous study (2) showed that LPCVD films deposited at 580°C were amorphous, while those deposited above 600°C were polycrystalline immediately after the deposition. By contrast, at atmospheric pressure, temperatures even higher than the 625°C normally used for LPCVD polysilicon deposition can also produce amorphous films (3). Since amorphous films are unstable upon further heat cycling, their compatibility with integrated circuits must be carefully considered, or deposition conditions must be chosen to avoid obtaining such films.

Because the normally used LPCVD silicon deposition temperature (625°C) is near the amorphous-to-polycrystalline transition, a more detailed investigation of the dependence of the structure and other properties of LPCVD silicon films on the deposition temperature was undertaken. The LPCVD system used in the present study was completely independent of that employed in the previous investigation (2) so system-to-system variations could be observed.

The structure of the films was examined by both transmission electron microscopy and x-ray diffraction. The dependence of the sheet resistance on film deposition temperature was considered both for a gaseous predeposition from a $POCl_3$ source and for implanted phosphorus, and the oxidation rate of both undoped and phosphorus-doped films was investigated. For the latter studies, dopant concentrations were chosen to maximize the resistivity differences between the various films; the differences expected in practical cases may be less.

Key words: films, LPCVD, silicon.

Film Deposition

A series of films was deposited every 25°C over the temperature range from 525° to 725°C, and the films were compared to polysilicon deposited at atmospheric pressure and a temperature of approximately 960°C, the temperature often used for deposition of atmospheric pressure polysilicon.

All films were deposited onto lightly doped, 7.6 cm diam silicon wafers covered with 100 nm of thermally grown silicon dioxide. The wafers were not cleaned between the oxidation and the silicon deposition. The LPCVD films were deposited in a resistance-heated reactor (4) with a uniform temperature profile measured at atmospheric pressure just outside the evacuated deposition chamber. A single thermocouple within the vacuum indicated a temperature there within 4°C of that measured outside the chamber.

Wafers were loaded vertically, with their faces perpendicular to the axis of the tube. The wafers were spaced 0.48 cm apart and were inserted into the chamber at the desired deposition temperature. A constant silane gas flow of 53 cm^3/min was used in all depositions, and the deposition rate consequently varied with temperature; it was approximately 10 nm/min at 625°C. The target film thickness was 0.5 μm, and films deposited at all except the lowest temperatures were reasonably close to this value. The films deposited at 525°C (denoted LP525) were only about half the desired thickness. The thicknesses of the polycrystalline silicon films were usually measured with an automated spectrophotometer, and selected measurements were confirmed with a manual spectrophotometer and a mechanical surface profilometer. The latter was also used to determine the thicknesses of the amorphous films, which are highly absorbing and have a different

Table I. Average grain size as a function of deposition temperature

index of refraction from single crystal or polycrystalline silicon.

Transmission Electron Microscopy

Films deposited at each temperature were analyzed by transmission electron microscopy and diffraction.[1] The samples were prepared using a jet thinning technique. Diffraction patterns of films deposited at 525°, 550°, and 575°C exhibited the diffuse halos characteristic of amorphous samples [Ref. (4), Fig. 6a]. The micrographs also exhibited no structure over the majority of the area. However, small inclusions were seen within the structureless background. The density of these inclusions appears to increase with increasing deposition temperature, and one might speculate that they represent incipient crystallites, suggesting that the amorphous film is unstable. The inclusions are probably not an artifact of the sample preparation technique.

Micrographs of the film deposited at 600°C exhibited a very fine grain polycrystalline structure, with an average grain size of 55 nm, as indicated in Table I. The diffraction pattern was also characteristic of polycrystalline material; the second halo of the amorphous samples deposited at lower temperatures split into two rings, and some spots appeared superposed on the rings.

Films deposited over the temperature range 625°-725°C appeared qualitatively different from those deposited at lower temperatures, but generally similar to each other [Ref. (4), Fig. 6b]. Larger grain polycrystalline material was observed in the micrographs, with a much more ordered structure than at 600°C. The average grain size was in the range 72-87 nm for all of these films (Table I). Diffraction patterns showed the ring-dot structure characteristic of polycrystalline material, with the dots much better defined than in the film deposited at 600°C.

From this portion of the study, we may conclude that silicon films deposited in the LPCVD system at temperatures of 575°C and below are amorphous while those deposited above 600°C are polycrystalline, with the transition temperature close to 600°C. The proximity of the transition to 600°C suggests that this temperature should be avoided in order to obtain the same structure repeatably.

X-ray Diffraction

The preferred orientation of the crystallites was examined by x-ray diffraction on samples from the same wafers used for the transmission electron microscopy study. The intensities of the {111}, {220}, {311}, {400}, and {331} peaks were measured to indicate the amounts of {111}, {110}, {311}, {100}, and {331} texture present in the films. The relative amounts are plotted in Fig. 1 as a function of deposition temperature for the low pressure films and for a sample deposited at atmospheric pressure (AP) and a higher temperature (960°C). Neither the {311} or the {331} texture was dominant in any film investigated. All data are normalized for the strength of the signal expected from a randomly oriented film (5) and corrected for the film thickness (6).

No structure was seen in the 525° or 550°C films, but some was observed in the films deposited at 575°C,

[1] The analysis was performed by Advanced Research and Applications Corporation, Sunnyvale, California.

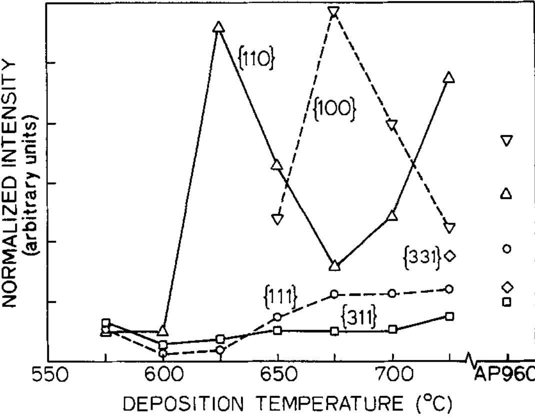

Fig. 1. X-ray texture as a function of deposition temperature for LPCVD silicon films and for an atmospheric pressure film.

which had been found to be basically amorphous by transmission electron microscopy. This x-ray texture can perhaps be related to the inclusions visible in the amorphous background of these films. The {110} texture shows a distinct peak at a deposition temperature of 625°C followed by a minimum at a higher deposition temperature and then a subsequent increase. The {100} texture has a maximum coincident with the {110} minimum. Except at the lower temperatures, the {111} texture shows a monotonic increase with increasing deposition temperature. The average grain size shown in Table I correlates with the amount of {110} texture, although this may be an artifact of the method of determining the grain size.

The structure seen in these low pressure films may be compared to that observed in films deposited in an rf-heated reactor at atmospheric pressure over a wide temperature range. Figure 2 shows previously reported data measured on films deposited elsewhere at atmospheric pressure (7). Each film was about 0.6 μm thick, and at all except the lowest temperatures, the deposition rate was held constant at about 0.12 μm/min.

As in the low pressure films, the {110} texture in these atmospheric pressure films shows a maximum at intermediate temperatures, followed by a minimum and then a subsequent increase. While this behavior is qualitatively similar to that observed in the low pressure films, the temperature range over which it is seen is markedly different. The {111} texture also shows similar trends in the two cases, with a monotonic increase with increasing deposition temperature at all except the lowest temperatures. In both cases the x-ray signal seen at the lowest temperatures may arise from inclusions in basically amorphous films. [The transition temperature between polycrystalline and amorphous deposits is generally

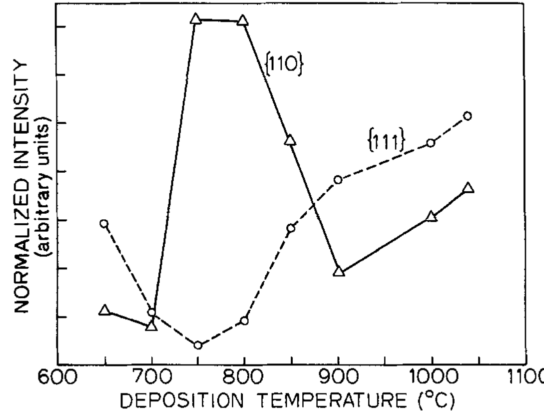

Fig. 2. X-ray texture as a function of deposition temperature for submicron atmospheric pressure films studied previously (7).

felt to be in the high 600°C temperature range for typical atmospheric pressure deposition conditions (3)].

Although the sensitivity of the x-ray diffraction measurements in the previous study of atmospheric pressure films was not adequate to reveal {100} texture in the submicron films, in thicker films the {100} texture was dominant in the temperature range where the {110} texture was minimum (7). This behavior is consistent with the {100} maximum seen in the low pressure films (Fig. 1).

The markedly different temperature range over which similar behavior is observed in the low pressure and atmospheric pressure films may be related either to the different deposition pressures or to the different deposition rates. It is known that large quantities of hydrogen may be adsorbed on the silicon surface during deposition of silicon from silane at atmospheric pressure in a hydrogen ambient (8). Not only does the presence of this hydrogen retard the silane decomposition reaction, but the adsorbed hydrogen also appears to impede surface migration of the silicon atoms which must move on the surface to form a given structure. Thus, with deposition rate held constant, a higher deposition temperature is needed to form a similar structure at atmospheric pressure than at low pressure, since additional energy is required to allow the same amount of surface migration.

More detailed comparison of the experimental data is complicated by the different deposition rates and the fact that the deposition rate was constant in the atmospheric pressure depositions while it varied with deposition temperature in the present experiment. A higher deposition rate R_D is expected to affect the structure in a similar manner to a lower deposition temperature, with the structure determined by the ratio R_D/D (9), where D is the diffusivity representing the motion of the silicon atoms on the surface before they are covered by subsequently arriving silicon atoms. Since D is strongly temperature dependent, a large change in deposition rate is needed to compensate for a small change in temperature in order to retain a given structure. A brief x-ray diffraction study of the structure formed at 625°C at several different deposition rates ranging from 5.6 to 14.7 nm/min in the low pressure system suggests that a factor of two change in deposition rate is approximately equivalent to a change of 30°C in deposition temperature near 625°C.

Where corresponding data are available, the temperature dependence of the dominant {110} texture in films in this study was similar to that of the previous investigation of LPCVD films (2). Except for an apparent 12°C temperature calibration difference, the two independent deposition systems produced similar films, lending support to the basic nature of the behavior seen. (Only a small portion of this apparent difference may be related to the slightly different deposition rates.) Of particular importance, the transition between the deposition of amorphous and polycrystalline films occurred at nearly the same temperature in both LPCVD systems and at a temperature markedly lower than that seen in atmospheric pressure systems.

Sheet Resistance

Since circuit speed may be critically dependent on the resistance of long polysilicon lines, the dependence of the sheet resistance on the deposition temperature of the silicon films was investigated. In one set of samples, phosphorus was added from a $POCl_3$ gaseous predeposition. In order to maximize any differences in resistance between the different samples (10), the predeposition was performed at a low temperature (900°C) with a relatively small amount of $POCl_3$. The gaseous ambient during the predeposition consisted of 3800 cm^3/min of N_2 diluent, 1000 cm^3/min of O_2, and 200 cm^3/min of N_2 saturated with $POCl_3$ by passing it through liquid $POCl_3$ at 22°C. The $POCl_3$ source was on for 30 min, and this portion of the cycle was followed by 5 min of N_2 before the wafers were slowly pulled from the furnace in 10 min. After removing the phosphorus glass in dilute HF, the sheet resistance was measured at five locations on each wafer with the results shown in Fig. 3 (solid lines). The sheet resistances on <111>- and <100>-oriented, single crystal wafers (with no deposited films) doped at the same time, averaged 44.3 Ω/□ (±5%).

The wafers were then protected with a low temperature deposited oxide to prevent surface damage and dopant loss and annealed for 80 min at 1000°C in a dry N_2 ambient. The sheet resistances measured after removing the deposited oxide are shown by the dashed lines in Fig. 3. The films deposited at the three lowest deposition temperatures have an unstable, amorphous structure, which crystallizes at annealing temperatures below 800°C, forming grains which may be even larger than those found in initially polycrystalline films (2). Consequently, the temperature of the $POCl_3$ predeposition will itself be adequate to form large crystallites in these films, leading to a low resistance since fewer grain boundary and other trapping sites are available to remove dopant atoms and carriers from the conduction process. The small change during the subsequent 1000°C anneal in these films indicates that the recrystallized structure in the initially amorphous films is reasonably stable.

At deposition temperatures of 600°C and above, a polycrystalline structure is formed during the film deposition. The decrease in resistance with increasing deposition temperature seen in Fig. 3 indicates a decreasing trap density, even though the average grain size in the as-deposited films does not vary greatly with deposition temperature.

The marked decrease in the resistance seen after the 1000°C anneal may be attributed to a decrease in the defect density or to an increase in the grain size with this additional heat-treatment, as well as to movement of dopant atoms out of the grain boundaries. This decrease in resistance is especially significant in the polycrystalline films deposited between 600° and 650°C, consistent with a less stable structure in these films.

Phosphorus was added to other samples by ion implantation of 5×10^{15} ions/cm^2 at an energy of 50 keV. The films were then annealed at 550°C in dry N_2 for 75 min. High sheet resistances (greater than 10 kΩ/□) were measured on the films deposited at 525° and 550°C, probably reflecting their amorphous structure, while the sheet resistances of the initially polycrystalline films decreased with increasing deposition temperature from 3 kΩ/□ to 300 Ω/□ for dep-

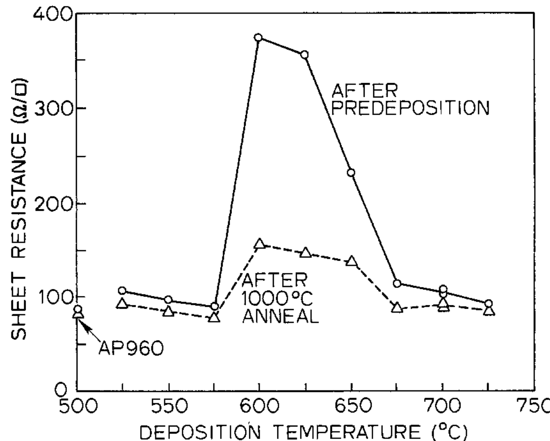

Fig. 3. Sheet resistance as a function of deposition temperature after a 900°C $POCl_3$ predeposition (solid lines) and after a subsequent 80 min anneal at 1000°C in dry N_2 (dashed lines).

osition temperatures varying from 600° to 725°C. The film deposited at 575°C showed intermediate results, with some conduction observed after the 550°C anneal, suggesting that this film is very unstable. After a subsequent 1000°C anneal the resistances of the initially amorphous films were lowest (approximately 40 Ω/□), reflecting the influence of the large grain size in these films after annealing. The sheet resistances of the initially polycrystalline films ranged from 74 to 60 Ω/□, again with the highest resistances for films deposited at the lowest temperatures.

It should be noted that the conditions of this experiment were chosen to maximize the differences in resistance between the various samples, especially in those doped from a $POCl_3$ source. At higher dopant concentrations, the trapping sites become saturated so that the effective carrier concentration becomes much less strongly dependent on the grain size (11). Impurity-assisted grain growth (12) may also become as important as the structure of the initial film so that the resistivity differences between samples are less. For practical implant doses, however, significant differences may still be seen.

In a related experiment reversible changes in the sheet resistance of polysilicon samples were briefly investigated as the annealing temperature was varied. Low pressure films deposited at 625°C were doped with $POCl_3$ at 950°C to produce a sheet resistance of 12.5 Ω/□ after the predeposition cycle. The samples were then sequentially annealed at different temperatures in the range from 400° to 1000°C for 80 min in a dry N_2 ambient, with the same samples receiving all annealing cycles. The samples were not protected by deposited oxide during these heat-treatments. After each anneal, the sheet resistance was measured, with the results shown in Fig. 4 for a sample which received 15 successive annealing cycles.

The resistance generally returns to a similar value as the annealing sequence is repeated, suggesting that dopant atoms segregate to grain boundaries at lower temperatures and are dispersed into the grains at higher temperatures (13, 14). As the dopant atoms are dispersed, they become active, lowering the resistance. This behavior indicates that dopant segregation at grain boundaries, as well as carrier trapping there, is important in determining the resistivity of polycrystalline-silicon films. The slightly higher resistance seen after the second sequence of annealing cycles may be attributed to the slightly different temperatures used in the two sequences or to a small loss of phosphorus since the wafer surfaces were not protected during the heat-treatment.

It is relevant for practical applications of polysilicon to note that the resistance is maximum after an intermediate temperature anneal and decreases at higher temperatures. At the lowest temperatures, the equilibrium value of the resistance is probably much higher than shown in Fig. 4, but the anneal time is not adequate for equilibrium to be reached. Consequently, only a limited amount of dopant is able to segregate at the grain boundaries during the anneal, and the resistance only increases slightly from its high temperature value. It follows from this reasoning that the resistance would be much higher than indicated in Fig. 4 after a low temperature anneal if this low temperature anneal followed an anneal at an intermediate temperature, rather than one at a high temperature. Thus, the resistance of the polysilicon in an integrated circuit depends on the sequence of thermal processes after the polysilicon is doped.

Oxidation

In order to reveal further differences between the various types of polysilicon, the oxidation rate was briefly considered. Both the $POCl_3$-doped and the implanted samples described in the previous section were oxidized along with undoped samples which did not receive any further heat-treatment after they were deposited. The films were oxidized at 850°C in a steam ambient to emphasize the surface reactions which dominate the oxidation kinetics in this region. In order to obtain oxide thicknesses that were convenient to measure with a u.v. spectrophotometer (15), the undoped samples were oxidized for 150 min while the doped samples were oxidized for only 75 min.

The oxide thickness measured on the undoped samples are shown in Fig. 5 along with oxide thicknesses measured on <111>- and <100>-oriented single crystal control wafers which were not covered with silicon films. The oxide thicknesses on the undoped films are close to that on lightly doped, <111>-oriented, single crystal silicon. The oxide thicknesses on all initially polycrystalline low pressure films (deposited at 600°-725°C) were within 8% and were slightly less than that on <111> silicon, probably indicative of the slower oxidation of other crystal orientations within the polycrystalline structure. Within the group of polycrystalline films there appears to be some correlation of the oxide thickness with the detailed orientation of the crystallites seen in Fig. 1. The thickest oxide is obtained on films with dominant {110} texture (625° and 725°C) while the minimum occurs in the intermediate range where the {100} texture is dominant. The oxide thickness on the initially amorphous films appears to be somewhat greater than that on <111> silicon. This thicker oxide may be related to the less stable structure in these films and the change in the structure during the oxidation cycle, since an 850°C heat cycle is sufficient to convert the amorphous structure to a polycrystalline one.

The oxide thicknesses on the doped samples appear to be dominated by the average dopant concentration in the film (dopant atoms/cm² divided by film thickness) so that thinner films oxidize more rapidly than

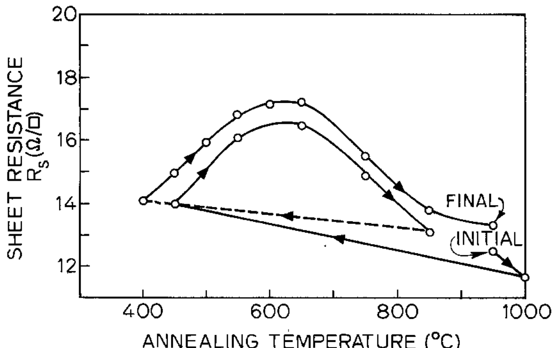

Fig. 4. Sheet resistance as a function of annealing temperature as the same phosphorus-doped sample is sequentially annealed. The film was deposited at 625°C.

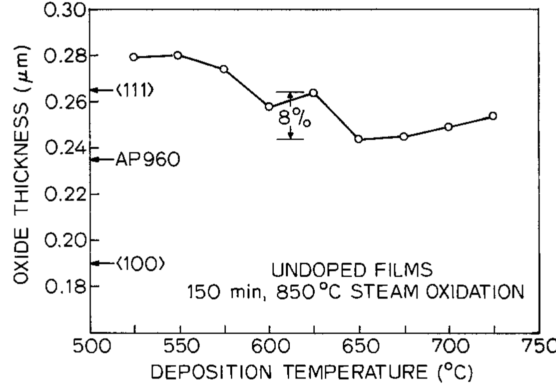

Fig. 5. Oxide thickness as a function of deposition temperature for undoped films after a 150 min steam oxidation at 850°C.

thicker films even if the structure is the same (15). While some similar dependence on film deposition temperature was seen for the implanted and annealed films as for the undoped films, the trends were less pronounced. No clear trends were seen for the $POCl_3$-doped films that were subjected to a 1000°C anneal before oxidation, suggesting that grain-growth effects preceding oxidation may have dominated the oxidation kinetics.

Index of Refraction

The thickness of a deposited polysilicon film is usually measured by optical interference with either manual or automated spectrophotometers. Since the index of refraction of a polycrystalline-silicon film is close to that of single crystal silicon in the wavelength range of interest (16), analysis of the measurements is straightforward. Application of this technique to an amorphous silicon film is complicated by the different index of refraction and the large absorption, which decreases the reflected intensity available and shifts the apparent location of interference extrema.

To investigate the refractive index of amorphous silicon films, steps were etched in some amorphous and polycrystalline silicon films, and the films were measured with a surface profilometer and a spectrophotometer. From the thickness determined by step-height measurements and the wavelengths of the interference extrema measured with the spectrophotometer, the real part of the index of refraction of the amorphous films deposited at 525° and 550°C was determined as a function of wavelength, as shown in the upper curve of Fig. 6. The same films were then annealed at 900°C in N_2 for 40 min to crystallize the amorphous films, and the measurements were repeated. The index of refraction of the crystallized, initially amorphous films is shown by the lower curve of Fig. 6 and is now similar to that of crystalline silicon. Similar changes in the refractive index have recently been reported when amorphous films formed by atmospheric pressure CVD were crystallized (17). In the present experiment the properties of similarly treated, initially polycrystalline films did not change during the anneal.

Since the optical properties may depend on the detailed nature of the amorphous films, and consequently their deposition conditions, data obtained for amorphous films deposited at 525° or 550°C cannot be used with confidence for amorphous films obtained under markedly different deposition conditions.

Summary

Silicon films deposited by low pressure chemical-vapor deposition may be either amorphous or polycrystalline immediately after deposition, depending primarily on their deposition temperature. The amorphous films are unstable and crystallize readily on further heat-treatment, such as those seen in integrated circuit processing. The properties of the amorphous films may differ significantly from those of crystalline silicon. The polycrystalline films, which are deposited above 600°C, are more stable. Their crystal structure is a strong function of the deposition temperature.

The resistance obtained on doping LPCVD silicon films depends on the film deposition temperature, although this dependence decreases after annealing the films at high temperatures. The resistance also changes reversibly as dopant atoms segregate at grain boundaries at lower temperatures and are dispersed into the grains at higher temperatures.

The oxidation rate is only a weak function of the deposition temperature for undoped films, although the initially amorphous films appear to oxidize somewhat more rapidly. The oxidation rate of heavily doped films is dominated by the dopant concentration, and the effect of deposition temperature is secondary. The index of refraction of the amorphous films is significantly larger than that of the polycrystalline films. Because of the marked differences between the properties of amorphous and polycrystalline films, deposition near the transition temperature should be avoided.

ABSTRACT

Thermally stimulated depolarization (TSD) of novolac and novolac allyl ether electrets prepared at different polarizing temperatures of 36°, 56°, and 66°C with field strength of 1-3 kV/cm is compared with that of resols. Effects of the differences in chemical structure on the position of the TSD peaks and amount of stored charge are discussed. A correlation exists between these peak positions and chemical transformations occurring in the resin as indicated by infrared and differential thermal analytical studies.

Although electret formation in many of the common thermoplastic materials is known, very few papers are available on thermosetting resins like the phenolics (1), epoxy resins (2), polyimides (3), and synthetic melanins (4). Electrets of such resins are of interest since they are likely to be more thermally stable than those of thermoplastics and also because they are used in the electrical industry. The exact nature of the chemical phenomena occurring during the process of curing in thermosets is not fully understood. In recent years differential thermal analysis (DTA) and infrared spectral studies have been successfully applied (5, 6) for studying the curing phenomena. While it is well established that in the thermal depolarization of polar dielectrics, peaks corresponding to various relaxation processes can be identified, no report is available on the possibility of correlating the position of such peaks with chemical changes occurring on the polar groups.

Preliminary work (1) done on electret formation in semicured resols was encouraging. The present work is an extension of these studies to novolacs and novolac allyl ether and aims at a correlation between structural effects and electret behavior.

Experimental

As described earlier (1), resols were prepared by the standard method, and cast on an aluminum electrode by filling a square shaped mica cavity placed on it, followed by curing at the desired temperature to get sample I.

Novolacs and novolac allyl ether were prepared by the method described by Hui and Yip (7). These novolacs could not be cast on the aluminum electrode as described in Ref. (1), because during curing of novolacs excessive gas formation occurred and some of the gas was generally trapped. However, a few samples could be prepared without porosity by mixing novolac with hexamethylene tetramine (HMT) at ratios of 3:1 and 2:1 in methanol and pouring the solution in a mica cavity as above. These samples were cured at 70°C for 12 hr and dried in a vacuum dessicator to get samples II(a) and II(b).

A further set of samples was prepared by mixing novolac with HMT in the ratio 5:1 in methanol. The excess of methanol was removed by heating at 60°C for 30 min. These samples were then dried under vacuum, powdered, and made into pellets in vacuum under a load of 9 tons to get samples III.

As an alternative method of sample preparation, filter paper (Whatman 41) was dipped in a methanolic solution of novolac and novolac allyl ether and cured in an oven for 24 hr at 60°C. The weight increase of the paper after curing was a measure of the sample taken. These were dried in a vacuum dessicator to get samples IV and V, respectively. After preparation, all the samples (I to V) were stored under vacuum to avoid interference of adsorbed moisture in the experiments. The samples were characterized by infrared and DTA techniques and the conductivities were measured as a function of temperature.

For electret formation samples I to V were sandwiched between aluminum electrodes and polarized at different temperatures as shown in Table I, in a specially designed oven at a field strength of 1-3 kV/cm for 1 hr. Without removing the voltage source, the samples were cooled to room temperature over a period of 1 hr and thereafter the voltage source was disconnected. The depolarization current from the samples was measured as a function of time and temperature for a linear rate of heating of 4°C/min. Similar experiments were carried out with the filter paper alone, to confirm that there was no electret effect in the blank paper.

Results

As already reported (1) resols I show depolarization peaks with T_m at 110°-160°C. The position of the peaks varied to some extent with the sample preparation, including conditions of curing. At high fields the presence of more than one overlapping peaks was noted. Since the resins are thermosetting, it was not possible to completely separate out the two peaks by peak cleaning as described by Perlman (8). Once the sample is heated to higher temperatures, changes in chemical structure would have occurred and the sample cannot again be polarized and studied by TSD. However, it was possible to locate the position of the second peak alone by heating the polarized samples to 110°C, cooling, and reheating. A sharper peak was thus obtained at about 130°C, for resols polarized at 76°C with a field of 1 kV/cm.

In the case of novolacs the results were very much dependent on the conditions of preparation. Table I summarizes the depolarization data of novolacs cured with and without HMT. Figure 1 is a TSD plot for novolacs cured without HMT (sample IV). In this case only one peak is observed at 110°C. This peak is fairly sharp and does not shift with temperature of polarization (T_p). When cured with HMT [samples II(a), II(b), and III] the TSD spectra became more complicated.

In the case of novolac allyl ether (sample V) the T_m appears at 130°C as seen from Fig. 2. At higher

T_p, additional broad peaks occur at 150°-180°C. However at these temperatures the samples tend to melt and more detailed analysis could not be made and no further attempt was made towards the peak assignments.

The activation energy (E_a) was calculated for some samples by the initial rise method as well as from semi-log plots of resistance (R) of the unpolarized samples as a function of temperature. A representative plot is shown in Fig. 3.

Discussion

In the absence of charge injection, the two basic mechanisms by which charge storage is expected to occur are by dipole orientation and space charge effects. In the semicured phenolics the dipoles available are the phenolic-OH and $—CH_2OH$ substituents on the phenol ring. The bridging of the rings are basically through methylene units and a few ether bridges may also be present. The nature and number of the various groups would depend on the initial phenol: formaldehyde ratio, conditions of condensation including pH, temperature, and presence of curing agents.

DTA studies on novolac formation (5) have indicated only one peak at 90°-110°C, attributed to condensation through formation of simple methylene linkages. Thus plain novolacs are normally expected to have only the phenolic —OH, and methylol groups would not be present to any significant extent. The

Table II. Principal infrared absorption peaks

Group	Wave number of peaks, cm^{-1} [Ref. (7), (9)]	Novolac without HMT	Novolac allyl ether	Resol
—OH	3350	Present	Almost absent	Present
Benzene ring	1450-1600	Present	Present	Present
Allyl double bond	990, 920	Absent	Present	Absent
CH_2—OH	1010	Almost absent	Almost absent	Present
—CH_2—O—CH_2—	1075	Absent	Absent	—
—CH_2—	1445, 910	Present	Present	Present

infrared absorption of our semicured novolac samples are shown in Table II. Absence of a band at 1075 cm^{-1} indicates the absence of dimethylene ether bridges. The peak due to the phenolic —OH at 3400 cm^{-1} is quite prominent. The band at 1010 cm^{-1} corresponding to —CH_2OH is not significant. In our TSD experiments on novolac paper laminates (sample IV), we observe only one peak at about 105°-110°C, in agreement with DTA results. Possibly this peak is associated with the phenomenon of curing. In fact sample III which is a mixture of novolac and HMT in the pellet form, also gives only one peak around 110°C. This indicates that cellulose-novolac interface or possible air trapping, is not responsible for this peak because these are present in sample IV but not in III.

In preparing sample III, time was not allowed for curing, and the HMT only served to lightly cross-link the matrix to enable pellet formation. However, novolac samples II(a) and II(b) containing HMT and resol (sample I) were allowed to cure. In such cases additional peaks are observed at 150°-160°C and may be attributed to the depolarization of —CH_2OH groups with simultaneous condensation to form ether linkages. In fact, the DTA and infrared studies on resol formation (6) have indicated that phenols condense, with —CH_2 bridge formation, at 110°C, and monosubstituted phenols condense at 148°C. At 160°C, substituent methylol groups come together to form the dimethyl ether and at 200°-210°C these may cleave. Thus the peaks at 200°-210°C observed in samples II(a) and II(b) possibly correspond to charge storage in the —CH_2—O—CH_2— linkages which cleave at this temperature.

Generally, under comparable conditions the i_{max} and stored charge are in the order novolac > allyl novolac > novolac cured with HMT. The addition of HMT enables novolacs to cross-link extensively and makes the orientation of dipoles difficult during the polarization process. However, resols store more charge as compared to novolac cured with HMT, probably through the increased number of —CH_2OH groups present.

The E_a values obtained by the initial rise method for the first peaks in the types of samples are of the same order (Table I). These match fairly well with the values obtained by conductivity measurement in the same temperature range.

Thermal Quenching of Luminescence in a Disordered Compound: $EuNa_2Mg_2(VO_4)_3$

Hajime Yamamoto,* Setsuko Seki, Jean-Pierre Jeser,[1] and Tsutomu Ishiba

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

Luminescence of $EuNa_2Mg_2(VO_4)_3$ is six times as bright as that of YVO_4:Eu under 365 nm light excitation at room temperature, but it suffers from thermal quenching at higher temperatures. The quenching is mainly caused by nonradiative relaxation from the emitting states. Energy diffusion among the lowest excited states, $^5D_0$, to sinks is a main reason of relatively weak quenching below 500°K. At higher temperatures, drastic quenching due to nonradiative relaxation within each Eu^{3+} ion is observed. Disordered distribution of Eu^{3+} and Na^+ revealed by optical and powder x-ray diffraction measurements is considered to induce the thermal quenching. Similar strong quenching beginning at around 500°-600°K is observed also for other disordered compounds, $EuK_5(MoO_4)_4$ and $EuA(MoO_4)_2$ (A = Na, K, and Rb).

Since Danielmeyer and his colleagues (1, 2) found that NdP_5O_{14} is useful as a miniature laser material in 1972, various concentrated rare earth compounds called "stoichiometric"[2] materials have been studied extensively. These compounds are characterized by separations as great as 5-6Å between nearest neighbor rare earth ions, and consequently, by small interionic interaction even at high concentrations such as 10^{22} ions/cm^3. Later, this characteristic naturally attracted attention to phosphor applications as well (3, 4).

The present work was also initiated with the aim of finding efficient "stoichiometric" Eu^{3+} phosphors. During the course of investigations, it was found that $EuNa_2Mg_2(VO_4)_3$ and its modifications with garnet structure show bright luminescence under 365 nm light excitation at room temperature. However, it was also found that luminescence efficiency and lifetime of the lowest emitting state $^5D_0$ greatly decrease at higher temperatures.

It is known that Eu^{3+} and Na^+ occupy equivalent sites in the garnet structure (5). If their distribution is ordered, the shortest distance between Eu^{3+} ions is 6.2Å, so that $EuNa_2Mg_2(VO_4)_3$ would be a "stoichiometric" material. Meanwhile, it was found that in several known "stoichiometric" Eu compounds, lifetimes of $^5D_0$ are independent of temperature. This is not consistent with the result for $EuNa_2Mg_2(VO_4)_3$ and raises doubts that this material is not "stoichiometric." This observation motivated the present work to find the reasons for thermal quenching. Analysis of the crystal structure and optical properties has revealed that Eu and Na are distributed in a disordered way. Therefore, the material is actually not a "stoichiometric" compound. The shortest distance between Eu ions is 3.8Å. Mechanism of the thermal quenching and its relationship with disordered distribution is discussed in the Discussion Section. Thermal quenching as measured by an increase in decay rates of the $^5D_0$ state was also found for other compounds, $EuK_5(MoO_4)_4$ and $EuA(MoO_4)_2$ (A = Na, K, Rb, and Cs). All of these compounds, except for $EuCs(MoO_4)_2$, show an indication of disordered distribution of Eu and alkali ions.

Experimental

Sample preparation.—$Eu_xR_{1-x}Na_2Mg_2(VO_4)_3$, (R = Y or La, $0.1 \leqq x \leqq 1.0$).—The method used to prepare the series of materials can be described by taking $EuNa_2Mg_2(VO_4)_3$, (x = 1) as an example. Essentially, the material is prepared by firing mixtures of high purity Na_2CO_3, Eu_2O_3, $MgCO_3$, and NH_4VO_3 at 850°C in air for 24 hr. However, the preparation conditions had to be refined, because fired products did not have single phase garnet structure due to formation of a zircon structure, $EuVO_4$. Thermogravimetric and differential thermal analysis as well as x-ray diffraction measurements showed that $EuVO_4$ is formed at a temperature lower than the formation temperature of $EuNa_2Mg_2(VO_4)_3$ and that $EuVO_4$ formation proceeds more rapidly at a fast (20 deg/min) heating rate than at a slow (5 deg/min) heating rate. It was also confirmed that $EuVO_4$ once fired at 850°C can be converted to $EuNa_2Mg_2(VO_4)_3$ by refiring with Na_2CO_3, $MgCO_3$, and NH_4VO_3 at 850°C. Therefore, the quantity of $EuVO_4$ can be minimized by repeating that refiring process two or three times. The x-ray powder pattern of samples prepared in this way showed that the intensity of the strongest diffraction line of $EuVO_4$ was less than 5% that of $EuNa_2Mg_2(VO_4)_3$.

Other materials.—Europium alkali molybdates and tungstates were prepared by firing stoichiometric mixtures of Eu_2O_3, alkali carbonates, and MoO_3 or H_2WO_4 in air at 620°C. X-ray diffraction analysis showed that samples prepared this way are single phase.

More usual compounds were prepared in conventional ways: $EuPO_4$ by firing a mixture of Eu_2O_3, $(NH_4)_2HPO_4$, and Na_2CO_3 in O_2 at 1160°C for 3 hr; $EuVO_4$ by firing a mixture of Eu_2O_3 and NH_4VO_3 in air at 1200°C for 2 hr. The last material, EuP_5O_{14}, was prepared by one of the authors (J-P. J.) at the Max Planck Institut, Stuttgart.

Optical measurements.—Luminescence spectra were measured in two different ways. Low resolution spectra covering the whole visible region were measured by a Nikon P-250 monochromator which has a dispersion of 6 nm/mm. A photomultiplier signal was processed by a data acquisition system, Hewlett-Packard 9825A, to obtain corrected spectra. Peak wavelengths and shapes of emission lines were obtained from high resolution spectra measured with a Spex 1400 monochromator with a dispersion of 1 nm/mm. In both cases, the excitation source employed was a high pressure Hg lamp combined with a $CuSO_4$ solution filter and a glass filter, Toshiba UV-D1A, which cuts off visible light.

Excitation spectra were measured by the conventional method with a Hitachi MPF-4 spectrometer. For measurements of decay characteristics, an Avco-

Key words: luminescence, thermal quenching, nonradiative processes.

[2] Use of the word "stoichiometric" is not correct in this case, because it usually refers to the ratio between cations and anions and not to the ratio between two kinds of cations. So in this work, we use this word always with quotation marks.

Everett Model 1000 tunable dye-laser system was used as an excitation source.

The laser was operated at 464 nm, which corresponds to the $^7F_0 \rightarrow {}^5D_2$ transition of Eu^{3+}. Pulsed duration was 6 μsec, and spectral width was about 6 nm. Luminescence from a sample was focused on a slit of a Nikon P-250 monochromator. Usually, the wavelength of the monochromator was set at the position of the main peak of (Eu, Y)$Na_2Mg_2(VO_4)_3$, which is 609.7 nm, in order to eliminate emission from the by-product (Eu, Y)VO_4. The luminescence was detected with an HTV R 666S photomultiplier. The photomultiplier signal was stored by a Biomation Model 1010 waveform recorder and averaged by a signal averager, Toyo Model 1010S. The average of 50 or 100 decay curves was converted to a semilogarithmic plot by the data acquisition system 9825A.

Raman spectra of powder samples were measured at room temperature by using a Cary 82 Raman spectrometer. Powder was charged in a quartz capillary and mounted parallel to the entrance slit of the spectrometer. The incident laser light came into the bottom of the capillary and propagated along the wall of the capillary. Scattered light was collected by a condenser lens and focused on the slit efficiently.

Results

Luminescence spectra.—The luminescence spectrum of $EuNa_2Mg_2(VO_4)_3$ is quite similar to the reported spectra of $NaCa_{1.9}Eu_{0.1}Li_{0.1}Mg_{1.9}(VO_4)_3$ (6) and of $Ca_{2-2x}Na_{1-x}Eu_xMg_2(VO_4)_3$, $(0 < x \leqq 1.0)$ (7), which have garnet structure. In the systems $(Eu_xR_{1-x})Na_2Mg_2(VO_4)_3$, (R = Y or La, $0.1 \leqq x \leqq 1.0$), luminescence spectra have essentially the same features irrespective of x, except for the widths of the lines. This result agrees with x-ray diffraction data which show that these systems form perfect solid solutions. It was also found that temperature changes in the range of 77°-570°K do not cause any significant changes in low resolution spectra.

Local site symmetry around Eu^{3+} ions was examined by observation of crystal-field structures in the luminescence spectrum of $EuNa_2Mg_2(VO_4)_3$. The dodecahedral site in the garnet structure has site symmetry D_2. The numbers of the crystal-field components of the ^7F_J states expected from group theory agree well with the observed numbers except for $^7F_3$, in which three lines are missing. It can be safely concluded that Eu^{3+} occupies the dodecahedral site, since the missing lines were quite possibly not detected because of their low intensities.

Relative luminescence intensities vs. Eu concentration and temperature.—The relative intensities of the $^5D_0$ emission of $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$ under 365 nm excitation at room temperature as a function of the Eu concentration are shown in Fig. 1. The broad maximum light output is found at around 70%, or 3×10^{21} Eu ions/cm^3. This density is relatively large compared with typical doped phosphors and is closer to the values found in "stoichiometric" phosphors. For example, the density of Eu ions is 5×10^{20} ions/cm^3 in YVO_4:Eu(4%), and 4×10^{21} ions/cm^3 in EuP_5O_{14}. The fact is that $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$ is not a "stoichiometric" material, as is discussed later. The high optimum concentration is commented on in a later section.

At room temperature, $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$, $(0.1 \leqq x \leqq 1)$, is a more efficient phosphor than the commercial phosphor YVO_4:Eu.[3] At $x = 0.7$, the former is 8.4 times as bright as the latter. An investigation of compounds with modified chemical composition led to the finding that $Eu_{0.7}La_{0.3}Na_2Mg_2(VO_4)_3$ is 14.6 times as bright as YVO_4:Eu. In Fig. 2 are shown the brightness data of $EuNa_2Mg_2(VO_4)_3$, $Eu_{0.7}La_{0.3}Na_2Mg_2(VO_4)_3$, and YVO_4:Eu under 365 nm excitation as a function of temperature. As is well known (8), YVO_4:Eu shows a steep increase in efficiency with increasing temperature. In contrast, (Eu, R)$Na_2Mg_2(VO_4)_3$, (R = Y or La), suffers from a drastic thermal quenching. In this way, the two kinds of vanadates show quite contrary temperature dependence. The thermal quenching of (Eu, R)$Na_2Mg_2(VO_4)_3$ can also be observed by means of excitation spectra at varying temperatures: Fig. 3 shows the result for $EuNa_2Mg_2(VO_4)_3$. The 4f-4f excitation lines of Eu^{3+} as well as the broad band due to host absorption lose intensity with increasing temperature. The intensity of the $^7F_0 \rightarrow {}^5D_2$ excitation line at 464 nm is plotted against temperature in Fig. 4. Its temperature dependence is nearly the same as that of the intensity under 365 nm excitation, which indicates that the main loss processes occur at $^5D_2$ and/or the lower states, $^5D_1$, $^5D_0$.

Excitation and diffuse reflection spectra were measured at room temperature for a series of $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$ in the region of 290-600 nm. Changes due to variation in x were not found near the host absorption region. In other words, the charge transfer band from O^{2-} to Eu^{3+} was not detected.

Decay characteristics.—The temperature dependence of the decay characteristics of $^5D_0$ emission was mea-

[3] Exactly speaking, PO_4^{3-} ions substitute 6 mole percent of VO_4^{3-} in this phosphor. The Eu concentration is 4 atom percent.

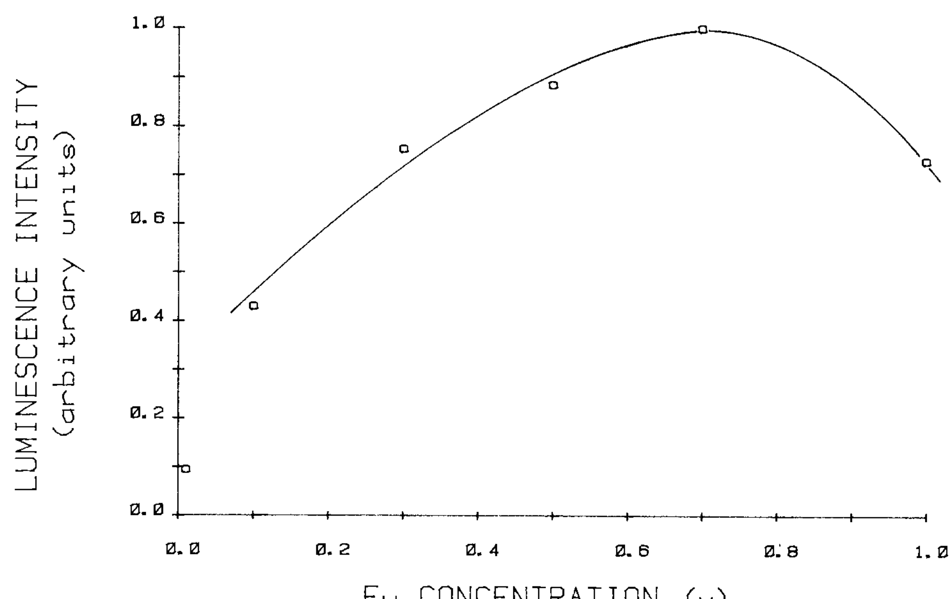

Fig. 1. Dependence of the luminescence intensity of $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$ on Eu concentration $(0.1 \leqq x \leqq 1.0)$ at room temperature. Excitation was made with a high pressure Hg lamp and the luminescence from the $^5D_0$ state was monitored.

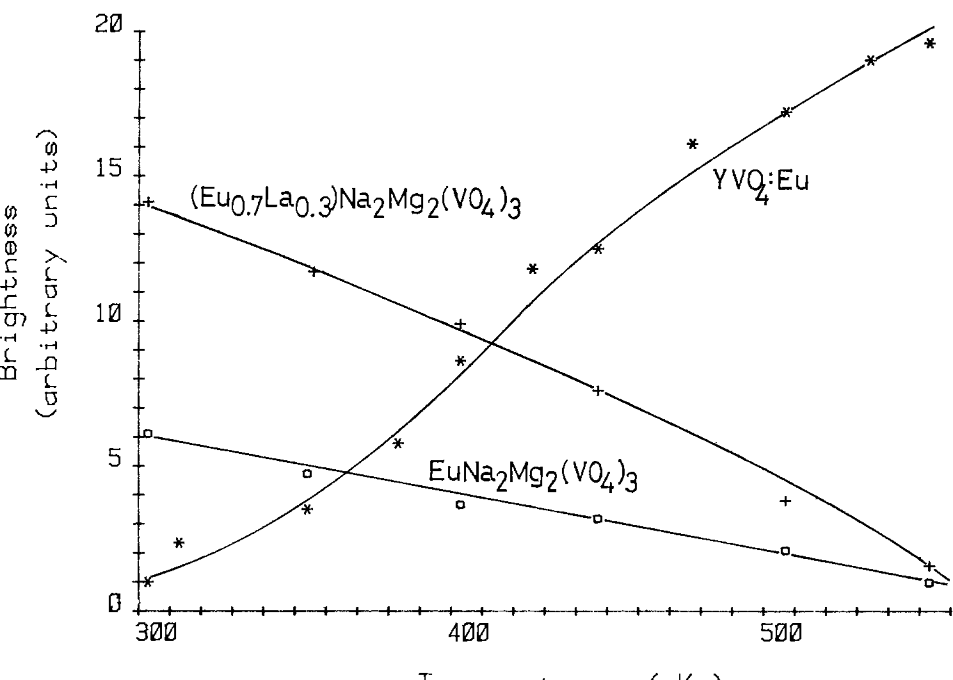

Fig. 2. Temperature dependence of brightness under 365 nm light excitation at room temperature. (□) $EuNa_2Mg_2(VO_4)_3$, (+) $Eu_{0.7}La_{0.3}Na_2Mg_2(VO_4)_3$, and (*) YVO_4:Eu. Brightness is normalized at the value of YVO_4:Eu at room temperature.

sured for $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$, ($x$ = 1, 0.5, and 0.1) from 77° to 600°K.

The decay characteristics depend on both the Eu concentration and temperature. Some examples are shown in Fig. 5. The decay curves are nearly exponential when the Eu concentration and temperature are both sufficiently low or high. In other regions [for example, at a low Eu concentration (x = 0.1) and a high temperature (above 650°K), or at a high Eu concentration (x = 1.0) and an intermediate temperature (near 500°K)] decay curves are strongly nonexponential. However, at long times after the excitation pulse, an exponential component is observed. This component probably originates in diffusion-limited relaxation and its rate is written as

$$1/\tau = 1/\tau_0 + 1/\tau_D \qquad [1]$$

where $1/\tau_0$ is the radiative decay rate and $1/\tau_D$ is the decay rate due to diffusion. The exponential decay rate, $1/\tau$, is plotted against temperature in Fig. 6. It increases with increasing temperature as indicated by a decrease in the excitation-line intensity at 464 nm (Fig. 4). The temperature dependence of the decay rates differs greatly in the two regions. Below 500°K, the decay rate shows relatively small changes with temperature. At 77°K the decay rates are nearly the same for the three Eu concentrations. This value should be the intrinsic radiative transition probability. Above 500°K the decay rate increases greatly. The nonradiative decay added to the lower temperature rate is insensitive to the Eu concentration. The activation energy is $(9 \pm 1) \times 10^3$ cm^{-1} for the three concentrations. This behavior forms a sharp contrast with that in the lower temperature region, where nonradiative decay increases greatly with the Eu concentration. The result given in Fig. 4 shows that the most important factor on thermal quenching is energy loss within Eu^{3+} ions. The loss processes take place

Fig. 3. Excitation spectra of $EuNa_2Mg_2(VO_4)_3$ at various temperatures. Luminescence intensity was monitored at 610 nm with a bandwidth of 1 nm.

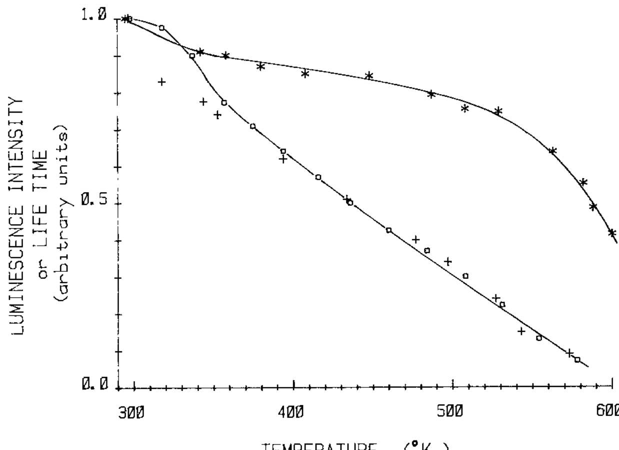

Fig. 4. Temperature dependence of the $^5D_0$ lifetime (*); the $^5D_0$ luminescence intensity excited by 464 nm light, which corresponds to the $^7F_0 \rightarrow {}^5D_2$ transition (□); and the $^5D_0$ luminescence intensity under 365 nm excitation corresponding to the VO_4^{3-} absorption (+). The data are normalized to room temperature values. The $^5D_0$ luminescence intensity under 464 nm excitation was obtained by an integration of excitation peak in Fig. 3. The intensity under 365 nm excitation was obtained independently by using a high pressure Hg lamp.

(b) $x = 0.5$; curve d, 77°K; curve e, 443°K; and curve f, 645°K. (c) $x = 0.1$; curve g, 77°K; curve h, 385°K; and curve i, 680°K. Note how decay curves deviate from exponential forms indicated by broken straight lines.

mainly at the $^5D_0$ state, as shown in Fig. 6. In general, the energy-level structure of Eu^{3+} is unfavorable for quenching of $^5D_0$ emission by multiphonon emission, since $^5D_0$ is widely separated from the highest metastable state $^7F_6$. In fact, it is rather unusual that the lifetime of $^5D_0$ gets shorter with increasing temperature. As a comparison, the $^5D_0$ lifetimes of various compounds including Eu^{3+} were measured as functions of temperature. The studied materials are (*i*) "stoichiometric" materials, EuP_5O_{14}, $EuNa_5(MoO_4)_4$, and $EuNa_5(WO_4)_4$; (*ii*) Eu compounds with a normal distance (3-4Å) between the nearest Eu ions, $EuPO_4$, $EuVO_4$, $EuA(MoO_4)_2$ with A = Na, K, Rb, or Cs, and $EuK_5(MoO_4)_4$; and (*iii*) a doped material, YVO_4:Eu (4%). The decay rates of YVO_4:Eu, $EuPO_4$, and the "stoichiometric" materials are nearly independent of temperature from room temperature to 680°K. The decay rate of $EuVO_4$ decreases from room temperature to 450°K, but at higher temperatures stays constant (Fig. 7). On the other hand, $EuA(MoO_4)_2$ and $EuK_5(MoO_4)_4$ show drastic increases in the decay rate with increasing temperature above 500°K, just as $(Eu, Y)Na_2Mg_2(VO_4)_3$ does (see Fig. 8).

Here we add a brief description of decay characteristics. The "stoichiometric" compounds and the doped phosphor, YVO_4:Eu, show nearly single exponential decays. Other compounds show more or less nonexponential decays. Since in most cases, the tail of a decay curve can be reasonably approximated as exponential, its decay rate was taken as the representative value and plotted in Fig. 7 and 8. The decay curve of $EuPO_4$ is composed of two exponential parts with comparable intensities. For convenience, the smaller rate is given in Fig. 7. The compounds, $EuNa(MoO_4)_2$,

Fig. 6. Temperature dependence of decay rates for $Eu_xY_{1-x}Na_2Mg_2(VO_4)_3$. (□) $x = 1.0$, (*) $x = 0.5$, and (+) $x = 0.1$. In the inset, the lower temperature region for $x = 1.0$ is magnified. The ordinate of the inset figure is the nonradiative decay rate, $1/\tau - 1/\tau_0$, where $1/\tau$ is the observed decay rate and $1/\tau_0$ is the radiative decay rate, 1.15×10^3 cm^{-1}, indicated by the dash-dot line at the bottom of the main figure. The solid curve in the inset was calculated according to Weber's formula (see text).

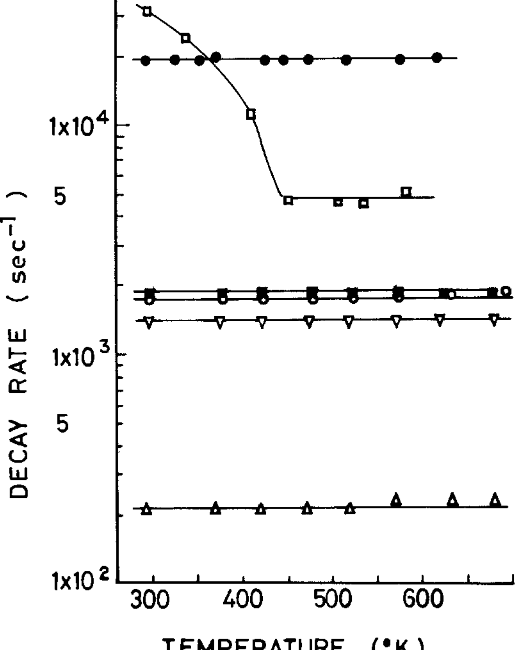

Fig. 7. Temperature dependence of decay rates. (△) EuP_5O_{14}, (▽) $EuNa_5(WO_4)_4$, (○) $EuNa_5(MoO_4)_4$, (■) YVO_4:Eu, (●) $EuPO_4$, and (□) $EuVO_4$.

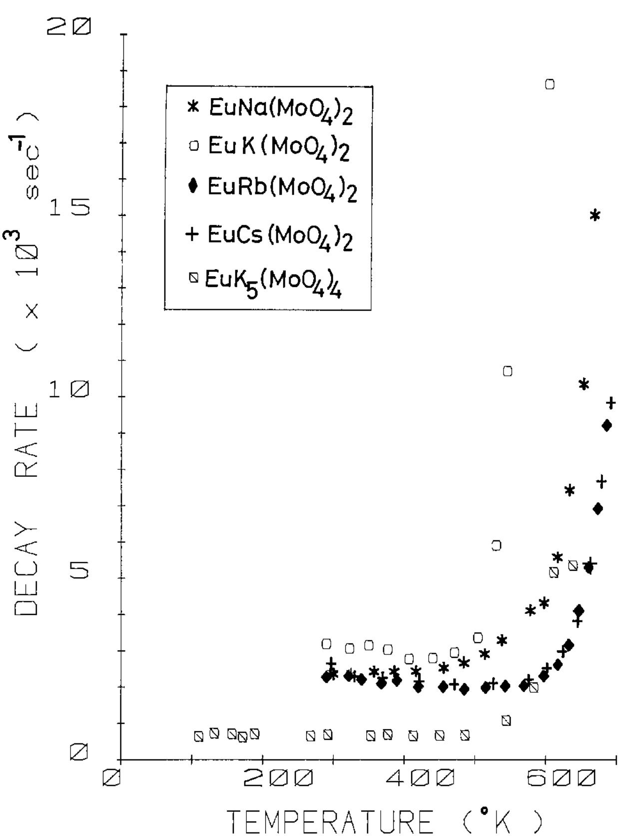

Fig. 8. Temperature dependence of decay rates. (*) EuNa-(MoO)$_4$)$_2$, (□) $EuK(MoO_4)_2$, (♦) $EuRb(MoO_4)_2$, (+) $EuCs(MoO_4)_2$, and (⧅) $EuK_5(MoO_4)_4$.

$EuK(MoO_4)_2$, and $EuK_5(MoO_4)_4$ have fast components in the initial period of decay. The decay rate was determined at the tails of the curves. This is good approximation below about 400°K since the intensity of the fast component is not large. However, as the thermal quenching occurs, the whole decay curve looks like the sum of two or more components of comparable intensity. Fitting with an exponential form is only moderately good. In Fig. 8, the slowest component within the measured time span (0.2-1 msec) is plotted. In their initial periods, $EuRb(MoO_4)_2$, $EuCs(MoO_4)_2$, and $EuVO_4$ also show fairly strong fast components. The slower components, however, can be fitted with exponential forms even above 500°K.

These characteristics suggest that there are complicated factors controlling decay curves in these materials.

Luminescence line widths.—The widths of Eu^{3+} luminescence lines were measured at 77°K for $EuNa_2Mg_2(VO_4)_3$ and the compounds shown in Fig. 7 and 8 as a means of checking the regularity of the crystal field around Eu^{3+} ions. A convenient probe is the strongly forbidden $^5D_0 \rightarrow {}^7F_0$ line, which usually has a width of less than a few cm^{-1}. The results are given in Table I. The compounds $EuNa_2Mg_2(VO_4)_3$, $EuNa(MoO_4)_2$, $EuK(MoO_4)_2$, $EuRb(MoO_4)_2$, and $EuK_5(MoO_4)_4$ show inhomogeneous broadening, while the other compounds have normal narrow lines. It has been reported that $EuK_5(MoO_4)_4$ has a disordered lattice, in which Eu^{3+} and K^+ are randomly distributed at equivalent sites (9). Therefore, it is most straightforward to assume that $EuNa_2Mg_2(VO_4)_3$ is also a disordered compound. These compounds show a decrease in the $^5D_0$ lifetime with temperature (Fig. 6 and 8). An exception is $EuCs(MoO_4)_2$, which shows a decrease in the $^5D_0$ lifetime in spite of normal narrow widths at 77°K. So far, no phase transition has been found on this compound (10).

Table I. Half-widths of $^5D_0 \rightarrow {}^7F_0$ emission lines at 77°K. For materials marked with (*), half-widths of $^5D_0 \rightarrow {}^7F_1$ lines are given, since $^5D_0 \rightarrow {}^7F_0$ lines were not found.

Materials	Line width (cm^{-1})
YVO_4:Eu	2.3
EuP_5O_{14}	3.5
$EuNa(MoO_4)_2$	14.3
$EuK(MoO_4)_2$	11.8
$EuRb(MoO_4)_2$	13.3
$EuCs(MoO_4)_2$	4.1*
$EuNa_5(WO_4)_5$	4.0*
$EuK_5(WO_4)_5$	16.7
$EuNa_2Mg_2(VO_4)_3$	14.7

Raman spectra.—Raman spectra of powder samples were measured at room temperature as another means of observing lattice irregularity. In this experiment, $YNa_2Mg_2(VO_4)_3$ and YVO_4 were compared with each other. The Raman spectrum of single crystal YVO_4 has been measured and its assignment is well established (11). Our powder Raman data agree well with the crystal data.

The spectrum of $YNa_2Mg_2(VO_4)_3$ is similar to the published spectrum of Na_3VO_4 (12) in the number and energies of the lines. As the symmetry of VO_4^{3-} in Na_3VO_4 is T_d, that of VO_4^{3-} in $YNa_2Mg_2(VO_4)_3$ is also T_d in the first approximation. The half-widths of the YVO_4 lines are 2-3 cm^{-1}; the lines of $YNa_2Mg_2(VO_4)_3$ are much broader, with the half-widths of 10-15 cm^{-1}. This result suggests that the structure of VO_4^{3-} in $YNa_2Mg_2(VO_4)_3$ fluctuates statistically around the average configuration with the T_d symmetry. If Y^{3+} and Na^+ ions randomly occupy the dodecahedral site, their disordered arrangement will cause a weak distortion from T_d. In this sense, the Raman spectrum is not inconsistent with the disordered arrangement.

Calculation of x-ray powder diffraction intensities.—In the previous sections, a disordered distribution of Eu^{3+} and Na^+ was assumed based on spectroscopic data. To confirm this assumption, x-ray powder diffraction intensities were calculated for both ordered and disordered distributions. Calculation was performed by a computer program which outputs diffraction angles, interplanar spacings, Miller indexes, and intensities. Input data were obtained by the following procedures. Atomic positions of lattice points were cited from the work of Wyckoff (12). The positions of the Eu sites in the ordered distribution were uniquely determined by the two conditions: (*i*) eight Eu ions are positioned in 24 dodecahedral sites in a unit cell in such a way that each ion is separated from the others as far as possible, and (*ii*) translational symmetry is reserved.

In the disordered distribution, Eu^{3+} and Na^+ ions randomly occupy 24 sites with occupation probability of 1:2. Therefore, the atomic scattering factor, f, of the site was assumed to be a weighted average of the scattering factors of Eu and Na

$$f = (1/3)f_{Eu} + (2/3)f_{Na} \qquad [2]$$

The calculated diffraction intensities are plotted against the Miller indexes in Fig. 9. When normalized at the strongest line, line intensities in the disordered distribution are, in general, smaller than those in the ordered distribution. In addition, one finds some vanishing lines in the disordered distribution. They are (101) to (211) at small angles, (321), (631), (721), and (732).

The observed diffraction pattern (open circles in Fig. 9) resembles the disordered distribution pattern (filled triangles) more than the ordered distribution (open triangles). Therefore, the assumed disordered distribution seems plausible.

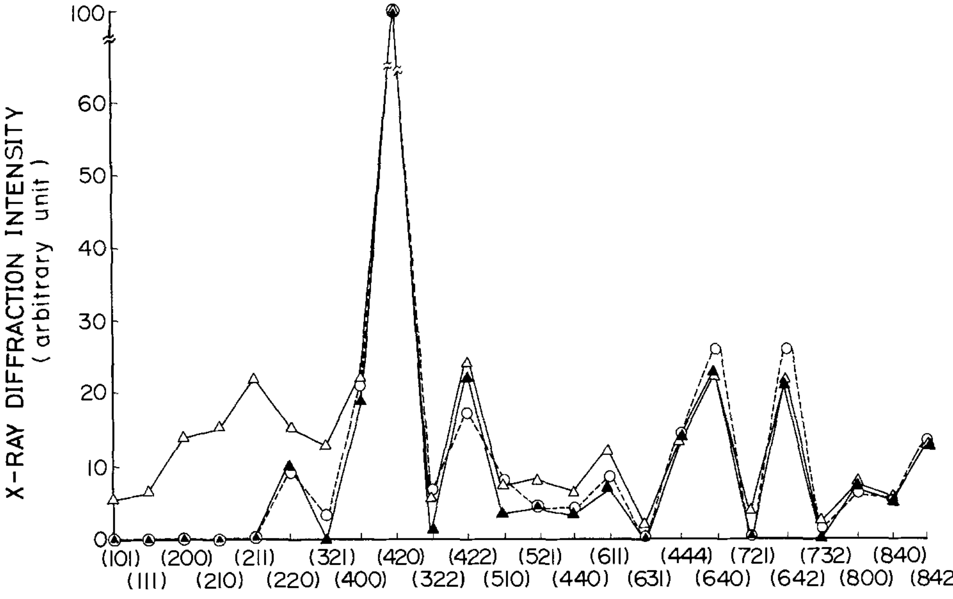

Fig. 9. Powder x-ray diffraction intensities. (○) Observed, (△) calculated for the ordered distribution, and (▲) calculated for the disordered distribution.

According to this result, the shortest distance between Eu ions is not 6.2Å as expected for the ordered "stoichiometric" compound, but only 3.8Å. With such a short minimum separation, the characteristics typical of a "stoichiometric" compound should no longer be retained.

This statement does not seem consistent with the fact that the optimum Eu concentration is nearly as high as that in "stoichiometric" compounds. A picture which may help understanding this point was proposed by Sommerdijk, Bril, and Hoex-Strix (13). They found that, in $NaCa_2Mg_2(VO_4)_3$:Dy^{3+} which also has garnet structure, the optimum Dy concentration is about 20%. The high concentration was explained as resulting from inefficient energy transfer from host lattice to Dy^{3+}. In (Eu, Y)$Na_2Mg_2(VO_4)_3$ as well, energy transfer from VO_4^{3-} to Eu^{3+} is not efficient. This is shown by an observation that green emission from the VO_4^{3-} group is seen at high Eu concentrations such as 50%. Therefore, the above picture will work also in this case.

Discussion

The increase in the $^5D_0$ decay rate with increasing temperature is presumably caused by an increase in nonradiative decay rate, because the luminescence intensity decreases with temperature. In this section, possible mechanisms for these nonradiative processes are discussed.

As previously stated, the $^5D_0$ decay rate of (Eu, Y) $Na_2Mg_2(VO_4)_3$ depends on the temperature and Eu concentration in different ways in two temperature regions. Below 500°K, the decay rate depends strongly on the Eu concentration, and is, therefore, caused by interionic interaction. Above 500°K, the nonradiative decay rate added to the lower temperature rate is insensitive to the Eu concentration, which indicates that the nonradiative decay takes place within each ion.

Several processes have been proposed as candidates for the thermal quenching mechanism of $^5D_0$ luminescence. These include (*i*) nonradiative decay via a charge-transfer state which has a crossover point with the $^5D_0$ and ^7F_J states (14), and (*ii*) temperature-dependent diffusion of the $^5D_0$ states to quenching centers.

Multiphonon emission from $^5D_0$ can be neglected because the lattice vibration frequencies in $YNa_2Mg_2(VO_4)_3$ are not particularly high (section on Raman spectra). It is tempting to think that a phase transition might occur at the temperature dividing the two regions, since the decay rate builds up very steeply at around 500°K. We checked this possibility by measuring powder x-ray diffraction patterns and thermal differential analysis. However, no evidence was found to support that there is a phase transition.

After these possibilities are ruled out, the quenching characteristics above and below 500°K can be most reasonably ascribed to the above-mentioned (*i*) and (*ii*), respectively.

In the following, the temperature dependences in the two regions are discussed separately in more detail.

The lower temperature region.—Temperature-dependent decay of $^5D_0$ has been well studied in glasses containing Eu^{3+} ions. It is useful to recall here the mechanisms proposed for energy migration in glasses. In 1971 Weber (15) proposed a model in which energy migrates efficiently only between the transitions $^5D_0 \rightarrow {}^7F_1$, $^7F_2$ and $^7F_1$, $^7F_2 \rightarrow {}^5D_0$ because the $^5D_0 \rightarrow {}^7F_0$ transition is strongly forbidden. This mechanism requires thermal population of the metastable states $^7F_1$ and $^7F_2$ and gives rise to strong temperature dependence of the $^5D_0$ decay rate. Essentially the same mechanism was considered by Takushi and Kushida (16) in their work on a $Ca(PO_3)_2$:Eu glass.

We tested this model following the procedure shown by Weber. The nonradiative decay rate by diffusion, $1/\tau_D$, is given by

$$1/\tau_D = 4\pi D\cdot q\cdot \rho \qquad [3]$$

where D is a diffusion constant, q the concentration of sinks, and ρ the interaction distance between an energy donor and a sink. When energy transfers from a donor to a sink by dipole-dipole interaction, ρ can be expressed as

$$\rho = 0.68(C/D)^{1/4} \qquad [4]$$

where C is an interaction constant.

The temperature dependence of D was calculated according to an approximation which considers only the thermal population of ^7F_J states

$$D \propto \Sigma_f g_f\cdot \exp(-E_f/kT)\,(g_f/g_i)\,(f_{ij}^2/\nu_{ij}^2\cdot \Delta\nu_{ij}) / \Sigma_f g_f\cdot \exp(-E_f/kT) \qquad [5]$$

where E is the energy of a level, f_{ij} the oscillator strength, ν_{ij} the frequency, and $\Delta\nu_{ij}$ the line width, all of the transition between an ith and jth levels, and g the degeneracy of a level. Among the ground states, $^7F_0$, $^7F_1$, and $^7F_2$ become significantly populated near or above room temperature. The right-hand side of Eq. [5] was calculated by using f_{ij}'s obtained from

the observed radiative decay rate ($1/\tau_0$), 1.15×10^3 sec^{-1}, and branching ratios. From Eq. [3] and [4], one finds $1/\tau_D \propto D^{3/4}$. Accordingly, the 3/4 power of D is compared with the observed ($1/\tau - 1/\tau_0$) in the inset of Fig. 6. Thermal broadening of homogeneous line width was neglected. The agreement between the predicted temperature dependence and the measured variation of $1/\tau_D = (1/\tau - 1/\tau_0)$ is satisfactory. Therefore, it can be concluded that the above model essentially accounts for the observed result in the lower temperature region. Phonon-assisted energy transfer no doubt occurs between mismatched energy levels. However, it does not seem necessary to take into account this mechanism to explain the measured variation of the decay rates.

Energy migration via thermally populated $^7F_1$ and $^7F_2$ states could occur in any concentrated Eu compounds if the separation between Eu ions is small enough. The fact is that the increase in the decay rates with temperature observed for $EuNa_2Mg_2(VO_4)_3$ was not found for other disordered compounds, such as $EuK_5(MoO_4)_4$, or for $EuPO_4$ and $EuVO_4$. All these compounds show strongly nonexponential decay curves and these decay characteristics do not change with temperatures below 500°K. This is an indication of little energy migration among $^5D_0$ states in these compounds. It seems that a high Eu concentration and a small distance between nearest neighbor ions are necessary but not sufficient conditions for energy migration.

The higher temperature region.—As stated before, the drastic nonradiative process above 500°K proceeds through a thermally populated charge-transfer state (CTS). The activation energy of the decay rate observed for $EuNa_2Mg_2(VO_4)_3$ (9×10^3 cm^{-1}) is within a reasonable region to be explained by the configurational coordinate model. It is comparable to the activation energy in $LaAlO_3$:Eu (1.4×10^4 cm^{-1}) (17) or in La_2O_2S:Eu (1×10^4 cm^{-1}) (18). The higher excited states, $^5D_1$ and $^5D_2$, are deactivated at lower temperatures by the same mechanism, which explains a trend that the $^5D_0$ luminescence intensity excited at the $^7F_0 \rightarrow {}^5D_2$ transition decreases more than the $^5D_0$ lifetime does (see Fig. 4).

There is, however, a difficulty that the CTS is not found in excitation and reflection spectra up to 300 nm (section on relative luminescence intensities). Within the framework of the configurational coordinate model, the only way to avoid this difficulty is to assume that the CTS has large Franck-Condon offset. An example of the effect of offset on thermal quenching is given by the recent work of de Hair and Blasse (19). Large offset is realized, when the CTS can spatially expand or, specifically in this case, when a cation sharing an oxygen with Eu^{3+} is loosely bonded with the oxygen. All the materials which show the thermal quenching under consideration contain alkali ions. As is well known, alkali ions become mobile in many compounds through vacancies, dislocations, or interstitial sites at sufficiently high temperatures. Even if they do not really jump from one site to another, they will have large amplitude of oscillation. In other words, an alkali-oxygen bond is weakened at high temperatures.

As a preliminary check of ionic conductivity, a-c conductivity was measured on sintered $EuNa_2Mg_2(VO_4)_3$ and $EuK(MoO_4)_2$, and on a single crystal $EuCs(MoO_4)_2$. The conductivity was measured by a conventional method at 1V peak-to-peak voltage with a frequency of 1 kHz. When the temperature is varied from 670° to 770°K, the conductivity of $EuNa_2Mg_2(VO_4)_3$ changes from 2×10^{-7} to 8×10^{-6} $(\Omega\ cm)^{-1}$, and that of $EuK(MoO_4)_2$ changes from 4×10^{-7} to 3×10^{-6} $(\Omega\ cm)^{-1}$. The conductivity of $EuCs(MoO_4)_2$ changes from 1×10^{-7} to 5×10^{-7} $(\Omega\ cm)^{-1}$ in the range of 520°-670°K. These values are of the same order of magnitude as the conductivity of a regular ionic conductor, LiF (20). This fact indicates that a small fraction of alkali ions actually moves in the lattices. In this respect, there is some reason to propose the above hypothesis.

Among the compounds studied here, the disordered materials seem to favor the characteristic thermal quenching. A reason one can speculate is that strain caused by expansion of an Eu-O bond is more easily accommodated in disordered lattices than in ordered lattices.

The most straightforward way to test this hypothesis is to measure luminescence quenching in an ordered phase. Attempts were made to prepare the ordered phase of $EuNa_2Mg_2(VO_4)_3$ by annealing. Modification of chemical composition was also tried to search for ordered vanadates with garnet structure. However, these experiments were unsuccessful.

Conclusions

The dominant factor of the thermal quenching of luminescence from $EuNa_2Mg_2(VO_4)_3$ is nonradiative processes working on the emitting states of Eu^{3+}. Dependence of the decay rate on temperature and Eu^{3+} concentration differs very much in the two temperature regions: below and above 500°K. Below 500°K energy diffusion among Eu^{3+} ions increases the decay rate. Optical and powder x-ray diffraction data show that Eu^{3+} and Na^+ ions are randomly distributed on the dodecahedral sites in the garnet structure. The shortest distance between Eu^{3+} ions has a normal value of 3.8Å, which is not as large as would be expected in an ordered state. The short minimum distance between Eu^{3+} ions makes energy diffusion possible. Above 500°K nonradiative relaxation occurs inside single Eu^{3+} ions. This is tentatively explained by a model in which the $^5D_0$ state is deactivated through a thermally populated charge transfer state. The most reasonable explanation of the nonradiative process above 500°K is that the adiabatic potential curve of the Eu^{3+} charge transfer state has large offset, because of soft surrounding of Eu^{3+}. A similar thermal quenching characterized by a drastic increase in $^5D_0$ decay rates is also found for several disordered Eu alkali molybdates. The result suggests that the charge transfer state can expand easily in Eu alkali compounds, particularly when ions are randomly distributed.

Acknowledgments

Possible correlation between luminescence quenching and ionic conductivity was suggested by Dr. Hidehito Ohbayashi. He also measured electrical conductivity on the authors' samples. His inspiring suggestion and cooperation in experiments are very much appreciated. The authors are indebted to Mr. Hideji Fujii who developed the computer program to calculate powder x-ray diffraction intensities, and to Dr. Toshikazu Shimada who built a setup for powder Raman spectroscopy. In the initial stage of this work, Dr. Atsushi Suzuki, Dr. Tadashi Fukuzawa, and Mr. Osamu Kanehisa contributed to optical measurements and discussions. Helpful discussions with Dr. Koichi Urabe and Mr. Yasutoshi Kashiwada are also acknowledged.

The D-C MOSFET Dopant Profile Method

M. G. Buehler

National Bureau of Standards, Electron Devices Division, Washington, D.C. 20234

ABSTRACT

Dopant profiles can be determined from d-c measurements on a four-terminal surface-channel MOSFET. The region from about three Debye lengths from the oxide-silicon interface to a maximum depth, limited by the avalanche breakdown in silicon, can be profiled by this method. Within three Debye lengths of the surface, the depletion approximation fails, and in this region the profile has a characteristic dip which is easily recognized. Other limitations include effects due to the field dependence of the channel mobility, short channel effects, and the lack of parallelism of the depletion edge with the interface. The method is illustrated by dopant profiles of bulk wafers, implanted layers, and a diffused layer. The dopant densities covered by these profiles vary from 6×10^{14} cm^{-3} to 2×10^{18} cm^{-3}.

The feasibility of measuring dopant profiles by analyzing the d-c characteristics of a MOSFET was reported previously (1, 2). Because the measurement requires the use of direct currents, it is easily implemented with automated data acquisition equipment that is normally used to measure the traditional MOSFET electrical characteristics. In this paper the method is applied to the measurement of dopant profiles that cover the range from 6×10^{14} cm^{-3} to 2×10^{18} cm^{-3}. Examples of measurements on homogeneous, diffused, and implanted layers are given. This paper explores the various factors that influence the measurement of the dopant profiles.

The MOSFET d-c profiler utilizes a four-terminal surface-channel MOSFET for evaluating the dopant density in the silicon under the gate (1, 2). The dopant profile is obtained by sequentially moving the depletion region through the silicon by using the back-gate bias effect. As the gate-source voltage, V_{GS}, is changed, the drain-source current, I_{DS}, is held constant by adjusting the source-body voltage, V_{SB}. These voltages plus the silicon and oxide dielectric constants and the oxide thickness are sufficient to compute the dopant profile.

Dopant Profile Equations

The profile equations can be derived for the case of uniformly doped silicon by assuming that the depletion approximation (3) is valid and by ignoring charge in the oxide, interface states, and work function differences between the metal and silicon. These are unimportant factors as long as they are stable quantities. Consider a surface-channel MOSFET operated with a negligibly small drain-source voltage, V_{DS}. For this condition, the following derivation assumes that the gate-channel and channel-body voltages are equivalent to the gate-source voltage, V_{GS}, and the source-body voltage, V_{SB}, respectively.

Key words: semiconductor, diffusion, implantation.

At the oxide-silicon interface the solution to Poisson's equation using Gauss' law yields

$$Q_o = qn_s + Q_b \qquad [1]$$

where n_s is the inversion-layer charge density per unit area, Q_o is the charge per unit area on the gate, Q_b is the charge per unit area induced at the interface by the charge in the depletion region, and q is the electronic charge. If the charge in the inversion layer is held constant as V_{GS} is varied, Eq. [1] becomes

$$dQ_o/dV_{GS} = dQ_b/dV_{GS} \qquad [2]$$

because $dn_s/dV_{GS} = 0$. This reveals the essence of the measurement; that is, the change in the charge on the gate balanced by the change in the charge induced at the interface due to the charge in the depletion region of the silicon. This is achieved by adjusting V_{SB} at each new V_{GS} value so that n_s is constant.

The additional relationships needed in the derivation are given next. In the oxide

$$Q_o = \epsilon_o E_o = \epsilon_o (V_{GS} - 2\psi_b)/X_o \qquad [3]$$

where ϵ_o is the oxide dielectric constant, E_o is the oxide electric field, X_o is the oxide thickness, and ψ_b is the bulk potential difference between the Fermi level and intrinsic Fermi level. For a one-dimensional model, Poisson's equation and Gauss' law yield

$$Q_b = qNW \qquad [4]$$

where N is the dopant density and W is the width of the depletion region in the silicon. Assuming the inversion layer approximates a one-sided step junc-

tion (3), one obtains

$$V_{SB} + 2\psi_b = (qN/2\epsilon_s)W^2 \quad [5]$$

where ϵ_s is the silicon dielectric constant.

The combination of Eq. [2]-[5] can be manipulated to obtain the dopant profile equations

$$W_m = (\epsilon_s X_o/\epsilon_o)(dV_{SB}/dV_{GS}) \quad [6]$$

and

$$N_m(W_m) = (\epsilon_o^2/q\epsilon_s X_o^2)/(d^2V_{SB}/dV_{GS}^2) \quad [7]$$

where the subscript m refers to quantities derived from the measured voltages, V_{SB} and V_{GS}. Although these equations were derived for a uniform dopant density, it has also been shown that they are valid for an arbitrary dopant density (1).

