The experimental data of Pt surface area from fuel cell electrodes as a function of operating time are shown in Fig. 1. Results obtained using both the TEM and electrochemical area determinations are presented. The surface area of the Pt can be seen to decline rapidly at first and then tends to level off with an area of about 20 m^2/g being reached after 20,000 hr. Figure 2 shows that a good linear relationship exists between ln surface area and ln t, as would be predicted using various theoretical models (12).

TEM photographs of the catalysts from four of the electrodes used in this study are shown in Fig. 3. These photographs show more dramatically the changing rate of surface area loss with time.

The effect of operating potential on the loss of surface area is shown in Fig. 4. The fraction of the initial surface area remaining after 100 hr can be seen to be

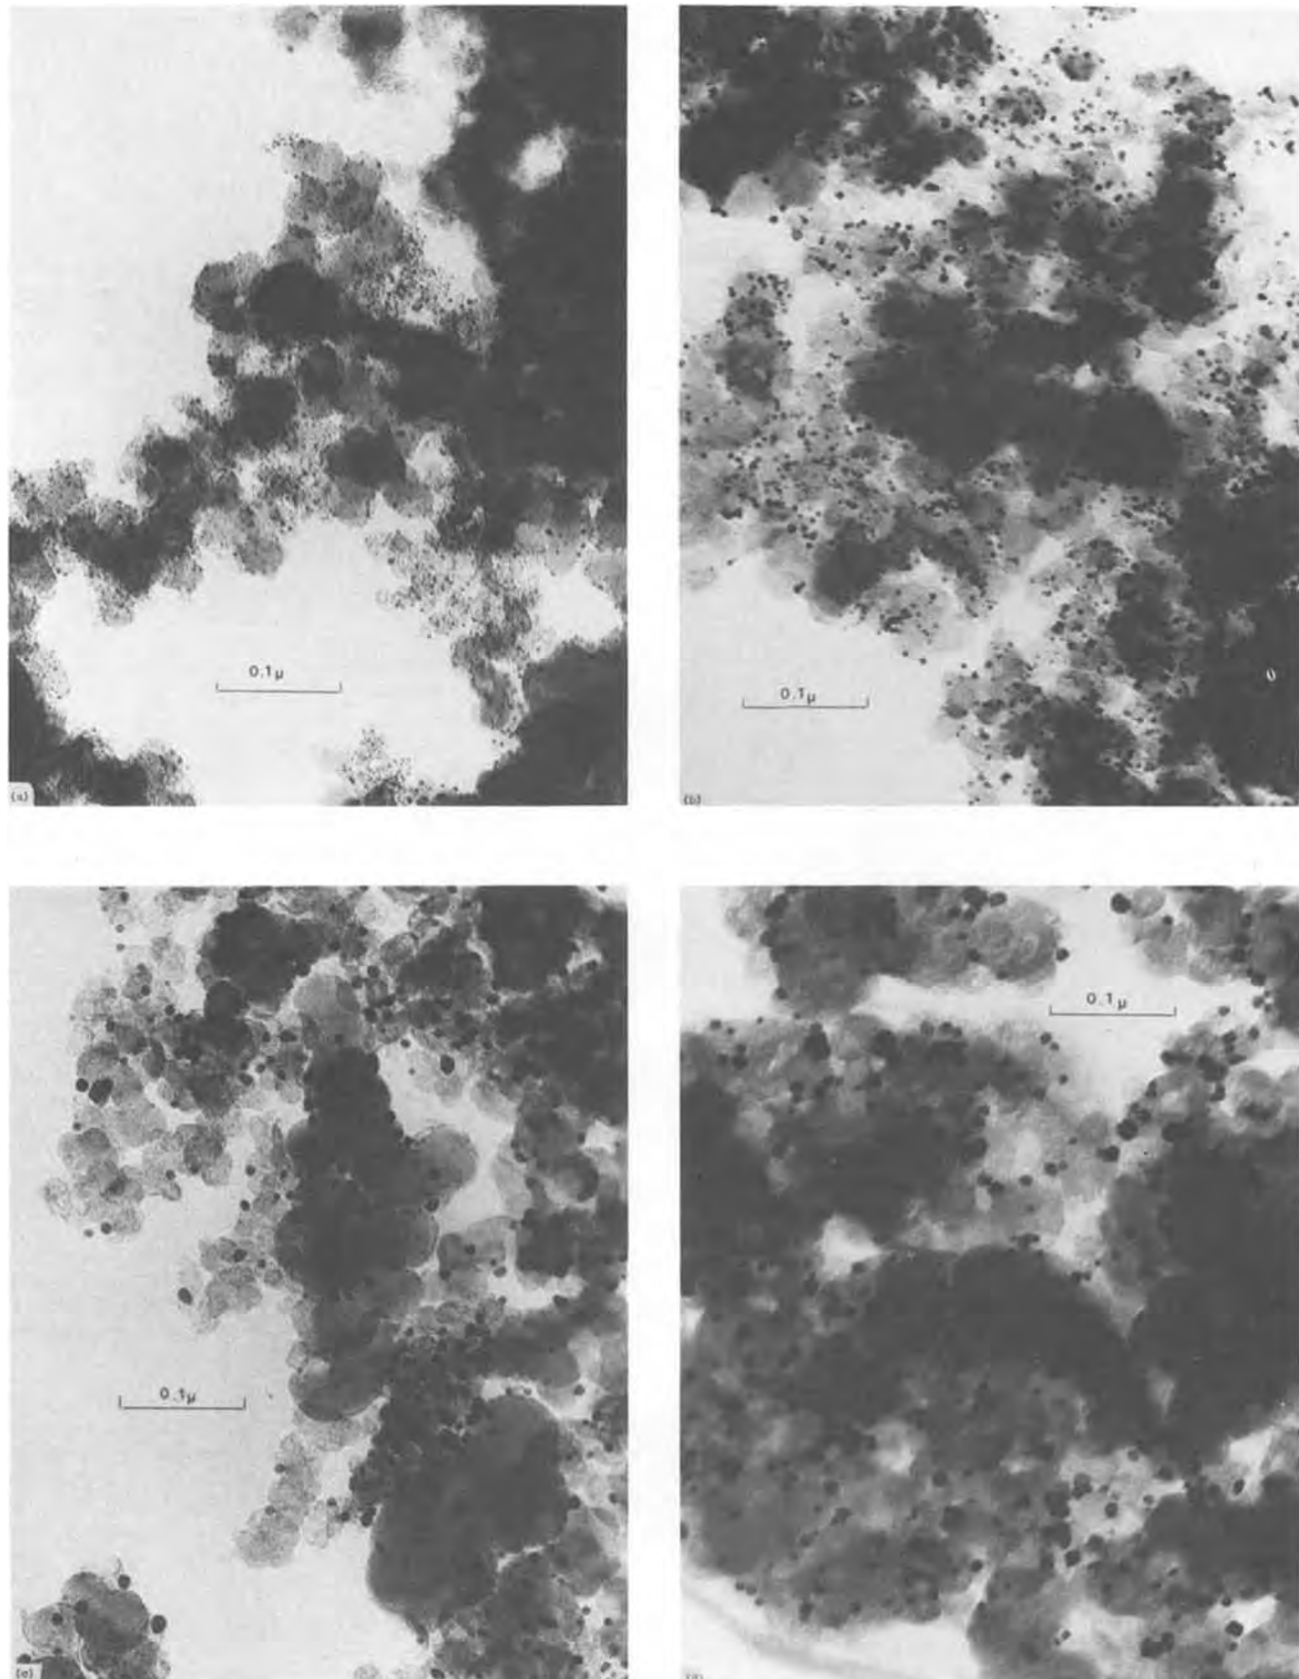

Fig. 3. Electron micrographs of Pt supported on Vulcan XC-72 after various times of operation at 191°C in H_3PO_4. (a) 0 hr; (b) 100 hr; (c) 1,050 hr; (d) 20, 201 hr.

relatively insensitive to operating potential, although the final area is somewhat lower at 0.7V (fuel cell cathode potential) than 0.0V (fuel cell anode potential).

The results of the carbon film experiments are shown in Fig. 5 and 6. Figure 5(a) shows a transmission electron micrograph of the sample before any exposure to H_3PO_4. An extremely fine (1.0-1.5 nm particle size) and uniform distribution of the Pt is evident. After 24 hr of exposure to the H_3PO_4, agglomerates of significantly enlarged Pt particles of fairly uniform size can be seen [Fig. 5(b)]. After further exposure to 100 hr accumulated time, further agglomeration of the Pt particles can be seen [Fig. 5(c)]. The size of the prime particles appears to have changed little between 24 and 100 hr.

Figure 6 is a micrograph taken after 24 hr exposure showing a region where an interface between the Pt on carbon and the salt-shielded carbon zone exists.

Discussion

The surface area of Pt supported on carbon decreases considerably in H_3PO_4 at 191°C at fuel cell cathode potentials, from between 50 and 60 m^2/g at 100 hr to about 20 m^2/g after 20,000 hr. The surface area, however, is maintained much above that which would result for unsupported Pt black. The initial surface area for Pt black is 20-30 m^2/g and rapid surface area loss results; a surface area equal to about 10 m^2/g is reached after 200 hr at 150°C in 96% H_3PO_4 (4).

The significance of this area loss on fuel cell performance depends on the change in activity of the catalyst as the surface area of the catalyst changes. For a constant Tafel slope of 90 mV/decade (9) and constant catalyst activity per unit Pt area, a change in surface area by a factor of 2 results in a loss in performance of 27 mV and a factor of 3 in 42 mV. However, Bregoli (21) has shown that the catalytic properties of Pt are crystallite size dependent, with the current per unit of Pt surface area and the Tafel slope for oxygen reduction increasing as the surface area of the Pt decreases. The changing activity of the Pt results in a reduced performance loss due to loss of Pt surface area.

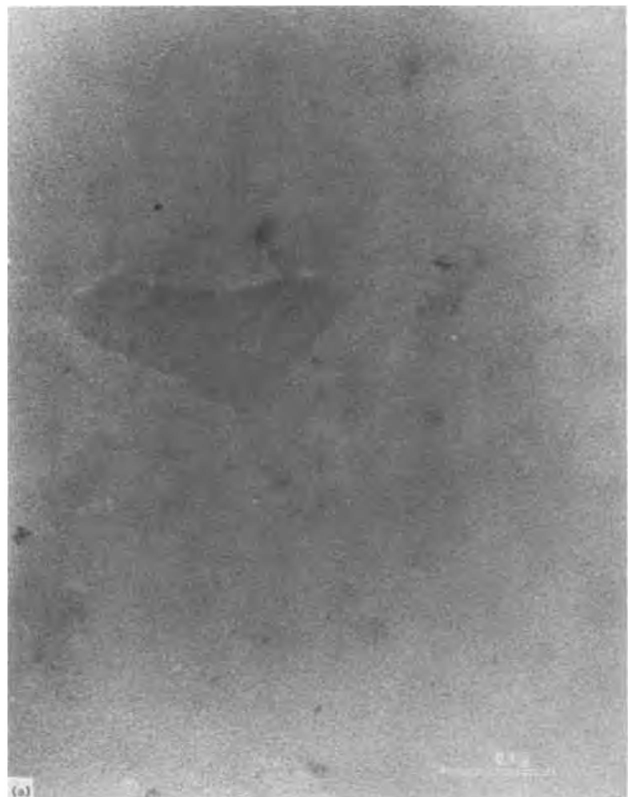
The experimental data obtained in this study can be used to help ascertain the mechanism by which Pt surface area loss occurs. As shown in Fig. 2, a good linear relationship exists between ln area and ln t. This would be predicted if the general sintering model of Ruckenstein and Pulvermacher (12), which considers crystallite migration, collision, and coalescence, applies to the present experimental situation and if the initial surface areas of the catalysts tested were the same. A least squares correlation of the data is highly significant (considering the catalysts tested had slightly different initial metal areas) and would indicate that the sintering mechanism is rate controlled by particle migration rather than particle coalescence [calculated n value is 6.4; see Ref. (12)] and that the mechanism does not change as the catalyst ages. Routine TEM analysis of sintered catalysts (see Fig. 3) always show the Pt crystallites to be roughly spherical and not elongated or "necked" as one might expect to see if coalescence of particles was rate limiting. One must be cautioned, however, against attaching too much significance to conclusions based on agreement between results using the model of Ruckenstein and Pulvermacher and experimental data obtained here since there are experimental data previously reported which cannot be explained by this model (22), and other parameters not included in the model are thought to be important. Therefore, other experimental data must also be used to determine the mechanism by which Pt surface area is lost.

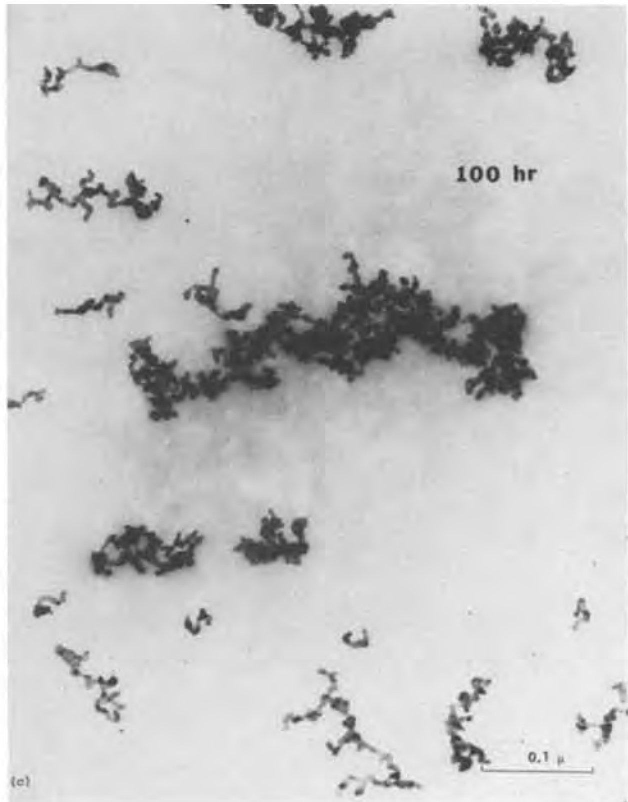
The study of the effect of operating potential and the TEM studies can be used to provide additional information. Figure 4 shows that the electrode operating potential has only a small effect on the rate of surface area loss. If the dissolution of an electroactive species such as a platinum ion were the mechanism by which Pt surface area is lost, a much stronger potential dependency would be expected. A small potential dependency was also found for Pt black (4) and Pt supported on graphitized carbon black (16, 18). The nature of the liquid environment (organic liquids, water, 96% H_3PO_4) also was found to have a smaller effect on the rate of Pt area loss than would be expected if Pt dissolution were important (16). Post-test quantitative analyses for Pt on the electrodes which provided the area loss data shown in Fig. 1 and 2 showed no significant change in Pt loadings over the duration of the tests. If dissolution occurred to a high degree, decreased Pt loadings would be expected on the cathodes and corresponding loading increases would result at either the anodes or matrices where dissolved Pt would be reduced out of solution. Based on the results of these tests at various potentials, a dissolution-redeposition mechanism can be eliminated as the primary mechanism by which Pt area is lost over the potential range investigated.

The TEM photographs of fuel cell catalyst in Fig. 3 show that the Pt crystallites are initially distributed uniformly over the carbon support material but are located at the interstices of the carbon prime particles after a period of operation. Little clustering of the Pt crystallites is evident. Pt migration might occur through the migration of adsorbed atoms or atom clusters or by the migration of entire crystallites along the carbon surface. If the entire crystallite migrates, sintering of clusters of crystallites must be occurring rapidly in the time scale of this experiment.

The distribution of particle sizes of sintered supported catalysts is believed to allow discrimination between crystallite and atom migration processes (23, 24). Pt particle size distributions for the present sintered catalysts were typically like those previously reported for Pt supported on graphitized carbon black (18), with no tail on the small particle diameter side of the peak in the distribution curves such as would be expected if an Ostwald ripening/atom migration process were occurring (23). The absence of small particles in the sintered catalysts shown in Fig. 3b, c, and d adds visual support to this argument. However, there is disagreement on the interpretation of crystallite size distribution analyses for distinguishing between these two mechanisms (25, 24). The TEM photomicrographs of Pt deposited on carbon film shown in Fig. 5 provided additional information on this question.

Figure 5a shows the initial, uniform dispersion of 1.0-1.5 nm Pt particles on the surface of the carbon film substrate. Figure 5b shows the Pt crystallites after being potentiostated at 0.7V for 24 hr in 102 w/o H_3PO_4 at 191°C. The crystallites have increased in size to about 8 nm and considerable clustering is observed. An approximate mass balance calculated by analyses of of TEM micrographs of this sintered Pt indicates that the Pt cannot all be present as spherical crystallites, but that some of it must be present as flat rafts or islands. The variation in darkness of some of the crystallites indicates that some regions are thickening into more spherical particles. This first stage of area loss could have occurred either by atom or crystallite migration. If atom migration occurred, some Pt particles less than 1.0 nm would be expected to be present. However, these are difficult to observe. If particle migration occurred, some coalescence of particles must have taken place since the Pt particles have grown from the 1.0-1.5 nm range to about 8 nm. A considerable degree of necking can be seen between these larger particles, indicating that smaller particles might have completely coalesced. After 100 hr of exposure (Fig. 5c), the size of the prime particles does not appear to have changed significantly, but much more clustering and sintering of clusters is evident. This change can occur only if the Pt crystallites move; atom migration would be expected to result in growth of the 8 nm crystallites.





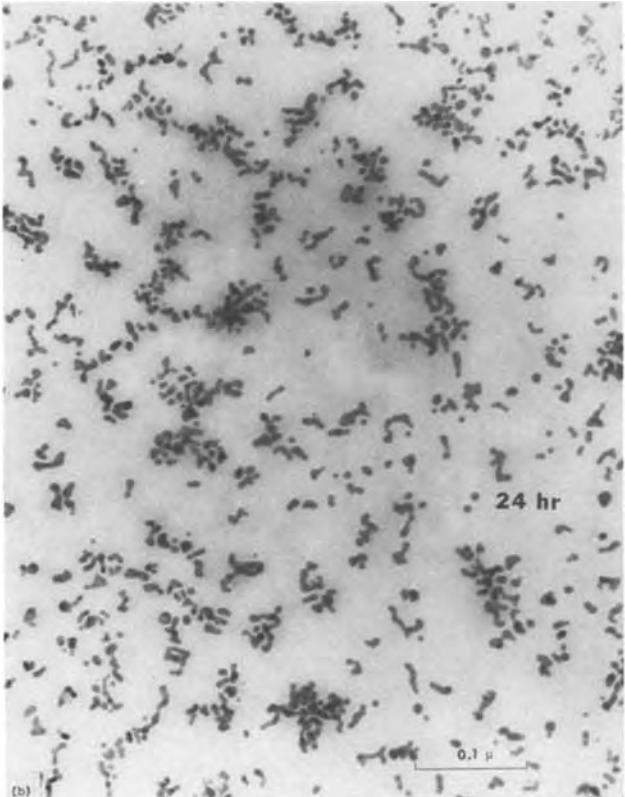


Fig. 5. Electron micrographs of Pt supported on carbon film after various times at 191°C in H_3PO_4 at 0.7V. (a) 0 hr; (b) 24 hr; (c) 100 hr.

This clustering implies that the rate-determining step for sintering during this time period on the carbon film is coalescence and not migration or the activation of a crystallite to migrate. This clustering is not evident for the fuel cell catalysts supported on high surface area carbon (Fig. 3). It may be that this type of surface requires more activation for the crystallites to become mobile and migrate, such that coalescence is not rate determining. The fact that the Pt has sintered so much more rapidly on the carbon film lends support to this hypothesis.

Several observations can be made from areas which were partially shielded during the Pt vapor deposition and show an interfacial region between the Pt on carbon and the bare carbon areas. Figure 6 shows such a region after 24 hr exposure to the acid environment. In this region the Pt chain length is less and the clean void space around custers indicate that some of the Pt was transported over distances in excess of 100 nm. This observation also provides evidence against a process involving significant dissolution/redeposition of the Pt. Dissolution would be most likely to occur with the

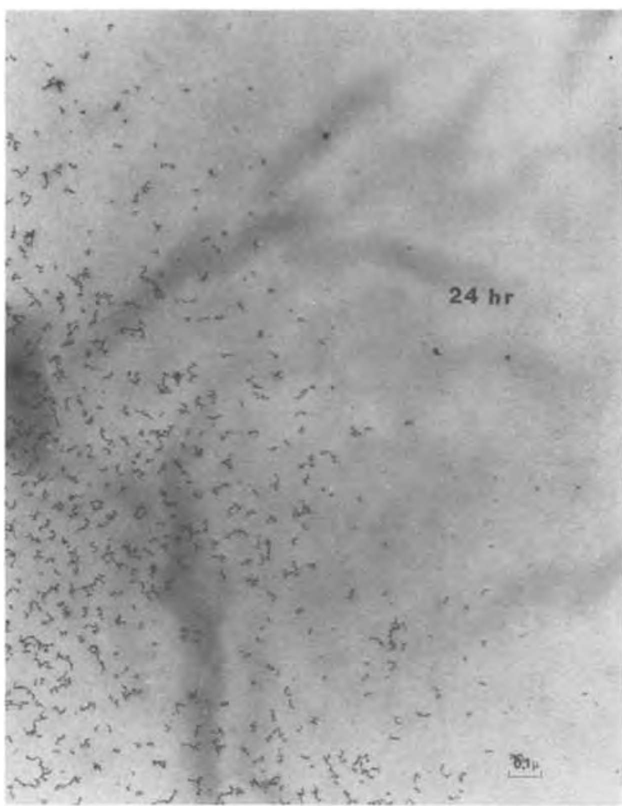

Fig. 6. Electron micrograph showing the interfacial region of the Pt-carbon and salt-shielded carbon areas after exposure to H_3PO_4 at 191°C for 24 hr.

Pt in its original highly dispersed state. In addition, the Pt is supported on essentially a planar carbon surface and is exposed to a relatively large volume of electrolyte. Under these circumstances, it is very unlikely that any Pt which might dissolve could plate out of solution somewhere else on the carbon surface. Thus, the presence of clusters formed by Pt which has been transported over large distances argues against significant dissolution of the Pt, and implies that the forces between the carbon surface and the Pt are sufficient to restrict the Pt crystallites to the carbon surface.

All things considered, this study using Pt supported on a carbon film indicates that crystallite migration is the major mode of surface area loss. And, in fact, the surface treatment of graphitic supports to retard crystallite migration was found to affect the rate of Pt area loss in 102% H_3PO_4 at 191°C (18). Previously, Bett *et al.* presented data demonstrating that the rate of area loss for Pt supported on graphitized carbon black is dependent on the concentration of the dispersed Pt in a gas phase environment (17), but is independent of Pt concentration over a range of 5-20 w/o in a H_3PO_4 environment (16). They reasoned that, if in the mechanism of crystallite migration the rate-determining step is the migration of the crystallite across the surface of the support, the rate of Pt area loss should depend on the Pt concentration. Thus they concluded that in the gas phase environment the migration of Pt crystallites on the carbon surface is the process by which Pt is transferred from one crystallite to another, but that atom migration was the mechanism in H_3PO_4. However, since the present studies indicate that crystallite migration is the major mode of area loss, the rate-determining step is apparently not the migration but some other process, perhaps the activation of a crystallite to become mobile.

Conclusions

The experimental results lead to the following conclusions:

1. Supporting Pt on carbon results in an H_3PO_4 fuel cell catalyst that maintains a surface area above 20 m^2/g for 20,000 hr at 191°C. Longer time data are not yet available.

2. The mechanism by which Pt surface area is lost for Pt supported on carbon in an H_3PO_4 acid environment is not a dissolution-redeposition mechanism in the potential range from 0 to about 0.75V. Although atom migration on the support may be a secondary factor, crystallite migration is the major mode of area loss.

Electrical Data of Sodium/Sulfur Cells Operating with Dissolved Catholyte

G. Weddigen

Brown, Boveri & Cie AG., Central Research Laboratory, D-6900 Heidelberg, Germany

ABSTRACT

Usual sodium/sulfur cells have an operating temperature of 300°C or higher. Thus the precipitation of solid polysulfides can be avoided during discharge until a stoichiometry of Na_2S_3 has been obtained in the sulfur compartment. Using organic solvents it becomes possible to discharge sodium/sulfur cells even up to the catholyte composition of Na_2S. Besides this the operating temperature can be lowered to 150°C (1). It is shown how rechargeability and internal resistance depend on temperature, solvent, and additives.

Many groups throughout the world are developing Na/S cells of the type

$$\text{Na(melt)}/\beta\text{-alumina}/y\cdot\text{S(melt)} + z\,\text{Na}_2\text{S}_x\text{(melt)}, \quad 300°\text{-}350°\text{C} \quad [1]$$

Even at this relatively high operating temperature of 300°-350°C the cells can only be discharged up to an average sodium polysulfide composition of Na_2S_3 as the more sodium-rich compounds exhibit melting temperatures above 350°C. Thus only one-third of the theoretical cell capacity and only three-fifths of the theoretical energy density can be realized.

Experiments with cells of the type (1-3)

$$\text{Na(melt)}/\beta\text{-alumina}/(y\cdot\text{S} + z\,\text{Na}_2\text{S}_{x\,\text{dissolved}}), \quad 130°\text{-}180°\text{C} \quad [2]$$

show that the following cell properties are changed in comparison to cell type [1]: (*i*) the internal resistance is increased, (*ii*) capacity and sulfur utilization are increased, (*iii*) the current density is decreased, (*iv*) the corrosion rate is decreased, (*v*) the operation temperature is lower, (*vi*) plastic materials with lower specific weight can be used as cell components and (*vii*) in the sulfur electrode a new phase boundary occurs

$$\text{Na}_2\text{S}_{x\,\text{solid}}/\text{Na}_2\text{S}_{x\,\text{dissolved}}$$

The organic solvent has to fulfill the following requirements: (*i*) stability with respect to sulfur and sodium polysulfide at 130°-180°C, (*ii*) solubility for polysulfides and sulfur, and (*iii*) high dissolution speed of liquid sulfur layers and solid Na_2S layers in organic Na_2S_x solutions.

In the case of cell type [1] the open-circuit voltage of a charged cell amounts to 2.08V. In case of cell type [2] a higher open-circuit voltage (2.14-2.17V) is obtained. It can be explained by the temperature dependence on the emf and by the solvation energy arising from the reactions

$$\text{S} + \text{solvent} \rightarrow \text{S(dissolved)} \quad [3]$$

and

$$\text{Na}_2\text{S}_x + \text{solvent} \rightarrow \text{Na}_2\text{S}_x\text{(dissolved)} \quad [4]$$

Results

Stability tests.—The organic solvents considered are hydrocarbon compounds. In contact with sulfur the C—H bond can be decomposed and the following reactions are imaginable

$$2\text{C—H} \begin{cases} \nearrow \text{H}_2 + \text{S} \rightarrow \text{H}_2\text{S exothermic} \\ \searrow 2\text{C} + \text{S}_1 \rightarrow 2\text{CS}_2 \text{ endothermic} \end{cases}$$

Key words: organic electrolyte, Na/S cells, solubility, energy density.

One can conclude that the C—H bond must be stabilized by the fact that the reaction conditions do not promote a fast reaction rate.

In order to study the thermal stability of solvents in the presence of sulfur and Na_2S_x, the solvents were boiled under reflux over several weeks. 50g of solvent and 5g of sulfur were used in these experiments which were carried out in a nitrogen atmosphere.

The H_2S gas generated by the attack of sulfur on C—H groups and N—H groups was determined daily over a period of several weeks.

Figure 1 shows some examples of the stabilities of different solvents as reacted with sulfur. It is obvious that the structure and nature of functional groups in the different solvents must lead to different results in stability. Theoretical considerations show that sulfur, being a nucleophilic chemical substance, exhibits a great reactivity towards CH acidic C—H groups. The result of such an attack consists of the evolution of H_2S gas and in the formation of a C=C double bond. Certain neighboring functional groups such as —SO_2— or —O— can increase the acidic character of the C—H bond. On the other hand, basic groups such as —$N(CH_3)_2$—can decrease the acidic character of a C—H bond in a solvent molecule. The solvents diethylene glycoldimethylether (curve 1) and tetrahydrothiophene —S—S dioxide (curve 2) have CH groups and neighboring functional groups which increase the CH acidic character. These solvents were decomposed in contact with sulfur.

In the case of tetramethylurea and of NN'diacetyl NN'dimethylethanediamine no H_2S evolution could be observed (curves 3 and 4).

Solubility and conductivity tests.—Some examples of solubilities of sodium polysulfides in organic solvents are given in Table I. One can conclude from this table that the solubilities of Na_2S_4 and Na_2S are

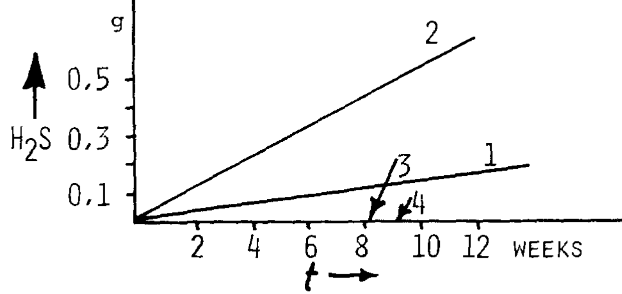

Fig. 1. H_2S evolution of solvents as a function of time. Curve 1, diethylene glycoldimethylether; curve 2, tetrahydrothiophene-S-S dioxide; curve 3, tetramethylurea; and curve 4, NN'diacetyl NN'-dimethylethanediamine.

Table I. Solubilities of Na_2S_x in organic solvents

Substance	Solvent	Temperature (°C)	Solubility (g/l)
Na_2S_4	Glycol	166	583.9
Na_2S	Glycol	170	175.0
Na_2S_4	Ethanol	55	108.0
Na_2S_4	Phenol	140	27.0

Table II. Resistivities of saturoted Na_2S_4 and Na_2S-solutions

Solvent	Dissolved substance	ρ (Ωcm) 90°C	110°C	130°C	150°C	170°C
Ethyleneglycol	Na_2S_4	58.8	35.5	22.9	14.8	10.9
Diethylenetriamine	Na_2S_4	67.6	36.3	21.7	14.0	77.6
Furfurylalcohol	Na_2S_4	216.0	166.0	137.0	105.0	X
Dimethylformamide	Na_2S_4	65.3	48.0	36.8	28.8	X
Ethyleneglycol	Na_2S	26.9	19.9	14.0	10.6	8.6

high enough in the above mentioned solvents. Unfortunately glycol is not sufficiently stable during long time tests due to the weak acidic character of the OH groups.

The resistivities of saturated Na_2S_4 and Na_2S solutions have been determined. The results (Table II) show that the resistivities are of the same order of magnitude as the resistivity of β-alumina at 150°C.

Half-cell tests.—The results of cathodic half-cell measurements are summarized in Table III.

One can conclude from Table III that mixtures of solvents enable in most cases higher cathodic current densities to be obtained than with pure solvents. This can be explained by the fact that the additives have increased the solubility of Na_2S_4 and the dissolution speed of cathodically deposited Na_2S.

Cell tests.—Cell tests were carried out in reusable glass and metal cells (4). β-alumina containing 2 weight percent (w/o) of magnesia was used as a sodium ion conductor. This solid electrolyte has a specific resistance of approximately 30 Ωcm at 150°C.

A complete cycle (stoichiometry variations between S and Na_2S) could be measured with O-toluenenitrile as solvent. This solvent exhibits a relatively weak polarity. Therefore, only a current density of 0.1 mA/cm² could be obtained. In another cell 90 cycles with a practical capacity of 70% (100% corresponds to stoichiometry changes between sulfur and Na_2S) were obtained using N methylpyrrolidon as solvent. This is shown in Fig. 2. In this case the current density increased up to 2 mA/cm² during discharge and to 4 mA/cm² during charge. The addition of tetracyanoethylene enabled one to charge the cell with a higher current density. This experiment was interrupted by the destruction of the β-alumina tube.

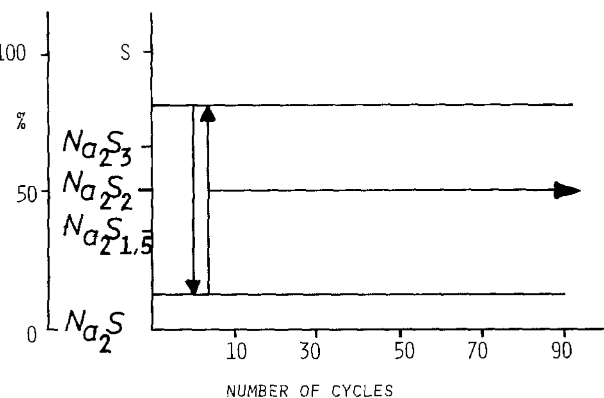

Fig. 2. Stoichiometry changes during cycle tests. Solvent: N methylpyrrolidon.

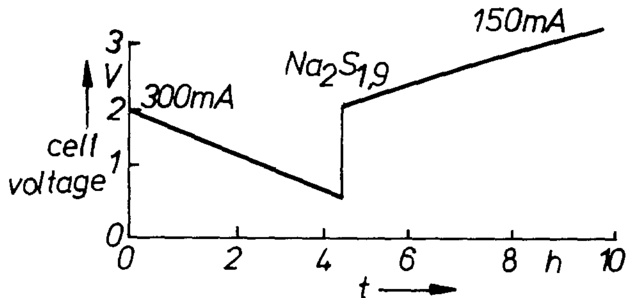

Fig. 3. First cycle of l.t. Na/S cell solvent: N methylpyrrolidon

Another cell with an electrolyte area of 40 cm² could be discharged with a current density of 8 mA/cm². The sulfur electrode contained C_6N_4 and tetramethylsulfonamide as additive and N methylpyrollidon as solvent. In the first discharge cycle 52% of the theoretical capacity could be realized (Fig. 3).

The results of some other cell measurements are represented in Table IV. If the ratio between the mass of sulfur and solvent is higher than 0.1 and the current density higher than 5 mA/cm² only small capacity values $C/C_o < 50\%$ can be obtained. In this case the existence of a solid Na_2S_x phase in the sulfur electrode causes a high diffusion resistivity as the mass transfer between this phase and the liquid phase is very slow. This resistivity contribution could be prevented during the charge cycle of experiment 7. Here the resistivity of surface unity amounted to only 13 Ωcm². This value is to be expected with respect to the specific resistivity of β Al_2O_3 at 150°C and the results of the half-cell measurements.

Conclusions

It has been shown that solvents exist which are stable against sulfur and sodium polysulfides at 150°C. By using these solvents or mixtures, the sulfur utilization can be doubled in comparison to the capacity of cell type (1). Low temperature sodium sulfur cells can be operated at 150°C with charging and discharging current densities between 3 and 20 mA/cm². The cell properties of the 300°C cell and the 150°C cell are compared in the Tables V and VI. The energy densities of the two cell types become equal when the power of the 150°C cell is 1/10 of the 300°C cell.

The Corrosion of Steel by Aqueous Solutions of Hydrogen Sulfide

D. R. Morris,* L. P. Sampaleanu,[1] and D. N. Veysey[2]

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick, Canada

ABSTRACT

Steel corrosion has been investigated through polarization studies in aqueous H_2S systems of acid pH using a rotating disk electrode cell. H_2S does not change the Tafel slopes of the anodic and cathodic processes. The anodic curves are shifted toward more negative potentials mainly due to the decrease of the reversible potential of iron, while the exchange current density appears to remain unchanged. The cathodic process maintains the reversible potential and the exchange current density of the H_2S free system, but the H^+ diffusion control gradually disappears. A corrosion current density dependence on the H_2S concentration is found which matches that obtained from published weight-loss experiments. The product of corrosion, mackinawite is essentially nonadherent and in certain circumstances enhances the corrosion rate. A new method for the compensation of ohmic overpotential in polarization measurements is described.

The corrosion of steel by aqueous H_2S is a significant technical problem in two major industrial areas. In oil refineries and natural gas treatment facilities, the process conditions vary widely due to natural causes (1-4). Replication of the conditions for laboratory work is difficult. The Girdler-Sulphide (GS) process for the production of heavy water involves the use of H_2S as the deuterium exchange agent. The process prescribes the basic pressure/temperature conditions, hence laboratory replication is simpler.

This paper presents the results of studies of the corrosion of carbon steel by deaerated aqueous solutions of H_2S at 25°-30°C using the potentiostatic polarization method and under long term (up to 1000 hr) dynamic exposure conditions.

Theory

According to the electrochemical theory of corrosion, the corrosion process takes place at a mixed potential, E_{corr} between the reversible potentials, E_{revFe} for the anodic process and E_{revH} for the cathodic process, in the absence of oxygen.

The reversible potential, E_{revFe} for the Fe^{2+}/Fe electrode is given generally by (5)

$$E_{revFe} = -0.44 + 0.030 \log [Fe^{2+}] \quad [1]$$

For the particular case involving aqueous H_2S solutions, the concentration of ferrous ions, $[Fe^{2+}]$ is related to the first and second ionization constants of H_2S, K_1 and K_2, the solubility product of FeS, K_s, and the Henry law constant, k, for the H_2S solution. Inserting numerical values of K_1, K_2, and K_s equal to 9.1×10^{-8}, 1.1×10^{-12}, and 3.7×10^{-19} at 18°C, respectively (6), and k equal to 8.3 atm (mole liter^{-1})$^{-1}$ (7) at 18°C gives

$$E_{revFe} = -0.39 - 0.06\,pH - 0.03 \log p_{H_2S} \quad [2]$$

where p_{H_2S} is the partial pressure of H_2S.

According to Hilbert *et al.* (8), iron with a high density of crystal imperfections dissolves by a catalyzed mechanism (CM) whereas iron with low surface activity dissolves by a noncatalyzed mechanism (NCM). The dissolution reaction is activation controlled with a Tafel slope $b^a = 0.04$ V/decade for the NCM (8-10) and $b^a = 0.03$ V/decade for the CM (11).

The influence of the ferrous ion concentration on the reaction rate is disputed; Bockris and Reddy (12) claim an electrochemical reaction order, $p_{Fe^{2+}}{}^a$

$$p_{Fe^{2+}}{}^a \equiv \left(\frac{\partial \log i}{\partial \log [Fe^{2+}]} \right)_{E,pH} = 1 \quad [3]$$

where i is the current density. Hilbert *et al.* (8) state that all authors agree that the reaction rate shows no dependence on $[Fe^{2+}]$.

The electrochemical reaction order related to pH, $p_{pH}{}^a \equiv (\partial \log i/\partial\, pH)_{E,Fe^{2+}}$ is agreed to be (8, 12), $p_{pH}{}^a = 1 \pm 0.1$ (NCM) and $p_{pH}{}^a = 2 \pm 0.3$ (CM).

The exchange current densities, i_o A-cm^{-2} for the Fe/Fe^{2+} electrode at $pH = 0$ and $[Fe^{2+}] = 1$ are reported as (8), $\log i_o = -8.11$ to -8.51 (NCM) and $\log i_o = -10.28$ to -12.7 (CM).

The influence of anions on the process of iron dissolution is not well understood. Florianovich *et al.* (13) conclude that anions in addition to OH^- ions play a direct part in the anodic reaction; an effect consistent with a model in which specific adsorption of the anion changes the surface area for the Fe/Fe^{2+} exchange has also been advanced (9, 10).

The reversible potential, E_{revH} for the H^+/H electrode is given by (5)

$$E_{revH} = -0.06\,pH - 0.03 \log p_{H_2} \quad [4]$$

The reaction proceeds in two stages, according to the generally accepted Volmer-Heyrovsky mechanism (14)

$$H^+ + e^- = H_{ads} \quad \text{(Volmer)} \quad [5]$$

$$H^+ + H_{ads} + e^- = H_2 \quad \text{(Heyrovsky)} \quad [6]$$

The cathodic reaction of hydrogen exhibits a Tafel slope $b^c = 0.118$ V/decade (12) which may vary slightly depending on the degree of H_2 coverage of the electrode. The bulk of reported Tafel slopes is between 0.110 and 0.120 V/decade. According to Bockris *et al.* (9), the exchange current density i_o is pH dependent, $\partial \log i_o/\partial\, pH = -0.5$; at $pH = 3$, $i_o = 1.6 \times 10^{-6}$ A-cm^{-2}.

The total amount of hydrogen produced by the cathodic reaction is equivalent to the metal weight loss and may be used as a measure of the overall corrosion rate. However, in certain circumstances, dangerous corrosion effects may occur with little weight loss due to hydrogen embrittlement of the metal. This situation arises when the Heyrovsky mechanism is hindered, leading to the diffusion of H atoms into the metal and the phenomenon of hydrogen embrittlement. H_2S is known to promote this phenomenon but a mechanism for its action has not been generally accepted. Technically, a solution to the problem has been found

through the specification of the maximum applied stress and/or hardness of the steel used.

Experimental

Polarization cells.—Polarization measurements about the corrosion potential were conducted with two designs of cell, the ASTM standard cell (15) and a rotating disk electrode cell (RDE). The design of the working electrodes used in the two cells is shown in Fig. 1. The auxiliary electrode for the ASTM cell was located on a chord plane in front of the working electrode to improve the spatial symmetry of the electrical field. This arrangement gave good reproducibility of the experimental results.

The detailed design of the RDE cell is described elsewhere (16). It was fabricated such that the only materials in contact with the electrolyte, aside from the electrodes, were glass and Teflon. Electrical contact to the rotating shaft was made via copper and mercury.

The steel specimens used as the working electrodes were machined from rod stock of 1020 carbon steel and sleeved as shown in Fig. 1. The surfaces were prepared according to standard procedures (15). Auxiliary electrodes were platinized platinum (17). As the electrolyte was sodium chloride based, no treatment was applied to remove occluded chloride.

A KCl saturated calomel reference electrode was used for all measurements; $E_{ref} = +241.5$ mV SHE. The reference electrode was bridged to the Luggin capillary with cell electrolyte via a beaker containing 1M NaCl solution.

The electrolyte solutions were prepared from reagent grade chemicals and twice distilled water. The solutions were NaCl based, blended with HCl for *p*H control with a total chloride concentration of 0.2M. The buffering agent used was acetic acid-sodium acetate. Before use the solutions were deoxygenated with bubbling nitrogen for at least 30 min, followed by H_2S bubbling for another 30 min when required. The cells were purged with nitrogen before the electrolyte was siphoned in and once wet, the electrode did not contact oxygen. The composition of the H_2S/N_2 gas mixture was controlled by the use of calibrated rotameters.

Auxiliary equipment comprised a Wenking potentiostat, a Keithley electrometer, and Honeywell digital multimeter and a thermostated water bath in which the polarization cells were immersed. Additionally for the RDE cell a speed control unit and a stroboscope were used.

The current-voltage curves were obtained using a hand-switched potentiostatic potential step every five to ten minutes, to give at least five experimental points per current decade. The current densities observed were essentially stable. The bulk of the experiments were conducted with the RDE cell at 200 rpm.

Results from initial experiments were obscured by significant ohmic overpotentials. Compensation for the ohmic overpotential is usually effected with the aid of a positive feedback circuit (18) (FBC) in conjunction with a cell substitute circuit representing the equivalent of the cell circuit, including a polarization voltage and two resistors to satisfy the relation

$$R_f/R_g = R_c/R_\Omega \qquad [7]$$

where R_c and R_Ω are the resistors in the substitute circuit; R_f and R_g are compensating resistors in the FBC. The essential difficulty is the determination of the ratio R_c/R_Ω. An elaborate method using a rapid response voltmeter, an oscilloscope, and a fast switching device to create transients shorter than 1 msec is recommended (18). To overcome these difficulties an alternative method was devised (see Appendix). This method is fast, accurate, and provided that the position of the Luggin capillary may be controlled by a screw movement, does not require any extra equipment. In the present work, the cell did not have this provision and the capillary was adjusted manually through the cell top passage. The exact position was followed with a crossline reticle finder with micrometer control.

Flow loop.—A flow diagram of the corrosion test loop is shown in Fig. 2. It consisted essentially of standard 1 in. (2.54 cm) diam glass pipeline in the form

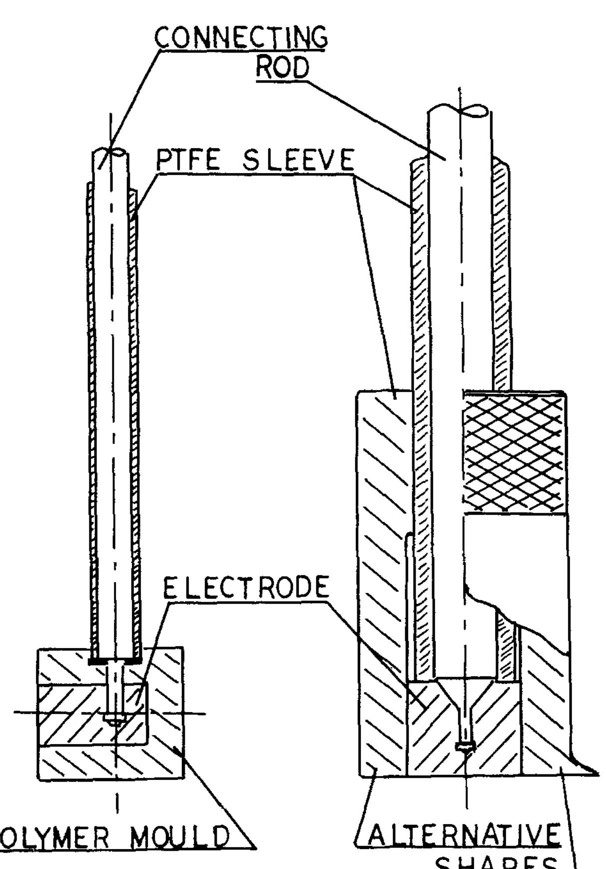

Fig. 1. Sectional view of working electrodes. Left: ASTM cell, right: RDE cell.

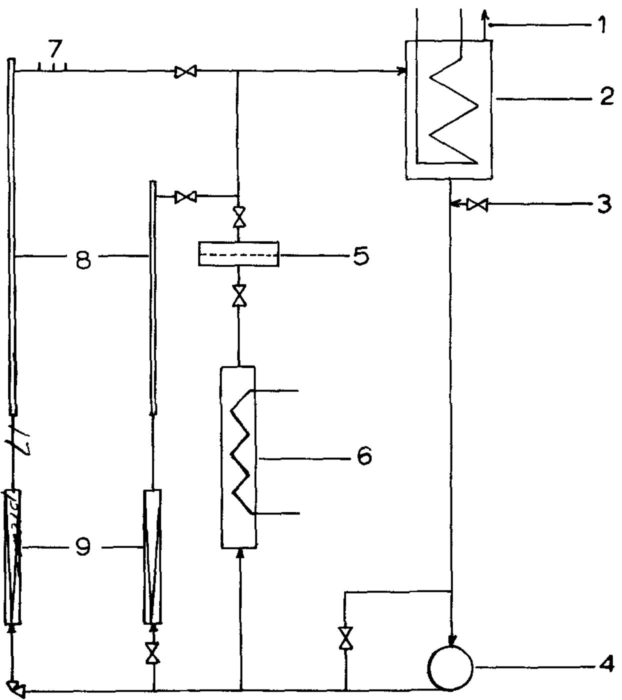

Fig. 2. Diagram of flow loop. Legend: 1. Gas outlet, 2. Header tank, 3. Gas inlet, 4. Pump, 5. Filter, 6. Heat exchanger, 7. Location of electrodes, 8. Test sections, 9. Rotameters.

of a closed circuit with two parallel test sections, a stainless steel header tank fitted with the (stainless steel) cooling coil of a refrigerator unit (Blue M Electric Company Model PCC 24SSA3), and a pump (Crane Dynapump Model 880E) incorporating a bypass. A third parallel line incorporated a Q.V.F. heat exchanger and a sieve plate filter to trap particles of corrosion product. Calibrated rotameters were installed upstream of each test section; the solution flow rate to each test section was controlled manually. Gas connections were fitted as shown in order that the distilled water could be deoxygenated initially with nitrogen and subsequently saturated with H_2S gas. The gas outlet line included a trapping arrangement to prevent ingress of air. Deoxygenation of the distilled water was achieved in the loop by purging with nitrogen over a 2 hr period; this reduced the oxygen concentration to 0.3 ppm or less. H_2S gas at 1 atm was then introduced and the solution circulated for at least 4 hr prior to insertion of the test specimens. A continuous flow of H_2S gas was maintained during the experimental work. The test loop was mounted on plywood and situated in a polyethylene enclosed cage in front of a walk-in fume hood. Ancillary equipment, installed to monitor the solution properties and the corrosion potential of the test specimens, comprised a glass pH electrode (Fisher Scientific Model E-12), a sulfide ion electrode (Orion Research, Model 94-16), and a double junction reference electrode DJE (Orion Research, Model 90-02). Output signals were recorded via a digital pH meter (Orion Research, Model 701) using a strip chart recorder (Yokagawa Company, Model LER 12A).

The pH electrode in conjunction with the DJE was calibrated periodically using standard buffer solutions of pH 4.0, 7.0, and 11.0 at 25°C. The sulfide ion electrode in conjunction with the DJE was calibrated at 25°C using standard solutions of NaOH saturated with H_2S at 1 atm. The slope $\partial E_s/\partial \log [S^{2-}]$, where E_s is the potential of the sulfide ion electrode and $[S^{2-}]$ is the sulfide ion concentration, was measured as −26.7 mV/decade in satisfactory agreement with the calculated value −29.6 mV/decade.

The corrosion potential was measured in conjunction with the DJE by adapting the assembly holder such that electrical contact with a corrosion specimen was achieved. The potential of the DJE was determined to be +125 mV SHE at 25°C.

Carbon steel test specimens were machined from AISI 1020 rod stock to a diameter of 0.5 in. (1.27 cm) and an exposed length of 1.5 in. (3.81 cm), Fig. 3. Test specimens were prepared according to ASTM specification (17), weighed, and mounted in a test assembly within 30 min of preparation. A test assembly comprised multiple specimens and was mounted in an annular geometry in the test section, Fig. 3.

Each test specimen was electrically insulated from others in the assembly using fiberglass impregnated Teflon spacers machined to the same dimensions as the test specimens. The two test assemblies were centered in the test sections using spiders. The upper and lower assembly holders were machined from Perspex; the lower was sufficiently long (6.7 in. 20 cm) to act as a calming section for the inflowing solution. The upper holder was of an adjustable length to accommodate changes in the overall length of the test assembly arising from variations in the number of specimens installed. The above arrangement of test specimens permitted the rapid removal and replacement of specimens comprising the assembly at any time within the overall duration of an experiment. Hence the average corrosion rate could be determined over different time intervals at the solution flow rates prevailing in the two test sections.

Upon removal from the loop each specimen was washed in acetone, gently air dried, and weighed. The corrosion product was mechanically removed by rubbing with acetone-soaked paper towels while rotating

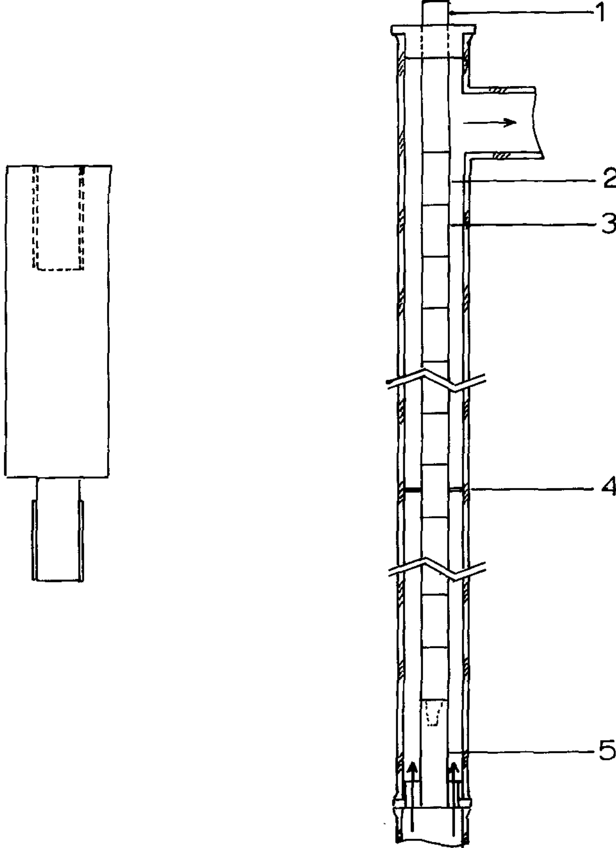

Fig. 3. Corrosion specimen and test assembly for flow loop. Legend: 1. Top holder, 2. Test specimen, 3. Teflon spacer, 4. Centering spider, 5. Bottom holder.

a drill press at low speed. This was sufficient to remove lightly adherent corrosion product. The specimen was again washed in acetone, air dried, and weighed. In later experiments the specimen was then cleaned in a special solution (25 g/liter stannous chloride, 10 g/liter antimony trioxide in 50% hydrochloric acid). It was found that this solution did not appreciably attack bare metal during exposures up to 2 min. The specimen was immersed for 10-20 sec in the cleaning solution at room temperature, washed with water, and rubbed with a soft pencil eraser. This was repeated until no more scale was visible. The specimen was then washed in acetone, air dried, and weighed.

Samples of the corrosion product were kept under nitrogen and subsequently analyzed by x-ray diffraction using Co radiation.

Experiments were conducted in the manner described at 25° ± 0.5°C using water saturated with H_2S at 1 atm with solution velocities in the range 0.1-13.3 ft/sec (0.03-4.05 $msec^{-1}$) and for specimen exposure times in the range 5-1400 hr.

Results and Discussion

The corrosion potential.—Over the pH range investigated, the corrosion potential of steel, E_{corr}, in systems with and without H_2S exhibited a linear relationship

$$E_{corr} = E^{\circ}_{corr} - 0.059\, pH \qquad [8]$$

where E°_{corr} is a constant. At $pH > 4$ slight curvature was observed in agreement with other data (9, 13, 19).

For H_2S-free electrolytes, E°_{corr} had a spread of up to 80 mV depending on the degree of agitation. With the RDE cell, the corrosion potential at pH = 2 was shifted from −318 mV SHE at 300 rpm to −394 mV at rest; the largest variation took place between rest and 100 rpm.

In H_2S systems, the corrosion potential becomes more negative, due to the change in the reversible potential

of iron with H_2S concentration according to Eq. [2]. The hydrogen reversible potential is unaffected by the H_2S concentration. Further, the presence of H_2S at low concentrations reduced the corrosion potential variation with rotational frequency; for $p_{H_2S} > 0.5$ atm the corrosion potential was independent of frequency. The largest variation of the corrosion potential was 60 mV with the RDE at 2000 rpm observed as the partial pressure of H_2S was raised from 0 to 1 atm; the major part of this change occurred over the dilute range of H_2S partial pressure.

The changes of corrosion potential of specimens in the flow loop with exposure time and flow rate were small over the ranges studied. The initial corrosion potential of a new test specimen was approximately −460 mV SHE changing to −450 mV after 5 hr exposure to the corroding solution at $pH = 4$. Thereafter it remained essentially constant for exposure times up to 6 days. An increase of the linear velocity of the corroding solution from 0 to 10 ft/sec (0 to 3 $msec^{-1}$) after 2 hr exposure was accompanied by a change in the corrosion potential of 1.4% in the noble direction. After six days exposure, a change of solution velocity had no influence on the corrosion potential.

These results indicate that the presence of H_2S progressively eliminates the strong concentration polarization of the H_2S-free system.

Polarization studies.—As a preliminary to the polarization measurements, the performance of the RDE cell was examined by measurements of the limiting current density i_L as a function of the rotational frequency, w. Plots of i_L *vs.* $w^{1/2}$ were linear in accord with theory (20). At $pH = 2.1$ $p_{H_2S} = 0.19$ atm, i_L increased by a factor of approximately 1.3 relative to the value for the H_2S-free system, again indicating the progressive elimination of concentration polarization. This is attributed to additional hydrogen discharge from H_2S by the overall reaction

$$2H_2S + 2e^- = H_2 + 2HS^- \quad [9]$$

Over the same H_2S concentration variation but at higher pH, Bolmer (21) obtained about one order of magnitude increase of i_L. However, Bolmer's work was conducted in a static system under which circumstances, stirring by the evolved gas would have a decisive effect. These effects would be minimized in the RDE cell.

The anodic polarization curves are shown in Fig. 4 and 5. Data for Fig. 4 were obtained at $pH = 3.9$-4.0; the parameter is p_{H_2S} equal to 0, 0.19, 0.50, and 1.0 atm. With the exception of data at $p_{H_2S} = 0.5$ atm. all data were taken in acetate buffered solutions. On Fig. 5 the parameter is the solution pH at p_{H_2S} equal to 0 and 0.19 atm. From these data, Tafel slopes are in the range $38 < b^a < 45$ mV/decade in good agreement with values reported by Bockris *et al.* (9).

The spacing of the curves of Fig. 4 is essentially the same as the spacing calculated for the reversible potential of iron at $pH = 4$ from Eq. [2]. This is illustrated

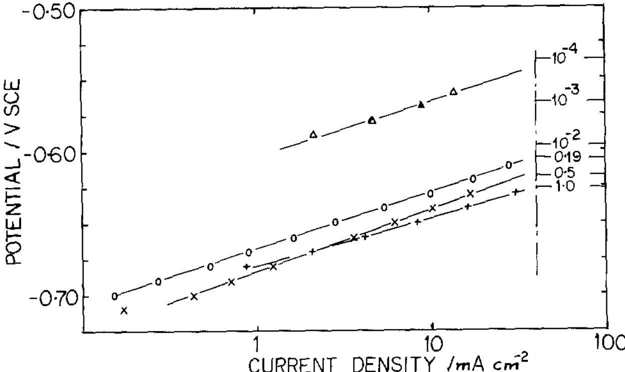

Fig. 4. Influence of H_2S concentration on anodic polarization. Solution pH: 3.9 to 4.0; Parameter is p_{H_2S} (atm).

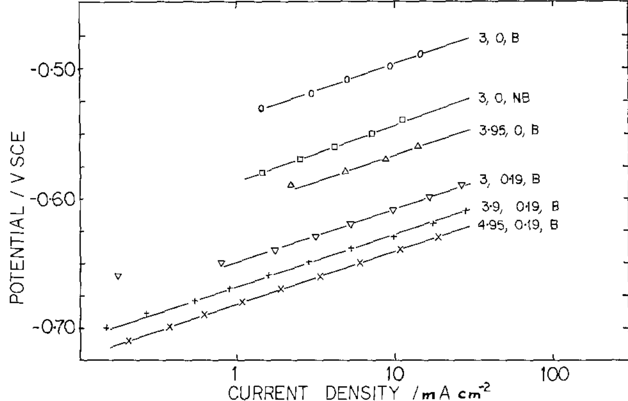

Fig. 5. Influence of buffering and pH on anodic polarization. Parameter is solution pH at p_{H_2S} = 0 and 0.19 atm. B = buffered, NB = no buffer.

on Fig. 4 arbitrarily taking as reference the curve at $p_{H_2S} = 1$ atm. Thus, variations of H_2S concentration are only causing changes in the reversible potential of iron; the exchange current density remains the same. The latter is thus calculated to be $i_o = 8.9 \times 10^{-6}$ $A\text{-}cm^{-2}$, in good agreement with reported values for the Fe/Fe^{2+} electrode (8, 9).

From Fig. 5, based on just two pH values, the buffered, H_2S-free solutions show an electrochemical reaction order, $p_{pH}{}^a = +1.8$ consistent with the reaction proceeding by the catalyzed mechanism (8). At $p_{H_2S} = 0.19$ atm, $p_{pH}{}^a \sim +0.4$ suggesting a change of mechanism relative to the H_2S-free system.

The results of some cathodic polarization experiments using buffered solutions of $pH = 3$ are presented in Fig. 6. For the H_2S-free solution, a limiting current density, $i_L = 1.06$ mA cm^{-2} was observed at an overpotential of 170 mV in agreement with the measurements of Bockris *et al.* (9). This diffusion control is eliminated by the presence of H_2S as noted earlier. Tafel slopes, $b^c = 110$ and 116 mV/decade are observed at $p_{H_2S} = 0.5$ and 1.0 atm in agreement with the theory for the discharge of the H^+ ion (9). The Tafel line is insensitive to $[H_2S]$ changes in agreement with previous observations (21, 22); the slight shift observed at $p_{H_2S} = 0.5$ and 1.0 atm is within the fluctuations due to hydrogen preconditioning of the electrode.

Polarization diagram and corrosion current density.—The results of this work and those of Bockris *et al.* (9) are presented in the polarization diagram, Fig. 7. It was shown experimentally that the shift of the anodic curves by a change of H_2S concentration is due to the shift of the reversible potential of iron. Hence the corrosion reaction order $n \equiv (\partial \log i_{corr}/\partial \log [H_2S])_{pH} = 0.20$ from geometrical considerations with $b^c = 0.110$ V/decade and $b^a = 0.041$ V/decade. At $pH = 3$ the

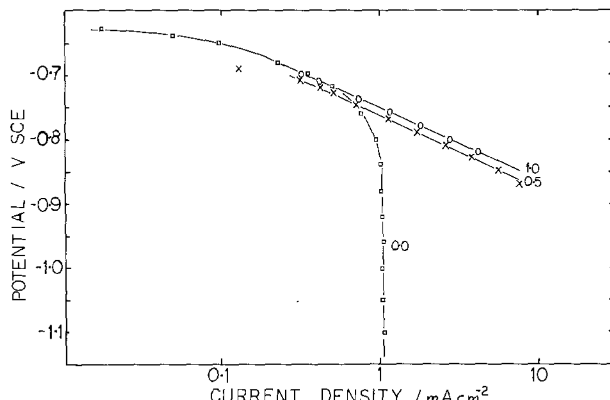

Fig. 6. Influence of H_2S concentration on cathodic polarization, at $pH = 3$. Parameter is p_{H_2S} (atm).

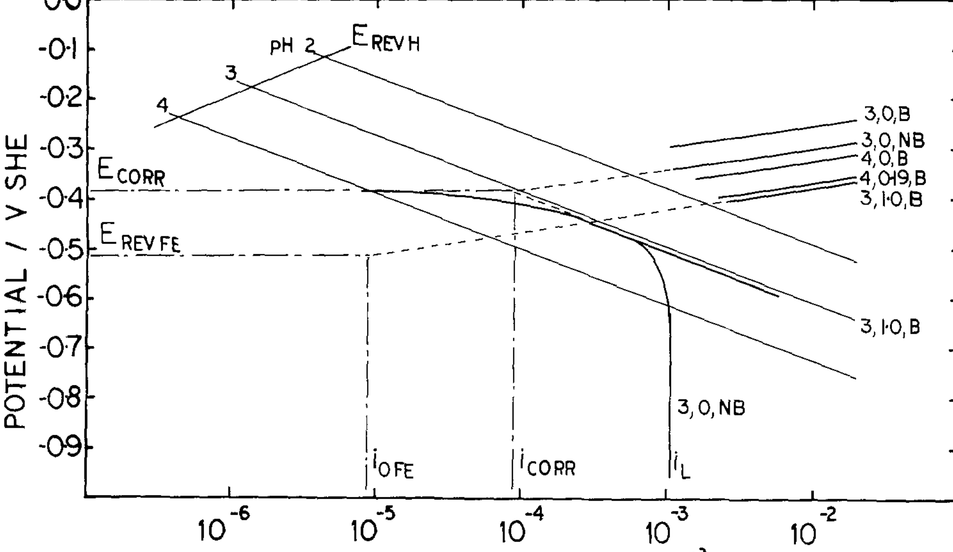

Fig. 7. Polarization diagram, system Fe + H_2S + H_2O. Light lines, from Bockris *et al.* (9). Numerals indicate solution pH. Heavy lines, this work. Numerals indicate solution pH and p_{H_2S} (atm), respectively. B = buffered, N.B. = no buffer.

corrosion current density, i_{corr} is given by

$$i_{corr} = 3.1 \times 10^{-4}\, p_{H_2S}{}^{0.20}\ \text{A-cm}^{-2} \qquad [10]$$

This is the form of dependence reported by Bartonicek (23), based on weight-loss experiments. Since the data obtained in this work reflect initial corrosion rates, whereas those of Bartonicek are averaged over the 6 hr duration of his experiments, direct comparison is not possible. For this reason his corrosion rates are approximately 85 and 38% smaller at p_{H_2S} = 1 atm and 10^{-4} atm, respectively, than values calculated from Eq. [10].

Based on a limited number of experiments, the experimental finding that $\Delta E = \Delta E_{revFe}$ might be true only over a narrow pH range. A more general expression may be obtained considering that H_2S causes not only a change of E_{revFe} but also of the exchange current density i_{oFe}. In this case, again from geometrical considerations

$$n = \frac{1}{b^c + b^a}\left(0.03 + b^a \frac{\partial \log i_{oFe}}{\partial \log [H_2S]}\right) \qquad [11]$$

Besides including the previous case, this expression produces smaller or larger n depending on the sign of the derivative.

Rate of corrosion.—A summary of the corrosion rate data obtained from the flow loop as a function of the solution velocity and exposure time are presented in Table I and illustrated in Fig. 8. The time average corrosion rate $\bar{r}$ is defined by the expression

$$\bar{r} = m/s\Theta \qquad [12]$$

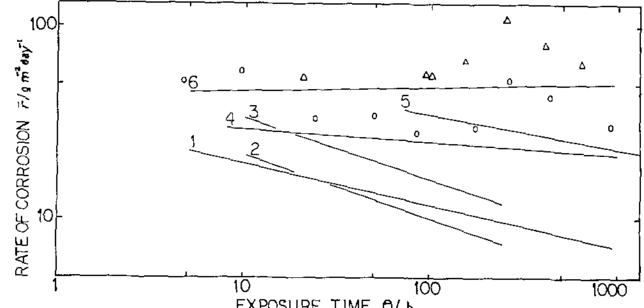

Fig. 8. Time-average corrosion rate of AISI 1020 steel. p_{H_2S} = 1 atm, temperature = 25°C. Legend: see Table I. ⊙ Solution velocity = 3.0 $msec^{-1}$, △ solution velocity = 3.1 $msec^{-1}$.

where m is the mass of metal ionized in the exposure time Θ and s is the surface area of the specimen exposed to the corroding solution. A power law relation between $\bar{r}$ and Θ of the form

$$\bar{r} = \alpha\Theta^{\gamma} \qquad [13]$$

is assumed where α and γ are constants. Values of α and γ are given in Table I together with the correlation coefficients as a measure of the fit of the data to the assumed equation. Owing to the large scatter of data, only those pertaining to line 6 are shown in Fig. 8.

Time-average corrosion rates yere generally in the order range 10-100 gm^{-2} day^{-1}, (equivalent to 0.5-5 mm penetration per year), the lower order values

corresponding to long term exposure ($\theta > 10^2$ hr) at solution velocities less than about 2 $msec^{-1}$. At solution velocities in excess of about 2 $msec^{-1}$, corrosion rates generally retained initially high values and in certain instances exceeded these values. This observation will be discussed later. The "initial" corrosion rate observed at $\theta = 1$ hr (values of α listed in Table I) averaged 50 ± 19 gm^{-2} day^{-1}, in satisfactory agreement with the value 75 gm^{-2} day^{-1} calculated from Eq. [10]

The corrosion rate r defined as

$$r = \frac{1}{s}\left(\frac{m_2 - m_1}{\theta_2 - \theta_1}\right) \qquad [14]$$

where m_1 and m_2 are the masses of metal ionized during the exposure times θ_1 and θ_2 were also calculated. Neglecting changes in the surface area of the specimen, the value r approximates the instantaneous corrosion rate at the mean exposure time $\bar{\theta} = (\theta_1 + \theta_2)/2$. Due to the large scatter of data, the values r show wide variations; the results are included in Table I as the average value, r_{avg} together with the standard deviation. These data emphasize the increasing corrosion rate with increasing solution velocity though the trend is somewhat obscured at high flow rates by the large standard deviation.

The corrosion product release rate, $\bar{r'}$ is a measure of the rate of removal of metal from the specimen. It is defined by the expression

$$\bar{r'} = (m - 0.64f)/s\theta \qquad [15]$$

where f is the mass of the corrosion product, taken to be FeS, adhering to the specimen after the exposure time θ. From the definitions of $\bar{r}$ and $\bar{r'}$, the ratio P may be defined

$$P = \bar{r'}/\bar{r} = 1 - (0.64f/m) \qquad [16]$$

with the limiting values, $P = 0$ in which case all the corrosion product remains on the specimen, and $P = 1$ in which case all the corrosion product is removed. Values of P with the standard deviation σ are included in Table I both for all the data at a given solution velocity and for data obtained in the time span 0-100 hr exposure. It is evident that in all experiments, the corrosion product is largely removed by the flowing solution ($P \rightarrow 1$). At low solution velocity ($< \sim 2$ $msec^{-1}$) there is a suggestion of greater retention of corrosion product particularly in the first 100 hr exposure. Thus the lower corrosion rates observed may be due to a protective action of the corrosion product film.

X-ray diffraction measurements of samples of the corrosion product revealed the presence of mackinawite ($Fe_{1+x}S$). Pyrite (FeS_2) was not present. No significant differences in the nature of the products were observed for either static or dynamic exposure conditions.

Metallographic examination of cross sections of specimens showed an increasing extent of surface roughness with increasing exposure time to the corroding solution. The surface roughness is defined as the standard deviation of the surface from the mean surface line observed with a microscope. The results obtained at the solution velocity of 3.1 $msec^{-1}$ are presented in Table II. Similar measurements were made of the scale roughness and thickness which also increased with increasing time of exposure. However the scale was observed to be discontinuous on the surface due, presumably, to occasional and random removal by the solution. The metal then exposed would exhibit a larger apparent corrosion rate than a fresh specimen due to the increased surface area with increasing roughness. Evidently, at high solution velocities ($> \sim 2$ $msec^{-1}$) the scale is more readily sloughed off leading to enhanced apparent corrosion rates in some instances.

Table II. Surface examination of steel specimens exposed to $H_2S + H_2O$ solutions. Solution flow rate: 3.1 $msec^{-1}$

Duration of exposure/hr	Surface rough-ness/μm	Scale rough-ness/μm	Scale thick-ness/μm
0	1.9		
260	6.2	8.9	26
980	33	28	55

These results complement those of Tewari and Campbell (24, 25) who studied the corrosion of carbon steel using the rotating disk technique. In the laminar flow regime at 22°C, $p_{H_2S} = 1$ atm, these authors reported corrosion rates in the order of 10 gm^{-2} day^{-1}, and concluded that the corrosion rate was controlled by the rate of the chemical reaction between mackinawite and hydrogen ion and by the transport of $FeSH^+$ ions to the bulk solution. At 120°C, $p_{H_2S} = 15.8$ atm in the transition and turbulent flow regimes, corrosion rates in the order range 20-200 gm^{-2} day were observed. The authors also noted that the mass of iron sulfide scale remaining on the steel specimen ($\sim$ 200 gm^{-2}) was approximately independent of the rotational frequency and exposure time indicating that the corrosion product was continuously removed from the specimen. In the work reported here, in the fully turbulent regime (Re > 8500) the corrosion product is largely removed ($P \rightarrow 1$) as noted earlier. The mass of product remaining on the specimens varied in the order range 6-60 gm^{-2} for exposure times of 10-1000 hr.

The nature of the various iron sulfides and their influence on the corrosion of steel have been reviewed by Smith and Miller (26) in which they point out that the formation of iron sulfides will in certain conditions not give protection to the metal, but will contribute a new corrosion mechanism to such systems. Thus they quote the work of King (27) who showed that the presence of mackinawite depressed the potential required for cathodic protection of steel below that normally considered adequate. Earlier, Greco and his coworkers (28) found that with increasing concentration of H_2S, increasing amounts of mackinawite [identical to Kansite (29)] relative to other sulfides were formed and that the formation of mackinawite was accompanied by an increasing corrosion rate. Meyer *et al* (30) found the initial corrosion product to be mackinawite tarnish, which provided some protection to the underlying metal. After some 200 hr exposure to the corroding solution the mackinawite tarnish grew into a thicker mackinawite scale and was accompanied by an increasing corrosion rate. Subsequent behavior depended on the presence or absence of sodium chloride in the solution; in the absence of NaCl, the outer layers of mackinawite transformed to pyrrhotite and pyrite, which provided protection to the metal. They proposed that the mackinawite tarnish, consisting of discrete crystallites consolidated into a disjointed permeable scale leading to increased electronic conductivity consequent upon an increased defect density. Similar results regarding the influence of NaCl were found by Ewing (31). This proposal is supported by the work of Mara and Williams (32) who found in particular that mackinawite was an excellent anodic and cathodic depolarizing agent.

Further evidence regarding the influence of the morphology of the scale is provided by the work of Macdonald *et al.* (33), who studied the corrosion of steel in the presence of wet elemental sulfur under aerobic and anaerobic conditions. Corrosion rates were found to increase rapidly after an induction period which was found to be a function of the initial pH of the system, the particle size of sulfur, and the presence of oxygen. In particular they noted that the onset of catastrophic corrosion was accompanied by the formation of H_2S and mackinawite and a shift in the corrosion potential to more positive values. They postulated

a mechanism in which the mackinawite acted as a catalyst of the corrosion process.

It is evident from the above discussion that iron sulfide is unreliable as a protective scale; on the contrary the formation of mackinawite may promote the corrosion process. Some evidence in support of the concept of an induction period noted by Meyer *et al.* (30) and by Macdonald *et al.* (33) was obtained in this work. This is shown in Fig. 8 in which the time-average corrosion rates at the solution velocities of 3.0 and 3.1 $msec^{-1}$ are included. These two sets of data are combined in the line 6 of Fig. 8. A significant increase in the time average corrosion rate is observed after an exposure time of the order 200 hr. Data obtained at other solution velocities showed the same phenomenon. However, the scatter of data is such as to preclude quantitative evaluation.

Conclusions

1. In the presence of H_2S, the corrosion potential of steel becomes more negative. This change is due to the change in the reversible potential of iron with change of H_2S concentration according to Eq. [2].
2. The presence of H_2S does not change the Tafel slopes of the anodic and cathodic processes within the investigated *p*H domain.
3. The exchange current density of the anodic process is unaffected by H_2S.
4. The cathodic process maintains the reversible potential and the exchange current density of the H_2S free system, but the H^+ diffusion control gradually disappears with increasing H_2S concentration.
5. The necessity for ohmic overpotential correction has been emphasized and a new method for compensation is described.
6. A corrosion current dependence on H_2S concentration has been found which agrees with that found from published weight-loss experiments.
7. The product of corrosion, mackinawite, is essentially nonadherent, particularly at solution velocities in excess of about 2 $msec^{-1}$, equivalent to a Reynolds number of about 28,000.
8. The presence of mackinawite scale in certain circumstances may enhance the corrosion rate above the initial value obtained from polarization measurements. This is in accord with earlier observations.

APPENDIX

Compensation of Ohmic Voltage Drops in the Polarization Experiments

As noted earlier, the results of initial polarization experiments were obscured by significant ohmic overpotentials; a compensation method necessitating substantial additional equipment is described by the potentiostat manufacturers (8). Britz has recently reviewed the general problem (34). In what follows, a simple method of compensation is described suitable under conditions of stable current density; this method requires little extra equipment. The method is enumerated as follows in conjunction with Fig. 9 and Ref. (18).

1. Select the polarizing voltage of the feedback circuit (FBC) as usual with no current through the loop cell-FBC. The potentiometer for R_g is turned to $R_g = 0$.
2. Place the tip of the Luggin capillary at the normally required distance S from the electrode.
3. Select the control voltage E_1 on the potentiostat control. When the current density is stable, at i_1, the following relation holds

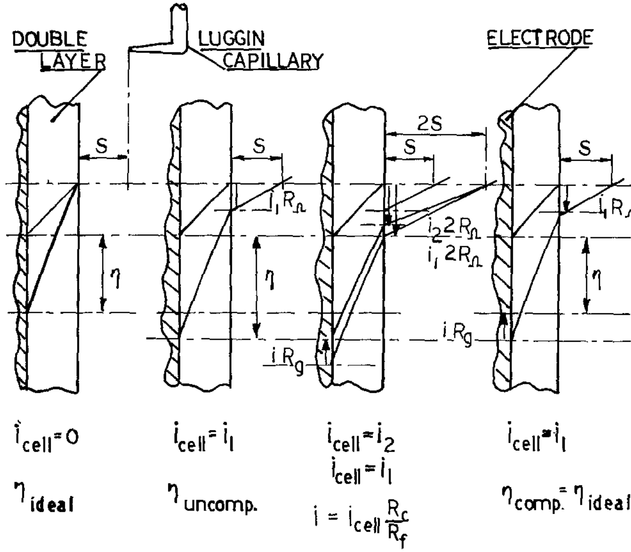

Fig. 9. Principle of new method for compensation of ohmic overpotential.

$$\eta_1 + i_1R_\Omega = E_1 \quad \text{[A-17]}$$

where η is the process overpotential under study and $iR_\Omega = E_\Omega$ is the ohmic overpotential to be compensated.

4. Change the Luggin tip location from S to $2S$. To this corresponds an electrolyte resistance $2R_\Omega$. The current density and the overpotential change to new values

$$\eta_2 + i_2\,2R_\Omega = E_1 \quad \text{[A-18]}$$

5. Compensate the FBC to a value R_{g1} which returns the current to i_1. Then one has

$$\eta_1 + i_1\,2R_\Omega = E_1 + i\,R_{g1} \quad \text{[A-19]}$$

The last term is a compensating voltage produced by the current i of the FBC over the resistor R_{g1}. Subtracting Eq. [17] and [19], one obtains

$$i_1R_\Omega = iR_{g1} \quad \text{[A-20]}$$

The total resistance of the FBC is selected to be much larger than that of the cell so the current i is small relative to i_{cell}

$$i = (R_c/R_f)\,i_{cell} \quad \text{[A-21]}$$

In view of Eq. [7], Eq. [20] and [21] are identical; hence R_{g1} is the value which will compensate the ohmic overpotential due to R_Ω corresponding to the distance S.

6. Return the Luggin capillary from $2S$ to S. The adjustment is now complete and the control voltage matches the process overvoltage, η since

$$\eta_3 + i_3R_\Omega = E_1 + i_3\frac{R_c}{R_f}R_{g1} = E_1 + i_3R_\Omega \quad \text{[A-22]}$$

or, for any other change of E, $\eta = E$.

The above method was found to be fast and accurate in the polarization experiments described.

Mechanism of Passivity Breakdown of High Purity Cadmium

M. G. Alvarez and J. R. Galvele*

Comisión Nacional de Energía Atómica, Departamento de Materiales, 1429 Buenos Aires, Argentina

ABSTRACT

The passivity breakdown of high purity cadmium in NaCl, Na_2SO_4, and KI aqueous solutions was studied. The pitting potential was measured by potentiostatic polarization techniques, surface scratching techniques, and galvanostatic techniques. The effect of *p*H and aggressive anion concentration on the pitting potential was investigated. The passivity breakdown potential of cadmium in 1.0M NaCl solution (*p*H 11 and 12.5) and in 0.5M Na_2SO_4 solution (*p*H 9-12.5) was found to be due to localized acidification on the metal-solution interface. No pitting potential was found for cadmium either in 1.0M KI solution (*p*H 11) or in 1.0M NaCl solution (*p*H 9). Thermodynamic considerations showed that no stable oxide film is formed in those solutions.

The present work is part of a research program in which the passivity breakdown mechanism of several high purity metals and binary alloys was studied in the presence of different electrolytes. The results obtained in the case of high purity aluminum (1-5), high purity zinc (6), high purity iron (7, 8), and binary Al-Cu (2, 9), Al-Mg (10), and Al-Zn (10) alloys have been published. These results suggested that in all the systems so far studied the pitting potential was the potential above which localized acidification could be maintained on the metal-solution interface (11-13). The purpose of the present work is to prove that such a mechanism can be applied to the passivity breakdown of high purity cadmium.

The literature about pitting of cadmium is not abundant. According to Kadyrov *et al.* (14) cadmium exhibits pitting in NaCl solutions and in NaCl plus NaOH solutions at $-0.50V_{(NHE)}$. Augustynski (15) measured the pitting potential of zinc, cadmium, and manganese in borate buffered solutions with different aggressive anions. This author found that in all cases the pitting potential was close to the normal equilibrium potential of the metal with its ions.

In the present work the anodic behavior and passivity breakdown of cadmium were studied in alkaline solutions of the following salts: NaCl, Na_2SO_4, and KI. The effect of the *p*H and the aggressive anion concentration on the pitting potential was also investigated. The results obtained indicated the pitting potential changes with the composition of the solution in the way predicted by the theory (11-13). This came to confirm that with this metal, too, localized corrosion appeared above the pitting potential as a result of localized acidification on the metal-solution interface.

Experimental

Specimens 1 mm thick were prepared by hot-rolling 8 mm diam 99.999% cadmium rods from "Colnbrook-Buck," England. Intermediate etchings with HNO_3 10% (v/v) were made in the preparation sequence of the samples to minimize metal contamination. The hot-rolled material was cut into rectangular 20 mm long × 10 mm wide coupons which were annealed for 2 hr at 270°C in argon and furnace cooled. A copper wire lead was soldered to one of the faces of the samples. The soldered face and the edges of the samples were covered with an epoxy resin cured at 70°C, leaving a free surface of about 1 cm^2 exposed. Before the measurements the samples were chemically polished for 1 min in a solution of 5 cm^3 HNO_3 conc plus 5 cm^3 H_2O_2 (100 vol.) plus 30 cm^3 ethanol, at room temperature.

The anodic behavior of high purity cadmium was studied in the following solutions: (*i*) 1.0M NaCl (*p*H 12.5, 11.0, 9.0, and 3.0); (*ii*) 2.5, 0.25, 0.1, 0.025,

and 0.01M NaCl (pH 11.0); (*iii*) 0.5M Na_2SO_4 (pH 12.5, 11.0, 10.0, 9.0, and 3.0); and (*iv*) 1.0M KI (pH 11.0).

The solutions were prepared with analytical grade reagents and doubly distilled water and were deaerated with purified nitrogen (16). Nitrogen was bubbled through the solutions during the tests. The *p*H of the solutions was adjusted by addition of the corresponding acid or base.

All measurements were made at 25° ± 0.5°C in a Pyrex glass cell with a platinum counterelectrode. Potentials were measured through a Luggin capillary with a mercurous sulfate reference electrode for the experiments with Na_2SO_4 solutions and with a saturated calomel electrode for the other solutions. An intermediate salt bridge with the working solution and a porous plate were used to avoid electrolyte contamination during the measurements in KI solutions. All potentials are reported in the normal hydrogen electrode scale (NHE).

Potentials were kept constant with a Tacussel PRT 40-1X potentiostat, while they were measured with a Tacussel S6Z-R2 electronic millivoltmeter. The currents were recorded with a Sefram BS recorder. A LYP Electronic Potentiostat and a Toshin Electron TO2N1 recorder were used for galvanostatic experiments.

Quasi-stationary potentiostatic curves were obtained by changing the potential in steps of 10 or 20 mV, starting from the corrosion potential. The current was measured after 10 min at constant potential. The breakdown potential was also measured by the scratching technique developed by Pessall and Liu (17), with the modifications described in a previous publication (6). Before the experiments, the samples were subjected to a cathodic reduction in the test solution by means of a 20 min polarization at −0.86V. Afterward, the samples were left at open circuit to reach a stationary potential. This occurred after about 15 min.

The galvanostatic technique was also used to measure the pitting potential in some of the solutions. In those cases a constant anodic current density of $2 \cdot 10^{-5}$ A/cm² was applied to the specimens, allowing the potential to reach a stationary value. In these galvanostatic experiments the specimens were pretreated for 15 min with a cathodic current density of 10^{-6} A/cm².

Results

Anodic behavior of cadmium in NaCl solutions.—Anodic polarization curves were obtained for high purity cadmium in the following solutions: 1.0, 0.1, and 0.01M NaCl solutions, *p*H 11.0. All the curves showed a passive zone, where the current density was lower than 10^{-6} A/cm², and a breakdown potential above which high current increases and passivity breakdown were observed. The breakdown potentials obtained through this method had a considerable dispersion, particularly in solutions with low chloride ion contents. Figure 1 shows the dispersion found in 0.1M NaCl solution (*p*H 11.0). A similar dispersion was observed in 0.01M NaCl solution (*p*H 11.0), Table I. Wide dispersion in the pitting potentials measured by potentiostatic methods was also reported for zinc (6).

Due to this difficulty the breakdown potential had to be determined through the scratching technique. Figure 2 shows the repassivation time values obtained for high purity cadmium in 0.1M NaCl solution (*p*H 11.0). The values obtained in three independent experiments are plotted and show a good reproducibility of the method. Above the pitting potential, −0.48V, the repassivation time was one order of magnitude above that found at lower potentials. Similarly, when plotting the changes in current, after scratching, the current was found to increase sharply below the pitting potential, Fig. 3, but after a few seconds it returned

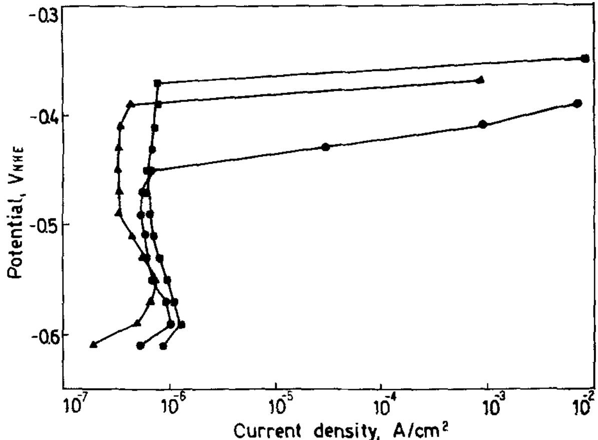

Fig. 1. Anodic potentiostatic polarization curves of high purity cadmium in deaerated 0.1M NaCl solution, *p*H 11.0, 25°C. High dispersion is found in the pitting potentials measured by this technique.

to values typical of the passive zone. However, when the surface scratching was performed at a potential just 10 mV higher than the pitting potential, the initial current rise was more abrupt and decreased slowly with frequent oscillations. It took above 4000 sec to reach a current value of the order of the initial one. The progressive accumulation of corrosion products on the scratch itself clearly indicated that this current decrease was not the result of a true repassivation process but that of a mechanical obstruction due to the corrosion products plugging up the scratched zone. Finally, when a potential of −0.46V was applied, the current did not decay after scratching, but reached values two orders of magnitude above those of the passive zone. The small dispersion found in the repassivation time, at potentials below the pitting potential, is attributed to differences in the scratch length and depth. Similar observations were made for 2.5, 1.0, 0.25, 0.025, and 0.01M NaCl solutions, *p*H 11.0. Table I summarizes the measured breakdown potentials. As reported by many authors (13) for the passivity breakdown of other metals, the pitting potential of high purity cadmium changes with the change in the aggressive anion concentration. The higher the aggressive anion concentration, the lower the pitting potential. A semilogarithmic representation of the data in Table I shows that there is a linear relation between the pitting potential and the logarithm of the NaCl concentration.

For the lowest NaCl concentration solutions (0.025 and 0.01M) there is a slight deviation from this law, leading to higher pitting potentials. Disregarding these two values, a logarithmic curve fitting gives the

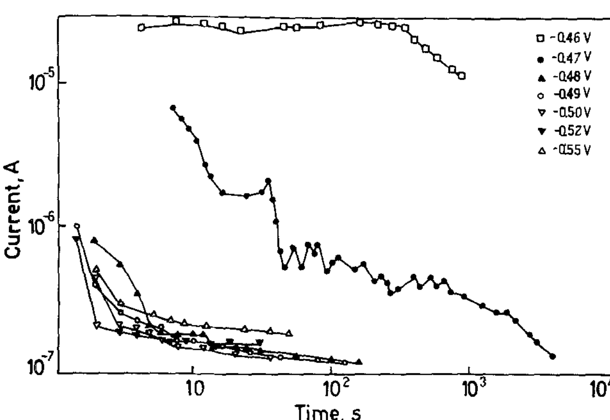

Fig. 3. Potentiostatic current-time curves, after scratching the metal surface. High purity cadmium in deaerated 0.1M NaCl solution, pH 11.0.

following relation between the pitting potentials and the NaCl concentration

$$E_p = -0.528 - 0.053 \log C_{NaCl} \quad [1]$$

where E_p is the pitting potential, in volts, and C_{NaCl} the molar NaCl concentration. The deviation observed for the two lowest concentrations is assumed to be due to uncompensated ohmic drop in the solution, in front of the pits.

The effect of pH on the pitting potential of cadmium in NaCl solutions was investigated in 1.0M NaCl solutions at pH 12.5, 11.0, 9.0, and 3.0. The results are reported in Table I. An increase in the pH from 11.0 to 12.5 was found to produce an increase in the pitting potential of about 30 mV. No passivity was found in the 1.0M NaCl solution, pH 3.0. The stationary corrosion potential in this solution after a 4 hr exposure was −0.61V. The samples showed corrosion at all the potentials above the corrosion potential. A linear relation was found between the potential and the logarithm of the current density in the range between 10^{-5} and 10^{-3} A/cm². The slope of the curve was approximately 27 mV, Fig. 4.

The behavior of cadmium in 1.0M NaCl solution, pH 9.0, was intermediate between those observed in acid solutions and in strongly alkaline solutions. The polarization curve in this medium, Fig. 5, showed a sort of passive zone followed by a breakdown potential. Nevertheless, repassivation time measurements, Fig. 6, showed that the pseudo-passive zone observed in Fig. 5 was not a stable condition. No repassivation was detected at any potential, in the pH 9.0, 1.0M NaCl solution.

Anodic behavior of cadmium in Na_2SO_4 solutions.— The anodic polarization curves of high purity cadmium in deaerated 0.5M Na_2SO_4 solutions, pH 11.0 were found to be similar to those obtained in NaCl solutions. A passive zone was found, followed by a passivity breakdown potential. A remarkable dispersion was observed in the values of the breakdown potentials thus obtained. As in NaCl solutions, the surface scratching technique gave more reproducible results of pitting potentials than the potentiostatic polarization technique. At potentials below −0.45V slight current fluctuations were observed even before scratching. But it was only when higher potentials were applied that a sensible change in current behavior took place after scratching. Duplicate experiments suggested that −0.45V was the most probable value for the breakdown potential.

The galvanostatic method was used to confirm the pitting potential value of cadmium in the Na_2SO_4 solution, pH 11.0. Figure 7 shows an example of the

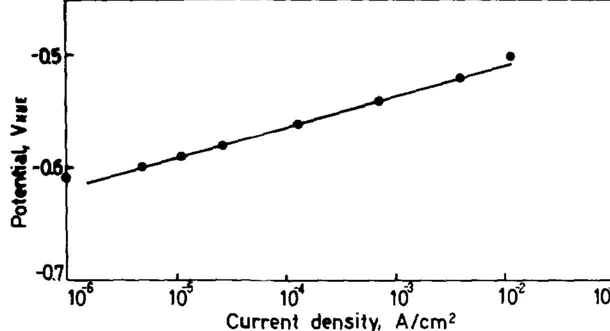

Fig. 4. Potentiostatic anodic polarization curve of high purity cadmium in deaerated 1.0M NaCl solution, pH 3.0, 25°C.

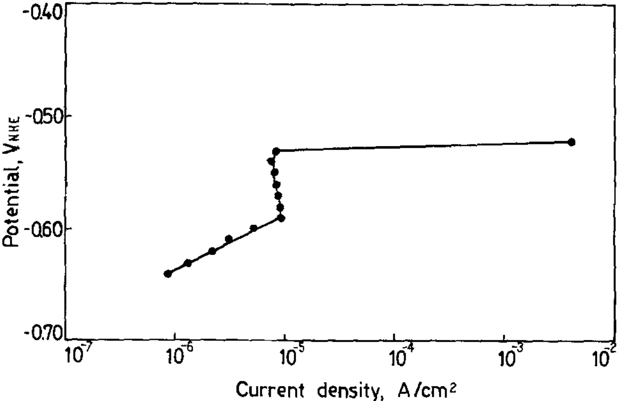

Fig. 5. Pseudo-potentiostatic anodic polarization curve of high purity cadmium in deaerated 1.0M NaCl solution, pH 9.0, 25°C. The passive zone is unstable when tested with other techniques.

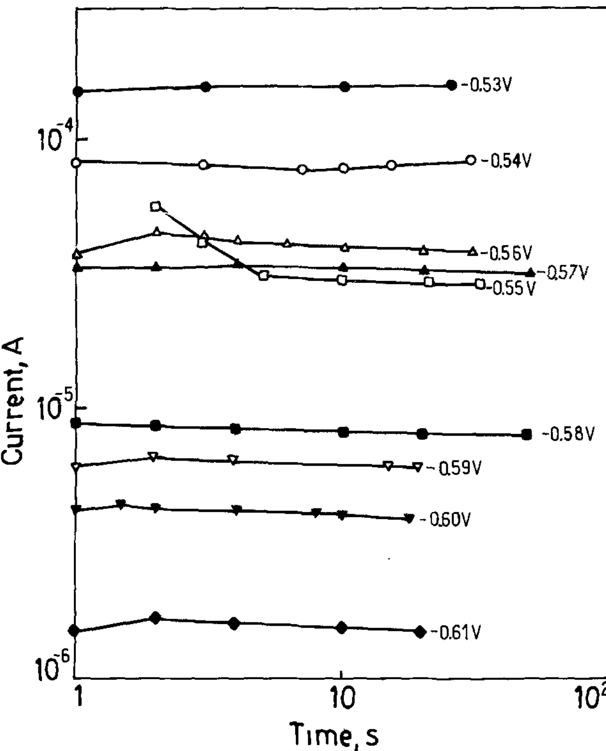

Fig. 6. Potentiostatic current-time curves, after scratching the metal surface. High purity cadmium in deaerated 1.0M NaCl solution, pH 9.0, 25°C. No passivity is found at any of the potentials tested.

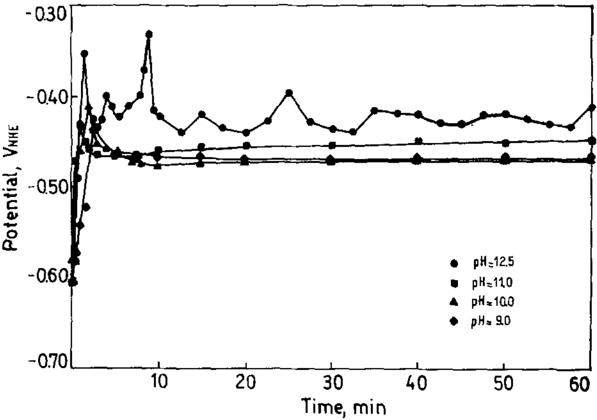

Fig. 7. Galvanostatic potential-time curves for high purity cadmium in deaerated 0.5M Na_2SO_4 solution, at 25°C and various pH values. Current density: 2×10^{-5} A/cm^2. The stationary potential is taken as the pitting potential of the metal.

potential-time curves obtained. At the beginning of the anodic polarization the potential rise denoted that a passivating film was being formed. Once the attack had started, the potential began to decrease and, after about 40 min, a stationary potential, taken as the pitting potential, was obtained. The value obtained was equal to that found by the surface scratching technique. Corroded areas were observed on the metallic surface as soon as the potential began to decrease.

The galvanostatic method was used to study the effect of pH on the pitting potential of cadmium in Na_2SO_4 solutions (Fig. 7). Measurements were performed in deaerated 0.5M Na_2SO_4 solutions, pH 12.5, 11.0, 10.0, and 9.0. The results are reported in Table I. Up to pH 10.0 the pH had no effect on the pitting potential. At higher pH values, the higher the pH the higher the pitting potential. Stationary potentials were observed in all the solutions, with the only exception the pH 12.5 solution. In this solution the potential was observed to oscillate between -0.44 and -0.41V, the pitting potential was assumed to be somewhere in between. In the region of pH values where the pitting potential changed with the pH, a linear relation between pitting potential and pH was observed. By linear regression the following equation was found

$$E_p = -0.647 + 0.018\,\text{pH} \qquad [2]$$

Electrochemical measurements were also performed in pH 3.0, 0.5M Na_2SO_4 solution. Cadmium did not show passivity in this solution. Anodic polarization experiments, Fig. 8, showed that there was a linear relation between the potential and the logarithm of the current density. A Tafel slope found was of approximately 18 mV/decade. The corrosion potential of cadmium, after a 4 hr exposure in this solution, was found between -0.53 and -0.56V.

Anodic behavior of cadmium on KI solutions.—Potentiostatic anodic polarization curves of cadmium in deaerated 1.0M KI solutions, pH 11.0, showed an apparent passive zone, followed by a breakdown potential. An important difference was found though: the passive range was very narrow, between -0.70 and -0.64V, and the breakdown potential was about 200 mV lower than that in the other solutions when applying the same technique (Table I). The passive current density, above 10^{-6} A/cm^2, was higher than the corresponding values in chloride and sulfate solutions.

Repassivation-time measurements proved that there was no actual passivity breakdown process in this medium, similarly to what was observed in pH 9.0, 1.0M NaCl solution. The after-scratching current-time curves showed that no potential could be found where a discontinuity occurred. Moreover, there was a clear increase in the current when the potential was increased, indicating the absence of any repassivation process.

Pitting morphology.—The attack observed on high purity cadmium, above the pitting potential, had the same characteristics for all the electrolytes tested. After passivity breakdown, the pits spread quickly, covering great areas of the metallic surface, Fig. 9. Dissolution developed along certain preferential crystallographic planes and looked like crystallographic etching. As dissolution proceeded, heavy accumulation of corrosion products was detected on the metal surface. This morphology, lacking the characteristic pit localization, was also observed on high purity zinc in the presence of the same aggressive solutions (6).

As shown for high purity zinc (6), the type of attack is a function of the properties of the surface oxide film. When the film is easily soluble in the acidified solution in the pit, the attack spreads easily along the surface. When the dissolution rate of the

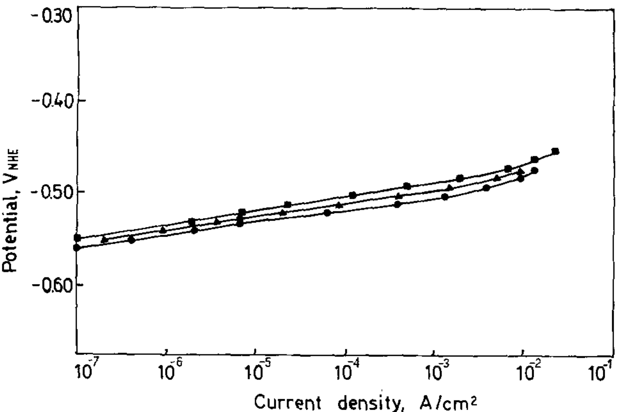

Fig. 8. Potentiostatic anodic polarization curve of high purity cadmium in deaerated 0.5M Na_2SO_4 solution, pH 3.0, 25°C.

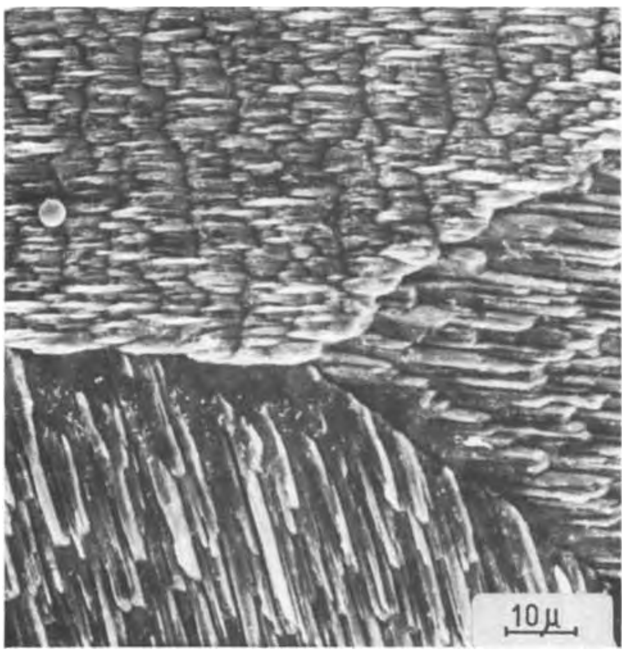

Fig. 9. Scanning electron micrograph of high purity cadmium exposed to deaerated 1.0M NaCl solution, pH 11.0, 25°C, above the breakdown potential.

oxide film, in the acid solution, is sluggish, the surface propagation of the attack is hindered by the film, and typical pits are found. In the case of cadmium, the surface oxide film offers little opposition to the spreading of the attack.

Discussion and Conclusions

Anodic polarization curves and surface scratching experiments performed in alkaline NaCl solutions and Na_2SO_4 solutions indicated that cadmium undergoes passivity breakdown in the presence of these electrolytes. For the attack to begin on the passive metallic surface, the potential must exceed a certain critical value: the breakdown potential. Even when the passivating film is mechanically disrupted, no pitting develops if the potential is below the pitting potential. The exposure of the bare metal to the corrosive environment leads to repassivation at potentials lower than the pitting potential. This suggests that the oxide film is acting as an inert barrier in the pitting process, but does not interfere with the anodic reaction that occurs at the breakdown potential. Similar conclusions were drawn when the surface scratching technique was used to study the pitting of zinc in several electrolytes (6). The same conclusion was reached through straining metal experiments with aluminum in NaCl and $NaNO_3$ solutions (4, 5), with zirconium in NaCl solutions (18), and with stainless steels in NaCl solutions (19).

According to a pitting mechanism recently proposed by Galvele and co-workers (4, 6, 7, 10-12) the necessary condition for pitting initiation and propagation is the maintenance of local acidification on the metal-solution interphase. Then the pitting potential is the minimum potential at which such local acidification can be maintained. The source of protons in the acidified zone is the metal ions produced by anodic dissolution

$$Cd = Cd^{++} + 2e \quad [3]$$

followed by metal ions hydrolysis equilibrium

$$Cd^{++} + H_2O \rightleftarrows Cd(OH)^+ + H^+ \quad [4]$$
$$Cd(OH)^+ + H_2O \rightleftarrows Cd(OH)_2 + H^+$$

As first pointed out by Hoar (20), the aggressive anions for pitting are strong acid anions. This is because they will not interfere with the reaction [4].

If reducible anions are absent, there are only two processes responsible for proton consumption in the acidified zone. One will be hydrogen evolution, which is the only cathodic reaction possible in the locally acidified zone

$$2H^+ + 2e = H_2 \quad [5]$$

and the other will be proton diffusion from the acidified zone to the bulk of the solution

$$H^+_{pit} \xrightarrow{\text{dif.}} H^+_{solution} \quad [6]$$

The open-circuit potential of the metal in the acidified solution, E_c^*, will be that at which the rate of reaction [3] equals the rate of reaction [5]. If the metal in the neutral or weakly alkaline unbuffered solution of a strong acid salt is exposed to a potential equal to E_c^*, the acidification will not survive. Since the rate of reactions [3] plus [4] is equal to the rate of reaction [5] no net production of protons will occur. Meanwhile, process [6] will dissipate any previously existing acidity.

At a potential below E_c^* reaction [5] will be greater than reaction [3]. Protons will be consumed, and eventually an alkalinization will take place on the metal solution interface. The metal ions will precipitate as oxides, or hydroxides, and will plug any defects on the passive film. Consequently, for values of the potential below E_c^*, the metal will form protective films and any disruption of the film will lead to its reformation. The dissolution process due to the existence of localized acidity in the solution close to the metal surface will only be possible when the potential surpasses E_c^*. According to this, the breakdown potential should be equal to, or higher than, the corrosion potential of the metal in the pit-like solution

$$E_p \geqq E_c^* \quad [7]$$

As shown in previous publications (11, 12) to compensate for process [6], and keep the pits active, a net anodic current density should circulate through the pits, *i.e.*, a certain polarization, η, should be applied. Then, the minimum potential for pitting would be

$$E_p \simeq E_c^* + \eta \quad [8]$$

The value of η could be estimated from either Fig. 4 or 8 if the current density inside the pits at the pitting potential is known. No direct measurements of the current density inside the pits of cadmium are available. Nevertheless, during the anodic polarization curves, it was found that the current density, when the corrosion was extended to all the surface, was of the order of 10^{-2} A/cm^2. These values were measured above the pitting potential, and it can be expected that at the pitting potential the current density should be lower. From Fig. 4 and 8 it is found that to have a current density of the order of 10^{-3} A/cm^2 a potential of -0.53V would be necessary in the chloride containing pit-like solution (Fig. 4) and a potential of -0.50V in the sulfate containing pit-like solution. These values compare very well with the pitting potentials reported in Table I. The pitting potential measured in 1.0M NaCl solution, *p*H 11, was -0.53V, while the value measured in 0.5M Na_2SO_4 solution, *p*H 9.0 and 10.0, was -0.47V.

Equation [8] gives the minimum pitting potential, according to the localized acidification mechanism. Transport considerations (11) showed that the pitting potential is increased by the presence of inhibitors in the solution. If the metal has a logarithmic type of polarization curve, then, in the presence of inhibiting anions, the pitting potential follows an equation of the type

$$E_p = A + B \log C_{inh} \quad [9]$$

A and B are constants, and C_{inh} is the concentration of the inhibiting species. According to the localized acidification mechanism for pitting, the inhibitors could be either anions of weak acid salts (buffers) or OH^- ions. From the ionic concentration diagrams (11) it was also concluded that the value of B in Eq. [9] should be close to the Tafel slope for the metal in the acidic pit-like solution. Equation [2], which is of the type of Eq. [9], was found for cadmium in alkaline Na_2SO_4 solutions. As predicted by the theory, the value of the constant B, 0.018V, was found to be equal to the value of the Tafel slope for cadmium in acid Na_2SO_4 solution, Fig. 8. In NaCl solutions, on the other hand, an increase of one unit in the pH of the solution was found to lead to an increase of 20 mV in the pitting potential. Here again there is good agreement with the theory, since the Tafel slope found for cadmium in acid NaCl solutions was 27 mV.

When the concentration of the aggressive anion is modified over a big range of concentrations, the change of the potential gradient, ϕ, inside the pits must be accounted for (11). According to the pitting theory, when the change of the value of ϕ is the only cause for the changes observed in the value of E_p, an equation of the type

$$E_p = A - 0.059 \log C_x \quad [10]$$

should be found, where A is a constant, and C_x is the concentration of the aggressive anion. Equation [1] is in good agreement with Eq. [10], showing that the change in ϕ is the only cause for the observed changes of E_p.

From transport considerations of the pitting process (11) an equation of the type

$$E_p = E_c^* + \eta + \phi + E_{inh} \quad [11]$$

should hold true for the passivity breakdown of metals. Good correlations were reported for pitting of aluminum and binary aluminum alloys (10), of molybdenum containing ferritic stainless steels (21), and of high purity zinc (6), iron (8), and nickel (8). The present results show that the same equation could be applied for high purity cadmium.

As pointed out by Augustynski (15), the passivity breakdown for cadmium is close to the normal equilibrium potential of the metal with its ions. This is shown in Fig. 10, where the pitting potential values are plotted on the Pourbaix diagram for cadmium (22). As shown in Fig. 10, the corrosion potential of cadmium in the acid solution, E_c^*, is very close to the equilibrium electrode potential of the metal for a very dilute solution of metal ions. This is because of the high overpotential for hydrogen evolution on cadmium (23). The current densities involved in the pitting process of cadmium are low, and since the Tafel slope is low too, the contribution of η to the pitting potential will be small. The same happens with ϕ. In conclusion, the value of E_p will be still in the range of the equilibrium electrode potentials of the metal.

The results in 1.0M NaCl solution, pH 9.0 (Fig. 6) and those in 1.0M KI solution, pH 11.0 are difficult to explain in view of the equilibrium Pourbaix diagram of Fig. 10. According to this diagram a $Cd(OH)_2$ oxide film should be stable in both solutions. Hence, a passivity breakdown process should be expected. Nevertheless, the diagram in Fig. 10 does not account for the soluble complexes formed by cadmium in chloride and in iodide solutions. If new diagrams are drawn (24), accounting for all these complexes, Fig. 11 and 12, no stable solid film is found in those solutions. The hydroxide stability range in KI solution is very small, and the metal remains active at almost any pH value. In the 1.0M NaCl solution, on the other hand, passivity could be found at pH values between 11.0 and 13.5.

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Sucursal 4—Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The electrosorption of methane on platinized platinum and the potentiodynamic oxidation of the electrosorbed species in $1N$ H_2SO_4 solution is studied at 60°C. Two electrosorbed species are distinguished through the I/E characteristics recorded under different perturbation conditions. These species are assigned to COH-type and CO-type adsorbed species. The latter can be transformed into the former by electrochemical reduction in the potential range of the hydrogen adatoms. The number of the electrocatalyst sites per adsorbed species is estimated. The reported results contribute to the understanding of the kinetics of the methane electrooxidation under both stationary and nonstationary electrolysis conditions.

The electrooxidation of methane on a platinum electrocatalyst occurs at an appreciable rate in aqueous phosphoric, sulfuric, or perchloric acids in the 60°-150°C range (1-5). The electrochemical adsorption characteristics of this reaction on platinum-Teflon diffusion electrodes has also been investigated (6, 7). When methane is brought into contact with a platinized-platinum electrode, a shift of the potential in the cathodic direction is observed (2, 3). The rest potential in acid solutions in the presence of methane is determined by the hydrogen adatom electrooxidation reaction (2, 3). This has been taken as evidence of a dehydrogenation reaction on the platinum surface involving the organic molecule (2, 3, 8).

The studies of the methane adsorption by different electrochemical pulse techniques indicate that the electrode contains an adlayer of the so-called C_1 species, which were considered as partially oxygenated species (4, 6, 7). In the anodic polarization of the electrode under stationary conditions, the overall methane electrooxidation reaction occurring at potentials preceding that of the oxygen evolution reaction yields CO_2 and H^+ ions with practically 100% efficiency. The corresponding Tafel line involves a slope equal to the RT/F ratio (5). When the equilibration potential of the $Pt/H_2SO_4(aq)$ (methane) interface is larger than 0.35V, there is practically no chemisorbed product accumulated and the electrochemical reaction actually takes place on a platinum surface free of chemisorption products (6).

Despite these results, the structural and energetic characteristics of the surface species involved in the reaction, as well as the kinetics and mechanism of the reaction under both stationary and nonstationary conditions, are not yet clearly established. Thus, from the differences observed between the results obtained on smooth platinum and on platinized platinum for various electrocatalytic reactions involving reactants such as carbon monoxide and formaldehyde, it follows that they are due not so much to an actual difference in the adsorption process itself but rather to the possible occurrence of processes involving the interconversion of electrosorbed species (9). By using adequate perturbation techniques it would be possible to ascertain the nature and quantity of the electrosorbed species on the electrocatalyst surface and to establish the characteristics of the predominant electrosorbed species when the electrooxidation process takes place under stationary conditions. Following these lines of thought, the present paper attempts to elucidate the electrosorption characteristics of methane on platinized platinum in sulfuric acid solution and its relation to the hydrocarbon electrooxidation process through the application of different combined potentiodynamic sweep techniques.

Experimental

A conventional three-compartment Pyrex glass electrolysis cell and platinized-platinum electrodes prepared as previously described in the literature (10, 11) were used. The working electrode real area was determined through the charge of the hydrogen electrosorption current peaks. A hydrogen reference electrode (RHE) in the free-methane electrolyte ($1N$ H_2SO_4) was employed. The potentials of the working electrode are referenced to the RHE.

The $1N$ H_2SO_4 solution was prepared from the AR chemical (Merck) and triply distilled water. The standard purity criterion for the electrolyte solution consisted in reproducing the conventional potentiodynamic current/potential (I/E) profile of the $Pt/H_2SO_4(aq)$ interface (12) after holding the potential at a value close to that of the potential of zero charge of the system for at least a 2 hr period.

Experiments were run either in the nitrogen-saturated electrolyte (blanks) or in the presence of methane (ultrahigh purity, Matheson) under 1 atm saturation at 60°C. Most of the runs were made under a continuous gas bubbling at 30 cm^3/min.

Preceding the hydrocarbon adsorption, the working electrode was subjected to the pretreatment already described (11, 13). After the electrode pretreatment the potential was held at a preset value, E_{ad}, to adsorb methane during a certain time, t_{ad}. Immediately afterward a triangular potential sweep was applied either toward the positive, program (a), or the negative-going potential direction, program (b), at a constant potential sweep rate, v (Fig. 1). From the potentiodynamic I/E displays the charge required to electrooxidize the adsorbed hydrocarbon layer, Q_{ox}, was determined after the proper corrections for both the double layer effect and the electrode surface oxidation (10).

Experiments at constant E_{ad} and t_{ad} and different v's were performed in order to select the suitable potential sweep rate range for the methane electrooxidation under hydrocarbon readsorption-free conditions. From the charge/potential sweep rate plot (10) it was found that

at $v \geq 0.05$ V/sec the methane readsorption-free condition for the electrochemical reaction was fulfilled.

Results and Interpretation

The adsorption characteristics of methane on platinum.—The adsorption of methane on platinized-platinum electrodes was studied over a wide range of E_{ad} (0.1-0.4V) at a constant t_{ad} and over a wide range of t_{ad} (5-250 min) by keeping E_{ad} constant. The amount of adsorbed species was evaluated through the charge integrated from the potentiodynamic anodic I/E curves. The electrooxidation of the adsorbed species takes place within the 0.5-0.8V range and it exhibits a double anodic current peak under the experimental conditions shown in Fig. 2. At E_{ad} = 0.3V and short t_{ad}, the I/E displays exhibit a predominant contribution of the anodic current peak located at more positive potentials. Contrarily, as t_{ad} increases the overall anodic charge also increases but the relative contribution of the anodic current peak located at more negative potentials becomes more noticeable (Fig. 2). Simultaneously, the residual hydrogen adatoms electrooxidation charge located between 0.30 and 0.40V decreases as t_{ad} increases. At a constant E_{ad}, the adsorbed hydrocarbon electrooxidation charge reaches a maximum value at the time required in order to attain a hydrocarbon stationary coverage, $t_{ad,ss}$. Reasonable straight lines are obtained in the Q_{ox} *vs.* log t_{ad} plot (Fig. 3), whose slope depends on E_{ad}. The I/E displays obtained after the hydrocarbon adsorption at $t_{ad,ss}$ and at a constant E_{ad} in the 0.2-0.4V range (Fig. 4) exhibit a maximum electrooxidation charge, $Q_{ox,M}$, equal to 0.113 mC/real cm^2 at 0.26V (Fig. 5). The maximum anodic charge associated with the methane electrooxidation is lower than that corresponding to one monolayer of hydrogen adatoms. The anodic current peak exhibits again the partial overlapping of the two anodic current peaks whose contributions change accordingly with E_{ad} (Fig. 4). At E_{ad} = 0.2V and E_{ad} = 0.4V the anodic current peak located at more positive potentials contributes predominantly

to the total anodic current while the reverse is observed when E_{ad} is close to the potential where the maximum hydrocarbon adsorption takes place.

The methane electrosorption process.—The occurrence of an electrosorption process was made evident by applying to the interface a potentiostatic step at E_{ad} just after step B of the electrode pretreatment (Fig. 1) and simultaneously recording the anodic current transient up to its stationary value. The major contribution in the overall transient current is attributed to the electrooxidation of hydrogen adatoms produced during the electrosorption process and presents an initial abrupt increase followed by a smooth decay (Fig. 6). The current related to the electrooxidation

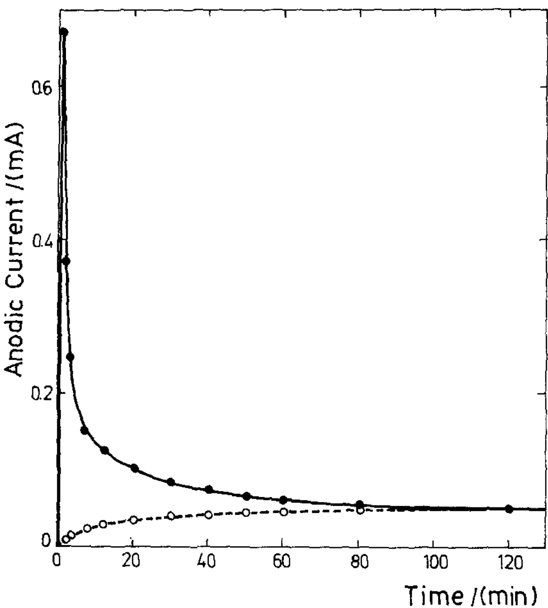

Fig. 6. Potentiostatic I/time plot at $E_{ad} = 0.28V$. Real electrode area = 1366 cm^2. ●, Overall transient anodic current after correction for the blank; ○, estimated current related to the electrooxidation of the residual electrosorbed species.

of the residual electrosorbed organic species is substracted from the overall transient anodic current after assuming that the former depends linearly on the hydrocarbon surface coverage degree (14) and that the surface coverage by the adsorbed hydrocarbon species increases linearly with log t. The anodic charge, Q_D, after correction both for the blank and for the electrooxidation reaction is ascribed to the methane dehydrogenation. The charge corresponding to the electrooxidation of the residual organic species, Q_{ox}, is determined through the potentiodynamic scan immediately after the stationary current is attained. For $t_{ad} = t_{ad,ss}$, the Q_D/Q_{ox} experimental ratio approaches two limiting values. Thus, when $0.24V \leq E_{ad} \leq 0.36V$, $(Q_D/Q_{ox})_{exp} \rightarrow 2$ while when either $E_{ad} = 0.2V$ or $E_{ad} = 0.4V$, $(Q_D/Q_{ox})_{exp} \rightarrow 3$ (Table I). Similarly, when $E_{ad} = 0.3V$ for $t_{ad} \leq 5$ min, $(Q_D/Q_{ox})_{exp} \rightarrow 3$ while for $t_{ad} > 5$ min, $(Q_D/Q_{ox})_{exp} \rightarrow 2$ (Table II).

Kinetic relationships from the potentiodynamic runs.—Within the range of either E_{ad} or t_{ad} where only the anodic current peak located at more positive potentials is observed the anodic current peak height, I_p, after the correction for the blank fits a linear dependence with v and the current peak potential, E_p, fits an E_p *vs.* log v relationship whose slope is equal to the 2.3($2RT/F$) ratio (Fig. 7 and 8). An E *vs.* log I linear plot is derived from the initial ascending portion of the

I/E display at any v in the 0.01-0.1 V/sec range (Fig. 9). The slope of the best straight line is also equal to the 2.3($2RT/F$) ratio.

The potentiodynamic I/E displays under controlled electrosorption.—The shape of the I/E display in the 0.3-1.5V range is modified when after adsorption at E_{ad} during t_{ad}, a negative-going potential excursion is run from 0.3 to $-0.025V$ covering the hydrogen adatom potential region, *e.g.*, after applying program (b) (Fig. 10). Thus, during the first potential sweep the charge pertaining to the hydrogen adatoms is lower than that

recorded during the following triangular potential scan due to the blocking of the electrode surface by the residual organic species. During the second successive potential sweep, as the electrosorbed organic species are electrooxidized and no hydrocarbon readsorption becomes possible, the hydrogen adatom current peaks whether anodic or cathodic appreciably increase in height. Nevertheless, the surface blockage affects mainly the hydrogen adatom current peaks located at more positive potentials. During the second positive going potential excursion the anodic charge associated with the electrooxidation of the organic species in the 0.5-0.8V range is practically no longer observed.

To evaluate the charge related to the hydrogen adatom monolayer the following procedure was followed. The hydrogen evolution I/E line, depicted in Fig. 10 which fits an $E/\log I$ plot was extrapolated down to $I = 0$. The extrapolated line yields the cathodic charge related to the hydrogen evolution reaction and permits a reasonable estimation of the I/E profile corresponding to the adsorption of hydrogen adatoms. The decreasing portion of the latter exhibits an inflection point near 0.05V and reaches the $I = 0$ condition corresponding to full hydrogen adatom coverage at -0.01V as given by pseudocapacity data (15).

The blocking charge Q_b is defined as the difference between the hydrogen adatom charge required to form a monolayer in the absence of methane and the charge related to the hydrogen adatoms formed in the methane-saturated solution. The Q_b/Q_{ox} ratio in the 0.24-0.34V range is close to one (Table III).

The comparison of the I/E displays run with the perturbation programs (a) and (b) shows a remarkable difference in the potential range associated with the electrooxidation of the methane electrosorbed species. Thus, the first I/E profile (Fig. 10) obtained after applying program (a) starts with a surface which is appreciably covered by the electrosorbed species which is electrooxidized at more positive potentials. This is obtained by the proper adjustment of both E_{ad} and t_{ad}. If the electrooxidation of the electrosorbed species is preceded by a negative-going potential scan covering the whole potential range related to the hydrogen adatoms species, *e.g.*, after applying program (b), the immediately following positive potential-going I/E profile shows that the complex anodic current peak after hydrogenation shifts toward more negative potentials and simultaneously the charge involved in the electrooxidation process is practically equal to that observed in the first positive-going potential I/E profile run with program (a).

Table III. Q_b/Q_{ox} ratio at t_{ad} = 15 min and different E_{ad}

E_{ad} (V)	Q_b/Q_{ox}
0.24	1.0
0.30	0.9
0.34	0.8

To confirm the different hydrogenation capabilities of the electrosorbed species, experiments were also made having the electrocatalyst surface mainly covered by the electrosorbed species which is electrooxidized at the more negative potential. In this case after the potentiodynamic hydrogenation the immediately following positive-going potential scan shows that the I/E profile corresponding to the electrooxidation of the adsorbed species remains practically unaltered.

Further evidence of the different hydrogenation capability of the two types of electrosorbed organic species is obtained by running the same kind of experiment as described above but including a potential holding at 0.05C for different periods of time, t_c (Fig. 11). As the cathodization time increases the electrooxidation profiles of the electrosorbed species progressively moves toward more negative potentials yielding a reasonably stable I/E profile only when the cathodization time exceeds 5 min. The potentiodynamic I/E profile in the hydrogen adatom region changes as already described regardless of the type of perturbation applied to the interface.

All these experiments indicate that the electrosorption of methane on platinum implies the formation of at least two adsorbed species, one of which can be transformed into the other through a potential-controlled hydrogenation.

Stationary I/E measurements.—The stationary I/E measurements were made by applying to the electrochemical interface different potentiostatic steps at preset potentials in the 0.20-0.55V range just after step B of the electrode pretreatment (Fig. 1). The steady current value at the preset potentials are attained after periods of time comprised between 10 and 190 min depending on the preset potential value (Fig. 12). The experimental $E/\log I$ plot corresponds to a curve (Fig. 13). The lower potential region of the $E/\log I$ plot approaches a limiting straight line whose slope is equal to the $2.3(RT/F)$ ratio while the upper potential region approaches a limiting current.

Discussion

The electrocombustion of methane on platinized platinum is expressed by the following overall anodic reaction

$$CH_4 + 2H_2O = CO_2 + 8H^+ + 8e \quad [1]$$

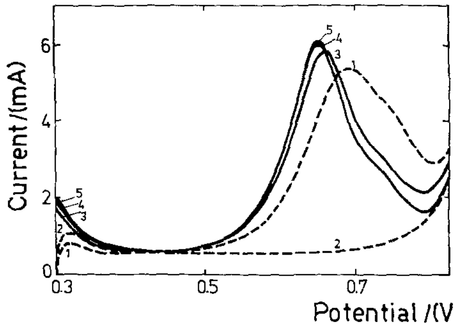

Fig. 11. Potentiodynamic I/E profiles at 0.2 V/sec. E_{ad} = 0.3V; t_{ad} = 30 min. Real electrode area = 42 cm^2. - - -, First (curve 1) and second (curve 2) I/E profiles run with program (a); ——, I/E profiles run with program (b) but including a potential holding at 0.05V just after step D for different t_c: curve 3, t_c = 10 sec; curve 4, t_c = 1 min; curve 5, t_c = 5 min.

This reaction is free of hydrocarbon readsorption contribution when it proceeds potentiodynamically at potential sweep rates larger than 0.05 V/sec. Under potentiostatic conditions reaction [1] involves an electrosorption proceess preceding the proper electrooxidation reaction. Methane electrosorbs slowly on platinum through a dissociative mode. Under most of the experimental conditions chosen to study the adsorption process, the reaction is partially diffusion controlled (14). This is not unexpected since the solubility of methane in water at 25°C and 1 atm pressure is 24.4g $CH_4/10^6$g H_2O (16). In the adsorption of methane, hydrogen- and oxygen-containing chemisorbed species were shown to appear on the Pt electrocatalyst after a prolonged contact of the latter with the methane-saturated electrolyte at open circuit (3).

The present results indicate that in the electrosorption process at least two well-distinguished hydrocarbon residual surface species are involved. It has been suggested that the surface species resulting from methane adsorption on platinum in acid electrolytes may be $-$CHO, $\equiv$COH, or a similar species (4, 7). The former involves a single bond with platinum and three electrons per platinum site while the latter implies bonds with three platinum sites, requiring one electron per site. The CO-type species are produced on platinum during the adsorption of different compounds such as CO and formaldehyde (17, 18), although COH-type species are also formed from both substances as revealed by radiochemical techniques (19, 20). Furthermore, it has been demonstrated that the adsorbed surface species can interact with each other or with hydrogen adatoms or adsorbed OH radicals so as to form new adsorbed species or to desorb as stable organic molecules (9). Thus, it has been proposed that the electrooxidation of methanol on platinum occurs via the interaction of adsorbed $\equiv$COH particles with adsorbed OH radicals (21, 22)

$$(\equiv COH)_{ad} \xrightarrow[-H_2O]{+(OH)_{ad}} (=CO)_{ad} \xrightarrow{+(OH)_{ad}} (-COOH)_{ad} \xrightarrow[-H_2O]{+(OH)_{ad}} CO_2 \quad [2]$$

The adsorbed OH radicals are produced in the preceding fast electrochemical step in acid solutions

$$H_2O = (OH)_{ad} + H^+ + e \quad [3]$$

and in alkaline solutions

$$OH^- = (OH)_{ad} + e \quad [4]$$

which at 0.3-0.9V (RHE) can be regarded as being in equilibrium (23, 24). Hence, all these results suggest the possibility of a gradual hydrogenation of the CO-type species into the COH-type species, as is experimentally demonstrated in the present paper. Then, the Q_D/Q_{ox} experimental ratio furnishes an indication as to the most probable type of adsorbed species which predominates during the electrosorption process under constant potential conditions.

The existence of the first electrosorbed species can be explained through the electrosorption of methane according to the following reaction

$$CH_4 + H_2O \rightleftarrows (COH)_{ad} + 5H^+ + 5e \quad [5]$$

Therefore, the major contribution in the anodic transient current recorded during the potentiostatic electrosorption at a potential which is in the neighborhood of the maximum adsorption potential, corresponds to the deprotonation of methane yielding the adsorbed COH species. Reaction [5] is probably a complex process involving 5 F/mole of electrosorbed species. Now, under potentiodynamic conditions, the electrosorbed species is electrooxidized according to

$$(COH)_{ad} + H_2O \rightleftarrows CO_2 + 3H^+ + 3e \quad [6]$$

where 3 F/mole of electrosorbed species play a part in the reaction. Therefore, from reactions [5] and [6] the Q_D/Q_{ox} ratio equals 1.7, a figure which is near to the lowest limit for the Q_D/Q_{ox} experimental ratio.

On the other hand, the existence of the second adsorbed species from the methane electrosorption process results from the reaction

$$CH_4 + H_2O \rightleftarrows (CO)_{ad} + 6H^+ + 6e \quad [7]$$

yielding a CO adsorbed species and six protons per adsorbed methane molecule. Reaction [7] corresponds to another limiting situation for the electrosorption of methane on platinum which predominates at short t_{ad} or at constant E_{ad} or when either E_{ad} = 0.2V or E_{ad} = 0.4 V at $t_{ad,ss}$. When reaction [7] occurs the potentiodynamic electrooxidation corresponds to the following process

$$(CO)_{ad} + H_2O \rightleftarrows CO_2 + 2H^+ + 2e \quad [8]$$

This second possibility for the electrosorption and electrooxidation of methane on platinum involves a Q_D/Q_{ox} ratio equal to 3. Therefore, the relative contribution of the two electrosorption processes depends on E_{ad} and t_{ad}, so that tht experimental values which lie between 1.9 and 3.2 indicate the composite nature of the electro-

sorption process preceding the proper electrooxidation reaction.

The existence of two different adsorbed species opens the possibility that the CO species can be electrochemically reduced to the COH species according to

$$(CO)_{ad} + H^+ + e \doteq (COH)_{ad} \quad [9]$$

Reaction [9] is obviously potential dependent. Furthermore, if two residual organic species are formed during the electrodeposition process whose relative contributions depend on E_{ad} and t_{ad}, the fact that Q_b is essentially equal to Q_{ox} (Table III) implies that each COH species blocks three adsorption sites of the electrocatalyst while each CO species involves only two adsorption sites. According to reaction [9] the electrooxidation current peak located at more negative potentials is that related to the COH species and that located at more positive potentials corresponds to the contribution of the CO species. As a matter of fact, the potential range of the current peak assigned to the electrooxidation of the CO-type adsorbed species coincides with the potential range where the CO-electrosorption current peaks are observed (25-27), although the corresponding I/E profile is apparently more complex than thought earlier (28).