In the actual measurement of a dopant profile the inversion layer charge, n_s, is presumed to be held constant by maintaining a constant drain-source current, I_{DS}. The success of this assumption and others can be judged from the current expression for the MOSFET operated in the linear range ($V_{DS} < 2\psi_b$)

$$I_{DS} = qn_s\mu(Z/L)V_{DS} \quad [8]$$

where μ is the channel mobility, Z is the channel width, and L is the channel length. In order for the profile equations to be valid, certain assumptions must be maintained. These are listed in Table I. Also listed is the effect on the dopant profile of violating an assumption. If these assumptions hold, then the channel current is proportional to n_s and holding I_{DS} constant holds n_s at a fixed value.

Channel Mobility Effect

The measured dopant profiles are influenced by the field dependence of the channel mobility. A model for this effect follows from the measurement constraint that $dI_{DS}/dV_{GS} = 0$. The combination of this constraint with Eq. [1], [3]-[8] leads to the expressions for the true depletion width

$$W = W_m/(1 - F_1) \quad [9a]$$

where

$$F_1 = G_{DS}(X_o/\epsilon_o)(L/Z)(d\mu^{-1}/dV_{GS}) \quad [9b]$$

and for the true dopant density

$$N = N_m(1 - F_1)^2/(1 + F_2) \quad [10a]$$

where

$$F_2 = G_{DS}(qN_mWX_o^2/\epsilon_o^2)(L/Z)(d^2\mu^{-1}/dV_{GS}^2) \quad [10b]$$

In these expressions G_{DS} is the channel conductance given by $G_{DS} = I_{DS}/V_{DS}$.

The magnitude of the effect on the measured dopant density can be estimated from an empirical expression (4) for the channel mobility in a MOSFET operated in the linear range

$$\mu = \mu_o/[1 + \theta(V_{GS} - V_T)] \quad [11]$$

where μ_o is the zero-field channel mobility, θ is a coefficient, and V_T is the threshold voltage. The combination of Eq. [10] and [11] yields

$$N = N_m(1 - RG_{DS})^2 \quad [12a]$$

where

Table I. Effect of the violation of the ideal assumptions on dopant profiles

Parameter	Ideal assumption	Effect
Channel mobility, μ	$\mu \neq \mu(V_{GC})$	Increase in N_m
Channel charge density, n_s	Sheet of charge	Dip in N_m near interface
Channel length, L	$Q_b = qNW$	Negative slope of profile
Channel width, Z	No fringing fields	No effect for circular MOSFET
Drain-source voltage, V_{DS}	Depletion edge parallel to interface	Fall-off of profile near interface

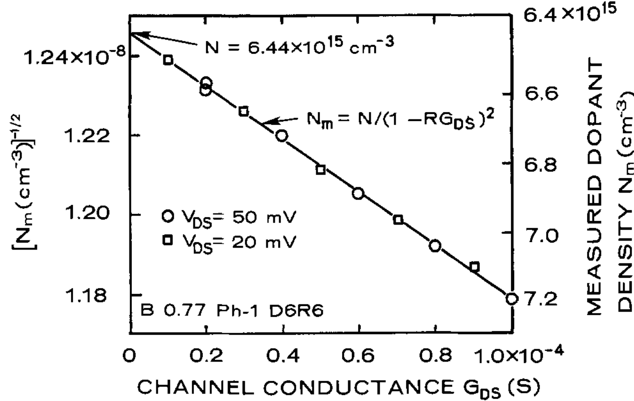

Fig. 1. Influence of the channel conductance on the measured dopant density. The intercept at $G_{DS} = 0$ is the true bulk dopant density for this p-channel MOSFET fabricated in phosphorus-doped 0.77 Ω · cm silicon. For $G_{DS} = 0.2 \times 10^{-4}$S, the N_m value was taken from the flat portion of profile like the one shown in Fig. 4).

$$R = (X_o/\epsilon_o)(L/Z)(\theta/\mu_o) \quad [12b]$$

Notice that for the above mobility expression, $F_2 = 0$.

Experimental results for an n-type wafer are shown in Fig. 1 where N_m is plotted against G_{DS} for two values of V_{DS}. The fit of the data to the model is adequate which indicates that the expression in Eq. [11] is satisfactory. The true dopant density, N, is obtained from the zero-conductance intercept and the R-value is obtained from the slope. For this sample the effect is small; that is, a ten-fold change in G_{DS} caused only an 11% change in N_m. For other MOSFET's, the magnitude of this effect can be estimated from the resistance parameter, R, as given in Eq. [12b].

The effect of the electric field on the channel mobility was studied in other samples; the results are listed in Table II. The μ_o/θ ratio is also listed and was calculated from the R-values using the appropriate values for X_o, ϵ_o, and L/Z in Eq. [12b]. For the circular MOSFET's used in this study, $Z/L = 18.22$.

Depletion Approximation Limit

In deriving the profile equations, it is assumed that the depletion approximation is valid. This approximation assumes that the depletion layer is free of holes and electrons. For reverse bias values of V_{SB}, the inversion layer charge can be modeled effectively as a sheet of charge at the interface. For forward bias values of V_{SB}, the depletion width becomes smaller and the inversion layer charge spreads to take up a larger fraction of the depletion layer. As this happens, the depletion approximation no longer holds.

This effect was studied using a theoretical model (5) which assumes that p-type silicon is uniformly doped, that there is no work function difference, no interface states, no oxide charge, and negligible leakage currents. Under these conditions, the electric field in the oxide at the interface is

$$E_o = V_{GS}/X_o = (\epsilon_s/\epsilon_o)E_s(\psi_s) \quad [13]$$

where E_s is the electric field in the silicon at the interface for a surface potential ψ_s. The channel charge per unit area is given by

$$n_s = \int_0^{X_c} n(x)dx = \int_{\psi_o}^{\psi_s} [n(\psi)/E_s(\psi)]d\psi \quad [14]$$

Table II. Channel conductance parameters

Wafer	Type	Resistivity (Ω · cm)	N (cm⁻³)	R (Ω)	μ_o/θ (cm²/sec)
B3.0B-3	p	3.0	4.80×10^{15}	217	3.12×10^4
C21B-3	p	21	6.68×10^{14}	404	1.65×10^4
B0.77Ph-1	n	0.77	6.44×10^{15}	536	1.16×10^4

where X_c is the effective channel thickness, ψ_0 is the potential near the edge of the depletion region ($\psi_0 = 0.1\ \psi_b$), and ψ is the potential difference between the bulk and depletion layer intrinsic Fermi levels. The channel charge per unit volume is given by

$$n(\psi) = (n_i^2/N_A) \exp [\beta(\psi - V_{SB})] \quad [15]$$

where n_i is the intrinsic charge density, N_A is the acceptor density, and $\beta = q/kT$ where k is the Boltzmann constant and T is the temperature. The electric field in the silicon at the interface is given by

$$E_s(\psi) = (2qN_A/\epsilon_s\beta)^{1/2}F(\psi) \quad [16a]$$

where

$$F(\psi) = [e^{-\beta\psi} + \beta\psi - 1 + (n_i/N_A)^2(e^{\beta(\psi-V_{SB})} - \beta\psi - e^{-\beta V_{SB}})]^{1/2} \quad [16b]$$

For $T = 300K$ and a particular value of N_A, the above equations were solved to obtain V_{SB} as a function of V_{GS} at a fixed value of n_s. The computations required double-precision arithmetic and proceeded as follows. At a given value of V_{GS} and an estimated value of V_{SB}, Eq. [13] and [16] were solved for ψ_s by an iteration procedure. Then Eq. [14] was integrated and the resulting value of n_s was compared to a target value. From this comparison, a new value of V_{SB} was derived and the procedure repeated until n_s reached the target value.

Dopant profiles were obtained from Eq. [6] and [7] by numerically differentiating the $V_{SB} - V_{GS}$ table established by the above procedure. The results are shown in Fig. 2. The distance was normalized by the Debye length $\lambda = (2\epsilon_s/qN_A\beta)^{1/2}$. The results indicate that the failure of the depletion approximation causes a dip in the profile at a distance near 3λ from the interface. This dip is observed experimentally.

The profiles shown in Fig. 2 are different from the profiles determined from the pulsed capacitance technique for measuring dopant profiles using MOS capacitors (6). With this technique, the profiles simply rise within 2λ to 3λ of the interface (7).

Other Limitations

The MOSFET d-c profile measurements are influenced by a variety of other effects also indicated in Table I. A sloping depletion edge, fringing fields found at the ends of a linear MOSFET, and short channel effects (8) can distort the profiles. However, for the large circular MOSFET used in this study, these effects are negligible. As shown in the previous section, profiles are limited to distances greater than 3λ from the interface. The maximum depth is limited by avalanche breakdown of the channel to body, source to body, or drain to body junctions.

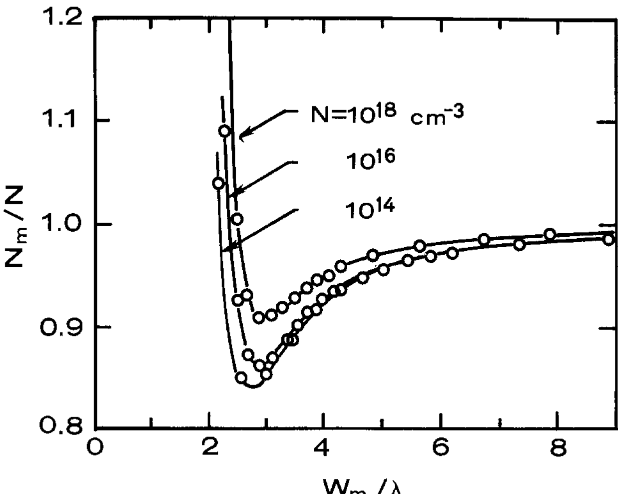

Fig. 2. Normalized dopant density profile showing the dip in the profile which is characteristic of the failure of the depletion approximation. This data was derived from a theoretical model where the dopant density was assumed to have a constant value, $N = 10^{14}$, 10^{16}, or 10^{18} cm^{-3}.

Experimental Results

The MOSFET used in this study has a circular geometry with a source radius of 216 μm (8.5 mil) and a drain radius of 305 μm (12.0 mil); the effective Z/L ratio is 18.22 (9). The oxide thickness was determined from 1 MHz capacitance measurements using a MOS capacitor located near the MOSFET. The experimental dopant profiles were obtained using the operational amplifier circuit described elsewhere (1). In this circuit V_{SB} is automatically adjusted as V_{GS} is incremented so that I_{DS} is held constant. The data acquisition is computer controlled as is the data reduction and presentation.

Two profiles are presented to illustrate the application of this method. The first profile, shown in Fig. 3, was obtained on a (111)-oriented 0.81 $\Omega \cdot$ cm boron-doped silicon wafer. The initial 0.35 μm thick pyrogenic oxide was grown at 1100°C for 50 min. Then a phosphorus source-drain was deposited at 950°C for 20 min which was followed by an 80 min diffusion-oxidation cycle at 1100°C. Finally, a boron channel stop was deposited at 1050°C for 15 min which was followed by a 35 min diffusion at 925°C. The total gate oxide thickness was 0.42 μm.

The boron redistribution effect (3) is clearly shown in Fig. 3 as is the dip in the profile near the surface. The dip in the profile near the surface is in qualitative agreement with the theoretical predictions shown in Fig. 2. Also shown in Fig. 3 is the 3λ limit curve and the zero-bias point for the profile. The profile begins to deviate from the expected profile (indicated by the solid line) near the zero-bias point. The profile is especially inaccurate for distances within 3λ of the interface.

The second profile, shown in Fig. 4, was obtained from a (111)-oriented 0.77 $\Omega \cdot$ cm phosphorus-doped silicon wafer. The initial 0.35 μm-thick pyrogenic oxide was grown at 1100°C for 30 min. Then a boron source-drain was deposited at 935°C for 35 min which was followed by an 85 min diffusion-oxidation cycle at 1100°C. Finally, a phosphorus channel stop was deposited at 1025°C for 15 min which was followed by a 35 min diffusion at 925°C.

The phosphorus pile-up effect (3) is quite apparent in Fig. 4 as is the dip in the profile near the surface. The expected profile is shown by the solid line. As with the previous example, this profile is reliable up to the zero-bias point and inaccurate for distances within 3λ of the interface.

A summary of various profiles is shown in Fig. 5 along with the 3λ, zero-bias, and breakdown (5) limits. The dip portion of a profile is shown by a dashed line. The boron profile (Fig. 3) is repeated as curve (d), and the phosphorus profile (Fig. 4) is

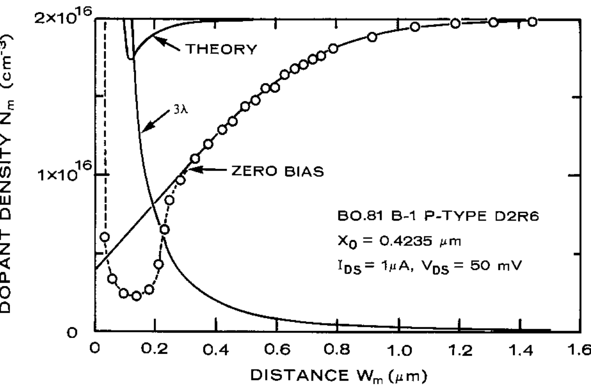

Fig. 3. Dopant profile of boron-doped 0.81 $\Omega \cdot$ cm silicon showing boron redistribution due to thermal oxidation.

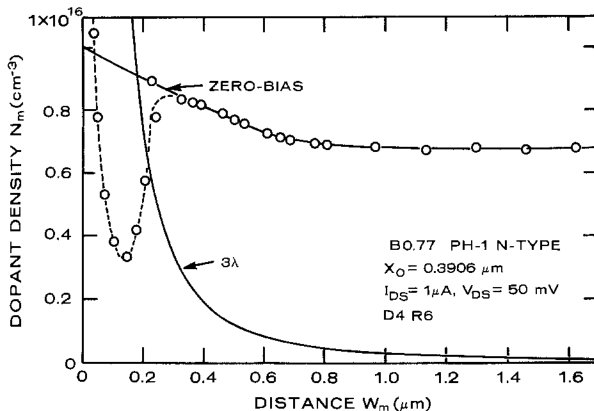

Fig. 4. Dopant profile of phosphorus-doped 0.77 Ω · cm silicon showing phosphorus pile-up due to thermal oxidation.

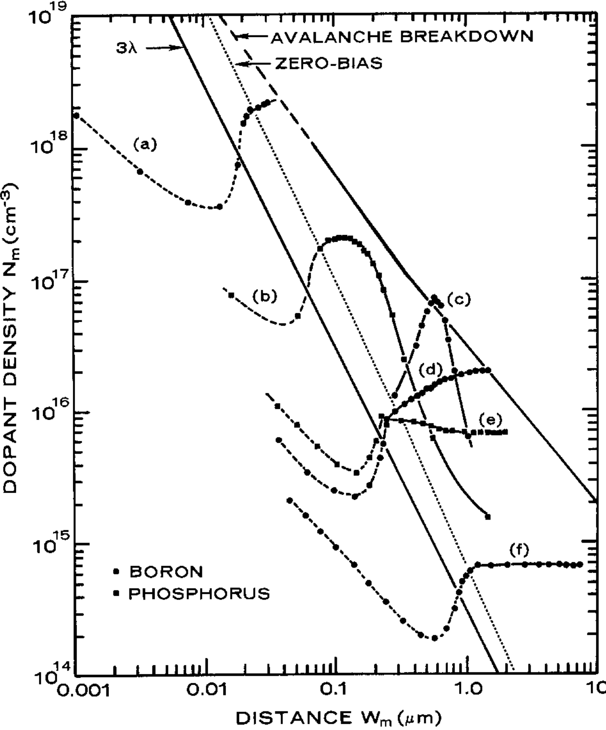

Fig. 5. Dopant profiles of curve (a) boron diffusion; curve (b) phosphorus implant; curve (c) boron implant; curve (d) boron-doped bulk (see Fig. 3); curve (e) phosphorus-doped bulk (see Fig. 4); and curve (f) boron-doped bulk.

repeated as curve (e). Curve (f) was obtained on a lightly doped boron wafer that was fabricated in a manner similar to the wafer whose profile is shown in Fig. 3. Curve (b) is a phosphorus layer implanted at 180 keV through a 0.1-μm-thick oxide layer to a dose of 4×10^{12} cm^{-2} and annealed at 900°C for 30 min in dry nitrogen. The starting wafer has a phosphorus density of 1×10^{15} cm^{-3}. Curve (c) is a boron layer implanted at 280 keV through a 0.1 μm-thick oxide layer to a dose of 2.6×10^{12} cm^{-2} and annealed at 900°C for 30 min in nitrogen. The starting wafer had a boron density of 3×10^{15} cm^{-3}. Both layers were implanted 7 degrees off the (111) axis of the silicon wafer. Curve (a) is the profile of a boron diffusion with a sheet resistance of 273 Ω/□ and a junction depth of 1.8 μm. A phosphorus source-drain was diffused into the boron layer to form the MOSFET. Only a small fraction of the entire diffusion profile is revealed and it lies between 0.02 and 0.03 μm from the interface.

Discussion

The profiles presented in this paper cover the dopant density range from 6×10^{14} to 2×10^{18} cm^{-3}. Of the various limitations discussed, the most important is the failure of the depletion approximation which prevents accurate profiles near the oxide-silicon interface. A unique dip in the profile identifies the region of erroneous data. A theoretical model explains the shape of the experimental observations but underestimates the magnitude of the effect.

The field dependence of the channel mobility can also influence the measurement of the dopant profile. This effect can be minimized by proper MOSFET design ($R \approx 0$) and by proper measurement conditions ($G_{DS} \approx 0$) as seen in Eq. [12]. The empirical mobility expression, Eq. [11], adequately describes the observed effect.

Future work involves the comparison of this method with other methods (for example, the diode C-V method). In addition, the short channel effect on the measure profiles is being studied with the use of MOSFET that are linear and more compact than those used in this study.

Silicon Oxidation Studies: Morphological Aspects of the Oxidation of Polycrystalline Silicon

E. A. Irene,* E. Tierney, and D. W. Dong

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Previous studies have shown that the oxide grown from polycrystalline silicon displays degraded reliability in terms of higher leakage current and premature dielectric breakdown as compared with the oxide grown from single crystal silicon. Present transmission electron microscope studies of the morphology of polycrystalline silicon films and the oxide grown therefrom show several novel features. The polycrystalline silicon becomes rougher after oxidation, the oxide displays thickness undulations which replicate the previous grain boundaries with thinner oxide over grain boundaries, and the oxide forms intergranularly as well as on the free silicon surface. Despite the intergranular oxide formation, the film skin of oxidized polycrystalline silicon does not become significantly more compressive. The surface roughness features of the polycrystalline silicon and oxide and the film stress values are explained by a Si creep mechanism. From these studies some aspects of the reliability of polycrystalline silicon and oxide are understood.

The thermal oxidation of polycrystalline silicon (poly-Si) is technologically important because the SiO_2 film produced from this oxidation, (from here on referred to as poly-OX), is needed to provide electrical isolation for conducting poly-Si lines and therefore the poly-OX must be a reliable, low conductivity, dielectric.

Kamins and MacKenna (1) have reported that at lower oxidation temperatures where the oxidation mechanism is predominantly surface reaction controlled, the rate of oxidation of poly-Si is characteristic of the random orientations of the poly-Si grains. The different oxidation rates across the surface would cause roughening. At higher oxidation temperatures where the oxidation is predominantly diffusion controlled, a smoother poly-Si surface is produced. Andersen and Kerr (2) have reported that the higher than expected electrical conductivity found for poly-OX films (3, 4) is due to Si asperities which they observed on the poly-Si surface and which can cause local electric field enhancement. It was also reported (2, 4) that higher temperature oxidation produces a lower conductivity poly-OX.

Based on these apparently concordant studies (1-4), it appears that the morphological and electrical characteristics of poly-OX are reasonably well understood. However, our recent transmission electron microscope (TEM) observations on poly-OX (5, 6) to be detailed in this paper, strongly suggest that the morphology of the poly-OX itself (rather than, or in addition to, the poly-Si morphology) can cause the observed high conductivities of poly-OX. Furthermore the origin of poly-Si surface irregularities is elucidated from the TEM observations. A better understanding of poly-Si and poly-OX evolves which is based on the growth of a morphologically complex oxide film, poly-OX.

The present study is essentially a morphological characterization of the oxide films grown as a result of thermal oxidation of poly-Si. As a first step, the poly-Si itself is characterized by TEM and our results are compared with some of the relevant literature. Doped and undoped poly-Si films are oxidized from 800° to 1200°C for short and long times and the morphological results compared. In addition film stress measurements were performed on the poly-Si and poly-OX films, since these measurements were needed to confirm the mechanisms deduced from the morphological observations.

Key words: oxidation, films, dielectric.

Experimental Procedures

Sample preparation.—Poly-Si films were deposited on thermally oxidized Si wafers by chemical vapor deposition, CVD, using gaseous SiH_4 diluted in N_2. The CVD reactor temperature was either at 650°C to prepare initially amorphous silicon films or at 800°C to prepare initially polycrystalline films. In this study TEM observations were made on undoped and $POCl_3$ doped films, prior to and after oxidation.

TEM.—For TEM observations on poly-Si and poly-OX films, the Si substrates and oxide on Si were removed by chemical etching using $HF-HNO_3$ mixtures by a previously outlined procedure (7) or by first prethinning using $HF-HNO_3$ then using pyrocatechol-ethylenediamine-H_2O mixtures at elevated temperatures (8) to remove single crystal and polycrystalline silicon but leaving oxide for observations, and thirdly ion milling was occasionally used as an additional method to insure that the TEM observations were independent of the sample preparation procedures.

In some cases the poly-Si samples were oxidized and then thinned for TEM observation, however we found it useful to first thin a poly-Si specimen for TEM observation and then to oxidize the specimen and reobserve the same specimen for oxidation effects. In this case oxidation occurred from both sides of the poly-Si samples. We found no essential differences between these procedures except for the extent of oxidation.

Film stress.—The film stress of poly-Si films on oxidized Si substrate wafers was measured before and after oxidation of the poly-Si so as to observe any sintering and oxidation effects on the residual film stress. The method was to observe substrate bending by means of counting the Newton rings which are produced by optical interference between an optical flat and the curved substrates. The exact method used was previously discussed (9).

Experimental Results

Morphology of poly-Si.—For chemically vapor deposited silicon films, the temperature for the deposition is important in determining whether the silicon film is amorphous or crystalline. Figure 1 shows as-deposited silicon films prepared at 650°C on an oxidized silicon surface in a resistance heated CVD system in 1(a) and in a radiant heated system in 1(b). In both cases the material is composed of small Si crystals imbedded in an amorphous Si matrix. The silicon deposited below 600°C appears to be totally

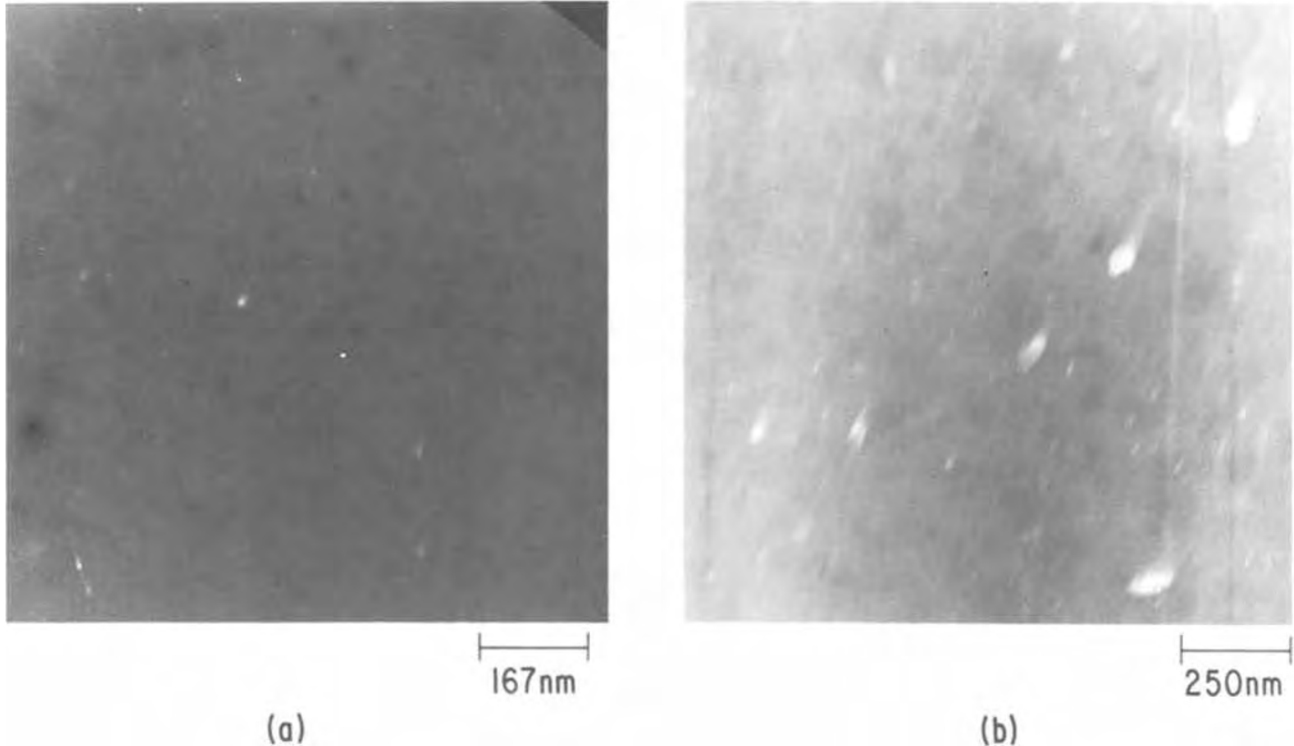

Fig. 1. Deflected aperature dark field TEM micrographs of poly-Si deposited onto an oxidized silicon substrate at 650°C by the decomposition of SiH_4 in (a) a resistance heated furnace and (b) a radiant heated system.

amorphous by TEM while at CVD temperatures above about 700°C the films are entirely polycrystalline. These results are similar to published TEM studies on Si films [see for example Ref. (10)]. The specific polycrystalline morphology is dependent upon the temperature and time of annealing and on doping (10, 11).

The changes which occur in poly-Si films as a result of oxidation heat-treatments are of particular importance in the present study. Figure 2 compares the poly-Si morphology for films prepared at 650°C in 2(a), (b), and (c) to films prepared identically but doped by $POCl_3$ deposition and drive-in at 900°C in 2(d), (e), and (f). All the samples were oxidized in dry O_2 to produce about 30 nm SiO_2 at 800°C for (a) and (d), 1000°C for (b) and (e), and 1100°C for (c) and (f). From this comparison it is seen that the undoped samples all possess a more dendritic morphology which is characteristic of rapid crystallization but little grain growth. As the temperature exposure increases the number and size of equiaxed grains increase. Grain growth to equiaxed grain morphologies occurs readily for the doped samples and this is probably due to the increased mobility of Si atoms in the presence of P in Si (12).

Replicas of the surfaces of as-deposited and doped samples are shown in Fig. 3. It is seen that for the samples which received either an 800° or 1100°C heat-treatment, the surfaces are rougher for the undoped samples, *i.e.*, there are more and sharper protuberances. Figure 2 has shown that the lateral dimensions of the grains are larger for the doped material. Therefore, it appears that due to the increased mobility of Si in the presence of P (12) lateral grain growth is possible for the doped samples but more difficult for the undoped poly-Si grains which extend upward rather than laterally.

As apparent from Fig. 3(d), ridges on the replica outline the poly-Si grain boundaries. Since the replica is a negative impression of the poly-Si surface, the ridges represent depressions at the grain boundaries. Rather than being grain boundary grooves associated with the attainment of minimum radius of curvature, we believe that these features are due to intergranular oxidation. Evidence that these grooves widen and deepen with oxidation will be shown later.

The TEM observations show that doping and temperature determine the grain structure. P doping yields larger grains with smoother surfaces. Nearly dendritic morphologies are observed for undoped samples.

Morphology of poly-OX.—As was shown in Fig. 2 there are basically two poly-Si grain morphologies: one is primarily dendritic and the other equiaxed. The tendency toward the equiaxed morphology increases as the mobility of Si atoms increases as a result of a higher processing temperature and/or phosphorous dopant concentration. The heavily doped poly-Si is more representative of an industrially useful case while the oxidation of the undoped material is of scientific interest. Figure 4 shows a comparison of the oxide grown on single crystal Si in 4(a), undoped poly-Si in 4(b), doped poly-Si in 4(c), and in 4(d) doped poly-Si but thinned for TEM by ion milling rather than chemical etching so as to obviate any possible chemical etching artifacts. It is seen that the SiO_2 grown on single crystal Si is comparatively featureless. The poly-OX, however, clearly shows thickness undulations. The thin regions of the poly-OX outline the previous grain boundaries as is especially apparent in Fig. 4(c) and (d) where the grain boundaries of the poly-Si are well defined. For the more complex poly-Si grain morphology, *i.e.*, smaller grains and mixed dendritic and equiaxed morphologies, the thickness undulation patterns are also more complex as seen in 4(b). The use of chemical etching and ion milling yielded essentially the same morphologies. Chemical etching, being more rapid and equally reliable, will be used throughout this study.

In order to clarify the magnitude of the intergranular oxidation effect and to further confirm the above thickness undulation observations in the absence of possible etching effects, the following experiment was performed. A poly-Si film on SiO_2 on Si was prepared for TEM examination in the usual way (7) leaving

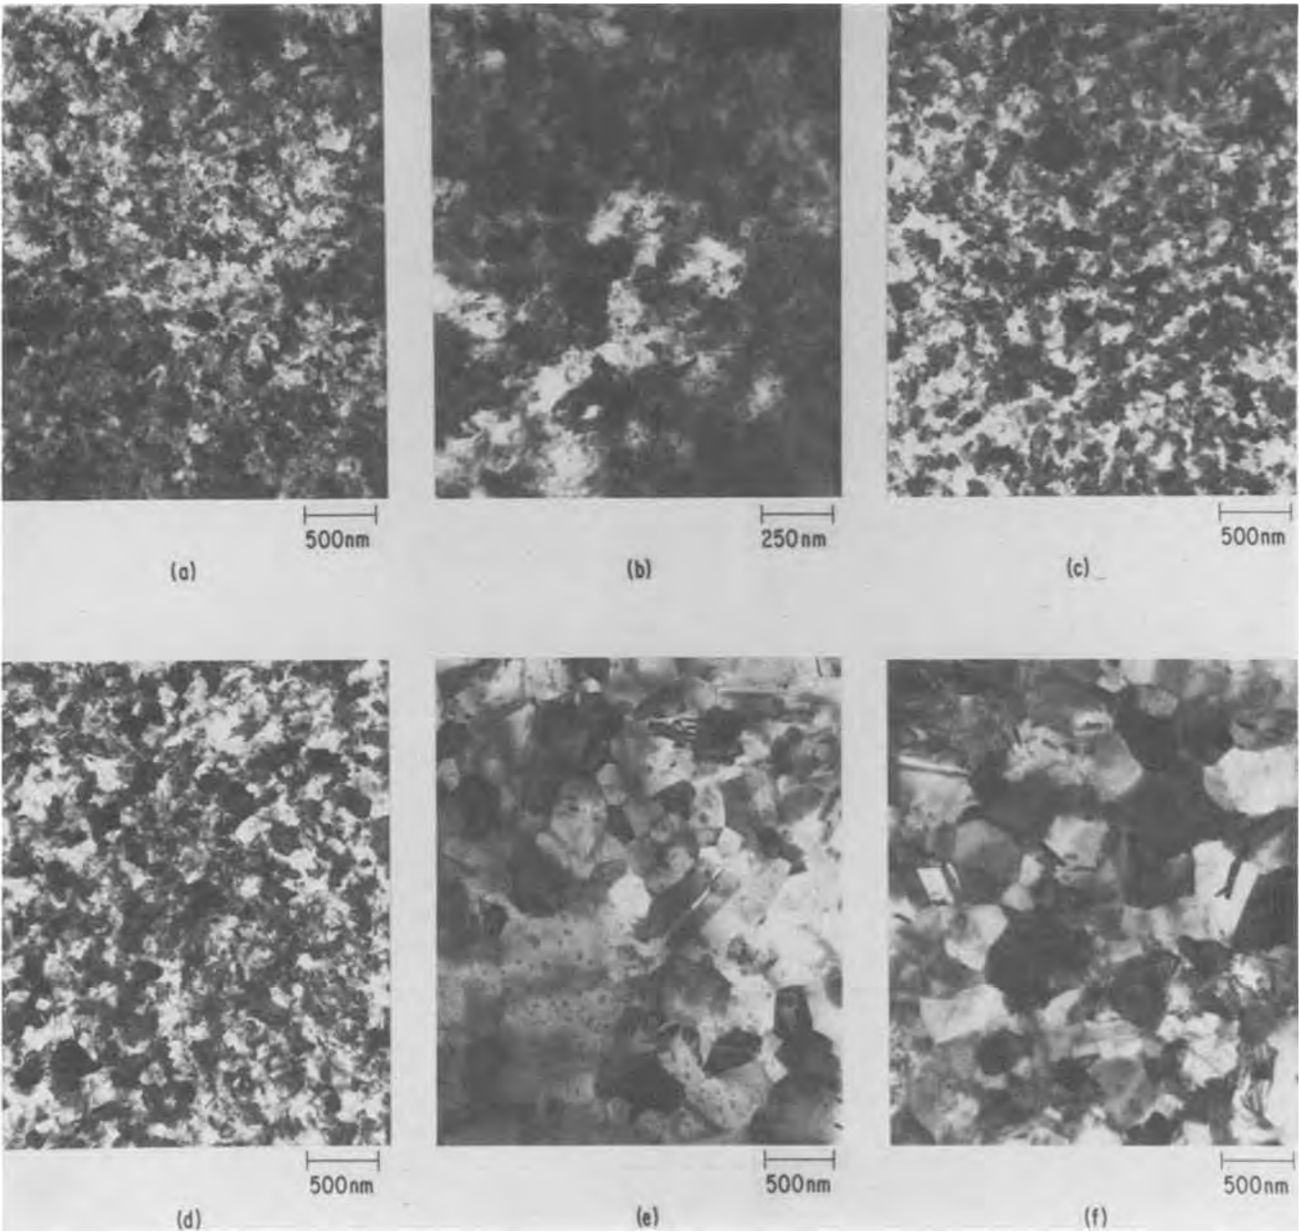

Fig. 2. Comparison of poly-Si deposited at 650°C oxidized (a) at 800°C, (b) 1000°C, and (c) 1100°C to produce 30 nm SiO_2. For (d), (e), and (f) the samples are the same as (a), (b), and (c), respectively, with the exception that (d), (e), and (f) have received $POCl_3$ doping. The SiO_2 was removed in HF prior to TEM.

an area of poly-Si thin enough for examination as shown in Fig. 5(a). This sample was then oxidzed repeatedly and examined after each oxidation to determine the effects of further oxidation treatments: the results are shown in Fig. 5. In 5(b) the sharply outlined relatively darker areas which have broad slip bands; bending contours and thickness fringes are the remnants of partially oxidized poly-Si grains. Surrounding these grains is poly-OX which has a graded thickness. The thinnest regions are nearest the previous grain boundaries. In some areas actual separation of the poly-OX occurs at the thinnest poly-OX regions. For illustration purposes Fig. 5(b) shows an area with a higher incidence of separation than is usual. Figure 5(c) is a more representative one with further advanced oxidation. We believe that the separation phenomena in 5(b) is due to the contraction of the silicon grain remnants upon cooling from the oxidation temperature. The silicon grain remnants contract more than the oxide causing tensile forces to be exerted at the already thinned oxide regions. Figure 5(c) shows the smaller crystalline remnants of the grains at the darkest hence thickest regions of the films. After the initial thinning to produce 5(a) the sample was not chemically or otherwise treated in any way after oxidation, except to make the TEM observations, and therefore the sample is coated with an oxide film parallel to the plane of the micrographs. This oxide film forms as a result of the oxidation of the free surface of the poly-Si grains as with the oxidation of single crystal Si. As oxidation progresses the oxide on the free surface grows thicker and thereby reduces the total electron transmission through the sample. This effect plus the fact that diffuse scattering occurs because the oxide is amorphous causes the micrograph images to become less sharp for samples with thick oxides. Figure 5(d) shows the sample oxidized completely for ~ 18 hr. The very thick regions represent the grain centers which are consumed last but because of the greater oxide thickness the features of these regions are not discernable.

During oxidation the poly-Si surface becomes roughened more than the oxide although even the poly-OX surface is rough relative to the oxide grown on single

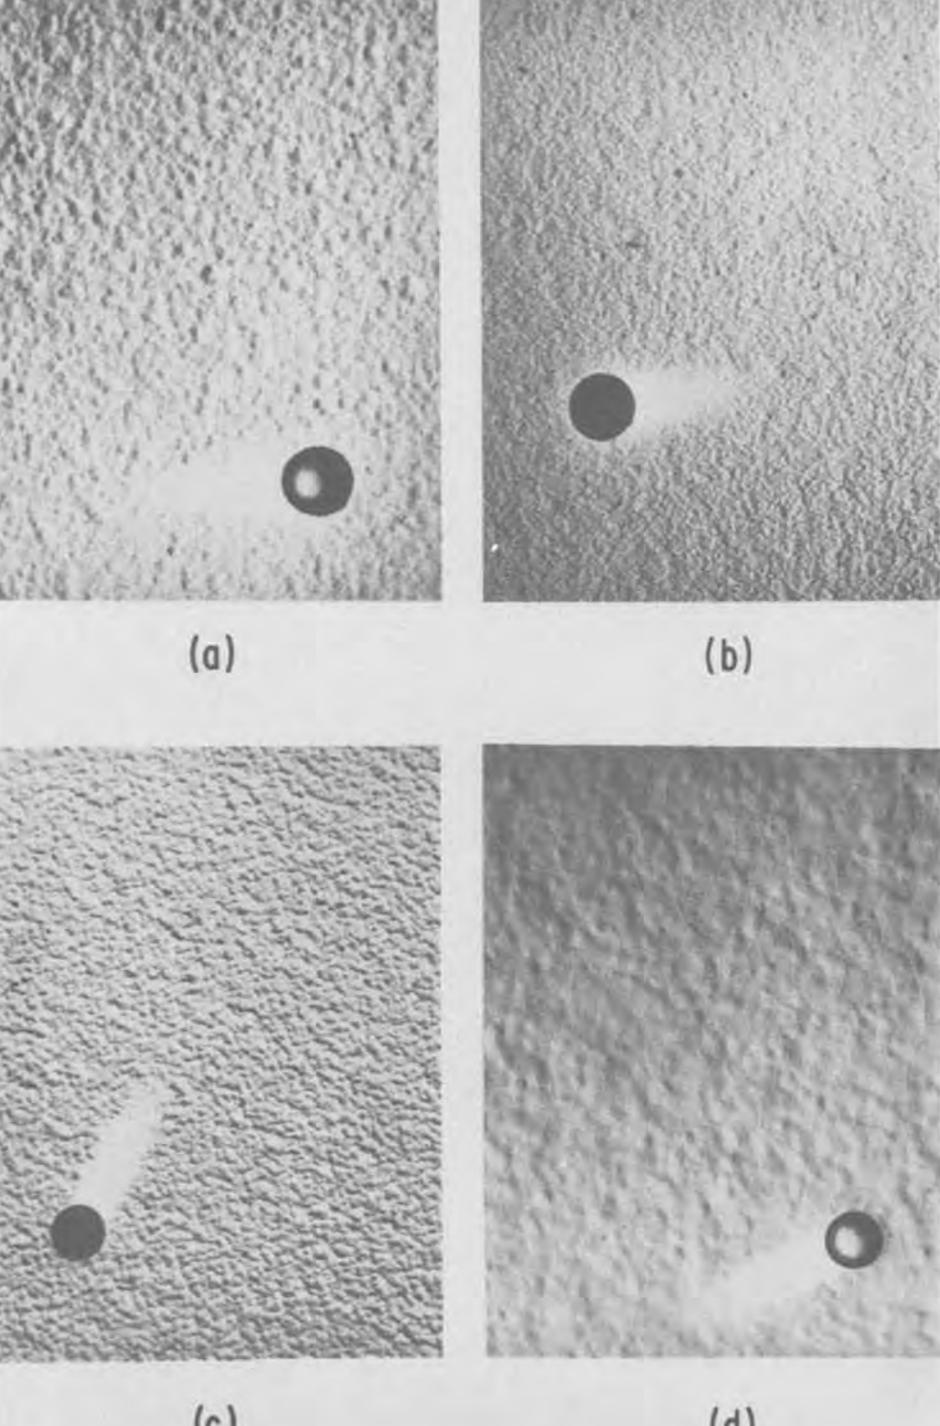

Fig. 3. Replicas (negative) of CVD silicon films (a) deposited at 650°C, undoped, 800°C oxidation, (b) deposited 650°C, $POCl_3$ doped, 800°C oxidation, (c) deposited at 800°C, undoped, 1100°C oxidation, (d) deposited at 800°C, $POCl_3$ doped, 1100°C oxidation. The oxide was ~30 nm and removed prior to replication.

crystal silicon. This is seen in Fig. 6(a) and (c) which show oxidized poly-Si and 6(b) and (d) which show the same samples with the oxide removed.

From these TEM observations several conclusions can be made. Firstly, the poly-OX is not uniformly thick, *i.e.*, it has thickness undulations which replicate the previous grain boundaries with the thinnest poly-OX being near previous grain boundaries. Secondly, oxidation occurs intergranularly as well as on the free surface. The poly-Si surface, although initially rough, becomes further roughened as a result of oxidation. These characteristic features of the oxidation of poly-Si will enable a mechanism to be proposed.

Stress in poly-Si films.—When Si is converted to SiO_2 there is more than a twofold (2.2) increase in volume. For the oxidation of single crystal Si this volume is obtained by the outward expansion of the oxide film from the single crystal surface that is being oxidized. However, for the case of poly-Si oxidation in which oxidation occurs not only on the free surface but also intergranularly, the volume required for oxidation is not as readily available. The intergranular mode of oxidation could lead to the buildup of a large compressive stress in the plane of the poly-Si film. Experience has shown that even for total oxidation of poly-Si, the films do not show any mechanical failure due to stress buildup. Thick poly-Si films (10^3 nm) have been reported (13) to impart a substantial tensile stress to silicon substrates. It was also reported (13) that this tensile stress could be reduced by adding oxygen to the CVD ambient. In a recent detailed study of the wafer deformation caused by poly-Si films (14), a tensile poly-Si film stress was also reported. This tensile stress increased during

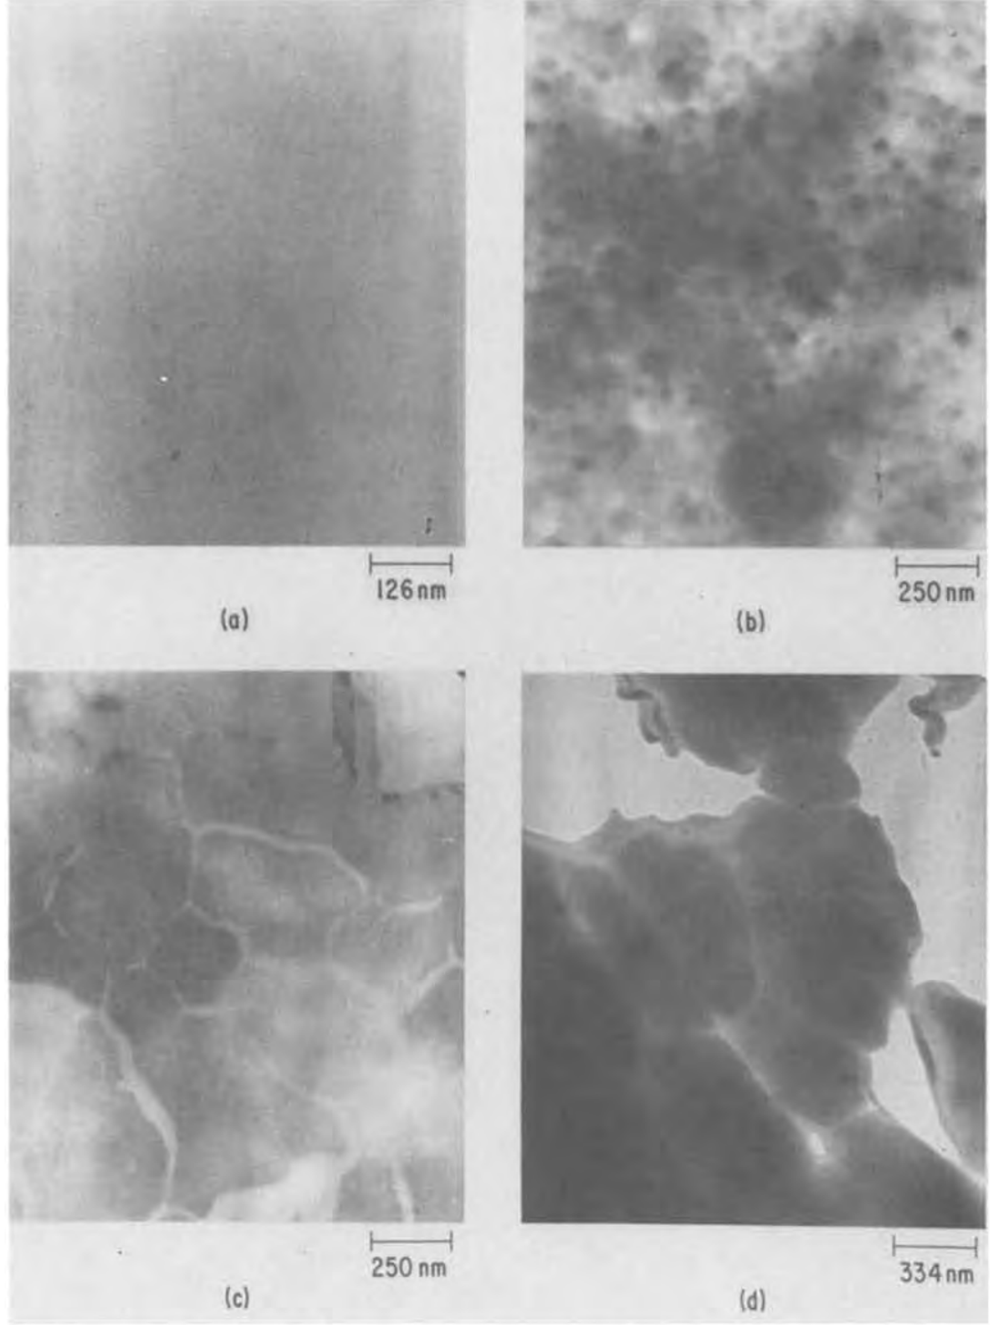

Fig. 4. Comparison of oxide grown at 1000°C in dry O_2 on (a) single crystal Si, (b) undoped poly-Si, (c) doped poly-Si and, (d) doped poly-Si but prepared for TEM by ion milling.

inert ambient (N_2 or Ar) anneals due to sintering but decreased if O_2 was added to the annealing ambient. These studies (13, 14) strongly support the contention that intergranular oxidation can lead to a compressive stress.

In order to determine the change in film stress before and after oxidation of poly-Si, several poly-Si samples both undoped and $POCl_3$ doped were measured before and after oxidation. It is seen in Table I that for all samples the total change in stress after oxidation is small. The doped samples all became more compressive (−) while the undoped became more tensile (+) after oxidation. We believe that the scatter in the data is primarily due to the smallness of measured changes. These stress results can be understood by considering that the grain morphology of the undoped poly-Si samples is immature with respect to further high temperature heat-treatments. As shown in Fig. 2 the undoped samples undergo grain growth during oxidation. Grain growth causes a reduction in volume by eliminating grain boundaries and with the volume decrease of the film, a more tensile stress is expected. Therefore, for the undoped material there are two opposing processes occurring during oxidation: intergranular oxidation causing a more compressive film stress and grain growth causing a more tensile stress. Apparently

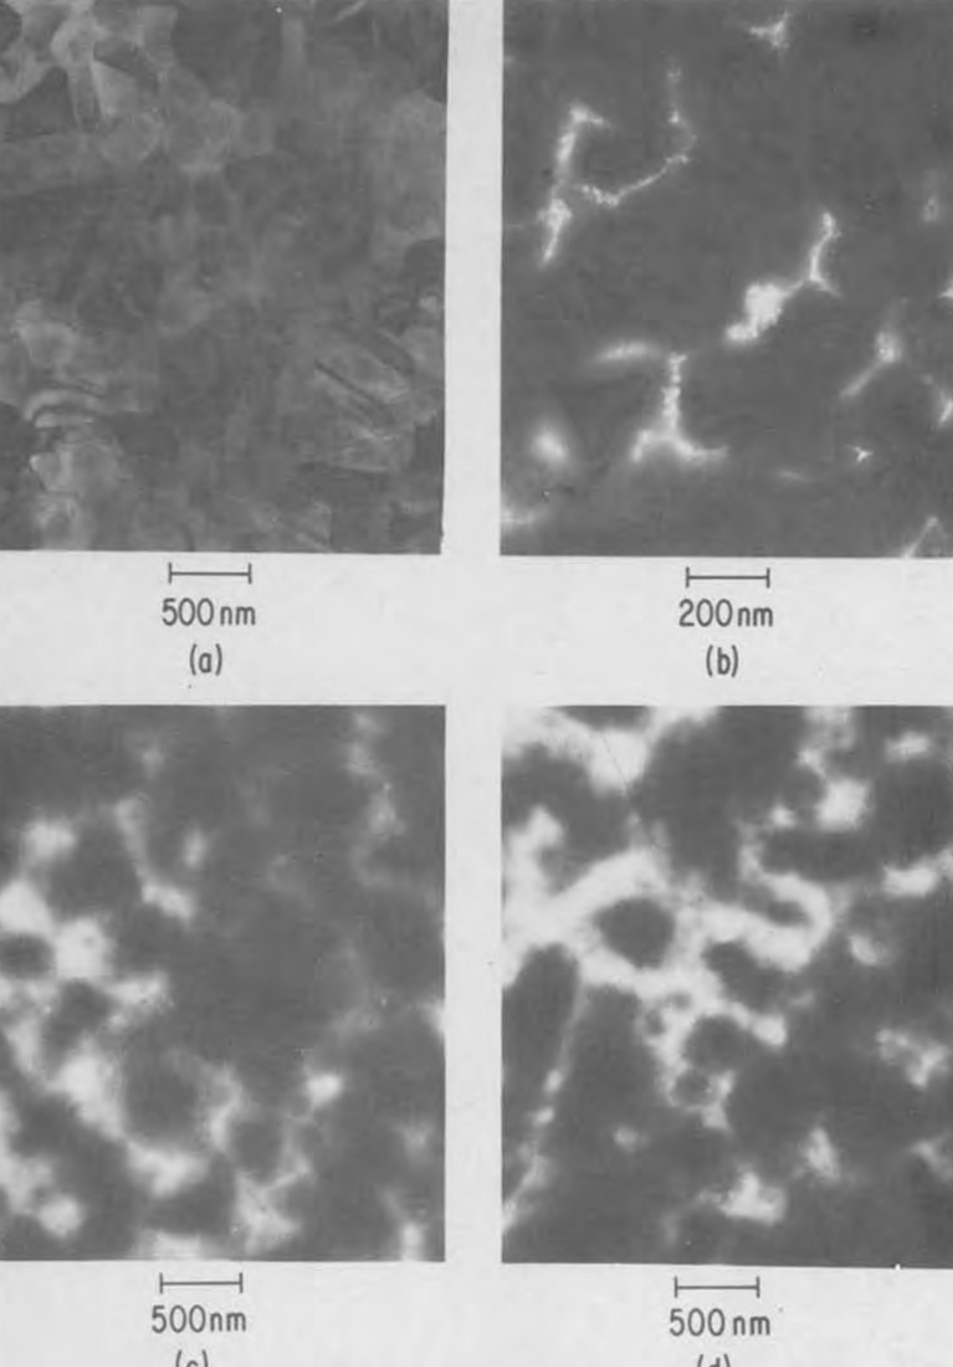

Fig. 5. Progressive stages of oxidation of poly-Si, (a) unoxidized, (b) oxidized to produce ~50 nm SiO_2, (c) oxidized to produce ~150 nm SiO_2, (d) completely oxidized ~300 nm SiO_2.

grain growth is more dominant. For the doped material, the grain morphology is more mature hence the dominant effect during oxidation is due to intergranular oxidation which results in a compressive stress.

Intuitively a large compressive stress is anticipated due to intergranular oxidation. The magnitude of this stress can be estimated by considering ~50 nm diam grains with 1 nm intergranular oxide formed (from Fig. 4 and 5, only 1 nm intergranular oxide is a very conservative value). From these values a film stress of more than 10^{11} dynes/cm^2 is calculated which yields more than 10^2 more Newtons rings than is observed. It is clear that such a large stress would be easy to measure. The large discrepancy between the anticipated stress attributed to intergranular oxidation and measured stress strongly suggests that matter flows to create the necessary volume to accommodate intergranular oxidation and preclude the buildup of a large compressive stress.

Model for the oxidation of poly-Si.—The low stress values for poly-Si oxidation means that either Si and/or SiO_2 plastically deforms or creeps to relieve the stress and preclude film failure. If SiO_2 flows under oxidation conditions, then each oxidizing grain boundary acts as a source of SiO_2 and from each boundary SiO_2 would flow. The net result would be a thicker poly-OX at previous grain boundaries. Since negative thickness undulations are observed, it is concluded that Si creeps from the grain boundaries in order to relieve the strain.

A Nabarro-Herring type creep mechanism (15, 16) closely describes the situation at hand. In this mechanism a compressive stress is exerted in the grain boundaries by the growing oxide in a direction parallel to the plane of the poly-Si film. To relieve the strain vacancies flow toward the oxidizing boundary, thereby supplying the volume necessary to relieve the compression. Si atoms flow in the opposite direction thereby causing the grains to elongate in a direction

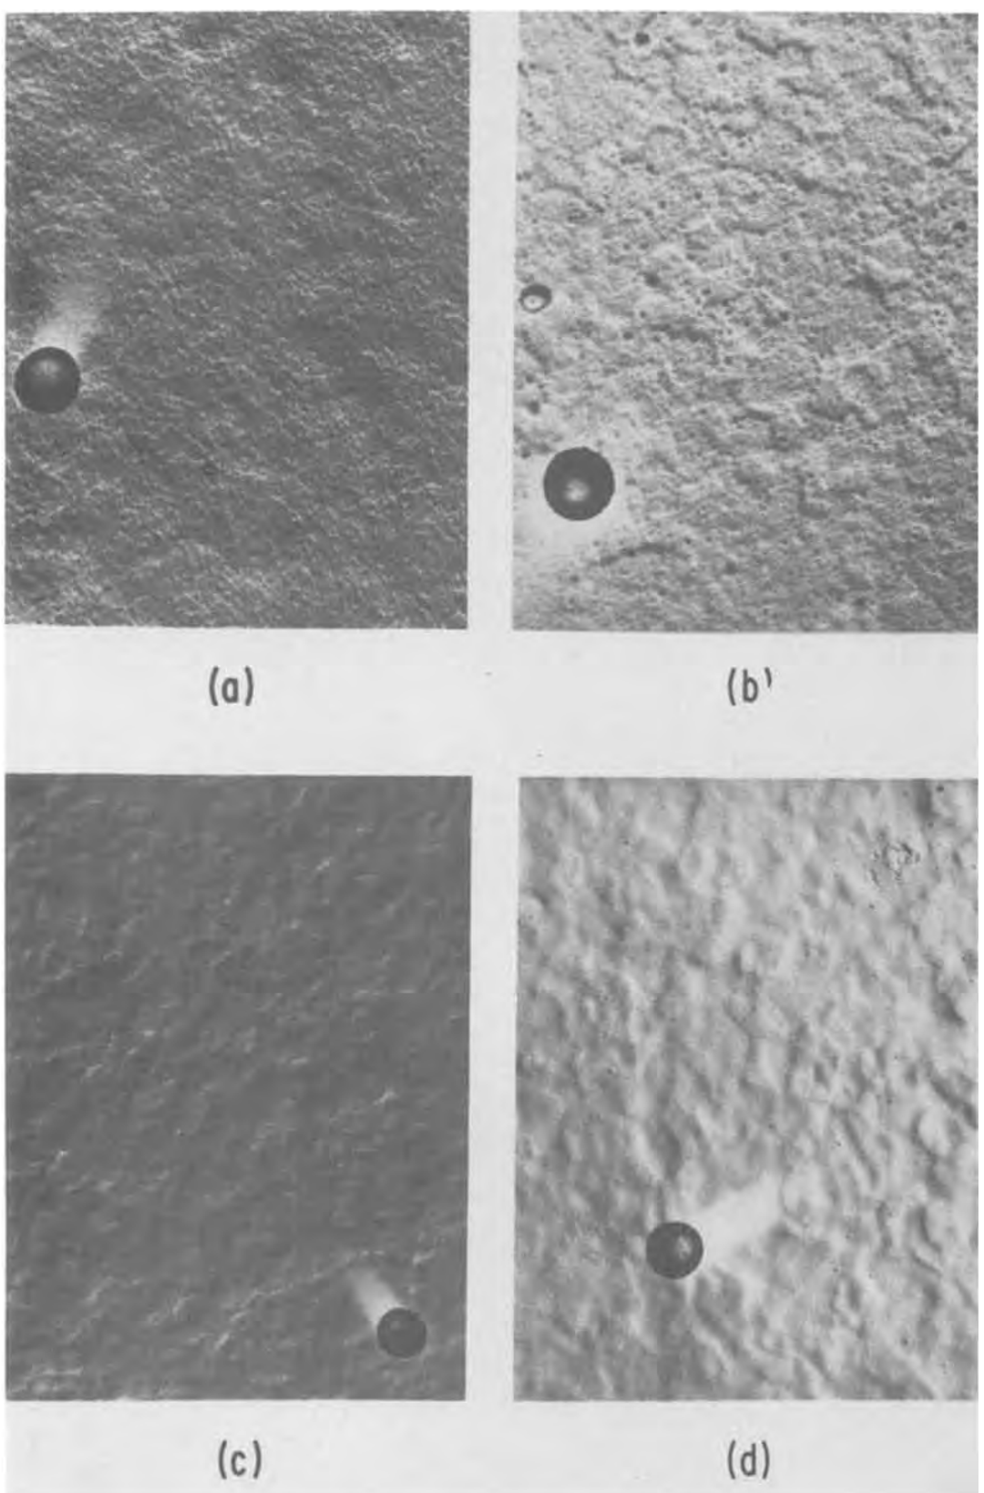

Fig. 6. Replicas of the surface of oxidized poly-Si and poly-Si with the poly-OX removed, (a) 650°C prepared, doped, oxidized to ~50 nm at 1000°C, (b) same as (a) but oxide removed, (c) 800°C prepared, doped oxidized to ~50 nm at 1000°C, (d) same as (c) but oxide removed.

normal to the stress. This type of mechanism has been observed to occur at high temperatures and under low stress which are the conditions where intergranular silicon oxidation commences.

The operation of this mechanism is clarified by consideration of Fig. 7. Figure 7(a) shows the idealized grain morphology for poly-Si showing the free and grain boundary surfaces. As oxidation ensues a stress, τ, builds up in the grain boundaries as a result of the volume increase resulting from intergranular oxide formation. The small arrows show the direction of motion of Si atoms away from the source of the strain and towards the midgrain regions so as to relieve the strain. This motion of Si depletes the amount of Si at the grain boundaries and enhances the amount at the midgrain regions thereby elongating the grains normal to the stress. Simultaneous with the Si motion, oxidation also occurs and hence there is consumption of Si both in the grain boundaries and at midgrain regions. Therefore, the net result is a thinner oxide formed at previous grain boundaries due to Si depletion and a thicker oxide of midgrain regions that receive the excess Si. This flow of Si and the growth of the oxide is seen in 7(c) and (d) where d_e is the extra growth of oxide due to the Si which flowed to the midgrain regions.

At higher oxidation temperatures it may be expected that SiO_2 as well as Si flows. This would result in less severe poly-OX thickness undulations for higher temperature oxidations and more severe for lower temperature oxidation. Figure 8 shows a comparison of the same sample as used in Fig. 5 oxidized

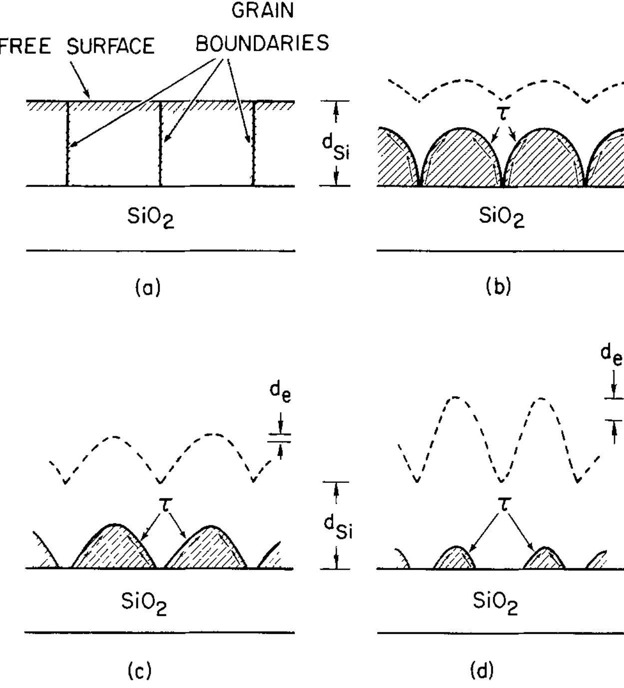

Fig. 7. Model for the intergranular oxidation of poly-Si (a) unoxidized, idealized grain structure, (b), (c), (d) progressive stages of oxidation.

nearly completely and to the same extent at 800°C [8(a)] and 1150°C [8(b)]. Less severe thickness undulations are seen for the higher temperature case.

In summary, a consistent explanation is realized by considering an Si creep mechanism as the predominant factor in determining the overall poly-Si and poly-OX morphology after oxidation.

Implications of the model.—From a comparison of dark and photo currents in poly-OX (4), a uniform barrier lowering effect was ruled out as the cause of higher than expected currents in poly-OX. Localized field enhancement effects due to protuberances on the poly-Si surface were deemed causative of the observed high conductivity of poly-OX (2-4). The present study has shown that surface roughness of poly-Si is a direct result of intergranular oxidation of poly-Si. Also the original poly-Si grain morphology while being a function of preparation temperature and doping does not greatly affect the surface roughness of poly-Si after oxidation. This explains why higher than normal poly-OX currents are seen for poly-OX grown on doped and undoped poly-Si even though the original grain sizes and morphologies are vastly different.

In addition to poly-Si surface roughness effects, the present study also showed that the poly-OX has thickness undulations. The TEM micrographs show that the thin regions of poly-OX over previous grain boundaries represent a smaller area than the thick poly-OX over midgrain regions. As estimated from the micrographs, the poly-OX is more than 25% thinner near previous grain boundaries. The usual film thickness measuring techniques used to measure poly-OX thicknesses such as interference, ellipsometry, or mechanical step height techniques will yield poly-OX thicknesses representative of the larger areas, *i.e.*, the thicker regions. However, the electronic currents in poly-OX are determined by the thinnest regions which yield the maximum field for an applied voltage. Therefore, the reported electric fields for poly-OX based on the conventionally measured poly-OX thicknesses could be erroneously low. It is interesting to note that a 30-35% decrease in film thickness will yield ~1.5 increase in field which is sufficient to

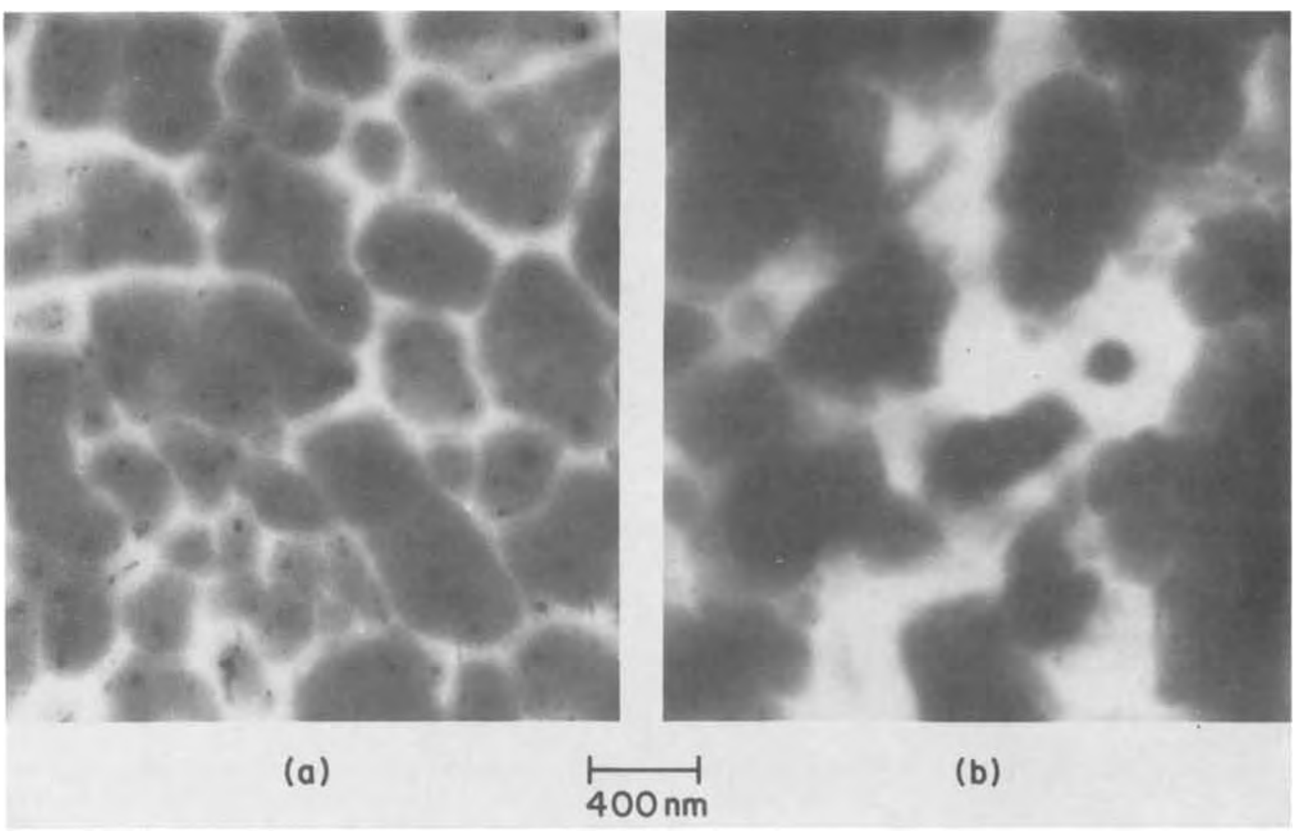

Fig. 8. Poly-Si samples as in Fig. 5, oxidized to the same extent in dry O_2 (a) 800°C and (b) 1150°C

explain some of the reported field enhancement effects in poly-OX (4).

We have found initial electrical shorts in some devices which utilize poly-Si lines. The shorts extend through the poly-Si lines and through an underlying oxide to the substrate or another line. The shorts occur as a result of removing the poly-OX on a line using an HF based chemical etchant so that metal can be evaporated for the contact to the poly-Si line. This shorting problem is understood by considering that due to intergranular oxidation of poly-Si, poly-OX forms in the grain boundaries of the poly-Si lines. When the surface poly-OX is removed by chemical etching, the etchant penetrates into the intergranular poly-OX and in some places where intergranular oxidation is extensive, through the underlying oxide. Evaporated Al will fill these holes thereby causing the electrical shorts. These reliability implications are treated in more depth in a separate publication (17).

Conclusions

TEM studies of the oxidation mechanism of poly-Si has revealed the following: (*i*) there is intergranular oxidation as well as oxide forming on the free silicon surface; and (*ii*) the intergranular oxidation of poly-Si leads to poly-Si roughness and thickness undulations in poly-OX.

A Si creep mechanism describes the oxidation behavior and the morphological features that develop as a result of oxidation help to explain some electrical reliability aspects of poly-OX.

Evaluation of Ultrathin Native Oxide on GaAs Surface

I. Sakai, M. Hirose, and Y. Osaka

Department of Electrical Engineering, Hiroshima University, Hiroshima 730, Japan

ABSTRACT

This paper describes a new method to determine the thickness of the interfacial oxide layer of metal/n-GaAs Schottky barriers from their capacitance-voltage characteristics and photoresponse. It is found that the thickness of the native oxide formed on an etched n-GaAs surface appreciably increases with decreasing carrier concentration. This is interpreted in terms of the chemical activity of the GaAs surface which is remarkably enhanced with the presence of holes at the surface.

Oxygen atoms adsorbed on a chemically cleaned semiconductor surface produce a very thin oxide layer even at room temperature. The thickness of such native oxide on an etched GaAs surface has been estimated to be 10-30Å from ellipsometry (1). Shiota *et al.* (2) have investigated oxide layers formed on GaAs cleaned by different kinds of etchants by Auger electron spectroscopy, and found an etching procedure best suited to the preparation of GaAs(100) surface with the least amount of residual oxide thickness (∼10Å). GaAs MESFET's (3) and GaAs Schottky-type solar cells (4) should have thin interfacial oxide layers between metal and GaAs. At present, there is no straightforward technique to evaluate electrical properties or thickness of the residual oxide layer for a metal/GaAs system.

In this paper, we describe a new method to determine the thickness of the interfacial oxide layer of a metal/GaAs Schottky barrier from its capacitance-voltage characteristics and photoresponse. It was found that the oxide thickness at a metal/etched GaAs interface decreases with increasing bulk carrier concentration.

Key words: gallium arsenide, native oxide, Schottky barrier.

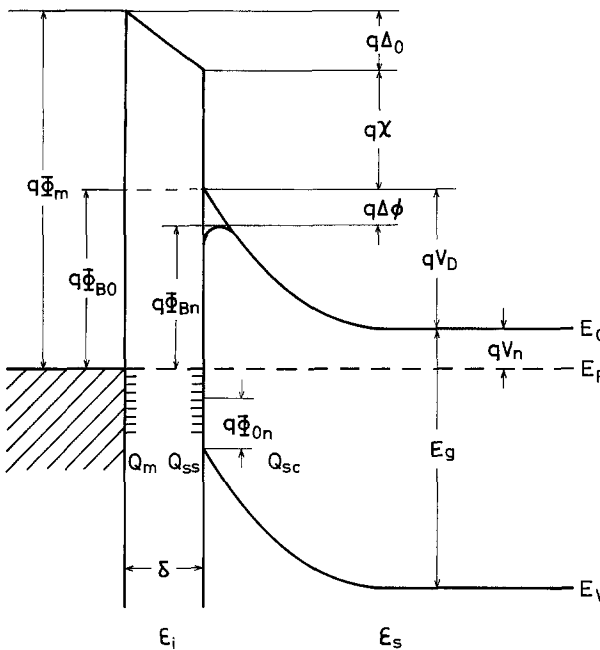

Fig. 1. Energy band diagram of metal/GaAs Schottky barrier. Φ_m: metal work function, Φ_{Bn}: barrier height, χ: electron affinity of GaAs, $\Delta\phi$: image force barrier lowering, Φ_{0n}: energy level determined by distribution of GaAs surface state charge, δ: thickness of interfacial layer, Δ_0: potential difference across oxide layer, Q_m: surface charge density on metal, Q_{SS}: surface state charge density on GaAs, Q_{SC}: space charge density in GaAs, V_D: diffusion voltage, V_n: Fermi energy, ϵ_i: permittivity of interfacial layer, ϵ_S: permittivity of GaAs.

Theory

Figure 1 illustrates the energy band diagram of a Schottky barrier diode including an interfacial oxide layer and surface states on GaAs. From this figure, the differential capacitance of a GaAs Schottky barrier is given by (5)

$$\frac{1}{C^2} = \frac{\delta^2}{\epsilon_i^2} + \frac{2}{qN_D\epsilon_s}\left(V_D - V - \frac{kT}{q} + \Delta_0 - \frac{\delta Q_{ss}}{\epsilon_i}\right) \quad [1]$$

Using the relation $\Delta_0 = (\delta/\epsilon_i)(Q_{ss} + Q_{sc})$, one obtains (6)

$$\frac{1}{C^2} = \frac{2}{qN_D\epsilon_s}\left\{-V + \left(V_D - \frac{kT}{q} + \alpha\right)\right\} \quad [2]$$

$$\alpha = \frac{\delta}{\epsilon_s} qN_D W_0 \quad [3]$$

Here, W_0 is the thickness of the depletion layer at zero bias. Then

$$\delta = \frac{\epsilon_i}{2\epsilon_s} \cdot \frac{\alpha}{V_D - \frac{kT}{q} + \alpha} W_0 \quad [4]$$

Since the barrier height $\Phi_{Bn}(C\text{-}V)$ measured by the capacitance-voltage ($C\text{-}V$) characteristic involves the effect of the interfacial layer, $\Phi_{Bn}(C\text{-}V)$ is described by

$$\Phi_{Bn}(C\text{-}V) = (V_D + V_n - \Delta\phi) + \alpha \quad [5]$$

The effective barrier height is directly obtained from the photoresponse of a Schottky barrier because all of photoelectrons emitted from metal to GaAs are able to tunnel through the very thin oxide layer. The Fowler plot of the photoresponse provides the barrier height $\Phi_{Bn}(\text{photo}) = V_D + V_n - \Delta\phi$.

Therefore, the thickness of the interfacial oxide layer δ is given by the following equation

$$\delta = \frac{\epsilon_i}{2\epsilon_s} \cdot \frac{\alpha}{V_i} W_0 \quad [6]$$

Here, $\alpha = \Phi_{Bn}(C\text{-}V) - \Phi_{Bn}(\text{photo})$, and V_i is the intercept voltage in $1/C^2$ *vs.* V plot.

Experimental

A boat grown n-GaAs(100) wafer was mechanochemically polished and then cleaned by H_2SO_4:H_2O_2:H_2O = 3:1:1 solution for 40 ~ 60 sec, or by Br_2 + CH_3OH mixture for 1 min followed by rinse in HCl:H_2O = 1:2. Immediately after this cleaning, the wafer was transferred into an oil-free vacuum system and Au dots as thick as ~1000Å were evaporated onto the top surface since Au film should not react with native oxide around room temperature. Some of the GaAs wafers were annealed in H_2 or O_2 atmosphere, and then cleaned by Br_2 + CH_3OH mixture and successive rinse in HCl:H_2O = 1:2, or by rinse in HCl:H_2O = 1:2 only, prior to fabrication of Schottky barriers.

Results

Figure 2 shows representative $C\text{-}V$ characteristics for Au/n-GaAs Schottky barriers. $1/C^2$ *vs.* V plot in high bias range is nonlinear only for a wafer with a low carrier concentration (~10^{16} cm^{-3}) on account of deep traps in the GaAs substrate. In such case, $1/C^2$ *vs.* V plot could be corrected by the method of Vasudev *et al.* (7) (see curves b-1 and b-2 in Fig. 2). This obtained intercept voltage is only by 8% smaller than that determined from the straight line portion of the $1/C^2$ *vs.* V plot at low biases.

Figure 3 represents the Fowler plots of photoresponse for Au/n-GaAs Schottky barriers. Using Eq.

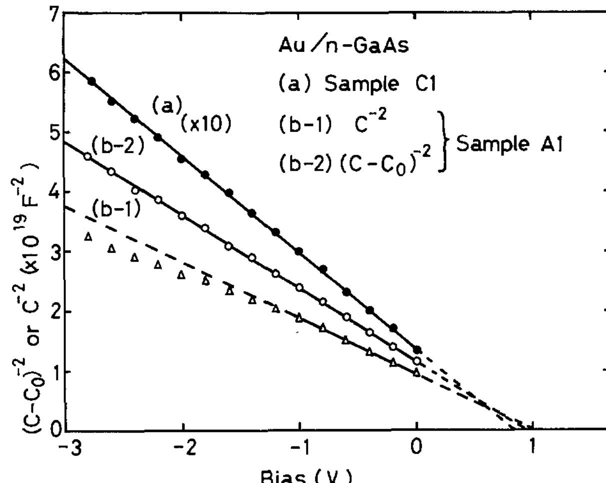

Fig. 2. Capacitance-voltage characteristics of Au/n-GaAs Schottky barriers.

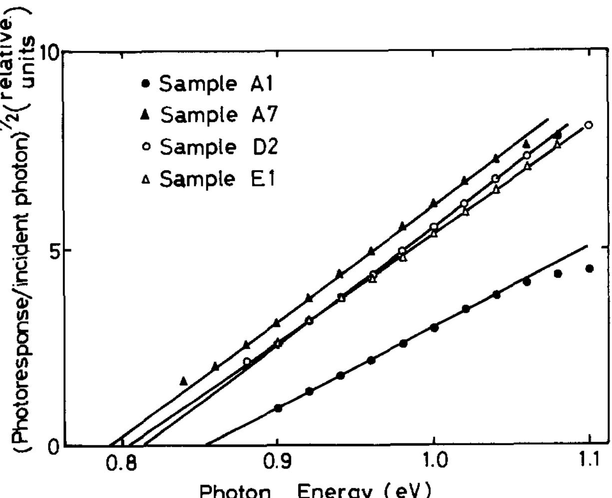

Fig. 3. Photoresponse of Au/n-GaAs Schottky barriers with different thickness of interfacial layer.

[6], we can determine the oxide thickness δ. The small photocurrent for sample A1 is attributable to a thick native oxide layer (65Å) grown at room temperature. For all the thickest oxide (114Å) of sample A7, the photoresponse is larger than that of sample A1. Note that the oxide of sample A7 was grown in O_2 atmosphere at 500°C. From ellipsometry at 5460Å, the refractive index of the thermal oxide grown at 500°C was found to be 1.56 which is close to the value of Ga_2O_3 (8). This indicates that the amount of As atoms in the thermal oxide (sample A7) should be much less than that in the native oxide (sample A1), leading to a smaller barrier height of the oxide for sample A7. Table I summarizes calculated oxide thicknesses for unannealed samples. Here, permittivity of the oxide was assumed to be 5.4 (9). The oxide thickness tends to increase with decreasing carrier concentration. The minimum thickness of oxide for sample E1 is compatible with result of ellipsometry (1). The accuracy of a calculated oxide thickness is estimated to be better than 10%, if one takes an ambiguity of the intercept in the $1/C^2$ *vs.* V plot and the Fowler plot into account.

The oxide thicknesses for the samples chemically cleaned after annealing in H_2 or O_2 atmosphere are given in Table II. Some of these oxide thicknesses might be a little smaller than those indicated in Table II, because the permittivity of the oxide for samples in this table was again assumed to be 5.4. Actually, the permittivity for the thermal oxide grown at a high temperature is smaller than that for the oxide grown at room temperature, as suggested by ellipsometry which provides a refractive index of 1.85 at 5460Å for the native oxide grown at room temperature (1, 10) and of 1.56 for the thermal oxide grown at 500°C. The result of Table II shows that etching in Br_2+CH_3OH mixture for more than 1 min can remove most of the thermal oxide layer on a substrate with a high carrier concentration. On the contrary, aqueous HCl solution appears to be less efficient to dissolve the thermal oxide. This is inconsistent with the result of Murarka (11) who showed that thermal oxide grown in air was insoluble in a Br_2+CH_3OH mixture.

Discussion

In Fig. 4 the thickness of native oxide δ at Au/GaAs interfacial region is plotted against the carrier concentration n for unannealed samples. The slope of the straight line yields the empirical relation

$$\delta \propto n^{-1/3} \quad [7]$$

The effective barrier height Φ_{Bn} which is obtained from the Fowler plot is shown as a function of carrier concentration in Fig. 5. The value of Φ_{Bn} is fitted to the equation

$$\Phi_{Bn} = -\frac{kT}{q}\ln n + \Phi_0 \quad [8\text{-a}]$$

or

$$n \propto \exp\left(-\frac{q\Phi_{Bn}}{kT}\right) \quad [8\text{-b}]$$

The electron concentration at the GaAs surface n_s for a metal/GaAs system is written by

$$n_s \propto \exp\left(-\frac{q\Phi_{Bn}}{kT}\right) \quad [9]$$

Using Eq. [7]-[9], the oxide thickness is related to

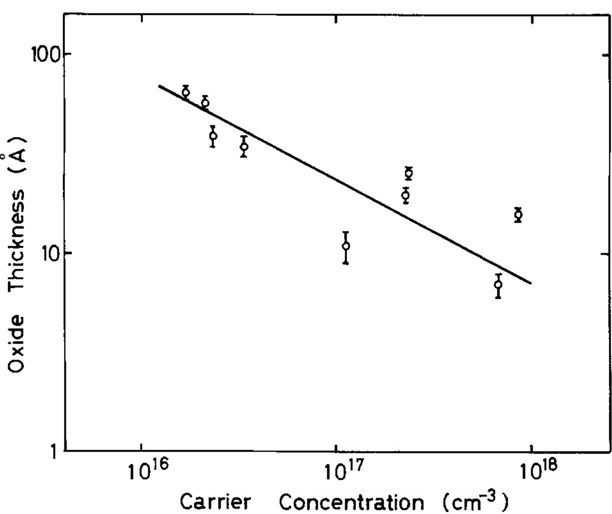

Fig. 4. Thickness of native oxide at Au/GaAs interface as a function of carrier concentration.

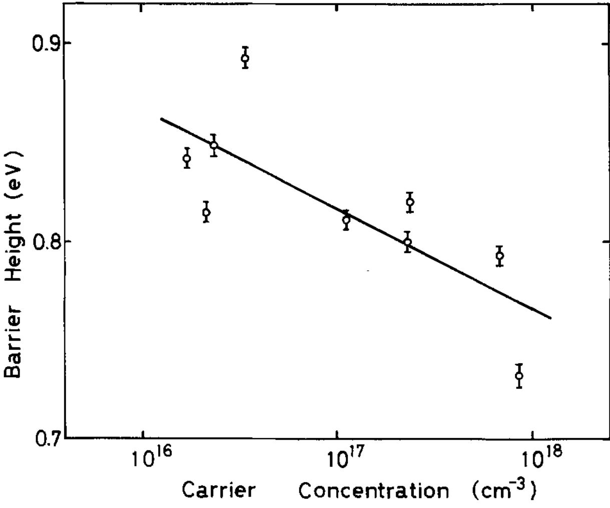

Fig. 5. Barrier height of Au/n-GaAs Schottky diodes as a function of carrier concentration.

the hole concentration at the GaAs surface p_s as

$$\delta \propto p_s^{1/2} \quad [10]$$

If the native oxide layer is sufficiently thin, the oxidation process is controlled by reaction rate at the GaAs surface (12). Note that holes at the GaAs surface produce broken bonds of GaAs which can react with oxygen atoms, resulting in oxidation of GaAs. Therefore the thickness could be related to the hole concentration at the GaAs surface.

The permittivity of the native oxide layer on GaAs, which is dependent on oxidation processes, was regarded as a parameter in the present analysis. The optical refractive indexes are 1.56 for the thermal oxide of GaAs at 5460Å and 1.8 ~ 1.9 (1, 10) for the native oxide. The electrostatic permittivity for both the oxides should be correspondingly different in the similar range. In the present study, an electrostatic permittivity of 5.4 (9) for the thick anodic oxide film was employed for calculating the oxide thickness. The validity of this permittivity is supported by the fact that the optical refractive index for thin native oxide is almost identical to that for thick anodic oxide (1, 10). The relationship $\delta \propto n^{-1/2}$ is well satisfied, even if the actual permittivity is slightly different from 5.4.

In conclusion, it has been clarified that the chemical activity of n-GaAs surface for oxidizing agent is remarkably enhanced with lowering of the bulk electron concentration.

A Study of Stacking Faults during CMOS Processing: Origin, Elimination and Contribution to Leakage

ABSTRACT

An investigation of the generation of the stacking faults in silicon during the CMOS processing has been carried out using n-type 2-5 Ω-cm 7.5 cm diam (100) silicon wafers obtained from different manufacturers. Various thermal oxidation steps and the etching or cleaning steps preceding such oxidations were evaluated. It has been found: (*a*) Stacking faults were produced in densities of less than $1000/cm^2$ in 1050°C wet oxidations; (*b*) the p-tub drive-in (1200°C/15.5 hr/10% O_2-90% N_2) generated stacking fault nuclei which grew into stacking faults (in densities of $\geq 10^4/cm^2$) during subsequent oxidations; (*c*) all stacking fault nucleation centers of type (*b*) and most of type (*a*) could be gettered by the presence of mechanical damage (such as the saw damage) on the back side of wafers, and densities $\sim 10^2/cm^2$ (*a*), and $\sim 0/cm^2$ (*b*) were found; (*d*) stacking faults thus formed contributed to leakage currents even when they appear not to be decorated with impurities. Various experiments leading to the above conclusions have been described and the results have been discussed. It is highly recommended that wafers with damaged back sides be used during processing in order to minimize the generation and growth of stacking faults and the leakage associated with such faults.

The presence of oxidation-induced stacking faults (OISF) in the silicon near the oxide-silicon boundary is detrimental to the electrical performance of devices (1-13). In a recent paper, Dishman *et al.* (2) have reported the results of their investigation of the excess leakage in CMOS integrated circuits. Evidence was presented that the anomalous component of the junction leakage in devices was due to the occurrence of decorated stacking faults at the intersection of the silicon surface with the p-n junction boundary. We have investigated the role of processing in producing stacking faults in silicon at the oxide-silicon boundary. In the early part of the study it became apparent that the large density ($\gtrsim 10^4$ cm^2) of OISF was very commonly but not always associated with the wet oxidation following the 1200°C boron drive-in, which is carried out to create the so-called p-tub (for CMOS circuits) in the n-type wafers. It will be shown that such generation of stacking fault nuclei (which grow into faults during subsequent oxidation) was completely suppressed in 2-5 Ω-cm wafers with intentionally (or unintentionally) created back side mechanical damage. The data

Key words: gettering, oxidation, SIC.

relating the density of faults with the measured leakage on finished devices are also presented.

Experimental Procedure and Results

Unless otherwise mentioned, only n-type, 7.5 cm diam (100) wafers were used in these investigations. The experimental technique consisted mainly of Secco etching the wafers after a given oxidation and examining the stacking faults on such wafers. Oxidation was always carried out at 1050°C in the stream of oxygen bubbling through water maintained at 98°C. Stacking faults were then revealed by the removal of the oxide and etching in Secco etch.

In the early stages of the CMOS processing silicon wafers went through the following processing steps:

1. Clean and wet oxidation at 1050°C.
2. Photolithography and etching to open window in oxide.
3. Boron implant 1×10^{13} cm^{-2} at 30 keV, resist strip, clean.
4. Boron drive-in, 1200°C/15.5 hr in 10% O_2-90% N_2.
5. Etch oxide off, clean, wet reoxidation at 1050°C.

In preliminary experiments we examined a large number of the wafers pulled out at various steps. The conclusions of these first examinations were:

(*a*) Wafers pulled after step 1, to determine the density of OISF produced during wet oxidation alone, eliminated the possibility that this oxidation alone produced OISF in densities greater than 10^3/cm^2. (Only float zone crystal produced large densities of stacking faults, see Table I.)

(*b*) Following step 5, some wafers had a very large density of OISF (10^5-10^7 cm^{-2}). On the other hand, others which were processed with those above at the same time had a low density of similar OISF ($< 10^3$ cm^{-2}). As shown in Fig. 1 faults in the density of 10^4 cm^{-2} or more were usually distributed in such a way that they formed circular striations which appeared similar to swirl patterns (14).

(*c*) The boron drive-in step played a role as a source of OISF in densities greater than 10^3/cm^2. Initially the results appeared highly nonreproducible from run-to-run (each run containing several wafers from various manufacturers).

These observations also led to the further investigations. It was rather easy to visibly distinguish between the wafers with OISF density $\gtrsim 10^4$ cm^{-2} and those with a lesser number of faults, as a large density of faults caused the front surface to appear blotchy. Wafers with lesser number of faults were shiny. Blotchiness could be due to a "dirt" effect or a nonuniform (not striated) distribution of oxygen.

P-tub implant eliminated as a cause.—Ion implantation of low boron doses (1×10^{13} cm^{-2}) followed by oxidation has been shown not to produce stacking nuclei in any appreciable numbers (15). We confirmed this by carrying out experiments with boron-implanted wafers (which did not go through drive-in) and did not observe any high density stacking fault blotchiness after a 1050°C wet oxidation. (Implantation-sputter related effects have been observed to cause stacking fault nuclei near the rim of the sample holder, see Appendix).

§ One area had blotchiness which contributed most.

Boron drive-in and back side damage play a role.—Wafers (from different manufacturers) with no implantations were driven-in (annealed) at 1200°C for 15.5 hr in 10% O_2-90% N_2. The oxide was etched off and the wafers were reoxidized in oxygen bubbled through 98°C water for 47 min at 1050°C. Stacking faults were then revealed by removing oxide and by a Secco etch of 30 sec. The results are summarized in Table II. If the results of manufacturer Z are excluded, a comparison of Table II with Table I indicated that the boron drive-in and not the wet gas oxidation was responsible for blotchiness. Wafers from manufacturers of Table II were also given a one-step wet oxidation, as those in Table I, and the stacking fault densities were low. These results lead to two important conclusions: (*i*) High density stacking fault blotchiness was never observed on the wafers from manufacturer Z and (*ii*) wafers from all other

Table II. Density of stacking faults on wafers subjected to p-tub drive-in and reoxidation*

† Average of measurements on several wafers. Occasionally, a few wafers in the lot will have stacking fault density less than $10^2/cm^2$. Other times only part of the wafer will have very high density faults. In latter case, usually the part having faults will have circular striations.

manufacturers usually showed high OSIF for 1200°C drive-in plus reoxidation at 1050°C, but not for a 1050°C oxidation alone.

In order to understand the observed results, we carefully examined wafers from all manufacturers. It was found that the wafers obtained from manufacturer Z had a rough back surface due to saw damage which was not entirely removed during back side etching. Cross sectioning showed the depth of the saw damage to be about 15 μm. Wafers from all other manufacturers (including float zone wafers) had a comparatively smoother back surface (as a result of the longer etching by the supplier). Figure 2 shows the back surfaces of the wafers from manufacturers Z and RE in two magnifications. The difference in the degree of the surface roughness is evident. The rougher surface had scattered the light at all angles and thus appeared bright (Fig. 2b). The more polished surface (Fig. 2a) (examined in exactly the same light conditions) reflected the light away from the camera except at the scratched identification marks near the flat of the water. The roughness of the back of wafers Z was probably responsible for gettering the fault nuclei during the oxidation process. Mechanical damage gettering has been advocated in the past (16-19) to getter undesirable impurities in a way phenomenologically similar to the commonly used phosphorus diffusion gettering (20). It has not been documented that mechanical damage prevents the formation of OISF through the CMOS process. To evaluate the role of mechanical damage the following experiments were carried out.

Removal and addition of back side damage.—Part of the back surface and all of the front surface of the wafers from the manufacturer Z (rough back side) were masked. The exposed back surface was then etched in a silicon etch to remove ~25 to 74 μm of silicon. The back surface that had been etched was then smoother and appeared similar to the back surfaces of the wafers from other manufacturers. After etching, the mask material was removed and the wafers were cleaned. These wafers together with unetched wafers from manufacturer Z and all others, were then processed with a 1200°C oxidizing drive-in and 1050°C wet oxidation.

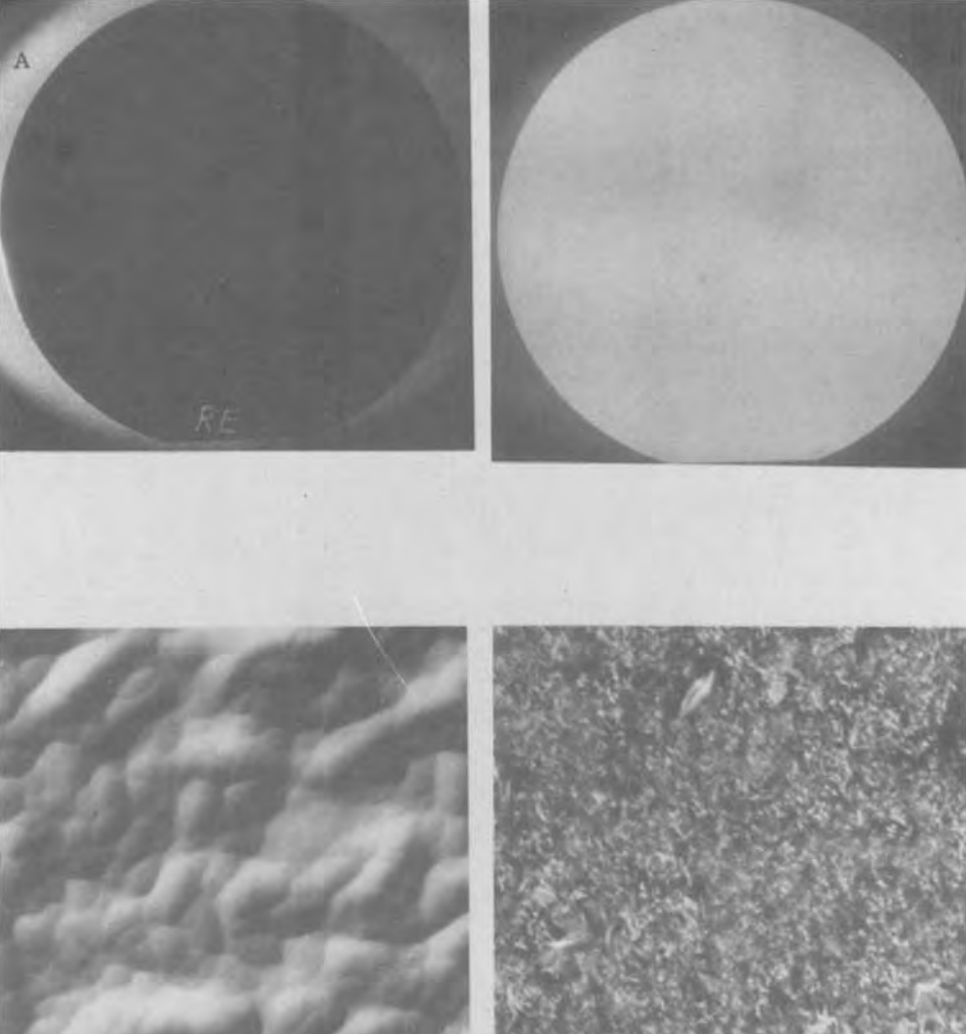

Fig. 2. Micrographs showing the comparative roughness on the back of a wafer with blotchiness (on front) due to stacking faults (a) 1.12× and (c) 1000×, and the wafer with no blotchiness (on front) (b) 1.17× and (d) 1000×.

In a reverse experiment back surfaces of the wafers, from all manufacturers with the exception of Z, were ground on a 180 grit polishing paper to produce mechanical damage. Such wafers, together with as-received wafers from all manufacturers were processed through drive-in and wet oxidation.

Figure 3 shows the front surface of a Z-wafer after removal of the back side damage in the "cross" region. (Ignore the narrow uneven vertical white band across the wafer surface. This band is a result of loss of adherence of the mask material protecting the front surface of the wafer during the back surface etching.) The dark triangular regions had stacking fault density of less than 100/cm^2 and replicate the protected, unetched back surface. The blotchy "cross" area in the middle had a density of faults $\gtrsim 10^5$/cm^2, where back surface damage had been etched away. High magnification photomicrographs showing the boundary between the gettered and ungettered regions, and the stacking faults in the ungettered regions, are shown in Fig. 4. The optical examination of the wafers from the addition of damage experiment confirmed the findings of the removal of damage. All wafers which had been subjected to the mechanical damage on the back surfaces, irrespective of who manufactured them, were clean of stacking faults. All other control wafers in both experiments showed exactly the behavior as described earlier. The results clearly demonstrated the gettering by the residual mechanical damage on the back side of the wafers.

Repeated drive-in experiment.—In this experiment only wafers from the manufacturer Z were used. Figure 5 describes a step-by-step scheme of this experiment. The wafers were cleaned and (oxidized) annealed at 1200°C for 15.5 hr in 10% O_2-90% N_2 ambient. The front surfaces of some (group I) of these

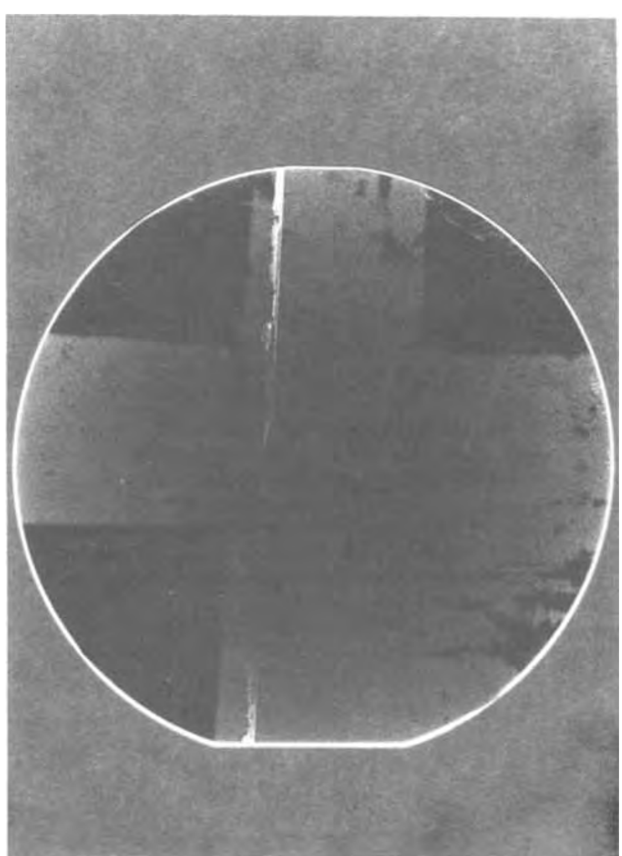

Fig. 3. Micrograph of the front of the wafer with black areas and blotchy surface areas. The blotchiness on the front is due to very large density of stacking faults. Black areas do not have stacking faults in such numbers. The back of the wafer was etched in the regions where blotchiness occurred.

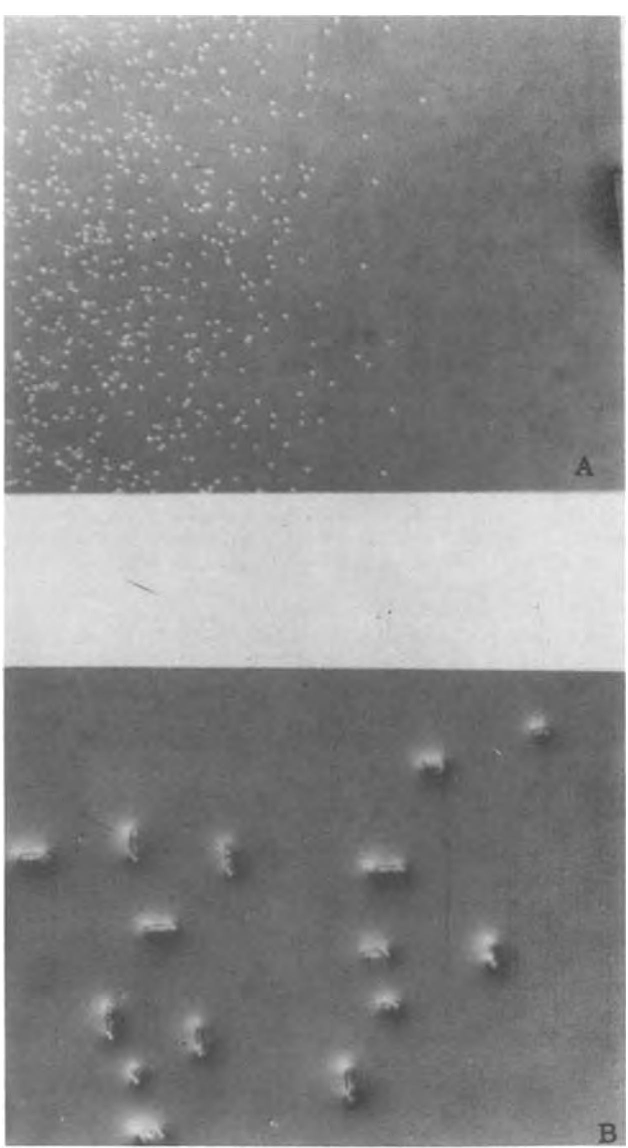

Fig. 4. High magnification photomicrographs of (a) the boundary between blotchy and black areas of the wafer shown in Fig. 4 and of (b) the stacking faults in the blotchy area. (a) 60×, (b) 1000×.

wafers were then protected by use of electroplaters tape and the backs were etched in a silicon etch to remove the mechanical roughness. After tape removal, degreasing, and cleaning, the oxide was etched off these and off a few of the remaining (group II controls) unetched wafers. All group I and II were then subjected to second 1200°C, 15.5 hr drive-in 10% O_2-90% N_2. After the second drive-in, all wafers (including the rest (group III control) of those held after the first drive-in) were placed in BHF to remove the oxide. They all were then reoxidized in wet oxygen at 1050°C for 50 min and etched in Secco etch (following an oxide removal etch) for a 30 sec etch. Blotchiness due to OISF was present only on the wafers subjected to the second 1200°C drive-in after the back surface etch. All other wafers, with undisturbed back surface and with the first or second drive-in, had no blotchiness. These results thus established that, to effectively getter nucleation centers, the damage on the back surface of the wafers should be present during all subsequent oxidizing heat-treatments. This also means that nucleation centers were continuously introduced or formed during the drive-in. These nuclei are getterable, through repeated drive-in cycles, as long as sufficient mechanical damage is present on the back surface.

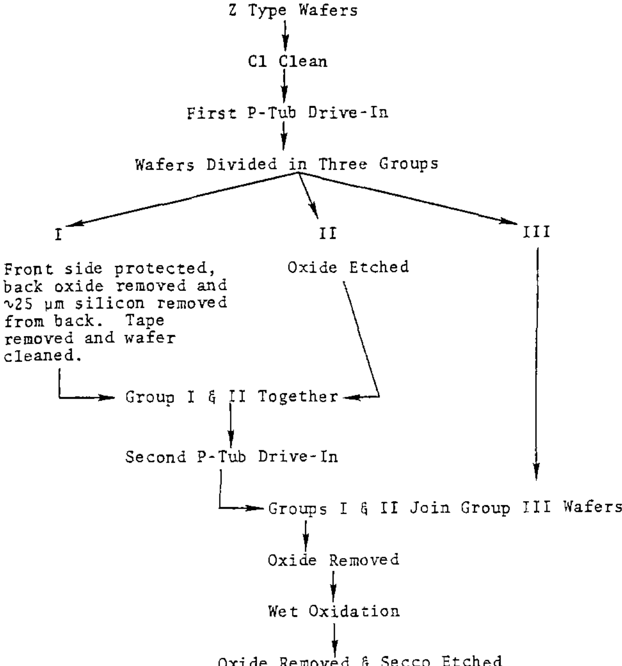

Fig. 5. Step-by-step scheme of the repeated drive-in experiment

Depth distribution of stacking fault density.—In this experiment, the depth distribution of the stacking fault density due to the boron drive-in and reoxidation was determined for samples with polished backs. Sequential front side etching and density count revealed a slight increase in the OISF density up to ~4-5 μm in silicon. Beyond this depth no new stacking faults appeared. The front surfaces of such wafers (with blotchiness) were Syton polished to remove an additional 10-15 μm (a total of 15-20 μm). After cleaning, wafers were reoxidized in wet oxygen at 1050°C and were examined after Secco etch. If a blotchiness appeared on the wafer, the above polishing and oxidation steps were repeated until no blotchiness was observed. In all cases, blotchiness was gone after removal of ~25-30 μm of silicon. Blotchiness was never observed below 30 μm no matter how many low temperature oxidations were carried out. If, however, such wafers were subjected to a second boron 1200°C drive-in and 1050°C reoxidation, the blotchiness (not necessarily exactly similar to one before polishing) would reappear. These experiments clearly indicated that the boron drive-in created stacking fault nuclei in silicon close to the SiO_2-Si surface (within 25-30 μm of surface).

Relation of stacking faults and leakage.—The contribution of undecorated stacking faults to leakage is determined here.

Dishman *et al.* (2) have presented evidence showing that the anomalous component of the junction leakage in devices made on 7.5 cm diam wafers was due to the occurrence of decorated stacking faults at the intersection of the silicon surface with the p-n junction boundary. Following the suggestion of Seidel (2), reduction in the leakage current to an acceptable level on devices was achieved by stripping the back surface oxide before phosphorus diffusion gettering near the end of the processing sequence. This gettering process removed impurities from the decorated faults and improved device performance. A defect evaluation of such device wafers was carried out.

In this experiment, we examined fully processed wafers after their device evaluation. Wafers with a spectrum of leakage currents were collected. Junction leakage currents had been measured at special test features on the whole wafer, depending on the particular device there were 5 to 11 such test patterns on a wafer. After physically locating such test features, all the top layers (*e.g.*, Al, dielectric, etc.) were removed by etching. The test features under investigation were clearly visible, usually free of any etch artifacts. Finally, wafers were given Secco etch of 30 sec to reveal stacking fault features if any.

Wafers with both high and low density of faults were found. In all these wafers, the faults appeared undecorated (2). Since there was a wafer-to wafer variation in the leakage currents we sought to obtain a correlation between the density of stacking faults near the test features and the leakage current. We, therefore, computed the density of faults on and near the test features. We also counted the number of stacking faults which intersected the boundaries of these test features such that a leakage path could develop from the test structure to the substrate. Figure 6 shows a typical test pattern and the large density of faults crowding the pattern.

A plot of the leakage as a function of the stacking fault density is shown as Fig. 7. A reasonably good straight line can be drawn through the data points indicating a monotonic dependence of the leakage on the stacking fault density. The straight line thus obtained could be curve fitted to an equation

$$I = 1.5 \times 10^{-8}\, d^{0.3}\ \text{A/cm}^2 + Io \qquad [1]$$

where I is the leakage current in A/cm², d is the density of stacking faults per cm², and Io is $\sim 1 \times 10^{-9}$ A/cm².

We have also computed the number of stacking faults which intersect the boundaries of the test features such that a leakage path could form between test features and the surrounding material. (It is thus assumed that the faults present within the boundaries of the test features and those close to such boundaries are not contributing to leakage.) Figure 8a shows a plot of the leakage current as a function of the number of stacking faults that intersect the boundaries of the test features. In the absence of a stacking fault intersecting the device boundaries, the leakage is $\sim 2 \times 10^{-10}$A. By subtracting this number from the total leakage current and then plotting the leakage current as a function of the number of faults which intersect the boundaries, we obtain a straight line fit as shown in Fig. 8b. The leakage in this case is thus given by

$$I = 1.5 \times 10^{-12}\, N_I^{2.2} + 2 \times 10^{-10}\text{A} \qquad [2]$$

Where N_I is the number of faults intersecting the boundaries of the devices for which leakage current was measured.

Discussion

In the preceding, evidence has been presented to establish the following:

1. Stacking faults were produced in densities of less than 1000/cm² in low temperature oxidations such as a 1050°C wet initial oxidation.

2. With the exception of the back side damaged wafers, the boron drive-in (*i.e.*, 1200°C/15.5 hr anneal in 10% O_2-90% N_2) generates stacking fault nuclei near the exposed surface of the silicon wafer. Such nuclei are not produced at low temperature wet oxidations and are not produced in bulk (about ~25 μm away from the surface) silicon. The nuclei once formed grow into stacking faults on subsequent wet gas or steam oxidation.

3. All such stacking fault nucleation centers can be gettered by introducing mechanical damage on the back surface of the wafers.

4. Stacking faults thus formed contribute measurable leakage currents even when they appear not to be decorated with impurities.

Finally fully processed wafers taken from split lots (Z-type *vs.* M-type wafers and Z-type *vs.* X-type) were stripped and examined for stacking faults. Only

Fig. 6. Photomicrographs of the full processed, electrically characterized and etched wafers showing the test pads and high density of faults surrounding such pads. Note that faults seem to be undecorated (2).

the wafers with a high degree of back side polish exhibited significant stacking fault densities. Z- and X-type wafers, both having residual saw back side damage, were essentially free of stacking faults. Thus, in the presence of the back side damage, stacking fault formation is suppressed throughout the processing. It must, however, be noted that the experiments of the first type (on wafers with back side damage) show that the back side saw damage does not suppress all stacking fault formation, when very strong stacking fault nuclei are present with wet oxidation ambients. Such nuclei are very less in number, usually, $\lesssim 10^2/cm^2$ and occasionally up to $10^3/cm^2$. Therefore, it cannot be concluded that remnant saw damage will always guarantee zero stacking fault density. It may, however, be concluded that most stacking faults, which would otherwise form, are gettered. It is highly recommended that wafers with mechanical damage on the back surface (such as Z wafers) be used in the device processing line.

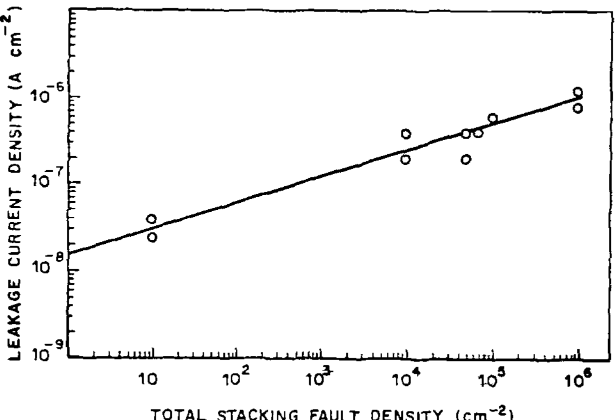

Fig. 7. Leakage current measured on the test pads as function of total stacking fault density around these pads.

Defect nucleation and growth.—One may attribute the formation of stacking fault nuclei, during the boron drive-in, to the bulk nuclei near the surface and/or high temperature annealing, especially in oxygen. From Fig. 1 it would appear that the stacking faults are distributed in a manner similar to as-grown microdefects in the so-called Swirl pattern (14) or in the striated distribution observed in dislocation-free float zone and Czochralski materials. One is thus tempted to suggest that the high density stacking fault blotchiness observed after the heat-treatment in our experiments, could be due to the nucleation and growth of faults at the microdefects in as-grown material. Working with both float zone and Czochralski wafers, Ravi

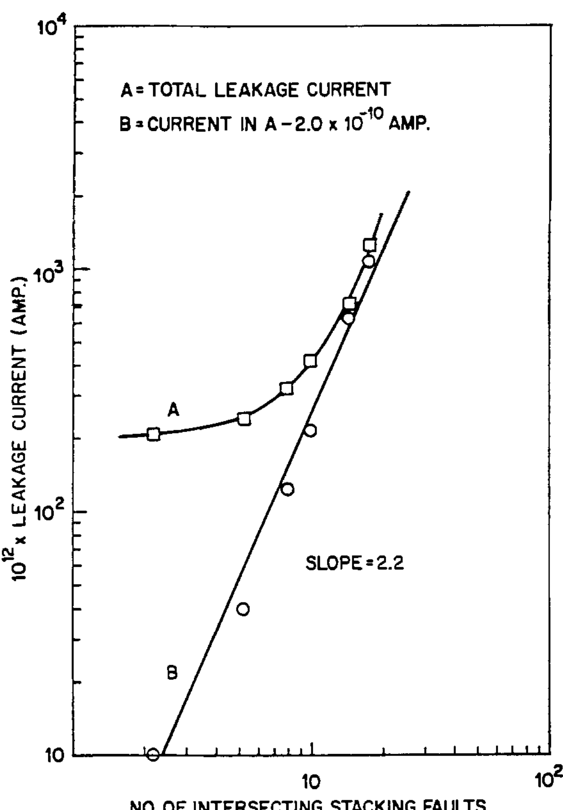

Fig. 8. Leakage current measured on the test pads as a function of the number of the stacking faults which intersect the test pad boundaries.

(22) has shown that long oxidation at temperatures as high as 1200°C resulted in the formation of discrete precipitates. Ravi (22) attributed the formation of striations (such as those shown in Fig. 2) to inhomogeneous distribution of vacancy clusters where the precipitates form during annealing. Maher *et al.* (23) have found that extrinsic stacking faults formed during heat-treatment of silicon contained colonies of coherent microprecipitates at their center. Mahajan *et al.* (24) proposed that the first stage in the evolution of stacking faults can be envisaged to be a localized oxidation leading to the formation of silicon-oxygen clusters. It would appear from our results that the boron drive-in was necessary for the formation of OISF during subsequent oxidations. The role of the boron drive-in is, therefore, to generate defects along the growth striations. Abe *et al.* (25) have recently shown that the presence of growth striations in Czochralski material is mainly due to heterogeneous distribution of oxygen and that a 1200°C/16 hr anneal in oxygen is required to generate defects along those striations. It may be noted that the occasional absence of blotchiness on the wafers (even with polished surface, *i.e.*, without any damage to getter) after drive-in and reoxidation was observed only in Czochralski materials. This absence of formation of faults could be attributed to the absence of the growth striations in these wafers or the presence of bulk gettering oxygen precipitates.

The role of oxygen during anneal becomes very apparent when one considers the depth distribution of stacking faults. It was found that the stacking fault nuclei formation during the boron drive-in was limited to ~20-30 μm of silicon from the SiO_2-Si interface. Mahajan *et al.* (24) have proposed a model in which a localized oxidation of silicon is assumed to occur in the vicinity of existing heterogeneities in the silicon. Nucleation of faults then occurs due to generation of silicon interstitials in large enough concentration to plate out into an extrinsic fault. If the concentration of Si interstitials (and hence that of oxygen to cause localized oxidation) is not large enough, nucleation of fault will not take place. During a 1200°C (or a high temperature) drive-in, oxygen can diffuse to an approximate depth of $\sqrt{4DT} \sim 42$ μm (26). Thus, it may be assumed that beyond a certain depth in silicon, the concentration of oxygen falls below a concentration required to nucleate faults at the bulk defect centers. Thus, the results of experiment could be attributed to oxygen diffusion depth limited nucleation. The presence of both the heterogeneities and oxygen is necessary to nucleate faults. In absence of one or the other (for example due to mechanical damage gettering) faults do not form.

It may be pointed out that although OISF up to 70 μm in length have been observed on the samples annealed in 100% oxygen for 15.5 hr at 1200°C, stacking faults were not visible in our optical examinations of the Secco-etched wafers after boron drive-in. It has been shown recently by Murarka (27, 28) that the growth of the faults is considerably retarded in reduced oxygen partial pressures such as 10% used during the high temperature drive-in. It has also been shown that the stacking fault retrogrowth temperature is considerably lower in such an ambient. Both of these effects could reduce the size of OISF's so that they are too small to be detected optically. These faults could form nucleation centers for the growth during low temperature wet oxygen or steam oxidation following a boron drive-in.

Gettering of the defect nuclei.—It has been shown that no matter what is the source of nucleation of OISF during boron drive-in, the defect nucleation can be completely suppressed by the gettering action of the mechanical damage on the back of the wafer. Gettering induced by back surface damage is not new. Pomerantz (16) had suggested the same technique to get rid of process-induced defects. Strain generated due to mechanical damage could lead to the precipitation of the impurities in the damaged region or enhance their diffusivities in the bulk silicon. This results in the entrapment of the impurities and point defects which are responsible for nucleation of faults, into the damaged back layer of the silicon. In addition, it is possible that the back side damage competes for silicon interstitials with stacking fault nuclei (or less likely is a source of vacancies for the stacking fault suppression).

Contribution of the faults to leakage in the devices.—The presence of the faults in the silicon provides a strained region of interest for impurities which could be entrapped in such regions. These impurities may have ionization levels in the bandgap of the silicon and thus provide charged generation levels. If the fault lies in or across a space charge region the levels will generate leakage.

For the present we do not have any model to explain the relationships of types described by Eq. [1] and [2]. It is hard to synthesize an argument (similar to one given for impurity decorated faults) for a fault which is free of any impurities. A fault in the lattice produces a strained region. If the strain is large enough, it could affect the nature of the semiconductor energy levels. A large number of faults, when present together in a small area, could perhaps cause such an effect leading to unexpected leakage. The role of such a large number of stacking faults in causing leakage is apparent in Fig. 7 and 8. The results may be compared to leakages measured on emitter base junction with stacking faults (29), where the electric fields are larger than those shown for the MOS leakage test junction.

APPENDIX

The Effect of Wafer Holders in the Ion Implanters

During our investigations with boron-implanted, driven-in, and reoxidized wafers, we had always without exception observed a large density of stacking faults in an area within approximately 1 mm from the edge of the wafers. At low magnifications faults appeared to form a circular ring around the wafer as shown in Fig. A-1. Figures A-1b-d clearly show these faults. Such an effect was never observed in nonimplanted wafers. In the present series of experiments, an as-implanted (but not heat-treated) wafer was Secco etched. A differential etching near the edge of the wafer resulted in a ring about 1 mm away from the edge. The differential etching occurred due to different etch rates of n (near the edge) and p (rest of the wafer, due to B-implant) type material. No stacking faults were present on the wafer. The presence of this ring could be associated with a rim of aluminum in the wafer holder for the implantation. Wafers are held against this rim during ion implantation. As shown in Fig. A-2a, the rim which is about a millimeter wide thus shields the wafer edge from the ion beam. Thus, no implantation occurs on the wafer under the rim (hence, the differential etching effect). The ion beam, however, can cause sputtering from the aluminum rim and leads to implantation of the species (near the edge of the wafers) which are probably the nucleating centers for the stacking faults. The contamination resulting from the contact of the wafer with the metallic rim could also introduce impurities responsible for stacking fault nucleation. We shall call this effect a rim effect. Such preferential nucleation at the edge of the wafer cannot be associated with damage from p-tub implants. The ion implanted dose is small compared to the doses required to produce centers for stacking faults as reported by Rozgonyi and Seidel (15). Appearances of blotchiness could never be associated with the p-tub boron implants. In order to verify this rim effect, we implanted a few wafers in a different commercial ion implanted. In this machine, the wafers are loaded in cassettes in such a way that they rest against a plate with an angular cutout as shown in Fig. A-2b. The wafers were subsequently processed and Secco etched in the same manner as described earlier. Microscopic examination of these wafers showed the rim effect in exactly the same geometry as shown in Fig. A-1; thus, confirming our explanation given above to

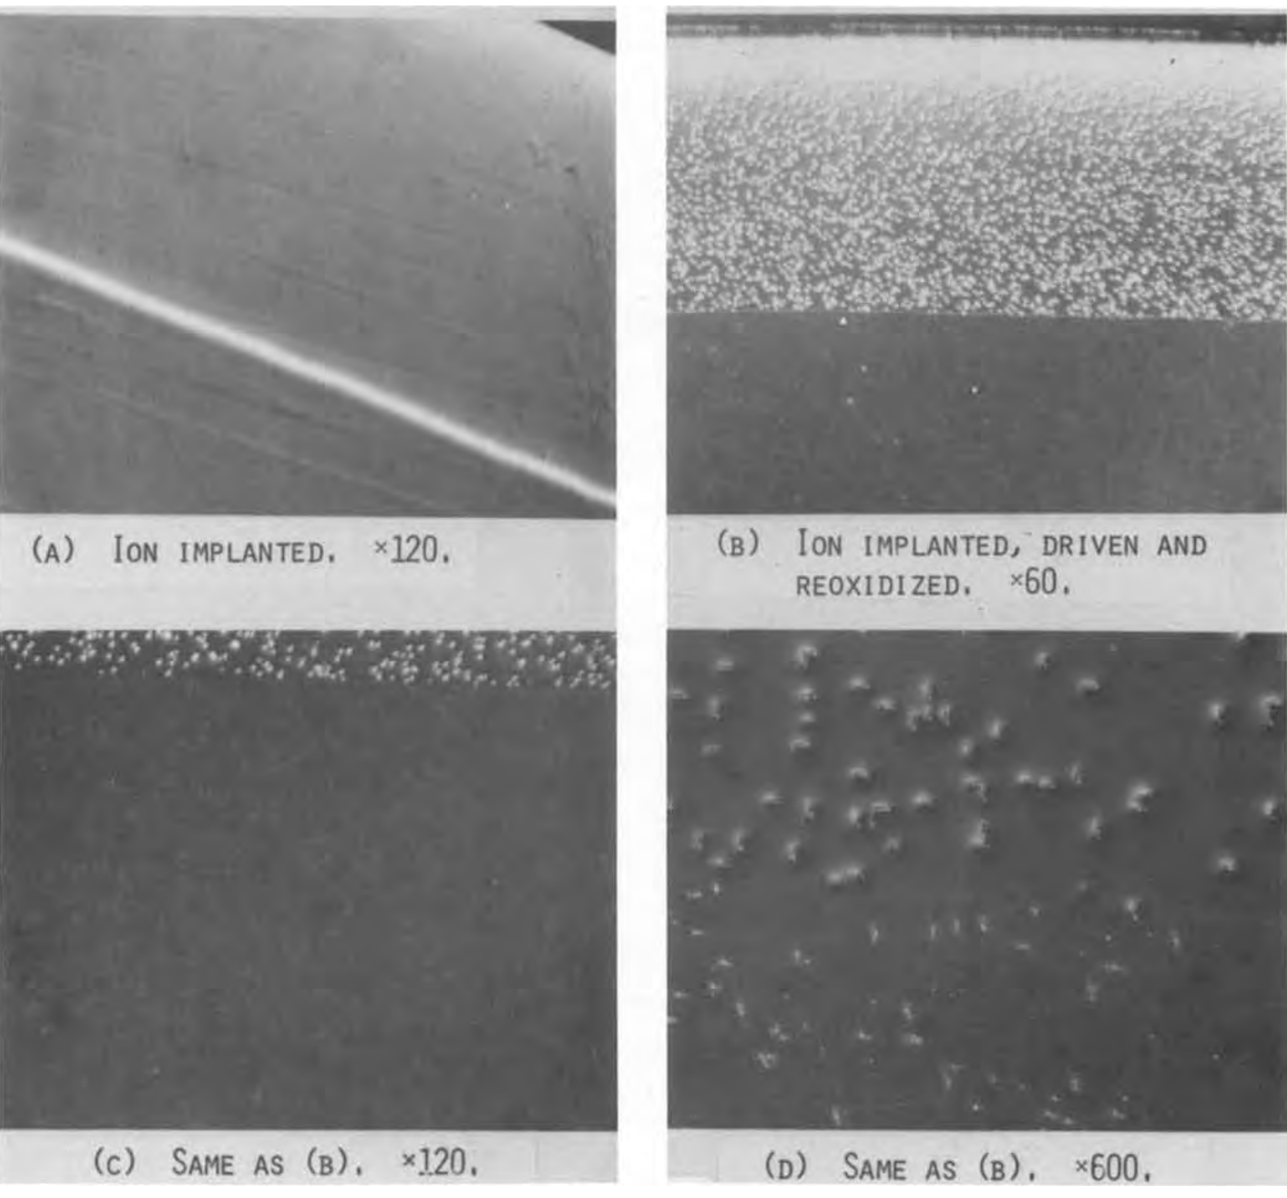

Fig. A-1. Photomicrographs showing the rim effect (see text) presumably due to backsputtering, which leads to formation of stacking fault nuclei, from the wafer holder during the ion implantation.

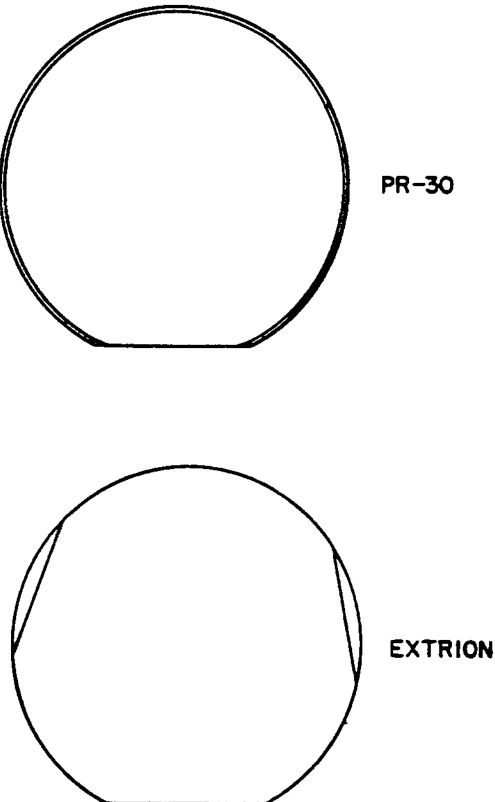

Fig. A-2. Schematic drawings of the metallic holders in PR-30 and Extrion ion implanters. Wafers are held against the metal at the outer edges as shown. (Not to scale.)

account for the rim effect. It may be recalled here that Katz and Moller (21) have reported that sputtering of nickel and other impurities in the same commercial implanter had led to the generation of a high density of stacking faults during later oxidations. All the results mentioned in the above paragraphs were obtained on wafers with back surfaces free of saw damage. To check the effect of mechanical damage gettering on the nucleation centers apparently caused by impuritites associated with the rim of the metal holding the wafer (the rim effect), we used wafers with rough back surfaces, those manufactured by Z. These wafers were implanted with boron in a different implanter, driven-in, and reoxidized. Secco etch of these wafers revealed a p-n etch rate associated ring similar to that observed on just implanted wafers (Fig. A-1a). Only a few stacking faults in the rim area or in the rest of the wafer were observed. This indicated that mechanical damage on the back of the wafer was able to getter the nucleation centers due to the rim effect.

ABSTRACT

Electrochemical photovoltaic cells rely on the junction formed between a semiconductor and electrolyte to accomplish photovoltaic conversion. As a result, they offer certain technical features that make them an attractive alternative to all solid-state solar cells, especially if thin film photoelectrodes are used. This paper describes the fabrication and evaluation of thin film CdSe electrodes for use with sulfide/polysulfide electrolyte in these cells. The effects of electrode preparation and electrolyte concentration on efficiency and stability are presented. *I-V* curves and action spectra are also discussed. Simple depletion layer theory is applied to monochromatic photocurrent curves and a correlation between efficiency and minority carrier diffusion length is shown. Conversion efficiencies (AM1) as high as 5% are reported.

The photoelectrochemical effect has been known for many years (1); only recently, however, has a significant effort been directed toward the practical application of this effect to photovoltaic energy conversion (2-8). Electrochemical photovoltaic cells, which utilize the junction formed at the interface between a semiconductor and an electrolyte for photoconversion, have several technical features that make them an attractive alternative to solid-state solar cells for low cost photovoltaic conversion: (*i*) the photovoltaic junction is formed spontaneously on immersion of a semiconductor of one carrier type in a suitable electrolyte; (*ii*) the geometry of the junction is such that radiation can impinge directly on the space charge region, minimizing surface recombination losses; (*iii*) the most promising materials investigated are direct bandgap materials, which promote the use of thin film electrodes which are an important factor in ultimately producing low cost devices (9). This paper presents some of our results on making thin film n-CdSe photoelectrodes and their photoelectrochemical characterization. CdSe used in conjunction with sulfide-polysulfide containing electrolytes is a system capable of achieving AM1 conversion efficiency of 10% or greater (8, 10). Therefore, it can be considered as a candidate system for future practical application.

Experimental

Thin films of polycrystalline CdSe were deposited on commercially pure (99.9%) titanium substrates (0.254 mm thick), which were cleaned in a chromic-sulfuric acid mixture and degreased in isopropyl alcohol. Films were made by evaporation of CdSe as well as co-evaporation of Cd and Se. In both cases materials of 99.999% purity (Ventron Corporation, Danvers, Massachusetts) were evaporated from Ta or W boats with a background pressure $\sim 10^{-6}$ Torr. Substrate temperatures were held at ~100°C during deposition; film thicknesses were varied from ~0.5-2 μm and deposition rates varied from ~5-50 Å/sec. Film thickness was determined with a quartz crystal thickness monitor (Sloan Technology, Santa Barbara, California) and in some cases confirmed from SEM micrographs. Some co-evaporations were done using an automated rate controller (INFICON, Syracuse, New York) for the Se source, which was found more difficult to control manually than the Cd source. After deposition, the electrodes were heat-treated in air at temperatures from 300° to 500°C for 5-60 min. A copper wire was attached to the back of the electrodes with silver-filled epoxy or indium solder. Common epoxy was used to cover the back and sides of the electrodes. The exposed area was ~1 cm^2. In some cases the electrodes were etched from 5-30 sec in 50% HCl:50% H_2O before use.

For photoelectrochemical evaluation, the semiconductor electrode was the working electrode in a conventional three-electrode cell with a platinum foil counterelectrode (~15 cm^2) and a calomel reference electrode (SCE). The semiconductor electrodes were illuminated through an optically flat Pyrex or quartz window that had been epoxied into a Pyrex beaker modified for this purpose. The CdSe electrodes were positioned ~1 mm from the window to minimize electrolyte absorption without limiting mass transport in the cell. Photoelectrochemical experiments were done at room temperature (~22°C). Baseline data for comparison with experiments done on thin film electrodes were obtained using CdSe single crystal electrodes (Cleveland Crystal Corporation, Cleveland, Ohio), which were prepared for photoelectrochemical evaluation according to procedures found in the literature (5).

Selected electrolytes in the composition range of 1F-2.5F Na_2S and 0.1F-2.5F S in 1F NaOH were used for specific experiments. Most high light intensity (>10 mW/cm^2) *I-V* curves were measured using 2.5F Na_2S, 1.0F S, 1F NaOH electrolyte, while most spectral response curves (<1 mW/cm^2) were measured using 2.5F Na_2S, 0.01F S, 1F NaOH electrolyte. All solutions were made from reagent grade chemicals under an Ar atmosphere. Ar was bubbled through the test cell during electrochemical experiments.

Voltammetric measurements were made with a PAR (Princeton Applied Research, Princeton, New Jersey) Model 173 potentiostat and Model 175 universal programmer using a scan rate of 2 mV/sec and recorded directly on an HP 7040A X-Y recorder (Hewlett Packard, San Diego, California).

The cell was illuminated with the output of a 1 kW filtered (AM1) Xe light source (Schoeffel Instruments, Westwood, New Jersey) for determination of white light *I-V* curves. The same source was used with a

monochrometer (Jarrell-Ash, Waltham, Massachusetts) or a series of narrow band pass filters (Ditric Optical, Marlboro, Massachusetts) for spectral response curves. The radiant power was measured using a thermopile detector (Epply Laboratory, Providence, Rhode Island).

Capacitance-voltage measurements were done using a GR 1657 Digibridge (Gen Rad, Concord, Massachusetts) and a Harrison 6112A power supply. The CdSe electrode potential *vs.* SCE was monitored using a DVM (Fluke Manufacturing Company, Seattle, Washington).

An x-ray diffractometer (Picker Inst., Cleveland, Ohio) was used to determine crystalline phase and orientation and a scanning electron microscope (AMR Corporation, Bedford, Massachusetts) was used for microstructural observations and chemical analysis of the thin films with an Edax attachment (Edax International Inc., Prairie View, Illinois). Transmission spectra of various electrolytes and CdSe films deposited on glass substrates were obtained using a Carey 14 spectrophotometer (Applied Physics Corporation, Monrovia, California).

Results

Compound evaporation produced n-type films irrespective of deposition conditions and conversion efficiencies (η) obtanied with these films (regardless of postdeposition heat-treatment) were <1%. Compound evaporation was abandoned in favor of co-evaporation of Cd and Se, which afforded better control of film stoichiometry. The as-deposited co-evaporated films were polycrystalline and predominantly single phase hexagonal CdSe with a (0001) growth texture. Some x-ray patterns indicated the presence of a small amount of cubic CdSe in which case a (111) growth texture was observed. The films adhered fairly well to the Ti substrate and were quite uniform and monolithic. Figure 1 shows a scanning electron micrograph of a typical as-deposited film. Crystallite sizes are small (<1000Å), and there is a suggestion of a columnar growth structure, which is consistent with the observed growth texture. The as-deposited films showed little or no photoresponse when tested potentiostatically and peeled from the substrate after a short period of time in the electrolyte. Postdeposition heat-treatments in air were found to improve the *I-V* performance and adherence of the thin film electrodes dramatically.

Figure 2 shows representative data indicating the effect of several heat-treatment temperatures (all for 15 min) on *I-V* performance. It can be seen that the best performance is obtained at 400°C. At temperatures greater than 400°C film thinning due to evaporation became significant and the *I-V* performance is not as good as at 400°C. The effect of heat-treatment time was also investigated. Heat-treatment for more than 15 min at 400°C did not improve performance further. As a result of this evaluation, a heat-treatment of 400°C for 15 min was adopted as a "standard" so that the effect of variation of deposition parameters and resultant electrode efficiency could be investigated systematically. *I-V* traces of thin film sandwich structures (*i.e.*, In/CdSe/Ti substrate) before and after the standard heat-treatment indicated that it improves the ohmicity of the CdSe/Ti contact and reduces the resistivity of the films from $\sim 10^8$ to $\sim 10^4$-10^5 Ω-cm. Scanning electron micrographs indicated a slight increase in crystallite size with heat-treatment.

The *I-V* performance of heat-treated electrodes was found to depend on electrolyte concentration at light intensities typical of terrestrial solar fluxes. Figure 3 shows the effect of increasing the electrolyte concentration from 1F to 2.5F Na_2S and S on *I-V* performance of a thin film electrode. The drop-off in efficiency with increasing light intensity in the 1F electrolyte is due to reductions in short-circuit current density (J_{sc}) and fill factor (FF). The open-circuit voltages (V_{oc}) were comparable for both solutions owing to the

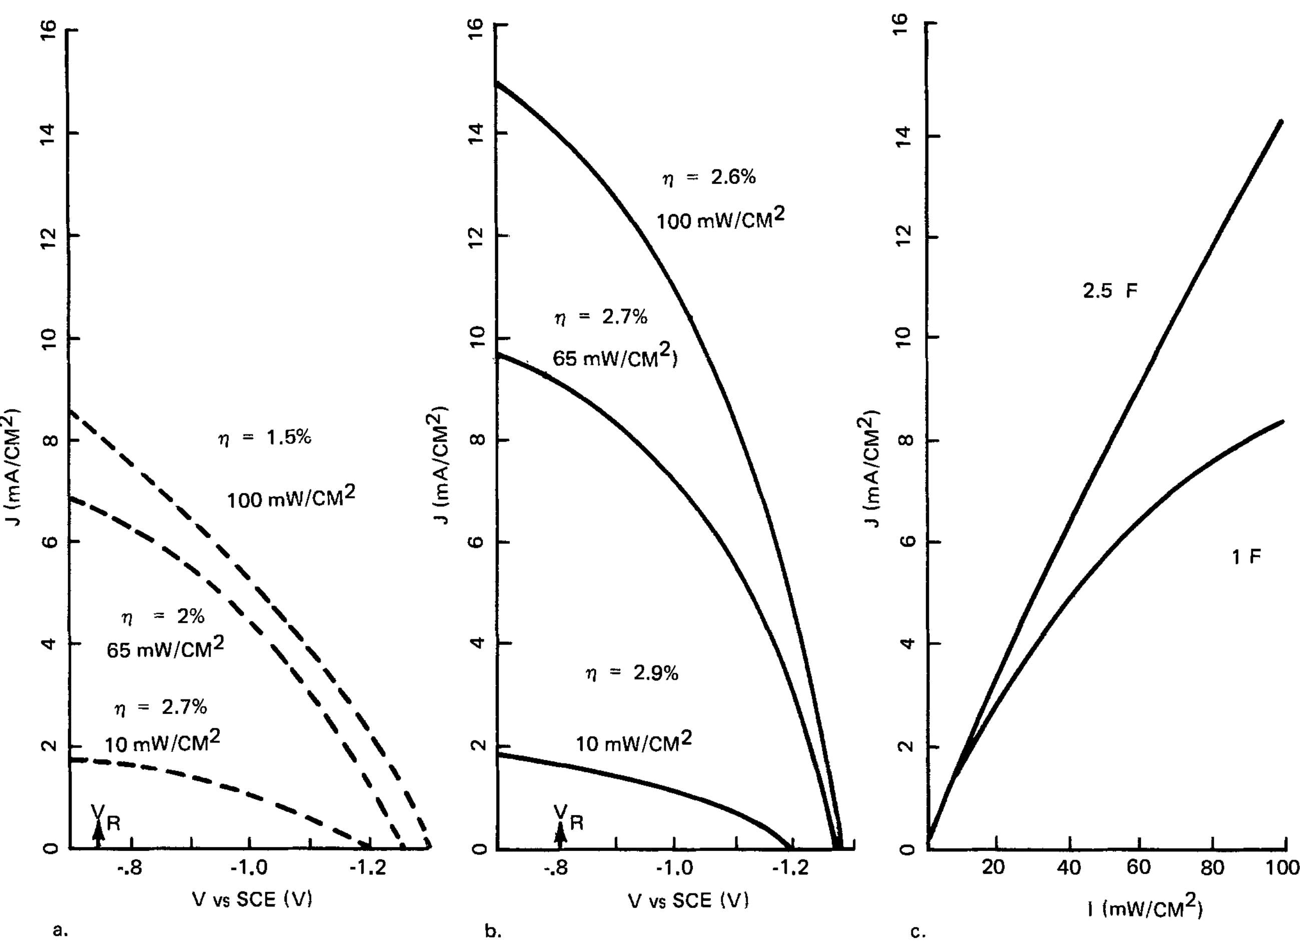

Fig. 3. The effect of electrolyte concentration on *I-V* performance at various light intensities: (a) 1F Na_2S, 1F S; (b) 2.5F Na_2S, 2.5F S. V_r indicates the electrolyte rest potential in the dark.

minimal change in redox potential (−0.76V *vs.* SCE for 1F and −0.79V *vs.* SCE for 2.5F) and therefore the amount of band bending in a given electrode. As shown in Fig. 3a and b, the maximum photopotential in each solution is comparable at similar intensities so that the difference between the redox potential and maximum photopotential (*i.e.*, V_{oc}) does not vary significantly. However, J_{sc} was strongly affected by concentration variation (Fig. 3c). The J_{sc} in 1F electrolyte at 100 mW/cm² light intensity is less than 60% of the value in the 2.5F electrolyte at the same intensity. The FF also changes significantly: in going from 10 to 100 mW/cm² in 1F electrolyte, the FF drops from 0.42 to 0.31; in 2.5F electrolyte, it drops from 0.46 to 0.40. The combination of these factors gives rise to the observed efficiency saturation in the 1F electrolyte. Subsequent experiments indicated that the S concentration, which also changes the visible absorption of the electrolyte considerably, could be reduced to ~1F without adversely affecting η at 100 mW/cm². In view of these results the electrolyte composition was standardized at 2.5F Na_2S, 1F S, 1F NaOH for all white light *I-V* curves at 10 mW/cm² intensity or greater.

The *I-V* performance of thin film CdSe electrodes varied from deposition to deposition and was found to depend primarily on how constant the individual elemental deposition rates could be controlled. Table I summarizes the variation in photovoltaic performance data recorded for 12 sequential co-evaporations with only slight variation in deposition control parameters. All samples were subjected to the standard heat-treatment, and *I-V* data were taken in 2.5F Na_2S, 1F S, 1F NaOH electrolyte at 50 mW/cm². The variation of properties in Table I is consistent with that previously reported for co-evaporated semiconductor thin films (11, 12) and can be attributed to slight differences in film stoichiometry, defect structure, and crystallite size that result from the deposition method and subsequent heat-treatment. These electrodes were fabricated using manual control of the evaporation sources, with good reproducibility.

Analysis of Edax spectra indicated that nominally stoichiometric CdSe films resulted after the standard heat-treatment; no systematic variation in Cd/Se ratio however, could be correlated with the I-V performance variation observed in Table I, most likely because of the limits of detectability of Edax (±0.2%); this should not be taken to indicate that the films do not differ on a microchemical basis.

The variation of performance of sample 2 with light intensity is shown in Fig. 4. It can be seen from these data the V_{oc} follows a logarithmic relation with increasing intensity, while J_{sc} varies nearly linearly, as expected. The fill factor, however, and thus the efficiency fall off slightly. The variation of solar cell parameters with light intensity found with

sample 2 is typical of samples with higher efficiencies; whereas films with efficiencies less than 1% showed more pronounced saturation effects in short-circuit current and fill factor.

Figure 5 presents a typical transmission spectrum of a fired film (glass substrate). It can be seen that there is absorption beyond the bandgap energy (720 nm). This type of behavior has been reported for thin films of CdSe processed in the same temperature regime and attributed to the large number of crystallite defects that give rise to the observed bandtailing (13). A film thickness of 0.8 μm was calculated from the interference fringes.

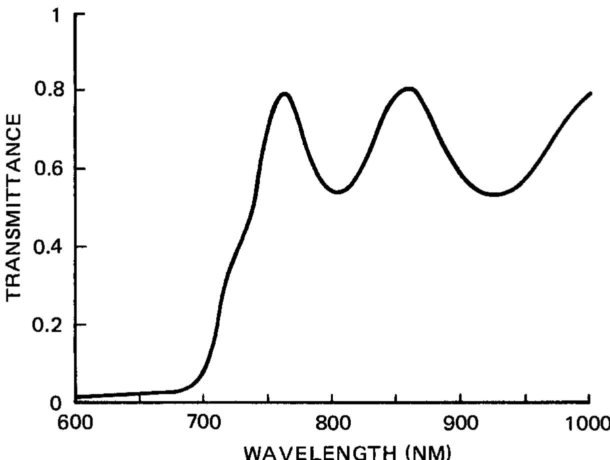

Fig. 5. Transmission spectrum of a fired CdSe film ~0.8 μm thick.

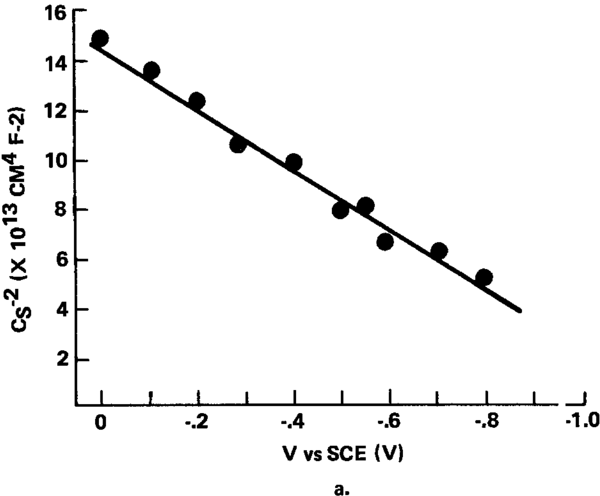
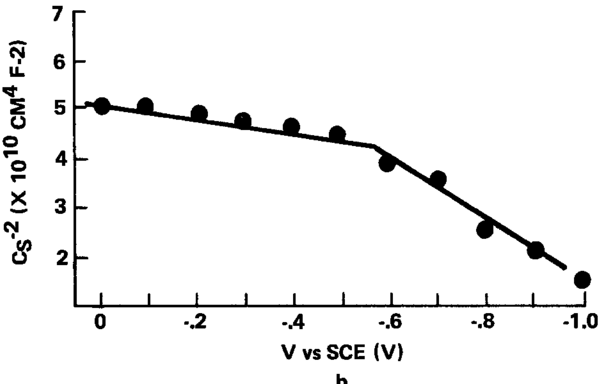
Attempts were made to quantify the differences in electronic properties of various films so that correlations among processing parameters, electronic properties, and *I-V* performance could be established. A study of the change in space charge layer capacitance, as a function of applied potential was undertaken to determine the donor density and flatband potential using the well-known Mott-Schottky relation (14)

$$C_s^{-2} = \frac{2}{q\epsilon\epsilon_0 N_D}\left(V_A - V_B - \frac{kT}{q}\right) \qquad [1]$$

where C_s is the space charge capacitance per unit area, q the electronic charge, ϵ the semiconductor dielectric constant [10 for CdSe (15)], $\epsilon_0 = 8.86 \times 10^{-14}$ F/cm, V_A and V_B are the applied potential and the flatband potential (*vs.* SCE) respectively, N_D the donor density, k Boltzmann's constant, and T the absolute temperature (kT/q can be neglected at room temperature).

Figure 6 shows representative C_s^{-2} *vs.* V_A plots for a single crystal sample, a thin film electrode, and a bare heat-treated Ti substrate. Linear, single slope plots of C_s^{-2} *vs.* V_A were obtained for single crystal samples (Fig. 6a) from which reasonable values of N_D and V_B could be obtained; for example, $N_D = 1.2 \times 10^{17}/\text{cm}^3$ and $V_B = -1.4$V *vs.* SCE. However, most thin film electrodes exhibited linear plots with two slopes (Fig. 6b). This type of behavior has been observed previously with polycrystalline samples in electrochemical cells and attributed to the presence of both shallow and deep donor levels in the samples studied (16). In our case the measured capacitance values were large (in some cases >10 μF/cm^2), which results in anomalously high calculated donor densities for both slopes ($>10^{20}/\text{cm}^3$). C_s and N_D values of this order yield de-





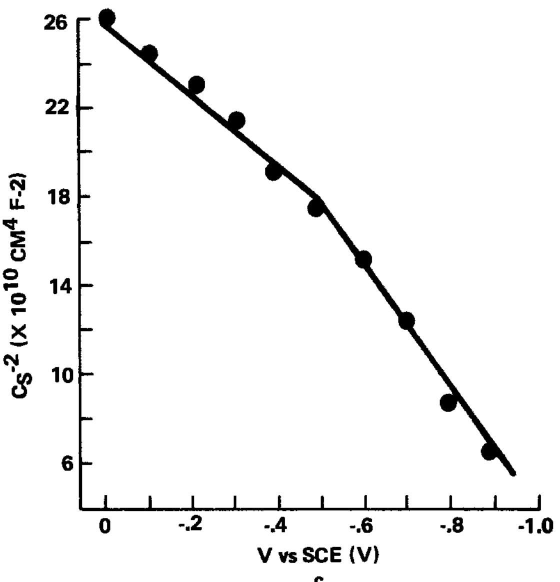


Fig. 6. C_S^{-2} *vs. V plots for (a) CdSe single crystal, (b) CdSe thin film, and (c) heat-treated Ti substrate.*

pletion layer widths of less than 100Å calculated from the depletion layer relation (17)

$$d = \left(\frac{2\epsilon\epsilon_0\psi_s}{qN_D}\right)^{1/2} \quad [2]$$

where ψ_s is the voltage drop across the space charge layer, taken here to be ~0.7V, the difference between V_B and the reversible redox potential for the electrolyte. Table II presents C_s at zero bias, N_D, and η for several thin film electrodes. There is no apparent correlation between N_D values and η. Electrode efficiency varies by an order of magnitude, yet the C_s and N_D values are almost constant. This observation and the fact that the good *I-V* performance of the thin film electrodes would not be expected with very narrow depletion layer widths led us to investigate the *C-V* performance of the Ti substrate alone. Figure 6c shows a typical result for an uncoated Ti substrate after the standard heat-treatment. It can be seen that the characteristic break in the curve is present. X-ray diffraction analysis of the heat-treated substrate indicated the presence of TiO_2 (rutile). Calculations using Eq. [1] and $\epsilon = 120$ for TiO_2 (18) result in $N_D \sim 10^{19}/cm^2$ and $d \sim 200$Å, which are reasonable values in view of the growth conditions of such a thin film.

Table II. Zero bias capacitance, calculated donor densities, and AM1 power efficiencies of several thin film electrodes

Sample	C_s (μF/cm^2)	N_D (cm^{-3})	η (%)
1	6.0	9.6×10^{20}	0.15
2	6.4	7.8×10^{20}	3.1
3	8.7	1.1×10^{21}	2.7
4	11.6	9.3×10^{20}	1.8
5	7.6	8.8×10^{20}	0.05

An explanation of the CdSe thin film *C-V* results is found by noting that Eq. [1] is based on the assumption that the semiconductor-electrolyte interface can be treated as three capacitances in series: the semiconductor depletion region, the Helmholtz layer, and the Gouy layer. At high ionic concentration in the electrolyte the capacitance of the Gouy layer can be neglected. The capacitance of the Helmholtz layer is much larger than that of the depletion region and can also be neglected so that Eq. [1] results and can be used to investigate the semiconductor depletion layer. However, the data presented here are complicated by the existence of pinholes and cracks in the CdSe thin film resulting from heat-treatment, which allow contact between the electrolyte and substrate. We interpret the observed C_s^{-2} *vs.* V_A behavior as an indication that the measured C_s represents contributions from the CdSe, as well as the oxidized Ti substrate. Therefore, Eq. [1] is not applicable to analysis of these data, and the lack of correlation shown in Table II is attributed to the effect of exposed substrate area. These results suggest that analysis of C_s^{-2} *vs. V* data is not useful for thin film electrodes unless complete substrate coverage is assured.

Analysis of monochromatic and white light *I-V* curves and action spectra proved to be the most useful in quantifying the performance of various thin film electrodes. Figure 7 compares the normalized spectral response curves of a single crystal sample ($\eta = 6.5\%$) and a thin film electrode ($\eta = 3.9\%$) taken in 2.5F Na_2S, 0.01F S, 1F NaOH electrolyte. This electrolyte minimizes the absorption correction necessary at the blue end of the spectrum (transmittance of 1 mm thickness of this electrolyte at 400 mm is 0.975). Peak external quantum efficiencies were 75% for the single crystal and 60% for the thin film electrode. Both curves show a fall off of response at shorter wavelengths, but it is more pronounced in the thin film sample. The thin film action spectrum also exhibits a greater response beyond 720 nm than the single crystal curve. Thin film electrodes generally showed significant photoresponse at wavelengths with energies less than the bandgap energy of CdSe, as in Fig. 7, curve b. This is consistent with the thin film transmission spectra, which show absorption >720 nm. Sub-bandgap photocurrents have been reported previously (5, 19) and attributed to defect states at energy levels within the bandgap that are responsible for the optical transitions (or band tailing) stimulated by light of less than bandgap en-

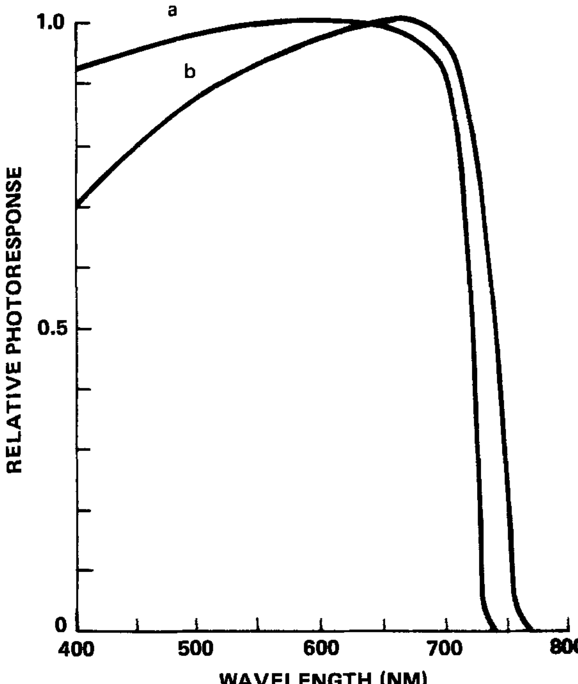

Fig. 7. Action spectra for single crystal CdSe (a) and thin film CdSe (b) electrodes.

ergy. These sub-bandgap photocurrents in effect extend the spectral response of the CdSe so that a greater portion of the solar spectrum can be utilized.

Etching these electrodes does not result in a significant increase in *I-V* performance as reported for single crystal and large grained polycrystalline hot pressed pellet electrodes (5, 19). This indicates that, although surface layer recombination losses are present in the thin film samples as evidenced by the drop off of spectral response in the blue, recombination centers resulting from the defect structure of the thin film electrodes are not restricted to the surface layer, but extend into the film.

Direct comparison of the *I-V* curves (50 mW/cm²) for these two samples (Fig. 8) shows that the fill factors are comparable (~0.60), but the thin film has a lower J_{sc} (6.3 mA/cm² *vs.* 7.8 mA/cm²) and V_{oc} (0.5V *vs.* 0.68V), which results in a lower over-all efficiency (3.9% *vs.* 6.5%). The lower J_{sc} is due to the defective nature of the thin film while the lower V_{oc} results from the higher dark currents observed for thin film electrodes under forward bias compared to single crystal samples. This difference in V_{oc} is attributed to the defective nature of the thin film

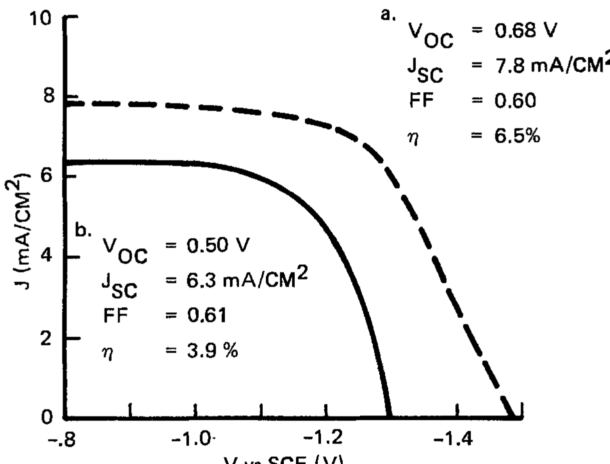

Fig. 8. Light *I-V* curves for single crystal CdSe (a) and thin film CdSe (b) electrodes at 50 mW/cm² (simulated AM1).

electrodes as well as to areas where the substrate and the electrolyte are in contact directly. The lower V_{oc} for the thin film electrode is also consistent with the interdependence of V_{oc} and J_{sc} predicted from simple solar cell theory (*i.e.*, $V_{oc} \propto \ln J_{sc}/J_{dark}$).

The difference in the performance of various electrodes could be quantified by analysis of their monochromatic *I-V* curves. Figure 9 shows photocurrent efficiency (N_p) *vs.* potential curves at 700 nm for the same single crystal and thin film samples used to obtain Fig. 7 and 8 as well as two other thin film electrodes. These curves were obtained by taking the difference between the light and dark current densities and dividing by the calculated photon current at 700 nm, which was ~0.35 mA/cm². The variation in photocurrent efficiency and curve shape with over-all power efficiency can readily be seen in these curves.

Discussion

Recently, the dependence of the output stability of CdSe photoelectrodes on electrolyte composition has been studied in some detail (5, 20-23); however, the dependence of η on electrolyte composition has only been noted briefly. Our results show that the electrolyte composition has a significant effect on η at light intensities that would be encountered in normal solar cell applications. The V_{oc} is not significantly affected by the change in concentration from 1F to 2.5F Na_2S and S, but the observed saturation of J_{sc} and decrease of FF in 1F electrolyte with increasing light intensity indicate that the transfer kinetics are not sufficiently rapid to accommodate the higher photon fluxes. Apparently, the 1F electrolyte cannot provide sufficient reduced polysulfide species to the interface rapidly enough to react with the hole flux being swept to the CdSe surface. This unfavorable kinetic situation should, in principle, result in destabilization of the semiconductor because of incomplete scavenging of holes by the electrolyte, allowing dissolution reactions [3] and [4] to proceed

$$CdSe + 2h^+ \rightarrow Cd^{2+} + Se \quad [3]$$

$$Cd^{2+} + S^{2-} \rightarrow CdS \quad [4]$$

The net effect of this dissolution process has been shown to be a decrease of photocurrent output with time (6, 20, 23). We have observed a decrease in photocurrent output (*i.e.*, J_{sc}) in 1F electrolyte from 10 to 1.5 mA/cm² after passage of 1500 C/cm².

This situation is improved greatly as the electrolyte concentration is increased so that with a concentration of 2.5F Na_2S and 1F S in 1F NaOH, J_{sc} and FF do not decrease significantly with increasing light intensity. Output stability is also improved and the output of an electrode operating at J_{sc} of 10 mA/cm² remains constant (within ±5%) with passage of 1500 C/cm². However, longer term experiments do indicate a slight drop off in output with time. Although short term stability and *I-V* performance are enhanced by increasing the polysulfide concentration, the long term stability (*i.e.*, several years) required for device applications remains to be established. We have observed Se/S substitution in some electrodes using Auger spectroscopy and are continuing longer term stability studies.