On the assumption that the electrooxidation of COH-type species occurs at more negative potentials while that of the CO-type species takes place at more positive potentials, the electrooxidation charge of each species can be related to the dehydrogenation charge involved in the electrosorption process. Thus, the total dehydrogenation charge, Q_D can be related to the corresponding electrooxidation charges according to

$$Q_D = 1.7(Q_{ox})_{COH} + 3(Q_{ox})_{CO} \quad [10]$$

The $(Q_D/Q_{ox})_I$ and $(Q_D/Q_{ox})_{II}$ ratios shown in Tables I and II involve the experimental Q_{ox} and the Q_D estimated according to Eq. [10] from the decomposition of the overall anodic potentiodynamic I/E profiles into two partial current contributions represented by two Gaussian functions (Fig. 14). The former ratio denoted by the subscript I implies that the peak location at more negative potentials corresponds to the COH species while that located at more positive potential values is related to the CO species. The charge ratio indicated with the subscript II corresponds to the reverse assignment of the two current peaks. Nevertheless, it should be pointed out that evaluation of Q_D from the potentiostatic transients may involve a small contribution due to the probable electroreduction of traces of CO_2 present at the electrochemical interface generated during the electrosorption process particularly when the latter occurs at $E_{ad} < 0.24$V. This means that the experimental Q_D values used up in Tables I and II are the minimum Q_D values and, consequently, the reported $(Q_D/Q_{ox})_{exp}$ figures should be taken as the lower limiting values of the $(Q_D/Q_{ox})_{exp}$ ratios. Therefore, from the data assembled in Table I one deduces that in the 0.24-0.36V range, under hydrocarbon stationary coverage conditions, the main electrosorbed species is the one identified as the COH-type species.

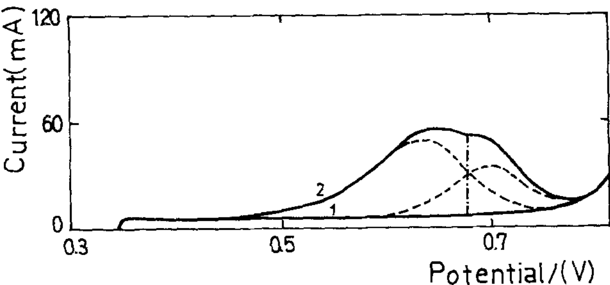

Fig. 14. Potentiodynamic I/E profile at 0.1 V/sec, $E_{ad} = 0.34$V and $t_{ad,ss}$ (curve 2). Real electrode area = 1366 cm². The estimated separate current contributions are represented by the dashed curves. Blank (curve 1).

Contrarily, when the hydrocarbon adsorption takes place at either 0.2 or 0.4V during $t_{ad,ss}$ the CO species is apparently the predominant species on the electrocatalyst surface. Furthermore, for those experiments run at a constant E_{ad} and different t_{ad} (Table II), during the initial electrosorption the CO species apparently predominates on the surface while on increasing t_{ad} the COH species becomes the main species on the electrocatalyst surface. These conclusions are relevant to understanding the kinetics and mechanisms of the overall reaction under different experimental conditions.

The dependence of both I_p and E_p on v and the Tafel slope equal to the $2.3(2RT/F)$ ratio, which are worked out from the potentiodynamic data at $E_{ad} = 0.4$V, should be directly related to the electrooxidation of the CO-type species. Accordingly, this reaction which finally yields CO_2 and H^+ ions should comprise an initial single electron transfer step as rate determining. The possible sequence of consecutive reactions can be written in the following way

$$(CO)_{ad} + H_2O \doteq (COOH)_{ad} + H^+ + e \quad [11a]$$

$$(COOH)_{ad} \doteq CO_2 + H^+ + e \quad [11b]$$

where step [11a] is rate determining, under a Langmuirian type of adsorption isotherm for the CO-type species. This means that any interaction effect should be, in principle, negligible, a situation which is not far from reality as the prevalence of the CO-type species on the electrode surface is only accomplished under a low degree of surface coverage, that is, when the adsorption occurs either at low adsorption times or at potentials located at both sides far enough from the maximum electrosorption potential.

Finally, a comment on the Tafel plot related to the methane overall electrooxidation process is relevant at this stage. The fact that the average composition of the adsorbed species depends both on E_{ad} and t_{ad}, and that different times are required to reach the hydrocarbon stationary surface coverage at each E_{ad}, indicates that any Tafel-type plot derived from stationary measurements should be handled with extreme care in order to draw mechanistic conclusions on the electrochemical reaction. Under these circumstances it is not surprising that the Tafel plot corresponds in face to a curve which approaches a limiting current at potentials higher than 0.3V (Fig. 13). However, the initial portion of this curve can be to a certain extent arbitrarily approximated to a straight line which approaches the slope RT/F on a log I region less than one decade. This slope has been recently reported for the stationary electrooxidation of methane at potentials lower than 0.2V (5) and was used, together with the pH and the hydrocarbon partial pressure dependences of the electrochemical reaction, for the mechanistic interpretation of the reaction in terms of the following successive stages

$$CH_4 = (CH_3)_{ad} + H^+ + e \quad [12a]$$

$$(CH_3)_{ad} \rightarrow \text{intermediates} \quad [12b]$$

where stage [12b] was assumed to be rate determining. Nevertheless on the basis of the previous discussion this slope cannot be taken as a definitive criterion to derive the mechanism of the electrochemical process. Furthermore, under stationary conditions, the actual situation may be even more complex since, apart from a possible diffusional contribution at the higher overpotentials, the reaction may involve in addition to the COH- and the CO-type species, a relative number of other adsorbed intermediates such as COOH-type, CH, CH_2, and CH_3 species, as already pointed out for the electrooxidation of more complex organic molecules on platinum (26, 29).

Galvanostatic Oxidation of Nickel in Borate Buffer Solution

B. MacDougall,* D. F. Mitchell, and M. J. Graham

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario K1A 0R9, Canada

ABSTRACT

Anodic oxide films formed on nickel in pH 7.65 borate buffer solution in both the passive potential and oxygen evolution regions have been analyzed by RHEED, Auger spectroscopy (in conjunction with argon ion sputtering), and O K_α x-ray emission spectroscopy. In the passive potential region, a highly epitaxed, single crystal NiO film is formed with a limiting thickness of ~12Å. In this potential range, even very long times of anodizing do not alter the oxide epitaxy or increase its thickness. In contrast, polarization in the potential range where oxygen is evolved results in the development of considerable oxide misorientation and a significant increase in oxide thickness. While long times of polarization (>20 hr) in this potential region produce oxide films hundreds of angstroms thick, the current efficiency for oxide growth is <1%. These thick anodic oxide films are quite different from thermally prepared, compact films of NiO and appear to have an open-cellular, sponge-like structure with an oxygen:nickel ratio approaching 1.3. This oxide probably forms by a direct oxidation rather than a dissolution/precipitation reaction.

The passive oxide film produced by potentiostatic oxidation of nickel in neutral and acid sulfate solutions is NiO (1-4). The stability of this film towards open-circuit breakdown and cathodic reduction depends strongly on both the time and potential of anodic treatment, in contrast to the overall film thickness which is almost constant at 9-12Å (0.13-0.17 μg oxygen cm^{-2}) (5-8). It has been reported by other workers (9-11) that oxide films several thousand angstroms thick can be produced galvanostatically on nickel in neutral borate solution but not in sulfate solutions. The reason for the difference appears to be the much higher solubility of the oxide film in sulfate solution in comparison with the borate electrolyte. While it is agreed that thicker oxide films can be formed on nickel in neutral borate solutions, little is known about their nature and their relationship to the passive films formed in the potential

region between nickel dissolution and oxygen evolution.

The present paper presents the results of an investigation of the anodic oxidation of nickel in pH 7.65 borate buffer solution under galvanostatic conditions. The electrochemical data are complemented by solution analysis for Ni^{2+} to determine the current efficiency for oxide growth. Also, electron diffraction, Auger electron spectroscopy, and x-ray emission analysis have been used to determine the structure, thickness, and composition of the oxide films.

Experimental

Polycrystalline specimens, 1 × 2.5 × 0.02 cm thick, were prepared from Materials Research Corporation zone-refined nickel sheet of 99.996% purity (1). They were degreased with benzene, chemically polished, electropolished for 2 min at 23°C in a 57 volume percent (v/o) sulfuric acid solution at 0.5 mA cm^{-2}, and then annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were again electropolished immediately before use in an experiment. Potentials quoted in this paper are referred to the saturated calomel electrode which is 0.245V with respect to the standard reversible hydrogen electrode. Electropolished nickel electrodes were galvanostatically anodized either with or without cathodic reduction of the prior oxide film, as discussed in detail elsewhere (12). Solutions were deaerated pH 7.65 borate buffer, and were analyzed for Ni^{2+} by carbon rod atomic absorption spectroscopy, the lower limit of detection by this method being 0.2 μg cm^{-2} (sample area = 5 cm^2; cell volume = 50 ml). X-ray emission (13, 14) and Auger electron spectroscopy (Physical Electronics Incorporated Model 590) were used to determine oxide film thickness. The structure of the oxide film on a Ni(111) single crystal electrode was investigated by reflection high energy electron diffraction (RHEED).

Results and Discussion

Anodic galvanostatic charging data.—Electropolished nickel has a 6Å (0.087 μg oxygen cm^{-2}) "air-formed" film of NiO (1, 2, 4, 7) which can be cathodically reduced in neutral borate solution (9, 15). In this work, anodic charging curves were obtained for both the oxide-covered and oxide-free electropolished nickel electrodes (Fig. 1), the latter being obtained after cathodic reduction at 80 μA cm^{-2} for 5 min. For the oxide-free surface (Fig. 1, curve a), an initial potential arrest is followed by a region of almost linear increase of anodic potential, V_a, with anodic charge,

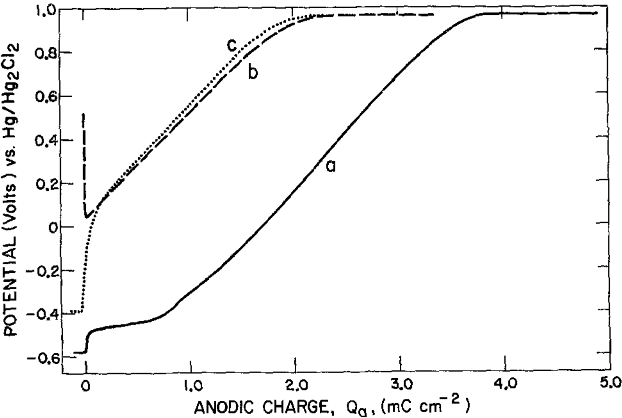

Fig. 1. Anodic galvanostatic charging profiles for electropolished polycrystalline nickel electrodes in pH 7.65 borate buffer at 80 μA cm^{-2} following different pretreatments: curve a, cathodic reduction at 80 μA cm^{-2} and open-circuit exposure (——); curve b, immersion in solution at 80 μA cm^{-2} (- - -); curve c, immersion in solution on open circuit for 10 min (····).

Q_a; eventually a steady-state potential plateau is reached. The initial region is usually considered to be due to active nickel dissolution ($Ni \rightarrow Ni^{2+} + 2e$) whereas the linear transition region is thought to be mainly due to growth of an oxide film, *e.g.*, $Ni + H_2O \rightarrow NiO + 2H^+ + 2e$, and corresponds to the passive potential region in constant potential experiments. The potential plateau at 0.95V could be associated with transpassive nickel dissolution and/or oxygen evolution and/or a thickening of the oxide film.

If an electropolished nickel electrode is immersed in the solution under anodic galvanostatic polarization, *i.e.*, without cathodic reduction of the air-formed oxide (Fig. 1, curve b), the active metal dissolution region is avoided. At 80 μA cm^{-2}, the immersion potential is 0.05V and V_a increases almost linearly with Q_a to the plateau region at 0.95V. The slope between 0.05 and 0.95V is similar for curves a and b, suggesting that the state of an electropolished nickel surface is similar to that of an initially oxide-free nickel surface which has been anodically polarized to 0.05V at 80 μA cm^{-2} [*cf.* Ref. (12)]. The anodic charging profile for electropolished nickel is not influenced by a prior 10 min open-circuit exposure to the pH 7.65 borate solution (Fig. 1, curve c), which means that the open-circuit treatment has little influence on the nature of the air-formed film. The transient charge associated with curve b, ~2.0 mC cm^{-2}, is independent of charging rates between 5 and 80 μA cm^{-2}, a result compatible with a surface charging process.

In order to detect changes in the nature of the oxide film during galvanostatic charging, an anodically polarized Ni(111) single crystal was removed at various stages during anodic charging at 10 μA cm^{-2} (Fig. 2), and examined by RHEED. [One specimen was reimmersed in the solution after examination by diffraction and the subsequent charging profile almost immediately approached that for an electrode maintained in solution. It thus appears that removal of the electrode from solution, washing, and vacuum pumping in the diffraction apparatus have little influence on the state of the surface oxide as anticipated from previous work (5).] The electron diffraction patterns included in Fig. 2 indicate that the epitaxy of the NiO film is maintained throughout the transient region but is lost in the plateau region. As the potential increases to more anodic values in the transient region, the metal reflections become less pronounced, an indication that there is additional oxygen uptake. At the same time, the measured NiO lattice parameter changes gradually from 2% expanded on electropolished nickel to 1% expanded (Fig. 2, point B) to $<0.2\%$ expanded at the end of the transient region (Fig. 2, point C), *i.e.*, the oxide lattice parameter gradually approaches that expected for stoichiometric NiO. In the plateau region, the oxide changes from a highly epitaxed, single crystal overgrowth to an NiO with a fiber axis normal to the surface (Fig. 2, point D). The absence of metal reflections after charging in the plateau region for 24 hr (Fig. 2, point E) indicates that the oxide thickness increases in this region. This last observation agrees with the results of Ord *et al.* (9, 10) who found that the oxide thickness increases considerably with time of anodic treatment in the plateau region.

To determine the current efficiency for oxide growth in the transient region, the solution was analyzed for Ni^{2+} after charging electropolished nickel to 0.9V (Fig. 1). The amount of nickel in solution is 0.3 μg Ni^{2+} cm^{-2} of electrode, corresponding to 1.0 mC cm^{-2} of charge. Since the total anodic charge is 2.0 mC cm^{-2}, the current efficiency for oxide growth is 50%. Thus, the total oxide thickness after charging is 12Å (0.17 μg oxygen cm^{-2}) because the oxide on electropolished nickel is 6Å thick (0.087 μg oxygen cm^{-2}). It is unlikely that the 1.0 mC cm^{-2} of charge asso-

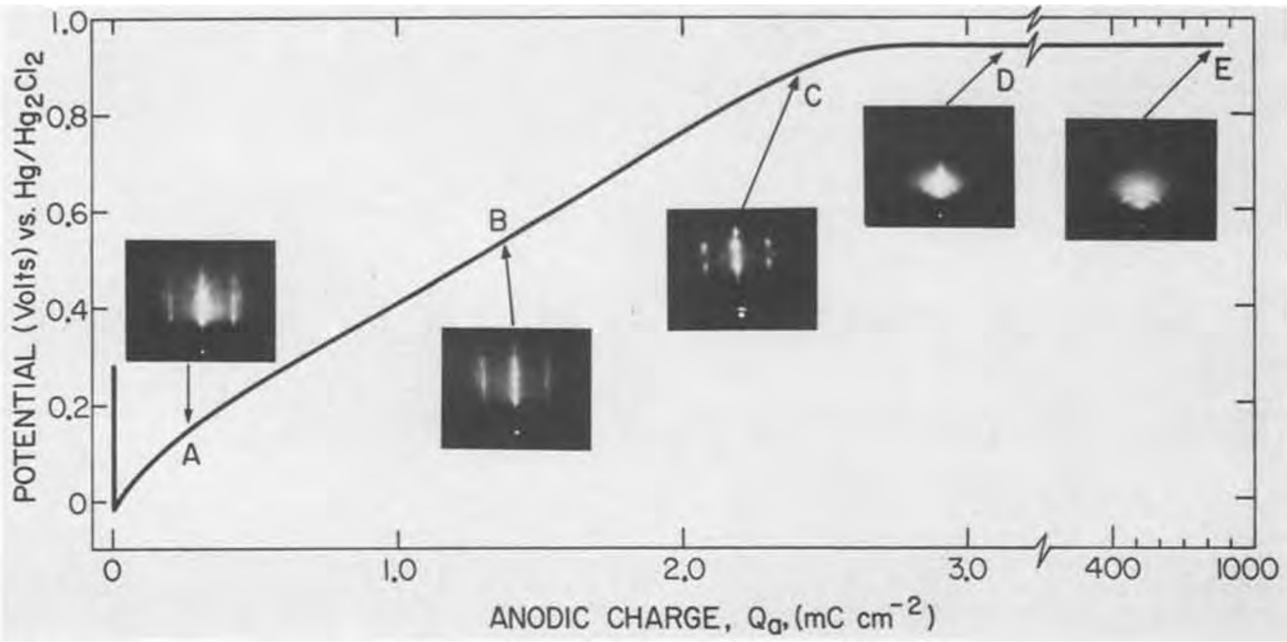

Fig. 2. Anodic galvanostatic charging profile for an electropolished Ni(111) electrode at 10 μA cm^{-2}. The electrode was removed at points A, B, C, D, and E for reflection high energy electron diffraction (RHEED) examination; the diffraction patterns are from the [112] direction using 75 kV electrons.

ciated with nickel dissolution is simply due to chemical dissolution of the oxide since the oxide is resistant to dissolution in pH 7.65 borate buffer solution (Fig. 1, curve c). Also, as mentioned earlier, the transient charge is independent of charging rate between 5 and 80 μA cm^{-2} and if chemical dissolution were playing a major role, the decrease in transition time by a factor of *ca.* 16 should greatly diminish the extent of chemical dissolution and thus the transient charge. It thus appears that the anodic potential causes nickel to dissolve and thereby lowers the efficiency of oxide growth.

To determine the current efficiency for the oxide formation in the plateau region, the solution was analyzed for Ni^{2+} and the thickness of the oxide determined by Auger analysis as a function of time of anodic charging of electropolished nickel. A charging rate of 80 μA cm^{-2} was chosen in order to develop a thick oxide film and to compare with previous work in the borate solution (9, 10). The amount of Ni^{2+} in solution did not increase above the 1 mC cm^{-2} equivalent dissolved in the transition region even for extended time periods in the plateau region [*cf.* Ref. (15)]. This may not, however, mean that the current efficiency for oxide growth is 100% in the plateau region since oxygen evolution may be consuming a significant portion of the anodic charge.

Quantitative Auger analysis.—Auger analysis of the oxide film on polycrystalline nickel (see Appendix) after anodic charging to 0.9V indicates the presence of 12Å of NiO (0.17 μg oxygen cm^{-2}), a value in excellent agreement with that obtained for anodic films on nickel formed in neutral or acid sulfate solutions (1-8). After 5 min in the plateau region at 80 μA cm^{-2}, the oxide thickness was determined by Auger analysis to be 16Å (0.23 μg oxygen cm^{-2}) indicating a current efficiency for oxide formation of ~10%. The oxide stoichiometry was estimated to be close to NiO from the ratio of nickel to oxygen signal intensities. Such an increase in oxide film thickness above the 12Å (0.17 μg oxygen cm^{-2}) detected in the passive region can only be achieved by polarization in the potential plateau region. Indeed, potentiostatic anodic polarization of electropolished nickel, either with or without a prior cathodic reduction, for very long periods of time ($\geq$24 hr) in the passive potential region (*e.g.*, at 0.7V) will not increase the film thickness above ~12Å.

Thicker oxide films prepared by anodizing electropolished nickel at 80 μA cm^{-2} for times >10 min were analyzed by the Auger technique in conjunction with Argon ion sputtering. Figure 3 shows the ratio of the oxygen to nickel peak to peak intensities (denoted by *P/P*) of a number of films, anodized for various periods of time, as a function of sputtering time. Because the analysis comes from an area encompassing about ten grains of the polycrystalline sheet, the signal intensities are average values. The same general result is obtained from analysis of only one grain, but there is a grain-to-grain variation in the *P/P* ratio of as much as a factor of three. There is an almost uniform decrease in the *P/P* ratio with sputtering time for the anodically formed films (Fig.

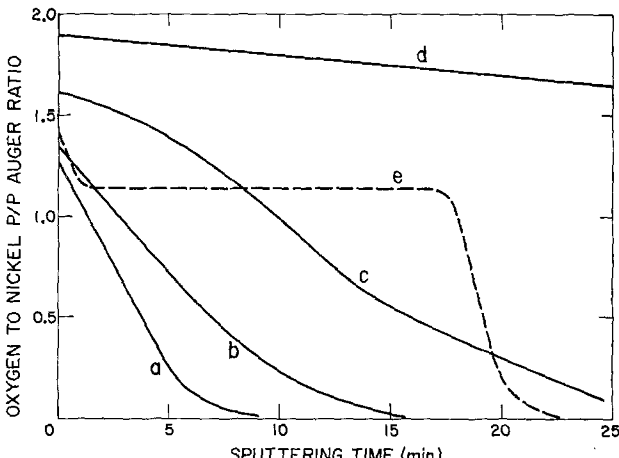

Fig. 3. Variation of the oxygen 510 eV (peak to peak) to nickel 848 eV (peak to peak) Auger signal intensity ratio (*P/P*) with time of argon ion bombardment for electropolished nickel electrodes anodized at 80 μA cm^{-2} in pH 7.65 borate buffer for the following times: curve *a*, 5 min; curve b, 30 min; curve *c*, 24 hr; curve *d*, 200 hr. Also shown is the sputter profile (- - -) for a thermally grown NiO film (curve e). Argon ion beam condition is 1 kV, 53° from normal incidence; sputter rate is 0.07 μg oxygen cm^{-2} min^{-1} for the thermal NiO film.

3, curves a-d), a result which is different from that normally obtained with a thick (>25Å), thermally formed NiO film (Fig. 3, curve e). With the latter, there is an initial decrease in P/P representing disproportionation due to sputtering, followed by a period of constant P/P ratio representing 90-95% of the time required to sputter through the film. Finally a rapid decrease is observed on sputtering through the metal-oxide interface. The most likely interpretation of the "long" interface observed for the anodic oxide films is that they are present as an open-cellular sponge with a large variation in point to point mass on a lateral scale in the 10Å range.[1]

An alternate but less likely interpretation is that some form of severe disproportionation is occurring during sputtering. The initial P/P ratio for specimens anodized for long times (curves c and d) is higher than that for the thermal NiO film (curve e), and indicates an oxygen to nickel ratio approaching 1.3. High oxygen-content material is probably also present in the films formed at shorter times of anodic treatment but its analysis is masked by the "thinness" of the oxide in some areas which allows a signal contribution from the underlying metal.

As indicated in the Appendix, the oxide thickness can be estimated from the time required for the P/P ratio to decrease to ~2/3 of its initial value. This is approximately the time required to remove one-half of the oxide layer. Using this time and assuming that the anodic film sputters at the same rate as the thermal film, *i.e.*, 0.07 μg oxygen cm^{-2} min^{-1}, oxide thicknesses calculated for the various anodic treatments are given in Table I.[2] To verify that the oxide thicknesses determined by this method are accurate, the samples anodized for 30 min, 24 hr, and 200 hr were also analyzed by O $K\alpha$ x-ray emission spectroscopy to determine the average oxygen uptake. The values, as seen in Table I, are in agreement with those determined by Auger analysis.

The anodic film formed on electropolished polycrystalline nickel after 24 hr at 80 μA cm^{-2} was examined in some detail by the Auger technique. The analysis from a number of grains indicates that the average thickness of the oxide sponge is ~1.3 μg oxygen cm^{-2}. To determine the oxide thickness variation from one metal grain to another, a large sample area was sputtered for set periods of time, after which oxygen Auger signal maps of the surface were obtained. In this way, assuming a uniform sputtering rate from grain to grain, variations in oxide thickness over the surface could be obtained. The minimum oxide thickness was found to be ~0.6 μg oxygen cm^{-2} whereas the maximum was ~1.7 μg oxygen cm^{-2}. The fact that the oxide thickness depends on the metal substrate orientation is an indication that the oxide does not form by a dissolution/precipitation mechanism; also, the electron diffraction pattern for this oxide (Fig. 2, point E) is not as compatible with a precipitated oxide as it is with one formed via a surface oxidation process. It thus appears that growth of this oxide probably occurs at the metal interface with electrolyte penetrating through the existing oxide to reach the bare nickel metal. Each new layer of oxide forms beneath the existing oxide and pushes the latter further into the solution. The penetration of electrolyte through the oxide should not be too difficult when the oxide is in the form of a sponge.

Using the average thickness value of 1.3 μg oxygen cm^{-2} for the oxide sponge, the current efficiency for oxide growth at long times of anodic charging is extremely small (<1%). The majority of the charge must be consumed by the oxygen evolution reaction, and the occurrence of this reaction may be contributing to the breakdown of oxide epitaxy in going from the transient to plateau regions. It is interesting to note that the thickness of the oxide formed in the transient region is limited to ~12Å (0.17 μg oxygen cm^{-2}) no matter how long the time of anodizing. This limiting thickness may correlate with the fact that the oxide epitaxy is maintained throughout the transient region and is only lost in the plateau region (Fig. 2). Upon loss of the oxide epitaxy, the film thickness increases above the 12Å limiting value, but with a very low current efficiency for oxide growth.

[1] Replica electron micrographs of the oxide surfaces show a uniform roughening, with height variations of ~50Å.

[2] Oxide thicknesses are quoted as μg oxygen cm^{-2}. While it is reasonable to convert to angstroms the thickness of thin oxides produced in the transient region (assuming a roughness factor of 1 and an NiO density of 6.75, *i.e.*, 1 μg oxygen cm^{-2} ≡ 69.2Å NiO), it is not so for the oxides produced at long anodization times in the plateau region which are open-cellular sponges of unknown density.

Table I. Average oxide film thicknesses as a function of time of anodizing of electropolished Ni electrodes at 80 μA cm^{-2} in pH 7.65 borate buffer solution determined by (a), Auger electron spectroscopy in conjunction with Argon ion sputtering, and (b), O K_α x-ray emission analysis of some of the samples

Time of anodic treatment	Oxide film thickness (μg oxygen cm^{-2}) (a) Auger analysis	(b) X-ray emission analysis
5 min	0.23 ± 0.02*	
30 min	0.5 ± 0.1	0.58 ± 0.02
24 hr	1.3 ± 0.2	1.23 ± 0.06
200 hr	6.5 ± 1.0	>5

* Thickness obtained by quantitative thin film Auger analysis (see Appendix) where sputtering is not required.

Summary

The present work shows that the thickness and structure of anodic oxide films formed galvanostatically on nickel in pH 7.65 borate solution change dramatically at potentials more anodic than 0.9V. At lower anodic potentials, the NiO film thickness is limited to ~12Å (0.17 μg oxygen cm^{-2}) whereas at the higher potentials the thickness can increase to more than 1.5 μg oxygen cm^{-2}. This increase in oxide thickness is correlated with a degeneration of the single crystal oxide epitaxy and a conversion of the oxide from a compact film to a porous, sponge-type oxide. The thickness of this oxide film depends on the conditions of polarization and the metal substrate orientation. At long times of polarization in the plateau region at 80 μA cm^{-2}, *e.g.*, 24 hr, the oxide thickness variation from grain to grain is between ~0.6 and ~1.7 μg oxygen cm^{-2}. This anisotropy of film thickness indicates that the oxide grows by a direct surface oxidation reaction rather than a dissolution/precipitation mechanism.

APPENDIX

Auger Analysis

The quantitative thin film Auger analysis used was based on the concepts of Gallon (16) and Pons *et al.* (17). In the latter treatment for a sample containing various elements, the contribution from each atomic layer (i) of a given element I towards the overall

Auger peak to peak signal (P/P) for element I is given by $h_I^{(i)} = \alpha_I k_I^i N_I^{(i)}$. In this equation, α_I is the sensitivity coefficient for element I, k_I^i is the contribution coefficient (also known as the absorption coefficient) of layer (i) to the total signal, and $N_I^{(i)}$ is the number of atoms of element I in layer (i). H_I is the sum of all the individual layer contributions for element I, which for a total of x layers is

$$H_I = \sum_{i=0}^{i=x} h_I^{(i)} = \sum_{i=0}^{i=x} \alpha_I k_I^i N_I^{(i)} \quad \text{[A-1]}$$

It should be noted that the contribution coefficient (of value <1) is raised to the power i; *i.e.*, for the first atomic layer of the surface (which is not covered by any layer), $i = 0$ and $k_I^\circ = 1$.

Using Eq. [A-1], Auger analysis of bulk NiO of uniform composition gives a P/P ratio ($\equiv H_O/H_{Ni}$) equal to the ratio $\frac{\alpha_O}{\alpha_n}\frac{(1-k_{Ni})}{(1-k_O)}$. For thin films of NiO on Ni, the increase in P/P with increasing layer by layer NiO coverage can be calculated using this ratio (1.43) and Eq. [A-1], in conjunction with the approximation of Pons *et al.* (17) for calculating the contribution coefficients. The results of these calculations are represented graphically in Fig. 4 for a total of 15 layers, or 30Å of NiO assuming 1 layer of NiO is equivalent to 2Å. Nickel samples were prepared with 6 and 12Å of NiO [thicknesses were determined independently by x-ray emission spectroscopy (13, 14)] and the oxygen to nickel P/P Auger ratios were found to be in good agreement with those given by Fig. 4. Oxide film thickness up to ~16Å can thus be accurately obtained from the measured oxygen to nickel P/P ratio. For thicker NiO films, this P/P ratio falls off significantly with increasing oxide thickness as seen in Fig. 4. Sputtering is required in order to determine the oxide thickness which is estimated from the time required for the P/P ratio to decrease to ~2/3 of its initial value. This is approximately the time required to remove 1/2 of the oxide layer.

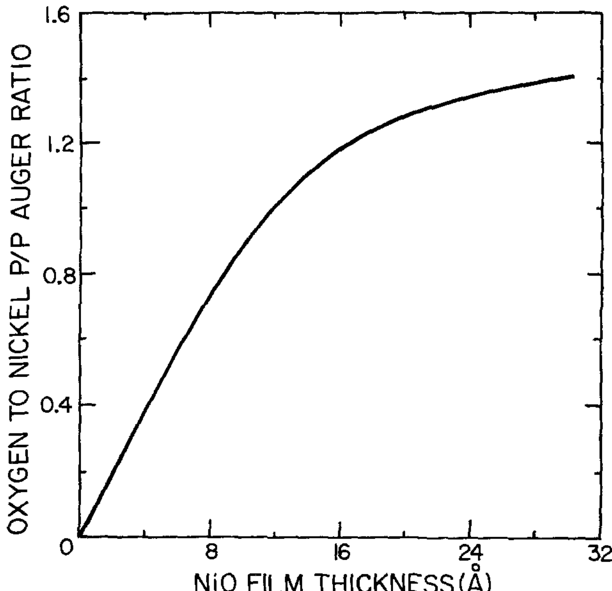

Fig. 4. Variation of the calculated oxygen 510 eV (peak to peak) to nickel 848 eV (peak to peak) Auger signal intensity ratio (P/P) with NiO film thickness.

Anodic Polarization Behavior of Mild Steel in Hot Alkaline Sulfide Solutions

Desmond Tromans*

Department of Metallurgical Engineering, University of British Columbia, Vancouver, British Columbia, V6T 1W5 Canada

ABSTRACT

Anodic polarization studies have been conducted in an aqueous solution of 2.5M NaOH + 0.423M Na_2S, at 92°C, and compared with studies in 3.35M NaOH. Anodic films were examined by electron diffraction and x-ray energy analysis and all results compared with published data on $S\text{-}H_2O$ and $Fe\text{-}S\text{-}H_2O$ equilibria. In particular, it was concluded that the delay of passivity in the sulfide solution, relative to NaOH, was due to the incorporation of S^{2-} ions into the Fe_3O_4 lattice to render it nonprotective. Passivity did not occur until the lattice S^{2-} content was decreased at more noble potentials, this process being influenced by anodic oxidation of aqueous S^{2-} ions. The polarization behavior is relevant to corrosion and stress corrosion cracking in the pulp and paper industry.

Mild steel is frequently exposed to hot aqueous alkaline sulfide solutions in the Kraft process (1) for converting (digesting) wood chips into pulp. The industrial solutions, known as white liquors, usually contain 2.1-2.8M NaOH and 0.21-0.64M Na_2S, together with several impurities and a room temperature pH near 14 (2). They encounter mild steel at ~90°C in white liquor clarifiers and storage vessels, and at 150°-170°C in digesters. However, in spite of the importance and long-term use (>50 years) of the Kraft process in the pulp and paper industry, few electrochemical polarization studies have been conducted on mild steel in hot alkaline sulfide solutions, and no studies have been reported on the anodic films.

The major reported polarization studies on mild steel in simulated alkaline sulfide pulping solutions were conducted by Mueller (2) at 30°-97°C, and Kesler and Bakken (3) at 35°C. Electrochemical interpretation of their data was limited and important details at low current densities were not revealed bv their data plots of linear current density *vs.* linear potential. However, they demonstrated an active-passive transition and their work has been used as the basis for understanding corrosion in white liquors (4), and the use of polysulfide oxidants (4, 5) and impressed anodic currents (6) for corrosion protection.

The present study was designed to provide a more thorough understanding of the anodic polarization behavior of mild steel in a hot NaOH + Na_2S solution representative of white liquor. Polarization curves were obtained containing more detail than those previously reported (2-4), and were compared with those obtained in NaOH only. Anodic corrosion films were identified, and the results were interpreted using the data of Biernat and Robins on $S\text{-}H_2O$ (7) and $Fe\text{-}S\text{-}H_2O$ (8) equilibria.

Experimental

Test-piece.—Studies were conducted on mild steel having a weight percentage composition of 0.22 C, 0.55 Mn, 0.28 Si, 0.11 Ni, 0.10 Cr, 0.01 P, 0.032 S, and remainder Fe. It was in the form of cold drawn 9.5 mm diam rod, with a Rockwell hardness of R_B78. Cylindrical test pieces were sectioned, each having a total surface area of 500 mm^2. The surfaces were mechanically polished with 240 grit paper, degreased in clorethane, cleaned in 10 volume percent (v/o) HCl, and rinsed in water, alcohol, and dried. This procedure gave reproducible corrosion potentials and polarization behavior.

Key words: anodic films, passivity, stress corrosion, white liquor.

Solutions.—The alkaline sulfide solution was similar to that used by Kesler and Bakken (3). Its molar composition was 2.5 NaOH + 0.423 Na_2S (total Na^+ of 3.35M). Comparative tests were conducted in 3.35M NaOH. All solutions were freshly prepared from distilled water purged with nitrogen, reagent grade NaOH, and hydrated Na_2S flake containing 59.4% Na_2S by weight.

Polarization.—Polarization tests were conducted in 800 ml of solution at 92°C, using a Princeton Applied Research (PAR) single compartment corrosion cell (Model 9700) with two graphite counterelectrodes and Model 178 electrometer probe. The cell was heated with a Corning heating mantle connected to a variable transformer, allowing manual control of temperature to within ±1°C. The solution was continuously stirred and purged with nitrogen.

Test-pieces were introduced into the cell at 92°C and allowed to remain under free corrosion conditions for 900 sec before conducting a single anodic scan on each specimen. The potential was potentiodynamically increased at 1 mV/sec with a PAR potentiostat (Model 173) coupled to a universal programmer (Model 175) and logarithmic current converter (Model 376). The potentials were measured with respect to a saturated calomel electrode (SCE) placed outside the test cell at 25°C. A Luggin capillary, placed 1 mm from the test piece, was connected to the reference electrode via a KCl salt bridge. No attempt was made to correct for the small potential differences arising from concentration effects and thermal gradients in the salt bridge. Potential and logarithmic current were plotted autographically on a Houston Omnigraph 2000 recorder. All data are reported as logarithmic current density (i) *vs.* potential (E) with respect to the standard hydrogen electrode scale (V_{SHE}), where $E_{SCE} = +0.2416$ V_{SHE}.

Film analysis.—Following polarization, anodic films were investigated by *in situ* electron diffraction analysis at 100 keV in the high resolution diffraction chamber of an Hitachi HU 11A electron microscope. The test-pieces were washed in water, rinsed in alcohol, dried, and placed in the chamber. Diffraction patterns were obtained by transmission through protuberances on the specimen surface. Films beneath loose corrosion products were studied after wiping away the loose products with soft tissue in alcohol. In addition, films were studied via x-ray energy analysis at 20 keV in an ETEC Autoscan scanning electron microscope using an Ortec Si/Li detector (7000 series) and multichannel analyzer (Model 6200).

Results

Polarization behavior.—Representative anodic polarization curves for the NaOH and alkaline sulfide solutions are shown in Fig. 1. In both cases, mild steel exhibited a corrosion potential (E_{corr}) near -0.89 V_{SHE} in the active state and underwent an active-passive transition. However, current densities were higher in the alkaline sulfide, the peak current density exceeding that in NaOH by a factor of ~ 35 and the minimum passivation current density being in excess by a factor of ~ 25.

The onset of passivity occurred above -0.77 V_{SHE} in NaOH, whereas in the alkaline sulfide it commenced above the major current peak at -0.66 V_{SHE}. A minor current peak occurred in the sulfide solution at -0.77 V_{SHE}.

Anodic potentials near the major current peak in the alkaline sulfide solution were associated with a visible brownish discoloration of the solution around the specimen and formation of a loosely adherent brown-black corrosion film. This film ceased to thicken above -0.63 V_{SHE} and the increased anodic currents above -0.5 V_{SHE} were not associated with any additional discoloration of the solution. The onset of passivation in the NaOH solution above -0.8 V_{SHE} was accompanied by formation of an adherent black film.

Anodic films.—Electron diffraction studies of specimens removed from the alkaline sulfide solution at -0.6 V_{SHE} failed to disclose any diffraction spots or rings from the loosely adherent brown-black film, indicating an amorphous structure. Figure 2 is a scanning electron micrograph of the *in situ* film showing its porous and fine powdery nature. Samples of the film were isolated from the specimen by carefully scraping with a wooden spatula. X-ray energy spectra were obtained from samples mounted on a carbon substrate. These were compared with spectra obtained from FeS_2 (pyrite) and FeS (pyrrhotite) under identical instrument conditions. Ratios of the integrated intensities S/Fe for the K_α peaks, after allowing for background subtraction, were $FeS_2 = 2.01$, $FeS = 1.06$, film $= 1.03$. Hence, the brown-black film was identified as amorphous FeS. This conclusion was consistent with the fact that freshly precipitated FeS has been shown by Berner (9) to be both noncrystalline and black in color.

In situ electron diffraction studies of anodic films formed in the passive region beneath amorphous FeS were obtained after wiping away the loose FeS, as described in the "Film analysis" section. Studies were also conducted on the unwiped adherent film formed in the passive region in NaOH. In all cases, ring patterns were obtained characteristic of a cubic spinel structure. The details are shown in Table I. The lattice parameters for iron oxide spinels are reported to be $a_o = 8.32\text{-}8.34 \times 10^{-10}$m for γ-Fe_2O_3, and 8.39×10^{-10}m for Fe_3O_4 (10). The lattice parameter for the thiospinel, Fe_3S_4, is reported to be $a_o = 9.876 \times 10^{-10}$m

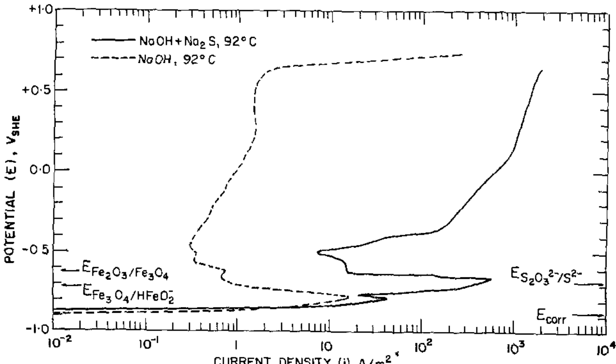

Fig. 1. Anodic polarization behavior of mild steel in NaOH and NaOH + Na_2S solutions.

Fig. 2. Scanning electron micrograph of loosely adherent, amorphous FeS film.

(11). Thus, at -0.6 V_{SHE} in the alkaline sulfide, the film is believed to be basically an Fe_3O_4 spinel containing substitutional S^{2-} ions, *e.g.*, $Fe_3O_{4-x}S_x$, where $x \approx 0.19$ based on a weighted average of lattice parameters.

Discussion

Aqueous equilibria.—Biernat and Robins (8) have calculated Fe-S-H_2O equilibria at 100°C which are relevant to the present study. The data show that at the commencement of the polarization test (E_{corr}), the stable dissolved S species is S^{2-} and Fe dissolves in the active condition as $HFeO_2^-$. Equations which are particularly useful are shown below

$$Fe_3O_4 + 2H_2O + 2e^- = 3HFeO_2^- + H^+ \quad [1]$$

$$E_{Fe_3O_4/HFeO_2^-} = -1.74 + 0.037\,pH - 0.037 \log [HFeO_2^-]^3, V_{SHE} \quad [1a]$$

$$3Fe_2O_3 + 2H^+ + 2e^- = 2Fe_3O_4 + H_2O \quad [2]$$

$$E_{Fe_2O_3/Fe_3O_4} = +0.261 - 0.074\,pH, V_{SHE} \quad [2a]$$

$$FeS + 2H_2O = HFeO_2^- + S^{2-} + 3H^+ \quad [3]$$

$$3\,pH = 40.09 + \log ([HFeO_2^-]\,[S^{2-}]) \quad [3a]$$

With reference to Eq. [1a] and [2a], the *p*H values of the test solutions were estimated from the dissociation constant for water at 100°C [1.62×10^{-12} (12)], the activity of [OH^-] and the activity of [H_2O]. The value of [OH^-] was estimated by approximating molar concentrations to molalities (*M*) and extrapolating the activity coefficient data of Harned and Owen (13) to 100°C. The activity of water was assumed to be ~ 0.95 (14). The estimated *p*H values are shown in Table II.

Table I. Experimental lattice parameters of spinel passive films

Solution	E (V_{SHE})	a_o (10^{-10} m)	Probable film
NaOH	-0.5	8.36 ± 0.02	γ-Fe_2O_3 + Fe_3O_4
NaOH + Na_2S	-0.6	8.46 ± 0.02	Fe_3O_4 containing S^{2-} ions ($Fe_3O_{4-x}S_x$)
NaOH + Na_2S	-0.5	8.39 ± 0.02	Fe_3O_4

Table II. Calculated E values

Solution	pH	$[HFeO_2^-]$ (M)	$E_{Fe_3O_4/HFeO_2^-}$ (V_{SHE})	$E_{Fe_2O_3/Fe_3O_4}$ (V_{SHE})
NaOH	~12.1	6.83×10^{-6}	−0.719	−0.634
NaOH + Na_2S	~12.0	6.6×10^{-6}	−0.721	−0.627

The activities of $[HFeO_2^-]$, required for Eq. [1a], were calculated after traversing the large current peak in NaOH and the minor current peak in alkaline sulfide (see Fig. 1). The total coulombs passed was determined and the concentration of $HFeO_2^-$ estimated by assuming all current involved dissolution of Fe to form $HFeO_2^-$. The concentrations were assumed to be the same as the activities, and are shown in Table II.

The potentials corresponding to Eq. [1a] and [2a] at 100°C are shown in Table II. Within the accuracy of the thermodynamic data and activity estimates, the E values may be compared with the tests at 92°C and are placed on Fig. 1.

Equation [3a] represents deposition of FeS from solution. The pH at which this occurs may be estimated from $[S^{2-}]$ and $[HFeO_2^-]$ activities. In the alkaline sulfide test solution, $[S^{2-}]$ was approximated to the molar concentration of S^{2-} (*i.e.*, 0.423) and the maximum value of $[HFeO^{2-}]$ was estimated by determining the number of coulombs required to reach the major current peak at -0.66 V_{SHE} and assuming this represented dissolution of Fe as $HFeO_2^-$. In this manner $[HFeO^{2-}]$ was found to be $\sim 1.04 \times 10^{-4}$M, which upon inserting in Eq. [3a] yielded a pH of ~12. This pH value was in agreement with the pH of the solution (see Table II) and shows that formation of the amorphous FeS film occurred via Eq. [3] and [3a]. In practice, concentration gradient effects in the diffusion layer at the metal surface (kinetic factors) could locally raise the value of $[HFeO_2^-]$ and produce formation of FeS before the major current peak was reached, as was frequently observed.

One additional reaction which must be considered is the anodic oxidation of S^{2-} during polarization. Generally, in oxidation of white liquors, oxidation to $S_2O_3^{2-}$ is the first and most rapid stage (15, 16). Therefore, this reaction will be considered using the data of Biernat and Robins (7) at 100°C, as shown below

$$S_2O_3^{2-} + 6H^+ + 8e^- = 2S^{2-} + 3H_2O \quad [4]$$

$$E_{S_2O_3^{2-}/S^{2-}} = 0.034\text{-}0.056\,pH + 0.0093 \log ([S_2O_3^{2-}]/[S^{2-}]^2) \quad [4a]$$

Consequently, approximating $[S^{2-}]$ to the molar concentration of S^{2-}, and using a value of $[S_2O_3^{2-}]$ equivalent to 10^{-6}M, which is a reasonable activity to form during polarization without invalidating the previous calculations, it is seen that $E_{S_2O_3^{2-}/S^{2-}}$ is equal to -0.68 V_{SHE}. This value is placed on Fig. 1. Thus, the marked increase in current above -0.5 V_{SHE} is believed to be due to oxidation of S^{2-} via Eq. [4].

Overall events.—The present results and calculations suggest that the onset of passivation (reduction of current) in NaOH is associated with formation of Fe_3O_4 films, with maximum passivation being associated with formation of γ-Fe_2O_3 at $E_{Fe_2O_3/Fe_3O_4}$. This is consistent with Vetter's (17) view of the Flade potential.

In alkaline sulfide solution, it appears that Fe_3O_4 starts to form, causing a minor current peak (near -0.77 V_{SHE}), and then becomes nonprotective due to the incorporation of S^{2-} ions into the lattice to form $Fe_3O_{4-x}S_x$. Thus, dissolution of Fe continues with increasing E and is accompanied by deposition of amorphous FeS when the solubility product is exceeded (near the major current peak at -0.66 V_{SHE}). The onset of passivation occurs when the S^{2-} content of the $Fe_3O_{4-x}S_x$ film is decreased to $x \approx 0.19$, maximum passivation occurring when $x \approx 0$ and Fe_3O_4 is formed.

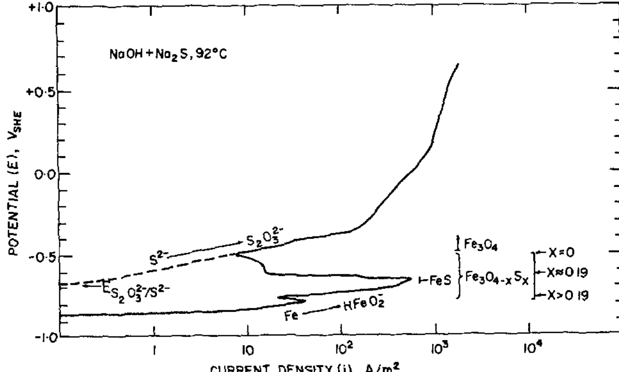

Fig. 3. Schematic diagram of anodic polarization behavior of mild steel in NaOH + Na_2S showing sequence of events.

Stabilization of the film by reduction of the lattice S^{2-} content appears to be related to oxidation of aqueous S^{2-} to $S_2O_3^{2-}$. The sequence of events is shown schematically in Fig. 3.

It should be noted that the onset of passivity in the sulfide solution also appears coincident with $E_{Fe_2O_3/Fe_3O_4}$ (see Fig. 1). However, this is believed to be fortuitous because the electron diffraction data do not reveal the presence of γ-Fe_2O_3 (Table I). Furthermore, the higher minimum current densities observed at maximum passivation in the sulfide solution, relative to NaOH, indicate different passive films in the two solutions. This is consistent with the views of Foley *et al.* (18) on the higher electrical conductivity of Fe_3O_4 relative to γ-Fe_2O_3.

Stress corrosion cracking.—The occurrence of stress corrosion cracking of mild steel in highly alkaline solutions has been associated with a small range of potentials near the nose of the active-passive current peak (19, 20). Thus, the displacement of the nose of the active-passive current peak to higher E values in the alkaline sulfide solution, relative to NaOH (see Fig. 1), indicates that stress corrosion cracking will occur at more noble potentials in the sulfide solution. This prediction is being investigated further.

Conclusions

Anodic polarization studies on mild steel exposed to aqueous NaOH, and NaOH + Na_2S solutions at 92°C were consistent with the following conclusions:

1. An active-passive transition was observed in both environments. Larger current densities and displacement of the active-passive transition to higher potentials were observed in the sulfide solution.
2. Passivation commenced in NaOH with formation of Fe_3O_4, maximum passivation occurring with formation of γ-Fe_2O_3 at $E_{Fe_2O_3/Fe_3O_4}$.
3. Passivation was delayed in NaOH + Na_2S, due to incorporation of S^{2-} into the Fe_3O_4 lattice to form a nonprotective film, possibly $Fe_3O_{4-x}S_x$. Further active dissolution of iron occurred, exceeding the solubility product of FeS to deposit a nonprotective amorphous layer.
4. Passivation commenced in NaOH + Na_2S at higher potentials when the lattice S^{2-} content of $Fe_3O_{4-x}S_x$ was decreased to a critical value (probably at $x \approx 0.19$), maximum passivation occurring when Fe_3O_4 was formed. The decrease in lattice S^{2-} content was influenced by anodic oxidation of aqueuos S^{2-} to $S_2O_3^{2-}$.

Trapped Oxygen in Aluminum Oxide Films and Its Effect on Dielectric Stability

Walter J. Bernard* and Philip G. Russell

Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

Anodic oxide films formed on aluminum in aqueous borate solutions contain substantial amounts of trapped oxygen, presumably in an adsorbed state within film cavities. Under some conditions the film has relatively stable electrical properties, but the release of the uncombined oxygen by reaction of the film with hot water brings about a sudden and nearly complete loss of barrier properties. The Faradaic charge required to restore high dielectric strength to the film is related to the quantity of oxygen evolved.

The anodic oxidation of aluminum foil, on which a surface layer of hydrous oxide has been previously formed, results in the growth of a duplex oxide film whose barrier portion suffers from an unusual instability. Alwitt and Dyer (1) refer to this phenomenon as "relaxation" and cite a number of ways in which it may be induced. In some instances it appears to occur spontaneously in the anodizing electrolyte, after a variable and ill-defined induction period.

This instability, if uncorrected at the time of processing, can result in a serious reduction of the ability of the dielectric film to sustain a high electric field, and the passage of a substantial charge in a suitable electrolyte is needed to restore the barrier oxide to its original state. A practical method for correcting this instability (widely practiced commercially) is through a brief treatment of the freshly anodized foil in hot distilled water, followed the recharging to the original anodization voltage (1-3). The reaction of the water with the oxide greatly accelerates the complete relaxation of the dielectric and reanodization results in a stable oxide.

The effect may be better understood by reference to Fig. 1, in which it is graphically demonstrated. Aluminum foil is coated with a hydrous oxide layer by immersion for a short period (typically, 5-10 min) in boiling water and is then anodized to several hundred volts in an aqueous borate solution. If the anode foil is held at constant potential (V_A) for several minutes, the current (I_D) decays to a small fraction of the anodization current (I_A), showing the normal behavior of a stable anodic oxide. But if the foil is then removed from the electrolyte, treated in boiling water for, say, 2 min, and returned to the anodization cell with the application of the same current (I_D) that was measured at the termination of the oxide formation step, it will display an initial barrier voltage close to zero. A substantial passage of charge, of the order of a few percent of the anodization charge, will then be required in

Fig. 1. Voltage and current-time curves for barrier oxide formation on aluminum foil. The reanodization voltage-time curve was obtained after a 5 min barrier postboil. These curves are typical of the results obtained with both polished and etched foils.

Key words: anodic oxidation, hydrous aluminum oxide, dielectric relaxation.

order for the anode to sustain the original anodization voltage. An important conclusion drawn from these observations is that the dielectric damage incurred during relaxation is not uniform over the entire surface of the anode, since the apparently complete loss of barrier properties can be restored by a relatively small degree of reanodization.

An analysis of the process is complicated by the fact that the barrier oxide itself can undergo hydration in contact with boiling water (4) and the repair of dielectric damage from this reaction would also contribute to the charge passed after relaxation. The hydration reaction alone, however, cannot account for the observations since it has been established that hydration of anodic oxide occurs with relative uniformity across the oxide surface (5) and not at isolated areas as is indicated by the evidence in this case. A quantitative measurement of the relaxation effect must therefore separate these two contributions to the reanodization charge.

It has been suggested by Alwitt and Dyer (1) that the cause of the unstable dielectric is the presence of voids which are sealed off in the growing oxide during the anodization process and subsequently exposed during a boiling water treatment. Through transmission electron microscopy, Kudo and Alwitt (6) have detected the presence of fine vertical cracks in the barrier film, which may possibly represent the voids that have been postulated. Such oxide-free cavities or channels are consistent with our observations. However, it is our belief that these cavities are not empty but are filled with oxygen acting as a trapped dielectric that the postanodization water reaction releases as a gas. This belief is based on the observation of an apparent evolution of a gas from the oxide surface within seconds of the immersion of the foil in boiling water, and which has been identified by us as oxygen. The presence of gaseous oxygen in the unrelaxed film has also been detected by Alwitt and Dyer (1) and by Crevecoeur and deWitt (7). In the latter paper the authors attribute the generation of oxygen during anodization to the presence of crystalline γ-Al_2O_3 in the film. They have shown that at 90°C the development of γ-Al_2O_3 can begin at voltages as low as 30V and that beyond 150V the predominant oxide in the barrier layer is the crystalline form.

In this paper we present quantitative measurements on the amount of oxygen trapped in the oxide film and relate these measurements to the relaxation phenome non.

Experimental

Barrier film formation.—Barrier films were formed on both high purity (99.99%) electropolished foil and commercially etched high voltage anode foil (99.97%). The plain foil was electropolished by a standard procedure using an acetic anhydride-perchloric acid mixture. All samples had an apparent surface area of 77.4 cm^2. Deionized water further purified through distillation was used in all aqueous solutions, water rinses, and for boiling water treatment of the foil both before and after the formation of barrier oxide, referred to as "preboil" and "postboil," respectively.

The anodization electrolyte (30 g/liter H_3BO_3 + 2.1 g/liter borax) had a *p*H of ~6.3 and a resistivity at 90°C of 500 Ω-cm. Anodizations were carried out at 90°C in a jacketed cell containing two platinum cathodes mounted on a Teflon support. Pyrex rods extending from this support into the electrolyte kept the anode foil well centered between the cathodes during anodization. A stream of nitrogen gas directed at the electrolyte surface minimized spattering.

The following procedure was established for producing barrier films on foil samples: first, a hydrous oxide layer (pseudoboehmite) was grown during a 10 min preboil step. Anodization was then carried out at constant current, I_A, to 350V (Fig. 1) and held at this voltage until the decay current, I_D, was one-tenth the value of I_A. The cell was then disconnected from the power supply and the field was allowed to decay to zero. The slow field decay shown in Fig. 1 was observed with barrier oxide formations on polished foil. The field decayed much faster with etched foil samples. After a water rinse, one of several postanodization steps was carried out: (*i*) barrier hydration (postboil); (*ii*) high temperature treatment (500°-600°C); (*iii*) storage in air at room temperature; and (*iv*) storage at 85°C in a glycol-borate electrolyte. This was then followed by reanodization to the original barrier voltage (350V) which was carried out at constant current, I_R, (final value of I_D). When the sample was used for O_2 analysis the reanodization step was omitted in most cases. The anodization current was 1A and 100 mA for etched foil and polished foil, respectively. In the case of etched foils where I_R was 100 mA the voltage drop across the electrolyte was less than 2.0V, and therefore the subsequent measurement of potential at 100 mA provides an accurate estimate of the thickness of the barrier oxide. The charge passed during the constant voltage period was measured graphically on a recorder trace.

The 10 min preboil step insures that the barrier film on polished foil does not suffer from short-term instability; that is, the relaxation of the dielectric can be delayed until it is deliberately induced by a procedure such as postboiling. In most samples examined here it was observed that if the barrier film was given a water rinse little or no charge was required to reach the barrier voltage during the reanodization step.[1] On the other hand, barrier films on etched foil show some instability. After a water rinse usually 1-2% of the anodization charge, q_A, (see Fig. 1) is required to reach the barrier voltage during reanodization. Further details on the stability of barrier films is given later.

Measurement of capacitance.—The capacitance of a given sample was measured at 120 Hz after three different steps in the formation process: (*i*) anodization, (*ii*) postanodizing treatment, and (*iii*) reanodization. The sample cell contained two platinized platinum electrodes suspended from a Teflon support, approximately 1.25 in. apart, and a measuring electrolyte (50 g/liter H_3BO_3 + 1.9 g/liter NH_3; *p*H ~7.0) kept at 25°C. The sample was placed midway between the electrodes and the capacitance recorded after a 2 min stabilizing period.

Gas chromatographic analysis for O_2.—Quantitative measurement of the total uncombined oxygen (*i.e.*, available in the gaseous form) in the oxide film was made by gas chromatographic (GC) analysis of the gas evolved during chemical stripping of the oxide from the aluminum substrate. The amount of O_2 lost from the film during a relaxation process was then determined by difference.

The oxygen gas was stored in a sample storage tube. This storage tube consisted of a test tube made from heavy wall Pyrex tubing (~5 in. in length with an OD of ¾ in.) and an O-ring seal (Cajon Ultra-Torr Fitting) connected to a needle valve outlet (Hoke 3700 series with O-ring stem packing) which formed a gas-tight container with the test tube. During analysis a storage tube was connected to the sample loop of the chromatograph (F&M Model 720). After evacuation of the loop the stored gas sample was divided between the loop and the storage tube. In this way the sample loop contained the same molar fraction of oxygen that was contained in each sample storage tube before a given analysis. Separation of O_2 and N_2 was carried out with helium as the carrier gas on a column containing Linde molecular sieve 5A, 60-80 mesh, at 60°C. Detection was made by a thermal conductivity bridge.

A typical recorder trace made during O_2 analysis is shown in Fig. 2 for both polished and etched foil sam-

[1] The preboil time was varied from 0 to 10 min in a series of formation experiments on polished foil. A preboil of at least 5 min was found to be necessary for the formation of a stable barrier film.

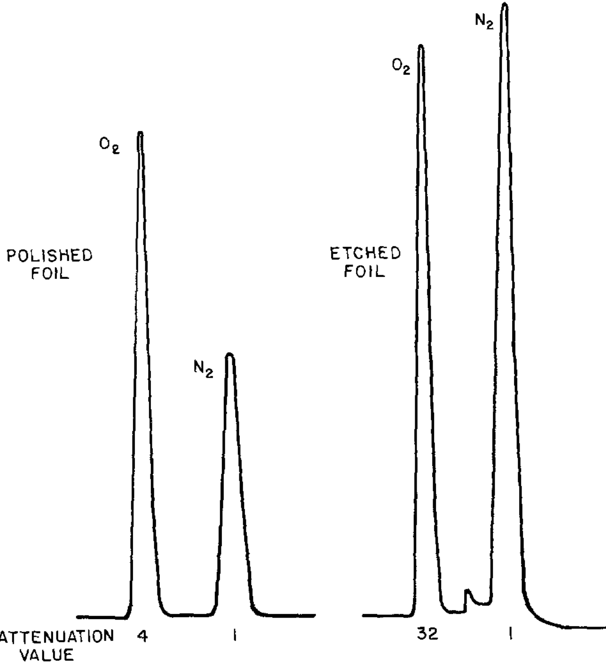

Fig. 2. Recorder trace from polished and etched foil samples prepared with freshly boiled and cooled stripping solution. The signal attenuation is given under each peak. The variation in the strength of the N_2 signal from sample to sample as shown here is due to small differences in the air content of the stripping solution just prior to the degassing step. Small variations in time of boiling, rate of boiling, and cooling time most likely account for changes in the air content of the stripping solution.

ples. The area under each curve is given by the product of the peak height above the base line times the half-width. A correction to the observed O_2 signal is made by subtracting from this signal the O_2 signal equivalent to the observed N_2 signal. This correction is especially important for polished foil samples where the observed N_2 signal may be as large as ~25% of the observed O_2 signal. The N_2 signal is the result of dissolved air being released from the stripping solution in the sample storage tube during the stripping process which was carried out at 85°C for a period of several hours.

The following procedure for sample preparation was found to minimize the amount of N_2 present: each sample is cut into 12 strips and placed in a sample tube along with 10 ml of stripping solution (2% CrO_3 + 4.25% H_3PO_4) which has been boiled for 1 min and cooled immediately before using. The storage tube is evacuated and then backfilled with purified helium (99.995%). This degassing procedure is repeated a second time. The storage tube containing a degassed sample is then placed in a water bath at 85°C where stripping of the barrier film occurs for a specified period of time prior to GC analysis for O_2 and N_2. In some of the earlier experiments where the stripping solution was not boiled just before degassing, larger amounts of N_2 were found to be present during O_2 analysis.

Correction factors for use in subtracting the unwanted O_2 component from dissolved air were determined from reference experiments. In these experiments polished foils without either a preboil layer or barrier film and with both freshly boiled and nonboiled stripping solutions were used during sample preparation. The results in Table I show that a 1 min boil of the stripping solution just prior to degassing removes ~73% of the dissolved air. In each case the O_2 to N_2

Table I. Determination of correction factor, O_2/N_2

No. of samples	Sample and preparation*	O_2 signal area (cm²)	O_2/N_2
6	Polished foil, stripping solution not boiled	11.30 ± 1.62	0.533 ± 0.012
5	Polished foil, stripping solution freshly boiled†	3.07 ± 1.49	0.524 ± 0.013
7	Polished foil given 10 min preboil. Stripping solution not boiled	2.82 ± 0.58	0.470 ± 0.032
4	Etched foil given 10 min preboil. Stripping solution freshly boiled†	1.25 ± 0.30	0.454 ± 0.021

* In these experiments 10 ml of stripping solution is added to the sample tube containing foil cut into 12 strips. The stripping process is carried out for 5 hr prior to GC analysis for O_2 and N_2.
† The stripping solution was boiled for 1 min and cooled just before addition to the sample tube.

correction ratio does not vary much from the mean value and is in close agreement with the value expected for air dissolved in water.[2] It should be noted that when the solution degassing process is carried out with foil having a hydrous oxide layer, the O_2 signal and the O_2/N_2 ratio are decreased. This has been attributed to the observation that there is a significant retention of the H_2 within the hydrous oxide produced by the reaction with boiling water; this loosely trapped gas escapes under reduced pressure and helps to remove dissolved air, enhancing the solution degassing process. This enhancement does not occur with samples having a barrier film formed on a foil with a hydrous oxide layer. In this case there is much less gas (dissolved air) escaping under reduced pressure.

A calibration curve (Fig. 3) for converting the O_2 signal area to moles of O_2 was constructed using eight air-helium gas mixtures from Matheson (Certified Standards). A wide range of gas mixtures was required since the maximum quantity of O_2 obtained from the etched foil samples was 9.6 times larger than the amount from polished foil samples. (This number, which is a measure of the increase in surface area of etched foil over polished foil, is in good agreement with the value of 8.9 obtained by capacitance measurements). An expansion of the lower portion of this curve (4 points) was used in order to obtain a more accurate calibration factor for determining the moles of O_2 from polished foil samples. The moles of O_2 present in a calibration sample were calculated from

[2] The O_2 to N_2 signal ratio observed for air (~21.0% O_2, ~78.1% N_2) is 0.284. In water ~33.8% of the dissolved air is O_2. Assuming that N_2 is the only other dissolved component the ratio expected for an air sample obtained from water is 0.539.

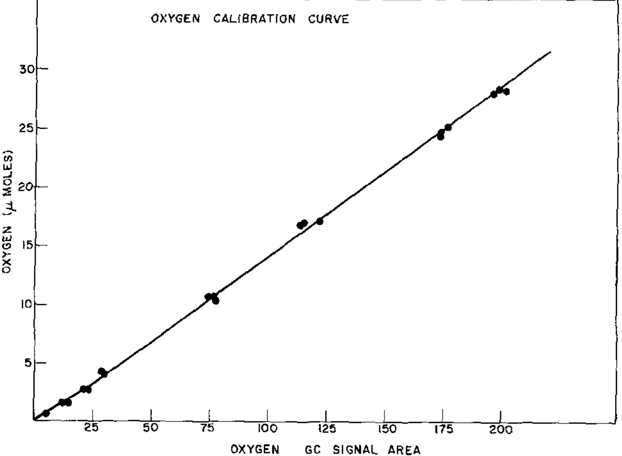

Fig. 3. Calibration curve for conversion of the O_2 GC signal area to micromoles of O_2.

the ideal gas law. A mercury manometer was used to measure pressure during backfilling of the storage tube with one of the air-helium gas mixtures. The volume of the gas space in the storage tube was determined after O_2 analysis.

The amount of O_2 released from the barrier increases rapidly with stripping time (Fig. 4 and 5). About three-quarters of the total O_2 from etched foil is released during the first 15 min while the corresponding amount from polished foil is only one-third. Furthermore, since the results in Table I show that chemical stripping of the hydrous oxide alone does not result in any detectable generation of O_2, all the O_2 that is measured must be contained within the barrier portion of the final film structure. After 3 hr there is little if any increase in the O_2 signal; however, in all the experiments reported here, the samples were stripped for 5 hr prior to O_2 analysis to ensure complete removal of O_2 from the oxide. Even with such prolonged treatment it was found that a small amount of residual oxide was not dissolved. Investigation by reflection electron diffraction showed that the aluminum substrate was still covered in places by crystalline γ-Al_2O_3.

Results and Discussion

In Fig. 1 a 5 min postboil on a 350V barrier oxide on polished foil is shown to reduce the barrier to about 10V. That this reduction occurs over only a small fraction of the surface is indicated by the fact that the voltage rises to 200V on the passage of only 0.39C, or 1.0% of the original anodization charge. An additional 2.37C is then required to restore the film to its original barrier thickness at the decay current of 10 mA. Similar results were obtained with etched foil samples. In one case after a 4 min barrier postboil only 11.4C or 2.7% of the original anodization charge was required for the voltage to reach 200V.

The presence of cavities in the film containing uncombined oxygen can be postulated to explain the reanodization curve. The first steps in the curve, *i.e.*, the region up to 200V, can be ascribed to the filling with fresh oxide of deep-lying film cavities exposed during the boiling water treatment. The slower final stage is probably only partially due to the filling of cavities since at least some portion must be associated with the repair of barrier oxide that had been converted to hydrous oxide during the postboil (5). It would be difficult to determine how much hydrous oxide is generated since it is obviously not a uniform process but only occurs at those locations where barrier oxide has been exposed on the opening of the cavities. The bulk of the barrier oxide is protected by a thick layer of hydrous oxide and would not undergo any significant attack during the short postboil, but the interior of the barrier layer would be susceptible to hydration.

It is also apparent from the rate of reanodization that the process is not uniform over the entire oxide surface. The original rate of anodization is 0.96 V/sec, while the rate of reanodization (normalized to I_A) is 6.76 V/sec.

The relaxation of the dielectric oxide is accompanied by the release of oxygen gas. In Fig. 6 and 7 the rate at which oxygen is evolved for polished and etched

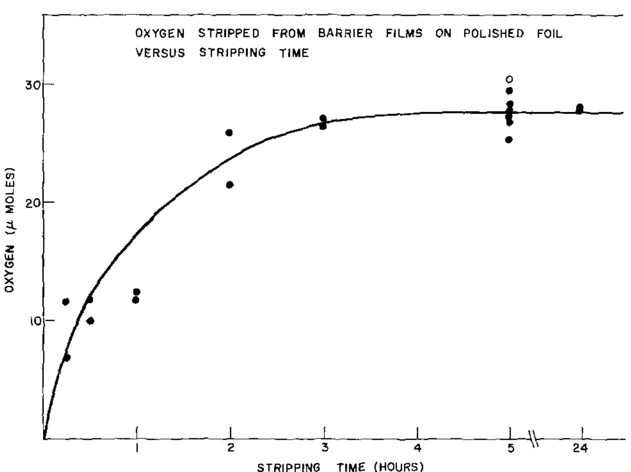

Fig. 4. O_2 content of barrier films on polished foil. The mean value of the O_2 content is 0.0357 μmole/cm^2. This value was obtained with the results for 5 hr (except 0) and 24 hr stripping.

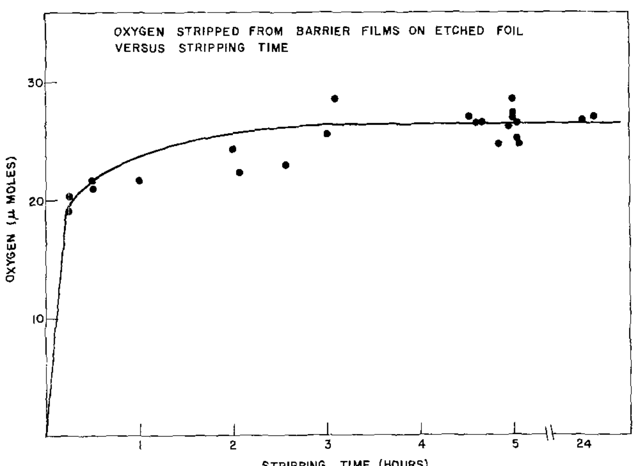

Fig. 5. O_2 content of barrier films on etched foil. The mean value of the O_2 content is 0.343 μmole/cm^2. This value was obtained from the results of samples stripped for more than 4 hr.

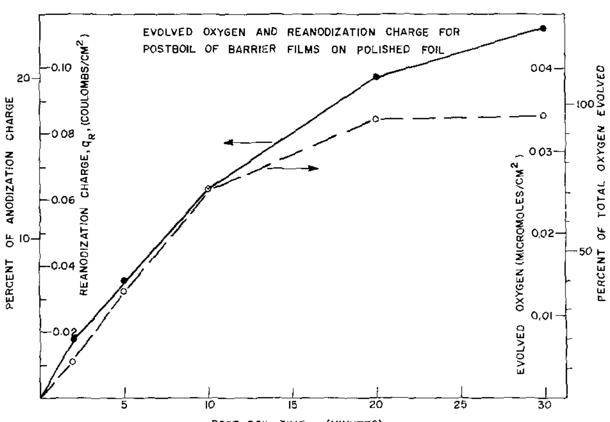

Fig. 6. The percent of total O_2 evolved and the percent of anodization charge required during reanodization for various postboil times of barrier films on polished foils.

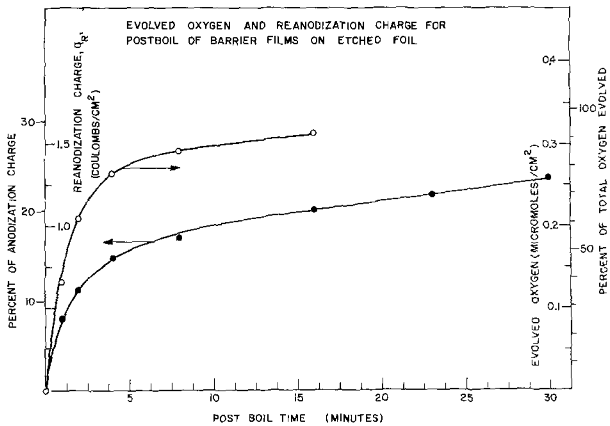

Fig. 7. The percent of total O_2 evolved and the percent of anodization charge required during reanodization for various postboil times of barrier films on etched foils.

foils is compared to the charge required to reanodize to the original film thickness. The percent of the total oxygen available that was evolved during the postboil period was determined by measuring the residual oxygen and comparing it to the total amount known to be present after anodization (Fig. 4 and 5). The fact that the amount of reanodization parallels the quantity of oxygen evolved suggests that the presence of oxygen is intrinsic to the phenomenon. Capacitance measurements (Fig. 8 and 9) also show that the reaction is not a uniform one but must involve penetration through the dielectric nearly to the substrate. Values of capacitance after postboiling are many times larger than can be accounted for simply on the basis of uniform hydration of the dielectric.

These observations are consistent with the following picture of the overall process: in the anodization of aluminum, part of the dielectric is grown through the conversion of low density hydrous oxide to barrier oxide (8), and the resulting reduction in volume results in shrinkage cavities which are filled with electrochemically generated oxygen. Crevecoeur and deWitt have reported that crystalline γ-Al_2O_3 is formed when the anodization is carried out in hot solutions, as we have done here, and they attribute the evolution of oxygen to the presence of this oxide (7). The oxygen trapped within the cavity also functions as a dielectric and thus permits the continued growth of the oxide film. Although the final film displays an apparent stability, the presence of the oxygen-filled cavities leaves it susceptible to mechanical damage and chemical attack that may bring about a sudden and catastrophic loss in dielectric strength. Boiling water, through its ability to hydrate anodic oxide, apparently attacks singularities in the oxide associated with the oxygen-filled cavities. This action effectively ruptures the "sealed" cavity and allows the oxygen to escape. We have shown that hydration (or some other form of chemical attack) is a necessary step since the use of boiling aqueous phosphate solutions, which are known to prevent hydrous oxide formation (5), does not bring about dielectric relaxation or the evolution of oxygen. For example, it was found that treatment in boiling 0.1M $NH_4H_2PO_4$ for periods up to 10 min has a constant, and small, effect on the reanodization charge. Little more than 1% of the original charge required to form the oxide was needed, or about the same that was measured after a single cold water rinse. The concentration of uncombined oxygen in the film was undisturbed by this treatment.

The manner in which oxygen is retained within the oxide cavities is a matter of some speculation. That it cannot be contained as a gas at ordinary pressures is easily demonstrated by consideration of the volumes involved. In Fig. 4 the total amount of O_2 from complete film stripping was found to be 0.036 μmoles/cm^2, equivalent to 8.06×10^{-4} ml/cm^2 at STP. Since this greatly exceeds the calculated volume of the oxide dielectric itself (4×10^{-5} ml/cm^2) it is apparent that the O_2 before release must be under extremely high pressure or in a condensed state. It seems likely that it is strongly adsorbed on the surface of the oxide walls and is released upon reaction of the oxide with water. O_2 adsorption on alumina has been reported by a number of investigators (9, 10) and has been shown to be stable at relatively high temperatures. We have found this to be the case with oxygen in these films as well, as shown in Table II. Storage in air or in a glycol-borate electrolyte at 85°C results in an extremely slow loss of O_2 and barrier properties, while vacuum treatment alone had no measurable effect. However, heating to 600°C for 1 hr allowed about 55% of the entrapped oxygen to escape.

It was also observed that the reanodization charge after high temperature treatment was much less than that required after a postboil since there is no barrier damage from hydration. It should be possible to obtain a relaxation charge due to the release of entrapped O_2 during the dielectric relaxation from this charge but only qualitative measurements are possible at this point because heat-treatment introduces other complicating factors (hydrous oxide dehydration and possible thermal oxidation of the aluminum substrate) that can affect the results.

The Polarographic and Potentiostatic Reduction of Dichloromalononitrile: A Carbene Intermediate

Robert C. Duty and Barry V. Pepich

Chemistry Department, Illinois State University, Normal, Illinois 61761

ABSTRACT

The polarographic reduction of dichloromalononitrile in acetonitrile produced one polarographic wave ($E_{1/2}$ = 0.47V at 0°C *vs.* Ag/AgBr reference electrode). A plot of E_{dme} *vs.* $i/i_d - i$ produced a 1-electron reduction for the rate-controlling step. A postulated mechanism suggested a dicyanocarbene, and a large-scale potentiostatic reduction with tetramethylethylene as the trapping agent produced the adduct of dicyanocarbene, 1,1-dicyano-2,2,3,3-tetramethylcyclopropane. The yield of the cyclopropane adduct was less than 1%, and was identified by chromatographing the reduction mixture on two different SCOT columns, OV-101 and OV-17. Dicyanocarbene has been prepared previously by debromination of dibromomalonitrile and dehydrobromination of bromomalononitrile, but this is the first reported generation of dicyanocarbene via electrochemical processes.

The existence of dicyanocarbene was proposed as early as 1957 by Cairns *et al.* (1), who debrominated dibromomalononitrile with copper powder in boiling benzene. Cairns was unable to establish direct proof for the carbene's existence because he was unable to isolate their predicted product, 7,7-dicyanobicyclo[4.1.0] heptane. In the absence of a carbene acceptor, tetracyanoethylene was isolated as the main product which led Cairns to postulate the existence of dicyanocarbene. Since 1957, dicyanocarbene has been examined more closely.

In 1965, Swenson *et al.* (2) presented more evidence for the carbene's existence by preparing 1,1-dicyanotetramethylcyclopropane from tetramethylethylene (TME) and bromomalononitrile. The proposed carbene was postulated to form by the extraction of hydrogen bromide from bromomalononitrile using triethylamine. However, Boldt *et al.* (3) published a paper in 1966 demonstrating that Swenson's cyclopropane derivative could be obtained under the same conditions without the formation of a dicyanocarbene intermediate. Also, during 1965, Ciganek (4) published a comprehensive manuscript on the reactions of dicyanocarbene. He generated the carbene using dicyanodiazomethane in two different ways. It was found that simple heating at 70°C or irradiation with ultraviolet light were both efficient ways to generate the desired intermediate, dicyanocarbene. At the present, these various methods are the only documented ways to generate the proposed dicyanocarbene.

Key words: polarography, chromatography, reduction.

According to available literature, no electrochemical studies have been conducted on the generation of dicyanocarbene. Dichlorocarbene has been generated electrolytically from carbon tetrachloride by Wawzonek *et al.* (5) who also reported the generation of phenylcarbene from the electrochemical reduction of benzal chloride (6). The phenylcarbene was trapped as the 1-phenyl-2,2,3,3-tetramethylcyclopropane adduct with tetramethylethylene albeit in very low yields. A carbene precursor, 9,9-dichlorofluorene, was reduced polarographically and potentiostatically and yielded a dimerized product of fluorenylidene, a diradical, or triplet carbene (7). These two methods, polarograph and potentiostat, were used to reduce dichloromalonitrile in the presence of tetramethylethylene to establish proof for the existence of the dicyanocarbene intermediate.

Experimental

Apparatus.—A Heath Model EUW-401 polarograph with Heath Model EUW-19-2 operational amplifier was used to record the polarograms on a Heath Model Eu-20B recorder. The polarographic cell was a three electrode cell with a platinum anode and an Ag/AgBr reference electrode.

The potentiostat used in this experiment was a Princeton Applied Research Model 173 Potentiostat/Galvanostat with a Princeton Applied Research Model 178 Electrometer Probe. The reduction mixture was analyzed using a Hewlett Packard Model 5830A Gas Chromatograph with a Hewlett Packard Model 18850A G.C. Terminal. To obtain good separation two 50 ft

Perkin Elmer Scot Columns were used; subtrates OV-17 and OV-101.

Reagents.—Aldrich dichloromalononitrile (97%) and Aldrich tetramethylethylene (99+%) were used in the reduction without further purification. Eastman Reagent Grade tetra-n-butylammonium bromide (0.175M) was used as the supporting electrolyte after it had been recrystallized from anhydrous ethyl acetate to insure a polarographically pure product. Three recrystallizations were required.

In the preparation of 1,1-dicyano-2,2,3,3-tetramethylcyclopropane, Eastman practical grade malononitrile, Baker reagent grade bromine (99.7%), and Mallinckrodt reagent grade triethylamine were used. Acetonitrile (Mallinckrodt-Nanograde) was refluxed with 0.5g sodium hydride per liter and distilled through a glass helice column (70 × 2 cm OD) under a dry nitrogen atmosphere. The distilled acetonitrile was stored under dry nitrogen in brown bottles.

Polarographic procedure.—A polarogram was recorded in an acetonitrile solution of 1×10^{-3}M in dichloromalononitrile and 0.175M in supporting electrolyte (tetra-n-butylammonium bromide in acetonitrile). The capillary had a drop time of 3.10 sec in distilled water at a mercury height of 60 cm. The $m^{2/3}t^{1/6}$ value for the capillary was 4.56. The value obtained for αn at 0°C equaled 0.42 and was in the range (0.4-0.6) for the gain of one electron (8, 9).

Potentiostatic reduction procedure.—An H-cell (7) was used in which the cathode and anode were separated by a medium fine sintered glass frit. The volume of the cathode was 60 ml and the anode volume was 50 ml. The mercury pool cathode was vigorously stirred throughout the reduction by a small magnetic stirrer. A coiled 12-gauge platinum wire was used as the anode with an Ag/AgBr nonaqueous reference electrode which contained the supporting electrolyte. The cell resistance was approximately 30Ω as measured from the anode potential (1.2V) and the initial cell current (40 mA). The reduction was carried out in a thermostat bath in the temperature range of 0° to +5°C under a purified nitrogen atmosphere.

Five grams of dichloromalononitrile (0.0371M) was added to the cathode compartment which contained 10 ml TME and 25 ml of the 0.175M supporting electrolyte in acetonitrile. The anode contained 40 ml of the acetonitrile solution. The current ranged between 100 and 160 mA. The potentiostat was turned off after 4.5 hr with the current reading 20 mA.

The catholyte at the beginning of the reduction immediately changed color from clear to yellow and finally to an opaque reddish-brown color. The catholyte was rotary evaporated, and the distillate and pot residue were collected. An ether extraction of the pot residue ensured that no product was left behind. The yellow ether extract and the distillate were combined and concentrated on a steam bath for G.C. analysis.

Preparation of 1,1-dicyano-2,2,3,3-tetramethylcyclopropane (I).—Bromomalononitrite was starting material for the preparation of I, and 1.6g (2% yield) was prepared with a melting point of 62.0°-62.5°C. (Lit. mp 64°-65°C) (10). Compound I was prepared by a scaled-down procedure of Swenson (11). Long needle-like clear crystals from hexane (0.1g) were obtained with a melting point of 49°-51°C (Lit. mp 51.5°-52°C) (11).

Gas chromatographic analyses.—The initial G.C. column, which was used to establish retention times, was a Perkin-Elmer Scot OV-17 column. The instrumental conditions used appear in Table I. A 0.1 μl sample of 1,1-dicyano-2,2,3,3-tetramethylcyclopropane in hexane was injected and found to have a retention time of 27.7 min. The reduction mixture was chromatographed, and only a single peak occurred within ±10 min of the standard peak at 27.7 min. To establish whether or not both peaks corresponded to the compound in question

Table I. Instrumental conditions used for gas chromatography

Column	OV-17	OV-101
Initial temp.	50°C	50°C
Time at T_1	10 min	5.0 min
Rate	4°C/min	4°C/min
Final temp.	200°C	140°C
Time at T_2	4 min	2.0 min
Carrier gas	7 ml/min (He)	6 ml/min (He)

(1,1-dicyano-2,2,3,3-tetramethylcyclopropane), the reduction mixture was spiked with a small amount of the standard solution and injected again. The only peak found in the 20 min window had a retention time of 27.7 min. Thus, the cyclopropane structure had been formed as one of the reduction products and its yield as measured by spiking the sample was less than 1%. To further confirm the validity of this conclusion, the same procedure was utilized with a Perkin-Elmer OV-101 column under different instrumental conditions (see Table I). Again, the standard solution, the reduction solution, and the spiked reduction solution were run, and a retention time of 17.8 min was recorded. The closest peak in the reduction mixture was located at 27.06 min. This peak exhibited no notable change in retention time (0.06 min) or peak area (701 area counts) as compared to the peak in question (8992-34,218 area counts). Consequently, with two different substrates producing different retention times for 1,1-dicyano-2,2,3,3-tetramethylcyclopropane which agreed with unknown peaks in the reduction mixture, the generation of dicyanocarbene at the electrode surface was confirmed. This technique of identifying compounds with retention times from different chromatographic columns has been documented by a study of isomers of aromatic mono, di, and trichlorinated toluidines (12).

Results and Discussion

A Heath Polarograph Model EUW-401 (see Apparatus section) was used to ascertain the reduction pathway for dichloromalononitrile. In Fig. 1, the polarogram is shown with the half-wave potential at 0.47V at 0°C. Only one polarographic wave was observed for which a reduction scheme is proposed

$$N{\equiv}C\text{-}C(Cl)_2\text{-}C{\equiv}N \xrightarrow[-Cl^-]{1e\ (slow)} [(NC)_2\dot{C}Cl]^{-} \quad [1]$$

$$[(NC)_2\dot{C}Cl]^{-} \xrightarrow[-Cl^-]{1e\ (fast)} [NC\text{-}\ddot{C}\text{-}CN] \text{ dicyanocarbene} \quad [2]$$

$$[NC\text{-}\ddot{C}\text{-}CN] \xrightarrow{TME} (NC)_2C\langle C(CH_3)_2\text{-}C(CH_3)_2 \rangle \quad [3]$$

$$\text{or } [NC\text{-}\ddot{C}\text{-}CN] \xrightarrow{[NC\text{-}\ddot{C}\text{-}CN]} (NC)_2C{=}C(CN)_2 \text{ (TCE)} \quad [4]$$

This mechanism is supported by ascertaining the number of electrons involved in the rate-controlling step according to the procedure of Meites (13). In this method for irreversible polarographic waves, a plot of E_{dme} *vs.* $i/i_d - i$ was constructed for dichlorodicyanomethane. The values of E_{dme} and i (the current at each equal increment of 20 mV) were taken from the rising portion of the polarogram. The slope of this plot is equal to $-0.0542/\alpha n$ where α is the transfer coefficient and n is the number of electrons in the rate-controlling step. The value of αn has been shown to fall in the range of 0.4-0.6 for a one-electron reduction in a rate-

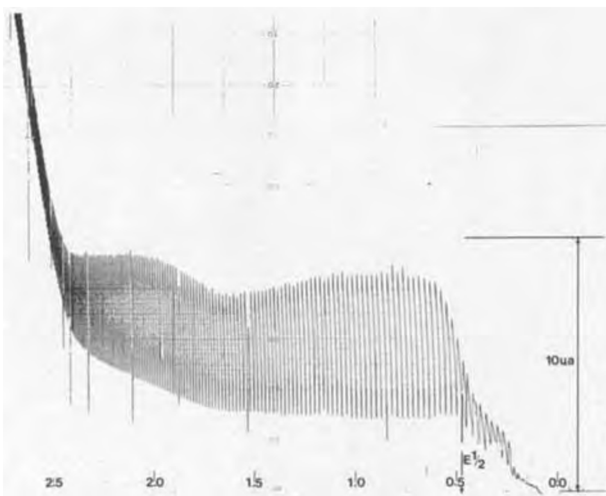

Fig. 1. Polarogram of dichlorodicyanomethane

controlling step (8, 9). Consequently, since αn was 0.42 for dichlorodicyanomethane, this is consistent, but not absolute proof, for the mechanism shown above. In fact, since a very low yield of trapped product was obtained (less than 1%), more than one mechanism is undoubtedly occurring. A most plausible mechanism for reduction of organic halides is through a one-electron reduction to the free radical which, subsequently, is reduced to the carbanion.

Simonet (14) has published evidence of this for his α-bromo acetylene compounds, and Erickson has demonstrated an equivalent mechanism with his excellent study of gem-dihalocyclopropane structures (9). In addition, Casanova has shown this to be true for the reduction of α-bromoketones (15).

The diffusion current constant ($I_d = i_d/\text{cm}^{2/3}t^{1/6}$) as calculated from Fig. 1 was 1.38. This value has limited significance because it is readily apparent from observing the solution prior to a polarographic run that a reaction is occurring, undoubtedly, with the mercury. These observations have been noticed previously with reactive halides by Wawzonek (16). This was confirmed in our polarogram by running the same solution at 15 min intervals. In the second run the diffusion current had decreased by approximately 25%.

Additional evidence for a reaction with mercury was obtained by running the reaction at 25°C. At this higher temperature a very rapid increase in current (greater than 20 μamp) appeared at 0.1V. This initial wave had the same appearance as the prewaves which were shown for benzyl mercuric iodide (16) which was polarographed under similar conditions as the dichloromalononitrile. The prewave had a maximum current which dropped back to the level of the residual current after a few tenths of a volt. This maximum could be caused by the adsorption onto the surface of the mercury drop of the reduction product, an organomercurial free radical, as explained by Wawzonek for benzyl mercuric chloride (16).

The reduction of dichlorodicyanomethane was diffusion-controlled and did not exhibit a kinetic or an absorption current at the electrode surface. The diffusion-controlled reduction current was directly proportional to the square root of the mercury height. Thus, one would expect a rapid gain of the second electron in Step 2 leading to the formation of a carbene intermediate. A similar electrochemical mechanism has been proven for 9,9-dichlorofluorene (7). A carbene formed in this manner can add to a double bond yielding a cyclopropane derivative, or dimerize to form TCE. An explanation of these two products is more easily explained if one examines the dicyanocarbene spin states.

It seems reasonable that the cyclopropane derivative was formed mostly from the singlet state of the carbene. Singlet states have been shown to be much more reactive toward substrate molecules and to react stereospecifically by Ciganek (4). Unfortunately, there was no way to examine the stereospecificity of the reaction since TME was employed as the substrate.

It is felt that the TCE product is formed via the triplet or diradical spin state. Due to the nature of the experimental procedure it seems plausible that some TCE would be formed. The reducing surface employed was a small pool of mercury. Thus, due to migration of dichloromalononitrile towards the cathode surface the concentration of TME would be reduced. If two carbenes were formed and had time to relax to the triplet state, one could observe TCE as a product. At the present only Cairns *et al.* (1) have observed TCE as a product of a proposed carbene intermediate.

Cairns explains that the formation of TCE was due to the absence of a suitable substrate since benzene was employed as a solvent. If one accepts that Cairns had actually formed a carbene intermediate, then it seems very likely that the TCE produced was also formed via triplet dicyanocarbene since the benzene molecules would have aided in the singlet-triplet transition.

It has been shown that the ground state for dicyanocarbene is a linear triplet (17, 18). This triplet is resonance stabilized by the two cyano groups which account for its extended lifetime and ability to dimerize. Some work has been done with stabilized carbenes where the carbene carbon is attached to two atoms each bearing an unshared pair of electrons. It has been reported that I (19), II (20), and III (21) have long enough half-lives to exist in equilibrium with their dimers, although this conclusion has been proved incorrect in the case of I via crossover experiments (22)

I II III

If this is in fact the case, then one might expect a very small equilibrium between dicyanocarbene and its dimer, TCE, although it would not be expected to exhibit as much stability as the above species. Further work might be attempted on trapping this diradical with a different substrate. If the diradical does exist in any residual amount at all, it should be possible to shift this equilibrium using mild conditions. A consideration might also be made on attempting to generate dicyanocarbene from TCE.

Manuscript submitted May 8, 1979; revised manuscript received Jan. 14, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Oxidation State Changes and Structure of Electrochromic Iridium Oxide Films

J. D. E. McIntyre,* W. F. Peck, Jr., and S. Nakahara*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Oxidation state changes, completeness of oxidation, and densities of anodically formed, electrochromic iridium oxide films have been determined by combined gravimetric, coulometric, and reflection spectroscopy analyses. The results show that the oxidation state of Ir ions in the oxide is changed from III to IV during the anodic coloration process [0.25 to 1.25V(RHE)], rather than II to IV as previously postulated, and that virtually all Ir ions in the film are accessible for electrochemical oxidation and reduction. The mean density of the oxide film is 2.0g cm^{-3}, as compared to 11.68 for bulk crystalline IrO_2. The structure of the film was shown by electron microscopy to consist of oxide grains 0.05-0.1 μm in diameter, surrounded by voids. In addition, the presence of a high density of microvoids ~25Å in diameter was detected. The highly porous structure of the film permits ready access of the electrolyte to the oxide grains throughout the entire film and facilitates the rapid coloration and bleaching (~40 msec) observed in aqueous electrolytes. The apparent accessibility of all Ir ions in the film also implies rapid transport, within the oxide grains, of the mobile charge-compensating ions which must be injected and ejected to preserve electroneutrality. Mechanisms of ion and electron transport are discussed.

In recent communications from this laboratory (1, 2), the results of studies of the anodic formation and electrochemical and spectroscopic properties of hydrous anodic iridium oxide films have been presented. Owing to the rapid and reversible coloration and bleaching which these films exhibit during redox cycles (transparent ⇄ blue-black), this electrochromic system has potential application in electro-optic display devices (1, 3). In contrast to other electrochromic oxides such as WO_3 (4), coloration in these films is produced by anodic oxidation rather than cathodic reduction.

The structure and composition of these hydrous oxide films and their influence on the kinetics and mechanism of the electrochromic effect are of considerable current interest. In addition, highly conducting iridium and ruthenium oxide films are excellent electrocatalysts for O_2 evolution (5-11) and serve as stable anode materials for Cl_2 evolution (12-16). From analyses of the anodic oxygen layer on iridium by x-ray emission, electron diffraction, and electron microscopy, Michell *et al.* (17, 18) concluded that in the oxidation process $Ir(OH)_2$ is converted to IrO_2 on the iridium metal electrode surface by a reaction involving transfer of $n = 2$ electrons to the metal substrate and simultaneous ejection of an equal number of protons into the electrolyte. For a film with a charge capacity of 24 mC cm^{-2}, measured with a linear potential sweep extending from 0.06V to 1.5V(RHE), the thickness was estimated to be 22 nm. In their soft x-ray emission measurements, determination of the n-value necessitated an estimation of the parameters, R_∞, the ratio of the peak height of the oxygen emission line to background for an oxide of infinite thickness, and μ, the absorption coefficient, from a calibration for tantalum oxide (19). This method was stated to permit the weight of the oxide film to be determined within 10% (17, 18). Film thicknesses were calculated by assuming the anodic oxide film density to be the same as that for bulk IrO_2 (11.68g cm^{-3}).[1]

Although iridium forms a variety of chemical species in which the metal ion oxidation state ranges from 0 to VI, only the I, III, and IV compounds are commonly found (20-23). The report of the electrochemical formation of a stable divalent oxide which could repeatedly be cycled to a higher oxidation state was therefore surprising. Secondly, the film thicknesses calculated by Michell *et al.* (17) are smaller by a factor of ~10 than those calculated on the basis of recent optical measurements (11, 24, 25). In order to resolve these apparent discrepancies we have determined the oxidation state changes, completeness of oxidation, and densities of anodic iridium oxide films by alternative techniques, using combined weight-loss, coulometry, and reflection spectroscopy measurements. In addition, the structures of these films were investigated by scanning and transmission electron microscopies.

Key words: ion transport, electrochromism, microscopy, anodic film.

[1] At the time of the work of Michell *et al.*, optical constant data for anodic iridium oxide films (11) were not yet available for determination of film thicknesses by ellipsometry or reflectometry.

Experimental

Iridium metal is highly resistant to corrosion under static potential conditions, but a hydrous anodic oxide film can be grown on its surface by square-wave or triangular-wave potential cycling (2). Subsequently, this film can be completely removed from the electrode surface by cycling in 5M H_2SO_4 (18, 26), or by soaking in hot 5M H_2SO_4 (2) or hot chromic acid (27). In addition, the oxide film can be removed by holding the electrode at an anodic potential >1.63V(RHE) in 1M H_2SO_4 or by repetitively cycling to ~1.7V (28). This fact suggested that the weight of the film could be determined directly by accurately weighing the electrode with a microbalance before and after film stripping. Although the exact composition of the hydrous electrochromic oxide is not yet known with certainty, the atomic weight of Ir (192.22) is so high relative to those of O and H that the total Ir content in the oxide film should be approximated quite closely by the weight loss. Further, the amounts of Ir lost from the metal electrode due to dissolution in the electrolyte during film growth can be estimated by also weighing the bare metal electrode before film growth and after film stripping.

In the present studies, anodic iridium oxide films were grown on precleaned-and-weighed Ir metal electrodes in 0.5M H_2SO_4 at 25°C by cycling the potential with 0.5 Hz square waves between 0.0 and 1.5V(RHE), as previously described (2), until films with the desired charge capacity (20-25 mC cm^{-2}) were obtained. The number of coulombs required to oxidize a film in color-bleach cycles with cathodic and anodic limits of 0.25 and 1.25V(RHE), respectively, was measured with an analog coulometer during triangular potential sweeps at 150 mV sec^{-1}. As shown previously (2), these potential limits prevent changes in film thickness and also the evolution of O_2 and H_2 gases. After completion of the coulometric measurements, the sample electrode was removed from the electrolyte in the bleached state while under potential control at 0.25V(RHE). The electrode was then rinsed in distilled water, air-dried at room temperature, and further dried in an oven at 110°C for 1 hr to remove excess water. The electrode was then reweighed to determine the net weight change produced by growth of the oxide film and dissolution of Ir metal ions in solution.

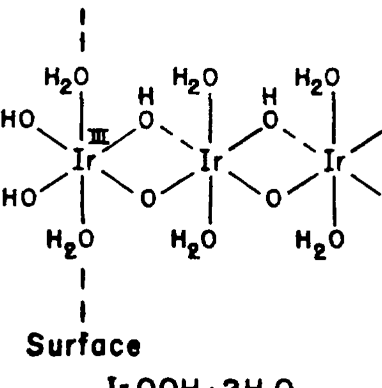
The film was next stripped from the electrode to determine the residual weight of the Ir substrate. Oven-dried oxide films were found not to be soluble in hot 5M H_2SO_4 or chromic acid, even on long exposure. It was found, however, that the dried film could be stripped from the electrode by cycling in 0.5M H_2SO_4 with 150 mV sec^{-1} linear potential sweeps between 0.25 and 1.75V(RHE) for ~5 min. This procedure "undermined" the dehydrated oxide film and allowed it easily to be wiped off the surface. Final stripping of any residual oxide was accomplished by soaking in hot 5M H_2SO_4 at ~80°C for 1 hr. After rinsing and drying at 110°C, the electrode was weighed again to determine the weight of the bare Ir substrate and hence the weight of the oxide film removed. Blank runs with nonoxidized Ir metal electrodes showed that there was negligible weight loss of metal (≤1 μg) produced by this stripping procedure.

All weights were determined with a Perkin-Elmer Autobalance Microbalance, Model AD2Z, employing a substitution weighing method which permitted use of a 20 mg full-scale range with a resolution of 1 μg. The average precision of the weighings was ±1 μg.

Scanning electron micrographs of an anodic iridium oxide film grown on an Ir metal substrate were taken in the secondary electron emission mode with an ETEC Corporation Autoscan Scanning Electron Microscope operated with an accelerating voltage of 20 kV. For transmission electron microscopy, an anodic oxide film was grown in 0.5M H_2SO_4 by cycling the potential of a thin (400 nm) Ir metal film, which had been electron-beam evaporated onto a pyrolytic graphite substrate, until the metal was completely converted to oxide. The oxide film was then lifted from the graphite surface with transparent adhesive tape. Subsequently this tape was dissolved in CCl_4 to free the film. TEM micrographs of the isolated film were taken with a Japan Electron Optics Laboratory JEM-200 electron microscope operated at 200 kV.

Results and Discussion

The results of the weight-loss and charge measurements on three different samples are summarized in Table I. The number of coulombs of positive charge injected during film coloration [0.25 to 1.25V(RHE)] was corrected for the component due to double-layer charging. This correction is small, amounting to only ~3% of the total charge passed. Its magnitude (~0.7 mC cm^{-2}), however, indicates that the real surface area of the oxide layer is very high. The oxidation state change per Ir atom was calculated assuming the composition of the bleached state to be $Ir(OH)_3$ (≡$IrOOH \cdot H_2O$). This composition is in best agreement with the results of nuclear reaction and Rutherford backscattering analyses of the H and O contents of the film, measured by bombarding the film with 0.9 MeV $^3He^+$ ions in a Van de Graaff ion accelerator (30). These analyses showed that there are significant amounts of strongly bound H contained in both bleached and colored states of the film, which are not removed by extended pumping under high vaccum conditions (<10^{-6} Torr). If the bleached film were assumed to consist of $IrOOH \cdot 2H_2O$ units bound in a network configuration, *viz.*



the molecular weight would be increased from 243.3 to 261.3 and the calculated oxidation state changes would be increased correspondingly from 0.99 to 1.06. Similarly, if foreign anions such as SO_4^{2-} are incorporated in the oxide film during growth, as shown to be the case by infrared spectroscopy measurements (31), then the calculated oxidation state changes should also be slightly higher than the values shown in Table I. Since the anodic tail of the main oxidation peak centered at 0.98V(RHE) appears to overlap part of an anodic peak at higher potentials (Fig. 1), the end point of 1.25V chosen for the coloration step must also be regarded as uncertain to about this extent.

Table I. Oxidation state changes of anodic iridium oxide films [0.25-1.25V (RHE)]

Specimen	Square-wave growth cycles (0.0-1.5V)	Q_a* (mC cm^{-2})	Weight of surface oxide (μg cm^{-2})	Oxidation state change
A	250	23.0 (24.4)	59.0	0.98
B	250	23.1 (23.7)	59.2	0.98
C	250	23.2 (23.9)	58.0	1.01

* ( ), before correction.

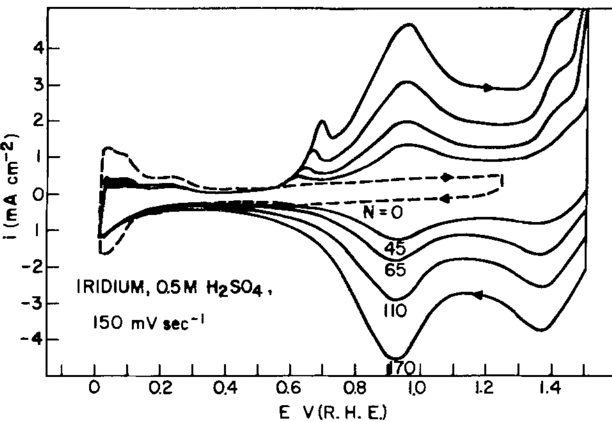


Fig. 1. Cyclic voltammograms of an Ir electrode in aqueous 0.5M H_2SO_4 electrolyte at 25°C. - - -, oxide-free surface; ———, oxide-covered electrode after N growth cycles. Potential sweep rate = 150 mV sec^{-1}.

Oxidation state changes were also calculated from the weight differences of the bare Ir electrodes before and after film growth and stripping. With this method, no assumption need be made concerning the actual film composition, since the measured weight loss is entirely due to Ir. If, however, some of the Ir metal dissolves into the electrolyte during oxide film growth, as shown (18, 26), then the net weight loss will correspond to the sum of these processes and the calculated oxidation state changes will be too low. In the present experiments, the average n-value calculated by this method was 0.87 ± 0.015, indicating that an amount of Ir metal corresponding to 10-20% of that incorporated in the oxide is lost to the electrolyte by dissolution during film growth.

The above results are in very good agreement with an oxidation state change of 1 during color-bleach cycles, rather than 2 as postulated by Michell *et al.* (17, 18). The transformation of the color of the film from transparent to blue-black during oxidation strongly indicates that this process corresponds to a change of oxidation state from III to IV. The final blue color of the anodic film is very similar to that of thin IrO_2 films formed by thermal oxidation. The coloration of this mixed valence system may be attributable to intervalence transitions of the type

$$Ir(5d^6) + Ir(5d^5) \xrightarrow{h\nu} Ir(5d^5) + Ir(5d^6)$$

made possible by the introduction of holes into the $5d(t_{2g})$ subband of the oxide. The conclusion that the final valence state is IV is further supported by Raman (32) and XPS (33) studies of the geometric structure and electronic properties of the anodic films in both colored and bleached states.

The anomalously high values of the oxidation state changes reported by Michell *et al.* appear to have arisen from their choice of the potential limits 0.06 and 1.5V(RHE) for coulometry in 1M H_2SO_4. As noted previously (1, 2), such limits are suitable for film growth, but not for color-bleach cycles. It is evident from the forms of the cyclic voltammograms of an Ir electrode in acid solution (cf. Fig. 1) that both a second redox process and O_2 evolution can occur if the anodic limit is extended to 1.5V(RHE). In the present studies, the measured values of anodic charge passed during linear potential sweeps at 150 mV sec^{-1} from 0.25 to 1.50V(RHE) were ~50% greater than those recorded with a limit of 1.25V. Still greater values might result from increased evolution of O_2 during the slower (40 mV sec^{-1}) sweeps employed in Ref. (17) and (18).

From combined optical and coulometric measurements (24, 25), it is possible to determine the film thickness very accurately. For a film such as specimen A (Table I), which had a charge capacity of 23.0 mC cm^{-2} (corrected), the thickness was calculated to be 295 nm. The density of the hydrous oxide film is, therefore, ~2.0g cm^{-3}. This value is much lower than that of anhydrous bulk IrO_2 (11.68g cm^{-3}) and reflects the very porous nature of the anodic oxide layer (see below). This high porosity is also evidenced by the low apparent refractive index of the anodic film (1.41-1.44), determined by *in situ* ellipsometry (11). The latter value is actually a composite of the refractive index of the oxide grains and that of the electrolyte contained within the film pores.

If it is assumed that the coulometric values of Michell *et al.* (17) are higher by a factor of ~2 than those measured in the present studies for oxide films containing equal amounts of Ir, then it can be seen that the film weight determinations by the two independent techniques are in quite good agreement. Studies of contrast ratio enhancements produced by optical interference effects in these electrochromic surface films (24, 25) have confirmed that the films used in the present work were *ca.* one-half the wavelength of visible light in thickness. The film thickness estimates of Michell *et al.* (17) are apparently low by a factor of 7-10, owing to their use of the density of bulk IrO_2 in their calculations.

The porous nature of the film deduced from these results was confirmed directly by scanning and transmission electron microscopy studies. Figure 2 is an SEM micrograph of an anodic oxide film grown on an Ir metal substrate, which reveals a high density of pores 0.05-0.07 μm in diameter. Figure 3 is a TEM micrograph of an anodic iridium oxide film grown on a pyrolytic graphite substrate and stripped. It is evident that the film structure consists of oxide grains 0.05-0.1 μm in diameter surrounded by voids. The oxide grain size determined in the present studies is in close agreement with the TEM measurements made by Michell *et al.* (5) using a replication technique. In addition to macrovoids, the presence of microvoids ~25Å in diameter was detected in the present study. Such structures are very similar to those of chromate films grown by elec-

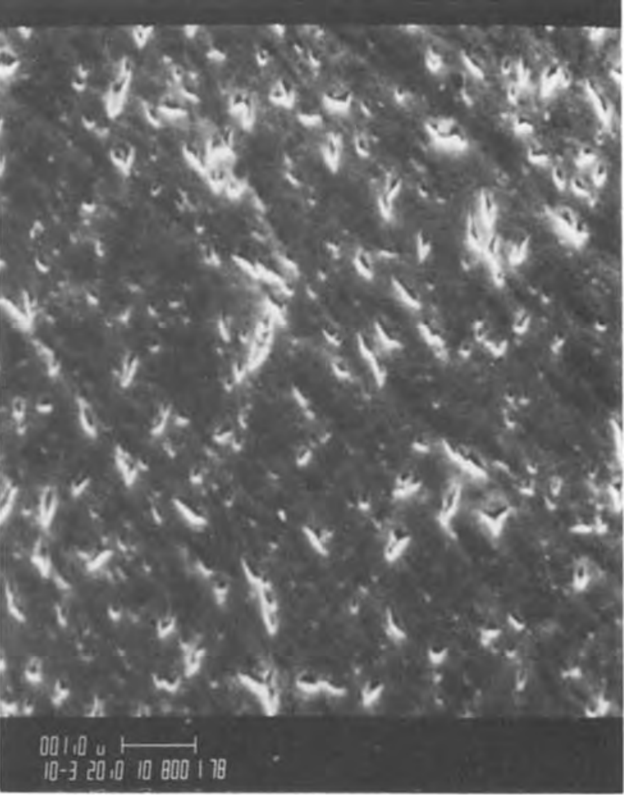

Fig. 2. SEM micrograph of an anodic iridium oxide film showing the high density of pores. Original magnification: 10,000×.

trochemical precipitation (34). This suggests that anodic iridium oxide layers may be formed by a dissolution-precipitation process induced by potential cycling. Results of a more detailed electron microscopy study of film structure will be presented separately. The highly porous structure observed in the present study permits ready access of the electrolyte to the oxide grains throughout the entire film and is presumed to be responsible in large part for the rapid coloration and bleaching times (~40 msec) observed for electrochromic iridium oxide films in aqueous electrolytes.

The above results have significant implications for establishing the mechanism of charge neutralization within the oxide during coloration and bleaching. During anodic coloration, electrons are transferred from the oxide to the Ir metal substrate. Simultaneously, an equivalent amount of ionic charge is transferred across the oxide-electrolyte interface to maintain electroneutrality inside the oxide (2). In principle, this charge compensation can be accomplished either by ejection of cations or by injection of anions. From the close agreement of the measured oxidation state change with that expected on chemical grounds, we conclude that virtually all of the Ir ions in the oxide film are accessible for oxidation and reduction. It would be highly improbable that such close agreement could be obtained if the oxidation state change were 2. This would require that exactly half of the Ir ions in the film be oxidized and reduced in each color-bleach cycle, the other half remaining inaccessible or inert.

Reflectivity transients observed during bleaching in aqueous, unbuffered Na_2SO_4 (*p*H 3.5) electrolyte show that part of the film is bleached in an initial rapid step (2). At low cathodic overpotentials, the remainder is bleached in a much slower process, controlled by diffusion of ionic species in solution. The relative magnitudes of these two components are dependent on the amplitude of the applied cathodic potential, indicating that the compensator ions required to maintain local charge neutrality inside the bulk oxide can be supplied by three sources in this dilute acid solution: (*i*) bound H_2O and OH groups on the oxide surface; (*ii*) free H_2O in the electrolyte contained within the film pores; and (*iii*) hydrated H^+ species in the bulk electrolyte. The rapid bleaching component is attributed to sources (*i*) and (*ii*), which do not require mass transport. Now the charge-compensating ions must be externally supplied to the bulk oxide phase, either from the oxide surface or from the bulk electrolyte. The oxide grain-size determinations in the present study indicate that the majority of the Ir ions are situated within the bulk of the oxide rather than at its surface. Also, it may be assumed that no more than one or two OH or H_2O groups bound to the surface Ir ions are exposed to the electrolyte at the interface (see above). These facts imply that the majority of the compensator ions must be supplied from the bulk electrolyte, *i.e.*, sources (*ii*) and (*iii*). There are insufficient bound species initially present on the surface [source (*i*)] to satisfy the charge neutralization requirements.

Both cation (1, 2, 35) and anion (36, 37) transport mechanisms have been postulated to occur in electrochromic iridium oxide films. In the first, protons are proposed to migrate along a hydrated IrO_2 chain network (see above), by a Grotthuss-type mechanism analogous to that occurring in water and ice (35). This process may be assisted by quantum mechanical proton tunneling. Desolvated protons could also migrate through open tunnels in the oxide lattice similar to those which occur in anhydrous crystalline IrO_2 (38). The structure of the anodic iridium oxide film, however, is amorphous (32, 33) and it is not yet known whether similar tunnels exist in the grains of this material. Tunnels of the type occurring in the rutile-like structure of IrO_2 are much too narrow ($r \approx 0.65$Å) to permit insertion of anions such as F^- ($r = 1.36$Å), OH^- ($r = 1.53$Å), or CN^- ($r \approx 1.9$Å). It is therefore not evident how compensator ions such as these could be injected into the bulk oxide, as proposed in the anion mechanism(36, 37), so that all Ir ions are oxidized and reduced in the solid-state electrochromic redox reaction. A high concentration of point defects in the amorphous oxide film, *e.g.*, $O^=$ vacancies, might make such insertion possible, but normally this process should be very slow at 25°C. Nor is it clear why, in a hydrous oxide/aqueous electrolyte system, the mobility of an OH^- ion in the solid oxide should be greater than that of a free proton, which has the same absolute charge but much lower mass and no geometric barriers to prevent its migration. A lower proton mobility would imply that this species is more tightly bound in the solid, *e.g.*, to $O^=$ ions, than are mobile OH^- ions to the Ir cations. The rapid isotopic exchange of D and H observed in these hydrous oxide films (30) indicates that the protons are highly labile.

Finally, we not that on the basis of measurements of the small amplitude a-c response of anodic iridium oxide films, it has been suggested (39) that the kinetics of the redox reaction are controlled by the mobility of reduced lattice sites in the oxide. The structural studies in the present investigation suggest an alternative but related phenomenon should also be considered as a possible rate-limiting factor, *viz.*, electron transport across oxide grain boundaries.

Metal Filmed-Semiconductor Photoelectrochemical Cells

S. Menezes,* A. Heller,* and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Voltammetric and light to electrical energy conversion characteristics of metallized semiconductor Schottky junctions with redox solution contacts are reported. Electrodeposited noble metal films on n-GaAs establish contacts to reversible aqueous redox couple solutions that can sustain solar photocurrent levels with low loss, requiring only a thin metal layer adequate to photovoltaic barrier formation. Possible advantages in lateral conductivity, relative to solid-state Schottky devices, and in surface stability and redox electrolyte independence, relative to semiconductor-liquid junction solar cells, are weighed against both the absorptive losses in the metal layer and the practicalities of obtaining sufficient integrity in the film to serve the semiconductor corrosion protection function. Gold, platinum, and rhodium plated n-GaAs with carbon counterelectrodes and ferro-ferricyanide solutions give 2-6% conversion efficiency under solar irradiance.

Stability of the semiconductor-liquid electrolyte interface is essential for practical solar-to-electrical conversion or electrosynthesis with cells based on the photovoltaic properties of these junctions. Among the expedients proposed to circumvent the chemical or photoanodic reaction of the semiconductor with the electrolyte is the limiting case of total removal of the active junction from electrolyte contact by interposition of a thin, unreactive metal film between the two phases (1-5). This requires that, in the hybrid cell, the metal and semiconductor form a Schottky barrier for the photoactive junction. In this scheme, the electrolytic redox couple solution with necessary counterelectrode becomes a simple front contact (4).

* Electrochemical Society Active Member.

Key words: energy conversion, photovoltaic, solar, voltammetry.

Prior workers have reported cyclic current-voltage curves of metallized GaP at stationary electrodes (1-4). That the photopotentials of such cells are a function of the metal-semiconductor pairing and relatively independent of the redox couple was demonstrated therein for gold-coated GaP and Si electrodes (1). Analyses of voltammetric behavior and issues in light to electrical power conversion were not described.

Recent suggestions in this area (6-8) utilize illuminated p-n junctions, metallized to form ohmic contacts at both the p and the n regions which, in contact with an electrolyte, drive a net electrolytic reaction. In this concept, based on silicon particles, the current flow is local rather than to an external load, but the considerations of metal-semiconductor interface stability determining the long-term performance in corrosive elec-

trolytes are related, whether this junction is ohmic (6-8) or blocking (1-5).

Schematic possibilities for these cells are given in Fig. 1. The hybrid cell is B, containing elements of a Schottky barrier solid-state cell A, and a semiconductor-liquid junction cell C. Cell A in practice has additional metallization and contact fingers on the metal layer to supply a low resistance front contact whereas cell C necessarily has a counterelectrode (CE) to complete the equivalent function. In all cases, the semiconductors themselves would have an ohmic back contact, not indicated in Fig. 1.

Cell B has a semiconductor-metal barrier with two electrolytic contacts in series (anode and cathode). This implies that lateral conductivity in the metal plane is less of a constraint on overall device series resistance than in cell A, since the electrolytic solution provides a parallel path. The electrolytic part of the hybrid depends in its dynamic contact resistance (I-V slope) on both anode and cathode voltammetry, but the Fermi level (Nernst potential) of the solution itself ought not to influence open-circuit voltage. If the solution presents a low enough resistance, the M layer in cell B may be made as thin (for improved light transmission) as needed for its functioning in a Schottky junction and for isolation of the semiconductor from the electrolyte. The electrolyte interface in cell C is profoundly different. It is involved in defining the barrier height, band bending, cell voltage, and power output.

The arrows in Fig. 1 indicate the light path through the respective cells to the photoactive junction. The light must traverse the metal layer and/or the solution plus cell window in the respective cases. Contact fingers in cell A structure cause further light loss. The dashed lines over the counterelectrode of Fig. 1 indicate that the losses will vary to the extent that the counterelectrode affects light transmission. This loss is a function both of geometry and electrode material. All the present experiments employ configurations in which the counterelectrode does not block the light path.

When the hybrid cell contains a kinetically reversible redox couple, the exchange currents at both the Schottky barrier metal and counterelectrode can be higher than the photogenerated currents. If, in addition, the electrolyte is highly conductive, the hybrid cell will have an ohmic contact characteristic and low impedance. With suitably transparent redox couples, not now restricted by the severe requirements of competing against semiconductor corrosion, and with appropriate counterelectrode design, this "contact" might absorb very little light. Then, if the metallization of the semiconductor did not produce too severe light absorption and reflection, or if transparent conductive electrodes such as SnO_2/Sb or In_2O_3/Sn were used, a hybrid cell like B might have interesting properties as an energy converter relative to both the conventional solid-state (A) and liquid junction (C) counterparts. This work is an examination of some characteristics of the metallized semiconductor-electrolyte structure, with such possibilities in mind.

Our previous consideration (5) of type B cells was restricted to their use for modeling light and mass transfer flux limitations in liquid junction cells, C, in a case where the interface was not subjected to parallel

Cell

B	SC | M | R-O | CE	
C	SC | R-O | CE	

Fig. 1. Schematic of photocell structures. Arrows indicate light path. SC = semiconductor, M = metal, CE = counterelectrode, and R-O = redox electrolyte.

photocorrosion. In this paper, we are drawing the first quantitative comparison between the hybrid cell B and the metal Schottky cell A with respect to their impedance and kinetic characteristics. We have continued in the present effort to prepare all metal films by electrodeposition (5, 9) as the method of choice for large areas, rather than by evaporation (1-4).

Experimental

n-Gallium arsenide of 2.4×10^{15} cm^{-3} carrier concentration, not deliberately doped, was cut in either (111) or (100) directions. Back ohmic contacts were applied prior to shaping specimens into disks and attaching them to steel shafts with silver epoxy. Electrodes were potted in insulating epoxy and the n-GaAs surface was repolished to a Linde A (0.3 micron) finish, followed by 1:1 H_2SO_4-H_2O_2 etch to a semimatte (gray) condition.

The plating solutions and conditions employed for Au, Pt, and Rh films were, respectively, 20 g/liter $KAu(CN)_2$-50 g/liter diammonium citrate at 70°C and 10 mA/cm^2, "Platinex III" (OxyMetal Industries) at 80 C and 20 mA/cm^2, and "Rhodex" (OxyMetal Industries) at 50°C and 10 mA/cm^2. The latter two are proprietary baths. Plate thicknesses were calculated from the faradaic efficiency, nearly 100% for deaerated gold baths, and the supplied manufacturer's plating rate estimates for Pt and Rh. They were not otherwise measured.

A front contact for Au-plated GaAs type A electrodes was made by pressing on a ring of indium with an inner opening just less in diameter than that of the gold film. For the size of the active electrode disks in these and also type B cells, 0.5 cm or less, imperfect circularity and the nonuniformity of the incident laser beam lead to perhaps $\pm$ 10% relative uncertainty in power efficiency determination.

Electrochemical experiments were performed in two- or three-electrode configurations, with potential control, in a cell with an optical window at its bottom, under nitrogen atmosphere. In three electrode runs either the saturated calomel electrode (SCE) or the poised electrolyte redox potential from carbon or platinum electrodes was used as reference.

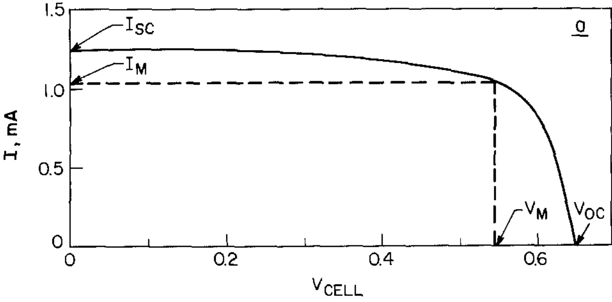
Radiant sources were either a 10 mW He-Ne laser or a 100W tungsten-halogen lamp. Light intensity was varied by a Glan prism polarizer based optical attenuator (Karl Lambrecht Corporation) with a rotatable element driven by a 1 rpm motor. A pellicle beam splitter (Oriel Corporation) inserted in the light beam directed 8% of the light to a silicon detector (Metrologic Corporation) whose analog output was linearly or logarithmically recorded. The 100W lamp, a 160 Hz chopper (Bulova Corporation) and an Oriel Corporation 7240 grating monochromator comprised the spectral source. Photocurrent response was synchronously detected (PAR 128) and corrected for light source and grating output within the $\pm$ 10% flat region of the power detector, between 400 and 1000 nm. For transmission spectra Au or Pt films evaporated on glass slides were inserted between the spectral source and the detector.

Electrolytes were prepared with reagent grade chemicals and triply distilled water.

Solar power conversion efficiency data were obtained as previously described (10). Rotating disk electrode methodology was also identical to established practice (11).

Results and Discussion

The current-voltage curve of a type A cell of electrodeposited Au on a n-GaAs single crystal disk, with circumferential indium contact to the Au at the disk edge, is shown in Fig. 2, curve a. The open-circuit voltage of a different specimen, similarly prepared, is displayed as a function of laser beam power, P, in curve b.



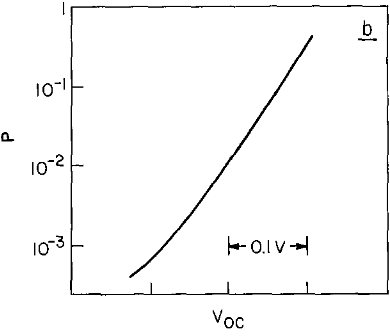


Fig. 2. Behavior of electroplated Au on n-GaAs diode with indium front contact under 632.8 nm laser illumination; (a) photocurrent-voltage characteristic with open-circuit voltage (V_{oc}), short-circuit current (I_{sc}), and maximum power product ($I_m V_m$) defined on figure and (b) V_{oc} as a function of illumination intensity, P, normalized to approximate intensity of (a).

The current-voltage curve has a fill factor, $I_m V_m / V_{oc} I_{sc}$, of 0.7 and a power conversion efficiency of about 6%. The open-circuit voltage increases by 67 mV for each tenfold increase in irradiance over the linear region of the plot, corresponding to a quality factor (ratio to 2.3 kT/q) of 1.1 for the Schottky barrier. The absolute value of the voltage (not shown) varies with film thickness, average irradiance, and light spot size.

These data indicate that the electroplated structure operates as anticipated for an Au-n-GaAs Schottky device. When employed as a rotating disk electrode (RDE), it shows the behavior of Fig. 3. curve a, with a 2 mm $Fe(CN)_6^{-4}$-pH 5 buffer solution under controlled potential scan and laser illumination. The level of illumination is so maintained that the limiting current is due to mass transfer of $Fe(CN)_6^{-4}$, not light flux (5). The dark current of the electrode is essentially nil through the potential region of Fig. 3. The curve for a conventional gold disk, under the same experimental conditions, save illumination, is shown as curve b of Fig. 3. The curves are displaced in potential by the Schottky barrier voltages expected for the junction in Fig. 1, cell type B.

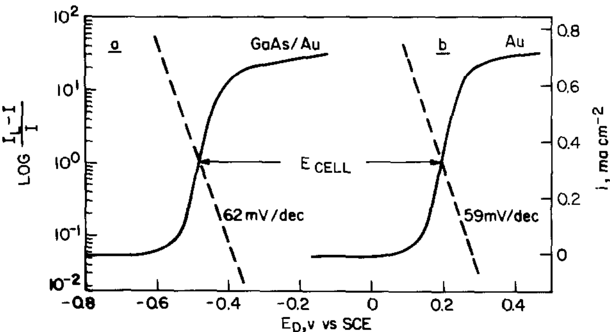

Fig. 3. Current-voltage curves at 1600 rpm rotating disk electrodes of (a) electroplated Au on n-GaAs (laser illuminated) and (b) Au (unilluminated), both in 2 mm $Fe(CN)_6^{-4}$ + pH 5 0.5M acetate buffer. Log $[(I_L - I)/I]$ vs. disk potential, E_D, plots are superimposed on the respective curves, with I_L = convective diffusion limited current.

Logarithmic analysis of the two waves, also included in Fig. 3, confirms their similar shape, $\log[(I_L - I)/I]$ vs. E_D plots giving 59 and 62 mV/decade values for the Au and illuminated Schottky junction electrodes, respectively. These logarithmic slopes are those of one-electron reversible redox couples, as normally found for $Fe(CN)_6^{-4}$ on gold.

Open-circuit voltage, V_{oc}, and short-circuit current, I_{sc}, for a typical Au-n-GaAs type electrode in a $Fe(CN)_6^{-4}/Fe(CN)_6^{-3}$ solution, recorded separately as a function of input power, are shown in Fig. 4. The 0.25M concentration of $Fe(CN)_6^{-4}$ is more than sufficient to produce a light-limited short-circuit current condition at laser source or solar irradiance levels. I_{sc} is linear (unity slope in the log-log coordinates) with beam intensity over the more than three decades displayed, showing constant quantum efficiency. The slope of the V_{oc} plot in the linear region at higher intensities is 65 mV/decade, in good agreement with the equivalent data of Fig. 2 for the solid-state cells.

Electrodeposited Schottky barriers have been made on the n-GaAs single crystal substrate with nominally 200Å thick Pt and Rh, as well as Au. Examples of each of the three are shown in the V-I plots collected in Fig. 5 for the 0.25M $Fe(CN)_6^{-4}$ electrolyte, with the appropriate maximum power conversion efficiency for 632.8 nm light indicated on the respective curves. Open-circuit voltages in the 0.6-0.7V range are obtainable for all three metals, which are sufficiently noble (have high enough work function) to act as stable anodes in the oxidation of $Fe(CN)_6^{-4}$ in an acetate buffer, as needed in hybrid (type B) cells.

For Au and Pt electroplates, the photocurrent spectra for both type A (classical Schottky) and B (hybrid) cells and the transmission spectra of the respective metal films, evaporated on glass, are compiled in Fig. 6 and 7. Since the thickness of metal layers for each of the traces for the same element differs, the results within the figures cannot be rigorously compared. The

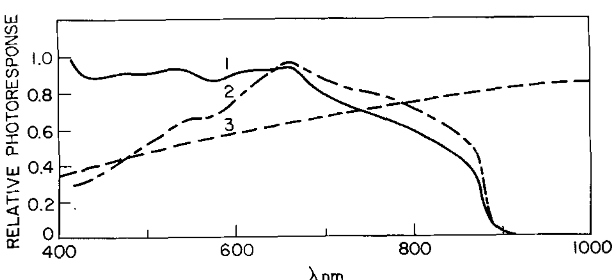

Fig. 7. Curves identical to those of Fig. 6 with Pt substituted for Au.

spectra indicate, however, the loss in type B cells due to electrolyte absorption at short wavelengths and, for the gold case, the increase in transmission for the metal around 500 nm. The choice of the colored $Fe(CN)_6^{-3/-4}$ solution reflects our inability to find completely transparent redox solutions in which the metal filmed semiconductors would be stable under prolonged photoanodic use. Attack by some colorless redox media is attributed to residual porosity and undercutting, leading to eventual adhesive failure of the metal film (4), when the exposed GaAs does not form sufficiently protective anodic products (passivating oxides). This process is often evidenced in a current peak prior to attainment of the limiting current in rotating disk potential scans.

Current-voltage curves under solar irradiance for a set of Au, Pt, and Rh electroplates are shown in Fig. 8. The conversion efficiencies are indicated on the curves. Values in the range 2-6% are typical. These values are difficult to reproduce closely because of deficiencies in control of the plating step.

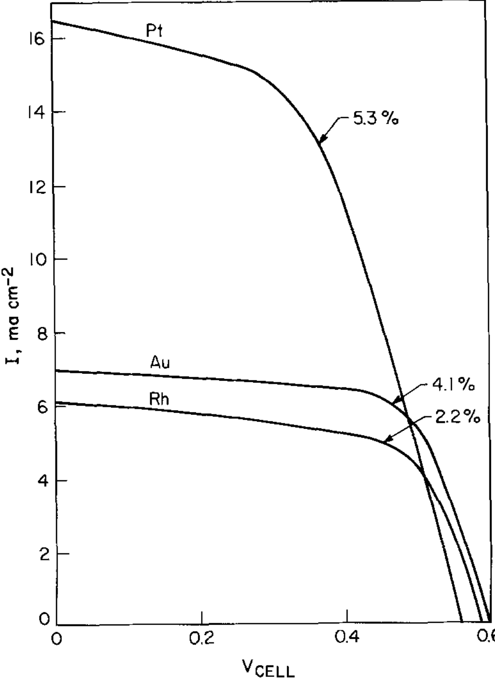

Fig. 8. Experiments as in Fig. 5 but with solar irradiances of 69, 93, and 90 mW/cm^2; respectively, for Au, Pt, and Rh plated n-GaAs electrodes.

Of the three solutions used to plate the electrodes of Fig. 8, the gold plating bath is the least corrosive to the GaAs substrate and yields the most reproducible electrodes. The other, proprietary, baths are acidic and sensitive to contamination by the corrosion reaction products, Ga(III) and As(III). Such effects add to the porosity and thus to substrate attack in the hybrid solar cells.