Optical transmission spectra and action spectra of the CdSe thin films indicate the presence of defect states that give rise to photoabsorption at energies less than that required for a band-to-band transition. For example, action spectra show a significant response at 750 nm. This band tailing could result from grain boundaries as well as impurities or lattice defects within the crystallites themselves. It has been shown that in semiconductor thin films with small crystallite size grain boundary recombinations are the current-limiting mechanism because the grain boundaries act as "sinks" for minority carriers as

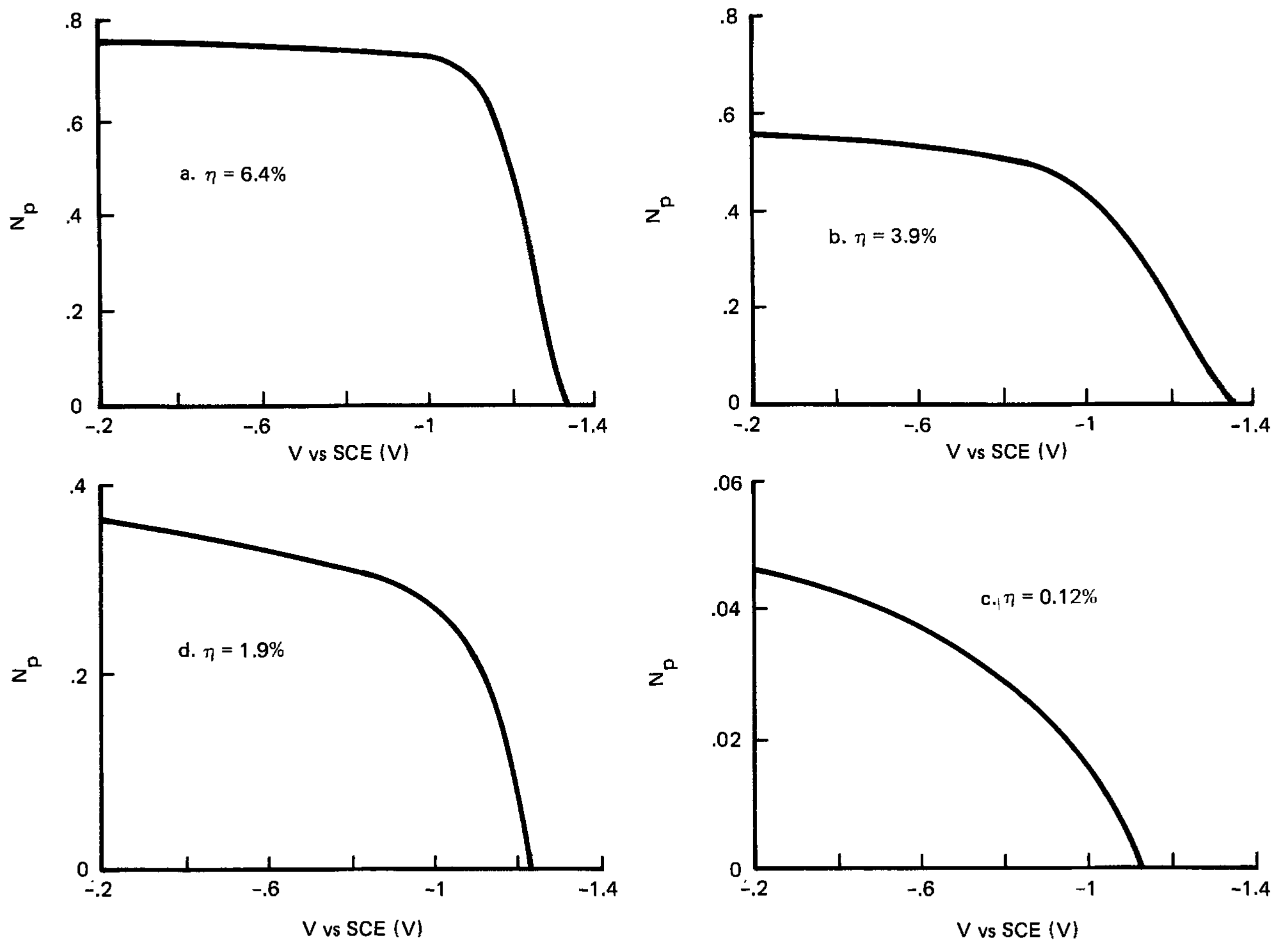

Fig. 9. Monochromatic photocurrent efficiency vs. applied potential curves at 700 nm: (a) single crystal, (b) thin film 1, (c) thin film 2, (d) thin film 3.

well as barriers to majority carrier flow (24). We suggest that this is the cause of the I-V behavior with intensity variation of reasonably efficient thin film electrodes (Fig. 4). The reduction in fill factor with increasing photon flux can be attributed to recombinations due to grain boundaries or defect sites in the space charge layer that become more pronounced with higher photon flux under forward bias (near the maximum power point). Yet, we find power efficiencies just slightly less than those reported for large grained (10-20 μm) hot pressed CdSe electrodes (25). The large grained CdSe electrodes have higher V_{oc} values (0.72 compared to 0.5), presumably due to lower dark currents, lower fill factors (0.5 compared to 0.6), and comparable J_{sc} values.

As noted earlier, analysis of C-V data did not prove to be useful for calculating thin film donor densities and flatband potentials. Thus, an alternate technique was necessary to begin to quantify the relationship between electrode I-V performance, semiconductor properties, and processing conditions. Analysis of photocurrent efficiency *vs.* electrode potential curves was quite useful in this regard.

N_D values as well as minority carrier diffusion lengths, L_p, could be calculated for various thin film electrodes by application of depletion layer theory to these curves in the reverse bias direction (*i.e.*, potential positive of -0.8V *vs.* SCE). The internal photocurrent efficiency, N_p, for negligible recombination losses can be approximated by (17)

$$N_p = 1 - e^{-\alpha d}/1 + \alpha L_p \quad [5]$$

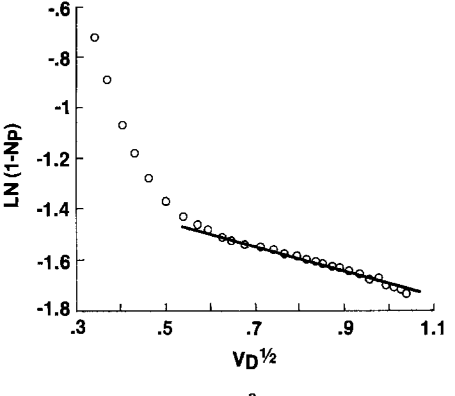
where α is the absorption coefficient at a chosen wavelength, d is the depletion layer width, and L_p is the minority carrier diffusion length. This relationship can be combined with Eq. [2] to yield (26)

$$\ln(1 - N_p) = -\alpha\left(\frac{2\epsilon\epsilon_0}{qN_D}\right)^{1/2} V_d^{1/2} - \ln(1 + \alpha L_p) \quad [6]$$

Applying this relation to a plot of ln $(1 - N_p)$ *vs.* $V_d^{1/2}$, N_d can be calculated from the slope and L_p from the intercept. In using this analysis on the data of Fig. 9 it was assumed that all the voltage drop in the semiconductor electrolyte interface is across the depletion region and that V_d is given by the difference between the applied potential and the potential of zero anodic photocurrent, which is fairly close to the flatband potential. Figure 10 presents the replotted data, and Table III summarizes the calculated values of N_d and L_p (α at 700 nm $\equiv 3 \times 10^4$ cm^{-1}). It can be seen from these data that the conversion efficiency is more sensitive to L_p than N_d, which is expected for defective polycrystalline semiconductors such as these (24, 27). L_p is a function of lifetime and mobility, which in turn are related to scattering centers and recombination centers within the crystallite itself or at grain boundaries. In these films it is likely that grain boundaries as well as defects within the crystallites themselves are limiting L_p.

Table III. Comparison of N_D and L_p values obtained from photocurrent analysis and power conversion efficiency

Sample	Power efficiency, η (%)	N_D (cm^3)	L_p (μm)
Single crystal	6.5	8×10^{16}	1.46
Thin film 1	3.9	6×10^{16}	0.40
Thin film 2	1.9	5×10^{16}	0.13
Thin film 3	0.12	1×10^{18}	0.006



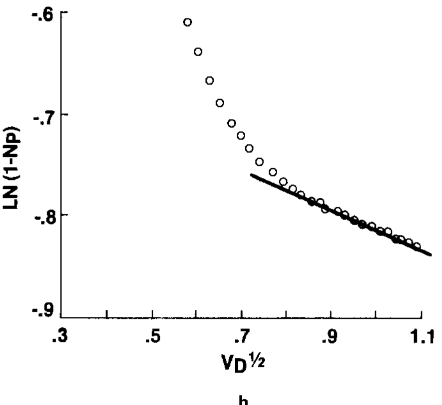


Fig. 10. Data of Fig. 9 replotted for determination of N_D and L_p: (a) single crystal, (b) thin film 1, (c) thin film 2, (d) thin film 3.

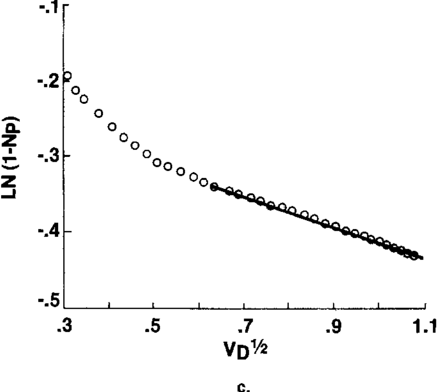

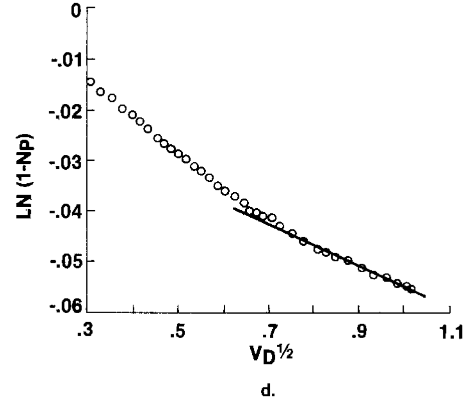

The model used in this analysis is not adequate to predict completely the *I-V* behavior of semiconductor liquid junction devices, particularly under forward bias, due to the inherent assumption that recombinations within the space charge region can be neglected. However, within the limits defined here (*i.e.*, reverse bias and a wavelength that minimizes surface recombination effects), this depletion layer model does yield very useful information in terms of sample-to-sample variation for the thin film electrodes and can be used to correlate *I-V* performance with donor density and minority carrier diffusion length. We have developed a more comprehensive model that will be presented in a future publication (28).

Summary

Thermal vacuum evaporation of Cd and Se has been used to produce CdSe thin film electrodes for use as photoanodes in electrochemical photovoltaic cells. Postdeposition heat-treatment of these electrodes in air has been found to greatly improve their *I-V* performance under illumination. In addition, polysulfide electrolyte concentration has been shown to have a significant effect on the *I-V* behavior of the CdSe thin films at light intensities typical of solar fluxes. Selection of deposition conditions, heat-treatment schedule, and electrolyte composition has resulted in conversion efficiencies in excess of 5%.

The use of *C-V* data to determine doping densities and flatband potentials of the CdSe films was hindered by substrate effects, which were due to pinholes and cracks in the heat-treated films. Analysis of action spectra indicated the films were defective, evidenced by the drop off of photoresponse at shorter wavelengths, as well as the presence of sub-bandgap energy photocurrents. Finally, by applying simple depletion layer theory to monochromatic photocurrent curves, N_D and L_p were determined and a correlation between η and L_p found.

VPE Growth of InGaP/InGaAs Structures for Transferred-Electron Photocathodes

Varian Associates, Incorporated, Corporate Solid State Laboratory, Palo Alto, California 94303

ABSTRACT

Vapor phase epitaxial growth has been used to prepare InGaP/InGaAs structures for use as a transferred-electron photocathode. Growth parameters have been established for InGaP growth using equal size metal sources with the hydride process. Field-assisted photoemission has been demonstrated and better than 1.0% overall efficiency at 1.06 μm was obtained.

In 1974, Bell, James and Moon (1) demonstrated a bias-assisted p-InP cathode using for the first time the mechanism of transferred-electron (TE) photoemission. TE photoemission is based on the fact that for certain III-V semiconductors such as InP, InGaAsP alloys, and GaAs, electrons can be promoted to the upper conduction band valleys with reasonable efficiency by applying modest electric fields. Photogenerated electrons which successfully transfer to the upper valleys have a good probability of being emitted over the surface energy barriers into vacuum.

A cathode design which potentially offers high 1.06 micron sensitivity, is a p-InGaP/p-InGaAs heterojunction TE cathode. The electron emitting layer p-InGaP has higher X and L levels than that of p-InP; therefore it is anticipated (based on experimental NEA work) that the surface escape probability from a p-InGaP emitter would be superior to that of p-InP, and hence offer improved performance over that of either the p-InGaAsP direct emitter cathode or the p-InP/p-InGaAsP heterojunction cathode (2, 3). The InGaAs is the optical absorbing layer, which dictates that it have a 1.15 eV or lower bandgap at 300°K. Thus the InGaAs composition should be approximately 18% In, *i.e.*, $In_{0.18}Ga_{0.82}As$. The InGaP composition lattice matched to $In_{0.18}Ga_{0.82}As$ is approximately 60% In, *i.e.*, $In_{0.60}Ga_{0.40}P$.

The vapor phase epitaxial (VPE) growth of the InGaP/InGaAs heterojunction structures is presented here. The main emphasis is on establishing the growth conditions for InGaP layers lattice matched to InGaAs. Although various InGaP/InGaAs heterojunction devices have been reported in the literature, the growth conditions have not been discussed (4-6). The growth of InGaAs graded layers on GaAs substrates has been reported and is used in our work (7-9). InGaP lattice matched to GaAs has been reported and forms the basis for the heterojunction growth conditions established in this study (10-12). A brief summary of the previous work on the VPE growth of InGaP is given first. This is followed by a description of the experimental setup and the procedures used. The growth parameters and the characterization of the grown layers are discussed in the next section followed by a short conclusion.

Previous Work on InGaP/GaAs

The basic equations governing the growth of InGaP can be written as follows

$$yM + HCl \rightarrow yMCl + (1-y)HCl + \frac{y}{2}H_2$$

$$MCl + \frac{1}{3}PH_3 + \frac{1}{6}P_2 + \frac{1}{12}P_4 \rightleftarrows MP + HCl$$

where M represents either of the In and Ga metals and P_2, P_4 are the products formed by the decomposition of PH_3 at high temperatures (10).

The growth of InGaP ternary alloys is complicated by the need for precise control of a number of parameters. Due to the large difference in their free energies of formation, the GaP component is much more readily deposited than InP (10). This makes it necessary to have a large In(HCl)/Ga(HCl) ratio for growing InGaP lattice matched to GaAs. For a fixed set of other conditions the In/Ga ratio needed for growing a particular composition increases with the deposition temperature. With increasing deposition temperature, larger changes in the In/Ga ratio are therefore needed to effect small changes in the composition. It is essential that a steady temperature be maintained because the composition is a strong function of the deposition temperature. The change in the composition is of the order of 0.3 mole percent (m/o) per degree centigrade (11).

The growth of InGaP can be accomplished with either stoichiometric (*i.e.*, Σ MCl = Σ P) or off-stoichiometric conditions. A surplus of P tends to promote InP deposition while a surplus of HCl lowers the InP content (12). At higher source temperatures the conversion of HCl to MCl is more efficient, and this effects

the composition by changing the total HCl present in the deposition zone. The decomposition of PH_3 also increases with temperature. The extent of PH_3 dissociation is important since InP deposition is more favorable through a reaction of InCl with PH_3 rather than with P_2 or P_4 (12). It is also important to ensure adequate mixing of gases for good homogeneity of composition. Finally, it is imperative that a clean, leak-free system be maintained.

Although thermodynamic calculations for InGaP growth have been performed, the results cannot be directly used for growing desired compositions since the study concluded that the experimental conditions deviate from equilibrium (10). Also, the growth parameters used in other studies usually are not directly applicable because of the differences in reactor design, furnace profile, etc. Hence for each new reactor system, it is necessary to go through an initial stage of experimentation to determine the optimum conditions for the desired growth.

Experimental Set-up

A schematic diagram of the reactor used for vapor phase epitaxial (VPE) growth of InGaP is shown in Fig. 1. The growth system can be divided into three zones. In the first zone, In and Ga metal sources are placed in two separate chambers and a mixture of HCl and H_2 is passed over each. The HCl reacts with the metal sources to form volatile metal chlorides which are swept downstream. The system has a provision for using either electronic grade HCl/H_2 gas mixture or higher purity HCl from cracking $AsCl_3$ at high temperatures. Since under typical growth conditions the HCl flow over the Ga source is much smaller than that over the In source, extra H_2 is added to the HCl(Ga) so that equal total flow of gases over both the sources can be maintained. This ensures equal residence time of gases on the sources. A baffle is placed in each of the source chambers to enhance mixing and residence time and to avoid back-diffusion of gases toward the sources.

In the central zone various gases are introduced. Bypass H_2 and HCl for etching the deposits on the reactor walls and the substrate are also brought in. For p-type doping, an H_2 stream passing over a heated Zn pellet is used. Electronic grade gas mixtures of 10% PH_3/H_2 and 10% AsH_3/H_2 are also introduced in this zone. All the gas flows are controlled by Tylan mass flow controllers. In the third zone deposition takes place.

Procedures

The temperature profile of the three-zone resistance heated furnace is shown in the reactor schematic diagram. All the results discussed below were obtained with this profile. The optimum position for growth has been experimentally determined to be about 8 cm downstream from the PH_3 and AsH_3 entry position, as shown in Fig. 1. Thus, the growth takes place at 720°C on a temperature slope of 5°C/cm. The bypass H_2 flow is adjusted to obtain maximum deposits at the substrate position.

A typical growth experiment consists of 15 min of thermal equilibration, followed by 10 min of MCl saturation, and then 5 min for stabilization of growth conditions with AsH_3 and/or PH_3 flows. Growth is allowed after this 30 min period. The MCl saturation step is important and if omitted results in poor growth. To ensure MCl saturation when the HCl flow for growth is small (*e.g.*, only 2 cm^3/min HCl flow over the Ga source for the InGaP growth), about 50 cm^3/min HCl is passed for 2 min before reducing it to the appropriate value.

The reactor wall deposits are etched away in a separate run after each growth. This eliminates any possibility of contaminating the InGaP growth with As or the InGaAs growth P. It also ensures the same starting conditions for each growth and the reproducibility of the results is assured.

A few attempts were made to grow the complete heterojunction structure in one run. This was difficult since the InGaAs growth produces excessive wall deposits which require etching of the reactor for about the same time duration as the growth itself. Attempts to do this without taking out the sample were not reproducibly successful since uncontrolled etching does take place causing poor InGaP growth. Hence InGaAs and InGaP layers are grown in separate runs.

To prepare the GaAs substrate for InGaAs growth, the first step is pad polishing with Br_2-CH_3OH solution. Just before putting in the reactor, the polished substrates are ultrasonically solvent cleaned (TCE, ACE, Alconox) and a 4:1:1 etch (H_2SO_4:H_2O_2:H_2O) is used followed by IPA rinse. For InGaP growth the graded InGaAs layers are lightly polished in $<1\%$ Br_2-CH_3OH solution and then solvent cleaned before putting in the reactor. No 4:1:1 etch is used since it could remove too much of the grown layer.

The grown layers were characterized using x-ray diffraction for lattice constant determination, 77°K photoluminescence (PL) measurements, and vacuum

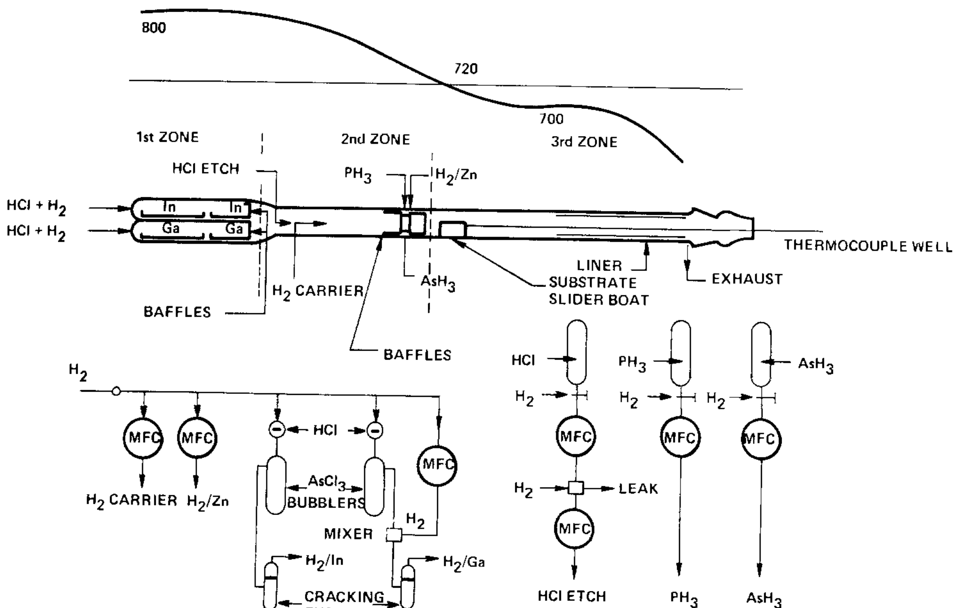

Fig. 1. Schematic diagram of the InGaP/InGaAs VPE growth system.

photoemission studies. The composition values are calculated from the equations developed by Moon *et al.* (13). The difference between bandgap (E_g) at 77° and 300°K is taken to be 0.07 eV for both InGaAs and InGaP. The composition values determined from these techniques are in reasonable agreement with eath other. The background doping of this reactor has been found to be about 10^{15} cm^{-3} for InGaP layers grown on GaAs(Cr).

VPE Growth

InGaAs growth.—For InGaAs growth on GaAs, equal flow of AsH_3 and total MCl (50 cm^3/min) are used. Under typical growth conditions a thin layer of GaAs is grown first, followed by a graded region, and finally a constant composition layer of desired thickness. Step grading is used in our experiments since it results in reduced overall dislocation density (6). A digital Data Trak programmer, Model 6610, is used to change the HCl flows over the sources in a specified manner for step grading. The step grading program is based upon InGaAs growth parameters experimentally established in this lab and published data (7-9). The grading rate is about 5 m/o/μm.

The InGaAs layers are shiny in appearance with a fine cross-hatch pattern. This arises from the dislocation network generated in the graded region (9). Sharp PL spectra are obtained from these layers. Van der Pauw measurements on p-type $In_{0.18}Ga_{0.82}As$ grown on GaAs(Cr) gave mobility values of 944 cm^2/V-sec at 77°K and 146 cm^2/V-sec at 300°K. The corresponding doping levels were $1.9 \cdot 10^{16}$ cm^{-3} and $7.4 \cdot 10^{16}$ cm^{-3}. Typical growth rates are 0.15-0.2 μ/min.

InGaP growth.—To establish appropriate conditions for growing InGaP, two experimental approaches were used. First, the ratio of In(HCl)/Ga(HCl) was changed and second, the PH_3 flow compared to MCl was changed. Since excess PH_3 compared to MCl tended to produce a poor quality surface, it was decided to grow InGaP under conditions of $PH_3 < MCl$. This finds support in a study of GaAs grown by the hydride process where improved lifetime and diffusion length of minority carriers are obtained when $AsH_3 < GaCl$ (14).

To grow InGaP layers lattice matched to InGaAs substrates, the HCl flow over the In source is adjusted. The HCl flow over the Ga source and the PH_3 flow are kept fixed at 2 cm^3/min and 50 cm^3/min, respectively. Since 77°K photoluminescence is routinely used to characterize the grown layers, a relationship between the In(HCl) flow needed to grow lattice-matched InGaP layers and the InGaAs bandgap (E_g) at 77°K has been established and is shown in Fig. 2. The same program was always used for growing InGaAs; the variations in the composition grown are believed due to minor changes in the system, *e.g.*, the source surface areas which change as the sources are used up, change in the source and substrate temperatures from run to run. Also, each time the reactor is taken down for cleaning and reinstalled, the positioning is not identical and the temperature profile can be slightly shifted. The scatter in the In(HCl) flows needed to grow lattice-matched InGaP is also due to the same reasons. The In(HCl) flow used for growing InGaP lattice matched to GaAs is 54 cm^3/min.

It must be emphasized that very critical control of parameters is needed to grow good quality InGaP layers. A 2 cm^3/min change in the In(HCl) flow can easily ruin the growth. It has been found that when the grown layer is shiny in the middle and dark around the edges the In(HCl) needs to be reduced for lattice-matched conditions. When the In(HCl) flow is less than required the growth is patchy and dull in appearance. From Auger studies As has often been seen on the surface of such wafers. However, a certain amount of lattice latching has also been observed while growing InGaP on graded InGaAs. Two such layers of differing E_g at 77°K (1.18 and 1.21 eV) were placed next to each other and lattice-matched growth of InGaP was obtained on both of them. The In(HCl) flow used was intermediate between the flows needed for lattice-matched growth separately.

These growth conditions have been established for equal source boats, each of which has a surface area of 15 cm^2. For unequal sources these conditions are not appropriate and lattice-matched growth is not obtained. Also, for equal sources but with substantially different surface area, the conditions would have to be adjusted slightly.

The relationship between the InGaAs bandgap at 77°K and that of InGaP is shown in Fig. 3. No attempt has been made to draw the expected relationship since a wide variation exists in the reported InGaP bandgap *vs.* composition in the literature (15). These data points are for the best heterojunctions grown. The best growths are characterized by sharp PL spectra, uniform coverage, specularly reflective surfaces, and good cleaving characteristics. For the few samples where x-ray diffraction was performed, the layers were found to be lattice matched.

The InGaP layers lattice matched to InGaAs substrates are shiny in appearance and the surface has a characteristic cross-hatch pattern as shown in Fig. 4. The asymmetry in the pattern follows from the asym-

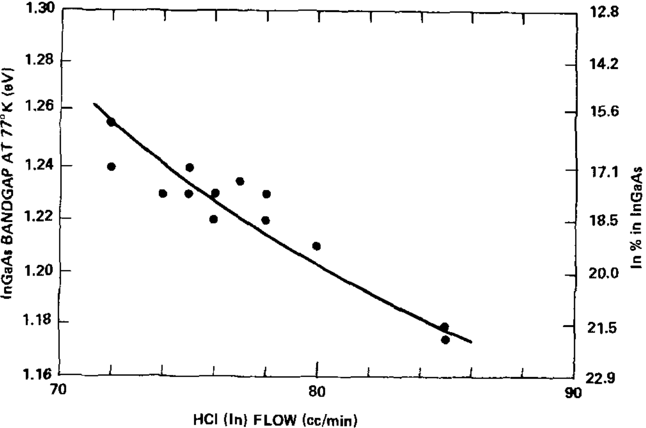

Fig. 2. Relationship between the InGaAs bandgap at 77°K and the In(HCl) flow required for lattice-matched InGaP/InGaAs growth.

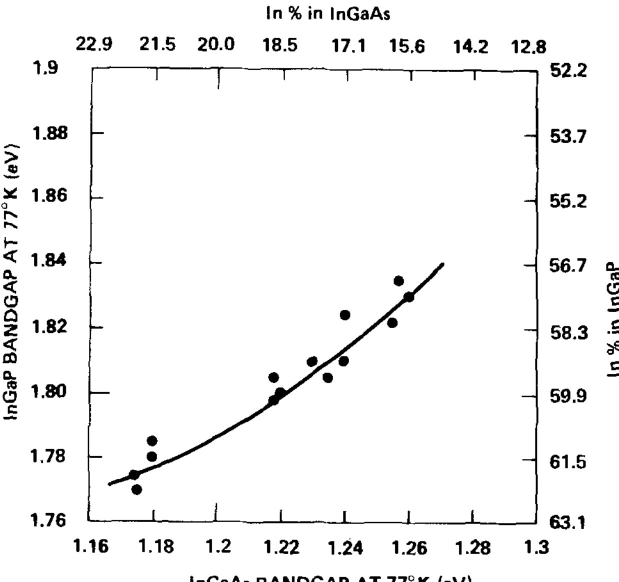

Fig. 3. Relationship between the InGaAs and InGaP bandgaps at 77°K for lattice-matched layers.

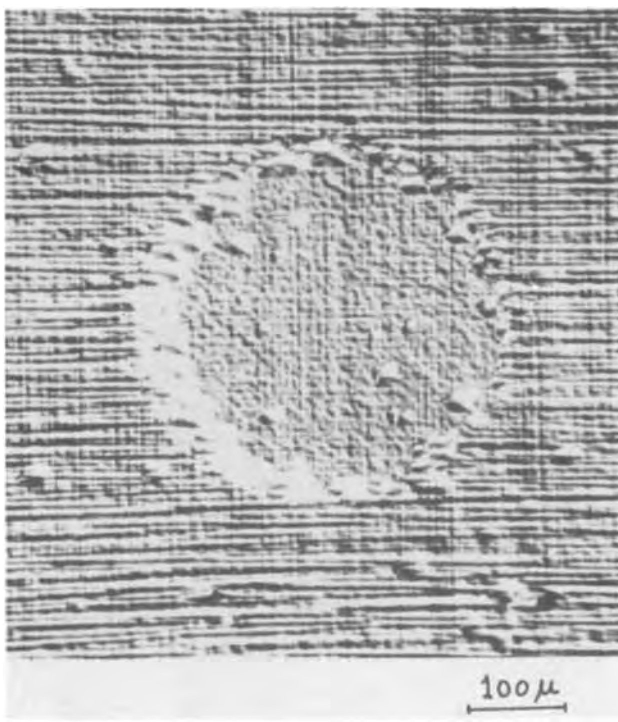

Fig. 4. Crosshatch patterns on InGaP and InGaAs layers. InGaP did not grow in the circular region.

metry in the zinc blend structure as discussed by Olsen *et al.* (16). It is found that the surface of the InGaP lattice matched to GaAs has no cross-hatch. Similar findings have been reported earlier when InGaP graded on GaP was found to have a cross-hatch pattern on the surface while InGaP grown directly on GaAs showed no cross-hatch (17). Thus, the cross-hatch seen on the InGaP surface grown on graded InGaAs substrate is due to the substrate itself. This is clearly seen in Fig. 4, which shows the cross-hatch pattern on a wafer where the InGaP did not grow in a few localized regions.

Lattice-matched InGaP/InGaAs growths are found to cleave easily without cracking and show a sharp interface, whereas mismatched layers are difficult to cleave; cracking on cleavage of imperfect layers has been reported earlier (5). A cleaved picture of the InGaP/InGaAs/GaAs structure is shown in Fig. 5.

Sharp PL spectra of FWHM of <50 meV are obtained from lattice-matched InGaP/InGaAs layers; for mismatched layers the PL spectrum is very broad. A sharp PL spectrum is also indicative of compositional homogenity (18).

To obtain different p-type doping levels the Zn heater temperature is varied while the H_2 flow is kept fixed at 50 cm^3/min. The doping levels have usually been determined by *C-V* measurements. The doping levels achieved in the InGaP layers for various Zn pellet temperatures are shown in Fig. 6. The PL spectra for p-InGaP have a distinct Zn peak and the

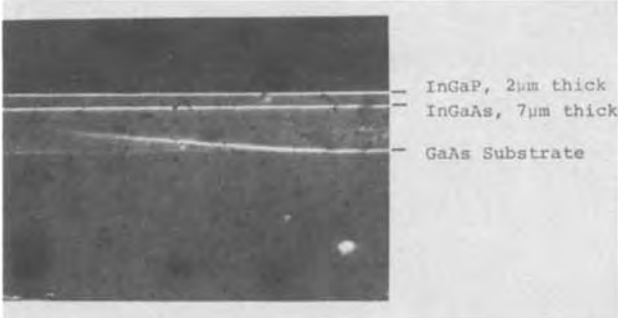

Fig. 5. Cleaved picture of the InGaP/InGaAs/GaAs structure

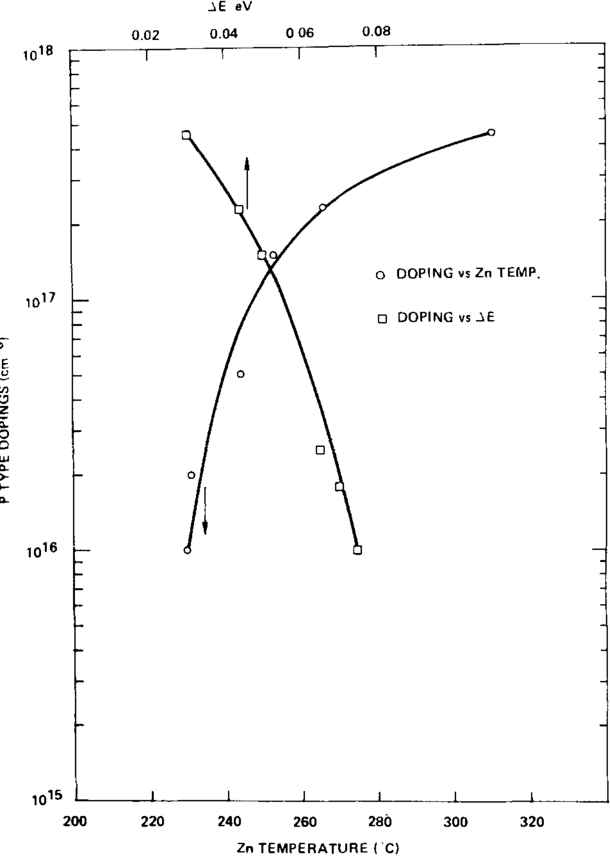

Fig. 6. Doping level in the InGaP layer as a function of the Zn temperature and the ionization energy as measured from the photoluminescence spectrum.

ionization energy measured is a function of doping itself (12). The established relationship is also shown in Fig. 6. The ionization energy is a slow function of the In% as well (19), but the doping level effects dominate in Fig. 6 since the data are for $In_xGa_{1-x}P$ layers with $x = 0.60 \pm 0.03$ only.

Van der Pauw measurements have been somewhat difficult due to contacting problems associated with a high bandgap material. For InGaP lattice matched to GaAs, a hole mobility of 104 cm^2/Vsec was measured at room temperature for a carrier concentration of $8.4 \cdot 10^{15}$ cm^{-3}. Typical growth rate for InGaP is 0.1 μ/min.

Conclusion

Growth parameters have been established for growing InGaP lattice matched to InGaAs. To improve the reproducibility of the results, it would be beneficial to design a source region such that the surface area exposed and the residence time of gases over the sources are kept as nearly constant as possible. For better resolution in controlling the InGaP composition, the flows should all be increased since with 2 cm^3/min flow over the Ga source even 1 cm^3/min change in the In(HCl) flow makes a difference. Field-assisted photoemission from InGaP/InGaAs cathodes has been demonstrated and better than 1% overall efficiency at 1.06 micron has been obtained with this structure.

Acknowledgments

The authors wish to thank Dr. R. L. Bell for his continued support and useful discussions and Dr. G. A. Antypas for supplying the GaAs substrates. Thanks are also due to Mr. L. Garbini, Mrs. C. E. Hooper, and Miss S. Fonte for x-ray analyses, *C-V* measurements, and Van der Pauw measurements, respectively. This work was supported by the Air Force Avionics Laboratory under Contract F33615-76-C-1351, Wright-Patterson AFB, Ohio 45433.

Advances in Transmission Electron Microscope Techniques Applied to Device Failure Analysis

T. T. Sheng and R. B. Marcus

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Special techniques have been developed for routine preparation of transmission electron microscope samples from integrated circuit devices. These methods, which are described and illustrated in this paper, are the preparation of replicas of fractured multilayer structures, vertical cross sections, horizontal cross sections, and feature enhancement on cross-section samples through the use of special staining and etching treatments.

Transmission electron microscopy (TEM) has played an active role in materials studies related to the processing and fabrication of microelectronic devices. TEM has been an important research tool in providing essential information in generic studies of oxidation, interdiffusion, implant damage, and annealing and propagation of defects. In a device processing and failure analysis environment, however, problems continuously appear on the scene which demand fast analysis and solution. TEM has traditionally been of little use in this type of environment because of difficulties of sample preparation. Although there is some published information on the application of TEM to processing problems in real device structures (1, 2), most published TEM work on processing problems has been done on special samples with geometries more suitable for TEM analysis and which are made to simulate the real device (2).

For a number of years we have used TEM in a device processing and failure analysis working environment. TEM has been used to solve a large number of processing problems related to vertical and horizontal shorts, junction leakages and voltage breakdowns, poor contacts, and variations in resistivity and oxidation kinetics. We are able to use TEM on these problems mainly because procedures have been developed for preparing samples so that regions of interest in real device structures can be studied and information obtained within a short time period. TEM is thus made an equal partner along with other in-process testing procedures towards the analysis and solution of processing-related problems as they arise.

TEM is often used in conjunction with other analytical approaches for device failure analysis studies. Cooperative work with optical microscopy, scanning electron microscopy (in the secondary electron, voltage contrast, and EBIC modes), Rutherford scattering, and Auger electron spectroscopy have been particularly useful. Although cooperative analysis of this type lengthens the time of the analysis, the information obtained from these studies is usually well worth the extra time.

The main purpose of this paper is to describe the procedures which have been developed for preparing device samples for TEM studies. Electron micrographs of typical samples are used to illustrate the type of information obtained from these studies. Most of our interaction has been with silicon semiconductor device processing and most of the illustrations reflect this bias. Samples for TEM analysis are prepared from any

Key words: electron microscopy, failure analysis, integrated circuits.

point in the processing sequence, including finished and tested devices.

Four main sample preparation techniques will be described: edge fracture replica, horizontal section, vertical section, and feature enhancement. The first technique is a method for preparing a replica of a fractured surface of a device; the second and third techniques are methods for preparing device material for direct study in the electron microscope; the last technique is a means of enhancing the contrast of device features (in horizontal or vertical sections) that would otherwise be difficult to see in the electron microscope.

A major aid in TEM failure analysis studies is the use of a TEM test pattern which is incorporated at a number of sites on each device wafer. This test pattern contains all the morphological features of interest compressed into a small area so that a sample can be made with nearly 100% certainty of capturing the region of interest for TEM study using any of the four sample preparation techniques.

Sample Preparation Technique-Edge Fracture Replica

Multilayer device structures can be examined by fracturing in a direction normal to the surface and studying a shadowed replica made from that surface. The replica technique is a very old one for the study of surface texture (3). In the usual variation of the method a small amount of a heavy metal is deposited at an oblique angle to a surface, resulting in thickness variations that depend on the angle of inclination of the local surface. Shadows are cast by surface protuberances whose far side (away from the metal source) form an angle with the surface greater than the inclination of the metal source to the surface. A carbon film is deposited over the surface and is then withdrawn, extracting the deposits of heavy metal. The replica with regions of varying heavy metal deposit is then examined in the electron microscope, and local variations in metal thickness produce variations in electron absorption which result in an image that is closely related to the texture of the original surface.

In the method to be described, advantage is taken of the fact that multilayer structures generally do not fracture cleanly through all layers, but one of the layer edges at an interface is usually set back slightly. A shadowed replica can be made simultaneously of the exposed interfacial surfaces and of the fracture surfaces. The technique for preparing such a replica from a 0.020 in. wafer is illustrated in Fig. 1 and is described below; the fractured surface is assumed normal to the device surface. (*i*) Scribe two co-linear marks on opposite sides of the region of interest. (*ii*) Fracture. Sandwich the wafer between glass slides with scribe marks lining up along the slide edges. Apply a downward force so that the working surface (containing the scribe marks) is the first to break. (*iii*) Shadow and replicate. The shadow angle is 15° to both surfaces (sample surface and fracture surface). The carbon angle is 45° to both surfaces. (*iv*) Strip the shadowed replica by dissolving the underlying material. The chemical etchant must act slowly. Violent dissolution with bubble formation will break up the replica. For samples of oxide and poly layers on silicon a convenient etch is: $HOAc:HF:HNO_3 = 6:6:10$ diluted 1 part to 10 parts HOAc.

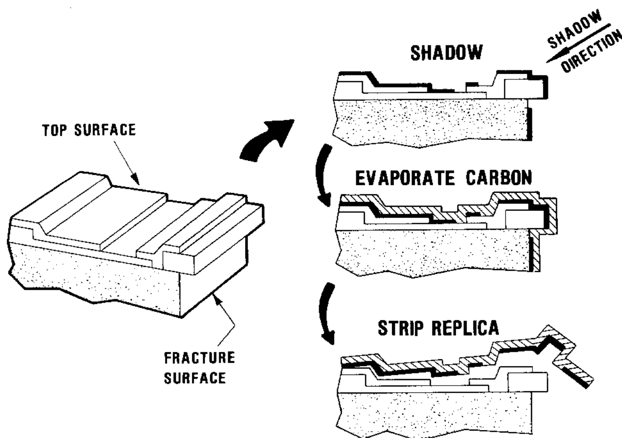

Fig. 1. Edge fracture replica technique

Electron micrographs of edge fracture replicas are shown in Fig. 2 and 3. Note that in Fig. 2 the surface textures of the substrate, gate oxide, poly, and top SiO_2 can be seen, and the edges of the three top oxide layers can be distinguished. The texture of the top surface of the gate oxide is related to the poly grain structure, which can be determined from studying both the fractured and top surfaces of the poly. The three top oxides can be distinguished because of differences in the microtexture of these layers.

In Fig. 3, the B-glass, polysilicon, and field oxide layers are easily distinguished. An important piece

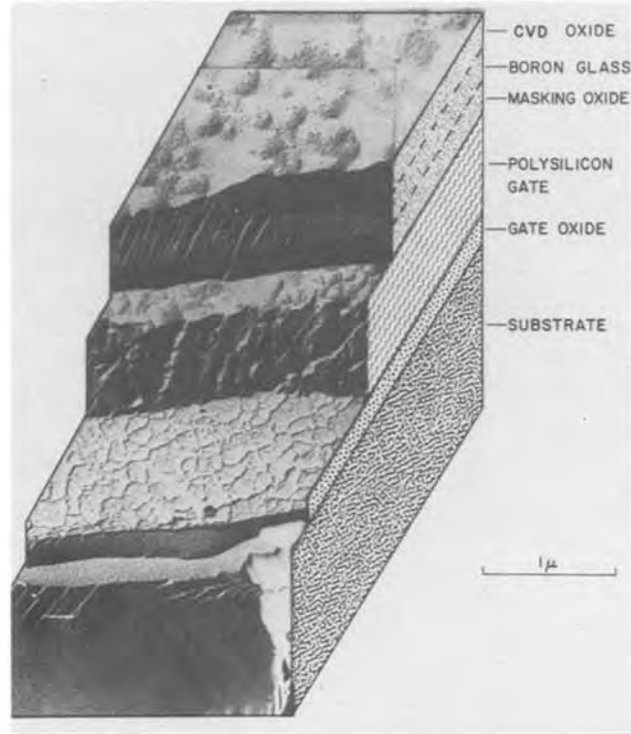

Fig. 2. TEM photo of fracture replica of multilayer structure on a silicon substrate. The fractured edges of the three top oxide layers are distinguished, and the surface textures of three layers plus the substrate can be seen.

Fig. 3. TEM photo of edge fracture replica through a sample of B-glass on poly over oxide on a silicon substrate.

of information is contained in the region at the edge of the poly runner. After patterning the poly and treating with BHF, an undercut was produced (arrow) which filled up with B-glass. The B-glass flows sufficiently so that the oxide undercut is unimportant as a failure mode.

Sample Preparation Technique-Horizontal Section

When a sample is to be examined directly in the transmission electron microscope at 100-200 keV, it first must be thinned to ~ 1000Å. Thin film samples which are prepared parallel to the wafer surface are referred to in this paper as "horizontal sections." These can be made in such a way that the original surface remains as one surface of the sample, or a section can be prepared from a region below the surface in cases where an interface needs to be examined.

Chemical thinning of silicon and SiO_2 is faster than ion milling and for this reason is preferred as the final thinning process for preparing horizontal sections. In cases where multilayer structures are present and chemical attack of different layers occurs at widely different rates, ion milling must be used. The main steps in preparing horizontal sections are illustrated in Fig. 4 and described below: (*i*) Mechanically lap the sample to < 100 μm using No. 400 grit paper. (*ii*) Cut a disk using an ultrasonic cutter with the area of interest approximately at the center. The disk should be of a size appropriate for the sample holder of the electron microscope. (*iii*) Using wax, mount the disk face down on a clear sapphire plate. Wax should protect the front surface and edge of the disk but the back surface of the disk should be exposed. The transparency of the sapphire aids in determining the end point during thinning. (*iv*) Chemically etch the sample until a small hole is formed. This is accomplished for a silicon sample by ~ 5 min immersion in 6:6:10 HF:HOAc:HNO_3. Etching is stopped by flooding the sample with DI water. (*v*) Dissolve the wax in a solvent and remove the sample. The taper at the edge of the hole is usually sufficiently small so that a sample transparent to 100 keV electrons can be produced which extends back from the hole ~ 10-40 μm. (*vi*) If a region say 0.5 μm depth below the surface is to be examined, the front surface must be ion milled. Using an IMMI ion milling machine with Ar gas at 10 μm chamber pressure, and an ion beam from one gun operating at 6 kV and 100 μA beam current striking a sample at 15° angle rotating at 15 rpm, the thinning rate for Si is ~ 1.0 μm/hr.

An example of the application of the horizontal section technique to the solution of processing problems is illustrated in Fig. 5. High leakage at pn junctions on van der Pauw testers was localized to specific sites [2 in Fig. 5(A)] by SEM EBIC analysis. The site was marked with polymerized hydrocarbon from SEM study [Fig. 5(B)] and a horizontal section prepared and examined in the TEM. The leakage site was found to be coincident with a stacking fault crossing the junction [Fig. 5(C)] and further TEM study [Fig. 5(D-F)] showed the fault to contain a copper-rich precipitate. More extreme gettering procedures were then used to remove precipitates, and although stacking faults were still produced during processing, junction leakage was lowered drastically (4).

HORIZONTAL SECTION

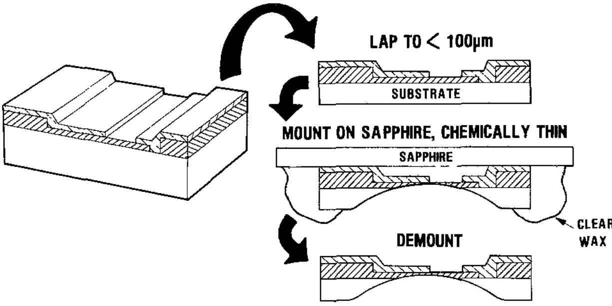

Fig. 4. Steps in preparing a horizontal section for TEM study. The wafer is lapped to <100 μm thickness, mounted on clean sapphire and chemically etched until a small hole appears.

Sample Preparation Technique-Vertical Section

The preparation of a section normal to the device surface requires somewhat more labor than does the preparation of a horizontal section. The method is illustrated in Fig. 6 and is now described: (*i*) Lap the sample to <100 μm using No. 400 grit paper. (*ii*) Scribe and cleave a small number of pieces ~ 1.5 mm × 3 mm, so that the region of interest is near the center of each piece. (*iii*) Bond a stack of the cleaved pieces face-to-face or face-to-back using epoxy. The epoxy should be squeezed out between the pieces so that only thin epoxy films of approximately uniform thickness separate the pieces. (*iv*) Imbed the stack in an epoxy "button" using a round silicone rubber mold such as Model No. 23650 from Ladd Research Industries. (*v*) Lap and polish both sides of the button to a final thickness of <100 μm. No. 400 grit paper followed by ~5 min of No. 600 paper followed by polishing with 3 μm grit works well for silicon device samples. (*vi*) Cut a disk ultrasonically with the area of interest approximately at the center. Because of the fragile nature of this assembly, it is useful at this point to epoxy bond the disk to a small molybdenum ring whose OD corresponds to the sample holder size of the electron microscope. (*vii*) Ion mill both surfaces simultaneously until a small hole develops in the sample. Regions from the edge of the hole extending back ~ 50 μm are usually thin enough for TEM study.

Two important points should be noted regarding use of this technique. Because of uncertainties regarding the exact site at which a hole appears in the sample, and because the hole is sometimes larger than 100 μm diameter, [the sample thickness after step (*i*)], it is useful to have 4-5 pieces comprise one sample button. A second point regards the different speed at which materials are ion milled. Epoxy mills faster than most other materials. If the epoxy between (face-to-back) pieces is milled away, the outer edge of the surface of the face will also tend to suffer some erosion from ion milling, and this material will be lost to TEM study. This loss can be prevented by coating the wafer with a sacrificial layer of ~ 0.5 μm poly, SiO_2, or Si_3N_4 just before TEM sample preparation.

Examples of the application of the vertical section technique to failure analysis problems are shown in Fig. 7, 8, and 9. Figure 7 shows three stages in processing using a selective oxidation technique for growing the isolation oxide (a-c), with severely thinned gate oxide at the "bird's beak" edge as shown in 7(c). After a change in processing, gate oxidation no longer produced the thinning (5) as shown in Fig. 7(d). Figure 8 shows a TEM of a vertical section through a two-level poly structure showing the extreme one-sided thinning of poly I, and the narrow gap at the "cat's paw" separating poly II from the substrate; this latter morphological feature was the cause of a low breakdown voltage in these devices (6). Figure 9 shows two P-glass contact window sites in an MOS device; an aluminum to poly contact is shown in Fig. 9(a) and an aluminum to substrate contact is shown in Fig. 9(b). The disturbance of the silicon due to pitting can be seen in both figures.

Sample Preparation Technique-Image Enhancement

Electron micrograph image contrast from single crystal silicon, poly, or various metallization is pri-

Fig. 5. Study of origin of pn junction leakage sites: (A) shows an SEM photograph of a test pattern with the leakage site, 2, marked by EBIC study. (B) is an optical photo showing the leakage site marked by polymerized hydrocarbon. (C-F) are TEM photos of a stacking fault containing a precipitate which intersects the pn junction. Viewing conditions were adjusted for extinction of the stacking fault contrast in (E) and (F).

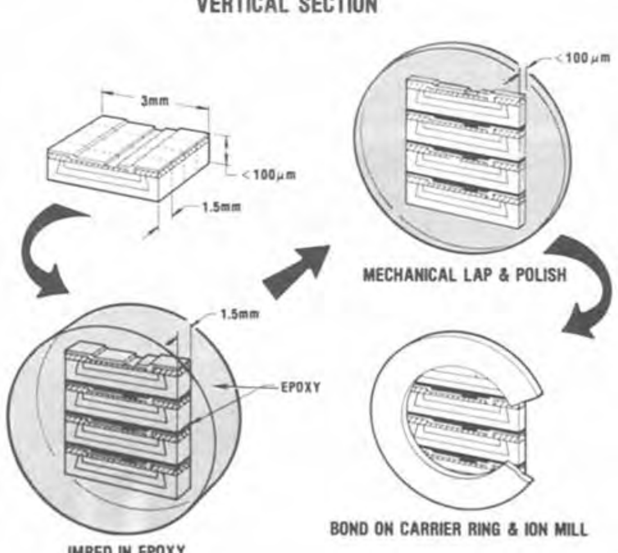

Fig. 6. Steps in preparing vertical section for TEM study. The wafer is lapped to <100 μm, diced into small pieces and bonded face-to-face or face-to-back in an epoxy button. After further lapping and polishing to <100 μm thickness and bonding to a carrier ring, the sample is further thinned using ion milling.

marily controlled by diffraction effects which are determined by crystal orientation, thickness, and defect structure. The ability to resolve small features in these materials, including the definition of layer edges is usually not a problem and is mainly limited by the condition of the electron microscope. The material on opposite sides of a pn junction in silicon does not differ in any of the essential properties just mentioned, however, and in order to make the junction visible, methods must be used for enhancing contrast by changing the thickness of either the n or p region by selectively removing material. We have delineated p^+n and n^+p junctions by dipping both horizontal and vertical cross-section samples into 0.25% HNO_3 in HF for 2-4 sec under strong light. Figure 10 shows a vertical cross-section sample through a "stained" p^+n junction at the edge of a poly gate (which has been removed). The p+ region was made with boron and the Si substrate contains phosphorus. The curvature of the stained region under the gate can be seen and accurately measured. It is not known if the transition seen in the micrograph corresponds exactly to the p+n junction, but it is safe to assume, as in more typical cases of angle lap-staining on larger samples, that the transition lies parallel to the junction. Figure 11 shows micrographs of another n+p junction made by implanting and diffusing As into p-type silicon. The junction is not delineated in the two face-to-face

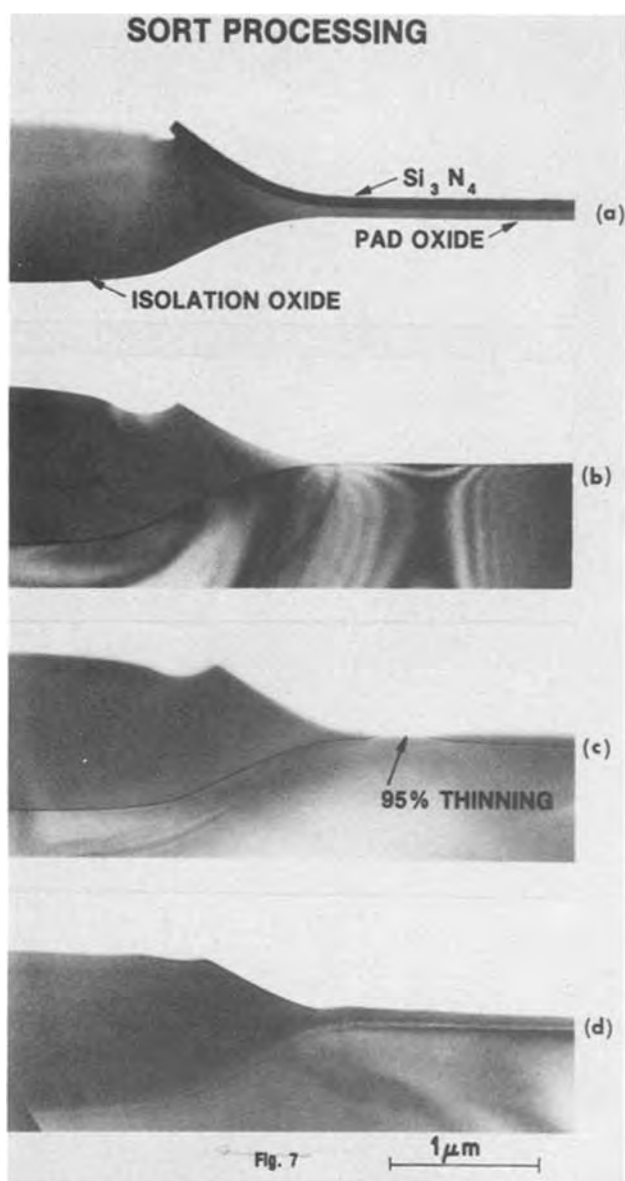

Fig. 7. TEM photos of vertical cross sections through samples at various stages in processing (a)-(c) leading to a gate oxide thinning (c), and a sample after a processing change was introduced to eliminate thinning (d). The Si_3N_4 and pad SiO_2 layers shown in (a) have been removed in (b), and gate oxide has been grown in (c) and (d).

samples prepared by ion milling (a), but appears after 4 sec etch (b) and 8 sec etch (c). The n+ region is preferentially etched and converted to an amorphous layer, probably an oxide, after 8 sec etch.

Image contrast from amorphous or nearly amorphous layers such as SiO_2 or Si_3N_4 is primarily controlled by variations in thickness in a given phase or differences in scattering power when going across a phase boundary. The change in scattering power across a thermal SiO_2-CVD SiO_2 interface is usually too weak to give useful contrast changes, but can be enhanced by light treatment with buffered HF which etches CVD SiO_2 significantly faster than thermal SiO_2. Very small voids in amorphous material can be made visible by adding a heavy metal "stain" to these regions, or by opening the void to a convenient size for study by additional etching. Figure 12 shows micrographs of a vertical cross section (a) at the edge of a poly gate and the corresponding horizontal cross section (b) from a generically identical region. The sample shown in (b) corresponds to the region bounded by the dashed lines in (a). After source-drain implant and diffusion, a phosphorus-containing

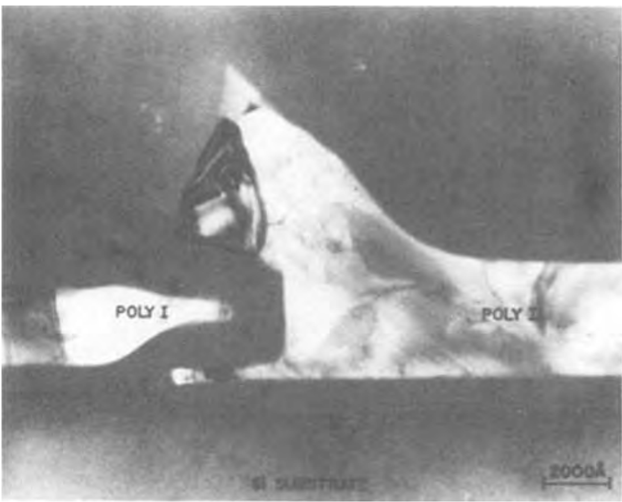

Fig. 8. TEM photo of a vertical cross section through a two-level poly device. The narrow gap separating poly II and the substrate at the "cat's paw" was the cause of low breakdown voltages in these devices.

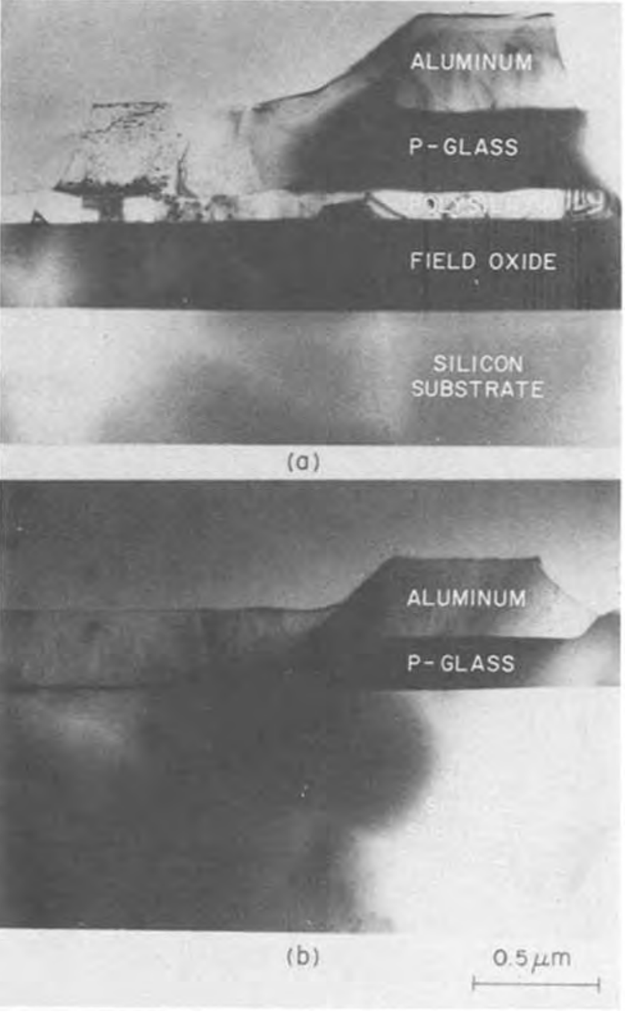

Fig. 9. TEM photos of vertical cross section through n-channel MOS device showing aluminum to poly contact (a) and aluminum to substrate contact (b).

P-glass had been deposited over the device, leaving a small void under the edge of the poly gate due to severe etch-back of oxide when the source-drain regions were etched to expose the silicon. OsO_4 stain was applied to the horizontal section, and capillary action drew the stain into the void region, enhancing

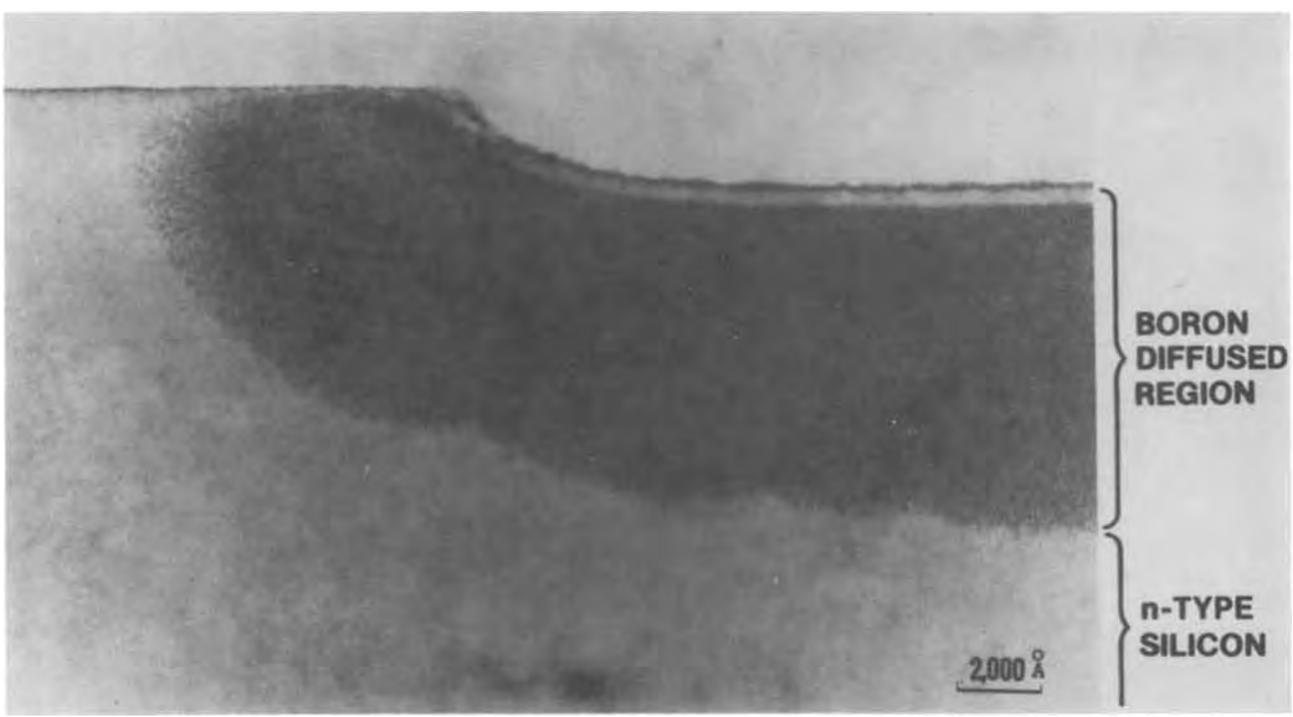

Fig. 10. TEM photo of a vertical cross section through a "stained" p + n junction in the region of the gate

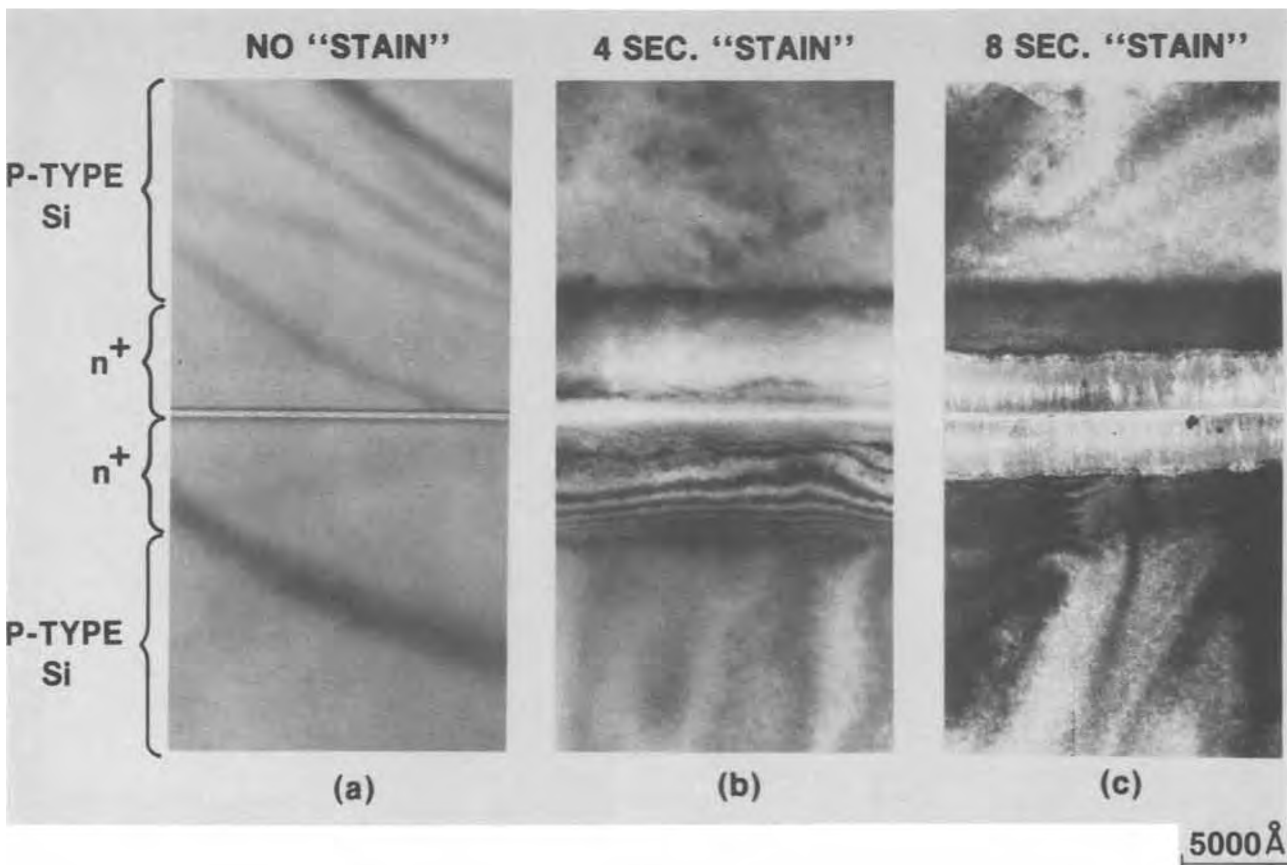

Fig. 11. TEM photos of vertical cross sections through n^+p samples after sample preparation by ion milling (a), after 4 sec "stain" (b), and after 8 sec stain (c).

the TEM contrast in this region due to the large scattering of electrons by osmium.

TEM Test Pattern

Horizontal and vertical section samples usually contain regions thin enough for TEM study over a distance less than ~ 40 μm from the edge of the hole. The probability that a sample contains a specific feature of interest in the electron transparent region is increased to nearly 100% when a special test pattern is incorporated in the wafer, and the TEM sample is prepared from this test pattern. The test pattern contains all the essential morphological features (contacts, steps, gate oxide, etc.) compressed in a region less than 40 μm along the surface and extending 1 mm in the orthogonal surface direction. The 40 μm (or smaller) unit is repeated a sufficient number of times to cover a total distance of 2 mm. An example

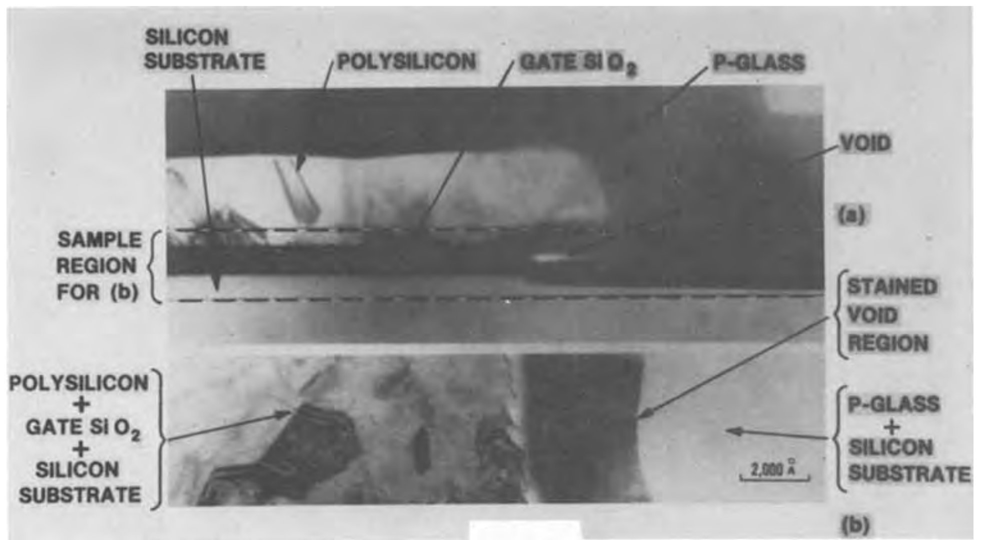

Fig. 12. TEM photos at the edge of a poly gate. A vertical cross section (a) shows a void under the edge of the poly, and a horizontal cross section (b) shows the void region in enhanced contrast because of the addition of OsO_4 stain.

of a test pattern incorporated in an n-channel device code which uses selective oxidation is shown in Fig. 13. The lower illustration shows the position of four test chips on the wafer (not drawn to scale) and the upper illustration shows the composition of the 27 μm unit which is repeated 74 times. The test chips are small and are inserted adjacent to alignment features so that no active device space is used.

The main requirements in designing such a test chip (other than incorporating all the essential processing features) are that (*i*) the total area be similar to that described in Fig. 13, *e.g.*, 1 mm × 2 mm with the repeat unit running parallel to the 2 mm axis, (*ii*) the direction parallel to the 2 mm axis be a cleavage direction, (*iii*) the repeat unit be less than ~ 40 μm, (*iv*) at least 3 test chips appear on a wafer, and (*v*) the test chips not be bunched together but rather separated; each one needs to be separately cleaved from the wafer.

Summary

Four techniques for preparing SIC device samples for TEM study have been described. Of these methods, vertical and horizontal sections have provided the most useful information on a nearly routine basis.

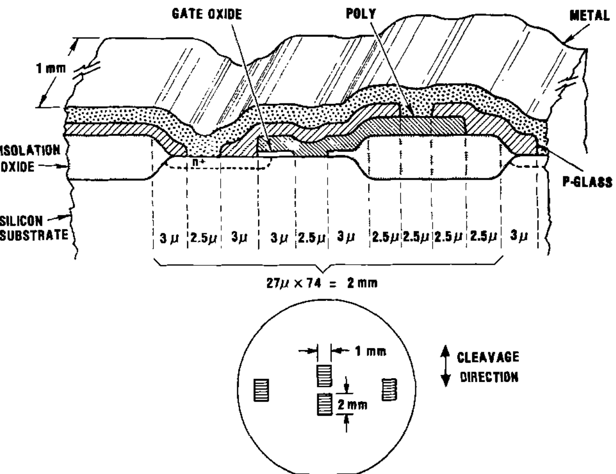

Fig. 13. Schematic illustrations of a TEM test pattern for n-channel device code using selective oxidation showing composition of repeat unit (upper) and position of pattern on wafer (lower).

Edge fracture replica and image enhancement techniques are used in special cases. All of these techniques are used from time to time in conjunction with other analytical methods in providing in depth studies when the occasion demands, and the literature contains many such examples of such cooperative efforts. Examples of cooperative efforts from this laboratory are the correlation of TEM studies with optical microscopy for the revealing of laser annealing (7), with Rutherford scattering for the revealing of Ar bubble in Si (8), and laser-induced reactions of metal films with Si (9), with Auger electron spectroscopy for determination of depth profiles of phases and elements in oxidized GaAlAs (10), and with SEM in the EBIC mode for revealing the role of decorated stacking faults in causing pn junction leakage in CMOS devices (4).

Silicon Deposition on a Rotating Disk

Richard Pollard*,[1] and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A one-dimensional model has been developed which describes the interactions among hydrodynamics, multicomponent heat and mass transfer, and reaction kinetics for the rotating disk system. The analysis includes variable physical properties and finite interfacial velocity and has provision for an arbitrary number of simultaneous homogeneous and heterogeneous reactions. The model has been applied to the chemical vapor deposition of silicon from silicon tetrachloride in excess hydrogen. Predictions for the dependence of silicon production rate on disk temperature and rotation rate are compared with available experimental data.

Many chemical syntheses with important industrial applications involve simultaneous homogeneous and heterogeneous reactions. In the semiconductor industry there is considerable interest in chemical vapor deposition of high quality silicon and germanium. Tubular reactors, where reactant gases pass across the growing surface, have been used for silicon deposition from $SiCl_4$ (alternatively, $SiHCl_3$ or $SiCl_2$) in excess hydrogen. Experimental studies in these systems have included spectroscopic identification of gas phase species and measurement of composition, temperature, and velocity profiles in the diffusion layer adjacent to the susceptor surface (1-4).

A theoretical analysis of silicon deposition in a tubular flow reactor has considered the effects of heat, mass, and momentum transfer (5). However, the complex nature of the transport processes necessitated incorporation of certain assumptions, such as constant physical properties and fully developed flow profiles, into the model.

The rotating disk has been used to study chemical vapor deposition because the hydrodynamics and mass transfer characteristics of this system are relatively well understood. A one-dimensional model has been developed for the transport-limited reaction of iodine and germanium (6). This analysis includes the effects of density variations in the boundary layer, multicomponent diffusion, and finite interfacial velocity. However, it is assumed that the system is isothermal and that the axial velocity depends linearly on the distance from the disk surface. Epitaxial growth of silicon has also been studied by the rotating disk method (7). The model includes natural convection and temperature variations but it assumes constant physical properties and equilibrium in the gas phase, and it is not able to account fully for the experimentally observed temperature dependence of silicon growth rate.

This paper presents a general approach to the analysis of silicon deposition on a rotating disk. The model considers multicomponent heat and mass transfer, coupled with laminar fluid flow, and simultaneous homogeneous and heterogeneous reactions with finite reaction rates. Variable physical properties are included, as well as a finite interfacial velocity at the disk surface. The analysis can be used to investigate the influence of disk temperature and rotation rate on the deposition process and to consider the rate-limiting factors in the system. The formulation of the silicon deposition problem has been developed in a general manner so that it can be readily applied to a wide variety of different physical situations.

Transport Phenomena

Momentum, heat, and mass transfer for a rotating disk are modeled subject to the following restrictions: (*i*) steady-state operation, (*ii*) laminar flow of Newtonian fluid, (*iii*) no viscous dissipation of energy, (*iv*) radiation and natural convection neglected, (*v*) no end effects, and (*vi*) ideal gas mixture. These assumptions simplify the calculational procedure significantly. The ideal gas condition is necessary in the absence of information required to justify a more sophisticated equation of state. The validity of assumptions (*iv*) and (*v*) is discussed below.

With these restrictions, it can be shown that the velocity component normal to the disk, and the gas composition, depend only on the axial coordinate, so that the surface is uniformly accessible from a mass transfer standpoint. Consequently, the transport properties are also independent of radial position, and the problem becomes one-dimensional.

The transformation of von Kármán (8) suggests that, with cylindrical coordinates, the velocity components and the pressure can be expressed as (9)

$$\left.\begin{aligned} v_r = r\Omega F(\zeta), \quad v_\theta = r\Omega G(\zeta), \quad v_z = \sqrt{\nu_\infty \Omega}\, H(\zeta) \\ p = \mu_\infty \Omega P(\zeta) + g_z \int_0^z \rho dz \end{aligned}\right\} \quad [1]$$

where

$$\zeta = z\sqrt{\Omega/\nu_\infty} \quad [2]$$

and where the direction of gravitational acceleration is taken to be perpendicular to the disk surface. Equation [1] defines dimensionless functions F, G, H, and P and shows how velocity components and pressure depend on disk rotation speed and on the coordinates for radial and axial position, r and ζ.

The steady-state equations of motion and continuity of the fluid are

$$\rho \underline{v} \cdot \nabla \underline{v} = -\nabla p - \nabla \cdot \underline{\underline{\tau}} + \rho \underline{g} \quad [3]$$

$$\nabla \cdot (\rho \underline{v}) = 0 \quad [4]$$

where the viscous stress for a Newtonian fluid is

$$\underline{\underline{\tau}} = -\mu[\nabla \underline{v} + (\nabla \underline{v})^T] + \frac{2}{3}\mu \underline{\underline{I}} \nabla \cdot \underline{v} \quad [5]$$

Substitution of Eq. [1] into Eq. [3] and [4], gives

$$2F + H' = -H \frac{d \ln \rho}{d\zeta} \quad [6]$$

Key words: silicon deposition, rotating disk, chemical vapor deposition of silicon, modeling.

for the continuity equation and, with Eq. [5]

$$\left.\begin{aligned} F^2 - G^2 + HF' &= -\frac{\rho_\infty}{\rho}\frac{d}{d\zeta}\left(\frac{\mu F'}{\mu_\infty}\right) \\ 2FG + HG' &= \frac{\rho_\infty}{\rho}\frac{d}{d\zeta}\left(\frac{\mu G'}{\mu_\infty}\right) \end{aligned}\right\} \quad [7]$$

$$\frac{\rho}{\rho_\infty}HH' + P' = \frac{4}{3}\frac{d}{d\zeta}\left[\frac{\mu}{\mu_\infty}(H' - F)\right] + \frac{2\mu F'}{\mu_\infty} \quad [8]$$

for the equations of motion (10). The boundary conditions include

$$\left.\begin{aligned} F = 0, \quad G = 1 \qquad &\text{at } \zeta = 0 \\ F = G = 0 \qquad &\text{at } \zeta = \infty \end{aligned}\right\} \quad [9]$$

In addition, the normal velocity component is related to the mass transfer rate at the surface by the definition for the mass average velocity

$$\underline{v} = \frac{1}{\rho}\sum_i M_i \underline{N}_i \quad [10]$$

where N_i is the molar flux of species i.

The fluid density ρ, used in the equations above, is directly related to total gas concentration by

$$\rho = \overline{M}c \quad [11]$$

where $\overline{M} = \sum_i x_i M_i$. The concentration is, in turn, related to pressure with the ideal gas law

$$p = cRT \quad [12]$$

A steady-state, thermal energy equation for an ideal gas mixture can be rewritten as (11)

$$c\tilde{C}_p\underline{v} \cdot \nabla T = \nabla \cdot (k\nabla T) + \underline{v} \cdot \nabla p - \sum_i (\underline{J}_i \cdot \nabla \overline{H}_i + \overline{H}_i R_i) \quad [13]$$

provided that viscous energy dissipation and the Dufour energy flux can be neglected. The last term on the right represents thermal effects due to interdiffusion of species and homogeneous chemical reactions, $\underline{J}_i$ is the flux of species i relative to the mass average velocity, given by

$$\underline{J}_i = \underline{N}_i - c_i\underline{v} \quad [14]$$

and $\tilde{C}_p$ is the mean specific heat of the mixture, defined as

$$\tilde{C}_p = \sum_i x_i \tilde{C}_{pi} \quad [15]$$

Equation [13] can be expressed in dimensionless form as

$$\frac{\tilde{C}_p}{\tilde{C}_{p\infty}}HT' = \frac{T}{\mathrm{Pr}_\infty T_\infty}\left[\frac{k}{k_\infty}T'' + T'\frac{d(k/k_\infty)}{d\zeta}\right] + \frac{RTH}{\tilde{C}_{p\infty}}\frac{d\ln p}{d\zeta} + \frac{sTT'}{T_\infty} + UT \quad [16]$$

The dimensionless quantities Pr_∞, s, and U are defined by

$$\mathrm{Pr} = \frac{p\mu_\infty\tilde{C}_{p\infty}}{p_\infty k_\infty \overline{M}_\infty} \quad [17]$$

$$s = \frac{-p_\infty \sum_i \mathcal{J}_i \tilde{C}_{pi}}{p\tilde{C}_{p\infty}} \quad [18]$$

and

$$U = -\frac{p_\infty \sum_i \tilde{H}^*_i \mathcal{R}_i}{pT_\infty \tilde{C}_{p\infty}} \quad [19]$$

respectively, where $\mathcal{J}_i = \underline{J}_i/c_\infty\sqrt{\nu_\infty\Omega}$, $\mathcal{R}_i = R_i/c_\infty\Omega$, and $\overline{H}_i = \tilde{H}^*_i$ for an ideal gas. The temperatures of the disk and the bulk fluid are specified as boundary conditions for Eq. [16].

The multicomponent diffusion equation (11)

$$c_i\left(\nabla\mu_i + \overline{S}_i\nabla T - \frac{M_i\nabla p}{\rho}\right) = RT\sum_{k\neq i}\frac{c_i c_k}{c\mathcal{D}_{ik}}\left[\underline{v}_k - \underline{v}_i + \left(\frac{D_k^T}{\rho_k} - \frac{D_i^T}{\rho_i}\right)\nabla\ln T\right] \quad [20]$$

describes the motion of species i relative to the surrounding fluid. If thermal diffusion is assumed to be negligible, and if the gas mixture behaves ideally, Eq. [20] may be written in dimensionless form as

$$\nabla x_i + x_i\left(1 - \frac{M_i}{\overline{M}}\right)\nabla\ln p = \sum_{k\neq i}\frac{x_i\mathcal{J}_k - x_k\mathcal{J}_i}{D_{ik}} \quad [21]$$

where D_{ik} is a dimensionless transport property for binary interactions, defined as $D_{ik} = c\mathcal{D}_{ik}/c_\infty\nu_\infty$. For a mixture of n species, there are $(n - 1)$ independent force balances in the form of Eq. [21], and there are $\frac{1}{2}n(n - 1)$ independent transport properties because D_{ii} is not defined and, by Newton's third law of motion, $D_{ik} = D_{ki}$.

A steady-state material balance in the gas phase is

$$\nabla \cdot \underline{N}_i = R_i \quad [22]$$

where R_i is the net homogeneous rate of production of species i.

Equation [21] can be inverted numerically to give explicit expressions for the fluxes, which can then be substituted into Eq. [22] to give a dimensionless material balance

$$\frac{d^2x_i}{d\zeta^2} = \sum_{k\neq i}\left[\frac{x_i\mathcal{R}_k - x_k\mathcal{R}_i}{D_{ik}} - \frac{cH}{c_\infty D_{ik}}\left(x_i\frac{dx_k}{d\zeta} - x_k\frac{dx_i}{d\zeta}\right) + \mathcal{J}_k\frac{d}{d\zeta}\left(\frac{x_i}{D_{ik}}\right) - \mathcal{J}_i\frac{d}{d\zeta}\left(\frac{x_k}{D_{ik}}\right)\right] \quad [23]$$

for the one-dimensional problem considered here. There are $n - 1$ independent force balances with the form of Eq. [23] which can be used, in conjunction with the relationship between the fluxes

$$\sum_i M_i\mathcal{J}_i = 0 \quad [24]$$

to describe mass transfer in a multicomponent system.

In this way, it is possible to incorporate the conservation conditions while still leaving the overall continuity Eq. [4] to be counted as one of the hydrodynamic equations. Furthermore, arbitrary selection of one component is not required in order to replace a species material balance with Eq. [24] or to invert the Stefan-Maxwell relations [21].

At the disk surface, $n - 1$ Stefan-Maxwell relations, Eq. [21], are used, together with the relationship between mole fractions, $\sum_i x_i = 1$. Far from the disk, the compositions approach their equilibrium values at the bulk fluid temperature.

Chemical Reactions

The equations derived above, which describe the transfer of heat, mass, and momentum for a disk ro-

tating in an infinite medium, can be used to predict the behavior of systems with an arbitrary number of homogeneous and heterogeneous reactions.

To illustrate the use of this technique, epitaxial deposition of silicon from an input mixture of $SiCl_4$ in excess hydrogen is analyzed. Thermodynamic studies indicate that, for the temperature range of interest, five principal species are present in the gas phase: H_2, HCl, $SiCl_4$, $SiHCl_3$, and $SiCl_2$ (12). Dichlorosilane (SiH_2Cl_2) has also been detected under some experimental conditions, but this species is not considered explicitly in the present study.

Several mechanisms have been proposed for the formation of silicon from $SiCl_4$ (2, 13, 14). Here, it is assumed that $SiCl_4$ can be reduced either homogeneously or heterogeneously by the following reversible reactions

$$SiCl_4 + H_2 \rightleftharpoons SiHCl_3 + HCl \quad [25]$$

$$SiHCl_3 \rightleftharpoons SiCl_2 + HCl \quad [26]$$

On the surface, the deposition reaction

$$SiCl_2 + H_2 \rightleftharpoons Si(s) + 2HCl \quad [27]$$

can also take place. This mechanism may need to be refined subsequently to match experimentally observed behavior.

The net rate of each reaction is regarded as the difference between the rates of forward and backward reactions and can be represented as

$$r_l = k_{lf} \prod_i x_i^{\nu_{il}} - k_{lb} \prod_i x_i^{-\nu_{il}} \quad [28]$$

$$\nu_{il} > 0 \quad \nu_{il} < 0$$

where k_{lf} and k_{lb} are rate constants for forward and backward reactions, respectively. The exponent ν_{il} is the stoichiometric coefficient for species i in reaction l. It is positive for reactants and negative for products and may be obtained from Eq. [25]-[27], which are assumed to be elementary reaction steps.

The temperature dependence of the rate constants in Eq. [28] is assumed to be given by

$$k_{lb} = A_l e^{-E_l/T} \quad [29]$$

where E_l can be regarded as an activation energy for reaction l.

In the model, five independent parameters are used to describe the kinetic behavior: E_a; $\theta_1 = k_{3b}/k_{1b}$; $\theta_2 = k'_{2b}/k'_{1b}$; $\theta_3 = k_{1b}{}^2\, e^{E_a/T_s}/c_\infty \nu_\infty\, k'_{1b}$; $\theta_4 = 10^2\, e^{-E_a/T_s}\, c_\infty \Omega/k'_{2b}$. The term E_a represents an activation energy for the deposition process. Different activation energies could be chosen for each reaction but it is assumed that the temperature dependence of the deposition rate will be influenced more by the activation energy for the rate-limiting step than by the activation energies for the other reactions. The parameters θ_1 and θ_2 describe the relative rates of the two heterogeneous and the two homogeneous reactions, respectively. θ_3 is a ratio of the rates of the heterogeneous and homogeneous reactions and θ_4 specifies the rate of homogeneous production of $SiCl_2$, as described by Eq. [26], relative to the mass transfer rate characterized by the disk speed, Ω.

The forward and backward rate constants are related by an equilibrium constant $K_l = k_{lb}/k_{lf}$, which is defined in terms of equilibrium reactant and product compositions as

$$K_l = p^m \prod_i x_{ie}^{-\nu_{il}} \quad [30]$$

In Eq. [30], the activity of any solid phase is taken to be unity, and m represents the net number of molecules produced by reaction l. The temperature dependence of k_l is predicted from standard heats of reaction $\Delta H(T)$, with

$$\left[\frac{\partial \ln K_l}{\partial(1/T)}\right]_p = -\Delta H(T)/R \quad [31]$$

and from free energy data at 25°C (15), to give expressions of the form

$$\ln K_l = \alpha_l + \beta_l/T + \gamma_l \ln T \quad [32]$$

The coefficients α_l, β_l, γ_l, used for the reactions are summarized in Table I.

In the gas phase, the net rate of production of species i is given as

$$R_i = \sum_l \nu_{il} r_l \quad [33]$$

At the surface, a similar summation for the heterogeneous reactions represents the molar flux N_i from the surface relative to the interface. The variables N_i and R_i link the rates of the individual reactions to the equations that describe heat, mass, and momentum transfer for the rotating disk.

Interactions among the governing differential equations are caused directly by the inclusion of a finite interfacial velocity (see Eq. [10]) and variable physical properties in the analysis. Relationships for the temperature and composition dependences of physical parameters needed in the model are summarized in the Appendix.

For the example of chemical vapor deposition of silicon, with five species in the gas phase, the steady-state behavior is described by a set of 15 coupled, nonlinear, ordinary differential equations. These equations, subject to specified boundary conditions, can be solved numerically by a finite difference technique accurate to $0(h^2)$ (11, 16, 17). The model can be used to study the influence of process variables on the rate of silicon deposition and on the profiles for compositions, velocities, and temperature in the diffusion layer. Parameters that must be specified in the model include surface and bulk temperatures, inlet gas composition, disk rotation rate, and operating pressure.

Results and Discussion

Preliminary computer simulations indicated that pressure variations through the diffusion layer are small and that they do not affect the overall behavior significantly. Consequently, results are presented for a constant operating pressure, which is taken to be 1.013 bar. In addition, the influence of bulk gas composition is not considered explicitly in this study, and results are for an inlet gas mixture of 1 mole percent $SiCl_4$ in hydrogen. The values chosen for pressure and composition correspond to standard operating conditions for chemical vapor deposition of silicon (5).

A typical composition profile, with the disk temperature controlled at 1473°K and a bulk gas temperature of 293°K, is shown in Fig. 1. The gas mixture is assumed to be at equilibrium at the bulk temperature, far from the disk. Closer to the surface, the mole fractions alter in response to the specified homogeneous and heterogeneous reactions.

Spectroscopic methods have been used to measure composition profiles in the diffusion layer for silicon deposition in a horizontal channel reactor, where reactant gases flow over the susceptor surface (3, 4). These measurements indicate the presence of a maximum in $SiCl_2$ concentration approximately 2 mm from the surface. The magnitude of the maximum mole

Table I. Equilibrium constants for silicon deposition reactions: coefficients for Eq. [32]

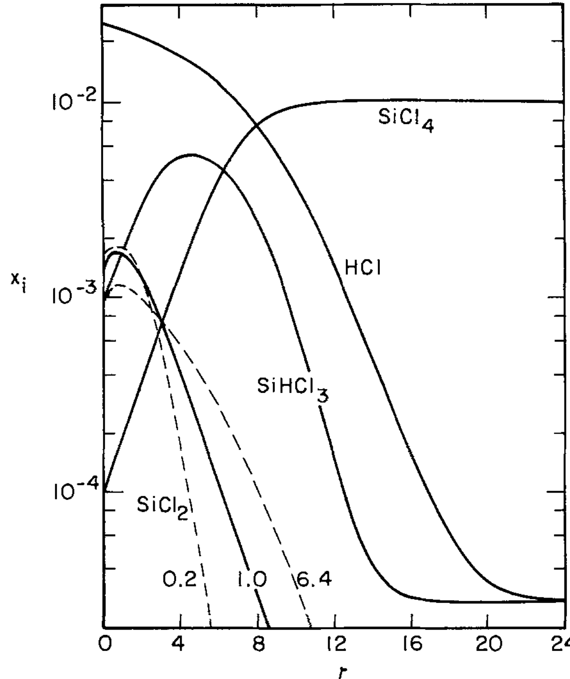

Fig. 1. Typical composition profiles in diffusion layer adjacent to rotating disk. Parameter values: T_s = 1473°K; T_∞ = 293°K; Ω_b = 12.57 rad/sec; $p_\infty = 1.013 \times 10^5$ N/m²; $(x_{H_2})_\infty$ = 0.99; θ_1 = 25.0; θ_2 = 10.0; θ_3 = 1.25; θ_4 = 5/6; E_a = 1258.18°K. Dashed lines represent x_{SiCl_2} profiles for different disk speeds, Ω/Ω_b.

fraction becomes larger further from the leading edge of the crystal. Analogous behavior is expected with the rotating disk system since smaller rotation rates, and hence larger diffusion layers, should correspond, at least qualitatively, to positions further downstream in the channel flow reactor. This is exemplified by the dashed lines in Fig. 1 which show the position dependence of $SiCl_2$ mole fraction calculated at rotation rates larger and smaller than the base value. In addition, the model predicts a maximum in the $SiHCl_3$ composition profile, at greater distances from the disk surface than the $SiCl_2$ maximum.

Figure 1 is calculated for a particular set of kinetic parameters that give a qualitative match between theoretical and experimental composition profiles. The relative importance of each parameter is discussed below in the context of rotation rate and surface temperature effects. However, it is noted here that in order to obtain a maximum in $SiCl_2$ composition it is necessary to eliminate the possibility for heterogeneous $SiCl_2$ production. This is in keeping with some mechanisms that have been postulated for the deposition process.

An approximate estimate of the diffusion layer thickness can be obtained from the composition profiles, even though some species reach their bulk compositions closer to the surface than others. For the example in Fig. 1, an approximate thickness is 5 cm, which is considerably larger than values of 10^{-2}-10^{-3} cm often encountered with electrolyte solutions.

If the size of the disk and the diffusion layer are comparable, it is necessary to consider the influence of radial effects on observed deposition rates. A singular perturbation analysis of the elliptic region at the edge of a rotating disk that results from radial diffusion has been developed previously for fluids with high Schmidt numbers (18). This approach can be generalized to give the ratio λ of maximum overall mass transfer rates, with and without radial diffusion effects, as

$$\lambda = 1 + 1.9193\text{Re}^{-3/4}\text{Sc}^{-1/3} \quad [34]$$

for any fluid but for large values of $\text{ScRe}^{3/2}$. With average values for physical properties and with Ω = 12.57 rad/sec and r_0 = 2.5 cm, it may be shown that $\lambda \simeq 1.1$. This analysis indicates that radial effects can contribute to an increase in overall silicon deposition rate under these conditions, although at higher rotation rates the influence of edge effects will be reduced, in accordance with Eq. [34].

For the operating conditions used in Fig. 1, the variations of some physical properties are shown in Fig. 2. The density changes by a factor of 6 across the diffusion layer in direct association with changes in T and $\overline{M}$. Viscosity and thermal conductivity both vary by factors of about 3. This leads to a maximum in the axial velocity profile in the boundary layer, as illustrated in Fig. 3. In this example, the magnitude of the interfacial velocity, which arises from chemical reactions at the disk surface, is −2.0 mm/sec. An assumption of zero interfacial velocity can lead to errors of approximately 1-6% in deposition rate, dependent on the process conditions.

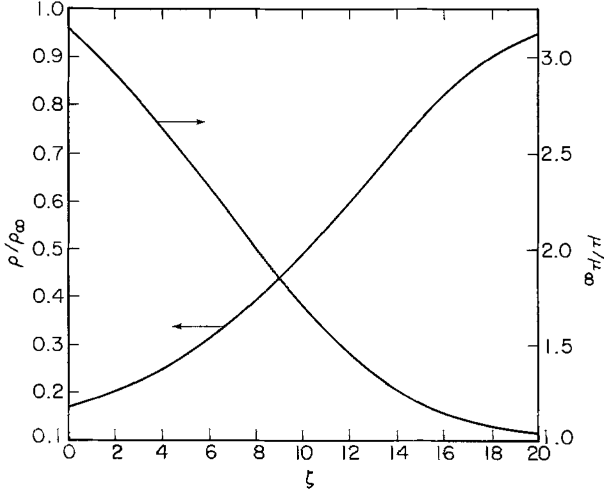

Fig. 2. Dependence of viscosity and density on distance from surface of rotating disk. Parameter values as for Fig. 1. ρ_∞ = 0.1536 kg/m³; $\mu_\infty = 9.602 \times 10^{-6}$ kg/m · sec.

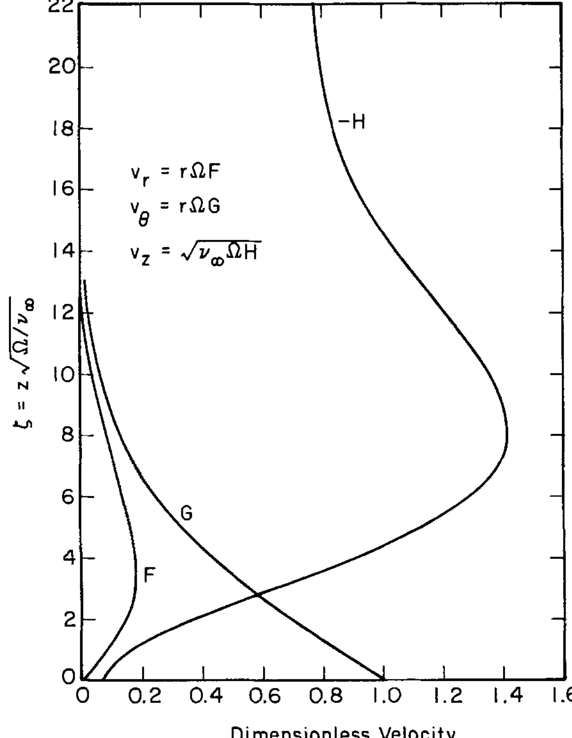

Fig. 3. Velocity profiles for silicon deposition on a rotating disk. Parameter values as for Fig. 1 and 2.

Measurements of silicon deposition rates at various susceptor temperatures and for a fixed rotation speed show that there are two regimes of temperature behavior in the range 1273°-1523°K. At higher temperatures an apparent activation energy for deposition lies in the range 4-13 kJ/mole, whereas at lower temperatures it is reported as 90-125 kJ/mole (7). This change in temperature dependence is attributed to a shift from reaction rate control to mass transfer control as the disk temperature is raised.

An experimental curve, obtained with a rotation rate of 12.5 rad/sec, is given in Fig. 4, where the parameter S represents the actual deposition rate, made dimensionless with the quantity $c_\infty\sqrt{\nu_\infty\Omega}$. The dashed line is the locus of maximum deposition rates calculated with the mathematical model. It can be regarded as a combined thermodynamic-mass transfer limit since, for this curve, the reactions are locally at equilibrium but the finite mass transfer rate through the diffusion layer limits the fraction of the bulk fluid that can reach the disk surface.

There are several possible explanations for the discrepancy between the thermodynamic-mass transfer limit and experimental results at high temperatures. First, errors in estimates of collision diameters and interaction energies for some combinations of species could lead to incorrect predictions of physical properties such as diffusion coefficients and viscosity (see Appendix). Errors may also arise from incorrect predictions of equilibrium constants (see Table I). A thermodynamic evaluation of the Si-H-Cl system shows that the parameters K_l are particularly sensitive to the standard heat of formation of $SiHCl_3$ (12).

Radial effects can lead to enhanced mass transfer rates. However, it has been shown (see below Eq. [34]) that the magnitude of this effect is insufficient to account fully for the differences between experiment and theory. Nevertheless, it should be noted that the analysis of radial dependences does not consider the influence of hydrodynamic disturbances that could arise from axial motion at the disk edge.

Even though inlet gases are at 293°K, the wall temperature in the experiment is recorded as 673°K (7) and heat transfer between the disk and walls and the inlet gas (*e.g.*, by radiation) could raise the bulk gas temperature substantially. Figure 5 shows the temperature dependence of dimensionless deposition rate with $T_\infty = 673°K$. The discrepancy between experimental results and the thermodynamic-mass transfer limit is reduced with this new boundary condition, but significant differences still exist.

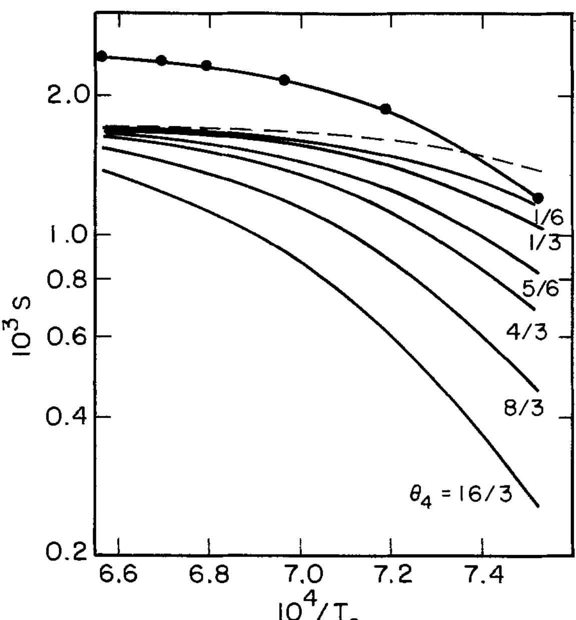

Fig. 4. Dependence of dimensionless silicon deposition rate on disk temperature. S = actual deposition rate/$c_\infty\sqrt{\nu_\infty\Omega}$. Dotted line: experimental data (7), Ω = 12.57 rad/sec. Dashed curve: thermodynamic-mass transfer limit for deposition rate. Full curves: theoretical predictions for different values of θ_4, with other parameters as in Fig. 1-3.

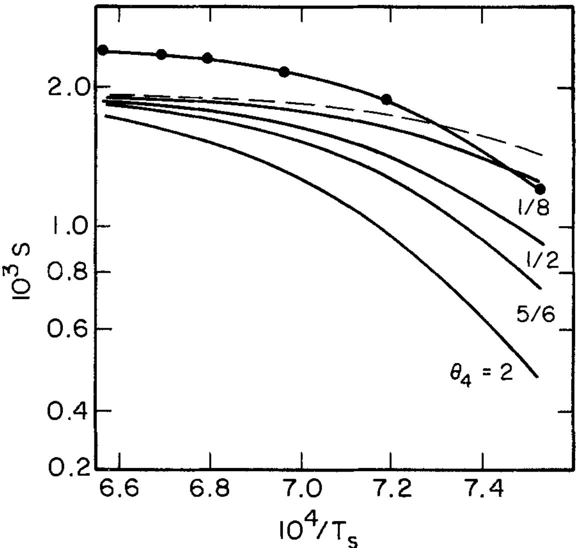

Fig. 5. Dependence of dimensionless silicon deposition rate on disk temperature. As Fig. 4, but $T_\infty = 673°K$.

Another possible explanation for the enhanced mass transfer rate is natural convection. The ratio

$$\frac{\mathrm{Gr}}{\mathrm{Re}^2} = \frac{(T_s - T_\infty)g}{T_{av}\Omega^2 r_0} \quad [35]$$

can be used to represent the ratio of buoyancy forces to viscous forces in the system. With $T_s - T_\infty = 1200°K$, $T_{av} = 1000°K$, $r_0 = 2.5$ cm, and $\Omega = 12.57$ rad/sec, this ratio is approximately 3.0. For an upward-facing disk, it has been shown (1) that natural convection is the dominant heat transfer mechanism for $\mathrm{Gr/Re^2} > 4.1$ and that forced convection dominates when $\mathrm{Gr/Re^2} < 0.4$. Consequently, for the disk considered in the example, there will be a transition region for $10.72 < \Omega$ (rad/sec) < 34.31. Unfortunately, experimental information for silicon deposition on a rotating disk is only available for conditions where natural convection could be important. Therefore an exact match between experimental results and theoretical predictions based on forced convection should not be expected. Nevertheless, under different conditions, such as larger disks and higher rotation rates, the model presented will have greater quantitative significance.

Despite the uncertainty in the absolute magnitude of the deposition rate, Fig. 4 and 5 both show that the thermodynamic-mass transfer limit does not adequately explain the temperature dependence of the deposition rate over the whole temperature range considered. With finite kinetic parameters it is possible to obtain a satisfactory match between the shapes of the theoretical and experimental curves. In Fig. 4 and 5, the kinetic parameters θ_1, θ_2, θ_3, and E_a are fixed, and θ_4 is varied. The sets of curves can be interpreted as showing the effect of variations either in rotation rate at fixed k'_2 or in k'_2 at fixed Ω. Inspection of Fig. 4 ($T_\infty = 293°K$) shows that a value of $\theta_4 = 5/6$ provides a reasonable fit between the shapes of the experimental and theoretical curves. As the surface temperature is decreased, the $\theta_4 = 5/6$ curve moves away from the thermodynamic-mass transfer limit and the deposition rate becomes more dependent on kinetic factors. However, as T_s is reduced further, equilibrium limitations are expected to become important again and eventually, below a surface temperature of approximately

1108°K, silicon deposition will no longer be thermodynamically feasible.

It is necessary to consider the sensitivity of the results to the values chosen for the kinetic parameters. Figures 6 and 7 show predicted temperature dependences for different values of E_a, with fixed values of θ_1 and θ_2 and with the value of θ_3 matched at 1473°K for the different activation energies. The diagrams show that the overall shapes of the curves do not depend noticeably on E_a for $0 \leq E_a \leq 6290.90$.

Variations in θ_1 and θ_3 cause relatively small changes in calculated temperature profiles, for fixed values of θ_2, θ_4, and E_a. Changes in θ_2 have a more noticeable effect but, as with alterations in E_a, it merely shifts the value of θ_4 which best fits the shape of the experimental curve. From these results it is evident that the dependence of silicon deposition rate on temperature alone is insufficient to be able to predict the most appropriate values for the kinetic parameters.

Information is also available on the dependence of deposition rate on disk speed (7). Figure 8 shows experimental results and theoretical predictions with the same kinetic parameters (θ_1, θ_2, θ_3, E_a) that were used in Fig. 4. The deposition rate S_b is made dimensionless with a specified rotation rate Ω_b which is taken as 26.18 rad/sec, close to the midpoint in the range of experimental data. The parameter Ω_s, which equivalent to θ_4, represents the rotation rate which corresponds to the curve that best fits the shape of the data in Fig. 4. (For example, a stipulation that the best curve in Fig. 4 has a rotation rate of 12.57 rad/sec yields the curve $\Omega_s = 12.57$ rad/sec on Fig. 8.) From the standpoint of temperature dependence, it would seem most acceptable to choose $\Omega_s = 12.57$, since this is the rotation rate at which the experiments were performed. However, this curve follows the thermodynamic-mass transfer limit too closely in Fig. 8 and does not match the experimental data, which are almost independent of rotation rate.

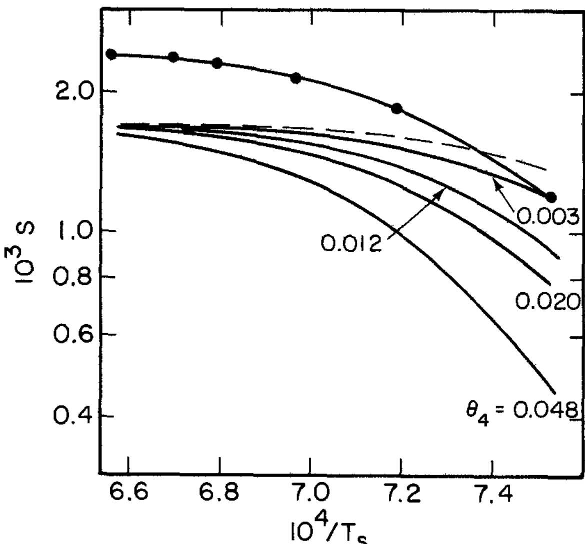

Fig. 6. Dependence of dimensionless silicon deposition rate on disk temperature. As Fig. 4, but $E_a = 6290.90$°K and $\theta_3 = 38.071$.

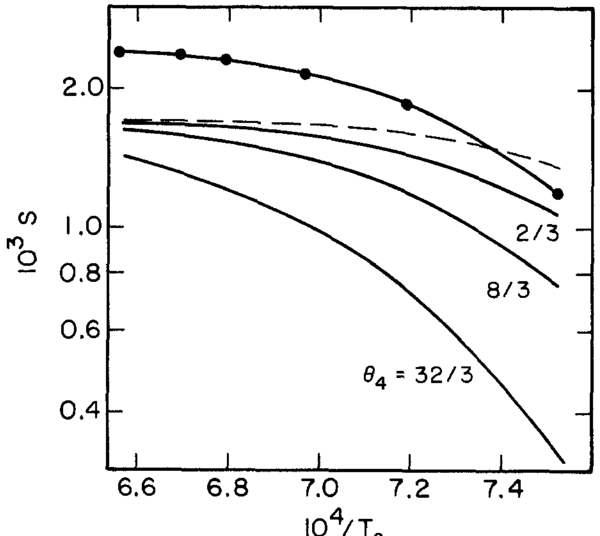

Fig. 7. Dependence of dimensionless silicon deposition rate on disk temperature. As Fig. 4, but $E_a = 0$ and $\theta_3 = 0.5321$.

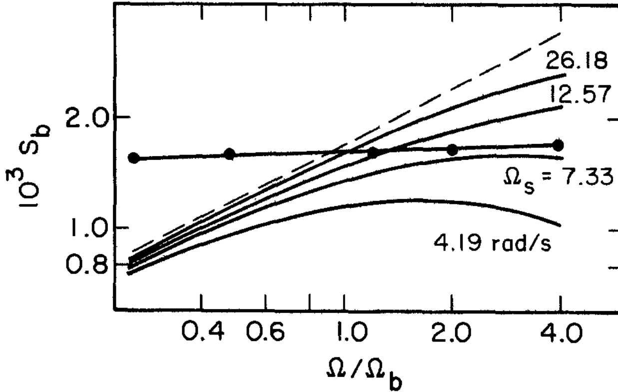

Fig. 8. Dependence of dimensionless silicon deposition rate on disk speed. $S_b = S\sqrt{\Omega/\Omega_b}$. Dotted line: experimental data $T_s = 1473$°K. Dashed curve: thermodynamic-mass transfer limit for deposition rate. Full curves: theoretical predictions for different values of Ω_s (equivalent to θ_4). Parameter values: $T_s = 1473$°K; $T_\infty = 293$°K; $\Omega_b = 26.18$ rad/sec; $p_\infty = 1.013 \times 10^5$ N/m^2; $(x_{H_2})_\infty = 0.99$; $\theta_1 = 25.0$; $\theta_2 = 10.0$; $\theta_3 = 1.25$; $E_a = 1258.18$°K.

At low speeds, mass transfer control might be expected, as illustrated by the thermodynamic-mass transfer limit ($S_b \alpha \sqrt{\Omega}$), whereas at higher speeds the rotation rate dependence could change markedly as reaction rate control is approached. A higher disk speed not only raises the rate at which reactants can reach the disk surface, but it also affects the rate at which intermediate species in the reaction sequence can be convected away from the disk. In addition, the relative importance of the homogeneous and heterogeneous reactions can shift as Ω is changed. Consequently, it is conceivable that, under some circumstances, an increase in Ω could lead to a reduction in deposition rate.

These effects become apparent as the parameter is reduced below $\Omega_s = 12.57$ rad/sec. At $\Omega_s = 7.33$ rad/sec, the theoretical curve rises from the thermodynamic-mass transfer limit to the experimental line as the rotation rate is increased. Below 26.18 rad/sec, the experimentally observed behavior cannot be matched because the results lie above the predicted limit. This may be due to error in the assessment of the thermodynamic-mass transfer curve as discussed earlier and, in particular, it might result from natural convection which would be expected to be more important at low disk speeds. Therefore, it is possible that, for these experimental conditions, there is no range of rotation rates for which forced convection mass transfer controls the system behavior. Furthermore, Fig. 8 is practically unchanged for modest changes in kinetic parameters, and it is not possible to choose different values for θ_1 to θ_4 or E_a which would provide a substantially better fit of the experimental data. It should also be noted that natural convection could alter the shapes of the temperature curves in Fig. 4, as well as the absolute value of the thermodynamic-mass transfer limit.

Notwithstanding the possible influence of natural convection, prediction of a consistent set of kinetic

parameters, which fit the observations, is hampered by the relatively short ranges of T_s and Ω for which data are available. Also the surface temperature in Fig. 8 lies, ostensibly, in a mass transfer controlled region, and therefore one should not expect to be able to use this information to obtain well-defined kinetic information. In principle, it should be possible to use experimental data in the reaction controlled regime to obtain better estimates of the kinetic constants.

It is also necessary to assess the extent to which the predicted behavior is influenced by the assumed reaction mechanism. The mechanism proposed includes homogeneous and heterogeneous production of $SiHCl_3$, homogeneous decomposition of $SiHCl_3$ to give $SiCl_2$, and reduction of $SiCl_2$ on the disk surface to yield silicon. Under some circumstances, significant quantities of SiH_2Cl_2 can be present in the gas phase (12). This could be produced by

$$SiCl_2 + H_2 \rightleftharpoons SiH_2Cl_2 \qquad [36]$$

and it could decompose on the surface to give silicon directly. Consequently, it might be regarded as an intermediate in the overall conversion of $SiCl_2$ to silicon so that inclusion of SiH_2Cl_2 in the model would not be expected to alter the predictions significantly. Incorporation of SiH_2Cl_2 as an additional species would not cause operational difficulties with the model but it would necessitate additional equilibrium data and consideration of another independent kinetic parameter.

Direct reactions of the form

$$SiCl_4 + 2H_2 \rightleftharpoons Si + 4HCl \qquad [37]$$

have not been included because they are kinetically less favorable than the elementary processes used in the analysis. An additional reaction which could be included in more sophisticated studies of reaction mechanisms involves disproportionation of $SiCl_2$ according to

$$2SiCl_2 \rightleftharpoons Si(s) + SiCl_4 \qquad [38]$$

Again, an additional kinetic parameter would be needed in the model.

The rate-determining step for the reaction sequence considered (Eq. [25]-[27]) is thought to be homogeneous production of $SiHCl_3$ (Eq. [25]). Heterogeneous formation of $SiHCl_3$ becomes more important when the bulk gas temperature is higher. The basis for this postulate is that, for the range of T_s and Ω considered, the relative rate of the backward and forward reaction was consistently smallest for this step. This theory is supported by observations of higher deposition rates from $SiHCl_3$, rather than $SiCl_4$, under parallel experimental conditions (19).

Conclusions

A model has been developed which describes the interactions among hydrodynamics, multicomponent heat and mass transport, and reaction kinetics for the rotating disk system. The analysis includes variable physical properties, finite interfacial velocity, and simultaneous homogeneous and heterogeneous reactions.

This model has been used to study chemical vapor deposition of silicon from $SiCl_4$ in excess hydrogen. The effects of disk speed and temperature on the silicon deposition rate have been investigated, and several features of the process have been elucidated:

1. The diffusion layer thickness is 1-10 cm, which is considerably larger than values commonly encountered for liquid systems. Nevertheless, radial diffusion does not affect predicted mass transfer rates markedly.

2. Physical properties, such as density and viscosity, vary by factors of between 3 and 6, through the diffusion layer. This distorts the fluid flow profile and gives a maximum in the axial velocity.

3. With five gas-phase species and a set of five independent kinetic parameters, the shape of the predicted temperature dependence of deposition rate matches experimental results. At high surface temperatures, a combined mass transfer and thermodynamic limit controls the deposition rate, but as the disk temperature is lowered kinetic limitations gradually became more important. At much lower temperatures, thermodynamic considerations again dominate, and deposition is no longer feasible below approximately 1108°K. However, effects not included in the model, such as natural convection, could be responsible for discrepancies in absolute magnitudes of predicted and observed deposition rates and in the influence of disk speed on the system behavior. Furthermore, the kinetic parameters cannot be specified uniquely from the limited experimental data available.

4. Homogeneous and heterogeneous reactions are both important in chemical vapor deposition of silicon. For the range of conditions studied, the rate-limiting step is found to be formation of the intermediate species $SiHCl_3$, by reduction of $SiCl_4$.

APPENDIX

Physical Properties

Viscosity.—The temperature dependence of the viscosity of each species in the gas phase is predicted from the Chapman-Enskog kinetic theory (10)

$$\mu_i = \frac{2.6693 \times 10^{-5}\sqrt{M_i T}}{\sigma_i^2 \Omega_{\mu i}} \qquad [A-1]$$

The parameter σ_i is the collision diameter, and $\Omega_{\mu i}$ is a dimensionless function which depends on kT/ϵ_i, where ϵ_i is a characteristic energy of interaction between molecules and k is Boltzmann's constant. For each species, Eq. [A-1] is rewritten in the simplified form

$$\mu_i = \delta_{1i} T^{\psi_{1i}} \qquad [A-2]$$

and values for δ_{1i} and ψ_{1i} are given in Table II. The viscosity of the gas mixture is calculated with the Wilke correlation (20)

$$\mu_{mix} = \sum_{i=1}^{n} \left(x_i \mu_i \Big/ \sum_{j=1}^{n} x_j \Phi_{ij} \right) \qquad [A-3]$$

where

$$\Phi_{ij} = [1 + (\mu_i/\mu_j)^{1/2} (M_j/M_i)^{1/4}]^2 / [8 + 8 M_i/M_j]^{1/2}$$

Diffusivity.—Diffusion coefficients for binary interactions are estimated from (10)

$$\frac{c\mathcal{D}_{ij}}{\sqrt{T}} = \frac{2.2646 \times 10^{-5} \left(\frac{1}{M_i} + \frac{1}{M_j} \right)^{1/2}}{\sigma_{ij}^2 \Omega_{\mathcal{D}ij}} \qquad [A-4]$$

where σ_{ij} is a mean collision diameter which is taken as $(\sigma_i + \sigma_j)/2$. The dimensionless quantity $\Omega_{\mathcal{D}ij}$ is

Table II. Values for parameters in Eq. [A-2] and [A-8]

Species, i	μ_i (Nsec/m²)		k_i (W/m · °K)	
	$10^7\delta_{1i}$	ψ_{1i}	δ_{2i}	ψ_{2i}
H_2	2.05	0.66	2.64×10^{-3}	0.725
HCl	1.06	0.87	7.36×10^{-5}	0.941
$SiCl_4$	0.75	0.87	4.10×10^{-5}	0.900
$SiHCl_3$	0.70	0.87	1.30×10^{-5}	1.070
$SiCl_2$	1.20	0.82	4.10×10^{-5}	0.900

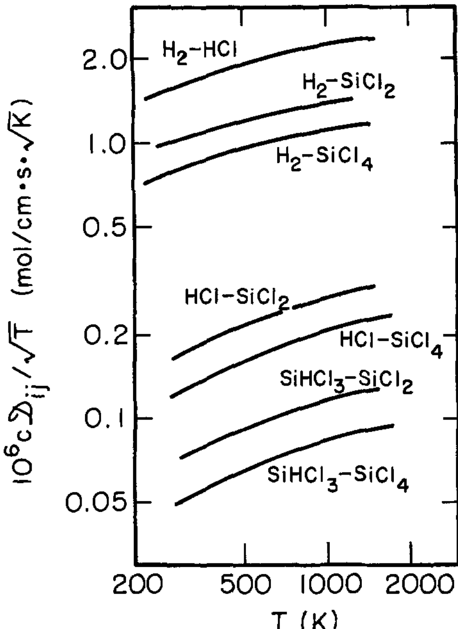

Fig. 9. Temperature dependence of binary diffusion coefficients

analogous to $\Omega_{\mu i}$ used for the viscosity calculations, but the characteristic of the intermolecular potential field should now represent both species i and j, and is assumed to be given by $\epsilon_{ij} = \sqrt{\epsilon_i \epsilon_j}$. Figure 9 shows the temperature dependence of diffusion coefficients obtained from Eq. [A-4]. In the analysis, a simplified form

$$c\mathcal{D}_{ij} = B_{ij}T^{l_{ij}} \qquad \text{[A-5]}$$

is chosen with parameters which best fit the curves in Eq. [9] over the temperature range of interest (see Table III).

Specific heat.—The temperature dependence of the heat capacity of each species is obtained from

$$\tilde{C}_{pi} = \alpha_i + \beta_i T + \gamma_i T^2 \qquad \text{[A-6]}$$

where the coefficients are summarized in Table IV.

Thermal conductivity.—Eucken's equation for polyatomic gases (10)

$$k_i = (\tilde{C}_{pi} + 5R/4)\,\frac{\mu_i}{M_i} \qquad \text{[A-7]}$$

is used to relate the thermal conductivity and viscosity

Table III. Values for parameters in Eq. [A-5] for diffusion coefficients

Species i	Species j	B_{ij}	l_{ij}

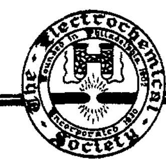
Technical Notes



Changes in Thickness and Infrared Spectrum of Phosphosilicate Glass Film with Heat-Treatment in H_2 Gas

Hideaki Takeuchi and Junichi Murota

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino, Tokyo, 180 Japan

Phosphosilicate glass (PSG) films deposited by chemical vapor deposition (CVD) techniques are important materials for insulation layers in MOS LSI's (1). Structural changes in PSG films with heat-treatment in atmospheres of N_2 gas, Ar gas, and steam have been studied (2-5). However, little is known about structural changes in PSG film with heat-treatment in H_2 gas. In the present work, the changes in thickness and infrared (*IR*) spectrum of a PSG film with heat-treatment in H_2 gas were investigated. It was found that voids are formed in the film and the integrated absorbance of P = O band near 1330 cm^{-1} is reduced by high temperature heat-treatment in H_2 gas.

Experimental

PSG films were deposited at 420°C in a horizontal reactor using an SiH_4-PH_3-O_2-N_2 gas system. The thickness of the as-deposited film was about 6300Å. The substrates used were p-type Si wafers of 30-50 Ω-cm with mirror polished (100) surface. The Si substrates were thermally oxidized before PSG film deposition in order to prevent phosphorus diffusion into the substrates from the PSG films (4). The PSG films were heat-treated in atmospheres of H_2 and N_2 gas. In some cases, films heat-treated in H_2 gas were subsequently heat-treated in O_2 gas or N_2 gas. Film thicknesses (T_{PSG}) were measured with a Taylor Hobson Talystep. Cross sections of the heat-treated films were observed by a scanning electron microscope. The total phosphorus weight (W_P) per square centimeter of the film was determined by x-ray fluorescence techniques and neutron activation analysis. The *IR* spectrum of the film was measured with a double beam *IR* spectrophotometer. The integrated absorbance of the P = O band ($A_{P=O}$) was estimated from the product of the absorbance and the half-width of the P = O absorption band (6).

Key words: voids formation, phosphosilicate glass, chemical vapor deposition, P=O absorption band.

Results

Figure 1 shows the T_{PSG} change of film containing 9 weight percent (w/o) phosphorus (as-deposited) as a function of heat-treatment temperature in H_2 and N_2 gas. In H_2 gas, the T_{PSG} increases drastically above 1000°C but not below 950°C. In N_2 gas, no increase in the T_{PSG} takes place under the present con-

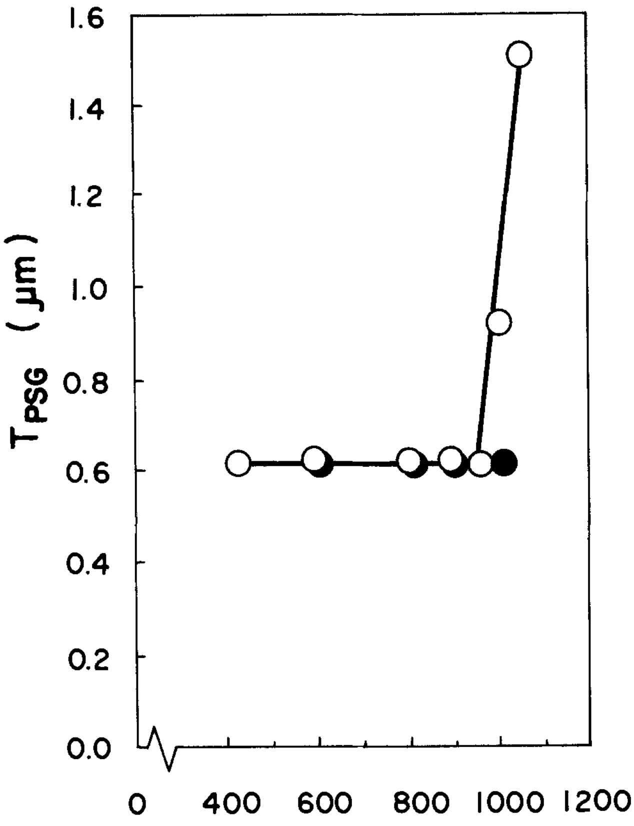


Fig. 1. Dependence of T_{PSG} on heat-treatment temperature with H_2 or N_2 gas for 20 min. Open circles are results in H_2 and closed circles are results in N_2. Phosphorus concentration and T_{PSG} of as-deposited film are 9 w/o and 6300Å, respectively.

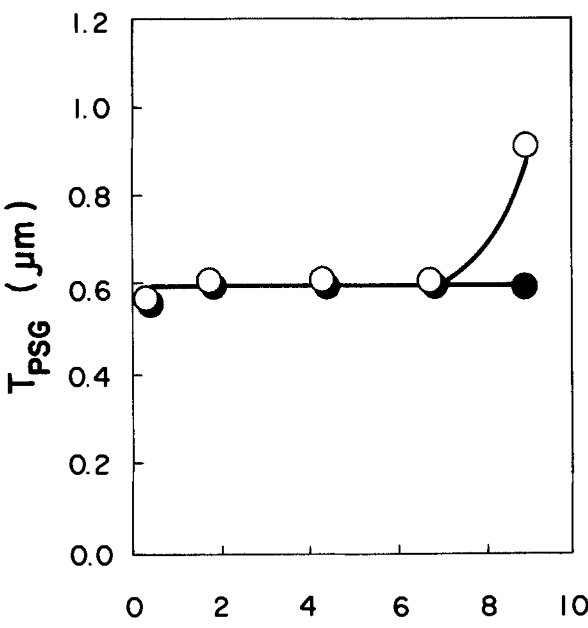

Fig. 2. Relationship between T_{PSG} and phosphorus concentration (as-deposited) with heat-treatment in H_2 or N_2 gas at 1000°C for 20 min. Open circles are results in H_2 and closed circles are results in N_2. The T_{PSG} of as-deposited film is 6300Å.

ditions. Figure 2 shows the T_{PSG} change as a function of phosphorus concentration in the film with heat-

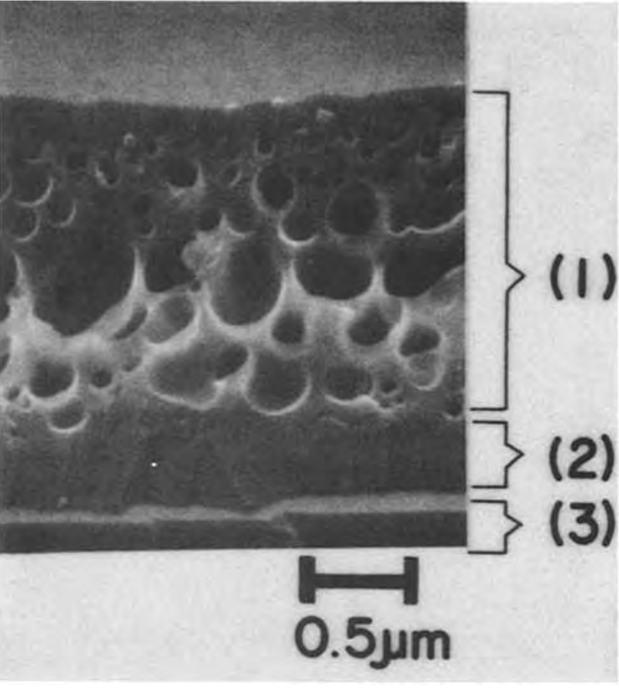

Fig. 3. Scanning electron micrograph of a cross section of PSG film of which T_{PSG} expanded with heat-treatment in H_2 gas at 1000°C for 20 min. Phosphorus concentration of as-deposited film is 9 w/o: (1) PSG film; (2) thermally grown SiO_2 film; (3) Si substrate.

treatment at 1000°C. For lower phosphorus concentration (below 7 w/o) films, no increase in the T_{PSG} takes place in H_2 gas. A cross section of a film which became thicker with heat-treatment in H_2 at 1000°C is shown in Fig. 3. Many voids, with sizes ranging from 0.1 to 0.3 μm, are distributed in the film. The total volume of the voids is in good agreement with the PSG film volume increment, where the total volume of the voids was estimated from the number and the sizes of the voids on the assumption that the voids are spherical. PSG films which expanded in thickness with heat-treatment in H_2 gas were subsequently heat-treated in O_2 or N_2 gas at 1000°C. The results are shown in Table I. With heat-treatment in O_2 gas, the T_{PSG} decreases to that of the as-deposited film and the voids are diminished. With heat-treatment in N_2 gas, the T_{PSG} does not change, *i.e.*, the voids are not diminished. From these results, it is supposed that voids are formed in the PSG film by reduction in H_2 gas and are diminished by oxidation in O_2 gas.

To elucidate the reaction in the PSG film, *IR* spectra of PSG films heat-treated in H_2 or N_2 gas were studied. It was found that the changes in $A_{P=O}$ were different between H_2 and N_2 gas. In Fig. 4, the changes in $A_{P=O}$ and W_P of PSG film containing 9 w/o phosphorus (as-deposited) are shown as a function of heat-treatment temperature. In N_2 gas, the $A_{P=O}$ increases initially with increasing temperature and is saturated above 800°C. This increment of $A_{P=O}$ agrees with the results reported by Kern *et al.* (2, 3). In

Table I. Changes in T_{PSG} with heat-treatment under various conditions

Heat-treatment conditions	T_{PSG} (A)
As-deposited	6300
H_2 gas 1000°C 20 min	9300
H_2 gas 1000°C 20 min + O_2 gas 1000°C 60 min	6300
H_2 gas 1000°C 20 min + N_2 gas 1000°C 60 min	9400

Phosphorus concentration of as-deposited film is 9 w/o.

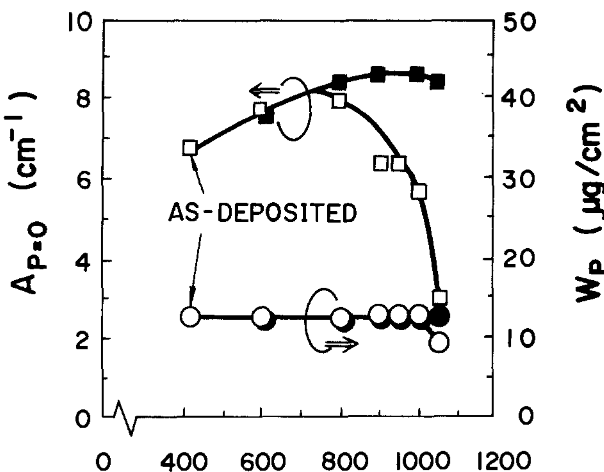

Fig. 4. Dependence of $A_{P=O}$ and W_P upon heat-treatment temperature with heat-treatment in H_2 or N_2 gas for 20 min. Open squares and circles are results in H_2; closed squares and circles are results in N_2; phosphorus concentration of as-deposited film is 9 w/o.

H_2 gas, the $A_{P=O}$ increases initially with heat-treatment temperature and decreases above 800°C. The decrease of the $A_{P=O}$ above 800°C cannot be explained by phosphorus loss during the heat-treatment because the W_P does not decrease with heat-treatment, except for the heat-treatment at 1050°C in H_2 gas. From this result, it is suggested that P = O bonds dissociate with heat-treatment in H_2 gas. Assuming that some volatile gases such as phosphorus species or H_2O are generated by the reduction of the P = O bonds, voids are expected to be formed because of the combination of the increased volatile gas pressure and the low viscosity of the PSG film due to higher heat-treatment temperature and higher phosphorus concentration. More work on the behavior of phosphorus in PSG film under heat-treatment in H_2 gas is needed to understand the void formation mechanism.

In conclusion, the structural changes of PSG film with heat-treatment in H_2 gas are different from those in N_2 gas. In H_2 gas voids are formed in the PSG film in association with the film thickness increment, and the integrated absorbance of the P = O band near 1330 cm^{-1} decreases with high temperature heat-treatment.

Acknowledgments

The authors wish to express their gratitude for encouragement to Mr. M. Kondo, and to Mr. F. Yanagawa for executing the study. They also would like to thank Dr. E. Arai for his useful discussions and valuable advice, and Mr. I. Kawashima for x-ray fluorescence analysis.

Manuscript submitted Aug. 20, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Nippon Telegraph and Telephone Public Corporation.

Oxygen Precipitation in Silicon at 650°C

P. E. Freeland

Bell Laboratories, Murray Hill, New Jersey 07974

A great deal of attention has focused on the precipitation of oxygen (1) in silicon in the temperature range 1000°-1200°C because of the relevance to device processing, there has been relatively little work (2) at lower temperatures around 600°C. [In some recent work associated with laser annealing studies it was desirable to produce a large number of small defects by heat-treating silicon at as low a temperature as possible consistent with a reasonable time (3).] In this study, we follow the oxygen precipitation behavior of a crystal heated at 650°C for 10 days by infrared absorption, x-ray anomalous transmission, and x-ray Pendellösung fringes. In previous precipitation studies (4) at higher temperature (1000°C) the above three diagnostic techniques have supplemented each other and have been valuable aids in determining the degree and nature of precipitation in bulk crystals.

Experimental

The Czochralski crystals used had been especially grown to contain a high oxygen concentration (5). The 3 in. diameter crystals were oriented, sliced, and polished to a thickness of 2.5 mm. They were chemically cleaned and then heated at 650°C in an H_2 atmosphere for 10 days. The heat-treatment was done in a quartz-lined furnace and the sample was supported on a silicon substrate. Following this treatment the sample and its as-grown control were subjected to the tests described below.

Key words: silicon, oxygen precipitation.

Results

Infrared absorption.—The infrared absorption spectra of the heat-treated and as-grown samples are shown in Fig. 1. Curve A for the as-grown sample shows a large

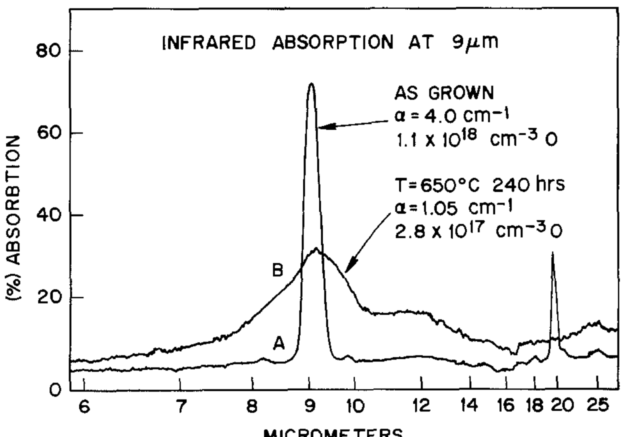

Fig. 1. Infrared absorption spectra of as-grown (curve A) and heat-treated silicon (curve B).

absorption peak at 9 μm which is a measure of the dissolved oxygen. The peak value of the absorption coefficient is $\alpha = 4.0\ cm^{-1}$ which corresponds to an oxygen concentration of $1.1 \times 10^{18}\ cm^{-3}$ according to the calibration determined by Kaiser *et al.* (6). [See recent review (7).] This value is high compared to the values of about 7-8 $\times 10^{17}\ cm^{-3}$ found in crystals of similar diameter at the seed end. For the as-grown spectra, there is also an absorption peak at 19.4 μm which corresponds to the ν_2 symmetry bending vibration mode of the Si_2O configuration, according to Hrostowski and Kaiser (8). These curves were obtained with a low oxygen, low carbon floating zone high purity crystal as

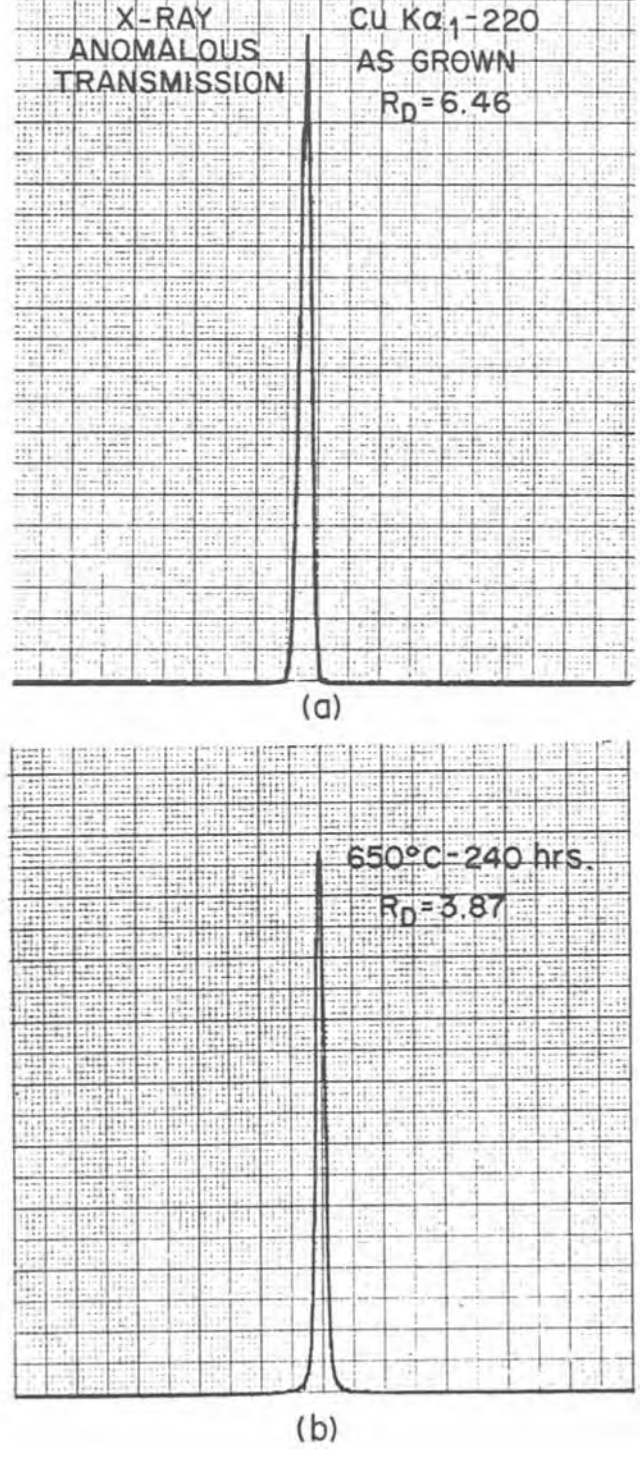

Fig. 2. X-ray anomalous transmission spectra of as-grown (curve a) and heat-treated silion (curve b).

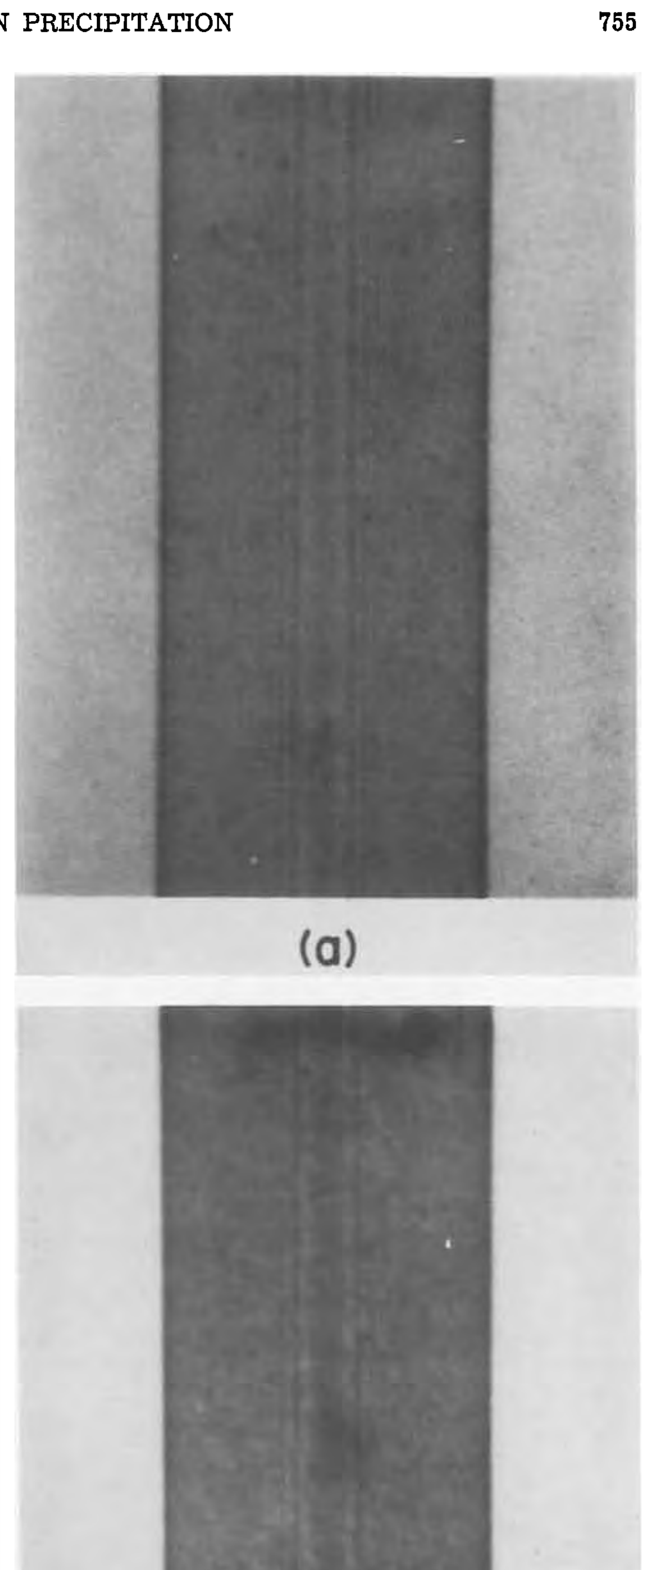

Fig. 3. (a) X-ray section topograph of as-grown high oxygen silicon ($1.1 \times 10^{18}\ cm^{-3}$) using $AgK_{\alpha 1}$ radiation; (b) x-ray section topograph of silicon with high oxygen content after heat-treatment (650°C-240 hr).

a reference in a dual beam spectrometer. No trace of carbon is observed in the spectra for the Czochralski silicon at 16.5 μm. After heat-treatment, spectra curve B shows a much lower absorption at 9 μm, $\alpha = 1.05$ cm^{-1} which corresponds to an oxygen concentration of 2.8×10^{17} cm^{-3}. Note that the peak at 19.4 μm has disappeared entirely. This suggests that this peak might be a more sensitive indicator of the precipitation process. Note also that the 9 μm peak in curve B is considerably broadened probably due to contributions from the precipitated oxygen. From the 9 μm data one would conclude that a large amount of precipitation has occurred even at the relatively low temperature of 650°C.

X-ray anomalous transmission.—This method was shown to be a very sensitive indicator of the precipitation of oxygen in silicon heated for varying times at 1000°C (9). The results of x-ray anomalous transmission integrated intensity measurements are shown in Fig. 2. In the as-grown sample (Fig. 2a) the integrated intensity was $R_d = 6.46$ (arbitrary scale). The beam size was 1 mm^2 and no variation in integrated intensity was observed in different regions of the sample before or after heat-treatment. After heat-treatment at 650°C, $R_d = 3.87$, a decrease of only about 40%. Clearly the x-ray method is less sensitive than the infrared method where the intensity has decreased by a factor of 4. This result is diametrically opposed to the findings in previous experiments on silicon heated at 1000°C where the x-ray intensity R_d changes by 2 orders of magnitude before any change is observed in infrared at 9 μm.

Pendellösung fringe section topographs.—Section topographs were taken of samples before heat-treatment (Fig. 3a) and after heat-treatment (Fig. 3b). Although the samples were not ideal thickness for AgKα radiation ($\mu t > 1$) where μ is the absorption coefficient and t the specimen thickness); fringes are evident in the as-grown sample and are only slightly less clear in the heated sample. However, the heat-treated sample topograph does have a mottled background appearance and edges which are not as dark as the as-grown sample topograph. This is an indication of a decrease in crystal perfection. In contrast, samples heated at 1000°C for only 1 hr show the presence of precipitate in section topographs (4). After 6 hr at 1000°C, the fringes have completely disappeared and are replaced by bands of defects (4).

Conclusion

It is well known that because of the large volume expansion accompanying oxygen precipitation in silicon ($Si + 2O \rightarrow SiO_2$; $V_{SiO_2}/S_{Si} \approx 2$) the crystal is highly strained (9). The high sensitivity of the x-ray method in earlier experiments (9) is due to the large precipitate size which is of the order of or larger than the Pendellösung length ($\sim$18 μm). At low temperatures where the precipitate size is expected to be small, probably much smaller than the Pendellösung distance, the x-ray anomalous transmission method is no longer as sensitive to these precipitates. Another x-ray technique such as diffuse scattering of x-rays in the vicinity of the Bragg peaks would be more relevant. Previous experiments at 1000°C had led to the conclusion that the x-ray dynamical diffraction method was more sensitive than infrared absorption to oxygen precipitation in silicon. This is no longer true at low temperatures where the x-ray dynamical diffraction method is not very sensitive to the small precipitate size. In this temperature range, the infrared measurement is a better indicator of oxygen precipitation.

Chlorine Evolution Reaction on Tin Oxide Anodes in an $AlCl_3$-NaCl Melt at 175°C

I. Uchida,* H. Urushibata, and S. Toshima

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980, Japan

ABC

Sodium tetrachloroaluminate melts are of special interest from the viewpoint of molten salt batteries and metal winning processes. One of the problems relating to them is developing suitable anode materials workable for chlorine evolution reaction. The previous investigations on chlorine electrode in the melts have been done by employing glassy carbon (1-3) and graphite and platinum (4). Carbon is the most popular with regard to chemical durability and economic accessibility. However, it is noted that carbon electrodes except glassy carbon show considerable swelling and disintegration in the melts. Recently, we reported on the chlorine evolution on tin oxide electrodes in LiCl-KCl eutectic at 450°C (5) and characterization of the interface between tin oxide and the chloroaluminate melts of different pCl at 175°C (6), noting that Sb-doped tin oxide is a versatile electrode material stable in the melts.

In the present paper we show current-potential curves of chlorine evolution on the tin oxide electrodes with different doping levels, comparing them with the kinetic behavior of glassy carbon electrodes (GCE).

Experimental.--Sb-doped tin oxide electrodes were polycrystalline films prepared on Pyrex substrates in rectangular shape by a spray method. Electrode surfaces were held vertically in the melt. Details of the film preparation and the electrode construction are given elsewhere (6). A rod of GC was sealed into Pyrex tubing with a technique described previously (7) and cut off at 45°. Purification of the melt and experimental procedures were described previously (5,6). Measurements were carried out at 175±2°C and electrode potentials were given with respect to the potential of an Al electrode in the melt saturated with NaCl.

Results and discussion.--Fig. 1 shows the steady-state current vs. potential curves of chlorine evolution measured in the melt of pCl=1.1. The Tafel slope observed on GCE was close to RT/F. According to Letisse et al. (2), the Tafel region corresponds to the oxidation of free Cl^- ions and the plateau is the limiting current of Cl^-, while the further increase of current beyond the diffusion limit is due to the oxidation of $AlCl_4^-$. Thus we have two chlorine evolution reactions at the different potential regions,

$$2Cl^- = Cl_2 + 2e^-$$

$$4AlCl_4^- = Cl_2 + 2Al_2Cl_7^- + 2e^-$$

Arvia et al. reported that the Tafel slope on graphite at 190°C is RT/2F (4), suggesting that the rate-determining step is a combination process expressed as $Cl(ad)+Cl(ad) \longrightarrow Cl_2$. Our result on GCE was larger than that of Arvia et al., being rather close to the Tafel slope on GCE obtained by reconstructing the data in ref. (2).

The polarization behavior on semiconducting tin oxide electrodes was different from that on GCE, showing the notable dependence on electron concentration of the oxides as seen in the curve (b) and (c). The shoulder observed on a low-doped tin oxide electrode (N_d = $7x10^{19}$ cm^{-3}) at lower current densities is not due to the diffusion of Cl^-, and the difference between the low-doped and high-doped (N_d = $3x10^{20}$ cm^{-3}) specimens in the polarization behavior is too large to

*Electrochemical Society Active Member.

Key words: semiconductor, electrode, Tafel slope.

be explained in terms of the effect of ohmic drop. The cell resistances measured between the reference and the tin oxide electrodes(area=0.5 cm^{-2}) were about 15 ohm and there was no considerable difference between the two specimens. Thus it was demonstrated that the high-doped electrode shows fairly improved polarization similar to the behavior of GCE. However, a well-defined Tafel slope was not obtained in this case. As described in auqeous systems (8) and in melt systems (5,9), highly doped tin oxide electrodes are metal-like electrodes, indicating the reversible behavior for simple charge transfer reactions, because the space charge barrier present at the semi-conductor surface is highly trans-parent to electrons due to tunneling.

It has been reported that the differential capacity measured at the SnO_2-melt interface obeys the Mott-Schottky relationship (6). The carrier densities given in this work and flat band potentials were determined from the Mott-Schottky plots. The flat band potential in the melt of pCl=1.1 was found to be 1.49 V for the high-doped SnO_2 and 1.68 V for the low-doped one. Obviously, the chlorine evolution takes place at potentials more positive to the flat band potentials where the space charge barrier is extremely thin particularly for the high-doped SnO_2. The electron tunneling through the space charge barrier is much easier at the high-doped SnO_2 electrode than at the low-doped one. The presence of the shoulder in the polarization behavior at the low-doped one suggests that the tunneling process may involve two mechanisms, tunneling via surface states in the band gap and direct elastic tunneling.

Since the preparation of SnO_2 having much higher carrier densities ($\sim 10^{21}$ cm^{-3}) is technically possible as obtained by Elliott et al.(8), more improved polarization than the curve (b) would be expected with such highly doped specimens. It is of interest to develop SnO_2-based electro-catalyzers usable in melt systems by applying the oxide-coating technology used in the production of DSA.

Reduction of Oxygen on Silver Electrodes in Ternary Alkali Carbonate Eutectic Melt

A. J. Appleby*

Electric Power Research Institute, Palo Alto, California 95303

S. B. Nicholson

Institute of Gas Technology, Chicago, Illinois 60616

Tyurikov et al.[1] have described results obtained for reduction of oxygen on various substrates in a number of carbonate melts. They show that on smooth silver electrodes currents were greater than those on gold. Unless their observation can be explained by geometric factors, this result is inconsistent with the supposition of an essentially diffusion-controlled mechanism involving initial chemical formation of peroxide and superoxide ions from O_2 and $CO_3^=$, as described in previous work (2,3).

Accordingly, a study of oxygen reduction on immersed silver electrode, with a polished 0.5 cm^2 surface was conducted. Apparatus and experimental procedure were as in previous work (2,3). Potentials are given on the 0.33 atm O_2/0.66 atm CO_2 scale. Potentiostatic results obtained at 650°C under steady-state conditions in a 10% O_2-10% CO_2 atmosphere may be summarized as follows:

1. Extremely high current densities (> 10 times those on gold) were obtained on silver electrodes that had been dipped in H_2O_2 or nitric acid before being inserted into the carbonate cell. These electrodes had rest potentials of about -250 mV (well below the theoretical value of -101 mV) and the cathodic currents slowly decayed over a period of days when the electrodes were polarized at -900 mV.

2. Electrodes that had been untreated with oxidizing agents, or that had been hydrogen-reduced, showed lower current densities, which decayed more quickly, and somewhat lower rest potentials.

3. After 2-3 days for oxidized electrodes and after a few hours for reduced or untreated electrodes, currents had decayed to the same order of magnitude as those on gold at -900 mV. The high initial currents were stirring-independent; the final currents were stirring-dependent, as observed on gold[3]. Rest potentials on these electrodes fell to about -775 to -800 mV.

Figure 1 shows a comparison of oxygen reduction on an unoxidized electrode a short time after being placed in the cell and on the same electrode after 8 hours exposure to the melt. The very large current density, which was independent of stirring, indicates that the oxygen being reduced is present in or on the metal. As silver normally contains large quantities of dissolved oxygen that occlude at high temperatures, the current observed is clearly due to the reduction of this material. The high rest potentials under these conditions indicate the occurrence of an oxide passivation phenomenon.

Key Words: molten carbonate fuel cell, cathode, silver

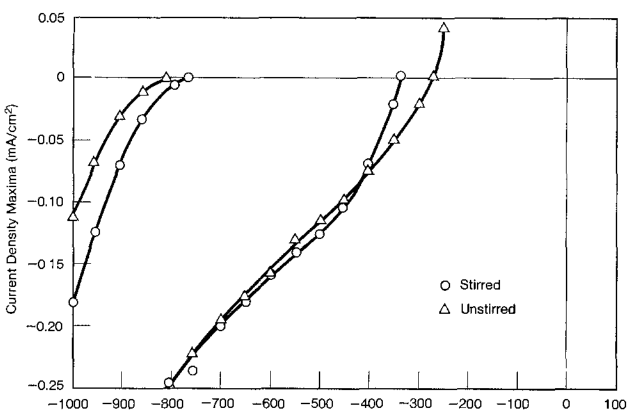

Figure 1. CATHODIC REDUCTION OF OXYGEN ON SILVER: COMPARISON OF ELECTRODE IN FRESH CONDITION AND AFTER 8 HOURS EXPOSURE TO MELT AT -800 mV. POTENTIALS ON 0.33 atm O_2/0.66 atm CO_2 SCALE.

In a molten carbonate fuel cell, it therefore appears that silver cathodes act as oxygen transfer agents, for which the bulk of the oxygen diffuses through the metal. Corrosion is slowed by a combination of passivation due to oxide formation and concentration polarization due to dissolved silver ions. The effect of this type of polarization is evident in the stirring-dependence of the rest potential in Figure 1.

Figure 2 shows the effect of an 8-minute exposure of the silver electrode to the atmosphere above the melt at 650°C. In this case, the amount of oxygen adsorbed after this short exposure is considerable, and it is not entirely reduced after one polarization cycle.

Li/TiS_2 Cell with Solvate Melt

B. M. L. Rao* and L. P. Klemann*

Exxon Research and Engineering Company, Advanced Energy Systems Laboratory, Linden, New Jersey 07036

Li/TiS_2 solid electrolyte cells with solvate complexes of lithium salts have been recently disclosed (1). In this paper, we present the behavior of Li/TiS_2 cells in a low-temperature melt consisting of LiI:glyme solvate.

Lithium iodide forms solvate adducts with glyme(s) (mono-, di-, tri-glyme) which result in crystalline solids and ultraconcentrated solutions in 1-4 mole ratio of the solvent per mole of the solute. The solid adducts may be generated by mixing, melting, (∿70°C), and cooling the ingredients in a 1:1 to 1:2 mole ratio of LiI:glyme(s). At a higher solvent ratio (∿2.5-3), solid compositions co-exist with ultra-concentrated solutions, and compositions with >4 moles of solvent per mole of solute are liquids, at room temperature.

Fig. 1 illustrates the specific resistivity composition data for the LiI:glyme(s) melts at 95°C. The data indicate that the solvate adduct melts are ionic liquids, which may be of interest in the development of high energy density lithium cells, based on low temperature (<100°C) fused salts.

The LiI:glyme (1,2·dimethoxyethane, b.p. 85°C) adduct is a light yellow solid (m.p. 60-65°C) in the composition range 1.75-2.85 moles of solvent per mole of solute. A Li/TiS_2 cell was tested in this electrolyte at 75°C.

The test cell consisted of a lithium anode ∿90 mAh/cm² (1"x1"x0.02" foil on nickel grid), a pressed powder, 45 mAh/cm² TiS_2 cathode (1"x1"x(0.04"-0.05"), 10 W/O teflon, 40-50% porous), a fiber glass separator (0.015" thick, 75% porous), and was held together with a fiber glass strap. The cell was assembled in a helium dry box and was contained in a suitable glass jar with provision for external electrical connections. The cell was operated at 75°C after adding LiI:glyme molten electrolyte of composition 1.75-2.25 moles of glyme per mole of LiI.

First discharge data for Li/TiS_2 cells at 10-20 mA/cm² is given in Fig. 2. It is noted that the material utilization (% M.U.) of the cathode-limiting cell is ∿90% of the theoretical capacity to 1.5 V. The cells were not rechargeable under the ambient temperature conditions of this work. We note the recent report wherein a sodium-TiS_2 cell has been operated at 130°C in an electrolyte of NaI-triglyme[2].

The following experiments were carried out to understand the lack of rechargeability of the cells.

1. Lithium electroplating and anodic stripping experiments were done in the electrolyte in half-cell mode using a lithium reference and a nickel grid working electrode. The electrodeposition resulted in plating of a black, non-adherent deposit, which yielded 30% anodic stripping efficiency, and gassing was noted at the working electrode during the electrodeposition and stripping experiments. In the pre-lithium deposition potential region, a background current of ∿1 mA/cm², probably associated with the gassing reaction, was noted.

2. TiS_2 half-cell studies indicated that the cathode is inherently rechargeable.

3. Examination of the spent cell revealed a blue-grey film on the lithium anode; also, a yellow discoloration was seen on the cathode side of the separator. Finally, a TiS_2 cathode had expanded ∿100% in thickness.

4. X-ray diffraction studies on the discharged TiS_2 cathode indicated intercalation of the glyme, in addition to the expected formation of Li/TiS_2.

Analysis of the experimental results suggested that the lack of rechargeability may be associated with very strong complexing of Li^+ ions by glyme. Strong complexation of Li^+ by multidentate chelating ethers might be expected to inhibit the molecular process of cation release required for adatom formation during electrodeposition. Inhibition of the desolvation process might, in turn, make alternate reaction pathways preferable energetically, and such an alternate pathway seems to be the gassing (reductive degradation of glyme) reaction at the polarized electrode. If the strong complexation of Li^+ ion inhibits the

release of the cation, additional effects would be expected at the TiS_2 cathode during the discharge of the cell. In this case, intercalation of lithium occurs, but not without substantial co-intercalation of the strongly coordinated polyether ligand, as witnessed by the excessive expansion of the cathode and the X-ray diffraction data. The co-intercalation of the polyether offers one plausible mechanistic interpretation for the point of inflection observed in the discharge curve (Fig. 2), although this offering is speculative. Discharge performance did not appear to be severely affected by the polyether co-intercalation.

Other points worth highlighting are as follows:

(a) The cells may be discharged at high rates in the low temperature melt, and

(b) the cells may be stored in solid electrolyte mode to favor long storage life.

These features render the solvate adduct an attractive candidate for a low-temperature Li/TiS_2 thermal cell.

Auger Electron Spectroscopy Depth Profile of Thin Oxide on a Ti-Mo Alloy

Daniel Laser

Department of Chemistry, Tel-Aviv University, Ramat Aviv, Israel

Harris L. Marcus

Department of Mechanical Engineering/Material Science and Engineering, University of Texas at Austin, Austin, Texas 78712

Recently we investigated[1] the growth and properties of thin oxide films which were grown on a titaniun electrode. It is the aim of this communication to describe some properties of an anodic oxide which were grown on a Ti-Mo alloy.

For the formation of a controlled oxide thickness on a bare substrate to be used as an AES sample, the previously described[1] method was employed which consists of polishing the electrode surface (3μ diamond dust embedded in a polishing cloth) while holding it at a cathodic bias (-0.95V vs SCE) and then applying to it a positive linear potential scan.

The alloy studied was the β-III, a Ti based metastable alloy (Ti, 11.5 Mo, 4.5 Sn, 6 Zr) the stress-corrosion behaviour of which was studied by Hickman et al[2] and which was used as received without any heat treatment.

The current/potential curve during the anodic potential scan of the alloy electrode in slightly acidic solution is shown in fig. 1, where it is compared to the voltammogram of pure Ti and pure Mo under the same conditions.

As in the case of pure Ti, the voltammogram is distinguished by an extended potential interval (∿ 2V) in which the anodic current which is attributed to oxide formation remains constant. Such a mode of oxide growth results in the formation of a homogeneous film the thickness of which varies linearly with the applied potential at full current efficiency.[1] However, the "dissolution peak" which is observed at pure Ti (∿ -0.65V) is missing. This is in agreement with the finding of Tomashov et al[3] who find a suppression in the dissolution rate of Ti at the prepassive state when alloyed with Mo in the β phase and will be discussed later.