The behavior of the gold bath is reproducible enough to investigate the behavior of the hybrid (B) cell as a function of metal thickness. The data obtained are shown in Fig. 9. The abscissa is calculated from the coulombic increments of constant current electroplating. For each point the short-circuit current was measured after an added layer of gold was plated. As expected, the short-circuit current drops with thickness. However, a straight line for Beer-Lambert law conformity with the data of Fig. 9 requires constant reflectivity and absorptivity of the gold film and constant current efficiency and film uniformity in the deposition. Extrapolation of the experimental plot to zero thickness yields an intercept corresponding to a 60% ± 10%

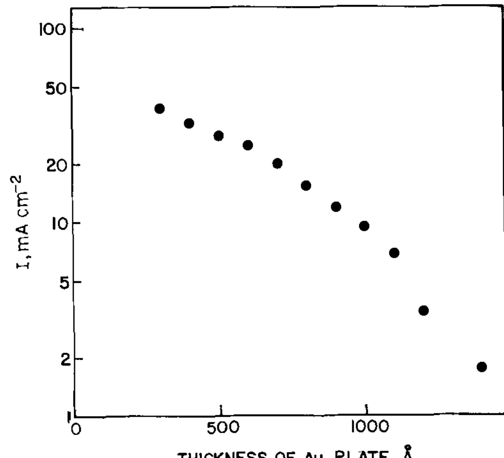

Fig. 9. Short-circuit current, I_{sc}, plotted logarithmically as a function of the thickness of Au electroplate on the n-GaAs substrate for the conditions of Fig. 4.

quantum efficiency for the incident laser beam. (The irradiance was measured by replacing the cell by a detector. The quantum yield or current efficiency for the metal thickness corresponding to that of the electrode used in obtaining the solar efficiency in Fig. 8 is about 32%).

It has been suggested above that the Au-n-GaAs electrode operates stably in the pH 5 $Fe(CN)_6^{-4}$ solution. The observed change in photocurrent under tungsten-halogen illumination is shown in Fig. 10. I_{sc} is stable under these conditions only for about an hour before significant decline is apparent. However, replacement of the solution from a reservoir, without doing anything further to the electrode, at intervals marked by the arrows on Figure 10, restores the initial activity. Thus, the decline is due to photodegradation of the electrolyte rather than the electrode.

Other solutions that were used, *e.g.*, colorless Fe(II)-Fe(III) phosphate media at pH 2, proved corrosive and the output decline with time was indeed associated with metal layer disruption and GaAs attack. Activity could not be restored without etching and replating.

Passage of current in the cathodic direction for type B cells and the equivalent forward conduction curve for the type A structure are shown in Fig. 11. The essentially straight (log current)-voltage regions have virtually the same decade slopes (65 mV for B, 67 mV for A) over several orders of magnitude. The type B cell begins to deviate from linearity at the highest currents when mass transter of $Fe(CN)_6^{-3}$ exerts influence and the cathodic current approaches a limit. Subject to this transport effect, the electrolytic contact operates without introducing extraneous behavior and the exponential factors are in agreement with those earlier observed for the open-circuit voltage shift with light intensity, as is expected for such Schottky junctions.

Conclusions

Hybrid cells with metallized semiconductors and electrolytic contacts (type B) have interesting characteristics as photovoltaic power sources. The power conversion efficiencies of the examples cited are, however, below those of semiconductor-liquid junction cells of type C. The major loss is in short-circuit current, which is roughly half that of the presently leading 12% n-GaAs selenide-polyselenide cell (12). However, the behavior of the series junctions (photoactive semiconductor-metal, metal-redox plus redox-counterelectrode) yields relatively high fill factors even under intense illumination. The operating characteristics prove the expected low resistance of the metal/redox couple contact.

The cell output is independent of redox potential and dependent on the electron transfer kinetics at both metal and counterelectrode electrolyte interfaces. This behavior is shown by logarithmic analysis of the I-V trace in the rotating disk electrode regime to be reversible for the $Fe(CN)_6^{-4/-3}$ couple at the gold-plated n-GaAs surface and therefore to contribute negligibly to cell loss with decimolar redox couple concentrations (plus supporting electrolyte for increased conductivity). Cell characteristics are basically determined by the quality of the as-plated metal-semiconductor interface. Open-circuit voltage-light intensity and forward conduction V-I plots both give $\sim$1.1 ($2.3\ kT/q$) decade slopes, very close to ideal for Schottky barriers, and independent of whether the electrolyte contact is present or not. This further confirms the low loss at the electrolyte interfaces, until mass transfer limitations are reached.

Plating thickness studies show that, on the single crystal substrate, quantum efficiencies of 50% ought to be obtainable with very thin (tens of angstroms) films for the type B cell. Platinum films, though more difficult to reproduce than gold with available electrodeposition methods, show better quantum efficiencies at sufficient metal thickness for electrode stability in pH 5 acetate buffered solutions.

Porosity in the deposited layers and photoanodic attack at the base of the pores appear to be the mechanism of the thin film failure in the electrolyte solutions. This is reflected voltammetrically by peaks in the RDE current response on initial voltage scan under illumination and from the n-GaAs substrate behavior in the different electrolytes. Only data from the pH 5 acetate-$Fe(CN)_6^{-4/-3}$ system is shown here, although the initial curves in other electrolytes, aside from porosity effects, are comparable to the extent that the redox couples in question are kinetically reversible. Photodegradation in the acetate buffer is due to reactions of the $Fe(CN)_6^{-4/-3}$ couple rather than failure of the gold-plated n-GaAs electrode.

Arrows indicate times at which solution in cell was renewed; dotted line is the maximum current attained in fresh solution.

Improvements in the integrity of the metal film, either by modification of the electrodeposition step or by the use of other preparative procedures, are necessary to find a combination of electrode and electrolyte that has useful photostability. Applying a matte etch (12) to reduce the semiconductor reflectance and thus to increase the short-circuit current (as done in the n-GaAs-selenide cells) is not feasible in the present work as the surface becomes too rough for the electrodeposited products to cover the semiconductor protectively at the desired metal thickness.

P-Type GaP as a Semiconducting Photoelectrode

M. A. Butler* and D. S. Ginley*

Sandia Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

The nature of p-type GaP photocathodes as employed in photoelectrochemical cells has been explored in some detail. These cathodes are found to be unstable in both acid and base. The flatband potential has been measured, using capacitance techniques, as well as the pH for zero surface charge, the point of zero zeta potential (PZZP). These data provide a measure of the electron affinity which is in excellent agreement with that calculated using our electronegativity model. The onset of photocurrent occurs at ~0.7V negative of the flatband potential. It is demonstrated that this is due to a localized state acting as a recombination center. Experimental evidence for this state comes from the infrared photoresponse of these photoelectrodes. It is suggested that this is the same bulk state which controls the efficiency of GaP electroluminescence diodes.

While a number of groups have examined p-GaP with respect to its fundamental properties (1) and as a photocathode for use in photoelectrolysis (2-5), there exists in the literature considerable conflicting information. This is especially true with regard to its stability as a photoelectrode. Therefore we have undertaken a detailed study of the properties of p-GaP photocathodes. In addition to the stability question we wished to study the discrepancy which exists between the flatband potential as measured by capacitance data and the potential for photocurrent onset. For p-GaP, this difference is ~0.7V. While such effects have not been observed for the metal-oxide semiconductors in aqueous media, they appear to be more prevalent in the nonoxide semiconductors, particularly p-type materials, and will obviously play an important role in determining the usefulness of these materials. This study of p-GaP electrodes also provided the first check of our electronegativity model (6) for predicting flatband potentials in a nonoxide p-type semiconductor.

The samples were single crystals of GaP cut perpendicular to the [111] axis, and Zn doped to a density of $\sim 5 \times 10^{17}$ cm^{-3} as determined by Hall mobility and conductivity measurements. The contacts were made by alloying in In:2 weight percent Zn. All electrochemical measurements were made using a conventional three-electrode electrochemical cell with a PAR 173 potentiostat and 174 programmer. Illumination was by a 150W Schoeffel xenon lamp with Schoeffel grating monochromator. The list of electrolytes used in these experiments is shown in Table I. All were prepared from spectral quality reagents and solvents.

Stability

Since stability is of crucial importance in determining the eventual utility of any photoelectrode for photoelectrolysis, we took particular care in ascertaining the electrode's stability in both acidic and basic solutions. The normal techniques for evaluating stability were employed: photocurrent stability, observation of the electrode surface, mass loss, and analysis of the electrolyte. Table I summarizes some of the stability experiments. In general with no stabilizing redox couples present it is found that the p-GaP photocathode is unstable. Approximately one to three electrons

Table I. Stability of p-GaP

Electrolyte	Fraction of current contributing to decomposition and end products.
0.1M NaOH	10^{-3} current produces Ga^{3+} in solution
0.1M H_2SO_4	3×10^{-4} current produces Ga^{3+} in solution and grayish surface layer
0.1M $HClO_4$	Similar to H_2SO_4 but more active surface etching
0.1M H_3PO_4	Deposition of Ga metal on surface

per thousand in the photocurrent take part in a decomposition reaction in all of the electrolytes.

Interestingly the photocurrent degradation rate depends strongly on the nature of the electrolyte as is illustrated in Fig. 1. Here we plot photocurrent *vs.* total charge through the external circuit. Note the expanded scale at the top of the figure which refers to the H_2SO_4 results. In general the $HClO_4$ results (not shown) closely parallel those in H_2SO_4, though detailed differences do show up in voltammetric measurements. All of the experiments were run under identical conditions. In a 0.1M NaOH electrolyte the photocurrent was observed to decay very rapidly with time. Analytical atomic absorption results indicate that Ga was going into solution probably as the hydroxide. The rapid decay of the current implies that as surface Ga is leached a passivating phosphate layer is formed which is insulating. Etching of these electrodes in aqua regia restores their performance.

In 0.1M H_3PO_4 we again observe a rapid decay of the photocurrent. However, in this case, no Ga is observed in solution. Instead a dark gray surface layer forms on the electrode. We feel that this layer is Ga metal caused by the reductive decomposition reaction. This is substantiated by linear sweep voltammetry as shown in Fig. 2. Here trace one represents the initial photocurrent and trace two the photocurrent after aging. If at this point we scan from the cathodic regime (trace 2) to the anodic regime, a peak is observed centered between +0.25 and +0.5V *vs.* SCE. The larger peak

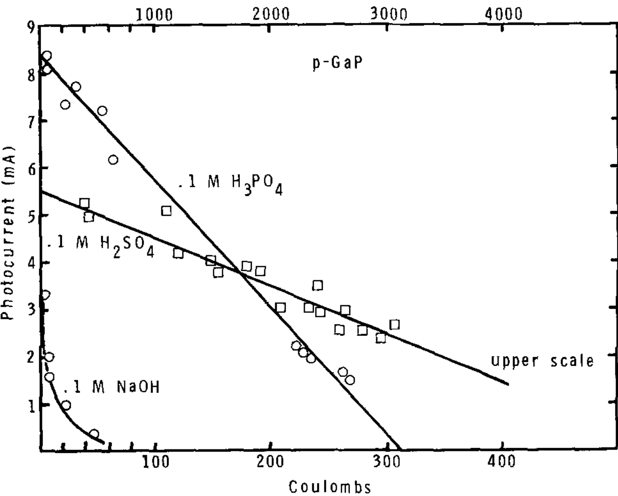

Fig. 1. Photocurrent for p-GaP illuminated with white light as a function of total charge passed through the interface. Note the different scales for different electrolytes.

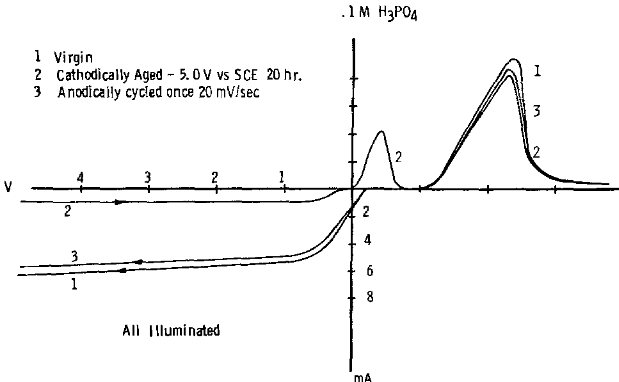

Fig. 2. The current-voltage characteristics for Zn-doped GaP in 0.1M H_3PO_4 illuminated with white light. The data were taken in the order shown. The potential is measured vs. SCE. The peak at +0.4V observed only for the first scan after cathodic aging corresponds to stripping of Ga metal from the surface. The peak observed in all scans around +2V is not light sensitive.

at a more positive potential is discussed below. After one scan through this oxidative peak the electrode surface returns to its original orange color and the initial photocurrent is restored as shown in trace 3. The peak cannot be reproduced until the electrode has been aged again. This peak corresponds well with the potential for Ga oxidation and we feel that the metallic gallium on the surface is being oxidized into a soluble form.

The decrease in the photocurrent in Fig. 1 most probably comes from adsorption of the light by the Ga metal surface film. The observed linear decrease in photocurrent with total charge is only an approximation. Assuming a film thickness $\overline{X}$ proportional to total charge and a frequency independent optical absorption coefficient α for the Ga film, we would expect an exponential decay of the form

$$i_{photo} = i_o \exp(-\alpha\overline{X}) \qquad [1]$$

However, the initial form of the decay will appear linear within the accuracy of the data.

In the more oxidizing acids, $HClO_4$ and H_2SO_4, a slightly different behavior is observed. Again Ga is observed in solution but the photocurrent decreases more slowly. The reason for this is that the Ga produced is reoxidized into the electrolyte at the interface by the acids and leaves an essentially fresh electrode surface. The fact that the surface remains essentially virgin and that the photocurrent does not decline rapidly explains the previous observations in the literature indicating that this electrode is stable in H_2SO_4. For $HClO_4$ linear sweep voltametric measurements show oxidative current peaks after aging in the potential range for which they were observed for H_3PO_4. This may be gallium metal or other gallium compounds on the surface. The apparent darkening of the electrode surface in these electrolytes may be due to formation of such gallium compounds and/or surface roughening.

It is clear from this data that p-GaP is unstable in acidic or basic media and that the observed relative stability of the photocurrent is a function of the electrolytes' ability to remove the gallium products from the electrode surface. Since the actual rate of decomposition, approximately one part in a thousand, is basically independent of the electrolyte, it might be possible to modify the electrode surface to stabilize the electrode as has been recently shown for ZnO (7) and Si and Ge (8, 9).

The above results are all for cathodically biased p-GaP, as it would be operated in a photoelectrochemical cell. For anodic bias another effect of interest is observed. Figure 2 shows that for scans to anodic potentials in 0.1M H_3PO_4 a peak in the *I-V* characteristics is observed around +2V (SCE). We believe that this is evidence of passivation of the GaP surface by growth of an insulating film. This behavior is also observed in 0.1M $HClO_4$ but not in 0.1M H_2SO_4 or 0.1M NaOH for our particular experimental conditions. When scanning in the reverse direction, the peak is smaller and the electrode can be cycled back and forth many times with reproducible results.

Flatband Potential

The flatband potential V_{FB} has been measured using the Mott-Schottky technique (9). As illustrated in Fig. 3 the data are well behaved and show little frequency dependence. The doping density extracted from the slope agrees well with the value from solid-state measurements. Our measured V_{FB} agrees well with previous data (10) as shown in Fig. 4.

An important question is whether our electronegativity model (6) that has been previously applied to n-type semiconductors would work as well for this p-type main group semiconductor. The relationship which exists between V_{FB} and the semiconductor electron affinity *EA* is given by

$$eV_{FB} = EA + E_g - E_o - e\Delta_{FC} - e\Delta_{pX} \qquad [2]$$

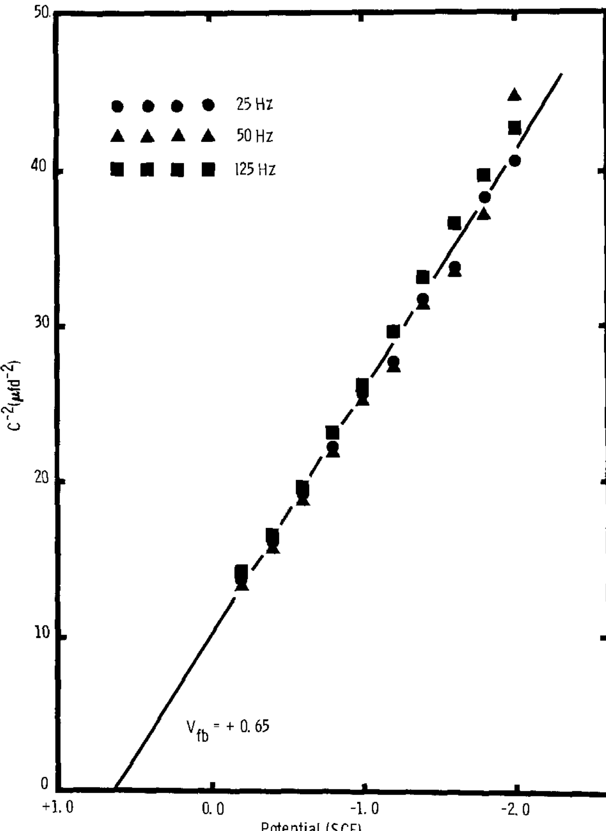

Fig. 3. Mott-Schottky plot for Zn-doped GaP in 0.1M H_3PO_4. The data were taken by modulating the potential with a sawtooth and detecting the square-wave component of the current. The slope corresponds to a doping density of ~7 × $10^{17}/cm^3$ for the electrode area of 1 cm^2.

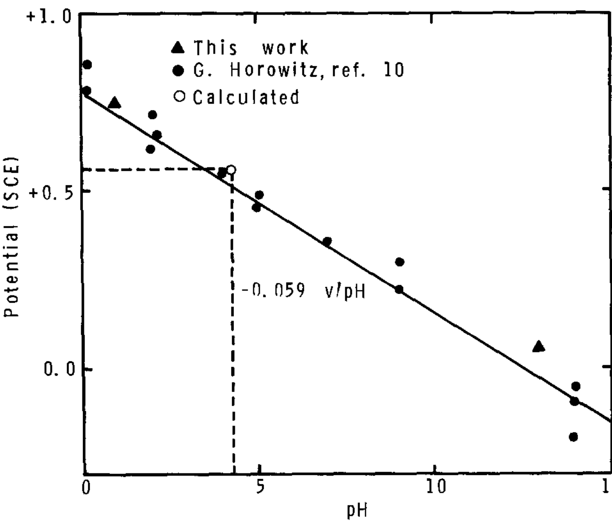

Fig. 4. Variation of the flatband potential with pH. The solid line has a slope of 59 mV per pH unit. The open circle is the calculated V_{FB} at the measured PZZP.

where E_g is the semiconductor bandgap, E_o is the position of the reference electrode (SCE) with respect to the vacuum level (4.75 eV), Δ_{FC} is the difference between the doped Fermi level and the top of the valence band, and Δ_{px} the potential drop in the Helmholtz layer due to adsorbed ions. Note that for p-type materials the additional term E_g occurs in this relationship to account for the position of the Fermi level in the p-type semiconductor. For Zn-doped GaP the term Δ_{FC} is <0.1V and may be neglected.

The various potential-determining ions in the electrolyte will contribute charge to the Helmholtz layer as a function of the relative equilibrium constants for chemisorption on the electrode surface. For aqueous electrolytes and semiconductors where the hydroxyl and the proton are potential determining there will exist a unique pH, which is a function of the intrinsic pKa of the electrode, where equal numbers of H^+ and OH^- are adsorbed. At this point, the zero zeta potential (PZZP), the net charge of the ions adsorbed on the electrode surface is zero and therefore the potential drop across the Helmholtz layer, Δ_{px}, is also zero. This point may be evaluated by a number of techniques, the simplest of which is the pH drift technique. Here, the pH of the solution is monitored while adding powdered semiconductor material. The pH will drift to the PZZP from either side, and at the PZZP the addition of more powdered semiconductor results in no net change in pH. The data for a series of drift experiments on GaP are illustrated in Fig. 5. As can be seen the PZZP is observed to be at a pH of approximately 4.3. Thus, at this pH the correction term Δ_{px} will be equal to zero. It is interesting that a well-defined PZZP is observed for this electrode in contrast to many nonoxides which do not show a clearcut pH dependence of V_{FB}. This is most probably due to the fact that the phosphide ions on the GaP surface are oxidized to phosphates which interact strongly with the aqueous media.

The electron affinity (*EA*) of the semiconductor is given by (6)

$$EA = [\chi(Ga)\chi(P)]^{1/2} - \tfrac{1}{2} E_g \quad [3]$$

where χ is Mulliken's atomic electronegativity. Using a bandgap of 2.2 eV (12) we obtain a value for *EA* of 3.1 eV. Thus the flatband potential at the PZZP (pH = 4.3) is predicted to be +0.55V (SCE). As we can see in Fig. 4, this calculated value is in excellent agreement with the measured flatband potential. This result further confirms the general applicability of the electronegativity model to semiconductor-electrolyte interfaces.

Photoresponse

GaP is a semiconductor with an indirect gap at ~2.2 eV and a direct gap at ~2.8 eV (12). These characteristics are clearly evident in its spectral response shown in Fig. 6. The small quantum efficiency is related to the small depletion layer thickness (less than 0.1 μm for this sample) and short diffusion length (typically 1 μm or less for these poor quality samples). The optical absorption depth for photon energies below the direct gap is several microns. Therefore improvements in the quantum efficiency should be possible by decreasing the doping level to increase the depletion layer thickness to near the optical absorption depth.

A more interesting question is the dependence of the photoresponse on applied potential. Generally one

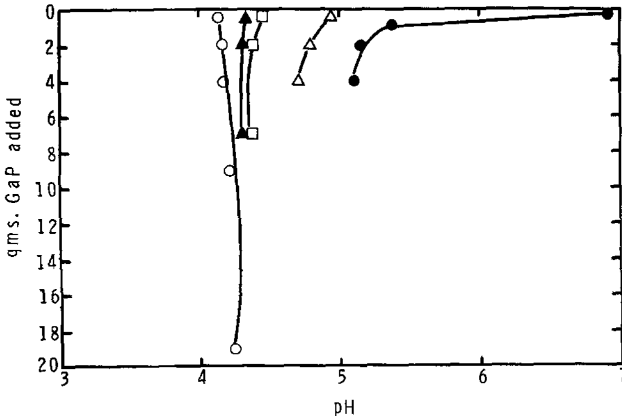

Fig. 5. A series of experiments where the pH of the solution as a function of the amount of powdered GaP added has been demonstrated. The data shows that zero net surface charge occurs at about pH = 4.3.

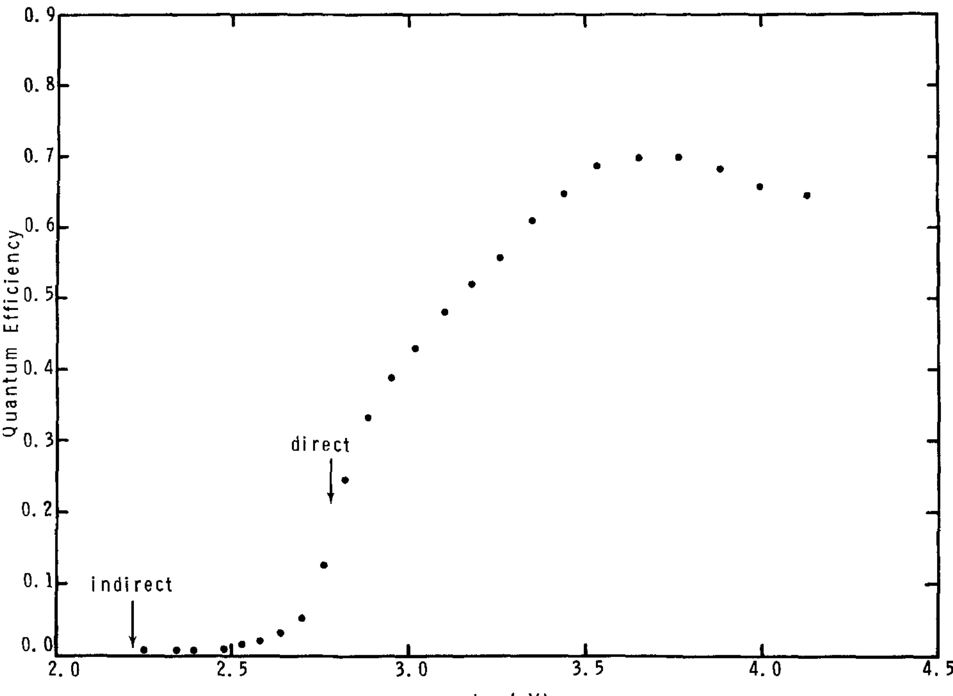

Fig. 6. The spectral response of GaP:Zn in 0.1M H_3PO_4 biased at —1.0V (SCE). The data is uncorrected for reflection and adsorption losses.

would expect that the photocurrent onset should occur at the flatband potential. This is true for the metal oxide semiconductors, such as WO_3 in aqueous electrolytes (13). However we see in Fig. 7 that the photocurrent onset occurs ~0.7V negative of the flatband potential for p-GaP. This behavior has been previously noted (14). The obvious explanation for this behavior is the existence of a recombination center at or near the semiconductor surface which short circuits the

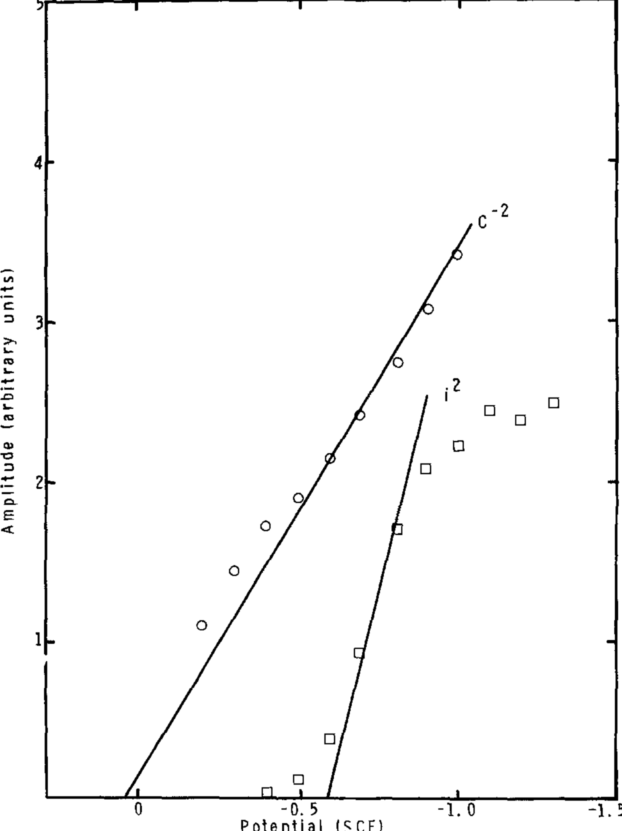

Fig. 7. Comparison of the flatband potential as determined by capacitance measurements (C^{-2}) and the photocurrent (i^2) onset for Zn-doped GaP in 0.1M NaOH. The discrepancy between the two is about 0.7V.

photoelectrolysis process (15). This mechanism is illustrated more clearly in Fig. 8. In Fig. 8a the empty localized state allows the photoexcited electron in the conduction band to take path 1 as well as path 2. Path 1 short circuits the photocurrent. In Fig. 8b the localized state is filled and path 1 is not available to the photoelectron in the conduction band. Thus we would expect the photocurrent through the interface to drastically decrease or stop when the Fermi level falls below the energy of the localized state in the gap. The discrepancy between the flatband potential and photocurrent onset in p-GaP could be explained by such a localized state ~0.7 eV above the top of the valence band.

Confirming evidence for this picture can be obtained by considering Fig. 8b. Since the localized state is filled with electrons, it should be possible to photoexcite them into the conduction band, where they can contribute to the photocurrent. The experiment has been done and the results are shown in Fig. 9. The peak occurring at 1.4 eV is very near where it would be expected. Since the localized state is ~0.7 eV above the valence band and the bandgap is ~2.2 eV, the *IR* peak should occur at about 1.5 eV. The measurements were extended down to 0.4 eV and no other *IR* photoresponse was observed. The *IR* photocurrent has the same turn on potential as the photocurrent induced by bandgap radiation. This is

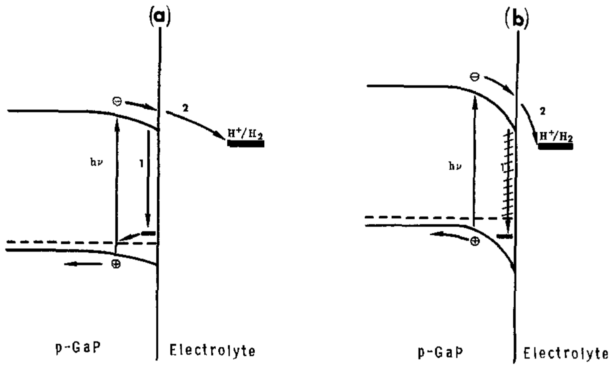

Fig. 8. The p-GaP electrolyte interface for two different bias conditions. (a) Here the Fermi level is below the localized state and thus it is empty. It can act as an electron recombination center. (b) Here the Fermi level is above the localized state and here the localized state cannot act as an electron recombination center.

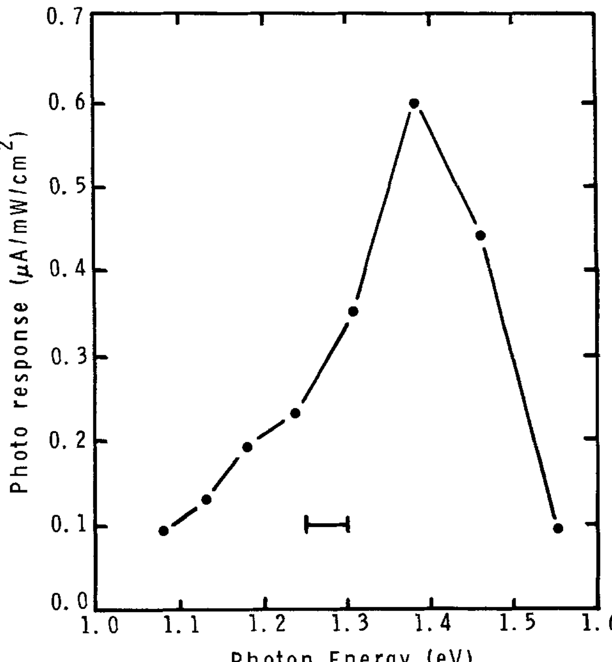

Fig. 9. Infrared photoresponse of p-GaP in 0.1M $HClO_4$ at −1.5V (SCE). The resolution of the monochromator is indicated.

exactly what would be expected if the same state were responsible for both effects.

An important question to ask is the nature of this localized state. To act as an efficient recombination center it must occur near the GaP surface. The strength of the IR photoresponse (up to 0.6 μA/mW cm^2) shown in Fig. 9 would be very difficult to explain for states confined to the interface (true surface states). A state related to the bulk properties of the material is thus implied. However we noticed that the *IR* response is enhanced if the sample is previously aged cathodically in $HClO_4$ with incident white light, again suggesting that the phenomenon is somehow tied to the surface.

There was a possibility that the localized state is related to the oxygen content of the p-GaP. Experiments were performed on epitaxial single crystal p-GaP samples in which oxygen was intentionally excluded. The flatband potential and photocurrent onset potential were not significantly shifted from those where oxygen was present.

The most likely explanation of the recombination center is the following. A bulk state is known to exist 0.75 eV above the valence bandedge (16). This state is not related to any known impurity but by acting as a nonradiative recombination center it plays an important role in determining the efficiency of GaP electroluminescence diodes. The number of these recombination centers has been found to be directly related to the concentration of gallium vacancies (17). This does not necessarily imply that the center is a gallium vacancy, but rather that the possible complexes (18) forming the defect center may involve gallium vacancies. Further evidence for this state comes from photoemission and electron energy loss spectroscopy which show a "surface state" 0.8 eV above the valence band in phosphorus-rich GaP (19). We believe that this bulk state is the one responsible for the discrepancy between the flatband potential and photocurrent onset potential in p-GaP photocathodes. The increased *IR* response and thus concentration of recombination centers with aging probably comes from the gallium leaching during the photocorrosion of the p-GaP as was discussed in the stability section.

Summary

In this paper we have attempted to explore the properties of p-GaP as a photocathode in a photoelectrolysis cell. Our results indicate that this material is unstable in both acid and base with essentially the same decomposition pathway in both but that the photocurrent stability depends strongly on the nature of the electrolyte. Passivation of the electrode was observed for aging in the anodic regime. The pH at which the net surface charge is zero (PZZP) was found to be 4.3. These results, together with the capacitively measured flatband potential, allowed the first test of our electronegativity model for p-type semiconductors. The good agreement found further supports the contention that the electronegativity model is applicable to all semiconductor-electrolyte interfaces. The discrepancy between the flatband potential and the photocurrent onset potential was shown to be due to a bulk recombination center located 0.7 eV above the valence band. This localized state was observed directly by optical excitation of electrons from this state into the conduction band. We suggest that this state is the same recombination center which controls the efficiency of solid-state electroluminescence in LED's made from GaP.

These results offer some encouragement for the practical application of p-GaP photocathodes. The sensitivity of the photocurrent stability to the electrolyte composition suggests that modification of the decomposition kinetics may be possible. Identification of the recombination center as the bulk state which determines the efficiency of electroluminescence diodes means that the same techniques may be used to improve the performance of both devices.

Transient Studies of Glucose, Oxygen, and Hydroquinone at a Membrane-Covered Rotated Disk Electrode

David A. Gough and John K. Leypoldt

Department of Applied Mechanics and Engineering Sciences, Bioengineering Group, University of California at San Diego, La Jolla, California 92093

ABSTRACT

The membrane-covered rotated disk electrode was used to evaluate transport and reaction of three representative solutes after a step change in electrode potential. An analysis is proposed that allows complete characterization of solute transport properties in the membrane from a single measurement for diffusion-limited processes. For partially reaction-limited processes, certain kinetic constants can be estimated provided that transport properties are known from independent experiments. Using a well-characterized membrane, reactions of oxygen and hydroquinone were studied as examples of diffusion-limited processes. Glucose oxidation, a process in which there is a complex dependency on reaction kinetics, was also studied and certain rate constants estimated. These results provide a foundation for characterization of transport in novel membranes.

In previous papers (1-3), we described a membrane-covered, rotated disk electrode that may be useful in the development of membranes for use with new chemical-specific sensors. In this device both a disk electrode and a reference electrode are mounted on a rotating shaft over which a hydrophilic membrane is placed. With such a configuration the current distribution between the working electrode and the nonrotated counterelectrode can be made symmetrical by using a high conductivity background electrolyte. This allows the disk electrode to be uniformly accessible to both reactant and electrolyte, thus ensuring a uniform potential distribution across the disk surface. Under these conditions, a well-defined mass transport regime is established in which the diffusion boundary layer thickness in solution is precisely determined by electrode rotation rate and the limiting current reflects combined membrane and solution mass transfer resistances. At low rotation rates the diffusion boundary layer is relatively large, making transport through solution the major contribution to total diffusional resistance. Under such conditions, the current is analogous to the conventional Levich current (4) and proportional to the square root of rotation rate. At high rotation rates, however, where the solution diffusion boundary layer is small, the resistance of the solution becomes negligible. Here, the diffusion current is independent of rotation rate and limited by permeability of the membrane.

The steady-state diffusion current i_d is given by the following equation (1)

$$i_d = i_L \left[\frac{1}{1 + \dfrac{P_s}{P_m}} \right] \quad [1]$$

Key words: membrane characterization, rotating disk electrode, chemical analysis.

where i_L is the Levich current without membrane (4)

$$i_L = 0.62 n \mathbf{F} \pi R^2 D^{2/3} \nu^{-1/6} \omega^{1/2} C_B \quad [2]$$

in which n is the number of electrons transferred, $\mathbf{F}$ is the Faraday constant, R is the electrode radius, D is the molecular diffusion coefficient in solution, ν is the kinematic viscosity, ω is the angular rotation rate, and C_B is the bulk solute concentration. P_s is the solution permeability or mass transfer coefficient given by

$$P_s = \frac{D}{\delta_d} \quad [3]$$

where δ_d is the diffusion boundary layer thickness (4) in solution

$$\delta_d = 1.61 D^{1/3} \nu^{1/6} \omega^{-1/2} \quad [4]$$

and P_m is the membrane permeability

$$P_m = \frac{\alpha D_m}{\delta_m} \quad [5]$$

in which α is the partition coefficient or equilibrium ratio of solute concentration in the membrane to solute concentration in solution, D_m is the solute diffusivity in the membrane, and δ_m is the membrane thickness.

We used the relationship in Eq. [1] to estimate the permeability of Cuprophane PT-150, a commercial hydrophilic membrane, to $Fe(CN)_6^{-3}$ (1) and to O_2 and hydroquinone (2). Steady-state diffusion currents were measured over a range of rotation rates and the membrane permeability for each solute was calculated from plots of $1/i_d$ *vs.* $1/\omega^{1/2}$ by extrapolation to infinite rotation rate. The values of permeability thus determined were in agreement with results for solutes of comparable molecular weight obtained by conventional meth-

ods. It was not possible to further resolve the permeability into its components of the partition coefficient and diffusivity without additional independent measurements.

In another paper (3), we developed a method for estimation of solute diffusivity in the membrane based on analysis of the transient current after a step change of bulk solute concentration. This method is analogous to standard time lag methods commonly used for gas-membrane systems except that the concentration boundary layer in solution was taken into account. Thus, with values for diffusivity obtained by this method and of membrane permeability from steady-state measurements, the partition coefficient and diffusivity in the membrane can be calculated, allowing a complete characterization of transport properties of the membrane from a single experiment.

In the present paper we analyze the transient produced after abruptly imposing the measurement potential. Experimental results are reported for oxygen and hydroquinone as examples of processes that are strictly diffusion limited, and for glucose, where there exists a complex dependence on electrode kinetics. The analysis of this transient is proposed as an alternative method of characterizing solute transport in the membrane for diffusion-limited processes or, in the case of kinetic-limited processes, for estimation of certain kinetic constants.

Previous Work

It has been shown by Levich (4) that the conventional rotated disk electrode has some unique advantages for the investigation of kinetic-limited processes. The concentration boundary layer is of constant thickness across the disk making the electrode surface uniformly accessible to the diffusant. Since conditions for mass transfer are therefore identical at any point on the disk surface, the concentration of reacting species and the reaction rate are also uniform over the entire surface. For a given concentration boundary layer thickness, there exists a single-valued relationship between the concentrations at the surface and in the bulk. Thus, the thickness of the concentration boundary layer is not a function of reaction kinetics. Although these features are not generally characteristic of other mass transfer regimes, they are obtained when the electrode is covered by a hydrophilic membrane and greatly simplify the analysis of kinetic-limited processes.

Some fixed-potential studies have been previously conducted with the solutes employed in this investigation. In our previous studies on steady-state oxygen reduction at a platinized-platinum electrode both with and without a membrane (2), it was found that electrode prepolarization is helpful for obtaining highly stable and reproducible oxygen diffusion currents. In the absence of oxygen a small but significant anodic background current was observed at the working potential of -200 mV *vs.* a saturated silver, silver chloride electrode (SSCE). This current was independent of rotation rate and quantitatively the same with or without the membrane. Taking the background current into account, a Levich current corresponding to a four-electron process was obtained and membrane permeability was determined as before.

Some relevant previous work has also been reported on electrochemical glucose oxidation. Lerner *et al.* (5) employed a platinized-platinum rotated disk electrode without a membrane to study glucose oxidation over the potential range of -200 to 200 mV *vs.* SSCE. An electrode prepolarization treatment was used for surface activation in which the electrode was polarized first at 900 mV for 2 min, then at -300 mV for 3 min before recording each current-time curve at the specified measurement potential. These investigators found that the current-time curves were strongly dependent on electrode potential and that excellent reproducibility could be obtained with this measurement protocol. Nevertheless, they found that the current constantly decayed and did not attain a steady-state value even after several hours, suggesting the existence of a slow electrode deactivation process occurring in parallel with glucose oxidation. Over a limited potential range of -200 to -50 mV the current decay exhibited a logarithmic dependence on time. In this potential region the current i was described by the following relationship

$$i = k_e C(1-\theta) \quad [6]$$

where k_e is a constant at a particular electrode potential, C is the glucose concentration at the electrode surface, and θ is the fraction of the electrode surface covered by deactivating species as a function of time, given by

$$\theta = k_2 \ln (t/k_3) \qquad \text{for } 1 \leq t/k_3 < e^{1/k_2} \quad [7]$$

where t is time and k_2 and k_3 are constants having, respectively, no units and dimensions of time. Variable electrode rotation rate had little effect on the glucose current showing that the process was predominately kinetic controlled. The overall charge transfer number for glucose oxidation was dependent on potential and time, and under the conditions studied ranged from 4 to 20. Gebhardt *et al.* (6) obtained similar results.

The oxidation of hydroquinone at a rotated disk electrode has also been studied previously both with (2) and without (4) a membrane. This process involves uncomplicated reaction at the electrode surface and the diffusion coefficient has been reported (4). We found, as did previous investigators (7), that without the membrane the electrode surface roughness had no effect on diffusion-limited processes, suggesting that electrodes with high roughness factors can be employed without precluding application of the Levich analysis.

Theoretical Analysis

We consider a disk electrode rotating at constant angular frequency ω, covered by a homogeneous gel membrane of thickness δ_m. As before (1), we let $z = 0$ at the membrane-solution boundary with z positive in the direction normal to the plane of the membrane away from the membrane surface. Initially, the electrode potential is such that there is no reaction of the chemical of interest at the electrode surface. Thus, there is no flux of that solute across the membrane-electrode interface and the solute is distributed at equilibrium between the membrane and solution. At time $t = 0$ the electrode potential is abruptly adjusted to a new value at which the chemical of interest can now react at the electrode surface. For a thin membrane, neglecting mass transfer at the edge, the governing equation within the membrane is

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial z^2} \qquad -\delta_m \leq z \leq 0 \quad [8]$$

where C_m is the chemical concentration in the membrane and D_m is the molecular diffusion coefficient within the membrane. If the initial bulk solute concentration is C_B, then

$$C_m(z, 0) = \alpha C_B \quad [9]$$

where α is the partition coefficient of the solute in the membrane. For $t > 0$ we assume that the reaction follows a first-order kinetic law with a first-order reaction constant k. The boundary condition at the electrode-membrane interface is therefore

$$D_m \frac{\partial C_m}{\partial z}(-\delta_m, t) = k \frac{C_m}{\alpha}(-\delta_m, t) \quad [10]$$

where the rate constant depends on the roughness factor and takes into account any differences between the membrane geometric area and the effective electrode

area. In certain cases, the rate constant may also depend on electrode potential. The partition coefficient is included in this expression to account for the equilibrium concentration difference between the membrane phase and the thin, aqueous layer adjacent to the electrode surface. The boundary condition at the membrane-solution interface is more difficult to model exactly and we therefore assume a linear concentration profile in solution with a boundary layer thickness equal to the Levich diffusional boundary layer thickness given previously in Eq. [4]. Thus, at the membrane-solution interface we have the following boundary condition

$$D_m \frac{\partial C_m(0,t)}{\partial z} = \frac{D}{\alpha\delta_d}[\alpha C_B - C_m(0,t)] \quad [11]$$

The above equations can be expressed in nondimensionalized form by introducing the following variables and parameters

$$\tau = \frac{D_m t}{\delta_m^2} \quad [12]$$

$$\overline{C}_m = \frac{\alpha C_B - C_m}{\alpha C_B} \quad [13]$$

$$y = 1 + z/\delta_m \quad [14]$$

$$h = \frac{k\delta_m}{\alpha D_m} \quad [15]$$

$$\mathrm{Bi} = \frac{D\delta_m}{\alpha D_m \delta_d} \quad [16]$$

Equations [8], [9], [10], and [11] then become

$$\frac{\partial \overline{C}_m}{\partial \tau} = \frac{\partial^2 \overline{C}_m}{\partial y^2} \qquad 0 \leq y \leq 1 \quad [17]$$

$$\overline{C}_m(y,0) = 0 \quad [18]$$

$$\frac{\partial \overline{C}_m}{\partial y}(0,\tau) - h\overline{C}_m(0,\tau) = -h \quad [19]$$

$$\frac{\partial \overline{C}_m}{\partial y}(1,\tau) + \mathrm{Bi}\,\overline{C}_m(1,\tau) = 0 \quad [20]$$

A method for solving equations of this form has been given elsewhere (8). The solution is

$$\overline{C}_m(y,\tau) = \frac{-1}{1+\mathrm{Bi}^{-1}+h^{-1}}[y-(1+\mathrm{Bi}^{-1})] - 2\sum_{k_n} \frac{h(k_n^2+\mathrm{Bi}^2)(k_n\cos k_n y + h\sin k_n y)}{k_n\{(k_n^2+h^2)(k_n^2+\mathrm{Bi}^2+\mathrm{Bi}) + h(k_n^2+\mathrm{Bi}^2)\}} e^{-k_n^2\tau} \quad [21]$$

where the summation is over the roots of the following equation

$$\tan k_n = \frac{k_n(h+\mathrm{Bi})}{k_n^2 - h\mathrm{Bi}} \quad [22]$$

The measurable quantity of interest is the flux $j(\tau)$ at the electrode surface, which in nondimensionalized form is

$$\frac{j(\tau)}{P_m C_B} = \frac{-\partial \overline{C}_m}{\partial y}(0,\tau) = \frac{1}{1+\mathrm{Bi}^{-1}+h^{-1}} + 2\sum_{k_n} \frac{h^2(k_n^2+\mathrm{Bi}^2)}{\{(k_n^2+h^2)(k_n^2+\mathrm{Bi}^2+\mathrm{Bi}) + h(k_n^2+\mathrm{Bi}^2)\}} e^{-k_n^2\tau} \quad [23]$$

From this equation it can be seen that after a sufficiently long time the flux approaches a steady-state value given by

$$\frac{j_{ss}}{P_m C_B} = \frac{1}{1+\mathrm{Bi}^{-1}+h^{-1}} \quad [24]$$

The steady-state current is therefore

$$i_{ss} = n\mathbf{F}\pi R^2 j_{ss} = i_L \left[\frac{1}{1+\mathrm{Bi}+\frac{\mathrm{Bi}}{h}}\right] \quad [25]$$

where i_L is the limiting Levich current given in Eq. [2]. From Eq. [25] it can be seen that the steady-state current is reduced by the presence of membrane and finite electrode kinetics. The parameter Bi is the Biot number (9) and represents the ratio of membrane to solution mass transfer resistance. The parameter Bi/h in Eq. [25] represents the ratio of finite kinetic to solution resistances.

The anticipated results of a partially kinetic-limited process can be obtained from conversion of the flux described by Eq. [23] into current density. Figure 1 is a plot of time-dependent, normalized current density for various values of h at constant Biot number. Experimentally, these conditions could be realized for different values of the rate constant obtained by operating at different electrode potentials or by varying the electrode roughness factor. The figure shows that the time to reach steady state increases with decreasing values of h and that the steady-state current decreases with h. The effect of different Biot numbers at constant h is plotted in Fig. 2. Such results might be obtained in practice by varying rotation rate or by using membranes of different molecular permeability. With increasing values of Bi, where transport through solution becomes relatively rapid, the time to reach steady state decreases and the ultimate current density increases.

An important special case of the above equations is when kinetics of the electrode are very rapid compared to diffusion within the membrane. This corresponds to the parameter h becoming very large and therefore in the limit as $h \to \infty$ the time-dependent current becomes

$$\frac{i'(\tau)}{n\mathbf{F}\pi R^2 P_m C_B} = \frac{j'(\tau)}{P_m C_B} = \frac{1}{1+\mathrm{Bi}^{-1}} + 2\sum_{k'} \frac{k'^2+\mathrm{Bi}^2}{k'^2+\mathrm{Bi}^2+\mathrm{Bi}} e^{-k'^2\tau} \quad [26]$$

where values for k' are the roots of the following equation

$$k' \cot k' = -\mathrm{Bi} \quad [27]$$

This provides a means of determining the solute diffusivity in the membrane. For τ of order 1, Eq. [26] can be approximated by the following monoexponential expression

$$\frac{i(t)}{n\mathbf{F}\pi R^2 P_m C_B} = \frac{1}{1+\mathrm{Bi}^{-1}} + 2\frac{k'^2_1+\mathrm{Bi}^2}{k'^2_1+\mathrm{Bi}^2+\mathrm{Bi}} e^{-k'^2_1\tau} \quad [28]$$

where k'_1 is the smallest root of Eq. [27]. At steady-state Eq. [26] becomes

$$i'_{ss} = i_L\left[\frac{1}{1+\mathrm{Bi}}\right] \quad [29]$$

which is equivalent to Eq. [1].

In Fig. 3 the normalized current density for a solute that reacts under strict diffusion control as described by Eq. [26] is plotted as a function of dimensionless time.

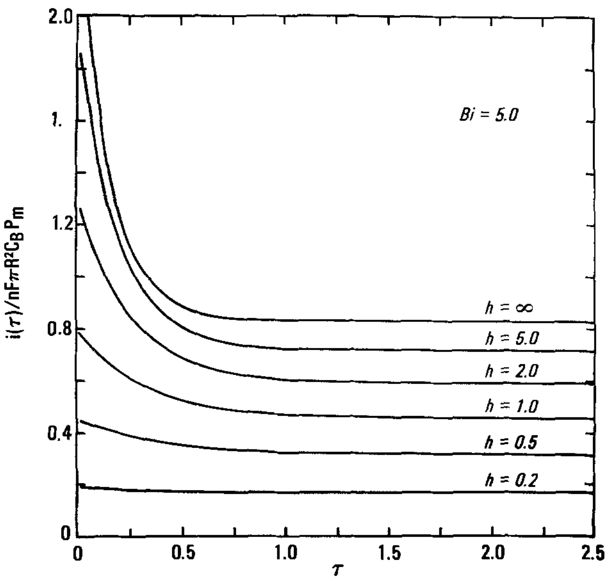

Fig. 1. The effect of variable h at constant Bi on the normalized, time-dependent current density.

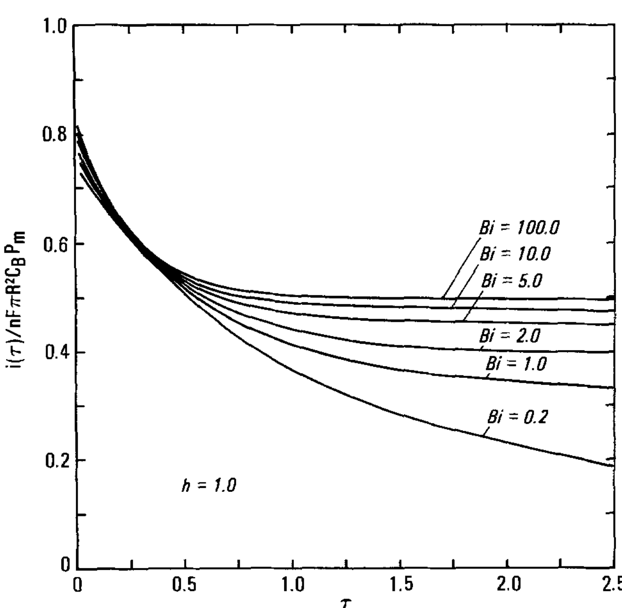

Fig. 2. The effect of variable Bi at constant h on the normalized, time-dependent current density.

The curves are given for different values of Bi that, in practice, could be obtained with the same membrane at different rotation rates or with membranes of various permeabilities. The values of Bi chosen represent a linear increase in $\omega^{1/2}$, and it can be seen that the steady-state current densities yield the characteristic nonlinear dependency on rotation rate described previously (1). The figure demonstrates that the time to reach steady state increases with decreasing values of Bi, as would be anticipated from the contribution of the concentration boundary layer.

We now consider a special case in which the effective electrode area is a slowly varying function of time, as is observed in glucose oxidation (5).

The expressions for the effective electrode area, the rate constant, and the partially kinetic-limited current are modified to include a time dependency. The effective electrode area as a function of time $A_{\text{eff}}(t)$ is described by Eq. [6] and [7], which state that

$$A_{\text{eff}}(t) = A_0(1 - k_2 \ln t/k_3) \quad [30]$$

where A_0 is the original effective surface area at time $t = k_3$. The kinetic parameter is written as

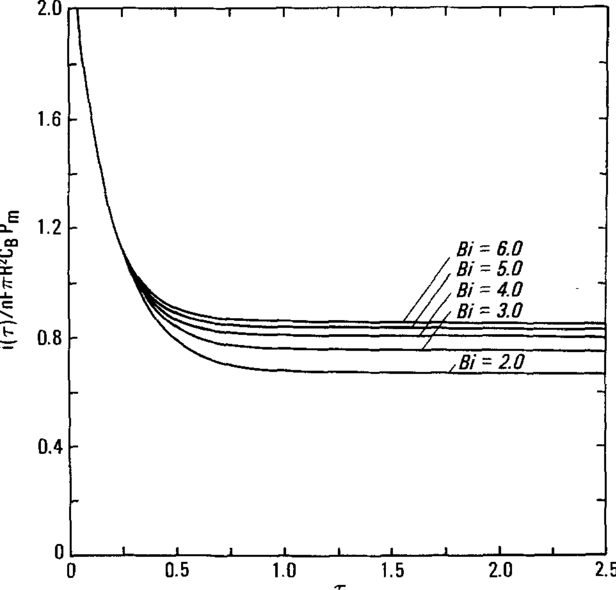

Fig. 3. The effect of variable Bi under strict diffusion control on the normalized, time-dependent current density.

$$h^* = \frac{k_1 A_0 (1 - \theta) \delta_m}{\alpha D_m A_g} \quad [31]$$

where A_g is the electrode geometric area, k_1 is a rate constant for glucose oxidation, and θ is given by Eq. [7]. The partially kinetic-limited current given by Eq. [25] then becomes

$$i(t) = \frac{nFA_0k_1C_B}{A_g}(1 - k_2 \ln t + k_2 \ln k_3) \left[\frac{1}{1 + h^* + \frac{h^*}{\text{Bi}}} \right] \quad [32]$$

Consequently, although the current decays approximately with the logarithm of time, the slope of the decay would be affected by a relatively impermeable membrane. Assuming that the kinetic constants k_1, k_2, and k_3 are not altered by the presence of the membrane, the anticipated ratio Φ of the current slope without membrane to the current slope with membrane is given by the equation

$$\Phi = 1 + h^* + \frac{h^*}{\text{Bi}} \quad [33]$$

Equations [32] and [33] provide a means for estimation of either certain kinetic constants or mass transfer properties, provided that values for the complementary process are known from independent experiments.

Experimental

Apparatus and electrode construction.—A disk electrode 0.80 cm in diameter was machined from 0.5 mm thick platinum plate and spot welded at the center to a length of platinum wire. The disk and wire were cemented into an electrode body fashioned from 1.9 cm diam Lucite rod and the disk surface polished to a mirror finish. A cavity in the electrode body with a small opening at the inactive portion of the disk surface near the edge of the platinum electrode was the receptacle of the reference electrode. This cavity was filled with saturated KCl and a chlorided silver wire inserted. The liquid junction at the edge of the disk electrode was partially occluded with a linen fiber to minimize convective outflow of electrolyte. A conventional Luggin capillary reference electrode was employed in studies without a membrane. In either case, electrode potentials are reported with reference to the saturated silver, silver chloride electrode, which is

+600 mV *vs.* the reversible hydrogen electrode under these conditions. The counterelectrode was a high surface area platinum wire that had been sealed in an adjustable glass tube and mounted to the vessel lid.

The rotating shaft was mounted on a Teflon bearing and attached to the vessel lid. Electrical contact was made between the rotating electrodes and the potentiostat through concentric, mercury-filled channels. Further details of electrode construction have been given elsewhere (1).

The electrochemical cell was a single compartment, water-jacketed vessel in which all three electrodes were placed. The lid was mounted to the vessel with a gas-tight seal and provision was made for passage of the purge gas through the cell.

The rotating shaft was directly coupled to a stepper motor (Model M-062, Minarik Corporation) and rotation rate controlled by a complementary regulator (Model TBM of the same manufacturer). The apparatus was adjusted so that each complete revolution of the shaft was made in 200 equal steps, each step being initiated only after a train of 4 pulses from a voltage-controlled oscillator (Model 180, Wavetek Corporation). The voltage input for determination of oscillation frequency was supplied by a voltage programmer (Model 176, Princeton Applied Research Corporation). Thus, the electrode rotation rate could be precisely maintained over a range of 0-3000 rps.

The electrochemical measurements were made with a potentiostat (Model 173, Princeton Applied Research Corporation), equipped with a digital coulometer (Model 178). Measurements were recorded on an X-Y recorder (Model 7037, Hewlett-Packard Corporation). Thermostatic conditions were maintained by a constant temperature water circulator (Model FE, Haake Corporation).

All solutions were prepared from analytical grade reagents and distilled, deionized water. Studies involving glucose and oxygen were conducted at 37°C with a supporting electrolyte of 0.1N KCl in $10^{-2}M$ sodium phosphate buffer, pH 7.3. In experiments with oxygen, the supporting electrolyte was equilibrated with the atmosphere and concentration calculated using standard solubility tables. In all other experiments the solution was purged with prepurified nitrogen. Glucose solutions were made from anomerically equilibrated stock solutions. Studies with hydroquinone were conducted with $20 \times 10^{-3}M$ solute in 0.1N KCl containing $5 \times 10^{-4}M$ H_2SO_4 at 37°C.

Properties of the membrane, Cuprophane PT-150 were characterized elsewhere (10) by conventional methods. The membrane ionic resistivity measured previously (1) was negligible compared to the membrane resistance to reactants. Thickness of the hydrated membrane was estimated to within ±0.0005 cm with a precision micrometer.

Procedures.—A platinized-platinum electrode was used in all but specifically mentioned experiments with the intent of operating under diffusion control. The following method was employed for platinization (7). After polishing and cathodic cleaning in 1N HCl, the electrode was platinized in a solution containing 5% (w/v) chloroplatinic and 0.03% (w/v) lead acetate. Six alternate anodic and cathodic galvanostatic pulses of 100 mA/cm^2 current density, each 1 min in duration, were applied to the electrode while rotating. This treatment was followed by a thorough rinse with distilled water. This platinization method typically produced an initial electrode roughness factor of approximately 2000. However, the surface area dropped dramatically during the first several days of use to a stable value of approximately 650. We found, as did previous investigators (7), that the surface area remained remarkably stable over a period of months after the initial aging phase, provided that care was taken during the membrane mounting procedure to avoid disturbing the deposit. Surface area was determined without a membrane in place by galvanostatic hydrogen stripping in 1N H_2SO_4. A value at 210×10^{-6}C was used for the equivalent charge of 1 cm^2 adsorbed hydrogen.

A suitable working potential for each solute was first determined without the membrane using a Luggin capillary reference electrode. This was done by recording current-time curves at fixed potentials in increments of 50 mV over the potential range of interest. For oxygen and glucose, each measurement was immediately preceded by a sequence of electrode prepolarizations for surface activation consisting of anodization for 2 min at +900 mV followed by cathodization for 3 min at −300 mV. The background current in the absence of reactant was similarly recorded. With hydroquinone, prepolarization was not necessary and experiments were conducted by stepping the potential from approximately +300 mV where the current was insignificant to the working potential. Some acceptable working potentials were: oxygen, −200 mV; glucose, −100 mV; and hydroquinone, +700 mV. For oxygen and hydroquinone, steady-state measurements at various rotation rates and concentrations were also made. Calculations of diffusion coefficients in solution were based on the limiting Levich currents or, in the case of glucose, estimated from other studies (11). It was not necessary to activate the electrode before individual measurements of solutes that attained steady state. Moreover, a reproducible Levich current was obtainable for several hours after a single activation treatment. In certain measurements, slight compensation for iR drop was necessary.

These experiments were then repeated with the membrane in place using the internal reference electrode. Steady-state membrane permeability for oxygen and hydroquinone was calculated from plots of i_d^{-1} *vs.* $\omega^{-1/2}$ by extrapolating to the intercept at $\omega^{-1/2} = 0$, taking the background current into account. No significant IR drop was observed using the internal reference electrode with the membrane in place.

Results and Discussion

Hydroquinone.—Transient results for hydroquinone are shown in Fig. 4. The dashed lines are recordings without a membrane of current density normalized by concentration for several values of $\omega^{1/2}$. The steady-state current densities were linearly proportional to $\omega^{1/2}$ and used in determination of the diffusion coefficient of hydroquinone in solution. The time required for the current to reach steady state decreased slightly with increasing values of $\omega^{1/2}$, as predicted by previous models of the current transient at rotated disk electrodes without membranes (12, 13). The normalized current density with the membrane for two values of $\omega^{1/2}$ is recorded in the solid lines. With a membrane, the current density at comparable values of $\omega^{1/2}$ was reduced, and longer time was required to reach steady state. Nevertheless, the shape of the curves with or without the membrane was similar, with the exception of the initial slope at less than 1 sec. Initially, the background current density with membrane decayed rapidly, then slowly approached steady state. The background current density was independent of rotation rate and the presence of the membrane.

Oxygen.—As shown in Fig. 5, the results were qualitatively different with oxygen. The anodic movement of the electrode potential from the prepolarization potential of −300 mV to the working potential of −200 mV caused the transients to come from the anodic direction and cross through zero before finally arriving at cathodic steady-state values. In addition to the direction of the transients, the time to reach steady state for the background currents was substantially greater than for the oxygen currents. Moreover, the transient component of the background current was strongly dependent on the rotation rate and working potential and was affected by the presence of the mem-

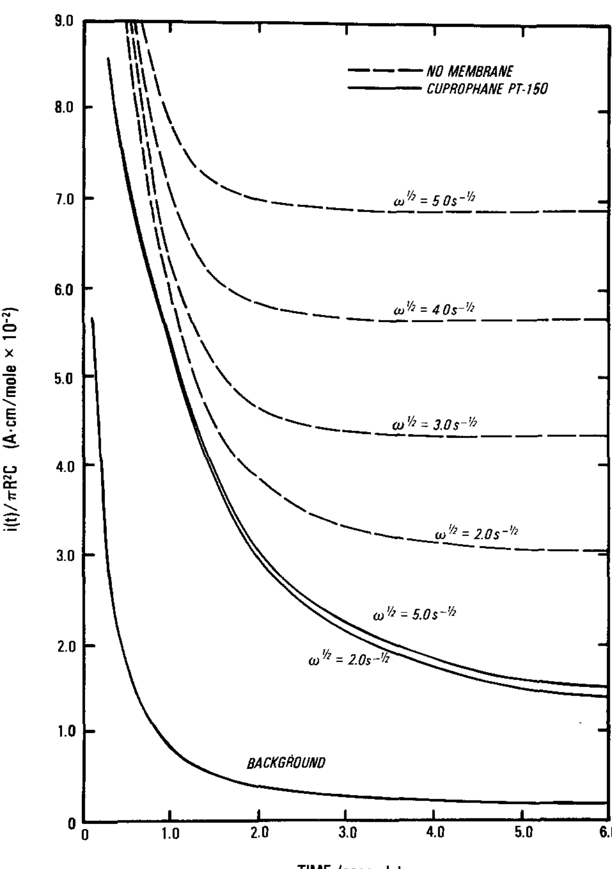

Fig. 4. The transient response with hydroquinone

brane. Nevertheless, the transient background currents, both with and without the membrane, eventually reached a common steady-state value that was independent of rotation rate.

The use of these data for determination of the diffusion coefficients of oxygen and hydroquinone in the membrane is shown in Fig. 6. Here, the logarithm of individual values of normalized current density minus the normalized steady-state current density was plotted as a function of time. Data points were calculated

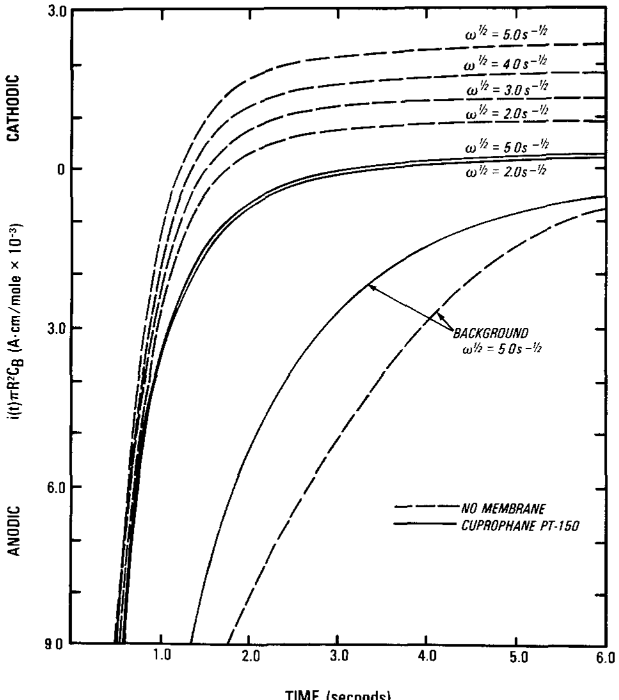

Fig. 5. The transient response with oxygen

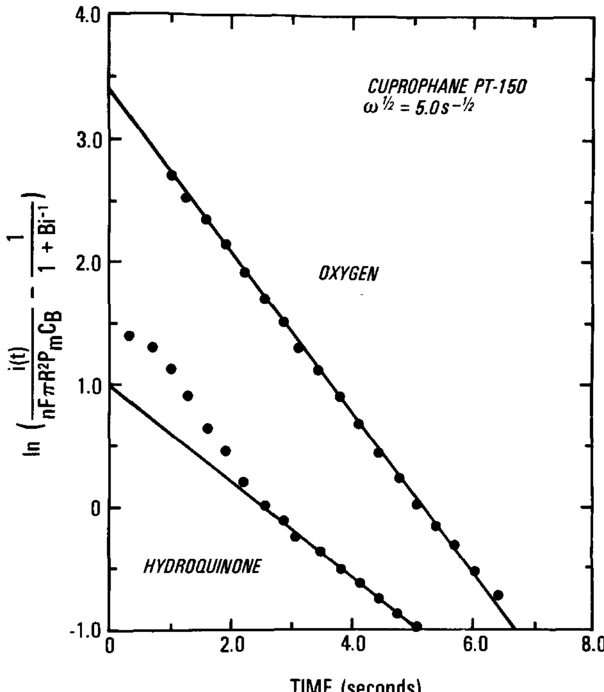

Fig. 6. The determination of the diffusion coefficient in the membrane for oxygen and hydroquinone.

from Fig. 4 and 5 for the same rotation rate. The diffusion coefficients were estimated from the slopes according to Eq. [28].

Although the oxygen data points closely approximated a straight line, the hydroquinone data points deviated significantly from linearity during the first 2 sec. Some degree of nonlinearity was representative of most trials. Departure from linearity suggests the possibility that various electrochemical process with distinguishable relaxation constants may have been involved in the transient response. While the physical nature of such processes and their significance to the eventual operation of chemical-specific sensors are not presently clear, these results may provide a point of departure for future studies. Thus, although the method proposed here is useful for the determination of diffusion coefficients in membranes, the analysis is based on a monoexponential transient and must be acknowledged as an approximation in certain cases.

The experimentally determined transport properties for oxygen and hydroquinone are summarized in Table I and compared to previous results for ferrocyanide (1). Values of the membrane molecular resistivity R_m, of membrane permeability, and of the diffusivity in solution were obtained from steady-state measurements. The effective diffusivity in the membrane D_{eff} is the product of the partition coefficient and the solute diffusivity in the membrane and was calculated from the steady-state permeability. In our previous study (1), D_{eff} was resolved into the components of α and D_m by an independent measurement of α, but in the present study D_m and D_{eff} were measured directly and α calculated.

Since transport of these solutes in cellulosic membranes has not been characterized previously there is no standard for direct comparison of these results. Nevertheless, indirect comparison based on other solutes (10, 11) can be made by reference to the ratio D_{eff}/D and the solute molecular weight. The present results are consistent with predictions based on such comparisons. In addition, the values reported here are comparable within experimental error to our other results (3) obtained with a time lag method.

Glucose.—The transient glucose current with the membrane in place is shown in Fig. 7. The current

* 15°C.

initially dropped rapidly, then began a logarithmic decay analogous to that described previously without the membrane (5). The current density at any given time was nonlinear with concentration, indicating that the process was still partially reaction limited. The background current shown by the dashed line decayed exponentially rather than logarithmically and was comparable to or larger than the glucose current at low concentrations. This is probably a result of the complex glucose oxidation process and invalidates the simple subtraction of the background current. Kinetic control of this process was evident from the nonlinearity of the current with concentration, the dependence of the current on the electrode roughness factor, and the relatively small effect of rotation rate.

The logarithmic nature of the glucose current decay is shown in Fig. 8. Values of glucose current density taken from Fig. 7 without subtraction of the background current density were plotted against the logarithm of time. While most values at greater than 75 sec closely fit a straight line, the current density at shorter times was frequently higher than expected. The deviation was probably due to initial glucose oxidation by an alternate mechanism involving a greater charge transfer number. Such an explanation would be consistent with the observations of Lerner *et al.*

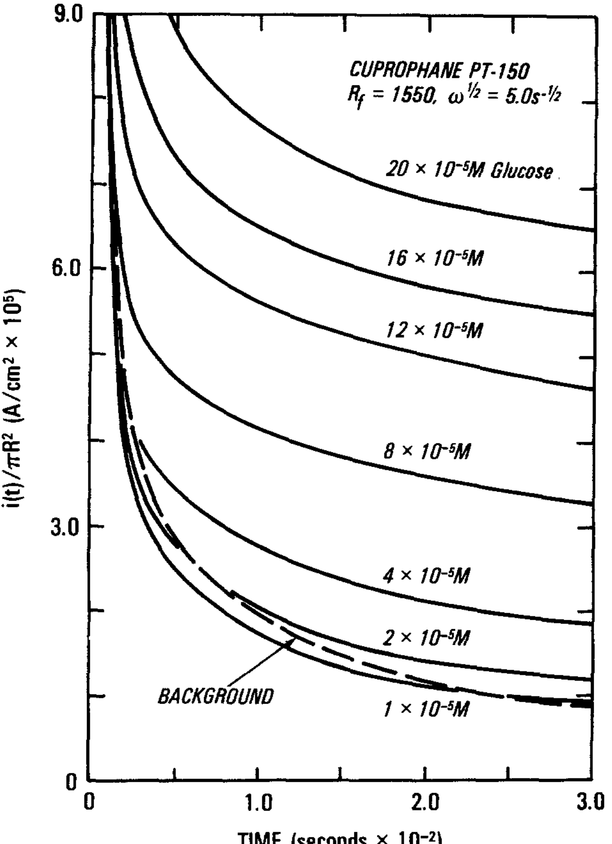

Fig. 7. The transient response to glucose with a membrane present.

(5) of a decreasing charge transfer number during the initial phase of fixed potential glucose oxidation without a membrane. The time during which this initial oxidation phase was significant is represented by the constant k_3 in Eq. [32] and was estimated from Fig. 8 to be approximately 75 sec. Thus, for times greater than k_3, characterization of the glucose current decay as linear with the logarithm of time seems reasonable.

In Fig. 9 a comparison is made of the glucose current density with and without a membrane for two electrode roughness factors. Both with and without the membrane, the current density was substantially greater at the higher roughness factor, reflecting reaction control. However, with the membrane, the current density at a given time was reduced by proportional amounts for both roughness factors. Although the process was clearly under reaction control, the membrane had a slight effect on the slope of the current density decay, thus permitting the use of Eq. [33]. Since the reaction and transport properties could not be determined independently in these experiments, we chose to estimate the transport properties by linear interpolation from Table I on a basis of molecular weight and to use Eq. [31] and [33] to calculate values of the kinetic constants. These values could then be used in future studies with other membranes for determination of relative transport properties. The values used were: D, 9.0×10^{-6} cm²/sec; D_{eff}/D, 0.1; and α, 0.75. For the conditions of our experiment, this led to values of 3.60×10^{-4} and 2.91×10^{-4} cm/sec for P_m and P_s, respectively, and 8.08 for Bi. Results of the calculations are summarized in Table II. Values of Φ were determined from averages of several measurements. At either roughness factor the magnitude of h^* was substantially smaller than that of Bi, as expected for a process under reaction control. There was no measurable dependence of Φ on time, suggesting that θ in Eq. [31] may be negligible, thereby permitting determination of values for the product k_1A_o. Further resolution of k_1 and A_o on the basis of roughness factor was not warranted because the roughness factor as determined by hydrogen stripping was not expected to be equivalent to the surface area after prepolarization in the presence of the reactant. Values of k_2 were determined from the slopes of the current decay without membrane in Fig. 9 at greater than 75 sec using Eq. [32]. For this calculation, the charge transfer number was assumed to be 4, as suggested by previous studies (5). The values of k_2 shown in Table II were small compared to unity, justifying the treatment above in which θ was neglected. Rate constants have not been reported in the literature so that quantitative comparisons with previous studies could not be made. However, the glucose current density without the mem-

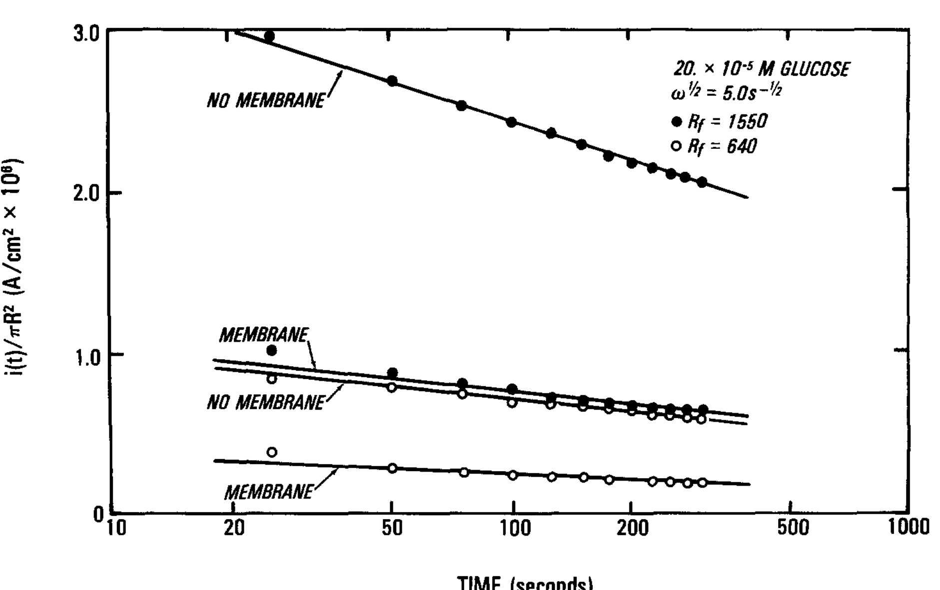

Fig. 9. The effect of roughness factor on glucose oxidation, with and without a membrane.

brane observed throughout our study was about 50% that reported by Lerner *et al.* (5) when adjusted for roughness factor, rotation rate, and concentration. This discrepancy may be due to the differences in iR drop compensation and may have an effect on the value of k_2. Nevertheless, the rate of current decay as calculated from the values of k_2 and k_3 obtained in our study was comparable to previous experimental findings (5).

The nature of the glucose current can depend on the electrochemical technique employed. In another study (3), we analyzed the fixed potential glucose current at a membrane-covered rotated disk electrode after incremental increases in glucose concentration. A treatment for surface activation was not employed. The current decayed linearly with time after each addition of glucose and although the current density with the membrane for a given concentration was much higher, the process was still nonlinear with concentration and limited by reaction. Thus, the kinetic constants and logarithmic decay described in the present study are not necessarily observed for other modes of electrode operation.

One general feature of the analysis is the assumption that transients in solution are sufficiently rapid to produce a linear concentration profile in the concentration boundary layer. It has been shown elsewhere (13, 14) that transients within the concentration boundary layer at a rotating disk electrode decay with a time scale

$$t_s \sim \frac{\delta_d^2}{3.10D} \quad [34]$$

whereas transients in the membrane die out with a time scale

$$t_m \sim \frac{\delta_m^2}{k'_1{}^2 D_m} \quad [35]$$

For the assumption of a linear profile within the concentration boundary layer it is necessary that

$$\frac{t_m}{t_s} >> 1 \quad [36]$$

The plausible values for transport parameters obtained for oxygen and hydroquinone suggest that this assumption is reasonable. However, the attainment of this condition may be in question where the analysis is applied to more highly permeable membranes.

An essential condition in the analysis was the assumption of an equilibrium distribution of the reactant

in the membrane at the time of imposing the measurement potential. In the case of oxygen and glucose significant reaction was likely during the prepolarization treatment, with the result that this condition may not have been completely satisfied. Nevertheless error due to the initial reactant distribution was expected to be minor for membranes of high permeability.

These studies prepare the way for characterization of new membranes that may eventually be incorporated in novel, biochemical-specific sensors.

Conclusions

1. An analysis of current transients after adjusting the electrode potential at the membrane-covered rotated disk electrode is given. Cases are described in which the process is strictly diffusion limited, partially reaction limited, and partially reaction limited with the effective surface area decreasing with the logarithm of time.

2. The membrane-covered rotated disk electrode and the transient analysis can be employed to evaluate the permeability, the partition coefficient, and the diffusion coefficient in membranes from a single experiment for solutes that are readily consumed at the electrode. The system may also be useful to analyze transport and reaction of solutes that are partially reaction limited.

3. This study confirms previous reports of the effectiveness of certain electrode prepolarization procedures for obtaining highly reproducible glucose oxidation currents. At a potential of -100 mV *vs.* Ag/AgCl without a membrane, the glucose oxidation current decays with the logarithm of time, as previously reported. Moreover, we find that these properties are also obtained with a membrane covering the electrode, although the membrane decreases the current density and the slope of current decay.

4. The analysis developed here is useful to describe the process of glucose oxidation at the membrane-covered electrode and to estimate certain reaction rate constants.

Influence of Electrolyte Composition on Electrode Kinetics in the Molten Carbonate Fuel Cell

P. G. P. Ang* and A. F. Sammells*

Institute of Gas Technology, Chicago, Illinois 60616

ABSTRACT

Electrode kinetics of fuel oxidation on nickel and cobalt electrodes is discussed for three selected molten carbonate mixtures. The measurements were made using a potential step technique. The highest exchange current values were found on nickel anodes in all melts, and the highest of these values were found in the melt comprised of 43.5 mole percent Li_2CO_3-31.5 mole percent Na_2CO_3-25 mole percent K_2CO_3. In this ternary melt the exchange current density on nickel varied from 78 mA/cm^2 for intermediate-BTU fuel to 22 mA/cm^2 for low-BTU fuel at 650°C. The exchange current density was found to have an electrochemical reaction order parameter at constant overpotential of around 0.25 for hydrogen, carbon dioxide, and water. Electrochemical performance of the two anode materials in the three melts is discussed, and a tentative reaction mechanism is suggested for the oxidation reaction.

The molten carbonate fuel cell (MCFC) operates at 650°C and consists of a porous nickel anode together with a porous nickel cathode, both of which are pressed against what is called the electrolyte tile. This tile contains both an inert matrix into which can be supported a variety of alkali carbonate mixtures which, at the fuel cell operating temperature, are molten.

The empirical electrode reactions taking place in this cell are

$$\text{Anode: } H_2 + CO_3^{2-} \rightarrow CO_2 + H_2O + 2e^-$$

$$CO + CO_3^{2-} \rightarrow 2CO_2 + 2e^-$$

$$\text{Cathode: } 2e^- + CO_2 + \tfrac{1}{2} O_2 \rightarrow CO_3^{2-}$$

The CO present at the fuel cell anode may react electrochemically as indicated above, but at the cell operating temperature of 650°C the water-gas shift equilibrium $CO + H_2O \rightleftarrows CO_2 + H_2$ will be attained more rapidly. Hence the major contribution of CO to the fuel cell anode performance may be in hydrogen produced via the water-gas shift reaction.

Several factors must be considered in the selection of a molten carbonate mixture supported on the lithium-aluminate ($LiAlO_2$) matrix of the tile. These factors are (*i*) ionic conductivity, (*ii*) solubility of reactants and reaction products, (*iii*) the diffusion coefficients of reactants and products, (*iv*) the rate of the anodic and cathodic reactions, (*v*) electrolyte vapor pressure, and (*vi*) stability of the lithium-aluminate matrix. Electrolyte vaporization losses appear to be related to the hydroxide content in the molten carbonate mixture, with the highest concentrations occurring in lithium carbonate (1). Projected electrolyte tile lifetimes have already been reported (2). Reactant-gas solubility has generally been found to decrease with increasing lithium carbonate content. Maximum solubilities have been found in ternary mixtures rich in K_2CO_3 and lean in Li_2CO_3 (3).

Polarization data for hydrogen oxidation has shown little dependency on the nature of the metal (4). Experimental evidence has indicated that polarization at such electrodes for the hydrogen-oxidation reaction in molten carbonates may be controlled more by the local buildup of reaction products (H_2O, CO_2) than by the diffusion of hydrogen in the melt (5). Some work has already been reported for hydrogen oxidation on fully immersed (6, 7) and partially submerged anodes in molten carbonate melts (8, 9). This latter work has shown that diffusion of reactants through the thin film electrolyte meniscus can play a significant role in the overall rate of the anodic reaction. Determination of the electrode kinetics for fuel oxidation requires the use of techniques that will enable effective separation of activation overpotential from any diffusion overpotential that may exist at the anode under the experimental conditions.

Experimental

Anode materials (nickel and cobalt rod) were purchased from commercial sources (Materials Research Corporation, Orangeburg, New York). The nickel and cobalt were Marz grade with purities of 99.995% and 99.99+%, respectively. All measurements were performed in an electrochemical half-cell. Fuel gas mixtures were purchased premixed from Matheson Gas Company. The initial and after humidification gas compositions were determined by gas chromatographic analysis and were in agreement with predicted values. Humidification of the inlet gas was performed by passing it through a column of water in a large test tube. A gold wire in equilibrium with 33.3% O_2-66.7% CO_2 inside an alumina tube served as a reference electrode (10, 11). The wire communicated with the melt through a small hole (0.015 in. diam) at the bottom of the tube. The potential of the working electrode was controlled by a Wenking ST72 potentiostat. The potentiostat had a risetime of about 1 μsec when a step voltage was applied. A piece of round gold foil was used as the counterelectrode. Electrolyte mixtures were prepared from a mixture of Li_2CO_3, Na_2CO_3, and K_2CO_3 (Mallinckrodt, Analytical Reagent). Compositions used in the study were Li_2CO_3-38 mole percent (m/o) K_2CO_3 (Li/K), which has a high ionic conductivity and a reasonably high reactant-gas solubility; 52 m/o Li_2CO_3-48 m/o Na_2CO_3 (Li/Na), which combines good electrolyte conductivity and a high sodium content for low vapor pressure to minimize electrolyte vaporization losses; and the ternary 43.5 m/o Li_2CO_3-31.5 m/o Na_2CO_3-25 m/o K_2CO_3 (Li/Na/K) to evaluate electrochemical performance at temperatures below 650°C.

A Tacussel Type GSTP2B pulse-sweep generator was used to control the potentiostat. The output voltage of the Tacussel generator was monitored with a digital voltmeter (Fluke, Type 8020A). Steady-state, linear voltage sweep, and transient pulse techniques were

* Electrochemical Society Active Member.

Key words: electrode kinetics, molten carbonate fuel cell.

used to study the current/voltage relationships of the electrode. The signals were recorded on a Hewlett-Packard 7046 X-Y recorder. Signals from the transient techniques were displayed and photographed on a Tektronix Type 547 oscilloscope. To eliminate errors caused by mass-transfer effects, the transient potentiostatic technique was used so that more precise kinetic information could be obtained. Electrode measurements made with this transient potentiostatic technique were performed using appropriate *IR* compensation within the potentiostat. Without such compensation, a large transient capacitive current was usually seen. Such an effect can cause some error in the current extrapolated to time zero. In order to achieve *IR* compensation, part of the voltage at the current recorder terminal of the potentiostat was picked up from an external potentiometric voltage divider (250Ω) and fed back into one of the potentiostat control inputs. The feedback voltage was then adjusted until the system almost started to oscillate. The positive feedback resulted in an increase of the control voltage proportional to the cell current. A Lindberg Hevi-Duty SB furnace with 3-zone temperature control was used to heat the cell. The temperature of the melt was read by an alumina-sheathed thermocouple and was displayed on a digital readout (Newport Laboratories, Incorporated, Model 267A-KCl-07). Fuels used in the course of this work are listed in Table I.

Results and Discussions

Before kinetic data could be obtained for the hydrogen-oxidation reaction, it was essential to determine whether the rate of the anodic reaction was controlled by diffusion- or mixed-control. Linear voltage sweep measurements at various sweep rates are shown in Fig. 1 for a completely immersed nickel wire anode in the ternary Li/Na/K melt at 650°C under conditions of fuel (intermediate-BTU) bubbling (50 ml/min). Figure 2 shows the voltage sweep measurements taken with the fuel bubbling turned off immediately prior to the linear voltage sweep. In both cases, we can see a dependency of the current density measured on the voltage sweep rate; the higher the sweep rate, the higher the observed current density. If we compare the measured current at a fixed voltage sweep rate, higher values are obtained for the melt subjected to continuous bubbling. Linear sweep measurements were also performed on a nickel wire partially submerged in the melt (approximately 50%) so that the half of the nickel wire above the electrolyte bulk would be covered with a thin film of the melt and would, therefore, approximate those electrochemical conditions present within the fuel cell porous electrode. With continuous fuel bubbling, linear voltage sweep measurements were performed with sweep rates between 0.15 and 150 mV/sec, and a dependency of the current density on the voltage sweep rate was again observed, indicating the continued presence of diffusion- or mixed-control effects at a partially submerged nickel wire. The limiting current density obtained with a sweep rate of 0.15 mV/sec at an overpotential of approximately 150 mV is around 3 mA/cm². In a porous electrode where the ratio of real to apparent area can be expected to be about 400, this current density would correspond to an apparent value of 1.2 A/cm².

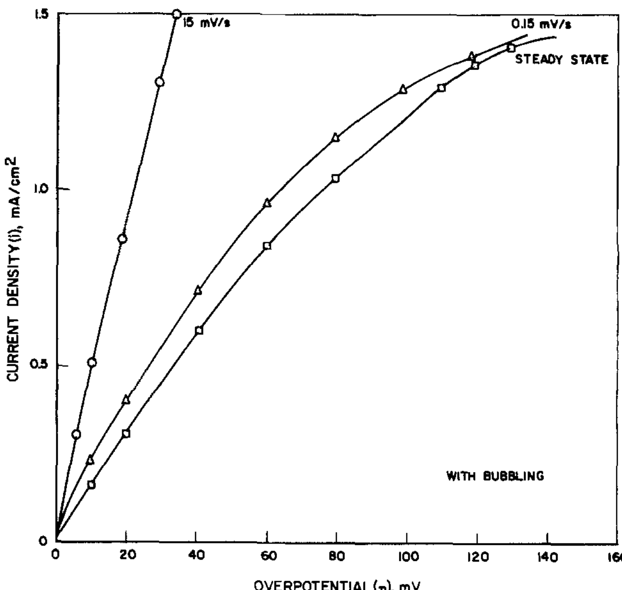

Fig. 1. Dependency of polarization curve on linear voltage sweep rate for a fully immersed nickel wire (fuel continuously bubbled into melt).

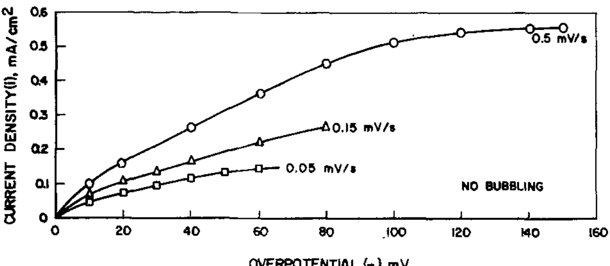

Fig. 2. Dependency of polarization curve on linear voltage sweep rate for a fully immersed nickel wire (no fuel bubbling into melt at time of measurement).

Steady-state polarization measurements for completely immersed nickel and cobalt are shown in Fig. 3 and 4, respectively.

These steady-state polarization curves differ from those obtained initially on new electrodes by exhibiting rapidly increasing currents at high anodic overpotentials (~150 mV for nickel and ~100 mV for cobalt).

Upon removal of the high anodic potentials, approximately 30 min was required to reach the initial open-circuit potential. However, if upon removal of the anodic overpotential the working electrode was potentiostated back to its initial open-circuit potential, large (several mA/cm²) cathodic currents were observed. It can be speculated that the sudden increase in currents at high anodic overpotentials is a consequence of electrode surface oxidation. The oxidation potentials of nickel and cobalt are expected to be within the potential range of these steady-state experiments.

In order to gain some mechanistic understanding of the electrochemical process occurring it was of interest to make electrode kinetic measurements.

The measurement of the electrode kinetic parameters under the mixed-control conditions have been performed using transient potentiostatic techniques (12) on both nickel and cobalt electrodes under conditions of total and partial immersion in the candidate molten carbonate electrolytes. This technique involves applying a potential step to the nickel or cobalt working electrode, and recording the current as a function of time. Under such conditions of mixed control, the as-

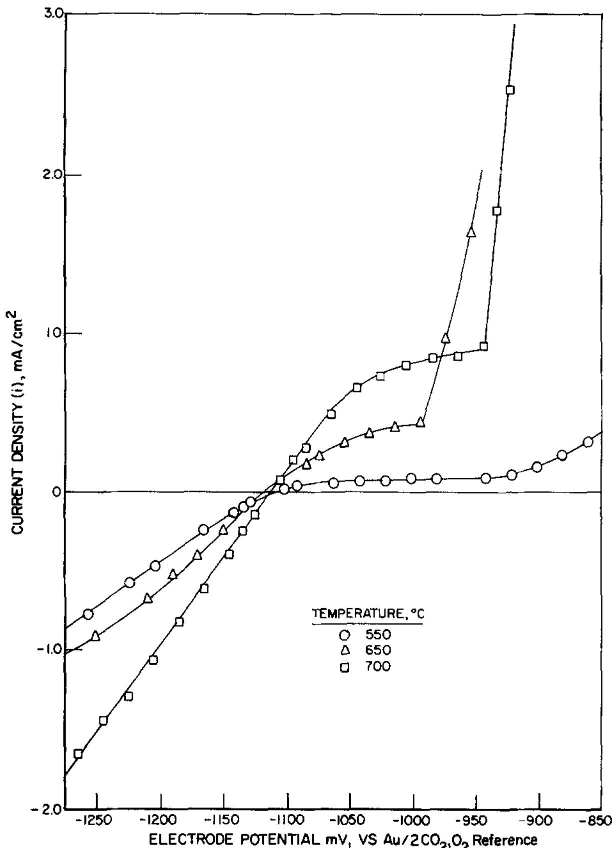

Fig. 3. Steady-state polarization curves for nickel in Li/Na/K carbonate melt.

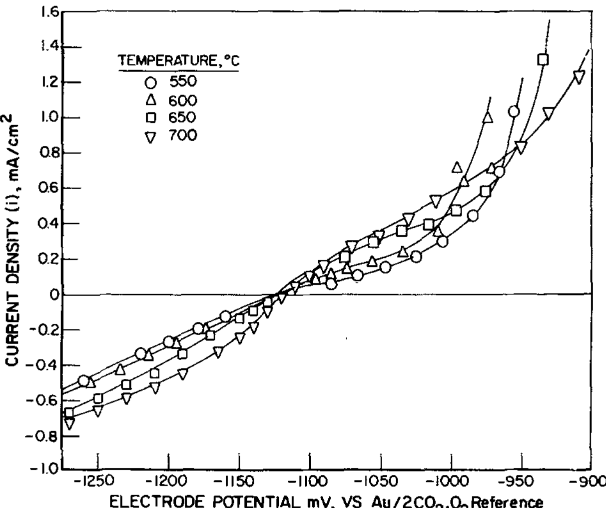

Fig. 4. Steady-state polarization curves for cobalt in Li/Na/K carbonate melt.

sumption is made that at time zero only activation control will be present; that is, sufficient supply of electroactive species will be present, together with minimum reaction products, so that any mass-transfer effects will be minimized. A typical oscillograph obtained using this transient potentiostatic technique is shown in Fig. 5. A 20 mV anodic voltage step (from the resting potential) is shown for a nickel electrode (top traces). The bottom traces show the current variations on three different time scales between 0.05 and 2.0 msec/div. Highest reproducibility of the kinetic current, $i(0)$, was obtained by extrapolating currents between 0.3 and 0.5 msec to time zero. Here, the kinetic current is found to be 39 mA/cm^2 for the Li/Na/K melt at 650°C in the intermediate-BTU fuel. Care was taken so that the extrapolated current values were free of interference

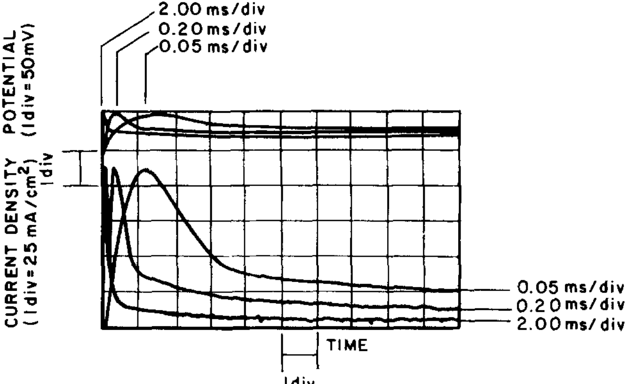

Fig. 5. IR-compensated potentiostatic measurement on nickel wire in Li/Na/K at 650°C with intermediate-BTU fuel [three time scales were used for potential (top traces) and current (bottom traces)].

from capacitive currents. With appropriate *IR* compensation the capacitive current can be clearly distinguished. Following the transient capacitive spike, the current can be seen to decrease because of diffusional processes.

This potential step technique has been applied to both nickel and cobalt electrodes in the three candidate molten carbonate mixtures discussed earlier. Various fuel compositions and different temperatures were used so that comparative kinetic data could be obtained from the three candidate melts. Extrapolated current densities at time zero $i(0)$ were plotted *vs.* the applied potential steps η. Figure 6 shows a representative activation polarization plot for nickel in the Li/Na/K ternary melt using intermediate-BTU fuel. For an activation-controlled process the current-voltage is given by the relationship

$$i(0) = i_o[e^{\alpha_A \eta \mathbf{F}/RT} - e^{-\alpha_C \eta \mathbf{F}/RT}] \quad [1]$$

In the low overpotential region, this equation can be approximated by

$$i(0) \simeq i_o(\alpha_A + \alpha_C)\eta \mathbf{F}/RT$$

or

$$i_o \simeq \frac{RT}{(\alpha_A + \alpha_C)\mathbf{F}} \frac{di(0)}{d\eta} \quad [2]$$

Thus, the exchange current density, i_o, can be calculated from the slope of the current density, $i(0)$, *vs.* overpotential, η, curve. We assume a value of 2 for the sum of the apparent transfer coefficient α_A and α_C based on a total of two electron transfer processes and a stoichiometric number 1. For the specific case above i_o was

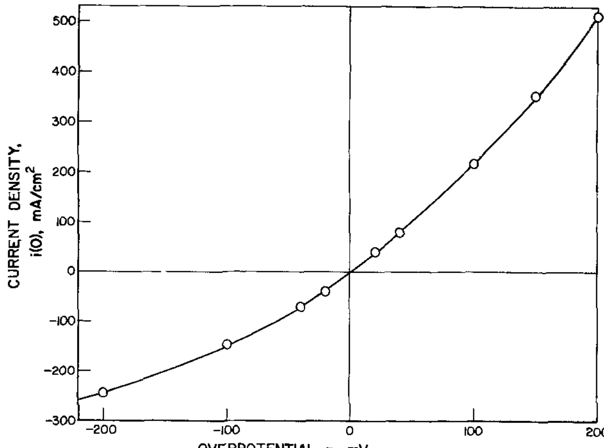

Fig. 6. Polarization curve at a nickel electrode from $i(0)$ values extrapolated via potential step technique (fuel: 40% H_2, 17% CO_2, 10% CO, and 33% H_2O at 650°C).

calculated using Eq. [2] to be 78 mA/cm² for a nickel electrode. This potential step technique was applied to electrodes that were both fully and partially immersed in molten carbonate mixtures. Under each experimental condition, the extrapolated kinetic current densities agreed within 20%, the major source of inaccuracy being caused by instrumentation noise effects in the fuel bubbled, partially raised, electrode case. This gave good support to the validity of this technique for separating activation kinetic data under the mixed-control conditions present.

Exchange current density values were also obtained from Allen-Hickling plots of the potential step data. For the Allen-Hickling plot, Eq. [1] can be rewritten as

$$\log \frac{i}{e^{(\alpha_A+\alpha_C)\eta F/RT} - 1} = \log i_o - \frac{\alpha_C \eta \mathbf{F}}{2.303RT} \quad [3]$$

If we assume $\alpha_A + \alpha_C = 2$, then a plot of

$$\log \frac{i}{e^{(\alpha_A+\alpha_C)\eta F/RT} - 1} \; vs. \; \eta \quad [4]$$

can give the value of α_C from the slope and a value of i_o from the intercept.

Typical Allen-Hickling plots at 650°C for nickel and cobalt are compared in Fig. 7 using intermediate-BTU fuel. From the intercept at zero overpotential, exchange current densities were generally found to be higher for nickel (85 mA/cm²) compared with those for cobalt (28 mA/cm²).

Agreement between 10 and 20% was generally found between exchange current density values obtained from low overpotential data and Allen-Hickling plots. The curves for the anodic and cathodic side of the Allen-Hickling plots shown in Fig. 7 differ for both cobalt and nickel, probably indicating a change in the reaction mechanism between the anodic and cathodic direction. The cathodic reaction mechanism has yet to be clarified.

From the anodic slope shown in Fig. 7 for nickel, we obtain $\alpha_A = 0.7$ and $\alpha_C = 1.3$, and for cobalt $\alpha_A = 0.74$ and $\alpha_C = 1.26$. From the cathodic slope, for nickel we obtain $\alpha_C = 0.48$ and $\alpha_A = 1.52$, and for cobalt $\alpha_C = 0.59$ and $\alpha_A = 1.41$.

The above charge-transfer coefficients given for the ternary melt are representative of values obtained for all three melts with the temperatures and fuel compositions used in this work.

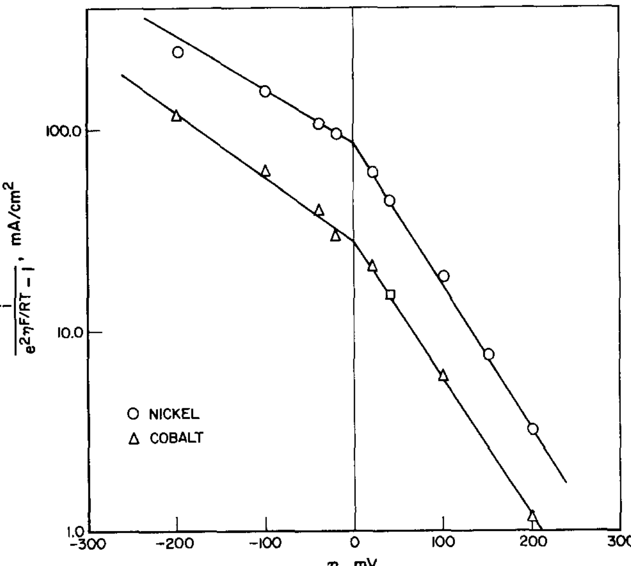

Fig. 7. Allen-Hickling polarization curve from potential step data (nickel and cobalt electrodes, Li/Na/K melt, intermediate-BTU fuel, 650°C)

In the high anodic overpotential region, oxidation of the electrode surface may become significant, giving currents higher than that caused by fuel oxidation only (see Fig. 3 and 4). This would result in higher α_A values in the anodic region. As a consequence, only data obtained from the low overpotential region was used for mechanistic interpretations. To gain more insight into the validity of the α_A and α_C values corresponding to fuel oxidation at nickel and cobalt electrodes, activation data were generated on a gold electrode in the Li/K melt at 650°C using intermediate-BTU fuel, as shown in Fig. 8. The corresponding Allen-Hickling plot from this activation data is shown in Fig. 9. Here we obtain $i_o = 16$ mA/cm², $\alpha_C = 1.56$, and $\alpha_A = 0.44$. These values of α_A and α_C on a gold electrode where gold dissolution is absent are in close agreement to values obtained using nickel and cobalt electrodes. We can, therefore, tentatively conclude that nickel and cobalt anodic dissolution at low applied overpotentials is minimal and consequently the oxidation of fuel proceeds with $\alpha_C = 1.5$ and $\alpha_A = 0.5$ in the absence of electrode oxidation effects.

The dependency of the i_o on hydrogen content is shown for both nickel and cobalt for the Li/K, Li/Na/K, and Li/Na melts at 650°C in Fig. 10, 11, and 12, respectively. In these figures, a straight line was drawn through the data points; however, those points falling off these lines should not be interpreted as experimental error, but rather as reflecting the interdependency between H_2, CO_2, H_2O, and CO by way of the water-gas shift reaction

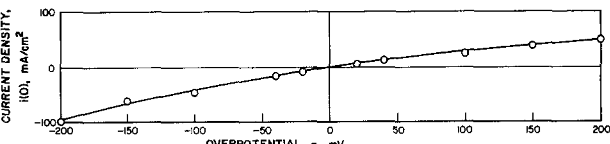

Fig. 8. Current-voltage characteristics from transient potentiostatic experiments on gold in 650°C Li/K melt with intermediate-BTU fuel.

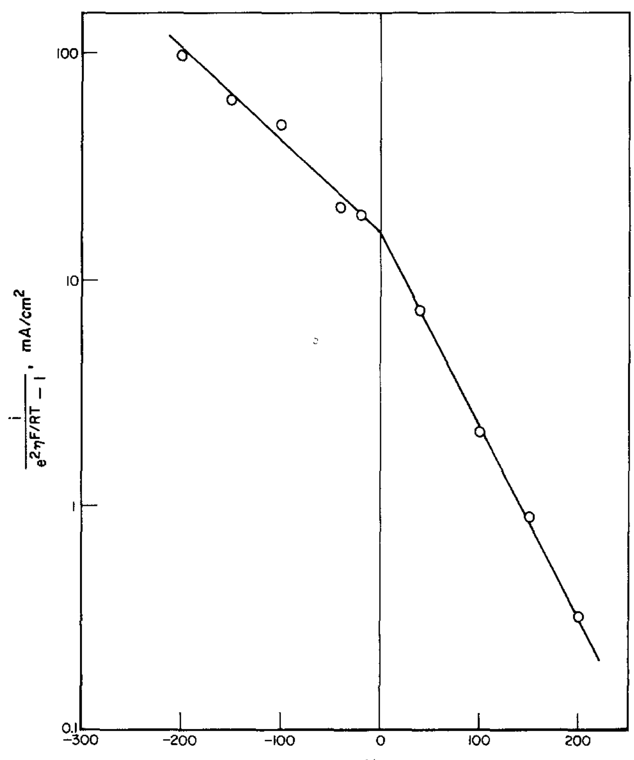

Fig. 9. Allen-Hickling polarization curve from potential step data (gold electrode, Li/K melt, intermediate-BTU fuel, 650°C).

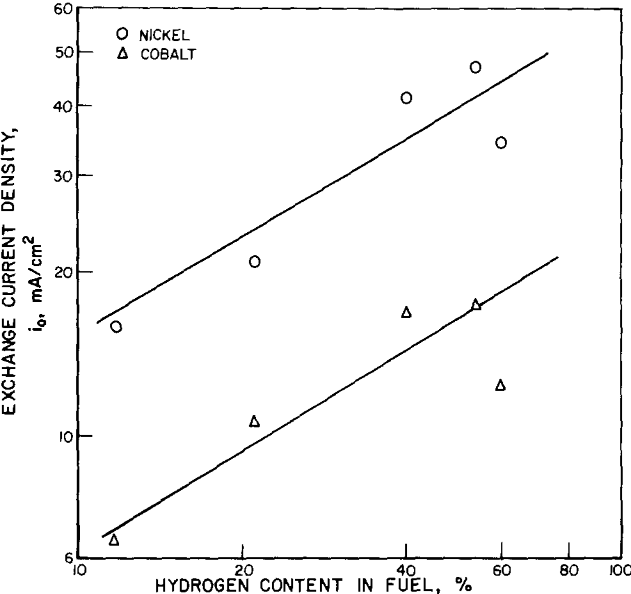

Fig. 10. Dependency of exchange current densities of nickel and cobalt on hydrogen content using various fuels (Li/K melt at 650°C).

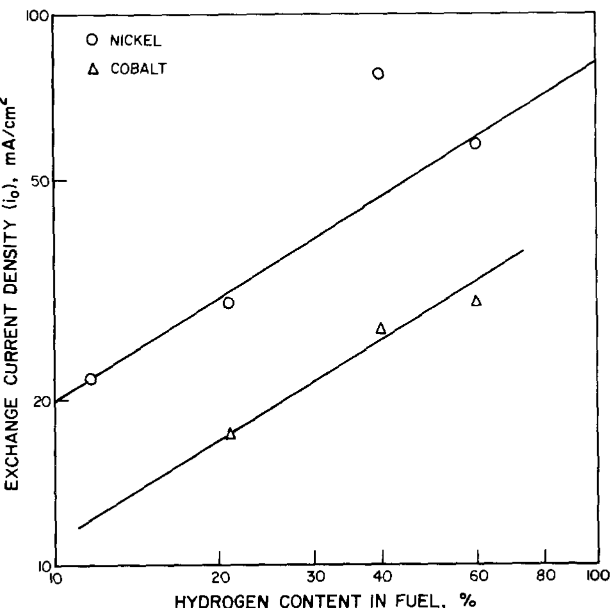

Fig. 11. Dependency of exchange current densities of nickel and cobalt on hydrogen content using various fuels (Li/Na/K melt at 650°C).

$$H_2O + CO \rightleftarrows H_2 + CO_2 \quad [5]$$

The slope of these lines would suggest an electrochemical reaction order parameter at constant overpotential of approximately 0.5 for hydrogen. However, this value could not be considered reliable since it is not possible to independently vary the hydrogen content without changing the overall gas composition (see Table I). The open-circuit potential of the working electrode upon changing the gas composition was observed to vary by around 60 mV, in agreement with calculated values.

An estimation of these electrochemical reaction order parameters at constant overpotential (13, 14) for hydrogen, carbon dioxide, and water in the fuel were calculated from the following equation

$$i_o = k^* (H_2)^a (CO_2)^b (H_2O)^c \quad [6]$$

where k^* is a proportionality constant; a, b, and c are, to a first approximation, the electrochemical reac-

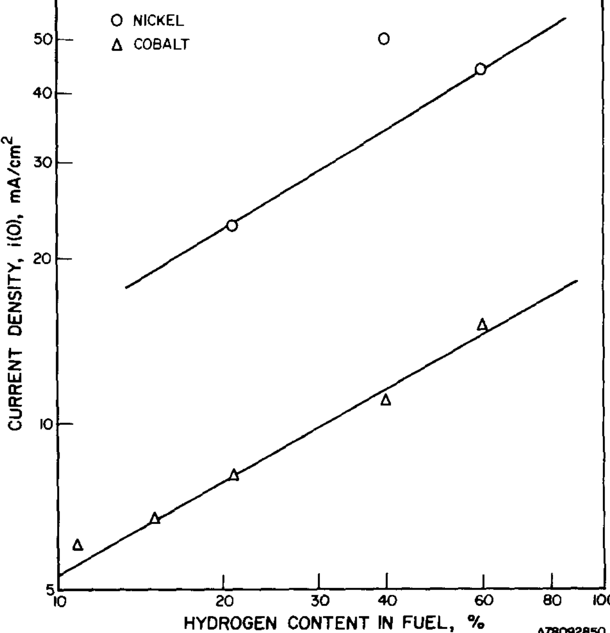

Fig. 12. Dependency of exchange current densities of nickel and cobalt on hydrogen content using various fuels (Li/Na melt) at 650°C).

tion order at constant overpotential for H_2, CO_2, and H_2O, respectively.

Knowing the respective concentrations of H_2, CO_2, and H_2O, then, by the water-gas shift reaction (Eq. [5]) the CO content is automatically fixed. If i_o is measured in four different fuels, then the four unknowns k^*, a, b, and c can be determined. The above equation can be written in the logarithmic form

$$\log i_o = k + a \log(H_2) + b \log(CO_2) + c \log(H_2O) \quad [7]$$

where $k = \log k^*$. Using i_o values obtained with fuel gas compositions corresponding to high-, medium,-low-, and very-low-BTU fuel (Table I), Eq. [8] can be written in a matrix form, *e.g.*, for nickel in Li/K

$$\begin{bmatrix} 1.54 \\ 1.62 \\ 1.34 \\ 1.20 \end{bmatrix} = \begin{bmatrix} 1 & -0.22 & -1.13 & -0.65 \\ 1 & -0.39 & -0.79 & -0.48 \\ 1 & -0.67 & -1.04 & -1.26 \\ 1 & -0.93 & -1.24 & -1.36 \end{bmatrix} \begin{bmatrix} k \\ a \\ b \\ c \end{bmatrix} \quad [8]$$

These linear simultaneous equations were solved on a programmable calculator to find the solution

$$\begin{bmatrix} k \\ a \\ b \\ c \end{bmatrix} = \begin{bmatrix} 2.02 \\ 0.258 \\ 0.275 \\ 0.178 \end{bmatrix}$$

Thus, Eq. [7] can be written as

$$i_o = 104.7 (H_2)^{0.258} (CO_2)^{0.275} (H_2O)^{0.178} \quad [9]$$

A variety of approaches can be pursued for the development of the reaction mechanism (13-15). We have followed the general procedure described by Newman (13).

We considered several reaction mechanisms for fuel oxidation that might give the i_o dependency shown in Eq. [9]. These mechanisms have been discussed by us at length in our earlier report (16). We have found the following reaction mechanism to satisfy this criterion

$$H_2 + 2M \underset{k_{1C}}{\overset{k_{1A}}{\rightleftarrows}} 2\,MH \quad [10]$$

$$MH + CO_3^{=} \underset{k_{2C}}{\overset{k_{2A}}{\rightleftarrows}} OH^- + CO_2 + M + e^- \quad [11]$$

$$MH + OH^- \underset{k_{3C}}{\overset{k_{3A}}{\rightleftarrows}} H_2O + M + e^- \quad [12]$$

This mechanism assumes that (*i*) Eq. [11] is the rate-determining step; (*ii*) Langmuir adsorption isotherm; and (*iii*) there is low coverage, θ, of MH.

At equilibrium, one can write for Eq. [10]

$$\frac{\theta}{1-\theta} = \left(\frac{k_{1A}}{k_{1C}} C_{H_2}\right)^{1/2} = K_1^{1/2} C_{H_2}^{1/2} \quad [13]$$

The net current from Eq. [12] is

$$i_3 = \mathbf{F}(k_{3A}\theta C_{OH^-} e^{\beta_3 FV/RT} - k_{3C} C_{H_2O}(1-\theta) e^{-(1-\beta_3)FV/RT} \quad [14]$$

V is the potential difference between the electrode and the electrolyte. At equilibrium, when $i_3 = 0$

$$C_{OH^-} = \frac{k_{3C}}{k_{3A}} C_{H_2O} \frac{1}{(K_1 C_{H_2})^{1/2}} e^{-FV/RT} \quad [15]$$

For Eq. [11] the net current is

$$i_2 = \mathbf{F}[k_{2A}\theta C_{CO_3^=} e^{\beta_2 FV/RT} - k_{2C} C_{OH^-} C_{CO_2}(1-\theta) e^{-(1-\beta_2)FV/RT}] \quad [16]$$

Upon substitution for C_{OH^-} from Eq. [15] into the equilibrium expression for Eq. [16] for the equilibrium potential V_o, we can write

$$e^{FV_o/RT} = \left[\frac{k_{2C}}{k_{2A}} \frac{k_{3C}}{k_{3A}} \frac{1}{K_1 C_{H_2}} \frac{C_{H_2O} C_{CO_2}}{C_{CO_3^=}}\right]^{1/2} \quad [17]$$

Replacing V for $Vo + \eta$ in Eq. [16], where η is the overpotential, we obtain

$$i_2 = \mathbf{F}\left\{k_{2A}\theta C_{CO_3^=} e^{\beta_2 F\eta/RT} \left[\frac{k_{2C}}{k_{2A}} \frac{k_{3C}}{k_{3A}} \frac{1}{K_1 C_{H_2}} \frac{C_{H_2O} C_{CO_2}}{C_{CO_3^=}}\right]^{\beta_2/2} - k_{2C} \frac{k_{3C}}{k_{3A}} \frac{C_{H_2O}}{(K_1 C_{H_2})^{1/2}} C_{CO_2}(1-\theta)\, e^{(-2+\beta_2)F\eta/RT} \left[\frac{k_{2C}}{k_{2A}} \frac{k_{3C}}{k_{3A}} \frac{1}{K_1 C_{H_2}} \frac{C_{H_2O} C_{CO_2}}{C_{CO_3^=}}\right]^{\frac{-2+\beta_2}{2}}\right\} \quad [18]$$

From Eq. [13] for low coverage we have $\theta = K_1^{1/2} C_{H_2}^{1/2}$ and $1 - \theta \simeq 1$. Thus, Eq. [18] becomes

$$i_2 = \mathbf{F}\left\{k_{2A} K_1^{1/2} C_{H_2}^{1/2} C_{CO_3^=} \left[\frac{k_{2C}}{k_{2A}} \frac{k_{3C}}{k_{3A}} \frac{1}{K_1 C_{H_2}} \frac{C_{H_2O} C_{CO_2}}{C_{CO_3^=}}\right]^{\beta_2/2} e^{\beta_2 F\eta/RT} - k_{2C} \frac{k_{3C}}{k_{3A}} \frac{C_{H_2O}}{(K_1 C_{H_2})^{1/2}} C_{CO_2} \left[\frac{k_{2C}}{k_{2A}} \frac{k_{3C}}{k_{3A}} \frac{1}{K_1 C_{H_2}} \frac{C_{H_2O} C_{CO_2}}{C_{CO_3^=}}\right]^{\frac{-2+\beta_2}{2}} e^{(-2+\beta_2)F\eta/RT}\right\} \quad [19]$$

Comparing this with the general relationship for activation polarization

$$i = i_o(e^{\alpha_A F\eta/RT} - e^{-\alpha_C F\eta/RT}) \quad [20]$$

we obtain

$\alpha_A = \beta_2$ assuming $\beta_2 = 0.5$ we obtain $\alpha_A = 0.5$

$\alpha_C = 2 - \beta_2 \simeq 1.5$

The dependency of i_o on the gases (for $\beta_2 = 0.5$) is

$$i_o \sim [C_{H_2}]^{0.25}[C_{CO_2}]^{0.25}[C_{H_2O}]^{0.25} \quad [21]$$

The theoretical value of $\alpha_A = 0.5$ compares reasonably well with our experimentally determined α_A of 0.7 for nickel and cobalt and 0.5 for gold. Table II compares experimentally determined i_o values at 650°C with those calculated, assuming electrochemical reaction order parameters at constant overpotential of 0.25 for H_2, CO_2, and H_2O on nickel anode in three different melts and with four gases. Similar data for cobalt is shown in Table III.

The highest exchange current densities were measured on nickel and cobalt in the Li/Na/K ternary melt with all fuel compositions used. In these tables, we can see that good agreement exists between experimental and calculated i_o values.

We have seen in Fig. 1 and 2 that currents were dependent upon the rate of fuel bubbling through the melt. The current increased further when the nickel wire was partially raised from the electrolyte. This suggests that in this system the current is limited by the rate of fuel gas delivery through the melt into the electrode. In the porous electrode of an actual fuel cell, the situation is rather different, however. Fuel gas is delivered directly at the electrode from the rear side while the front side is facing the electrolyte tile. Thus, the gas can reach electroactive sites directly, or through a layer of melt, or by diffusion through the metal. Diffusion of hydrogen through nickel may be quite significant (17). Thus, there may be a very high local concentration of hydrogen in the porous electrode. The solubility of hydrogen in nickel at 650°C has been shown to be around 2.5×10^{-5} g mole/cm³ atm (18), and its diffusivity to be 3×10^{-5} cm²/sec (19).

We have seen from Eq. [9] that the exchange current density does not depend only on hydrogen concentra-

Very low-BTU	6.7	7.20

tion but also on the other fuel components. In particular, the significance of water present in the melt appears to play an important role in the overall reaction rate.

Some preliminary work was performed on the temperature dependency of the exchange current density on nickel and cobalt electrodes in the Li/Na/K melt over the temperature range of 550°-700°C. No correction was made for changes in hydrogen concentrations caused by the temperature dependency of Eq. [5]. However, the calculated changes over this temperature range were below 10%. Figure 13 shows plots of log i_o *vs.* $1/T$ for nickel and cobalt using low-BTU fuel.

The activation energy (ΔE) was calculated from the relationship

$$\Delta E = \frac{R}{0.434} \frac{d(\log i_o)}{d(1/T)} \quad [22]$$

Here we get activation energies of 6.65 kcal/mole and 7.31 kcal/mole for nickel and cobalt, respectively.

Of the three molten carbonate compositions evaluated, the highest kinetic rates for fuel oxidation were found in the ternary melt of 43.5 m/o Li_2CO_3-31.5 m/o Na_2CO_3, and 25 m/o K_2CO_3 with both nickel and cobalt anodes. The higher α_A and i_o values found for nickel and cobalt compared with those found for gold may indicate that stable surface oxide species may be responsible for the enhanced kinetics in the former two anode materials.

Comparison of the ionic conductivities at 600°C for all three melts gives values of 1.20 Ω^{-1} cm^{-1}, 1.15 Ω^{-1} cm^{-1}, and 1.79 Ω^{-1} cm^{-1} for, respectively, the Li/Na/K, Li/K, and Li/Na melts. If ionic conductivity were the only consideration, then clearly the Li/Na melt would be favored. This melt, however, does not have such favorable kinetics as the ternary melt.

From a consideration of gas solubility of the three candidate melts, the highest values for both fuel and oxidant appear to occur in the ternary melt (20, 21), thereby possibly giving higher limiting current density values than the other two candidates. Some work has been reported (22) on the expected lifetimes of each of these melts, based upon projected carbonate vaporization losses and the corresponding extrapolated cell lifetimes. For the Li/Na/K, Li/K, and Li/Na carbonate melts at 600°C, projected cell lifetimes were, respectively, 6.4×10^5, 6.3×10^5, and 10.3×10^5 hr. Clearly, the Li/Na melt has a 40% greater projected lifetime compared with the other two melts.

The Li/Na/K melt is worthy of further consideration because of a higher fuel and oxidant solubility, faster electrode reactions for fuel oxidation, and, particularly, because its lower melting point, compared with the other two candidates, offers the possibility of operating the molten carbonate fuel cell at temperatures somewhat below the normal operating temperature of 650°C. This lower operating temperature may not only extend the electrolyte tile life, but also that of the other fuel cell components. The relatively low activation energy values ($\simeq$7 kcal/mole) from the ternary melt, using both nickel and cobalt electrodes, also acts as further encouragement for low operating temperatures without sacrificing too much kinetic performance for the fuel oxidation reaction. However, at lower operating temperatures, diffusional factors may become predominant under the probable mixed-control conditions present.

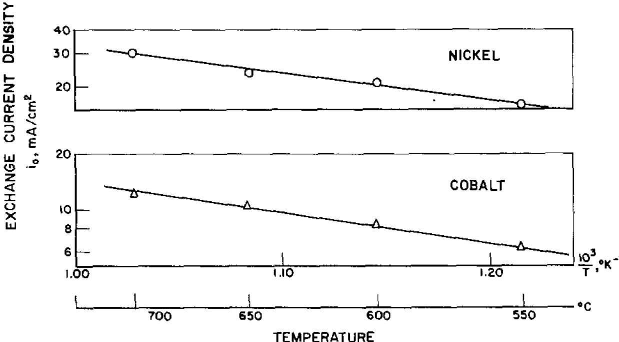

Fig. 13. Dependency on temperature of i_o values obtained using transient potentiostatic measurements (nickel and cobalt electrodes in low-BTU fuel).

Electrochemistry of Uranium (IV) in Acidic $AlCl_3$-NaCl Melts at 175°C

F. Meuris, L. Heerman, and W. D'Olieslager

Laboratorium voor Radiochemie, Katholieke Universiteit te Leuven, Celestijnenlaan 200 F, 3030 Heverlee, Belgium

ABSTRACT

Solutions of uranium (IV) in acidic $AlCl_3$-NaCl melts (52-70 mole percent $AlCl_3$) at 175°C were prepared by dissolving uranium (IV) oxide or chloride. The electrochemistry of uranium (IV) in these melts, investigated by pulse polarography and cyclic voltammetry, corresponds to two reversible one-electron reactions. For the U(IV)/U(III) redox couple, the reaction is given by

$$UCl_x^{(4-x)+} + e^- \rightarrow U^{3+} + xCl^-$$

where $3 \geq x \geq 1$, the lower values of x being found for the most acidic melts. Thus, uranium (IV) exists in solution as UCl_3^+, UCl_2^{2+}, and UCl^{3+}. For the U(V)/U(IV) redox couple, the reaction is written as

$$UCl_y^{(5-y)+} + e^- \rightarrow UCl_x^{(4-x)+} + (y-x)Cl^-$$

where $(y - x) = 3$ over almost the entire pCl range covered in this work. Therefore, the uranium (V) species in solution are formulated as UCl_6^-, UCl_5, and UCl_4^+. However, since some oxide impurities are probably always present in molten chloroaluminates, the existence of a $UOCl_y^{(3-y)+}$ species cannot be totally excluded.

The electrochemical behavior of uranium (IV) oxide (UO_2) and uranium (VI) oxide (UO_3) in the NaCl-saturated $AlCl_3$-NaCl melt at 175°C was reported previously (1). This paper reports some results on the electrochemistry of uranium (IV) in acidic melts [52-70 mole percent (m/o) $AlCl_3$] at the same temperature. Morrey (2) investigated the absorption spectrum of UCl_4 in $AlCl_3$-KCl melts and concluded that his data are consistent with the postulate that the species is $U(AlCl_4)_x^{(4-x)+}$ (such as $U(AlCl_4)_6^{2-}$; the coordination number of the uranium species is six or less) is present in solutions containing an excess of $AlCl_3$. The same author also determined the solubility of UCl_4 in $AlCl_3$-KCl melts as a function of the temperature (250°-400°C). A rough extrapolation of the data given in his paper indicates a solubility of approximately 2×10^{-2}M (after conversion from mole fraction to molar concentrations) for a melt with a 55 m/o $AlCl_3$-45 m/o KCl composition at 175°C. In this work, solutions of uranium (IV) were prepared by dissolving either uranium (IV) oxide (UO_2) or uranium (IV) chloride (UCl_4) and it was found possible to use concentrations as high as 4×10^{-2}M, at least in more acidic solutions.

Experimental

All experiments were carried out in Pyrex glass cells (with a tight fitting Teflon top) (3) under a purified nitrogen atmosphere (VAC dry box equipped with a Model HE-493 Dri-Train for constant recirculation of the inert gas through a column of activated copper and molecular sieves). A homemade proportional temperature controller with a Chromel-Alumel Pyrex-sheathed thermocouple was used to maintain the temperature of the melts at 175° ± 1°C.

The NaCl-saturated $AlCl_3$-NaCl melt was prepared and purified by the procedure described by Boxall *et al.* (3). The melts were acidified by adding solid $AlCl_3$ (Fluka AG; puriss.) which was purified by sublimation in sealed glass ampuls (samples which remained colored after sublimation were rejected). The pCl of the melts was calculated from the potential of an aluminum wire electrode (Alfa Inorganics; m5N) using the equilibrium constants given by Boxall *et al.* (4).

The working electrodes used for cyclic voltammetry and pulse polarography were made by sealing a 3 mm diam tungsten rod (Alfa Inorganics; m3N8) or a glassy carbon rod (Le Carbone-Lorraine) in a Pyrex glass tube. A tungsten foil electrode (3 × 3 cm; Alfa Inorganics; m3N8) was used for the coulometry experiments. The reference electrode was a 1 mm diam aluminum wire spiral placed in a separate compartment with a leak-free ceramic filter tip. The reference electrode compartment was filled with a NaCl-saturated $AlCl_3$-NaCl melt. The potential of this reference electrode against an aluminum electrode in a 1:1 melt (50 m/o $AlCl_3$) was calculated as −0.176V and corresponds well with the value quoted by Bartak and Osteryoung (5), −0.175 ± 0.001V [for the calculation, the composition of the NaCl-saturated melt was taken as 49.75 m/o $AlCl_3$ (6)]. The aluminum counterelectrode was also placed in separate compartment.

Uranium (VI) oxide (UO_3), uranium (IV) oxide (UO_2), and uranium (IV) chloride (UCl_4) (all obtained from Alfa Inorganics) were used as received. The uranium content of the melts was determined by standard analytical procedures and converted to

Key words: uranium, fused salts, $AlCl_3$-NaCl melt, pulse polarography, cyclic voltammetry.

molar concentrations using the density data of Fannin *et al.* (7).

A PAR Model 173/176 potentiostat, a PAR Model 175 function generator, and a Houston Model 2000 X-Y recorder were used for cyclic voltammetry. A PAR Model 379 digital coulometer was used for controlled-potential coulometry. A Tacussel unit UAP-4 was used for pulse polarography. Potentials were measured with a Beckman Model 4500 digital pH meter.

Results and Discussion

Experiments with solutions of uranium (IV) oxide (UO_2).—The cyclic voltammograms of uranium (IV) oxide solutions for different melt acidities, shown in Fig. 1, exhibit two well-defined reduction-oxidation waves (peaks A/A' and B/B'). Controlled-potential coulometry at 1.1V indicates a one-electron reduction ($n = 1.01 \pm 0.04$) and, therefore, peaks A/A' are attributed to the U(IV)/U(III) redox couple.

The separation between the cyclic voltammetric peaks, approximately 0.090V, is very close to its theoretical value (0.086V) and is independent of the scan rate, as is expected for a reversible electrode reaction (results obtained with either tungsten or glassy carbon electrodes are identical). The peak potentials shift toward more positive values as the acidity of the melt is increased, but quantitative data on this point are given in a separate section. The peak heights ($i_p^A/i_p^{A'} \cong 1$) increase linearly with $v^{1/2}$ (v = scan rate; 0.020-0.400 V/sec) and with the concentration ($0.93\text{-}4.25 \times 10^{-2}$M). Furthermore, the peak heights are independent of the acidity of the melt.

The second reduction-oxidation wave, peaks B/B', is observed at rather positive potentials, very close to the potential limit of the solvent. For this reason, only the height of the anodic peak B' can be measured accurately (and then only if the acidity of the melt is not too high). This peak has almost the same height as peaks A/A' and, therefore, peaks B/B' are attributed to the U(V)/U(IV) redox couple.

The peak separation is again independent of the scan rate and close to its theoretical value for a reversible one-electron process. Solutions of uranium (V) can be prepared by the controlled-potential oxidation of uranium (IV) solutions but some evolution of chlorine is difficult to avoid at the positive potentials necessary for the reaction to be complete.

A normal pulse polarogram and a differential pulse polarogram of a uranium (III) solution (prepared by the controlled-potential reduction of uranium (IV)) are shown in Fig. 2. The plots of log ($i/i_d - i$) *vs.* E, shown in Fig. 3, have slopes of 0.088V for the U(IV)/U(III) couple and 0.085V for the U(V)/U(IV) couple,

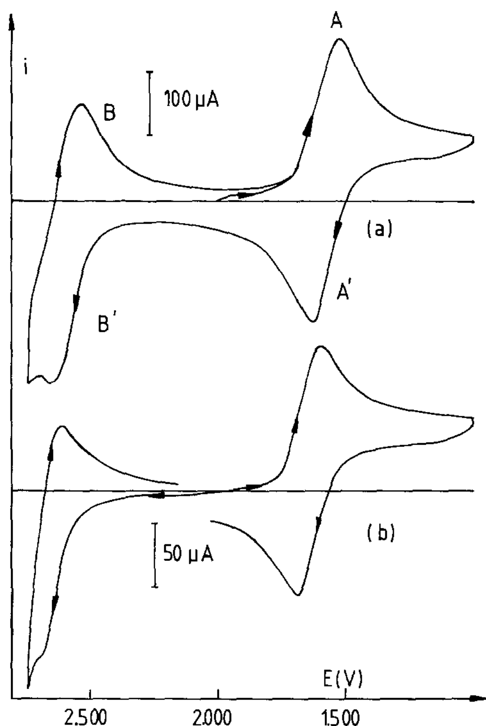

Fig. 1. Cyclic voltammogram of uranium (IV) oxide solution. Area of tungsten indicator electrode = 7.07 mm². Scan rate = 0.1 V/sec. (a) Mole percent $AlCl_3$ = 59.0; uranium concentration = 3.13×10^{-2} mole/liter, (b) m/o $AlCl_3$ = 65.0; uranium concentration = 1.63×10^{-2} mole/liter.