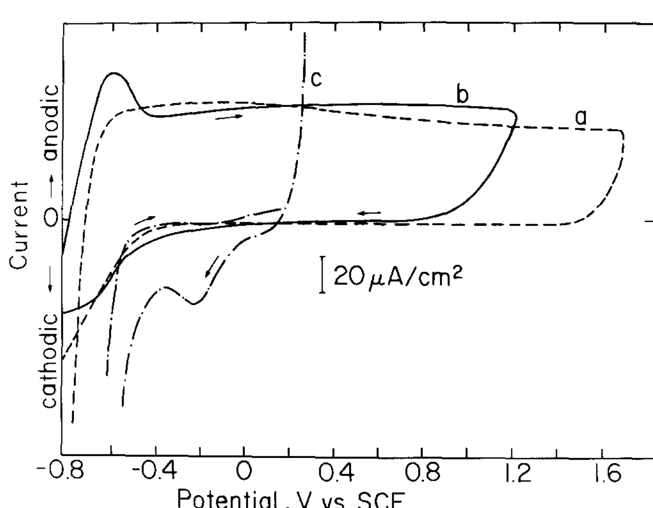

Fig. 1. Current voltage curve for a - β III alloy, b - Ti and c - Mo in 1N Na_2SO_4,PH 2.3.

Little is known about the composition of anodic oxides of alloyed Ti. Recently Paleolog et al[4] assumed that the anodic oxide of a Ti-Ni alloy consists mainly of TiO_2 with Ni doping at the metal/oxide interface.

We adopt a similar picture with regard to the distribution of Mo within the oxide of the β-III and in order to probe it the oxides were subjected to Auger Electron Spectroscopy (AES)

Key Words: Alloy, Electrode, AES, sputtering

depth profiling immediately after their formation with the use of a PhI Model 590A Scanning Auger system equipped with sputtering, multiplexing and in situ fracturing facilities.

The difficulties in quantitative AES application to very thin (<100A) TiO_2 films and to Mo oxides have been described before[5,6]. However, our aim was to locate the Mo distribution within the oxide. The appearance of the Mo major peaks (186,221 ev in the $\frac{dN}{dE}$ mode) in the absence of the 27ev peak which is characteristic of metallic Ti, proves the existence of Mo within the oxide if the escape depth of the 27 and 221(186)ev Auger electrons are assumed to be about equal. The depth profile of the oxide is shown in fig. 2. The outer layer of the oxide (oxide/solution interface) consists exclusively of TiO_2 and the Mo concentration increases toward the metal oxide interface. The increase in the carbon concentration increases toward the metal oxide interface. The increase in the carbon concentration in this region is attributed to the polishing procedure prior to film formation (polishing with diamond dust). It should be noted that a similar apparent distribution of Mo can result if: (a) There is a preferential sputtering of Ti over Mo[7] which leads to the surface accumulation of Mo during the sputtering, or (b) Mo is gradually reduced by the ion beam,[6] or continuously changes its oxidation state while penetrating the film in such a way that its Auger peak shape is changed and enhanced even without any increase in its concentration.

Possibility (a) should also be manifested after the film is completely sputtered through; however the Mo signal then reaches a steady state. Also the Auger peak of Mo oxide grown at 1V did not change during the sputtering which eliminates the second possibility. We believe the chemical state of Mo within the oxide to be that of Mo ion (Mo^{+3} or Mo^{+5}), which because of its size, does not fit the TiO_2 phase and thus exhibits in it a much slower mobility than the Ti ion. It probably does not reach the solution/oxide interface except in the very early stages of film growth.

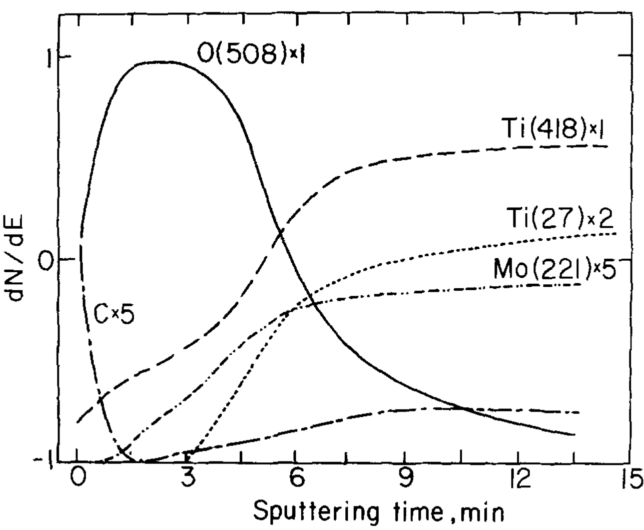

Fig. 2. AES depth profile of oxide formed at β III alloy at 2V vs SCE, solution as in fig.1. Sputtering by 3 kev Kr^+ ions.

The absence of the Ti dissolution peak (fig.1) may be relevant to the superior behaviour of this alloy in corrosive media[2,3] when the bare substrate might be exposed to solution. Two explanations, which are supported by the AES findings, can be provided for this observation. Firstly: In the AES of pure Mo or of its oxide the 221 ev Auger peak is smaller than the 186 ev peak, but the 221 ev peak of Mo in the alloy is bigger than the 186 ev one (in the $\frac{dN}{dE}$ mode, fig.3). This reflects some specific interaction between Ti and Mo in alloyed state, which may possibly stabilize the Ti atom in the solid compared to its state in pure Ti. Secondly: At -0.95V while polishing, Ti dissolves into solution[1], but

this electrode potential is too negative for the Mo dissolution[8] and it seems, therefore, feasible that the substrate surface prior to film formation is enriched with Mo which provides a barrier for the Ti dissolution. Indeed, the concentration of Mo which is found by AES after the oxide is removed by sputtering and which represents its quantity at the surface prior to anodization, is much higher than its concentration at the surface which was obtained by the in situ fracturing of the alloy (fig.4)

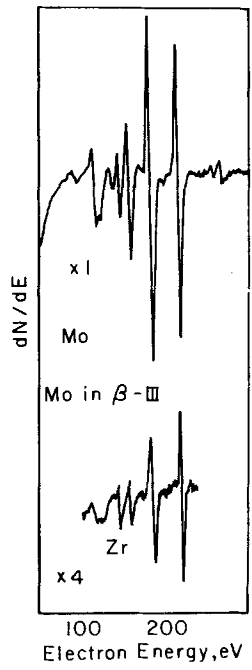

Fig. 3. AES of Mo in its pure state and in β III alloy.

The Electrodeposition of Metal Chalcogenides

A. S. Baranski and W. R. Fawcett*

Guelph-Waterloo Centre for Graduate Work in Chemistry,
Department of Chemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

Although metal chalcogenides can be grown on the parent metal by anodic oxidation in a sulphide containing electrolyte (1,2,3), and by cathodic reduction from aqueous solutions containing soluble metal and chalcogen compounds (4,5), no effective method of growing smooth coherent films of these compounds from non-aqueous solutions in a cathodic process has been reported in the literature. Recently, a general method of cathodic electrodeposition of metal chalcogenides on a variety of conducting substrates has been developed in this laboratory. The principle of the technique involves dissolving a salt containing the desired metal ion and the elemental chalcogen in a suitable non-aqueous solvent and depositing the metal ion at a suitable cathode under current control; the metal chalcogenide is formed by rapid reaction of a freshly deposited metal monolayer with the dissolved chalcogen. The technique has proven successful in depositing thin films of CdS, HgS, PbS, Tl_2S, Bi_2S_3, Cu_2S, NiS, CoS and CdSe. The substrate conductors have included Pt, Au, stainless steel, Ni, Zn and glass covered with a conducting film of SnO_2. The non-aqueous solvent was usually dimethylsulphoxide (DMSO) but deposits of good quality were also obtained from dimethylformamide (DMF) and ethylene glycol.

In the case of CdS, good quality deposits were obtained from DMSO solutions containing 6 g $litre^{-1}$ sulphur and 10 g $litre^{-1}$ $CdCl_2$ where electrolysis was carried out between Pt electrodes with a current density ≤ 2.5 mA cm^{-2} at 110°C. The quality of the deposit was independent of sulphur and $CdCl_2$ concentration; moreover, addition of up to ten percent water to the solution had no significant effect on deposit quality. In this case there was no need to separate anolyte and catholyte compartments. Deposit characteristics depended on temperature, highly non-stoichiometric deposits being obtained below 90°C. This result undoubtedly reflects the need for the chemical reactions accompanying electron transfer to proceed at a rate sufficiently high to maintain an almost stoichiometric electrodeposit.

The properties of the electrodeposited CdS films are very interesting with respect to their potential use in photovoltaic devices. X-ray examination of the films has shown that the crystallites are all oriented with their [111] planes parallel to the electrode surface. Although their specific resistivity is rather high ($\sim10^6$ Ω cm), it may be considerably reduced by adding NaI to the catholyte compartment of a cell in which the anolyte and catholyte are separated by a barrier such as a fritted glass disc.

The technique for producing films of PbS, Bi_2S_3, NiS, CoS and Tl_2S was the same as that for CdS, $CdCl_2$ being replaced by $PbCl_2$, $BiCl_3$, $NiCl_2$, $CoCl_2$ and TlCNS, respectively. Slightly modified procedures were used in other cases. Cu_2S was electrodeposited from a solution containing 5 g $litre^{-1}$ CuCN, 5 g $litre^{-1}$ CsCl and 6 g $litre^{-1}$ S. The cuprous cyanide salt was used to prevent the formation of undesirable intermediates which arise when other copper salts are used; the CsCl was added to increase solution conductivity. In the case of HgS, the solution contained 23 g $litre^{-1}$ HgI_2 and 8 g $litre^{-1}$ KI together with the usual amount of sulphur. In the presence of iodide ion, the reduction potential of Hg^{++} is shifted into a more negative region where complications due to oxidation processes are not present. CdSe was most conviently deposited from a DMF solution saturated with selenium and containing 10 g $litre^{-1}$ $CdCl_2$ and 10 g $litre^{-1}$ KI. A lower current density (~0.5 mA cm^{-2}) was employed because of the reduced chalcogen concentration.

The semiconductor properties of the electrodeposited films have been examined in cells of the configuration

$$Pt|M_nX_y|1M\ Na_2S,\ 1\ M\ NaOH|Pt$$

where M_nX_y represents a metal chalcogenide with metallic cation M^{+a} and chalcogenide anion X^{-b}(an=by). Illumination of a Pt electrode covered with metallic chalcogenide resulted in an anodic photocurrent in the cases of CdS and Bi_2S_3 indicating that the film had the properties of a n-type semiconductor. On the other had, Tl_2S in the same configuration behaved as a photocathode, that is, as a p-type semiconductor (6). NiS and CoS had metallic conduc-

tivity and showed good catalytic properties for electrode processes involving sulphur compounds in which the sulphur is in a low oxidation state (7).

A detailed study of the properties of the electrodeposited films by scanning electron microscopy is currently in progress. The results of this investigation as well as an investigation of the mechanism of the process will be reported in future papers.

On the Limiting of Minimum Size of SOS/MOS Devices by the Microtwins in the Silicon

W. E. Ham,* M. S. Abrahams, and C. J. Buiocchi

RCA Laboratories, Princeton, New Jersey 08540

Abstract

Plan view TEM micrographs of operating SOS/MOS transistors clearly show the extent and distribution of the silicon microtwins throughout the junction and channel regions. Numerous microtwins are found in the junctions without causing any detectible electrical problems. It is suggested that these defects will probably not be a fundamental limitation to geometrical reduction of SOS/MOS devices. The twins cause a dependence of field effect mobility on current flow direction.

There has been concern expressed that crystal imperfections in epitaxial silicon (100) on sapphire (1102) films in the thickness range usually used for MOS devices (0.4-0.7 μm) may limit the size reductions possible in the devices. Size reduction is generally considered to be critical to the successful implementation of devices in VLSI (Very Large Scale Integration) and VHSI (Very High Speed Integration) applications. We show in this note TEM micrographs which give a clear indication of the extent, distribution, and physical size of the most common defects in the SOS epi films, namely the microtwins, in an operating MOS transistor. It is shown that one can expect a population of these microtwins in any size device that might reasonably be considered for VLSI or VHSI applications.

We have shown previously that four systems of microtwins exist in typical SOS films used for devices using TEM methods [1-6]. X-Ray data has also indicated the presence of these systems [7]. This previous TEM work all used cross sectional samples which are only 1000 - 2000 Å thick in a direction parallel to the Si-sapphire interfacial plane (The X-Y plane). Typical VHSI devices might have minimum X-Y plane geometries ten or more times this size. The cross sectional views show that many of the microtwins intersect the top surface of the film where the surface channel exists. It is usually found that the top surface density of two of the four [111] twin systems is much greater than that of the others.

Information on the distribution of the defects in the X-Y plane is also necessary to determine their probable impact on very small geometry devices and on P-N junctions. In order to determine this distribution, MOS devices which were fabricated by conventional processes in the factory were examined using a vertical (or plan) view for the TEM specimen. The micrographs to be shown are from a transistor which was carefully measured for electrical performance before it was formed into a TEM compatible form. The transistor was typical of thousands of similar well behaved devices which were also measured.

The TEM specimens have had the polysilicon gate removed from the top of the epi island but the polysilicon remains on the adjacent sapphire as shown in Figure 1. The polysilicon remaining on the sapphire clearly indicates the approximate position of the source and drain p-n junctions since a self-aligned process was used for their formation. The device chosen for this micrograph has nominal channel dimensions which would be considered large for most VHSI applications. However the relatively large size coupled with a clear picture of the junction regions allows one to construct any size device that is desired on the micrograph.

Figure 2 shows a bright field TEM image obtained by thinning the specimen entirely from the sapphire side to a point where a very small amount of sapphire remains under the silicon. The entire channel region is visible in the low magnification micrograph (Fig. 2B) and the distribution of the microtwins is evident. It is especially relevant that there is no noticable boundary present between the heavily doped source and drain regions and the lightly doped silicon in the channel region. There are numerous twins present in the junctions.

Since normal device operation is found in this transistor, it is reasonable to project that these microtwins will not be an obstacle to geometrical reduction of SOS devices to the micron and sub-micron range. Of course, traditional small device effects should be expected, but this data clearly shows that microtwins in the junction will not cause significantly inferior performance.

It has been found, however, that a maximum in the field effect mobility exists when the current flow direction is parallel to only one of the two vectors shown in Fig. 2D. For the device shown in Figure 2, a mobility degradation exists since the current flow direction is at ~45° to the vectors. The magnitude of this effect depends on the twin density on the respective [111] planes but is not strongly dependent on the type of surface channel (N or P). As the current flow direction is rotated through 360° in the plane of the sapphire surface (using test structures previously described [8]) maxima and minima occur with 180° symmetry. A typical ratio of maximum to minimum mobility for films with twin densities similar to that shown in Fig. 2 is 1.4 for both electrons and holes. This bipolar effect would not be expected if a simple stress mechanism were responsible for the anisotropy. A cooperative effect between the two twin systems which intersect the top surface is probably responsible. For very high twin densities [9] ratios as high as 10 have been observed. A more detailed discussion of these orientation effects is in preparation.

Effect of Carbon on the Dissolution of Fused Silica in Liquid Silicon

B. Bathey, H. E. Bates,* and M. Cretella**

Mobil Tyco Solar Energy Corporation, Waltham, Massachusetts 02154

Dissolution of industrial silica in molten silicon was studied by Chaney and Varker (1). For EFG silicon ribbon growth (2), graphite is generally used as a die material with either a graphite or quartz crucible to contain the melt. Since various reactions are possible between oxygen, silicon, and carbon (3,4,5), an effort was made to measure the dissolution rate of silica in the presence of carbonaceous atmosphere.

The experimental procedure consisted of inserting a GE-204 quartz rod into liquid silicon at a given temperature. After four hours exposure at temperature, the rod was removed from the melt and the change in the diameter of the rod was measured to calculate the dissolution rate. It was found that the addition of carbon into the melt increased the dissolution rate of quartz. Fig. 1 shows the effect of adding various amounts of carbon to the melt on the dissolution rate. It was also found that the dissolution was slightly higher for radio frequency stirred melts compared with resistance heated melts. Fig. 2 shows the dissolution rates with and without carbon in the melts as a function of temperature on Arrhenius plots. For melts with carbon, a SiO_2/C surface area ratio of about 10.5 was selected. This is a typical ratio for an EFG ribbon production unit. However, it is possible to estimate approximately the results at other ratios from these two graphs.

The depth of the groove developed in the liquid-solid-ambient (argon) interface meniscus due to surface tension driven convective flow was very irregular and no correlation with exposure time could be established.

After exposure to liquid silicon, quartz samples were examined by X-ray diffraction. In addition to α-cristobolite, β-SiC was detected. The following reactions are possible between quartz and carbon depending upon the melt temperature and the partial pressure of the gas species.

$$2C + SiO_2 \rightarrow SiC + CO_2 \quad [1]$$

$$3C + 3SiO_2 \rightarrow SiC + 2CO_2 + 2SiO \quad [2]$$

$$4C + 2SiO_2 \rightarrow SiC + 3CO + SiO \quad [3]$$

$$3C + SiO_2 \rightarrow SiC + 2CO \quad [4]$$

$$C + SiO_2 \rightarrow SiO + CO \quad [5]$$

$$C + 2SiO_2 \rightarrow 2SiO + CO_2 \quad [6]$$

Among these reactions [4] and [5] are thermodynamically favorable. Schmid et al. (3) have made a complete thermodynamic analysis of these reactions and established the regions of stability of these reactions as a function of pressure and temperature. On the basis of the experimental evidence and thermodynamic analysis, we conclude that the presence of carbon in the melt enhances the dissolution of silica.

A Cyclable Lithium Organic Electrolyte Cell Based on Two Intercalation Electrodes

M. Lazzari

Centro Studio Processi Elettrodici del C.N.R., Polytechnic of Milan, Milan, Italy

and B. Scrosati*

Istituto di Chimica Fisica, University of Rome, Rome, Italy

Lithium organic electrolyte batteries based on intercalation or topochemical reactions are currently considered of great interest as high energy, secondary power sources.
However, while the complete reversibility of the intercalation electrodes has been extensively proved(1-3), still remain some problems in overall cell rechargeability, mainly related to the lithium electrode, which presents a very poor plating-stripping efficiency in organic electrolytes(4-6).
This problem has been largely emphasized and various solutions, especially directed to the selection of improved electrolyte media(7), have been proposed.

In alternative, we have considered the possibility of replacing the lithium electrode with another intercalation electrode, in order to realize a cell with two intercalation electrodes having a different lithium activity.
With **respect** to systems using lithium negatives, such a combination should result in lower potential values but in higher rechargeability characteristics.
Indeed, the benefical effect of this combination has been already proved in our laboratories for the cyclability of copper solid-state cells(8).

To test its validity also in lithium organic electrolyte cells, we have considered the Li_xWO_2/Li_yTiS_2 system.
The choice has been motivated by the fact that both Li_xWO_2(9) and Li_xTiS_2 (1,2) are reversible electrodes and have e.m.f. values vs Li which range from 1.1V to 0.5V and from 2.6V to 1.9V, respectively, for $0<x<1$.
Consequently, the e.m.f. range of the Li_xWO_2/Li_yTiS_2 system should fall between 2.1V (x=1 , y=0) and **0.8** V(x=0 , y=1), a range which may be considered of practical interest.

As preliminary test of the above considerations, we have first assembled a small cell of the type

$$Li\ /\ LiClO_4\text{-}PC\ /\ WO_2 \qquad [1]$$

by subsequently contacting in a teflon container having nickel terminals, a lithium disc, three glass wool separator discs soaked with 1M $LiClO_4$ solution in propylene carbonate(PC) and a small amount (typically around 20 mg) of powdered WO_2.
After discharge at 0.1 $mAcm^{-2}$ to 0.5 V cut-off, the cell was disconnected and the lithium disc replaced with powdered TiS_2, in order to form the cell

$$Li_xWO_2/\ LiClO_4\text{-}PC\ /\ TiS_2 \qquad [2]$$

Cell [2] had an open circuit voltage (OCV) of 2.0V at 25 °C.
A typical example of 'charge-discharge'

*Electrochemical Society Active Member

Key words: cyclable lithium batteries, intercalation electrodes.

cycles,which practically involve the reversible transference of lithium across the cell,is shown in figure 1.

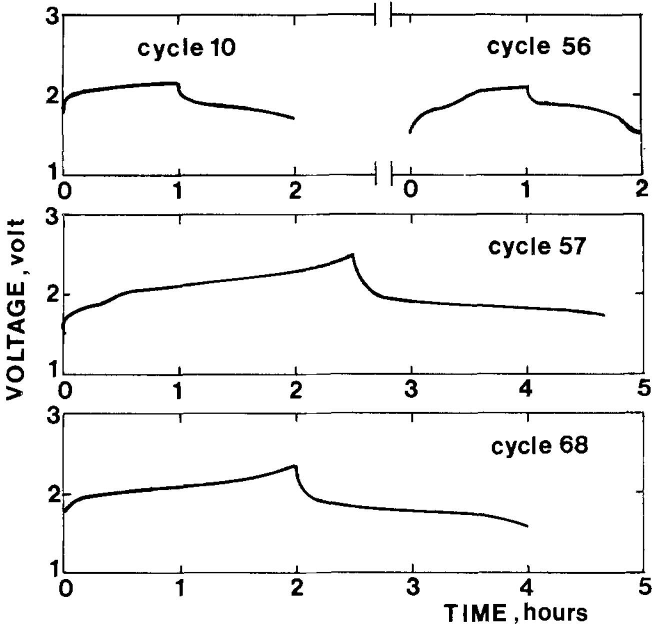

Figure 1. Typical 'charge-discharge' cycles of cell [2] at 0.1 $mAcm^{-2}$ and at room temperature.

Upon prolonged cycling,no massive indications of cell deterioration,such as progressive increase of internal resistance and substantial lack of 'charge-discharge' efficiency were noticed.

The results appear encouraging for expanding in more details the preliminary study here reported as well as for extending the investigation of lithium 'concentration' cells to other electrodic systems.
This research activity is presently in progress in our laboratories.

Safety Studies on Li/SO_2 Cells

II. Kinetics of Lithium-Organic Solvent Exothermic Reactions

A. N. Dey* and R. W. Holmes

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

An isothermal DTA technique was developed for studying the kinetics of the heterogeneous exothermic reactions involving lithium metal and organic solvents used in the Li/SO_2 batteries. The results showed that while film forming agents such as SO_2 and PC retard the Li + AN exothermic reaction (the crucial reaction for Li/SO_2 cell safety), the organic solvents such as MF, DME, DG, and THF enhance the Li + AN exothermic reaction most probably due to an enhanced solubilizing effect on the Li film. The above solvents by themselves were found to be quite stable with Li.

Li/SO_2 organic electrolyte system is one of the most advanced high energy density systems (1-4) known to date and is available from several manufacturers. Although these batteries are quite abuse resistant for a variety of applications, it was attempted to explore the feasibility of improving the abuse resistance of these cells even further so that these are safe under all user conditions. We carried out DTA (differential thermal analysis) of individual cell components (5) as well as the cells (6) in an effort to identify the reactive cell constituents which could initiate and/or propagate a thermal runaway. The commercially available Li/SO_2 cells contain an Li anode, porous carbon cathode pasted on expanded aluminum grid, and an organic electrolyte containing LiBr, acetonitrile (AN), and liquid SO_2. SO_2 acts as the cathode active material.

From the DTA studies we have shown that the reactions most likely to initiate a thermal runaway are the Li-organic solvent reactions, particularly the exothermic Li-acetonitrile reaction which occurs at room temperature. For this reason, we chose to concentrate on the study of the kinetics of this reaction in an effort to find ways and means of quenching it. We also carried out kinetic study of several other organic solvents in an effort to find suitable candidates for replacing acetonitrile in the electrolyte of the Li/SO_2 cells or adding to it, if possible. The extent of the reaction is proportional to the heat evolved and the rate of the reactions is proportional to the rate of the heat evolution at a constant temperature and at a constant surface area of the Li. Therefore, an isothermal DTA technique was used to study these reactions. The experimental details and the results are reported here.

Experimental

The Mettler TA2000 Differential Thermal Analysis System with the high pressure hermetic crucibles, described elsewhere (5), was used for the isothermal DTA runs. A 0.098 in. diam piece of 0.005 in. thick Li foil weighing 0.00029g was placed in the DTA sample crucible in an argon filled dry box. 20 μl of the appropriate organic solvent was injected into the crucible and the crucible sealed. The Li disk size, weight, and the location inside the sample container as well as the volume of the organic solvent were kept as constant as possible from run to run. The mixtures were then heated very quickly to various temperatures in the DTA furnace and maintained at those temperatures while the differential temperatures were recorded as a function of time yielding isothermal DTA thermograms at the various temperatures.

All the organic solvents used were of the highest purity available from Eastman Kodak and were used as received except for PC which was vacuum distilled over Li foil prior to use.

The Li foils were used as received from the Foote Mineral Company and contained 1% Na as impurity. The foils were shiny in appearance and all the experiments were carried out using freshly punched Li from one roll except for some preliminary experiments with AN for which the Li disks were punched several days prior to the experiments. Although the Li foil was shiny in appearance it is reasonable to assume that it has a thin protective film and the freshly punched areas of the disks are probably most active towards the organic solvents. Therefore, the duration between the punching of a Li disk and the isothermal run was kept constant in order to reduce any variation of the activity of the Li surface from run to run.

Results and Discussion

Some typical isothermal DTA thermograms at various temperatures for the Li + AN system are shown in Fig. 1. It can be shown that the slopes of the rising portion of the DTA thermogram at the point of inflection of the temperature-time curve can be expressed as

$$\frac{d\Delta T}{dt} = k\left(\frac{\Delta H}{L+S}\right) \quad [1]$$

where ΔH = heat of the reaction, k = zeroth order rate constant, L = heat capacity of reaction mixture, and S = heat capacity of container, when the DTA furnace is maintained at a constant temperature and the chemical reaction obeys zeroth order kinetics.

* Electrochemical Society Active Member.

Key words: DTA, kinetics, battery, organic.

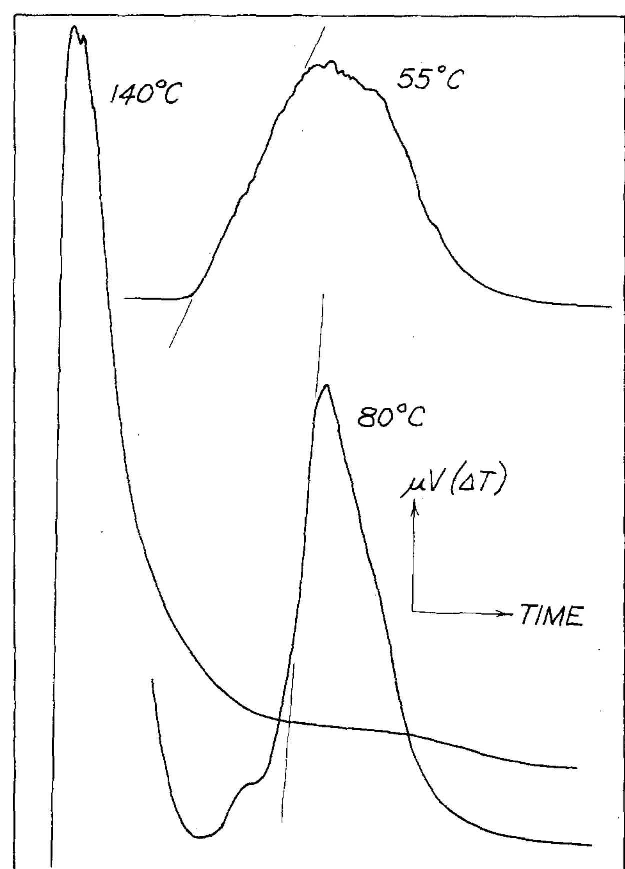

Fig. 1. Typical isothermal DTA thermograms of Li + AN system at various temperatures.

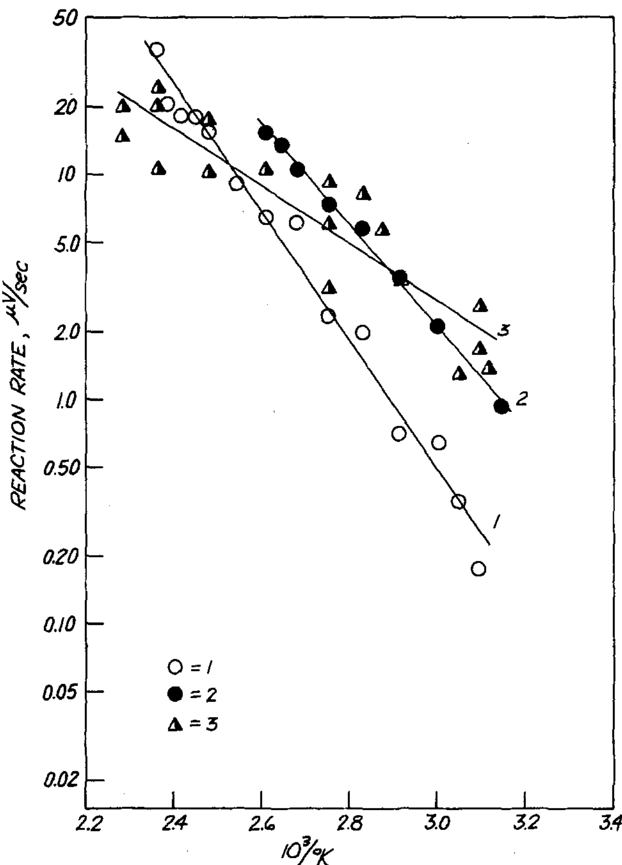

Fig. 2. Arrhenius plots of the Li + AN system; curve 1, with Li disks aged in dry box; curve 2, freshly cut Li disks; curve 3, with 0.32M LiBr in AN.

Since ΔH, L, and S are constants, the slope is proportional to the rate constant of the Li^+ solvent reaction which is controlled by the reaction temperature and the surface area of the Li disk which was kept constant for all the runs.

An Arrhenius plot of the above slopes as a function of the reaction temperature for the Li + AN system with Li disks cut several days prior to the experiment is shown in Fig. 2. The plot is linear and the energy of activation as determined from the least squares slope (excluding the point at the lowest temperature) was 13 kcal mole^{-1} with a frequency factor of 8. A similar plot of the same system with freshly cut Li disks as shown in Fig. 2 was also linear and had a higher reaction rate and a slightly lower activation energy; 10 kcal mole^{-1}. This probably reflects the effect of the Li film (formed during storage in the dry box) on the kinetics of the Li + AN reaction.

The effect of LiBr on the kinetics of the Li + AN reaction was studied and the Arrhenius plot is also shown in Fig. 2. The activation energy of the reaction was reduced further to 6 kcal mole^{-1} possibly indicating the catalytic effect of Li^+ (7) on the Li + AN reaction.

Although PC was found to be rather inert towards Li at room temperature, it reacted with Li at higher temperatures. The energy of activation as determined from the linear Arrhenius plot, shown in Fig. 3, was 22 kcal mole^{-1}.

The effect of addition of PC on the Li and AN reactivity was studied. The results are shown in Fig. 3. The addition of PC, up to 20%, resulted in a lowering of the reaction rates without altering the energy of activation significantly. This probably indicates that the Li + AN reaction is occurring through a film which only lowers the reaction rates without altering the activation energy. PC is known (8) to form an insoluble film of Li_2CO_3 on Li thus protecting it from further attack. With 50% PC, the reaction rates were

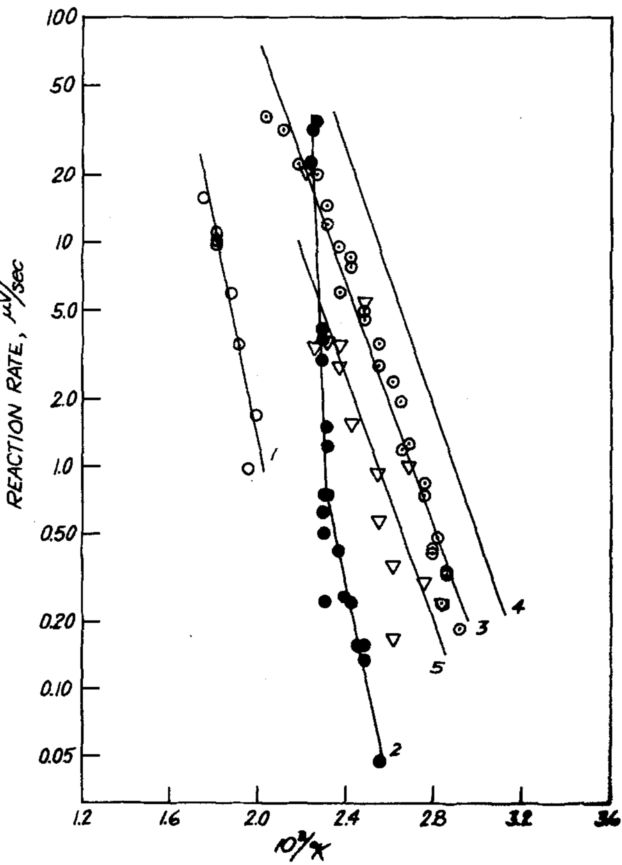

Fig. 3. Arrhenius plots of the Li + AN + PC system; curve 1, 0% AN; curve 2, 50% AN; curve 3, 80% and 95% AN; curve 4, 100% AN; and curve 5, 0% PC and 3% SO_2.

reduced drastically, and the Arrhenius plots showed two linear regions corresponding to activation energies of 22 and 113 kcal $mole^{-1}$ for the lower and the upper region, respectively. In this mixture, the reaction temperatures are very high, and as such, complex reactions may occur to give rise to this type of behavior.

The addition of small amounts of SO_2 (3%) to the AN resulted in a sharp reduction of the reaction rates, as shown in Fig. 3, without altering the energy of activation. This demonstrates the excellent film forming ability of small amounts of SO_2 and its efficacy in reducing the Li + AN reactivity, the key element in the safety of the Li/SO_2 cells.

Li was found to be stable in MF (methyl formate) at ambient temperature and reacted only at very high temperatures. Surprisingly, the reaction rates were found to be considerably lower than those of the Li + PC. Also the energy of activation, as determined from the Arrhenius plot shown in Fig. 4, was almost twice that of the Li + PC, *viz.* 43 kcal $mole^{-1}$.

The effect of MF on the Li + AN reaction was studied. The reaction rates increased significantly with 5% MF present giving rise to a nonlinear plot as shown in Fig. 4. At higher concentration of MF, the reaction was too rapid, particularly at the higher temperature, so that it was not possible to measure the rates by the isothermal DTA method. A substantial part of the reaction was completed during the heating period so that the slopes were not representative of the reaction rates. The Arrhenius plots with 20% MF were found to be meaningless as shown in Fig. 4. In a normal isothermal DTA run, as shown in Fig. 5(a), the first short peak represents the difference in temperature between the sample and the reference during the short heating period. Note that the differential temperature reached the base line before it shot up as a result of the exothermic reaction. Also the area under this major peak, representing the heat released, is very similar for all the runs at various temperatures for a particular system, indicating the correctness of our assumptions regarding reasonable adiabaticity. The abnormal isothermal runs with the Li + AN + MF system, is shown in Fig. 5(b). Note that the differential temperature does not reach the base line after the first short peak (corresponding to the heating of the sample) prior to the reaction exotherm, indicating that the reaction was already initiated during the heating up period. Also, the areas under these exothermic peaks are different from run to run. These results demonstrate the limitation of this technique which is applicable to only those heterogeneous reactions which have a sufficiently long induction period during which the samples may be heated without any substantial reactions. In systems such as Li + AN + MF, the induction periods are too short, most likely due to the increased solubility of the reaction products in the mixed solvents. Thus, although MF by itself is less reactive to Li, addition of it to AN increased the Li solvent reactivity to a greater extent than the reactivity with the individual solvents. The above results indicate that although pure MF may be used by itself in Li/SO_2 cells, the mixture of MF and AN may be deleterious from a safety standpoint. The reported (9) unsafe behavior of Li/SO_2 cells with MF in the electrolyte may be due to the presence of other impurities which may act as cosolvents with MF to dissolve the protective lithium film.

The Li + DME (dimethoxyethane) reaction was found to be extremely slow at the moderate to high temperatures used in our studies. However, the reactivities of AN + DME mixtures of Li were examined successfully. The Arrhenius plots, shown in Fig. 6, were found to be linear. The reaction rates were increased significantly by the addition of DME to AN and the activation energies were reduced. The results again point to a solubilizing effect of the AN + DME mixed solvents towards the lithium film formed as a result of the Li-solvent reaction.

Table I. The activation energy and the frequency factor of various Li-organic solvent heterogeneous reactions determined by isothermal DTA method

Reactions	Activation energy (kcal mole^{-1})	Frequency factor
1. Li + AN	13.1 ± 0.5	8.3
2. Li (freshly cut) + AN	10.3 ± 0.3	7.1
3. Li + 0.32M LiBr, AN	5.9 ± 0.6	4.3
4. Li + PC	22.3 ± 3.2	9.8
5. Li + AN/PC (95/5)	15.0 ± 0.6	8.8
6. Li + AN/PC (80/20)	11.1 ± 0.6	6.6
7. Li + AN/PC (50/50)	{ 21.7 ± 2.5 112.9 ± 22.6	10.8 56.8
8. Li + AN/SO_2 (97/3)	12.5 ± 2.1	7.0
9. Li + MF	42.7 ± 5.2	16.7
10. Li + AN/DME (95/5)	5.9 ± 0.5	3.9
11. Li + AN/DME (80/20)	9.1 ± 0.9	6.4
12. Li + AN/DG (95/5)	9.5 ± 0.3	6.6
13. Li + AN/THF (95/5)	9.6 ± 0.8	6.6

Similar runs with AN + DG (diglyme) and AN + THF (tetrahydrofuran) systems (Fig. 7) also showed enhanced reactivity.

The energy of activation and the frequency factors of all the above reactions are presented in Table I.

Conclusions

The isothermal DTA technique developed for studying the kinetics of the heterogeneous reactions involving Li and organic solvents at various temperatures provided an effective tool to assess the usefulness of solvent additives to the Li/SO_2 electrolyte in improving the safety of the Li/SO_2 cells. The results show that whereas SO_2 and PC are effective in reducing the Li + AN reactivity, organic solvents such as MF, DME, THF, and DG enhance the Li + AN reactivity and are unsuitable electrolyte additives for safety, although these may be used in place of AN in the electrolyte.

Electrochemistry of Amorphous V_2S_5 in Lithium Cells

A. J. Jacobson and S. M. Rich

Exxon Research and Engineering Company, Corporate Research, Linden, New Jersey 07036

ABSTRACT

Amorphous V_2S_5, prepared by thermal decomposition of $(NH_4)_3VS_4$, has been found to react readily with n-butyl lithium to give amorphous compositions $Li_xV_2S_5$ ($x \leq 6.0$). In lithium electrochemical cells, V_2S_5 cathodes react with 2.5 Li per vanadium above 1.40V on primary discharge at 0.5 mA/cm^2. Eighty-five percent of this capacity is recovered on the first recharge to 2.8V also at 0.5 mA/cm^2. On subsequent cycling the capacity eventually falls to 30% of the initial value with an accompanying change in the voltage composition profile.

Interest in ambient temperature secondary lithium batteries has focused recently on the use of crystalline compounds as cathode materials (1). In particular the layered dichalcogenide, TiS_2, has been found to possess many of the desirable characteristics for a lithium battery cathode (2). The Li_xTiS_2 system exists as a continuous nonstoichiometric phase for $0 \leq x \leq 1$ and has a high free energy of formation (3). Reaction with lithium produces only a small volume expansion of the TiS_2 lattice which together with high lithium diffusivity results in a highly reversible cathode system. Several other layered and chain structure compounds have also been investigated, including the trichalcogenides (4, 5), $KFeS_2$ (6, 7), $NbSe_4$ (8), MPS_3 (M = Ni, Fe) (9, 10), and MoO_3 (11-14). Many of these systems have, in principle, increased capacity over TiS_2 for reaction with lithium in that they contain either high oxidation state transition metal ions, *e.g.*, Mo(VI)O_3, or polyanion bonds in addition to a reducible transition metal. However, for most of these compounds and also for many of the dichalcogenides reactions with lithium result in structure changes of the host lattice which limit reversibility (3). In addition to the layer and chain structure compounds, the reaction of lithium with a number of three-dimensionally connected oxide structures including V_6O_{13} (15), Cr_3O_8 (1, 16, 17), TiO_2 (anatase) (18), and a number of MO_2 oxides with the rutile structure (19) have been studied. Of these, V_6O_{13} when prepared by thermal decomposition of ammonium metavanadate has recently been reported to have high energy density (800 W-hr kg) and good secondary characteristics.

We recently reported that amorphous MoS_2 (a-MoS_2) prepared by a low temperature precipitation technique exhibits superior characteristics to crystalline MoS_2 in lithium cells (20). Higher coulombic capacities were obtained and the lithium a-MoS_2 reaction was found to be highly reversible. While the Li/a-MoS_2 system itself does not possess high energy density, the electrochemical results have led us to explore more generally the reactions of alkali metals with amorphous materials, and in this paper we describe results obtained for a-V_2S_5 which formally contains vanadium in its highest oxidation state (V).

Amorphous V_2S_5 (a-V_2S_5) is prepared by the thermal decomposition of $(NH_4)_3VS_4$ in vacuum or in an inert atmosphere and is stable over only a limited temperature range (21-23). For example, Prasad and Müller (23) reported the formation of V_2S_5 from $(NH_4)_3VS_4$ in 1 atm N_2 at 190°C and its decomposition above 290°C with loss of sulfur and the formation of crystalline V_2S_3. a-V_2S_5 is considered to be a definite composition and not a mixture of a lower sulfide and noncrystalline sulfur. No sulfur can be extracted with CS_2 and V_2S_5 dissolves in aqueous alkalis to form thiovanadates (VS_4^{3-}). A model for the structure of V_2S_5 has been determined from an analysis of the x-ray diffuse scattering (24). From the radial distribution function, six V-S distances at 2.34Å and six V-V distances at 3.42Å were obtained compatible with a microcrystalline model based on a distorted CdI_2 layer structure. The excess sulfur is accommodated at the edges of small (20Å) particles containing approximately 15 vanadium atoms.

In this report we describe our results for the synthesis of amorphous V_2S_5 and its chemical and electrochemical reactions with lithium.

Key words: cathode, amorphous vanadium sulfide, lithium, nonaqueous cell.

Experimental

Ammonium thiovanadate was prepared by a modification of previously described procedures (20, 21). Sodium pyrovanadate ($Na_4V_2O_7$, 28g) was dissolved in 100 ml water and 300 ml of 55% $(NH_4)_2S$ added. The solution was cooled to 0°C. Pure H_2S was bubbled through the solution for a total of 5 hr. After this time dark violet crystals were precipitated in the reaction flask. The apparatus was purged with nitrogen and the crystals removed by vacuum filtration, washed with $(NH_4)_2S$ and ethanol and dried under nitrogen. The dry crystals were transferred to a helium filled glove box. The composition was confirmed by elemental analysis which gave 5.27% H, 17.71% N, 22.02% V, 54.84% S (calc 5.15% H, 18.02% N, 21.84% V, and 55.00% S). Thermogravimetric analysis data for the decomposition of $(NH_4)_3VS_4$ were obtained using a du Pont thermal analyzer. Data were obtained in argon at a heating rate of 10°C/min and are shown in Fig. 1. The results are in good agreement with those obtained previously (22, 23). The first weight loss corresponds to the formation of V_2S_5 (obs 44.5%, calc 43.8%) which is stable between 200° and 350°C. The second weight loss is due to the formation of $VS_{1.53}$ and an x-ray powder pattern of the TGA residue confirmed this to be crystalline V_2S_3. Large samples of V_2S_5 were prepared by decomposition of $(NH_4)_3VS_4$ at 275°C in flowing helium. After reaction the reaction tube was sealed and transferred to a helium filled glove box. V_2S_5 is sensitive to atmospheric oxidation at room temperature and must be handled under inert conditions. In some circumstances, particularly when the initial $(NH_4)_3VS_4$ particle size is small, we have obtained V_2S_5 samples which were pyrophoric.

Samples of V_2S_5 were reacted with n-butyl lithium in (Foote Mineral Company) hexane (24). After reaction the solid products were removed by filtration and washed with hexane. The unreacted butyl lithium was determined by addition of standard HCl and back titration with standard NaOH. When a 1.6M solution of butyl lithium was used, the reactions were extremely vigorous, sufficient heat being evolved to boil the hexane. The reaction could, however, be moderated by initially adding to the solid sample dry hexane to reduce the butyl lithium concentration. The titration

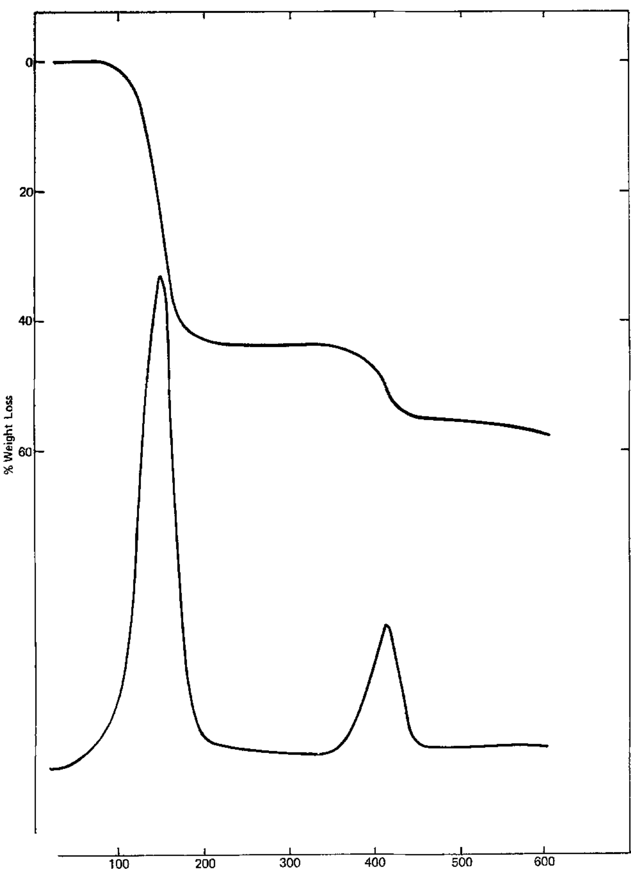

Fig. 1. Thermogravimetric analysis data for $(NH_4)_3VS_4$ in argon

results indicated a limiting composition of $Li_6V_2S_5$, but in some cases especially when the reaction was allowed to proceed rapidly or when a large excess of n-butyl lithium was added, a milky white solid was observed suspended in the supernatant hexane, indicative of side reactions. X-ray powder patterns of V_2S_5 and lithiated products of different compositions were recorded with samples protected from atmospheric oxidation and hydrolysis by Kapton films. All powder patterns were broad and contained no sharp Bragg peaks.

For electrochemical measurements, cathodes were prepared by hot pressing at 300°C a mixture of cathode material mixed with 14-16 weight percent (w/o) Teflon into expanded stainless steel mesh. The cathode area was 2 cm^2. In some cases, 40 w/o graphite was added to the cathode mix. Cells were constructed by surrounding the cathodes with polypropylene separators and lithium sheet anodes. The assembled cells were immersed in a 2.0 molar solution of $LiClO_4$ in dioxolane[1] as the electrolyte contained in a polypropylene bag. Electrochemical measurements were made with PAR potentiostats equipped with voltage limiting devices under constant current conditions.

Electrochemical Results

First discharge data for four cells tested under different conditions are given in Table I. The voltage composition profile for cell No. 1 is shown in Fig. 2 for the first discharge and first recharge to 2.8V at 0.5 mA/cm^2. The discharge data are smoothly varying over the whole composition range and there is a definite though broad down turn (end point) towards the end of the discharge. The mean discharge voltage is 1.96V which together with the capacity of 1743 C/g of V_2S_5 or 484 mA-hr/g of V_2S_5 gives a gravimetric energy density of 949 W-hr/kg. On recharge, 84% of the discharge capacity is recovered and a definite re-

[1] Such solutions are potentially explosive.

Table I. First discharge data for Li/V_2S_5 cells

Cell	w/o graphite	i (mA/ cm^2)	Lower cutoff voltage	Capacity (C/g V_2S_5)	e/vanadium
1	0	0.5	1.65	1743	2.37
2	40	0.5	1.60	1697	2.30
3	0	0.5	1.40	1871	2.54
4	0	2.5	1.40	1562	2.12

charge end point is observed. The first cycle data for cell No. 2 are closely similar even though the cathode contained 40 w/o graphite added to improve current collection, indicating that V_2S_5 itself is probably a good electronic conductor. Cell No. 3 was discharged to a lower cut off voltage of 1.40V with increases in both capacity (1743 C/g or 520 mA-hr/g) and energy density (1004 W-hr/kg, at a mean voltage of 1.93V). Cell No. 4 was discharged at a higher rate, 2.5 mA/cm^2, with a corresponding reduction in capacity.

The second cycle data are shown for cell No. 1 in Fig. 2. Apart from a small increase in the mean discharge voltage (1.96 to 2.05V) the voltage composition profile for the second cycle closely resembles the first cycle data in overall shape. There is, however, a significant further loss in capacity. The capacity continues to decrease with repeated cycling under the same conditions. Thus on cycles 10, 20, and 30 the capacities are 41, 35, and 33% of the initial capacity, respectively. The capacity on cycle 30 corresponds to 0.77 Li/V. The losses in capacity on cycling as a percentage of first discharge capacity for all four cells are nearly identical. The fall in cycling capacity is also accompanied by pronounced changes in the voltage composition profiles. Data for cycles 12 and 30 are shown in Fig. 3. On cycle 12 the mean discharge voltage is 2.12V and on cycle 30, 2.28V, to be compared with values of 1.96 and 2.05V, respectively, for cycles 1 and 2. The voltage efficiency also improves on cycling; the voltage difference between the discharge and recharge profiles at half discharge capacity are 340, 250, 130, and 100 mV for cycles 1, 2, 12, and 30. Normally on cycling cells, decreased charging efficiency is expected due to increasing *IR* effects. The V_2S_5 data, however, strongly suggest that the initial V_2S_5 is being converted into another phase. The new phase reacts with less lithium but does so in a highly reversible manner. After cycle 30 a series of polarization curves to 1.60V were obtained at different discharge current densities (Fig. 4) all with a 0.5 mA/cm^2 recharge rate. The successive loss in capacity on increasing discharge rate up to 8 mA/cm^2 can almost entirely be accounted for by cell *IR;* again showing the high reversibility of the system at this point.

X-ray diffraction patterns of the spent cathodes were taken under Kapton films. No evidence was found for the formation of any crystalline phases just as found

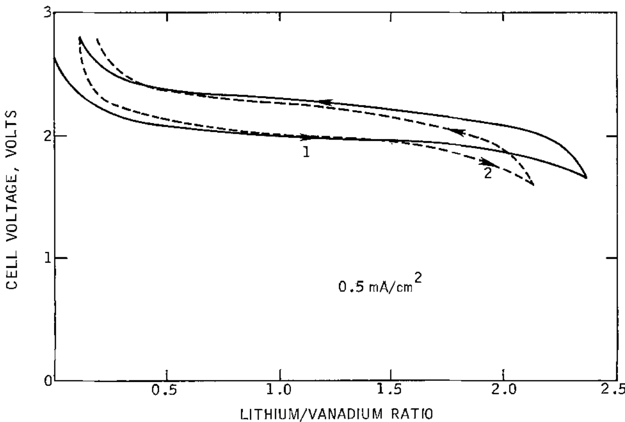

Fig. 2. First and second cycle data for $Li/LiClO_4$-dioxolane/V_2S_5

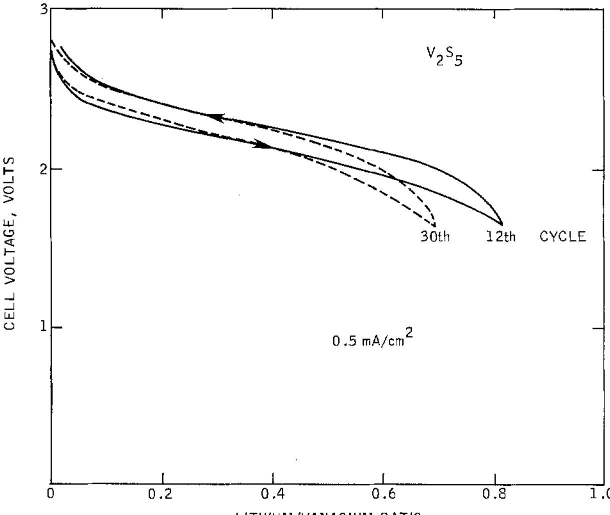

Fig. 3. Cycle 12 and cycle 30 data for $Li/LiClO_4$-dioxolane/V_2S_5

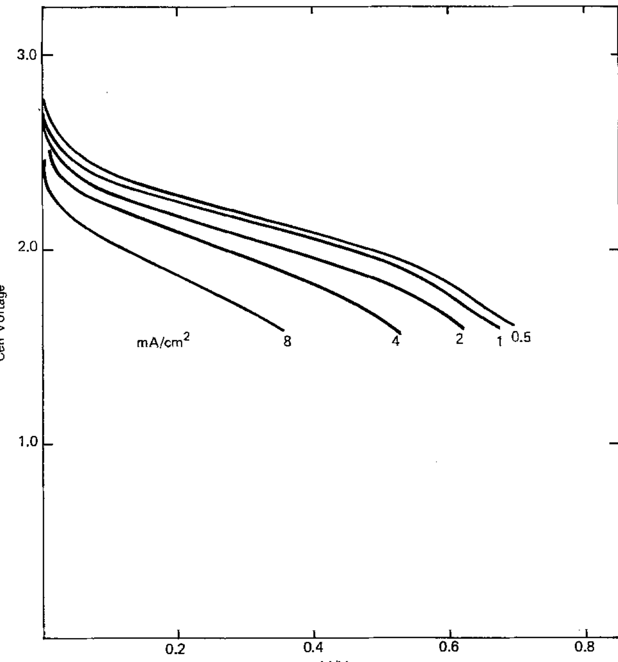

Fig. 4. Polarization data for Li/V_2S_5

for $Li_xV_2S_5$ compositions prepared by reaction with n butyl lithium.

Conclusions

Amorphous V_2S_5 has been found to react readily with n-butyl lithium and electrochemically to give amorphous $Li_xV_2S_5$ compositions. On primary discharge electrochemically to 1.40V V_2S_5 reacts with five lithiums at a mean voltage of 1.93V to give a gravimetric energy density of 1 kW-hr/kg. On cycling the capacity initially drops and subsequently levels out at approximately 30% of the initial discharge capacity; 300 W-hr/kg. During the initial capacity fading, the mean discharge voltage increases as does the voltage efficiency suggesting the formation of a second amorphous phase which is highly reversible towards reaction with lithium. Diemann's microcrystalline model (25) for the structure of V_2S_5 suggests that a possible explanation for the observed behavior might be the removal of edge sulfur atoms as lithium sulfide with polymerization to form amorphous VS_2. Some preliminary results for amorphous VS_2 prepared by low temperature precipitation have been reported (26) and a more detailed comparison with the V_2S_5 data is in progress (27). It is interesting to note that a-V_2S_5 behaves quite differently to crystalline VS_2 (28). In the latter system the electrochemical capacity at ambient temperature is limited to 0.5 Li/VS_2 by the occurrence of distorted intermediate phases. In contrast, capacity faded V_2S_5 cells cycle 0.7-0.8 Li per vanadium at comparable voltages with little polarization and no evidence for discontinuities in the voltage composition profile.

A Study of the Calcium-Thionyl Chloride Electrochemical System

Robert J. Staniewicz[*,1]
GTE Laboratories, Incorporated, Power Sources Center, Waltham, Massachusetts 02154

ABSTRACT

The use of calcium metal as an anode in $SOCl_2$ electrolytes was investigated. Calcium showed an open-circuit potential (OCP) of 3.22V *vs.* a carbon cathode in 1M $Ca(AlCl_4)_2$-$SOCl_2$ electrolyte. Hermetically sealed D cells, when discharged at 1 mA/cm², displayed level discharge plateaus of 2.8V. SEM photographs indicated the rapid formation of a crystalline layer on the anode; the composition of this film was established as $CaCl_2$. Storage of calcium samples in $Ca(AlCl_4)_2$-$SOCl_2$ electrolyte resulted in corrosion of the metal. This corrosion was particularly pronounced at 55°C and it appeared to be a fundamental behavior which was not eliminated by rigid control of electrolyte purity. The following cell chemistry was suggested by chemical analysis of discharged electrolytes and cathodes

$$2Ca + 2SOCl_2 \rightarrow SO_2 + 2CaCl_2 + S$$

Electrodeposition experiments indicated no evidence for the plating of Ca onto a nickel substrate.

One of the principal incentives for investigating the $Ca/SOCl_2$ system is that calcium anodes have the prospect for higher temperature operation when compared with lithium anodes. The higher melting point of calcium (839°C) compared to lithium (180°C) would obviate the possibility of anode melting under high temperature stress, *e.g.*, as a result of large short-circuit currents generated in a high power cell configuration. A comparison of the calculated theoretical energy densities of lithium and calcium/$SOCl_2$ cells is presented below assuming reaction products of SO_2, S, and either LiCl or $CaCl_2$. These values indicate that

	Cell potential (V)	Energy density (W-hr/cm³)	Specific energy density (W-hr/kg)
Li	3.65	2.00 (32.8 W-hr/in.³)	1474 (667.9 W-hr/lb)
Ca	3.64	1.97 (32.3 W-hr/in.³)	1230 (557.0 W-hr/lb)

the energy densities of the $Ca/SOCl_2$ system compare favorably with $Li/SOCl_2$ and therefore provided another encouragement for investigating calcium as an anode in $SOCl_2$. Furthermore, calcium is also more abundant than lithium and has the propitious physical property of higher electronic conductivity.

The work reported here is an investigation and evaluation of the $Ca/SOCl_2$ system as an alternative to the $Li/SOCl_2$ system and coincidentally provides insight into the discharge and deposition behavior of metal/inorganic electrolyte systems.

Experimental

Electrolytes and solvents.—The thionyl chloride was obtained from Mobay and was fractionally distilled from lithium chips in a dry room of less than 3% relative humidity. The $AlCl_3$, puriss grade, was used as obtained from Fluka.

The Alfa-Ventron $SbCl_5$ was vacuum distilled at 17 Torr and a light yellow fraction was collected between 70° to 72°C. Anhydrous $FeCl_3$ was prepared by refluxing Baker-Analyzed $FeCl_3 \cdot 6H_2O$ with $SOCl_2$. The Anachemia reagent $CaCl_2 \cdot 2H_2O$ was dehydrated by incrementally vacuum drying to 300°C. All other chemicals and solvents used were of reagent grade quality.

Several procedures were explored to prepare $Ca(AlCl_4)_2$ electrolyte. The preferred procedure for preparation involved addition of $AlCl_3$ to $SOCl_2$ followed by $CaCl_2$ (5% excess). This mixture was refluxed in a dry room overnight and subsequently filtered in a dry box. By this procedure, a 2M $Ca(AlCl_4)_2$ solution could be prepared although they were quite viscous and displayed lowered conductivity (*vide infra*). The average stoichiometric ratio of Al:Ca in the electrolyte was 2.02 to 1. The $Ca(SbCl_6)_2$ and $Ca(FeCl_4)_2$ electrolyte solutions were prepared similarly to the above procedure for $Ca(AlCl_4)_2$. The tetraethylammonium tetrachloroaluminate electrolyte was made by addition of a $SOCl_2$ solution of tetraethylammonium chloride to a lithium tetrachloroaluminate solution. The lithium chloride which precipitated was filtered, yielding the $(Et_4N)(AlCl_4)$ solution.

Calcium.—The rolled calcium metal (0.050 cm) was obtained from Kaweckiberylco Industries, Reading, Pennsylvania and was mechanically abraded of the oxide coating in an argon atmosphere dry box and washed with anhydrous ethyl ether. An alternative and more convenient method of cleaning the calcium surface has been reported (1) and was used for the calcium samples which were vacuum annealed (500°C, 6×10^{-5} Torr). Despite the fact that the annealed calcium was quite smooth and flexible, the rate of corrosion (*vide infra*) in the electrolytes was not significantly reduced. Thus, all the reported work was accomplished with the abraded unannealed calcium. Analysis of the Ca metal by atomic absorption indicated the following composition, 0.265% Mg, 0.234% Al, 0.077% Sr, 0.003% Fe, 0.0028% Na, and 0.0005% Li. A sample of vapor-deposited Ca on (0.020 in.) steel was obtained from Catalyst Research Corporation, Baltimore Maryland and also evaluated.

Instrumental methods.—Conductivity measurements were obtained using a glass conductivity cell consisting of two heavy gauge parallel platinized platinum electrodes fixed in a glass holder. The cell constant was experimentally determined using standard KCl aqueous solutions (2, 3). Resistance measurements were made at room temperature (25° ± 1°C) using a General Radio Model 1656 impedance bridge coupled with an external signal generator, PAR Model 175 Universal Programmer. The solutions were prepared by appropriate dilution of a 2.00M standard $Ca(AlCl_4)_2$ solution.

Key words: inorganic, battery, electrodeposition, corrosion.

The infrared spectra were obtained using a Beckman Model IR-10 recording spectrophotometer. For electrolyte evaluation, the infrared cells were either Infrasil quartz cells or Barnes Engineering NaCl cavity cells.

For the plating experiments, a PAR Model 173 Potentiostat/Galvanostat was coupled with an HP X-Y recorder set in the time mode. Cell discharges were generally through a constant load consisting of a precision resistor and monitored by means of a Fluke 2240 B Datalogger.

Scanning electron micrographs of calcium samples were obtained using a JSM-U3 Scanning Electron Microscope equipped with a PAR x-ray energy analyzer. Calcium samples exposed to anhydrous $Ca(AlCl_4)_2$ electrolyte under varying durations and temperatures were withdrawn from the sealed glass ampuls, washed three times with anhydrous $SOCl_2$, and vacuum dried. All operations were conducted in a dry box. The calcium samples were mounted on brass holders with silver paint and transferred to the microscope under anhydrous conditions by means of a specially designed argon transfer chamber. The micrographs were obtained at an accelerating voltage of 20 kV in the secondary electron mode at a goniometer tilt of 42°.

Experimental cell assembly.—The initial survey of electrolytes was accomplished using the flooded three electrode configurations shown in Fig. 1. Two methods were utilized for assembly of the 1 × 2 cm calcium electrodes; the early procedure for maintaining mechanical and electrical contact to the Ni lead was by means of a stainless steel fastener while the latter and more effective method involved welding the Ca in a dry room to a Ni substrate (0.005 cm Ni shim stock). The cathodes (1 × 2 × 0.1 cm) consisted of a carbon-Teflon mixture supported on Ni Exmet. The cells were assembled in a dry room and filled in a dry argon glove box (2-3 ppm H_2O). For the chemical analyses of discharged cathodes and electrolytes, larger cathodes and calcium anodes were utilized. For calcium deposition experiments, the geometry was maintained by use of a Teflon holder in which planar rectangular electrodes were situated 1 cm apart. The effective area of the Ca anode and the Ni cathode was 1.6 cm^2. The reference calcium electrode was positioned 2 mm from the working Ni surface. A limited number of investigations were also carried out with thin cathodes of ~50 μm. These experiments were designed to evaluate cathode capacity for lithium and calcium cells.

The hermetic "D" cell's cross section is presented in Fig. 2. The point of interest is the treatment of the calcium for use as a cylindrical anode. Calcium metal was welded to 0.005 cm Ni shim stock which acted as a current collector. The Ni foil in turn was welded to the stainless steel "D" can as depicted.

Results and Discussion

Electrolyte preparations.—A survey of possible calcium electrolyte salts revealed that solutions of $Ca(AlCl_4)_2$ in $SOCl_2$ could be made by appropriately refluxing excess $CaCl_2$ with an $AlCl_3$-$SOCl_2$ solution. The reflux served a twofold purpose. First, it allowed sufficient time for the dissolution of the solid $CaCl_2$ to insure a 1:2 stoichiometric ratio of Ca:Al. Second, the reflux provided an avenue for the $SOCl_2$ to act as a desiccant for OH groups present. These products of hydrolysis are minor contaminants introduced by the $CaCl_2$ and $AlCl_3$ solids, both of which are hygroscopic.

The presence of excess $AlCl_3$ in $SOCl_2$ would manifest itself by a corrosive effect on the calcium metal; the initial effect is reaction of the $CaCl_2$ film on the calcium with the Lewis acid followed by reaction of the bare metal with the solvent.

It may also be possible that $AlCl_3$ reacts directly with the Ca metal

$$3Ca + 2AlCl_3 \rightarrow 2Al + 3CaCl_2$$

The net result is an undesirable corrosion of the metallic calcium. The determination of calcium and aluminum in the electrolyte solutions demonstrated a stoichiometric ratio of Ca:Al of 1:2 with the concomitant conclusion that no excess $AlCl_3$ was present and therefore any possibility of corrosion by $AlCl_3$ was eliminated at the outset of the study.

$$CaCl_2(\text{solid}) + 2AlCl_3(SOCl_2)_y + x\,SOCl_2 \rightarrow Ca(SOCl_2)_m{}^{2+} + 2AlCl_4(SOCl_2)_n{}^-$$

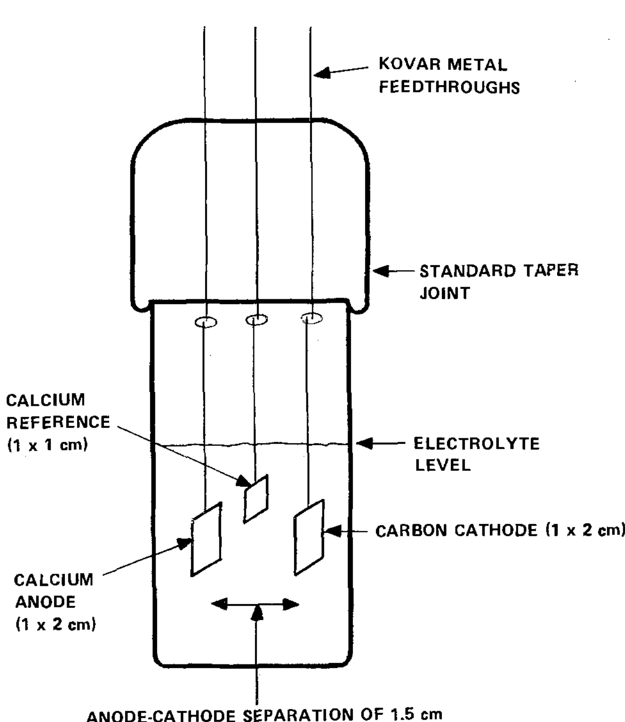

Fig. 1. Flooded three electrode cells used to survey the various electrolytes.

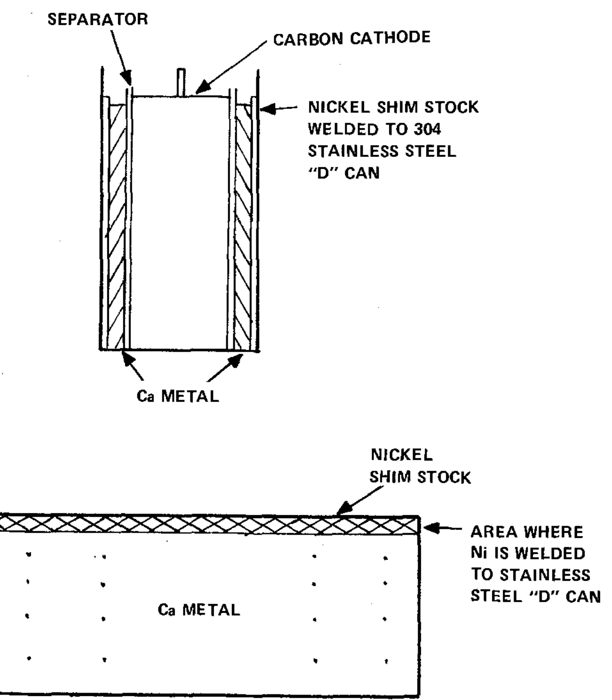

Fig. 2. Cross section of a calcium "D" cell

The contamination of $SOCl_2$ electrolyte with hydrolysis materials such as $AlCl_3OH^-$ and HCl has been suggested to be deleterious to the lithium anode performance and by analogy would be harmful to the Ca electrode

$$2SOCl_2 + 2AlCl_3OH^- + Ca \rightarrow H_2 + 2SO_2 + CaCl_2 + 2AlCl_4^-$$

$$2HCl + Ca \rightarrow CaCl_2 + H_2$$

The $AlCl_3OH^-$ species shows an infrared absorption at 3400 cm^{-1} while the HCl molecule absorbs at 2800 cm^{-1} in $SOCl_2$ (4) and thus an infrared scan of the electrolyte is diagnostic of the purity of the solution. An infrared spectrum of the refluxed electrolyte showed no absorption for HCl, $AlCl_3OH^-$, or SO_2 (symmetrical vibration at 1330 cm^{-1}). Therefore, the products of the desiccation reaction, SO_2 and HCl, are expelled at reflux temperature as evidenced by the absence of their infrared maxima

$$AlCl_3OH^- + SOCl_2 \rightarrow SO_2 \uparrow + HCl \uparrow + AlCl_4^-$$

A conductivity study (uncorrected for viscosity) of the electrolyte solutions (Fig. 3) showed a maximum specific conductivity of $0.6 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ at ~1M $Ca(AlCl_4)_2$. The concentrated solutions, 1.6 and 2.0M $Ca(AlCl_4)_2$ appeared significantly more viscous. Thus, the shape of the conductivity curve may arise from several influences: (*i*) viscosity effects, (*ii*) significant solute-solvent interactions, and (*iii*) solute-solute interactions as a result of the polarizing ability of the doubly charged Ca^{2+} ion. It should be noted that the maximum conductivity of the $Ca(AlCl_4)_2$ electrolyte is only approximately 30% of that observed for $LiAlCl_4$ ($2.04 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$) at the same temperature (5).

A survey of $Ca(FeCl_4)_2$, $Ca(SbCl_6)_2$, and $(Et_4N)(AlCl_4)$ as suitable electrolyte salts was also undertaken. Solutions of composition 0.5M $Ca(FeCl_4)_2$, 0.75M $Ca(SbCl_6)_2$, and 1M $(Et_4N)(AlCl_4)$ were prepared as discussed in the Experimental section, and were also evaluated in terms of calcium corrosion and cell performance.

Compatibility studies.—To ascertain the corrosion rate of calcium metal in the various electrolytes, sealed glass ampuls were prepared containing the metal and the appropriate electrolyte. Table I summarizes those tests.

It should be noted that is was not possible to monitor weight changes of calcium metal exposed to $SOCl_2$ electrolyte because the $CaCl_2$ formed was not adherent.

Upon immersion of shiny calcium metal into 1M $Ca(AlCl_4)_2$ the following immediate observations were noted: (*i*) small dark areas appeared randomly over the surface and especially at the cut edges of the metal; (*ii*) these areas transformed to gray areas within several days; and (*iii*) long-term storage resulted in samples which appear dull gray and which have distinct corroded or etched areas. Removal of the samples from the electrolyte followed by washing with $SOCl_2$ resulted in samples which had a significant film of white crystals covering the Ca surface. The Ca samples exposed to distilled $SOCl_2$ did not initially display the corrosion exhibited by Ca in electrolyte, however, after 10 months of storage at room temperature, crystalline $CaCl_2$ deposits appeared in these $Ca/SOCl_2$ ampuls. The calcium samples stored 3 months at 55°C in $SOCl_2$ did not show significant corrosion deposits.

Table I. Relative corrosion of calcium metal stored with various electrolytes

Electrolyte	Relative corrosion at room temperature	Relative corrosion at 55°C
$Ca(AlCl_4)_2$	Moderate	Rapid
$Ca(SbCl_6)_2$	Rapid	Very rapid
$Ca(FeCl_4)_2$	Rapid	Very rapid
$Li(AlCl_4)$	Moderate	Rapid
$Et_4N(AlCl_4)$	Very rapid	—
Solvent only ($SOCl_2$)	Slow	Slow

The rate of calcium degradation in $Ca(AlCl_4)_2$ electrolyte at room temperature appeared to diminish after 1 month as ascertained by observing the $CaCl_2$ deposits at the ampul bottom. Sample storage at 55°C in electrolyte indicated progressive corrosion with substantial disintegration of the metal after 6 months of storage. The corrosion was not uniform, but instead specific sites underwent more rapid reaction as evidenced by the mechanical breakup of some pieces and relative integrity of others.

The composition of the solid film on the Ca was determined both by x-ray emission and x-ray diffraction to be $CaCl_2$. The scanning electron micrographs (Fig. 4-7) depict the transformation of the calcium surface with varied time and temperature storage in electrolyte and $SOCl_2$. Some comments on these photographs appear in order. The samples exposed to electrolyte at room temperature showed a crystal growth pattern which did not change dramatically with the duration of exposure to electrolyte; only the quantity and thickness of the $CaCl_2$ are indicated as variables. The $CaCl_2$ layer did not appear especially well-formed under 1000× magnification and manifested an aggrega-

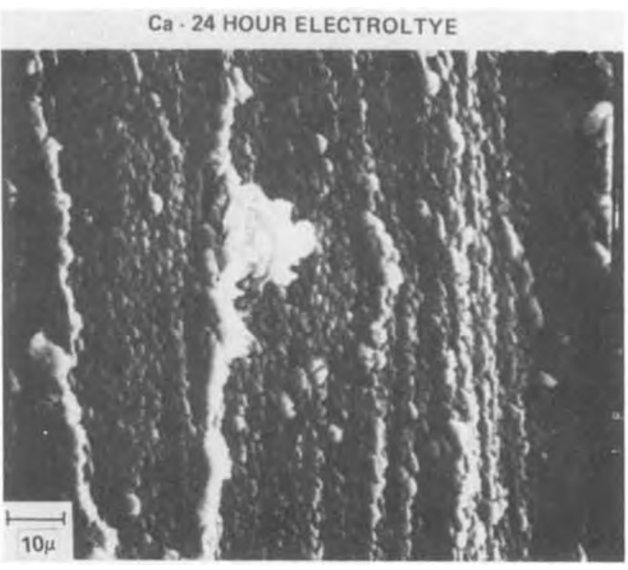

Fig. 4. Micrograph of Ca exposed 1 day to electrolyte (1000×)

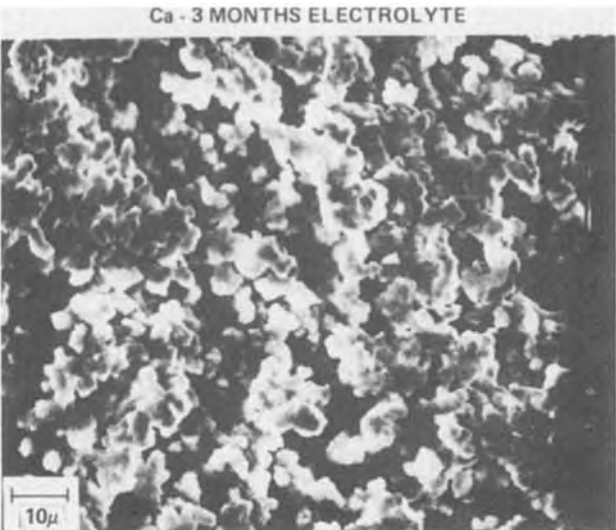

Fig. 5. Micrograph of Ca exposed 3 months to electrolyte (1000×)

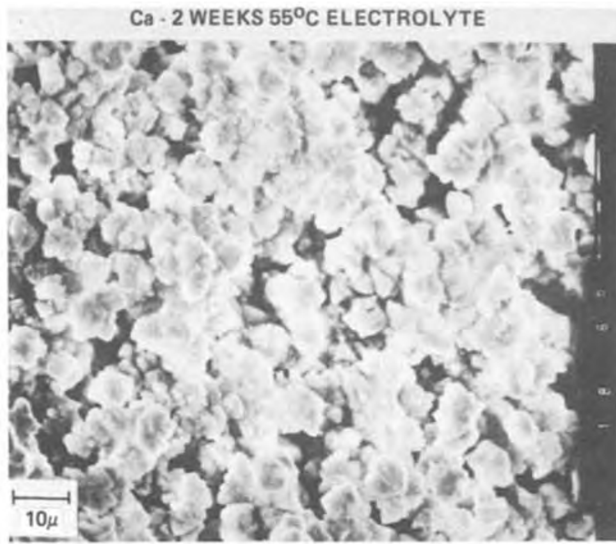

Fig. 6. Micrograph of Ca exposed 2 weeks at 55°C to electrolyte (1000×).

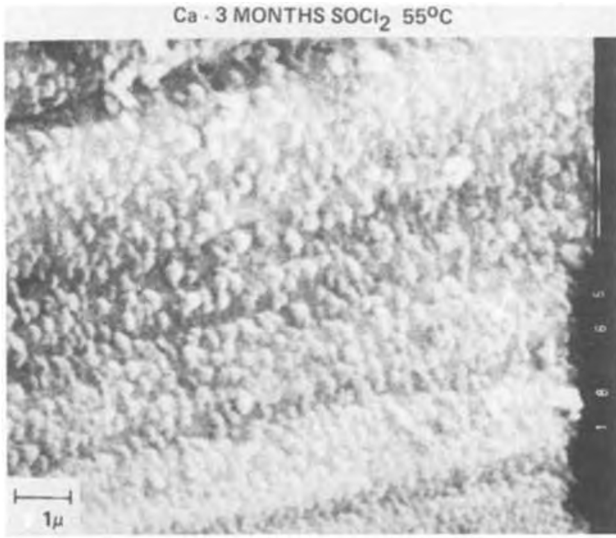

Fig. 7. Micrograph of Ca exposed 3 months at 55°C to $SOCl_2$ (10,000×).

tion of small crystallites. This $CaCl_2$ morphology differs from the independent observations of Dey and Peled regarding the crystal growth of lithium and lithium alloys stored in $LiAlCl_4$ electrolyte at room temperature (6-8). They reported well-defined crystals of considerably larger size. Storage of Ca at 55°C resulted in transformation of the crystallites into larger crystals, a result also affirmed by Peled (7) with lithium alloys. The calcium metal stored 3 months at 55°C in $SOCl_2$ (Fig. 7) showed at 10,000× magnification a compact layer of $CaCl_2$ and significantly reduced corrosion when compared to the electrolyte storage tests.

The compatibility tests of Ca metal with $Ca(FeCl_4)_2$, $Ca(SbCl_6)_2$, and $(Et_4N)(AlCl_4)$ electrolytes all showed accelerated corrosion when compared with the $Ca(AlCl_4)_2$ standard. The solutions are not considered viable alternatives and therefore were the subject of limited further evaluation. The interest with the tetraethylammonium tetrachloroaluminate salt arose from the supposition that the presence of metallic cations, Ca^{2+} or Li^+, in solution contributes to a catalytic corrosion of the bulk calcium metal and that replacement with a nonmetallic cation would reduce corrosion. In fact, the opposite was observed, in that complete disintegration of the Ca metal occurred after 1 week storage in the $Et_4N(AlCl_4)$-$SOCl_2$.

Electrolyte compatibility tests were also conducted with annealed calcium in which the CaO coating was removed by chemical means, but no significant decrease in corrosion was observed. It has been anticipated that reduction of the work hardening and surface roughness would result in lowered contact between the current collector and the anode. The projected consequence of this better contact may be higher anode utilization.

Experimental cell discharge.—The initial survey of calcium discharge was conducted in flooded cells. Newly prepared cells showed initial open-circuit potentials between 2.9-3.0V which slowly increased and stabilized at 3.22V after 12 hr. Figure 8 shows the discharge data for a typical Ca/Ca $(AlCl_4)_2$-$SOCl_2$ flooded cell when a 2000Ω load (0.7 mA/cm² Ca) was imposed. Of note is the fairly level cathode discharge and increasing anode polarization as discharge continued. The anode discharge was not uniform as evidenced by the pitting which was particularly pronounced on the edges. The Ca reference suffered similar though less severe corrosion during the cell discharge. The increasing anode polarization is probably the result of increased thickness of the passivating layer as discharge continued. The white corrosion material which appeared on the anode was identified by x-ray diffraction as $CaCl_2$. It is believed that this material was formed by the continued reaction of calcium with the $SOCl_2$, possibly the result of the morphology of the porous $CaCl_2$ film which may be characteristic for the electrolyte. Failure of these flooded cells typically resulted from corrosion and the subsequent mechanical disintegration of the anode.

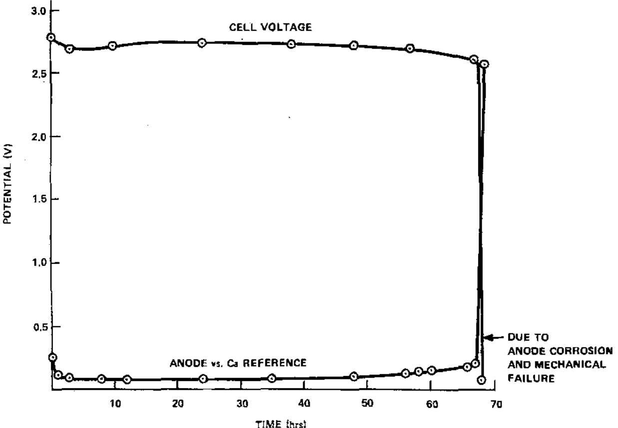

Fig. 8. Discharge profile for a $Ca/Ca(AlCl_4)_2$-$SOCl_2$ cell through a 2000Ω load. The OCP of the cell is not shown.

Based on the coulombs passed during discharge, only 50% utilization of the anode was realized. The remaining calcium either suffered corrosion or became mechanically detached from the Ni lead.

Calcium was also surveyed using $Ca(FeCl_4)_2$, $Ca(SbCl_6)_2$, and $LiAlCl_4$ electrolytes. In general the Fe and Sb based anions showed poor performance in terms of lower discharge voltage and lower anode utilization, while the $LiAlCl_4$ electrolyte compared favorably with the $Ca(AlCl_4)_2$ electrolyte.

Hermetically sealed "D" cells were assembled containing 1.0M $Ca(AlCl_4)_2$ electrolyte which had a theoretical capacity based on the calcium anode mass of 4.1 A-hr (4.5 × 9.7 cm; 3.0-3.1g). Typically, the freshly filled cells showed open-circuit potentials of 3.00-3.05V which rose after 6 hr to 3.15-3.20V. The cells were discharged through a 70Ω precision resistor which simulated a 1 mA/cm² (Ca surface area ~44 cm²) discharge rate. The cells were divided into several groups for storage at ambient room temperature and 55°C. This data is summarized in Table II and Fig. 9 shows the discharge curves for three representative fresh "D" cells discharged at room temperature It should be noted that the experimental capacity of freshly filled cells and the cells stored 1 month at room temperature was ~50% of the capacity based upon the mass of the calcium. Elevated temperature and longer storage time at room temperature both seriously reduce the cell capacity to ~40% of the rated value, presumably a result of continued parasitic reaction between the $SOCl_2$ and the Ca metal. The discharged cells were opened and the interior was inspected. A grayish salt existed between the Ni substrate and glass separator, where the anode had been, indicative of anode corrosion. The cathode capacity had not been exceeded as evidenced by continued cell discharge when a new Ca anode was inserted into the cell.

The capacity of cathodes as a function of the electrochemical system, $Li/LiAlCl_4$-$SOCl_2$ and $Ca/Ca(AlCl_4)_2$-$SOCl_2$ was also investigated. The failure of the cathodes in $Li/SOCl_2$ cells has been suggested to result from accumulation of LiCl in the pores of the cathode (9). In fact, a comprehensive study of the reaction profiles and composition of cathodes for $Li/SOCl_2$ has been reported (10). The capacity of the cathodes as a first order model should be related to the molar volume of the deposited salt, LiCl or $CaCl_2$ per equivalent of charge passed. The equivalent volume of LiCl is 20.5 cm³ and that of $CaCl_2$ is 25.8 cm³. The model assumes the following reaction mechanisms (*vide infra*)

$$2Ca + 2SOCl_2 \rightarrow 2CaCl_2 + SO_2 + S$$

$$4Li + 2SOCl_2 \rightarrow 4LiCl + SO_2 + S$$

Relatively thin carbon cathodes (40-60 μm) were discharged in the study at various current densities with both Ca and Li anodes and the appropriate electrolyte. A plot of the logarithm of the rate *vs.* the normalized cathode capacity for both Li and Ca cells is shown in Fig. 10. Based on the comparison of the equivalent volumes, a calcium cell's cathode capacity is calculated to be ~80% of a similarly constructed

Table II. Discharge data for hermetic $Ca/SOCl_2$ "D" cells

Cell	Number of cells	Capacity (A-hr)	Average life above 2V (hr)
Fresh	10	2.0	52.3
1 month at 25° ± 2°C	2	2.0	51.5
1 month at 55°C	3	1.7	43
2½ months 25° ± °C	3	1.6	44

Capacity based on anode mass = 4.1 A-hr.

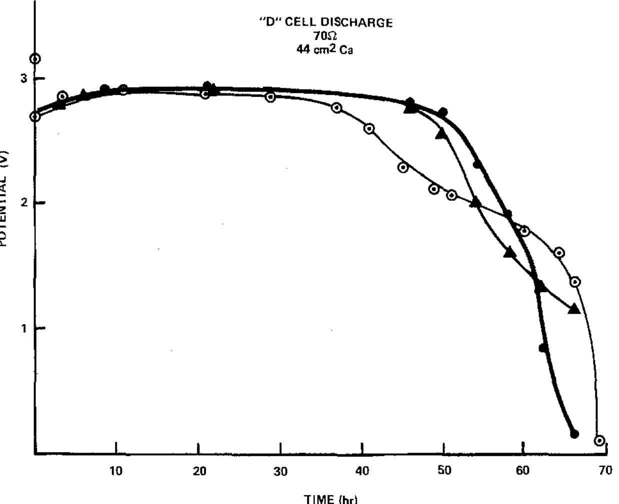

Fig. 9. Discharge curves for 3 freshly filled "D" cells through a 70Ω load (1 mA/cm² Ca). The circled point above the discharge curve shows the OCP of the cells.

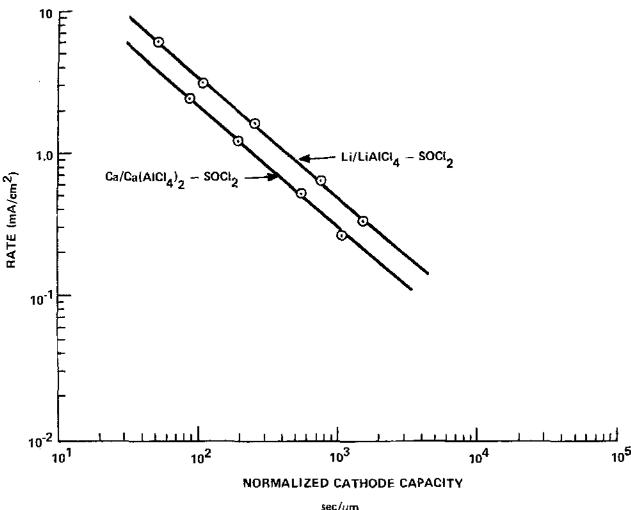

Fig. 10. Logarithm of the rate *vs.* logarithm of the cathode capacity for $Ca/SOCl_2$ and $LiSOCl_2$ cells.

lithium cell. From the data in the graph, the calcium cell's capacity is ~58% of the Li cell. Thus, the proposed model (based solely on the molar volume of the deposited salt) is too simplistic and other factors, *e.g.*, the mobility of Ca^{2+} and Li^+ ions in $SOCl_2$ and diffusion of Ca^{2+} and Li^+ into the cathode pores should be considered. It may well be that, despite the use of thin cathodes, the interior of cathodes is particularly underutilized as the result of the lower mobility of Ca^{2+} relative to Li^+. The results of this particular study do indicate however that the cathode capacity for a calcium cell will be lower than for a similarly constructed lithium cell.

We have also investigated whether leaving the oxide coating intact is beneficial to the $Ca/SOCl_2$ system. A relatively large piece of oxide-coated calcium (20 cm²) was exposed to 1M $Ca(AlCl_4)_2$ electrolyte at 55°C and initially showed significantly reduced corrosion, although the cut edges showed some corrosion. At a specific site along one edge, pitting commenced and a circular corroded area of ~1 cm² was apparent after 2 months storage at 55°C. The corrosion at this site continued progressively throughout the duration of the test. It should be stressed that corrosion was initiated at this singular site with the other edges having small areas where white crystalline deposits appeared and which apparently self-healed. Electrodes were also constructed from the oxide-coated calcium and evaluated. This calcium could not

effectively be welded to nickel substrate and thus the calcium was mechanically fixed to a nickel lead. Flooded cells using oxide-coated anodes and references showed initial open-circuit potential (OCP) of ~3.10V and were discharged through a 2000Ω load. The A-hr capacity of such cells was ~0.075 A-hr (40% of that expected based on the anode mass) and the discharged anode remained relatively intact but showed a 3V polarization *vs.* the reference. These anodes were collected, intentionally hydrolyzed, and the resulting solutions titrated for $Ca(OH)_2$ to assess the available Ca metal. The analysis showed that approximately 40% of the original Ca remained entrapped within a CaO and $CaCl_2$ coating and that approximately 20% corrosion had occurred. This is a significant improvement in the corrosion rate and indicates that the oxide coating does provide a protective film through which the Ca can discharge but eventually the remaining Ca metal is electronically isolated.

Vapor-deposited Ca on steel was also evaluated in the $Ca(AlCl_4)_2$-$SOCl_2$ electrolyte. This material was obtained from Catalyst Research Corporation of Baltimore, Maryland and was 0.020 cm thick with an average Ca density of 1.51 g/cm^3. A flooded cell was constructed which showed an OCP of 3.25V and when discharged showed only a 25% utilization of the Ca with the remainder of the Ca apparently suffering parasitic corrosion. The reference electrode was also inspected after discharge and this inspection revealed that the steel substrate was devoid of calcium metal. Significant deposits of $CaCl_2$ were observed at the bottom of the cell as a result of the anode and reference corrosion.

Cell chemistry.—There are many possible overall cell reactions for the Li/$SOCl_2$ system (11), among these the following two reactions

$$8Li + 3SOCl_2 \rightarrow 6LiCl + Li_2SO_3 + 2S$$

$$4Li + 2SOCl_2 \rightarrow 4LiCl + SO_2 + S$$

have been mentioned frequently for room temperature discharge. The second reaction is now considered the probable overall reaction, although some specific unanswered questions still remain (11). It was therefore considered beneficial and informative, by comparison, to identify qualitatively the products of the Ca/$SOCl_2$ cell reaction at room temperature.

Before discharge, no SO_2 was detected in the infrared spectrum of the electrolyte. After discharge, a large infrared absorption appeared at 1330 cm^{-1} which is diagnostic of SO_2 dissolved in $SOCl_2$ and as the electrolyte was protected from H_2O contamination, the SO_2 resulted from the reduction of $SOCl_2$.

A discharged carbon cathode was first washed with $SOCl_2$ to remove $LiAlCl_4$ then leached with distilled water to remove water soluble products. A portion of the solution was immediately withdrawn and tested for sulfite by addition of an acidified $KMnO_4$ solution. The solution did not decolorize and thus no reducing agents such as SO_3^{2-} were present. Addition of an aqueous Ba^{2+} solution to a portion of the leached cathode solution did not result in precipitation of solid, thus SO_4^{2-} was not present. A white solid recovered from the leach solution was shown to be a single phase of $CaCl_2$ by x-ray diffraction techniques. Although the discharged electrolyte was not specifically tested for the presence of dissolved sulfur, the conclusive evidence presented for SO_2 and $CaCl_2$ suggests the following overall cell reaction at room temperature

$$2Ca + 2SOCl_2 \rightarrow SO_2 + 2CaCl_2 + S$$

It should be stressed that the overall products of this electrochemical reaction do not necessarily imply a specific mechanistic pathway and, in fact, significant temperature changes may favor another pathway and concomitantly different products. The Li/$SOCl_2$ cell is a good example of where the relation of temperature and mechanism have yet to be definitively elucidated (11, 11a).

The lower capacity for thin cathodes in Ca/$SOCl_2$ (*vide supra*) should also be emphasized in light of finding $CaCl_2$ in the cathode. Per equivalent of charge passed, the $CaCl_2$ precipitated in the cathode matrix would occupy a larger molar volume than LiCl and hence a lower cathode capacity.

Electrodeposition of calcium.—The experimental assembly used for deposition experiments contained 1.0M $Ca(AlCl_4)_2$-$SOCl_2$, a Ca reference, Ca anode, and nickel substrate or cathode. The open-circuit potential between the planar nickel electrode and the calcium electrode was about 3V. When a constant current of 0.125 mA/cm^2 was applied to the nickel working electrode, the potential of the nickel (measured against the Ca reference) decreased very slowly from 3 to 2V after 70 min. On turning off the current, the nickel potential rose quickly to near 3V. When a larger constant current of 1.25 mA/cm^2 was applied to the nickel electrode, the potential of the nickel decreased rapidly from 3 to −10V and remained at that potential until the current was turned off, whereupon, the potential rose immediately to anodic values and was near 3V within 20 min (Fig. 11).

There is little evidence for calcium deposition on the Ni substrate. When the nickel is made cathodic, the surface can directly transfer electrons to the $SOCl_2$, thus, solvent reduction can occur. The products of the reaction may be SO_2 and S, which are soluble in $SOCl_2$, and $CaCl_2$, which precipitates on the Ni surface, inhibiting electron transfer (voltage driven to −10V). Considering the model of the solid electrolyte interphase (SEI) advanced by Peled (12, 12a), the Ni^- is now covered by a $CaCl_2$ SEI layer. Calcium chloride is essentially an electronic insulator, thus the current must now depend on the migration of ions through the passivating film (ionic current) to the Ni surface (Fig. 12). However, the cation transport numbers of alkaline earth halides is low (13), with the anion transport number likely close to unity. Thus, the current will predominately be carried by the anion defect sites as shown in Fig. 12. By this hypothetical mechanism, Cl^- must move outward through defect sites to precipitate as $CaCl_2$ on the surface and leave Ca as a deposit on the Ni substrate. Apparently this process does not function efficiently. This mechanism would require destruction of $CaCl_2$ at the nickel surface, and the growing of $CaCl_2$ crystals at the interface with the solution, at a rate commensurate with the current being drawn. These crystals, almost certainly dendritic, could offer no protection to the calcium, and so the deposit would be corroded as fast as it was plated.

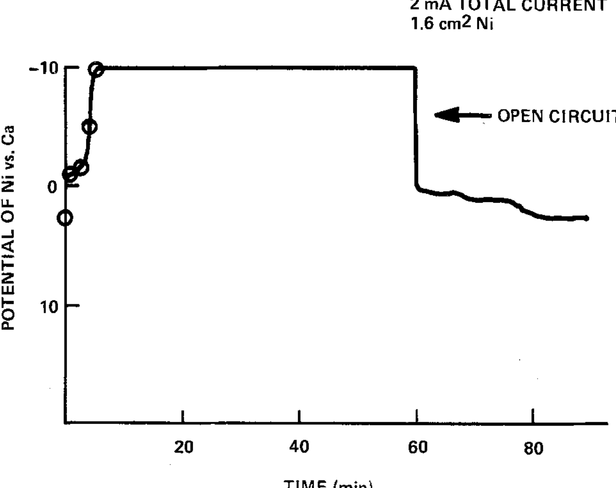

Fig. 11. Calcium deposition to Ni substrate in 1M $Ca(AlCl_4)_2$-$SOCl_2$.

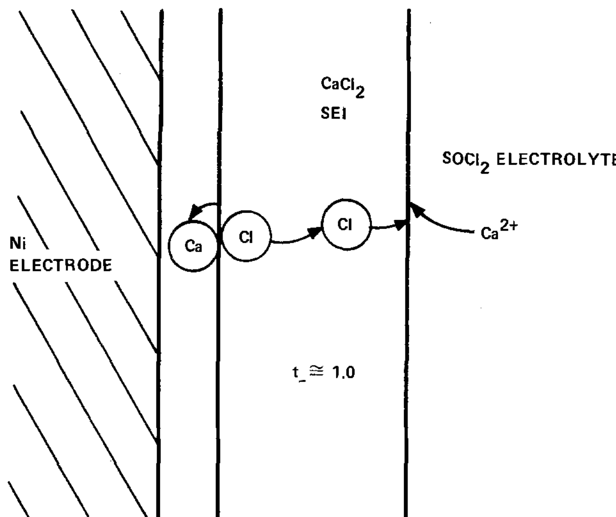

Fig. 12. Model for calcium deposition through a solid electrolyte interphase layer of $CaCl_2$. Ionic current is carried by anion as a result of the low transport number of the calcium cation.

In contrast, the plating or dissolution of lithium through a lithium salt SEI would not require the growth or the demise of crystals of the lithium salt, since lithium ions could simply pass through this layer. With lithium, the process either of plating or particularly of anodic oxidation would require only that the SEI be physically transported, intact, as the metal was plated or stripped.

Calcium corrosion.—The accelerated corrosion of abraded Ca metal in the thionyl chloride electrolytes as compared to $SOCl_2$ alone is puzzling at first glance. The extensive investigations with lithium and the LiCl film in $SOCl_2$ are available for contrast and comparison. Lithium appears far less reactive both in $SOCl_2$ and the various suitable electrolytes which is evidenced by discharge of cells at efficiencies approaching 100% utilization of the lithium anode. Peled and Dey independently have proposed compatible explanations of the nature of the film growth and morphology (6-8). In particular, Dey (8) has considered the Pilling-Bedworth ratio (14) which relates the molar volume of the coating or film to the molar volume of the metal. This use of this ratio was originally confined to explanations of protective and nonprotective metal oxides. The effectiveness of the coating was judged according to the ratio R

$$R = \frac{V_s}{nV}$$

where V_s is the molar volume of a Li or Ca compound, n is the number of gram atoms of Li or Ca in one mole of the compound, and V the gram atomic volume of Li or Ca. When this ratio is greater than 1, the compound forms a protective film. The following examples are included for comparison

Compound	R
Li_2O	0.57
Li_3N	0.64
Li_2CO_3	1.34
LiCl	1.58
CaO	0.66
$CaCl_2$	1.98

It is obvious from these considerations that LiCl would be expected to be protective and in fact has been shown to be kinetically protective for lithium in $SOCl_2$. The same conclusion would be drawn for $CaCl_2$ on Ca, yet we have not found this to be the case. The discrepancy lies in the relative simplicity of the Pilling-Bedworth ratio, and corrosion treatises (15, 16) indicate that only a qualitative agreement is expected. Other considerations such as a coefficient of expansion equal to the metal substrate, good adherence, and low electrical conductivity are equally important (16). In addition to these factors, the intrinsic qualities such as mechanical film breakdown, chemical breakdown of the film, and breakdown by undermining at any fortuitous imperfection, provide a more complete view of film protection or nonprotection (16).

The presence of dissolved salts aggravates the calcium corrosion, a result not unexpected when considering the $Li/SOCl_2$ system where the nature of the dissolved salt apparently changes or influences the LiCl film growth rate and morphology (17, 18). Finally, the calcium corrosion may also result from the presence of relatively high amounts of magnesium and aluminum which would be expected to be present at the grain interfaces and which may give rise to galvanic corrosion cells within the anode.

The open-circuit potential of the calcium-$SOCl_2$ cell differs considerably from the value calculated from thermodynamic functions (see the introduction). This discrepancy may arise from two considerations: first, the thickness of the SEI may affect the potential (6) and second, active corrosion implies a corrosion current and a consequent lower potential through polarization of the anode.

Summary and Conclusions

In addition to the above generalized discussion of calcium corrosion, the salient results of this investigation were:

1. Suitable electrolytes such as $Ca(AlCl_4)_2$ can be prepared if attention is paid to the purity of materials and water is painstakingly excluded.
2. Corrosion of the calcium metal in electrolytes is a significant problem under the conditions studied. The corrosion occurs during storage, and apparently, more rapidly under anode discharge when the SEI or $CaCl_2$ film may be thinner and more susceptible to continued reaction with the $SOCl_2$.
3. Cathode capacities when compared to $Li/SOCl_2$ cells are lower, a probable result of the larger molar volume occupied by $CaCl_2$ and lowered mobility of calcium ions relative to lithium ions in the electrolyte.
4. Both SO_2 and $CaCl_2$ were confirmed as products of cell discharge intimating that the electroreduction of $SOCl_2$ proceeds to S, SO_2, and Cl^-

$$2Ca + 2SOCl_2 \rightarrow 2CaCl_2 + SO_2 + S$$

5. The calcium plating experiments in $SOCl_2$ suggested that calcium metal was not electrodeposited on the nickel substrate. This behavior may result from a rapid corrosion rate or fundamental transport problems through the $CaCl_2$ film formed on the substrate.
6. Vacuum annealing of the calcium reduces the work hardening and results in better anode utilization, although corrosion is not eliminated.

Acknowledgments

Role of Oxide Defects in the Anodic Oxidation of Nickel

B. MacDougall*

National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R9

ABSTRACT

The galvanostatic oxidation of nickel electrodes in pH 2.8 Na_2SO_4 requires the presence of a prior oxide film in order to avoid the active nickel dissolution region. Either the 6-8Å NiO film on electropolished nickel or that formed during the early stages of anodic passivation can serve as an appropriate starting surface for galvanostatic experiments. Anodic charging of such electrodes gives a distinct transition region over a potential range of almost 1V. The current efficiency for nickel dissolution during the potential transient is high (>80%) with only a small portion of the charge contributing to oxide growth. This situation persists even at high charging rates and/or high solution pH's where it appears that chemical dissolution of the oxide is not playing an important role. The results suggest that the standard high field oxide growth mechanism is not operative during galvanostatic oxidation of nickel. The results are best explained in terms of a defective oxide film where the change of potential during the transient is associated with an increase in the state of film perfection. Anodic charge consumption would be mainly due to a continuous breakdown and repair of the oxide film at defect sites, most of the charge going towards $Ni \rightarrow Ni^{2+} + 2e$ during inefficient film repair. The increase in anodic potential with increasing perfection of the film is interpreted in terms of an overvoltage effect, *i.e.*, the area over which breakdown and repair is occurring decreases with increasing film perfection and therefore the anodic current density increases. At potentials > +0.4V, the rate of increase in oxide film perfection decreases and an eventual steady state is reached. The influence of potential of anodization and solution pH on nickel dissolution, oxide repair, and oxide perfection is discussed. The defect model of oxide film development is shown to apply equally well during potentiostatic oxidation of nickel, the NiO film reaching an almost steady thickness very soon after the potential step anodization with the continual long-term decrease of anodic current with time of anodization being due to a localized increase in oxide film perfection.

The anodic oxidation of nickel in acid or neutral electrolytes has been extensively studied by workers using potentiostatic (1-7), potentiodynamic (8, 9), and galvanostatic charging techniques (10-13). It is generally accepted that a surface oxide film on the nickel electrode is responsible for retardation of the nickel dissolution reaction and that, on a previously oxide-free nickel surface which is polarized into the passive potential region, the oxide composition is NiO as opposed to $Ni(OH)_2$ or higher oxides of nickel. On the other hand, there is still controversy concerning the mechanism of film growth with regard to changes in oxide thickness and/or electronic conductivity with time and/or potential of anodization, with several models having been presented in the literature. In previous work, MacDougall and Cohen found no substantial change in oxide thickness with time or potential of anodization, a film of 9-12Å of NiO forming very rapidly on the electrode surface after polarization in the passive potential region (1, 2, 4, 14, 15). Correspondingly large changes in the stability of the oxide towards open-circuit breakdown were explained in terms of a defect model of the NiO film, film stability being determined by the character of the oxide at localized weak points in the film. Since the total surface coverage by these defects is quite small (≲2%) and the surface analysis measurements are averages representative of the entire oxide, the

Key words: defects, electrode, passivity, oxidation.

measured film thicknesses and stoichiometries are essentially independent of film perfection. This model was substantiated by: (*i*) electron microscopic examination of single crystal nickel electrodes following open-circuit oxide breakdown; (*ii*) solution analysis for Ni^{2+} at various stages during film breakdown; and (*iii*) both anodic and cathodic polarization experiments (16, 17).

A model for passive oxide film formation on nickel has been presented by Ord *et al.* (12) to explain an ellipsometrically determined increase in oxide film thickness during galvanostatic anodic charging in both neutral sulfate and borate solutions. The oxide thickness appeared to increase from 2 to 18Å during anodic charging, this increase paralleling an increase in anodic potential. This suggested a high field oxide growth mechanism similar to that proposed by other workers for oxide growth on nickel under potentiostatic conditions in acid solutions (18, 19). The oxide film was believed to be a poor electronic conductor and thus able to sustain a substantial potential drop across it. The oxide giving rise to the potential transient was believed to be NiO while that formed in the plateau potential region was probably βNiOOH with a higher electronic conductivity than NiO(12).

An important issue in the anodic oxidation of nickel under both potentiostatic (18) and galvanostatic (19) conditions concerns the current efficiency for oxide growth in the passive potential region, *i.e.*, what portion of the overall anodic current goes towards an increase in film thickness? It is recognized that corrections must be made for chemical dissolution of the oxide, *i.e.*, $NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$, because an electron-transfer reaction occurs to replace the dissolved oxide, *i.e.*, $Ni + H_2O \rightarrow NiO + 2H^+ + 2e$. The problem is that the charge associated with this coupled reaction may represent a large part of the measured anodic charge but it does not contribute to an actual increase in the amount of oxide on the surface. The usually accepted method of correction is to assume a constant rate of chemical dissolution, and thus a constant anodic current contribution, which depends only on solution *p*H (18-20). The dissolution current can then be subtracted from the overall anodic current to give the rate of oxide growth. It appears, however, that this method may be too simplistic in that the anodic currents may be associated with other processes besides oxide growth and chemical dissolution. In particular, work on the anodic oxidation of iron and nickel (21, 22) indicates that chemical dissolution of the oxide may only be responsible for a small portion of the anodic current not contributing to oxide growth. The majority of the nonoxide growth anodic current is believed to be due to metal dissolution ($M \rightarrow M^{2+} + 2e$) under the influence of a high electric field within the oxide. Other work would seem to indicate that the rate of oxide chemical dissolution is dependent on the anodic potential (7, 23), *i.e.*, the rate of $MO + 2H^+ \rightarrow M^{2+} + H_2O$ is determined by the potential across the oxide-electrolyte interface as well as the solution *p*H. This means that during oxide growth, (*i*) oxide chemical dissolution, (*ii*) electrochemical oxide dissolution, and (*iii*) field assisted metal dissolution may be contributing to the measured anodic current, in which case the correction term could depend on time and potential of anodization as well as solution *p*H. Interpretation of current efficiency data for growth of thin oxide films is therefore a complicated matter.

In the present paper, the mechanism of the anodic passivation of nickel under galvanostatic and potentiostatic conditions will be investigated by directly measuring the current efficiency for oxide growth on preoxidized electrodes. The roles of the various reactions responsible for lowering the oxide current efficiency will be studied by working at different anodic changing rates and solution *p*H's. An alternative to the high-field oxide growth model will be presented to explain the results, this model involving changes in the defect character of the oxide during anodization. The role of breakdown and repair of oxide at the defect sites will be discussed and it will be shown how localized reactions may be responsible for a large part of the charge consumption during both galvanostatic and potentiostatic polarization.

Experimental

Polycrystalline specimens, 1 × 2.5 cm, were prepared from zone-refined nickel sheet of 99.996% purity as described elsewhere (1). They were degreased with benzene, chemically polished (1), electropolished for 2 min at 23°C in a 57 volume percent (v/o) sulfuric acid solution at 0.5 $A\text{-}cm^{-2}$, and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were electropolished again immediately before use in an experiment. Potentials quoted in this paper are referred to the Hg/Hg_2SO_4 reference electrode in 0.15*N* Na_2SO_4 (+0.665V with respect to the standard reversible hydrogen electrode). Deaerated solutions of 0.15*N* Na_2SO_4 were adjusted to *p*H 2.8. Experiments were conducted at 25°C. Electropolished electrodes were either potentiostatically or galvanostatically anodized both with and without cathodic reduction of the prior oxide film. Solutions were analyzed for Ni^{2+} by carbon rod atomic absorption spectroscopy, the lower limit of detection by this method being 0.2 $\mu g\ cm^{-2}$ (sample area = 5 cm^2; cell volume = 50 ml). X-ray emission spectroscopy was used to determine oxide film thickness (1).

Results

Transient Results

Galvanostatic oxidation of nickel.—Figure 1 shows the anodic galvanostatic charging profiles for nickel electrodes in *p*H 2.8 Na_2SO_4 at 4, 20, and 200 $\mu A\ cm^{-2}$. The electrode pretreatment consists of electropolishing and immersion in the *p*H 2.8 electrolyte with an applied cathodic current of 20 $\mu A\ cm^{-2}$ to remove the prior 6-8Å NiO film (1). The potential is then stepped to −0.3V for 30 sec to avoid the potential region of active metal dissolution. The starting surfaces are thus covered by an anodically formed oxide film. A constant potential plateau is observed at potentials more anodic than the reversible potential for oxygen evolution in the present system, *i.e.*, +0.4V. The plateau potential, and thus the reaction over-

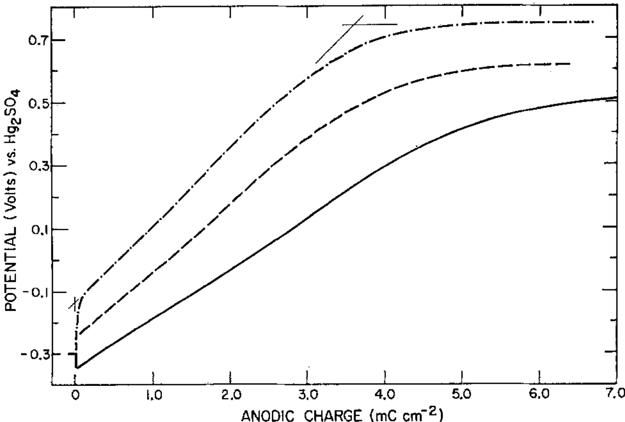

Fig. 1. Anodic charging curves for nickel electrodes in *p*H 2.8 Na_2SO_4 at 4 $\mu A\ cm^{-2}$ (——), 20 $\mu A\ cm^{-2}$ (– – –), and 80 $\mu A\ cm^{-2}$ (–·–). Electrode pretreatment consisted of electropolishing, cathodic reduction, and stepping the potential to −0.3V for 30 sec. The standard method was used for determining the transition time of the anodic arrest and is illustrated for the 80 $\mu A\ cm^{-2}$ charging profile. The points of intersection of the extrapolated lines for the various charging processes are taken as defining the beginning and end of the change transient.

voltage, is dependent on the anodic charging rate with a Tafel slope of *ca.* 0.13V. Between the initial potential and that of the plateau, the potential increases steadily at an almost constant rate (*i.e.*, dV_a/dQ_a = constant[1]) giving rise to what will be defined as an anodic transient.

The transient charge is plotted as a function of anodic charging current in Fig. 2. The transient charge is almost independent of anodic charging current above *ca.* 50 μA cm^{-2}. At lower charging rates, Q_a^t increases with decreasing i_a^g, an observation that can be explained in terms of an increased amount of chemical dissolution of the oxide at the longer transition times. The value of the anodic charging current at which Q_a^t becomes independent of i_a^g increases with decreasing pH and decreases with increasing pH, in agreement with a chemical dissolution model. At pH 2.8, an anodic charging rate of 80 μA cm^{-2} is used to study the transient oxidation of nickel in order to avoid the region of large changes of Q_a^t with i_a^g (Fig. 2).

Role of the air-formed oxide film.—It is known (1) that nickel electrodes which have been electropolished in 57 v/o H_2SO_4 and subsequently exposed to the air are covered with a 6-8Å "air-formed" NiO film. The possibility of using this previously characterized film as a means of avoiding the active potential region was investigated. When electropolished nickel is immersed in pH 2.8 Na_2SO_4 at 80 μA cm^{-2}, the potential rapidly adjusts to −0.14V and then increases almost linearly with Q_a until +0.7V (Fig. 3). Shown for comparison in Fig. 3 is the result obtained with an initially oxide-free electrode which was given a 30 sec anodization at −0.3V prior to anodic charging. After this treatment, initiation of galvanostatic charging with 80 μA cm^{-2} results in an immediate potential increase to −0.18V, *i.e.*, close to the −0.14V observed with electropolished nickel, followed by an anodic transient almost identical to that obtained with electropolished nickel. The results suggest that this anodic oxide film is similar in character to the air-formed film. Also shown in Fig. 3 is the anodic charging profile obtained with an electropolished nickel electrode which was anodized at −0.3V for 30 sec without prior reduction of the air-formed oxide film, *i.e.*, it was immersed in the electrolyte under polarization at −0.3V. The presence of the 6-8Å NiO film reduces the transient charge by only a small amount. The fact that the presence of the oxide film on electropolished nickel does not alter the overall transient oxidation

[1] In the text, V_a and t_a refer to the potential and time of anodization; i_a is the anodic current; Q_a is the anodic charge passed; i_a^g is the anodic galvanostatic charging current, and Q_a^t is the anodic transient charge.

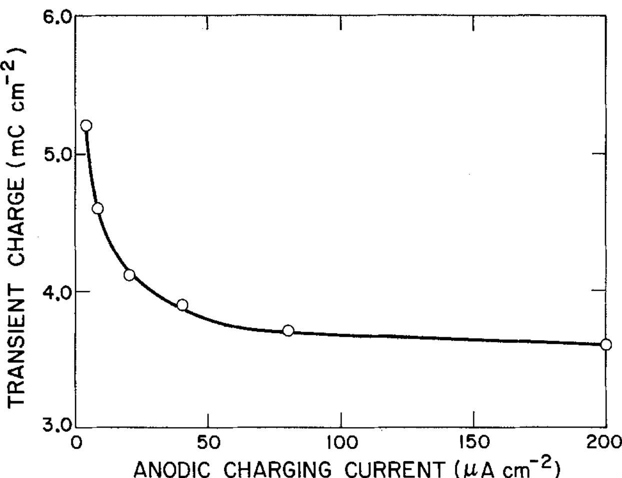

Fig. 2. Variation of the transient charge with anodic charging current, in pH 2.8 Na_2SO_4, for nickel electrodes electropolished, cathodically reduced, and anodized at −0.3V for 30 sec.

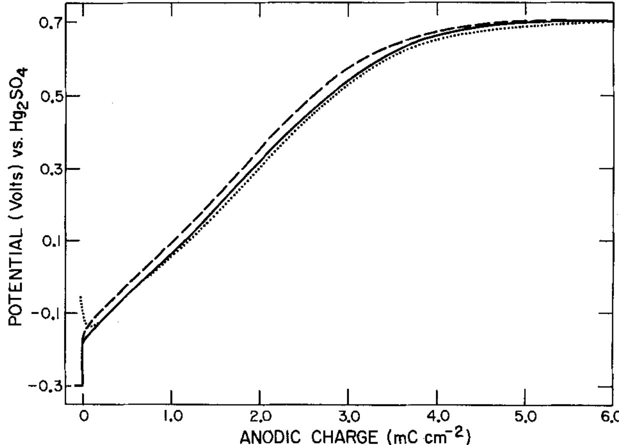

Fig. 3. Anodic charging curves for electropolished nickel electrodes in pH 2.8 Na_2SO_4 at 80 μA cm^{-2} after different pretreatments: (···) immersion in solution at 80 μA cm^{-2}; (——) cathodically reduced with the potential stepped to −0.3V for 30 sec; (– – –) immersion in solution at −0.3V for 30 sec without prior cathodic reduction.

characteristics means that it can serve as a "partially passivated" surface from which to start oxidation studies.

Role of pH and temperature.—Figure 4 shows the anodic galvanostatic charging profiles, at 80 μA cm^{-2}, for electropolished nickel electrodes at pH 2.0, 2.8, and 6.0. The anodic transient charge decreases by *ca.* 20% in going from pH 2.0 to pH 6.0. The plateau potential is independent of pH; also the immersion potential does not vary substantially with pH. (Changes in the reference electrode potential do not account for this result since the Hg/Hg_2SO_4 reaction is independent of pH.) Also shown in Fig. 4 is the effect on the anodic charge of a decrease in temperature from 25° to 6°C at pH 2.8. The anodic charging profile is similar to that obtained at 25°C except that the entire curve is shifted to more positive potentials.

Solution analysis for Ni^{2+}.—The solution was analyzed for Ni^{2+} at various times during anodic charging of electropolished surfaces. The amount of Ni^{2+} in solution increased with the quantity of charge passed and accounted for >80% of the anodic charge over the entire transient region at both pH 2.8 and 6.0 (Table I). This situation continued into the plateau potential region.

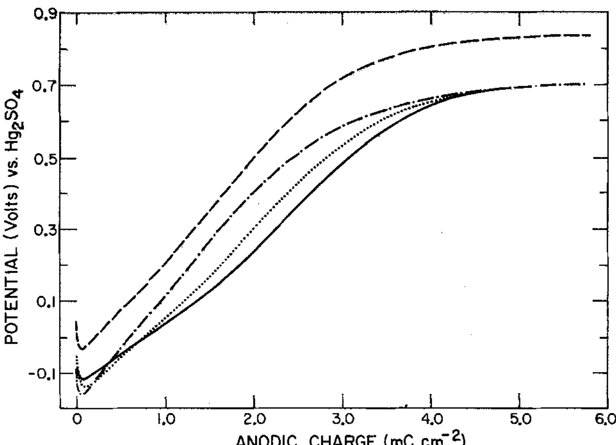

Fig. 4. Anodic charging curves for electropolished nickel electrodes at 80 μA cm^{-2} in 0.15*N* Na_2SO_4 solutions of different pH's: (——) pH 2.0; (···) pH 2.8; (–·–) pH 6.0. Solution temperature is 25°C. Also shown is the result obtained in pH 2.8 Na_2SO_4 at 6°C (– – –).

Table I. Quantity of Ni^{2+} in solution as a function of amount of anodic charge passed during the galvanostatic oxidation of electropolished nickel at 80 $\mu A\ cm^{-2}$. The transient charge has been converted to $\mu g\ Ni^{2+}\ cm^{-2}$ by assuming a current efficiency of 100%

Solution pH	Transient time (sec)	Anodic charge ($\mu g\ Ni^{2+}\ cm^{-2}$) ±2%	$[Ni^{2+}]$ in solution ($\mu g\ cm^{-2}$) ±10%
2.8	4.5	0.1	<0.2
2.8	22.0	0.54	0.48
2.8	29.3	0.71	0.72
2.8	38.8	0.95	0.80
2.8	55.0	1.34	1.10
2.8	125.0	3.05	2.90
6.0	36.0	0.88	0.84

Surface analysis of oxide films.—X-ray emission spectroscopy was used to determine the thickness of NiO films formed during galvanostatic charging. For both the air-formed or anodic prior oxide films, the NiO film thickness obtained by galvanostatic charging in pH 2.8 at 80 $\mu A\ cm^{-2}$ (to +0.6V) was 9-12Å, *i.e.*, an increase of ~50% over the 6-8Å of air-formed NiO originally present on electropolished nickel.

The structure the oxide film formed on nickel by galvanostatic charging was studied by reflection electron diffraction using a Ni (111) single crystal. (The single crystal gave anodic charging profiles which were almost identical to those obtained with polycrystalline nickel.) The oxide formed by anodic charging at 80 $\mu A\ cm^{-2}$ (to +0.6V) is a highly epitaxed NiO whose character appears to be independent of prior removal of the air-formed oxide.

Long-Term Potentiostatic Results

The role of the air-formed oxide film in the potentiostatic oxidation of nickel was investigated by immersing an electropolished nickel electrode into the solution at 0 volts and comparing the i_a/t_a decay with the case where the air-formed oxide film was previously reduced before the potential was stepped to 0 volts. The results are shown in Table II. The presence of the air-formed oxide film reduces the initial i_a by a factor of 100 times, *i.e.*, active nickel dissolution is greatly inhibited by the film. However, after *ca.* 3 sec of anodization at 0 volts, the currents are the same in both cases. Figure 5 shows the long term decay of anodic current with time (from 15 min to 160 hr) at 0 volts.

The nature of the long term anodic currents in Fig. 5 was investigated by analyzing the solution for Ni^{2+} at various times. An electrode was anodized at 0 volts for 1 hr and then removed to the air for 15 min. Upon reimmersion in a fresh pH 2.8 solution at 0 volts, a very small anodic charge flowed and the original current (corresponding to 1 hr at 0 volts) is reached within 60 sec. This indicates that the oxide film had changed very little during the 15 min air exposure [*cf.* Ref. (4)]. During this 60 sec reanodization, solution analysis indicated <0.2 $\mu g\ cm^{-2}$ of Ni^{2+} in solution. The same experiment was repeated but this time the reimmersed electrode was left in the solution at 0 volts for 24 hr. During this time, 8.8 mC cm^{-2} of anodic charge passed and 2.9 $\mu g\ cm^{-2}$ (±10%) of nickel dissolved as Ni^{2+}. This amount of Ni^{2+} corresponds to 9.5 mC cm^{-2}, *i.e.*, within experimental error all the long term anodic charge can be accounted for by the dissolution reaction $Ni \rightarrow Ni^{2+} + 2e$. This is in agreement with previous x-ray observations (1-4) that the overall thickness of nickel oxide films is almost independent of time of anodization.

Table II. Anodic currents as a function of time of anodization at 0.0V in pH 2.8 Na_2SO_4 for electropolished nickel electrodes with (A) and without (B) cathodic reduction of the air-formed oxide film

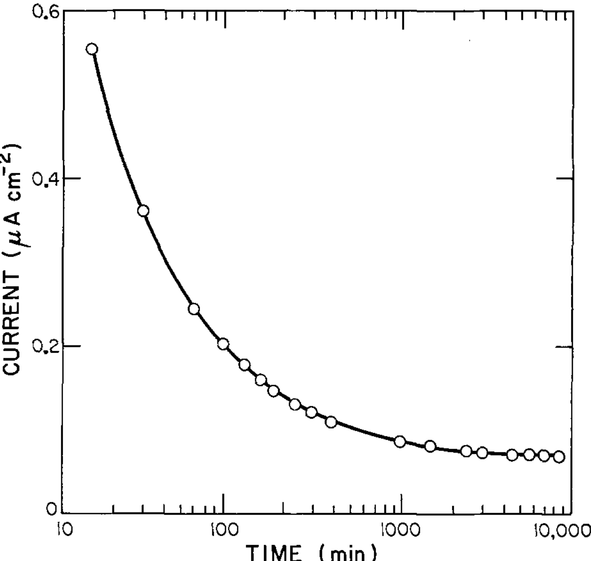

Fig. 5. Decay of the anodic current with time of anodization at an anodic step potential of 0 volts for an initially oxide-free nickel electrode. Solution is pH 2.8 Na_2SO_4.

To determine the influence of V_a on i_a, a nickel electrode was anodized at 0 volts for 1 hr, the anodic current falling to 0.24 $\mu A\ cm^{-2}$. The potential was then rapidly adjusted to −0.2V and the current initially decreased to 0.03 $\mu A\ cm^{-2}$ and began to increase very slowly. Open-circuit decay experiments indicate that the character of the oxide formed at 0 volts (t_a = 1 hr) is not affected by the potential step to −0.2V for at least the first half hour, *i.e.*, the character of the oxide is frozen for a substantial period of time after the potential step to a less anodic potential. If the anodization had been at −0.2V from the start, the anodic current would have been 0.25 $\mu A\ cm^{-2}$ after 1 hr of anodization. In the present case, i_a continues to increase from 0.03 $\mu A\ cm^{-2}$ for up to 10 hr after the potential step from 0 volts indicating that the film is taking a very long time to adjust to the form associated with anodization at −0.2V.

The effect of potentiostatic holding at −0.3V and 0 volts, for various periods of time, on the anodic charging profiles is shown in Fig. 6. Potentiostatic holding increases the anodic value to which the potential abruptly jumps with application of the constant anodic charging current and this results in a decrease of the anodic transient charge. The potential jump to the higher anodic value indicates that the character of the oxide film is dependent on the time as well as the potential of anodization, in agreement with previous observatious from open-circuit work (4). With increasing time at −0.3V or 0 volts the film is converting to a higher potential form through changes in the character of the oxide.

Discussion

Distinct transients are observed over a potential range of almost 1V during anodic galvanostatic charg-

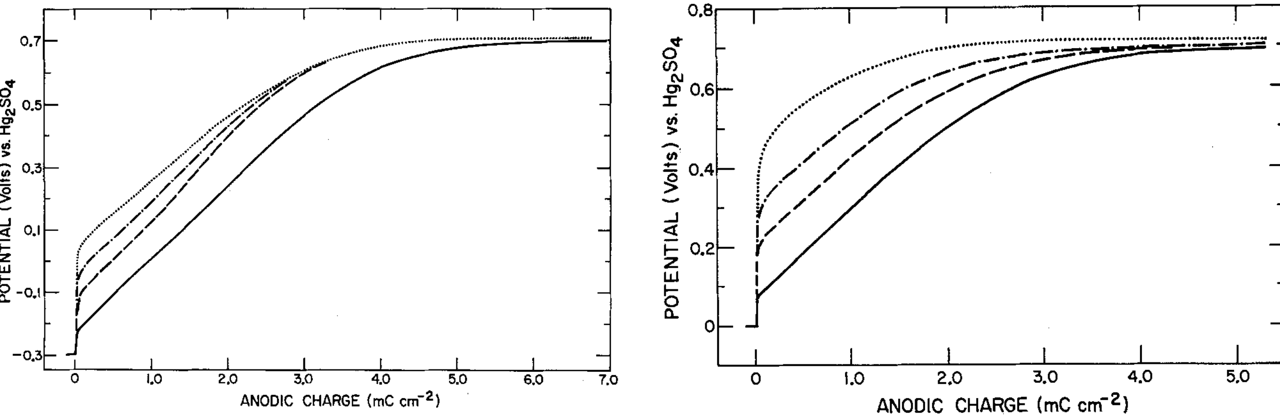

Fig. 6. (a, left) Anodic charging curves for previously oxide-free nickel electrodes in pH 2.8 Na_2SO_4 at 80 μA cm^{-2} as a function of time of anodization at -0.3V: (——) 10 sec; (– – –) 2 min; (–·–) 15 min; (···) 20 hr. (b, right) As in (a) but with an anodization potential of 0 volts.

ing of either electropolished or anodically pretreated nickel electrodes (Fig. 1 and 3). Similar results have been obtained by other workers (12, 19) which have been interpreted in terms of a high field oxide growth mechanism where the transient increase in anodic potential is due solely to an increase in thickness of the nickel oxide film. In the present work, the transient charge (up to $+0.6$V at a charging rate of 80 μA cm^{-2} and assuming a 100% current efficiency for oxide growth) is equivalent to 20Å of NiO so that the total NiO thickness (including the prior oxide) should be $\sim$27Å after galvanostatic charging. X-ray emission measurements indicate, however, that the majority of the transient charge does not contribute to an increase in oxide thickness since the oxide is $\sim$9-12Å thick after anodic charging and the prior oxide itself was 6-8Å. In agreement with this, solution analysis for Ni^{2+} indicates that the current efficiency for nickel dissolution is >80% throughout the transient region (Table I), *i.e.*, the transient charge is mainly associated with nickel dissolution rather than oxide film growth. It could be argued that a high field mechanism with a very low oxide formation current efficiency is responsible for the apparent increase in oxide thickness from $\sim$7 to $\sim$10Å, chemical dissolution of the oxide being responsible for the low current efficiency. However, this seems unlikely since the transient charge does not vary substantially with *p*H (Fig. 4) or with i_a^g above *ca.* 80 μA cm^{-2} (Fig. 2), the oxide formation current efficiency remaining very low (<20%) throughout (Table I). Thus the standard high field oxide growth mechanism does not seem to apply and an alternative model is required to explain the existence of the distinct anodic transient during galvanostatic charging of preanodized nickel electrodes.

Three possible interpretations of the results will now be presented. The first involves a potential dependent rate of oxide dissolution with the rate increasing with anodic potential, *i.e.*, electrochemical oxide dissolution (7, 23). The argument would be that the resistance of the oxide to dissolution increases throughout the transient region and consequently the anodic potential must increase in order that the constant anodic current can be consumed. In this model, a high electric field does not have to be present across the oxide since the potential responsible for dissolution is across the oxide-solution interface. The second interpretation involves a modified high field oxide growth mechanism whereby the field across the oxide is responsible for nickel dissolution. In this model, nickel ions diffusing across the oxide film can either incorporate into the oxide film or dissolve in solution (*cf.* 21, 22) and the majority would thus appear to dissolve. The increase in anodic potential in the transient region would be a monitor of either an increase in oxide thickness or a change in its electronic properties (*e.g.*, conductivity) so that higher anodic potentials are required to maintain the same anodic reaction rate. Both of the above models assume that the dissolution process is uniform with all sites over the surface of the oxide being essentially equivalent. The third and preferred interpretation is one which considers a defective oxide film and this will now be presented in some detail.

The defect model of the oxide film evolved from previous constant potential work where it was found that the thicknesses of anodically formed nickel oxide films were 9-12Å, independent of V_a and t_a in both acid and neutral solutions (1-4, 14-17). At the same time, however, the stability of these anodic oxide films towards open-circuit dissolution was highly dependent on the conditions of anodization. These earlier results were explained in terms of a defect model of the oxide film in which a small coverage of defective oxide determines the stability of the film, the number and/or stability of these defect oxide sites being dependent on the anodic treatment. With increasing time or potential of anodization in the passive region, the stability of the oxide at the defect sites increases and the oxide film becomes more perfect. Since the majority of the film is nondefective, the overall character of the film (*e.g.*, thickness, stoichiometry) does not vary substantially with anodic treatment and changes in the oxide at the defect areas would be difficult to observe. It may also be that small changes in the overall character of the oxide have a drastic influence on the number and/or stability of defect areas. The present results show that anodic holding at any V_a leads to a decrease of the subsequent transient charge (Fig. 6), *i.e.*, the processes occurring during potentiostatic holding and anodic charging through the transient region appear to be similar. Therefore, the defect model will now be used in an attempt to explain the anodic galvanostatic charging results.

When electropolished nickel is immersed in a *p*H 2.8 Na_2SO_4 solution with an anodic charging current of 80 μA cm^{-2}, the potential adopted by the electrode is determined by the number and stability of oxide defect sites, these being the areas where electrochemical reactions can occur and where the anodic charge can thus be consumed. The most probable mechanism for charge consumption is localized oxide breakdown (*e.g.*, $NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$) followed by inefficient film repair involving competition between $Ni \rightarrow Ni^{2+} + 2e$ and $Ni + H_2O \rightarrow NiO + 2H^+ + 2e$. The kinetics of breakdown and repair of the oxide will determine the extent of the nickel dissolution reaction. It is known that the 6-8Å NiO film on electropolished nickel is extremely defective, breaking down on open circuit in <90 sec in *p*H 2.8 Na_2SO_4 (4) and there

are thus many defect sites which will be breaking down (and repairing) upon immersion in the solution at 80 $\mu A\ cm^{-2}$. During anodization at 80 $\mu A\ cm^{-2}$, the perfection of this oxide film increases, *i.e.*, the number and/or stability of oxide defect sites changes so that fewer sites are breaking down and/or the sites are breaking down less frequently (16). The increase in potential throughout the transient region could therefore be due to a decrease in the effective active area, with corresponding increase in anodic overvoltage, as the film perfects. Although the effective active area decreases during the transient, the rate of change of V_a with Q_a does not change dramatically. Since dV_a/dQ_a is a measure of the rate of perfection of the oxide, the current efficiency for oxide perfection must decrease with increasing V_a. The fact that the 80 $\mu A\ cm^{-2}$ can be consumed by the reduced active area with no change in the rate of perfection means that the current efficiency for repair of the oxide must also decrease with increasing V_a and this can be related to more of the anodic current going towards nickel dissolution. There is probably some connection between repair and perfection of the oxide[2] so that their current efficiencies move hand in hand, *i.e.*, any decrease in the current efficiency for film repair probably results in a corresponding decrease in that for film perfection.

During galvanostatic oxidation, the rate of increase in film perfection (*i.e.*, dV_a/dQ_a) begins to diminish at *ca.* + 0.4V (Fig. 4). Eventually, a steady state of perfection is reached and a potential plateau results, the higher anodic potentials leading to rather high rates of nickel dissolution (Table I). This region is often referred to as the transpassive region of nickel dissolution (5, 7, 8, 18, 24, 25). It is known from previous work (4) that the stability of NiO films, potentiostatically formed for a constant t_a, towards open-circuit dissolution decreases with increasing anodic potential when $V_a > 0.4V$, *i.e.*, at approximately the same potential where the anodic transient begins to flatten out. This increase in breakdown susceptibility of the film at the higher anodic potentials may be associated with oxidation of Ni^{2+} to Ni^{3+} within the oxide, the occurrence of elements of the oxygen evolution reaction, or a change in the structure and epitaxy of the oxide film.

The lack of influence of solution *p*H on both the potential of immersion of electropolished nickel and the plateau potential (Fig. 4) is somewhat unexpected in terms of the present model. When electropolished nickel is immersed in a solution of higher *p*H, it is expected that the amount of effective active area should be less than with a more aggressive (*i.e.*, lower *p*H) solution and this should result in an increased anodic overvoltage for nickel dissolution. However, a surface intermediate such as $NiOH_{ads}$ may be playing a role in both nickel dissolution and oxide formation (6), in which case a change in solution *p*H will not only change the reversible potential of oxide formation and the rate of film breakdown but may also alter the kinetics of the nickel dissolution reaction. If the exchange current density for nickel dissolution increases with increasing *p*H, as has been suggested by other workers, this could compensate for the decrease in active area and leave the immersion potential almost constant. A similar explanation can be advanced for the lack of influence of *p*H on the plateau region at +0.7V. The influence of temperature in shifting the entire charging profile in the positive direction is quite dramatic (Fig. 4) and may be associated with a decrease in the rate of film breakdown and a corresponding increase in the anodic overvoltage for oxide formation and nickel dissolution.

[2] Repair occurs whenever the oxide film breaks down locally and reforms; perfection occurs when a repair event leads to an increase in the local film stability so that either the oxide is more resistant to breakdown or subsequent repair occurs more rapidly.

As was mentioned earlier, the increase in perfection of the oxide film can be associated with either an actual decrease in the number of active defect sites or an increase in the stability of the active sites without any great change in their total number. In either case, the effective active area decreases. It has been found that the nickel surface roughens in a general way when the potential is maintained in the plateau region or potentiostatically in the passive region for long periods of time. This observation suggests that there is not a small static number of active defect sites undergoing breakdown and repair since such a situation should give rise to heavy localized attack. It may thus be that the more appropriate model is one where the total number of defect sites does not change substantially during film perfection. However, the frequency of any particular site breaking down does decrease with increasing film perfection so that, during any particular time period, fewer sites are active the more perfect is the film. Over a long period of time, all of the defect sites originally present on the surface break down and thereby give rise to the general surface attack. It may also be that breakdown is a random process, in terms of where it will occur on the electrode surface, and that all surface sites are susceptible to breakdown at some point in time. The exact nature of the defective oxide areas and their relationship to the overall character of the film is still open to speculation.

The results obtained during the potentiostatic oxidation of nickel can also be interpreted in terms of the defect model of the oxide film. It appears that, after a potential step to 0 volts, the oxide film reaches an almost steady-state thickness within the first five seconds (Table II). However, it is known that the stability of the film towards open-circuit breakdown increases (and the i_a decreases) with increasing t_a over a period of several days (2, 4, 14-17). This can be interpreted in terms of a perfecting of the film with a corresponding decrease in the effective active defect area, the oxide film formed during the first 5 sec at 0 volts being extremely defective. The results indicate that this film is initially similar to the air-formed film on electropolished nickel, *i.e.*, very defective, and this explains previous observations that the open-circuit breakdown characteristics of the anodically formed oxide film is the same, independent of prior removal of the air-formed film. The i_a, which is a measure of the active defect area at any V_a, is dependent on V_a and t_a. When the potential is rapidly shifted to $-0.2V$, after a 1 hr anodization at 0 volts, the defect area associated with the anodization at 0 volts is initially frozen, *i.e.*, the defect state of the oxide does not change. As mentioned previously, it is known that oxide film stability increases with increasing potential of anodization (4) (in the passive region for a constant time), *i.e.*, the film formed at 0 volts is more stable than that formed at $-0.2V$. The decrease in i_a from 0.24 to 0.03 $\mu A\ cm^{-2}$, upon stepping the potential from 0 volts to $-0.2V$, is due to the influence of the lower V_a on the nickel dissolution reaction ($Ni \rightarrow Ni^{2+} + 2e$) the defect area of the oxide being initially constant at that established by the anodization at 0 volts. If the 1 hr anodization had been at $-0.2V$ from the start, the i_a would have been $>0.03\ \mu A\ cm^{-2}$ since the defect area of the oxide would have been higher, *i.e.*, V_a controls both the rate of stabilization (and therefore the defect area) of the film as well as the rate of anodic reactions at the defect sites. The proposal that most of the long-term i_a is not directly accounted for by chemical dissolution of the oxide is supported by the substantial decrease in i_a upon stepping the potential from 0 volts to $-0.2V$. The 0.21 $\mu A\ cm^{-2}$ difference in current would be equivalent to a thinning rate of 8Å of NiO hr^{-1} and since the oxide is only 10Å thick and the i_a at $-0.2V$ continues to

increase for up to 10 hr after the potential step, the majority of the anodic current cannot simply be due to $NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$. Very inefficient film repair is the most probable explanation with most of the measured i_a associated with nickel dissolution. The extremely slow increase of i_a with t_a at $-0.2V$ is probably due to slow, local dissolution of the film formed at 0 volts with replacement by the less stable film now being formed at $-0.2V$.

Summary

1. The current efficiency for oxide film formation during galvanostatic oxidation of preanodized nickel electrodes is less than 20%. The majority of the change is associated with nickel dissolution.

2. The low current efficiency for oxide growth is mainly due to nickel dissolution, $Ni \rightarrow Ni^{2+} + 2e$, during inefficient film repair, $Ni + H_2O \rightarrow NiO + 2H^+ + 2e$, after film breakdown, $NiO + 2H^+ \rightarrow Ni^{2+} + H_2O$. Chemical dissolution of the oxide cannot, by itself, explain the results.

3. The results are consistent with a model in which defects in the oxide film are perfected by both increased potential and time of anodization up to $\approx 0.4V$. At a constant changing current, the potential increases with increasing state of the film perfection since the effective breakdown area is decreasing.

4. The majority of the long-term anodic current observed during constant potential polarization is due to inefficient film repair, the potential controlling both the rate of $Ni \rightarrow Ni^{2+} + 2e$ and the rate of change of film perfection.

Acknowledgment

The author wishes to thank Dr. D. F. Mitchell for the x-ray measurements of NiO thicknesses, Mr. A. Desaulniers for the A.A. analysis of Ni^{2+}, and Drs. M. J. Graham and M. Cohen for helpful discussions and suggestions.

Noncatalytic Electrodes for Solid-Electrolyte Oxygen Sensors

David M. Haaland

Sandia Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

The catalytic effects of various electrode materials on nonequilibrium oxygen measurements using solid-electrolyte oxygen sensors have been investigated. Catalytically active electrodes can perturb the measurement of oxygen in nonequilibrium mixtures of oxygen and combustible gases. This paper reports the development of noncatalytic electrodes for accurate measurement of the free oxygen content in nonequilibrium gas mixtures containing O_2 and CH_4, C_3H_6, CO, or H_2. The effects of Pt, Au, Ag, Ag deposited on Pt, and S- or Pb-poisoned Pt electrodes on the measurement of oxygen in nonequilibrium gas mixtures were determined. These studies were made using solid-electrolyte oxygen sensors of a new internal-reference design as well as with traditional air-reference sensors. Pt electrodes are catalytic in all of the gas mixtures studied. Both Ag electrodes and Ag vapor deposited on Pt were found to be noncatalytic to CH_4 oxidation while Au electrodes were only slightly catalytic. Pt electrodes poisoned by S introduced as H_2S were also noncatalytic to CH_4 oxidation until the sulfur desorbed at ~800°C. The above electrodes were sufficiently catalytic to CO oxidation that they could not be used for quantitative nonequilibrium oxygen measurements when CO is present. Pt electrodes poisoned by Pb (introduced as PbS) produced the least perturbation of the nonequilibrium mixtures of oxygen with CH_4, C_3H_6, CO, or H_2. The Pb-poisoned Pt electrodes allow quantitative measurement of the bulk nonequilibrium oxygen concentrations at temperatures above 500°-550°C, depending on the combustible gas present. At lower temperatures, even the Pb-poisoned electrodes are catalytic. This suggests that Pb may poison the platinum activity by decreasing the heat of adsorption of adsorbed reaction species. Sulfur- or Pb-poisoned Pt or Pt with a thin layer (<200Å) of Ag had no adverse effect on the electrochemical O_2 pumping capabilities of Pt. Ag and Au electrodes performed poorly as electrochemical O_2 pump electrodes. The capability of solid-electrolyte oxygen sensors to measure the partial pressure of gas phase oxygen at the electrode surface was used to investigate the catalytic reaction mechanism of CO oxidation on Pt electrodes partially poisoned by Pb. The results are best fit by an Eley-Rideal mechanism where adsorbed O_2 reacts with gas phase CO. However, the data are not sufficiently definitive to rule out the Langmuir-Hinshelwood mechanism where adsorbed O and CO react on the surface. The methods used demonstrate that solid-electrolyte oxygen sensors can be useful experimental tools for identifying catalytic mechanisms.

Solid-electrolyte oxygen sensors have been used in a variety of applications for over two decades (1, 2). Almost all applications have either involved the monitoring of oxygen in inert environments or the measurement of equilibrium oxygen in reactive environments. For these purposes, platinum is the electrode material of choice due to its excellent oxygen electrode capabilities (*e.g.*, low polarization) as well as its high catalytic activity for driving oxidation reactions to equilibrium. In applications such as oxygen monitoring of automobile exhaust, any degradation of the platinum electrode catalytic activity is severely detrimental to the desired equilibrium measurement since oxygen is often present in thermodynamic nonequilibrium with reactive gases (3). However, in those applications where nonequilibrium oxygen content in the presence of combustible gases is the desired quantity to be measured, platinum electrodes are not appropriate. Noncatalytic electrodes for solid-electrolyte oxygen sensors would be necessary in these cases [*e.g.*, oxygen monitoring during air-fired *in situ* oil shale retorting (4) or coal gasification, control of air-fired furnaces for decreased pollution and maximized efficiency, or monitoring the presence of combustible gases (5)]. Reduction or elimination of the catalytic activity of the electrodes must be accomplished without diminishing the characteristics of electrodes which allow them to perform as good oxygen electrodes. Both nonplatinum electrode materials and poisoned platinum were tested for the purpose of making nonequilibrium oxygen measurements, and the results are presented in this paper.

Key words: oxygen sensors, noncatalytic electrodes, catalytic mechanisms, catalyst poisons.

Much of the data were collected with a new design of solid-electrolyte oxygen sensor which was developed for our primary application of *in situ* oil shale retorting. This sensor, which has been described elsewhere (4, 6), does not use a flowing gas reference or a fixed metal/metal oxide buffer reference. Rather, it uses electrochemical transfer of oxygen in and out of the internal volume of the sensor as a technique to generate its own internal reference. This self-contained sensor is ideal for remote oxygen sensing at temperatures too low for rapid equilibration of the normal internal metal/metal oxide references.

Some of the less catalytic oxygen electrodes were investigated in greater detail, and experiments were designed to elucidate the reaction mechanisms occurring on these electrodes. These experiments demonstrate the potential power of using solid-electrolyte oxygen sensors for investigating catalytic reaction mechanisms and determining the role poisons play in reducing catalytic activity.

Experimental Procedures

Initial studies were conducted using air-reference solid-electrolyte oxygen sensors of various electrolyte compositions. These were constructed of tubes of sta-

bilized zirconia closed on one end with a flowing air reference inside and platinum paste electrodes on the end tip of the tube [see Ref. (2) for a general description of these sensors]. However, in order to reach the constant temperature zone of the furnace, the tubes were required to be 50 cm long. At temperatures above ~600°C, the thermal gradients in the furnace beyond the constant temperature zone resulted in repeated fracture of the tubes of the high conductivity stabilized zirconias [*i.e.*, $(ZrO_2)_{0.90} \cdot (Y_2O_3)_{0.10}$ or $(ZrO_2)_{0.85} \cdot (CaO)_{0.15}$]. The thermal shock resistant electrolyte materials of $(ZrO_2)_{0.95} \cdot (Y_2O_3)_{0.05}$ had too high an impedance to be fully useful at the lower temperatures investigated.

Because of the problem outlined above, much of this work was completed using solid-electrolyte oxygen sensors of a design which has been described in detail elsewhere (4, 6). These oxygen sensors are composed of two independent electrochemical oxygen concentration cells separated by a ring of stabilized zirconia (see Fig. 1). The sealed internal volume serves as a fixed volume in forming an internal reference. Each cell is a thin disk of stabilized zirconia to which porous electrodes have been applied. One cell is an electrochemical pumping cell (Faraday cell) used to quantitatively pump oxygen into or out of the internal volume of the sensor. This oxygen transport is accomplished with an applied potential of the appropriate magnitude and polarity (generally 0.1V). The integrated pumping current is used to calculate the amount of oxygen transported (4 electrons/molecule of O_2). The second zirconia disk is used directly as an oxygen monitoring cell to measure the ratio of oxygen partial pressures inside and outside the sensor. The potential (E) developed across the cell is related to these partial pressures through the Nernst equation

$$E = \frac{RT}{4\mathbf{F}} \ln\left(\frac{P_{O_2}''}{P_{O_2}'}\right) \quad [1]$$

where P_{O_2}'' and P_{O_2}' are the partial pressures of oxygen outside and inside the sensor, respectively, R is the ideal gas constant, **F** the Faraday constant, and T is the temperature in Kelvins. The absolute oxygen partial pressure outside the cell is determined in the following manner. First, oxygen is electrochemically pumped out of the sealed internal volume of the sensor in order to provide a zero point reference. Oxygen from the surrounding gas is then electrochemically pumped back into the sensor by reversing the applied potential. Oxygen pumping is continued until the potential of the monitoring cell is zero (*i.e.*, partial pressures of O_2 inside and outside the sensor are equal). The integrated current (*i.e.*, moles of oxygen, n_{O_2}) required to achieve this condition is used along with the known internal volume (V) and the measured temperature to calculate the oxygen partial pressure (P_{O_2}) by application of the ideal gas law

$$P_{O_2} = \frac{n_{O_2}RT}{V} \quad [2]$$

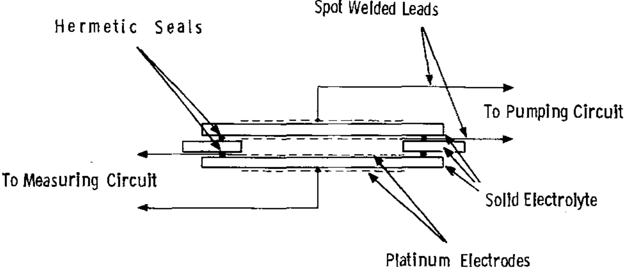

Fig. 1. Schematic diagram of the internal-reference solid-electrolyte oxygen sensor.

(For the temperatures and pressures used in this study, the accuracy of Eq. [2] is better than 1%.) In this manner, the need for a fixed or external reference is eliminated. The fraction of O_2 in the gas being monitored can be calculated if the total gas pressure is known. If there are no leaks or diffusion of oxygen into or out of the sensor, then once the pumping procedure is performed changes in external oxygen content can be continuously monitored by determining the potential of the measuring cell. $(ZrO_2)_{0.90} \cdot (Y_2O_3)_{0.10}$ was the solid electrolyte used because of its high ionic conductivity (*i.e.*, low temperature of operation). This material suffers poor thermal shock resistance, but the small size of the internal-reference sensor makes this property unimportant in these experiments since the sensor sees only a small temperature gradient.

For the most part, the sensor parts were sealed together with a glass-ceramic material which formed hermetic seals up to ~950°C (4). A few sensors, however, were prepared with zirconia-metal thermal compression seals (4). Electrodes were primarily prepared by air-firing metal pastes, although other preparation methods were used in specific cases which are detailed later. Electrode materials used included platinum, silver, gold, and poisoned platinum.

The experiments were performed within a 4 cm ID quartz tube located inside a two-zone Lindberg furnace. Ultrahigh purity Matheson nitrogen (99.999%) along with dry air, CH_4, CO, C_3H_6, and H_2 were metered through calibrated Matheson flow tubes to form gas mixtures of various compositions. The accuracy and repeatability of the flow tubes were generally found to be ~±5%. The normal total flow rate was 2500 standard cubic centimeters per minute (sccm) corresponding to a gas velocity of 200 cm/min. This is a typical value of the gas flows encountered in oil shale retorting applications. Input oxygen concentrations were of the order of 0.5% corresponding to the nonequilibrium oxygen content often encountered in a number of applications.

Catalytic mechanisms for the oxidation of CO on poisoned platinum electrodes were investigated and required a number of gas composition measurements. The partial pressure of oxygen gas at the surface of the electrode was measured by the internal-reference oxygen sensor while bulk gas phase oxygen concentrations were obtained with the use of a Taylor Servomex OA-137 paramagnetic oxygen analyzer. Since the paramagnetic oxygen analyzer examined the exhaust gases from the furnace, the possibility of continued homogeneous gas phase reaction beyond the location of the sensor existed in a few cases. This reaction, however, was found to be small except at temperatures above 700°C, and these cases will be noted. CO concentrations were determined from calibrated flow tube settings (using an individually calibrated flow tube with ±1% accuracy).

In addition, air-reference solid-electrolyte oxygen sensors with platinum paste electrodes were often used to simultaneously monitor catalyzed oxygen concentrations. Noticeable contamination of these electrodes by vaporization of nonplatinum electrodes or transport of the poison from the poisoned platinum electrodes was observed. Thus the oxygen partial pressures determined by this method are only upper bounds for the oxygen which would be measured by pure, catalytic platinum electrodes. However, the results do give an indication of the extent of catalytic reaction with platinum electrodes. The necessary use of thermal shock resistant $(ZrO_2)_{0.95} \cdot (Y_2O_3)_{0.05}$ in these air-reference sensors limited data to ≥600°C for oxygen contents of >0.1%.

Results

Platinum electrodes.—As many as four combustible gases were studied separately in the presence of oxygen. These included methane (CH_4), propene (C_3H_6),

carbon monoxide (CO), and hydrogen (H_2). CH_4 and CO were used to screen the catalytic activity of the various electrode materials. Only the platinum and Pt/Pb electrodes were studied in all four gases.

The ease of homogeneous reaction of combustible gases with oxygen, as well as ease of heterogeneous catalytic reactivity, was found to increase in the order given above. This is illustrated in Table I for a 50% stoichiometric excess of each gas in the presence of oxygen and nitrogen. These data were obtained with platinum paste electrodes on an air-reference solid-electrolyte oxygen sensor at a temperature of 700°C and a flow rate of 200 cm/min. The amount of oxygen introduced into the furnace in each case was ~0.5%. At slower flow rates or under stagnant conditions, the results more closely approach equilibrium oxygen values. The results do, however, illustrate qualitatively the relative extent of catalytic reaction on the platinum electrodes at these flow rates. Thus platinum electrodes are not useful for nonequilibrium oxygen measurements.

Silver electrodes.—Except at stagnant flow conditions, silver electrodes exhibit essentially no catalytic activity to CH_4 oxidation. Sandler has reported similar results for silver electrodes and has demonstrated that this property of silver electrodes makes possible a methane sensor when used in conjunction with a catalytic platinum electrode oxygen sensor (5, 7). A direct comparison of the oxygen levels measured by both silver and platinum paste electrodes on air-reference solid-electrolyte oxygen sensors is given in Table II at different temperatures for a large stoichiometric excess of methane. The same lack of reaction on the silver electrode surface was found over a wide range of flow rates and variations in oxygen and methane concentrations in the N_2 diluent. (The actual flow rates and concentration ranges investigated in this study were 2500-250 sccm, oxygen concentrations from 0.5 to 5%, and CH_4 concentrations from 0 to 10%.) The apparent decrease in catalytic activity with the platinum electrodes at higher temperatures is discussed later.

Unfortunately, the catalytic activity of silver electrodes to CO oxidation, although reduced from that of platinum, is still too high even for qualitative oxygen measurements. For example, a 0.5% oxygen level in the presence of a stoichiometric excess of CO resulted in an oxygen content at the silver electrode of 4×10^{-3}% compared with 1×10^{-5}% with platinum electrodes under the same conditions. In addition, the high solubility of oxygen in silver (8) can create some further complications, *e.g.*, the large hysteresis effects found in the current-voltage curves of these electrodes (4). In the present study, the problem with oxygen solubility was evident during the use of internal-reference oxygen sensors prepared with silver paste electrodes. The high oxygen solubility in silver resulted in a very slow release of oxygen from the inner pump electrode. This caused extreme overshoot errors in oxygen monitoring which rendered this silver-electrode internal-reference sensor useless.

Electrodes of silver vapor deposited on platinum.—An excellent oxygen pumping electrode that was noncatalytic to CH_4 oxidation was prepared by vapor deposition of a thin layer of Ag over a platinum electrode. The silver appeared to remain primarily on the surface as might be expected from the predicted strong Ag surface segregation of Pt-Ag alloys at high temperature (9). The layer of silver was adequate to eliminate catalytic surface reaction with CH_4 yet was sufficiently thin to prevent the problems associated with oxygen solubility in the Ag. It was found that the Ag layer on platinum could be formed by the construction of the internal-reference sensor with a silver-zirconia thermal compression seal (4), *i.e.*, the preparation of the seal resulted in a silver vapor deposit on the platinum electrodes. The silver layer was found to be <200Å as determined by Auger and sputter analyses. A sensor with this silver seal kept its noncatalytic silver layer even at prolonged periods of operation at 700° and 800°C. The results from this sensor closely paralleled those of an air-reference oxygen sensor with pure silver electrodes in that it was inactive to CH_4 oxidation but exhibited reduced (compared to pure Pt electrodes) but still significant catalytic activity to CO oxidation.

Gold electrodes.—Gold paste electrodes were investigated since oxygen is neither soluble in nor adsorbed on gold (10), and gold is less catalytic to oxidation reactions than Pt (11). Although significantly less reactive than platinum, gold electrodes were found to be slightly more catalytic than silver electrodes. The results of side-by-side air-reference solid-electrolyte oxygen sensors of $(ZrO_2)_{0.90}\cdot(Y_2O_3)_{0.10}$ with silver and gold electrodes are compared in Table III. Assuming no catalytic activity to methane oxidation with silver electrode, the percent of methane oxidation on gold is calculated and shown in the final column of the table. The low value for oxygen measured by the Au electrode sensor at 500°C is probably due to the poor oxygen electrode properties of gold at low temperatures since the measurement of O_2 and N_2 mixtures also resulted in low oxygen values at 500°C As with the electrodes previously examined, gold electrodes catalyzed the reaction of CO and oxygen. In addition, it

850	2.04	0.49	76

* CH_4 concentration was held constant at 7% during these experiments. Input oxygen concentrations were the same as measured by the Ag electrode sensor to within experimental error.

was found that gold performed poorly as an electrochemical oxygen pump electrode below 700°C. The oxygen pump rate below 700°C was so slow as to render the internal-reference solid-electrolyte oxygen sensors inoperative below this temperature when gold electrodes were used.

H_2S-poisoned platinum electrodes.—The success of Ag and Au electrodes for use in the measurement of nonequilibrium oxygen concentrations was limited primarily to CH_4-containing gas mixtures. Available nonmetal electrode materials have been found generally useful for oxygen sensor applications only at temperatures exceeding those for which nonequilibrium oxygen gas mixtures are found to exist (12). Therefore, effort was concentrated on poisoning the catalytic activity of platinum electrodes while retaining their excellent oxygen electrode capabilities. Since those properties which make platinum a good catalyst are often properties which make good oxygen electrodes (*e.g.*, adsorption and/or dissociation of oxygen), the use of catalytic poisons on oxygen sensor electrodes was expected to be of marginal success. This was not the case and may aid in defining the role platinum plays in both catalytic and oxygen sensor applications.

Sulfur is known to be an efficient poison of Pt catalytic activity (13, 14) and was introduced onto the electrode surface in the form of H_2S. Recent Auger and low energy electron diffraction studies on H_2S-poisoned Pt show that H_2S dissociates on Pt leaving only adsorbed elemental sulfur poison (13). In this study, the electrodes were found to be effectively poisoned to CH_4 oxidation after the addition of ~0.5% H_2S to the flowing gas mixture for several minutes at 600°C. The sensor was then capable of accurately monitoring oxygen content in a nonequilibrium mixture of oxygen and methane. Poisoning with sulfur caused no reduction in the efficiency of electrochemical oxygen pumping. The poisoning effects of the sulfur were found to continue at 700°C. Even with air flowing over the electrodes for 24 hr the poisoning persisted. However, after treatment of the catalyst at 800°C, the catalytic activity of the platinum was restored for all reaction temperatures. This is probably due to rapid desorption of sulfur and is consistent with results obtained on sulfur poisoning of platinum-based catalytic converters used for automobile emission control (15). Further studies showed these H_2S-poisoned electrodes to be relatively ineffective in reducing the catalytic activity of platinum to CO oxidation. This along with the rapid desorption of sulfur at 800°C limits the usefulness of H_2S-poisoned sensors for many applications.

Pb-poisoned Pt electrodes.—A recent patent by Takao *et al.* (16) has suggested that lead sulfide (PbS) can be used as a catalytic poison for Pt electrodes, but the limited results presented indicated that PbS/Pt electrodes were more catalytic than gold electrodes. However, since no detailed results were presented by Takao *et al.*, these electrodes were investigated further. Platinum electrodes containing 1 and 50 weight percent PbS were prepared by adding −400 mesh PbS powder to the du Pont 7919 platinum paste. This mixture was applied over a ~1.5 μm layer of sputtered platinum and fired in air at 700°C for several hours. These electrodes exhibited oxygen pumping capabilities which were similar to those of sputtered platinum electrodes. Since sputtered platinum has been found not to exhibit polarization characteristics at the temperatures employed here (6, 17), the PbS does not appear to introduce any new polarization which would reduce oxygen pumping rates. The air-fired electrodes were initially catalytic until they were reduced in a flowing mixture of 2% CO in N_2 at 700°C. The resulting electrodes from 50% PbS were quite effectively poisoned whether in oxidizing or reducing environments. The electrodes containing 1% PbS were not sufficiently poisoned for quantitative work.