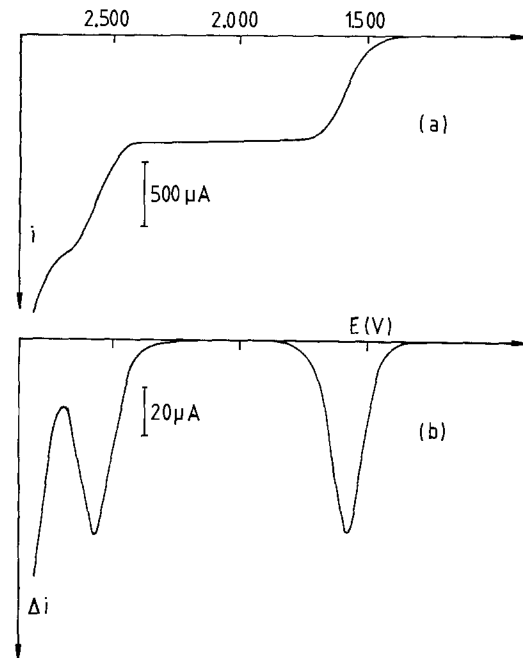

Fig. 2. Normal pulse polarogram (a) and differential pulse polarogram (b) of uranium (III) solution. Area of tungsten indicator electrode = 7.07 mm². Scan rate = 2 mV/sec. Mole percent $AlCl_3$ = 59.2. Uranium concentration = 2.88×10^{-2} mole/liter. Normal pulse polarogram: pulse width = 50 msec; pulse delay = 200 msec; current sampling = 80-85%. Differential pulse polarogram: pulse width = 50 msec; pulse delay = 300 msec; current sampling = 40-60%; pulse amplitude = 10 mV.

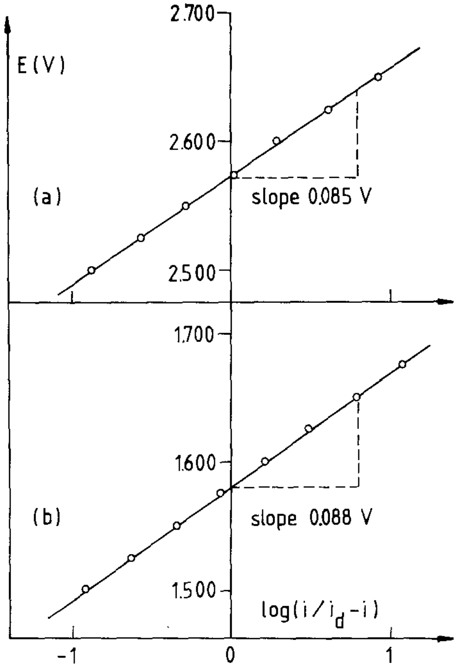

Fig. 3. Logarithmic analysis of the normal pulse polarogram of Fig. 2. (a) U(V)/U(IV) wave, (b) U(IV)/U(III) wave.

indicating the reversibility of the electrode reactions (the Nernst slope for a one-electron process is 0.089V at 175°C). The peak heights determined from differential pulse polarography increase linearly with the concentration and with the pulse amplitude as is shown in Fig. 4. From the data of this figure, the diffusion coefficient of the uranium (IV) species was calculated as $D = 2.98 \pm 0.24 \times 10^{-6}$ cm²/sec (cyclic voltammetry gives $D = 2.85 \pm 0.30 \times 10^{-6}$ cm²/sec; since $i_p^A/i_p^{A'} \cong 1$, the diffusion coefficient of the uranium (III) species has approximately the same value).

Experiments with solutions of uranium (IV) chloride (UCl_4).—A series of experiments was performed with solutions of uranium (IV) chloride. The cyclic voltammogram of such a solution, shown in Fig. 5, exhibits the same reduction-oxidation waves as described in the preceding section. It turns out indeed that the results obtained with solutions of uranium (IV) chloride and uranium (IV) oxide are identical. This indicates that the same uranium species (for the different oxidation states participating in the electrode reactions) are present in solution, irrespective of whether the solutions are prepared by dissolving either the oxide or the chloride.

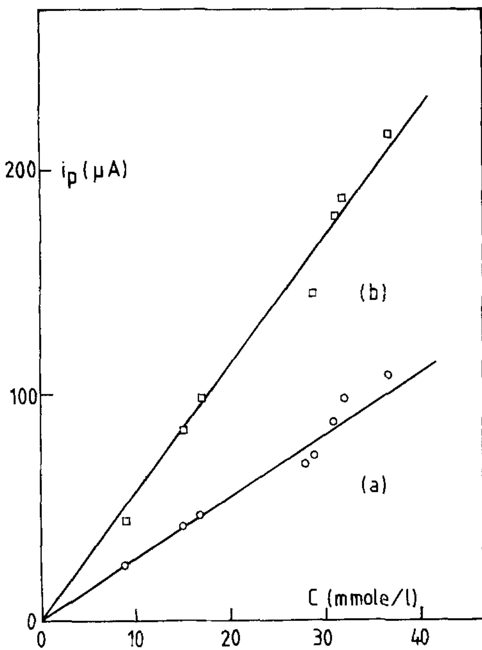

Fig. 4a. Peak height of differential pulse polarograms vs. uranium (IV) oxide concentration for the U(V)/U(IV) wave. Pulse amplitude = 10 mV (a) 20 mV (b). Other conditions as for Fig. 2.

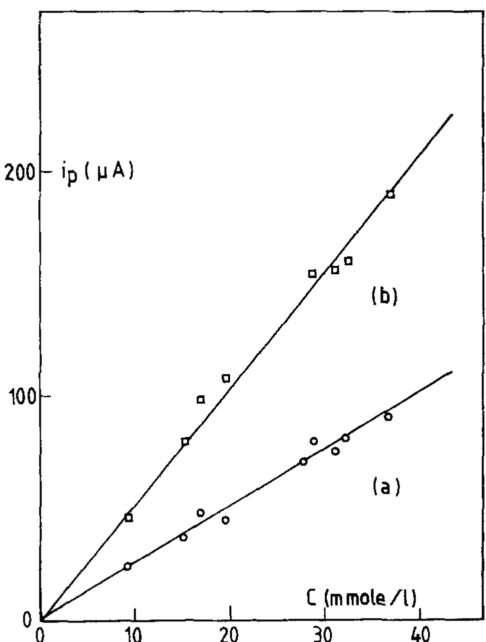

Fig. 4b. Peak height of differential pulse polarograms vs. uranium (IV) oxide concentration for the U(IV)/U(III) wave. Pulse amplitude = 10 mV (a) 20 mV (b). Other conditions as for Fig. 2.

Experiments with uranium (VI) oxide (UO_3).—Uranium (VI) oxide (UO_3) reacts with the melt to give solutions of uranium (V) as can be expected from the results presented in the preceding sections. Normal and differential pulse polarograms of the resulting solution are shown in Fig. 6 (these polarograms were recorded approximately 90 min after adding uranium (VI) oxide to the melt). The waves for the reduction of uranium (V) to uranium (IV) and uranium (III) are already described in the preceding section. However, an additional wave is observed at about 1.87V (for the polarograms of Fig. 6). This wave is much higher when a polarogram is recorded

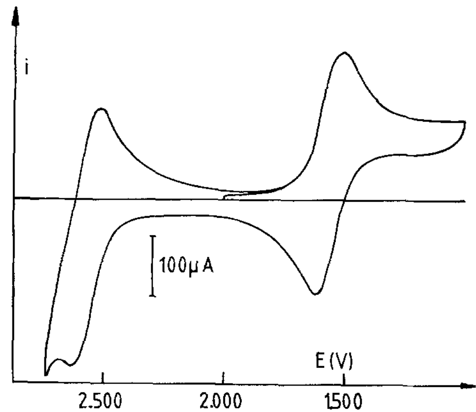

Fig. 5. Cyclic voltammogram of uranium (IV) chloride solution. Area of tungsten indicator electrode = 7.07 mm². Scan rate = 0.1 V/sec. Mole percent $AlCl_3$ = 58.5. Uranium concentration = 3.00 × 10^{-2} mole/liter.

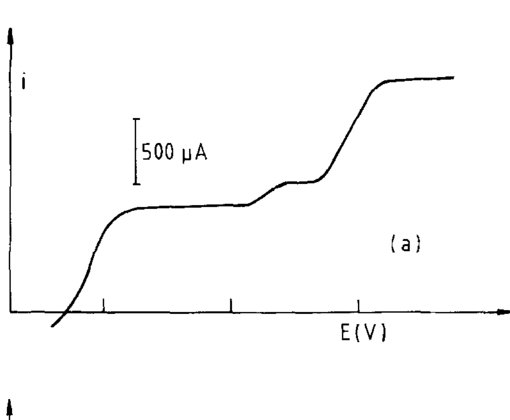

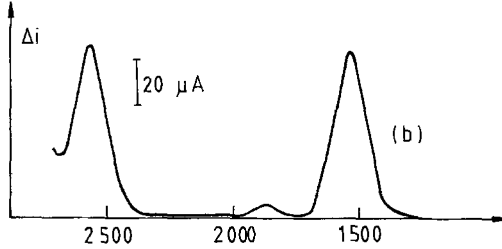

Fig. 6. Normal pulse polarogram (a) and differential pulse polarogram (b) recorded approximately 90 min after the addition of uranium (VI) oxide to the melt. Mole percent $AlCl_3$ = 56.8. Uranium concentration = 2.79 × 10^{-2} mole/liter. Other conditions as for Fig. 2.

immediately after adding uranium (VI) oxide to the melt but decreases rapidly with time and finally disappears completely. Therefore, it is believed that this wave is due to the reduction of a product formed in the reaction between UO_3 and the melt. However, because of its transient nature, this species has not been identified.

Effect of melt composition on half-wave potentials.— Nernst plots constructed from potential measurements during the controlled-potential reduction or oxidation of uranium (IV) solutions are shown in Fig. 7. The standard potentials determined from these measurements and the half-wave potentials obtained from differential pulse polarography and cyclic voltammetry are plotted *vs.* pCl (molar fraction scale) in Fig. 8 and 9 for the U(IV)/U(III) and U(V)/U(IV) redox couples, respectively. The values obtained with either uranium (IV) oxide or uranium (IV) chloride solutions fit nicely on the same lines for both redox couples. Numerical data are given in Table I.

Poturaj-Gutniak (8) concluded from spectral data that uranium (III) exists in acidic $AlCl_3$-NaCl melts either as U^{3+} or as a chlorocomplex (he formulated the species quite generally as $U(Al_2Cl_7)_nCl_{3-n}$; for the sake of brevity, solvation by $Al_2Cl_7^-$ ions is omitted further in this paper). Gilbert *et al.* (9) studied the precipitation of uranium (III) and uranium (IV) from acidic $AlCl_3$-NaCl melts at 175°C by cyclic voltammetry and pulse polarography and concluded that the reactions are given by

$$U^{3+} + 3Cl^- \rightarrow UCl_3 \text{ (solid)} \quad [1]$$

$$UCl_3^+ + Cl^- \rightarrow UCl_4 \text{ (solid)} \quad [2]$$

According to these authors (9), the differences observed by Morrey (2) between the spectrum of uranium (IV) in basic and acidic chloroaluminate melts can be accounted for by the transition from UCl_6^{2-} to UCl_3^+ species.

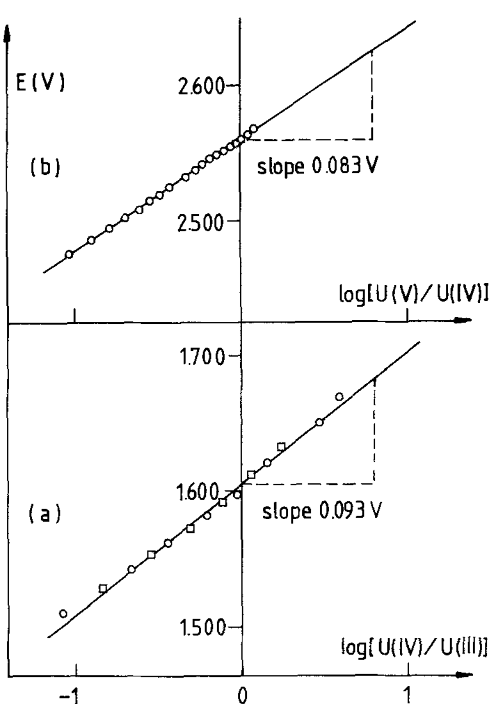

Fig. 7. Nernst plot obtained from potential measurements during the coulometric titration of uranium (IV) oxide solutions. (a) Reduction of uranium (IV) solutions (circles) and reoxidation of the reduced solution (squares); m/o $AlCl_3$ = 61.4; uranium concentration = 2.29×10^{-2} mole/liter. (b) Oxidation of uranium (IV) solution (the potential was kept constant during the oxidation at a value slightly more positive than the half-wave potential of the U(V)/U(IV) wave; m/o $AlCl_3$ = 58.2; uranium concentration = 1.57×10^{-2} mole/liter.

If one accepts that uranium (III) exists in solution as the U^{3+} ion, then the electrode reaction for the U(IV)/U(III) couple can be written as

Table I. Half-wave potentials of the U(V)/U(IV) and U(IV)/U(III) redox couples in acidic $AlCl_3$-NaCl melts at 175°C (a)

(g) From differential pulse polarography of uranium (IV) chloride solutions.

$$UCl_x^{(4-x)+} + e^- \rightarrow U^{3+} + xCl^- \quad [3]$$

The slope in Fig. 8 diminishes from approximately 0.267V ($x = 3$) to 0.089V ($x = 1$) as the acidity of the melt increases in the range $6.1 \leq pCl \leq 7.8$. The slope of 0.267V, which is obtained as a limiting value for the lowest pCl values used in this work, is in agreement with the work of Gilbert *et al.* (9). Thus, the results reported here confirm the existence of UCl_3^+ in the less acidic solutions used in this work (just before the precipitation of UCl_4). In the more acidic region, however, the species in solution must be formulated as UCl_2^{2+} and UCl^{3+}. It is perhaps worthwhile to note that a vapor complex between uranium tetrachloride and aluminum chloride, $UCl_2(AlCl_4)_2$, has been described by Gruen and McBeth (10, 11).

The electrode reaction for the U(V)/U(IV) redox couple can be written similarly as

$$UCl_y^{(5-y)+} + e^- \rightarrow UCl_x^{(4-x)+} + (y-x)Cl^- \quad [4]$$

The slope in Fig. 9 is 0.267V ($y - x = 3$) in the range $6.1 \leq pCl \leq 7$ and diminishes somewhat as the acidity of the melt is increased. The uranium (V) species in solution can then be formulated as UCl_6^-, UCl_5, UCl_4^+, and UCl_3^{2+} (with increasing acidity of the melt). However, since some oxide impurities are probably always present in molten chloroaluminates (12), reactions such as

$$UO_2Cl_y^{(1-y)+} + 2AlCl_4^- + e^- \rightarrow UCl_x^{(4-x)+} + 2AlOCl + (6+y-x)Cl^- \quad [5]$$

and

$$UOCl_y^{(3-y)+} + AlCl_4^- + e^- \rightarrow UCl_x^{(4-x)+} + AlOCl + (3+y-x)Cl^- \quad [6]$$

cannot be excluded *a priori* [AlOCl is the aluminum oxochloro complex most likely present in acidic melts (13)]. The variation of the half-wave potentials expected for reaction [5] ($dE_{1/2}/dpCl = 6 + y - x$) is much greater than was actually found in the experiments. On the same basis, however, reaction [6] and thus the existence of $UOCl_y^{(3-y)+}$ species cannot be totally excluded. Nevertheless, the existence of uranium (V) chloro complexes is not altogether unexpected. A vapor complex between uranium pentachloride and aluminum chloride, formulated as $UCl_5 \cdot AlCl_3$, has been described by Gruen and McBeth (11). Furthermore, UCl_6^- is a well-known species in a number of nonaqueous solvents. For example, solutions of UCl_6^- in thionyl chloride are readily obtained by dissolving uranium trioxide in the refluxing solvent (14, 15); these solutions are quite stable toward hydrolysis and/or disproportionation (16) and a number of hexachloro-uranates (V), $MUCl_6$, can be obtained from these solutions (15, 17). Since the spectrum of UCl_6^- is well-known (18), spectroscopic measurements would be helpful to confirm the existence of the uranium (V) species postulated in this paper.

Fluoride Electrodes with Reversible Solid-State Contacts

T. A. Fjeldly* and K. Nagy

Electronics Research Laboratory and Division of Applied Chemistry, SINTEF, The University of Trondheim, The Norwegian Institute of Technology, N-7034 Trondheim—NTH, Norway

ABSTRACT

Fluoride-selective LaF_3 membranes with reversible solid-state contacts have been prepared as layered structures of LaF_3, AgF, and Ag. In this report the preparation and properties of such contacts are discussed. All-solid-state fluoride electrodes with the present membrane structures have been tested, and the results compare favorably with those of conventional electrodes with internal filling solution.

With the advance of microelectronic techniques in the manufacture of ion-selective electrodes, a growing need for suitable solid-state inner membrane contacts has emerged. Solid contacts are more compatible with microelectronic manufacturing techniques than the conventional solution contacts, but also offer advantages in terms of miniaturization and electrode ruggedness, and permit the construction of electrodes that can withstand high temperature and pressure (*i.e.*, autoclaving).

In order to achieve the desired electrode quality in terms of sensitivity, response time, and stability, it is essential to use reversible membrane contacts. Reversibility is assured when a unique electrode reaction occurs when the electrode operates as an anode, and the inverse of the same reaction takes place when it operates as a cathode. Furthermore, at zero current, the contacted materials should be in thermodynamic equilibrium (1). Thus, nonreversibility does not assure thermodynamic equilibrium, and long-term potential drift can generally be expected (2). These effects depend on the rate of relaxation processes, for instance at the blocked interface between an electronic and an ionic conductor (3). In the basic ISFET (ion sensitive field effect transistor), like in conventional glass membranes, deviation from thermodynamic equilibrium within the membranes is responsible for increased response time (4). With a regular MOSFET (metal oxide field effect transistor) connected properly to an ion-selective membrane (4-6), the potential gradient across the oxide layer also represents a lack of thermodynamic equilibrium, but here the relaxation processes proceed extremely slowly and will normally not interfere with the measurements.

For the case of a solid junction between an electronic and an ionic conductor, reversibility is normally achieved when the parent metal M is in contact with a solid electrolyte MX. The reversible reaction taking place at the interface is then

$$MX + e^- \rightleftarrows M + X^- \qquad [1]$$

Other metal contacts are also possible provided their salt formation free energies are positive relative to the parent metal (7). Thus, the construction of proper contacts is straightforward in the case of the silver salt membranes (5, 7), where silver metal is conveniently used.

Similarly, the natural choice in the case of LaF_3 appears to be lanthanum metal. However, this material is difficult to handle since it oxidizes rapidly in air. Accordingly, the fabrication of such contacts will have to involve either a multilayer vacuum-deposited thin film structure, where the lanthanum is sealed from contact with air, or possibly the use of a lanthanum amalgam.

Another approach, which is the one used here, is to consider the LaF_3 as an ordinary electrolyte and construct a proper compound electrode of the second kind with which to contact it. The most obvious choice seems to be the structure (6)

$$Ag \mid AgF \mid LaF_3 \qquad [2]$$

which has the overall reversible reaction

$$AgF + e^- \leftrightarrows Ag + F^- \qquad [3]$$

In this case F^- ions are exchanged reversibly at the AgF-LaF_3 interface and electrons are exchanged reversibly at the Ag-AgF interface, as indicated in Fig. 1. The particular advantage of the Ag-AgF contact is that AgF itself is an Ag^+ ionic conductor (8), assuring a reasonably low overall ohmic resistance in the system. In this paper special attention has been given to the preparation and properties of this particular contact. But, other systems of the basic design, *i.e.*

$$M_1 \mid M_1X \mid M_2X \mid \qquad [4]$$

are also possible. Thus, contacts were also constructed based on a layered structure with Cu and $CuF_2 \cdot 2H_2O$. Recently a Czech patent appeared, reporting the use of a Bi-BiF_2 contact (9).

Preparation of the Contacts

In a first attempt at constructing an Ag-AgF contact on LaF_3, a near-saturated solution of AgF was applied

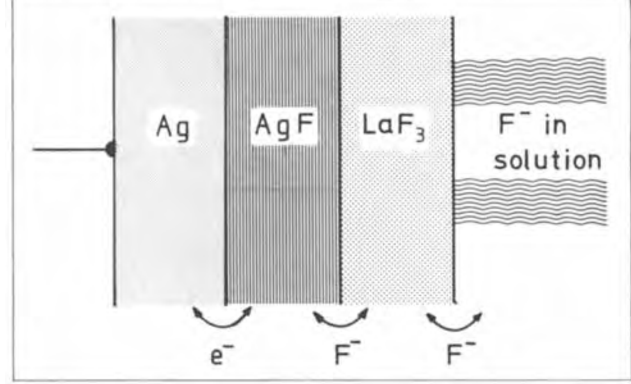

Fig. 1. Structure of the reversible solid-state contact on LaF_3

* Electrochemical Society Active Member.

Key words: ion-selective electrodes, contacts.

dropwise to the membrane surface. The water was evaporated by gently heating the membrane. Finally, a silver conducting epoxy contact was applied. All-solid-state ion-selective electrodes based on such membrane structures at first performed quite satisfactorily, but after a few days the contact deteriorated, presumably due to residual water left in the hygroscopic AgF.

By a similar procedure, $Cu\text{-}CuF \cdot 2H_2O$ contacts were also prepared, *i.e.*, by heating drops of $CuF \cdot 2H_2O$ solution to dryness on the surface of LaF_3. In this case the outer contact consisted of silver conducting epoxy admixed with copper metal powder. Solid-state ion-selective electrodes prepared from these structures performed satisfactorily for months, but eventually also deteriorated, for reasons unknown.

Satisfactory contacts were prepared by again turning to AgF. This time AgF, admixed with small amounts of LaF_3 (both Lab. grade chemicals from Merck), were melted on the surface of LaF_3 membranes at a temperature of about 450°C. This procedure served a dual purpose: a high quality fused contact was established and, at the same time, water was effectively expelled from the AgF. This process required great care, and the melting had to be performed in an inert, dry atmosphere in order to avoid excessive decomposition of AgF through the reaction path (10)

$$2AgF + H_2O \rightarrow Ag_2O + 2HF \quad [5]$$

$$Ag_2O \rightarrow 2Ag + \tfrac{1}{2} O_2 \quad [6]$$

Apparently, some reduction of silver still took place, and in a separate analysis on the contacts, about 80% water soluble fluoride was found to be retained through the melting. Metallic silver is therefore probably disperged throughout the AgF.

Immediately upon cooling, the AgF was sealed by the application of a silver-conducting paint or epoxy, which also served to complete the contact.

The properties of the melted junctions were tested electrically and evaluated after incorporation into solid-state ion-selective electrodes. For the electrical measurements LaF_3 specimens with symmetrical, double-sided contacts were prepared. For comparison, similar structures with blocked silver contacts and with conventional solution contacts were also tested. The contact areas were in all cases about 10 mm^2.

Electrical Measurements

Electrical properties such as the frequency-dependent admittance and the low frequency current-voltage characteristics were measured with the symmetrically connected LaF_3 specimens.

Complex impedance and admittance plots have been shown to be useful for determining the equivalent circuit for electrochemical systems (11-14). In the present case, similar measurements are useful to determine the electrical properties of the contacts. The complex admittance $Y(\omega)$ (ω is the angular frequency) of a system is the inverse of the impedance $Z(\omega)$, and may be written as

$$Y(\omega) = G(\omega) + jB(\omega) \quad [7]$$

The real part, $G(\omega)$, is the conductance and the imaginary part, $B(\omega)$, is the susceptance.

Figure 2 shows an admittance plot for the $Ag\text{-}AgF\text{-}LaF_3\text{-}AgF\text{-}Ag$ structure, measured in the frequency range 50 Hz to 4 MHz. The measurements were mostly performed with automatic LCR meters of the type: Hewlett-Packard Models 4275A and 4261A. The data points below about 100 kHz can be fitted with the arc of a circle centered slightly below the conductance axis.

Since the effects of the contacts and of the membrane substrate can be regarded as sequential physical processes, the consistent choice of an equivalent circuit requires that appropriate network elements be coupled in series (11). To a good approximation each such element can be represented by a resistance and a capacitance in parallel. At high frequencies the whole sequence will be shorted by the geometric capacitance. Based on such a model the admittance plot of the present sample suggests an equivalent circuit as shown in Fig. 2. The upper circuit branch, which contains a resistance in series with a parallel R-C network, gives rise to a semicircle centered somewhere along the positive conductance axis. The sharp increase in the susceptance at high frequencies results from C_0, a lumped combination of geometric and stray capacitance, represented by the lower branch of the equivalent circuit. In terms of the present structure it seems reasonable to associate the parallel R-C network in the upper branch with the two identical contacts (here lumped together for simplicity), while the series resistance is that of the LaF_3 substrate. There is no measurable parallel-capacitance within the substrate. Such capacitance is often associated with grain boundaries in polycrystalline samples (11), and is not to be expected in the present LaF_3 single crystals.

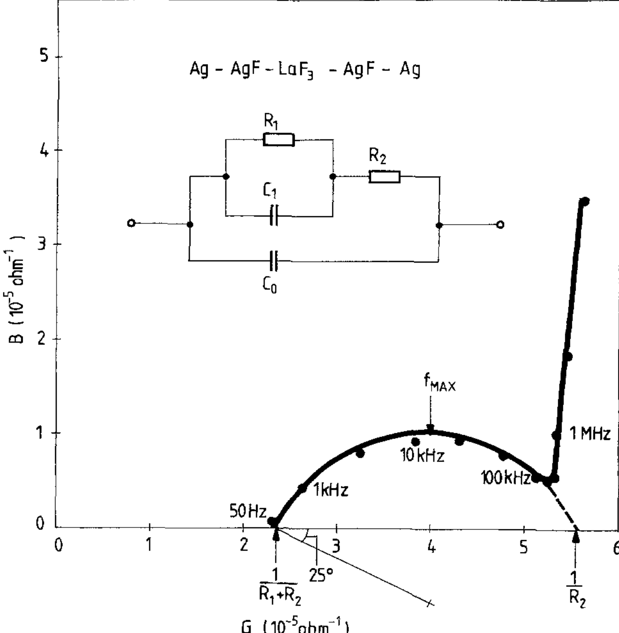

Fig. 2. Admittance plot for an LaF_3 membrane with symmetric Ag-AgF contacts. Dots indicate measured admittance at the frequency 50 Hz (curve tracer) and between 1 kHz and 4 MHz (LCR meters).

As noted, the admittance arc of Fig. 2 was depressed somewhat below the ideal semicircle of the suggested equivalent circuit, indicating that the present model for the contacts may be too simple. A more complete model should incorporate the fact that each contact possesses two interfaces, one at either side of the AgF-layer. Furthermore, the material boundaries are not well defined, both as a result of partial reduction of AgF to metallic silver, and because of the fused junction between AgF and LaF_3. Thus, at the next level of refinement the equivalent circuit model for the contacts should contain three R-C parallel circuits in series which, along with possible nonsymmetry in the system, would account for the observed distortion in the admittance plot. But numerical values for the electrical parameters can only be obtained for the simplest circuit model, for which a resultant ohmic resistance of $R_1/2 \simeq 12$ kΩ, and an effective parallel capacitance of $2C_1 \simeq 2.5$ nF are found for each contact. The series resistance of the 2 mm thick LaF_3 substrate is determined to be $R_2 \simeq 18$ kΩ.

The main source of the ohmic contact resistance is probably the overall electrode reaction of Eq. [3]. The ohmic resistance in the thin (~0.05 mm) AgF layer is expected to be quite negligible (8). The parallel capacitance probably originates at the smeared out material interfaces of the contacts.

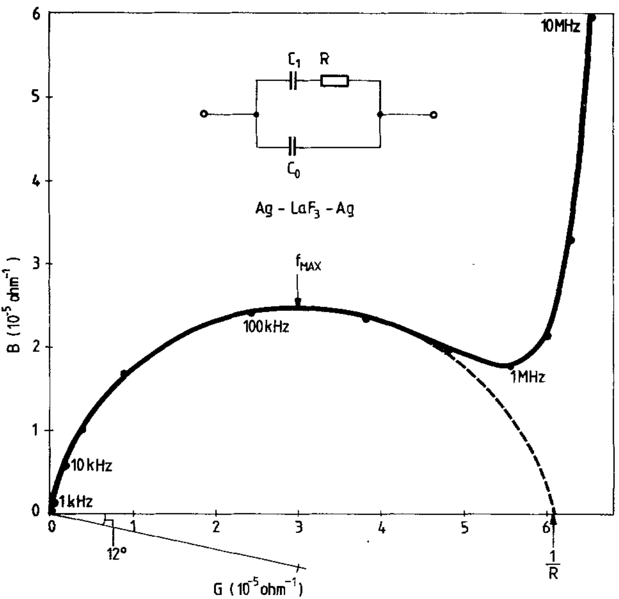

Fig. 3. Admittance plot for an LaF_3 membrane with symmetric silver contacts. Dots indicate measured admittance at frequencies between 120 Hz and 10 MHz (LCR meters).

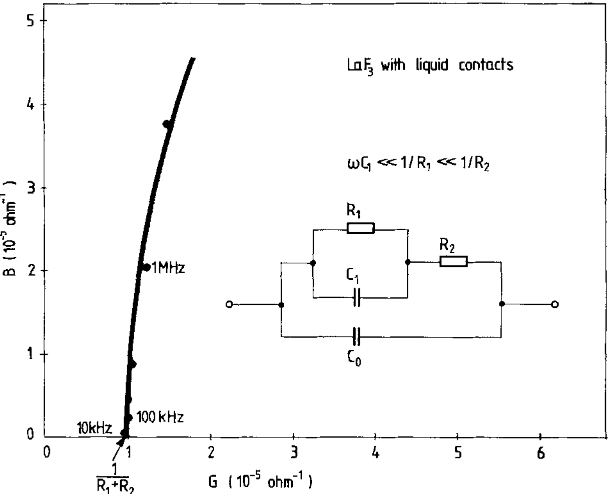

Fig. 4. Admittance plot for an LaF_3 membrane with liquid contacts (see text). Dots indicate measured admittance at frequencies between 10 kHz and 2 MHz (LCR meters).

Figure 3 shows the admittance plot for an LaF_3 substrate with blocked silver contacts. Qualitatively, this plot looks very much like the foregoing, except for the notable difference that the low frequency portion of the arc now passes through the origin. This suggests a similar equivalent circuit as before, but this time with negligible conductance in the contacts. The relative simplicity of the resulting circuit yields a particularly straightforward expression for the admittance behavior

$$B = \frac{C_0}{C_1}\left(\frac{G/R}{1 - GR}\right)^{1/2} + \left[\frac{G}{R}(1 - GR)\right]^{1/2} \quad [8]$$

The first term represents the steep increase at high frequencies as G approaches $1/R$, and the second term is the semicircle passing through the origin and with diameter $1/R$. The analysis of the experimental admittance plot yields an ohmic resistance of 16 kΩ for the substrate, in good agreement with the previous result. The relatively high frequency associated with the maximum point of the semicircle yields an effective parallel capacitance per contact of $2C_1 \simeq 0.14$ *n*F $(C_1 = (2\pi R\, f_{max})^{-1})$. The reason for this small value is not immediately obvious, but it may be associated with the use of silver-conducting epoxy for the contacts.

The admittance behavior was also measured for a commercial fluoride electrode with a conventional internal filling solution. The outer surface of the LaF_3 membrane was contacted with a solution of 0.5M NaCl and 0.5M NaF, in which a silver wire electrode was introduced. The resulting admittance plot for this structure is shown in Fig. 4. Presumably, the abrupt increase in the imaginary part of the admittance is again caused by the geometric capacitance. The intercept with the conductance axis suggests a total series resistance of 102 kΩ for the system. Using previous results for the LaF_3 bulk contribution, the effective single contact resistance is found to be about 40 kΩ for this case. At the frequencies considered, the effective parallel capacitance of the contacts appears to be quite small $(C_1 << [R_1\omega(10\ \text{kHz})]^{-1} \simeq 0.1$ *n*F). There has been some speculation on the possible formation of a gel layer on the surface of LaF_3 exposed to aqueous solutions (15). If so, this will have a significant bearing on the extent of the effective width of the interfacial space charge, and tend to reduce the double layer capacitance. On the other hand, a large interfacial capacitance will represent a short at the frequencies considered, and may instead combine with Warburg behavior to produce structure at low frequencies (16).

In applications, the low frequency behavior of the membrane structure is of particular interest, since it governs the electrode response times typically of interest in practical analysis. As an illustration of this behavior, Fig. 5 shows a 50 Hz curve tracer (Tektronix, Type 576) current-voltage characteristic for each of the three membrane structures discussed above. In general, the shape of the loop reflects the relative size of the real and the imaginary parts of the admittance. Thus, the loop degenerates into a straight line when the admittance is purely real and nonrectifying, *i.e.*, when the contacts are truly ohmic. It is interesting to note that the membranes with Ag-AgF and liquid contacts both give rise to similar, near degenerate loops while the blocked silver contacts produce a pronounced, elliptical shape.

Solid-State Fluoride Electrodes

Solid-state fluoride electrodes were prepared in two versions, one with a microelectronic impedance transforming network contained within the sensor body, and one with a direct electrical connection to an external high impedance voltmeter. The electrodes manufactured according to the microelectronic approach have a single chip preamplification circuit positioned in close proximity to the membrane, in order to reduce noise pick-up. Details of the electrode construction have previously been discussed (5, 6).

The electrodes were evaluated by determining their response in fluoride standards (*i.e.*, potential response *vs.* fluoride concentration), as well as their response time and stability. Lifetime is of vital importance, and is currently being investigated by continuous exposure of electrodes to fluoride solutions. So far, this test has lasted for five months without signs of electrode failure.

In Fig. 6 are shown typical response curves obtained with the present fluoride electrodes. The response was measured by pipetting known additions of NaF standard into stirred buffer solutions of either TISAB or 1M HCl. The curves are in close agreement with theory, with sensitivities of about 59 mV/decade (1M HCl) and 58 mV/decade (TISAB) at 24°C. The logarithmic Nernstian response extends down to about 2×10^{-6}M NaF when using the 1M HCl buffer, and to about 8×10^{-6}M NaF in the TISAB buffer. Both values are in reasonable agreement with the reported solubility of LaF_3 (17), and are in the same range as commercial electrodes with internal filling solution. The higher detection limit in TISAB is presumably the

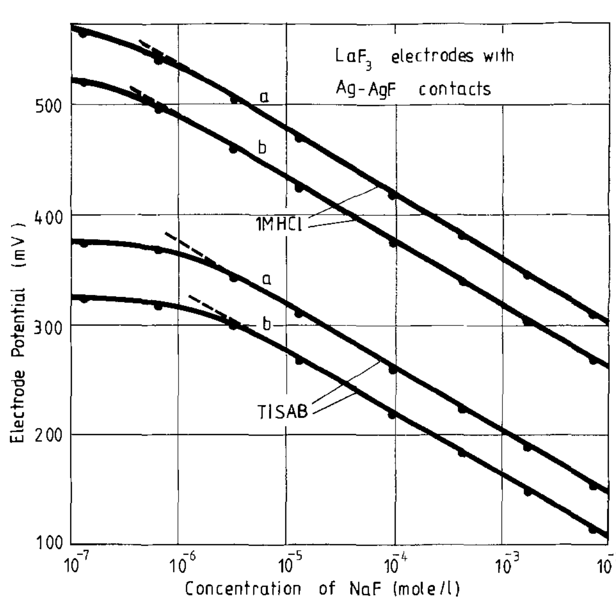

Fig. 6. Calibration curves obtained with LaF_3 electrodes with Ag-AgF contacts. Curves (a) are for electrode with integral impedance transforming network and curves (b) are for electrode with direct electrical connection to an external high impedance voltmeter. Reference electrode: Orion 96-01.

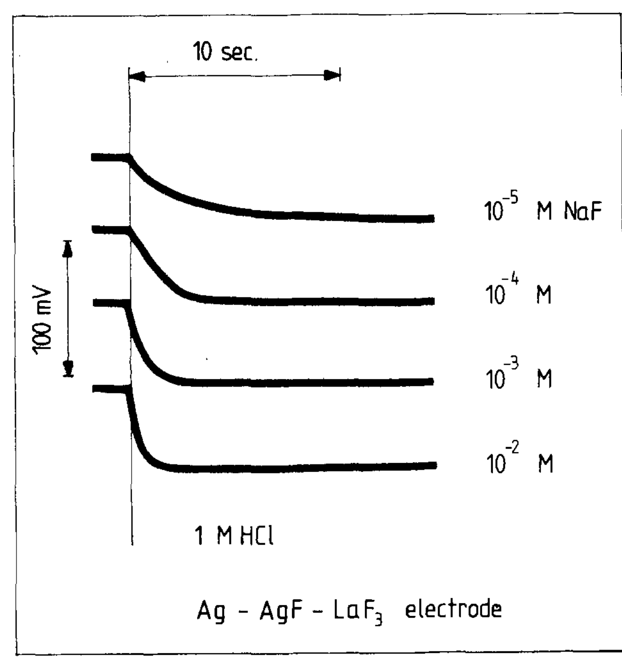

Fig. 7. Total response time of LaF_3 electrode with Ag-AgF contacts and integral impedance transforming network measured in a regular analytical setup (see text).

result of complexing of lanthanum, which is compensated for by increased dissolution of membrane material (18).

The response times of the electrodes were measured both with an injection technique and in a regular analytical setup. With the injection technique the fluoride electrode and a reference electrode were pointed against each other (6). A small drop of an initial solution provided contact between the electrodes, and a new solution with a different fluoride content was rapidly injected into the gap to displace the initial solution. With a suitable trigger arrangement the time response of the system could be monitored on a storage oscilloscope (Tektronix, Type 549). With this technique time constants in the range 20-100 msec, depending on the experimental circumstances, were measured for the present fluoride electrodes as well as for a commercial electrode (Orion, Model 94-09). Further details on these experiments will be published elsewhere (19).

In the regular analytical setup a stirred sample solution (50 ml 1M HCl buffer) was monitored under successive additions of known quantities of NaF. The time response was recorded on an x-t recorder (Watanabe Servo Recorder, Type 652) with a highest recording speed of 0.4 cm/sec. Typical results for a fluoride electrode with the Ag-AgF contact are shown in Fig. 7. For the highest concentrations (accumulated NaF concentration shown to the right) potential stability was achieved within one or two seconds, probably limited by the mixing and reaction times (*i.e.*, $F^- + H^+ \rightleftarrows HF$ and $HF + F^- \rightleftarrows HF_2^-$) in the liquid. Below about 10^{-4}M NaF, however, a steady increase in the response time became evident. It appears that under identical circumstances the present electrodes and the electrode with internal filling solution responded about equally fast (19). In contrast to these results Fig. 8 shows the response of an LaF_3 electrode with a blocked silver contact (3). In this case the response time was typically several minutes and, in addition, a long-term potential drift on the order of millivolts per minute was observed. It is reasonable to assume that this effect is associated with the lack of reversibility at the inner contact. In a comparable time scale (*i.e.*, up to 10 min)

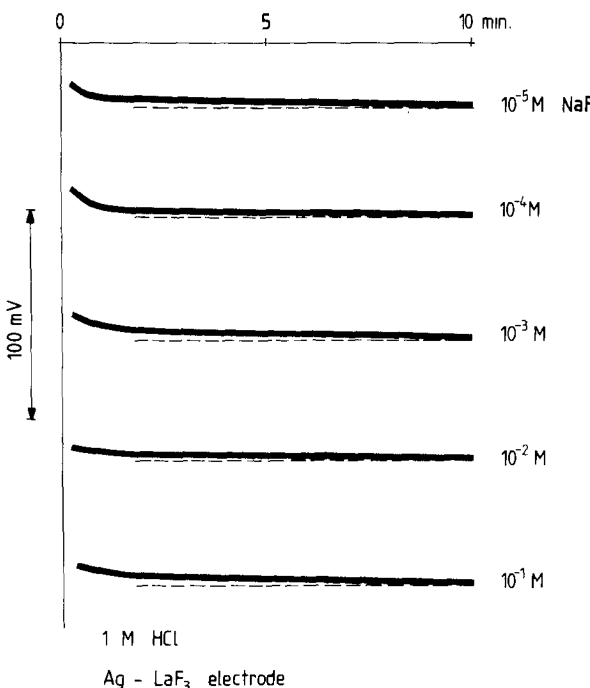

Fig. 8. Total response time of LaF_3 electrode with silver contacts

the potential drift in the Ag-AgF-LaF_3 electrode was an order of magnitude less.

Summary

Reversible solid-state contacts on LaF_3, based on the use of AgF and Ag, have been prepared and tested. The electrical properties of the contacts were investigated by means of the frequency-dependent complex admittance. This yielded values for the effective ohmic resistance (~1.2 kΩ/cm²) and the parallel capacitance (~ 25 nF/cm²) of the contacts. For comparison, similar analyses were also performed on samples with conventional solution contacts and with blocked silver contacts. A low frequency (50 Hz) curve tracer plot indicates that the current-voltage characteristics for both the Ag-AgF contacts and for the solution contacts are almost purely ohmic, *i.e.*, degenerate and nonrectifying.

Fluoride electrodes using the present Ag-AgF solid-state contacts behave very satisfactorily. In tests on sensitivity, response time, stability, and lifetime they compare favorably with commercial solution contact electrodes, while electrodes with blocked silver contacts suffer from increased response time, and lack of long-term stability.

Primary Current Distribution on a Sinusoidal Profile

Peter Fedkiw*

Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27650

ABSTRACT

The primary current distribution at a sinusoidal profile has been solved as a perturbation problem in the amplitude-to-wavelength parameter. The results are also applicable to diffusion-limited reactions on sinusoidal surfaces. The solution for the potential has been developed to the fourth order term. Wagner's solution to this problem can be recovered by including only the first two terms in the perturbation expansion. The expansion technique enables an estimate of the error caused by the neglected terms. The leveling efficiency of a mass-transfer controlled dissolution reaction is predicted to be always less than that given by Wagner's equation. Applications of the perturbation technique to other relevant problems are discussed.

The surface of any real metal on the microscopic scale is not smooth and will contain low and high spots. The greater accessibility to the counterelectrode of the high areas in comparison to the low areas causes these protrusions to preferentially receive more current during an electrochemical reaction. For a metal deposition reaction in the absence of leveling agents these peaks may grow with a consequent increase in surface roughness. It has been proposed that leveling agents induce a smooth metal deposit by preferentially adsorbing and reacting at the high points of the surface and thereby increasing the polarization required for the metal deposition (1-3). In the anodic direction (electropolishing), the high points of the surface preferentially dissolve in comparison to the low points. Wagner (4) examined the initial dissolution of a sinusoidal surface whose dissolution rate was controlled by the diffusion of an acceptor species for the metal ions from the bulk of the solution to the surface. Wagner's solution of the diffusion equation was limited to a sinusoid with an amplitude which was much less than the wavelength. His solution satisfied the boundary condition of zero acceptor concentration at the metal surface only in an approximate manner. In this paper a parameter perturbation in the amplitude-to-wavelength is applied to the primary current distribution at a sinusoidal surface. This is the electrical analog of the diffusion-limited dissolution of the profile. The current distribution is found for a uniform potential at the surface and the counterelectrode at infinity. The perturbation solution developed here identically satisfies all boundary conditions and furthermore, the error of the neglected terms can be assessed. It is demonstrated that Wagner's solution can be recovered from the first two terms in the expansion. The parameter perturbation solution technique may be used in other relevant problems. A short discussion is given on the application of this technique to computing the potential variation in the electrolyte adjacent to a sinusoidal surface at which a uniform current density is applied. This is physically relevant to the action of potential dependent adsorption of leveling agents on metal surfaces. A discussion on applying the solution technique to pulsating potential deposition is also presented. Work at this laboratory is currently in progress in these two areas.

Problem Statement

Figure 1 is a plot of the sinusoidal profile under consideration. The profile consists of a single frequency with a period length l' and an amplitude A'. (The prime signifies a dimensional length.) The origin of the coordinate system is placed such that the valley corresponds to $x' = 0$. The profile shape is described by the equation

$$y_w' = -A' \cos (2\pi x'/l) \qquad [1]$$

The potential at the sinusoidal surface is uniform and the counterelectrode at which a uniform current density is applied is at infinity. The potential in the solution will satisfy Laplace's equation subject to appropriate boundary conditions

$$\frac{\partial^2 \phi}{\partial x'^2} + \frac{\partial^2 \phi}{\partial y'^2} = 0 \qquad [2]$$

$$\phi(y' = y_w', x') = 0 \qquad [3i]$$

$$-\kappa \frac{\partial \phi}{\partial y'}\bigg|_{x',y' \to \infty} = i_A \qquad [3ii]$$

$$\frac{\partial \phi}{\partial x'}\bigg|_{y',x'=0,l/2,l} = 0 \qquad [3iii]$$

Condition [3iii] results from the symmetry of Laplace's equation and its boundary conditions. We therefore will only need to consider the region

$$y' \geq y_w', \quad 0 \leq x' \leq l/2$$

The concentration of a species which is controlled by diffusion to (or from) the electrode surface will also be governed by Eq. [2] and [3]. One need only replace the potential by the properly defined concentration, the conductivity by the diffusivity, and the applied current density by an expression for the diffusion flux which is usually written

$$j = -D\Delta C/\delta \qquad [4]$$

where δ is the diffusion layer thickness and ΔC is the driving force of bulk concentration minus the surface concentration of the reacting species. In order to formulate the concentration field problem in terms of the diffusion layer thickness however, it must be assumed that $\delta >> A'$. This follows if the concentration analog of Eq. [3ii] is to apply. Consequently, we prefer to consider the potential field problem in our discussion and to translate the results to the concentration field problem at the end of the analysis. Krichmar (5) has

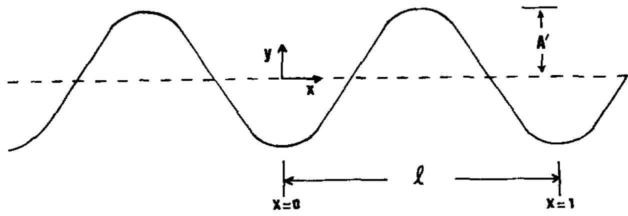

Fig. 1. Profile of a sinusoidal surface

* Electrochemical Society Active Member.
Key words: diffusion, current distribution, potential.

analyzed in an approximate manner the situation where δ is a function of position along the sinusoidal surface.

Mathematical Development

Define the following dimensionless quantities

$$X = x'/l, \quad Y = (y' - y_w')/l, \quad \Phi = (\kappa\phi)/(li_A) \quad [5]$$

Laplace's equation and its boundary conditions then transform to

$$\frac{\partial^2\Phi}{\partial X^2} + \frac{\partial^2\Phi}{\partial Y^2} + AL_1(\Phi) + A^2L_2(\Phi) = 0 \quad [6]$$

$$\Phi(Y = 0, X) = 0 \quad [7i]$$

$$\left.\frac{\partial\Phi}{\partial Y}\right|_{X,Y\to\infty} = -1 \quad [7ii]$$

$$\left.\frac{\partial\Phi}{\partial X}\right|_{X,Y=0,\,1/2} = 0 \quad [7iii]$$

The operators $L_1(\Phi)$ and $L_2(\Phi)$ are given by

$$L_1(\Phi) = -4\pi\sin 2\pi X\frac{\partial^2\Phi}{\partial X\partial Y} - 4\pi^2\cos 2\pi X\frac{\partial\Phi}{\partial Y} \quad [8]$$

$$L_2(\Phi) = 4\pi^2\sin^2 2\pi X\frac{\partial^2\Phi}{\partial Y^2} \quad [9]$$

The solution for Φ may be written as a perturbation in the dimensionless amplitude-to-period length ratio A

$$\Phi = \Phi_0 + A\Phi_1 + A^2\Phi_2 + \ldots \quad [10]$$

[Perturbation methods are discussed in the text by Nayfeh (6).] Equation [10] is substituted into Eq. [6]. Equations governing each of the expansion functions are found by equating equivalent terms in the A expansion

$$\frac{\partial^2\Phi_0}{\partial X^2} + \frac{\partial^2\Phi_0}{\partial Y^2} = 0 \quad [11]$$

$$\frac{\partial^2\Phi_1}{\partial X^2} + \frac{\partial^2\Phi_1}{\partial Y^2} = -L_1(\Phi_0) \quad [12]$$

$$\frac{\partial^2\Phi_n}{\partial X^2} + \frac{\partial^2\Phi_n}{\partial Y^2} = -L_1(\Phi_{n-1}) - L_2(\Phi_{n-2}) \qquad n \geq 2 \quad [13]$$

The boundary conditions on the zero-order solution may be written

$$\Phi_0(Y = 0, X) = 0 \quad [14i]$$

$$\left.\frac{\partial\Phi_0}{\partial Y}\right|_{X,Y\to\infty} = -1 \quad [14ii]$$

$$\left.\frac{\partial\Phi_0}{\partial X}\right|_{Y,X=0,\,1/2} = 0 \quad [14iii]$$

Consequently the higher order solutions satisfy homogeneous conditions

$$\Phi_n(Y = 0,X) = 0 \quad [15i]$$

$$\left.\frac{\partial\Phi_n}{\partial Y}\right|_{X,Y\to\infty} = 0 \quad [15ii]$$

$$\left.\frac{\partial\Phi_n}{\partial X}\right|_{Y,X=0,\,1/2} = 0 \quad [15iii]$$

Equations [11]-[15] have been solved through the fourth order term. The calculations are tedious but straightforward

$$\begin{aligned}\Phi(X,Y) &-Y + A[1 - e^{-2\pi Y})\cos 2\pi X] \\ &+ \pi A^2[(1 - e^{-2\pi Y}) + (e^{-4\pi Y} - e^{-2\pi Y})\cos 4\pi X] \\ &+ \pi^2A^3\Big[2(e^{-4\pi Y} - e^{-2\pi Y})\cos 2\pi X \\ &+ \left(2e^{-4\pi Y} - \frac{1}{2}e^{-2\pi Y} - \frac{3}{2}e^{-6\pi Y}\right)\cos 6\pi X\Big] \\ &+ \pi^3A^4\Big[(1 - 5e^{-2\pi Y} + 4e^{-4\pi Y}) \\ &+ \left(\frac{1}{6}e^{-2\pi Y} - 4\pi Ye^{-4\pi Y} + \frac{13}{3}e^{-4\pi Y} - \frac{9}{2}e^{-6\pi Y}\right)\cos 4\pi X + \left(-\frac{1}{6}e^{-2\pi X} + 2e^{-4\pi Y} - \frac{9}{2}e^{-6\pi Y} + \frac{8}{3}e^{-8\pi Y}\right)\cos 8\pi X\Big] + 0(A^5)\end{aligned} \quad [16]$$

The current along the wall can be evaluated by taking the normal derivative of Eq. [16]

$$\frac{i_n}{i_A} = -\frac{\partial\Phi}{\partial n} \quad [17]$$

The normal derivative is evaluated according to the procedure presented in the Appendix. We find

$$\begin{aligned}\frac{i_n}{i_A} &= \sqrt{1 + 4\pi^2A^2\sin^2 2\pi X}\,[1 - 2\pi A\cos 2\pi X \\ &+ 2(\pi A)^2\cos 4\pi X - 1) - 2(\pi A)^3(\cos 6\pi X - 2\cos 2\pi X) \\ &+ (\pi A)^4\left(6 - \frac{16}{3}\cos 4\pi X + 2\cos 8\pi X\right) + 0(A^5)\Big]\end{aligned} \quad [18]$$

In order to track the change in the surface roughness during a reaction, we are particularly interested in the current at $X = 0$ (valley) and $X = ½$ (peak). These are given by

$$\frac{i_p}{i_A} = 1 + 2\pi A - 2(\pi A)^3 + \frac{8}{3}(\pi A)^4 + 0(A)^5 \quad [19]$$

$$\frac{i_v}{i_A} = 1 - 2\pi A + 2(\pi A)^3 + \frac{8}{3}(\pi A)^4 + 0(A)^5 \quad [20]$$

The shape of the profile will change in the course of the deposition (or dissolution) reaction. An initial sinusoidal profile will become distorted to higher harmonics. Riggs (7) has developed a numerical routine which has included this shape change phenomenon. As a first approximation, however, let us assume that the profile retains its sinusoidal shape. The rate of change of the amplitude will be proportional to the difference between the peak and valley current. The amplitude of the profile can be tracked during the deposition (or dissolution) reaction by solving the following mass balance equation

$$\frac{dA'}{dt} = \frac{1}{2}\frac{V_i s_i}{n_R F}(i_p - i_v) \quad [21]$$

where s_i is the stoichiometric coefficient of the reactant from the general reaction under consideration

$$\Sigma\, s_i M_i^{z_i} \rightarrow n_R e^- \quad [22]$$

and V_i is the solid phase molar volume of reactant i. (The current is negative for a cathodic reaction and $s_i < 0$, therefore $dA'/dt > 0$, whereas for the anodic case, $dA'/dt < 0$.)

Equation [21] may be solved for $A(t)$ by use of Eq. [19] and [20]

$$\frac{A}{A_o} = \left[\frac{e^{4\pi v_s t/l)}}{1 - \pi^2 A_o{}^2 (1 - e^{4\pi v_s t/l})} \right]^{1/2} \quad [23]$$

where A_o is the initial dimensionless amplitude and v_s is the equivalent velocity of the solid phase if the current density i_A is applied at a flat surface

$$v_s = V_i \frac{s_i}{n_R F} i_A \quad [24]$$

Results and Discussion

Equations [16], [18], and [23] are the main results of this analysis. The perturbation solution in the parameter A has enabled us to estimate the accuracy of the solution. Table I demonstrates the convergence of this solution for $A = 0.10$. It shows the normal current evaluated at the valley and the peak. The current is given using various orders of the solution. The normal current at the valley has converged to within at least 6% with use of the highest order term. Wagner's solution for the same profile is given by the A^1 term in the expansion (see following discussion). The potential field (which is not illustrated) shows a greater convergence rate than its derivative, the current.

It can be demonstrated that Wagner's solution can be recovered by including only the first-order term in the perturbation solution, *i.e.*

$$\Phi = \Phi_0 + A\Phi_1 + 0(A^2) \quad [25]$$

Due to the nature of the Φ function at $X = 0$ and ½, the second order contribution to the current at these two points is zero. Thus even though Wagner's solution for the potential is accurate to $0(A^2)$, the peak and valley current which is calculated from his solution is accurate to $0(A^3)$. The nature and approximation of Wagner's solution to this problem have been developed and expanded upon. In Wagner's development the denominator of Eq. [23] is equal to 1.

Figures 2 and 3 are plots of the potential variation in the solution and the current distribution at the surface, respectively. These plots are for a dimensionless amplitude of 0.1. The abscissa length scale for both figures is measured in terms of the number of amplitude lengths above the average wall position.

Figure 2 shows that the potential in the solution quickly becomes independent of X. The three lines become indistinguishable on the scale of this graph for y/A values much larger than indicated. Equation [16] evaluated at $y/A = 6$ demonstrates that the maximum variation in the dimensionless solution potential (valley-peak) is $-0.56347-(-0.56797) = 0.00450$. This corresponds to a deviation of $\pm$ 0.40% about the average potential at this elevation. The counterelectrode may be placed anywhere above $y/A = 6$ and have very little effect on the profile's current distribution. We can utilize this result to interpret a diffusion-limited reaction at a sinusoidal surface. Thus if the concentration boundary layer for a mass-transfer controlled reaction

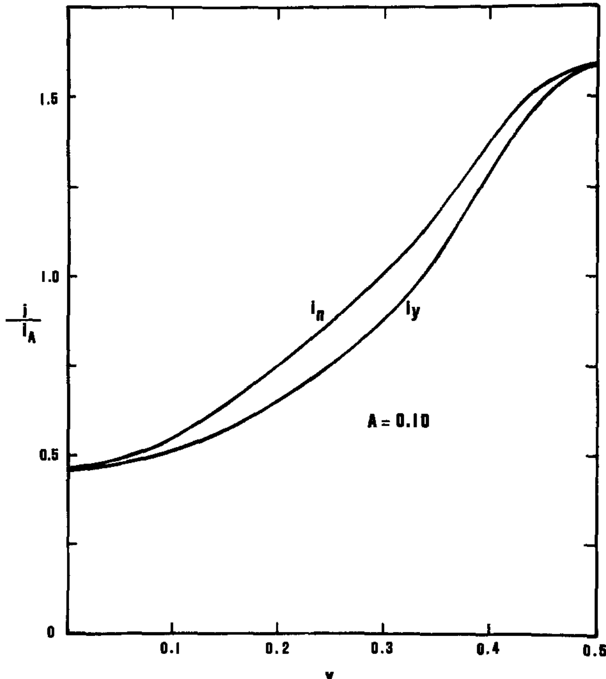

Fig. 3. The normal and y component of the current for the primary current distribution at a sinusoidal surface.

extends much above $y/A = 6$, the thickness of the boundary layer will have little effect on the current distribution at the surface. Of course the greater the boundary layer thickness for a given system, the lower

will be the resulting current. The analysis of this work enables us to quantify the statement $\delta >> A'$. The dashed line on Fig. 2 indicates the dimensionless solution potential if the current was applied at a flat surface. Less energy will be required to distribute the current to the peak areas in comparison to a flat surface. Furthermore, more current is distributed to the high points of the profile ($X > 1/4$) than to the low points of the profile ($X < 1/4$). Therefore for the same applied current, the dimensionless solution potential drop is greater (in absolute value) for the flat surface than the sinusoidal surface. Equation [16] shows that this difference is given by $\pi A^2 + \pi^3 A^4 + 0(A^6)$.

Figure 3 shows that at the average wall position ($X = 1/4$) neither the normal current nor the y component of the current equals the average applied current density. This would follow from Eq. [18] only if the first-order term is retained which is $0(A)$ after the square root term is expanded.

As an application of the analysis in this paper, the leveling efficiency of an anodically dissolved surface is discussed. Consider the sinusoidal profile of Fig. 1 to be anodically reacting under the mass-transfer controlled condition of an acceptor species diffusing from the bulk to the surface. This is the case discussed by Wagner. Following Wagner's nomenclature, let u represent the displacement of the surface from the initial position if the entire surface were flat. If t_R represents the reaction time, it follows that

$$u = v_s t_R$$

Equation [23] may be plotted to illustrate the leveling efficiency. The ordinate of Fig. 4 is the quantity $\ln (A/A_0)/(2\pi u/l)$ and the abscissa is the initial amplitude A_0. Inclusion of the higher order correction terms illustrate that the leveling efficiency is dependent upon the initial amplitude and the parameter u/l which is a measure of the number of wavelengths of the surface reacted. The leveling is always less than that predicted by Wagner's solution.

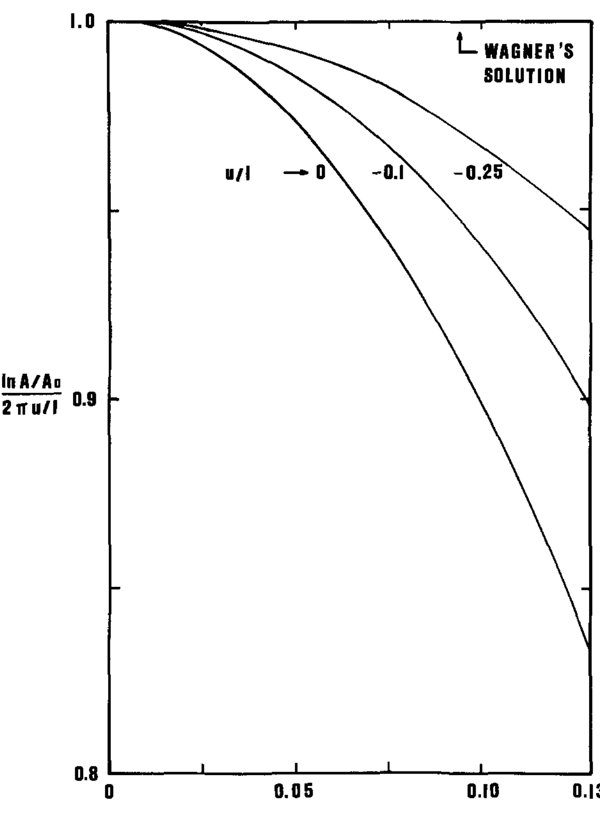

Fig. 4. Leveling of a sinusoidal surface as a function of the initial amplitude and the equivalent displacement of a flat profile.

As the surface is dissolved away u/l increases. Initially the deviation between the leveling predicted by Wagner's solution and the perturbation solution can be significant for nonzero A_0. However, as more and more of the surface is dissolved away, regardless of the initial amplitude, Wagner's solution is again a good approximation. As $u/l \to \infty$, all of the curves on Fig. 3 approach the value one for their abscissa.

The perturbation analysis given in this work may be applied in other physically important situations. If the normal current is uniform along the sinusoidal surface, a solution of the form assumed in Eq. [10] may still be applied to the potential. Laplace's equation will apply; however, the boundary conditions must be changed. The zero of potential may be defined to be at some reference plane located at $y = y_R$. This can be translated to the Y coordinate system by further assuming that $y_R' >> A'$. The wall boundary condition on the current will involve the parameter A as can be seen from the Appendix. Since the perturbation parameter appears in both the governing equation and its boundary conditions, this problem is mathematically more complicated than that developed here, but it is solvable. The solution of this problem will quantify the potential variation in the solution adjacent to the surface. This variation has relevance for the potential dependent adsorption of leveling agents.

The perturbation solution technique outlined here may also be applied to the transient problem of a pulsating potential applied to a sinusoidal profile. The various orders of the solution will thus be time-dependent in addition to their spatial dependence. Various boundary conditions at the surface can be applied. The surface concentration might respond in a Nernstian manner to the applied potential. Linear kinetics will be another limiting case of interest.

APPENDIX

A. Normal derivative

Let (n', t') be a local normal and tangent coordinate system along the surface

$$\left.\frac{\partial \phi}{\partial n'}\right|_{t'} = \left.\frac{\partial \phi}{\partial x'}\right|_{y'} \left.\frac{\partial x'}{\partial n'}\right|_{t'} + \left.\frac{\partial \phi}{\partial y'}\right|_{x'} \left.\frac{\partial y'}{\partial n'}\right|_{t'}$$

but: $$\left.\frac{\partial x'}{\partial n'}\right|_{t'} = -\sin\theta \qquad \left.\frac{\partial y'}{\partial n'}\right|_{t'} = \cos\theta$$

where θ is the angle between the tangent and x axis. Therefore

$$\frac{\partial \phi}{\partial n'} = \cos\theta \left[\frac{\partial \phi}{\partial y'} - \left(\frac{dy_w'}{dx'}\right) \frac{\partial \phi}{\partial x'} \right] \quad \text{[A-1]}$$

Since $\tan\theta = dy_w'/dx'$

it follows that $\cos\theta = \dfrac{1}{\sqrt{1 + \left(\dfrac{dy_w'}{dx'}\right)^2}}$

B. Normal derivative in (X,Y) coordinate system

The derivatives transform as

$$\left.\frac{\partial \phi}{\partial x}\right|_{y} = \left.\frac{\partial \phi}{\partial X}\right|_{Y} \left.\frac{\partial X}{\partial x}\right|_{y} + \left.\frac{\partial \phi}{\partial Y}\right|_{X} \left.\frac{\partial Y}{\partial x}\right|_{y}$$

$$= \frac{\partial \phi}{\partial X} - \left(\frac{dy_w'}{dx'}\right) \frac{\partial \phi}{\partial Y}$$

Also

$$\left.\frac{\partial \phi}{\partial y}\right|_x = \left.\frac{\partial \phi}{\partial Y}\right|_X$$

Substitution of these two terms into the nondimensional Eq. [A-1] gives

$$\frac{\partial \phi}{\partial n} = \cos\theta \left[\left(1 + \left(\frac{dy_w'}{dx'}\right)^2\right) \left.\frac{\partial \phi}{\partial Y}\right|_X - \left(\frac{dy_w'}{dx'}\right) \left.\frac{\partial \phi}{\partial X}\right|_Y \right]$$

If this is evaluated along the surface for the primary distribution

$$\left.\frac{\partial \phi}{\partial n}\right|_t = \sqrt{1 + \left(\frac{dy_w'}{dx'}\right)^2} \left(\frac{\partial \phi}{\partial Y}\right)_X$$

Technical Notes

Glassy Electrolyte Galvanic Cells

Tsutomu Minami, Tadashi Katsuda, and Masami Tanaka

Department of Applied Chemistry, University of Osaka Prefecture, Sakai-Shi, Osaka-Fu 591, Japan

Solid-state batteries have been studied extensively because of their advantages such as long shelf life, no cell leakage, wide temperature range of operation, miniaturization, and so on, compared with aqueous systems. These batteries are based on polycrystalline superionic conductors. Solid-state batteries using glassy superionic conductors have been reported in only a few papers (1-3), in spite of the fact that glasses have higher potentialities than polycrystals in the use as electrolytes in solid-state batteries; for example, higher conductivities than crystals (4, 5), isotropic properties, ease of forming no-grain boundary disks, formation of thin films, and especially miniaturization.

Key words: solid-state battery, superionic conductor, glassy electrolyte, solid-state ionics.

In previous papers (4, 5), we have reported glass-forming regions and conductivities of the glasses in the systems $AgI\text{-}Ag_2O\text{-}MoO_3$ and $AgI\text{-}Ag_2O\text{-}P_2O_5$; some of these have conductivities as high as 10^{-2} Ω^{-1} cm^{-1} at room temperature. The purpose of this paper is to present electrolytic properties of these glasses used in galvanic cells. Three compositions were chosen, as shown in Table I; two of these have very high

Table I. Properties of glassy electrolytes at 25°C

Glass No.	Composition (mole percent)	Total conductivity[a] (Ω^{-1} cm^{-1})	Electronic conductivity (Ω^{-1} cm^{-1})	Silver ion transport number[b]		Decomposition voltage (V)
				Emf method	Tubandt's method	
1	$75AgI \cdot 25Ag_2MoO_4$	1.1×10^{-2}	8.7×10^{-9}	0.999_6	0.992 ± 0.001	0.72
2	$60AgI \cdot 40Ag_2MoO_4$	6.0×10^{-4}	—	0.999_6	0.972 ± 0.021	—
3	$80AgI \cdot 20Ag_3PO_4$	1.2×10^{-2}	4.7×10^{-9}	0.997_2	—	0.74

[b] Ref. (4).

conductivities and are the most promising, and the other one a lower conductivity, for comparison with the above two. In the table several properties are summarized, some of which were cited from previous papers (4-6), and some will be shown below.

Pulverized samples were used in this experiment, as a first step toward miniaturized thin film batteries, on account of easy assembling of reproducible cells. The impedance of intergranules was reported to be small in these glassy superionic conductors (5-7).

As already reported (4, 5), the transport number of the glasses studied was determined to be practically unity by the emf and the Tubandt method. In the present investigation the small values of electronic transport number were measured by the Wagner d-c polarization technique (8). The cell used was the type

$$(-)\text{Ag/GE/Pt}(+) \qquad [I]$$

where GE denotes the glassy electrolyte. According to Wagner's analysis, the total electronic current, I, is given by

$$I = I_e + I_h = \frac{RTA}{FL}\left\{\sigma_e\left[1 - \exp\left(-\frac{EF}{RT}\right)\right] + \sigma_h\left[\exp\left(\frac{EF}{RT}\right) - 1\right]\right\} \qquad [1]$$

where I_e and I_h are the current due to electrons and holes, respectively, R the gas constant, T the absolute temperature, A the electrode area, L the sample thickness, F the Faraday constant, E the applied voltage, and σ_e and σ_h the conductivity due to electrons and holes, respectively. If $\sigma_e >> \sigma_h$, the second term in the braces is negligible and I becomes independent of E. If $\sigma_e << \sigma_h$, the first term is negligible and I varies exponentially with E. The experimental results shown in Fig. 1 indicate that $\sigma_e >> \sigma_h$ holds for the present glassy electrolytes; $\sigma_e = 8.7 \times 10^{-9}\ \Omega^{-1}\ \text{cm}^{-1}$ for curve 1 (Glass No. 1) and $\sigma_e = 4.7 \times 10^{-9}\ \Omega^{-1}\ \text{cm}^{-1}$ for curve 2 (Glass No. 3) were obtained (Table I).

When the voltage is further increased, the decomposition voltage is determined. Figure 2 shows the current-voltage curve of cell [I] at 25°C for Glass No. 1; the decomposition voltage of 0.72V is obtained. The voltage for Glass No. 3 was 0.74V (Table I).

Open-circuit voltages (OCV) were measured for the cell

$$(-)\text{Ag/GE/I}_2, \text{C}(+) \qquad [II]$$

The anode (silver powder) and the electrolyte layer were pressed under 2 t/cm² to form a pellet of 13 mm in diameter. The cathode mixture of iodine and carbon black (4:1 in weight ratio) was pressed to form a pellet. The cell was sealed with epoxy resin after the above two pellets were tightly contacted with screw bolts. The time dependence of OCV is shown in Fig. 3; the curves 1, 2, 3 are respectively for Glass No. 1, 2, 3. The initial values are 687.0, 687.0, and 685.4 mV for curves 1, 2, and 3, respectively, which were measured by the combination of a high impedance ($>10^{14}\Omega$) electrometer with a digital voltmeter. These values are very close to the theoretical value, 687.3 mV (9), for the standard emf of the formation of AgI by the reaction

$$\text{Ag} + 1/2\,\text{I}_2 = \text{AgI} \qquad [2]$$

The OCV are stable and decrease by 1-2 mV in 30 days.

Figure 4 shows the voltage-current characteristics of the cell

$$(-)\text{Ag, GE/GE/I}_2, \text{GE, C}(+) \qquad [III]$$

The anode was a mixture of silver powder and the sample electrolyte (1:1 in weight ratio) and the cathode was a mixture of I_2, carbon black, and the electrolyte (5:1:5 in weight ratio). The cell was con-

structed by the same way as cell [II]. The voltage shown in the figure is plotted after 30 sec discharge at each current density. The curves 1, 2, and 3 are respectively for Glass No. 1, 2, and 3. The cells for Glass No. 1 and 3 give the current density of 1 mA/cm^2 without serious polarization. The reason for the voltage decrease at higher current densities is probably attributed to cathodic and anodic polarization (3); the improvement of the cathode and anode assembly will serve the higher current density.

Discharge curves of cell [III] under different loads are shown in Fig. 5. The cell of Glass No. 1 (curve 1), for example, showed the initial current density of 73, 137, and 600 μA/cm^2 for the load of 10, 5, and 1.1 kΩ, respectively.

Figure 6 shows the steady current discharge curves of cell [III] for Glass No. 1; under 0.5 mA, for example, the cell had the capacity of 7.0 mA-hr and the energy density of about 1.7 W-hr/kg. The discharge parameters are summarized in Table II. These parameters are comparable to the cell using crystalline electrolytes (10). In view of the fact that the present results were obtained from handmade laboratory type cells, results from production type cells using the good qualities inherent in glasses would be expected to be even better.

Some Aspects on the Self-Discharge of LiAl/FeS Experimental Cells with Molten Salt Electrolyte

Reinhard Knödler* and Gotthold Böhme

Battelle-Institut e.V., Frankfurt am Main, Germany

and Waldemar Borger

VARTA Batterie AG, Kelkheim, Germany

The LiAl/FeS battery with molten KCl-LiCl electrolyte operates at a temperature of about 450°C and is a promising candidate for load-leveling and traction applications (1-4).

As part of the general R&D program of VARTA Batterie AG, Kelkheim, Battelle-Institut e.V., Frankfurt am Main was commissioned to conduct investigations into the self-discharge behavior of LiAl/FeS cells. Although it is well known from the measurement of coulomb efficiencies that the self-discharge rate is relatively low, quantitative data on this important property are not available. The objectives of the work described were therefore (*i*) to determine quantitatively the rate of self-discharge, (*ii*) to discover the reasons for self-discharge, and (*iii*) to examine the effect of cell leakages on the rate of self-discharge. In order to isolate the principal effects, the investigations were carried out in cell types in which self-discharge reactions caused by contacts between the electrodes could be excluded from the start. Thus, it was possible to determine the smallest possible self-discharge rate of this battery system. Since this work is in a preliminary stage, an explanation of possible mechanisms of self-discharge is not given. Work in this direction is now in progress.

Experiment

The cells had a utilized capacity of 6 A-hr, limited by the positive electrode. They were assembled in an argon atmosphere in a glove box and operated in open air.

Figure 1 shows the cell configuration. The electrodes were about 6 mm thick. The positive electrode was in contact with the stainless steel casing. It was prepared in the uncharged state by hot-pressing a mixture of Li_2S, Fe, and electrolyte powders. In order to prevent mass losses, the electrode was wrapped in a 300-mesh stainless steel screen. The preparation of the negative electrode is described in detail elsewhere (5). This electrode consists of a porous aluminum disk, also wrapped in a stainless steel screen. The distance between the electrodes was about 10-15 mm (investigations involving smaller spacings are now in progress). The capacity of the negative electrode was made about 30% higher than that of the positive electrode. Thus, the β-field of the Li-Al phase diagram has not been reached. The observed increase in voltage (see Fig. 2) therefore may be due to the formation of small amounts of FeS_2.

After having been assembled in the glove box the cells were soldered with a special solder. Conventional current feed throughs with ceramic bodies or spark plugs were used, which were carefully sealed with a ceramic cement. As the feed throughs were not in contact with the melt (see Fig. 1), it was possible to use 99.9% Al_2O_3 for the insulating ceramic. No attack was observed at these materials after the experiments. After heating to the operating temperature of 430°C, the cells were charged to 1.6V with constant current (in most cases at a 20 hr rate).

The actual rate of self-discharge was determined by operating the cell for some time at OCV (*i.e.*, without current) and subsequently recharging it to 1.6V with a constant current density of 20 mA/cm^2. The capacity loss, expressed in percent per day, has been calculated from the amount of charge needed for this procedure. This is called the self-discharge rate of the cell.

Results

Figure 2 shows an example of the behavior of the OCV as a function of the operating time. The decrease of the OCV to its final value of 1.33V was relatively rapid at the beginning of the experiment and slowed down as the operating time progressed. The self-discharge rate, as calculated from the various amounts of charge indicated in Fig. 2, is shown in Fig. 3a. This is a typical behavior which was observed in a series of cells. It shows that (*i*) at the beginning of the experiment the self-discharge rate is relatively high; it may reach values of up to 10% per day, (*ii*) the self-discharge rate decreases in the course of the experiment to values below 1% per day. This low value can be maintained even if the cell is cycled between

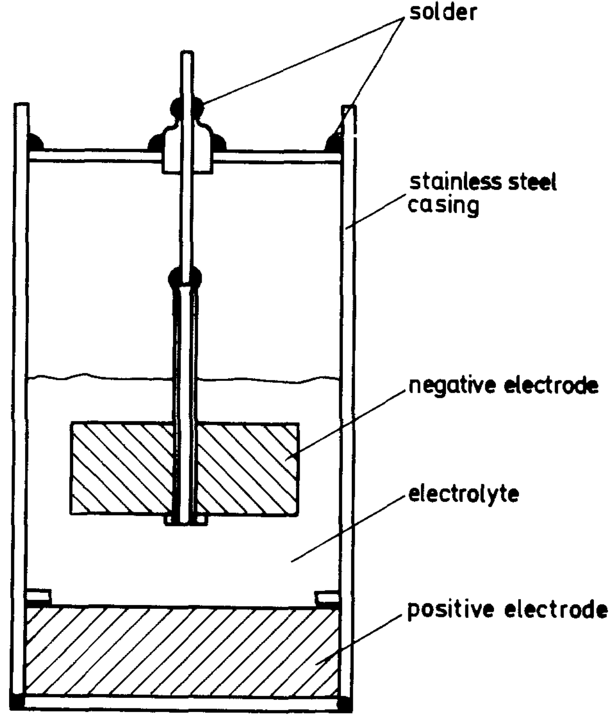

Fig. 1. Cell configuration

Key words: lithium metal sulfide battery, self-discharge, molten salt electrolyte.

Fig. 2. Open-circuit voltage after repeated charging to 1.6V with 10 mA/cm²

0.8 and 1.6V with current densities of up to 50 mA/cm². The decrease of the self-discharge rate can also be seen from the upward trend both in the starting voltage and the final voltage.

Experiments were carried out in order to determine the influence of a gas leakage into a cell on the self-discharge rate. For this purpose the cell atmosphere, normally consisting of argon, was replaced successively by nitrogen, oxygen, and air. Figure 3b shows the effect of these operations on the self-discharge rate. Within the accuracy of measurement, nitrogen did not influence the rate, whereas oxygen and air had a substantial effect. Air is obviously more deleterious than oxygen. This may be attributed to the moisture in the air. These observations were confirmed by examining the cell by x-ray spectroscopy after the experiment. Li_3N or related nitrides have not been detected within the limits of error, but considerable amounts of Li_2O_2 were present. The effect of H_2O is currently under study.

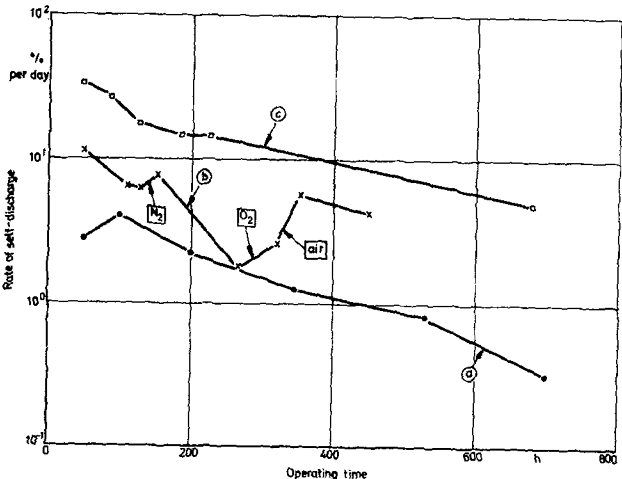

Fig. 3. Rate of self-discharge of different cells: curve a, argon atmosphere (pure electrolyte); curve b, nitrogen, oxygen, and air atmosphere (pure electrolyte); curve c, argon atmosphere and addition of 2 weight percent Li_2O to the electrolyte.

A further confirmation of the finding indicating that the occurrence of Li_2O_2 is responsible for the enhanced self-discharge rate was obtained by an experiment in which 2% by weight of Li_2O was added to the electrolyte before the experiment. Figure 3c shows that in this case the self-discharge rate is considerably higher than in the absence of Li_2O. It decreases as the operating time progresses, but the final value is still as high as about 5% per day. After the experiment, examination of the cell revealed that Li_2O was no longer present in the electrolyte but Li_2O_2 was formed instead. Thus, in the case of a cell leakage, an increase in the self-discharge rate to about 5% per day has to be expected, probably as a result of the formation of Li_2O_2. This statement is, of course, only valid if—as in the experimental cells used in this case—the electrodes are covered with electrolyte.

In order to confirm these findings, the electronic conductivities of pure LiCl-KCl melts and of melts with Li_2O and Li_2O_2 additions were measured in conductivity cells with blocking electrodes (made of molybdenum). These measurements were carried out by determining the frequency dependence of the cell impedance. In order to remain in the linear region of the current voltage curve according to the Hebb-Wagner theory (6), the sinusoidal voltage was always kept below RT/F. This is the reason why we were not able to distinguish between electron and hole conductivity.

Figure 4 shows measurements in pure LiCl-KCl melts and in melts with additions of Li_2O and Li_2O_2. At

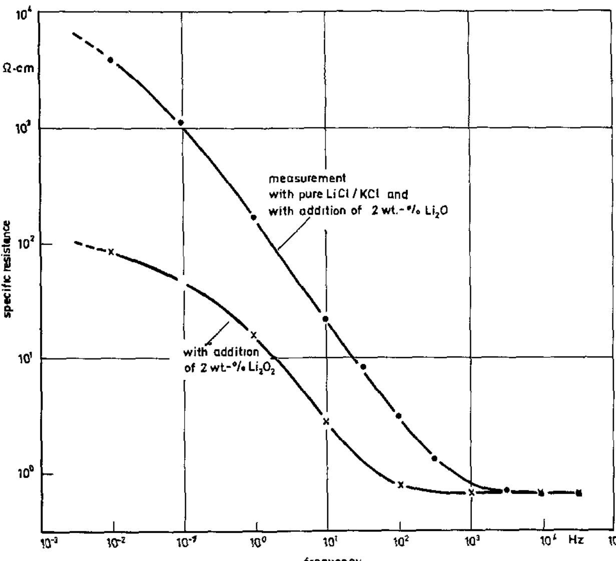

Fig. 4. Frequency dependence of the specific resistance of a cell with blocking molybdenum electrodes.

high frequencies the value for the pure ionic conductivity of the melt was obtained independent of the substances added. In the case of the pure melt and the melt with Li_2O the curve can be extrapolated to low frequencies to obtain a value of the order of magnitude of about 10^4 Ω·cm. This corresponds well with data already available on the electronic conductivity of the melt (7). If, however, Li_2O_2 is added instead of Li_2O, the specific resistance is about two orders of magnitude lower. According to these findings, the reason for the higher self-discharge in the presence of air may be the electronic conductivity of the melt caused by the formation of Li_2O_2. However, other possible mechanisms may be considered, *e.g.*, shuttle mechanisms as observed in the Ni-Cd battery. In this case an "intermediate" product, *e.g.*, Li_2O, would migrate between the two electrodes, becoming alternately oxidized and reduced thus causing self-discharge effects. Investigations in this direction are being continued.

Conclusions

The findings described above allow the following conclusions:

1. The self-discharge rate of LiAl/FeS cells is less than 1% per day. The rate decreases during operation of the cell and can be kept low even if the cell is being cycled.
2. The electronic conductivity of the molten electrolyte is drastically increased by the addition of Li_2O_2. In contrast, this effect does not occur with Li_2O. In a complete cell, Li_2O will be oxidized to Li_2O_2, thus causing self-discharge due to electronic conductivity.
3. The presence of air or oxygen in the cell atmosphere causes an increase in the self-discharge rate. Nitrogen has no effect. The consequence of the presence of air (or oxygen) is the formation of Li_2O_2 in the electrolyte. Thus, increased conductivity of the melt may be one of the reasons for the enhanced self-discharge.

Electrochemical Deionization Via Ion Adsorption Electrodes

Arnold Factor

General Electric Corporate Research and Development Center, Schenectady, New York 12301

and Thomas O. Rouse

General Electric Large Transformer Technical Resources Operation, Pittsfield, Massachusetts 01201

This report describes the first successful example of electrochemical deionization using ion adsorption electrodes based on organic redox polymers. In this system cations are reversibly bound to electrochemically generated anionic groups and anions to electrochemically generated cationic groups. The requirements for this type of electrochemical ion adsorption are illustrated in Eq. [1] and [2]. In these reactions,

Key words: redox polymers, desalinization, water deionization.

A and B must be insoluble and, when fabricated into an electrode, be able to undergo electrochemical reaction leading to the reversible formation of an insoluble

$$A + M_{sol'n}^{+} + e \rightleftarrows AM_{insoluble}$$

Cation adsorption (cathode) [1]

$$B + X_{sol'n}^{-} \rightleftarrows BX_{insoluble} + e$$

Anion adsorption (anode) [2]

product within the electrode. Cations M^+ and anions X^- must be removed from the water electrolyte in the formation of these insoluble products. Cation and anion-adsorbing electrodes together form an electrochemical cell which under an applied voltage is capable of demineralizing water for practical use. As illustrated in Fig. 1, the electrochemical reactions should proceed in either direction so that the cell can be rejuvenated by reversing the cell voltage and the adsorbed cations and anions rejected into a waste stream. On repetitively reversing the voltage, ions can be repeatedly removed from one stream and rejected into another.

Previously, this type of ion adsorption cell was examined by Arnold and Murphy (1) using activated carbons as the insoluble reactants. However, these cells showed limited adsorption capacities and poor cycle life.

It has been found that a deionization cell could be successfully produced based on the previously reported redox polymers, polyviologens (2). In this cell, the cation-absorbing cathode involved the reduction of the neutral, water-insoluble polyelectrolyte complex of polyxylylviologen and poly(styrene sulfonate) ($PXV(PSS)_2$) (2) to its anionic form, Eq. [3]. The anion-absorbing anode involved the oxidation of the cross-linked radical cation on polymesitylviologen ($PMV\text{-}V_2$) (2) to its dicationic form, Eq. [4]

[3a]

$$M_{sol'n}^+ + (PXV^{++})(PSS^-)_2 + e \rightleftharpoons (M^+)(PXV^+)(PSS^-)_2 \quad [3b]$$

[4a]

$$(PMV^+)(X^-) + X_{sol'n}^- \rightleftharpoons (PMV^{++})(X^-)_2 + e \quad [4b]$$

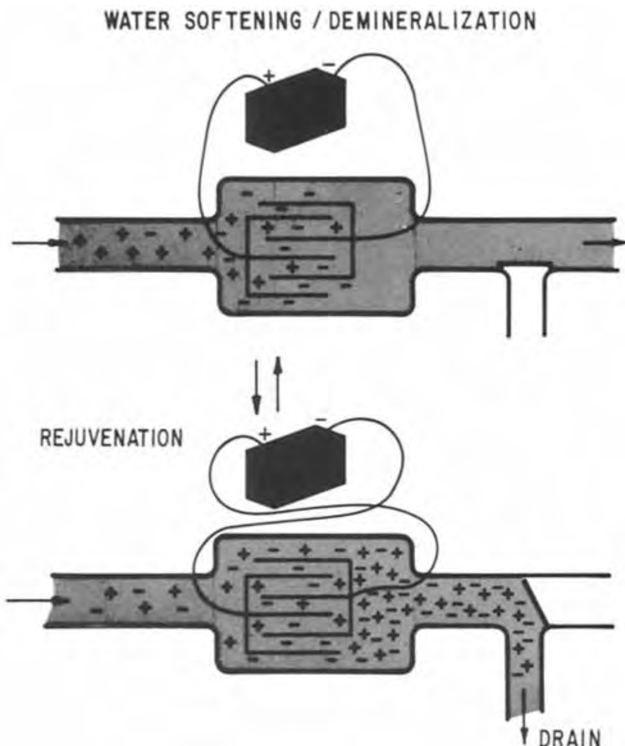

Fig. 1. Reversible ion absorption

Experimental

Electrode preparation.—Electrodes were prepared by intimately mixing weighed amounts of Pettinos 6427 graphite powder (surface area-10 m^2/g) and ground (to pass 400 mesh) redox polymer. The usual proportions were two parts graphite to one part electroactive material. An anhydrous solution of polyvinylidene fluoride (PVF) (Pennsalt Corporation) in dimethylacetamide (DMA) was added to the mixture as a binder. The resulting paste was painted on the lower section of one side of a 10 mil thick rectangular graphite foil (Union Carbide Company), and immersed in distilled water to leach out the DMA and set the binder. Leaching was continued in several fresh portions of water for a minimum of 12 hr. The binder content of the final porous body was normally 5%. The electrode normally consisted of 25 mg of porous material per cm^2 of foil. A contact was riveted to the foil prior to electrode fabrication.

The electrode capacity was found to greatly depend on the degree of dispersion of graphite in the polymer. The highest electrochemical capacities were achieved by forming the redox polymer in the presence of graphite followed by the addition of more graphite in the grinding step. In the case of the $PXV(PSS)_2$ electrode, the most efficient electrodes were prepared by precipitation of the complex onto an equal weight of graphite by flash vacuum evaporation of acetone from a $NaBr/acetone/H_2O$ (30/55/15 by weight) ternary solution (2, 4) of the complex. In this manner, electrodes were obtained with capacities up to 0.5 meq/g in 0.1M NaCl or 80% of the theoretical capacity. In the case of the electrodes formed from the cross-linked $PMV(Br)_2$, the most efficient electrodes were formed by polymerizing the redox polymer in the presence of graphite. Capacities up to 0.5 meq/g were obtained for electrodes containing 50% graphite, half of which was added during the grinding step.

Electrolysis—electrode optimization.—In this work, the final cell was constructed with a cathode and anode which had been separately optimized using constant current electrolysis (3). The electrochemical cells used in this study consisted of two compartments separated by a medium fritted glass disk and an agar-KCl plug. Generally, the electrolyte in the test electrode compartment was 0.5M NaCl. A reference electrode dipped into this same compartment. The electrolyte solutions were deaerated with nitrogen and covered with flowing nitrogen during electrolysis. The solutions were not stirred.

Electrolysis was performed at constant current against a silver sheet preanodized in chloride solution. Potentials were measured against a Beckman silver-silver chloride reference electrode. No evidence of silver migration into the test compartment was observed on prolonged cycling. Electrolysis currents

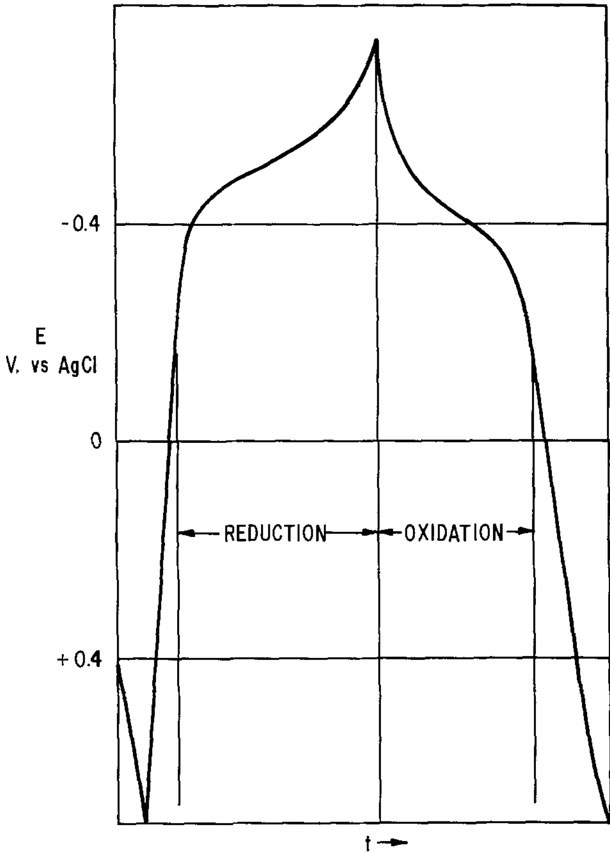

Fig. 2. Potential-time curve for poly-p-xylylviologen polystyrene sulfonate [$PXV(PSS)_2$], electrolysis time ~5 hr per half-cycle.

were in the range of 0.3-2 mA/cm^2, usually the former. Provision for automatically reversing the current at preset values of working electrode potential was made through a circuit activated by an optical meter and controller (Assembly Products, Incorporated) as illustrated in Fig. 2. Electrodes prepared without redox polymers gave only rapid and linear potential changes in the potential range of interest on current application and reversal. The coulombs consumed in these charging processes were subtracted in the data below.

Sodium and calcium analyses were done by atomic adsorption.

Demonstration of reversible deionization.—The cell used was assembled with a silver electrode between the cation and anion electrodes. The silver electrode was a fine screen, heat-sealed into a double wrap of nylon screen. The cell was filled with 0.0125M NaBr and the solution was deaerated by bubbling with nitrogen gas presaturated with water. The electrolysis current was held constant at 5.65 mA. The potential-time curves for the electrode of interest were recorded against a silver-silver chloride reference electrode. In addition, the cell potential was recorded when the ion adsorption electrodes were electrolyzed against each other. Duplicate analytical samples of electrolyte were removed at each step of the electrolysis and stored in polyethylene bottles.

Results and Discussion

In reporting the results of this work, the following abbreviations were used: $\%C$ = percent of theoretical coulombic capacity; $C_{c,a}$ = coulombic capacity in milliequivalents calculated from the coulombs passed during the cathodic, c, or anodic, a, half-cycle; $C_{c,a}^A$ = adsorption capacity in milliequivalents calculated for ion A from the change in solution concentration; and $C_{c,a}^A/C_{c,a}$ = coulombic efficiency for removal (or replacement) of ion A from solution.

As indicated above, the electrode capacity was found to greatly depend on the degree of dispersion of graphite in the polymer. The highest percent capacities ($\%C$) were achieved by forming the redox polymer in the presence of graphite followed by the addition of more graphite in the grinding step. While experimental electrodes were not subjected to exhaustive cycle life tests, the electrochemical capacity was observed to remain constant over a large number of cycles. For example, the capacity of a $PXV(PSS)_2$ electrode cycled in a solution of 0.0125M in NaCl and in NaBr was 0.39 meq/g in the first cycle, and 0.33 meq/g in the second through 160th cycle. Generally, similar behavior was found for both $PXV(PSS)_2$ and $PMV(X)_2$ electrodes in even more concentrated NaCl or $CaCl_2$ for as many as 300 cycles.

In the case of the $PXV(PSS)_2$ electrode, cations were shown to be electrochemically removed and replaced in solution with a coulombic efficiency of greater than 80%. The results of three electrolyses

are given in Table I. The last electrolysis, which contained both sodium and calcium ions, demonstrated that calcium ions were selectively removed and replaced with 90% coulombic efficiency even in the presence of a fourfold excess of sodium ions.

Additional chemical effects were apparent in this experiment. During equilibration of the electrode in the mixed electrolyte prior to the start of electrolysis, the sodium ion in solution increased by 0.14 meq while the calcium ion decreased by a like amount. This is due to the replacement of residual sodium ions in the electrode by calcium ions. During the 50 cycles, the calcium ion in solution had decreased by an additional 0.27 meq. The electrode was calculated to contain 0.86 meq of $PXV(PSS)_2$. Thus after 50 cycles the system lost 48% of its initial capacity to reversibly absorb ions.

The reversible adsorption of anions by a $PMV(Br)_2$ electrode and the demonstration of reversible demineralization by a cell made of a $PMV(Br)_2$ anode and a $PXV(PSS)_2$ cathode was demonstrated in the same experiment. The characteristics of the electrodes used are given in Table II.

In the first part of this experiment, anion adsorption by the $PMV(Br)_2$ electrode was demonstrated in a cell where a silver screen was used as the counterelectrode (Steps 2 through 4 in Table III). The theoretical cell reaction, shown in Eq. [5], predicts no net change in bromide ion concentration

$$(PMV^{++})(Br^-)_2 + Ag^\circ \rightleftarrows (PMV^+)Br^- + AgBr \qquad [5]$$

The occurrence of other reactions of the anion-absorbing material would cause changes in bromide ion concentration. The analytical results for bromide ions show that the postulated reaction did take place and bromide ions were removed from and returned to the solution nearly quantitatively.

Demineralization, Eq. [6], was demonstrated in the second segment of the experiment consisting of electrolysis of the anion-adsorbing electrode against the cation-adsorbing electrode (Steps 6 and 7 in Table III)

$$(PMV^+)(Br^-) + (PXV^{++})(PSS^-)_2 + Na^+ + Br^- \rightleftarrows (PMV^{++})(Br^-)_2 + (Na^+)(PXV^+)(PSS^-)_2 \qquad [6]$$

In Step 6, the reaction proceeded as written, both sodium and bromide ions were removed, and demineralization was demonstrated. In Step 7, the reaction was reversed and both cations and anions were returned to the electrolyte. The results for Step 6 reinforce the earlier conclusion that the reaction of the anion adsorbing material proceeded as anticipated.

Conclusions

These preliminary experiments demonstrate that an ion adsorption cell based on polyviologen redox polymers is feasible. In addition, the high selectivity shown for calcium ions over sodium ions for the $PXV(PSS)_2$ electrode would be particularly useful in applications requiring the selective removal of multivalent ions in the presence of monovalent ions, *e.g.*, water softening. Further work will be required to fully define the requirements needed to use the above cell in a practical application.

The Morphology of Viologen Films on Transparent Oxide Electrodes

Gabriel G. Barna*

Texas Instruments Incorporated, Dallas, Texas 75265

Viologens, the dialkyl derivatives of 4.4′-dipyridinium salts, have been widely investigated for possible use in electrochromic displays. Although electrochemical studies have been performed on the various alkyl derivatives (1), the 1,1′-diheptyl-4-4′-dipyridinium salts have been typically employed in display development. The kinetics of the cathodic deposition of this species, and the subsequent reoxidation of the purple film, have been studied (2, 3). Other work has been performed on the effect of the anions on the film formation and its adherence to the electrode (4). These papers have also addressed the question of the nucleation of the film (2) and have shown indirect evidence for the recrystallization of the deposited film (5).

During our development of a display package, a procedure was generated which resulted in the uniform deposition of this heptylviologen onto transparent oxide electrodes (6). By following the rigorous cleaning and surface activation procedures, sealed patterned cells could be constructed such that the deposited viologen film would be typically uniform in appearance. However, these cells generally degraded by a mechanism that prevented the complete erasure of the deposited film.

This paper describes the experimental technique that was employed to show that there is an open-circuit reorientation of the deposited heptylviologen film. The demonstrated change in the birefringence of the film proves that the material gradually assumes a greater degree of optical anisotropy. The nature of this ordered phase can only be surmised. Considering

* Electrochemical Society Active Member.
Key words: electrochromics, viologen films, reorientation.

that the molecular geometry of this species is very similar to the class of biphenyl liquid crystals, it is possible that the film gradually reorients itself into a liquid crystal-like phase, with some degree of intermolecular orientation between adjacent molecules. Or, the film can assume a truly crystalline form. The data generated cannot distinguish between these two cases. Therefore, in this paper, the less constraining term of "reorientation" will be employed. The "recrystallization" terminology sometimes used in the existing literature to describe this phenomenon is deemed to have more rigorous implications than can be supported by the available data. It is postulated that an accumulation of this reoriented material is responsible for the incomplete erasure of the film.

Experimental

The data were collected in sealed, patterned cells. The front plate was a piece of Nesatron 20 (PPG Industries) indium-tin oxide glass etched to form the usual seven segment "1888" pattern, with an insulating layer of SiO_2 then deposited over the leads. The backplate was a piece of regular soda-lime glass, with Pd thermally evaporated around its perimeter. Pd-black was subsequently electroplated onto this film, this perimeter electrode serving as the counterelectrode in the sealed cell. Prior to assembly, the backplate was extracted with deionized water and the front plate was cleaned and treated as previously described (6). The cell was assembled with an epoxy perimeter seal and filled, under nitrogen, with a 0.1M n-heptylviologen phosphate/1M dihydrogenphosphate solution. The fill hole was then epoxy filled.

Leads were attached to the counterelectrode and several individual segments on the front plate. One segment was turned on by applying −1 VDC between it and the counterelectrode. This viologen-deposited segment (poised by the equilibrium potential between the solid and dissolved radical cation) was then employed as the reference electrode in all the subsequent electrochemical experiments.

The cells were driven with a Wenking Model ST72 potentiostat and a Wenking VSG Voltage Scan Generator. The timing was obtained from an HP 3311A Function Generator and the charge measured with a PAR Model 379 digital coulometer. The electrooptical measurements were all performed in the three-electrode potentiostatic drive mode. For the cycling experiments, the viologen film was deposited during a 5 sec cathodic pulse at variable potentials, and reoxidized at +400 mV for 5 sec.

With the described perimeter counterelectrode, optical measurements could be made, in transmission, with a Leitz Wetzlar polarizing microscope. Using the 25X objective, the field of view was contained entirely within the driven segment. The transmitted light was fed directly, via the vertical optics of the trioptic head, into a Gamma Scientific photomultiplier tube equipped with a photopic filter. The signal was analyzed by a Gamma Scientific DR-2 Digital Radiometer. Illumination was provided by a tungsten lamp powered by a Leitz power supply. When the cell was first examined optically, it was noticed that the deposit was visible between crossed polarizers while the field of view was dark in the absence of the film. This proves that the film is birefringent, and hence that there exists an optical anisotropy in the individually visible 1-5 μm "crystallites." Since the purpose of this study was to monitor the change in the morphology of the film, all measurements were performed with the cell between crossed polarizers. The beam focuser was not used so as to keep the cell temperature at 30°C. The electrical and optical responses were monitored simultaneously on a two-channel strip-chart recorder. The mechanical offset between the two pens has been left unretouched in Fig. 1, *i.e.*, there is no delay time between the charge accumulation and the optical response.

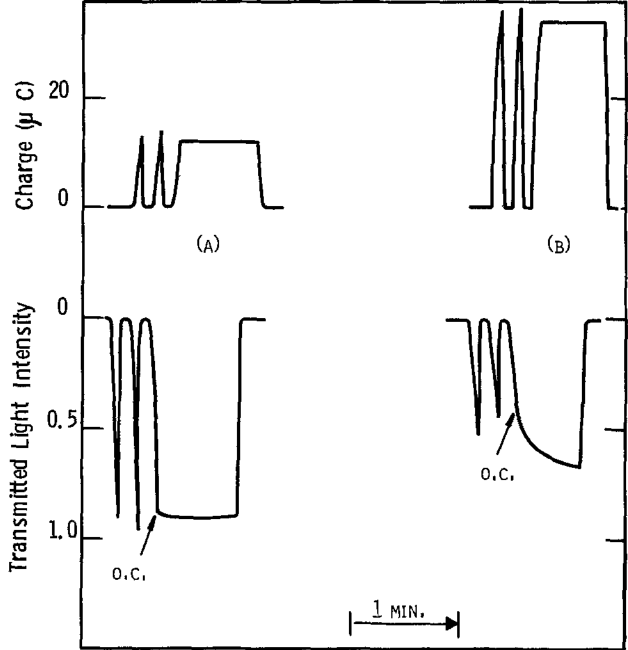

Fig. 1. Electro-optical response of a single segment under cycling and open circuit (O.C.) conditions: (A) −25 mV/+400 mV pulsing at 0.1 Hz (B) −30 mV/+400 mV pulsing at 0.1 Hz.

Results and Discussions

Cyclic voltamograms inside the sealed cells exhibited the typical reversible one-electron reduction and oxidation peaks. With respect to the internal reference electrode, the reduction and oxidation peaks are at −38 and +28 mV, respectively, at a 5 mV/sec scan rate.

The typical response of a single segment to the cathodic/anodic cycling is shown in Fig. 1. The top tracing is the charge response (ΔQ), the one on the bottom is the optical response. The experiment consisted of cycling the segment a few times, at a given cathodic potential limit, and then pulling the working electrode lead. This places the system on open circuit, at around 4 sec into the 5 sec cathodic pulse.

The optical response demonstrates the following sequence in the morphology of the growing film. When the film is first formed, part of it is immediately birefringent. However, the significant aspect of the data is the optical response of the deposit, after the segment has been placed on open circuit. For films deposited at the lowest overpotential (−25 mV *vs.* the internal reference segment), the optical response is constant on open circuit [Fig. 1(A)]. Films deposited at the higher overpotentials (−30, −50, and −75 mV *vs.* the same reference) exhibit a continually increasing optical leakage through the crossed polarizers [Fig. 1(B)]. This leakage cannot be due to the continual deposition of the viologen film, since at the open-circuit potential there is no driving force to plate more material. In addition, the amount of the optical transmission through the film at the time when the segment is placed on open circuit, as a function of the increasing cathodic potentials, is tabulated in Table I. During the approximately same time periods, more

Table I. Electro-optical characteristics of a deposited viologen film placed on open circuit, under crossed polarizers

Cathodic potential (mV)	ΔQ ($\times 10^{-4}$ C)	Δ Intensity	Optical leakage
−25	0.12	0.88	None
−30	0.34	0.40	Continuing
−50	0.47	0.18	Continuing
−75	0.53	0.12	Continuing

charge is deposited at the more negative cathodic potentials. This results in a denser film, which is characterized by a proportional relationship between the charge passed and the calculated absorbance of the film between parallel polarizers. However, the light transmitted through the crossed polarizers, when the segment is placed on open circuit, is inversely related to ΔQ. This implies that during the faster deposition of the film, there is less of a tendency for it to deposit in an oriented fashion. Left on open circuit, the film reorients itself to a phase with a higher degree of ordering and hence a greater optical anisotropy. The final morphology of films deposited at various overpotentials is not the same. The higher the overpotential, the less the optical transmission at steady state, implying a less ordered film.

These data firmly support the previous hypothesis (5) that the "aging" of the heptylviologen radical cation film involves a reorientation process. However, it is now clear that in addition to other influencing factors, this phenomenon is very dependent on the overvoltage at which the film is deposited. The data also confirm previous arguments (2, 6) that the number of active sites available for film nucleation is potential-dependent. Visual examination of the deposited films shows that the -25 mV film contains larger "crystallites" (3-5 μm) arranged in a discontinuous fashion, while the -50 mV film contains smaller "crystallites" (<1 μm) spaced more densely together. Hence films formed at more negative potentials nucleate at a larger number of sites, providing a greater number of less oriented deposits.

From a device point of view, these data can be used to postulate a cause for the commonly observed erasure problem. The typical timekeeping mode requires that the segments be switched as fast as possible, and that they be then placed on open circuit for 1 min. Hence the film is formed at high overpotential, which provides a dense deposit of small aggregates. During the open-circuit time period, the deposit reorients into an ordered phase. It can be postulated that this reoriented film is more difficult to erase, leaving after a large number of cycles, a visible residue on the segments.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 126, No. 4, 5, 9, 10, and 12, April, May, September, October, and December 1979.

Electrochemical Potential Spectroscopy

J. Thompson (pp. 608-616, Vol. 126, No. 4)

Brian E. Conway:[1] In a recent paper by Thompson, interesting effects associated with sorption of lithium ions into layer lattices leading to intercalation compounds, for example with TiS_2 and MoS_2, have been reported.

Special attention was directed to a "spectrum" of capacitance maxima which arise as the host lattice becomes progressively occupied by the guest ion, Li^+, on account of the electrode potential being sequentially changed in small steps. The response of the system was referred to as Electrochemical Potential Spectroscopy.

We would like to mention that very similar phenomena have been known for some years[2-4] with the occupation in two dimensions of two-dimensional lattices[4] on the surface of various noble metals, leading to multiple states of adsorption. The study of this kind of two-dimensional, multi-state surface compound formation has usually been followed by linear-sweep potentiodynamic methods[2] which lead directly to the observation of the corresponding capacitance measured as the current ÷ sweep-rate.

The characteristic of most two-dimensional lattice occupation processes is that multiple capacitance peaks arise, corresponding to a series of distinguishable states of adsorption below a monolayer.[2-4] Thus, the concept of electrochemical potential spectroscopy has existed with regard to the response of two-dimensional systems to a linear potential sweep for some time, really commencing with the experimental work of Will and Knorr in 1960.[2]

Various explanations of the multiple state adsorption which arises in a number of systems in monolayer formation on noble metals such as platinum, gold, rhodium, or palladium, have been offered.[5-7] The obvious possibility of polycrystallinity arises but multiple state adsorption is nearly always still observed on well-prepared single crystal surfaces.[8,9] Hence some kind of indirect heterogeneity at the atomic level must arise,[5,6] even on single crystal

planes, so that an adsorbate exists in distinguishable states and experiences a range of energies of adsorption as the monolayer is filled up. These can correspond to different overlay lattice structures with different geometrical arrangements[4,5] of the adsorbate on the host lattice, utilizing different groupings of hybrid-orbital bonds emerging from the surface, as the surface sites are occupied. In the case of lead deposition in a monolayer on gold,[10] there appears to be a sharp transition which could correspond (*cf.* 11) to a rearrangement of the surface lattice structure at about 55% of full final coverage, as is indicated by the reversibility of the sharp peak observed at this coverage. Reordering amongst various overlay structures is believed[11] to be involved, *i.e.*, similar to the effects in three dimensions.

We thought it would be worth directing attention to the relation between the three-dimensional lattice observations of Thompson and those found in two-dimensions for a number of elements as reported in recent and earlier papers, using cyclic voltammetry.

A. H. Thompson:[12] In his discussion, B. E. Conway compares measurements on Li_xTiS_2 to previous studies on surface adsorption and suggests that similar effects have been known for a number of years. In particular he states ". . . the concept of electrochemical potential spectroscopy has existed with regard to the response of two dimensional systems to a linear potential sweep for some time . . .". This statement shows that there is some confusion about what I have called Electrochemical Potential Spectroscopy (ECPS) that I would like to clarify.

I agree with Professor Conway that differential capacity curves have been used for a number of years to analyze surface studies of the type that he describes. They have also been used to study electrochemical cells such as Zn/MnO_2,[13] to study the double layer capacitance[14] and to study liquid metal alloys.[15] The differential capacity is clearly not a new feature of ECPS.

As I have defined ECPS, it is a method involving a sequential stepping of the electrochemical potential. The constant voltage steps are terminated when the current decays to a small value. The series of voltage steps produces not only the voltage-charge relation but also a discrete, precise measure of the derivative of V *vs.* Q. The derivative used is called the incremental capacity to distinguish it from the differential capacity obtained by continuous techniques such as linear sweep voltametry. The following are comparisons of the method and further definition.

With ECPS the effective rate discharge may be very low so as to obtain quasi thermodynamic results. The data were taken at a rate equivalent to a linear sweep in voltage at a rate of 10^{-2} μV/sec. It would require three years for linear sweep voltametry to give equivalent data at the same effective rate.

The ECPS measurement is not simply another coulometric titration since no attempt is made to obtain ideal equilibrium conditions. Rather, by stepping the voltage at a fixed current level, data are obtained under quasi thermodynamic conditions with the deviation from equilibrium being well defined. On a typical voltage step in my paper, it would require more than 36 hr to obtain a voltage that is constant within the voltage resolution employed of 100 μV. "True open-circuit data" would then require a minimum of one year to collect.

The ECPS measurement gives both quasi thermodynamic and kinetic data on each step.

The small voltage steps and low cutoff currents apply mild perturbations to the cell. These conditions are required in organic electrolyte based systems where large voltage excursions and high current levels may easily cause irreversible damage to the system.

With regard to the structural effects on surfaces as compared to those in intercalate systems, it would be quite interesting to compare two-dimensional deposition on a surface to the two-dimensional intercalation problem since the intercalate does not permit multiple layers to form. In fact, ECPS may provide useful data for the surface problem since measurements can be made at low rates which would be particularly attractive for low temperature measurements where equilibration times may be large and surface structures well formed.

Quantity of the Metal Deposited in Pulsed Plating vs. Direct Current Plating

Richard Haynes (pp. 881-882, Vol. 126, No. 5)

P. Radhakrishnamurty:[16] The author tried to show that the condition $\eta_P > \eta_{dc}$ must be satisfied to get a higher weight of the metal in pulse plating compared to d-c plating. That there exist several possibilities to achieve this result, besides $\eta_P > \eta_{dc}$ can be shown by means of a trivial exercise from basic principles.

It should be mentioned first of all that neither the mechanism of the deposition reaction nor the mode of control of the reaction is needed for the calculation of the weight of the deposit, as has been done in the paper under discussion. Thus the whole discussion regarding the presence of simultaneous HER/some other parallel reaction at the electrode surface, is of first order or second order etc., whether the metal deposition is under pure diffusion control, pure activation control, etc., are all irrelevant.

Secondly substitution of $(i_P)_1/(i_{dc})_1 = 3.76$ in Eq. [1] of Haynes paper is incorrect because $(i_P)_1$, $(i_{dc})_1$ refer to the current densities at a particular instant of time during the deposition whereas i_P, i_{dc} refer to the constant or average values of current density in pulse plating and d-c plating.

From basic principles, we have: weight of metal deposited = rate of metal deposition $\times$ time of deposition

$$\begin{aligned} W &= I_M \times E \times t \\ &= I_T \times \eta \times E \times t \\ &= i_T \times A \times \eta \times E \times t \end{aligned}$$

In the case of pulse plating

$$W_P = i_T \times \frac{\theta_1}{\theta} \times t \times A \times E \times \eta_P$$

Thus the necessary and sufficient condition for $W_P > W_{dc}$ is

$$i_T \times \frac{\theta_1}{\theta} \times t \times A \times E \times \eta_P > i_T \times t \times A \times E \times \eta_{dc}$$

Since $\theta_1/\theta < 1$, $W_P < W_{dc}$ if all other parameters are same in both d-c and pulse plating. However, by choosing the parameters conveniently W_P can be made greater than W_{dc}. Of a number of combinations of parameters available for example

$$\left[\frac{i_P}{i_{dc}} > \frac{\theta}{\theta_1}\right]_{\eta,A,t}, \quad \left[\frac{\eta_P}{\eta_{dc}} > \frac{\theta}{\theta_1}\right]_{i,A,t}, \quad \left[\frac{A_P}{A_{dc}} > \frac{\theta}{\theta_1}\right]_{i,\eta,t}$$

are some to achieve $W_P > W_{dc}$.

[16] Central Electrochemical Research Institute, Karaikudi 623006, India.

In conclusion, it may be said that to get a higher weight of metal deposited in pulse plating than in d-c plating there exist several possibilities to compensate for the drawback $\theta_1/\theta < 1$ present in pulse plating and one need not know about the mechanism of deposition for the above purpose.

LIST OF SYMBOLS

W weight of the metal deposited (g)
I_M partial current utilized for metal deposition reaction of interest, ampere
I_T total current passing through the cell, ampere
E electrochemical equivalent of the metal, g/A·sec
t time of deposition, sec
θ period of the pulse, sec
θ_1 time for which pulse is on, sec
η current efficiency of the metal deposition reaction of interest
A the surface area of the electrode, cm^2
Subscripts P and dc denote pulse plating and direct current conditions.

Richard Haynes:[17] What I have shown is a condition where pulsed current plating can yield a greater quantity of deposited metal than direct current plating when both are compared at the maximum possible rates. I have used the quantity of the deposit only as a simple indicator of the maximum possible deposition rates. The limit for the maximum possible reaction rate in my model is considered to be mass transport of the depositing metal for both pulsed and direct current plating. A parallel reaction scheme is always imposed when the current efficiency is less than 100% efficiency. The example given is easily shown to become the same as my equations when the weights are compared at the maximum possible rates of the deposition reaction

$$i_{T1P}\frac{\theta_1}{\theta}AE\eta_P > i_{T1dc}AE\eta_{dc}$$

For comparison at the maximum possible rates: A and E drop out and

$$i_{T1P} \text{ becomes } i_{T1P})_{max}$$

and

$$i_{T1dc} \text{ becomes } i_{T1dc})_{max}$$

For my model the rate limiting step is mass transport controlled so

$$i_{T1P})_{max} \equiv i_{T1P})_L$$

and

$$i_{T1dc})_{max} \equiv i_{T1dc})_L$$

which then becomes the same as my equation once substituted above. A definition of $(i_P)_1$ is given by K. Viswanathan *et al.*[18]

In summary, I have shown that there can, in theory, exist electrochemical conditions such that pulse plating can yield a greater quantity of metal when compared at the maximum plating rates which in my model is mass transport limited. I thank P. Radhakrishnamurty for asking for clarification on these points.

H. Y. Cheh (Divisional Editor):[19] The assumption that the upper limit of i_p/i_{dc} is equivalent to $(i_p)_1/(i_{dc})_1$, which has been made by Haynes is of doubtful validity. On the other hand, Radhakrishnamurty's analysis is not conclusive either. This is because E_p and E_{dc} are generally both functions of applied current density. Without kinetic information, there is no knowledge on the magnitude of E_p and E_{dc}. The three conditions presented are therefore meaningless. We have completed a more rigorous analysis on the current efficiency for simultaneous reactions by pulsed electrolysis. This work has been submitted to **This Journal** for publication.

The Potential Distribution at the TiO_2 Aqueous Electrolyte Interface

Micha Tomkiewicz (pp. 1505-1510, Vol. 126, No. 9)

David L. Ullman:[20] In this article, the author attributes nonlinearity in the Mott-Schottky plot of an unetched sample of TiO_2 to surface states that change their charge state in the course of varying the electrode potential. He then proceeds to present an analysis that ostensibly shows these to be fluctuating levels energetically located approximately in the center of the bandgap.

However, it appears from the author's Fig. 3 that these supposed states exchange charge most rapidly when there are practically no electrons at the surface. From data the author supplies, $n_s = n_1$ at the peak of this curve, and these may be calculated as follows

$$n_1 = n_s = 3.8 \times 10^{19} \exp((-0.48-0.8)/0.0256) = 7 \times 10^{-3} \text{ cm}^{-3} \quad [1]$$

The intrinsic carrier concentration may be estimated[21] to be not much more than 2×10^{-5} cm^{-3}, so it is clear that holes could not play much of a part in this process, either.

From the usually accepted model of trap kinetics,[22] it is clear that if transport through the space charge region is sufficiently rapid that n_s stays constant after the electrode potential has been changed, that as the traps exchange electrons to come into equilibrium with the surface potential, the equilibration will be a first-order process. A simple analysis shows that the relaxation time for this process is

$$\tau = \frac{1}{\sigma_n v_{th}(n_s + n_1)} \quad [2]$$

To evaluate this expression, we shall take for σ_n the value that Morrison[23] suggests as an upper limit for capture cross section, 10^{-12} cm^2. Assuming unit effective mass, we shall take the electron thermal velocity to be 10^7 cm/sec. We thus find

$$\tau = 7 \times 10^6 \text{ sec} = 2000 \text{ hr} \quad [3]$$

This argument applies whether we speak of filling or emptying the traps. Obviously, this is too long a time for the measurements to be made in any reasonable length of time. The slow rate of filling may be seen intuitively as due to the excessively low concentration of electrons at the surface at this potential; the slow rate of emptying, as due to the great energy difference between the states and the conduction band (on the order of 1.3 eV) and the resulting improbability of the transition.

In answer to these arguments, one might claim that the fluctuating nature of the energy levels causes them to exchange charge at a much faster rate than my analysis above shows. However, I will show that this is impossible.

In the case of filling empty traps, a "downward" fluctuation of trap energy would not change the situation, since both n_1 and n_s would remain infinitesimal. An "upward" fluctuation of energy might raise n_1 to some reasonable value, but only thereby making the probability of filling nil for thermodynamic reasons, since the trap energy would now be far above the surface Fermi level.

[23] S. R. Morrison, "The Chemical Physics of Surfaces," p. 44, Plenum Press, New York (1977).

For the case of emptying, one might argue that when a filled trap fluctuates upward, it is both thermodynamically and kinetically capable of emptying (from my Eq. [2]), and what is actually implied by my arguments is that the traps can empty going from cathodic to anodic potentials, but going from anodic to cathodic, will fill only as flatband is approached (that is, when n_s becomes substantial). Thus what would be implied by my arguments is a hysteresis in the capacitance *vs.* potential curves.

Unfortunately, this leads to a thermodynamic inconsistency. We see that these arguments lead to a mechanism of rapid emptying when n_s is low, but no comparably rapid method of refilling. Since the traps must be half-filled, and the rate of emptying equal to the rate of filling when $n_s = n_1$, this situation is impossible.

Yet another argument might be that the traps do indeed rapidly empty as they rise in energy, but refill by extracting electrons from (injecting holes into) the valence band upon downward fluctuation. However, it is a principle of catalysis (actually thermodynamics) that a route of forward reaction must also be a route of backward reaction. Thus the electrons and holes must be able to recombine through these states. But we have shown that trapping rates at vanishing carrier concentration is excessively slow, and reasonable carrier concentrations for this process to occur must imply an "equilibrium" n-p product far greater than n_i^2, and this is again thermodynamically impossible.

Tunneling is another relatively rapid process that might be contemplated, but while my knowledge of quantum mechanics is rather nil, it does seem to me that tunneling to and from a state near the intrinsic level is rather improbable. Rapid tunneling to and from an "upward" fluctuated state is impossible for the thermodynamic reasons discussed earlier.

Another defense that might be relied upon could be that there was error in the potential determination. Shifting the peak of the curve 180 mV cathodically would decrease the relaxation time by a factor of 1000, although 2 hr still seems unacceptably slow. However. it is difficult to see how such an error could be justified, particularly with modern measuring equipment. Flatband potentials are quoted to within 20 or 30 mV, and the curve appears well behaved on the cathodic side.

Finally, the crux of the matter appears to be this: at this range of potential there are practically no carriers at the surface, and whatever the mechanism, it is difficult to envision any physical entity responding so sharply to such vanishing concentrations, as required by the interpretation of Tomkiewicz.

As an alternative interpretation of the author's Fig. 2, I suggest that it is interesting, and perhaps not irrelevant, to note that the "nonlinear" portion of the upper curve is almost a straight line with a slope equal to that of the lower curve. However, I cannot say whether or not the roughness factor changed during the etching. If we hypothesize that the upper curve is the result of a lightly doped layer on top of the more heavily doped substrate, depletion region theory[24] allows us to estimate this thickness, noting that the break occurs at about 1V positive of flatband, and using other data we find in the article. This yields a top layer thickness of about 0.22 μm. Just how much the etch might have removed is impossible to say without knowledge of the etching time and kinetics.

The scatter in the "nonlinear" portion could be due to unavoidable error in the extraction of the capacitance element by relaxation analysis.[25] We note that the points showing greatest deviation represent the smallest values of capacitance, in series with an assumed constant resistance.

[24] A. S. Grove, "Physics and Technolobgy of Semiconductors," Chap. 6, John Wiley, New York (1967).
[25] M. Tomkiewicz, *This Journal*, 126, 2220 (1979).

However, we must confess that we do not know why there should be a thin layer of lightly doped material on top of a more heavily doped substrate, with an abrupt junction between the two.

Another criticism I have concerns the author's apparent assumption that flatband potential is invariant with doping level. This is inconsistent with the fact that two differently doped samples of a semiconductor must display an electronic potential difference when brought into intimate contact; they cannot then have the same potential relative to a third potential. The conclusion is that it is the bandedges that will remain constant when the Helmholtz potential is constant; flatband potential must vary Nernstianly with the bulk electron concentration.

The author also assumes that the various samples will have the same Helmholtz potentials in the same electrolyte. Considering that different samples may respond differently to the etching procedure due to different dopant concentrations, etc., this assumption seems to us to be rather dangerous.

M. Tomkiewicz:[26] While not fully agreeing with the authors detailed discussion on the possible mechanism of charge exchange between the bulk of the semiconductor and the surface or bulk states which reside near the middle of a gap of wide band semiconductors, his comments illustrate well our deficiency in understanding these processes. The existence of surface states on TiO_2 at this energy range was implied before,[27] with even more pressing need for efficient charge exchange between the surface and the bulk. This does not preclude the possibility of different interpretation but, just points to the fact that additional work is needed to clarify this problem. My data did not address the kinetic problem but it did demonstrate that under certain conditions the potential of the Helmholtz layer does not remain constant during a potential scan. The change in potential indicates charging and discharging in the layer. Because of the dimensions of this layer in concentrated aqueous solutions every state that lies in the layer in the potential range within the gap is attributed to surface states. The fluctuating level model explained the experimental energy distribution of the state but as I have shown in a later publication[28] this model is not unique in explaining the energy distribution. As to the authors comments on the dependence of the flatband potential on doping, it should be emphasized that the intercept to "zero doping" is at relatively high doping level and puts the flatband potential approximately 0.15V below the conduction bandedge.

Aside from this, there is some basic difference of interpretation of the flatband potential between the author and myself. It is true that the difference in energy between the Fermi level and the bottom of the conduction band will change with the doping level but the result will be shift in the conduction bandedge relative to the electrolyte. The flatband potential is the only measurable quantity which establishes the energy relationship of the semiconductor electrolyte system provided that the only potential drop in the system is across the space charge layer.

Occurrence of the Salt Film during Initiation and Growth of Corrosion Pits

T. R. Beck and R. C. Alkire (pp. 1662-1666, Vol. 126, No. 10)

J. Toušek:[29] In the last years considerable attention has been paid to the mechanism of localized corrosion of metals. Among others persuasive arguments have appeared about the presence of a thin salt layer along

the pit surface.[30-34] The paper discussed deals with the kinetics of pitting corrosion based on the salt film theory. Because the results of this work may be important for a further development of the localized corrosion mechanism, a discussion concerning this problem may be useful.

According to the authors, the purpose of their paper was to employ simple transport laws to gain a perspective of events which occur during early stages of pit initiation and growth. Under the presumption that the corrosion current in pits is controlled by the mass transport of corrosion products out of the pit, they have derived for the pit radius the equation

$$r = \left[r_1^2 + \frac{2DC_sM}{\rho} t \right]^{1/2} \quad [1]$$

and for the current density in the pits the equation

$$j_L = \frac{n\mathbf{F}DC_s}{\left[r_1^2 + \frac{2DC_sM}{\rho} t \right]^{1/2}} \quad [2]$$

The pit growth at relatively long exposition times has been measured in our laboratory and the calculation of pit radii and of actual rates of metal dissolution in the pits has been made. Corresponding kinetic equations have been derived from the relation for the pit growth and from the experimentally ascertained time dependencies of the total current density j and of the pit number z. The pit growth is expressed by the general equation

$$(2/3)\pi abc = (V_M/z\mathbf{F}) \int_0^{t-t_i} I dt \quad [3]$$

in which a, b, c are dimensions of the pit, V_M is the molar volume of metal, $\mathbf{F}$ is the Faraday constant, I is the current from one pit, t_i is the time at which the pit was initiated, and $t - t_i$ is the age of the pit. When measuring the localized corrosion of iron in the Na_2SO_4 + KCl solution, the following equations were found to be valid for the time dependence of the pit number and of the total current density[35]

$$z = Kt \quad [4]$$

and

$$j = At^2 \quad [5]$$

In these equations, K and A are constants. The pits have a hemispherical shape. From Eq. [3], [4], and [5], it is possible to calculate the pit radius as has been shown, *e.g.*, in[36,37]

$$r = \sqrt[3]{(3V_M/4\pi\mathbf{F})}\ \sqrt[3]{(At^2/K)} \quad [6]$$

The correlation between the pit growth given by Eq. [6] and [1] and the experimentally found pit radii is illustrated in Fig. 1. The comparison was made for macro-size and also for micrometer-size pits whose radii were taken from the paper published by Vetter and Strehblow. From Fig. 1, a good agreement follows between experimental values and those calculated from Eq. [6], which, as it is evident, expresses well the pit growth both for long and short exposition times. On the other hand, the values of pit radii gained from Eq. [1] do not agree well with those found experimentally.

According to Eq. [6], the pit growth is characterized by the slope $d \log r/d \log t = 2/3$. This value fits well the experimental time dependence obtained for both large and micrometer-size pits. Equation [1] requires

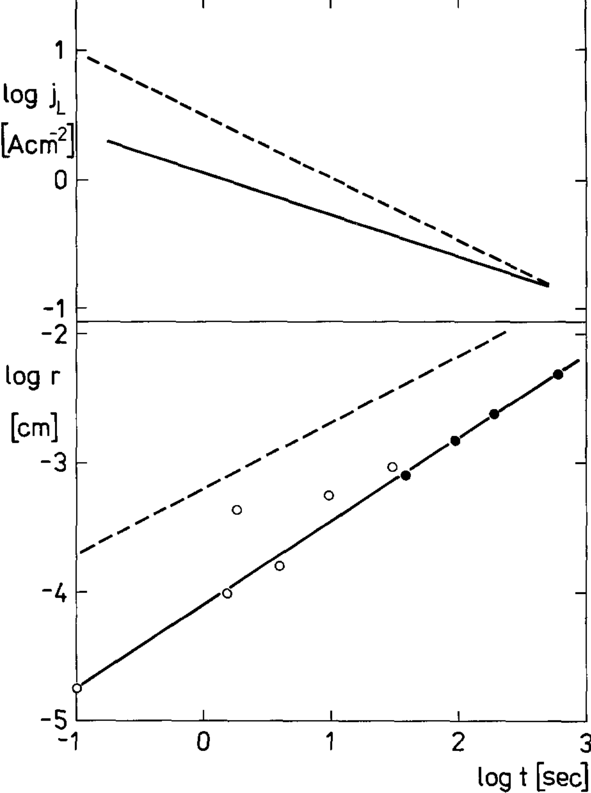

Fig. 1. Pit growth on iron in the KCl + Na_2SO_4 solution. - - - - - - - - - pit radius r and current density in the pits j_L predicted by Eq. [1] and [2]. ——— pit radius r and current density in the pits j_L predicted by Eq. [6] and [7]. Experimental values: ○ Vetter and Strehblow, ● Toušek.

for the slope [for sufficiently high exposition time, when $r_1^2 << (2DC_sMt/\rho)$] the value 1/2, which is at variance with the experimental results.

If we know the current from one pit and its area, the corrosion current in the pit can be evaluated[36]

$$j_L = \sqrt[3]{(16\mathbf{F}^2/9\pi V_M^2)}\ \sqrt[3]{(A/Kt)} \quad [7]$$

The drop of the current density j_L with time is given by the slope $d \log j_L/d \log t = -1/3$, whereas the slope calculated from Eq. [2] yields the value $-1/2$.

In the connection with Eq. [1] and [2] it is necessary to emphasize the experimental results, according to which the time dependence of pit radius and of current density in the pits varies with the corrosion environments composition and concentration.[36,38,39] In some cases, the corrosion current remains constant and the pit radius rises linearly with time. These facts are not involved in Eq. [1] and [2] according to which the time dependence of localized corrosion should be always the same.

It is possible to conclude that although the paper of Beck and Alkire brings many remarkable facts about the localized corrosion mechanism, some results presented here must be taken with care. Very probably, the salt film along the pit surface does not influence the metal dissolution kinetics in that way as it is assumed by the authors. According to our opinion, the salt film theory is not clear enough to explain the localized corrosion phenomena (kinetics and mechanism in general) as it has been supposed.

T. R. Beck[40] and R. C. Alkire:[41] Our publication expressed a salt-film hypothesis which led, by application

of first-principles, to Eq. [4] and [5] therein. This result, which introduced no adjustable parameters, gave agreement to within an order of magnitude of literature data obtained in several pit systems. It was therefore concluded that the hypothesis was reasonable, although several differences between data and hypothesis were yet to be resolved. In this work, the mathematical model represented the scientific hypothesis, and gave thereby a quantitative framework for incorporation of additional refinements in concept.