The 700°C air firing results in lead oxide formation (18) while the reduction step with CO should cause the formation of elemental lead. Lead oxide is insoluble in platinum (19) and the physical mixture of PbO and Pt has no significant effect on the catalytic activity of Pt. However, the lead formed during the reduction rapidly forms an alloy with the Pt (20) which is apparently relatively inactive. Oxidizing environments may cause the formation of insoluble PbO on the Pt/Pb electrode surface but PbO is also noncatalytic (19).

Oxygen measurements using poisoned Pt/Pb electrode sensors of the internal-reference type were compared with measurements obtained using catalytic platinum electrode air-reference sensors and with data from the paramagnetic oxygen analyzer. These results are presented in Tables IV-VIII. In those cases where reactive gases were present, the combustible gas was added with at least a 50% stoichiometric excess. Differences between the platinum electrode sensor and the poisoned electrode sensors indicate how effectively the catalytic activity of the electrode has been reduced by the lead. However, the presence of the poisoned electrodes in the vicinity of the pure Pt electrodes did result in reduced Pt activity probably due to a transfer of either Pb or S to the platinum. This is especially noticeable with the CH_4 mixture since only a small degree of contamination is effective in poisoning this reaction. The monitoring of the free oxygen content of exit gases with the paramagnetic oxygen analyzer was necessary to distinguish between the occurrence of catalytic surface reaction and gas phase reaction caused simply by thermal excitation. The percent difference column in each table is the percent difference between the poisoned electrode sensor results and those of the paramagnetic oxygen analyzer which was used as the reference.

Table IV shows the results of tests with ~0.5% oxygen in flowing nitrogen, *i.e.*, no combustible gas present. At temperatures of ~600°C and lower, the low ionic conductivity of the air-reference sensor causes it to respond extremely slowly at these relatively high oxygen concentrations, and equilibrium is not achieved during the measurement period. Although electrode polarization of the Pt paste electrodes may contribute to the slow equilibration experienced at these low temperatures, the fact that sensors made from high conductivity $(ZrO_2)_{0.90} \cdot (Y_2O_3)_{0.10}$ did not experience these problems until temperatures below 500°C indicates that ionic conductivity limitations are the dominant factor. Unfortunately, high conductivity $(ZrO_2)_{0.90} \cdot (Y_2O_3)_{0.10}$ did not survive the thermal gradients in the furnace and could not be used on a routine basis. The data in Table IV show good agreement between the poisoned electrode sensor and the paramagnetic analyzer.

Table V shows data obtained in mixtures of oxygen and nitrogen containing a stoichiometric excess of CH_4. Again the air-reference sensor results below 700°C

Table IV. Oxygen analyses in oxygen and nitrogen gas mixtures

‡ Results from earlier experiments with clean platinum electrode oxygen sensors.

were in error due to the high resistivity of these cells. Note that the close proximity of the PbS-poisoned electrode to the platinum electrode has introduced some poisoning into the platinum. This is confirmed by the data for platinum electrode sensors in the absence of PbS (see results in parentheses in Table V) which show the significant catalytic activity of pure platinum electrodes. The most important point to note in Table V is the lack of catalytic activity obtained with the Pt/Pb electrodes. The oxygen concentration at the electrode surface is in excellent agreement with the bulk gas phase oxygen concentration measured by the paramagnetic oxygen analyzer.

Table VI presents results for a stoichiometric excess of C_3H_6 in oxygen and nitrogen mixtures. C_3H_6 has been used previously as a molecule which most closely represents the average oxidation characteristics of combustible hydrocarbon molecules for predicting the behavior of catalysts in automotive catalytic converters (21). The gases are beginning to react spontaneously in the gas phase at 800°C. Agreement between the bulk oxygen content and the O_2 sensor results is good except at 500°C. At this temperature, there is surface reaction even on this poisoned electrode. This is observed even more dramatically for CO and H_2 oxidation. Thus at lower temperatures, reactants (O_2 and/or CO) still adsorb on the poisoned electrode surface and react, while at the higher temperatures the amounts of adsorbed reactants are small and, therefore, surface reaction is minimal. The net result is that catalytic efficiency on the poisoned electrode goes through a maximum at some temperature below 600°C. Decreased adsorption and reaction as temperatures increase is also seen with the pure platinum electrode results in Table II. Catalytic activity actually appears to decrease slightly with these electrodes as the temperature increases.

Table VI. Oxygen analyses in oxygen, nitrogen, and propene (C_3H_6) gas mixtures

Table VII gives similar results for a stoichiometric excess of CO in oxygen and nitrogen mixtures. Here the platinum electrode sensor shows extensive catalytic action at all temperatures. Full interpretation of the data in Table VII required some careful gas analyses by the paramagnetic oxygen analyzer over a continuous range of temperatures. At the flow rates of this experiment, it was found that CO and O_2 start to react spontaneously in the gas phase at ~700°C and reaction is nearly complete above 800°C. Therefore, the Pt/Pb electrode sensor results are higher than the paramagnetic analyzer results at 800°C because of the different measurement locations. The sensor is measuring the oxygen concentration at its location in the furnace while the paramagnetic analyzer is measuring oxygen contents of the gases after they exhaust the furnace. At 800°C, there is continued reaction in the gas phase in the high temperature zone beyond the location of the oxygen sensor. At 500°C, catalytic surface reaction is becoming significant.

Finally, Table VIII shows results for a stoichiometric excess of hydrogen in oxygen and nitrogen mixtures. Since homogeneous gas phase reaction was significant even at 600°C with 200 cm/min flow rate, flows were increased ~50% to reduce the extent of reaction for meaningful results to be obtained. At the flow rate used here, there is little gas phase reaction at 500° and 600°C while the reaction is nearly complete at 700°C. At 600°C, there is some reaction at the electrode but semiquantitative results are possible. This is in contrast to the platinum electrode sensor which records nearly equilibrium oxygen values. As in the case of CO and C_3H_6, reaction on the Pt/Pb electrode surface again becomes significant at the lower 500°C temperature. It should be noted that both the catalytic surface reaction at low temperatures and the homogeneous gas phase reaction at high temperatures observed in Table VI-VIII were independent of whether each temperature was approached from initially high or low temperatures. Although the data presented in these tables were obtained after equilibration at each temperature,

similar results were obtained during temperature ramping at 10°C/min.

Reaction mechanism studies using solid-electrolyte oxygen sensors.—Solid-electrolyte oxygen sensors are a valuable tool for the catalytic chemist since they allow the measurement of the partial pressure of oxygen at the surface of catalytic electrodes during catalytic oxidation. This can be accomplished at high temperature and pressure, and kinetic studies can be performed even under mass transport controlled conditions. Already oxygen sensors have been used in studying the oscillation reactions encountered during CO oxidation on platinum (22). In this study, they are used as an aid in examining the reaction mechanisms of CO oxidation on partially poisoned platinum electrodes.

The mechanisms of the catalytic oxidation of combustible gases in general and CO in particular have been investigated and reported numerous times [*e.g.*, see Ref. (15, 21)]. The primary mechanisms for CO oxidation on metallic catalyst surfaces include: (*i*) the Langmuir-Hinshelwood mechanism where both CO and oxygen adsorb on the surface before reacting and (*ii*) the Eley-Rideal mechanism where CO in the gas phase reacts with oxygen adsorbed on the surface. Both reaction mechanisms have been found to be operative at low pressure; the dominant one depending on the initial experimental surface conditions (23). We will show that it is possible to use solid-electrolyte oxygen sensors to identify catalytic mechanisms of oxidation reactions on reactive surfaces, especially if flow rates are sufficiently high to reduce the extent of reaction or if the catalytic rate is relatively slow. The latter is the case with the poisoned platinum electrodes used in this study.

The oxygen content of a flowing mixture of O_2, CO, and nitrogen over an isothermal electrode surface at high temperature was monitored by several methods during these experiments. An internal-reference solid-electrolyte oxygen sensor which was not completely poisoned by the PbS treatment was used to measure directly the partial pressure of gas phase oxygen at the surface of the partially catalytic electrode. It should be noted, however, that all Pt/Pb electrodes exhibited some surface reaction with a large stoichiometric excess of CO or H_2. The bulk gas phase composition of the oxygen away from the sensor electrodes was monitored by the paramagnetic oxygen analyzer. Finally the CO content at the surface of the electrode was determined from the input CO concentration and the extent of surface reaction as detailed later in the report. This information, if sufficiently accurate, is adequate to distinguish between reaction mechanisms if relative concentrations of the reactants are varied.

Under the experimental conditions studied, the reactants CO and O_2 are dilute relative to the nitrogen carrier gas, and it can be assumed that the reaction has no effect on the physical properties of the mixture. Also, the extent of reaction is kept relatively small, and therefore the temperatures are constant and the concentration of gases at the electrode surface are approximately constant over the area of the electrode. Under these conditions and at steady state, the consumption of oxygen at the electrode surface must be equal to the flux of oxygen to the surface by mass transport (convection and diffusion). Since the concentration of the reactants differ significantly from the bulk values only in a thin region near the electrode surface and the convection velocity is small in this region, we assume that diffusion is the important transport process. The diffusion of oxygen from the bulk gas phase to the surface at steady state is given by

$$J_{O_2} = -\frac{D}{RT}\frac{dP_{O_2}}{dx} \qquad [3]$$

where J_{O_2} is the molar flux of oxygen per unit time and area, D is the diffusion coefficient for O_2 diffusing through the gas, R is the gas constant, and T the absolute temperature. The time rate of change of oxygen concentration per unit area (r_{O_2}) due to reaction at the surface of the electrode is given by

$$r_{O_2} = \left(\frac{dn_{O_2}}{dt}\right) \Big/ A \qquad [4]$$

The form of r_{O_2} depends on the detailed surface reaction mechanism for O_2 reacting with CO. At steady state where the rate of reaction is balanced by the flux due to diffusion, we have

$$r_{O_2} + J_{O_2} = 0$$

or

$$r_{O_2} = \frac{D}{RT}\frac{dP_{O_2}}{dx} \qquad [5]$$

In order to distinguish between Langmuir-Hinshelwood and Eley-Rideal reaction mechanisms for the experimental conditions chosen, it is required to investigate the detailed reaction mechanism of each and determine the corresponding overall rate laws. The reaction mechanism which best describes the wide range of data presented by Sklyarov *et al.* (24), Bonzel and Ku (25), and others (26, 27) is the Eley-Rideal mechanism. They assume that the rate of dissociation of adsorbed O_2 is negligible compared to its reaction rate with CO. The reactions they consider include the following (σ = adsorption site)

$$O_2 + \sigma \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [O_2]_{ad}$$

$$CO + \sigma \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} CO_{ad}$$

$$[O_2]_{ad} + CO \xrightarrow{k_4} CO_2 + O_{ad}$$

$$O_{ad} + CO \xrightarrow{k_5} CO_2 + \sigma$$

Thus the reaction takes place between gas phase CO and both adsorbed molecular and atomic oxygen. The rate of CO_2 formation at steady state is given by Sklyarov *et al.* by

$$r_{CO_2} = -2r_{O_2} = 2k_4K_1P_{O_2}P_{CO}\left[1 + K_1\left(1 + \frac{k_4}{k_5}\right)P_{O_2} + \left(K_2 + \frac{k_4}{k_{-1}}\right)P_{CO} + K_2\frac{k_4}{k_{-1}}P_{CO}^2\right]^{-1} \qquad [6]$$

where K_1 and K_2 are the equilibrium constants for the first two reactions ($K_1 = k_1/k_{-1}$, $K_2 = k_2/k_{-2}$). Bonzel and Ku as well as Sklyarov *et al.* show that this expression fits their data over a wide range of temperatures and partial pressures of O_2 and CO. As described by Bonzel and Ku, Eq. [6] reduces to

$$r_{O_2} = -k_4K_1P_{CO}P_{O_2} \qquad [7]$$

at high temperatures (*i.e.*, where K_1 and K_2 are very small or alternatively the fractional surface coverages of adsorbed species are small compared to unity). These are reasonable assumptions at 700°C as indicated by lower temperature infrared data (28) and thermal desorption experiments (29, 30). It should be noted that the partial pressures P_{CO} and P_{O_2} in Eq. [7] are the partial pressures of the gases at the surface of the electrode [P_i(surf.)]. At steady state P_{O_2}(surf.) and P_{CO}(surf.) are constant and different from the bulk partial pressures [P_i (bulk)]. Therefore Eq. [7] becomes

$$r_{O_2} = -k_4K_1P_{CO}(\text{surf.})P_{O_2}(\text{surf.}) \qquad [8]$$

P_{O_2}(surf.) is reasonably assumed to be the partial pressure of O_2 measured by the oxygen sensors.

P_{CO}(surf.) is determined from the known input partial pressure of CO minus the amount reacted as calculated by the difference of the bulk and surface O_2 partial pressures, *i.e.*

$$P_{CO}(\text{surf.}) = P_{CO}(\text{bulk}) - 2[P_{O_2}(\text{bulk}) - P_{O_2}(\text{surf.})] \quad [9]$$

Substituting Eq. [8] into Eq. [5] yields

$$-k_4K_1P_{CO}(\text{surf.})P_{O_2}(\text{surf.}) = \frac{D}{RT}\frac{dP_{O_2}}{dx} \quad [10]$$

Separating variables and integrating yields

$$P_{CO}(\text{surf.}) = \frac{D}{k_4K_1\delta RT}\left[\frac{P_{O_2}(\text{bulk}) - P_{O_2}(\text{surf.})}{P_{O_2}(\text{surf.})}\right] \quad [11]$$

where δ is the thickness of the diffusion layer. Thus a plot of P_{CO}(surf.) *vs.* $[P_{O_2}(\text{bulk}) - P_{O_2}(\text{surf.})]/P_{O_2}(\text{surf.})$ should be linear if the above Eley-Rideal mechanism holds for our partially poisoned electrodes.

The Langmuir-Hinshelwood mechanism assumes the primary reaction mechanism is between adsorbed oxygen atoms and adsorbed CO (15, 21, 23, 31). Under these conditions, the reactions to be considered are

$$CO + \sigma \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} CO_{ad}$$

$$O_2 + 2\sigma \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} 2\,O_{ad}$$

$$CO_{ad} + O_{ad} \xrightarrow{k_7} CO_2 + 2\sigma$$

Assuming again low coverage of surface species at high temperatures (700°C) and the equilibration of reactions [2] and [3], the following high temperature Langmuir-Hinshelwood rate law is obtained

$$r_{O_2} = -k_7K_2K_3^{1/2}\,P_{CO}(\text{surf.})\,[P_{O_2}(\text{surf.})]^{1/2} \quad [12]$$

The linear dependence on CO partial pressure in Eq. [8] and [12] is a result of low surface coverage at high temperatures. This is in contrast to the inverse dependence on CO partial pressure observed by others at low temperatures (23-26) due to inhibition effects at high CO surface coverages. At steady state under diffusion-controlled conditions, the rate law for Langmuir-Hinshelwood kinetics from Eq. [12] takes the form

$$P_{CO}(\text{surf.}) = \frac{D}{k_7K_2K_3^{1/2}\delta RT}\left[\frac{P_{O_2}(\text{bulk}) - P_{O_2}(\text{surf.})}{[P_{O_2}(\text{surf.})]^{1/2}}\right] \quad [13]$$

A plot of P_{CO}(surf.) *vs.* the quantity in brackets in Eq. [13] will therefore be linear if this reaction mechanism is operative.

Plots in the form of Eq. [11] and Eq. [13] are presented in Fig. 2 and 3, respectively, for data taken at 700°C with Pt/Pb electrode sensors. A linear least squares fit of the data shows a better fit to the Eley-Rideal mechanism (the coefficient of determination for the Eley-Rideal mechanism is 0.999 while that for the Langmuir-Hinshelwood plot is 0.991). In addition, the least squares Eley-Rideal plot intersects the origin while that of the Langmuir-Hinshelwood intersects above the origin and the latter data show a slight systematic curvature about the least squares fit. However, while a better fit to the data is obtained for the Eley-Rideal mechanism, the data are not significantly accurate to exclude the Langmuir-Hinshelwood mechanism as indicated by the error bars in Fig. 2 and 3. More precise monitoring of the bulk CO and O_2 partial pressures would be required to definitely distinguish between these two mechanisms with such similar rate laws. Of course, if both reaction mechanisms are operative, then the rate law would be of an intermediate form between Eq. [11] and [13].

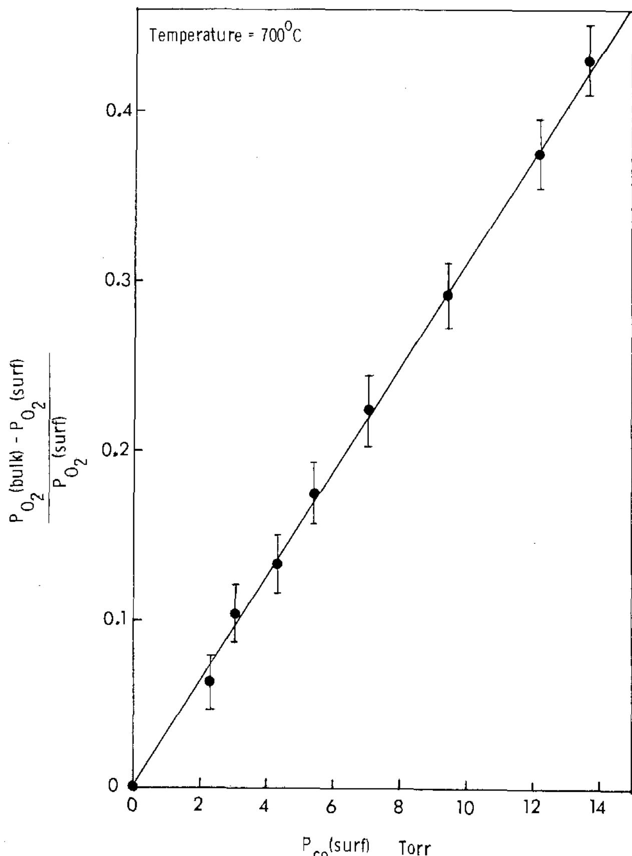

Fig. 2. Plot of data assuming that the catalytic oxidation of CO on a partially poisoned Pt/Pb electrode follows the Eley-Rideal mechanism, Eq. [11]. A linear least squares fit to the data is also shown.

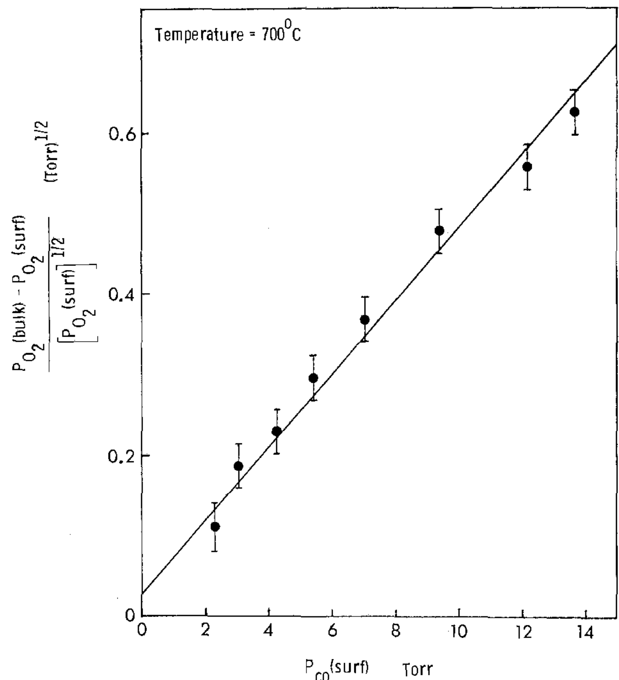

Fig. 3. Plot of data assuming that the catalytic oxidation of CO on a partially poisoned Pt/Pb electrode follows the Langmuir-Hinshelwood mechanism, Eq. [13]. A linear least squares fit to the data is also shown.

Information about the nature of the electrode poisoning by lead can be obtained from the fact that the Pt/Pb electrodes are relatively noncatalytic to CO oxidation at 700°C yet are fairly catalytic at 500°C. Thus the role of lead is not solely due to pore mouth blocking observed by others (32). Assuming the Eley-Rideal mechanism to be operative, the Pb may be decreasing the strength of the bond of adsorbed O_2 to the surface (or the adsorbed O and CO bonds if the Langmuir-Hinshelwood mechanism is important). Thus, the catalytic reaction rate would be affected to a greater extent at high temperatures than at low. Since Pb forms a solid solution with Pt, it may be assumed that as in other alloy systems (33), the role of the alloying with Pb is to decrease the heat of adsorption of the reaction species thereby decreasing the range of temperature at which catalytic activity is important. However, the possibility of changing surface composition or surface segregation of the Pt/Pb alloy with temperature cannot be ruled out.

The fact that neither sulfur nor lead decreases the rate of electrochemical oxygen pumping for electrodes which exhibit no polarization yields insight into the role of these species as catalytic poisons. Thus, these poisons reduce catalytic activity without greatly affecting any of the steps involved in the electrochemical pumping of oxygen. Although the dominant sources of electrode polarization are dependent on operating parameters (34), it would appear that Pb and S do not significantly impede dissociation and diffusion of atomic O through Pt, or O_2 diffusion through the electrode pores.

Summary

Both air-reference and the new internal-reference solid-electrolyte oxygen sensors were used in the search for noncatalytic electrodes for free oxygen measurement in nonequilibrium environments. Platinum electrodes catalyze oxidation reactions of combustible gases with the ease of reaction increasing in the order CH_4, C_3H_6, CO, and H_2. Gold and silver show limited or no catalytic oxidation with CH_4 but still exhibit significant catalysis of CO oxidation. Both silver and gold have limitations where the electrochemical pumping of oxygen is required. A thin layer of silver over platinum has the same catalytic characteristics of pure silver but exhibits oxygen pumping properties similar to platinum.

Poisoning of the platinum electrode with H_2S was effective in eliminating catalytic oxidation of CH_4, but the sulfur desorbs at ~800°C. H_2S-poisoned platinum is still somewhat catalytic to CO oxidation. Lead poisoning of platinum (introduced initially in the form of PbS) is significant in certain temperature ranges for CH_4, C_3H_6, CO, and H_2 at the flow rates studied. At the lower temperature ranges of operation of the solid-electrolyte oxygen sensors (500°-550°C), the catalytic activity of these poisoned electrodes is evident. These data support the theory that lead acts to decrease the heat of adsorption of oxygen on the surface of platinum. Oxygen sensors using these lead-poisoned platinum electrodes have been successfully tested in aboveground oil shale retorting experiments where the monitoring of nonequilibrium oxygen concentrations is desirable (4).

The use of poisoned electrodes, coupled with the solid-electrolyte oxygen sensor capability of measuring the partial pressure of gaseous oxygen at the surface of the electrode, allows the direct measurement of surface catalytic mechanisms. The data for the oxidation of CO on partially poisoned Pt electrodes is best fit by the Eley-Rideal mechanism where gas phase CO reacts with adsorbed molecular oxygen. However, the data are not sufficiently accurate to definitely exclude the Langmuir-Hinshelwood mechanism. The results demonstrate the possible use of the surface information obtained with solid-electrolyte oxygen sensors for obtaining reaction mechanism information. The information about oxygen partial pressures at the electrode surface may also aid in understanding the mechanisms by which poisons decrease catalytic activity.

Cermet Cathodes for High Temperature Water Electrolysis with Zirconia Cells

ABSTRACT

The steam electrolysis between 800° and 950°C has been investigated with a cell consisting of the following elements: electrolyte, 400μ of ytterbia stabilized zirconia; anode, 100μ of vacuum deposited tin doped india; cathode, a sputter deposited cermet of nickel and urania doped ytterbia stabilized zirconia. These cells can be operated below 1.5V at 1 A/cm^2 over 1000 hr.

High temperature water vapor electrolysis with solid electrolyte cells offers two advantages over the low temperature process currently in use, a thermodynamic and a kinetic one. The negative entropy of reaction of the water decomposition reaction causes a lower open-circuit voltage. Since the heat necessary to bring the water vapor up to the temperature of operation would be available from heat exchangers with the product gas, cell losses, and eventually the exhaust of the electricity generating plant, high temperature water electrolysis should lead to important savings of scarce free energy and lower costs of hydrogen production (1, 2). Furthermore, the rate of reaction of water decomposition becomes relatively fast at high temperatures and this leads to lower cathode polarizations at high current densities. However, these two advantages are partly compensated by severe stability problems of all cell components: *e.g.*, alkaline earth stabilized zirconia can be used in all applications except high temperature fuel cells and electrolyzers where only rare earth stabilization of zirconia has given stable conductivities so far. The particular problems with an electrode structure are illustrated in the paper. Because of these materials problems we did limit most of our experiments to 900°C which we believe represents a good compromise between performance and stability.

Thermodynamic Considerations

At room temperature the open-circuit voltage is determined by the standard free enthalpy of the reaction, since both hydrogen and oxygen are released to atmospheric pressure. For steam electrolysis the situation differs: Oxygen is not released but at 0.21 atm and therefore

$$\Delta G\ (900°C) = \Delta G°\ (900°C) - \frac{RT}{2} \ln 0.21 = -41.84\ \text{kcal/mole} \quad [1]$$

At the same time the open-circuit voltage will vary with the degree of decomposition of the steam at the cathode, α, defined as

$$\alpha = \frac{p(H_2)}{p(H_2O)}$$

Therefore, if we assume a simple Nernstian relation, the theoretical open-circuit voltage will be

$$E_{th}(\alpha) = \frac{RT}{4F} \ln \frac{\overset{\text{anode}}{p\ (O_2)}}{\underset{\text{cathode}}{p\ (O_2)}} = 0.906V + 0.05053 \ln \frac{\alpha}{1-\alpha}$$

$$4.76\ 10^{-6} < \alpha < 0.999999 \quad [3]$$

$$= E_{th}° + 0.05053 \ln \frac{\alpha}{1-\alpha}$$

The lower limit of validity is given by the equilibrium pressure of hydrogen in steam at 900°C and the upper limit by the onset of electronic conduction with the shift in stoichiometry in the zirconia electrolyte

$$O^{--} \xrightarrow[\text{lattice}]{} \tfrac{1}{2} O_2 + 2e + V_o$$

V_o oxygen lattice vacancy, for which we take an equilibrium voltage of E_{th} (900°C) = 1.66V which corresponds to an oxygen partial pressure of 10^{-15} atm (3, 4).

One sees from Eq. [3] that the measurements with a mixture of 50% volume hydrogen in steam correspond to the theoretical decomposition voltage. It is also worthwhile noting that the shape of the curve E_{th} (α) ensures that the decomposition voltage of 70% of all possible compositions lies within ±10% of $E_{th}°$. In Fig. 1 we compare some values measured with a specific feed gas flow of 1.7 cm/sec with Eq. [3].

Experimental

Setup (5).—Figures 2 and 3 show the cell structure which we have used in most of the measurements. The electrochemical cell is a flat hat of sintered sta-

bilized zirconia contacted on both sides by cermet disks of identical shape. Gas tightness is achieved by mechanical pressure. The cell shown in Fig. 3 has an active surface area of 5 cm². The anodic top cermet is contacted by another cermet hat, brazed to a steel mug. The cathodic cermet is brazed to a steel tube fitted into the exhaust tube. The whole is mounted onto two concentric gas feed/exhaust tubes. These feed tubes serve at the same time as connections for the electrical load. All measurements were made in "open" electrical furnaces against ambient air. The cell potentials are picked up by two platinum wires. Replacing a wire by a thermocouple allows one to compare the effective cell temperature with the value usually measured at 1 cm from the cathode rim. The cell temperature was found not to exceed the furnace temperature by more than 10°-15°C under fuel cell operation of 1 A/cm². The support ring serves for the addition of two more measurement points, namely, a platinum contact to the flat rim (border) of the anode and a "reference electrode" in the middle of the anode whose signal is discussed later.

Components.—The electrolyte is a membrane of ytterbia stabilized zirconia [nominal composition $(ZrO_2)_{0.92}(Yb_2O_3)_{0.08}$] of 0.4 mm thickness fired at 1850°C. Its electrical conductivity measured in air with 4 kHz (Tacussel CD 6N) as a function of temperature is given in Fig. 4. The anode is essentially made of 0.1 mm electron beam deposited tin oxide doped india (6) [nominal composition $(In_2O_3)_{0.96}(SnO_2)_{0.4}$] on a sublayer of urania doped ytterbia stabilized zirconia [$(ZrO_2)_{0.82}(Yb_2O_3)_{0.1}(UO_2)_{0.08}$]. Its electrical conductivity is shown in Fig. 5.

The cathode, a sputtered nickel zirconia cermet was the only component varied systematically in this phase of the program. Details are given in the next section.

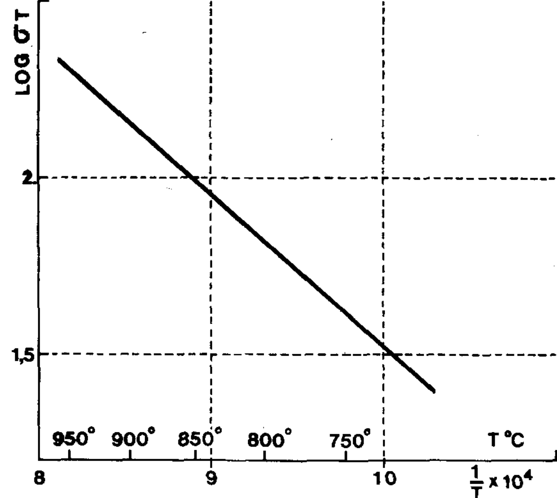

Fig. 4. Electrical conductivity of the electrolyte, $(ZrO_2)_{0.92}$-$(Yb_2O_3)_{0.08}$, as a function of temperature.

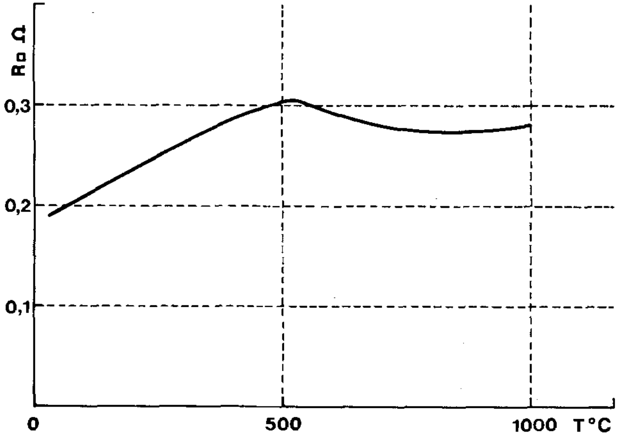

Fig. 5. Lateral resistance of the anode, $(In_2O_3)_{0.96}(SnO_2)_{0.4}$, as a function of temperature. Thickness 85μ. Density: 31.6 mg/cm². Measurements taken on an alumina substrate after 960 hr at 900°C in air with the Van der Pauw method.

Connectors.—These cermet hats are produced by firing a mixture of 70% Cr + 20% MgO + 10% Al_2O_3 at 1600°C under an argon pressure of 200 Torr. They introduce an electrical resistance of $5 \cdot 10^{-3}\Omega$, which was not corrected for in the measurements.

The mug and the support tubes are made of suitable ferritic chrome steel.

Electrical measurements.—In most of the experiments we did use a "reference electrode" formed by the dissection of two small (ϕ: 2 mm) opposing circles in the cathode and anode (gap widths: 1 mm). In principle such a contact should measure the halfway potential between the two electrodes. Since we can only contact the anodic spot, we were not able to verify the assumptions underlying the scheme of Fig. 6. Our "6-point" measurement can be summarized in the following way:

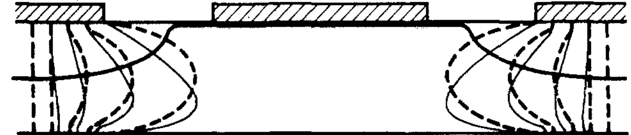

Fig. 6. Schematic representation of current lines and the equipotential surface around our "reference electrode." In principal both contacts should measure the same potential, corresponding to the half-plain of the disk. Thin lines indicate the electrolysis of very hydrogen-rich mixtures.

Connections	Cermet	Cathode	Electrolyte	Anode	Cermet 1	Cermet 2	Connections

cathodic load terminal — cathodic cell terminal — reference electrode — anodic rim — anodic cell terminal — anodic load terminal

← U_{conn} →

← E →

← cathodic half cell — anodic half cell →

U_{conn}, the potential drop between the anodic rim and the anodic cell terminal consists of: (*i*) the lateral resistance of the anode which can be related straightforwardly to its specific resistance (*e.g.*, 60 mV at 1 A/cm^2 for 0.3 Ω/square), (*ii*) the potential drop in the anode/cermet contact, and (*iii*) the potential drop in the cermet connection.

The difference between the load terminal voltages and cell terminal voltages was not systematically recorded.

For the cell measurements we used a galvanostatic pulse technique. Measurements were made with the automatic pilot shown in Fig. 7, constructed at CITROEN which fulfills the following functions: (*i*) checking of the furnace temperatures, (*ii*) galvanostatic feeding of up to 12 electrolysis cells, (*iii*) continuous recording and printing of temperature, current, and 3 voltages, and (*iv*) logical command for routine measurements all 10 hr for the long-time experiments and the manually triggered measurement of the polarization curves.

The sequence of a measurement is shown in Table I.

Table I. Sequence of measurement

Time	Load	Quantity measured at the terminals
0	j (A)	E: stationary electrolysis voltage
5 μsec	0	—
50 μsec	0	$E - U_R$
30 sec	0	E_{th}: open-circuit voltage

These sequences need some explanation. Usually galvanostatic current pulses would be applied incrementally, but then one is more limited by the performance of the electronic equipment. It is the rise time of the functional amplifier of the galvanostat for the large currents needed, which leads to the notion of 5 μsec, which was indeed the time necessary to raise the current in the incremental experiment. An additional advantage of the decremental procedure is that it introduces an empirically well-defined open-circuit voltage. In previous experiments with other electrodes we had often observed "long term polarizations," *i.e.*, open-circuit voltages that did stay below their original theoretical value after long periods of load for many minutes. In this case, 30 sec can be considered as much longer than the relaxation times of the electrode processes.

U_R will be referred to as the rapid part of the polarization. It was always found to behave ohmically as expected. $U_R = E - E_{th} - U_R$, the slow part of the polarization, can be associated with the diffusional and kinetic impedances of the electrode processes. If we are aware of the limits of this separation it can prove very useful in the development of the components (*e.g.*, a change in U_L (O_2) would imply a failure of the kinetic function of the anode, caused by sintering). In the same way we find the rapid and slow contributions to the half-cell potential from values recorded at the "reference electrode," so that we are left with the following observed quantities: U_R, rapid contribution to the cell polarization; U_L, slow contribution to the cell polarization; U_R (H_2), rapid contribution to the cathodic cell polarization; U_L (H_2), slow contribution to the cathodic cell polarization; U_R (O_2), rapid contribution to the anodic cell polarization; U_L (O_2), slow contribution to the anodic cell polarization. These data allow us in principle to distinguish the component which has failed.

Fabrication and Structure of the Cermet Cathodes

Process.—We use magnetron sputtering for the cathodes (7). While it is usual to employ rf power for the sputtering of cermets, we did use d-c because of its essentially better deposition rates. While the details of the process cannot be revealed at the moment, we can give the following summary (8): (*i*) multiple targets which can be activated and controlled separately; (*ii*) reactive gas sputtering or inert gas sputtering, depending, on the state of oxidation

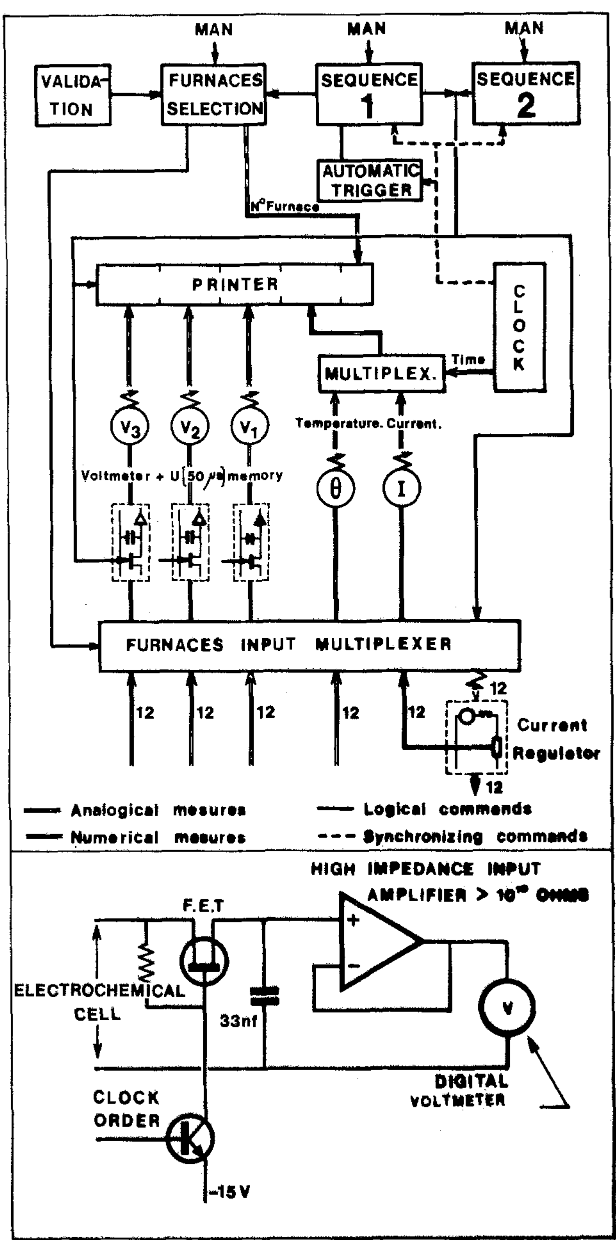

Fig. 7. Schematic representation of the measurement pilot. The insert shows the element used for the pulse measurements.

one wants to achieve for the deposit; and (*iii*) deposition rate of the order of 0.1 μ/min.

Composition.—We have used mixtures of ZrO_2, Yb_2O_3, UO_2, Ni, Ti, and Ag. The ceramic components correspond to a composition of $(ZrO_2)_{0.82}(Yb_2O_3)_{0.1}(UO_2)_{0.08}$. The nickel content was varied. The process also allows the manufacture of layered structures as well as a grading of the cermets. The additions of titanium and silver were abandoned when they did not lead to the expected benefits.

Structure.—The initial structure of the deposit is almost amorphous (grain size <30Å). Upon heating to the operating temperature of the electrolysis cell, the deposit crystallizes to a fine layer of completely stabilized zirconia, mixed with nickel (x-ray and SEM observations).

Electrical properties.—We have measured the electrical conductivity of various cermet compositions deposited on stabilized zirconia under hydrogen as a function of temperature up to 900°C. These measurements did reveal a critical composition of 40 volume percent (v/o) nickel (9). Below 40% the cermets reach a very high resistivity once heated. In agreement with Hill's theory (10) the temperature dependence of the resistance is exponential. This is even observed for the first irreversible rise. Above 40 v/o nickel, the cermets show a completely metallic behavior as shown in Fig. 8.

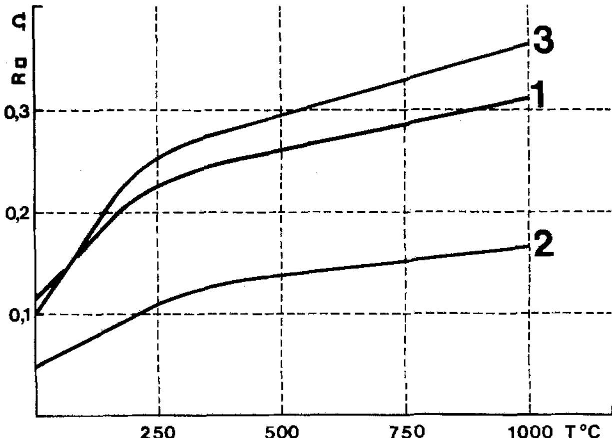

Fig. 8. Lateral resistance of three cermets layers as a function of temperature. Van der Pauw measurements on alumina in $H_2 + 3\%$ H_2O after sintering at 900°C. Curve 1. $(ZrO_2)_{0.82}(Yb_2O_3)_{0.1}(UO_2)_{0.08}$ 44.6 w/o + nickel 5μ. Curve 2. $(ZrO_2)_{0.82}(Yb_2O_3)_{0.1}(UO_2)_{0.08}$ 30.8 w/o + nickel 5μ. Results

We think the results one can obtain with the structure described are best illustrated with one example, a simple cermet cathode, 55.4 weight percent (w/o) of nickel with urania doped ytterbia stabilized zirconia of 6μ thickness. Figures 9-12 give the measurements of this cell at different water decomposition levels. We have combined in one figure the stationary current-

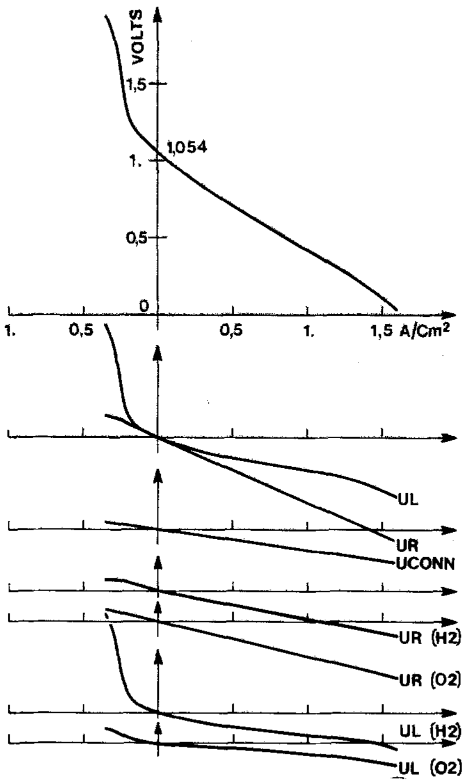

Fig. 9. Characteristic of a cell with components as described and a cathode of 6μ of cermet with 50% volume of nickel. Feed gas: 95% H + 5% H_2O at a specific flow rate of 1.7 cm/sec at 900°C after 643 hr of operation with an $\alpha = 1/2$ mixture at 900°C. The lower half gives the various contributions to the cell polarization.

voltage plot and the contributions of the different polarization mechanisms to the total polarization for fuel cell and electrolysis operation. The measurements were taken at 900°C after 694-713 hr of operation, under an electrolysis load of 1 A/cm² in a mixture with $\alpha = ½$.

Figure 9 shows that for the very low concentration of water vapor of 5%, diffusion limitation sets in below 0.2 A/cm². As it should be, almost all this polarization shows up as a slow polarization of the cathodic half-cell. Let us mention that this characteristic gives a maximum power density for fuel cell operation of 430 mW/cm². Furthermore one sees from these figures that the main contribution to the polarization of the oxygen half-cell comes from U_{conn}, *i.e.*, the limited lateral conductivity of the oxygen electrode; this pertains to fuel cell operation where the kinetic impedance of the oxygen dissociation reaction causes a larger slow polarization of the oxygen half-cell than the one observed in electrolysis for oxygen rejection.

Evidently the water dissociation reaction does not represent a problem with these nickel cermets. However, anodes where the last layer contains only 23.6 w/o of nickel initially have an additional slow cathode polarization of the order of 100-150 mV at 1 A/cm², which decreases with time. As long as they are nickel rich, the optimum anode thickness will be determined by a compromise between slow and fast polarization, *i.e.*, lateral collection resistance and oxygen diffusive resistance.

The rise in the slow polarization of the oxygen half-cell in Fig. 9 is an interesting example of the breakdown of our assumptions concerning the reference electrode. Indeed, as steam diffusion limitation sets in we must take electrode border effects into account, notably that the diffusion limiting current will be larger at the cathode edge facing the "reference electrode." In this situation, an electrode with uniform current density faces an electrode with nonuniform current density and this leads to a distortion of the current lines shown as additional thin lines in Fig. 6. This distortion displaces the equipotential line on which our "reference" sits at the cathode, increasing the size of the oxygen half-cell and therefore its potential drop. The inverse happens of course in Fig. 11 for the fuel cell operation under high water content. An interesting detail of this analysis is the flat portion of U_R (H_2) for cell voltages larger than 1.7V under 95% H_2 which indicates the onset of electronic conductivity in the zirconia under these large

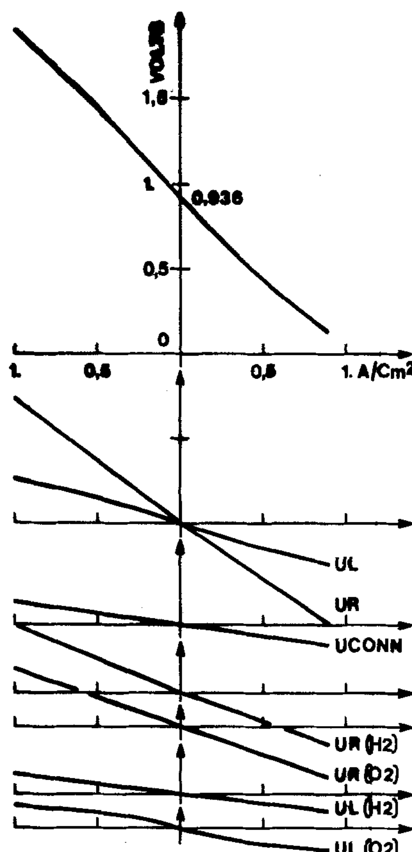

Fig. 13. Same as Fig 11, but at 800°C and after 813 hr of operation

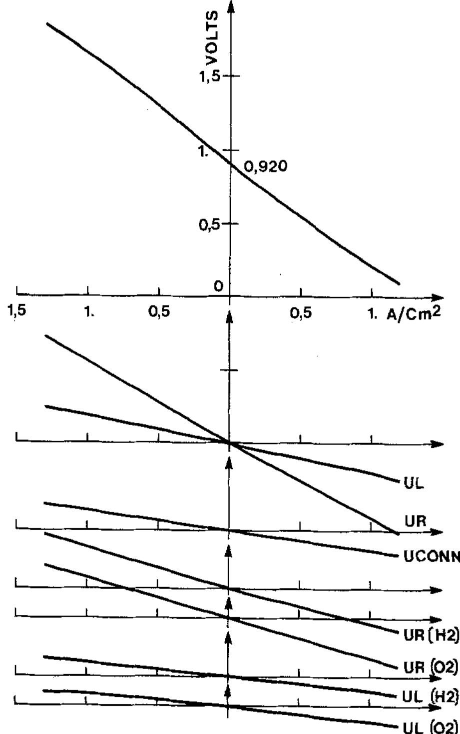

Fig. 14. Same as Fig. 13 at 850°C

polarizations. The value agrees roughly with previous observations (3, 4).

This onset of electronic conduction was observed in fact with a large number of cells of varying performance and cathode structure. In Fig. 13-16, we give the measurements at different temperatures: 800°, 850°, 900°, and 950°C made after 813-817 hr of operation in an $\alpha = 1/2$ mixture. Ones sees that above 850° there is no important slow (reaction) polarization with our electrodes. The sharp drop in performance at low temperatures is due to the use of a thick electrolyte. Table II compares the various calculated contributions to the polarization with the measured values. Since we compare values measured previously on other virgin cell components, the agreement is better than one could expect.

Long-term stability.—We had limited our long-term tests to 1000 hr for practical reasons. As a matter of fact most experiments were terminated before 1000 hr because of various accidents, since the cells used at that stage of the program did not support thermal cycling. Twenty five cells were tested. The result of the cell discussed in the previous section is given in Fig. 17 which again gives the various contributions to the polarization.

Over the period of 930 hr, the cell voltage under a load of 1 A/cm² only increased from 1.45 to 1.49V. All this deterioration can be traced to the cathode. After 930 hr the water supply of the saturator was interrupted over a weekend. The electrical load was maintained with a flow of pure hydrogen probably causing zirconia electrolysis. After repair, the cell started again but at a higher polarization.

Anode and electrolyte show no measurable or visible degradation. The behavior of the cathodes is less satisfactory. Under water electrolysis conditions, they show a large tendency to demix. This can easily be explained by the known: (*i*) weak interfacial tension of nickel on zirconia and (*ii*) hydrophylic nature of nickel, which leads, *e.g.*, to the decomposition of copper-nickel alloys in water vapor (10). This can lead to a complete segregation of nickel and within 100 hr. A complete nickel layer forms at the surface and can be stripped off by hand, leaving behind an insulating powdery layer of zirconia (Fig. 18).

Additions of titanium are known to stabilize nickel-zirconia cermets by increasing the wetting angle (11). But this is achieved in bulk cermets, where titanium concentrates in the surface of the nickel grains. We did not find any influence on the demixing, maybe because in the failing electrodes demixing is faster than titanium precipitation in the grain boundary.

The problem can only be overcome by a careful adjustment of the nickel content and/or layered structures. A further problem at the high end of the temperature is the evaporation of nickel, which theoretically reaches 2.5μ/1000 hr at 950°C. Indeed one cathode has been observed to be superficially insulating after 980 hr.

Conclusion

Steam electrolysis with thick zirconia cells can be achieved at 900°C with a cell voltage below 1.5V at 1 A/cm². Stability of the electrolyte and the vacuum-

deposited india anode does not represent a problem over 1000 hr of operation. Sputtered nickel/zirconia cermet electrodes are limited by demixing and nickel evaporation. Operation with a feed gas containing less than 20% of steam does not appear feasible. This will limit the decomposition level that can be achieved with a battery of cells in series.

Acknowledgment

We would like to thank Messrs. G. Horlaville and J. Stauchmann for their assistance in the experiments, Mr. G. Ducrot for the design of the measuring pilot, and Mr. J. Nougarou, Director of Research of CITROEN, for his continuous support and encouragement.

Oxygen Evolution on $La_{1-x}Sr_xCoO_3$ Electrodes in Alkaline Solutions

Y. Matsumoto, H. Manabe, and E. Sato

Department of Industrial Chemistry, Faculty of Engineering, Utsunomiya University, Utsunomiya, Japan

ABSTRACT

Anodic characteristics of $La_{1-x}Sr_xCoO_3$ (with $x = 0.2$ and 0.4) electrodes were investigated in alkaline solutions. It was found that the catalytic activities for the oxygen evolution reaction are relatively high and that the activity of the electrode with $x = 0.4$ is higher than that of $x = 0.2$. The secondary chemical step, *i.e.*, $CoOH + OH^- \rightarrow CoO^- + H_2O$, is rate-controlling in the oxygen evolution reaction. Therefore, it is concluded that the rate of the secondary chemical step is more rapid at the electrode with the higher value of x because of the beneficial effect of the higher positive charge on the Co cation on this step. $La_{1-x}Sr_xCoO_3$ electrodes are suitable for the anode material in alkaline solutions, because anodic dissolution scarcely occurs.

The anodic evolution of oxygen is of special importance in water electrolysis, because the activation overpotential at the electrode is the chief cause of efficiency loss in this process. Recently, low cost transition metal oxides such as MnO_2 (1-3), $NiCo_2O_4$ (4), $La_{1-x}M_xCoO_3$ (5), $La_{1-x}Sr_xMnO_3$ (6), and $SrFeO_3$ (7) have been reported to be good electrocatalysts for the anodic evolution of oxygen, and the catalysis of the latter two oxides is explained by applying the theory of σ^* band formation in the oxide to the oxide surface (6, 7). This concept predicts the catalytic activity of the oxide having the σ^* band to be high.

$La_{1-x}Sr_xCoO_3$ series oxides with perovskite-type structure such as $La_{1-x}Sr_xMnO_3$ and $SrFeO_3$ have also shown interesting electrocatalytic properties for electrochemical oxygen reduction (8-13). $La_{1-x}Sr_xCoO_3$, with the value of x over 0.2, exhibits high electrical conductivity because of the partially filled σ^* band in the oxide (14, 15), which also produces high catalytic activity according to the above concept. The properties of these oxides, which are resistive to anodic oxidation in alkaline solutions (11), make them extremely useful as the anode material in alkaline solutions. However, no details of the anodic characteristics are clear. Therefore, in this paper, the anodic characteristics of $La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and 0.4 electrodes as well as the catalytic properties for the anodic evolution of oxygen are studied in detail in alkaline solutions.

Experimental

$La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and 0.4 were prepared by using La_2O_3, $SrCO_3$, and CoO as the starting materials. These materials were mixed in stoichiometric quantities with an agate mortar and then heated at 1200°C for 6 hr in air. The prepared perovskite oxides, whose compositions were checked by x-ray analysis, were pressed into tablet form with 100 kg/cm^2, then sintered at 1350°C for 2 ~ 3 hr. The porosity of the sintered disk was determined by filling the pores with water. The porosities of these sintered disk samples were about 20% for both samples with $x = 0.2$ and 0.4. The specific resistivities measured by four probe method were $7 \times 10^{-4}\ \Omega \cdot cm$ and $2 \times 10^{-4}\ \Omega \cdot cm$ for $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.6}Sr_{0.4}CoO_3$, respectively. These specimens were waterproofed with polystyrene in order to obtain good reproducible results. Both end surfaces of these specimens were polished with No. 2000 emery paper, and an electrical lead was connected via silver paste on one side of the surface. The specimens were then mounted in glass tubes with epoxy resin. The real areas of the prepared electrodes were, of course, larger than the apparent areas.

The electrodes prepared by this manner were immersed in 0.5M H_2SO_4 for 10 sec as a pretreatment, followed by washing with distilled water. The solutions were pre-electrolyzed 1M KOH and various concentrations of K_2SO_4 which were of constant ionic strength but various pH values by adding a few drops of dilute KOH. An Hg/HgO electrode was used as the reference electrode and electrode potentials cited in this paper are referred to this electrode, unless otherwise stated. *IR*-free current/potential curves at steady state were obtained by correcting for the ohmic drops. The ohmic drops were observed by a synchroscope (SS-5057V, Iwatsu), using a current interruption technique.

The small amount of Co ion dissolved in the electrolyte was determined colorimetrically by the method using β-nitroso-α-naphthol as the color-producing reagent (16).

Results and Discussion

Figure 1 shows a typical voltammogram for a $La_{0.6}Sr_{0.4}CoO_3$ electrode in alkaline solution in the anodic potential region. A voltammogram similar to this figure was also obtained in the case of the $La_{0.8}Sr_{0.2}CoO_3$ electrtode. In the anodic potential region, no electrochemical reaction at the electrode itself, except for the anodic evolution of oxygen, was observed. Therefore, in the potential region covered, the electrode surface will still exist as the near stoichio-

Key words: oxygen evolution, perovskite type oxide, electrocatalysis.

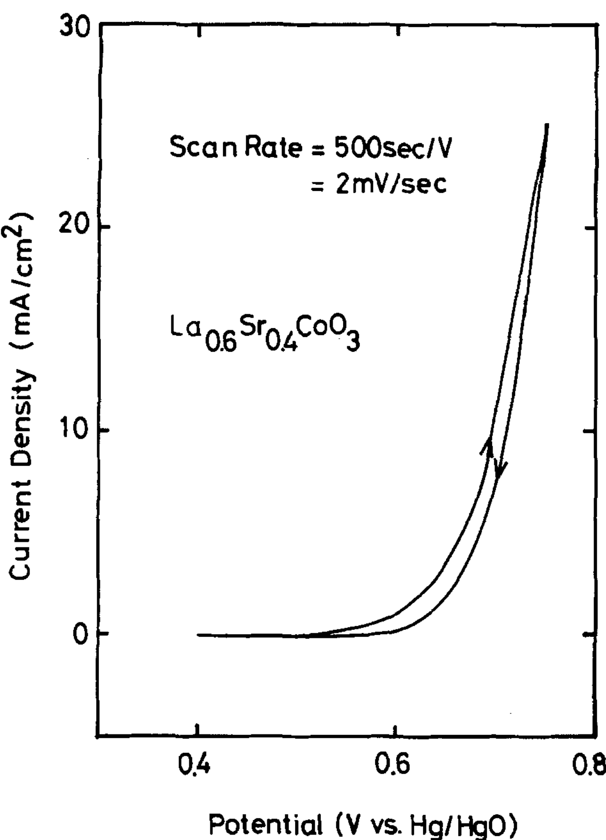

Fig. 1. Potential sweep voltammogram of $La_{0.6}Sr_{0.4}CoO_3$ in 1M KOH at 25°C.

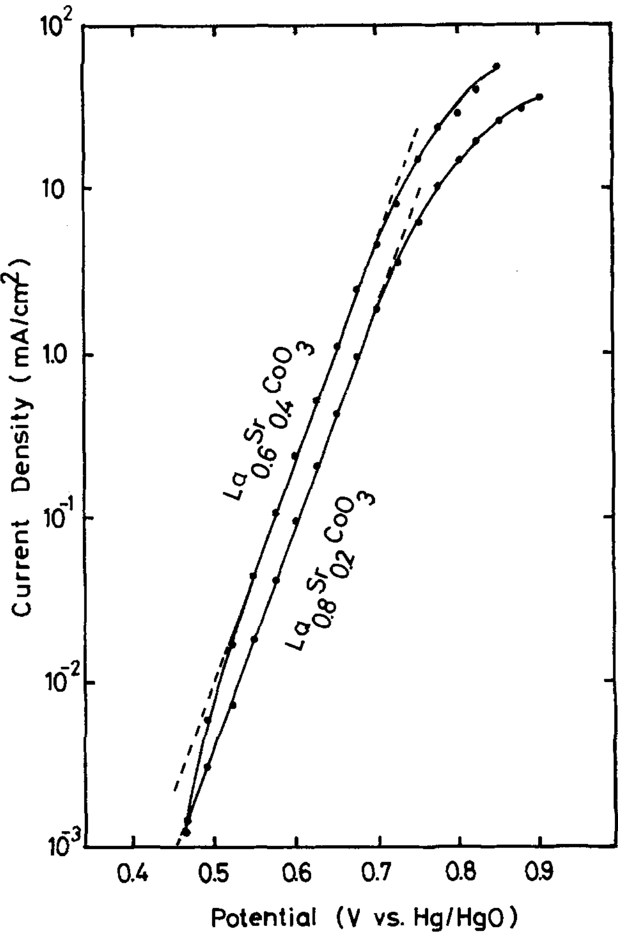

Fig. 2. Anodic polarization curves for oxygen evolution on $La_{1-x}Sr_xCoO_3$ electrodes in 1M KOH at 25°C.

metric compound, $La_{1-x}Sr_xCoO_3$, unaffected by the oxygen evolution. The above result shows that $La_{1-x}Sr_xCoO_3$ is preferable as the anode material in alkaline solution, although very slight anodic dissolution of the electrodes occurs in the high overpotential region (at 50 mA/cm^2) as described in a later section.

The *IR*-free polarization curves for the anodic evolution of oxygen are shown in Fig. 2. The standard potential of an oxygen electrode, which is the potential at zero overvoltage, is +0.303V (*vs.* Hg/HgO) in basic solution. Therefore, the overvoltages of $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.6}Sr_{0.4}CoO_3$ electrodes at 10 mA/cm^2 are 0.44 and 0.40V, respectively. The overvoltage in the case of $La_{0.6}Sr_{0.4}CoO_3$ electrode is almost same as those of $SrFeO_3$ (7) and $Ti/RuO_x/MnO_3$ electrodes (17) but is larger than that of DSA(RuO_x) (18), therefore, the catalytic activities of the $La_{1-x}Sr_xCoO_3$ series oxides for the oxygen evolution reaction are judged to be relatively high. The catalytic activity of the $La_{0.6}Sr_{0.4}CoO_3$ electrode is higher than that of the $La_{0.8}Sr_{0.2}CoO_3$ electrode. This fact suggests that the increase of the positive charge on the Co cation driven by the substitution of Sr^{2+} ion in the oxide has a favorable effect on the rate of the oxygen evolution reaction. The Tafel slopes, b, for the oxygen evolution reaction were 0.065V per decade, or near 2.303 (RT/F) in both cases.

The dependence of the current density on *p*H for the anodic evolution of oxygen at constant *E* is shown in Fig. 3 for the $La_{1-x}Sr_xCoO_3$ electrodes. The slopes obtained from the linear relationships were about 1.8, or near 2 in the both cases. We can, therefore, conclude that the reaction order of OH^- ion in the mechanism of the oxygen evolution reaction at $La_{1-x}Sr_xCoO_3$ electrodes is 2. The obtained kinetic parameters are summarized in Table I.

Consequently, the experimental results over all current densities for the anodic evolutions of oxygen at $La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and $x = 0.4$ electrodes can be formulated as follows

$$i = n\mathbf{F}ka^2_{OH^-} \exp(\mathbf{F}E/RT) \quad [1]$$

in alkaline solution, where k is the rate constant and other symbols have their usual meanings.

In alkaline solutions the following oxygen evolution mechanism

$$S + OH^- \rightleftharpoons SOH + e^- \quad [2]$$

$$SOH + OH^- \rightarrow SO^- + H_2O \quad [3]$$

$$SO^- \rightleftharpoons SO + e^- \quad [4]$$

$$2SO \rightleftharpoons 2S + O_2 \quad [5]$$

seems probable for oxide electrodes (6, 7, 19), where S stands for a site at the electrode surface and is presumed to be Co cation in the present case. In any case, any one of the O_2 reaction paths already proposed by Bockris (20) and Damjanovic *et al.* (21), will satisfy the present data with the assumption of Langmuirian adsorption conditions in alkaline solution if the 2nd step [3] is rate-determining. With this assumption the current expression in the Tafel region can be written as

$$i = n\mathbf{F}(k_1k_2/k_{-1})\, a^2_{OH^-} \exp(\mathbf{F}E/RT) \quad [6]$$

where k_1, k_{-1}, and k_2 are the rate constants for the 1st [2] and the 2nd [3] steps. The theoretically deduced rate equation [6] is consistent with the experimentally obtained expression [1]. The above proposed mechan-

Table I. Kinetic parameters for the oxygen evolution reaction on $La_{1-x}Sr_xCoO_3$ electrodes at 25°C

Electrode	Tafel slope (V)	i_0 (A/cm^2) (in 1M KOH)	$\left(\frac{\partial \log i}{\partial \log a_{OH^-}}\right)_E$
$La_{0.8}Sr_{0.2}CoO_3$	0.065	3.0×10^{-9}	1.8
$La_{0.6}Sr_{0.4}CoO_3$	0.065	7.4×10^{-9}	1.8

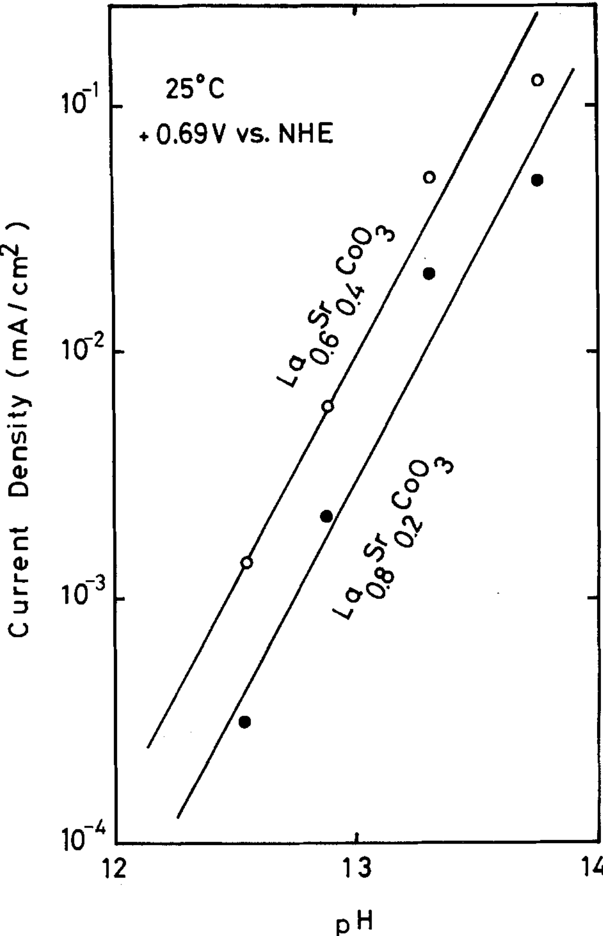

Fig. 3. pH dependences of current density of oxygen evolution reaction on $La_{1-x}Sr_xCoO_3$ electrodes at 0.69V vs. NHE (0.59V vs. Hg/HgO) at 25°C.

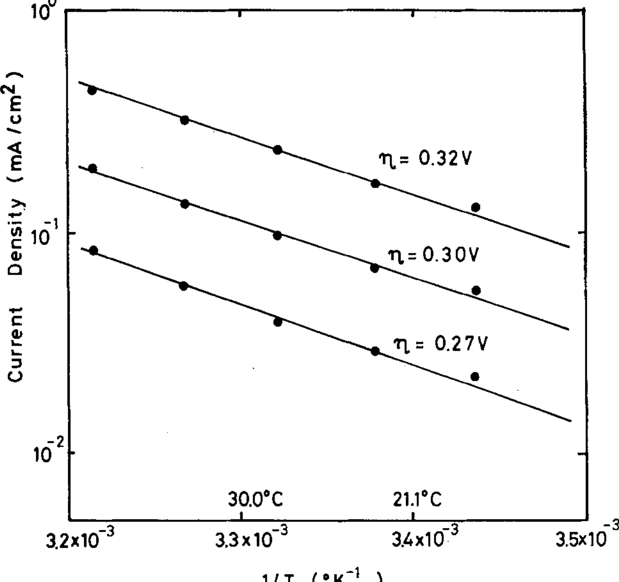

Fig. 4. Temperature dependences of current density of oxygen evolution reaction on $La_{0.8}Sr_{0.2}CoO_3$ electrode in 1M KOH at various overpotentials.

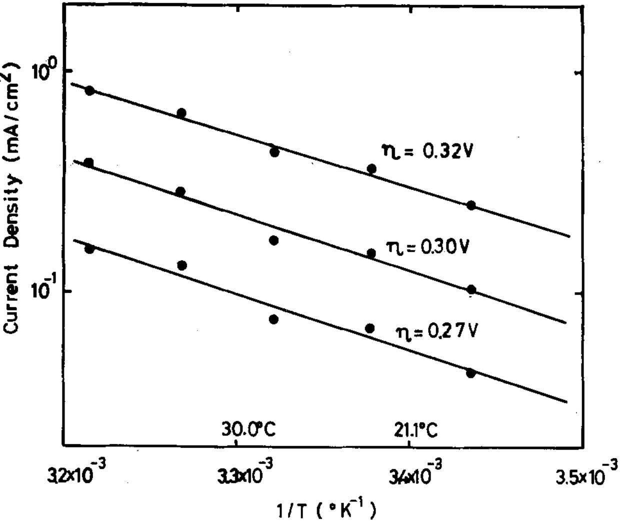

Fig. 5. Temperature dependences of current density of oxygen evolution reaction on $La_{0.6}Sr_{0.4}CoO_3$ electrode in 1M KOH at various overpotentials.

ism on the $La_{1-x}Sr_xCoO_3$ electrodes is same as that on $SrFeO_3$ electrode (7). The σ^* band is formed in the $La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and 0.4 (15), therefore, the rate of the electron transfer in the 1st step must be rapid at the surfaces of these oxides. This leads the other chemical step, *i.e.*, the 2nd step, to become the rate-controlling in analogy with the case of $SrFeO_3$ electrode (7).

Figures 4 and 5 show the typical Arrhenius plots at constant overvoltage for the oxygen evolution reaction in 1M KOH at $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.6}Sr_{0.4}CoO_3$ electrodes, respectively. An apparent activation energy can be calculated from the gradient of each straight line by using Eq. [7]

$$\Delta\tilde{H}^{\neq}(\eta) = -2.303R(\partial \log i/\partial(l/T))_\eta + \alpha n \mathbf{F}\eta [\text{cal/mole}] \quad [7]$$

where $\alpha n = 2.303RT/b\mathbf{F}$, α is the formal value of charge transfer coefficient, and $\mathbf{F}$ is the Faraday constant. Activation energies for the oxygen evolution reaction at $La_{0.8}Sr_{0.2}CoO_3$ and $La_{0.6}Sr_{0.4}CoO_3$ electrodes are summarized in Table II.

The dependence of current density i on the apparent activation energy at constant pressure p, overpotential η on polarization, and activity of reactant a can be expressed by the equation (2, 21, 22)

$$i = n\mathbf{F}A\, a^2_{OH^-} \exp(-\Delta\tilde{H}^{\neq}(\eta)/RT) \quad [8]$$

where A is the pre-exponential factor at given overpotential. From the comparison of this equation with Eq. [6], $\Delta\tilde{H}^{\neq}(\eta)$ will be expressed as follows

$$\Delta\tilde{H}^{\neq}(\eta) = \Delta H_1^{\neq} + \Delta H_2^{\neq} - \Delta H_{-1}^{\neq} - \mathbf{F}E(\eta) \quad [9]$$

where $\Delta H_1^{\neq}$, $\Delta H_2^{\neq}$, and $\Delta H_{-1}^{\neq}$ are the chemical activation energies for 1st and 2nd steps, respectively. From Eq. [8] the ratio of the current density for the oxygen evolution reaction at $La_{0.6}Sr_{0.4}CoO_3$ electrode to that at $La_{0.8}Sr_{0.2}CoO_3$ electrode is expressed by Eq. [10], if the pre-exponential factors A are supposed to be the same for both electrodes

Table II. Apparent activation energies on $La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and 0.4 electrodes and their differences in 1M KOH

Over-voltage η (V)	$\Delta\tilde{H}^{\neq}$ (kcal/mole)		Energy difference ($\Delta\tilde{H}_{x=0.2}^{\neq} - \Delta\tilde{H}_{x=0.4}^{\neq}$) (kcal/mole)
	$La_{0.8}Sr_{0.2}CoO_3$	$La_{0.6}Sr_{0.4}CoO_3$	
0.27	18.1	17.3	0.8
0.30	18.2	17.7	0.5
0.32	18.2	17.5	0.7
			0.67 (Average)

$$i_{x=0.4}/i_{x=0.2} = \exp\left[(\Delta\tilde{H}^{\neq}(\eta)_{x=0.2} - \Delta\tilde{H}^{\neq}(\eta)_{x=0.4})/RT\right] \qquad [10]$$

The current ratio obtained from Fig. 2 at 25°C is about 2.5 in all potential regions covering the Tafel relation. From Eq. [10], the difference between the apparent activation energies for $La_{1-x}Sr_xCoO_3$ with $x = 0.2$ and 0.4 electrodes is calculated to be about 0.54 kcal/mole. This is almost consistent with the average difference, 0.67 kcal/mole, in the apparent activation energies measured by Arrhenius plots as shown in Table II. This result confirms that the oxygen evolution reaction at $La_{1-x}Sr_xCoO_3$ electrodes proceeds with the activation control stated already. Since $\Delta H_1^{\neq}$ and $\Delta H_{-1}^{\neq}$ are negligible in comparison with $\Delta H_2^{\neq}$ in Eq. [9] because of the rate control of the 2nd step, $\Delta\tilde{H}^{\neq}(\eta) \approx \Delta H_2^{\neq}(\eta) - \mathbf{F}E(\eta)$ is derived in the present case.

At this stage, we can discuss the catalysis of the Co cation in the $La_{1-x}Sr_xCoO_3$ in the 2nd step shown by Eq. [3], in which S stands for the Co cation on the surface. The 2nd step implies that the rate of capture of the hydrogen atom in the CoOH by OH^- ion increases, when the density of the positive charge on this hydrogen atom increases. The increase of the positive charge density on the hydrogen atom in the CoOH will be brought about by the increase of the positive charge density on the Co cation. Since the positive charge density on the Co cation increases with the increase of x as a result of charge delocalization, it is concluded that the catalytic activity for the oxygen evolution reaction increases with the increases of x in the $La_{1-x}Sr_xCoO_3$ electrodes. This theory satisfies the experimental result very well.

Figure 6 shows the variations of the potentials with time during the anodic polarization at 50 mA/cm^2 in 1M KOH at 25°C. The potentials were virtually invariant for both the electrodes except for a small variation (less than 50 mV) in the initial stage. After electrolyzing for 72 hr at 50 mA/cm^2, the amount of the very slightly dissolved Co ion which exists as $HCoO_2^-$ ion in alkaline solution was determined by the manner described in the experimental section. From consideration of a Pourbaix diagram the anodic dissolution of the $La_{1-x}Sr_xCoO_3$ is proposed to be as follows

$$La_{1-x}Sr_xCoO_3 + (1-3x)\,OH^- + H_2O \rightarrow CoO_2 + (1-x)La(OH)_3 + xSr^{2+} + (1-x)e^- \qquad [11]$$

Then the CoO_2 produced on the electrode surface will decompose to $HCoO_2^-$ ion as follows

$$CoO_2 + OH^- \rightarrow HCoO_2^- + \tfrac{1}{2}O_2 \qquad [12]$$

The current efficiencies of the dissolutions of the $La_{1-x}Sr_xCoO_3$ electrodes calculated by using the above

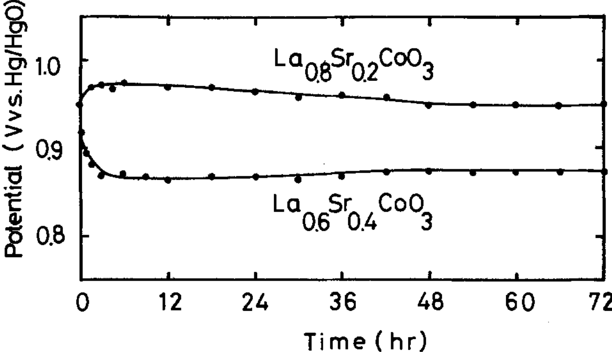

Fig. 6. Potential-time curves under anodic polarization of $La_{1-x}Sr_xCoO_3$ electrodes in 1M KOH at 50 mA/cm^2 at 25°C.

Table III. Current efficiencies of the anodic dissolution of $La_{1-x}Sr_xCoO_3$ electrodes at 50 mA/cm^2 in 1M KOH at 25°C

Electrode	Current efficiency (%)
$La_{0.6}Sr_{0.4}CoO_3$	6.8×10^{-6}
$La_{0.8}Sr_{0.2}CoO_3$	1.5×10^{-5}

Eq. [11] and [12] are shown in Table III. The efficiencies for both $La_{0.6}Sr_{0.4}CoO_3$ and $La_{0.8}Sr_{0.2}CoO_3$ electrodes are quite small. The smaller value of the efficiency in the case of $La_{0.6}Sr_{0.4}CoO_3$, compared to $La_{0.8}Sr_{0.2}CoO_3$, is believed to be caused by the smaller amount of Co^{3+} ion in the former oxide, when the Co cation in the oxide is expressed as Co^{3+} or Co^{4+} ion for convenience. The results in Figure 6 and Table III show that $La_{1-x}Sr_xCoO_3$ electrode is excellent for use as an anode material for long periods in alkaline solution. In conclusion, $La_{0.6}Sr_{0.4}CoO_3$ has good catalytic activity and appears to be a promising material for the anode in electrolysis of alkaline solutions.

The Electrochemical Oxidation of I in a Nonpolar Solvent Consisting of Al_2Br_6 and KBr in an Aromatic Hydrocarbon

M. Elam and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat Aviv, Israel

ABSTRACT

The mechanism of oxidation of I^- in a nonpolar solvent consisting of 1.0M Al_2Br_6 and 0.80M KBr in an aromatic hydrocarbon was studied. A chemical step following charge transfer, in which I^- is regenerated, was observed. It was postulated that bromination of the solvent occurred. Oxidation of Br^- by I_2 to IBr or Br_2 is possible in this system since the standard potentials for different redox couples are much closer than in aqueous solutions. Qualitative mechanistic information obtained from analysis of cyclic voltammograms was consistent with the mechanism derived on the basis of steady-state current/potential measurements. It was observed that iodine is reduced rapidly in this system if mesitylene is used as the solvent and much more slowly in benzene. The half-wave potential for the oxidation of I^- is about 1.10V *vs.* RAlE, compared to about 2.2V in aqueous solutions.

The chemical and electrochemical properties of a solvent system consisting of Al_2Br_6 and an alkali metal bromide (MBr) in an aromatic hydrocarbon (ArH) have been studied by Plotnikov and co-workers (1-9). In recent years there has been renewed interest in this system as a possible bath for the electroplating of aluminum (10-15). Apart from its practical importance this bath may be expected to exhibit unusual electrochemical behavior, due to the unique combination of its low dielectric constant and relatively high conductivity.

Some of the chemical and electrochemical properties of this system have been studied recently in our laboratory (16-22). A review of earlier work was given in Ref. (18), and a summary of work done in this laboratory was presented very recently (23).

In a previous study (21) surface phenomena occurring on different electrode materials in this solvent system were investigated. Glassy carbon was found to be inactive. On platinum a well-defined adsorption pseudocapacitance peak was observed, associated with the adsorption of bromine atoms on the surface. On gold electrodes several adsorption and desorption peaks could be discerned, yielding a rather complex pattern. The initial potential for oxidation of bromine was found to depend significantly on the type of hydrocarbon used as the solvent; decreasing from benzene to mesitylene with increasing chemical rate constant for the bromination of the hydrocarbon (24).

In the present work the kinetics of electrooxidation of I^- on platinum electrodes and the subsequent chemical reactions of the I_2 produced in this solvent system were investigated.

Experimental

The cell, electrodes, and electrochemical equipment employed for measurements of cyclic voltammograms were described in a previous publication (21). Steady-state Tafel plots were measured with the same setup, in which the function generator was replaced by a "first drop" polarographic unit (homemade), triggered by a Radiometer Type DLT-1 drop-life timer. This unit provides potential steps of increasing amplitude (6 mV increments) and adjustable length. The pulse width was set to 30 sec. This was found to be long enough for the current to reach its steady-state value in all ranges of potential and concentration studied. Between pulses the potential was held for an equal length of time at its initial value, where no Faradaic reaction took place. The solutions were stirred gently with a magnetic stirrer during these measurements.

For the determination of n, the number of electrons taking part in the over-all reaction, a large platinum gauze working electrode was used in order to decrease the time required for electrolysis.

All experiments were performed in rigorously dried and purified solutions, inside a glove box filled with purified argon. Details were given in earlier publications (16, 19, 21).

Results

Cyclic voltammetry.—A typical set of voltammograms taken at different concentrations of KI, employing benzene as the solvent, is shown in Fig. 1. The function $i/C°$ is plotted in this figure against the potential to eliminate the trivial effect of concentration. The influence of the solvent on the shape of the voltammogram is seen in Fig. 2. The peak potentials on the anodic and the cathodic sweeps are plotted as a function of log v ($v \equiv dE/dt$) in Fig. 3 and 4, respectively. Simple behavior is observed in Fig. 3 when benzene or mesitylene are used as the solvent, while ethyl benzene and o-xylene exhibit anomalous behavior, particularly at low concentrations of KI. On the cathodic sweep no reduction peak occurred when