By contrast, the foregoing discussion by Tousek illustrates that an empirical fit to pit growth data can be achieved with adjustment of two parameters, K and A, along with experimental observations which support the exponents on t indicated in both Eq. [4] and [5] in the above discussion. Evaluation of the foregoing discussion indicates that;

1. In Eq. [3] in the above discussion, the quantity z should not appear but should be replaced by n, g equiv/gmole. Within the integral, the current to a single pit, I, is also given by j/z.

2. For such conditions that empirical Eq. [4] and [5] are observed, then Eq. [6] follows provided that $t_i = 0$. This procedure, however, yields no understanding of the processes occurring in the pit.

3. Evaluation of the ten data points provided in Fig. 1 of the discussion indicates that the slope of the line which best fits the data by a least-squares analysis is 0.60, a value which lies between that put forth by Toušek (0.67) and by ourselves (0.50). If the single data point at 10^{-1} sec is disregarded, then the slope through the remaining nine points is 0.55.

While additional empirical manipulations could perhaps yield an improved fit of the data, we would encourage also the method by which hypotheses of mechanism are expressed in a fashion which permits a more rigorous comparison with first-principles and which gives, thereby, a clearer insight into the physical events which actually occur during pit initiation and growth.

The Electrochemical Behavior of Alkali and Alkaline Earth Metals in Nonaqueous Battery Systems—The Solid Electrolyte Interphase Model

E. Peled (pp. 2047-2051, Vol. 126, No. 12)

I. Warshawsky:[42] In connection with Peled's thesis concerning the presence of a solid electrolyte interphase, SEI, between the metal anode and electrolyte, a complicating factor in interpreting the kinetic data may be the presence of water as an impurity in many nonaqueous solvents. This ubiquitous impurity can be present in trace amounts even when the most stringent purification procedures and precautions have been used, including using vacuum line manipulations. Hence, in many battery systems utilizing alkali metals, a reaction can occur between the alkali metal and the aqueous impurity in the solvent, leading to hydroxide film formation at the metal-liquid interface.

In addition, the aqueous impurity can react with the SEI affecting both its thickness and texture, further complicating the problem of interpreting kinetic data obtained electrochemically during discharge.

The author's idea that a thicker more polarizable SEI occurs during discharge when the anion transference number, t_-, is greater than zero compared to the situation in which it is zero, with the electron transference number, t_e, being zero, can also be challenged. Consider, for example, the discharge process at the anode. According to the author's reasonable model for $t_- > 0$ and $t_e = 0$, film formation occurs continuously at two interfaces—at the alkali metal-solid electrolyte interface and at the solid electrolyte-liquid interface. Consequently, during discharge a process of bond-making and bond-breaking takes place continuously at the alkali metal-solid electrolyte interface, affecting the interaction between these two contiguous phases. Hence, we have a possible mechanism for a loosening and a flaking off of the solid electrolyte film from the alkali metal surface, exposing new metallic surface to the liquid. This then leads to a less polarizable electrode than would be the case if the film adhered to the metal surface continuously during discharge.

As Peled points out, the polarization process is complex. The above conclusion may need modification for systems where other factors, such as stresses and strains, are significantly involved in the formation of the SEI, affecting its structure and stability. That is, ordinary thermodynamic considerations may not prevail for the temperature and peculiar circumstances under which the SEI is forming while the battery is functioning. For instance, it is possible that the cation, anion, and vacancy concentrations at the metal-solid electrolyte interphase can be characteristic of a high temperature while further away from the interphase in the SEI, they may be characteristic of a low temperature, and their respective mobilities throughout the film also characteristic of a low temperature.

In any event, it is not as obvious as the author seems to imply that during discharge in which $t_- > 0$ and $t_e = 0$ that a thicker and more polarizable film forms compared to the situation in which $t_- = 0$ and $t_e = 0$.

A Finite Difference Numerical Analysis of Galvanic Corrosion for Semi-Infinite Linear Coplanar Electrodes

P. Doig and P. E. J. Flewitt (pp. 2057-2063, Vol. 126, No. 12)

D. J. Astley:[43] I would like to indicate an inaccuracy in the paper by P. Doig and P. E. J. Flewitt. On page 2063 the authors refer to the parameter $(i_o/wC)^{1/2}$,[44] and state that as the magnitude of this parameter increases so the "approximation of unidirectional current flow becomes more accurate." In fact although the approximation improves with decreasing w, the unidirectional current flow model becomes more appropriate as (i_o/C) decreases. This follows from first principles in that as the solution becomes less resistive and/or the electrochemical reaction becomes more polarizable, so the potential gradient normal to the electrode surface decreases.

I have demonstrated that the unidirectional current flow model approximation improves with decreasing (i_o/C) by comparing the predictions of this model with those obtained from Waber's series solution of Laplace's equation for both semi-infinite linear coplanar electrodes,[45] and for tubular coplanar electrodes with junctions perpendicular to the axis,[46] assuming linear polarization kinetics in all cases. Comparisons clearly indicate that, for a fixed anode/cathode size, corrosion potential difference (ΔE) and solution depth/tube radius, the approximation involved in using the unidirectional current flow model improves as i_o decreases and C increases. Thus for $i_o = 0.01$ Am^{-2} and $C = 4\ \Omega^{-1}$ m^{-1} (values typical for copper-base alloys, titanium, and seawater), the unidirectional model predicted interfacial potentials typically within 1 mV of those calculated from the series solution of Laplace's equation for electrode length = solution depth = 30 cm ($\Delta E = 150$ mV). For $i_o = 0.07$ Am^{-2} and $C = 0.6\ \Omega^{-1}$ m^{-1}, the approximation involved in using the simpler model worsened, although still tolerable, so that the greatest difference between interfacial potential predictions was about 5 mV.

Bare Surface Reaction Rates and Their Relation to Environment Controlled Cracking of Aluminum Alloys

I. Bare Surface Reaction Rates on Aluminum-7 Weight Percent Magnesium in Aqueous Solutions

F. P. Ford,[1] G. T. Burstein,* and T. P. Hoar

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge CB2 3QZ, England

ABSTRACT

Data have been obtained for electrode reaction rates on bare aluminum-7 weight percent magnesium immersed in aqueous solutions. The reactions investigated were metal dissolution, proton reduction, and oxide growth in sulfate and chloride containing solutions in the pH range 1.0-6.5. The bare metal surface was produced by rapidly and lightly scratching a potentiostatically controlled rotating disk electrode. The resulting current transients were measured under various conditions of electrode potential, electrolyte composition, temperature, and electrode rotation rate. Current densities of up to 8 A cm^{-2} on the scratch were measured in this way. The rates of metal dissolution and proton reduction are increased by many orders of magnitude by removing the high impedance surface oxide. Dissolution of the bare surface occurs with the following rate-determining step: $Al + H_2O \rightarrow AlOH_{ads} + H^+ + e^-$, the rate being independent of pH and sulfate (0.5M) or chloride (1-4M) content. Proton reduction occurs with the discharge step being rate controlling. The rate of nucleation and growth of the oxide film follows the empirical law $i_{at} = i_{am} \exp(-\alpha t^n)$. Initially $n = 1$, but at longer times changes to 0.5, the changeover occurring earlier with increase in anodic polarization and by the presence of Cl^-.

The generalized theory of stress-corrosion cracking, originally suggested by Mears, Brown, and Dix (1) and expanded upon by others (2-4) has long been accepted for aluminum alloys since it is capable of explaining qualitatively the variation of cracking rate with second-phase morphology and, possibly, with elementary changes in electrochemical conditions at the crack edge. In essence this theory proposes that crack propagation progresses from a nucleating notch (usually formed by intergranular attack associated with discrete second-phase particles) when sufficient stress concentration exists to cause ductile tearing at the notch edge. Accelerated dissolution then occurs preferentially at the resultant film-free regions and continues until the dissolution rate is decreased by oxide formation or the intergranular penetration is halted at a grain boundary of unfavorable orientation. Thereupon the cycle of slow intergranular corrosion followed by rapid growth of the oxide film starts again.

Recently, however, there is increasing evidence (5, 6) that an alternative mechanism involving hydrogen embrittlement may be valid in humid and aqueous environments. This evidence is based primarily on the similarity between the potential dependence of stress-corrosion susceptibility and of hydrogen permeation (7, 8), the fact that the tensile ductility may be reversibly reduced by cathodic charging (8), the observation of hydrogen gas bubbles nucleated at grain boundary precipitates (9, 10), and by the fact that slow cracking may occur at humidity levels where a bulk aqueous phase cannot theoretically exist in the crack (6, 11).

It is the prime object of this investigation to provide data that relates quantitatively the accelerated electrode reaction rate accompanying film rupture to the crack propagation rate of aluminum-7 weight percent (w/o) magnesium in aqueous solutions. Specifically, the rates of dissolution, proton reduction, and oxide growth on an initially bare metal surface are determined and these data enable theoretical propagation rates for both slip dissolution and hydrogen embrittlement models to be calculated for various conditions of electrode potential, anion content, and temperature. These theoretical rates are then compared with literature values of the crack propagation rate under static and cyclic stress conditions.

In Part I the data on the bare surface reaction rates are reported, and in Part II a comparison is made between the calculated and observed environmentally controlled crack propagation rates.

Experimental

The alloy investigated was a high purity binary of nominal analysis Al-7 w/o Mg (supplied by Alcan International Research Laboratories, Banbury, England); spectrographic analysis gave: 7.03% Mg, 0.001% Si, 0.001% Fe, 0.001% Cu, 0.004% Zn, 0.002% Ti, 0.001%

Mn, and the balance Al. The original hot-rolled sheet was heat-treated at 370°C for 4 hr and water quenched to retain a single phase magnesium supersaturated condition; this ensured that the measured current on the potentiostatically controlled specimen emanated from a homogeneous structure of known area. Results showed that there was no difference between mechanically polished and electropolished (in $HClO_4$, CH_3OH, glycerol) surfaces; for convenience experiments were conducted on surfaces polished to 6 μm diamond finish. These were degreased with alcohol.

Solutions were made up from AR grade NaCl or Na_2SO_4 to strengths 0.5-4M in doubly distilled water (conductivity $1 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$). The pH was adjusted to the required value in the range 1.0-6.5 by addition of HCl or H_2SO_4; after an experiment the pH was within 0.1 pH units of the initial value and the solutions were thus not further buffered. Prior to introduction to the experimental cell the solutions were either aerated (8 ppm oxygen) or deaerated to <0.01 ppm oxygen by flushing with nitrogen which had been previously purged of oxygen by the technique of Gilroy and Mayne (12). The electrolyte temperature was normally 21° ± 3°C but in experiments where the temperature was purposely altered, control was achieved either by a Teflon-coated immersion heater or by the addition of liquid nitrogen to the cell.

The specimen, in the form of a disk of area 0.50 cm^2, was force-fitted into the end of a cylindrical Lucite holder and the interface sealed with lacquer (Fig. 1). Electrical contact between the specimen and the stainless steel shaft (externally coated with Teflon) was made with a compression spring and that between the revolving shaft and an external terminal made with a mercury seal, which minimized spurious effects due to contact noise. The use of mercury as an electrical contact did not introduce any effects vis à vis possible reaction with the working electrode (which was separated from the contact by the glassware) as indicated by similar current density/time results obtained using a conventional carbon-brush contact. The solution flow was visibly turbulent for $\omega > 100$ Hz, although departure from laminar flow probably occurred at lower speeds. The Pt counterelectrode (area ~10 cm^2) was mounted on a Teflon base and placed symmetrically below the specimen surface in order to give a uniform

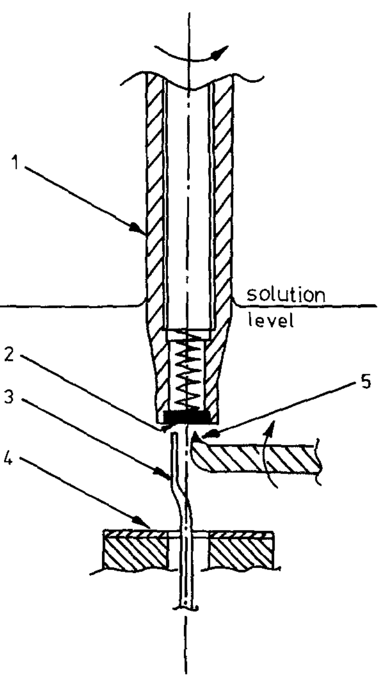

Fig. 1. Rotating disk electrode equipped for scatching. 1, Specimen holder; 2, specimen; 3, Luggin capillary; 4, counterelectrode; 5, diamond stylus.

potential field. The Luggin probe emerged from the center of the counterelectrode and was aimed at a point midway between the center and the periphery of the specimen. Preliminary results based on the dependence of current response on the probe position and size, and on interrupter-galvanostat experiments, indicated that negligible shielding and impedance effects were obtained using a 0.7 mm OD probe tip placed 1.0 mm from the specimen surface.

The electrode potential was potentiostatically controlled, the potential being monitored with respect to a saturated calomel electrode. A colorimetric check was made that no chloride was diffusing into the cell over time periods far in excess of those normally used.

In order to achieve a bare metal surface the surface oxide was mechanically removed by scratching the exposed circular surface of the rotating disk electrode with a diamond stylus. The diamond assembly, shown in Fig. 1, consisted of a gramophone stylus of tip radius 13 μm cemented to a Lucite holder which was mounted rigidly on a double bearing assembly. By the use of a calibrated screw the diamond could be made to traverse the specimen surface to create up to 10 separate concentric scratches during an experimental session. The diamond was normally held away from the specimen surface by a solenoid attracting a steel bolt let into the Teflon rod connected to the Lucite diamond holder. When appropriate the diamond was raised a height of ~2 mm onto the specimen by opening the solenoid circuit; the tracking weight was 2g. The diamond was allowed to bounce on the surface to produce individual scratches approximately 13 μm wide, 2 μm deep, and a length that was calculated from the linear velocity of the scratch v_s and the contact time. The contact time was controlled by the inertia of the diamond assembly and was independent of ω for $\omega > 10$ Hz; the contact time used in these experiments was 1 msec.

This method of production of a known area of bare surface is a modification of the technique developed by Lees (13), who relied on the production of a continuous scratch on a rotating disk to give a regenerated bare annulus. This latter method is powerful in that it provides an indication when a bare surface is maintained over the whole of the scratched area by monitoring the cell current with rotation speed, *i.e.*, the cell current becomes independent of rotation speed when the rotation periodicity is less than the nucleation time for oxide growth. Although this technique has been successful for such systems as stainless steel/chloride and brass/ammonia it is unsuitable for systems having nucleation times for oxide growth less the 5 msec, since it is experimentally difficult to achieve the required rotational frequency (>200 Hz) and maintain mechanical stability. Hence the modification in these experiments is a discontinuous scratching mode with a contact time ~1 msec.

In experiments which were to be conducted in deaerated solutions the cell was flushed with nitrogen and the previously deaerated solution then pumped into the cell until the rotating specimen was ~2.5 cm below the liquid surface. The corrosion potential was monitored for 3 hr by which time an approximately steady-state potential was achieved. The specimen was then potentiostatically controlled and the current recorded until a steady value was obtained on the filmed surface. The diamond was then dropped onto the surface and the current surge due to oxide removal was photographically recorded on the oscilloscope. A typical oscillogram is shown in Fig. 2. In this example the current surge deviates from the initial linear time relationship (shown dotted in Fig. 2). At less noble potentials this deviation does not occur; the reason for this is discussed below. The transient was quantified in terms of the initial current density on the filmed surface, the maximum anodic or cathodic current densities on the scratch (i_{am} and i_{cm}, respectively) during the first bounce and the subsequent rate of decay in

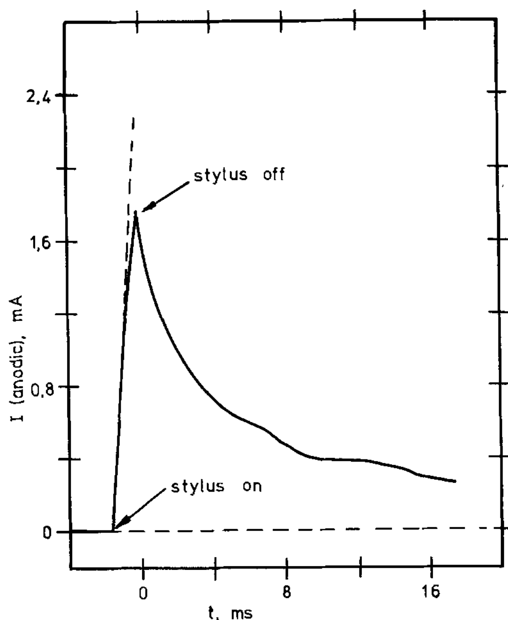

Fig. 2. Current transient caused by scratching electrode at constant $E = -825$ mV (SCE). $v_s = 384$ cm sec^{-1}. 1.0M HCl, pH = 1.0. $I_p = 0.0165$ mA.

current density. The current density on the scratch was calculated as $(I_s - I_p)/A$, where I_s is the current recorded during the transient, I_p the current recorded before scratching, and A the measured area of the scratch. There is a degree of uncertainty in this calculation due to an unknown surface-roughness factor on the scratch; this uncertainty is believed to be small, however, since the surface profile appears smooth when observed at magnifications of X10K.

Results

Polarization characteristics on filmed surfaces (steady state before scratching).—Figures 3a and 3b illustrate the polarization characteristics in deaerated 0.5M Na_2SO_4 and 1M NaCl, respectively, at pH 1.0 and 6.5. The curves were produced potentiodynamically at a sweep rate of 0.225 mV sec^{-1}. Reduction of H^+ with a linear $E/\log_{10} i_c$ predominates in the cathodic region; at more noble potentials anodic oxidation of Al occurs. The high degree of polarization of the latter ceases at -800 mV (SCE) in halide solutions when pitting is observed on the specimen. Reduction of O_2 was observed in aerated solutions; all results presented here were from deaerated solutions.

The addition of halide ions to the electrolyte increased i_a at constant E; in acid solutions this increase is approximately threefold and is constant over the range 1-4M NaCl. At more noble potentials pitting occurs in the halide solutions; the pitting potential varies between -805 mV (SCE) in 1M NaCl and -880 mV (SCE) in 4M NaCl.

The reduction reaction rate at constant E decreases with bulk pH and, in strongly acidic solution, is almost independent of halide content. At higher pH, however, the reduction rate is slightly higher in chloride solutions. The temperature dependence of i_c in the potential range -1200 to -1700 mV (SCE) gives an activation energy between 31 and 42 kJ mole^{-1}. Tafel plots are linear over some orders of magnitude of i_c, but changes in slope are observed at higher current densities. Values of $b_c = \partial E/\partial \log_{10} i_c$ in the linear region vary from -200 mV at pH = 1 to -120 mV at pH = 6.5.

Maximum dissolution and proton reduction rates on an oxide-free surface.—Figure 4 illustrates the variation of the maximum anodic current density i_{am}, on the scratched surface at -900 mV (SCE) with the linear velocity of the scratch v_s, for $1 < \omega < 200$ Hz. (Compare the magnitudes of i_{am} with i_a in Fig. 3.) v_s is defined at $2\pi r\omega$, where r is the distance between the center of rotation of the disk and the scratch. Although the reaction rate varies with anion content and electrolyte pH (Fig. 4), it is constant for $v_s > 100$ cm sec^{-1}. At lower v_s there is a small dependence of i_{am} on

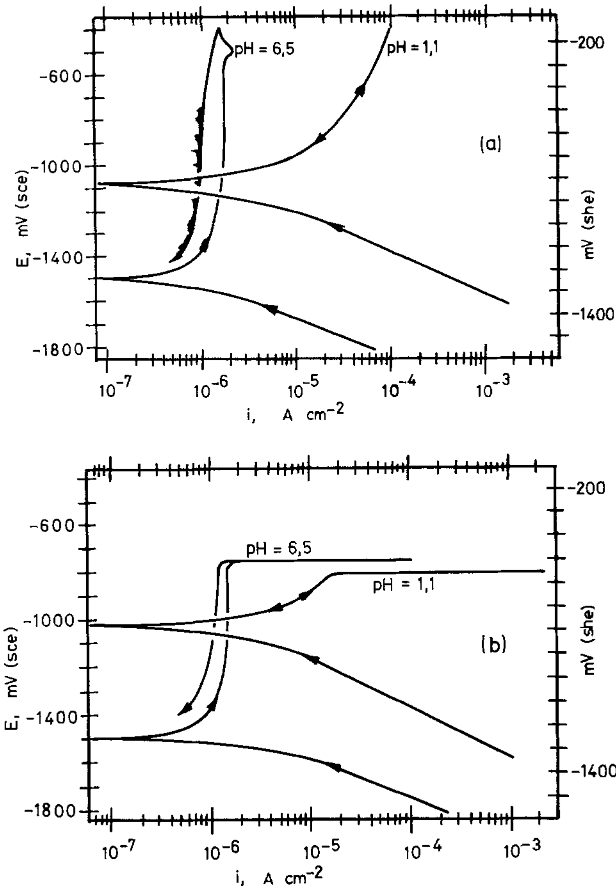

Fig. 3. Steady-state polarization of Al-7 w/o Mg. $dE/dt = 0.225$ mV sec^{-1}; $\omega = 10$ Hz. (a) 0.5M Na_2SO_4; (b) 1.0M NaCl.

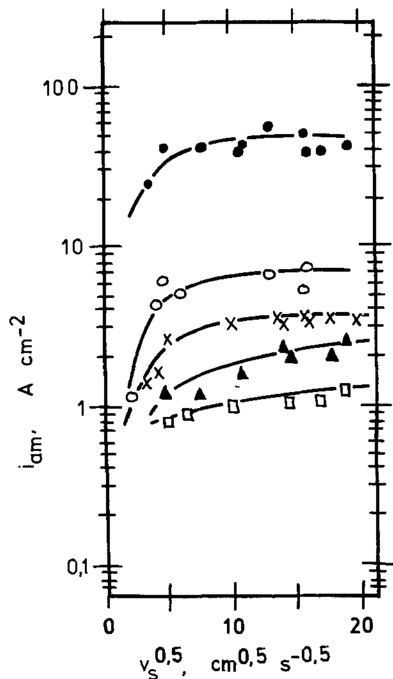

Fig. 4. Dependence of i_{am} on v_s at $E = -900$ mV (SCE) for electrolytes of different pH and anion content. ●, 4M NaCl, pH = 1.0; ○, 1M NaCl, pH = 1.0; ×, 0.5M Na_2SO_4, pH = 1.0; ▲, 1M NaCl, pH = 4.0; □, 1M NaCl, pH = 6.0.

v_s. Similar relationships were observed at −1000 mV (SCE) and −1300 mV (SCE). All subsequent experiments were conducted at $v_s > 200$ cm sec^{-1}.

The dependence of i_{am} on E is summarized in Fig. 5 for 1M NaCl solutions at various pH values and in Fig. 6 for acid solutions of various anion contents. Also shown in these figures are the data of Hagyard and Earl (14), who rapidly scratched pure Al in 1M KCl at pH =3.2. The graphs illustrate two major points. First, i_{am} at constant E is the same in all solutions over some potential range, the extent of which is specific to the solution pH and anion content; this common characteristic is denoted by the dotted line. (Note that this line is extrapolated beyond the experimental data at approximately 6 A cm^{-2}.) Second, at potentials just noble to this common range i_{am} may decrease or remain constant, before increasing upon further anodic polarization; this is most pronounced for the more acidic electrolytes.

The fact that the dotted line corresponds to the condition where a bare surface is maintained throughout the 1 msec scratch period is discussed in more detail below. Deviation from the dotted line at more noble potentials is due to the formation of a surface film of appreciable coverage within the 1 msec scratch time. It cannot be due to an ohmic potential drop since this was measured (using an interrupter-galvanostat) and found to have a maximum value of 10 mV. Neither can it be due to diffusion control at the high velocities used ($v_s > 200$ cm sec^{-1}, see Fig. 4). In addition the activation enthalpy for dissolution on the scratched surface in the potential region −1500 to −1000 mV (SCE) is low (15) in the range 12-17 kJ mole^{-1}, in contrast to 84-92 kJ mole^{-1} observed on dissolving surfaces with an initially air-formed film at pH 6.5.

At potentials more negative than −1500 to −1600 mV (SCE) the net current density on the scratch is dominated by the cathodic reaction. The maximum cathodic current density i_{cm} is shown as a function of pH and anion content in Fig. 7a and 7b. At high i_{cm} and less acidic pH, the reaction rate tends to become potential independent; under these conditions the rate is limited by diffusion of H^+ since the limiting value of i_{cm} is inversely proportional to pH (Fig. 7) and depends on $\omega^{1/2}$ (15). However, linear regions in $E/\log_{10} i_{cm}$ are apparent which are independent of ω and have a slope $b_c = -290$ to −320 mV in both sulfate and chloride electrolytes. Note that a similar b_c value was observed by Hagyard and Earl (14) for the proton reduction reaction on oxide-free pure aluminum in 1M KCl at pH 3.2.

Decay of reaction rate of scratched surfaces.—The change in reaction rate due to oxide growth on the scratch was examined in terms of the time dependence of the ratio i_{at}/i_{am}, where i_{at} is the anodic current density at time t after the diamond has bounced off the surface. The choice of this was based on the assumption that the decay would follow a law of the type $i_{at} = i_{am}f(t)$.

Figure 8 illustrates the effect of potential on the electrode reaction rate for various anion contents at pH = 1.0. In 0.5M Na_2SO_4 the decay rate due to oxide growth on the scratch increases as E becomes more noble (*i.e.*, as the overpotential for oxide formation increases). The same dependence is noted in the solutions containing Cl^- except that anomalous behavior is observed as the potential approaches the pitting potential. This is shown in Fig. 8 by the dotted lines and is characterized by a significantly slower decay rate than that observed in sulfate solutions. The effect becomes more marked as

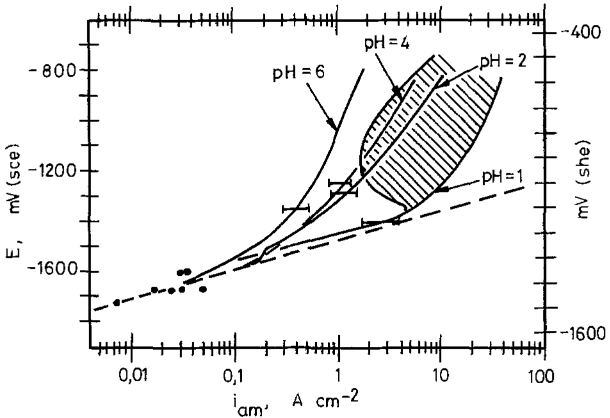

Fig. 5. Anodic polarization curve for bare metal dissolution in 1M NaCl as a function of pH. v_s = 200-400 cm sec^{-1}. Numbers give the electrolyte pH. Hatched area represents scatter of results which occurred at pH = 1 only. Error bars give the maximum deviation. Data points (●) are for pure aluminum in 1M KCl at pH 3.2 (14).

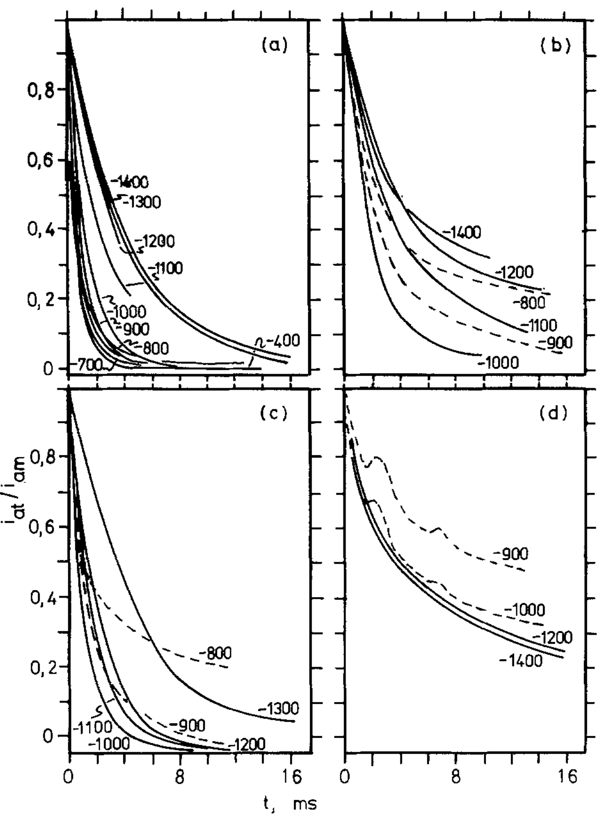

Fig. 8. Decay of i_{at}/i_{am} with t as a function of E (mV (SCE)) at $pH = 1.0$. (a) 0.5M Na_2SO_4; (b) 1M NaCl; (c) 2M NaCl; (d) 4M NaCl.

the Cl^- concentration increases, and in 4M NaCl "breakaway" current surges are observed during decay. It is expected that the decay rate should increase as the pH increases (*i.e.*, as the oxide becomes more thermodynamically stable at a given potential). In general this was observed, but the effect was not reproducible, possibly owing to the buildup of localized acidity associated with oxide formation.

Figure 9 shows the decay in cathodic reaction rate after scratching in various solutions at potentials approaching the reversible potential for solid-state oxide formation (~ −1800 mV (SCE) at $pH = 1.0$). As E becomes more cathodic and the oxide becomes less stable, so the effect of Cl^- in slowing down the decay rate becomes more appreciable, in a manner similar to that noted as the pitting potential is approached.

Discussion

Metal dissolution on a bare surface.—The linear regions in Fig. 5 and 6 (shown dotted) are summarized in Fig. 10, together with the data of Hagyard and Earl (14) (who used a 5 μsec contact time). That the data shown in Fig. 10 do in fact correspond to the condition where a bare surface is maintained throughout the 1 msec scratch period is indicated as follows. First, the $E/\ln i_a$ relationship is independent of sulfate (0.5M) and chloride (1-4M) content and solution pH and is linear. This is expected for a simple charge-transfer rate-controlled anodic dissolution reacion. Second, the data form a direct extrapolation of the work of Hagyard and Earl, whose scratch period was far shorter and thus even more likely to maintain a bare surface. Finally, the extent of the potential range over which the bare surface is maintained (Fig. 5 and 6) depends inversely on the expected stability of the oxide, *i.e.*, the potential range increases as the pH decreases, and as the concentration of Cl^- increases.

Figure 10 shows that the dissolution kinetics obey Tafel's law and gives a slope b_a — 118 ± 25 mV. Linearity is achieved over almost 4 decades of current density.

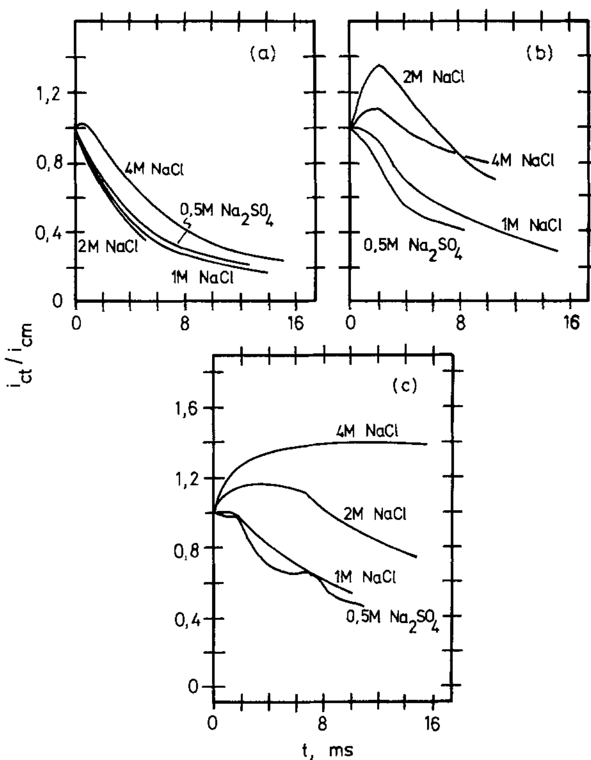

Fig. 9. Decay of i_{ct}/i_{cm} with t as a function of anion content at $pH = 1.0$. (a) $E = -1600$ mV (SCE); (b) $E = -1800$ mV (SCE); (c) $E = -2000$ mV (SCE).

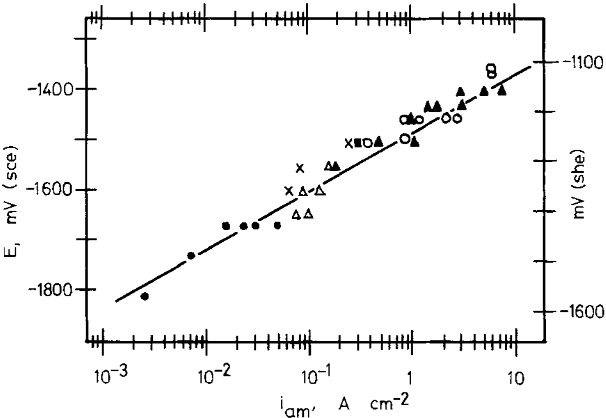

Fig. 10. Anodic Tafel line for dissolution of bare metal showing independence of reaction on electrolyte composition. $b_a = 118 \pm 25$ mV. ▲, 4M NaCl, $pH = 1.0$; ○, 1M NaCl, $pH = 1.0$; △, 1M NaCl, $pH = 4.0$; ×, 1M NaCl, $pH = 6.0$; ■, 0.5M Na_2SO_4, $pH = 1.0$; ●, 1M KCl, pH 3.2 (14).

Since the bare surface dissolution rate is independent of sulfate or chloride content (within the concentration ranges investigated) the reaction does not involve complexes of these anions, at least in the rate-determining step. It is also independent of pH. We thus conclude that the initial single electron transfer is rate determining

$$Al + H_2O \rightarrow AlOH_{ads} + H^+ + e^- \quad [1]$$

Reaction [1] proceeds with a rate given by

$$i_a = 3\mathbf{F}k_1 \exp (\beta_a \mathbf{F}E/RT) \quad [2]$$

which gives $b_a = 118$ mV and $\partial \log_{10} i_a/\partial \log_{10} H^+ = 0$, in good agreement with experiment, for $\beta_a = 0.5$.

Reaction [1] is probably the initial step in both the dissolution and passivation processes (which occur in parallel until the surface is completely covered with

oxide). The net remaining reactions may be, respectively

$$AlOH_{ads} + 5H_2O + H^+ \rightarrow Al^{3+} \cdot 6H_2O + 2e^- \quad [3]$$

$$2AlOH_{ads} + H_2O \rightarrow Al_2O_3 + 4H^+ + 4e^- \quad [4]$$

The mechanisms of reactions [3] and [4] are unknown, but they are probably electrode reactions since observations of Straumanis and Poush (16) and Spooner (17) have shown that, from the stoichiometry of the overall reaction, there are 3 electrons detected per atom of aluminum oxidized. Reaction [4] is probably a solid-state reaction with no intermediate dissolved phase at least in the early stage of oxide growth ($t < 2$ msec); the lack of dependence of i_{am} on V_s for $V_s > 100$ cm sec^{-1} (Fig. 4) indicates that, at these high solution flow rates, passivation does not occur by a dissolution-precipitation process, despite the very high current densities.

Repassivation.—The rate of decay of i_a was interpreted in terms of the rate of oxide growth after scratching, and obeys the following law

$$i_{at} = i_{am} \exp(-\alpha t^n) \quad [5]$$

α and n have values determined by plotting $\log_{10}(\ln(i_{am}/i_{at}))$ against $\log_{10} t$, shown in Fig. 11. i_{at} is the anodic current density at time t after the diamond stylus has left the surface. Two values of n are revealed in Fig. 11: an initial region where $n = 1$ and at longer times a region in which $n = 0.5$. The fact that some coverage of the bare scratch surface has in some cases (at more positive E) already occurred when the stylus leaves the surface is unimportant since, although it affects the surface area of bare metal, analysis of the data via Eq. [5] involves only ratios of current density. Figure 12 shows plots of Eq. [5] as a function of electrolyte composition and potential. As E becomes more noble the transition between the two laws for the sulfate electrolyte system occurs at shorter times. Increasing the Cl^- concentration also decreases the transition time, especially as the pitting potential is approached. A possible explanation for the change in n value is that the $n = 1$ decay law represents growth of a continuous oxide film, probably of monolayer coverage, that is relatively defect-free, whereas the $n = 0.5$ law represents thickening of the film, which also becomes increasingly defective, perhaps because of inclusion of alternative anions (Cl^- or SO_4^{2-}) in the solid lattice (18). It must be emphasized however, that when the oxide is ruptured in solutions containing Cl^- even as concentrated as 4M, rapid film growth always ensues; the effect of the Cl^- is merely to accelerate the onset of growth of the subsequent defective film. As indicated in Fig. 8 by the periodic current surges, partial break-

down of the film may occur at high concentrations of Cl^-.

The experimental results presented are in qualitative agreement wth those of Adams and Foley (19) and of Foley and Trzaskama (20) who investigated the change in uncontrolled open-circuit potential of various aluminum alloys upon continuously scratching the specimen in solutions containing different concentrations of anions. For instance, their observed open-circuit values on the scratched surface are in approximate agreement with those computed from the individual anodic and cathodic current densities in Fig. 5, 6, and 7, and their resultant change in open-circuit potential with time and its dependence on, for instance, sulfate and chloride anions, is in agreement with the expected effect from Fig. 8 and 9. However a direct quantitative comparison is not possible since the use by these authors of a continuous scratching technique with a rotation periodicity > 5 msec will not maintain a bare surface over the whole of the scratched area, as discussed in the Experimental section above; thus there is some question as to the surface condition initially being examined in these other investigations.

Although the experimental results of these authors (19, 20) and the present work are in qualitative agreement, there is a divergence in interpretation. Adams and Foley (19) and Foley and Trzaskama (20) suggest that the effect of anions on the passivation rate is due solely to the following reaction occurring in the liquid

$$Al^{3+} + xX^- + yOH^- + 2H_2O = Al(X)_x(OH)_y(H_2O)_z \quad [6]$$

were X^- is any anion. The interpretation from the present work is that, although the above reaction may well occur at longer times or in more stagnant solutions, the oxide forms first by an overall reaction given by Eq. [4], followed by incorporation of the anions into the film after a finite time period, which is dependent on the potential and the anion. The precise reaction sequence must await further experimentation.

Conclusions

1. The rates of dissolution of Al-7 w/o Mg and of proton reduction are increased by several orders of magnitude when the high-impedance surface oxide is mechanically removed.

2. The anodic dissolution kinetics of the bare alloy surface follow Tafel's law, the rate being independent of pH and sulfate (0.5M) and chloride (1-4M) content. The rate-determining step is

$$Al + H_2O \rightarrow AlOH_{ads} + H^+ + e^-$$

3. By comparison with previous results on pure Al the anodic and cathodic reaction kinetics for the pure metal and for Al-7 w/o Mg are similar.

4. Growth of an oxide film on the initially bare alloy surface occurs readily in acid sulfate and chloride solutions and follows the empirical law $i_{at} = i_{am} \exp(-\alpha t^n)$, where $n = 1$ initially but changes to 0.5 after some time. The changeover time is a function of both E and Cl^- concentration.

Effect of CO on the Low Temperature Diffusion of Cr and Si Through Thin Gold Films

Chin-An Chang*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Low temperature diffusion of Cr and Si through thin gold films is studied in N_2 and in (N_2 + CO) ambients. The out-diffusion of both Cr and Si to the gold surface is suppressed in the presence of CO. The results are discussed in terms of a model which considers the roles of both the gold film and the ambients used.

Recently there have been studies of ambient effects on low temperature diffusion in thin gold films. The diffusing species include both metals and Si (1-4). The out-diffusion rates can be either enhanced or suppressed depending on the ambient used. An enhanced diffusion is often observed in an oxidizing ambient, whereas a reduced one is observed in the presence of H_2. An understanding of such ambient effects is useful not only for the determination of the diffusion mechanism involved, but also for the control of metal-metal contacts, metal-Si contacts, Schottky barriers, and in such applications as the growth of large grain polycrystalline Si films (5).

In this paper we study the effect of CO on the out-diffusion of Cr and Si in thin gold films. As will be discussed later, CO is chosen because changes it produces in the work function of gold are different from those produced by oxidizing ambients, *e.g.*, steam and air. We are interested in studying whether this difference plays any role on the diffusion of Cr and Si through gold. We have found that the outdiffusion of both Cr and Si through thin gold films is suppressed in the presence of CO. This result is discussed in connection with other ambient effects on the various species diffusing through gold. A surface potential model is proposed for the observed ambient effects by considering the roles of both the gold film and the ambients used.

Experimental and Results

For the study of outdiffusion of Cr through gold, Cr and Au films, 2000-3000Å each, were successively evaporated on sapphire substrates. For that of Si through gold, thin films of gold, ~2000Å, were evaporated on (111)Si. The samples were annealed at 250°C for 1 hr in a flowing N_2 ambient and in an N_2 + CO(5:1) mixture. The N_2 flow rate was kept the same in both ambients. The samples were analyzed using both He^+-ion backscattering spectrometry and Auger spectroscopy.

Figure 1 shows the backscattering spectra for the Au/Cr samples. It shows significant out-diffusion of Cr to the gold surface, and also diffusion of Au into Cr. Less accumulation of Cr on the gold surface is observed in the presence of CO. Figure 2 shows the Auger depth profiling using Ar^{+}-ion sputtering for the sample annealed in N_2. It shows both Cr and oxygen near the surface, indicating oxidation of the accumulated Cr on the gold surface. The sputtering time needed for the disappearance of the Cr signal is 50 min for this sample. In contrast, the Cr signal for the sample annealed in N_2 + CO mixture disappeared after 7 min of sputtering.

Figure 3 shows the backscattering spectra for the out-diffusion of Si through gold. Accumulation of Si on the gold surface is observed for the film heated in N_2, but not for that in the N_2 + CO mixture. This is also confirmed by Auger analysis. The small amount of Si accumulation observed on the gold surface is expected in a nonoxidizing ambient (2). The broad peak located near channel 310 in Fig. 3 corresponds to the residual Ar from plasma etching cleaning of the Si substrates prior to gold evaporation.

We have also evaporated gold films on GaAs and studied the out-diffusion of Ga and As through gold. Using N_2 and N_2 + CO ambients, the diffusion rates for both Ga and As are reduced in the presence of CO. Details of this study will be reported elsewhere.

Discussion

We have shown that the out-diffusion of both Cr and Si through thin gold films is suppressed in the presence of CO. This result is now compared with the known ambient effects on the out-diffusion of various metals and Si through gold. Table I lists both the known ambient effects from literature and results of this study. Our results on Ga and As are also included for comparison.

As Table I shows, in an oxidizing ambient such as steam, air, and oxygen, an enhanced out-diffusion rate is observed over that in vacuum or nonoxidizing ambients. The presence of CO or H_2, however, reduces the out-diffusion rates. In oxidizing ambients, the out-diffused species on the gold surface were often found to be in the oxide form. This is thought to act as a sink for the out-diffused species and is responsible for the enhanced diffusion observed. Such a sinking effect is consistent with the observed higher diffusion rate of Si through gold in steam than in air, and that for Cu in the presence of chlorine (4). This effect alone, however, considers only the role of the ambients on the oxidation of the out-diffused species. It does not take into account the ambient effect on the properties of the metal film, nor the role played by the metal film itself. We will show that the latter considerations provide an alternative explanation to the observed ambient effects. They also allow a generalization of the known ambient effects using similar metal films, such as gold and silver. For example, no Si accumulation on a silver surface is observed when the Ag/Si system is heated in an oxidizing ambient (2). However, using sequential Ag/Au or Au/Ag films on Si, accumulation of Si is observed on the silver surface for the Ag/Au/Si system, but not on the gold surface for the Au/Ag/Si one. A similar result has been observed for Cr (6).

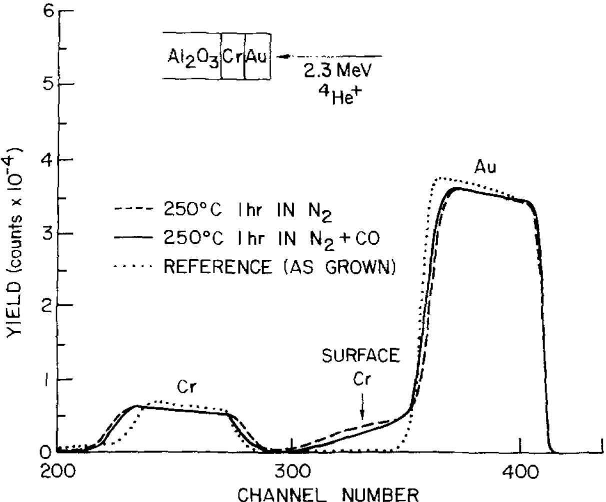

Fig. 1. Backscattering spectra of Au/Cr/sapphire samples heated in different ambients. 5 keV/channel.

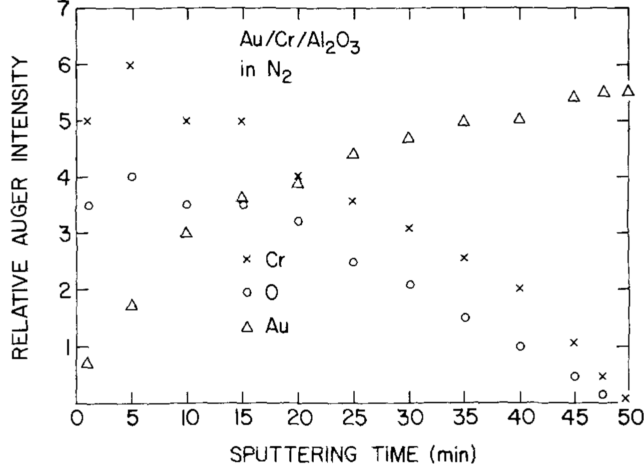

Fig. 2. Auger depth profiling of the Au/Cr/sapphire sample annealed in N_2.

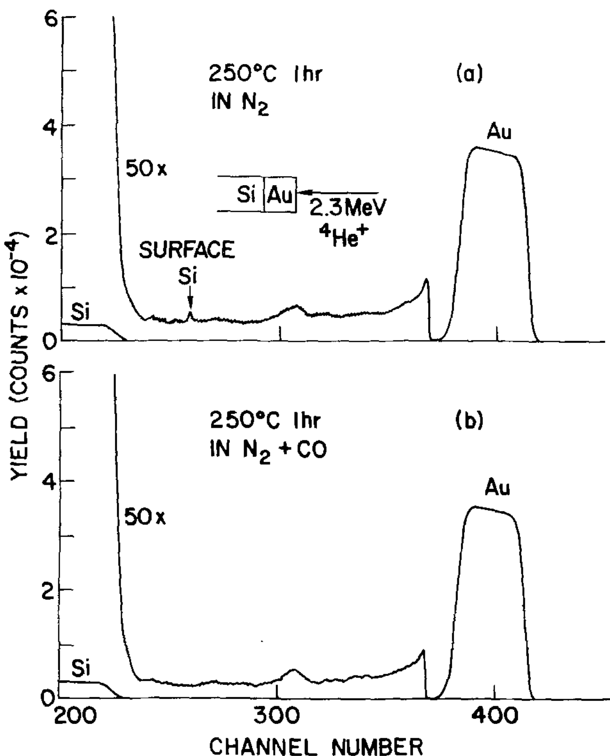

Fig. 3. Backscattering spectra of Au/Si samples: (a) 1 hr annealing at 250°C in N_2; (b) 1 hr annealing at 250°C in N_2 + CO(5:1). 5 keV/channel.

Here we propose a model to consider the roles of both the ambients and the metal films. We show that this model correlates very well the observed ambient effects on the various diffusing species in both gold and silver films. It is also consistent with the higher out-diffusion rate of Si in steam than in air. For the role of the metal films, we consider the electronega-

Table I. Observed ambient dependence of the out-diffusion rates in thin gold films

tivity difference between the metal film and the diffusing species; for that of the ambients we consider the ambient-induced surface potential changes of the metal film. Since the metal films studied are polycrystalline, it has been suggested that grain boundary diffusion is the dominant mechanism in these films (1-4). The grain boundary diffusion scheme plays a central role in our model.

All the diffusing species listed in Table I have smaller electronegativities than gold. The electronegativities of Cr and Si, for example, are 1.6 and 1.8, respectively, that of gold is 2.4 (7). The ionicity of Cr and Si in gold can be approximately estimated using Pauling's ionicity relation (7). It gives one-seventh and one-tenth of a positive unit charge for Cr and Si in gold, respectively. Such positively charged species in gold would be attracted to the gold surface if the ambient-induced surface potential changes are favorable. Indeed, upon exposure to air and steam, a decrease in work function of 0.5 and 1.2 eV, respectively, is observed for gold (8, 9). Such a decrease in work function is equivalent to an increase in the negative surface potential of the same magnitude (10). No work function data are available for gold in dry oxygen, but the resistivity measurement of gold in dry oxygen also shows an induced negative surface potential (11). These changes result from the corresponding increases in electron charge density on the gold surface due to adsorption of the ambient species. The extra charge will penetrate into gold and establish an electric field under the surface for some layers (12). For a polycrystalline gold film, this effect can be much more pronounced due to the small grains present. The ambient species are often known to diffuse into the metal film along the grain boundaries (13). This would create an electric field under the surface of each grain, similar to that described above for the film surface. The dissolved Cr and Si in gold, for example, would be attracted to the grain surface due to the attractive force in an ambient of steam, air, or oxygen. Once they reached the grain surface, rapid diffusion through the grain boundaries to the film surface would follow (14). The larger surface potential change of gold in steam than in air is also consistent with the higher diffusion rate of Si observed in the former ambient. Hydrogen and CO ambients, on the other hand, increase the work function of gold by 0.18 and 0.9 eV, respectively (15). The ambient-induced surface potential changes of gold in hydrogen and CO are, therefore, unfavorable to the out-diffusion of Cr, Si, etc., and this out-diffusion should be suppressed. Thus, we have shown a good correlation between the different out-diffusion rates observed and the ambient-induced surface potential changes of gold in these ambients.

This model is also consistent with the work using Ag and sequential Au-Ag films. The electronegativity of silver is 1.9, and the ionicity of Si in silver, for example, is less than one-tenth of that in gold. Much less ambient-enhanced out-diffusion of Si in silver is expected even in an oxidizing ambient. For the Au-Ag sequential films, since Si mixed with the metal only near the Si-metal interface at temperatures below the Si-metal eutectic point (2), our model shows that it is the metal film which is in direct contact with Si that determines whether the dissolved Si could be pulled to the grain surface or not. Thus, one expects an accumulation of Si on the silver surface for the Ag/Au/Si case, but not on the gold surface for the Au/Ag/Si one.

It is encouraging that our model, described in a simplistic way, correlates well the observed ambient effects on a variety of diffusing species in gold and silver films. The diffusion mechanism in these systems can, of course, be much more complicated. Other factors could also play important roles in determining the observed diffusion rates. The sinking effect mentioned earlier, for example, is clearly an additional favorable factor to enhancing the out-diffusion rates using oxidizing ambients. The effect of film thickness on the out-diffusion rate could also be incorporated into our model by considering a concentration gradient of the in-diffused ambient species along the grain boundaries. With increasing gold film thickness, fewer ambient species would be distributed along the grain surface near the interface which would weaken the described ambient effect. In addition, the in-diffused ambient species could also affect the initial interface mixing process which is very important to any subsequent out-diffusion through the metal films. Further studies are in progress to understand this last process.

Summary

We have shown that the presence of CO in an N_2 ambient suppresses the out-diffusion of Cr, Si, Ga, and As through thin gold films. A surface potential model is proposed by considering the roles of both the ambients and the metal films used. This model is shown to correlate both our results and the known ambient effects on a variety of diffusing species in both gold and silver films. Extension of this study to different ambients and to different metal films can be both interesting and useful to the semiconductor technology.

Autodoping Effects in Silicon Epitaxy

G. R. Srinivasan

IBM Data Systems Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This paper reviews some of the recent autodoping developments which have contributed to a quantitative understanding of this phenomenon. Special emphasis is placed on buried layer studies that are pertinent to the fabrication of integrated circuits. The paper also presents new data concerning the origin of autodoping, flow effects, autodoping differences between silane and $SiCl_4$ depositions, and the effect of HCl vapor etch on autodoping. An attempt is made to provide a theoretical framework within which these and other effects can be interpreted.

Autodoping in epitaxial silicon was first discovered in 1961 (1, 2), and numerous studies have appeared since then in literature (3-28) describing various aspects of this phenomenon. The term autodoping refers to the transfer of dopants from the substrates to the epitaxial layers during growth. The studies in the past have identified various mechanisms that are involved in this dopant transfer. For example, Thomas *et al.* (3) and Grossman (5) considered the transfer of dopants in the gas phase, whereas Rice (6) and Grove *et al.* (7) focused on the solid-state diffusion of the dopants from the substrate into the epitaxial layers. However, the clear separation of the solid-state and gas phase effects was not made until recently (13, 20, 24, 25, 28) when studies using high resistivity substrates with localized buried layers were begun. The use of such substrates has allowed quantification of autodoping in terms of various process and substrate parameters. In this paper, we limit our discussion to the buried layer studies, which are also more pertinent to the fabrication of integrated circuits in which buried layer structures are used as device elements. Further, this will also simplify the discussion, since complications arising out of back surface autodoping can be neglected for this case.

The vertical cross section of a buried layer structure is shown in Fig. 1a. Figure 1b shows typical vertical profiles of dopant concentration from this structure. These profiles correspond to sections on and off the buried layer. There are some characteristic similarities between the two profiles. Both show a peak near the substrate-epitaxy interface, although the peak in the "on" profile is a few orders of magnitude higher than that for the "off" profile. We can also observe that in the top layers of the epitaxy the two profiles tend to merge, which shows that the distribution mechanisms must be common for the two cases in these layers. In fact, this common region in the "on" profile corresponds to the so-called autodoping tail, which is a result of vertical autodoping. It is customary to refer to the "off" profile as the lateral autodoping peak. The region close to the substrate-epitaxy interface in the "on" profile is dominated by solid-state out-diffusion of the dopant, whereas the distribution in the autodoping tail is caused by dopant transport in the vapor phase. Figure 2 shows the resolution of the "on" profile into various components. We consider first the out-diffusion models, followed by a discussion of gas phase autodoping, which includes both the lateral and vertical autodoping.

Out-Diffusion Models

Rice (6) and Grove *et al.* (7) have solved the one-dimensional linear diffusion equation, which describes the out-diffusion of dopants into the epitaxy from uniformly doped substrates. Their solution simplifies to a complementary error function (erfc) distribution for cases for which $Vt > 2\sqrt{Dt}$, where V is the epitaxial growth rate, D is the solid diffusivity of the dopant in the epitaxy, and t is the growth time. This distribution has been verified for several cases of uniformly doped silicon substrates which have dopant concentrations up to 10^{19} cm^{-3} (8).

In order to extend the diffusion model to the case of buried layers, one must consider the redistribution of an existing nonuniform profile. One such attempt was made by Hu (11), who considered the redistribution of an initial erfc distribution. He was able to show that satisfactory analytical solutions can be obtained for cases where the initial erfc distribution is approximated by a Gaussian. However, his model requires the assumption of zero surface concentration at the growing surface, which evidently needs to be modified in view of the autodoping component. Also, in view of the high dopant concentrations that are typical of the buried layers, concentration dependence of the diffusion coefficient needs to be taken into account. In addition to these complexities, one must also consider the redistribution that would occur in the buried layer during the heat cycle prior to deposition. Quite evidently, the above-mentioned complications render it impossible to obtain an analytical solution to the diffusion equation. Therefore, it is necessary to solve numerically the nonlinear continuity equation

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left[D(c)\frac{\partial c}{\partial x} - VC \right] \quad [1]$$

with appropriate moving boundary conditions. Computer programs such as SUPREM (29) have been written to solve the above one-dimensional equation, and it is found that close agreement between theory and experiment is possible for at least the out-diffusion portion of the dopant profile.

Lateral Autodoping

Previous studies (13, 21, 24, 25, 28) have clearly established that lateral autodoping is brought about by the gas phase transport of the dopant vapor in the reactor. In what follows, we examine the lateral autodoping process in terms of the dopant evaporation during pre-epitaxial thermal cycle, and its redistribution in the reactor flow system and, finally, its reincorporation into the substrate and epitaxy.

Origin of autodoping.—Before we attempt to understand the detailed mechanism of autodoping, it is necessary to establish the time sequence in the epitaxial process at which most of the dopant transfer occurs. Clearly, since the maximum in the lateral autodoping profile occurs near the substrate-epitaxy interface, a major portion of the dopant redistribution must occur in the initial stages of epitaxial growth. In order to further define this stage of maximum autodoping, the following experiments were conducted. A P^- silicon wafer which had a localized (2.5 mm^2) arsenic diffusion at the center, was cut into parts, A and B, such that part A had the diffusion region and part B did not. The two parts were then placed on the susceptor of a horizontal epitaxial reactor. The cut between parts A and B was made close to the edge of the diffused area such that part B can be placed very close to, but not in contact with, the diffused region in part A. The spacing between parts A and B could be varied in order to obtain information on the dependence of the lateral autodoping with lateral distance from the edge of the diffused area.

The experiment consisted of prebaking parts A and B together in the epitaxial reactor using typical epitaxial H_2 flow conditions. The prebake was at 1150°C for 10 min without deposition. After cooling to room temperature, part A was taken out and was replaced by another P^- silicon wafer (C) which did not have any localized arsenic diffusion in it. The reactor was heated again to 1150°C with wafers B and C, and a standard 2 μm thick silicon epitaxy was deposited.[1] In a separate experiment, another P^- silicon wafer (D), which had an arsenic-diffused region as in A, was given a normal epitaxial deposition using the same growth and flow conditions as in the previous experiment but without any interruption between the prebake and deposition cycles. The wafers B, C, and D were subsequently profiled for several lateral distances from the diffused area by the spreading resistance technique. It was found that the profile from wafer C did not show any p-n junction (*i.e.*, the epitaxy was p-type), thus indicating that there was no autodoping on this wafer. On the other hand, wafer B showed substantial autodoping. In addition, wafer D showed arsenic autodoping, as expected. It was also found that the autodoping peak maximum concentration decreased with increased lateral distance from the diffused region for wafer D and also with the increase in lateral distance from the cutoff edge in wafer B.

In order to facilitate a comparison of these autodoping results, profiles are shown in Fig. 3 for wafers B and D, measured 2 mm laterally from the diffused region. We can see from this figure that the peak maximum concentration is about the same for both wafers B and C within the experimental uncertainty, although the integrated dose for wafer D is ~20% larger than that for wafer B.

On the basis of these observations, we draw the following conclusions: (*i*) since wafer C did not show any autodoping while wafer B did, although both were together during the deposition cycle, the autodoping in B is the result of its prebake with the diffused wafer A; (*ii*) the near equality of autodoping in wafers B and D show that the bulk of autodoping has already occurred at the prebake stage. We recall that wafer D had the diffusion area through the entire epitaxial cycle, whereas wafer B had the diffused silicon source only during the prebake part of the epitaxial cycle.

The fact that the major portion of autodoping occurs in the prebake cycle has also been noted by Joyce *et al.* (8) and by Deines and Spiro (34). Recently, Tabe and Nakamura (40) have also reported similar results. It is clear, then, that any satisfactory model for

[1] Unless otherwise noted, all epitaxial depositions in the autodoping experiments described in this paper are intrinsic depositions without the addition of an external dopant.

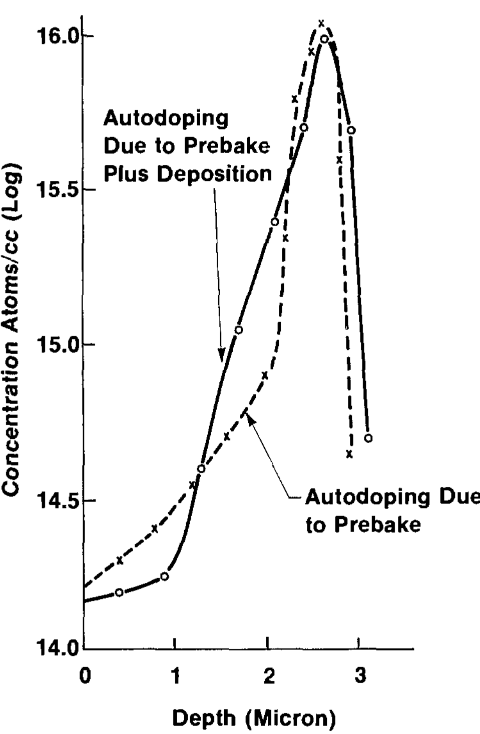

Fig. 3. Spreading resistance profiles from wafers B and D. (Wafer B, autodoping contribution due to prebake; wafer D, total autodoping.)

autodoping has to take into account the dopant transport that occurs during prebake. In the next section, we describe such a model developed by the present author (25).

Another interesting observation drawn from the above experiments is that autodoping occurred even when the source wafer A and the autodoped wafer B were not in physical contact. This fact rules out surface diffusion as the mechanism of dopant transport involved in lateral autodoping. Similar conclusions were reached by Pogge *et al.* (13), who found that autodoping from a diffused wafer occurred even when the diffused region was surrounded by an oxide ring.

Evaporation kinetics during hydrogen prebake.—This aspect of autodoping has been considered in some detail by the present author (25) who found that the maximum in a lateral autodoping profile is a decreasing function of both prebake time and temperature. This analysis showed that the autodoping peak maximum concentration can be related to these prebake parameters on the basis that the maximum in a lateral autodoping profile is directly proportional to the surface concentration over the diffused layer that existed just prior to epitaxial deposition. This expression for the autodoping peak concentration due to an initial rectangular dopant distribution in the diffused layer is given by (25)

$$C(T,t) = A \exp(\beta^2 t) \cdot \text{erfc}(\beta t^{1/2}) \quad [2]$$

where A is a constant of proportionality independent of temperature, T and t are prebake temperatures and time, respectively. $\beta = K/\sqrt{D}$, where K and D are, respectively, the evaporation velocity and solid diffusivity of the dopant in silicon. Both K and D were assumed to be Arrhenius functions of temperature. The above expression gave a good fit to the data yielding values for the arsenic evaporation velocity as a function of temperature. We also note that since the evaporation rate, r, is given by $r = KC_o(t)$, where $C_o(t)$ is the surface concentration, which can also be described by an expression similar to Eq. [2], the above equation describes the variation of evaporation rate with prebake time and temperature. The results of this study thus support the view that the dopant redistribution during a pre-epitaxial bake cycle is controlled by the evaporation of the dopant from the buried layer.

Effect of HCl vapor etch during prebake.—In the previous section, we considered the release of dopants during prebake in H_2. The dopant redistribution could conceivably change if there were other etchants in the system during prebake. HCl vapor etching is a common practice for silane epitaxial deposition, and hence it is instructive to study its effect on autodoping. Maeda and Takayama (17) studied this effect in the silane epitaxy grown on antimony-diffused silicon substrates. They found that the etched samples had less out-diffusion than the controls. They argued that the amount of silicon etching was not enough to account for this difference and interpreted this decreased out-diffusion as evidence for decreased arsenic diffusivity in silicon near the surface.

The effect of HCl etching on substrates with an arsenic buried layer has not been reported in the literature. To study this effect, the following experiments were conducted: P^- (100) silicon wafers of 10-20 Ωcm resistivity were diffused with arsenic ($C_o \sim 1.5 \times 10^{21}$/cm^3, $x_j \sim 1$ μm) to cover 62% of the wafer surface area in a dense pattern which had buried layers varying in size from 50 × 100 to 200 × 400 μm. A standard 1150°C epitaxial deposition of 2 μm thickness was made on one of these substrates in an rf heated horizontal reactor. The pre-epitaxial bake cycle used was 10 min at 1150°C in flowing H_2. In subsequent runs, HCl vapor etching (0.04% by volume) was included in the middle of the prebake cycle while keeping all other conditions unchanged. The HCl etching times used were 10 sec, 20 sec, and 1 min. The samples were profiled, both on and off the buried layers, using the spreading resistance technique. Profiles were made at the same distance and direction with respect to flow in all cases.

The autodoping results are shown in Fig. 4. We observe that while there is no significant change in autodoping due to the 10 sec etching, further increase in etching time caused a decrease in the autodoping peak maximum concentration. Since etching is also expected to produce changes in the buried layer characteristics, we show these data in Table I. We note from these data that (*i*) the decrease in off-profile maximum is accompanied by an increase in the buried layer sheet resistance, and (*ii*) the junction depth of the buried layer decreases with an increase in etching time. These two facts show clearly that the top layer of the buried layers are being etched away during the HCl etch, which, in turn, implies a change in the surface concentration, C_o, over the buried layers. Thus, it would appear that changes in autodoping due to HCl etching can be related to changes in C_o. In further experiments, we varied the etch cycle such that HCl was injected for 10 sec at different times in the prebake cycle and found no significant change in autodoping.

We conclude from the above results that the effect of HCl etching in the prebake cycle can be understood in

Table I. Autodoping effects of pre-epitaxial HCl vapor etch (0.04% HCl by volume, 1150°C deposition temperature, 0.25 μm/min growth rate)

Etch time (sec)	Buried layer characteristics Sheet resistance (Ω/□)	Junction depth (μm)	Lateral autodoping characteristics Peak max (atoms/cm³)	EPI sheet resistance (Ω/□)
0	9.01	4.24	2.2×10^{17}	1340
10	9.96	4.03	2.2×10^{17}	1370
20	15.70	4.01	1.37×10^{17}	1730

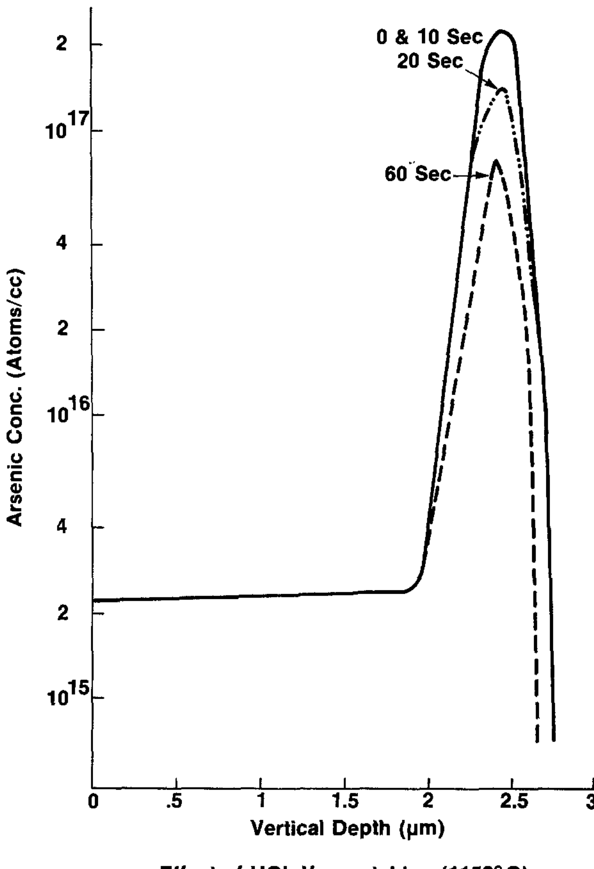

Fig. 4. Off-buried layer spreading resistance profiles for various periods of pre-epitaxial HCl vapor etch (etch temperature 1150°C).

terms of a change in C_o, which is consistent with the model developed in the previous section. We point out here, however, that HCl (or any other etchant) present during the deposition cycle could alter the autodoping characteristics through a different mechanism that involves changes in dopant incorporation. We shall consider this aspect later, when we discuss the autodoping differences between silane and $SiCl_4$ depositions.

Vapor distribution and gas flow effects.—The dopant vapor that is produced during the prebake is carried away by the reactor flow system which redistributes this vapor onto different areas of the substrate as well as to different substrates in the reactor. The fact that lateral transport of dopant occurs over large distances has been well documented (13, 20, 24). It is also known that transport in the direction of flow (*i.e.*, downstream autodoping) is larger than that against the main gas flow (upstream autodoping). A detailed understanding of this redistribution requires a knowledge of the flow pattern that exists in any particular reactor. Eversteyn *et al.* (30) have proposed a boundary layer concept according to which there is a relatively stagnant layer of gas above the susceptor. The boundary layer is estimated to be a few millimeters thick in a typical epitaxial run, and dopant impurities could become trapped in this layer. This model has been used to explain the qualitative features of autodoping in silicon epitaxy (13); however, this concept has not been quantitatively developed for autodoping.

Attempts have recently been made to characterize the flow system in terms of temperature and concentration profiles that exist in the gas of an epitaxial reactor. Sedgwick *et al.* (31) have measured the temperature profiles using Raman light scattering in an rf heated horizontal epitaxial reactor. They found that a thermal boundary layer exists in the flow system above the heated susceptor and that the vertical temperature distributions in the gas vary along the gas flow. Their results indicated a linear velocity distribution in the layer at the leading edge, and this distribution became more complex further downstream. Ban (32) has essentially confirmed these findings. At present, however, there is no good mathematical model that describes the flow distribution in an epitaxial reactor.

The effect of the variations in the main gas flow rate on lateral autodoping has been observed before. Bozler (21) reported a decrease in vertical autodoping of arsenic in silicon epitaxy as the flow rate was increased. However, Pogge *et al.* (13) reported that arsenic lateral autodoping in epitaxial silicon was relatively insensitive to changes in the main gas flow. In order to clarify this point and to provide a quantitative understanding of the flow effects, a systematic study was undertaken by the present author. The details of this study will be reported elsewhere (33a, b, and c).

Briefly, the experiments consisted of silicon epitaxial depositions made at 1150°C on P^- (100) silicon substrates which had a diametrical stripe of arsenic diffusion. The H_2 flow rates used in these experiments varied from 7 to 30 liters/min while other deposition conditions were kept constant. The growth rate was maintained constant at 0.13 µm/min for all different hydrogen flow rates by suitably adjusting the $SiCl_4/H_2$ ratio. Epitaxial vertical profiles for arsenic were measured at several distances from the stripe, both along the flow direction (downstream) and against it (upstream).

Figure 5 shows the variation of the autodoping peak concentration with lateral distance for a 15 liters/min flow rate. It can be seen that autodoping decreases with increase in the lateral distance, both for upstream and for downstream flow. This decrease is much faster in the upstream direction than for the downstream case. The present author has shown (33b) that the following equations describe the variation of autodoping peak maximum concentration with distance x from the stripe for both upstream and downstream cases

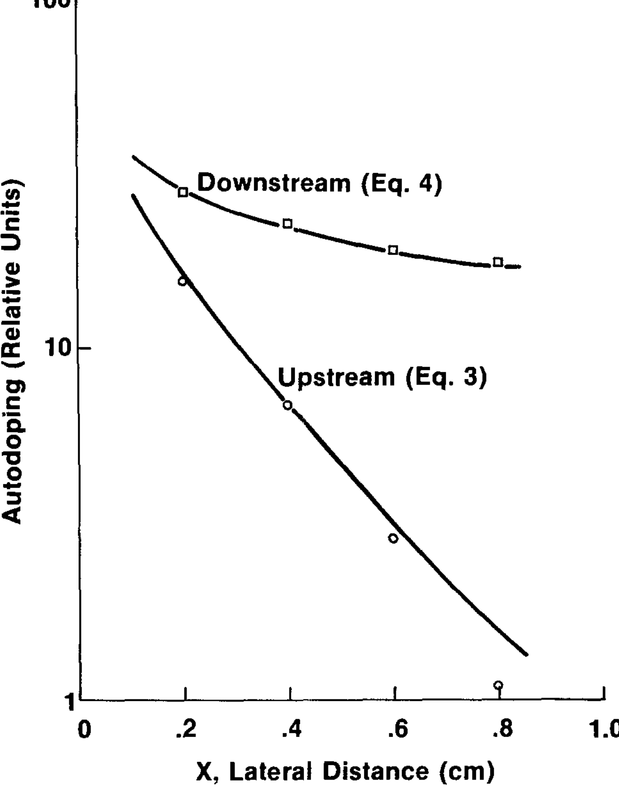

Fig. 5. Variation of autodoping peak maximum with lateral distance. (Deposition temperature 1150°C, growth rate 0.13 µm/min, H_2 flow rate 15 liters/min.)

$$C(\text{upstream}) = (A/u)(r/\sqrt{\pi})\{\text{erf}\sqrt{u(x+h)/D} - \text{erf}\sqrt{u(x-h/D)}\} \quad [3]$$

$$C(\text{downstream}) = (A/\sqrt{u})(r/\sqrt{\pi D})\{\sqrt{x+h} - \sqrt{x-h}\} \quad [4]$$

where C and D are the concentration and diffusivity of arsenic vapor in H_2, u is the linear velocity of H_2 flow, r is the evaporation rate per unit length of the stripe, x is the lateral distance from the edge of the diffused region, and $2h$ is the width of the stripe. A is a constant of proportionality that is constant for identical epitaxial deposition conditions. We can see from Eq. [3] and [4] that the gas concentration decreases roughly as $1/u$ for the upstream case and as $1/\sqrt{u}$ for the downstream case. The solid lines in Fig. 5 represent the plot of Eq. [3] and [4], respectively, for the upstream and downstream cases. This analysis yields a value of D (As/H_2) = 2.5 cm^2/sec, which is in reasonable agreement with the kinetic theory estimation of D. Figure 6 shows the variations of autodoping with gas velocity for both the upstream and downstream flows as measured at 4 mm distance from the stripe source. The solid lines represent Eq. [3] and [4] for $D = 2.5$ cm^2/sec. Once again, the agreement between the theory and experiment is quite good.

Autodoping under low pressure.—It is clear from the preceding discussion that changes in the flow patterns could significantly alter the dopant redistribution. One of the effective means to change the flow dynamics in an epitaxial reactor is to change the pressure. There have been several studies in literature (24, 27, 34-36) which show that lateral autodoping can be significantly reduced by lowering the reactor pressure to ~5 kPa (~40 Torr). It is found (27) that the reduced pressure also results in sharper profiles over buried layers.

Ogirima *et al.* (24) have studied recently the effect of pressure variation on autodoping and on growth kinetics for the case of silicon epitaxy using silane. They found that, for substrates with arsenic buried layers, autodoping decreases with increasing lateral distance from the buried layer region for all pressures studied. However, this variation is more isotropic with respect to the flow direction for pressures below 20 kPa (~150 Torr). Above 40 kPa (~300 Torr) pressure, the autodoping was found to be anisotropic, similar to the case for atmospheric pressure as discussed in the preceding section. They found, in addition, that lateral autodoping decreased linearly with the decrease in pressure. That is, a factor of 10 decrease in autodoping occurred when pressure was reduced to about 10 kPa (~80 Torr). Since autodoping is linearly proportional to reactor pressure, it is also proportional to the dopant partial pressure, providing that the dopant evaporation rate is itself not a function of pressure. This proportionality is to be expected when Henry's law is obeyed (25) which, in turn, implies that autodoping at reduced pressures may be controlled by the equilibration of arsenic at the vapor-solid interface.

The observation that there is considerably less flow-induced anisotropy in lateral autodoping at reduced pressures indicates that vapor diffusional transport is the dominant mechanism involved. The transport equation under such conditions yields an exponential decrease in vapor concentration with increasing distance from the vapor source, as indeed was the case in Ogirima's experiments.

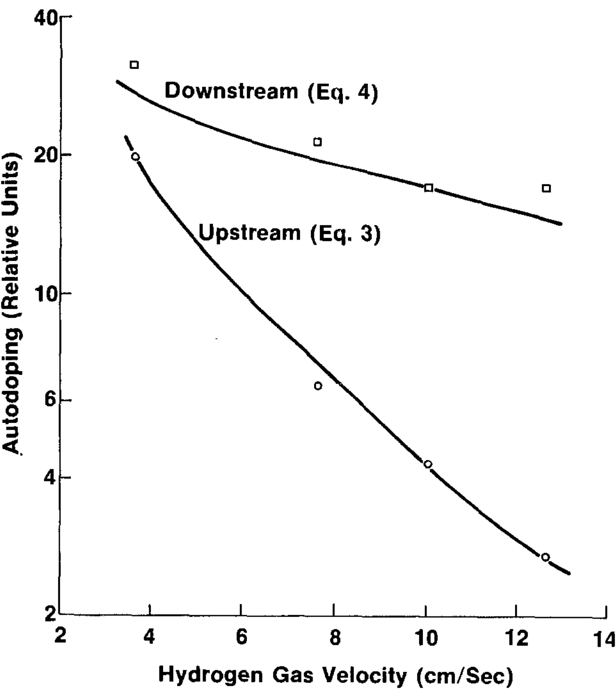

Fig. 6. Variation of autodoping peak maximum with carrier gas velocity. (Deposition temperature 1150°C, diffused stripe 4 mm.)

Dopant incorporation and growth parametric effects.—In the preceding sections, we considered the production of dopant vapor during prebake and its redistribution in the reactor flow system. We now examine the effects of growth parameters on the incorporation of the dopant vapor into the crystal.

Effect of deposition temperature.—Although the effect of epitaxial deposition temperature on the out-diffusion profiles is well documented in the literature, there was, until recently, very little information available on the temperature dependence of lateral autodoping. In a recent report (25), the present author has described the details of this effect for arsenic in silicon epitaxy using $SiCl_4$ depositions. Silicon substrates with localized arsenic diffused layers were used in this investigation, which allowed a separation of out-diffusion and lateral autodoping effects. It was found that lateral autodoping increased with decreasing deposition temperature, and that the slope in the autodoping *vs.* temperature curve was a function of deposition rate. These results indicated that lateral autodoping is not determined by the thermodynamic equilibrium between arsenic in the vapor and the arsenic incorporated into the epitaxy. The analysis suggested a kinetic limitation for the incorporation process.

Ogirima *et al.* (28) have recently repeated these measurements. They also found that the logarithm of the maximum concentration in the autodoping peak varies inversely as the deposition temperature. To account for this variation, they propose that the dopant incorporated into the epitaxy is directly proportional to that adsorbed on the substrate as given by the equation

$$C = (A/RT)\exp(E/RT)$$

where A is a constant, R is the gas constant, and E is the adsorption energy. However, the situation could be more complex than that suggested by the above equation, for the temperature variation of autodoping has to include both the prebake as well as the growth effects. It is also quite likely that these two components may be controlled by entirely different mechanisms (25), and hence it is necessary to separate out these two effects. Experimentally, it can be done by keeping one of these constant, while changing the other. As indicated in the section on Evaporation kinetics during hydrogen prebake, the autodoping variation due to changes in prebake suggests an evaporation mechanism. The autodoping changes due to changes in deposition temperature, on the other hand, may be due to the temperature variation of dopant trapping in the epitaxial layer. This aspect is considered next.

Effect of growth rate.—It has been known for some time that a reduction in the epitaxial growth rate has

a beneficial effect in reducing the vertical autodoping (21) as well as lateral autodoping (37). In a recent study (25) the present author had made quantitative measurements of the effect of growth rate on lateral autodoping using substrates with arsenic diffusions covering 20% of the wafer surface. These measurements showed that arsenic lateral autodoping in silicon epitaxy decreases almost exponentially with a decrease in growth rate down to a growth rate value of 0.2 μm/min. Below this value, the autodoping had remained insensitive to growth rate changes. We repeated these experiments using substrates which had 62% of the surface area covered by arsenic diffusion in a dense pattern as described previously. Autodoping results are shown in Fig. 7 in which the autodoping peak maximum concentration is plotted as a function of growth rate. The figure also shows a plot of the integrated dose in the lateral autodoping curve as a function of growth rate. We note from this figure that both the peak maximum as well as the total amount vary similarly, and that the growth variation extends to much lower growth rates for these high density buried layer wafers than for the case reported earlier.

The results were analyzed as before (25) on the basis of an impurity trapping model. The variation of the autodoping peak concentration is described by the following equation

$$C = C_b + (C_s - C_b) \exp(-V_i/V) \quad [5]$$

where C_b and C_s are the equilibrium dopant concentration in the bulk and surface, respectively, and V_i is a characteristic velocity for which the diffusional relaxation time at the surface is equal to the time for the growth of one monolayer of epitaxy. The model predicts an excess dopant concentration $(C - C_b)$ over the equilibrium value due to trapping, and this excess increases with the increase in growth rate, as described by Eq. [5]. A least squares fit to the peak concentration data, as shown by the solid line in Fig. 7, yields: $C_b = 2.3 \times 10^{16}$ cm^{-3}, $C_s = 9.7 \times 10^{17}$ cm^{-3}, and $V_i = 0.14$ μm/min. These values for densely patterned substrates are different from those obtained earlier for substrates with only 20% of the surface covered by the buried layers. For the present case, the results indicate a saturation effect, at moderately low growth rates, which was not observed for wafers with low density buried layers.

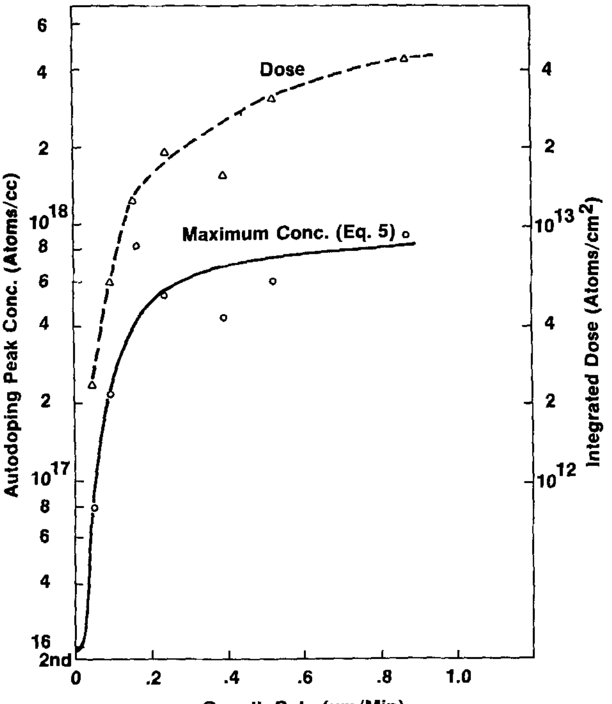

Fig. 7. Variation of autodoping peak concentration and integrated dose (area under the autodoping peak) with growth rate. (Deposition temperature 1100°C.)

Effect of silicon source species.—Epitaxial depositions of silicon use either silane or chlorosilanes as the source species. The two most common species are SiH_4 and $SiCl_4$. In the literature there is some indication that there is a difference in autodoping between the two. Many of the experiments, however, had used different growth conditions for the two cases, so that a one-to-one comparison was not possible. However, Suzuki and Endo (14) have compared the autodoping differences between silane and $SiCl_4$ using identical growth conditions. Their results showed that, for a growth temperature of 1100°C, a growth rate of 0.7 μm/min, and an H_2 flow rate of 3 liters/min, the silane produces a sharper profile than $SiCl_4$ on arsenic-doped substrates. They attributed this result to the absence of chlorine in the silane system which was presumed to be the dopant carrier. We have made detailed comparison of autodoping between SiH_4 and $SiCl_4$ depositions using localized buried layer substrates. Since our results are at variance with those of Suzuki and Endo, we will describe them here.

In our buried layer experiments, we used 10-20 Ωcm P^- (100) silicon substrates, which had arsenic diffusions ($C_o \sim 1.5 \times 10^{21}$ cm^{-3}, $x_j \sim 1.0$ μm) to cover 20% of the surface area in a 5-square pattern. Two-micron thick intrinsic epitaxial depositions were made at 0.08 μm/min and at 0.25 μm/min growth rates using an rf heated horizontal reactor. The main gas flow rate used was 20 liters/min. Results of these experiments are shown in Fig. 8-10. Figure 8 shows the autodoping peak maximum concentration as a function of deposition temperature for both silane and $SiCl_4$ depositions and for the two growth rates. Figure 9 shows the variation of the integrated area under the autodoping peaks with deposition temperature for the cases shown in Fig. 8. It is clear from these figures that autodoping for silane is worse than that for $SiCl_4$ for all the temperatures and growth rates tested. In Fig. 10 we show a typical comparison of on-profiles for silane and $SiCl_4$ depositions made at 1050°C and 0.08 μm/min growth rate.

The fact that $SiCl_4$ epitaxy produced a lower autodoping than silane epitaxy can be understood in terms of strain-enhanced etching of the depositing film that might occur at the impurity lattice sites by HCl (or Cl_2) released by the H_2 reduction of $SiCl_4$. Such an

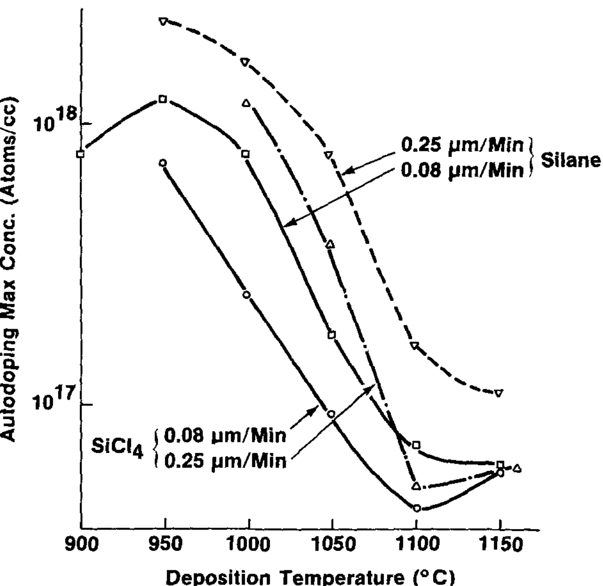

Fig. 8. Variation of autodoping peak maximum concentration with deposition temperature for silane and $SiCl_4$ depositions, using dose (area under the autodoping peak) with growth rate. (Depo-

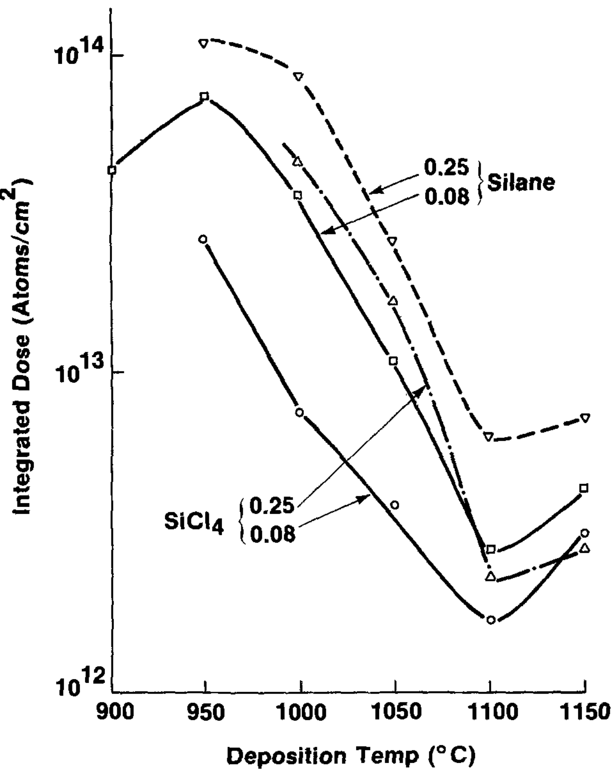

Fig. 9. Variation of autodoping dose (area under the autodoping peak) with deposition temperature for silane and $SiCl_4$ depositions using growth rates of 0.08 and 0.25 μm/min.

in situ etching could reduce the dopant incorporation in the film and, hence, autodoping. In silane deposition, such a mechanism for *in situ* etching does not exist. It would be interesting to see if reduction in autodoping would occur when HCl is included with silane during the entire deposition cycle. In fact, such an experiment was conducted by Langer and Goldstein (38) who observed a reduction in boron autodoping due to the addition of HCl during silane epitaxial growth. This result is consistent with the above model.

Dependence of autodoping on substrate parameters.—Among the primary factors that influence epitaxial autodoping are the characteristics of the substrate, which include the area of the buried layers on the wafer surface, the initial dopant distribution in the buried layers, the presence of other compensating impurities in the substrate and, finally, the number of substrates used in any given deposition run. Qualitatively, these factors are simple to account for in terms of the total amount of the dopant vapor produced during the prebake stages. For example, Fig. 11 shows the lateral autodoping peak obtained for two wafers, one with 20% of the wafer surface covered by arsenic diffusion, and the other with 62% covered. The epitaxial deposition conditions on these wafers were identical (deposition temperature, 1050°C; growth rate, 0.08 μm/min, species, $SiCl_4$), and profiles were made at 100 μm from the edge of the diffused region. It is clear from this figure that autodoping increases with an increase in the surface area of the buried layer. A theoretical model has been recently developed by the present author (33a, c) to account for this effect, which shows that autodoping increases as the square root of the buried layer density in the substrate.

Further we found, by etching a diffused arsenic layer to different depths and then growing epitaxy, that the logarithm of the maximum concentration in the autodoping peak was directly proportional to the logarithm of the surface concentration over the buried layer.

The effect of the variation on autodoping with the number of substrates in the run is well known. The larger the number of substrates, the larger is the autodoping (21). However, we found a saturation effect. That is, autodoping initially increases with the number of wafers in the load up to a point beyond which it does not change with any addition to the load. At this level of saturation, we assume that the gas layer region is saturated with the dopant vapor.

Autodoping profile modeling.—We have seen several process and wafer variables that factor into the autodoping effect. The next step is to use this information to arrive at a comprehensive model that allows an accurate dopant profile prediction in the epitaxy for a given set of process and substrate conditions.

The problem is quite complex, not so much for the number of factors that have to be included into any given model, but for the way in which these factors

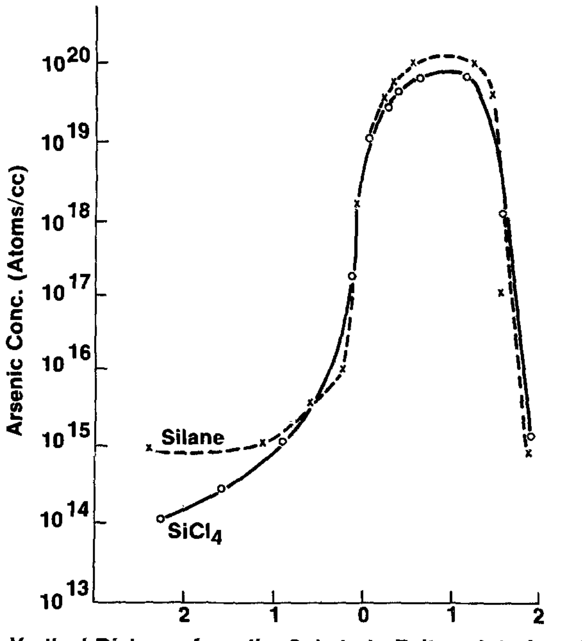

Fig. 10. Spreading resistance profiles over the arsenic buried layers for silane and $SiCl_4$ depositions. (Deposition temperature 1050°C, growth rate 0.08 μm/min.)

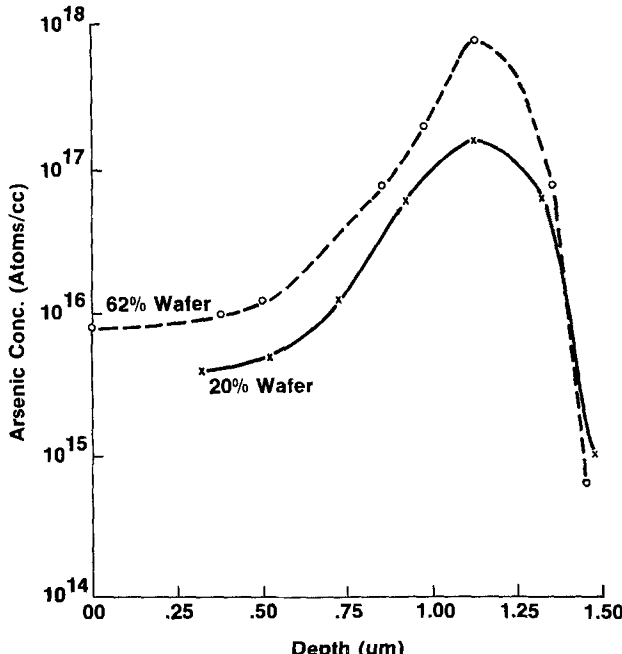

Fig. 11. Variation of autodoping with the percent area of the buried layer on the wafer surface. (Deposition temperature 1050° C, growth rate 0.08 μm/min.)

interact. For example, as discussed in the section on Dopant incorporation and growth parametric effects, the growth rate effect due to trapping is also a function of deposition temperature. It is therefore necessary to decouple these effects as much as possible before formulating a general autodoping model.

There have been several previous attempts to model the autodoping profile. A study by Thomas *et al.* (3) represents the first attempt at such a modeling, and they were able to obtain an exponential decrease in dopant concentration with epitaxial thickness on the assumption that silicon and the dopant atoms are deposited in the ratio that is present in the gas phase. Grossman (5) obtained a similar expression by assuming that the dopant vapor reincorporates into the epitaxy with a rate proportional both to the growth rate and to the concentration at the surface. His expression for gas phase autodoping is given by

$$C = C_0 \exp(-aKZ)$$

where a is a constant, K is the distribution coefficient between the solid and the adsorbed phase, and Z is the epitaxial thickness. However, it is known (39) that K itself is a function of growth rate and, indeed, it is this effect that gives rise to the dopant trapping discussed earlier.

Variations of this approach have also been used recently to model the autodoping profile. Bozler (21) considered the variations in vapor concentration due to flow and treated the dopant escape into the flow as a first-order kinetic equation. The vapor concentration in the flow stream thus falls off exponentially in time which, in turn, through a direct proportionality to the dopant concentration incorporated at the growing surface, yields an exponential decay of the dopant concentration with the film thickness. Bozler's model is attractive for its simplicity, but it does not consider the molecular diffusion of vapor in the gas flow. In addition, as before, the model does not include a growth rate effect on the partition coefficient.

Recently, Tabe and Nakamura (40) have proposed an adsorption model to account for the dopant profile in silicon epitaxial growth. Their model assumes, in contrast to the impurity trapping model discussed earlier, a thermodynamic equilibrium between the impurity in the adsorbed layer and that in the bulk epitaxy. However, their model yields a decrease, rather than an increase, in autodoping with increased growth rate, which is contrary to observations in the buried layer studies.

Yet another model for dopant profile is due to Langer and Goldstein (18). In this numerical approach, they consider dopant fluxes arising out of the substrate through evaporation and solve the one-dimensional linear diffusion equation. When they applied this to the case of boron autodoping (38), they found that, while a good agreement between the experimental and calculated profiles was found for areas at the center of a uniformly doped wafer, the model could not account satisfactorily for the lateral variation of autodoping in the wafer.

One way of dealing with the complex problem of autodoping modeling is to isolate various kinetic steps such as described in the preceding sections. The evaporation, redistribution, and incorporation should be factored into the total equation. The wafer effects could then be included into the equation as a scaling factor. We are at present proceeding in this direction and hope to communicate our results in the near future.

Autodoping Control Techniques

Previous discussion on the parameters that influence autodoping leads us to devise ways to reduce autodoping in epitaxial processes. These are: (*i*) low pressure epitaxial deposition, (*ii*) prolonged baking prior to epitaxy, (*iii*) use of high deposition and baking temperatures, (*iv*) use of low growth rate, (*v*) use of high flow rates, (*vi*) use of low vapor pressure species such as antimony over arsenic, (*vii*) reduced batch size, (*viii*) use of low surface concentration and surface density of the buried layers, and finally (*ix*) use of compensating doping. Obviously a whole range of these options is not available in any given situation. For example, use of deposition temperature may be dictated by the amount of out-diffusion allowed in the epitaxy and by the abruptness of the profile. Also, selection of the kind of dopant species may be restricted by other considerations such as solubility limit, lattice strain, and the resultant epitaxial quality. Reduced batch size is a throughput consideration. Use of low growth rate is limited by the amount of out-diffusion and throughput considerations. As far as the flow rates are concerned, the commercial reactors use flow rates which have been optimized in terms of thickness and dopant uniformity in the epitaxial films, and, as such, any significant change in the flow rate will have adverse impact on these parameters. The buried layer characteristics such as surface concentration and the surface density are mainly dictated by the device design constraints. The use of a purge in the deposition cycle is only slightly effective in reducing autodoping.

One of the promising ways to deal with autodoping problems is the low pressure technique. This technique, as discussed earlier, reduces autodoping in direct proportion to the reduction in pressure. Even here, there remain serious concerns regarding epitaxial quality and thermally induced slip. Another technique that combines the advantages of both low pressure and low temperature is molecular beam epitaxy. It has been demonstrated that atomically abrupt layer compositions can be obtained using this technique. However, the molecular beam technique as applied to silicon technology is still in its infancy, and further progress in terms of epitaxial quality and dopant uniformity is needed before it becomes an effective tool for fabricating integrated circuits.

Concluding Remarks

In the discussion presented here, we have attempted a quantification of the effects of various process parameters on autodoping in silicon epitaxial growth. We have examined several plausible models that are capable of quantitative explanation of these effects. While at present no comprehensive autodoping model exists, a reasonable amount of understanding has begun to develop, which should result in one in the near future.

Acknowledgments

I thank Messrs. J. A. Miller and W. Patterson for assistance in many of the experiments reported here.

Electrochromism of Anodic Iridium Oxide Films

III. Anion Mechanism

G. Beni,* C. E. Rice, and J. L. Shay*

Bell Laboratories, Holmdel, New Jersey 07733

ABSTRACT

We examine the electrochromic effect of anodic iridium oxide films (AIROF's) in aqueous and nonaqueous electrolytes. All experimental data in aqueous electrolytes are consistent with the hypothesis that electrochromism in AIROF's can occur via hydroxide ions, without insertion-extraction of protons from the electrolyte. We also report new experiments in which electrochromism of AIROF's takes place by insertion-extraction of anions (OH^-, F^-, CN^-) from nonaqueous electrolytes.

Several recent papers (1-7) have described the electrochromic properties of anodic iridium oxide films (AIROF's). Electrochromics are promising materials for passive display devices (8). They have a wide viewing angle and an open-circuit memory. They are suitable for large character displays and for all-solid-state devices. Earlier electrochromic research focused primarily on WO_3 in which coloration (9-12) takes place by simultaneous insertion of electrons and cations, *e.g.*, H^+, Li^+, Na^+, etc. The fastest response times ($\approx$0.1 sec) are obtained with protons in a humid environment. However WO_3-based devices degrade (13) in the presence of water. Thus, current research in WO_3-based displays is centered around Li^+ [Ref. (14)] and Na^+ [Ref. (15)] insertion devices employing nonaqueous electrolytes. Although these devices are more stable than those based on protons in humid environments, they have considerably longer coloring and bleaching times ($\approx$1.0 sec).

* Electrochemical Society Active Member.

Key words: electrochromism, electrolyte, ions.

AIROF's do not degrade in contact with water. They have been operated in aqueous solutions for $\approx 10^6$ cycles with no detectable degradation and no electrolyte decomposition. AIROF's also have fast coloring-bleaching times ($\approx$20 msec) and good contrast throughout the visible. All-solid-state (diffuse reflection) display cells have been demonstrated recently (7).

Initial descriptions of the mechanism of electrochromism in AIROF's were based on simultaneous electron and proton insertion, similar to electrochromism in WO_3, albeit with opposite polarity (1, 5). However, since we observed (2) that the speed of coloration and bleaching in AIROF's is independent of *p*H, this interpretation seemed questionable. Although the lack of dependence of color/bleach speed on *p*H was confirmed by the detailed studies of Gottesfeld and McIntyre (5) (hereinafter referred to as II), they nevertheless retained a proton injection description since they found all alternative mechanisms unacceptable.

The purpose of this paper is twofold: (*i*) to demonstrate that all available experimental data concerning

AIROF electrochromism in aqueous systems is satisfactorily explained by a hydroxide injection mechanism; and (*ii*) to report new experiments using nonaqueous electrolytes which demonstrate that AIROF coloring/bleaching in fact takes place by anion insertion/extraction in these systems.

In the next section we study the electrochromism of AIROF's in aqueous electrolytes. We reanalyze previous experiments and discuss the point of zero zeta potential. By a thermodynamic analysis of the isotherms, we show that electrochromism in AIROF's is well explained by the hydroxide ion mechanism. In the section "Water-Free Electrochromism" we present results of experiments performed in water-free electrolytes. We show that the anions OH^-, F^-, or CN^- are sufficient for electrochromism to occur in the nonaqueous systems studied. In "Discussion and Conclusions" we discuss the nature of the anion mechanism for electrochromism and its relationship to anodic film growth and electrocatalysis.

Electrochromism in Aqueous Solutions

During coloration (bleaching) an anodic (cathodic) potential typically removes (1) (injects) $\approx 10^{17}$ electrons/cm^2 from (into) a $\approx$3000Å thick AIROF in $\lesssim 40$ msec. Preservation of electroneutrality requires a simultaneous injection (ejection) of negative charge or ejection (injection) of positive charge at the AIROF/electrolyte interface. Assuming fast interfacial processes and fast diffusion within the AIROF, coloring-bleaching times are determined by the diffusion of the charged species from the electrolyte to the AIROF surface. For ions with bulk electrolyte diffusion coefficient D, the (unbuffered) ion concentration C necessary to inject N ions per unit surface in a time t is (16)

$$C = \frac{N}{\sqrt{(4Dt)}} \qquad [1]$$

For protons in aqueous solutions $D = 10^{-4}$ cm^2/sec [Ref. (17)] so that, with $N = 1.6\ 10^{-7}$ mole/cm^2 and $t = 40$ msec, we have $C = 4\ 10^{-5}$ mole/cm^3 or $pH = 1.4$. Thus, at $pH \gtrsim 1.4$ there are not enough protons available in the bulk electrolyte to bleach the AIROF in $\lesssim 40$ msec. But, as shown in Ref. (2), bleaching times of $\approx$20 msec are regularly obtained at pH as high as 14.

Following similar arguments, it was concluded in II that AIROF electrochromism in basic and mildly acidic aqueous solutions can be due to proton injection, only if the source of protons is free H_2O molecules and/or bound H_2O or OH groups on the oxide surface. In the latter case, the bleaching process is effectively a proton desorption from the surface into the AIROF. Since none of the electrochemical measurements discussed in II can distinguish between the desorption of a proton and the adsorption of a hydroxide ion (16), the question remains open as to whether protons or hydroxide ions give rise to the electrochromic effect in AIROF's.

To proceed further we begin by considering the nature of the water bound to the AIROF surface. In II it has been speculated that "owing to polarization by the coordinated metal ion," the bound H_2O has a higher concentration of H^+ than the free water. We shall see, however, that the opposite is true, and in fact, there is in most cases a preponderance of OH^- on the surface of an AIROF in an aqueous solution.

Point of zero zeta potential.—The point of zero zeta potential (pzzp) is the pH at which the net surface charge is zero. There is a sizable literature on the pzzp (18-24). For metal oxides the pzzp usually refers to specific adsorption of protons or hydroxide ions. Thus the pzzp is the pH at which the concentrations of adsorbed H^+ and OH^- are equal. At $pH \neq pH(\text{pzzp})$ a net charge is present on the oxide surface.

Most investigators (25-29) of the properties of the oxide/aqueous-solution interface suggest that the mechanism by which the surface charge is established may be viewed qualitatively as a two step process: surface hydration followed by dissociation of the surface hydroxide. The hydration step is an attempt by the exposed surface atoms to complete their coordination shells of nearest neighbors. Exposed cations accomplish this by pulling OH^- ions from the aqueous phase; oxygen ions accomplish this by pulling H^+ from the aqueous phase.

The equilibria at the surface of a metal oxide MO can schematically be represented (18) by

$$MO \cdot H_2O \rightleftarrows MO \cdot OH^- + H^+ \qquad [2]$$

$$MO \cdot H^+ + OH^- \rightleftarrows MO \cdot H_2O \qquad [3]$$

where $\cdot$ means "bound at the surface." Adding Eq. [2] and Eq. [3] we obtain

$$MO \cdot H^+ + OH^- \rightleftarrows MO \cdot OH^- + H^+ \qquad [4]$$

From which, at equilibrium

$$\Delta F + kT \log \frac{[H^+]_s}{[OH^-]_s} + kT \log \frac{[OH^-]}{[H^+]} = 0 \qquad [5]$$

where ΔF is the standard free energy of the reaction; $[H^+]_s$ and $[OH^-]_s$ are the concentrations of protons and hydroxide ions at the surface; k is the Boltzmann constant; and T is the absolute temperature. By definition, at the pzzp, $[H^+]_s = [OH^-]_s$ so that at room temperature

$$pH(\text{pzzp}) = 7 - \frac{\Delta F(\text{eV})}{0.12} \qquad [6]$$

Although ΔF is not known, it has been found (30) empirically that Eq. [6] is well satisfied by all studied metal oxides if one sets $\Delta F(\text{eV}) = \Delta M(\text{eV}) - 5.9$ where ΔM is the Mulliken electronegativity of the oxide. The Mulliken electronegativity of an element is the arithmetic mean of the atomic electron affinity A and the first ionization energy I, *i.e.*

$$\Delta M = (A + I)/2 \qquad [7]$$

The Mulliken electronegativity of a compound is the geometric mean of the electronegativity of the constituent atoms.

For IrO_2, $\Delta M = 6.7$ eV [Ref. (31)] and thus from Eq. [6], $pH(\text{pzzp}) = 0.33$. Similarly for Ir_2O_3, $\Delta M = 6.54$ eV [Ref. (31)] and $pH(\text{pzzp}) = 1.66$. Therefore, assuming that AIROF's have compositions close to IrO_2 or Ir_2O_3, the AIROF surface has a high concentration of hydroxide ions and a very low concentration of protons at all pH except for $pH \lesssim 1$. Moreover, it is obvious that by applying an anodic potential to the AIROF the equilibrium on the surface is further shifted toward enriching the hydroxide ion concentration.

It is clear therefore that the AIROF surface is usually covered predominantly with OH^-, and thus there is not a reservoir of H^+ as stated in II in support of the proton injection model. The extremely low value of the pzzp for the AIROF's also explains the insensitivity (2) to pH of the hydroxide ion insertion-extraction electrochromic process.

Further thermodynamic data supporting the hydroxide mechanism of electrochromism are presented in the next section.

Isotherms.—From measurements of the internal emf of AIROF's in aqueous solutions over the pH range 0-14 and temperature range 0°-75°C, it is apparent that (*i*) AIROF's develop an internal emf E during coloration and have the external properties of thin film batteries; and (*ii*) that their internal emf is a function only of the charge per unit volume Q. As a consequence of (*i*) and since the charging process is sufficiently fast, cyclic voltammograms for AIROF's yield directly dQ/dE *vs.* E, and thus provide the most convenient way to obtain the isotherm, $E(Q)$.

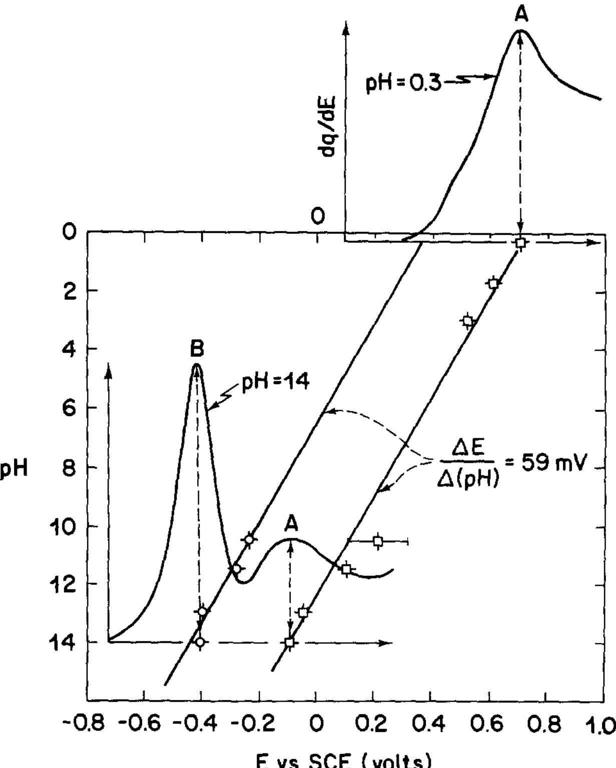

Fig. 1. *pH dependence of maxima in cyclic voltammograms for AIROF's at room temperature measured at a sweep rate of 100 mV/sec. The two solid curves are anodic scans and measure dq/dE (in arbitrary units) as a function of the internal emf E (in volts vs. a saturated calomel electrode) at pH $=$ 0.3 and pH $=$ 14. The square (round) points trace the pH dependence of the A(B) peaks. Both peaks shift at the rate of 59 mV/pH (solid lines).*

Figure 1 shows the pH dependences of the maxima in the cyclic voltammograms over the pH range 0-14 at room temperature. The two curves superimposed are anodic scans for pH $=$ 0.3 and 14, respectively (the processes are highly reversible and the cathodic scans are almost mirror images about the abscissa). The square points trace the pH dependence of the A peak which dominates the voltammogram in acidic solutions. It can be seen that this peak shifts at a rate of 59 mV/pH, which, from the Nernst equation, is in agreement (16) with insertion-extraction of hydroxide ions during electrochromism. At high pH a new peak B appears in the voltammogram. Its dependence upon pH is shown by the round points which also shift at a rate of 59 mV/pH. Simultaneous reflectivity measurements show that for pH $=$ 14 the electrochromic reaction takes place primarily around B.

The existence of two distinct electrochromic processes can be understood straightforwardly in terms of the hydroxide mechanism. At low pH, the hydroxide ions are supplied by the highly basic water bound at the surface. At higher pH, however, the OH^- are supplied primarily by the bulk electrolyte. We show below that these two ways of supplying hydroxide ions correspond to two thermodynamically distinct processes.

When hydroxide ions are supplied directly from the electrolyte (B process), the AIROF internal emf is given by (neglecting interactions)

$$E = E_B + kT \log[(q/(1-q)]^n \quad [8]$$

where E_B is the insertion energy per hydroxide ion and the second term is T times the configuration entropy per normalized charge $q = Q/Q_{max}$ per unit volume. The configurational exponent n is 1 or 2 according to whether or not the inserted hydroxide ion and the extracted electron are spatially correlated.

We find that Eq. [8] is experimentally verified with $n = 2$ to high accuracy for $0.02 \leq q \leq 0.98$. It follows from Eq. [8] that the shape of the current peak around the equilibrium value E_B is related to the internal emf E by

$$i \propto \frac{dq}{dE} = (4nkT)^{-1} \cosh^{-2}[(E - E_B)/2nkT] \quad [9]$$

where i is the current measured by cyclic voltammetry under reversible and fast-diffusion conditions, and absence of other reactions (we set the electronic charge $e = 1$). We find that the B peak has the form of Eq. [9] with $n = 2$. Values of dq/dE calculated from Eq. [9] using a configurational exponent $n = 2$ are compared with experiment in Fig. 2. Although there are no adjustable parameters (except for the trivial E_B) and no base line corrections, the agreement between theory and experiment is excellent over the entire range $0.02 \leq q \leq 0.98$.

The exponent $n = 2$ is also found (32, 33) for the configurational entropy of protons and electrons in WO_3. In WO_3 however, the dominant part of the internal emf is not the configurational entropy but an interaction term linear in q. In general this interaction term dominates the internal emf of cation insertion electrochromics (34). AIROF's are instead almost ideal entropy cells (4).

When the hydroxide ions are supplied by water bound at the surface, *i.e.*, in acidic solutions, the insertion process involves an additional statistically inde-

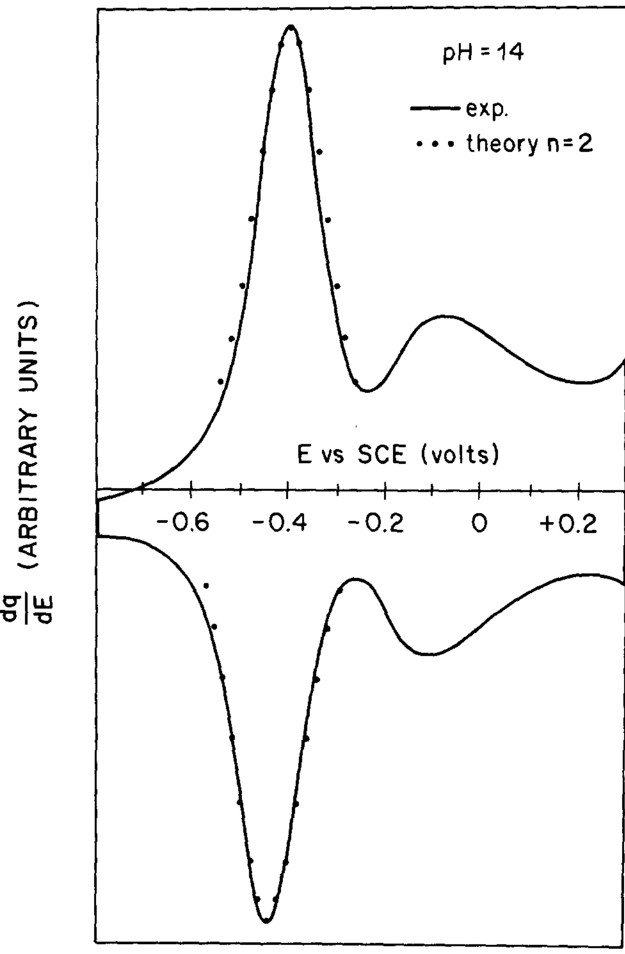

Fig. 2. *The derivative of the electrochromism isotherm of process B (cf. Fig. 1) at pH $=$ 14. The solid curve was obtained experimentally by cyclic voltammetry under reversible conditions and fast diffusion. The points are theoretical values from Eq. [9] using a configurational exponent $n = 2$. No other parameter enters the theory and no base line adjustments were made. For clarity in this figure we show only a few points rather than a continuous line.*

pendent event: the removal of an OH^- from the surface. Thus, the configurational entropy term must have an exponent $n = 3$ or 4, according to whether or not the OH^- removed from the surface is spatially correlated with the OH^- adsorbed on the surface from the bulk electrolyte. Moreover, since at the end of the process the surface has a modified configuration, the insertion energy E_A will be, in general, larger than E_B. This is clearly shown in Fig. 1, where $E_A - E_B = 0.3V$. In addition, Fig. 3 shows that indeed the configurational exponent for the A process is $n = 3$. This figure shows experimental data (solid line) and two theoretical curves using Eq. [9] with $E_B \leftrightarrow E_A$. The dotted line corresponds to $n = 3$ and the dashed line to $n = 4$. There are no adjustable parameters and no base line corrections. Taking the latter into account and subtracting out both the spurious component at high voltages and the small shoulder (origin unknown) at $\approx$0.45V (SCE), the best fit is obtained with $n = 3$. This result was independently checked by measuring the temperature dependence of the isotherms which is in good agreement with $n = 3$ (Fig. 4). As expected there is no linear term in q also for this process. An upper limit on the coefficient of the linear term is 0.01 eV for both A and B.

From Eq. [1] we estimate that the bulk electrolyte can supply enough free hydroxide ions for coloration at pH $\gtrsim$ 8. Consequently we expect the B peak to appear around this value of pH and to increase with pH relative to the A peak. This effect is clearly seen in Fig. 5 which shows the significant portions of cyclic voltammograms recorded in buffered solutions at various pH. To illustrate the emergence of the B peak we

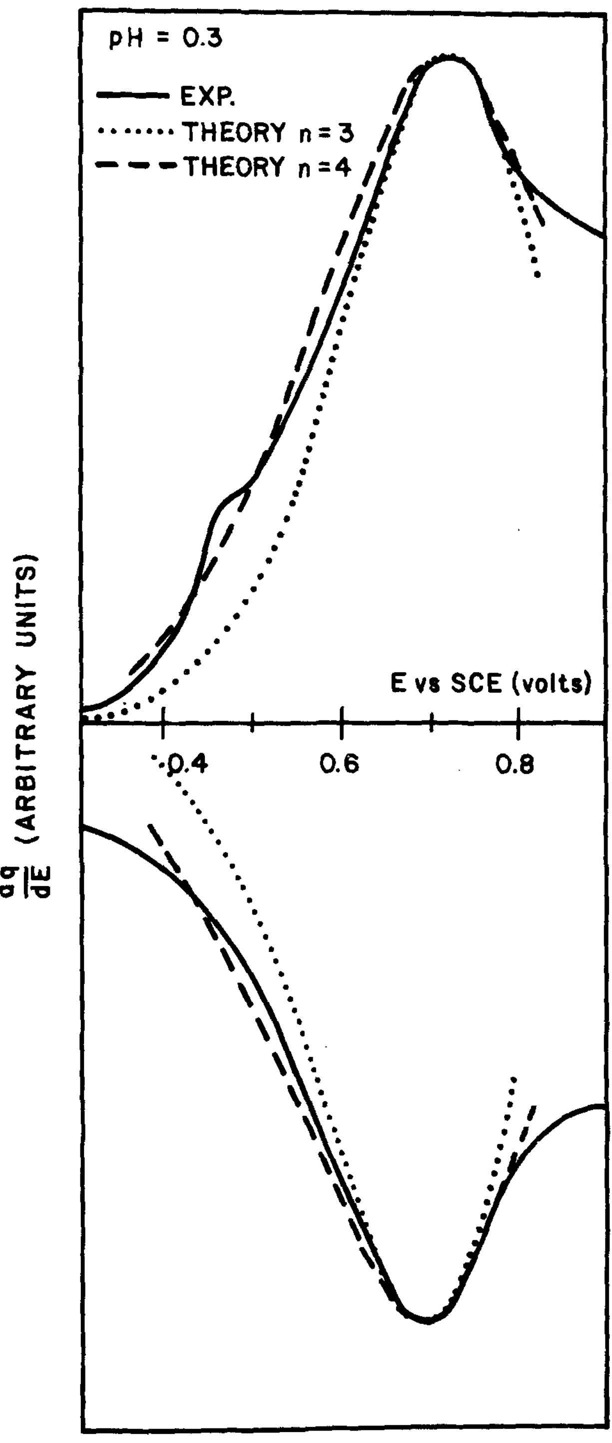

Fig. 3. The derivative of the electrochromism isotherm of process A (cf. Fig. 1) at pH = 0.3. The solid curve was obtained experimentally by cyclic voltammetry under reversible conditions and fast diffusion. The dotted (dashed) lines are theoretical values from Eq. [9] using a configurational exponent $n = 3$ (4). No other parameter enters the theory and no base line adjustments were made.

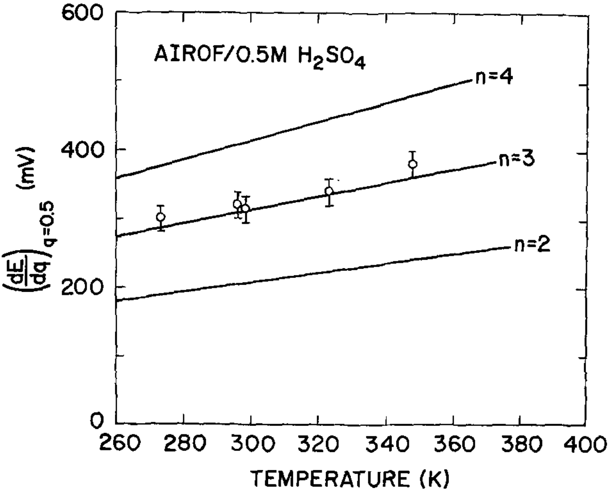

Fig. 4. Temperature dependence of the slope of the A-electrochromism isotherm at $q = 0.5$. The solid lines are theoretical values from Eq. [9] for configurational exponents $n = 4$, 3, and 2, respectively.

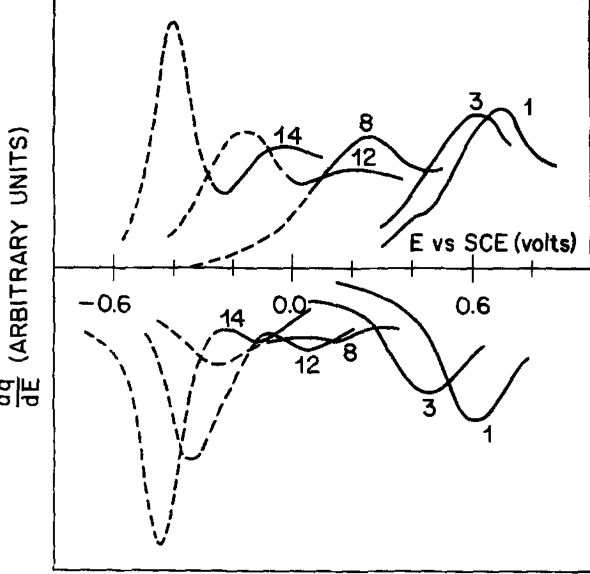

Fig. 5. pH dependence of the cyclic voltammograms for AIROF's at a sweep rate of 100 mV/sec in buffered solutions. Solid and dashed point indicate A and B peak, respectively. The emergence of the B peak is clearly visible in the cathodic scan at pH $\gtrsim$ 8.

have plotted the B peak part of the voltammogram as a dashed line. Especially in the cathodic scan, it is clearly visible that around $pH = 8$ the A peak is disappearing while the B peak is emerging.

In conclusion, all the experimental data in aqueous electrolytes are consistent with the hypothesis that electrochromism in AIROF's takes place via hydroxide ions.

Water-Free Electrochromism

In order to establish the relative role of protons and hydroxide ions independently of water we have studied the electrochromic performance of AIROF's in various water-free solutions. In these experiments the AIROF's were grown on iridium electrodes in aqueous 0.5M H_2SO_4 as described in Ref. (1). In this solution the normal-incidence reflectivity ($\lambda = 633$ nm) of the electrode in the colored state was 50% of that in the bleached state. After growth the electrodes were placed in a desiccator over Drierite at atmospheric pressure for at least one day to remove gross surface water. However, no attempt was made to rigorously remove all traces of water from the AIROF's.

Attempts to operate these dried AIROF electrodes in nonaqueous solutions of strong proton acids, $HClO_4$ or H_2SO_4 in dimethylsulfide (DMSO) or acetonitrile (AN), produced no evidence of electrochromic activity. For these experiments, the potential of the electrochromic electrode *vs.* an Ag/Ag^+ reference electrode (potential = 0.253V *vs.* aqueous SCE) was swept cyclically while gradually increasing the potential limits until a significant steady-state current flow signaled the onset of electrolyte breakdown. [A detailed description of a representative experiment has appeared in a previous communication (35)]. Figure 6(a) shows a cyclic voltammogram obtained with an AIROF working electrode in 0.01M $HClO_4$/DMSO. Over the entire 2.2V potential window scanned, no appreciable current was observed other than that due to electrolyte breakdown near the limits of the scan. The application of a 2.2V square wave potential with a pulse width of hundreds of seconds [Fig. 7(a)] produced no change in electrode reflectance. The same results were observed in all other nonaqueous acid solutions investigated. All solutions contained substantial concentrations of free protons as confirmed by titration with base, and by the fact that WO_3 electrodes could be electrochemically colored and bleached in these solutions [Fig. 6(c), 7(c)]. Thus in the absence of water, a supply of free protons is not sufficient for AIROF electrochromism.

A material which exhibits electrochromism by proton insertion-extraction may be expected to exhibit electrochromism also by other small cations. Indeed WO_3 can be colored not only by proton insertion but also by insertion of Li^+ [Ref. (14)] or Na^+ [Ref. (15)]. In

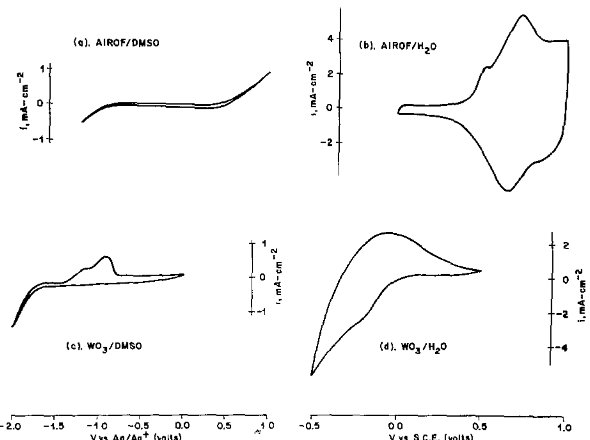

Fig. 6. Cyclic voltammograms of typical AIROF's and WO_3 films in aqueous and nonaqueous acid solutions. Scan speeds: (a) 20 mV/sec; (b) 100 mV/sec; (c) 20 mV/sec; (d) 50 mV/sec.

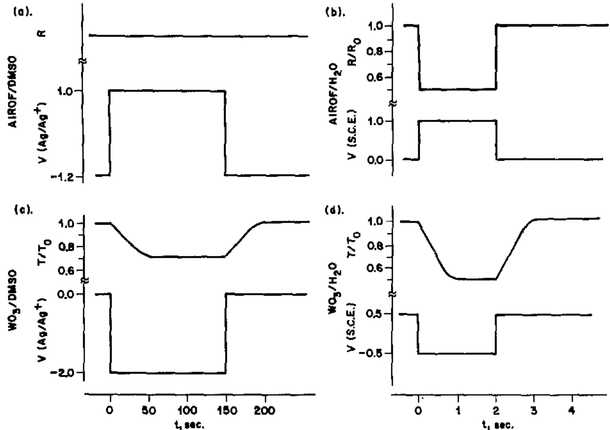

Fig. 7. Spectral response ($\lambda = 633$ nm) to abrupt potential change of AIROF's and WO_3 films in aqueous and nonaqueous acid solutions. Normalized reflectance $R/R_0 = R/R_{bleached}$; normalized transmission $T/T_0 = T/T_{bleached}$.

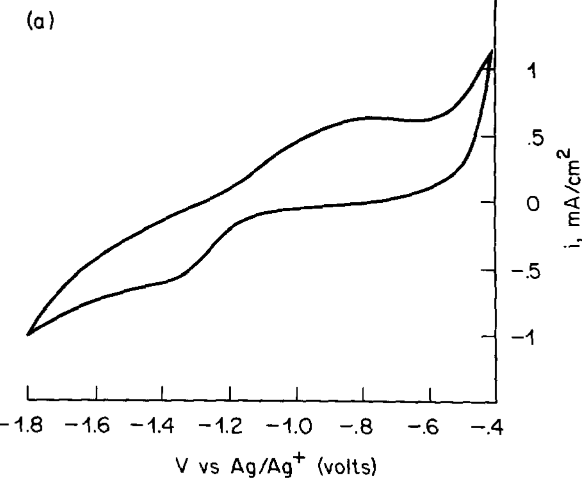
contrast, "lithiation" by cathodic reduction in a nonaqueous electrolyte (0.5M $LiAsF_6$ in acetonitrile) does not produce any electrochromic effect in AIROF's (II).

It is tempting to generalize these results and suggest that proton injection is equally unimportant for AIROF electrochromism in aqueous solutions. However, given the negative nature of these findings, several objections can be raised about this suggestion. For example, it is possible that electrochromism was not observed because the AIROF's color/bleach potential lies outside the available potential window in DMSO and AN. This explanation is improbable given the wide potential limits which were scanned. As further evidence against this possibility, the addition of trace amounts of water to these solutions causes electrochromism to be observed, with a color/bleach potential roughly equivalent to the coloration potential in totally aqueous acid solutions.

Another more serious objection is that the nonaqueous solvents may "deactivate" the AIROF by removing necessary water of hydration from within the oxide film. Indeed it is known that proton conductivity is inhibited or destroyed in solid-state proton conductors when all water is removed (36). In order to remove the objection that perhaps the AIROF cannot operate in any water-free solution, and to establish the role of hydroxide ions in the electrochromic process independently of water, we have studied AIROF electrode performance in nonaqueous solutions containing hydroxide ions.

The nonaqueous base experiments were performed in exactly the same way as the water-free acid studies described previously; in this case the solutions used were KOH or $(CH_3)_4NOH$ in ethanol or AN. Hydroxide ion concentrations ranged from 0.1 to 1M. (Full experimental details and results for these studies will appear in a separate paper.) In contrast to the results in nonaqueous acid, electrochromism could always be observed when AIROF electrodes were operated in these water-free hydroxide solutions. Figure 8(a) shows the cyclic voltammogram obtained with an AIROF in 0.1M $(CH_3)_4NOH$ in AN; clear evidence of coloration and bleaching peaks can be seen. This result contrasts sharply with the completely flat voltammograms obtained with solutions of acids in this solvent. Figure 8(b) shows the response of the electrode reflectance to the application of a square wave potential. The magnitude of the reflectivity change is similar to that obtained in aqueous solutions. The response time is slower due to the higher resistivity of the electrolyte. These results prove that the AIROF electrochromic reaction can indeed occur in nonaqueous electrolytes as long as the proper ion (hydroxide) is present.



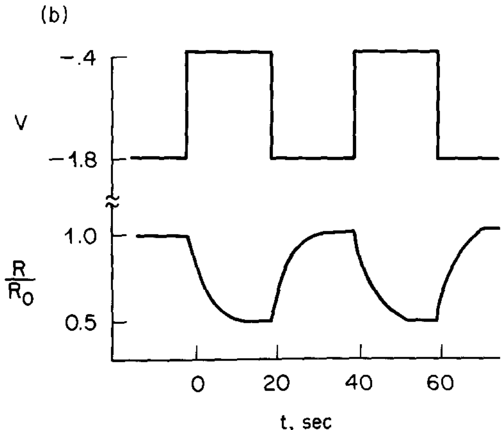


Fig. 8. (a) Cyclic voltammogram of AIROF electrode in 0.1M $(CH_3)_4NOH$ + 0.1M $(CH_3CH_2)_4NClO_4$/acetonitrile. Scan speed 10 mV/sec. (b) Changes in AIROF electrode reflectance with abrupt potential change. The electrolyte is the same as in (a).

One might anticipate that a material which exhibits electrochromism by hydroxide ions should also exhibit electrochromism by other anions of similar size and charge. Indeed we have found that coloration-bleaching of AIROF's occurs in water-free solutions containing F^- or CN^-. Thus although no electrode reflectance changes occur when a dry NH_4Br/ethanol solution is used (presumably Br^- is too large to insert readily into the AIROF), electrochromism does occur in NH_4F/ethanol. KCN/ethanol is also an effective electrolyte for AIROF electrochromism. Details of these experiments will be published elsewhere.

Discussion and Conclusions

The hydroxide ion mechanism of electrochromism is also consistent with the close connection between AIROF growth and electrochromism. The growth of an hydrous oxide film in aqueous solution requires, in general (16), the half-reaction

$$2\,OH^- \rightleftarrows H_2O + O^= \qquad [10]$$

which implies diffusion of hydroxide ions and/or metal cations through the forming oxide. From Ref. (3) there is evidence that Ir ions do not diffuse easily through the AIROF's. Thus hydroxide ions must diffuse through the AIROF during its growth.

AIROF's are grown typically (1) in aqueous solutions of 0.5M H_2SO_4 by continuously sweeping the potential of the Ir electrode between −0.25 and +1.25V (SCE). During the anodic (cathodic) sweep, the growth reaction Eq. [10] is shifted to the right (left), corresponding to OH^- insertion (extraction). Since coloration (bleaching) is observed during the anodic (cathodic) growth sweep, the electrochromic process is associated with the insertion-extraction of OH^-.

The hydroxide mechanism for AIROF electrochromism can be represented by a half-reaction of the form (37)

$$Ir(OH)_n + xOH^- \rightleftarrows Ir(OH)_{n+x} + xe^- \qquad [11]$$

The exact electrochromic reaction, however, must remain speculative until the exact AIROF composition is known. The AIROF composition is probably a form of hydrated iridium oxide. Iridium forms various kinds of oxides (38), the most common being Ir_2O_3 and IrO_2. In hydrated form they correspond to

$$Ir_2O_3(3H_2O) \rightleftarrows 2Ir(OH)_3 \qquad [12]$$

and

$$IrO_2(2H_2O) \rightleftarrows Ir(OH)_4 \qquad [13]$$

which describe the equilibria between the hydrated oxide form and hydroxide form of Ir_2O_3 and IrO_2, respectively. Although AIROF's are hydrous, the amount of molecular water is not easily ascertained. In fact we can now take as generally accepted (39) that metal hydroxides are "polymers" in which the metal ions are linked by bridges of hydroxyl pairs. The closeness of the hydroxyls in these diol bridges causes the latter to be unstable as they are converted to oxobridges with liberation of water (40). The question may be raised as to whether or not the amount of hydration is related to electrochromism.

Hydration (dehydration) is indeed a part of the OH^- insertion (extraction) process as shown by Eq. [10]. It seems unlikely, however, that the hydration-dehydration step of Eq. [10] is the fundamental part of the electrochromic process. In fact this would be inconsistent with the experiments in which coloration is obtained by insertion of F^- or CN^-. On the other hand, since dehydration of a mixed valence compound generally gives rise to coloration (41), it is possible that coloration of the AIROF might be obtained by dehydration.

The fundamental part of the electrochromic process is likely to be associated not with hydration-dehydration, but with the injection-extraction of the oxygen anions. The insertion of oxygen ions could cause coloration: (*i*) by changing the valence or iridium from 3 to 4, Ir^{IV} coordination compounds being typically more strongly colored than their Ir^{III} counterparts; (*ii*) by creating a mixed valence oxide, the coloration being due to intervalence transitions; or (*iii*) by creating defects. None of these mechanisms can be excluded at this stage and more detailed investigations are necessary to clarify the detailed nature of the electrochromic mechanism in AIROF's.

In summary, all available data in aqueous and nonaqueous solutions show that electrochromism in AIROF's takes place via anions. This contrasts with the cation mechanism of electrochromism which has been well established for WO_3 and other cathodically colored oxides. On the other hand, it has recently been shown (42) that in lutetium diphthalocyanine "coloration" from green to red occurs by injection of Cl^- ions from the electrolyte into the electrochromic film.

Anion electrochromism is of particular significance for solid-state display devices. Solid-state fluorine fast-ion conductors are known (36) and can conceivably be used in conjunction with AIROF's. Preliminary results to be reported elsewhere have shown that this is possible.

Finally, in addition to display device applications, hydroxide ion electrochromism is of fundamental importance for its relation to oxygen electrocatalysis. In most materials, high catalytic activity for oxygen evolution from the splitting of water has been found (43) to be associated with high affinity for hydroxide ions. As we have seen, AIROF's have high affinity for hydroxide ions and indeed they have superior catalytic activity for oxygen evolution (44). The detailed rela-

tionship between electrochromism and electrocatalysis remains a problem for future investigations.

X-Ray Diffraction Studies of Electrodeposited and Sputtered Hard Gold

E. T. Eisenmann

Bell Laboratories, Columbus, Ohio 43213

ABSTRACT

Studies of the oxidative softening of additive-free and cobalt-hardened gold lead to the conclusion that lattice strain is a major contributor to the hardness of these electrodeposits. Since strain hardening is not observed in gold from the melt, its occurrence in hard gold is claimed to derive from the polytypic structures, which seem to be characteristic of all high purity hard golds, plated as well as sputtered. Structural similarities of the gold polytypes and cobalt dicyanoaurate may be the reason for their electrolytic codeposition, which generates a distorted gold lattice. Oxidation or reduction of the light elements promotes the relaxation of lattice strains and leads, consequently, to the softening of electroplated hard gold.

Electroplated hard gold has been the subject of sustained fundamental studies ever since its use became preeminent in the electronics industry. This is not to say that the mechanical and physicochemical behavior of hard gold is thoroughly understood. Rather, new aspects of this material crop up occasionally when an industrial application fails to produce or to maintain the desirable properties. One case in point is the recent observation that cobalt-hardened gold loses its hardness within a few seconds when heated to 350°C in air.

The hardness of electroplated hard gold has been attributed to its small grain size (1). Grain growth was observed in cobalt-hardened gold at temperatures as low as 100°C, but significant softening of the deposit was found only after prolonged heating (1 hr) at temperatures in excess of 300°C (2). Nickel-hardened gold required 600°C to produce some grain enlargement and 700°C to slightly decrease the hardness (3). Isochronal annealing experiments in both investigations (2, 3) preclude, however, any judgment about the rate of the softening process. Koch (2) indicates that there is no mechanism by which hard gold could change metallurgically at 85°C to affect its performance as contact material. Structural changes of hard gold were also measured by Mohrnheim (4) in dependence of time and temperature, but no hardness data were taken.

The object of this investigation was to provide an adequate data base on the kinetics of the reactive softening of various electroplated hard golds. Hardness tests, in combination with electron microscopic inspections and x-ray diffractometer scans, were chosen as analytical tools, temporarily disregarding the chemical nature of the process.

Heat-Treatment of Plated Hard Gold

A series of experiments was designed to estimate the rate at which structural changes occur in cobalt-hardened gold in response to various heat-treatments. Samples were prepared by plating 15-20 μm of gold on 0.5 × 15 cm strips of nickel sheet, using a Selrex Autronex CI bath (Oxymetal Industries, Nutley, New Jersey), under standard conditions. Each strip was cut into 15 pieces, and each piece was used for a different heat-treatment. In the as-plated condition x-ray diffraction analysis yielded the lattice parameter a_0 = 4.059 ± 0.001Å, as calculated from the (422) peak. After heating in air at 340°C for 10 min, the lattice parameter was a = 4.076. Heating at the same temperature for 1 hr yielded the same result. Numerous samples were consequently heated at different temperatures for various times *t*, such that the resulting parameters a_t were evenly spaced over the range from a_0 to a. Plotting $(a - a_0)/(a - a_t)$ on a logarithmic scale *vs.* *t* yields curves as shown in Fig. 1. These curves provide a convenient way of interpolating the time required for any degree of completion of the change in the lattice parameters. Alternatively, the relaxation time t_R may be defined as the inverse slope of the linear part of the curves in Fig. 1. These relaxation times are plotted in Fig. 2 to summarize the results of various heat-treatments in air and forming gas (N_2-10% H_2).

The data are best fitted to two straight lines, suggesting that two distinct processes are operative, *i.e.*, oxidation and reduction. The lack of curvature indicates that no change of mechanism occurs within the range of temperatures studied.

The data presented in Fig. 2 reflect primarily a surface effect, because of the limited penetration depth of x-rays in heavy metals. For copper Kα radiation the half-value layer in gold is about 1.7 μm. This thickness value corresponds, approximately, to twice the reaction zone characterized by t_R. For structural changes occurring at depths greater than ~0.5 μm, x-ray diffraction is no longer a suitable tool for analysis. Scratch hardness tests (5) on cross sections of partially reacted hard gold were used, therefore, to monitor the continued progress of softening with time. This approach was also expected to elucidate the relationship between softening and the structural effects described above.

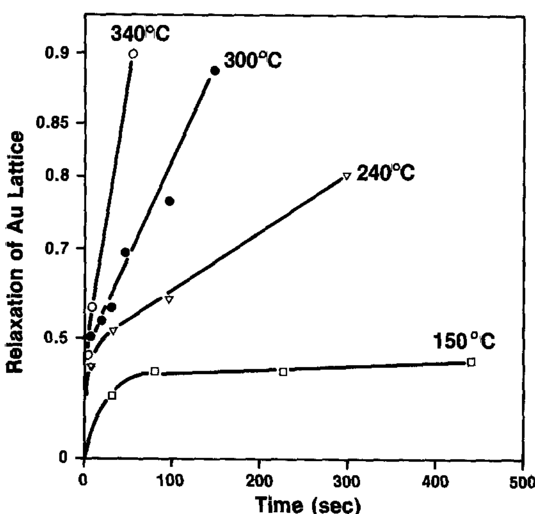

Fig. 1. Relaxation of the gold lattice in dependence of time and temperature.

Key words: polytypism, strain hardening.

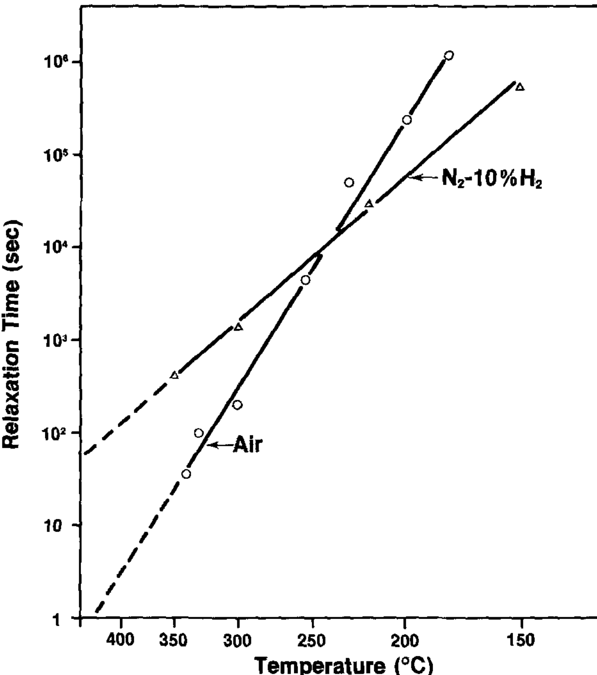

Fig. 2. Arrhenius plot of the relaxation time of structural changes in cobalt-hardened gold due to heating in air and forming gas.

The scratch hardness test is capable of detecting a hardness gradient with a spatial resolution of 1-2 μm. Within this limit numerous repetitions of the experiment indicated that a hardness step exists, rather than a continuum, between the reacted and unreacted regimes of the gold layer, Fig. 3a. Treatment of the cross section with a KCN-H_2O_2 solution led to preferred etching on the reacted part of the gold, giving rise to the formation of a spongy structure, Fig. 3b. Figure 4a shows the sharp boundary between the reacted and unreacted zones of the gold layer after prolonged etching, which in first approximation agrees with the location of the hardness step. The spongy gold shows no signs of crystallographic etching, apparently because recrystallization has not progressed very far, Fig. 4b. These observations suggest that the softening of hard gold is caused by the removal of nonmetallic material from the gold and by the formation of a spongy structure, rather than by grain growth alone.

The progress of the reaction boundary at 300°C was measured microscopically by means of the hardness step and thereafter by means of the etch pattern. According to Fig. 5 a systematic difference exists between the two measurements which is probably caused by erroneous readings of the hardness step. There is no evidence for a decrease in the velocity of the moving boundary with time as should be expected for a diffusion-controlled process. Hence it is concluded that reaction control prevails. Using the slope of the line in

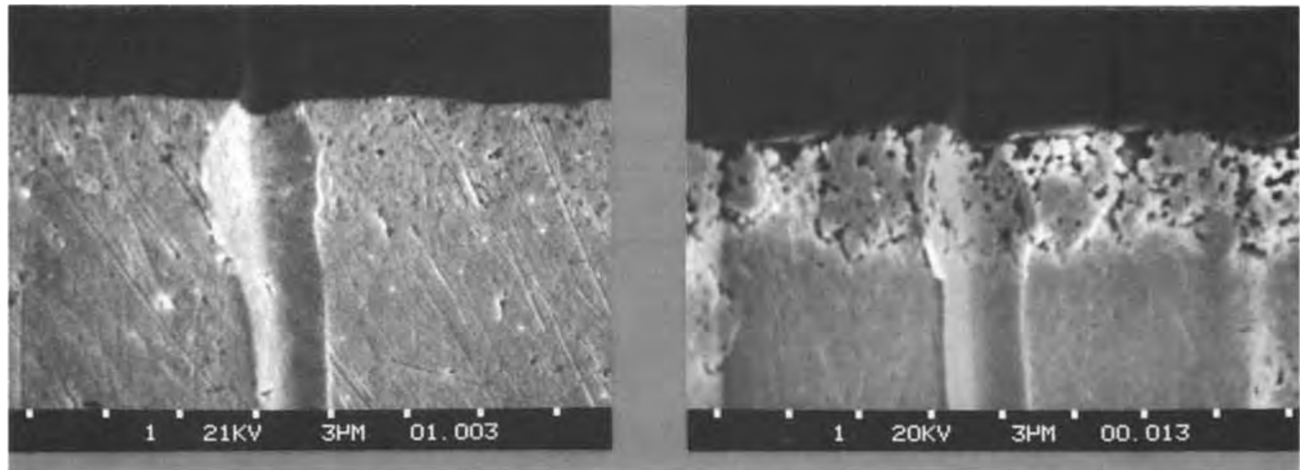

Fig. 3. Scratch hardness test on the cross section of partially softened hard gold: (a, left) polished surface, (b, right) etched surface

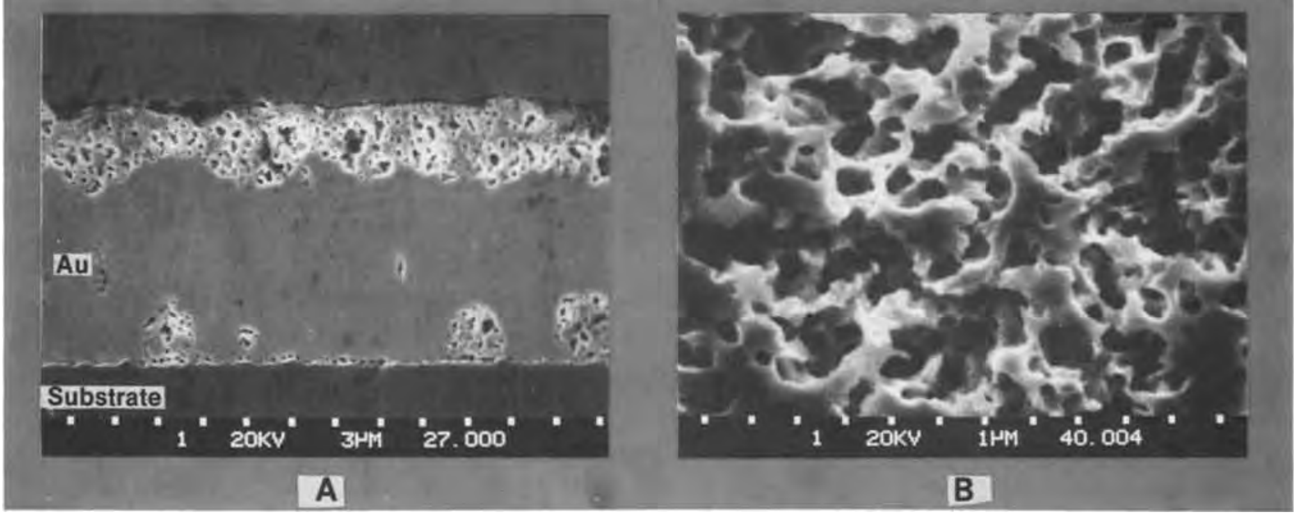

Fig. 4. (a) Boundary in partially oxidized hard gold, exposed by prolonged etching. (b) Gold sponge generated by etching oxidized hard gold.

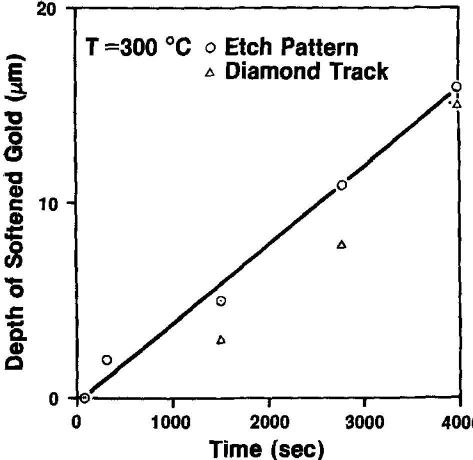

Fig. 5. Progress of the moving reaction boundary with oxidation time as measured by the etch pattern and by the scratch hardness test on cross-sectioned gold samples.

Fig. 5 one estimates a velocity of 0.004 μm/sec. This result is in good agreement with the relaxation time $t_R = 200$ sec, which follows from Fig. 2 for 300°C. Referring this time to one-half of the x-ray penetration depth of 1.7 μm yields 0.0043 μm/sec.

Further studies of the annealing characteristics of plated gold were carried out with deposits from an "additive-free" cyanoaurate solution at high overvoltage. This bath, which contained no hardening agent, was composed of 0.5 mole/liter monopotassium citrate and 0.5 mole/liter potassium cyanoaurate. When operated at 30°C and 100 mA/cm^2 under vigorous agitation, deposits resulted whose hardness approached that of cobalt-hardened gold, but had a lower content of impurities. Heating in air at 350°C followed by etching produced, accordingly, no spongy structure. However, a decrease in hardness was observed, as shown in Fig. 6. These data were obtained on the plated surface using a Knoop indenter at various loads. Both the as-plated and the annealed gold exhibit increasing hardness with increasing load. This behavior is opposite to that of cobalt-hardened gold (5) and could indicate a lesser hardness of the surface. However, scratch hardness tests[1] on cross sections yielded uniform hardness throughout all test samples, regardless of their heat-treatments. Figure 7 presents the variation of the Knoop hardness with time at 350°C as percent deviation from the as-plated values at 1 and 25g load. Also shown is the increase in lattice parameter, which accompanies the decrease in hardness. It is noted that 50 sec of heating causes a significant change in the lattice parameter, but affects only the hardness at 1g, not at 25g load. Continued heating produces a decrease of the higher load hardness as well and is associated with an additional expansion of the gold lattice.

[1] In scratch hardness tests, a Vickers indenter is loaded onto the surface and remains stationary, while the specimen is slowly pulled in the direction parallel to the diagonal of the square, pyramidal indentation. Variations in the rate of relative motion were suspected to influence the results due to "hydroplaning," but were never found to actually do so in a systematic evaluation.

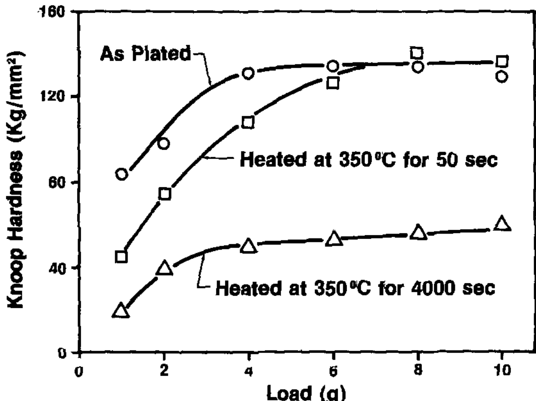

Fig. 6. Hardness of additive-free gold in dependence of the load at various stages of heat-treatments at 350°C.

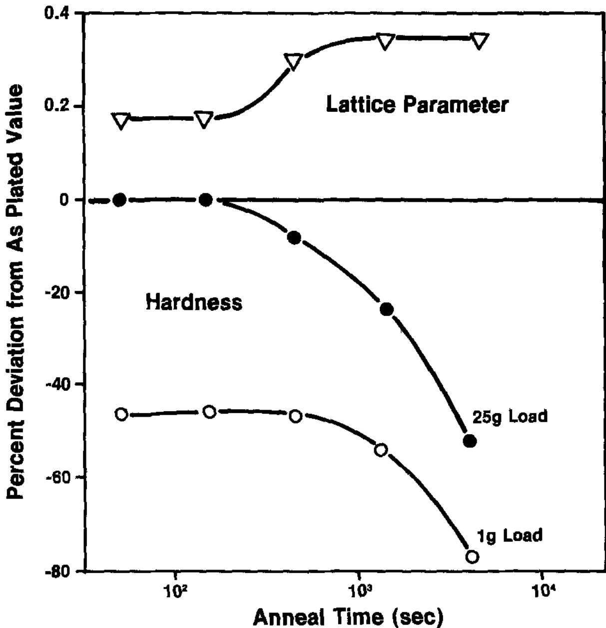

Fig. 7. The variation of hardness with anneal time at 350°C and the corresponding lattice relaxation.

A single principle emerges in two ways from these experiments with additive-free hard gold: (*i*) Electrodeposited gold can be strain hardened, contrary to gold from the melt. This follows from the load dependence of the hardness in Fig. 6, where increasing the strain imposed by the Knoop indenter produces an increase in hardness. (*ii*) Hard gold electrodeposits have a compressively strained lattice. Relaxation of the stress, due to heating, leads to a decrease in hardness, as demonstrated in Fig. 7.

It is concluded that hardness and lattice strains are correlated, even though strain hardening is not observed in gold from the melt. The capability of strain hardening of ("pure") plated gold appears to depend on the particular structure described in the following paragraph.

Detection of polytypism in hard gold.—Transforming cobalt-hardened gold into a gold sponge has been reported previously (6). Combined with the new observations, sponginess seems to indicate that inclusions of carbonaceous materials in as-plated gold are located in voids. From there they may be removed by reaction with oxygen (to form CO_2, N_2) or with hydrogen (to form CH_4, NH_3), thus exposing the already existing spongy structure. From the density of cobalt-hardened gold (17.8 g/cm^3) one estimates that the impurities occupy 8% of the deposit volume. If the pores contain a crystallized material, its characteristic reflections may be detectable in the x-ray diffraction pattern. Accordingly, the previously proposed hypothesis may be tested that cobalt-gold cyanide coordination complexes are incorporated into hard gold during electrodeposition (7).

Selrex Autronex CI gold was plated under standard conditions on a 6 cm^2 × 4 mm polished nickel substrate, to yield a thickness of approximately 20 μm. This specimen was scanned on the x-ray diffractometer from $2\theta = 2°$ upward. The reason for selecting this small diffraction angle was the fact that the hypothesized inclusions are characterized by large unit cells.

Confirmation of the hypothesis appeared to be at hand when reasonably strong, but diffuse and asymmetric reflections were observed at the 2θ angles 8.5°, 17°, and 26° (Cu K_α radiation). These diffraction lines coincide with the strongest reflections of $Co[Au(CN)_2]_2 \cdot 10\ H_2O$, which is known to decompose into gold and cobalt cyanide at 350°C in inert atmosphere (7). This information may be combined with the observation that cobalt-hardened gold changes its structural and mechanical properties under oxidizing conditions at 350°C. The extra diffraction lines were, therefore, expected to disappear in the course of such a heat-treatment. Instead, the relative intensities changed, the peak breadths and the asymmetry decreased, and additional reflections became evident.[2] Further sequential heat-treatments at higher temperatures produced eventually a decrease of the peak intensities, primarily because nickel diffused to the surface to form a dense layer of nickel oxide, which could not be removed with hydrochloric acid. The presence of nickel as surface oxide was concluded from electron probe measurements of the partially abraded surface. A strong nickel signal was obtained on the unabraded surface, but the abraded surface yielded no nickel signal at all.

These observations are inconsistent with the view that the extra diffraction lines are caused by a codeposited cobalt-gold cyanide coordination complex. In fact, Cohen and others (9) claim outright, on the basis of Mössbauer studies, that cobalt-gold cyanide coordination compounds are not present in cobalt-hardened gold. Yet, these authors analyzed only the bonding state of gold, rather than that of cobalt, in just two of at least four compounds worthy of consideration (10). With the precise nature of the contaminants in cobalt-hardened gold unresolved, alternatives for the origin of the extra diffraction lines were considered. Especially attractive appeared the possibility that a new modification of gold was formed due to the irreversibility of the electrocrystallization. Sputtered gold should then also crystallize with this structure because extreme irreversibility characterizes this deposition process. Numerous diffraction lines at low Bragg angles were indeed recorded for sputtered gold, as shown in Fig. 8. A sample of sputtered gold was removed from its substrate and annealed at 700°C for 56 hr. The diffraction pattern yielded then the d spacings listed in Table I, which allow indexing in the cubic system with the cell constant $a_o = 36.72$Å. This value is, with good accuracy, nine times larger than the cell constant of the fcc gold lattice. Because of this relationship, the extra lines in the diffraction pattern of sputtered gold are believed to indicate polytypism. As illustrated by silicon carbide (11), polytypes are formed by stacking identical layers in different arrangements.

The breadth and the asymmetry of the reflections at low Bragg angles precluded meaningful intensity measurements. None of these lines exceeded 3% of the intensity of the strongest line in the pattern, the (111) reflection of the basic fcc gold lattice. Continued annealing at up to 1000°C for 15 min was found to have little effect on the intensities.

To clarify whether or not the hardness of gold deposits is in any way tied to the polytypic structure, two additional series of tests were carried out with the following results.

1. All sputtered samples with hardness values ranging from 60 to 200 kg/mm (measured at 10g load) (1) showed numerous polytype reflections of varying intensities. However, no relationship to the as-deposited hardness data was evident. The effect of annealing on hardness was not evaluated.

[2] Oxidation decomposition of cobalt-hardened gold has been reported to lead to a cobalt oxide film at the surface of the gold and to a depletion of cobalt in the grain boundaries of the deposit (8). Accordingly, the intense purple discoloration observed on the present test sample was assumed to be cobalt oxide. It was removed with hydrochloric acid before the x-ray analysis.

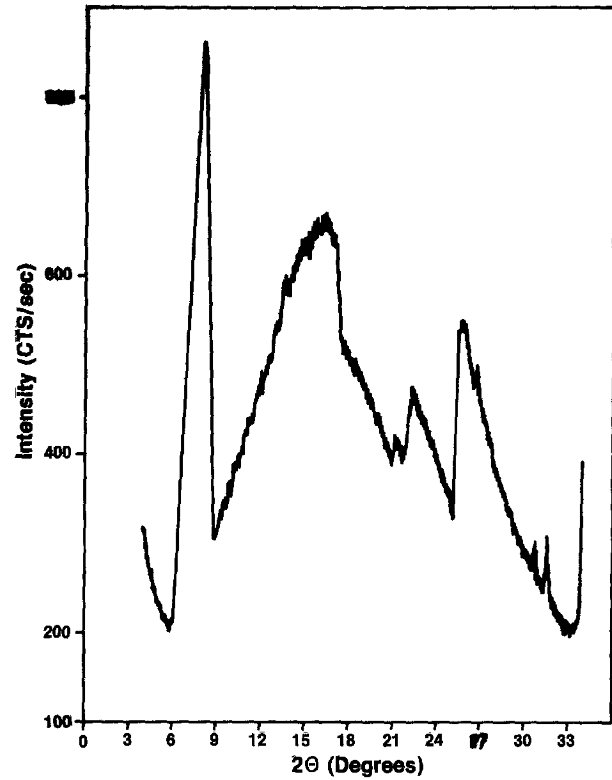

Fig. 8. Low Bragg angle reflections in as-sputtered gold

2. Various types of electroplated gold were tested for low angle reflections. High purity soft gold proved to be without additional reflections. All hard golds showed extra lines, though no correlation between the hardness and the intensity of these reflections was evident. Tested were cobalt- and nickel-hardened as well as "additive-free" hard golds plated from standard and from high speed baths. Typical patterns are listed in Table II and may be compared with that of sputtered gold in Table I.

It is surmised that polytypism in gold is a prerequisite but not a proportional factor in the development of hardness in high purity gold due to strain hardening.

An attempt was made to index the extra reflections of plated golds. Although the d spacings agree largely with those of sputtered gold, there is a conspicuous absence of the spacing d = 36.7Å. Also, there is clear evidence of the interplanar spacing d = 9.6Å, which is

inconsistent with a cubic cell constant of 36.72Å. Further studies are necessary to clarify these differences.

Updating the model of hard gold electrodeposition.—A causative relationship has been claimed to exist between the chemistry of cobalt (and nickel) cyanoaurate complexes and the deposition characteristic of hard gold (7). These compounds were assumed to be incorporated in the gold deposit at grain boundaries or, more specifically, in the pores of a gold sponge. X-ray diffraction measurements did not confirm this particular composite structure but led instead to the discovery of polytypism in gold. Therefore, the model of hard gold electrodeposition should be revised to account for this feature.

Previous studies showed that the electrode relaxation after cathodic prepolarization at constant current density is significantly slower for (cobalt) hard gold than for soft gold deposition (12). This effect indicates the enhancement of an adsorption process, possibly the change from AuCN to $Co[Au(CN)_2]_2$ in the adsorption layer. Concurrently, the activation energy for soft gold deposition was found to decrease with time, while it remained constant for hard gold deposition. It was suggested that the increased activation energy generates hardness via an increased nucleation rate which results in grain refinement (1). In view of the results of the present study it stands to reason that high energy levels during gold deposition are responsible for the polytypism, which by itself is insufficient to increase the hardness. Accordingly, some of the sputtered golds showed strong low angle x-ray reflections but were actually soft. Polytypisms in gold seems, however, to permit strain hardening. The strains in plated hard gold originate from the incorporation of impurities and cause extreme broadening as well as an angular shift of the x-ray diffraction peaks. Most likely, adsorption mixed crystals are formed by reason of structural equalities of the gold polytypes and the impurities. Support for this concept is derived for the case of cobalt-hardened gold from the observation that $Co[Au(CN)_2]_2$, the hypothesized impurity, grows epitaxially on sputtered gold.

The x-ray diffraction pattern of the epitaxial layer is significantly different from that of the crystalline powder which precipitates from homogeneous solution. This is shown in Table III. Therefore, it is concluded that sufficient analogies exist between the polytypic gold and cobalt dicyanoaurate to permit solid solution. Mismatched dimensions, on the other hand, would account for the lattice strain in hard gold.

The updated model of the electrodeposition of cobalt hardened gold presents itself as follows.

Table III. Diffraction patterns of $Co[Au(CN)_2]$

* Indexed in hexagonal system with a_o = 11.930A and C_o = 6.416A.

High overvoltage initiates the deposition and produces polytypism. Chemical adsorption of $Co[Au(CN)_2]_2$ interferes with the crystallization of the fcc structure. In order to permit either the overgrowth or the electrochemical breakdown of the adsorbed species, the electrode potential has to remain high compared to the conditions in soft gold plating. As a result, nucleation and continued growth of the polytypic structure take place.

Summary and Conclusion

Heat-treatments of electroplated cobalt-hardened gold in air and in forming gas produced structural changes which were evaluated by x-ray diffraction, hardness tests, and metallographic cross sectioning. The experimental results suggest that the light element impurities, which are commonly present in this type of hard gold, are removed by oxidation or by reduction, causing a thorough relaxation of the gold lattice and a loss of hardness. Above 250°C, the oxidation reaction proceeds at a higher rate than the reduction reaction, though the latter is less temperature dependent. Scratch hardness tests on cross sections of gold samples, which were heated in air at 300°C, revealed a hardness step. Etching of the cross sections confirmed that the oxidation reaction advances through the gold layer with a sharp boundary, indicating reaction control of the process rather than diffusion limitation.

The annealing of additive-free hard gold resulted in a similar relaxation of the gold lattice and caused a reduction in hardness. No hardness gradient was observed, however. Strain hardening was considered to account for the observed load dependence of the hardness data.

Testing a previously proposed hypothesis about the nature of the impurities in hard golds led to the observation that all plated hard golds show signs of polytypism while plated soft gold does not. Sputtered gold exhibits polytypism, regardless of its hardness. Evidence is discussed that hardness in electrodeposited gold is due, in part, to the lattice strain introduced by the inclusion of contaminants in polytypic gold.

It is concluded that all hard gold plates from cyanoaurate electrolytes are subject to principally the same deposition kinetics and, therefore, to the same hardening mechanism. Loss of hardness due to the reactive removal of the codeposited species will be similar in all of these hard golds, although the rate of softening may vary in dependence of the impurity levels. However, not even additive-free hard gold with its low impurity level is immune from the loss of hardness caused by short term heating at 350°C.

Radial Wafer-to-Wafer Uniformity of Plasma-Deposited Si-N Films

Frank D. Egitto[*,1]

Texas Instruments Incorporated, Dallas, Texas 75265

ABSTRACT

A multidimensional model relating the effects of reactor pressure and rf power to wafer-to-wafer radial uniformity for plasma deposited SiN_x films has been developed for a radial flow plasma reactor. The effects of pressure from 0.4 to 1.6 Torr (53.3 to 213.3 Pa) and power from 30 to 90W on percent nonuniformity are analyzed for constant gas flows. Inward radial depletion of silane can affect uniformity of deposition rate and index of refraction. The experimental technique used to obtain a "uniformity surface" and the theoretical considerations employed in analyzing the results are described.

In using a radial flow plasma reactor (1) (see schematic, Fig. 1) for depositing silicon-containing films, radial uniformity of deposition rate can be attributed mainly to three controlling factors. These are the radial gradients of electron density n_e, residence times τ of the reactant gases, and residual concentrations C_i (number of molecules of gas i per unit volume) of the reactant gases (2). Since the gases are continually depleted as they flow inward, $C_i(r_1)$ refers to that portion of gas i which is not consumed at radii greater than r_1. These gradients are illustrated in Fig. 2. The electron density is determined by rf power input while the residence times are controlled by reactor pressure which, for constant inlet

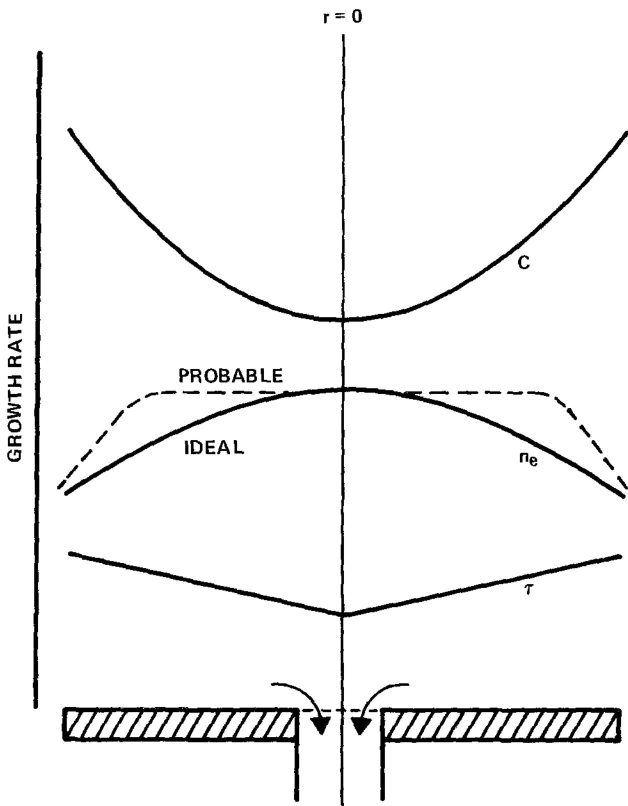

Fig. 2. Factors which affect radial uniformity: residual gas concentration (C), electron density (n_e), and residence time (τ). After Reinberg (2).

gas flows, is a function solely of pumping speed. Residual gas concentration, although influenced by gas flows, is also a function of both rf power and reactor pressure. Thus, at a given radius and constant inlet gas flows

$$n_e = f(\text{rf power})$$
$$\tau = g(\text{reactor pressure}) \qquad [1]$$
$$C = h(\text{rf power, reactor pressure})$$

Near the outer wall, the electron density falls off approximately as a zeroth order Bessel function (3), promoting higher deposition rates near the center of the reactor. However, τ decreases linearly with decreasing radius (2). Ideally, a balance between the effects of power and pressure is sought in order to obtain radial uniformity.

The object of this paper is to analyze the effects of power and pressure on SiN_x film deposition at constant gas flows and to develop a three-dimensional uniformity surface which can be used as a basis for a routine to obtain the optimum combination of these parameters. Each point on the uniformity surface will identify the radial wafer-to-wafer uniformity of deposition rate (vertical axis) corresponding to a given combination of power and pressure settings (horizontal axes).

Experimental

Depositions were performed in the radial flow reactor (1) shown schematically in Fig. 1. The outer diameter of the plates which were separated by 2.5 cm was 40.6 cm. Two silicon pilot wafers were centered at radii of 10.2 and 16.5 cm, respectively, and along a common radial line. The positions were held constant to 0.2 cm between runs. The substrate plate was heated to 300°C by resistance heaters adjacent to its underside. The platen temperature was monitored and controlled via a thermocouple positioned at its underside.

A SiH_4 flow of 12 SCCM, 14 SCCM of NH_3, 315 SCCM of N_2, and 362 SCCM of argon were admitted to the reactor chamber from below the substrate plate. These flows provided a reasonable film index of refraction throughout the power range of 30-90W and the pressure range of 0.4-1.6 Torr (53.3-213.3 Pa). The rf power was varied in 10W increments and at each of these power settings the pressure was varied in 0.2 Torr (26.7 Pa) increments by adjusting the pumping speed via a throttle valve. Pressure was monitored by a Validyne diaphragm vacuum gauge.[2]

An ellipsometer operating at 6328Å was used to measure film thickness and index of refraction of all films. Deposition times were adjusted for various powers and pressures in order to produce film thicknesses more easily measured by this technique. Measurements were taken at the centers of all test wafers.

Percent nonuniformity, *PNU*, was determined as follows

$$PNU = [(\overline{R} - R_I)/\overline{R}] \times 100 \qquad [2]$$

where R_I is the deposition rate on the inside wafer and $\overline{R}$ is the average of the inside and outside deposition rates. Thus, a positive value for *PNU* implies a greater rate on the outside wafer, a negative *PNU* indicates a greater rate on the inside wafer, and a *PNU* of zero defines a perfect radially uniform deposition rate.

PNU is plotted as a function of pressure for various rf powers in Fig. 3. The same data is illustrated as *PNU vs.* power for various pressures in Fig. 4. The three-dimensional uniformity surface is illustrated in Fig. 5. All points at which the uniformity surface intersects the power-pressure plane represent zero *PNU*, *i.e.*, possess radially uniform deposition rates. These power-pressure pairs constitute the balance sought in making uniform depositions. However, as explained below, not all of these uniformly thick films are suitable for semiconductor device manufacture and it is necessary to filter out those which are not.

[2] The AP10 Validyne Absolute Pressure Transducer is a variable reluctance transducer. Pressure displayed on the Model DM56A digital manometer is not a function of gas species.

Discussion

The degree to which deposition rates vary radially due to radial variations in electron density n_e or gas residence times τ depends on the reactor chamber pressure. At high pressures, gas velocities are lowest and residence times are longest. As a result, n_e is the controlling mechanism, encouraging relatively higher deposition rates at small radii than at large radii. At low pressures, residence times are shorter and the effect of n_e is diminished. τ becomes the controlling factor, encouraging relatively higher deposition rates at large radii than at small radii. Hence, as pressures are increased at a given power, a decrease in *PNU* is expected.

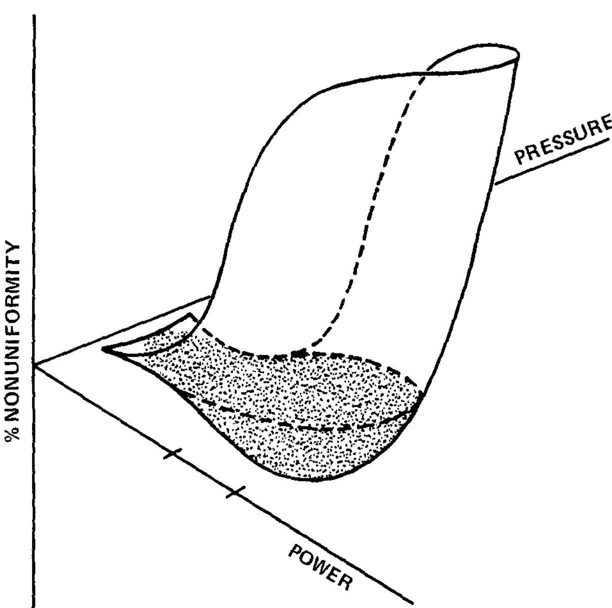

Fig. 5. Uniformity surface

However, this behavior is observed only over a limited pressure range. As the pressure is increased to values above this range, the outside rate is enhanced, relative to the inside rate, producing a quadratic dependence of *PNU* on pressure (Fig. 3). At the highest pressures shown, the relative deposition rate is increasingly greater on the outside wafer. For lower powers, uniformity is obtainable at two pressures while at higher powers uniformity may not be obtained at any pressure. The reason for this becomes apparent when one observes the behavior of the refractive index of the two test wafers as illustrated in Table I and Fig. 6. In Fig. 6, percent nonuniformity of index was determined as for deposition rates. It is observed that, when a uniform deposition rate is obtained at higher pressures, a large nonuniformity in index of refraction can occur. At these points, the index of the outer film is consistently and significantly larger than the inside index. This effect is produced by a rapid inwardly radial depletion of silane at pressures which are too high. At these pressures, the reactant gases move too slowly over the outer portion of the substrate plate and are deposited at an abnormally high rate. The depletion of the rate-controlling silane leads to the behavior of *PNU* illustrated in Fig. 3.

It has been demonstrated (2) that for rf powers from 10 to 80W, the percentage of silane depleted in the reactor is greater than the percentage of ammonia depleted (as measured downstream from the reactor chamber). In addition, silane is more easily dissociated than nitrogen. Since the silane concentration controls the silicon content of the film, silicon deficient films are deposited on inner wafers when the pressure is too high. As a result, inner wafers exhibit the lower index characteristic of a lower silicon to nitrogen ratio in the film. As pressure is increased even further, the effect of depletion can be observed

on outer wafers. In this pressure region much silane is consumed below the substrate plate.

As rf power is increased, the effects of silane depletion are observed at lower and lower pressures (Fig. 6). The gas flow shield reported by Sinha *et al.* (4) promotes uniform deposition at powers much greater than otherwise possible. This results from confinement of the discharge to the region above the substrate plate and, hence, reduced consumption of silane below the plate.

As rf power is increased, the increase of n_e at the outer edge of the reactor exceeds the increase at the center, although n_e remains maximum at $r = 0$. Thus, higher powers promote greater relative outside deposition rates. This is in agreement with the curves of Fig. 4 except at the lowest powers. At powers less than 50W, decreasing power tends to increase *PNU* toward zero. At these powers, a radially uniform deposition rate is obtained at all pressures. It is possible that this effect is due to the fact that at very low powers, ionization occurs primarily near the electrodes where the gas velocities are near zero, independent of radius. This follows from the expression for gas velocity given by (5)

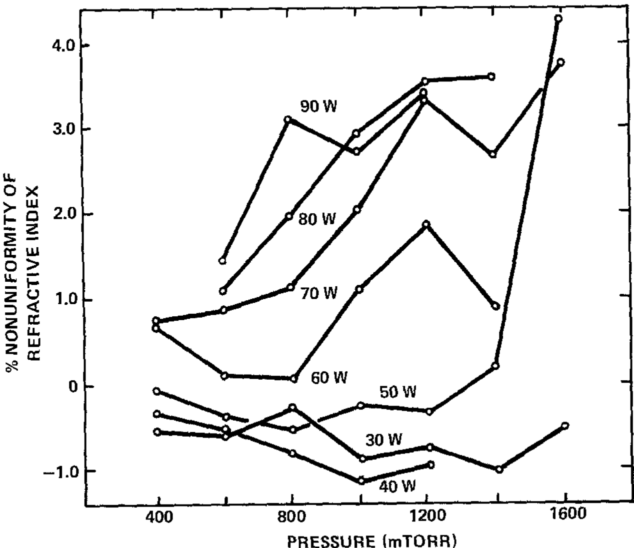

Fig. 6. Percent nonuniformity of SiN_x film refractive index as a function of pressure at various rf powers.

$$v(r, z) = \frac{-3Q}{8\pi br}\left[1 - \left(\frac{z}{b}\right)^2\right] \quad [3]$$

where Q is the volume rate of flow, $2b$ is the electrode separation, z is the distance from the midplane between electrodes, and r is the radius. The negative sign indicates that flow is radially inward. A slow, steady, laminar, incompressible Newtonian flow is assumed. Hence, at low power, pressure variations have little effect on uniformity.

Figure 5 can be used as a basis for a computer program to aid in obtaining depositions which are radially uniform in rate and index of refraction. Two techniques have been considered: one involving a linear approximation with the use of appropriate filters and the second employing a quadratic approximation.

It is obvious that the uniformity surface is not planar and a linear approximation may, at first, seem unsuitable. However, by using filters such as refractive index nonuniformities and variations in *PNU* as a function of variations in rf power or reactor pressure, one can arrive at a region of the uniformity surface where a linear approximation can be applied. A sample calculator flow diagram illustrating this routine is shown in Fig. 7 and such a program has been written for the Texas Instruments SR-60 programmable prompting calculator.

As shown in Fig. 3, the dependence of *PNU* on pressure (power constant) is quadratic in nature. Using three data points, *i.e.*, three *PNU*-pressure pairs, the zeros of the parabola at a given power can easily be obtained. These zeros are the pressures at which radially uniform deposition rates are obtained. Imaginary zeros imply a power which is too large to obtain uniformity at any pressure. In addition, when real zeros exist, their proximity is an indication of the amount by which the power may be raised without exceeding the maximum power at which uniformity is obtainable. Figure 3 shows that as rf power is increased, the zeros of the parabola become closer. The index of refraction will almost always be more uniform at the lower of the two pressures at which a uniform deposition rate is achieved.

Conclusions

Silane depletion, as well as reactor pressure and rf power, acts in determining radial uniformity of plasma-deposited silicon nitride films. For a given power and constant gas flows, uniformity of deposition rate is possible at two pressures (assuming the

power is not too great), the higher pressure usually accompanied by a large radial nonuniformity of refractive index. At very high powers, uniformity of rate is not achievable.

The three-dimensional uniformity surface can be used as a basis to develop a routine to optimize the SiN_x deposition process. Since the routine employs data taken as the process is set up, it will be reactor independent, although the shape and position of the surface may vary slightly for various radial flow reactors and reactor configurations.

Compensating for silane depletion by adjustment of inlet gas flow rates is possible, yet not straightforward. It appears obvious that the flow rate of SiH_4 should be increased. However, a corresponding increase in NH_3 flow rate would be required to avoid undesirably high refractive indexes. Assuming that pumping speed and residence times do not vary appreciably with the resulting pressure increase (throttle valve conductance remaining fixed), deposition rates at inner radii may increase relative to those at outer radii as the effects of depletion are diminished. An additional correction in reactor pressure or rf power may then be required.

ABSTRACT

Spectroscopic ellipsometric data from 1.5-5.8 eV has been analyzed to determine the *in situ* optical response of the interface between Si and its thermally grown oxide. Results for <100>, <110>, and <111> sample orientations show an interface of width $d_{ox} = 7 \pm 2$Å consisting of atomically mixed Si and O of average stoichiometry $SiO_{0.4\pm0.2}$. The optical data are not consistent with either microroughness at the interface or an abrupt transition between crystalline Si and SiO_2 or a significant accumulation of amorphous Si at the interface, but rather support a gradual transition region. The thickness and the average λ5461 refractive index $n = 3.2 \pm 0.5$ of this region are in agreement with the fixed-wavelength results, $d \sim 6$Å and $n \sim 2.8$, of Taft and Cordes. The oxide on the <110> surface is shown to have a density about 1.2% less than that of corresponding oxides on <100> and <111> surfaces.

There has been much recent interest in studying the properties of the interface between Si and its thermally grown oxide, not only because of its technological importance but also because it is the chemically simplest, most easily managed semiconductor-oxide system and hence the one most likely to be understood in fundamental terms (1). Recent experimental results have been summarized by Wager and Wilmsen (2). In short, the interface is too narrow to be analyzed by conventional ion-milling techniques, which not only have inadequate depth resolution but also destroy the interface during the measurement process. The most reliable information has come from recent experiments using nondestructive techniques. Krivanek and co-workers (3) used transmission electron microscopy with 3Å resolution to show that the crystalline Si (c-Si) substrate terminates abruptly (within one monolayer) with a 4-8Å modulation of a period of 200-500Å. Rutherford backscattering (RBS) was used by Feldman and co-workers (4) to show the existence of about two monolayers equivalent of excess Si, which could occur for example as two layers of nonregistered Si under stoichiometric SiO_2, or as a single nonregistered layer of Si together with ~5Å of SiO under stoichiometric SiO_2. Fixed-wavelength λ5461 null ellipsometry (NE) by Taft and Cordes (5) indicated an interface about 6Å wide of effective index about 2.8. XPS measurements on ultrathin or chemically profiled oxides show a gradual transition region ~5Å (6) or 7-10Å (7) with evidence that the SiO_2 bonding is affected up to 40Å from the interface (6).

In this paper, we present results of a spectroscopic ellipsometric investigation of the Si-SiO_2 interface from 1.5 to 5.8 eV. Our objective was to take advantage of the sensitivity of ellipsometry to thin films and of the widely different dielectric properties of c-Si, amorphous Si (a-Si), SiO_2, and their mixtures in the visible-near u.v. spectral region to perform *in situ* spectroscopy on the protected interface and to determine information about its microstructure and chemical bonding from its visible-near u.v. optical response. TEM, RBS, and NE can provide general information about microstructure, but not about chemical bonding which requires some form of spectroscopy. XPS in principle can provide the latter information, but its interpretation is dependent on electron escape depths. Because spectroscopic ellipsometry does not depend on transport assumptions, requires only a transparent ambient (as, for example, SiO_2), and is sensitive to monolayers, it is a natural technique to apply to this problem. The results demonstrate also that spectroscopic ellipsometry can be used to study layers as thin as a few angstroms even though buried under hundreds or even thousands of angstroms of transparent overburden.

Analysis of the ellipsometric data shows that the interface is best represented as a 7 ± 2Å region of Si and O of average stoichiometry $SiO_{0.4\pm0.2}$. These data show clearly that the mixing is on a atomic scale rather than occurring as regions identifiable explicitly as a-Si and SiO_2 as might be expected from microroughness or incomplete oxidation of particulate material. Also rejected is an abrupt junction between Si and SiO_2 or an accumulation of a-Si at the interface. No difference in the interface region is observed for the three different interface orientations investigated here, although the SiO_2 overlayer on the <110> interface is about 1.2% less dense than that on the <100> or <111> interfaces. The microstructure that emerges is a laterally uniform, graded transition region of atomically mixed Si and O of thickness and composition as mentioned above. The results are consistent with the RBS alternative of a monolayer of a-Si followed by 5Å of SiO. The graded nature is in agreement with XPS measurements (6, 7). Finally, because the λ5461 refractive index of $SiO_{0.4\pm0.2}$ is 3.2 ± 0.5, the present results are also in agreement with the fixed-

wavelength λ5461 null ellipsometric measurements of Taft and Cordes (5). Thus a completely consistent picture is obtained.

Experimental

Spectroscopic ellipsometer.—The spectroscopic rotating-analyzer ellipsometer (RAE) used to obtain these data has been discussed in detail elsewhere (8). In brief, the essential features include a Xe 75W short-arc source for high luminosity and efficient collection at relatively low power dissipation, a Cary 14 spectrometer for excellent scattered light rejection, quartz Rochon prisms for extended spectral range and source/detector depolarization, and computerized Fourier processing of the digitized detector output for high precision. The detector circuit includes a feedback loop to achieve system linearity to at least one part in 10^3 over the entire operating range. A shutter periodically interrupts the lamp output to allow component drift and stray light contributions to be evaluated and eliminated at each wavelength. The data are corrected (9) for the optical activity of the quartz Rochon prisms.

While precision of a few parts in 10^5 is achieved routinely accuracy limits are more difficult to assess. Nevertheless, the following observations are suggestive. In straight-through operation, the calculated polarization plane is constant to within $\pm 0.02°$ from 1.5 to 5.8 eV. Over the same range, the apparent a-c/d-c ratio is constant to within ± 0.001. At a fixed wavelength, the analyzer and polarizer azimuths track to within $\pm 0.01°$ over the ranges used, showing that the polarizer divided circle drive and the detector system is linear, and that source/detector residual polarization effects are negligible. Finally, calibration for a variety of samples routinely yields plane-of-incidence azimuths which are invariant to within $\pm 0.05°$, showing accurate reproducibility for sample alignment and also accurate compensation for the optical activity of the quartz Rochon prisms. Thus in direct angular measurements, the present photometric system is comparable to that of a good null ellipsometer, but somewhat less accurate than the $\pm 0.01°$ fixed-wavelength instrument used by Taft and Cordes (5). The a-c/d-c ratio uncertainty has no direct analog in null ellipsometry, but corresponds roughly to an uncertainty of $\pm 0.1°$ in ψ under worst-case conditions where the light leaving the sample is linearly polarized. These uncertainties are not large enough to affect the conclusions reached here on the basis of the data.

Sample preparation.—Three n-type single crystal Si wafers of 24-29 Ω cm resistivity and <100>, <110>, and <111> surface orientations were Syton polished to provide high quality specular surfaces. The wafers were precleaned by standard gate-oxide procedures, then cleaning oxides were grown in dry O_2 at 1000°C to a <111> thickness of 1000Å. These oxides were stripped, and final oxides were regrown under the same conditions to a <111> thickness of about 2000Å. All three wafers were processed simultaneously to eliminate any possible differences due to slight variations in processing and growth conditions. All processing was done on equipment used routinely for the production of high quality gate oxides.

The resulting oxides on the <100> and <111> wafers were about 2100 and 2300Å thick, respectively, and appeared absolutely uniform on visual inspection, although ellipsometric measurements showed a slight (5Å) nonuniformity in thickness over the wafers. The substantially thicker 2800Å <110> oxide showed an obvious thickness gradient over part of the surface, but about half the wafer was found to be sufficiently uniform for interface determinations to be performed.

To provide self-consistency checks, and particularly to establish conditions (10) for determining accurately individual model parameters such as the density of the SiO_2 overlayer, the samples were etched after the initial measurements to obtain further data at several different oxide thicknesses. We used a 5% HF-95% H_2O solution (5), which was observed to etch the <100>, <110>, and <111> sample oxides at 190, 120, and 200 Å/min, respectively. The <110> oxide also exhibited a different density than the <100> and <111> oxides, as is discussed below.

Data Processing

Determination of sample parameters.—Our general data reduction procedure has been discussed elsewhere (11). Briefly, we measure the complex reflectance ratio (optical impedance) of a composite sample from 1.5-5.8 eV and then compare these data objectively to model spectra calculated for a given hypothetical configuration by using standard equations (12) and linear regression analysis (13). The specific configuration studied here consists of a c-Si substrate, a possible interface, an oxide overlayer, and the air ambient. These constituents can be described by means of dielectric functions, thicknesses, possible void fractions and birefringence in the oxide, etc.

Because a single-wavelength ellipsometric measurement provides only two constraints, the parameters of the composite system are hopelessly underdetermined unless further conditions can be established. We generate the necessary constraints by making spectroscopic measurements and by including spectrally dependent and independently measurable data, such as the dielectric response of c-Si and SiO_2, as known quantities. This leaves only a few spectrally independent parameters such as oxide thickness to be determined by comparing model spectra to measured spectra. Thus a given model becomes highly overdetermined, and its validity can be judged readily by how well it fits the entire spectrum, not just at a single wavelength. Linear regression analysis (13) provides an objective and systematic way of minimizing the differences between the data and spectra computed for specific models and expressing the result in terms of best-fit model parameters and the unbiased estimator, $\hat{\sigma}$, of the mean square deviation, δ. We have shown previously (11) that linear regression analysis can be applied in this context not only as a systematic means of providing best-fit parameters, but also as a means of establishing correlations and confidence levels to show which parameters are well determined by the data and consequently should be emphasized and which parameters cannot be well determined by the data and consequently should be ignored.

Dielectric function data of constituents.—c-Si substrate.—No previously published c-Si dielectric function data exist that are sufficiently accurate and/or cover a sufficiently wide energy range to determine interface parameters. The best available low energy data are those of Hulthèn (14), determined below 3 eV by transmission measurements. The best wide-range data are those of Philipp (15), determined by Kramers-Kronig analysis of complex reflectance measurements, from 0-27 eV, with subsequent correction for the effect of oxide overlayers. The Hulthèn data are probably sufficiently accurate but do not cover an adequate spectral range. The Philipp data are probably accurate with respect to general amplitude values but are not available over a sufficiently fine grid and consequently show substantial shifts of threshold energies for interband transitions.

Accordingly, a c-Si spectrum was generated by accurately measuring the pseudodielectric function of a piece of the oxidized <110> sample that had been stripped in HF. Although the traditional approach is to correct these data by mathematically removing an overlayer of SiO_2, consistent interface results could be achieved only by mathematically removing the self-consistent 6Å overlayer of chemically mixed $\sim Si_{0.75}(SiO_2)_{0.25}$ that was determined by the interface analysis itself. This is in qualitative agreement with the results of Philipp (15), who noted previously that

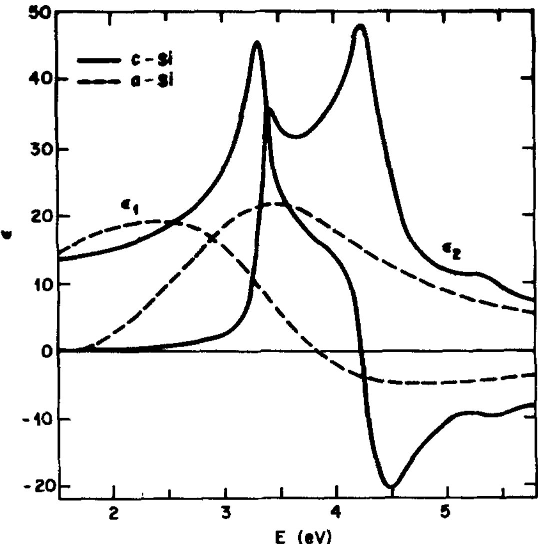

Fig. 1. Dielectric functions of c-Si and a-Si

the presence of an SiO_2 overlayer on stripped c-Si would lead to reflectance structure near 10 eV that is not observed.

Our resulting spectra are shown in Fig. 1. The ϵ_1 spectrum below the direct gap agrees with that of Hulthèn (14) to within 1½% and with that of Philipp (15) to within ½%. The maximum value of ϵ_2, 47.87, is slightly less than Philipp's value, 48.25, in agreement with discrepancies observed for Ge (16). Finally, the ϵ_2 values below the direct gap, which are exceptionally difficult to determine with an RAE, agreed with Hulthèn values to within 3%. However, because the transmission data are more accurate, our ϵ_2 data were replaced with Hulthèn's data below 2.5 eV. We thus believe these data to be the most accurate ever determined for c-Si over the visible-near u.v. quartz-optics range.

SiO_2 oxide.—The data base is the dispersion equation determined by Malitson (17) for fused silica. Taft (18) has shown that thermally grown oxides on c-Si differ at λ5461 from the Malitson data in at least two significant respects. First, thermally grown oxides show birefringence. Second, the index values depend on the growth temperatures and slightly on crystal orientation (only <100> and <111> data were given). The birefringence was shown (18) to arise entirely from the compressive stress in the thermally grown oxide, which in turn derives almost entirely from the mismatch in thermal expansion coefficients (19). Less clear is the origin of the index differences, which below 1200°C growth temperatures suggest the presence of different SiO_2 polytypes (18) and thus may not be related entirely to density differences.

For simplicity, we suppose that refractive index differences between our oxides and Malitson's data arise from density differences, which can be described accurately in the Bruggeman effective medium approximation (20). But this implies an assumption about the nature of the SiO_2 dispersion which presently cannot be tested. However, such effects do not appear to be important as is discussed more fully later.

Birefringence in the SiO_2 overlayer is incorporated by supposing different threshold shifts, $+\Delta E$ and $-0.5\,\Delta E$, for p- and s-wave polarizations, respectively, in the two higher energy Sellmeyer oscillators in the Malitson expression. The value $\Delta E = +0.017$ eV was chosen to give $n_e - n_o = 0.0007$ at λ5461 in agreement with the accurate measurements of Taft and Cordes (5). The effect on the complex reflectance ratio in model calculations was included by standard equations (12, 21).

Si-SiO_2 interface.—To determine the interface composition we require dielectric function spectra for the complete range $Si_x(SiO_2)_{1-x} = SiO_{2-2x}$, $0 \lesssim x \lesssim 1$. Experimental spectra are not available, but suitable interpolations can be obtained as follows.

First, we recognize two possible types of mixtures: physical, where optically identifiable regions of a-Si and SiO_2 coexist as, *e.g.*, microroughness or inclusions and host, on a scale small compared with the wavelength of light, and chemical, where the Si and O are mixed on an atomic scale. The former case is described by heterogeneous dielectric theory. We use the Bruggeman model together with data for a-Si that we obtained previously (22) and which are also shown in Fig. 1. The Malitson dispersion equation is used for SiO_2.

Specifically, the Bruggeman approximation (20) gives the effective dielectric function, $<\epsilon>$, of a heterogeneous material as

$$0 = f_a \frac{\epsilon_a - <\epsilon>}{\epsilon_a + 2<\epsilon>} + f_b \frac{\epsilon_b - <\epsilon>}{\epsilon_b + 2<\epsilon>} + f_v \frac{1 - <\epsilon>}{1 + 2<\epsilon>} \quad [1]$$

where f_x, ϵ_x, x = a, b, v are the volume fractions and dielectric functions of the separate phases a, b, and v = void, respectively; $f_a + f_b + f_v = 1$. For the interface, we take $f_v = 0$. Because the volume associated with an SiO_2 molecule is 1.55 times larger than that associated with an Si atom in a-Si, the relation between atomic fraction x and the parameters of Eq. [1] are

$$\epsilon_a = \epsilon_{a-Si}; \quad f_a = x/[x + 1.55(1 - x)] \quad [2a]$$

$$\epsilon_b = \epsilon_{SiO_2}; \quad f_b = 1.55(1 - x)/[x + 1.55(1 - x)] \quad [2b]$$

Spectra calculated for x in increments of 0.125 are shown in Fig. 2.

Spectra for chemically mixed Si and O are calculated in a model that we developed previously for another application and which is completely described elsewhere (23). Results for x values in increments of 0.125 are also shown in Fig. 2. The physical and chemical models differ in that the peak value of ϵ_2 remains at 3.5 eV until a relatively large SiO_2 fraction is present in the former case, but immediately starts shifting to higher energies with increasing O content in the latter case. This is a result of the electronegativity difference between Si and O which moves the average oscillator strength to higher energies in the blended material. Also, boundary screening inhibits the dilution effect of O in physical mixtures, requiring more O to achieve a given reduction in the long-wavelength refractive index than for atomically mixed material. The qualitative difference can be seen immediately by comparing the spectra for the $x = 0.75$ physically mixed and $x = 0.875$

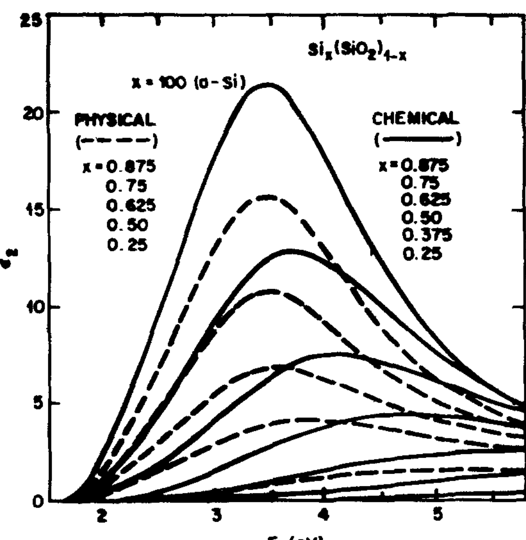

Fig. 2. Comparison of ϵ_2 spectra for physical and chemical mixtures of a-Si and SiO_2 for atomic fractions of a-Si in SiO_2 as indicated.

chemically mixed materials, which are essentially identical up to 3 eV and differ appreciably only in the u.v. Both cases have been observed: the former behavior describes spectra (24) of the composite material SIPOS, while the latter describes the atomically mixed material evaporated silicon monoxide (25).

We reemphasize that physical and chemical mixtures cannot be distinguished optically without determining the dielectric response in the near u.v. Thus the $n = 2.8$ value for the interface at $\lambda 5461$ obtained by Taft and Cordes (5) corresponds to either a physical mixture of $x = 0.65$ or a chemical mixture of $x = 0.73$. No further information can be obtained at a single wavelength.

Results

1-, 2-, and 3-parameter models.—Typical tan ψ, cos Δ data for an oxidized Si wafer of <100> orientation and oxide thickness 1360Å are shown in Fig. 3. These data exhibit the characteristic interference pattern with increasing energy as the optical standing waves in the oxide pass through increasing periods. Interface sensitivity is maximized for the p- and s-wave components near minima and maxima, respectively, in tan ψ as minimum reflectance implies maximum energy density at the interface as previously discussed (11, 26).

The results of least squares fitting 1-, 2-, and 3-parameter models to these data are shown in Fig. 4. The fitting was done at 83 points equally spaced over the 1.5-5.8 eV interval to the real and imaginary parts of ρ calculated from tan x and cos Δ. Rather than compare spectra directly in terms of tan ψ and cos Δ, we show the differences because in every case these are small and would not be seen on the scale of Fig. 3.

Figure 4 shows that a one-parameter model consisting of an ideal c-Si substrate, no interface, and an ideal SiO_2 overlayer does not reproduce accurately the peak in tan ψ. For this model the least squares procedure yields $d_{ox} = 1368.6 \pm 0.4$Å and $\hat{\sigma} = 0.0567$. The uncertainty shown here, and those which follow, refer to 90% confidence limits based on the mismatch between model spectra and data and do not include possible systematic errors. By allowing the void volume density to vary, most of the tan ψ discrepancy near 2 eV disappears although the phase spectrum, cos Δ, and the higher tan ψ mismatch are not improved. The parameters obtained in this two-parameter model are $d_{ox} = 1363.6 \pm 0.3$Å, void fraction $f_v = -0.0062 \pm 0.0004$, and $\hat{\sigma} = 0.0166$. Thus the fit as measured by $\hat{\sigma}$ is improved significantly, by more than a factor of 3. The negative void fraction simply means that the thermally grown oxide is effectively more dense than the fused-quartz reference, a result that has been well characterized for oxides on <100> and <111> wafers (18).

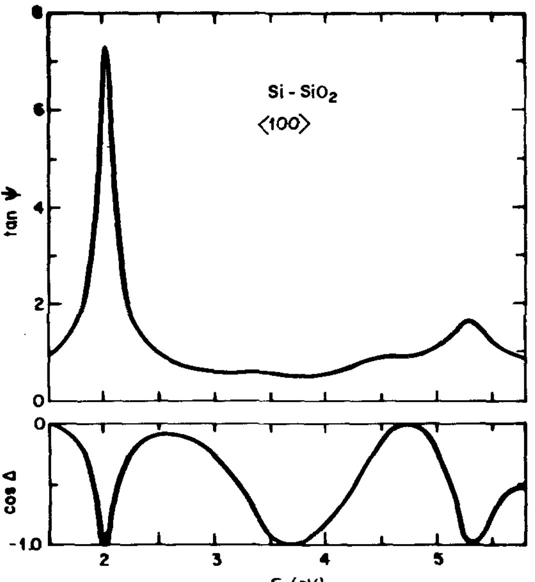

Fig. 3. Typical tan ψ, cos Δ data for an oxidized Si wafer. The orientation is <100> and the oxide thickness is 1360Å.

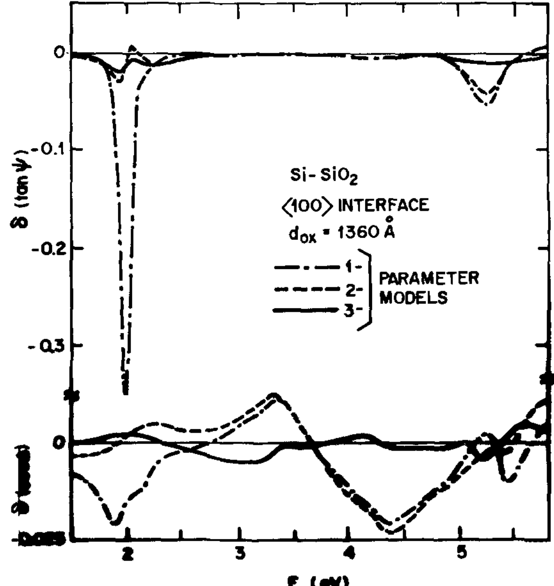

Fig. 4. Differences between theoretical and experimental tan ψ and cos Δ spectra for 1-, 2-, and 3-parameter models of the <100> SiO_2 interface for an SiO_2 overlayer of approximately 1360Å.

In terms of an equivalent refractive index at $\lambda 5461$, where $n_0 = 1.4602$ for fused quartz, the above void fraction corresponds to $n = 1.4631 \pm 0.0002$. This is less than the Taft value of 1.4678 obtained for <100> samples oxidized in dry O_2. Lower values obtain if traces of H_2O are present in the oxidizing atmosphere (18), whence the result is physically reasonable. Note that the thickness has decreased as n has increased to maintain the optical thickness, nd, essentially unchanged. The two-parameter model as used here includes birefringence, although its effect is relatively minor.

By incorporating an interface of chemically mixed $Si_{0.75}(SiO_2)_{0.25}$, the periodic discrepancy between data and model computations for cos Δ and the remaining 5 eV discrepancy for tan ψ are both largely eliminated. Specifically, we find $d_{ox} = 1359.9 \pm 0.5$Å, the interface thickness $d_{int} = 6.6 \pm 0.9$Å, $f_v = -0.0065 \pm 0.0002$, and $\hat{\sigma} = 0.0098$ in this three-parameter model. Thus the presence of an interface improves the overall fit by nearly another factor of 2. The void fraction is essentially unchanged but d_{ox} has decreased by nearly 4Å, showing that the oxide is trying to simulate the effect of the interface in the two-parameter model. The above improvement constitutes the existence proof for the interface.

Interface composition and thickness.—Having dielectric function spectra for the possible interface compositions, one can now use linear regression analysis in a 4-phase model with three free parameters (d_{int}, f_v, d_{ox}) to determine the "best" interface. Figure 5 shows the variation of $\hat{\sigma}$ for three oxide thicknesses on the <100> sample for the full range of interface composition $Si_x(SiO_2)_{1-x}$ from no interface ($x = 0$) to pure a-Si ($x = 1$) for both chemical and physical mixture models. Generally speaking, a consistent set of values of d_{ox}, d_{int}, and f_v was obtained near the residual minimum for each oxide thickness, although values away from the minimum showed wide variations as the least squares approach attempted to compensate the interface compositional error imposed by the model through various combinations of the three free parameters.

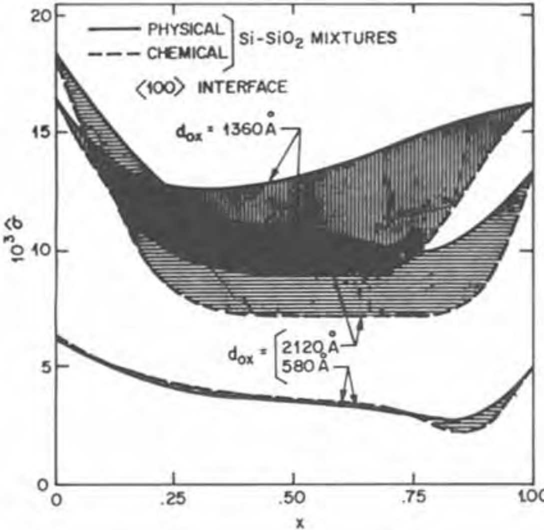

Fig. 5. Variation of 3-parameter 4-phase model residuals with interface composition for <100> Si-SiO$_2$ interface for SiO$_2$ overlayers of approximately 580, 1360, and 2120Å. Limits corresponding to physical and chemical mixtures are shown.

Conclusions immediately obvious from Fig. 5 are as follows. First, an interface is present, in agreement with previous work (1-7). $\hat{\sigma}$ always decreased for a finite interface, regardless of oxide thickness or assumed interface composition. Second, a chemically mixed Si-O interface gives better results than a physical mixture of Si and SiO$_2$. For the orientation shown, the difference is greatest for the thicker oxides although this is not generally true. Third, the statistically favored interface composition range is approximately $0.3 < x < 0.8$ based on Fig. 5.

The relatively broad compositional range allowed by Fig. 5 can be narrowed significantly by requiring consistency of the free parameters determined by the individual least squares fits on samples that differ only by etching the oxide to new thicknesses. In this context d_{ox} is clearly a meaningless parameter. However, f_v is the key to the analysis because its value is determined at $d_{ox} \sim 1400$Å with an order-of-magnitude less sensitivity to interface properties than at other thicknesses, owing to a particular favorable combination of parameters and measurement conditions (10). This occurs because of exceptionally good impedance-matching characteristics for s-wave polarization near 2 eV for the given combination of materials and measurement conditions, which for the small interface thicknesses used here depends almost entirely on the refractive index of the oxide overlayer. The independence on interface composition can be understood immediately by noting that at 2 eV all mixtures are transparent, as shown in Fig. 2.

If one requires that the values of f_v determined for overlayer thicknesses near 1400Å must also apply at other thicknesses, the results shown in Table I are obtained. Here, df_v/dx is calculated from least fit spectra for $x = 0.625$, 0.75, and 0.875, and the interpolated values of x obtained by requiring all f_v values to be equal to that at $d_{ox} \sim 1400$Å, for which $df_v/dx \cong 0$, are also shown. Uncertainties in x are calculated from equivalent uncertainties in f_v. The values of d_{int} are then obtained by interpolation from solutions for $x = 0.625$, 0.75, and 0.875.

The results of the analysis are shown in Table I and plotted in Fig. 6 and 7. We repeat that the error bars shown derive from 90% confidence levels based on the fits of specific models to the data, and do not include systematic errors. Nevertheless, all data are consistent with an interface 7 ± 2Å wide composed of a chemical (atomic) mixture of Si and O of average stoichiometry

Table I. Interface compositions determined by requiring consistency in f_v among all data for a given sample. Due to insensitivity to interface parameters, the value of f_v for $d_{ox} \approx 1400$Å is chosen as reference unless otherwise noted by parentheses (see text).

Sample	d_{ox} (Å)	df_v/dx	f_v	x	d_{int} (Å)
<100>	2120	−0.028	−0.0065 ± 0.0002	0.78 ± 0.06	8.3 ± 1.0
	1360	−0.003		(0.75)	6.6 ± 0.9
	584	−0.016		0.81 ± 00.3	5.4 ± 0.9
<111>	2282	−0.028	−0.0059 ± 0.0008	0.83 ± 0.08	7.7 ± 1.4
	1445	−0.002		(0.75)	6.0 ± 3.7
	659	−0.023		0.83 ± 0.06	6.0 ± 1.1
<110>	2805	−0.034	+0.0065 ± 0.0005	0.74 ± 0.06	8.3 ± 1.5
	2318	−0.037		(0.75)	9.6 ± 1.5
	2142	−0.031		0.82 ± 0.05	8.8 ± 1.1
	1407	0.000		(0.75)	4.7 ± 2.1
	604	−0.014		0.91 ± 0.09	6.3 ± 3.4

$Si_{0.8\pm0.1}(SiO_2)_{0.2\pm0.1} \cong SiO_{0.4\pm0.2}$. The three points corresponding to $d_{ox} \sim 1400$Å are shown without error bars in Fig. 7 because they cannot be determined from f_v and the residual minimum (see Fig. 4) is too broad to yield a definitive result. All three actually have a weak residual minimum near $x = 0.6$, but this value is not consistent with the well-defined values obtained at other oxide thicknesses. In deference to this tendency we have shaded the average x value slightly to lower values for these points. A second <110> point also failed to provide an f_v value consistent with the re-

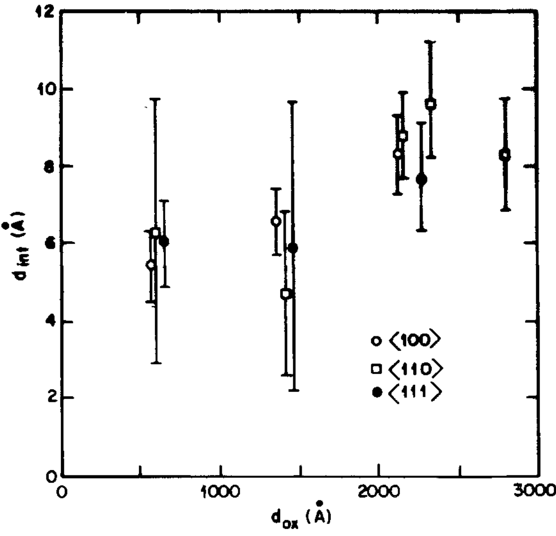

Fig. 6. Calculated interface thicknesses for <100>, <110>, and <111> samples after initial growth and at various stages of etching, from Table I.

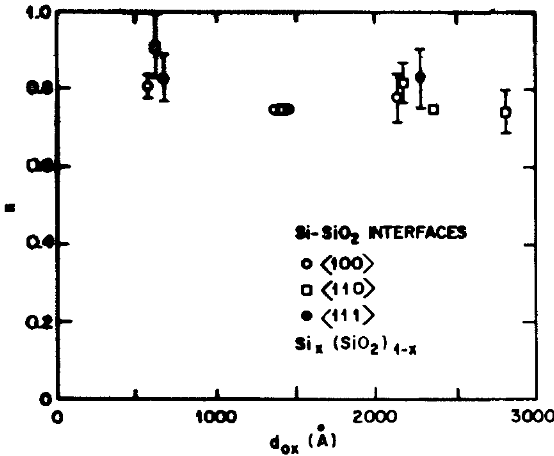

Fig. 7. Calculated interface composition x in chemically mixed $Si_x(SiO_2)_{1-x}$ after initial growth and at various stages of etching, from Table I.

maining data. Its contribution was defined similarly and its datum also shown in Fig. 7 without error limits.

The values of interface width determined here agree with that given in our initial report (11), which discussed data obtained on a single sample at a single value of oxide thickness. The uncertainty in the previously determined stoichiometry, SiO, could not be established from the single-thickness data and should be considered as superceded by the present results. All work, however, supports the conclusion that the interface Si and O are atomically mixed.

Discussion

Systematic errors.—If the data and analysis were exact and totally self-consistent, the interface parameters would be invariant with respect to oxide thickness and the residuals would reach negligibly small values. It is clear that this ideal has been approached but not completely reached; while the compositional data of Fig. 7 are reasonably constant, the results given in Fig. 6 show a trend of decreasing interface thickness as the oxide overlayer is gradually removed by etching. Because the interface is protected and cannot be affected by etching, this suggests that a small systematic error may be present.

The most probable sources of systematic errors are instrumental accuracy, nonuniformity (either in thickness or composition) of the oxide overlayer both in the as-grown and etched conditions, the ϵ spectrum for c-Si, or the ϵ spectrum for SiO_2. In self-consistent tests we have shown that the instrument accuracy approaches null ellipsometer accuracy as discussed in the Experimental section. Taft and Cordes have discussed the oxide uniformity problem at length and have concluded that the overlayer is uniform to the extent needed to analyze the interface problem (5). Moreover, their data show clearly that the etching procedure used there (and followed here) yields consistent results for 200Å increments from 7000Å to zero.

We next consider the ϵ data bases. With respect to that of c-Si, the effect of removing mathematically compositions and thicknesses from the stripped <110> sample data other than the self-consistent 6Å of chemically mixed $\sim Si_{0.75}(SiO_2)_{0.25}$ has been examined. No difference results if physically mixed spectra are used in place of chemically mixed spectra. Decreasing the removed thickness causes a general shift of all interface widths to lower values but does not affect either the trend or the conclusion that a chemically mixed interface is preferable to a physically mixed interface. Thus in principle the width data are subject to a general systematic uncertainty of no more than 2Å depending on possible future improvements of the ϵ data for c-Si. But we do not feel the possibility likely because of the agreement of the ϵ data with the Hulthèn and Philipp work as discussed in the section on Data Processing, and the fact that our interface results agree at λ5461 with those of Taft and Cordes.

We are left with the SiO_2 ϵ data. Taft has shown that the n values at λ5461 cannot be described below 1200°C as a simple compression of fused quartz and has suggested that other polymorphs of SiO_2 may be present in the oxide (17). Because these polymorphs should have different absorption thresholds and/or oscillator strengths, this implies that the Malitson dispersion equation will have only approximate validity: the dispersion in ϵ_1 at higher energies for thermally grown oxides may well deviate from the Malitson values. In principle, if sufficiently thick oxides can be grown this hypothesis can be checked directly with spectroscopic ellipsometry by reducing the data for the oxide ϵ_1 values assuming the presence of a known substrate and interface. If the oxide thickness approaches 1 micron, one could expect that the spectra are dominated by the oxide and that substrate and interface discrepancies would be minor.

A better SiO_2 representation was attempted by reducing the 2120Å <100> oxide data within the three-phase model and fitting the resultant spectrum to a three-term Sellmeyer oscillator with energies at the Malitson values and using the amplitudes as free parameters. The smoothly varying Sellmeyer terms average over the interference oscillations arising from the interface and extract the background, which is the intrinsic response of SiO_2. The results showed amplitudes of 12.73 ± 0.35, 4.36 ± 0.18, and 0.17 ± 0.10 eV for the oscillators at 18.2, 10.67, and 0.125 eV, respectively, compared to the Malitson values 12.617, 4.351, and 0.112 eV. The differences are not statistically significant, although the trend indicates a shift of the oxide absorption edges to lower energy. But the revised values changed interface thickness values by less than a few percent and did not affect the systematics of the results. Therefore, oxide effects alone appear to be ruled out.

Thus systematic errors cannot be traced to individual sources but rather may be an accumulation of effects from several sources. A further assignment of their origin would require more accuracy than presently attainable.

Microscopic structure of the interface.—The unusual effective average composition $SiO_{0.4\pm0.2}$ suggests that the layer whose effective thickness is 7 ± 2Å is actually graded in composition (6, 7), though laterally uniform. The connection between effective average and actual position-dependent dielectric functions, where the spatial variation is restricted to one dimension, has been considered in many contexts and most recently by Plieth and Naegele (27). In short, the spatial dependence can be replaced by a spatial average if the region is sufficiently thin, as is the case here. Specifically, for a thin layer on a uniform substrate (three-phase model) the change in the complex reflectance ratio is given by

$$\rho = \rho_0 \left\{ 1 + \frac{4\pi i n_a d \cos\phi}{\lambda} \frac{\epsilon_s(\epsilon_s - \epsilon_0)(\epsilon_0 - \epsilon_a)\sin^2\phi}{\epsilon_0(\epsilon_s - \epsilon_a)[\epsilon_s\cos^2\phi - \epsilon_a\sin^2\phi]} \times \left[1 - \frac{\epsilon_a\epsilon_0\epsilon_s}{(\epsilon_s - \epsilon_0)(\epsilon_0 - \epsilon_a)} \delta\epsilon \right] \right\} \quad [3]$$

where ϵ_s and $\epsilon_a = n_a^2$ are the dielectric functions of the uniform substrate and ambient, respectively, and

$$\epsilon_0 = \frac{1}{d}\int_{-d}^{0} dz\,\epsilon(z) \quad [4a]$$

$$\delta\epsilon_0 = \frac{1}{d}\int_{-d}^{0} dz[\epsilon^{-1}(z) - \epsilon_0^{-1}] \quad [4b]$$

It is supposed that the nonuniform response extends only over $-d < z < 0$.

The term involving $\delta\epsilon_0$ is a correction that does not appear in the classical three-phase model, that is, if the dielectric response of the interface is spatially invariant. If the interface is graded, it arises because the functional dependence on $\epsilon(x)$ of the wave equation for p-polarization is different from that for the s-polarization, leading to a different weighting in the spatial average (27). We express it as in Eq. [3] to estimate more easily its relative effect. Using the data of Fig. 1 and 2, it is straightforward to show that its magnitude is of the order of 0.2 for an assumed linear variation in dielectric response. Since we are concerned only with estimating possible limits to the variation, this is small enough to be neglected and the effective dielectric response obtained in the previous section can be taken to be the simple spatial average of the actual variation.

We consider next the probable location of the interface as determined by optical measurements. The interface is operationally defined as that region whose optical response is measurably different from that of the c-Si substrate and the SiO_2 overlayer. Considering the c-Si side first, the atoms in the outermost c-Si plane

have neither lattice nor lateral symmetry because they are bonded on one side to the adjacent disordered region. Moreover, at least some of those atoms will be involved in oxygen bonding to the disordered region even though the total oxygen concentration there may be small. Their dielectric response should therefore be more like a-Si than c-Si. Thus optical measurements would view the interface as containing the outermost c-Si plane. On the SiO_2 side, the optical interface would terminate before full stoichiometry is reached because, by Fig. 2, it is not possible to distinguish between $SiO_{1.5}$ and SiO_2 in the 1.5-6.0 eV region with presently attainable accuracy. We should not expect to distinguish from SiO_2 a possible slightly perturbed ~40Å SiO_2 region as suggested by XPS measurements (6). As mentioned earlier, the preference for chemical, rather than physical, mixing rules out microroughness and the possibility of small Si inclusions near the interface resulting from nonuniform oxidation.

From the spatial average argument, Fig. 2, and the results of the preceding section, it is apparent that no more than one-third (~2Å) of the interface could appear as a-Si if the remainder were at least as oxygen-rich as SiO. We can reject the case of a-Si followed by stoichiometric SiO_2 because the optical data would have shown a narrower interface, and in any event a-Si is not the favored stoichiometry. Thus the accumulation of a-Si at the interface does not occur. Because the outermost ~c-Si plane is fulfilling optically the function of an a-Si layer, we are left with a region that is effectively about 5Å of SiO, in agreement with one of the RBS alternatives. Although the interface is undoubtedly graded, the width is small enough for the spatial-average limit to be valid whence the optical data can provide no further information on its distribution.

We note finally that the average refractive index of the 7 ± 2Å region of $SiO_{0.4\pm0.2}$ at λ5461 is 3.2 ± 0.5, as compared to the Taft-Cordes λ5461 value of ~2.8 determined for their ~6Å interface. Thus the fixed-wavelength null ellipsometric and spectroscopic ellipsometric results are in agreement at the wavelength at which they overlap.

Acknowledgments

We thank E. Povilonis for kindly growing the oxide films used here. One of us (D.E.A.) wishes to thank H. R. Philipp for supplying a numerical listing of the c-Si ε data reported in Ref. (15).

Manuscript submitted Sept. 10, 1979; revised manuscript received Dec. 21, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Publication costs of this article were assisted by Bell Laboratories.

GaAs Oxidation and the Ga-As-O Equilibrium Phase Diagram

C. D. Thurmond,* G. P. Schwartz,* G. W. Kammlott, and B. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The phases formed from the oxidation of GaAs have been considered in the light of an estimated equilibrium Ga-As-O condensed phase diagram. Thermal oxidation leads to phases consistent with the phase diagram. Plasma oxidation and anodic oxidation lead to phases inconsistent with the phase diagram. Thermal annealing of the plasma and anodic oxide layers leads to reactions producing phases consistent with the phase diagram. It is concluded that plasma and anodic oxides are produced far from equilibrium and that the estimated phase diagram is a satisfactory approximation to the equilibrium ternary phase diagram.

The gallium-arsenic-oxygen equilibrium phase diagram is not known. We have been able to estimate an important portion of it from a combination of experiments and thermodynamics. Condensed phase equilibria below the melting point of As_2O_3 (278°C) have been considered. The stable phases occurring in this temperature region are assumed to be Ga(l, s), GaAs(s), As(s), As_2O_3(s), As_2O_5(s), $GaAsO_4$(s), and Ga_2O_3(s) based on an evaluation of available literature information (1).[1]

Two different approaches have been taken to obtain an estimate of the low temperature condensed phase ternary diagram. Both rest on the key assumption that all equilibria are between nearly pure phases. This implies that the solubility ranges of each of the eight phases are sufficiently narrow to assure they are pure phases insofar as their thermodynamic properties are concerned. In particular, it follows that the Gibbs energy of formation of each phase is that of the pure phase to an acceptable degree of approximation. An additional consequence of this assumption is that all ternary equilibria are pseudobinary.

The first approach is based on the fact that there are 13 possible phase diagrams under the pure phase assumption. Only a few experiments are needed to obtain a reasonable approximation to the equilibrium phase diagram.

The second approach makes use of the Gibbs energy of formation of each compound phase to calculate the equilibrium phase diagram. The Gibbs energy of formation of $GaAsO_4$ and As_2O_5, however, are not known. Nevertheless an important section of the phase diagram obtained from the first approach can be tested without this information.

Experimental and Results

At a chosen temperature below the melting point of As_2O_3, seven phases will make up the Ga-As-O condensed phase diagram. Various crystalline modifications of both Ga_2O_3 and As_2O_3 are known as well as a vitreous phase for As_2O_3. Cubic As_2O_3 (arsenolite) and β-Ga_2O_3 were selected because thermodynamic data for the other structural modifications were either not available or the differences in their Gibbs energies of formation were sufficiently small (a few kilocalories per mole) to enable only one phase to be considered. The assumption is made that at equilibrium these condensed phases are essentially pure in all reactions with other phases. This means that the ternary diagram will be made up of straight lines connecting one phase to another. The lines are called pseudobinary lines and the proposed ternary diagram will consist entirely of such lines.

We will take advantage of the fact that there are only 13 possible ternary phase diagrams that can occur from seven phases each of which is nearly pure. One of the 13 ternary phase diagrams will be the equilibrium phase diagram, and an estimate can be made of which it is from the results of several experiments. The 13 possible ternary diagrams are shown in Fig. 1 and have been found by inspection.

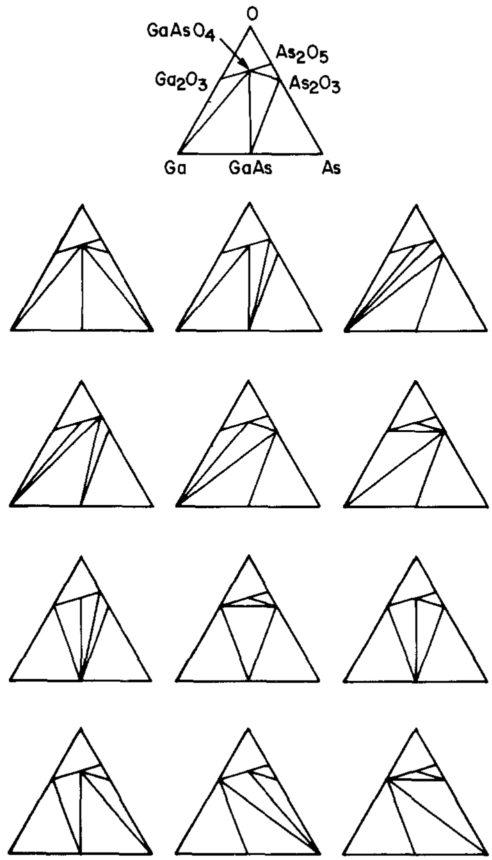

Fig. 1. The 13 ternary phase diagrams possible for the seven phases (Ga(s, l), GaAs(s), As(s), As_2O_3(s), As_2O_5(s), $GaAsO_4$(s), and Ga_2O_3(s). All phases are assumed to be pure.

Key words: thermal oxidation, plasma oxidation, ternary phase diagram.

[1] Although Ga_2O is a well-documented gas phase species, there is as yet no conclusive structure data to substantiate the assignments of Brukl and Ortner and Klemm and Von Vogel (1) that the brown-black powder which results from the reaction between Ga_2O_3 and Ga actually constitutes single phase stoichiometric Ga_2O.

Experiments with binary mixtures.—The first experiment was to anneal a mixture of powdered GaAs and As_2O_3 in an evacuated (5×10^{-7} Torr) quartz tube for 48 hr at 630°C. The molar ratio of GaAs to As_2O_3 was 3 to 1. X-ray diffraction identified the resulting products as crystalline As (hexagonal, A7 structure), β-Ga_2O_3 and unreacted GaAs which was initially present in excess. The absence of As_2O_3 in the recovered products was taken to indicate that the reaction had proceeded to completion. The experiment was repeated with the same results.

The kinetics of the reaction were sufficiently slow that incomplete reaction occurred in 48 hr for temperatures of ~500°C. Although 630°C is above the melting point of As_2O_3, it is still below the temperature at which GaAs ceases to evaporate congruently, *i.e.*, direct thermal decomposition of GaAs is not involved in generating arsenic. In addition, no evidence for metallic Ga is obtained after reaction. The only significant modification expected in the ternary phase diagram for some temperature range above the melting point of As_2O_3 (278°C) is the dissolution of other solid phases in the As_2O_3-rich liquid. We assume that the amount of dissolution of the other phases in liquid As_2O_3 is small and consequently the higher temperature anneals we have used give the phases that are stable at the lower temperatures. The fact that the reactions involved are for condensed phases implies that the heat capacities for the reactions will be small and therefore the Gibbs energies of the reactions will not depend much on temperature. We conclude from the results of the first experiment that As and Ga_2O_3 are the phases in equilibrium with GaAs. There are only two of the 13 possible diagrams that have this feature, the last two diagrams of Fig. 1.

A second experiment was carried out to distinguish between the two remaining phase diagrams. Thermal reaction of a 1:1 molar mixture of GaAs-As_2O_3 should produce $GaAsO_4$ according to one diagram; the other predicts Ga_2O_3 and As. Table I shows that As (hexagonal), β-Ga_2O_3, and vitreous As_2O_3 were detected. For the molar ratio utilized (1:1), the latter product represents excess unreacted As_2O_3. Raman scattering was used to identify this vitreous phase. $GaAsO_4$ was not observed by either x-ray diffraction or Raman scattering. In addition, the absence of GaAs indicated that the reaction had gone to completion. Figure 2 thus emerges as the phase diagram suggested by these experiments.

An additional experiment was used to check the conditions predicted by the derived phase diagram to give $GaAsO_4$. A mixture of As_2O_5 and GaAs in the mole ratio 2 to 1 was heated to 600°C for 48 hr. Raman scattering showed that the products were $GaAsO_4$ and vitreous As_2O_3. These are just the products anticipated from the phase diagram according to the reaction $2As_2O_5 + GaAs \rightarrow GaAsO_4 + 2As_2O_3$.

Thermodynamic calculations.—A check on the phase diagram of Fig. 2 can be made if the Gibbs energies of formation of the compound phases, GaAs, As_2O_3,

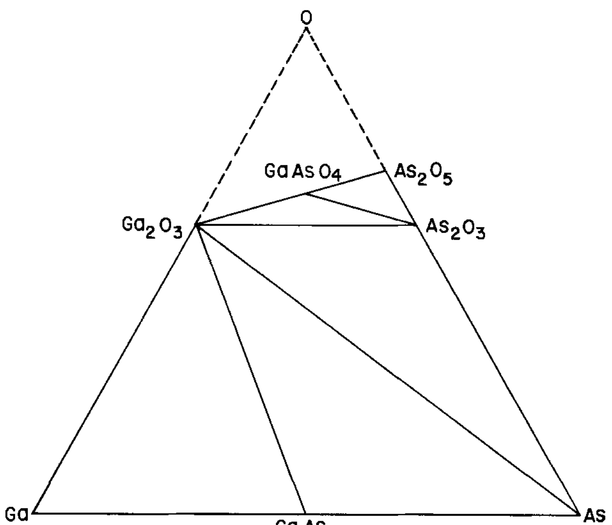

Fig. 2. An estimate of the Ga-As-O ternary condensed phase diagram for temperatures below the melting point of As_2O_3 (278°C, arsenolite). A portion of this phase diagram, the oxygen-rich region above the line Ga_2O_3-$GaAsO_4$-As_2O_5 and bounded at the sides by the dashed lines, has not been studied and is an excluded part of the Ga-As-O ternary diagram.

As_2O_5, $GaAsO_4$, and Ga_2O_3, were known. In fact, the Gibbs energy of formation is not known for $GaAsO_4$ and is not very certain for As_2O_5. The derived phase diagram Fig. 2 shows, however, that the portion of the diagram below the Ga_2O_3-As_2O_3 pseudobinary line does not involve the $GaAsO_4$ and As_2O_5 phases. Therefore, it is possible to calculate that portion of the phase diagram from the thermodynamic information available for GaAs, As_2O_3, and Ga_2O_3.

The total number of pseudobinary lines possible for the lower portion of the phase diagram of Fig. 2 is five and they are shown in Fig. 3. The equilibrium pseudobinaries can be found in a simple way from the three points where pseudobinaries cross. Such crosspoints have been used for many years to guide experiments in the determination of phase diagrams (2). They can also be used to obtain the stable pseudobinary of the crossing pair from the Gibbs energies of formation of GaAs, As_2O_3, and Ga_2O_3.

The composition of a crosspoint can be expressed in terms of the components of either of the pseudobinaries. This is equivalent to writing a stoichiometric equation giving the transformation of one set of compounds into the other. The conservation of atoms corresponds to the crosspoint composition. The three equations representing the three crosspoints of Fig. 3 are given in Table II. The stable pseudobinary may now be obtained by calculating the standard Gibbs energy for each of these equations from the Gibbs energies of formation of the compound phases. For the first crosspoint equation of Table II, the standard Gibbs energy is given by

Table I. Pseudobinary reactions

Pseudobinary	Composition (mole ratio)	Temperature (°C)	Time (days)	Products	Detection method*	Comments
1. As_2O_3-GaAs	1:3	652	2	Arsenic Ga_2O_3 GaAs	XRD XRD, XRF XRD	As_2O_3 not detected
2. As_2O_3-GaAs	1:1	630-650	2	Arsenic Ga_2O_3 As_2O_3	XRD XRD Raman	$GaAsO_4$ not detected $GaAsO_4$ not detected
3. As_2O_3-GaAs	2:1	630-650	2	Arsenic Ga_2O_3 As_2O_3	XRD XRD Raman	$GaAsO_4$ not detected $GaAsO_4$ not detected
4. As_2O_3-GaAs	2:1	630-650	2	$GaAsO_4$ As_2O_3	Raman Raman	Ga_2O_3 not detected

* XRD = x-ray diffraction, XRF = x-ray fluorescence.

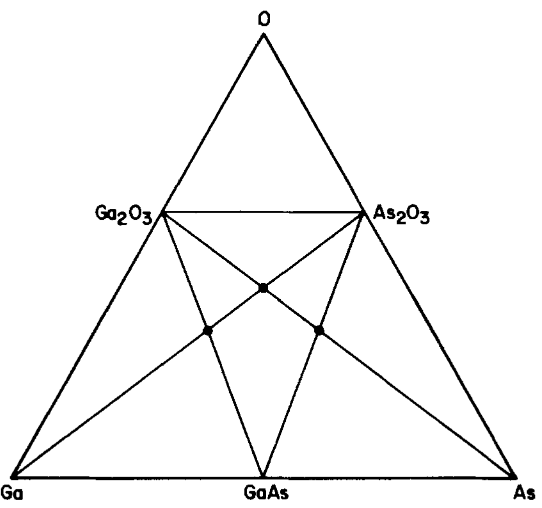

Fig. 3. The three crosspoints below the Ga_2O_3-As_2O_3 pseudobinary generated by the four pseudobinaries Ga-As_2O_3, GaAs-Ga_2O_3, GaAs-As_2O_3, and As-Ga_2O_3.

$$\Delta G^\circ = 2\Delta G^f(\text{GaAs}) + \Delta G^f(\text{Ga}_2\text{O}_3) - \Delta G^f(\text{As}_2\text{O}_3)$$

If ΔG° is greater than zero the reaction will not proceed and the Ga-As_2O_3 pseudobinary would be more stable than the GaAs-Ga_2O_3 pseudobinary. In fact, as shown in Table II, ΔG° is less than zero and consequently GaAs-Ga_2O_3 is the stable pair. A similar procedure was used for the other two crosspoint equations. The standard Gibbs energies have been calculated for the two temperatures 300° and 500°K. The Gibbs energies of formation used are given in Table III with the reference states indicated. The conclusion is reached that the stable pseudobinaries are Ga_2O_3-GaAs and Ga_2O_3-As. These are the two shown in Fig. 2 previously deduced from experiment.

Finally it is important to note that the two independent estimates of the diagram employing binary mixture experiments run at $T \simeq 630°$-650°C and thermodynamic calculations applicable to the condensed phase ($T < 278$°C) diagram were observed to yield equivalent results in all phase fields which were examined. In the following section, we assume that the thermal oxidation products of GaAs generated at elevated temperatures are consistent with the derived condensed phase diagram.

Applications of the Diagram

Despite the fact that a ternary phase diagram composed solely of pseudobinary tie lines constitutes a somewhat limited thermodynamic description of any real system, it is still possible to extract useful information from such a diagram. In this section we wish to consider the application of the phase diagram to predicting the oxide phases which result from the oxidation of GaAs.

Phases and their compositions.—The Ga-As-O diagram of Fig. 2 can be used to give the equilibrium phases expected under certain conditions used to oxidize GaAs. The composition of the phases can be determined by constructing a line which connects the oxidant to GaAs and examining the intersection of this line and the phase field boundaries it crosses.

The predicted phase compositions appropriate to oxidation using either O_2(g) or As_2O_3(s) are given in Fig. 4. As an example, consider O_2(g) oxidation. The chemical potential of O_2 will be lowest at the GaAs interface and increase monotonically to its gas phase value across the thickness of the growing oxide film. Consequently in describing the phases formed during oxidation, movement along the line from GaAs toward the O apex of the diagram will describe the formation of interface, bulk, and surface layers in that order. The process terminates at a point on the GaAs-O line which is fixed by the oxidation potential of the gas phase, *i.e.*, by the temperature and partial pressure of O_2. The three oxidizing conditions (weak, intermediate, and strong) given in Fig 4 correspond to terminations within the GaAs-Ga_2O_3-As, Ga_2O_3-As_2O_3-As, or Ga_2O_3-$GaAsO_4$-As_2O_3 phase fields, respectively. The molar ratios of the pseudobinary pairs (As, Ga_2O_3; 2:1) and (As_2O_3, Ga_2O_3; 1:1) are fixed at their intersection point values with the GaAs-O line.

O_2 oxidation can yield one, two, or three distinct composition regions depending on the oxidizing conditions (Fig. 4). For the case of As_2O_3(s) oxidation, only a single composition is predicted under all oxidizing conditions. Finally it should be remarked that the phase diagram cannot predict the relative thickness of the oxide film layers; Fig. 4 portrays a schematic representation of the oxidation of GaAs with emphasis on phase compositions not relative thicknesses of oxide layers.

Experimental oxidation results.—Six conditions are frequently employed in the oxidation of GaAs. Data pertinent to the various conditions have been divided into two tables comprised of thermal oxidation under O_2, As_2O_3, air, or O_2/As_2O_3 (Table IV) and anodiza-

tion via electrochemical and plasma methods (Table V). Two points should be mentioned prior to comparing the experimental data with the phase diagram predictions. Such a comparison involves the implicit assumption that oxide growth is sufficiently slow for phase formation to occur under "near equilibrium" conditions. Finally, care must be taken to account for volatilization phenomena which can alter the concentration of certain film components such as As_2O_3 and As.

Thermal oxidation.—Table IV presents a compilation of experimental results for the thermal oxidation of GaAs utilizing O_2, air, As_2O_3, or As_2O_3/O_2 mixtures as oxidants. The scope of the table has been limited somewhat to emphasize those analytical techniques which provide either direct bulk crystalline phase identification or spatial profiling information with concomitant valence state identification of the chemical components. An extensive processing review and bibliography containing III-V oxidation data up to 1977 can be found in Ref. (3).

For oxidation with O_2 or air, Table IV indicates that $GaAsO_4$, Ga_2O_3, As, and As_2O_3 have all been detected as phases resulting from the oxidation process. The diffraction techniques have identified β-Ga_2O_3 as the major film constituent (4-7) for all temperatures sufficiently high to produce crystalline products (7) ($T \geq 500$°C). Similar observations are available from x-ray photoelectron spectra (XPS) profiles (8-10).

In the case of $GaAsO_4$, relatively strong oxidizing conditions (high temperatures) are required before this product is observed by the diffraction techniques. The reasons for this are essentially twofold: XPS (9) results indicate that for low temperature growth an amorphous modification may exist which would not be identified by diffraction techniques; second, the measurement volume involved in x-ray diffraction requires that a significant quantity of that phase be generated before detection is possible. XPS (9, 10), on the other hand, provides evidence that $GaAsO_4$ may be formed at lower temperatures, primarily as a surface product. The spatial extent to which $GaAsO_4$ extends into the bulk oxide is difficult to ascertain due to artifacts associated with ion milling, but a conservative estimate would be less than 150A for growth below 600°C.

As_2O_3 is generally not observed in the bulk films except in trace amounts [a few mole percent (m/o)] although XPS does detect small quantities of this product (~10 m/o) right at the gas/oxide surface where it is normally accompanied by an additional pentavalent arsenic species. Since As_2O_3 is readily identified via XPS even when present in vitreous form, its absence throughout the bulk of thermally oxidized films is primarily associated with its high vapor pressure and subsequent loss through volatility.

Finally, Raman scattering (11, 12) has unambiguously identified the presence of crystalline arsenic in thermally oxidized films, and chemical etching experiments have shown that its concentration increases in the interfacial region. Similar concentration gradients of elemental arsenic have been observed by XPS (8-10) in conjunction with ion milling. The failure of the diffraction techniques to observe this crystalline phase is believed to be due to the low total concentrations actually present following extensive volatility losses.

Oxidation with As_2O_3/O_2 mixtures in closed tube (10) and "leaky box" (9) configurations both resulted in the incorporation of As_2O_3 in the outer sections

of the film. In the latter configuration the As_2O_3:Ga_2O_3 ratio was nearly 1:1 and the outermost surface (~150Å) of a film grown at 750°C was identified by reflection high energy electron diffraction (RHEED) as a single phase layer of $GaAsO_4$ (9). Complete profiling of the thinner films of Ref. (10) indicate that elemental arsenic was present throughout most of the bulk film and exhibits a concentration gradient which increases toward the substrate. Evidence for the retention of some As_2O_3 in the interfacial region is also present (10).

Limited data are available concerning the oxidation of GaAs under pure As_2O_3. Electron diffraction has identified beta phase Ga_2O_3, and Auger sputter profiling indicates that the major film constituents are gallium and oxygen with evidence for a weak arsenic signal which increases substantially in the interfacial region (13). The chemical form of the arsenic (elemental or As_2O_3) was not identified. Raman scattering explicitly demonstrates that elemental crystalline arsenic is present in these films (14).

The fundamental patterns observed in the experimental data on thermally oxidized GaAs are seen to be generally consistent with the phase predictions of the proposed phase diagram. In particular, $GaAsO_4$ surface layers can be formed under strong oxidizing conditions followed by a region composed primarily of Ga_2O_3 and As_2O_3 when conditions are such that volatilization of As_2O_3 is suppressed. The interfacial region is dominated by the presence of Ga_2O_3 and As, although the latter product always exhibits a strong concentration gradient resulting from its high diffusivity and volatility. For As_2O_3 as an oxidant, both Ga_2O_3 and As have been shown to be present, again with a strong concentration variation in the latter product which increases toward the substrate.

Anodic and plasma oxidation.—The situation for electrochemically (9-10, 15-23) and plasma (24-28) oxidized GaAs (Table V) stands in distinct contrast to what was observed for the case of thermal oxidation. Room temperature electrochemical anodization leaves amorphous oxide films (15, 16) whose major phase constituents are Ga_2O_3 and As_2O_3 (9, 10, 24). Water and As_2O_3 have been observed to volatilize from films anodized in aqueous base electrolytes during heating (20). Coulometry supports the trivalent assignments of the bulk film constituents with a measured electron number in the passive film formation regime of 6.0/g mole of GaAs consumed (18). Electrochemically anodized films appear to contain elemental arsenic only at the trace level (9-10, 17, 21-22); recent ellipsometric evidence suggests an unobservable concentration in carefully prepared bulk films and perhaps 6Å of absorbing material (assumed to be arsenic) in a 25Å wide interface (23).

Plasma oxides are likewise amorphous (24) and can be prepared as approximately 1:1 molar mixtures of Ga_2O_3 and As_2O_3 (25). Films prepared at high current densities contain ~1-2 volume percent (v/o) arsenic in the bulk films with an estimated interfacial arsenic concentration of 25Å in an approximately 84Å wide interface (26). Low current density (slow) growth has been observed ellipsometrically to yield significantly thicker arsenic deposits in the interfacial region (26). Thermally annealed plasma oxides have been examined by TEM (24), ellipsometry (27), and Raman scattering (28) and were observed to contain thick, crystalline arsenic deposits in the interfacial region in all cases. The implications of thermal annealing are considered in detail later.

The experimental data found in Table V thus indicate that the room temperature electrochemical or plasma oxidation of GaAs results in a reasonably uniform mixture of Ga_2O_3 and As_2O_3 which extends from the surface to the interface. Elemental arsenic has been detected as a component of very low con-

centration in plasma oxidized films (1-2 v/o); its presence in electrochemically anodized samples is below that level. The low arsenic concentration is in direct contradiction to the expectations of the phase diagram under any set of oxidizing conditions using O_2. For room temperature growth, loss by diffusion and volatilization would not be expected to account for the absence of this component. Finally, an interfacial mixture of GaAs, Ga_2O_3, and As_2O_3 is not consistent with the equilibrium phases predicted by the proposed phase diagram. Although the phase diagram is not appropriate for predicting phases grown from oxidants containing hydrogen (H_2O, OH^-, H_3O^+), the virtual equivalence of the observed products for electrochemical (aqueous electrolyte) and plasma (O_2 gas) anodization suggests that this is not the source of the noted discrepancies. One is led to conclude that either the proposed phase diagram is in error or that the oxidation products evolved in electrochemical and plasma anodizations form under conditions far from thermodynamic equilibrium.

The phase diagram indicates that As_2O_3 in contact with GaAs should react according to the equation

$$As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As \quad [1]$$

yielding at the interface Ga_2O_3 and As as the stable phases which can coexist at equilibrium with GaAs. The annealing experiments on anodic and plasma grown oxides previously mentioned support the above reaction. Chemical etching experiments in conjunction with Raman scattering (21, 22) have revealed that metallic arsenic deposits are being generated next to the GaAs substrate as they must if Eq. [1] is assumed to hold. TEM (24) measurements on thermally annealed plasma oxides likewise reveal the existence of crystalline arsenic domains next to the substrate. Anodic and plasma oxide films thus seem to grow under strongly nonequilibrium conditions; thermal annealing is observed to drive the system toward the favored equilibrium phases.

Summary

An estimate of the Ga-As-O phase diagram has been made from a combination of experiments and free energy calculations. The experiments were carried out at temperatures above the melting point, 278°C, of As_2O_3 (arsenolite) whereas the thermodynamic estimates were made for temperatures below the melting point of As_2O_3. A number of regions of the estimated phase diagram were explored by the higher temperature anneals. The phases found on cooling were in accord with the low temperature phase diagram. Thermal oxidation of GaAs by O_2 or As_2O_3 produces phases in the grown layer agreeing with the estimated phase diagram. Low temperature electrochemical and plasma oxidation of GaAs lead to phases which are not in agreement with the estimated phase diagram. Thermal anneals of these layers do produce phases consistent with the phase diagram, suggesting that the phases produced by electrochemical and plasma oxidation are due to nonequilibrium reactions. Experimental analysis of oxide layers by a number of complementary techniques are reported including relevant work reported in the literature.

Manuscript received Sept. 24, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

Contact Reliability Studies on Lead-Salt Diode Lasers

Wayne Lo and Fay E. Gifford

General Motors Research Laboratories, Physics Department, Warren, Michigan 48090

ABSTRACT

Deleterious changes in the electrical and optical properties of lead-salt semiconductor diode lasers have been traced to the diffusion of In into the surface layer of the lead-salt crystals. New contacting methods have been developed to eliminate this mode of degradation for $Pb_{1-x}Sn_xTe$ and $PbS_{1-x}Se_x$ diode lasers.

For lead-salt diode lasers made in our laboratories, we have observed two major modes of contact degradation. They are catastrophic failure (operation ceases abruptly) and a slow change in electrical and optical properties during room temperature storage. The first mode of degradation can be eliminated by using a properly designed mounting package (1). The second mode of degradation is manifested by a slow increase in contact resistance. In order to understand this latter mode of degradation, an investigation of contacting procedures was undertaken. The lasers used in this study were fabricated from single crystals of $PbS_{1-x}Se_x$ (2) and $Pb_{1-x}Sn_xTe$ (3) grown from the vapor phase.

Contact Degradation

For cw operation at temperatures approaching 40°K, we find that a contact resistance of 10^{-4} Ω-cm² or less is necessary. This is attributed to the low thermal conductivity of lead-salt materials (typically 0.07 W/cm-K *vs.* 3.0 W/cm-K for GaAs at 77°K) (4). Since lead-salt crystals have very high electron affinities, low resistance, ohmic contact to the n-type side of diodes can be obtained easily by using either Au, In, or In-Au combinations. It is the p-type contact that normally causes problems.

For the p-type side In-Au (5), In-Pt (6), and In-Pt-Au (7) structures have been reported as producing low resistance, ohmic contacts. More recently only In-Au combinations have been used (8, 9). We are not aware of any systematic studies on the long-term reliability of In-Au contacts. However, we found that they are not stable in our devices. During storage at room temperature over periods that range from days to months, the resistance of In-Au contacts can increase. Such increases are typically accompanied by increases in cw threshold current densities and laser emission frequencies, while at the same time laser output powers tend to decrease (10).

Figure 1 shows the *I-V* characteristics of a laser that has been subjected to life testing. It is evident that once a laser is mounted and tested, slow degradation occurs during room temperature storage, rather than during cw operation (including thermal cycling).

$PbS_{1-x}Se_x$ Lasers

We found that the increase in contact resistance is caused by the diffusion of In into the surface layer of the p-type side. Figure 2 shows an electron microprobe analysis of In and Pb concentration profiles near the metal-semiconductor interface before and after degradation. The samples were prepared with In-Au as the p-type contact. The degradation was accelerated by heating the sample to 100°C for 1 hr. This test condition is equivalent to room temperature storage of approximately one week (11). Both the degraded and the control samples were angle-lapped at a 3° inclination to provide a twentyfold improvement in spatial resolution normal to the interfaces.

Key words: contacts, IV-VI, lasers, reliability, interdiffusion.

The typical electron beam penetration depth is about 1-2 μm. The x-rays generated by the E-beam (the signal strength shown in Fig. 2) are absorbed partially by the contact metals before being detected. Au and Pt are good absorbers for the x-rays. We calculated that 70% of the x-rays generated in the crystal are absorbed by Au in a distance of 0.2 μm. This explains the sharp change in the Pb x-ray signal near the interface (and hence the good accuracy in identifying the interface). From Fig. 2 it is also noted that for a degraded sample, traces of In were found in the first few microns of the crystal below the contact. Since In is a donor in lead-salt materials, a reduction in hole carrier concentration near the surface is expected. We think that this is the reason for the increase in contact resistance (12).

Further study revealed that Au or Pt alone cannot form a barrier against In penetration, but a combination of Pt-Au does (1). It was also noticed that the reliability of the lasers depends on the thickness of the Pt and Au layers. We found that both layers have to be at least 0.2 μm thick in order to form a barrier against In diffusion. After depositing the Au and Pt layers on the p-type side of the diode a 10 μm layer of In is added. The n-type contact consists of a 0.2 μm layer of Au plus 5 μm of In. The entire contact structure is shown in Fig. 3. The p-type side of the crystal surface was purposely oxidized by exposure to air before evaporating the first layer of Au.

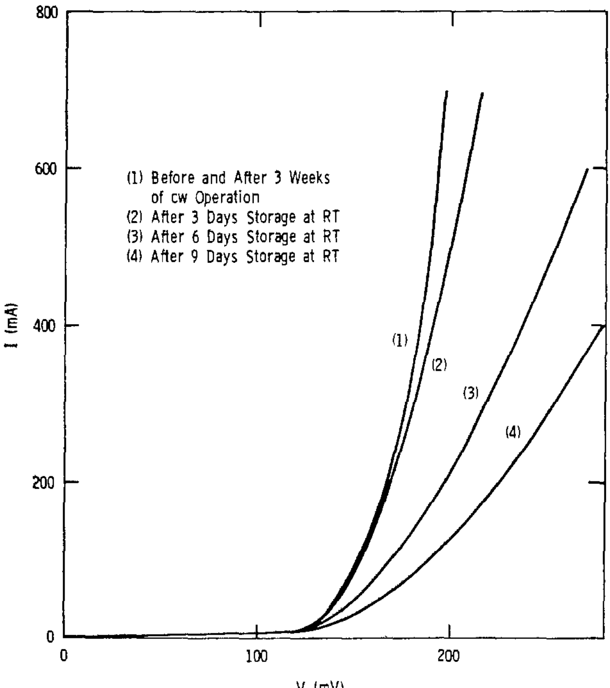

Fig. 1. *I-V* **characteristics of a $Pb_{0.92}Sn_{0.08}Te$ laser during operation and after storage at room temperature.**

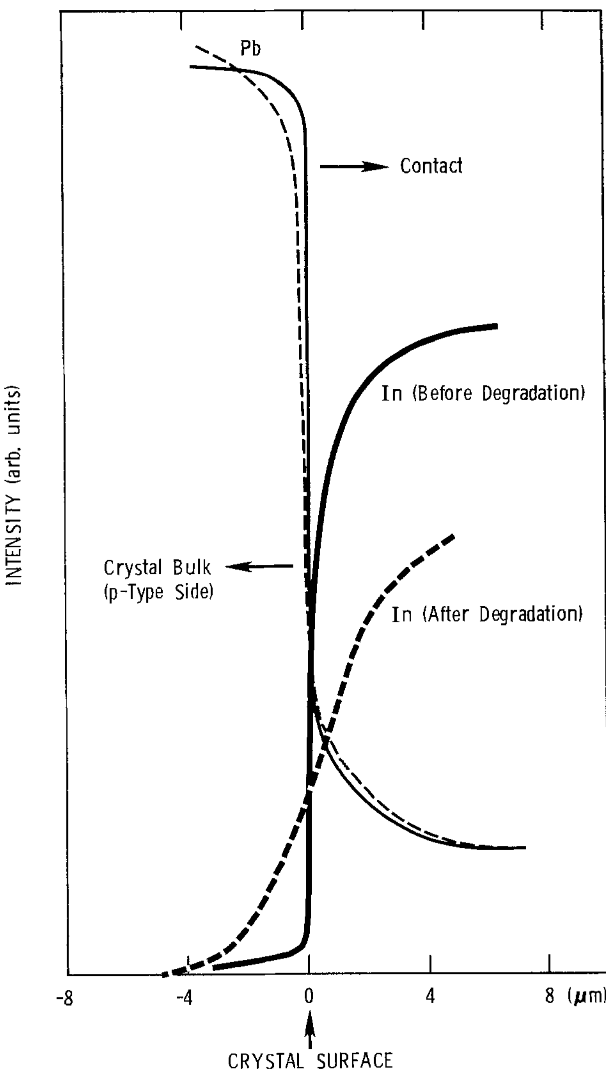

Fig. 2. Electron microprobe analysis of a crystal-contact interface for $PbS_{0.82}Se_{0.18}$.

This increases the hole carrier concentration near the surface and tends to stabilize the contact resistance (13).

$Pb_{1-x}Sn_xTe$ Lasers

The same three-layer structure of In-Pt-Au did not produce consistent results for $Pb_{1-x}Sn_xTe$ lasers. Different results were obtained for $Pb_{1-x}Sn_xTe$ with different x values. It is apparent that the Au-$Pb_{1-x}Sn_xTe$ interface properties vary as x changes. We have studied this interface and found methods for making low resistance, reliable contacts for all compositions of $Pb_{1-x}Sn_xTe$.

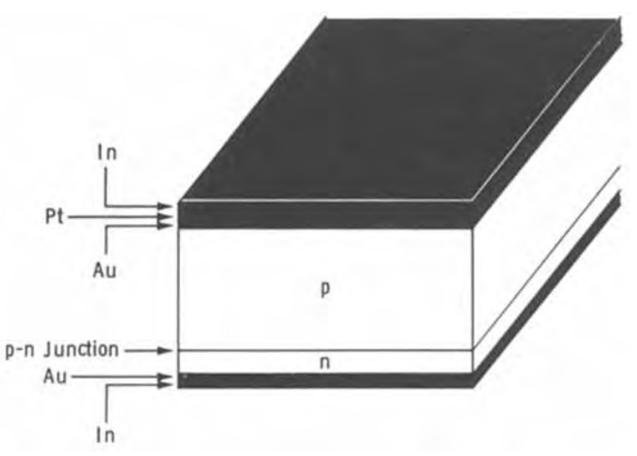

Fig. 3. Contacts for $PbS_{1-x}Se_x$ lasers

As shown in Fig. 4(a), the work function of a metal ($q\phi_M$) is defined as the energy difference between the vacuum level and the Fermi level (E_F). In semiconductors, the equivalent energy unit is called the electron affinity ($q\chi$). It is defined as the energy difference between the vacuum level and the conduction band minimum. A semiconductor is also characterized by its bandgap (E_g) and its quasi-Fermi level [E_{FP} for p-type material—Fig. 4(a)]. When a metal makes intimate contact with a semiconductor, the Fermi levels in the two materials must coincide at thermal equilibrium. Whether the contact is ohmic or a barrier depends on the energy difference between the metal work function and the total of the semiconductor electron affinity and bandgap.

In a p-type semiconductor, the barrier height (ϕ_{BP}) is defined as (14)

$$q\phi_{BP} = (E_g + q\chi) - q\phi_M \qquad [1]$$

where the effect of surface states has been ignored (15). This is consistent with the high dielectric constant. If ϕ_{BP} is positive, as shown in Fig. 4(b), charge carriers (holes) are depleted in the surface and the contact is a barrier. However, if ϕ_{BP} is negative, as shown in Fig. 4(c), an accumulation layer is formed in the surface and the contact is ohmic.

It has been reported that Au makes barrier contacts on p-type PbTe (15). It is speculated that, since the work function of Au and the electron affinity of PbTe are both 4.6 eV, the contact is not ohmic. Al-

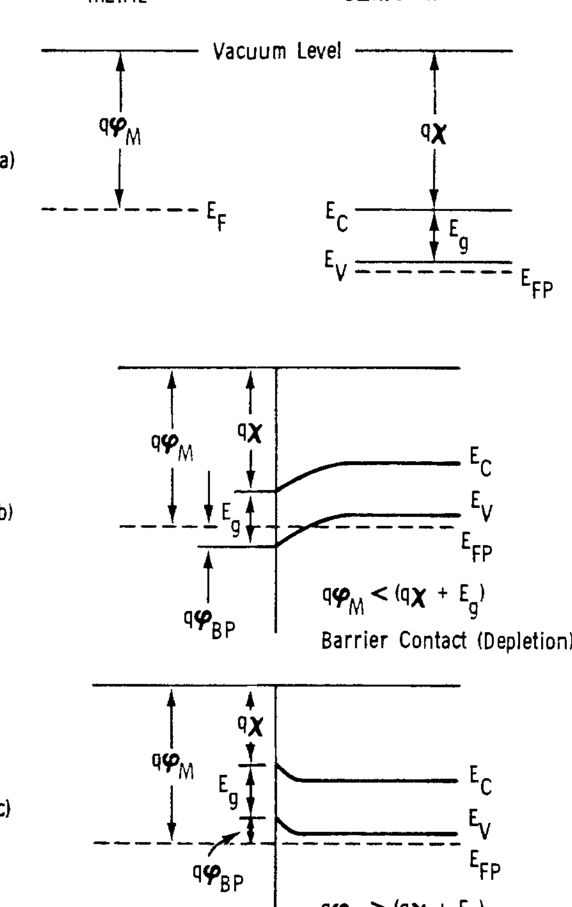

Fig. 4. Energy levels of a metal-semiconductor interface

though the exact value of the work function for Au is not certain (16), the approximate equality of work function and electron affinity could explain the barrier contacts. From Eq. [1], it is seen that the barrier height would be positive and equal to the energy bandgap E_g. It is interesting to note that as SnTe is added to PbTe to form $Pb_{1-x}Sn_xTe$, the bandgap of the semiconductor decreases. This tends to lower the barrier height and improves the contact resistance. However, in order to change the contact from barrier to ohmic (ϕ_{BP} goes from positive to negative) the electron affinity of the $Pb_{1-x}Sn_xTe$ system would have to decrease. The crossover between barrier contact and ohmic contact should then occur at a certain SnTe concentration. This has been observed in our experiments as will be discussed later.

From the previous analysis it is clear that the best contact metal for p-type $Pb_{1-x}Sn_xTe$ is not Au, but a metal with a higher work function. Among the metals, Pt is the one with the highest work function (5.4 eV). Therefore it was selected for experimentation.

Platinum can be applied to $Pb_{1-x}Sn_xTe$ by either vacuum deposition or electroplating techniques. Although the former is done in a cleaner environment, there are several practical problems. Films deposited at room temperature have very poor adhesion. Attempts to heat samples during evaporation lead to further degradation in contact resistance. For these reasons, only the electroplating method was used in our work.

Three Pt-plating solutions have been tried. Characteristics of these solutions and the results are summarized in Table I. The alkaline solution is not desirable because it attacks the sample surface and produces high contact resistance. The strong acid solution is also undesirable, because the results are not consistent (contact resistance varies widely). Best results have been obtained with the moderate acid solution.

Although properly plated Pt routinely produces low resistance ($\sim 10^{-5}$ Ω-cm^2) contacts on p-type $Pb_{1-x}Sn_xTe$ (17), the simple addition of a little In to facilitate mounting lasers on heat sinks did not provide reliable contacts. The Pt-In contacts degraded (resistance increased) after storage at room temperature for a few days. As found previously, the resistance increase was due to diffusion of the In through the Pt and into the $Pb_{1-x}Sn_xTe$. Therefore a more complex structure was tried.

The p-type material was originally plated with 0.15 μm of Au, followed by 0.2 μm of Pt and 10 μm of In. The contact resistance was 1-2 $\times$ 10^{-5} Ω-cm^2 for $Pb_{1-x}Sn_xTe$ with $x > 12\%$, but was much higher (8-15 $\times$ 10^{-5} Ω-cm^2) for $x < 8\%$. This is consistent with the physics of metal-semiconductor interfaces as applied to Au and $Pb_{1-x}Sn_xTe$. However, the contacts were very stable. No significant degradation was observed over extended life tests.

The results for the lower Sn concentration suggested that Pt should be applied first. We found that the best method starts with 0.2 μm of Pt followed by 0.15 μm of Au and 10 μm of In. The n-type side of the diode is contacted with Au and In. Typical contact resistance for diodes fabricated this way is in the 8-15 $\times$ 10^{-6} Ω-cm^2 range for $Pb_{1-x}Sn_xTe$ with all values of x.

Laser Tests

Over a period of ten months, groups of $PbS_{1-x}Se_x$ and $Pb_{1-x}Sn_xTe$ lasers (made with three-layer contacts on the p-type side) have been tested for thermal cycling, room temperature storage, and cw operation. For up to sixty thermal cycles and five hundred hours of cw operation, no significant changes in contact resistance, threshold current density, or optical properties were observed. The test results are summarized in Table II. This is a significant improvement over lasers that have been fabricated in the past, whose performance could degrade in a matter of a few days at room temperature.

However, we found that contact degradation can be induced by heating lasers to temperatures above 160°C, even for only a few seconds. Degradation can also be induced by operating lasers at cw current densities above 3 kA/cm^2. We believe that both of these processes enhance the diffusion of In through the Pt-Au barrier and change the surface properties of the p-type side of the laser. With proper handling and avoidance of high temperature, high current operation, these lasers should be reliable devices.

It is also noted that interdiffusion between In and Au, which has received much attention recently (18), cannot account for the change in contact resistance discussed in this paper (Fig. 1). The problem we are dealing with is In diffusion into the semiconductor surface. We found that the use of multilayered structures of Pt-Au or Au-Pt has significantly retarded this process. Further improvements over this con-

tacting method have since been developed and will be published elsewhere (11).

Conclusions

Slow degradation for lead-salt diode lasers has been attributed to a slow increase in contact resistance. This mode of degradation has been traced to migration of In into the surface layer of the p-type side of the lasers. By using combinations of Au-Pt or Pt-Au as barriers to prevent In migration, we have substantially increased the lifetime of these lasers.

The Growth of, and the Formation of Grain Boundaries in, Cu_2S Films Grown on Faceted Single Crystal CdS Substrates

C. H. Cheng and K. A. Jones*

Electrical Engineering Department, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

It is shown that large angle grain boundaries are formed in the Cu_2S film at the intersection of adjacent prismatic CdS planes and that small angle grain boundaries are formed at the intersection of adjacent prismatic and nonprismatic CdS planes and at the intersection of a nonprismatic plane with the basal plane. The large angle grains are formed because the orthorhombic Cu_2S c-axis is at most a 2-fold axis whereas the CdS axis is a 6-fold axis. It is shown that the open-circuit voltage is reduced in the vicinity of these grain boundaries. The small angle grain boundaries form because the effective c/a axis of Cu_2S is different than the c/a axis of CdS so that the Cu_2S is distorted when it is made to conform with the CdS substrate. The open-circuit voltage in the vicinity of these grain boundaries did not noticeably decrease. It is also shown that the growth rate and morphology of the Cu_2S films depend on the orientation and morphology of the CdS substrate.

The Cu_2S-CdS solar cell is usually made by growing a Cu_2S film on a textured polycrystalline CdS substrate film. Because the CdS film is so highly textured, it is frequently assumed that the Cu_2S-CdS interface is parallel to the basal plane of each. However, the interface plane is usually parallel to a number of different planes because the CdS grains are highly faceted (1, 2). In addition they can contain hexagonal flat tops and pyramids (3, 4) and hexagonal etch pits (5, 6), and even originally smooth CdS surfaces can be roughened by the preferential grain boundary attack by the Cu_2S (1, 7). Sometimes the CdS film is also purposely roughened using an HCl etch in order to reduce the reflection losses (8).

It has been shown that increasing the surface roughness increases the amount of lattice mismatch at the interface (9, 10) and therefore the density of interface recombination centers (11, 12). These recombination centers have the undesirable effects of decreasing the short-circuit current via interface recombination and of decreasing the open-circuit voltage by increasing the reverse saturation current by increasing the generation-recombination and the tunneling currents (13).

In this paper we show that grain boundaries form in the Cu_2S when it grows on a faceted CdS surface, even though the CdS is a single crystal, and that these grain boundaries can reduce the cell efficiency (14). Grain boundaries are formed because the Cu_2S (orthorhombic) and CdS (hexagonal) crystals belong to different crystal systems. That the Cu_2S grows at different rates (1, 15-17) with different morphologies is also confirmed. This has important implications for the manufacture of Cu_2S-CdS cells using a rough CdS substrate because a Cu_2S film of uniform thickness

* Electrochemical Society Active Member.

Key words: growth rate, morphology, orientation, open-circuit voltage.

cannot be grown on it and the reflectivity of the different exposed Cu_2S surfaces can be different.

This study was done by growing the Cu_2S on a number of faceted single crystal surfaces. Growth on the prismatic surfaces, which occurs during grain boundary penetration, was studied by growing the Cu_2S on CdS platelets containing ridges (18) and hexagonally shaped c-oriented needle single crystals of CdS. Growth on the rough substrate surface was modeled by growing the Cu_2S on the tapered tip of the c-oriented needles and on an etched (0001) single crystal surface.

Theoretical Background

It has been shown that the (100), (010), and (001) Cu_2S planes grow respectively parallel to the $(2\bar{1}\bar{1}0)$, $(01\bar{1}0)$, and (001) CdS planes (1, 15). Using the equivalent lengths of the Cu_2S unit cell, a/3, b/4, and c/2, and the three index notation for the CdS, it can be shown that the planar orientation relationship is given by $\bar{h}_o = \bar{A}\bar{h}_h$ where $\bar{h}_h$ is the CdS plane normal, $\bar{h}_o$ is the equivalent Cu_2S plane normal, and $\bar{A}$ is (9

$$\bar{A} = \begin{bmatrix} 3 & 0 & 0 \\ 4 & 8 & 0 \\ 0 & 0 & 2 \end{bmatrix} \qquad [1]$$

The d spacings for the equivalent planes are slightly different because the equivalent lattice parameters are slightly different, and most of the equivalent planes are not quite parallel because the mismatch, $\Delta a/a$, $\Delta b/b$, and $\Delta c/c$, in the directions parallel to the Cu_2S lattice parameters is slightly different. This lack of parallelism is what causes the small angle grain boundaries discussed below to form.

As is shown in Fig. 1, a small angle grain boundary can form at the intersection of adjacent prismatic planes. The (080) Cu_2S plane is parallel to the $(01\bar{1}0)$ CdS plane but the (340) Cu_2S plane is not quite parallel to the equivalent $(10\bar{1}0)$ CdS plane since $\Delta a/a$ is a bit smaller than $\Delta b/b$. The Cu_2S must, however, conform to the CdS substrate so that the (340) Cu_2S plane must be rotated $\Delta\theta$ in a clockwise rotation about the basal plane normal. This rotation can be accomplished by a tilt boundary which has a linear dislocation density, ρ

$$\rho \simeq \frac{\Delta\theta}{b} \qquad [2]$$

where b is the Burger's vector. For the prismatic planes $\Delta\theta = 0.0075°$. If one assumes that b = 4Å, which is about equal to the a-lattice vector of CdS, then $\rho \simeq 3.2 \times 10^3$ dislocations/cm. This, in turn, yields a dangling bond density of 8×10^{10} dangling bonds/cm^2 when it is assumed that the repeat distance along the dislocation line is 4Å and there is one atom with one dangling bond in the repeat distance (19).

Small angle grain boundaries are formed at the intersections of a nonprismatic plane with the basal plane and with a prismatic plane primarily because the effective c/a = c/2/a/3 ratio (1.69) is different than it is for CdS (1.63). The lack of parallelism of all the prismatic planes also has an effect, but the effect of the different c/a (γ) ratios is enough larger so that this effect can essentially be ignored. As is shown in Fig. 2, the nonprismatic Cu_2S film can be made to conform by a rotation, $\Delta\theta_r$, about the line formed by the intersection of the nonprismatic and basal planes. The amount of rotation is found from the difference in the angle, θ, that $\bar{h}_h$ and $\bar{h}_o$ make with the c-axis where θ is found from the equation (9)

$$\cos\theta_i = \frac{\sqrt{3}l}{2\gamma_i(h^2 + hk + k^2 + 3l^2/4\gamma_i^2)^{1/2}} \qquad [3]$$

where h, k, and l are the Miller indexes referred to the CdS lattice and the γ's are those of Cu_2S and CdS.

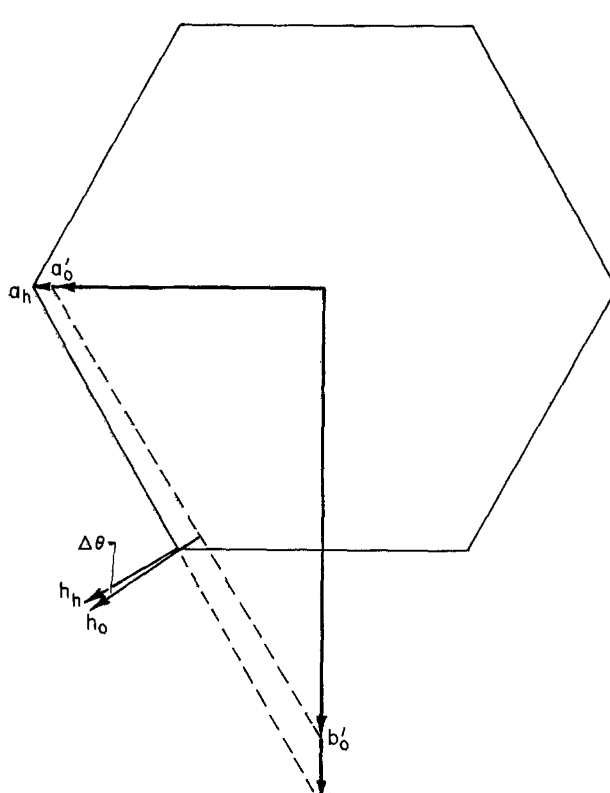

Fig. 1. The angular misorientation in the Cu_2S film at the intersection of adjacent prismatic CdS surfaces due to the difference in the mismatch in the a and b directions.

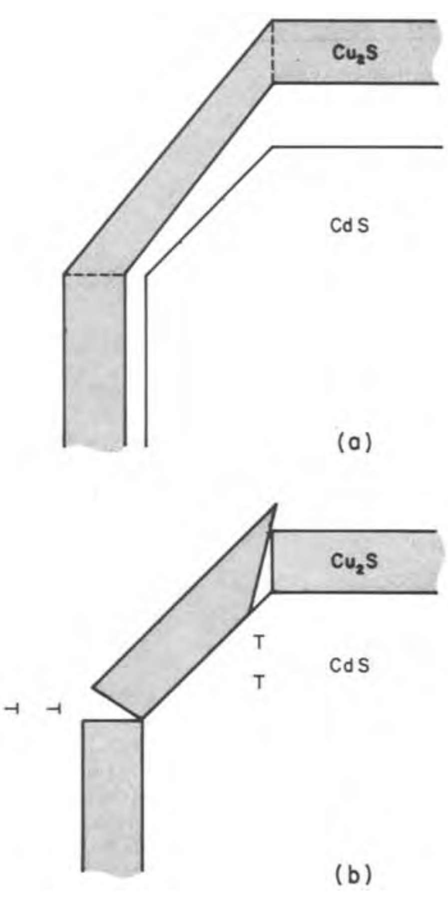

Fig. 2 (a) Schematic diagram illustrating that the effective γ for Cu_2S is larger than γ for CdS and (b) the tilt boundaries formed at the intersections of a nonprismatic CdS plane with a prismatic plane and with the basal plane when the Cu_2S is compressed to conform to the CdS.

The value of $\Delta\theta_r$ depends on which nonprismatic CdS plane is parallel to the interface. This is shown in Fig. 3 where $\Delta\theta_r$ is plotted as a function of θ for the (hOl) type planes. There it is seen that the maximum tilt occurs for $\theta \sim 45°$ where it is 1.15°. Values for specific planes are shown in Table I. For a tilt of 1° the tilt boundary will contain $\sim 4.4 \times 10^5$ dislocations/cm which, in turn, corresponds to a dangling bond density of 1.1×10^{13} per cm^2.

Small angle grain boundaries will also form at the intersections of adjacent nonprismatic planes. They form because the Cu_2S hexagonal flat top is "split down the seams" when it is compressed in order to conform to the hexagonal flat top. This is shown in Fig. 4. It has been shown elsewhere (20) that the tilt due to this splitting, $\Delta\theta_s$, is found from the equation

$$\sin\frac{\Delta\theta}{2} = \frac{\sqrt{3}}{2}\sin\phi_2\,(\cot\phi_1 - \cot\phi_2) \qquad [4]$$

where ϕ is the angle formed by the line that is parallel to the intersection of adjacent nonprismatic planes and the line that is parallel to the intersection of the nonprismatic and basal planes. It is found from the equation (20)

$$\cot\phi_i = \frac{2l[h_1^2 + h_1k_1 + k_1^2 - h_1h_2 - \tfrac{1}{2}h_1k_2 - \tfrac{1}{2}h_2k_1 - k_1k_2]}{(h_2k_1 - h_1k_2)[3l^2 + 4\gamma_1^2(h_1^2 + h_1k_1 + k_1^2)]^{1/2}} \qquad [5]$$

where the subscripts designate the nonprismatic planes $\bar{h}_1$ and $\bar{h}_2$ described in Fig. 4a. $\Delta\theta_s$ is also plotted as a function of θ in Fig. 3. There it is seen that it is less than $\Delta\theta_r$ and it peaks near $\theta = 60°$ where it has a value $\sim$0.85. The values for specific CdS planes are shown in Table I. Also, the dislocation and dangling bond densities are determined in exactly the same way as they were in the previous discussion.

Large angle grain boundaries can also be formed at the intersection of adjacent prismatic planes and adjacent nonprismatic planes because the basal plane normal for the CdS is a 6-fold axis whereas the equivalent Cu_2S direction is only a 2-fold axis. As is shown in Fig. 5, the (021) Cu_2S plane grows on the $(01\bar{1}2)$ CdS plane and the (344) Cu_2S plane grows on the $(10\bar{1}2)$ CdS plane if the orientation relationship is obeyed. However, the $(01\bar{1}2)$ and $(10\bar{1}2)$ CdS planes

are crystallographically equivalent, but the (021) and (344) Cu_2S planes are not. If, as is more likely, crystallographically equivalent Cu_2S planes grew on these CdS planes, a 60° grain boundary would form at the intersection of these two planes.

Experimental Procedure and Results

The CdS needle single crystals were grown using five 9's pure CdS powder by placing the powder in a 25 cm evacuated quartz tube and then putting the tube in a temperature gradient of ~2°C/cm with the hot end being at 1200°C. The platelets were grown using a modified Frerich's technique with the five 9's pure CdS being evaporated at ~1100°C transported by an argon carrier gas flowing at ~1 cm/sec and then being deposited at ~900°C (18). The bulk CdS crystals were donated to us by the 3M Company.

The bulk crystals were cut with an (0001) orientation, the positive (0001) face was identified after the crystal had been etched in HCl, and then it was mechanically polished with the last polish being made with 0.3 micron alumina. The surface was partially covered with a protective layer of black wax and the unprotected area was then etched for ~5 min in concentrated HCl. The prismatic surfaces of the CdS needles were left as is, and the nonprismatic surfaces were formed by polishing the tip so that the nonprismatic plane made an angle of 45° with both the (10$\bar{1}$0) and the (0001) planes. The nonprismatic plane was then almost parallel to the low energy (10$\bar{1}$2) plane (3).

Some of the crystals were examined in an optical microscope and a SEM, and then the Cu_2S was grown using the dipping technique described by Lindquist and Bube (17). Usually some of the crystal surfaces were protected with black wax, and they were dipped for times ranging from 5 min to 2 hr.

Photographs of the z-oriented CdS and Cu_2S are shown in Fig. 6. As is seen in Fig. 6a, the etched z CdS surface is composed of small hexagonal flat tops. Figure 6b shows how the surface morphology changes when a Cu_2S film covers the CdS substrate. There it is seen that the Cu_2S appears to nucleate on the different exposed CdS surfaces, and that grains appear to form when the film on the different surfaces grows together. In Fig. 6c and 6d it is seen that the morphology of the Cu_2S grown on the etched face (Fig. 6c) is very different from that grown on the smooth face (Fig. 6d).

Photographs of the Cu_2S film growing on adjacent prismatic surfaces of a CdS needle are shown in Fig. 7. The intersection of the Cu_2S film growing on adjacent prismatic CdS planes is shown in Fig. 7a and the same intersection after it had been treated with a KCN etch is shown in Fig. 7b. In the former it appears as if the Cu_2S film does not grow together perfectly, and in the latter it is seen that the intersection is preferentially attacked by the etch much as it would if there was a grain boundary there.

The effects of growing Cu_2S on a rough platelet surface is shown in Fig. 8 where there are photographs of a Cu_2S-coated CdS platelet cleaved parallel to the (0001) plane. There it is seen that the Cu_2S films growing on the different CdS planes appear to have different orientations, and there are boundaries at the intersections of the CdS planes. These boundaries could

only be cracks formed by stress concentrations at the notches, but they could also be caused by Cu_2S films with different orientations growing together.

A photograph of the Cu_2S growing near the intersection of the $(10\bar{1}0)$ and $(10\bar{1}2)$ CdS planes is shown in Fig. 9a. There it is seen that the morphology on the two surfaces is different and that the film on the $(10\bar{1}2)$ plane is thinner. That it is thinner is shown by the ridge formed at the intersection, the Cu_2S film on the $(10\bar{1}2)$ is thin enough to still replicate the scratches on the CdS substrate, and the film on the $(10\bar{1}2)$ surface is thin enough so that growth cracks have not yet formed. That the Cu_2S has substantially different growth rates on the different CdS surfaces is also shown in Fig. 9b where it is seen that the Cu_2S growing on the basal plane (horizontal) is thicker than it is growing on a prismatic plane (vertical).

The rocking curves for the $(10\bar{1}0)$ and (0002) CdS planes and the corresponding (080) and (004) Cu_2S planes made using a Cu_2S fine focus tube and a Lang camera are shown in Fig. 10. The dotted lines are parallel to the x-ray line source, and the tall, narrow double peaks are the α_1 and α_2 CdS peaks and the short, broad peaks are the Cu_2S peaks. An important point to be elaborated on in the next section is that the α_1 and α_2 CdS peaks for the $(10\bar{1}0)$ reflection in Fig. 10a and 10b are all located in the same position, but the (080) Cu_2S peaks shift or do not exist. Also, in Fig. 10c the (0002) CdS peaks are fixed but the (004) Cu_2S peaks are not and there is more than one peak.

A back wall cell was fabricated from a needle crystal that had one prismatic surface polished flat, but the back surface contained two sets of intersecting prismatic planes. These intersections are represented by dotted lines in Fig. 11a and 11b. Indium contacts were evaporated on to the front surface and ohmic contacts were made by annealing in nitrogen at 200°C for 5 min. The front surface was then covered by black wax and the crystal was dipped into a CuCl solution for ~2 hr. The black wax was removed and then a contact to the rear wall was made using silver paint. The results of a scanning light spot scan using a He-Ne laser is shown in Fig. 11c. There it is seen that the open-circuit voltage is less in the front wall contact area and, more significantly, in the vicinity of the intersecting prismatic CdS planes. This is what one would expect if a grain boundary was formed parallel to the lines of intersection.

Another back wall cell was constructed in a similar manner. The only difference is that the rear side of the CdS crystal contained a 45° beveled edge. This is represented by a dotted line in Fig. 12a. The solid curved line in the lower right-hand corner shows that the sides of the crystal were not everywhere normal to the front surface. The scanning light spot scan shown in Fig. 12b differs from that in Fig. 11c in that there is not a line of lower output that corresponds to the intersection of the two CdS planes on the back wall.

Discussion and Conclusions

The photographs in Figs. 6-9 support the idea that a grain boundary forms in the Cu_2S film at the intersection of adjacent planes in the CdS substrate. In Fig. 6a and 6b it appears that grain boundaries separate sections of the Cu_2S film that nucleate on different nonprismatic planes of the CdS hexagonal flat top. In Fig. 7 the Cu_2S film growing on adjacent prismatic planes of a CdS needle appears to grow together imperfectly at the intersection (Fig. 7a). That this is the case is supported by the observation that the Cu_2S at the intersection is preferentially attacked by an etch (Fig. 7b). In Fig. 8 there also appears to be an angular mismatch in the Cu_2S film at the intersection of prismatic CdS planes, and the Cu_2S growing on the different CdS surfaces has a different orientation.

One can also see from these photographs that the morphology of the Cu_2S depends on the surface preparation and orientation of the CdS substrate and that the Cu_2S growth rate has an orientation dependence.

In Fig. 6c and 6d one sees that the Cu_2S film is much rougher when it is grown on an etched z-face (Fig. 6c) than it is when the face is not etched (Fig. 6d). In Fig. 9a it is seen that the morphology of the Cu_2S growing on a prismatic CdS surface is different than it is growing on a nonprismatic surface. For reasons given in the previous section the film on the nonprismatic surface is also thinner. That the Cu_2S growth rate has an orientation dependence is also shown in Fig. 9b where it is seen that the film growing on the basal CdS surface is thicker than the one growing on the prismatic surface. An additional observation we made is that the rate of growth of the Cu_2S decreases with time more rapidly when growth occurs on polished z-face than it does on an etched z-face.. This could be due to the fact that the growth of Cu_2S is diffusion limited, and the diffusion rate is greater for films grown on an etched surface because these films contain more grain boundaries due to the fact that growth occurs on a rough substrate surface.

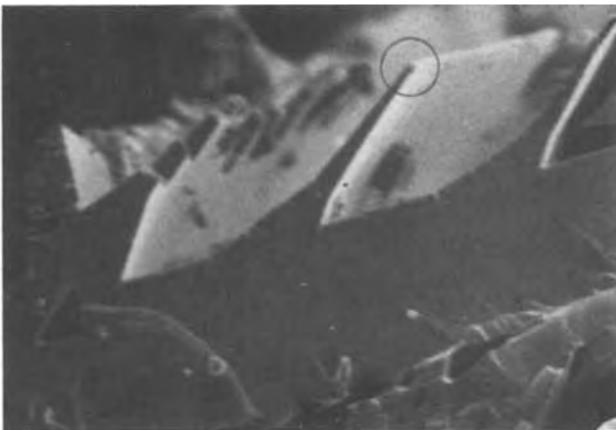

Fig. 8a. A photomicrograph of a (0001) cross section of a CdS platelet with a Cu_2S film growing on it (100×).

The x-ray rocking curve data in Fig. 10 can be explained by the formation of small angle grain boundaries at the intersections of a nonprismatic plane with a prismatic plane and with the basal plane, and the formation of large angle grain boundaries at the intersection of adjacent nonbasal planes. That small angle grain boundaries form can be seen in Fig. 10a. The angular separation ($\sim$0.3°) of the $(01\bar{1}0)$ CdS and (080) Cu_2S rocking curves for growth on the prismatic $(01\bar{1}0)$ surface (lower curves) is such that the two planes must be parallel. The (080) curve has a larger θ value since its d spacing is less. However, when the same reflections are recorded in the tapered region the (080) curve is shifted about a degree. It is shifted because the Cu_2S on the nonprismatic plane is related to the Cu_2S on the prismatic plane by a rotation of 1° about the horizontal axis. This is about what was predicted in the section on Theoretical Background.

It should also be pointed out that there is only one (080) reflection from the Cu_2S on the nonprismatic planes so that there is no splitting between adjacent nonprismatic planes. Rather, the sections of the Cu_2S film on the adjacent nonprismatic and prismatic planes make an angle of 60° with each other. This is due to the fact that a (010) C_2uS plane grows parallel to all six of the crystallographically equivalent $\{01\bar{1}0\}$ type CdS planes and this is shown in Fig. 10b. There is no (080) reflection from the Cu_2S growing on the top CdS plane because the (010) plane has been rotated 60° away from the (010) plane on the middle CdS plane in order to conform with the CdS crystal. When the crystal is rotated 60° about the c-axis, the reflections from the section that was originally the top section and is now the middle section are identical to those of the original middle section.

It should also be pointed out that there is only one (080) reflection from the middle section. Thus the Cu_2S growing on the nonprismatic CdS plane is not misaligned from the Cu_2S growing on the prismatic CdS plane by a rotation about the c-axis; it is only misaligned about an axis normal to the c-axis as was shown in Fig. 10a.

Fig. 8b and c. Enlargements of two regions at the intersection of two CdS planes (5000×)

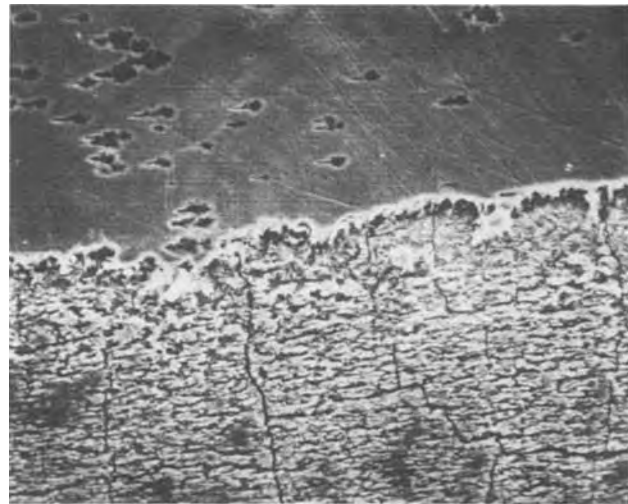

Fig. 9a. A photomicrograph of the Cu_2S growing near the intersection of a prismatic (lower) plane and a nonprismatic (upper) plane (500×).

Fig. 9b. A photomicrograph of the Cu_2S film growing on the (0001) CdS plane (horizontal) and on a prismatic plane (vertical) (500×).

The large angle rotations about the c-axis do not change the orientation of the basal plane, only rotations about axes in the basal plane do, and this is shown in Fig. 10c where the (0002) CdS and (004) Cu_2S rocking curves are recorded. There it is seen that the Cu_2S (001) plane in the sections of the Cu_2S film growing on the nonprismatic surfaces is related to the (001) Cu_2S growing on the basal surface by a rotation of 1° about the intersection of the nonprismatic and basal planes. The (004) reflection to the left of the (0002) reflection for the lower set of rocking curves is for a film with its (001) plane growing parallel to the (0001) CdS plane. The second (040) peak must be due to reflections from the Cu_2S growing on the nonprismatic planes.

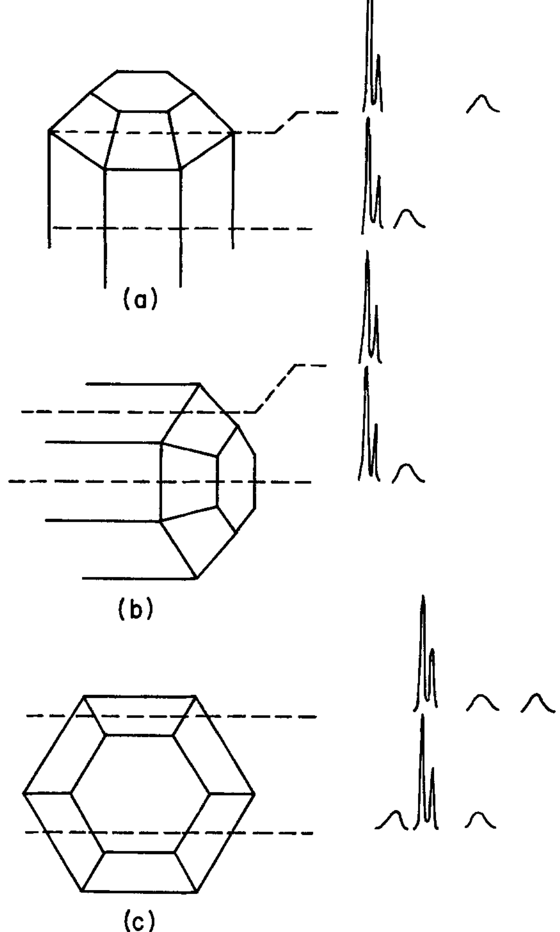

Fig. 10. (a) (01$\bar{1}$0) CdS and (080) Cu_2S rocking curves with the x-ray beam normal to the c-axis for growth on the prismatic (lower) and nonprismatic (upper) CdS planes. (b) (01$\bar{1}$0) CdS and (080) Cu_2S rocking curves with the x-ray beam parallel to the c-axis for growth of Cu_2S on a prismatic surface parallel to the plane of the paper (lower) and for growth on an adjacent prismatic plane. (c) (0002) CdS and (004) Cu_2S rocking curves for Cu_2S growth on the CdS basal plane and two nonprismatic planes (lower) and on three nonprismatic planes (upper).

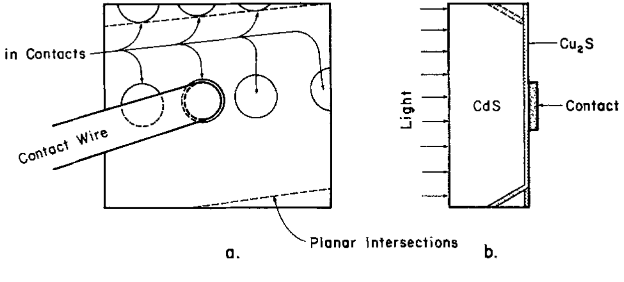

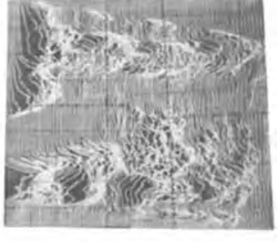

Fig. 11. The top (a) and side (b) view of the back wall cell with the Cu_2S film growing on adjacent prismatic CdS planes. (c) A scanning light spot scan of this cell.

There is a shift since there is a component of the rotation axis that is parallel to the x-ray line.

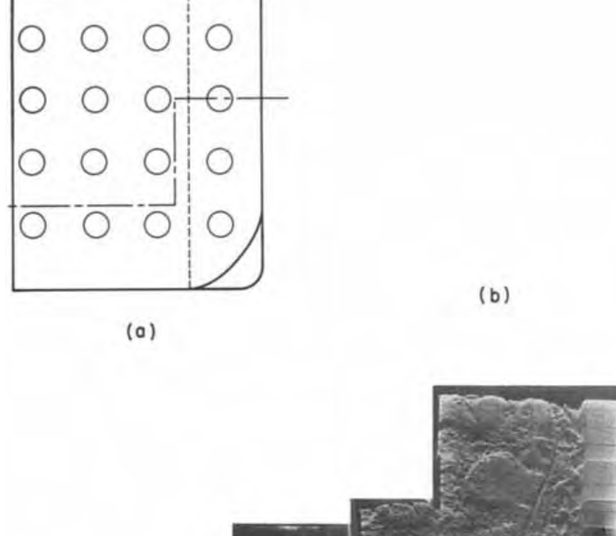

Fig. 12. (a) The top view of the back wall cell with the Cu_2S growing on adjacent prismatic and nonprismatic CdS planes. (b) A scanning light spot scan of the portion of this cell dotted in (a).

There are two (040) peaks, both of them shifted away from parallelism, in the upper set of curves. The closer peak is from the two sections of the film that have a component of the rotation axis parallel to the x-ray beam, and the more distant peak is from the section of the film for which the rotation axis is parallel to the x-ray beam.

That the large angle grain boundary formed at the intersection of adjacent prismatic planes has a detrimental effect on the cell characteristics is shown in the scanning light spot scan in Fig. 11c. There it is seen that the open-circuit voltage in the vicinity of the grain boundaries is reduced. It is likely that the reduction is due to an increased leakage current due to the shunts formed at the intersection of the grain boundary and the junction.

There is no equivalent detrimental effect in the open-circuit voltage at the intersection of the prismatic and nonprismatic planes in Fig. 12b. This could be due to the fact that the small angle grain boundary at the intersection does not have as detrimental effect as the large angle grain boundary formed at the intersection of adjacent prismatic planes. It could also be due to the fact that the intersection was formed by polishing so that the intersection was a bit rounded. Therefore the change in orientation could occur over a larger distance.

Generation Mechanism of Dislocations in Local Oxidation of Silicon

Kenji Shibata and Kenji Taniguchi
NEC-Toshiba Information Systems Incorporated, Kawasaki, Kanagawa, 210, Japan

ABSTRACT

Local oxidation conditions and film thickness combinations of Si_3N_4 and SiO_2 are studied to investigate the generation mechanism of dislocations using (001) oriented silicon wafers. The nature of dislocations in Si is examined by Secco etching and transmission electron microscopy is used for the determination of Burgers vectors. Dislocations have been generated in the film combinations with more than 2000Å Si_3N_4 or with less than 78Å SiO_2 at 1000°C oxidation in wet O_2. Edge and screw dislocations are found underneath and close to Si_3N_4 film, respectively. These dislocations are generated in the initial stage of oxidation.

Application of silicon local oxidation technology for the fabrication of integrated circuits has various significant advantages, such as packing density increase, reliability improvement in metal interconnection, and a capacitance reduction of the active regions. This technology has been increasingly advanced and adapted to LSI fabrications. At present, however, there are still a few problems to be solved. Local oxidation of silicon is performed by masking a part of the silicon surface with a chemical vapor deposited Si_3N_4 film. As is well known, high density dislocations are induced in the silicon substrate during local oxidation processing, if the intrinsic stress of the Si_3N_4 film exceeds the yield stress for silicon. A few works have been carried out on the crystallographic analysis of the dislocations (1) and on the processing method to reduce the defects (2-4). The induced defects were reported to be 60° type dislocations (1).

In this paper, the nature and distribution of dislocations induced by local oxidation are studied in detail, for various combinations of local oxidation conditions and film thicknesses of Si_3N_4 and pad SiO_2. It has been analyzed by transmission electron microscopy that two types of dislocations are induced, that is, edge dislocations located underneath Si_3N_4 film and screw dislocations near the Si_3N_4 film edges. On these results, the generation mechanism of dislocations is discussed.

Experimental

Substrates used were boron-doped, P-type, (001) silicon wafers of 6 ~ 8 Ω-cm. The sample preparation and experimental procedure employed in this study are shown in Fig. 1. Silicon substrate surfaces were covered with thermal SiO_2 films (pad SiO_2) ranging from 0 to 330Å thick, grown at 1000°C in dry O_2. Subsequently, Si_3N_4 films ranging between 500 and 3000Å in thickness were deposited chemically onto the pad SiO_2 films by SiH_4-NH_3 reaction at 800°C. After patterning these films as shown in Fig. 1, the exposed regions of silicon substrate were oxidized locally from 1.0 to 1.5 μm at temperatures of 900°, 1000°, and 1100°C in wet O_2. The film edges of Si_3N_4 were aligned parallel to <110> Si directions on the (001) surface.

After removing all the films, crystalline defects induced in the silicon substrate were examined by etch pits revealed by Secco etching (5). Furthermore, transmission electron microscopy (TEM) at 100 keV was used for the analysis of Burgers vectors and dislocation characterization. The samples for TEM observations were prepared by thinning the silicon substrates by chemical etching from the back side.

Results

Effects of pad SiO_2 and Si_3N_4 film thicknesses.—High intrinsic tensile stress (6) of Si_3N_4 film generates crystalline defects in silicon substrates, if it exceeds the yield stress for silicon during thermal oxidation. In this work, in order to study this stress effect, the relationship between the pad SiO_2 and Si_3N_4 film thicknesses on crystal defects was examined. Figure 2 shows the Secco-etched Si surface for a combination of no pad SiO_2 and 2000Å Si_3N_4 film as an example. In Table I, the degree of crystalline damage induced in the silicon substrates is summarized for various thickness combinations. These results were obtained from the etch pit observations by Secco etching. "Yes" and

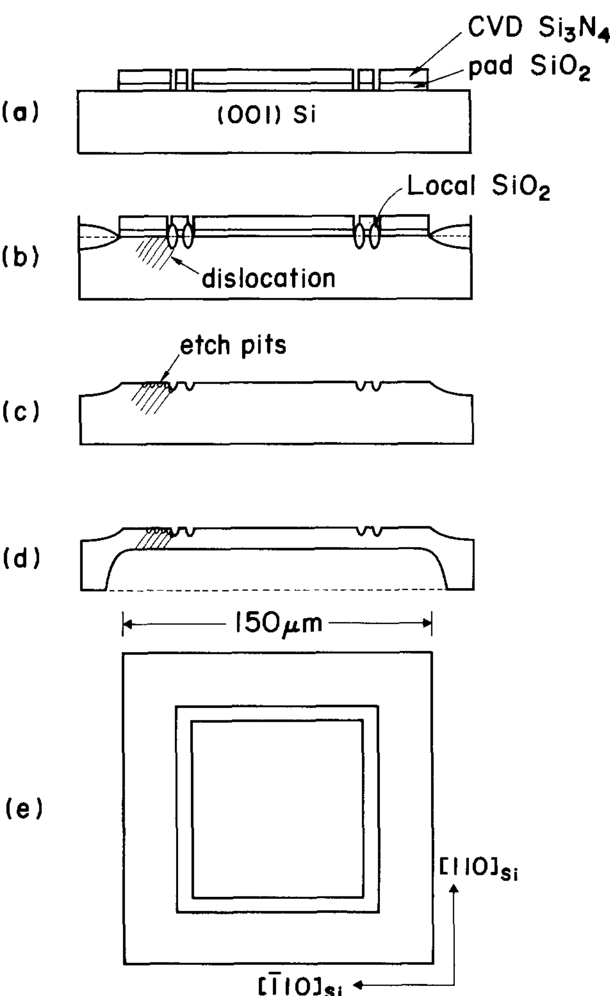

Fig. 1. Sample preparation and experimental procedure: (a) after patterning Si_3N_4 and SiO_2 films, (b) local oxidation, (c) sample for optical microscope inspections, (d) sample for transmission electron microscope inspections, (e) dimensions of top view observed.

Key words: local oxidation, integrated circuit, silicon nitride, silicon dioxide, dislocation.

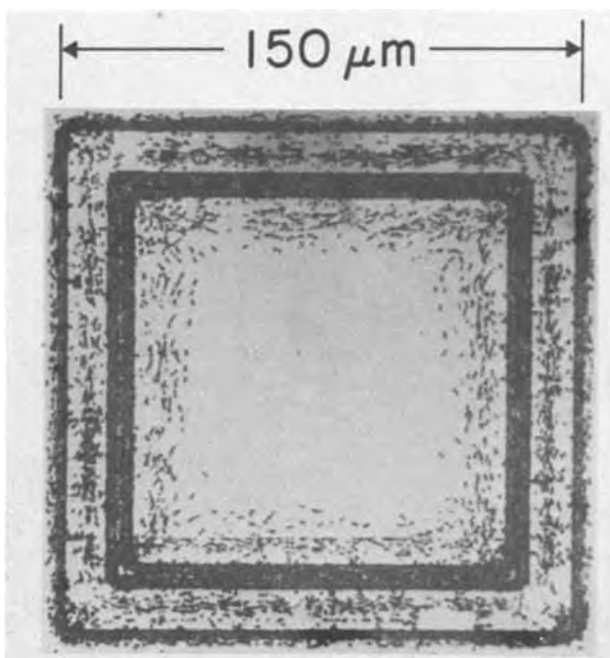

Fig. 2. Secco-etched Si surface for a combination of no pad SiO_2 and 2000Å Si_3N_4 film.

"Yes*" in this table indicate the amounts of etch pits in increasing order. The following results are obtained from Table I: (*i*) no dislocation is generated under Si_3N_4 thickness less than 2000Å except for no pad SiO_2, (*ii*) in the case of 3000Å Si_3N_4 film thickness, dislocations are generated regardless of pad SiO_2 thickness, and (*iii*) in the case of no pad SiO_2, a high density of dislocations is generated along Si_3N_4 film edges regardless of the Si_3N_4 film thickness, as seen in Fig. 2. These results mentioned above were studied in detail by transmission electron microscopy. The detailed examinations of these dislocations will be discussed later.

Effects of oxidation temperature and time.—No pad SiO_2 case was examined because the influence of oxidation conditions on the crystalline damages remarkably appear. The oxidation was carried out at 900°, 1000°, and 1100°C in wet O_2. Figures 3 and 4 show optical micrographs of Secco-etched silicon surfaces oxidized under the conditions of 1000 and 3000Å thick Si_3N_4 films, respectively. In the case of 1000Å Si_3N_4 film, a marked dependence on the oxidation temperature can be observed (Fig. 3). For a 900°C local oxidation, etch pits due to dislocations are randomly distributed in the vicinity of Si_3N_4 film edges. The amount of etch pits and the randomly distributed ones are decreased with increasing oxidation temperature, as seen in Fig. 3(b). It should be noted that no dislocations are formed in regions apart from the Si_3N_4 film edges at a higher oxidation temperature. On the other hand, in the case of 3000Å thick Si_3N_4 films, there is no significant

Table I. Crystalline damage degree induced in the silicon substrates for various thickness combinations of pad SiO_2 and Si_3N_4 films. "No" indicates no dislocations are generated. "Yes" and "Yes*" indicate the amount of etch pits in the increasing order.

Pad SiO_2 \ Si_3N_4	500Å	1000	2000	3000
0Å	–	Yes*	–	Yes*

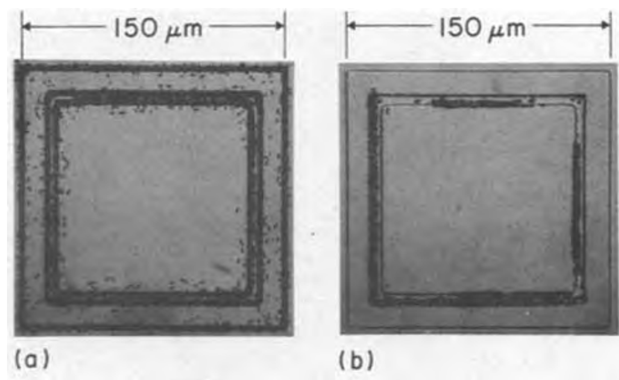

Fig. 4. Oxidation temperature dependence for 3000Å Si_3N_4 film with no pad SiO_2.

difference due to the oxidation temperature, as shown in Fig. 4. Furthermore, it can be seen that many dislocations are arrayed along the Si_3N_4 film edges and generated even in the region away from the Si_3N_4 film edges. These results are summarized in Table II. The localization degree of the generated dislocations increases in the order "E", "L", "VL", and "VVL." Table II shows the dislocations are localized with increasing oxidation temperature and with decreasing Si_3N_4 film thickness.

In the following, the oxidation time dependence is examined. It was found that density of dislocations does not depend upon the oxidation time (*i.e.*, local oxide thickness) in the range more than 20 min, for any oxidation temperatures and any combinations of pad SiO_2 and Si_3N_4 film thickness. This result suggests that the density of dislocations saturates within 20 min, and that the silicon substrate which has not been damaged at early stages of oxidation remains dislocation-free. The generation mechanism of dislocations can be explained by these results. It will be discussed later.

Observations of crystalline defects by transmission electron microscopy.—In Fig. 3 and 4, we divided the generated dislocations into two types, that is, one is

Table II. Localization degree of the generated dislocations for various oxidation temperatures and Si_3N_4 film thicknesses. "E", "L", "VL", and "VVL" indicate the localization degree increases in the order.

Oxidation Temperature \ Si_3N_4	1000Å	2000	3000

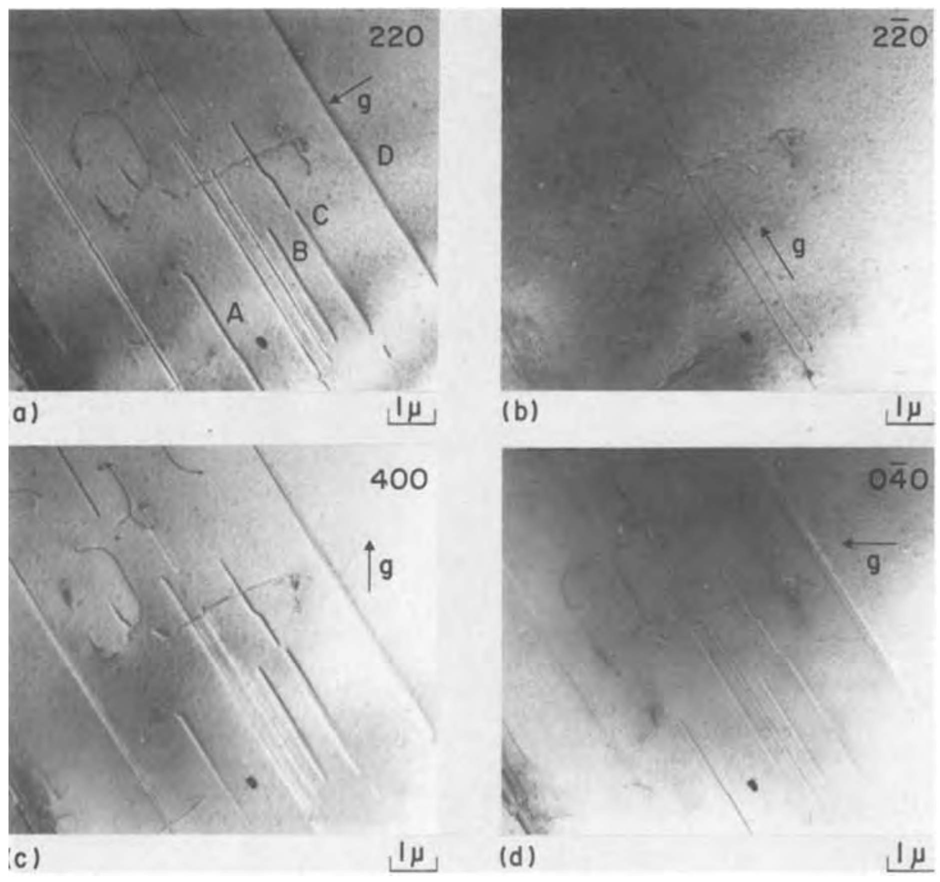

Fig. 5. Transmission electron micrographs of edge dislocations (A-type) underneath the Si_3N_4 film: in (a), (c), and (d), dislocations named A, B, C, and D are visible taken in [220], [400], [0$\bar{4}$0] reflection vectors, respectively; in (b) they are invisible taken in [2$\bar{2}$0] reflection vector.

arrayed close to the Si_3N_4 film edges and the other is arrayed underneath the Si_3N_4 films which is apart from the film edges. Transmission electron microscopy was used for the detailed inspection of the dislocations and the analysis of their Burgers vectors. Four different reflections of [220], [2$\bar{2}$0], [400], and [0$\bar{4}$0] were used to determine the crystallographic nature of the dislocations. Figure 5 is composed of four bright field images on the four different reflections in the same silicon region underneath the Si_3N_4 film which is apart from the film edges. In these micrographs, there are several straight dislocations paralleled to the Si_3N_4 film edges along a <110> direction of silicon. In Fig. 5(a), (c), and (d), all of the dislocations are visible, but in Fig. 5(b), the dislocations named A, B, C, and D in Fig. 5(a) have vanished. This observation proved that these dislocations consist of pure edge component having the $a/2$ [110] Burgers vector, and are named A-type dislocation hereafter.

Figure 6 shows bright field image transmission electron micrographs on the reflections of [$\bar{2}$20] and [$\bar{2}\bar{2}$0] in the region near the Si_3N_4 film edges. These micro-

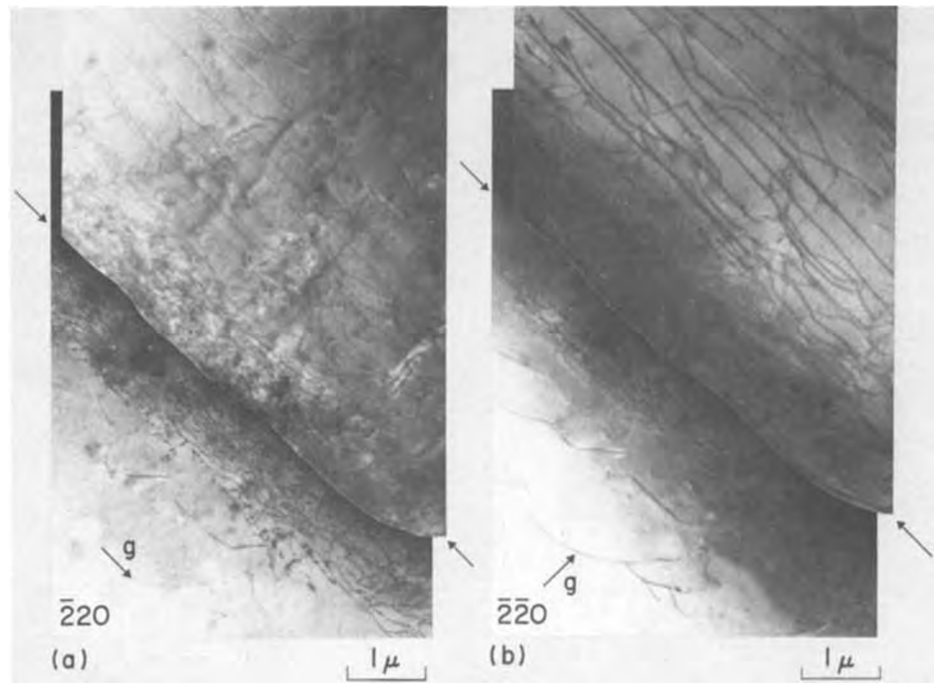

Fig. 6. Transmission electron micrographs of screw dislocations (B-type) close to Si_3N_4 film edge (indicated by arrows): in (a) dislocations are visible clearly in [$\bar{2}$20] reflection vector; in (b) they are almost out of image in [$\bar{2}\bar{2}$0] reflection vector.

graphs show both oxidized and unoxidized regions close to the film edge. High density dislocations tangling with one another have been observed along the Si_3N_4 film edges. This fact suggests that very high shear stress acts on silicon substrate, and leads to high density dislocations, which differ from A-type dislocations, and are identified as follows. As seen in Fig. 6, the dislocations close to the film edges have a clear contrast on the $[\bar{2}20]$ reflection and are almost out of image on the $[\bar{2}\bar{2}0]$ reflection, perpendicular to the dislocation lines. Therefore, these dislocations have the screw components, having the a/2 $[\bar{1}10]$ Burgers vector, and are named B-type dislocations hereafter. In conclusion, low density edge component dislocations (A-type) are generated in the regions underneath the Si_3N_4 films which are distant from the film edges. On the other hand, high density screw component dislocations (B-type) are generated in the region close to the film edges.

Discussion

In the case of no pad SiO_2.—High density dislocations are introduced in silicon substrates during high temperature local oxidation using a Si_3N_4 film, especially for the condition of no pad SiO_2 film. This generation mechanism of dislocations is explained by high intrinsic stress of the Si_3N_4 film. It is suggested that the stress acting on the silicon substrate during the high temperature oxidation exceeds the yield stress for silicon. It has been found in this work that the dislocations introduced by the Si_3N_4 film stress can be divided into two types, A-type and B-type. From this finding, it is considered that the stress state in the region close to the Si_3N_4 film edges is different from that far away from the film edges. Serebrinsky (7) reported the stress concentration near Si_3N_4 film edges by an elastic two-dimensional model. Therefore the stress acting on the silicon substrate underneath the Si_3N_4 film is considered to be low compared to that near Si_3N_4 film edges, and to be of the same order as the yield stress for silicon, which leads to the generation of low density edge (A-type) dislocations. In this region the movement and multiplication of dislocations and their interactions could not take place easily, because the stress is not high and, in addition, the silicon substrate surface is fixed by the Si_3N_4 film. On the other hand, in the region close to Si_3N_4 film edges, the stress acting on the silicon substrate exceeds the yield stress for silicon by far, and generates high density dislocations which are confirmed to be screw ones. These results are obtained by TEM observation of the samples which are prepared by thinning the silicon wafers from the back side. This means that dislocations located near the surface of silicon substrate after the local oxidation are screw ones.

It is probable that another type of dislocation distribute in the deeper region of the silicon substrate. In view of the aim to examine the depth profile of dislocations, the cross section of the silicon substrate is observed with etch pits. It can be seen from this result that numerous dislocations are generated at the Si_3N_4 film edges and the plastic deformation occurred by the drastic motion of dislocations. The dislocation mobility should be considered to study the dislocation motion in detail.

The mobility of edge dislocations is larger than that of screw ones, and 60° dislocations move faster than screw ones in germanium as representative of crystals with a high Peierls energy especially at higher stress and temperature (8). The same results would be expected in silicon, since the crystal structure of silicon is the diamond lattice and the same as that of germanium. Therefore the distance of dislocation motion from the dislocation sources which located in the silicon surface tends to increase with edge, 60°, and screw dislocations in that order, and it is reasonable that screw dislocations are observed in the surface region of the silicon substrate after the local oxidation.

It has been found in this work that the generated dislocation density in silicon does not depend upon the time for more than 20 min. Therefore, silicon substrate remains dislocation-free, if it has not been damaged at the beginning of oxidation. It is considered that the dislocations are not introduced during the cooling down process at the end stage of oxidation, because the dislocation density is not influenced by the local oxide thickness.

These discussions lead to the following conclusions on the generation mechanism of dislocations: (*i*) A-type dislocations are formed in the silicon region underneath Si_3N_4 films due to intrinsic Si_3N_4 film stress in the initial stages of oxidation if the film stress is over the yield stress for silicon at a high temperature, (*ii*) the screw (B-type) dislocations are multiplied from the Si_3N_4 film edges since the stress of Si_3N_4 film is extremely high compared to yield stress for silicon. This multiplication stops within 20 min during local oxidation.

In the case of pad SiO_2 existence.—EerNisse (9) and Patel (10) showed that the viscous flow of thermally grown SiO_2 occurred above 960°C. Therefore, the stress acting on silicon substrates by the Si_3N_4 film can be relieved above 1000°C during local oxidation if there exists a sufficiently thick pad SiO_2. At a lower temperature of 900°C, the stress is not relieved because the viscous flow of pad SiO_2 cannot occur, so that the crystalline damage is induced in the silicon substrate. The following results are obtained from this work: in the case of Si_3N_4 film thickness less than 2000Å, pad SiO_2 film at least 78Å thick is necessary in order to make the silicon substrate free of dislocations. However, in the case of Si_3N_4 film thickness more than 3000Å, the dislocation-free silicon substrates are not obtained even if a 330Å SiO_2 film are used. This result indicates that the stress acting on silicon substrates overcomes the yield stress for silicon in spite of the viscous flow of the pad SiO_2 for more than 1000°C oxidation.

Conclusion

The generation mechanism of the crystalline defects in silicon associated with the local oxidation technology has been investigated. Defect observations were carried out by Secco etching and transmission electron microscopy techniques.

It has been found by transmission electron microscopy observations that two types of dislocations are generated in silicon substrate by high intrinsic stress of Si_3N_4 films. A-type dislocations which have the edge component are parallel to Si_3N_4 film edges and to the <110> directions. These dislocations locate in the region covered by the Si_3N_4 film. On the other hand, B-type dislocations are of a high density and locate near the Si_3N_4 film edges, and have mainly the screw component. These dislocations are generated in silicon substrates at the beginning of high temperature local oxidation.

The stress in silicon due to Si_3N_4 films can be reduced by viscous flow of pad SiO_2 lying under the Si_3N_4 films at local oxidation temperatures above 960°C. The amount of induced dislocations decreases with pad SiO_2 film thickness and increase with Si_3N_4 film thickness. The dislocation-free conditions have been found in combinations of less than 2000Å Si_3N_4 and more than 78Å SiO_2 films.

ABSTRACT

The effect of lubricant environments on the structure of the surface damage induced in Si during the wafer sawing process was tested for four different lubricants: water, methyl silane solution, Kleenzol B, and dielectric oil. The nature of the saw damage was characterized by transmission electron microscopy and the depth profile of the damage determined by a taper-sectioning method. The results showed that the number and depth of surface damage is sensitive to the chemical nature of the saw lubricant. Lubricants that are good catalysts for breaking Si bonds can induce more fracture cleavage and produce less surface damage. Lubricants that can dampen more effectively the out-of-plane blade vibration can also reduce the surface damage. The chemomechanical effect of the lubricant environment was also tested by applying different potentials on Si crystal during the sawing. Correlation between the applied potential and the depth of damage in the dielectric oil environment was observed and possible mechanisms involved were discussed.

The sawing of boules into wafers is the most violent process to which semiconductor materials are subjected in the course of device fabrication. The damage introduced by this process into single crystal Si is so extensive that typically 90 μm must be etched off each side of the wafer in order to obtain practical yields for integrated circuit products. Careful and expensive procedures must be employed after sawing to achieve an adequate degree of wafer flatness. As the most advanced Si solar cell designs require starting wafers only 50 μm thick, this waste of a rather expensive commodity is a significant economic factor in the alternant energy field.

The nature and depth of surface damage induced in Si wafers as they are sawed from the single crystal is known to be sensitive to several operational variables, such as blade size, feed rate, blade tension, direction of sawing, etc. (1-5). When the wafers are subjected to subsequent lapping and polishing treatments, the depth of the induced damage depends mainly on the abrasive particle size (6, 7). Previously these sawing, lapping, and polishing (the so-called wafer shaping processes) were treated as physical processes in which the mechanical condition of the operating system is the controlling factor. Little attention was paid to the relation between the physicochemical conditions of the system and the surface damage structures. The purpose of this study is to show that the chemistry and electrochemical potential of the saw lubricant are important operational variables, and the depth of surface damage can be reduced by improving the lubricant environment.

The nature of the surface damage due to mechanical abrading has been shown to consist of a layer of chipped and cracked material at the surface and a layer containing varying density of dislocations underneath the surface (7, 8). The processes which introduce the dislocations into the damaged layers during the abrading process have not yet been determined in the literature. However, several mechanisms including the effects of local heating (8), hydrostatic pressure (6, 9), and formation of dislocation cracks (10) have been suggested. Although saw damage structures identified as microcracks have been reported (4, 5), the detailed structure of damage at different depths due to the sawing process has not been studied at high magnification.

The sawing process involves rupturing of chemical bonds to create new surface. For brittle materials, such as Si, this is believed to be largely a cleavage process although plastic flow is also possible at the surface (11). Any environment that can either reduce the surface free energy or increase the mobility of near-surface dislocations and the speed of the crack propagation should reduce the energy expended in

* Electrochemical Society Active Member.

Key words: silicon wafers, saw damage profiles, lubricant effects, transmission electron microscopy (TEM).

the sawing operation (12). On the other hand, the depth of damage, which depends on the detailed pattern of crack propagation and the dislocation motion in the plastically deformed region, can also be changed in different environments.

In this study four different lubricant environments were tested: (*i*) that of the standard production process—water, which is a strong catalyst for the making and breaking of Si covalent bonds (13); (*ii*) dielectric oil, which is chemically inert; (*iii*) a commercial cutting oil (Kleenzol-B); and (*iv*) a solution of methyl silane in 80 parts water, which is an even more active catalyst (13) for making and breaking Si and other covalent bonds than pure water. The methyl silane solution has been used in the oil drilling and ballmilling industries to minimize the energy of comminution.

Since the depth of saw damage is determined by the extent to which cracks, single dislocations, or dislocation networks can propagate into the bulk material from the surface (7, 8), any change in the mobility of dislocations in the Si crystal could affect the number and configuration of dislocations introduced during the sawing process. It has been suggested that for covalent crystals in a liquid lubricant, the electrical influence of the zeta potential can be felt at several microns below the surface, and the induced redistribution of the carriers could change the charge state of dislocations and point defects in these near-surface regions (14). It has also been predicted that the velocity of dislocations in Si or Ge crystal with the diamond structure is related to the dislocation charge (15). If these assumptions are valid, then we would expect the damage structure to be dependent on the surface potential. To test this effect, we applied, in the dielectric oil environment, a positive or negative potential on the Si crystal during the sawing and looked for the changes in the depth of damage.

In the previous studies of mechanically induced surface damage in Si, the depth of damage has been measured using a variety of techniques, *e.g.*, the x-ray rocking-curve method (6), the etching rate method (8), the photomagnetoelectric method (6), the photoconductivity decay method (6), step-etching with x-ray topography (1, 2, 16), transmission electron microscopy (5, 7), metallographic taper-sectioning method (17), etc. Only the last three methods can show the actual damage distribution. In this study the improved taper-sectioning method (18) was chosen because a rather accurate damage density profile from a large sample area can be obtained quite easily by this technique. Transmission electron microscopy was also used to study the nature of the saw damage.

Experimental Procedures

Test wafers were sawn from one vertically mounted Czochralski {100} oriented, p-type, 100 Ω-cm, Si single crystal on a commercial HAMCO ID-diamond saw with feed speed 2.54 cm/min and rotation speed 2100 rpm. The operational parameters of the six experiments are listed in Table I. The saw blade was brand new at the beginning of Experiment 1. The experiments were performed in the order listed and a total of 30 wafers were sawn in each experiment. The dielectric oil was used when the saw blade was most worn. The wear of the diamond saw blade was considered not important since typically 3000-4000 wafers can be sawn on a new saw blade before blade replacement is required.

Table I. The order and the different lubricant environments used in the six experiments

Experiment	Environments	Flow meter reading (mm)
1	Water	150
2	Solution of methyl silane in 80 parts water	120
3	Kleenzol B (commercial cutting oil)	150
4	Dielectric oil with no potential	150
5	Dielectric oil with +6V on crystal	150
6	Dielectric oil with −6V on crystal	150

Since the surface damage in the wafers from different experiments will be compared directly to each other, all the operation variables, except the lubricant environments, were carefully controlled to be constant. All six experiments were performed on the same Si crystal and on the same saw. Thickness and warpage measurements were then carried out by an ADE 6043 microsense capacitance gauge, and the surface features were observed by optical microscopy.

With the modified taper-sectioning method, the six samples from different experiments were mounted at a time on a 5° beveling fixture using quartz sticky wax (see Fig. 1). Before the rough lap the samples were covered with another Si wafer and thin layer of epoxy mixed with 0.3 μm alumina powder to protect the sharp edges from chipping off. Then, by use of 12 μm alumina particles suspended in water, the specimens were hand-polished until a flat taper surface was attained. This was then followed by a finer polish using 5 μm alumina powder to obtain a shiny surface. This mechanical polishing is known to generate surface damage. This damaged layer newly introduced from polishing was removed so as not to obscure the pre-existing saw damage. This was done by chem-mech polishing which does not generate additional surface damage. The polish solution used was 1 part Syton[1] HT-40 and 2 parts deionized (D.I.) H_2O. After polishing, samples were demounted and cleaned using trichlorethylene followed by acetone and ethyl alcohol. To reveal the saw damage, samples were etched for 25 sec in dilute Sirtl etch solution. The etch solution consists of one part HF and one part dilute Sirtl etch mix, which was prepared by mixing one gram CrO_3 with 4 ml D.I. H_2O. Immediately after the etch, the samples were rinsed for 5 min in D.I. H_2O. The distribution of saw damage was read directly from optical micrographs of the etched surfaces. The number of damage pits and their distances from the wafer surface were recorded and damage distribution profiles were plotted for each sample. The nature of saw damage structures were observed by transmission electron microscopy. Here the as-sawn wafers were etched from the back side to ~1 μm thickness by HF/HNO_3 solution so that the damage in the very top surface layer can be observed by TEM. In order to obtain a cross-sectional view of the saw damage, TEM samples were also prepared

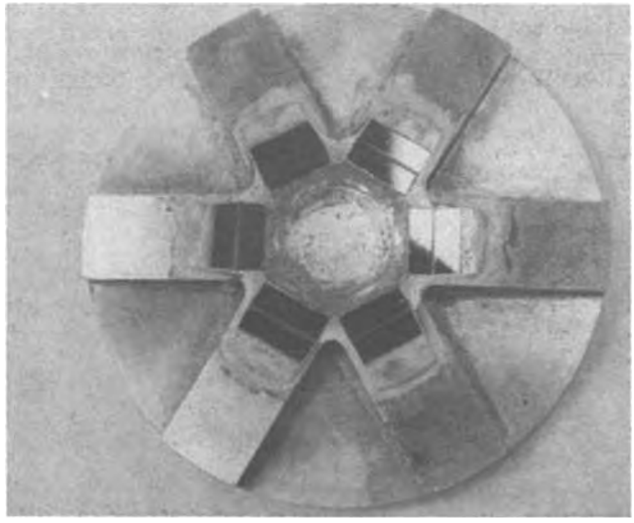

Fig. 1. 5° beveling fixture with wafer sections from six experiments mounted and polished.

by slicing the wafers along the plane perpendicular to the as-sawn surface and thinned down from both sides by an Ar-ion milling machine (19). A JEOL 200B electron microscope was used in this study.

Experimental Results

The results of thickness and warpage measurements on as-sawn wafers are listed in Table II. The thickness measurements indicated that sawing in dielectric oil can result in wafers with more uniform thickness in each wafer than sawing in water. However, the applied potential on the crystal during sawing would increase the taper to a value larger than that with water. The taper values for Kleenzol B and methyl silane solution are about the same as that for water. The measured absolute thickness values of wafers from different experiments showed that sawing in water leaves about 6-10 μm more material on the wafer than with any other process. In general, the distribution of wafer thickness is narrower in water than in any other lubricant except methyl silane, which gives a thickness distribution curve about a factor of two narrower than that for water. It is interesting to note that sawing in dielectric oil would on the average, leave about 8 μm less material on the wafer if a positive potential is applied to the crystal and about 4 μm more material for a negative potential, as compared to sawing without potential applied. The applied potential, positive or negative, also increases the warpage value as indicated in Table II (b). Here it is shown that Kleenzol B gives the largest warpage value.

The surface morphologies of wafers sawn in different environments are shown in Fig. 2. These optical micrographs indicate two kinds of surface structure: the brighter regions with scratches lying in the direction of blade motion are relatively flat, and the darker regions are places where larger pieces of silicon had chipped off. These chipped off regions are not in focus on the micrographs, but the through focus pictures showed that they are about 1 μm deep. When the saw blade cuts through the crystal, cracks are generated at the blade edge and as they propagate and meet in the crystal, small pieces of Si are knocked off and removed by the rotating blade. The diamonds plated on the edge and sides of the blade also abrade the newly cleaved surface. The cleavage and abrasive processes could give rise to two kinds of surface structure observed above. The surface morphologies of wafers sawn in Kleenzol B and in dielectric oil with +6V are very similar to that for methyl silane and dielectric oil with no potential, respectively, and, therefore, they are not shown in Fig. 2. The continuous diamond scratches in the abrasive region have a long-range ordering with periodicity of about twice the feed distance per rotation as can easily be seen in a low magnification micrograph [Fig. 2(b)].

The periodicity distance was found to be the same on the two wafer surfaces that are on opposite sides of the saw blade, but different for different lubricant environments. The periodicity distances for the six lubricants are listed in Table III. These ordered scratches might be due to the out-of-plane blade vibration and/or the noncircularity of the center hole in the blade (4). The latter should give rise to ordered structure in unit of λ, feed distance per rotation. This is not observed. Therefore the periodic structure on sawn surface must be predominantly from the out-of-plane blade membrane vibration. This is believed to be the major damage mechanism during ID sawing of silicon wafers (4). Different environments can result in different vibration frequencies as indicated in Table III. The size and distribution of the abrasive areas (brighter areas) in Fig. 2 is sensitive to the original depth of the chipped off region and the amplitude of the blade vibration. By comparing the micrographs in Fig. 2, it is noted that dielectric oil lubricant (with zero potential) increases, while the Kleenzol B and methyl silane decrease, the abrasive area. It is noted that an applied negative potential markedly decreases this area as well.

All the observations mentioned above were made on the "A" surface, which is the wafer surface still attached to the bulk crystal during sawing. The wafer surface on the opposite side of the blade is designated "B." The rupture features on both A and B surfaces are very similar to each other for the water, Kleenzol B, and methyl silane solution cases. But the B surface in dielectric oil with no potential shows much less abraded area than the A surface. This might be due to the greater vibration amplitude of the blade and wafer in this particular lubricant during the sawing process.

Figure 3(a) shows a cross section TEM micrograph of the saw damage in the wafer sawn in water. To the left side of the micrograph is the surface line of the as-sawn wafer. This surface is protected by an epoxy layer and another Si wafer during the sample thinning process. This micrograph and many others taken indicate that the surface damage induced by the sawing is mainly an array of cracks extending

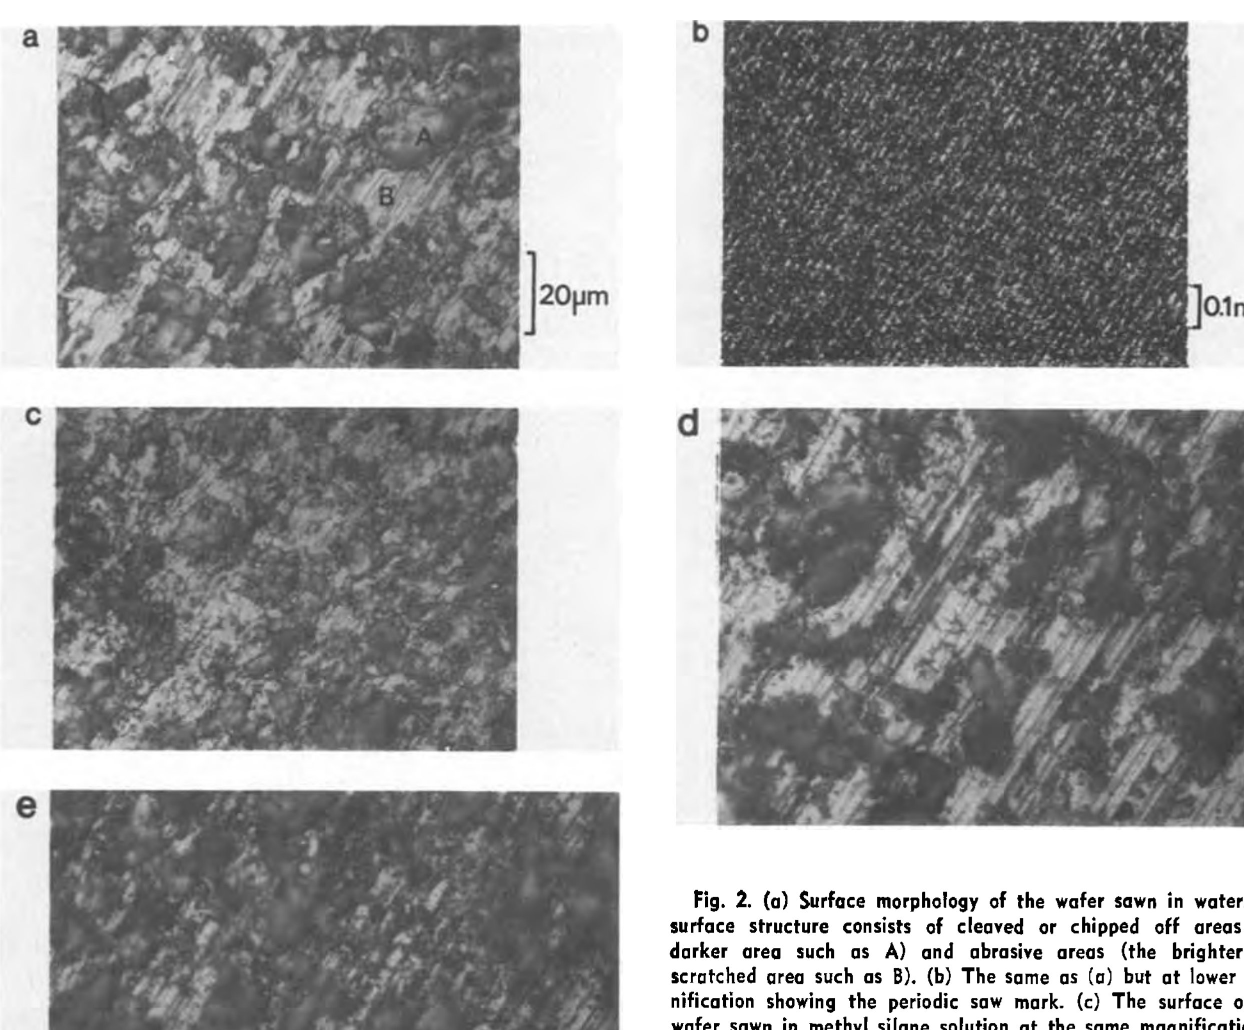

Fig. 2. (a) Surface morphology of the wafer sawn in water. The surface structure consists of cleaved or chipped off areas (the darker area such as A) and abrasive areas (the brighter and scratched area such as B). (b) The same as (a) but at lower magnification showing the periodic saw mark. (c) The surface of the wafer sawn in methyl silane solution at the same magnification as in (a) shows much less abrasive regions. (d) Surface structure of the wafer sawn in dielectric oil with no potential applied at the same magnification as in (a). The deep scratches and large abrasive areas indicate bigger amplitude of the blade vibration than in (a). (e) The same as (d) but with −6V applied on the Si crystal during the sawing. The abrasive areas are markedly decreased.

from the surface to the bulk. Dislocations were found only at the very top ~ 1 μm layer. The cracks propagate mainly along the {110} plane [*e.g.*, cracks A, B, and C in Fig. 3(a)] and the {111} plane [*e.g.*, cracks D and E in Fig. 3(a)]. In Fig. 3(a), the lengths of those cracks observed are less than 5 μm, however, this length cannot be considered as the typical depth of the damaged zone, since the TEM observation is limited to a very tiny sample area [0.5×10 μm in Fig. 3(a)]. Cracks were also found by TEM technique in the sample where the top ~ 30 μm layer has been removed by Syton polishing. The more accurate statistics of the distribution of the crack depth should be obtained by other methods which cover bigger sample area, *e.g.*, the taper-sectioning method used in this study.

Since the dislocations are found at the "hill top" area in the top 1 μm layer [*e.g.*, dislocation loops at F and G in Fig. 3(a)], it is believed that the occurrence of dislocation is related to the abrasive motion of the blade. This point becomes clearer if these dislocations are observed along the direction normal to the {100} wafer surface. For this purpose the samples were prepared by etching away from the back side of the wafer the whole wafer except the top ~ 1 μm thick layer on the front side. Figure 3(b) shows a group of dislocation half loops distributed along a straight diamond scratch at the wafer surface. These loops all lie on the {111} plane with their Burgers vectors also on this glide plane which demonstrates that they are punched into the surface by the diamond on the blade.

The depth profiles of the number of defects obtained by the taper-sectioning method for different saw lubricant environments are shown in Fig. 4(a) and (b). The defect numbers for each case were observed directly from 10 optical micrographs which represent the total defect underneath one line with length of 8.95 mm on the sawn wafer. Three micrographs, one for the water case and the others for the dielectric and methyl silane solution are shown in Fig. 5(a)-(c) as examples. The depth d was calculated from

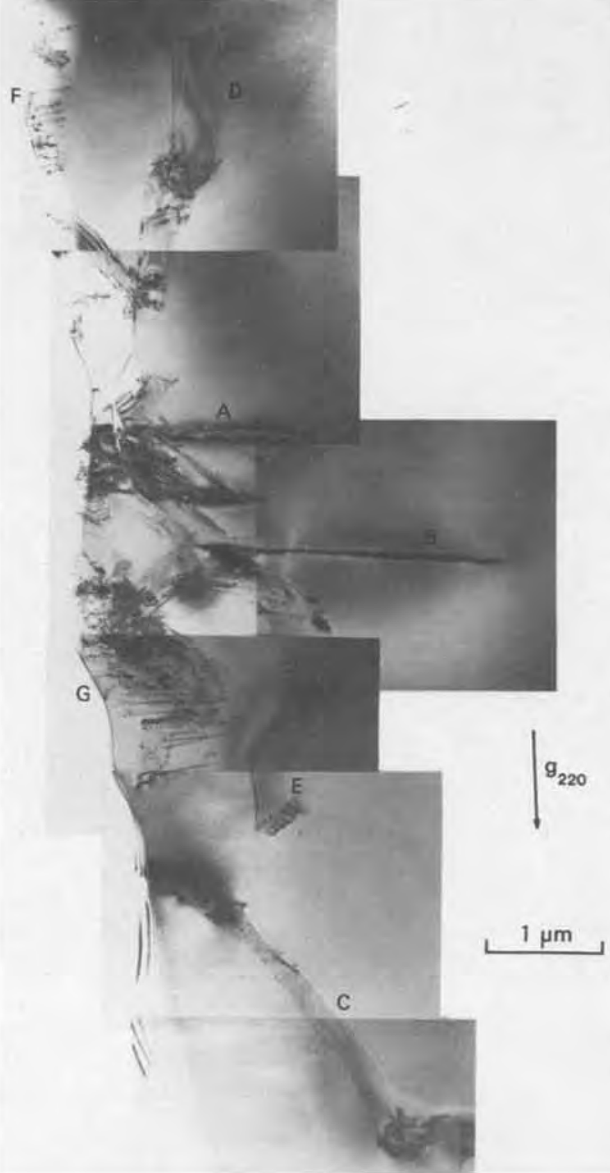
$$d = b \sin 5° \quad [1]$$

where b is the distance measured from the surface edge to the defect on the micrograph. The number of defects shown in Fig. 4 can be converted to crack or dislocation density D by

$$D(\text{cm}^{-2}) = 5.2 \times 10^3 \times N \text{ cm}^{-2} \quad [2]$$

where N is the number of defects shown in Fig. 3.

As shown in Fig. 5, the density of defects close to the surface is very high, thus the accuracy of the observation is limited by the size of the etch pits. Those defects that are too close to each other cannot be resolved in the micrograph, and, as shown by the TEM results, at the very edge (closest to the surface)



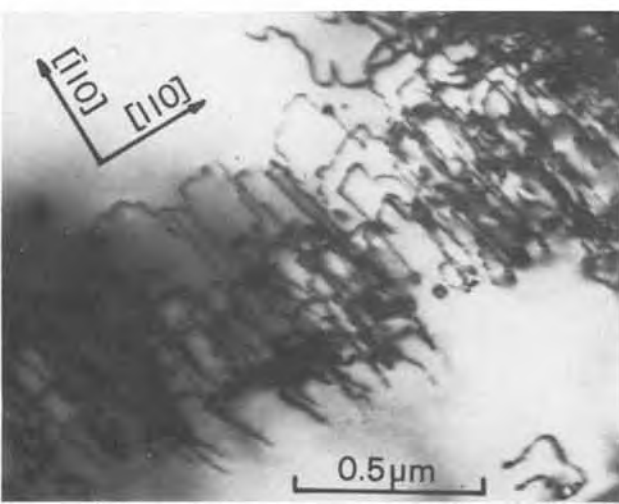


Fig. 3. (a, top) Cross-sectional TEM micrograph of the saw damage in the wafer sawn in water. (b, bottom) Dislocations in the top 1 μm surface layer of the wafer sawn in methyl silane solution.

the density of damages and the etch rate are so high that many defects are etched away from the wafer. It is therefore expected that the numbers plotted in Fig. 4 in the top ~4 μm layer are smaller than the actual values.

The damage profiles in Fig. 4 indicated that the number of defects drops markedly in the first 20 μm in the water case, and maintains a constant low value to about 50 μm. In the case of Kleenzol B and methyl silane solution, the number of cracks decreases by ~20% and ~50%, respectively, as compared to the water case in the top 10 μm. In Fig. 4(b) the dielectric oil increases the number of cracks by a factor of ~3 as compared to water in the first 10 μm but has the rest of the profile similar to that of water. The applied positive potential very obviously increases the number of defects in the 15-30 μm range by a factor of ~2 and also maintains a higher value from 30 μm to the depth of 90 μm. On the other hand, the applied negative potential decreases the number by a factor of ~2 in the first 15 μm as compared to the zero potential case.

It is noted that in all six experiments, etch pits were observed in the area deeper than 50 μm, where the defect concentration maintained at a value approximately equal to 5×10^3 cm^{-2}. These defects can be the very deep cracks induced during the sawing process or they can be the dislocations (*e.g.*, swirl defects) originally present in the Si crystal. By comparing Fig. 4(a) and (b), we find that the defect density in the 50-100 μm range is slightly higher in the dielectric oil case than in the three cases plotted in Fig. 4(a), which seems to suggest that at least part of the etch pits observed in this depth range must come from the saw damage, otherwise they should maintain at the same concentration since all the experiments were performed on the same Si crystal.

Discussion

Most of the previous investigations on saw damage in Si were concentrated on measuring the depth of damage so that the damaged layer can be removed before further processing. Due to the differences in crystals, operational parameters, measurement methods, and the definitions of damage used in these investigations, the depth of damage reported varies from 7 μm to more than 50 μm (20). In this study the optical microscopy observation on etched taper-sectioned surfaces showed that the saw damage distribution can extend to 90 μm or more under the surface. Schwuttke has reported previously that some of the saw damage structures are so deep in the crystal that they can affect the reliability of the finished MOS device even after 90 μm of material has been etched off both sides of the wafer (5).

The nature of saw damage is not understood in detail prior to this work because little work on mechanically induced surface damage had been done at high magnification. Stickler and Booker (7) have reported that the damage due to different abrasive particle size consists of individual dislocations for fine abrasive and strained dislocation networks and cracking for coarser abrasives. The dislocations observed in their work indicated that plastic deformation occurs in the abrasion process. Since plastic flow cannot usually occur in Si below 600°C, the presence of dislocations were explained as due to local heating (8), hydrostatic stress from sharp corners of the particles (6, 9), or developed from healed cracks (10). The sawing of Si crystal into wafers at ~2.5 cm/min feed speed and 2100 rpm rotation speed is certainly a more violent process than the abrading process. Meek and Huffstutler (4) argued from their etching and fracture stress measurements that the saw damage zones are predominantly microcracks rather than dislocations. Schwuttke (5), using TEM observation, characterized the very deep saw damage as microcracks. In this work, we observed the saw damage from both the top and the cross-sectional view angles at 30,000X magnification by TEM and characterized the damage structure as mainly cracks

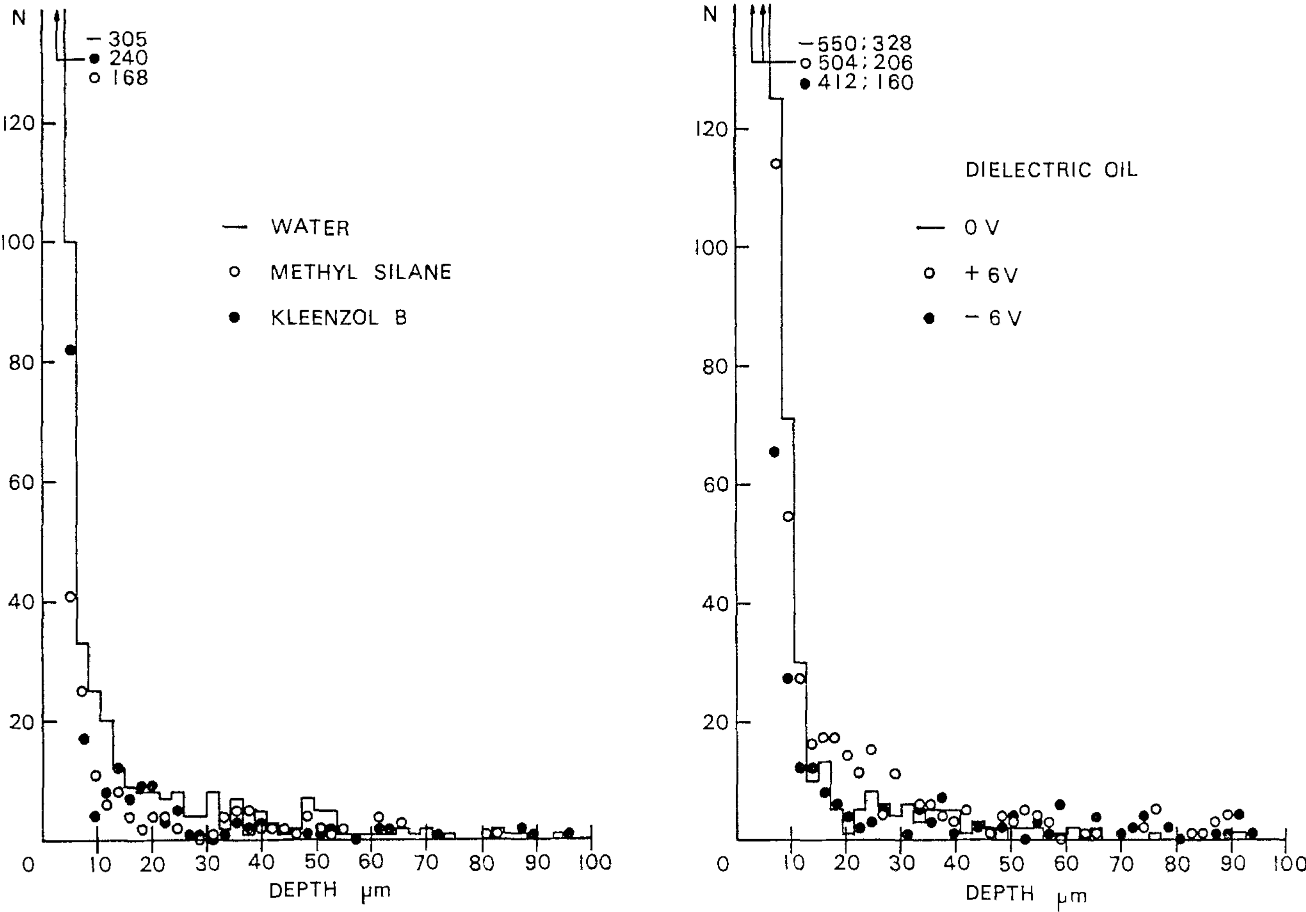

Fig. 4. (a, left) The depth profiles of the number of defects obtained by the taper-sectioning method for three different saw lubricants: water, methyl silane solution, and Kleenzol B. (b, right) The depth profiles of the number of defects induced by the sawing in dielectric oil with different potentials applied on the Si crystal.

extended roughly along both {110} and {111} planes. Dislocations were found only at the top ~1 μm layer and their occurrence was attributed to the abrasive motion of the saw blade.

One question that is being speculated about sawing is whether plastic flow occurs at the surface when we saw Si at room temperature. The presence of dislocations strongly suggests that it does. With a constant flow of lubricant it is very unlikely that the surface temperature ever reaches 600°C, the temperature at which Si starts to deform plastically. However, detailed TEM observation on Si after microhardness indentation at room temperature by Nikitenko and Eremenko (11) and by Hill and Rowcliffe (21) and the observation of saw damage in this work indicate clearly that dislocations are produced by a slip process in the vicinity of indentation as a result of high local shear stress. Gridneva *et al.* (22) concluded from their resistivity measurement that the surface layer of Si can transform into metallic phase if the hydrostatic pressure under the indenter has reached the critical phase transition pressure, which is about 140 kb (1.4×10^{10} N/m^2) at room temperature [critical pressure goes as low as 9×10^9 N/m^2 at about 600°C (23)], and that Si deforms plastically when it is in the metallic state. However, as pointed out by Hill and Rowcliffe (21), dislocations were observed to extend to several microns which is much deeper than the expected thickness of the metallic layer. Furthermore, shock wave compression experiments on Ge by Graham *et al.* (24) indicated that plastic flow can occur at stress levels less than half that required for the phase transformation. Hill and Rowcliffe (21) estimated the shear stress for plastic flow in Si to be ~22.5 kb.

Although the observed dislocation loops indicate that the local shear stress that the diamond particles on the ID blade can introduce on the Si surface during the high speed cutting has reached the value for plastic flow to occur, the major event that creates the kerf and governs the depth of damaged zone is the initiation and propagation of cracks. If we use the water case as a standard, we can make a detailed comparison between the effects of different saw lubricants and speculate on the possible mechanisms involved. The Kleenzol B and methyl silane solution are very good catalysts for breaking Si bonds and therefore could enhance crack nucleation and propagation (13). This is evident from the presence of more chipped off regions in Fig. 2(c). The scratches in Fig. 2(c) are shallower than those in (a) and (d) which might indicate that methyl silane solution and Kleenzol B impart less drag to the saw blade so that there is less out-of-plane blade vibration than when water or dielectric oil are used. These two effects would contribute to less damage produced during the sawing. [Fig. 4(a)].

On the other hand, the noncatalytic nature of the dielectric oil would be expected to make crack nucleation and propagation more difficult and, thereby, impart more drag on the saw blade than does water and increase the amplitude of vibration. This argument is in good agreement with the observation that the scratches in dielectric oil [Fig. 2(d)] are deeper than in water and also the number and depth of cracks are substantially increased [Fig. 4(b)].

No correlation was found between the blade vibration frequency (Table III) and depth of damage (Fig. 4). It is the amplitude of the vibration that can affect the depth of crack propagation the most. The sig-

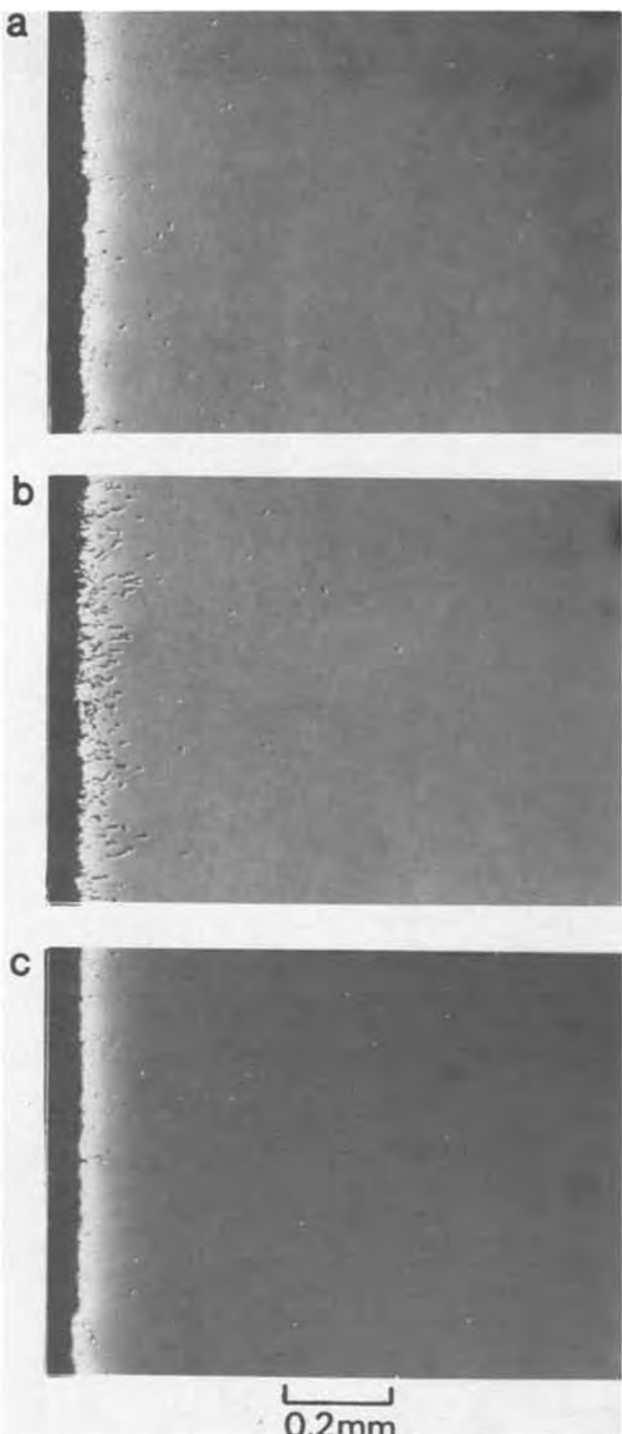

Fig. 5. (a) The beveled and etched sample section from the wafer sawn in water. The etch pits indicate the number and distribution of defects. (b) The sawing in dielectric oil introduces more surface defects than in (a). (c) The sawing in methyl silane solution introduces less surface defects than in (a).

nificance of the depth profile of crack distribution shown in Fig. 4 is that some of the cracks can extend to more than 90 μm deep. This seems to be in agreement with the finding of Schwuttke (5). As mentioned above, the blade vibration in the dielectric oil environment with no potential is such that there is more abrasion on the A surface than the B surface. Applying a positive potential does not significantly change the surface morphology or the depth of scratch on both A and B surfaces. But applying a negative potential does markedly decrease the abrasion on the A surface and slightly increase the depth of scratch on the B surface. It seems to suggest that the −6V potential applied on the crystal can reduce the amplitude of the blade out-of-plane vibration and the +6V potential does the reverse. This can explain the increase of crack numbers in the depth ranges 10-50 μm for the +6V case and the reduction of crack numbers in the depth range under 15 μm for the −6V case.

How the surface potential affects the blade out-of-plane vibration is not clear at present, but a possible explanation can be offered if we follow the Westwood theory (14) which states that dislocation mobility is least on a surface when the zeta potential is zero. The dielectric oil molecule may decompose during the sawing and become an electrolyte. The adsorption induced zeta potential may also be changed by the potential applied on the crystal and this change in turn affects the fracture processes. But the detailed mechanism, such as how the new charge environment affects the propagation of fast moving cracks, still needs to be worked out.

Conclusion

Six different lubricant environments were tested for the sawing of Si wafers: (*i*) water, which is used in the standard production process; (*ii*) a solution of methyl silane in 80 parts water; (*iii*) a commercial cutting oil (Kleenzol B); (*iv*) dielectric oil with no potentials; (*v*) dielectric oil with +6V applied on Si crystal; (*vi*) dielectric oil with −6V applied on Si crystal. The results showed that the saw lubricant is an important operational variable, and the depth of damage can be reduced by improving the lubricant environment.

TEM observations indicated that cracks are the main surface damage induced by the sawing process. Dislocations were found only at the very top layer (several microns) and were related to the abrasive motion of the saw blade.

Results of the optical microscopy on angle-lapped specimens of the cut surfaces indicated that the number and depth of the saw damage are less for Kleenzol B and methyl silane, but are much more for dielectric oil than for water. By combining the damage depth profile and the surface structure observations, it was determined that the lubricants that are good catalysts for breaking Si bonds can dampen more effectively the out-of-plane blade vibration and produce less surface damage.

The application of a potential on the crystal should change the barrier for dislocation or for crack propagation in Si. We have observed, in the case of dielectric oil, that the applied positive potential increases the depth of damage and the negative potential decreases the depth of damage, as compared to the sawing process without applied potential.

Kinetics of Chemical Vapor Deposition

J. Subrahmanyam,[1] A. K. Lahiri, and K. P. Abraham

Department of Metallurgy, Indian Institute of Science, Bangalore—560 012, India

ABSTRACT

A generalized mass transport model is developed for predicting the rate of deposition in chemical vapor deposition (CVD) systems. This combines the generalized method of obtaining equilibrium composition, with elemental flux balance expressions. This procedure avoids the usual problems encountered in calculating the rates in multicomponent systems, like writing overall reaction schemes. The dependence of multicomponent diffusivities on the fluxes is accounted in this model using an iterative procedure. The model developed is applied to the deposition of titanium carbide on cemented carbide tool bits from a gas mixture of titanium tetrachloride, toluene, and hydrogen. Experimental deposition rates were obtained using a thermogravimetric assembly. Mass transport controlled rates give an order of magnitude estimates of the observed rates.

Chemical vapor deposition (CVD) is a complex process with many variables to be controlled for obtaining a solid product with desired properties. Effective process control needs an understanding of the following: (*i*) nucleation (*ii*) thermodynamics, and (*iii*) kinetics. The theories developed for nucleation of the deposit in physical vapor deposition (1) cannot be successfully employed for chemical vapor deposition (2). However Campbell (3) showed that the supersaturation ratio can be used to predict the growth morphology in CVD systems. A thermodynamic analysis helps in elminating some of the undesirable systems and also in identifying the systems having potential for depositing a required solid. However the thermodynamic possibilities may have to be accepted with reservation on account of the kinetic limitations.

In CVD the deposition rate is either controlled by the chemical reaction rate at the substrate surface or by the mass transport through the gas film. If the chemical reaction rate is assumed to be high, mass transport controls the process. To predict the mass-transport controlled rates, equilibrium composition is to be assumed at the substrate surface. In CVD a number of reactants and products are present and it is difficult to write an overall reaction scheme. In addition, for each reaction scheme written, a new flux value can result. Recently Nolang and Richardson (4) developed a mass transport model for the rate of chemical transport in closed systems assuming equilibrium composition at the surface. These authors used free-energy minimization technique for computing the equilibrium composition. Average diffusivity values were used in their treatment. Their model cannot be directly applied to chemical vapor deposition process.

Chemical vapor deposition of titanium carbide on cemented tungsten carbide tool bits is an established industrial process. Lee and Richman (5) studied the effect of substrate material on the growth morphology of titanium carbide from titanium tetrachloride, toluene, and hydrogen gas mixture. They had collected some kinetic data and showed that mass transport controls the process at temperatures exceeding 1100°C and chemical reaction at lower temperatures.

In the present paper a mass transport model is developed for determining the deposition rate, applicable for all possible CVD systems. This combines the elemental flux balance expressions with generalized equilibrium computation. Moreover, more realistic multicomponent diffusivities are used in the present model in obtaining the rates. Experimental work was carried out to obtain the rates of chemical vapor deposition of titanium carbide from titanium tetrachloride, toluene, and hydrogen gas mixture on cemented tungsten carbide tool bits, using a thermogravimetric assembly. The experimental results are compared with the calculated mass transport controlled rates.

Mass Transport Model

The following assumptions are made in developing the mass-transport model:

[1] Present address: Bharat Heavy Electricals Limited, Materials Science Laboratory, Corporate Research & Development Division, Vikasnagar, Hyderabad — 500593, India.

Key words: mass transport, generalized equilibrium computation, flux balance, titanium carbide.

1. The deposition occurs from a flowing multicomponent gas mixture on a heated substrate.
2. The heterogeneous reaction rate is fast so that reaction attains equilibrium on the substrate surface.
3. No homogeneous reaction occurs within the gas film.
4. Thermal diffusivity is negligible compared to chemical diffusion.

The general expression for the flux of a species i in an n component gaseous mixture is given by (6)

$$N_i = -K_i(X_i^b - X_i^{eq}) + X_i^{av} \sum_{i=1}^{n} N_i \qquad [1]$$

For each species Eq. [1] can be written, but only $(n - 1)$ of them are independent since the flux of nth species can be obtained from the fluxes of other species and the equation

$$\sum X_i = 1 \qquad [2]$$

Equations [1] and [2] cannot be solved to obtain N_i values since X_i^{eq} values are also unknown. X_i^b can be obtained from the input composition.

For the formation of a compound AX_n from elements A and X, we can write

$$A + nX = AX_n$$

equilibrium constant

$$K = \frac{a_{AX_n}}{a_A \cdot a_X{}^n}$$

or

$$a_{AX_n} = e^{-\Delta F/RT} \cdot a_A \cdot a_X{}^n$$

Generalizing this expression for gaseous species and taking

$$a_{AX_n} = X_i^{eq}$$

$$X_i^{eq} = \exp\left(-C_i + \sum_e Y_e a_{ie}{}^g \right) \qquad [3]$$

where $\exp(Y_e)$ is the activity of the eth element in the system and $C_i = \Delta F/RT$

Similarly for solids

$$\exp\left(-C_j + \sum_e Y_e a_{je}{}^s \right) = 1$$

or

$$-C_j + \sum_e Y_e a_{je}{}^s = 0 \qquad [4]$$

By assuming a film model at the deposition site and making an elemental flux balance within the film we can write

$$\sum_{i=1}^{n} a_{ie}{}^g N_i + \sum_{j=1}^{m} a_{je}{}^s r_j = 0 \qquad [5]$$

$$\text{for } e = 1, 2, \ldots NE$$

Now substituting Eq. [1] and [3] in [5] we get

$$\sum_{i=1}^{n-1} a_{ie}{}^g \left[K_i \exp\left(-C_i + \sum Y_e a_{ie}{}^g \right) + X_i^{av} \sum N_i \right] + a_{ne}{}^g N_n + \sum_{j=1}^{m} a_{je}{}^s r_j = \sum_{i=1}^{n} a_{ie}{}^g K_i X_i^b \qquad [6]$$

$$\text{for } e = 1, 2, \ldots NE$$

where N_n is the flux of nth species, whose flux is obtained from the fluxes of rest of the species and Eq. [2].

Now Eq. [1], [2], [4], and [6] can be solved together $(n + m + NE$ number of equations) for the unknowns N_i, r_j, and Y_e.

In most of the CVD processes, hydrogen is the predominant species and the bulk flow term

$$\left[X_i^{av} \sum N_i \right]$$

is insignificant for all other species. By neglecting bulk flow term for all other species except hydrogen, Eq. [6] reduces to

$$\sum_{i=1}^{n-1} a_{ie}{}^g \left[K_i \exp\left(-C_i + \sum_e Y_e a_{ie}{}^g \right) + X_{H_2}{}^{av} \sum_i N_i \right] + a_{ne}{}^g N_n + \sum_{j=1}^{m} a_{je}{}^s r_j = \sum_{i=1}^{n} a_{ie}{}^g \cdot K_i \cdot X_i^b \qquad [7]$$

where hydrogen is the only predominant species, Eq. [6] can also be simplified as

$$\sum_{i=1}^{n-1} a_{ie}{}^g \left[K_i \exp\left(-C_i + \sum_e Y_e a_{ie}{}^g \right) \right] + a_{H_2e}{}^g N_{H_2} + \sum_{j=1}^{m} a_{je}{}^s r_j = \sum_{i=1}^{n} a_{ie}{}^g K_i X_i^b \qquad [8]$$

Eq. [1], [2], [4], and [7] form a set of $(n + m + NE)$ equations with unknowns Y_e, r_j, and N_i. The unknowns Y_e, r_j, and the flux of the nth species N_n can be obtained from a solution of Eq. [2], [4], and [8] forming $(1 + m + NE)$ number of equations. In the latter case, the fluxes of species other than nth species can be obtained from the following equation

$$N_i = -K_i \left[X_i^b - \exp\left(-C_i + \sum_e Y_e a_{ie}{}^g \right) \right] \qquad [9]$$

In this case the number of simultaneous equations to be solved is reduced by $(n - 1)$. The solution to the set of nonlinear equations was arrived at by using the Newton-Raphson method.

The multicomponent diffusivity D_{im} of a species i in the gas mixture depends on the fluxes of all the species (5), as can be seen from Eq. [10]

$$D_{im} = \frac{N_i - X_i \sum_i N_i}{\frac{1}{D_{ij}} (X_j N_i - X_i N_j)} \qquad [10]$$

Since hydrogen is the only predominant species in CVD systems, the binary diffusivity of ith species with hydrogen (D_{iH_2}) gives a good approximation for the multicomponent diffusivity. Hence these diffusivity values were used to get a solution for the set of simultaneous equations [2], [4], and [8]. The fluxes obtained from this solution were used in Eq. [10] to improve the multicomponent diffusivities. The solution procedure is exemplified for TiC deposition in the following sections.

Experimental

Materials.—The hydrogen gas (99.98% purity) was supplied by Indian Oxygen Limited, Bangalore. Titanium tetrachloride (99.99% purity) was supplied by Nuclear Fuel Complex, Hyderabad. The cemented carbide tool bits were supplied by Widia (India) Limited, Bangalore. These inserts were triangular in shape (composition): WC 70%, TiC-7%, Ta(Nb)C-13%, and cobalt 10%).

Apparatus.—A conventional thermogravimetric setup with a quartz spring assembly was used to note the

weight changes during the deposition. The cemented carbide tool bits were suspended using a molybdenum wire from the calibrated quartz spring (sensitivity: 3.48 cm/g maximum load: 5g). The weight changes in the sample were noted at regular intervals of time by means of a cathetometer (accuracy: ±0.01 mm). A calibrated optical pyrometer was used to measure the temperature. The vapors of titanium tetrachloride and toluene were transported to the reaction site by passing hydrogen over the respective liquids kept im-

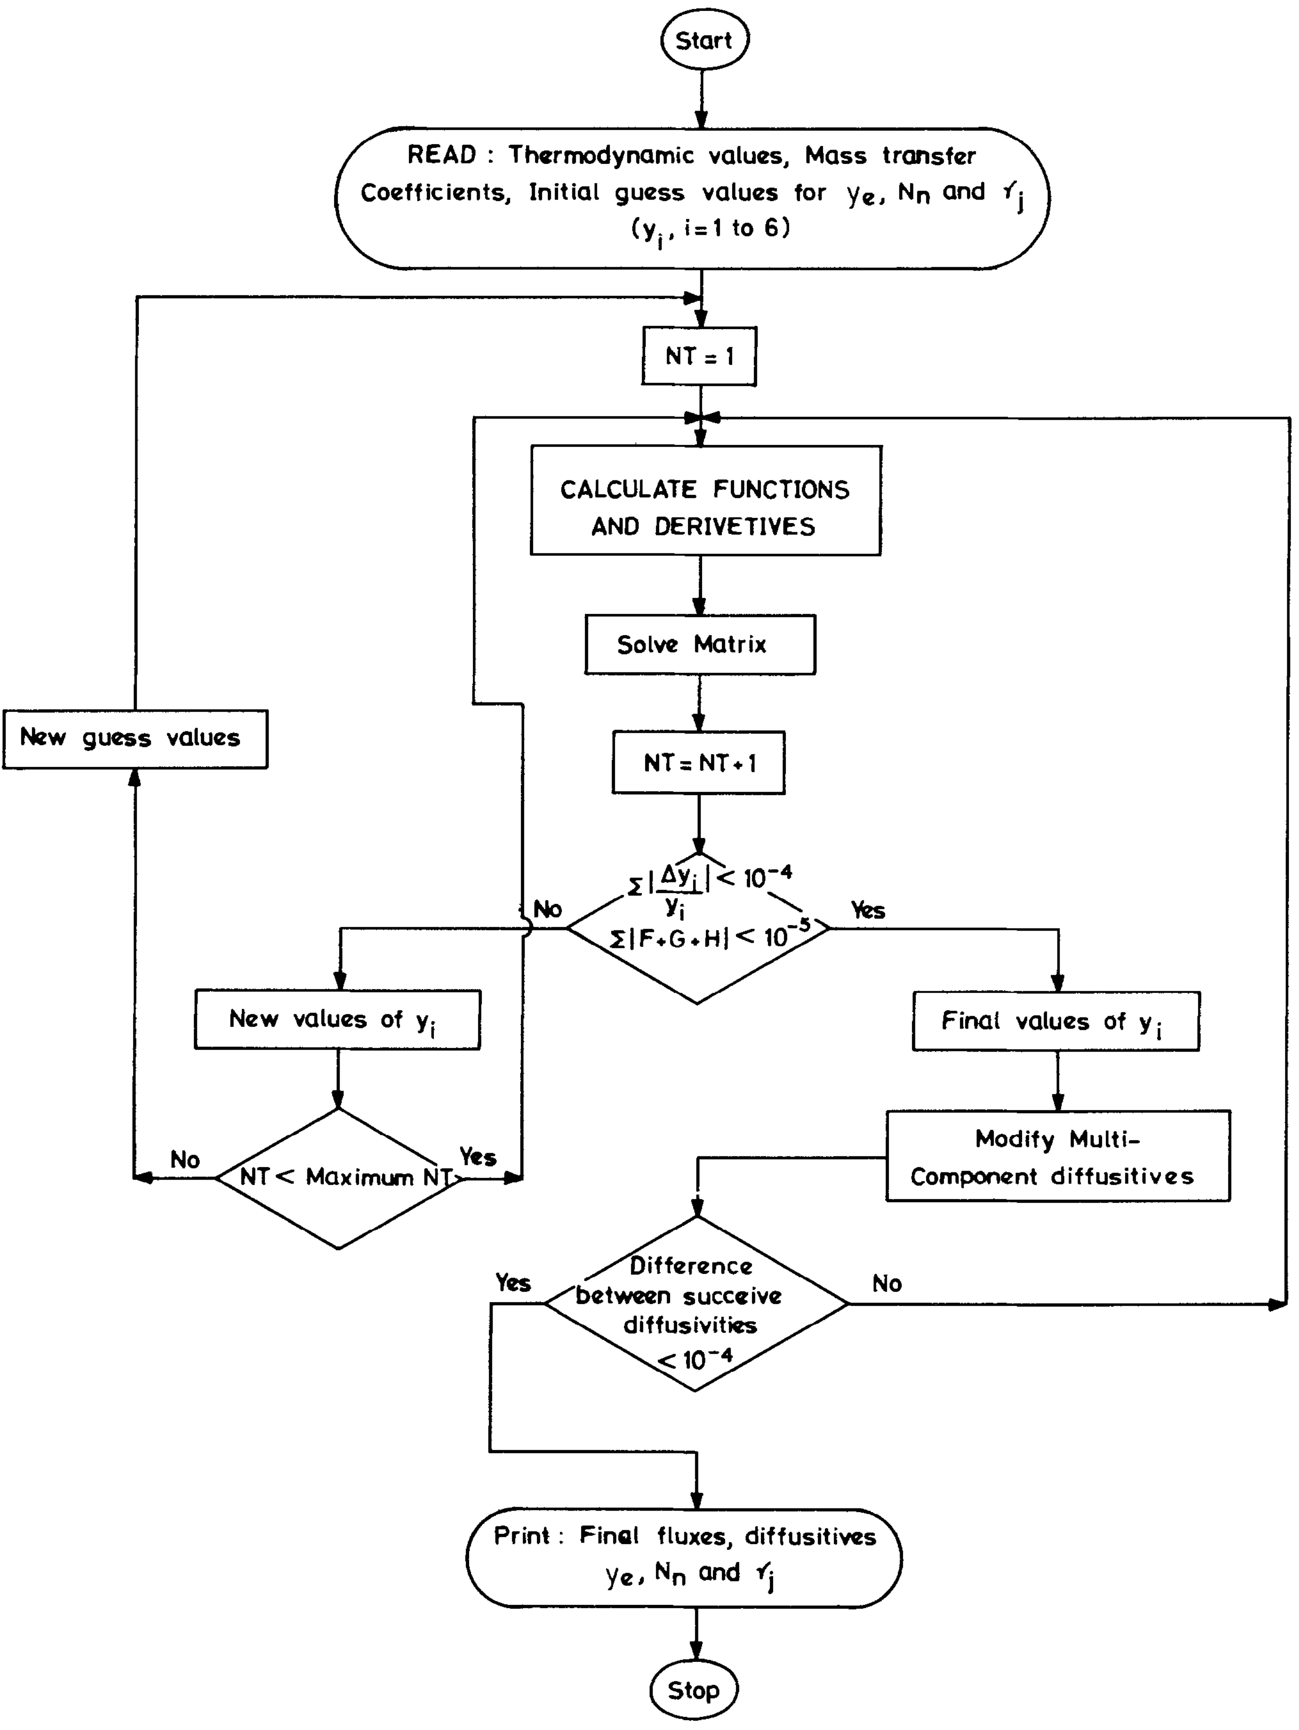

Fig. 1. Flow diagram

mersed in constant temperature baths (controlled to ±1°C). The flow rate of hydrogen was measured using a calibrated flowmeter. The experiments were conducted at atmospheric pressure.

Theoretical Deposition Rates

A thermodynamic analysis of the $TiCl_4$-C_7H_8-H_2 system (7) revealed that only the following gaseous species are present in significant amount at equilibrium: $TiCl_4$, $TiCl_3$, $TiCl_2$, C_3H_4, H_2, and HCl. In addition, toluene was also considered as one of the species in the calculation since toluene was an input gas. The system consists of seven gaseous species and four elements (Ti, C, H, Cl). TiC is the only solid that can be formed in the temperature range considered. For TiC deposition Eq. [8] can be expressed as

$$\sum_{i=1}^{6} a_{ie}{}^{g} \left[K_i \exp \left(-C_i + \sum_{e} Y_e a_{ie}{}^{g} \right) \right] + a_{H2e}{}^{g} \cdot N_{H2} + a_{TiC\,e}{}^{s} \cdot r_{TiC} = \sum_{i=1}^{7} a_{ie}{}^{g} \cdot K_i \cdot X_i{}^{b} \quad [11]$$

$$\text{for } e = 1, 2, 3, 4$$

where r_{TiC} is the rate of deposition of titanium carbide. Equation [11] together with Eq. [2] and [4] forms a set of $4 + 1 + 1 = 6$ equations. The quantities required to solve these equations are the thermodynamic functions, and the mass transfer coefficients. The thermodynamic functions were taken from Barin and Knacke (8). Mass transfer coefficient is given by $K_m = D_{im}/\delta$, where δ is the boundary layer thickness. It was difficult to evaluate the boundary layer thickness for the complex shape of the specimens used, from the available correlations. Hence independent experiments were carried out using naphthalene specimens to evaluate film thickness. These details are presented in the Appendix.

To start the iteration, the multicomponent diffusivity (D_{im}) values were approximated to D_{iH_2} as mentioned earlier and the solution to the set of equations [11], [2], and [4] was obtained. The solution to these equations gives Y values for the four elements, flux of hydrogen, and rate of deposition of titanium carbide, r_{TiC}. The fluxes of all other species were obtained from the Y values using Eq. [9]. These flux values were substituted in Eq. [10] together with the binary diffusivities, to get the improved values of the multicomponent diffusivities. These improved values were used to evaluate the mass transfer coefficient in the next iteration. The binary diffusivities were calculated using Sutherland's formula (6) for all gas pairs except for pairs with $TiCl_3$ and $TiCl_2$. Lennard-Jone's parameters required to use in Sutherland's formula were not available for $TiCl_3$ and $TiCl_2$. Therefore, Gilliland's formula was used to arrive at the binary diffusivities with these species. The scheme of solution is presented in the form of a flow diagram in Fig. 1.

Results and Discussion

Experimental results are shown in Fig. 2-5 as weight increase with time. An error analysis of the experimental data points showed that the standard deviation in the deposition rate is 0.1 mg/min. This deviation in deposition rate corresponds to an error of 15°K in temperature, which can be either due to fluctuation in the temperature of the substrate or due to an error in temperature measurement.

As shown in Fig. 2-5 the deposition rate is independent of time because the area of depositing surface nearly remains constant throughout the experiment. In heterogeneous systems like CVD an incubation period is possible due to difficulties associated with nucleation of deposit. However in the present work no incubation period was observed.

Figures 6 and 7 show Arrhenius plots of the logarithm of the observed deposition rates as a function of re-

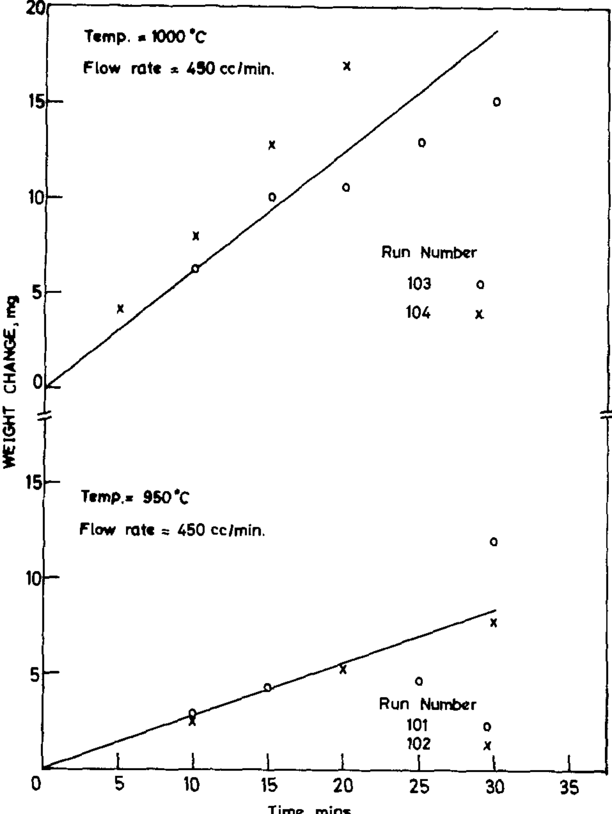

Fig. 2. Weight increase with time at 950° and 1000°C and at the flow rate of 450 cm³/min.

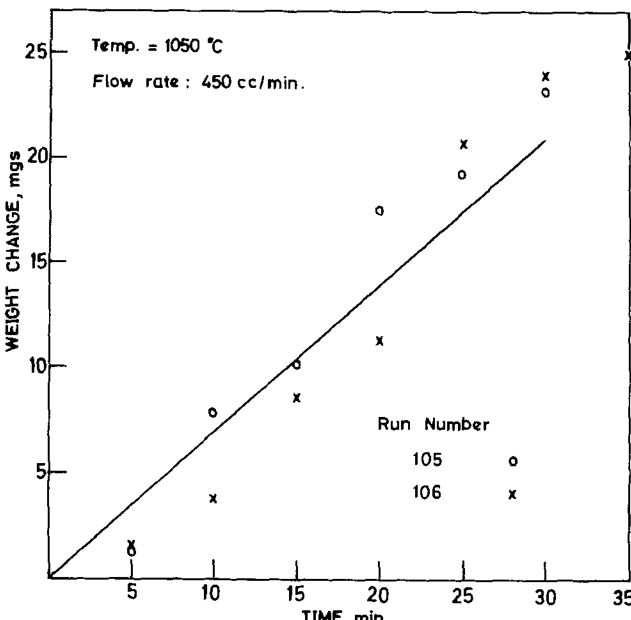

Fig. 3. Weight increase with time at 1050°C and 450 cm³/min

ciprocal temperature at flow rates of 450 and 950 cm³/min, respectively. Diffusion-controlled rates calculated using the mass transport model developed are also presented in Fig. 6 and 7. Assuming a first-order heterogeneous chemical reaction to occur on the substrate surface simultaneously with mass transfer through the film, the overall reaction rate r may be written as (9)

$$\frac{1}{r} = \frac{1}{r_1} + \frac{1}{r_2} \quad [12]$$

where r_1 = mass transport controlled rate and r_2 = chemical reaction rate. Chemical reaction rates (r_2) can be obtained from the experimental values and the cal-

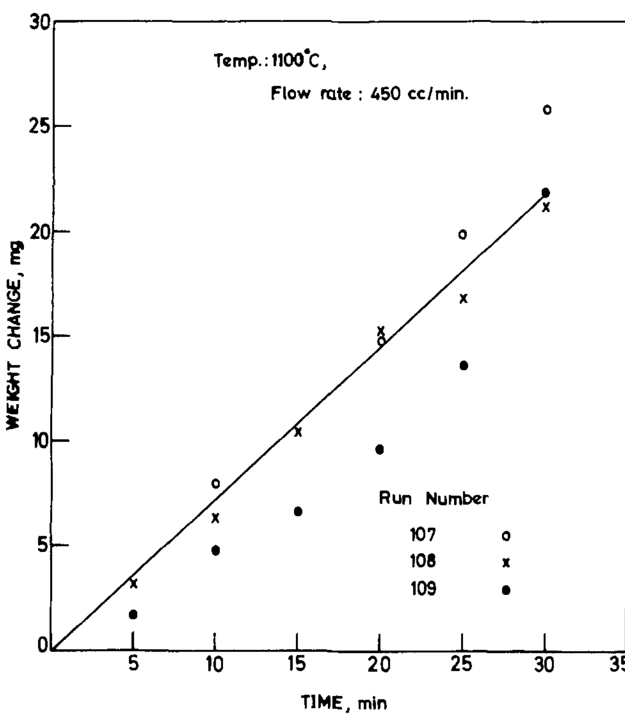

Fig. 4. Weight increase with time at 1100°C and at 450 cm^3/min

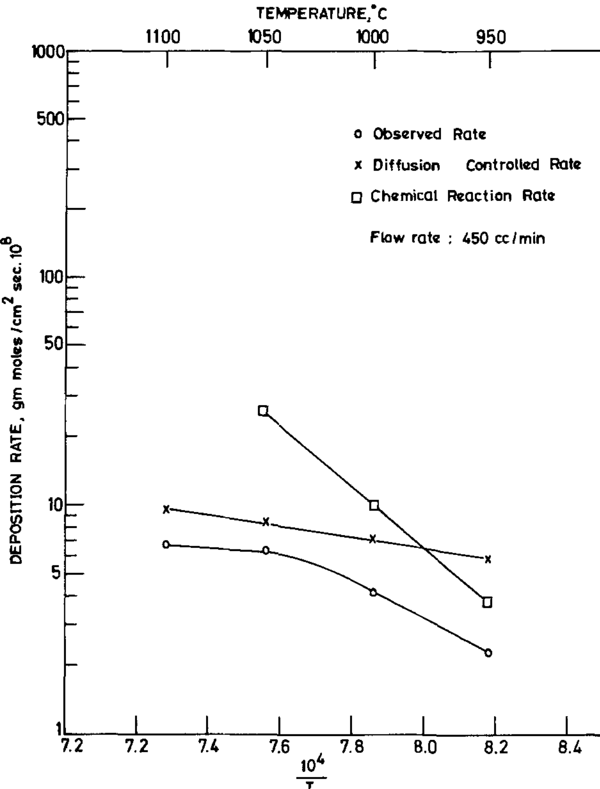

Fig. 6. Comparison of experimental and theoretical results at the flow rate of 450 cm^3/min.

culated mass tranport controlled rates using Eq. [12].

From Fig. 6 it is seen that at high temperatures and at a flow rate of 450 cm^3/min, the deposition rate is controlled by diffusion. It would appear that at lower temperatures both diffusion and chemical reaction are important in controlling the process. At higher flow rate, 950 cm^3/min, as can be seen from Fig. 7, the calculated mass transport controlled rates give an order of magnitude estimates of the observed rates.

It will be noted from Fig. 6 and 7 that the chemical reaction rates are different at the two flow rates 450

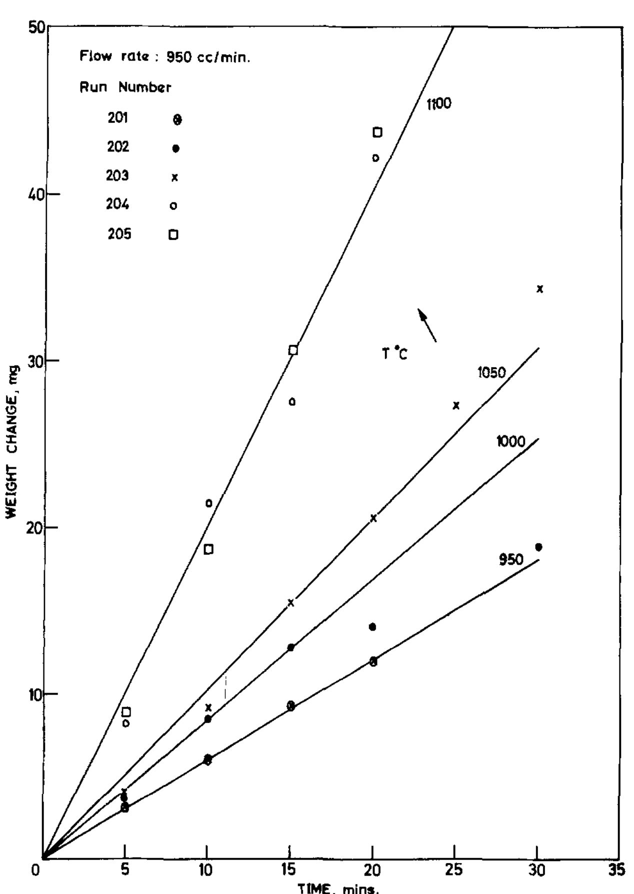

Fig. 5. Weight increase with time at the flow rate of 950 cm^3/min.

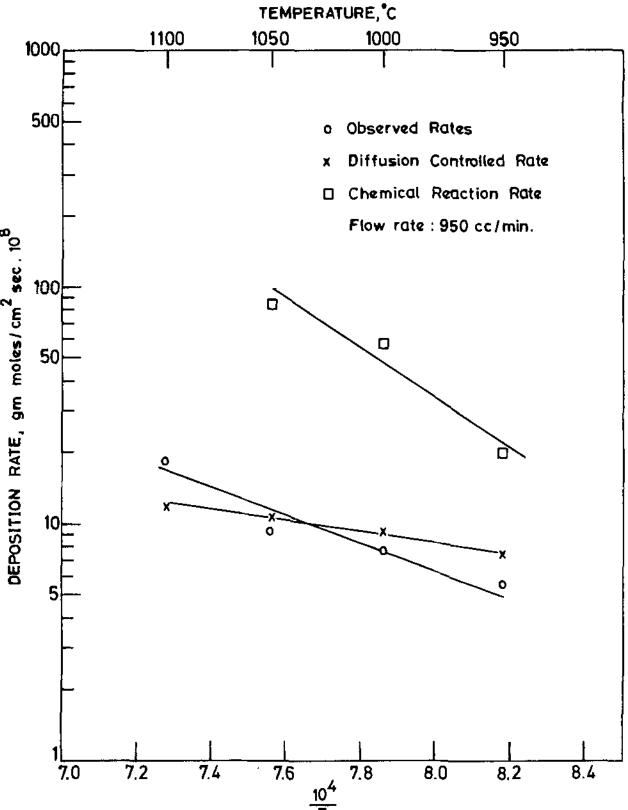

Fig. 7. Comparison of experimental and theoretical results at the flow rate of 950 cm^3/min.

and 950 cm^3/min. This can be attributed to the fact that in arriving at Eq. [12] it is assumed that a first-order chemical reaction occurs simultaneously with mass transfer at the reaction site. If the reaction is not first order such an equation cannot be written. In such a case chemical reaction rate r_2 calculated from Eq. [12] depends on flow rate (7).

Conclusion

A generalized mass transport model has been developed for CVD systems, combining the generalized equilibrium computation with the elemental flux balance expressions. This avoids a number of complications in calculating mass transport controlled rates in multicomponent and multiphase systems encountered in chemical vapor deposition. Kinetic experiments were conducted on the deposition of titanium carbide on cemented tungsten carbide tool bits in the temperature range 950°-1100°C and at two flow rates of hydrogen: 450 and 950 cm^3/min. Theoretical deposition rates, obtained using the mass transport model, compare well with the observed rates.

Manuscript submitted Dec. 1, 1978; revised manuscript received Nov. 15, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1980 JOURNAL. All discussions for the December 1980 Discussion Section should be submitted by Aug. 1, 1980.

APPENDIX

The specimens used for the kinetic experiments were triangular in shape. As it was difficult to obtain mass transfer correlations for such a shape, independent experiments were conducted to evaluate the mass transfer coefficients.

Naphthalene was used as the sample material in these experiments since it has been established (10) that mass transfer is rate controlling in its evaporation. Naphthalene specimens of nearly the same size and shape as that of cemented carbide tool bit were prepared from the commercially available naphthalene balls. The specimen was weighed and placed in the reaction chamber in the same fashion as the original samples. The hydrogen gas was passed at a constant flow rate for a specific time period. Then the flow was stopped and the sample was quickly removed and weighed again. From the weight loss, the flux N_A was calculated. The driving force $(C_A - 0)$ was obtained from the vapor pressure of naphthalene at the temperature of experiments. From the flux and driving force, the mass transfer coefficient and hence δ, the film thickness can be calculated.

Intensity Dependence of Photochemical Reaction Rates for Photoresists

John Albers and Donald B. Novotny

National Bureau of Standards, Electron Devices Division, Washington, D.C. 20234

ABSTRACT

The intensity dependence of photochemical reaction rates, and thus the exposure reciprocity, is investigated in terms of a kinetic model. This model assumes a two-step photochemical reaction and reactions that are first order in the concentrations of each of the various species. The model is applicable to both positive and negative photoresists and is specifically applied to the photoactive species of a typical negative photoresist with the efficiency of the polymer cross-linking assumed constant. The model predicts that there is a saturation effect at high intensities which serves as a rate-limiting step, thus limiting the applicability of exposure reciprocity. Calculations using this model indicate that exposure reciprocity should be obeyed for exposure times of 10 μsec or greater.

Photoresist films are exposed to ultraviolet light to produce images for microelectronic device fabrication. These exposures are generally about 10 sec in duration. While this duration is not particularly long, the possibility of rapid, high intensity exposures to reduce this time to a fraction of a second is appealing from the aspect of increased throughput on a mask aligner or other exposure unit.

A kinetic model is presented in which the photochemical reactions take place through an intermediate, photoexcited state. This model is investigated to assess the effects of the intensity dependence of the reaction kinetics of photochemical reactions. To this end, a system of first-order kinetic equations is postulated to take into account the photon intensity as well as the presence of the intermediate excited state. This system of equations is solved exactly using Laplace transform and matrix techniques and is carried out for a two-step photochemical reaction. Approximate solutions are obtained from the exact solutions using well-defined mathematical approximations. The approximate solutions show a separation of time scales: one associated with the rapid equilibration of the ground and excited states of the photoactive species and the other associated with the formation of the product. An effective rate constant governing the formation of the final reaction product is defined and its dependence upon the photon intensity is investigated. At high photon intensity, there is a photon-induced saturation of the equilibrium between the ground and excited states of the photoactive species. This saturation serves to limit the production of the photolysis product on a pseudo time scale defined by the intensity-time product and thus limit the validity of resist exposure reciprocity.

Kinetic Model

Consider a system of photochemically active molecules whose species is denoted by M. The system is exposed to monochromatic radiation of intensity I which causes a transition from the ground state of M to an excited state denoted by M*. Once in the excited state, the molecule may either return to the ground state or undergo a chemical reaction to form the final reaction product which is denoted by P. The kinetic model which describes the effect of the radiation upon the photochemically active species and the production of the final photolysis product may be represented by

$$\mathrm{M} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \mathrm{M}^* \overset{k_3}{\rightarrow} \mathrm{P} \qquad [1]$$

Key words: exposure, kinetics, photochemistry, photoresist.

where k_1 is the rate constant associated with the excitation of M to M* due to photon absorption, k_2 is the rate constant associated with the decay of the excited state species back to the ground state, and k_3 is the rate constant associated with the chemical reaction in which the final reaction product, P, is formed. In general, the rate constants k_1 and k_2 may be written as

$$k_1 = k_f I \qquad [2]$$

$$k_2 = k_f I + k_s + k_q \qquad [3]$$

where k_f is the Einstein coefficient associated with the induced photon absorption (emission), k_s is the rate constant associated with the spontaneous photon emission (1), k_q is the rate constant referring to all other linear decay modes of the excited state, and I is the photon intensity.

The concentrations of the three molecular species are denoted by M(t), M*(t), and P(t). If the photon energy is large compared to thermal energy ($h\nu/k_BT > 1$), then the initial conditions are

$$\mathrm{M}(0) = \mathrm{M_o} \quad \mathrm{M}^*(0) = \mathrm{P}(0) = 0 \qquad [4]$$

It is convenient to define a set of dimensionless concentrations as

$$m(t) = \frac{\mathrm{M}(t)}{\mathrm{M_o}} \quad m^*(t) = \frac{\mathrm{M}^*(t)}{\mathrm{M_o}} \quad p(t) = \frac{\mathrm{P}(t)}{\mathrm{M_o}} \qquad [5]$$

If the processes involved in the model are first order, then the equations governing the temporal evolution of the dimensionless concentrations may be written as

$$\frac{dm(t)}{dt} = -k_1 m(t) + k_2 m^*(t) \qquad [6a]$$

$$\frac{dm^*(t)}{dt} = k_1 m(t) - (k_2 + k_3) m^*(t) \qquad [6b]$$

$$\frac{dp(t)}{dt} = k_3 m^*(t) \qquad [6c]$$

While systems of coupled linear differential equations of the above form can be solved by using assumed particular solutions and solving the associated secular equations (2), the use of Laplace transforms offers a simpler and more straightforward technique for obtaining the solution. For this reason, salient details of the solution are presented here. Introducing the Laplace transform

$$\hat{f}(s) \equiv \mathcal{L}f(t) \equiv \int_0^\infty e^{-st}f(t)dt \qquad [7]$$

Eq. [6] becomes

$$s\hat{m}(s) - 1 = -k_1\hat{m}(s) + k_2\hat{m}^*(s) \qquad [8a]$$

$$s\hat{m}^*(s) = k_1\hat{m}(s) - (k_2 + k_3)\hat{m}^*(s) \qquad [8b]$$

$$s\hat{p}(s) = k_3\hat{m}^*(s) \qquad [8c]$$

This set of simultaneous equations may be solved to obtain

$$\hat{m}(s) = \frac{s + k_2 + k_3}{(s + K^+)(s + K^-)} \qquad [9a]$$

$$\hat{m}^*(s) = \frac{k_1}{(s + K^+)(s + K^-)} \qquad [9b]$$

$$p(s) = \frac{k_1k_3}{s(s + K^+)(s + K^-)} \qquad [9c]$$

where

$$K^\pm = \frac{L \pm (L^2 - 4M)^{1/2}}{2} \qquad [10]$$

$$L = k_1 + k_2 + k_3 \qquad [11]$$

and

$$M = k_1k_3 \qquad [12]$$

Making use of Laplace transform inversion formula

$$f(t) = \sum_{\text{residues}} e^{st}\hat{f}(s) \qquad [13]$$

where the residues are evaluated at the singularities of $\hat{f}(s)$ leads to the result that

$$m(t) = \frac{Y+1}{2}\exp\left\{-\frac{L+G}{2}t\right\} - \frac{Y-1}{2}\exp\left\{-\frac{L-G}{2}t\right\} \qquad [14a]$$

$$m^*(t) = W\left\{\exp\left\{-\frac{L-G}{2}t\right\} - \exp\left\{-\frac{L+G}{2}t\right\}\right\} \qquad [14b]$$

$$p(t) = 1 + \frac{Z-1}{2}\exp\left\{-\frac{L+G}{2}t\right\} - \frac{Z+1}{2}\exp\left\{-\frac{L-G}{2}t\right\} \qquad [14c]$$

where

$$G = (L^2 - 4M)^{1/2} \qquad [15]$$

$$Y = N/G \qquad [16]$$

$$Z = L/G \qquad [17]$$

$$W = k_1/G \quad \text{and} \qquad [18]$$

$$N = k_1 - k_2 - k_3 \qquad [19]$$

In order to investigate the dependence of the formation of the final photolysis product upon the light intensity, it is convenient to develop approximate solutions from the above exact solutions. This may be achieved by considering the exponential functions in Eq. [14]. It may be shown for all cases of physical interest that $L^2 > 4M$. Then

$$G = (L^2 - 4M)^{1/2} = L\left\{1 - \frac{4M}{L^2}\right\}^{1/2} = L\left\{1 - \frac{1}{2}\frac{4M}{L^2} - \frac{1}{4}\frac{(4M/L^2)^2}{2!} + \ldots\right\} \simeq L - \frac{2M}{L} \qquad [20]$$

where terms of second order and higher have been neglected. Therefore

$$\frac{L+G}{2} \simeq L \qquad [21]$$

and

$$\frac{L-G}{2} \simeq \frac{M}{L} = \frac{k_1k_3}{k_1 + k_2 + k_3} \qquad [22]$$

In a similar manner, the coefficients may be approximated by

$$\frac{Y+1}{2} \simeq \frac{k_1}{L} \qquad [23]$$

$$\frac{Y-1}{2} \simeq -\frac{k_2 + k_3}{L} \qquad [24]$$

$$W \simeq \frac{k_1}{L} \qquad [25]$$

$$\frac{Z-1}{2} = 0 \qquad [26]$$

$$\frac{Z+1}{2} \simeq 1 \qquad [27]$$

Using the above approximations and assuming that there is no quenching of the photoexcited species[1] ($k_q = 0$), the explicit form of k_1 and k_2 given in Eq. [2] and [3], respectively, yields

$$m(t) = \frac{k_fI}{L}\exp(-Lt) + \frac{k_fI + k_s + k_3}{L}\exp(-\gamma It) \qquad [28]$$

$$m^*(t) = \frac{k_fI}{L}\{\exp(-\gamma It) - \exp(-Lt)\} \qquad [29]$$

$$p(t) = 1 - \exp(-\gamma It) \qquad [30]$$

where

$$\gamma = \frac{k_fk_3}{(2k_fI + k_s + k_3)} \qquad [31]$$

There are two time scales associated with the solution. These are: the "fast" time scale which is determined by the time constant $1/L$ which is typically in the regime of 10^{-8} sec for strongly absorbing species such as the photoactive components of photoresists; and the "slow" scale which is determined by the time constant $1/\gamma I$. Physically, the "fast" time scale is associated with the equilibration of the M-M* system in the presence of the radiation field. The "slow" time scale is associated with the decay of the M-M* system into the final reaction product. Once $t > 1/L$, the "fast" time scale exponentials go to zero and then

$$m(t) + m^*(t) = \exp(-\gamma It) \qquad [32]$$

and

$$\frac{m^*(t)}{m(t)} = \frac{k_fI}{(k_fI + k_s + k_3)} \qquad [33]$$

Equation [33] states, on the "slow" time scale, that the ratio $m^*(t)/m(t)$ is time independent and hence

[1] It should be noted that for real processes at room temperature appreciable quenching often occurs, i.e., $k_q \neq 0$. The assumption that $k_q = 0$ is made for the purpose of calculating the minimum intensity at which reciprocity failure can occur and is discussed later in this paper.

has equilibrated. If M* produces P by means of the chemical reaction, then M undergoes a transition to M* to make up the difference and hence maintain the equilibrium. Hence, the M-M* subsystem, in a restricted sense, may be viewed as decaying in a coherent manner to the reaction product on the "slow" time scale.

Reciprocity

Simply stated, the principle of reciprocity maintains that $p(t)$ is a universal function of the exposure $I \cdot t$. That is to say, if $I_1 \cdot t_1 = I_2 \cdot t_2 = \ldots = I_n \cdot t_n$ then

$$p(I_1 \cdot t_1) = p(I_2 \cdot t_2) = \ldots = p(I_n \cdot t_n) \quad [34]$$

and the time dependence of the final reaction product is dictated by the product $I \cdot t$. As $I \cdot t$ is a measure of the total number of photons incident upon the sample during the time, t, the concentration of the photolysis product would, if reciprocity holds, depend only upon this number. This would indicate, as far as the concentration of the final photolysis product is concerned, that long exposures at low intensity are equivalent to short exposures at high intensity.

The important thing to remember is that Eq. [33] shows that for the "slow" time scale reaction, the effect of the intensity dependence of the m*/m equilibrium ratio becomes noticeable in the exposure process when $k_f/(k_s + k_3) \geq 10^{-2}$. At intensities smaller than this, $\gamma \cong k_f k_3/(k_s + k_3)$, $p(t) = p(I \cdot t)$, and reciprocity holds.

The underlying physical reason for reciprocity failure may be found by considering Eq. [33]

$$\frac{m^*(t)}{m(t)} = \frac{k_f I}{(k_f I + k_s + k_3)} \quad [33]$$

and Eq. [6c]

$$\frac{dp(t)}{dt} = k_3 m^*(t) \quad [6c]$$

Equation [6c] states that the rate of production of p may be increased by increasing $m^*(t)$. Equation [33] states that this may be achieved by increasing I at low I. However, if I is made sufficiently large, then $m^*(t)/m(t) = 1$. Increasing I further does not increase the concentration of M* and hence does not increase the rate of production of the final reaction product in a manner dictated by reciprocity. In effect, the M-M* equilibrium saturates at high I. This saturation effect is then the rate-limiting step at high I thus leading to reciprocity failure.

Application to Photoresist

The photokinetic data published by Blais (3) for a negative photoresist are used to estimate the values of the kinetic constants used in this model. An assumption made is that all photons absorbed in the absorption band of the photoactive species of the photoresist are responsible for populating the same electronically excited state from which photolysis to the final product occurs. This assumption should assure a conservative estimate of the high intensity reciprocity limit predicted by this model.

The constant k_s of Eq. [2] corresponds to the Einstein coefficient for spontaneous emission from an excited state and may be calculated by integrating the area under the absorption curve for this state. The value of k_s with the radiation wave number and the resist extinction coefficient in reciprocal length units of μm^{-1} takes the form (4)

$$k_s = 2880 \; \bar{\nu}_o^2 n^2 \int \epsilon d\bar{\nu} \quad [35]$$

where $\bar{\nu}_o$ is the wave number at the maximum of the absorption band, ϵ is the extinction coefficient, and n is the refractive index of the photoresist. A value of 1.5 is used which is representative of the refractive indexes of many photoresists (5, 6). Using the value of $\bar{\nu}_o = 2.82 \; \mu m^{-1}$ which corresponds to the maximum of the extinction coefficient, a value of $k_s = 2.2 \times 10^9 \; sec^{-1}$ was obtained from graphical integration of the data of Blais (3).

The rate constant k_f is calculated from the Einstein coefficient B for stimulated radiation. The probability per second for stimulated transitions over this absorption band is given by $\int \psi_\nu B d\nu = k_f I$ where the integration extends over the entire absorption band. The isotropic energy density ψ_ν at frequency ν is related to the intensity (7) by $\psi_\nu = 4\pi n I_\nu / c$ where I_ν is the spectral power distribution at the exposure plane per unit area per frequency interval at ν. Assuming the intensity to be constant across the adsorption band, which approximates the spectrum of a xenon flash lamp, and using $B = (\lambda^3_o/8\pi n^3 h) k_s$ (8), the following relation is obtained

$$k_f = \lambda_o^3 k_s / [2c^2(1/\lambda_s - 1/\lambda_\iota) n^2 h] = 4.4 \times 10^3 \; cm^2 \; J^{-1} \quad [36]$$

where:

λ_o = band center wavelength, 3.65×10^{-5} cm,

λ_s = short wavelength edge of the adsorption band, 3.05×10^{-5} cm, and

λ_ι = long wavelength edge of the adsorption band, 4.25×10^{-5} cm.

The value of $k_3 = 3.6 \times 10^7 \; sec^{-1}$ is calculated from Eq. [31] and the data of Blais (3) of $\gamma = 70 \; cm^2 \; J^{-1}$.

The high intensity limit for the onset of reciprocity failure is now calculated from the criterion $k_f I/(k_s + k_3) \geq 10^{-2}$. From this, it is found that reciprocity will fail for intensities of $I_f \geq 5 \times 10^3 \; W/cm^2$. Assuming an exposure of 50 mJ/cm² to be typical for complete exposure of photoresist films, I_f corresponds to exposure times of 10 μsec or less for reciprocity failure to occur by this mechanism.

The assumption that no quenching occurs (*i.e.*, $k_q = 0$ in Eq. [3]) made in applying this model to photoresist exposure and photolysis may not be obeyed. Quenching would cause the onset of reciprocity failure to occur at even higher intensities than those calculated. This is because k_q would now appear in the denominator of Eq. [33] reducing the value of $m^*(t)/m(t)$ and requiring larger intensities to satisfy the above criterion for reciprocity failure. Thus, from the values calculated using this model, it appears that this mechanism will not account for any reciprocity failures that may occur in the photolithographic fabrication of microelectronic circuits where the light intensities are generally less than 5 mW/cm² and exposure times are of the order of seconds.

Conclusions

Using a kinetic model, the intensity dependence of photochemical reaction rates has been investigated. At intermediate to high intensities, the equilibration of the ground and excited state concentrations of the photoreactive molecule saturates, thus limiting the production of the photolysis product on the pseudo time scale defined by the $I \cdot t$ product. Exposure reciprocity failures due to this mechanism do not occur in current photolithographic fabrication processes of microelectronic circuits. However, this model does provide a possible explanation of reciprocity failure if observed for very large I and small t.

Spreading Resistance Calibration for Gallium- or Aluminum-Doped Silicon

J. R. Ehrstein*

National Bureau of Standards, Electron Devices Division, Washington, D.C. 20234

Quantitative resistivity or doping density profile analysis by spreading resistance requires several considerations. The use of a sampling volume correction is required to account for the effects of layer nonuniformity on the measurements (1, 2). The use of calibration data accounts for the effects of the metal semiconductor contact interface on the relation between specimen resistivity and measured spreading resistance (3). Calibration response for any set of probes is known to depend on specimen conductivity type, crystallographic orientation, and specimen surface preparation (4). Although it is advisable to choose and prepare calibration specimens in as equivalent a manner as possible to the specimens being profiled, it is common practice to ignore possible effects due to dopant species and to use boron and phosphorus-doped silicon for all calibration work.

This note reports the results of an experimental test of the acceptability of using boron-doped silicon to calibrate spreading resistance measurements of aluminum- or gallium-doped silicon. Specimens of boron-, aluminum-, and gallium-doped Czochralski-grown silicon were obtained with resistivity values appropriate to the use of gallium and aluminum for diffusions in thyristors and other high power devices. The four-probe resistivity values of slices cut from the crystals are given in Table I. Resistivity variations along one diameter of each slice were measured by spreading resistance. In the region measured by the four-point probe, the spreading resistance data indicated that the maximum nonuniformity ranged from 3 to 13% depending upon the specimen.

Subsequent to sawing, all specimens were etched in a DI water solution of KOH (15% by weight) at 100°C for 10 min which removed about 15 μm of silicon from each side of the slices. All slices were mounted for simultaneous polishing to minimize extraneous effects due to differences in surface preparation. Polishing was done with colloidal silica, 3-4 μm nominal particle size, 12% by weight in water, which was brought to pH 10.4-10.6 with ethylene diamene. Polishing was done at a nominal load of 4 psi of specimen surface for 90 min. The polishing removed 25-35 μm of silicon from each of the slices. Following dismounting from the polishing fixture, the slices were degreased using a standard $NH_4OH/H_2O_2/H_2O$ process (5) and then baked at 150°C for 15 min in room ambient prior to measurement, as recommended for stabilizing p-type silicon surfaces following aqueous polishing (6).

A set of 25 spreading resistance measurements was taken over a 2.5 mm scan length near the center of each specimen and the average spreading resistance values calculated. Repeat measurement sets were then made for all specimens at locations adjacent to the original scan but at sufficient distance so as to sample a different portion of the specimen resistivity structure sensed by the four-probe technique. After all specimens had been aged for two weeks and then been freshly baked, a third set of measurements was taken on each specimen. All specimens were then repolished and baked, and a single set of spreading resistance measurements was taken. Two additional sets of measurements were taken on the gallium- and aluminum-doped specimens, one after repolishing and baking, the second within 24 hr of the first. In this manner a range of measurements over specimen nonuniformity, polishing replication, and time between polishing and measurement was obtained.

The spreading resistance data, summarized as the ratios of average spreading resistance to four-probe resistivity values, are shown in Fig. 1 for each measure-

Table I. Four-probe resistivity values of silicon specimens used in test

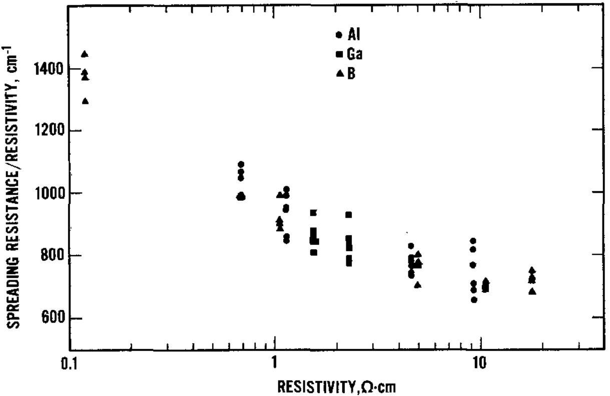

Fig. 1. Spreading resistance normalized to resistivity vs. resistivity for boron-, aluminum-, and gallium-doped (111) silicon.

ment set. This manner of representation gives a good visual magnification of variations due to resistivity or dopant species. Each point at a given resistivity represents the average of a set of spreading resistance measured over the 2.5 mm scan length. The standard deviations of the individual measurement sets ranged from less than 1% to nearly 3.5% of the measurement average. Consequently, the error bars for the sets are generally comparable to, or smaller than, the plot symbol and are not shown in the figure. The overall resistivity dependence of the plotted values is in good agreement with the response typically obtained in this laboratory on an all-boron composite specimen calibration block (4). The scatter between measurement sets for any specimen generally correlates with the magnitude of resistivity variation seen in the radial profiles for that specimen. The scatter is also caused in part by small, but measurable, changes in the response of the probes which occurred during the time span of the experiment. However, it is noted that the highest values measured for all aluminum- and gallium-doped specimens and for all but two boron-doped specimens occurred when the specimens were aged for two weeks and then rebaked before measuring.

Within the limits imposed by the measurement scatter, no difference can be detected between the spreading resistance response of boron-, aluminum-, or gallium-doped specimens. The use of spreading resistance calibration data obtained on boron-doped silicon specimens for interpretation of measurements on aluminum- or gallium-doped silicon appears to be an acceptable procedure.

Characterization of Dicing Process by X-Ray Section Topography

S. Yasuami

Toshiba Corporation, Toshiba Research and Development, Center, Saiwai-ku, Kawasaki 210, Japan

The dicing process usually consists of grooving a wafer with a diamond saw and then separating it by a roller into chips. The first process causes damage on the surface and this damage induces elastic strains in the wafer. Even after separating the wafer into chips, the chips are not free from these lattice distortions. It is often required that these distortions are checked in a fabrication process with nondestructive methods. X-ray diffraction topography (1) is the most suitable technique, because it is highly sensitive to the strain of crystal lattice. Schumaker and Rozgonyi (2), for example, studied the damage due to dicing by Berg-Barrett topography (3) and investigated the effects on quantum efficiency in GaP electroluminescent diode. In this paper, the effects of dicing with different kinds of diamond saw blades were studied by means of x-ray section topography (4) and the connection with the breakdown voltage of the p-n junctions was investigated.

Let us assume the (001) surface of the silicon wafer; the diameter and the thickness were about 76 mm and 395 μm, respectively. For the comparison of the effects of different blades, several lines were drawn on a single wafer using different diamond saw blades. The grooves were drawn along the [110] direction. A fine focused x-ray generator with an Ag target was used at 0.7 kW; the effective focus size was 40 μm square. The technique of taking section topographs was standard except that a fine slit of 10 μm width was used for limiting the width of the incident beam. Topographs were obtained using the 440 Bragg reflection. It took about 3 hr using the ILFORD L4 nuclear emulsion plate.

In Fig. 1, the grooves of (a) and (b) were made by 20 μm thick blades with different sizes of diamond abrasive particles [2-6 μm φ for (a), and 4-8 μm φ for (b)]. The grooves of (c) were drawn by the 40 μm thick blade with the same abrasive particles as that used for (b). Other conditions are listed in the figure caption. In the vicinity of the grooves, black and white intensity contrasts were observed. The resultant surface damage and its associated lattice strain are the causes of these contrasts (5). By observing the dis-

Key words: defects, diodes, stress-strain.

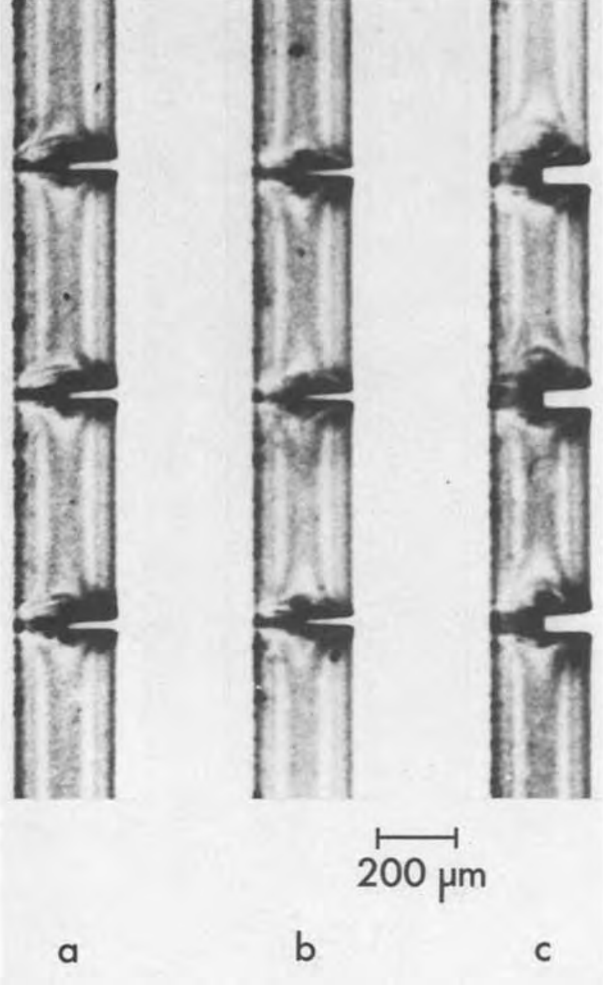

Fig. 1. Section topographs of a (001) silicon wafer grooved by different kinds of diamond saw blades. The thickness of the blades are 20, 20, and 40 μm for (a), (b), and (c), respectively. The abrasive particle sizes are 2-6, 4-8, and 4-8 μm ϕ for (a), (b), and (c), respectively. The common data are as follows: revolution rate of blades: 30,300 rpm, table leading rate: 76 mm/sec, flow rate of water for cooling: 0.5 liter/min, and groove depth: 150 μm. Reflection 440, AgKα radiation.

torted Pendellösung fringes, one can see that the [110] component of strain gradient is extended more than four times of the groove width. Clearly, the strain field is weaker for the thinner blade and/or for the finer abrasive particles. Here, the grooves appear narrower for the coarse abrasive particles, probably because of photographic effects.

Following the grooving process, the wafer was further pressed by a roller and separated into chips. The top of Fig. 2(a) shows the damage after the separation in the case of a groove of Fig. 1 (c). The strain still remained to the same extent as before the separation. The surface damage could be removed within 1 min in the etchant ($HF:CH_3COOH:HNO_3 = 1:2:3$) at 0°C. Figure 2(b) is the section topograph of the same specimen as that shown in Fig. 2(a) after etching. It is interesting that the net amount of etching is about 1 μm whereas the contrasts over 100 μm disappear. This fact is good indication that the lattice distortion induced by dicing in the bulk is purely elastic. The dark contrasts indicated by the arrows are caused by bending due to gravitation.

Often, some electric properties of solid-state devices are changed by the surface damage. A p-n junction was formed by diffusing boron dopants all over the face of an n-type wafer. The thickness of the p-region was about 50 μm. Grooves of about 40 μm in width, and about 160 μm in depth were drawn, and filled with

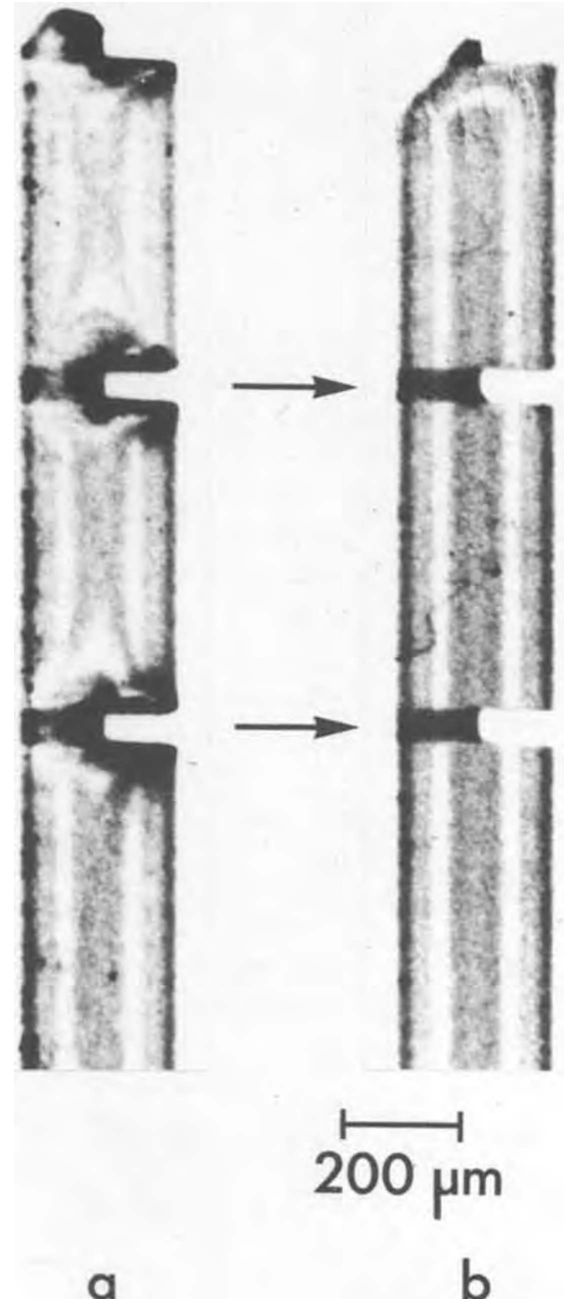

Fig. 2. (a) Section topograph of the wafer after the separation at a groove of Fig. 1(c). See the top part and compare with the grooves. (b) Section topograph after etching. Surface damage due to dicing is removed by slight etching. Reflection 440, AgKα radiation.

glass materials for passivation. At this stage, the breakdown voltage of the p-n junction was extremely low. If, however, the grooves were etched for about 10-60 sec, the breakdown voltage was increased by as much as 1000V. At this stage, section topographs showed that the surface damage was completely removed, although the residual strain as indicated by the arrows in Fig. 2(b) remained in the bulk crystal.

The experiments of this type are useful for the characterization of the crystals after the dicing process and the device designing.

Acknowledgments

Diffusion of Indium in $Hg_{1-x}Cd_xTe$

S. Margalit and Y. Nemirovsky

Department of Electrical Engineering, Technion-Israel Institute of Technology, Haifa, Israel

The semiconductor alloy system $Hg_{1-x}Cd_xTe$ has become the most useful and important material for infrared photon detectors. This alloy is very versatile: it can cover a wide wavelength range in the infrared by altering the mole fraction x of CdTe and is suitable for both photovoltaic and photoconductive detectors. An additional attractive feature of the system is the fact that the processing and technology do not vary appreciably for a wide range of composition x.

It is interesting to note that devices of $Hg_{1-x}Cd_xTe$ have been widely used as practical detectors long before their basic properties have been fully understood. Among the topics that should be further studied are the defect structure and the properties of dopants in $Hg_{1-x}Cd_xTe$.

Indium is commonly used in n-type $Hg_{1-x}Cd_xTe$ devices to form evaporated ohmic contacts. It can also be introduced into the $Hg_{1-x}Cd_xTe$ lattice during growth to control the conductivity of the "as grown" crystals, as has been done in CdTe (2, 3). Johnson and Schmit (4) have found that indium is a metal sublattice substituted donor and a very fast diffuser. During the low temperature annealing cycle of device processing and technology the indium which is present in the contacts diffuses into the lattice. Concentration gradients and consequently built-in electric fields (5) of the order of 10-20 $V \cdot cm^{-1}$ are formed. The distribution and the surface recombination velocity of photoexcited minority carriers are modified by these fields. Precise knowledge of the indium diffusion is therefore needed for the analysis of the photoresponse of the devices.

In view of the practical and theoretical interest in diffusion of indium in $Hg_{1-x}Cd_xTe$, this subject has been investigated and is reported in this note. The study describes the diffusion of indium from evaporated layers of indium into unoriented crystals of $Hg_{1-x}Cd_xTe$ with $x = 0.215$ and $x = 0.29$, in the temperature range of 70°-160°C. The temperature range under study is relevant for the technology of the devices and, in addition, it can be assumed that stoichiometry changes do not take place. Diffusion profiles are given as well as diffusion constants, the diffusion energy of activation, and the surface concentrations.

Experiments were performed on $Hg_{0.785}Cd_{0.215}Te$ and $Hg_{0.71}Cd_{0.29}Te$ with approximately 0.1 and 0.25 eV bandgap at 77°K, respectively. P-type wafers of low carrier concentration (approximately $1 \cdot 10^{15}$ cm^{-3}) and of random orientation were used. The samples were epoxied to a flat sapphire substrate which served as a reference surface and also masked the bottom face of the $Hg_{1-x}Cd_xTe$. The wafers were mechanically polished with 0.3 μm Al_2O_3 until a mirror-like flat surface was achieved. The front surface was then etched for 1-2 sec in 20% bromine in methanol to remove the polishing damage and thoroughly rinsed in methanol to get rid of the bromides. The thickness of the semiconductor was determined within ± 1 μm.

The diffusion process was carried out in two steps: first, a layer of 5000Å of indium was vacuum evaporated on the freshly etched surface of $Hg_{1-x}Cd_xTe$. In the second step the sample was diffused in vacuum.

In order to get reproducible results the samples were brought to room temperature in a manner that was repeatable from run to run. Abrupt quenching was avoided in order to preserve excess minority carrier lifetimes. Finally, the indium was removed in concentrated HCl and after that the properties of the diffused layer were evaluated.

The diffusion profiles were plotted by carrying out van der Pauw measurements (6) at 77°K on the surface, then lapping off a thin layer of typically 1-2 μm, and repeating the process. Petritz's (7) two layer formulation was used to determine the majority carrier concentration and the effective mobility of each lamina. Since the indium is believed to be electrically active substituted on metal lattice sites (4), the profile of electron concentration gives the profile of diffusion.

Typical diffusion profiles which were measured using the method outlined above are shown in Fig. 1. The calculated solid lines are the fit to the measured points, assuming the simplest possible model of a constant diffusion coefficient and an "infinite" source of deposited indium. These assumptions lead to a profile of the form of a complementary error function (5), $C(x) = C_s \operatorname{erfc}[x/2(Dt)^{1/2}]$, where C_s is the surface concentration and D is the diffusion coefficient and their values are determined from the best fit. It is shown in Fig. 1 that as the diffusion time progresses the surface concentration remains constant within the experimental error. It was also observed that the sheet conductance increases with the square of the diffusion time. It is therefore reasonable to assume that in the temperature range under study the simple model may be used. The surface concentration of indium which is obtained is $(3\text{-}6) \times 10^{15}$ cm^{-3}.

The measured sheet conductance as a function of the reciprocal of the diffusion temperature is shown in Fig. 2. The diffused sheet conductance is given by $\sigma = (2q\mu C_s)(D_0 t/\pi)^{1/2} \cdot e^{-E_A/2kT}$ where μ is the average mobility of the diffused layer, E_A is the diffusion energy of activation, and D_0 is the preexponential term of the diffusion coefficient. The data points for $x = 0.215$ are best fitted with the relation $\Delta G_{\square} = 25.7 \cdot e^{-0.37/2kT}$ leading to a diffusion energy of activation of 0.37 eV.

The energy of activation is practically the same for $x = 0.29$. However, the preexponential term of the sheet conductance differs by a factor of 2.7. It is known that the electron mobility at 77°K of bulk $Hg_{1-x}Cd_xTe$ decreases with increasing x (1). For $x = 0.215$ and $x =$

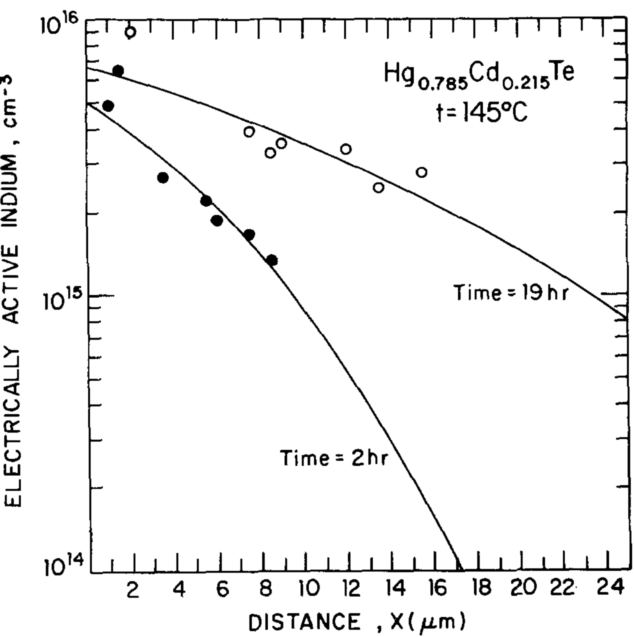

Fig. 1. Concentration profile of the electrically active indium in $Hg_{0.785}Cd_{0.215}Te$ vs. depth. The circles are measured points. The solid lines are calculated distributions assuming a complementary error function. The diffusions were carried out at 145°C for 19 hr and 2 hr for the upper and lower curves, respectively.

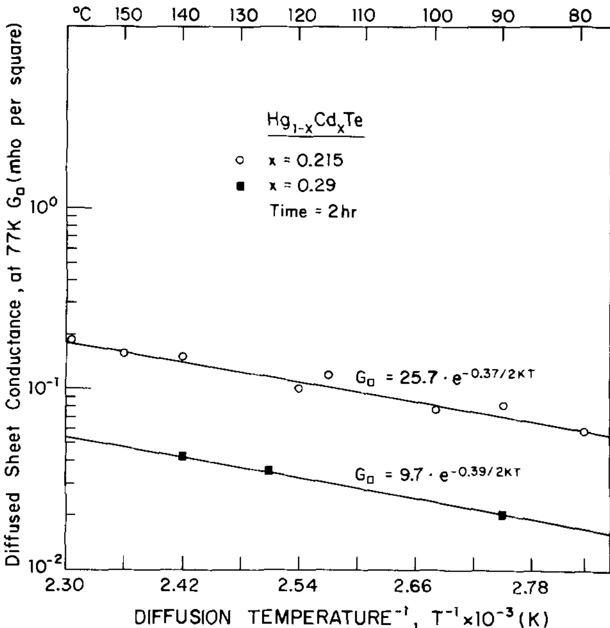

Fig. 2. The diffused sheet conductance measured at 77°K as a function of the reciprocal of the diffusion temperature. The diffusions were carried out for 2 hr. The points are for $Hg_{1-x}Cd_xTe$ with $x = 0.215$. The squares are for $x = 0.29$.

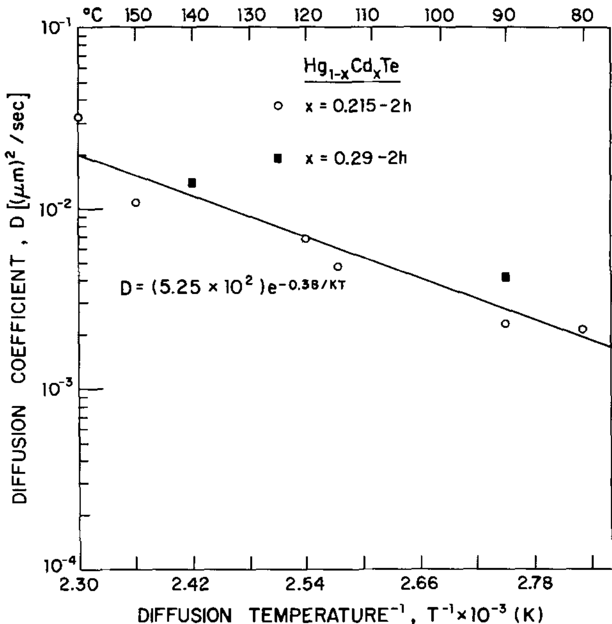

Fig. 3. The diffusion coefficients of indium in $Hg_{1-x}Cd_xTe$ for $x = 0.215$ as a function of the reciprocal of the absolute diffusion temperature. The lines are best fitted to the form $D = D_0 \cdot e^{-E_a/kT}$. The diffusions were carried out for 2 hr.

0.29 the mobility ratio is approximately 2.5. The reduced preexponential term for $x = 0.29$ is therefore due to a lower average mobility and probably to a slightly lower surface concentration.

From the slope of the lines of Fig. 2 and taking $\mu = 1.5 \cdot 10^5\ cm^2 \cdot V^{-1} \cdot sec^{-1}$ and $C_s = 6 \cdot 10^{15}\ cm^{-3}$ the preexponential term of the diffusion coefficient D_0 is obtained: $D_0\ (\mu m^2 \cdot sec^{-1}) = 5.1 \cdot 10^2$.

The measured temperature dependence of the diffusion coefficient is given in Fig. 3. The calculated best fit is $D\ (\mu m)^2/sec = (5.25 \cdot 10^2)e^{-0.38/kT}$. The diffusion energy of activation and the preexponential term of the diffusion coefficient correspond to that of Fig. 2. It should be noted that the data points of Fig. 2 are based on simple and straightforward measurements and are therefore the least susceptible to experimental errors.

It is interesting to note that the activation energy of the diffusion is the same for $x = 0.215$ and $x = 0.29$ and does not depend on the bandgap. $Hg_{1-x}Cd_xTe$ with $x = 0.215$ has a bandgap which varies between 0.215 eV at 100°C and 0.229 eV at 140°C (9). The bandgap of $Hg_{0.71}Cd_{0.29}Te$ varies in the same temperature range between 0.329-0.340 eV. The activation energies of a purely substitutional mechanism of diffusion are three to four times the energy gap of the semiconductors. Such a mechanism would have shown a dependence on the composition x corresponding to the bandgap variation with x. The fact that such a dependence is not observed and the fact that indium is a fast diffuser indicate that indium diffuses through the interstices in the metal sublattice. The mechanism of the diffusion and its dependence on the defect concentration for that particular crystal have not been established.

Indium undergoes a chemical reaction with $Hg_{1-x}Cd_xTe$. The mirror-like surface acquires a gray-matte appearance after the removal of the indium, even without annealing the samples at higher temperatures. The phase diagrams of In and the constituents of $Hg_{1-x}Cd_xTe$ indicate alloying either at room temperature, or in the temperature range under study (8). Since $Hg_{1-x}Cd_xTe$ is easily oxidized, this feature of the diffusion system is very favorable and ensures reproducible results.

The process of diffusion of indium into $Hg_{1-x}Cd_xTe$ forms a distribution of ionized donors near the surface. The ionized donor sites create an electric field which is given by $dv/dx = kT/q \cdot 1/n(dn/dx)$ where n is the local concentration of ions and k is the Boltzmann's constant. For shallow diffusions the resulting surface fields are (10-20) $V \cdot cm^{-1}$ at 77°K. Excess photoexcited minority carriers (holes in an n-type semiconductor) are pushed away from the surface and electrons are attracted there. The surface recombination velocity of excess carriers in n-type samples which were subjected to a shallow indium diffusion is therefore reduced. The measured effective lifetime of holes in n-type samples was shown to increase by approximately a factor of two as a result of such a shallow diffusion.

In summary, the diffusion of indium from evaporated layers of indium into randomly oriented crystals of

$Hg_{1-x}Cd_xTe$ with the composition $x = 0.215$ and $x = 0.29$, in the temperature range of 70°-160°C, has been investigated. For $x = 0.215$ the diffusion sheet conductance at 77°K of the resulting n-type layer in mho per square is $\Delta G_\square = 0.3 \cdot t^{1/2} \cdot e^{-0.37/2kT}$ where t(sec) is the diffusion time and T(°K) is the diffusion temperature. The energies of activation and the diffusion coefficients are the same within the experimental error for $x = 0.215$ and 0.29 and are shown to follow $D[(\mu m)^2/sec] = (5.25 \cdot 10^2) e^{-0.38/kT}$ giving the value of 0.37 ± 0.01 eV for the diffusion energy of activation. The surface concentration of indium is of the order of (3-6) · 10^{15} cm^{-3}. The diffused indium forms built-in fields of the order of 10-20 V · cm^{-1} which reduce the surface recombination velocity of photoexcited excess carriers.

Finally, it should be noted that the experimental conditions under which the results were obtained were intentionally chosen so as to be suitable for device processing and applications.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 126, No. 7, 11, and 12, July, November, and December 1979.

The Strain Distribution of the Interface between Substrate and Epitaxial Layer of Silicon by X-Ray Double Crystal Method

N. Miyamoto and E. Kuroda (pp. 1228-1234, Vol. 126, No. 7)

J. Nishizawa, M. Fukase, and H. Tadano:[1] It seems to us that the paper under discussion was intended to describe the experimental results of strain distributions in the epitaxial crystal silicon layer as the substrate by measuring the lattice constant in the <111> direction using an x-ray double crystal method.[2,3] However, we cannot be convinced of the results for the following two main reasons.[4]

(*i*) Lattice strain varies depending not only on the depth direction but also on the lattice plane parallel to the substrate surface as a function of the position within the sample investigated. But the authors of the paper have not described the irradiating point of the input x-ray beam on the surface of the sample. The radius of the crystal bending, and phenomena, lattice spacing, and the angle of bonding are known to vary with the direction and position of the sample.

(*ii*) There is no logical explanation of their conclusion that the subpeaks appearing in the rocking curve of the highly doped crystal layer epitaxially grown on the high resistivity silicon substrate is phenomenologically the same as Pendellösung fringes. Such fringes can be observed in the x-ray diffraction curve of a thin crystal film as a substrate from which the epitaxial layer is removed. We will examine in some detail the content of the paper under discussion.

Shape of the sample.—Since the elastic constant shows a variation with crystal orientation, the lattice strain exhibits very complicated changes. Therefore, the measurement of lattice strain should be carried with a highly symmetrical sample with respect to crystal orientation. The crystal surface of the sample used in the paper is parallel to the (111) plane. The crystal has three kinds of symmetry with respect to the axis of the <111> direction as shown in our Fig. 1. However, the shape of the sample in the paper is rectangular. In this case, the sides of the sample differ from each other. Sides A and B are {112} planes, and C and D are {110} planes. Therefore there is poor symmetry in the rectangular shape. When the surface of the sample is the (111) plane, it is easiest for the analysis to make the shape of the sample triangular. When the surface is parallel to the (100) plane, it is possible to make the side of the sample equivalent to the (100) plane by making the shape rectangular. Hence, it is easy to measure the lattice strain because the distribution of lattice strain is highly symmetric and the lattice strain does not show any radical change with the direction in the symmetric center. It would be interesting to measure such a sample.[5] We have urged the authors of the paper to carry out measurements at the axis.

Measured point by x-rays.—Lattice strain depends on the position within the sample even if the shape of

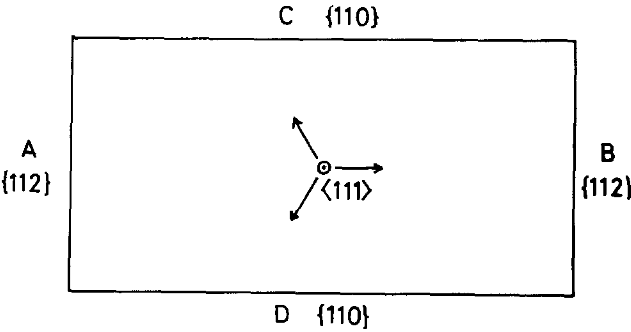

Fig. 1. Shapes of the sample and the symmetric axis of the sample. Arrow indicates the equivalent direction with the <111> direction.

the sample is a triangle. The paper merely introduces the idea which was suggested by one of us concerning the change of lattice spacing in depth direction. But there is no description about the point of x-ray irradiation, though the sample is not symmetric to the axis owing to the nontriangular shape and the complicated distribution of lattice strain. It seems that the authors have not considered the lattice strain in the direction parallel to the interface.

Since the change of the lattice strain in the crystal is interconnected three-dimensionally, it is necessary to measure the strain in the x, y, and z directions in order to determine the lattice strain, especially, when the shape of the sample is not symmetric in terms of crystal orientation. It is possible that the lattice strain in the center direction differs from that in the perpendicular direction including the center of the crystal. For this reason it is necessary to measure the strain in at least two directions.

The atoms in the diamond structure are in tetrahedral coordination. If the length and angle of each bonding are not clear, we cannot state the true lattice strain which is measured. For this reason, it becomes necessary to measure plural lattice planes and to analyze the data multi-dimensionally.

Figure 2 shows a simulation[6] of the change of the lattice spacings by using a two-dimensional simple cubic lattice. The change of the lattice spacing in the epitaxial layer in both directions is small near the symmetric center and becomes larger with the distance from the symmetric center. The degree of the change at the edge is more than ten times that at the symmetric center. Along with this change, the differential strain (the gap between the lower atomic plane and lattice spacing) also becomes larger with the distance from the symmetric center. Therefore the lattice constant in the vertical direction that is obtained from Young's constant or Poisson's ratio also changes widely depending on positions, though

[6] J. Nishizawa *et al.*, To be published.

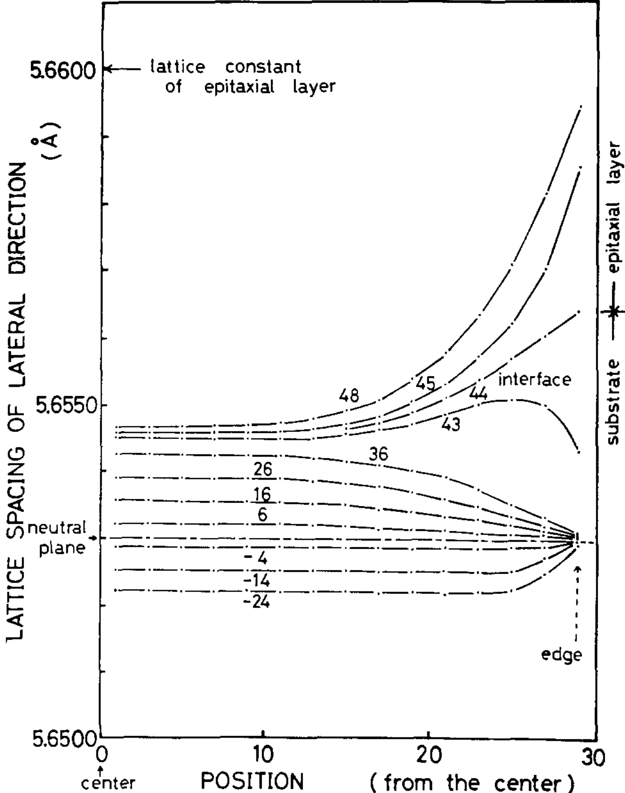

Fig. 2. Lattice spacing distribution in the lateral direction for the growing epitaxial layer made up of the atoms whose atomic radius is somewhat large.

the value is assumed to be constant in our approximate calculation. Figure 2 seems to be well suited to the actual case in spite of the simplicity of the analysis performed.

As described above, it appears that the change in lattice strain cannot be described only in terms of the findings in the depth direction, but the three-dimensional strain distribution should also be taken into consideration.

In a private communication with one of us the authors of the paper stated that the results presented are attained by measuring a crystal in which dislocations are not induced. However, the distribution of strain and stress should depend on position within the crystal. If the dislocation is induced within the sample, strain and stress around the dislocation are decreased (*i.e.*, the distribution of stress and strain around changes). But the distribution of strain and stress within the sample shows a similar distribution between dislocations or dislocation and free edge to the case between free edges where dislocations are not induced.

Curvature radius of the bending.—There is no description about the position of points x_1 and x_2 where Bragg angles θ_1 and θ_2 are measured to represent the bonding. Therefore it is not clear where and which direction is indicated by the value calculated from Eq. [2]. Lattice strain has a three-dimensional distribution as already described.

Moreover, the sample used in the paper has poor symmetry as discussed previously. Therefore the curvature radius of the bending must differ with the direction and point on the crystal surface, and their specific description should be made. For example, a sample grown on a thick substrate produces a large lattice strain especially in the epitaxial layer owing to the difference in lattice constant. Therefore the change in lattice strain with position is large and there should also be a difference in the curvature radius between the epitaxial layer and the substrate.

Even if a sample of the so-called "nonbending crystal" is macroscopically nonbending, it has considerable deformation as viewed from the crystal plane, and it naturally causes the strain which changes as a function of position. A strain in the vertical direction should result. The radius of the bending of the crystallographic plane is not infinite and the radius should also change vertically. Qualitatively there is no difference between the "nonbending" and bending of the crystallographic plane.

Strain distribution in depth direction.—Figure 9 is the sole result of the strain distribution in the paper. It is shown that the lattice strain is not constant near the interface in the range whose order is the same as the thickness of the epitaxial layer. There is a marked difference in curvature radius between the epitaxial layer and the substrate, which means that the lattice strain greatly changes with increasing layer thickness. So, the result shown in Fig. 9 seems to be reasonable. But the authors have given the following explanation by using the idea proposed by one of us: "For high concentration phosphorus-doped epitaxial layers, the lattice constant shrinks, because the covalent radius of phosphorus is smaller than that of silicon. The grown layer at the interface is pulled by the silicon substrate. Therefore, the grown layer expands in the direction parallel to the silicon surface and shrinks in the direction of the thickness. Consequently, the lattice constant distribution at the interface becomes more abrupt compared with isotropically strained samples. The actual distribution of the grown layer is considered to be more abrupt than shown in Fig. 9." But the results of Fig. 8 which constitute the basis of Fig. 9 are measured in the crystal after epitaxial growth and it shows a result of the measurements of the sample whose lattice has already been in the state of strain distribution. Therefore the lattice

strain determined from Fig. 8 is the value after the lattice has been already distorted (*i.e.*, Fig. 9 indicates the strain distribution of the lattice which involves strain to a certain extent). Therefore the authors' explanation about Fig. 9 is inconsistent with the assumption used in solving Fig. 9.

Interpretation of subpeaks.—The authors have shown the correlation between the thickness of the crystal and the period of "Pendellösung fringes" appearing on the diffraction curve of the reflected x-rays by Eq. [5], and stated that a series of the subpeaks observed between the two main peaks is due to the occurrence of Pendellösung fringes among x-rays reflected within the epitaxial layer. This conclusion is based on the fact that the correlation between the interval of neighboring subpeaks and the thickness of the epitaxial layer is analogous to that calculated from the equation. "Pendellösung fringes" appearing on the reflected x-rays are essentially some weak reflections of x-rays which appear across the strong reflection peak at the Bragg angle when the absorption of x-rays can be neglected during the impingement of x-rays on the crystal surface through the bottom. This raises two questions. In the first place, if "Pendellösung fringes" are observed on the rocking curve of x-rays reflected from the epitaxial layer, x-rays reflected at the lattice planes of the internal substrate should be included in the former reflected x-rays, because the substrate made of the same material exists under the epitaxial crystal layer. As one of us has advised the authors, it is very improper to neglect the x-rays reflected from the substrate, even if the lattice constant in the vertical direction changes abruptly at the interface. In effect, the peak of the x-ray rocking curve reflected from the substrate has been observed with the appearance of subpeaks in the immediate vicinity of the peak. The authors have only taken into account the thickness of the epitaxial layer and neglected the effect of the x-rays reflected from the substrate crystal, when the equation of "Pendellösung fringes" is applied. They have considered only the reflections from the epitaxial layer. We cannot understand such an approximation which is not fitted to the real situation. Even if the spacing of the lattice plane that causes reflections changes rapidly at the interface, it is unreasonable to take into account only the x-rays reflected from the epitaxial layer and to neglect the x-rays reflected from the substrate. When a large amount of x-rays are absorbed in the substrate and x-rays do not reach the bottom of the substrate, only a strong main peak appears and "Pendellösung fringes" should not emerge.

In the second place, if Pendellösung fringes appear in the rocking curve of x-rays reflected from the lattice plane of the epitaxial layer, subpeaks must appear at both sides of the main peak. But, judging from the authors' experiment, the subpeaks appear at only one side of the main peak in the rocking curve.

The interference of the x-ray reflected from the substrate and the x-rays reflected from the surface epitaxial layer is most likely to induce the subpeaks. Another possibility is that the deflection angle is distributed and causes a mutual interference due to a gradual change of the atomic surface distance as a function of position.

In conclusion, we would like to point out again here that the content of the paper under discussion is incomplete in the following respects. The distribution of lattice strain is considered solely in terms of the depth direction of the epitaxially grown crystal, though lattice strain has a three-dimensional distribution. We cannot agree with the view that the subpeaks appearing in the rocking curve of the epitaxially grown crystal is phenomenologically the same as Pendellösung fringes observed in the x-ray diffraction curve of a thin crystal film. We hope that the authors of the subject paper will reexamine our comments.

Techniques of Lapping and Staining Ion-Implanted Layers

C. P. Wu, E. C. Douglas, C. W. Mueller, and R. Williams
(pp. 1982-1988, Vol. 126, No. 11)

R. S. Turner and C. L. Aley:[7] The portion of the paper by Wu *et al* describing his research and theory of the staining mechanism using HF H_2O Cu stain seems well executed, and we agree with his conclusions within the framework of his study. However, his examination of junction depths in the article was limited to a few wafers of a very specific type. In addition to the variables that the authors define, there are other considerations that affect staining and subsequent junction depth determination. We have found in the course of measuring several thousand junctions with commercially available staining solutions somewhat similar to the Wu type stain, that some other variables include dopant concentration and type, semiconductor material type, crystal orientation, junction depth range, number of junctions, and their relative positions. We feel that because of the huge number of variables that are present, the Wu process is a good start, yet his conclusions have not necessarily been proven to be applicable to the wide range of staining applications in the industry.

In his paper, Wu goes into great detail explaining the need for, and the advantages of the geometric multiplying effect created by beveling. Although his statements and rationale are correct, he has overlooked a measuring method in wide use in industry and research that employs the same principle to a greater advantage. Happ[8] and McDonald[9] described a method wherein a radial section is machined into the wafer, penetrating the junction (see Fig. 1). After staining, the width of the groove at the surface and at the junction, W_1 and W_2, respectively, in Fig. 2, is measured through a microscope.

Junction depth, X_j, is then calculated per the following equation

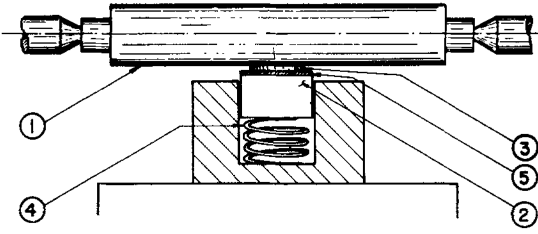

Fig. 1. Grooving apparatus: 1. grooving cylinder; 2. mounting block; 3. silicon slice; 4. spring; 5. glass cover plate.

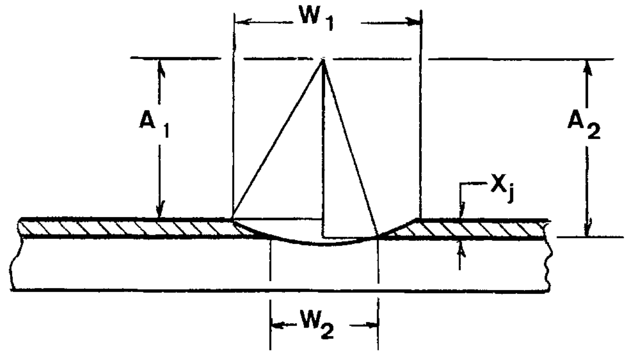

Fig. 2. Groove cross section

$$X_j = A_2 - A_1$$

$$X_j = \sqrt{R^2 - \left(\frac{W_1}{2}\right)^2} - \sqrt{R^2 - \left(\frac{W_2}{2}\right)^2}$$

The multiplying factor increases as the depth decreases, *e.g.*, for the 540Å layer described in the Wu paper, the 50:1 geometric multiplying advantage of the 1° angle lap is credited along with a 1009× microscope as being an important factor in achieving his 200Å repeatability. With a standard sectioning machine employing a groove radius of 19 mm, the multiplying effect is greater than 2000:1 for a junction of that depth, resulting in an equivalent angle of 0.05°. This geometric multiplying factor, when used in conjunction with only a 200× microscope, provides magnification of more than 400,000×. This results in an operator-to-operator repeatability of ±10Å.

Although the grooving method is essentially limited to use on undiced wafer material, and therefore the bevel lap techniques is more suited for individual chip failure analysis, the grooving method offers some distinct advantages other than the greater multiplying effect, such as: (*i*) as Wu correctly emphasized, when using the angle lap technique, laser angle verification is absolutely necessary. This is not required when determining junction depth by measuring penetration of a known radius. (*ii*) Because the groove is exposing the same layer twice (once on each side), the resultant X_j is an average of two separate bevel readings. (*iii*) When considering accuracy of the measuring method, it is generally best to discuss percentage of repeatability: 540 ± 200Å for the angle lap method results in a ±37% potential error; this can be compared to results of studies done using the grooving method on ion-implanted, laser annealed layers of 360 ± 10Å, or operator-to-operator repeatability of ±3%.

C. P. Wu:[10] If the manufacturers of the grooving apparatus for junction depth determination want an opportunity to describe the advantages and accuracies of their method, they should do so by submitting a paper for proper review by referees. Turner and Aley would need much more experimental data and theoretical arguments to substantiate their claim concerning their capability to determine junction depths to ±10Å, roughly two atomic layers.

High Field Intrinsic Ionic Conduction in Solids

Michael J. Dignam (pp. 2188-2195, Vol. 126, No. 12)

Lawrence Young:[11] In considering the alleged possibility of a quite large dependence on film thickness of the field at constant ionic current density under steady-state conditions, Dr. Dignam reproduced some of my data on the anodization of tantalum.[12] I wish to suggest that anyone interested in this point should also look at the extensive data for a range of current densities and temperatures which I gave in the second paper[13] of the series, in which a very precise optical method was used for the thickness. Dr. Dignam (page 2193) refers to the "assumption" that the field was constant. In fact, it was just that the results came out that way. As explained,[13] I had expected a transition from a thin film case (Mott-Cabrera), in which, with a limited space charge density, the film thickness is supposed to be too small to allow a significant total charge to be present, to the bulk or thick film case in which the condition of electroneutrality would determine the carrier concentration.

On page 2188 Dr. Dignam refers to the quadratic field term in the ionic transport equation "which was first demonstrated experimentally" by Young. He quotes the paper on steady-state data.[13] However, on a defect model the field dependence of both the defect concentration and the drift velocity affect the current under steady-state conditions. In a later paper[14] I used a stepped field method, which, as Vermilyea had pointed out, should give direct information on ionic velocity at constant defect concentration. In this connection there is also a question of the significance of the quadratic field terms. I invented this term for the steady-state case as the most natural way of describing my experimental results. What I found experimentally was that log J was not quite linear in E for steady-state conditions in dilute sulfuric acid. Also, $\partial \log J/\partial E$ was almost independent of temperature if calculated for a constant current but showed the expected temperature dependence if calculated for constant field. The curvature of log J *vs.* E plots was much more pronounced for film made in more concentrated sulfuric acid. I considered a range of explanations in this paper.[13] In the stepped field experiments[14] I found (Fig. 5) that $\partial \log J/\partial E$ was to a first approximation linear in the initial (steady-state) field and had the expected temperature dependence if calculated for a fixed initial field. Although I did not find or establish (Fig. 4) the required curvature of plots of log J *vs.* E for stepped fields, the nonlinear dependence on field of the activation energy for ionic transport was proposed as "the simplest suggestion" to explain the results. This dependence of activation energy on field is the basis of Dr. Dignam's and others' models. Quite different possibilities exist and Dr. Dell'Oca and I[15] proposed an explanation of the steady-state curvature of log J *vs.* E plots in terms of the two layer model of these films which is indicated by tracer and ellipsometry experiments. Mr. D. J. Smith is presently reinvestigating the kinetics of ionic conduction in these films.

On page 2189, Dr. Dignam refers to "equations proposed by Young" in which conducting species are generated "at a rate proportional to JnE". The interested reader will not find such equations in the two references which Dr. Dignam quotes[14,16] but should instead consult two much more recent papers.[17,18]

M. J. Dignam:[19] In response to the comments by Dr. Young on the above paper, I am grateful for these for partly redressing any negligence on my part for not fully documenting the many important contributions Dr. Young has made to the entire field of anodic films. I particularly regret the omission of his references 17 and 18.

Otherwise, I can find only one matter of disagreement arising between us in relation to this article, and that relates to whether or not there exist data of sufficient precision to rule out a dependence of field strength on film thickness (for thin films at constant current density and temperature) which for Ta_2O_5 would be of the order of a 7% decrease in field per factor of 10 increase in film thickness. Dr. Young apparently believes his data do rule out such a dependence while I am not convinced. The purpose of the paper, however, was not to contest this matter, but rather to examine certain consequences of the high field conduction model proposed by Bean, Fisher, and Vermilyea,[20] that had not been previously examined. Whether or not the behavior of anodically formed Ta_2O_5 is or is not in accord with a particular equation arising from this analysis is a matter of some interest, but is not the central issue in the paper. To make intelligent choices between alternative mechanisms, the full consequences of these mechanisms must be known. This paper makes a contribution in this direction.

Effects of Chloride Ion Impurities on the High Voltage Barrier Anodization of Aluminum

D. J. Sharp and J. K. G. Panitz

Sandia Laboratories, Albuquerque, New Mexico 87185

INTRODUCTION

Anodic oxide films grown on aluminum are divided into two categories: 1) thick, porous films generally applicable for dye adsorption, and 2) high dielectric-strength barrier films for capacitor device application. It has long been recognized that the specific dielectric strength of anodic barrier oxides depends critically on the purity of the aluminum and the anodization bath. Halides (especially chlorides) at concentrations in the range of parts per million have been reported to greatly increase the defects in anodic oxide films (1).

This work reports the use of constant current anodization curves using 99.99% purity aluminum specimens for evaluating bath purity and the effects of chloride ion contaminants as low as 50 parts per billion.

EXPERIMENTAL

The anodization bath used in this study consisted of 0.23 gms. of ammonium tartrate, 47 ml. of deionized water and 2000 ml. of spectroscopic grade ethyl alcohol. The solution was made by first dissolving the ammonium tartrate in water and then adding ethyl alcohol. Unannealed high purity aluminum wire (99.99%) of 0.5 mm diameter was cleaned in 2.0 normal NaOH and rinsed in deionized water immediately prior to use. The anodization cell consisted of a 350 ml. bath using a 99.99% pure gold cathode. Anodization was performed at room temperature (23°C) using an anodic current density of 1.0 mA/cm^{2}. The constant current curves illustrated in Figure 1 show the effect of increasing amounts of chloride ion (from HCl) on the rate of rise of anodic potential.

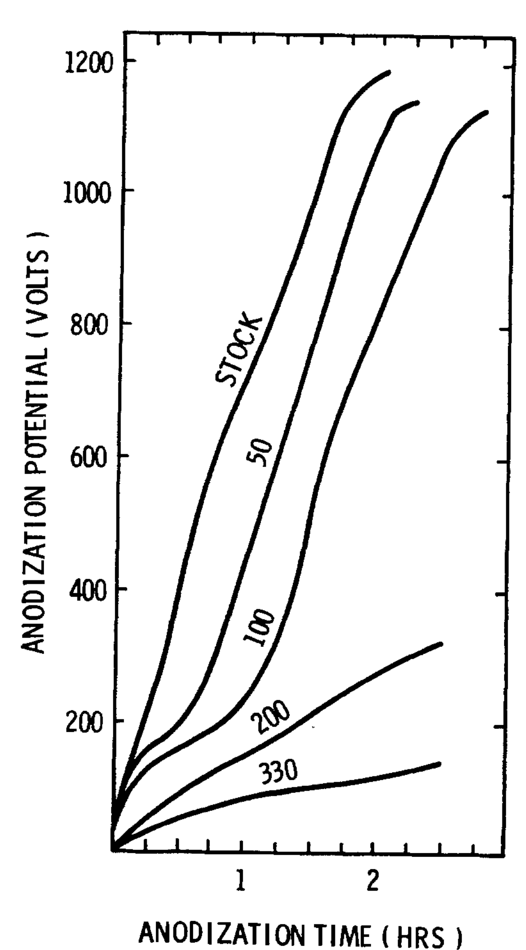

Fig. 1. Constant current anodization curves illustrate the effect of trace amounts of chloride contamination in parts per billion.

Chloride ion was introduced by aliquot dilutions of the original stock solution and added to the working bath so as to produce concentrations of 50, 100, 200, and 330 parts per billion respectively.

DISCUSSION

The first measured effect of chloride additions was noted at a concentration of 50 parts per billion, as an inflection in the rate of voltage rise. Scintillation of the aluminum wire sample was also observed at this point. At chloride ion concentrations above 100 parts per billion the potential did not rise above 400 volts, during the period of anodization (2-1/2 hrs.).

Normally during the anodization process, hydroxyl ions dissociate at the anode to produce oxygen and hydrogen ions. Chloride ions may compete with oxygen to form soluble aluminum compounds, such as $AlCl_3$, forming heavily defected dielectrics rather than the insoluble Al_2O_3 barrier films.

Low power microscopic examination of the samples (Figure 2) clearly revealed increasing degradation in the form of flaking and formation of poorly adherent oxide film.

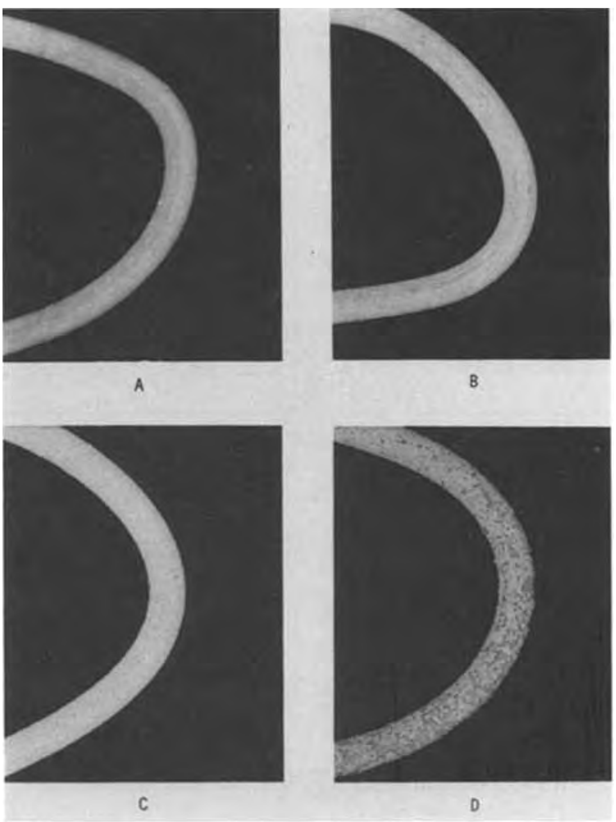

Fig. 2. Magnified view of aluminum wire samples showing degradation of oxide quality as a function of increasing chloride ion concentration. (A = 50 ppb, B = 100 ppb, C = 200 ppb, C = 330 ppb).

SUMMARY

The use of high purity aluminum wire samples to evaluate the effect of impurity concentrations of chloride ion, as low as 50 parts per billion, was used to provide a useful technique for trouble shooting or certifying an anodization bath. Contaminants at these low levels are easily introduced by careless handling and inadequate specification of materials used in conjunction with barrier layer anodization for capacitor applications.

Phosphosilicate Glass Bridge Structures*

A. Naumaan** and J. T. Boyd

Solid State Electronics Laboratory, Department of Electrical and Computer Engineering, University of Cincinnati, Cincinnati, Ohio 45221

We report herein the formation of phosphosilicate glass (PSG) bridge structures which span across V-grooves formed in silicon by anisotropic etching. These bridge structures consist of a PSG layer which has been deposited by chemical vapor deposition and then shaped by surface tension during heat treatment (1). Open space is clearly apparent beneath these bridge structures. The bridge structure has been observed to span V-grooves notches over lengths of 25 mm. Formation of the bridge structures has occurred on a number of samples for several different preparation conditions.

Experimental.--The standard techniques of photolithographic definition and anisotropic etching (2,3) were used to form V-grooves (having surface dimensions of 247.45μm x 25.4mm) in {100} oriented silicon wafers. The resulting grooves were then about 175μm deep. Following groove formation a .75μm thick layer of SiO_2 was thermally-grown on the wafer surface. PSG layers of 12μm or 22μm were then deposited by chemical vapor deposition at 400°C. Conditions for deposition were selected by considering published data (4-6). The deposited layers contained 10m% P_2O_5. Finally, the wafers were annealed for periods of either 60 or 120 mins. at 1100°C. Ambients during anneal consisted of either dry O_2, or O_2 or N_2 bubbled through 95°C deionized water. After annealing samples were cleaved perpendicular to the groove axis and the cleaved cross sections were observed in a scanning electron microscope (SEM). Photomicrographs of the samples were taken and used to obtain measurements of the structures under examination.

Results and Discussion.--We have observed that for some samples surface tension during PSG flow resulted in the formation of bridges which span across the V-groove about 15μm away from the apex of the groove from one sidewall to the other sidewall leaving empty space below. One such bridge structure is apparent in the SEM picture in Fig. 1. Since all samples exhibited considerable flow of the PSG layers, we conclude that bridge formation results for a restricted set of flow conditions. The fact that bridge formation did not occur for all samples is believed to be due to local variations in phosphorous concentration. Wafers were loaded vertically in the annealing furnace with groove axes parallel to the horizontal plane. The profile of the bridges is a function of the viscosity of the flowing PSG, surface tension and gravitational drag. In structures such as that shown in Fig. 1, surface tension has dominated gravitational drag whereas the converse is true in the case of the structure shown in Fig. 2. Fig. 3 illustrates the open space between a PSG bridge and the V-groove from a different angle. The lack of any supporting material between the bridge and the V-groove is clearly evident in this SEM photograph.

Thickness of the bridges at their thinnest point ranged from 3.4μm to 7.5μm. The length, considered to be the shortest distance between end points of the bridge side facing the groove apex, was in the range 10.1μm to 42.6μm. Length to thickness ratios varied from 1.7 to 7.8. Grooves containing the bridge structure were about 25mm long. They exhibited a smooth, continuous PSG layer surface under the microscope. Upon cleavage into samples 5mm or longer, the bridge structure was observed at both ends. This leads us to believe that the bridge extends along the full length of the groove. Radii of curvature of the bridge surfaces ranged from 10.4μm to 37.2μm.

Summary.--PSG layers were deposited

which flowed in response to high temperature annealing in such a way as to form bridge structures which span V-grooves etched in silicon. Formation by flow is supported by SEM observations of bridge profiles. Based on observations of a number of samples, we speculate that the bridge profile is a function of PSG viscosity, surface tension, and gravitational forces. However, further work remains to be done before the bridge forming process is completely characterized.

In Situ Identification of Surface Phases on Lead Electrodes by Laser Raman Spectroscopy

R. Varma,* C. A. Melendres,* and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

INTRODUCTION

There is need for "in-situ" characterization of electrode surfaces to determine the details of processes occuring at electrodes and facilitate the interpretation of current-potential measurements. Laser Raman Scattering appears promising in this application (1). In the work described here, we have used the technique to examine the solid phases formed on lead electrodes during anodic oxidation in sulfuric acid solution. Monitoring of surface phases on lead electrodes during cycling may provide valuable information regarding the factors affecting their cycle life and failure mechanism in lead-acid batteries (2).

Lead foils (0.5 cm x 6 cm x 0.05 cm, 99.999% purity) were anodized in 0.1N H_2SO_4 at constant potentials in a 3-compartment spectroelectrochemical cell using a PAR Model 173D Potentiostat. A Hg/Hg_2SO_4 reference and a platinum counter electrode were used. The laser beam was incident at the working electrode surface at an angle of 60°; the scattered light collected using a 90° illumination-collection optics and analyzed using a Spex Model 1401 double monochromator with photomultiplier tube detection. Coherent Radiation Model 52G Argon and Krypton Lasers were used for optical excitation. Following recording of spectra of the anodic films "in-situ", the electrode was taken out of the cell washed with distilled water, acetone, then dried, and spectra taken again. Samples of various oxides of lead were run as standards for comparison. Film composition was also determined by X-ray diffraction and the morphology examined by scanning electron microscopy (SEM).

Key words: Lead Electrode, In-Situ Raman Spectroscopy

Figure 1a shows the Raman bands observed from scattering off the surface of a lead foil anodized in 0.1 N H_2SO_4 solution at -0.451 V <u>vs.</u> Hg/Hg_2SO_4 for 12 to 72 hrs. Under this condition the electrode is expected to be coated with a layer of $PbSO_4$ (3,4). Raman spectrum of a compressed pellet of reagent grade $PbSO_4$ is shown in Fig. 1b. Excellent correspondence is evident for the bands at 436, 450 and 980 cm^{-1} of the 2 samples. The weaker bands at 1060, 1159, 607 and 641 are understandably not visible for the "in-situ" sample in Fig. 1a due to intensity loss by absorption and diffuse scattering. These bands were, however, also observed when the electrode was examined "ex-situ". X-ray diffraction analysis of the surface coating shows conclusively that the material is $PbSO_4$ with a rhombic crystal habit.

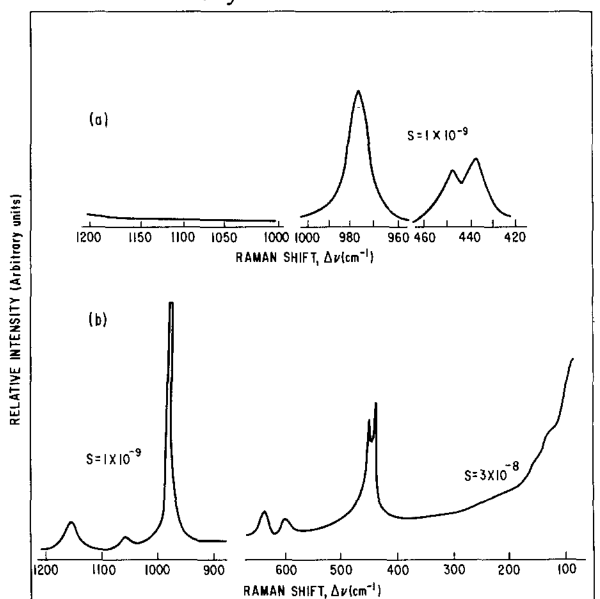

Figure 1. Raman Scattering with Ar^+ Ion Laser, λ= 4879.86 Å (a) In-Situ Spectrum Observed on Lead Electrode Anodized in 0.1N H_2SO_4 at -0.451V <u>vs.</u> Hg/Hg_2SO_4 (b) Spectrum Observed on Compressed Pellet (Commercial Sample) of $PbSO_4$. Laser beam power = 280 mW (s = detector sensitivity setting).

On anodizing a Pb foil at + 1.335 V vs. Hg/Hg_2SO_4 (following initial formation of the $PbSO_4$ film at -0.451 V) the white $PbSO_4$ coating transforms to a greyish black material. Raman scattering from the surface "in-situ" yields the spectrum shown in Fig. 2. with bands at 103, 113, 122, 138 and 286 cm^{-1} occasionally appearing. There also appeared to be an induction period of several minutes following laser irradiation before we would observe a spectrum. From the Pourbaix diagram of Pb in H_2SO_4 (4), one anticipated obtaining a surface coating of β-PbO_2 on the electrode under the present condition of electrolysis. X-ray diffraction analysis of the coating obtained and SEM study showed it to be β-PbO_2. It, however, appeared necessary to see if the lines observed can indeed be assigned to β-PbO_2 in view of previous reports that no infrared (5) and Raman (6) bands have been observed for β-PbO_2. Moreover, application of the selection rules for lattice and molecular vibrations, indicate that only 4 vibrational modes should be Raman active. Standard samples of β-PbO_2 were obtained from the ESB Battery Company and examined "ex-situ". Initial scans of the samples at laser power of less than 175 mW yielded only a very weak band at 150 cm^{-1}. On increasing the laser power to 350 mW, relatively strong bands at 84, 144, 288, 385, 424 and 550 cm^{-1} are observed (Fig. 3).

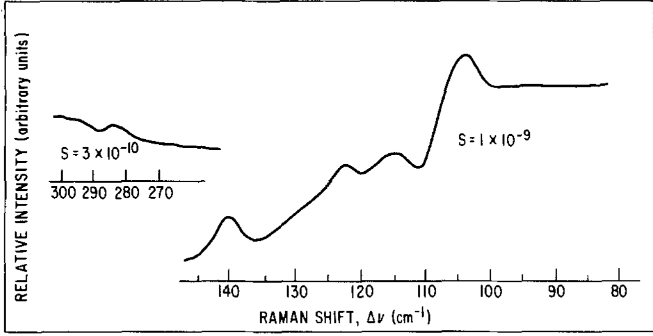

Figure 2. Raman Scattering, Ar^+ Ion Laser, λ= 4879.86 Å, In-Situ Spectrum Observed on Lead Electrode Anodized for 72 hours at +1.335 V vs. Hg/ Hg_2SO_4

Rotation of the sample causes these peaks to either disappear (with reappearance of the 150 cm^{-1} band) or to shift by 2 to 8 cm^{-1} towards lower frequency. At times, on prolonged laser irradiation of the stationary sample, we find the disappearance of the band at 84 cm^{-1} and the appearance of medium weak bands at 80, 92 and 104 cm^{-1}. The band at 134 cm^{-1} also shifts

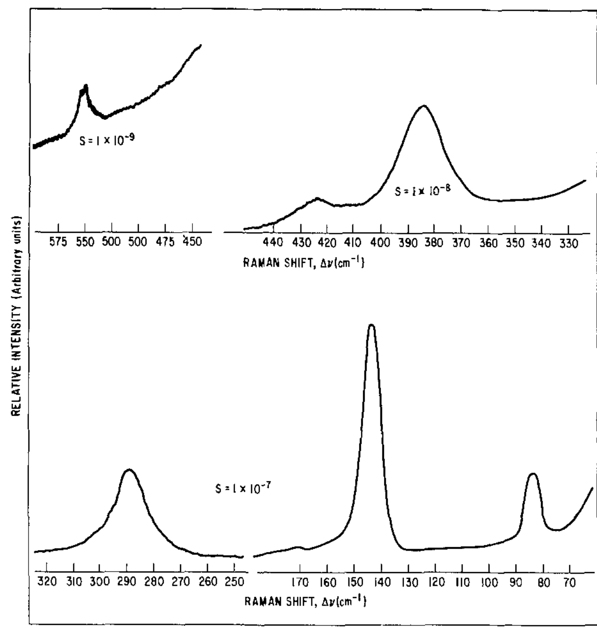

Figure 3. Raman Scattering from β-PbO_2 in KBr Pellet (60 : 40 By Weight), Ar^+ Ion Laser, λ = 5145 Å, Power = 300 mW.

to 140 cm^{-1} with significant loss in intensity. On removal of the sample from the spectrometer, we find peach-colored spots where the laser beam had impinged on the sample. It is evident that Laser irradiation has perturbed the sample significantly causing presumably some phase transformation of the β-PbO_2 to other lead-oxides which give rise to the bands observed. The bands at 92, 144 and 288 cm^{-1} are, within experimental error, the same as found by Reid (7) and Heidersbach et al (6) for PbO. We are at this point, however, unable to assign the other bands. It is evident that the bands found "in-situ" cannot be unequivocably assigned to β-PbO_2. This lends credence to other workers (6) findings that no Raman active bands for this molecule have been observed.

Finally, we have applied the technique for in-situ monitoring of phase transformations on an actual lead-positive battery plate during discharge. A fully charged PbO_2 plate was cathodically potentiostated at -0.451V vs. Hg/ Hg_2SO_4. Bands at 980, 436 and 450 cm^{-1} were observed to grow in intensity as the β-PbO_2 layer was being converted into $PbSO_4$.

In summary, we have found the technique of Raman Spectroscopy to be useful for "in-situ" identification of anodic films on

lead electrodes. Caution must, however, be exercised in the assignment of observed Raman bands to a particular surface composition since laser irradiation of the sample may induce chemical and phase transformation in it. The need for supplementing "in-situ" measurements with "ex-situ" studies is evident.

ACKNOWLEDGMENT

Support of the Division of Energy Storge of the Department of Energy is hereby acknowledged.

One of the authors (CAM) thanks F. A. Cafasso and the Division of Basic Energy Sciences of the Department of Energy for their support.

We are grateful to P. R. Fields, J. Unik and J. Ferraro of the Chemistry Division of Argonne for allowing the use of their Raman Spectrometer. We thank ESB Co. for providing standard samples of β-PbO_2.

Primary Li/$SOCl_2$ Cells

XI. $SOCl_2$ Reduction Mechanism in a Supporting Electrolyte

W. L. Bowden* and A. N. Dey*

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The electrochemical reduction of $SOCl_2$ has been investigated in organic solvents with supporting electrolytes, using cyclic voltammetry, coulometry, and UV-VIS spectroscopy. An overall 2.0F reduction was observed. Comparison of voltammograms of SO_2, S, and S_2Cl_2 with those of reduced $SOCl_2$ solutions demonstrated that intermediate species are formed in the reduction of $SOCl_2$. These intermediates decompose slowly to form S and SO_2. Reaction mechanisms consistent with these findings are discussed.

The Li/$SOCl_2$ inorganic electrolyte cell is the highest energy density system known to date (1-4). It consists of a lithium anode, a carbon cathode, and thionyl chloride, which functions both as solvent and cathode active material. While this system has been subject to intense development, there exist questions with regard to cell chemistry and cell safety. The cell stoichiometry [1] suggested originally by Dey and Schlaikjer (4) is the most generally accepted one. The reaction involves the formation of sulfur and sulfur dioxide in equimolar amounts, and the quantitative precipitation of LiCl (13) based on 2 F/mole of $SOCl_2$

$$2SOCl_2 + 4Li \rightarrow S + SO_2 + 4LiCl \quad [1]$$

Other formulations which include S_2Cl_2, SCl_2, $Li_2S_2O_4$, and Li_2SO_3 have also been proposed. These (1, 2, 5, 6) proposed reduction processes are accompanied by stoichiometries ranging from 2 F/mole to 2.67 F/mole $SOCl_2$.

Calorimetric (7) and DTA studies (8, 9) of Li/$SOCl_2$ D cells showed that chemical reactions occur, which liberate heat after the discharge of the cell. Since these reactions do not occur in an undischarged cell, it is reasonable to assume that the reduction of $SOCl_2$ is responsible, at least in part, for these spontaneous exothermic reactions. The reported spontaneous explosions of partially discharged Li/$SOCl_2$ cells on casual storage may also be initiated by reactions involving $SOCl_2$ reduction intermediates. Thus, knowledge regarding the nature of the unstable intermediates of $SOCl_2$ reduction may be useful as a guide for the improvement of the safety of the Li/$SOCl_2$ cells. We postulated (10, 11) the initial overall cell reaction to be

$$SOCl_2 + 2Li \rightarrow SO + 2LiCl \quad [2]$$

where SO may dimerize and then decompose to S and SO_2 or form polymers. Although there is substantial evidence (12, 13) in favor of cell stoichiometry [1] and the quantitative formation of LiCl and qualitative formation of S and SO_2, little is known regarding the intermediates formed during the discharge of $SOCl_2$.

* Electrochemical Society Active Member.

Key words: cathode, voltammetry, spectroscopy.

Attempts to use cyclic voltammetry (6, 14, 15) in neat $SOCl_2$-$LiAlCl_4$ solutions to study the discharge reaction were complicated by electrode passivation due to the precipitation of LiCl which is insoluble in $SOCl_2$. We have circumvented this electrode passivation problem by using a supporting electrolyte consisting of tetrabutylammonium hexafluorophosphate ($N(C_4H_9)_4PF_6$) ($TBAPF_6$) in organic solvents such as dimethyl formamide (DMF), methylene chloride, dimethylsulfoxide (DMSO), and acetonitrile (AN) for studying the $SOCl_2$ reduction. The electrode passivation was absent in the above solutions since both tetrabutylammonium chloride and S are soluble in the above solvents. We carried out cyclic voltammetry, coulometry, and UV-VIS spectroscopy in the above electrolytes. The results are reported here.

Experimental

Electrochemical experiments were performed using a PAR 173 potentiostat and PAR 175 function generator with associated ancillary equipment. Data were collected using conventional X-Y and strip chart recorders. Platinum working electrodes were pretreated by chromic acid followed by a wash with distilled water and air drying. Experimental solutions were routinely degassed with argon before the substrates were added. A silver chloride coated silver wire was used as a reference electrode. This electrode has a potential of 3.30V *vs.* Li in PF_6^--DMF solutions.

Experiments were performed in cells of conventional design. Coulometric experiments were carried out in a two compartment H-cell using a glass frit to prevent passage of material from the working and auxiliary electrode compartments.

Organic solvents were either Burdick and Jackson "Distilled in Glass" DMF, CH_2Cl_2, and DMSO or Eastman Spectro Grade acetonitrile. Supporting electrolyte was prepared by metathesis of tetrabutylammonium chloride and lithium hexafluorophosphate in acetone/water and purified by multiple recrystallizations from hot ethanol.

Results

The electrochemical characteristics of some of the impurities and proposed reduction products of $SOCl_2$

were examined by cyclic voltammetry in the organic supporting electrolyte solutions. In particular, sulfur, sulfur monochloride, and sulfur dioxide are materials of interest, while chloride ion is known (13) to be a reduction product.

Chloride.—A cyclic voltammogram on a Pt electrode in $TBAPF_6$/AN is shown in Fig. 1 which demonstrates the clean background. A suitable chloride source was found in tetramethylammonium chloride ($N(CH_3)_4Cl$; TMACl) which is both soluble and ionized in acetonitrile solution. A cyclic voltammogram obtained with a platinum wire electrode of a solution of TMACl and $TBAPF_6$ in AN is shown in Fig. 2. The oxidation of free chloride to chlorine and the associated reduction to chloride are clearly located about 1.1V positive of the reference potential.

Sulfur dioxide.—The electrochemical reduction of sulfur dioxide is itself of practical importance and reasonably stable solutions of sulfur dioxide in organic solvents are easily obtained. The reduction of SO_2 in DMF, acetonitrile, and methylene chloride has been examined. In acetonitrile, SO_2 is reduced in a diffusion controlled process at $E_{1/2} = -1.15V$ *vs.* the silver reference as shown in Fig. 3. The oxidation wave with E_p near +0.35V is much diminished at lower sweep rates and represents the oxidation of a product of the SO_2 reduction, *viz.* $S_2O_4^{2-}$ according to the reactions

$$SO_2 + e \rightarrow SO_2^- \quad [3]$$

$$2(SO_2)^- \rightarrow S_2O_4^{2-} \quad [4]$$

Even at the relatively high sweep rate of 1 V/sec there is little evidence for any other oxidation peaks corresponding to the oxidation of species such as SO_2^-. A similar voltammogram of SO_2 in dimethylformamide solution is shown in Fig. 4. Once more $E_{1/2}$ is near −1.15V and there is a kinetic oxidation wave due to SO_2 reduction products, but there is also a small wave near −0.13V which is due to a new product species. Finally, SO_2 was also examined in methylene chloride solution, where two oxidation peaks corresponding to the oxidation of SO_2^- and $S_2O_4^{2-}$ are more apparent, as shown in Fig. 5. In general the initial reduction behavior of SO_2 in organic solvents was

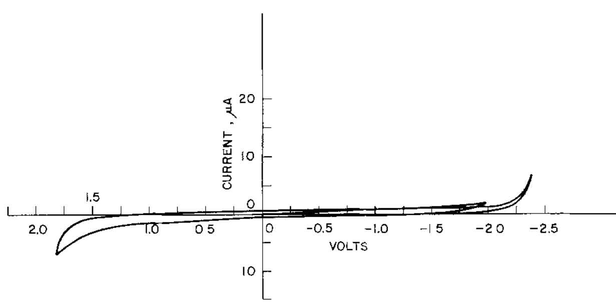

Fig. 1. Cyclic voltammograms of $TBAPF_6$ solution in acetonitrile on Pt electrode, background, scan rate 200 mV/sec.

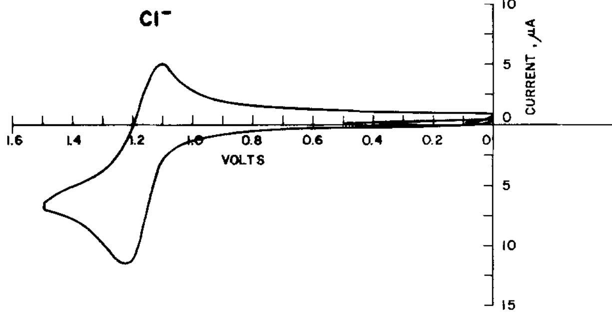

Fig. 2. Cyclic voltammogram of TMACl in acetonitrile/$TBAPF_6$, scan rate 200 mV/sec.

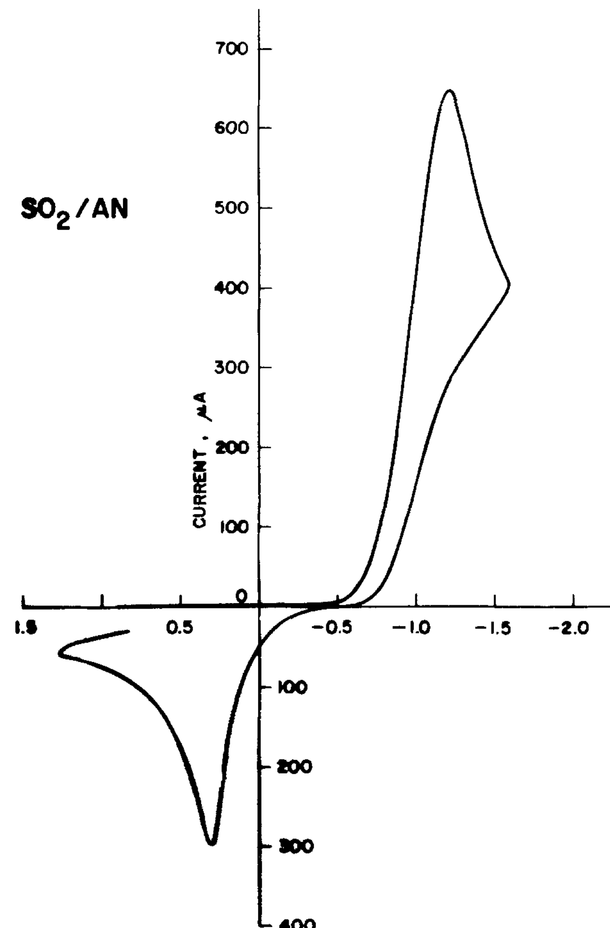

Fig. 3. Cyclic voltammogram of SO_2 in acetonitrile/$TBAPF_6$, scan rate 1 v/sec.

consistent with the established mechanisms (16) but the oxidation of the reduction products was substantially affected by the solvent, probably due to varying degrees of solvation of the two reduced species, SO_2^- and $S_2O_4^{2-}$.

Sulfur.—The cyclic voltammetry of sulfur was examined in dimethylformamide and methylene chloride because of the difficulty of dissolving sulfur in acetonitrile. In both methylene chloride and DMF, the reduction of sulfur is a rather complex phenomenon. The reduction of sulfur in CH_2Cl_2 as shown in Fig. 6 consists of two successive reduction waves whose relative heights are sweep rate dependent (as V increases the second wave becomes less prominent) at *ca.* −1.1 and −1.5V with an oxidation near 0.2V which

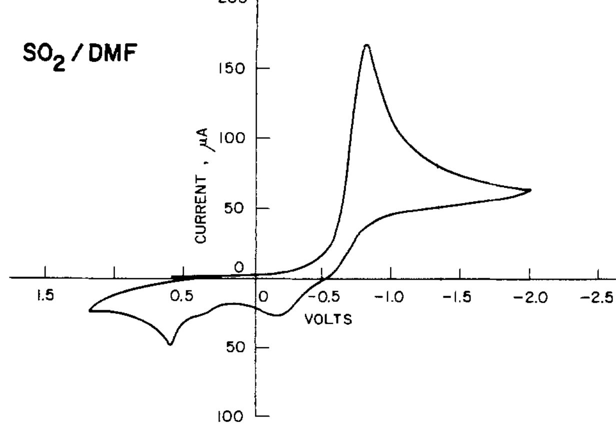

Fig. 4. Cyclic voltammogram of SO_2 in DMF/$TBAPF_6$, scan rate 200 mV/sec.

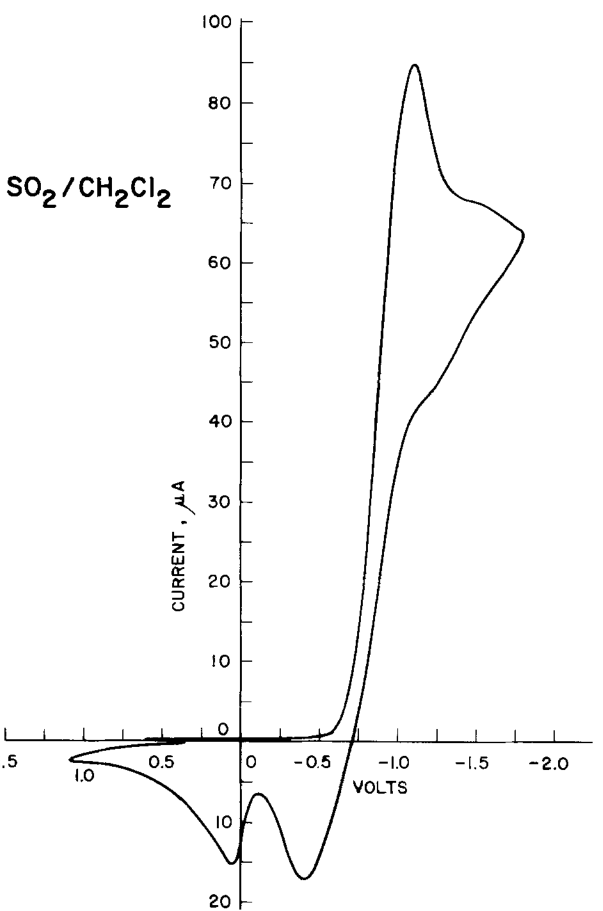

Fig. 5. Cyclic voltammogram of SO_2 in methylene chloride/$TBAPF_6$, scan rate 100 mV/sec.

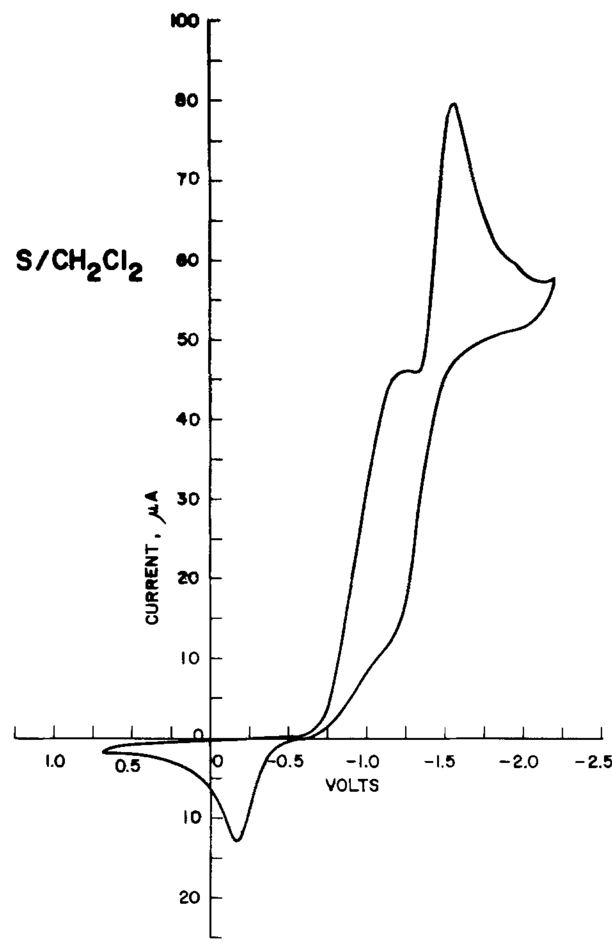

Fig. 6. Cyclic voltammogram of S in methylene chloride/$TBAPF_6$, scan rate 200 mV/sec.

is also sweep rate dependent and becomes more prominent as the sweep rate increases. Both of these reduction processes appear to be quite irreversible. The reduction of sulfur in DMF, as shown in Fig. 7 again consists of two irreversible, but more widely spaced waves near −0.6 and −1.15V. The shape of this second reduction wave is dependent on sweep rate. Finally there is an oxidation wave, also irreversible, at +0.25V. The species responsible for this oxidation has been shown by other voltammograms to be the product of the first reduction wave. The height of this oxidation wave is also a function of the sweep rate and becomes much more obvious at high sweep rates. In acetonitrile the cyclic voltammogram for sulfur is somewhat similar to that for DMF, although the second wave is much less well defined and the oxidation wave is near 0V.

Mixture of sulfur and sulfur dioxide.—Since both S and SO_2 are known to form in the cell, the cyclic voltammogram of a mixture of S with trace amounts of SO_2 in $TBAPF_6$-DMF electrolyte was obtained, and, as shown in Fig. 8, it contained only the two peaks corresponding to the reduction of S. Cyclic voltammograms of the same solution with slightly higher concentrations of SO_2, as shown in Fig. 8 curve (b), contain three reduction peaks, the middle one represents the SO_2 reduction. There was no noticeable interaction between S and SO_2 that could be detected by the cyclic voltammetry.

Sulfur monochloride.—In contrast to the other products examined, S_2Cl_2 showed a complicated electrochemical behavior in organic solvents. As shown in Fig. 9, the voltammogram of S_2Cl_2 in acetonitrile is dominated by an adsorption wave near −1.15V. This wave is followed by an apparently reversible reduction near −1.75V. On the return sweep there is peculiar behavior suggesting adsorption of S_2Cl_2 or its products on the electrode surface. At +1.1V we see the oxidation of the chloride generated during the reduction of S_2Cl_2.

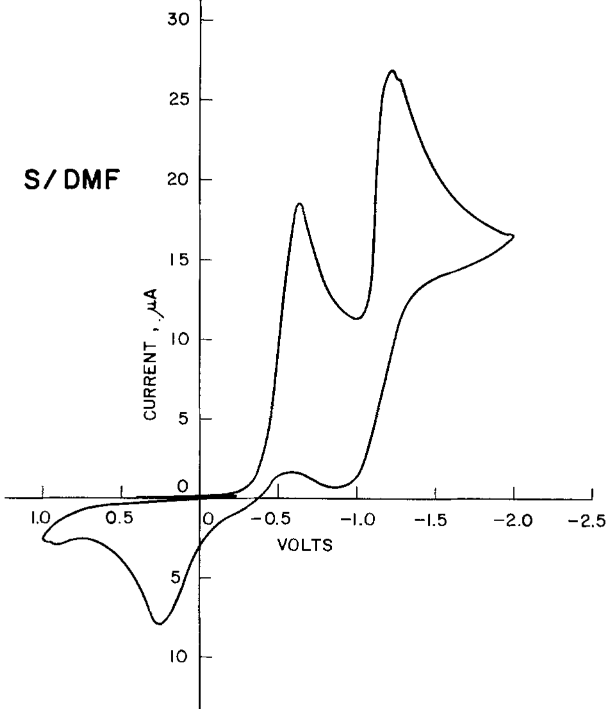

Fig. 7. Cyclic voltammogram of S in DMF/$TBAPF_6$, scan rate 500 mV/sec.

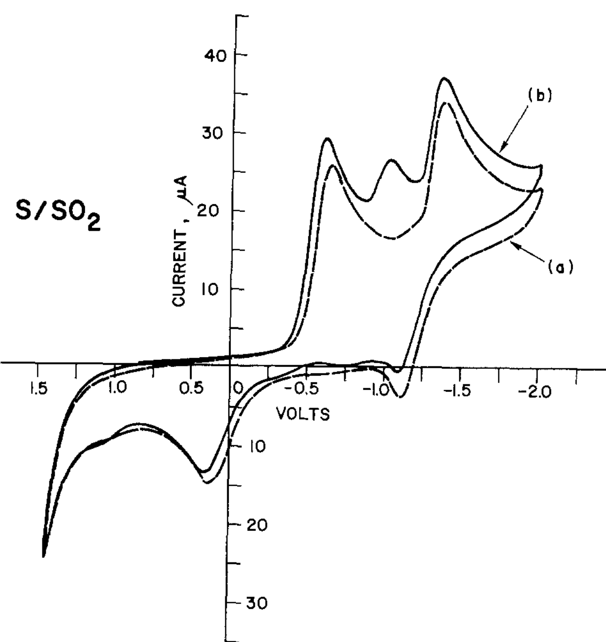

Fig. 8. Cyclic voltammograms of curve (a) S + trace SO_2 in DMF/$TBAPF_6$, curve (b) S + more SO_2, scan rate 200 mV/sec.

Thionyl chloride.—A series of voltammograms for ~10 mM $SOCl_2$ in CH_3CN/0.1N $TBAPF_6$ are shown in Fig. 10. In these voltammograms, on a constant current scale of 25 μA/cm, the sweep rate, V, was varied from 0.20 to 2.0 V/sec. As the sweep rate increases, the peak current increases, but an oxidation process near 0.0V appears at 500 mV/sec and becomes more prominent at 1.0 and 2.0 V/sec. The chemical entity which is being oxidized at this potential is not present in the solution originally since there is no anodic current at this potential until some of the thionyl chloride has been reduced. The sweep rate dependence of this oxidation wave shows that the species responsible for the oxidation is reacting fairly rapidly in solution. The oxidation and coupled reduction near +1.0V is due to oxidation of chloride ion to chlorine. The chloride itself is generated by reduction of thionyl chloride.

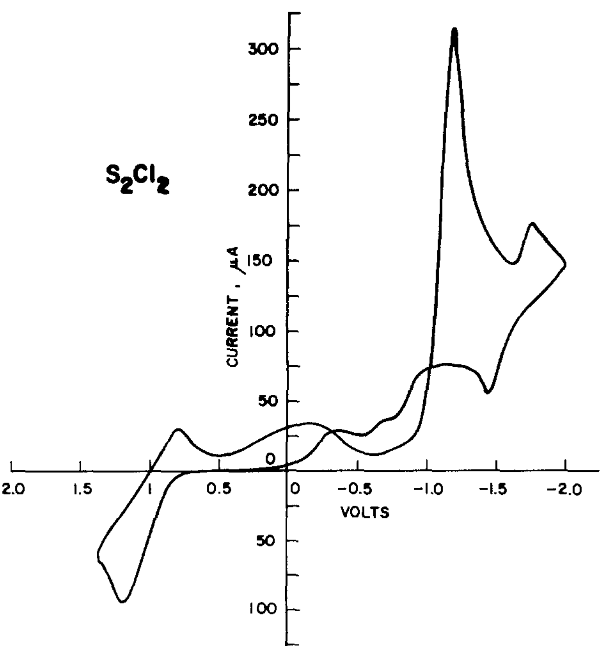

Fig. 9. Cyclic voltammogram of S_2Cl_2 in acetonitrile/$TBAPF_6$, scan rate 500 mV/sec.

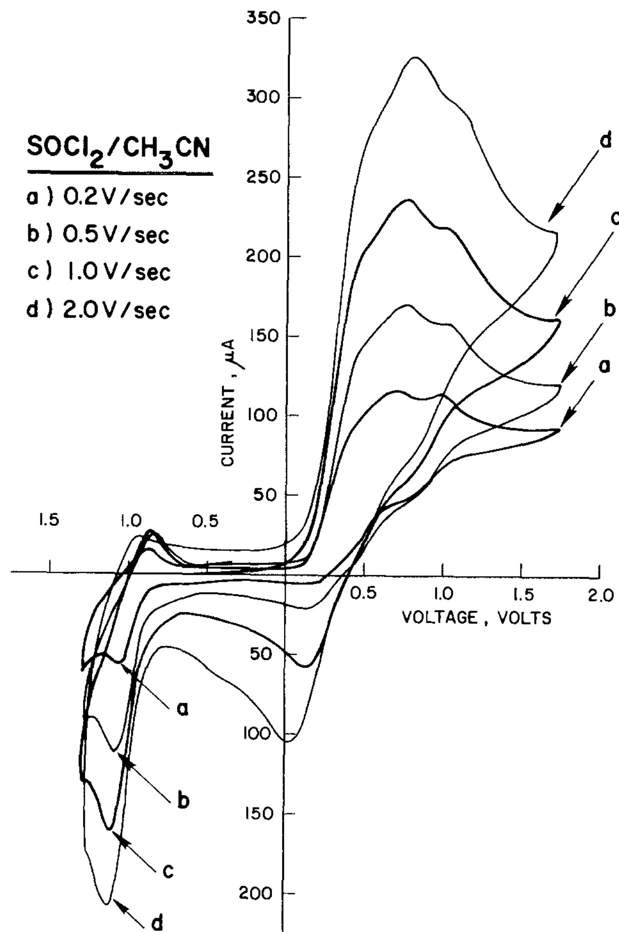

Fig. 10. Cyclic voltammogram of $SOCl_2$ in acetonitrile/$TBAPF_6$ at a Pt wire electrode showing the effect of sweep rate: curve a) 0.20 V/sec, curve b) 0.50 V/sec, curve c) 1.0 V/sec, curve d) 2.0 V/sec.

The effect of concentration on the $SOCl_2$ reduction has been examined. Cyclic voltammograms of $SOCl_2$ at various concentrations at a Pt electrode are shown in Fig. 11. For a given sweep rate of 500 mV/sec the oxidation near 0.0V becomes less prominent as concentration increases. From the sweep rate dependence of this oxidation, we can conclude that the species responsible for this oxidation wave is reacting either with thionyl chloride or with itself. Change in the reduction behavior was also noted as the wave near −0.65V became less prominent and the one near −1.0V more prominent as the concentration increased in CH_3CN solution.

For further comparison we ran cyclic voltammograms in dimethylsulfoxide (DMSO), a solvent which is regarded as very good for reduced species because of its ability to stabilize reactive materials by complexation. DMSO is also known to have a rather low activity of residual water because of the sulfoxide's coordinating ability. A cyclic voltammogram for $SOCl_2$ in DMSO/$TBAPF_6$ is shown in Fig. 12. The pattern of two successive reduction waves and an oxidation near 0.0V are very similar to that observed in DMF. The oxidation near 0.0V is quite prominent even at the 0.05 V/sec sweep rate, indicating that the reaction species involved is greatly stabilized by the DMSO solvent. The definition of the two reduction waves is very clear and there is little evidence for the appearance of the third wave near −1.0V which we noted in other solvents.

We have continued our work on the thionyl chloride reduction in DMF where the reduction appears to take place by the same mechanism. The better separation of the two reduction waves in DMF makes it a more attractive solvent for use in strictly electro-

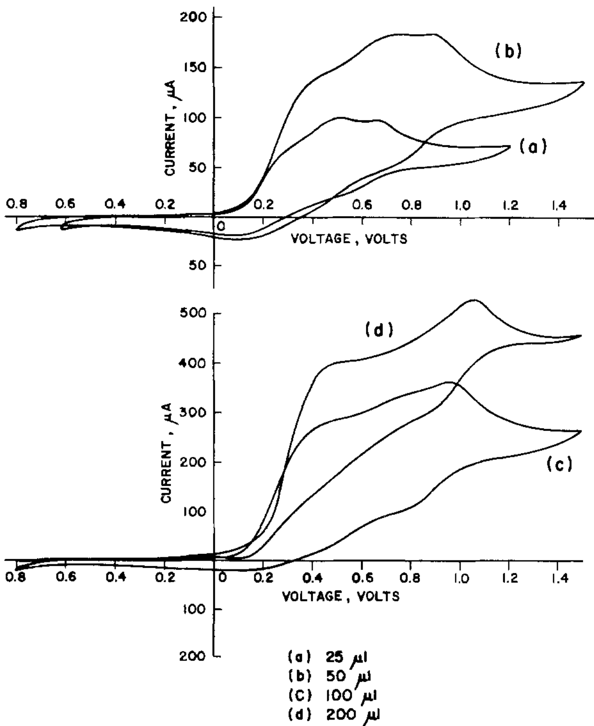

Fig. 11. Cyclic voltammograms of $SOCl_2$ in acetonitrile/$TBAPF_6$ at various concentrations. Curve a) 25 μl $SOCl_2$/75 ml CH_3CN (0.5 V/sec), curve b) 50 μl $SOCl_2$/75 ml (0.5 V/sec), curve c) 100 μl $SOCl_2$/75 ml (0.20 V/sec), curve d) 200 μl/75 ml (0.20 V/sec).

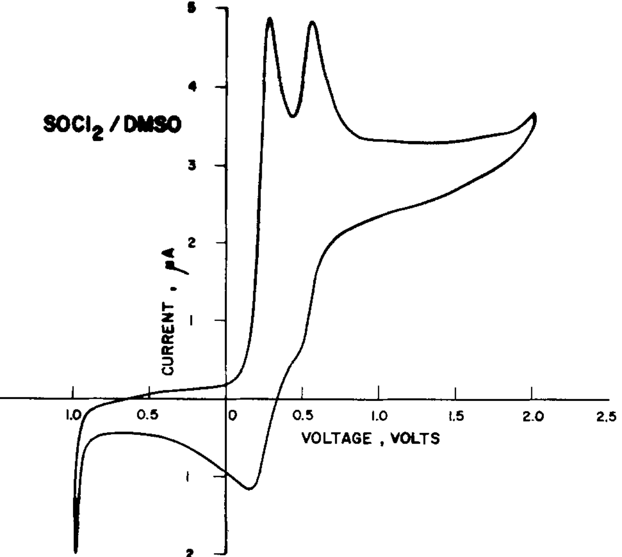

Fig. 12. Cyclic voltammogram of $SOCl_2$ in DMSO/$TBAPF_6$ at a Pt wire electrode (0.05 V/sec).

chemical studies on this system. Experiments in which sweep rate and concentration were systematically varied in DMF/$TBAPF_6$ gave similar results for the reduction of $SOCl_2$ to those found in acetonitrile. The second reduction wave remained more prominent in DMF, suggesting that coordination with DMF was stabilizing the species responsible for the reduction process.

To examine the formation of the intermediate species more closely we also examined the reduction at higher sweep rates than usual, recording the current/voltage trace on a storage oscilloscope. At sweep rates as high as 100 V/sec no qualitative change in the voltammogram could be observed. Except for uncompensated *IR* losses, the voltammogram was similar to those generated at lower sweep rates. We were also able to use the storage oscilloscope with multiple sweeps of the same voltage range to examine the relationships of the two reduction waves and the oxidation near 0V. Using this method we were able to generate a "steady-state" voltammogram of reduced thionyl chloride species. This voltammogram was unique in that the first thionyl chloride reduction wave was absent while the second reduction wave and the oxidation near 0V were still present. This indicates that the oxidation near 0.0V does not regenerate thionyl chloride since the first reduction wave, corresponding to the reduction of $SOCl_2$, is absent and as such the reduction of thionyl chloride is irreversible.

A cyclic voltammogram for 50 μl $SOCl_2$ in approximately 75 ml DMF (~14 mM) with 0.1M $N(C_4H_9)_4PF_6$ at a platinum wire electrode is presented in Fig. 13 curve (a). The reduction of thionyl chloride shows two successive reduction waves with $E_{1/2}$ at −0.20V for the first wave (17), with a peak potential which is sweep rate dependent, but near −0.37V, while the peak potential for the second reduction is near −0.65V. In addition to these reduction processes, there is an irreversible and broad oxidation on the return sweep near 0.0V. The small reduction wave near −1.25V is present in the background and presumably due to a trace impurity in the DMF. Both of the reduction peaks due to thionyl chloride are due to diffusion controlled processes as shown by the linear relationship of the peak cathodic current i_{pc} and $\sqrt{V}$, where *V* is the sweep rate. Under similar circumstances an adsorption controlled process would show i_{pc} linear with *V* and a kinetic controlled process that is not a simple function of *V* (17).

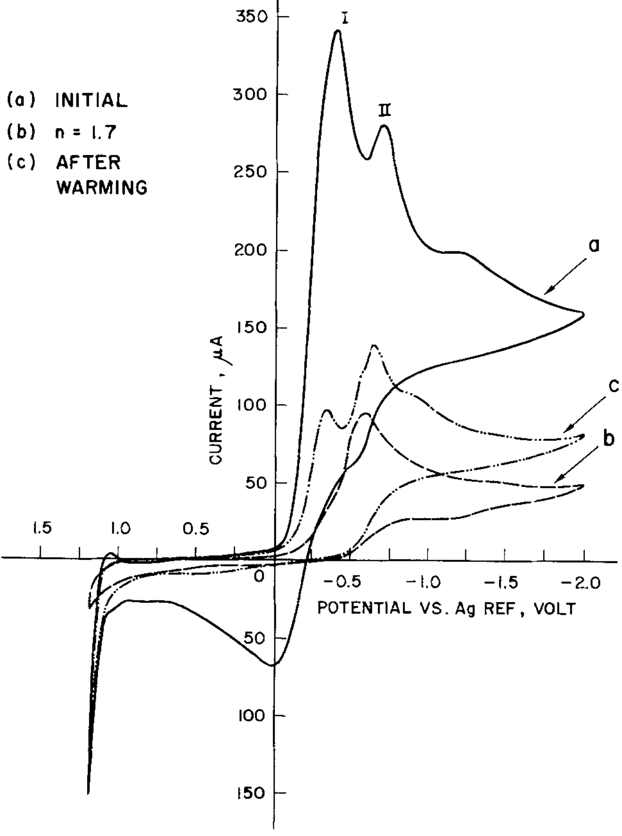

Fig. 13. Cycilc voltammograms of $SOCl_2$ in DMF/$TBAPF_6$, curve a) before electrolysis, curve b) immediately after exhaustive electrolysis at −0.25V, curve c) after warming solution, scan rate 0.2 V/sec.

This solution of DMF and thionyl chloride is sufficiently stable that an exhaustive electrolysis of the thionyl chloride can be performed at a platinum foil electrode. It is difficult to get completely reproducible n values from coulometry because of the closely spaced second reduction wave, but reduction at −0.25V gives an apparent n of 1.7-1.9 equivalents per $SOCl_2$. A cyclic voltammogram of this reduced $SOCl_2$ solution is shown in Fig. 13 curve (b). This reduced product is characterized by a reduction wave near −0.63V with little clear evidence for any oxidation processes. If this reduced solution is either allowed to stand or is slightly warmed with a water bath, some thionyl chloride is regenerated, as shown in Fig. 13 curve (c). If this material is then further reduced at −0.25V, n is 2.04 or very nearly 2.0, while a shoulder appears near −0.9V.

We have examined the coulometric reduction of $SOCl_2$ in DMF, acetonitrile, and methylene chloride. In all three solvents we have observed the regeneration of thionyl chloride by destruction of an intermediate species and have confirmed the Faradaic current of 2 equivalents of charge for each mole of $SOCl_2$ reduced. In particular, the reduction in acetonitrile is of interest since the UV-VIS solvent cutoff of 190 nm gives a much better spectral window than DMSO (268 nm), DMF (270 nm), or methylene chloride (230 nm). We were able to monitor the course of a coulometric reduction by using both cyclic voltammetry and UV-VIS spectroscopy to monitor changes in the solution. For comparative purposes, spectra of SO_2 and S in acetonitrile are reproduced in Fig. 14 and 15, respectively. The wavelengths of maximum absorbance, 279 nm for SO_2 and 277 for S are very similar to that of $SOCl_2$, 277 nm as shown in Fig. 16, however, there is a second band in the spectrum near 234 nm which is not present in the spectra of SO_2 and S. In this particular experiment 10 μl of $SOCl_2$ was used in 75 ml of CH_3CN to give a concentration of 1.83 mM $SOCl_2$ in CH_3CN. We experimentally determined that this concentration of ~ 2 mM was suitable for UV-VIS spectroscopy, cyclic voltammetry, and coulometry. Changes in the ultraviolet spectrum as a function of charge passed in the exhaustive electrolysis are shown in Fig. 17. From λ_{MAX}

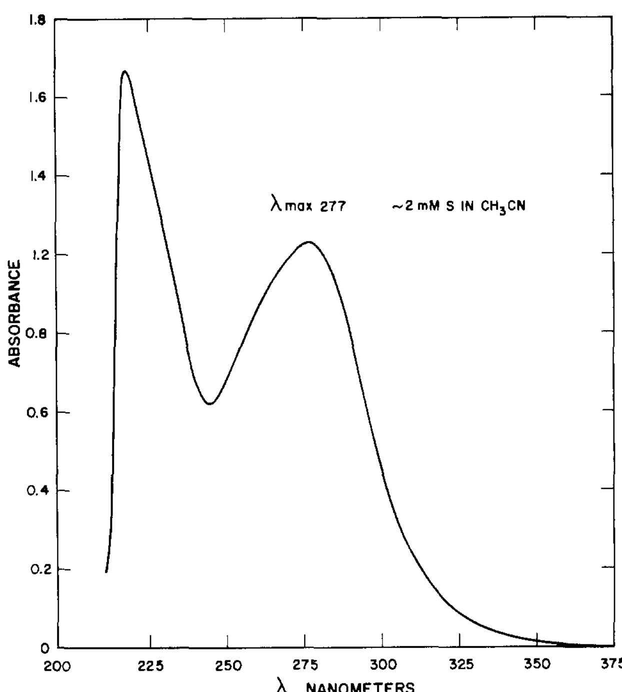

Fig. 15. UV-VIS spectrum of 2 mM S in acetonitrile, path length 1 cm.

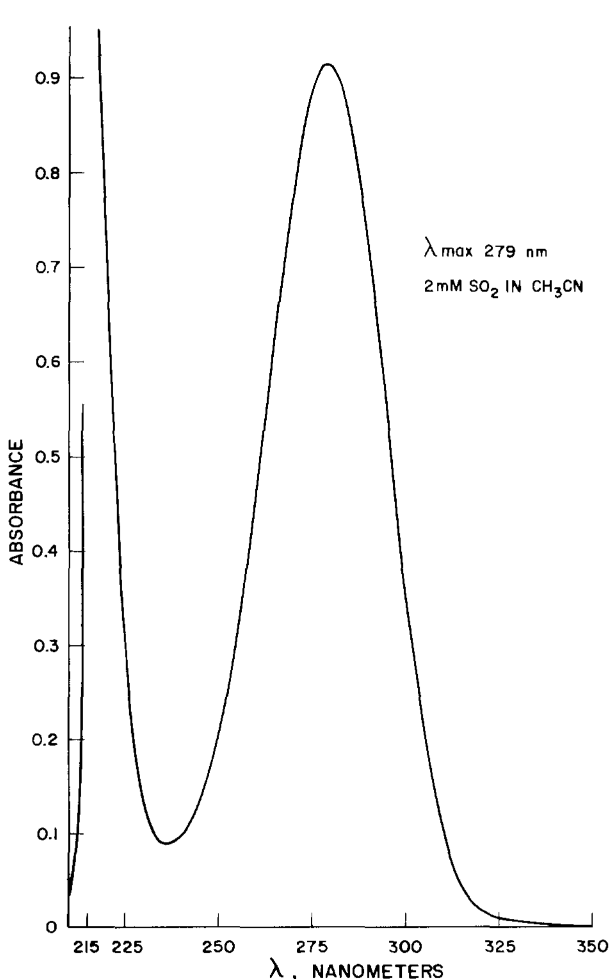

Fig. 14. UV-VIS spectrum of 2 mM SO_2 in acetonitrile, path length 1 cm.

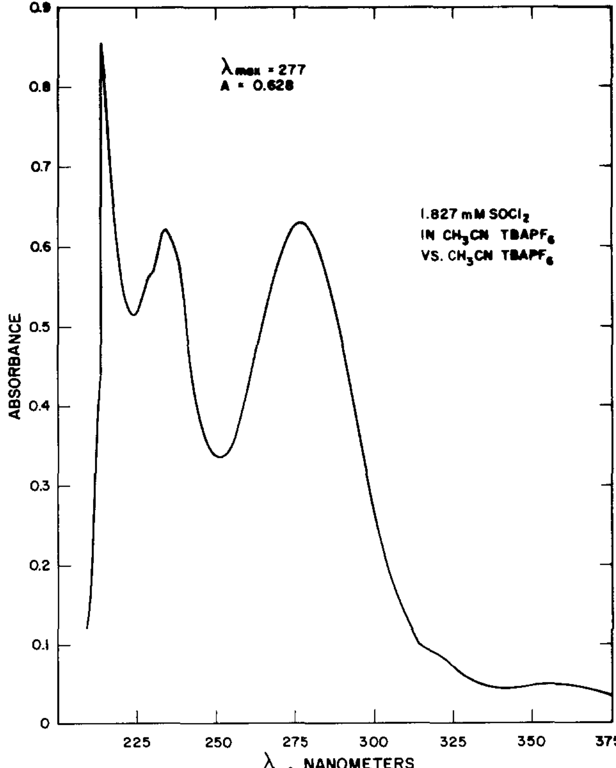

Fig. 16. UV-VIS spectrum of 1.8 mM $SOCl_2$ in acetonitrile/$TBAPF_6$, path length 1 cm.

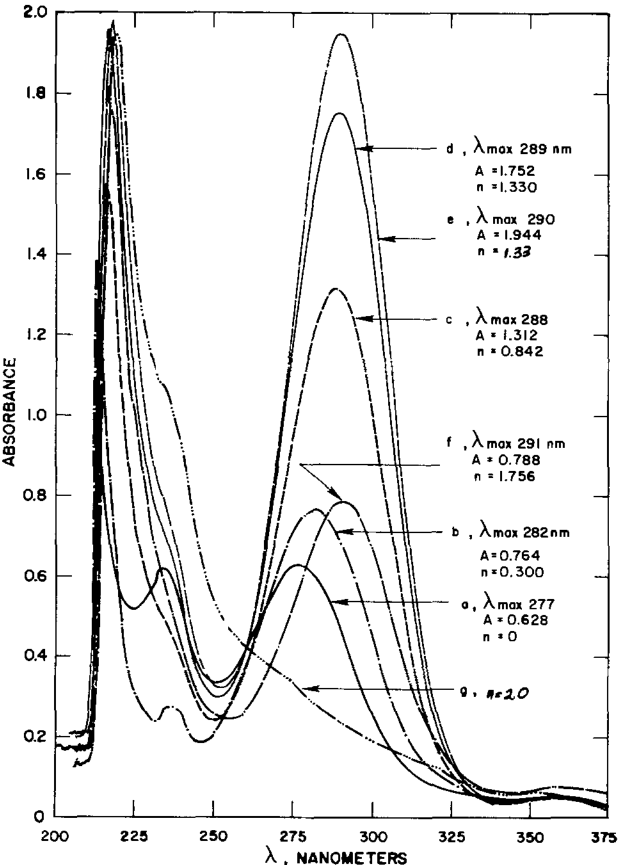

Fig. 17. Absorbance spectrum of 1.8 mM solution of $SOCl_2$ in acetonitrile/$TBAPF_6$, curve a) $n = 0.00$, curve b) $n = 0.30$, curve c) $n = 0.84$, curve d) $n = 1.33$, curve e) $n = 1.33$ after 16 hr, curve f) $n = 1.76$, curve g) $n = 2.0$ after 1 week stand.

272, $A = 0.628$ at $n = 0$ the λ_{MAX} gradually changes to 282, 288, 289, 290, 291 nm as A first increases then decreases to 0.764, 1.312, 1.752, 1.944, 0.764 corresponding to n of 0.30, 0.84, 1.33, 1.33, and 1.76, respectively. At $n = 2.0$ this absorption band is completely absent after storage for 1 week at room temperatures. During this reduction the small band near 234 nm in $SOCl_2$ also disappeared. The gradual change of A from 1.75 to 1.94 for $n = 1.33$ on overnight standing indicates that the intermediate species, corresponding to the absorption band, must be forming as a result of a slow secondary reaction of the intermediates of the $SOCl_2$ reduction. Accordingly, we cannot expect to see a simple relationship between absorbance and progress of the reduction.

Changes in cyclic voltammograms throughout the reduction are shown in Fig. 18. In Fig. 18(a) the solution was scanned before reduction ($n = 0.0$) in 18(b) at $n = 0.30$, in 18(c) at $n = 0.84$ and 18(d) at $n = 1.33$. In these voltammograms there is a consistent decrease in the first wave and relative enhancement of the second reduction wave. The wave due to electrogenerated chloride also increases. In the final voltammograms for $n = 1.76$ and $n = 2.0$, the initial wave is completely absent, while a third wave appears at more negative potentials.

To examine whether the reduction processes in bulk thionyl chloride electrolytes are comparable to those observed in dilute solution, we removed an aliquot of electrolyte from a partially discharged Li/$SOCl_2$ cell and examined the voltammetry of this sample in DMF solution. The resulting voltammogram was identical to one observed in the reduction of $SOCl_2$ in DMF.

Discussion

The coulometric data demonstrate an overall n value of 2.0 for the reduction of thionyl chloride. Reductions for extended times have given green, air-sensitive solutions possibly including polysulfides, but there is no evidence to suggest that this reflects any process occurring in $SOCl_2$ reduction since the cyclic voltammograms show that no further unreduced $SOCl_2$ is present.

The spectroscopic evidence shows that S and SO_2 are not formed during the reduction process itself. Instead a different species is formed with an absorption band near 291 nm. This is confirmed by the cyclic voltammograms which show only a slow formation of species reducing at potentials near those for S and SO_2. This intermediate species is reasonably stable and decomposes only slowly to generate more $SOCl_2$.

We propose the following reduction mechanism for $SOCl_2$ to explain the above cyclic voltammetric and UV-VIS spectroscopic observations. $SOCl_2$ undergoes two successive, one-electron transfers to generate SO

$$SOCl_2 + e \rightarrow SOCl + Cl^- \qquad [5]$$

$$SOCl + e \rightarrow SO + Cl^- \qquad [6]$$

It is likely that the E_o of the second step [6] may be positive of E_o of the first step [5] and as such both the electron transfers may occur at the first reduction wave (I) shown in Fig. 13 curve (a). The highly unstable nature of SO (18) and the presence of excess $SOCl_2$ at the early stages of the discharge, may lead to the complexation of SO with $SOCl_2$

$$SO + SOCl_2 \rightarrow SO{\cdot}SOCl_2 \qquad [7]$$

This species is sufficiently stable and is reduced in the second reduction wave (II) shown in Fig. 13 curve (a) and the unstable reduced product is oxidized at 0V corresponding to the oxidation wave shown in Fig. 13 curve (a). The complex dissociates to form SO and $SOCl_2$ on standing or warming of the solution

$$SO{\cdot}SOCl_2 \rightarrow SO + SOCl_2 \qquad [8]$$

This explains the regeneration of the first reduction wave [Fig. 13 curve (c)] on overnight standing. During the latter part of the discharge, when the concentration of $SOCl_2$ has decreased considerably, dimerization and polymerization of SO may occur

$$2SO \rightarrow (SO)_2 \qquad [9]$$

$$(SO)_2 + nSO \rightarrow (SO)_n \qquad [10]$$

These dimers and polymers may decompose on standing or heating to form S and SO_2 (18)

$$(SO)_2 \rightarrow S + SO_2 \qquad [11]$$

Observations regarding delayed pressure rise (20) and thermal activity in discharged cells (7) as well as lower cell capacity at lower temperature (19) are consistent with the above reaction scheme.

Although the above experiments were carried out on smooth Pt electrode, we believe that the results are applicable to the carbon substrates as well, particularly in the absence of any catalyst (homogeneous or heterogeneous). Addition of catalyst may alter the stability of the intermediate and as such may have significant effect on the performance and safety of the cells. We are in the process of investigating this aspect of the problem and the results will be reported later on.

The Reduction of Sulfuryl Chloride at Teflon-Bonded Carbon Cathodes

S. Gilman and W. Wade, Jr.

U.S. Army Electronics Technology and Devices Laboratory (ERADCOM), Power Sources Division, Fort Monmouth, New Jersey 07703

ABSTRACT

Polarization and discharge curves were measured for sulfuryl chloride reduction at Teflon-bonded carbon cathodes fabricated using a number of different carbon powders. Lithium chloroaluminate was utilized as electrolyte solute. At moderate current densities cathode polarization tends to normalize with respect to Brunauer, Emmett, Teller (BET) surface area of the carbon. Cathode life increases with increased porosity of the electrode. The porosity is required for good accommodation of product LiCl. A formulation incorporating both high BET area and porosity was developed and found to provide good electrochemical performance against lithium counterelectrodes. When sulfuryl chloride is reduced at the optimized cathode (against a lithium anode), the main products of reaction are LiCl (which is quantitatively deposited within the electrode's pores) and SO_2. This suggests the overall cell reaction: $2Li + SO_2Cl_2 \rightarrow 2LiCl + SO_2$. The addition of Cl_2 or SO_2 to the electrolyte causes decrease or increase of cathode polarization, respectively. This may be taken as evidence that the reduction, at moderate current densities, occurs through a Cl_2 intermediate resulting from heterogeneous decomposition of SO_2Cl_2. Reduction of undissociated SO_2Cl_2 may occur at high current densities or after the active area of the electrode is significantly reduced through deposition of product LiCl.

The potential usefulness of sulfuryl chloride for lithium inorganic electrolyte cells was recognized a number of years ago (1-3). However, development of a practical lithium-sulfuryl chloride cell has generally been assigned lower priority, by both governmental and industrial organizations, than the corresponding lithium-thionyl chloride system. One reason for the relative inattention to sulfuryl chloride cell technology has been the observed dissipation of the apparent high voltage and capacity advantage (observed at low current densities) when experimental cells utilizing Teflon-bonded carbon (Shawinigan black) cathodes are discharged at high rates (4). It was the purpose of this work to improve the performance-limiting Teflon-bonded carbon cathode and to gain mechanistic insights which will suggest further refinements in technology. The present work was performed using neutral lithium chloroaluminate solution (1.5 molar) in which lithium anodes are fairly stable and which is therefore suitable for primary cell use. As is the situation for the analogous thionyl chloride system, acidic (*e.g.*, $AlCl_3$-rich) solutions allow higher voltages and cathode service life under load, but are suitable only for reserve cell use.

Experimental

Preparation of electrolyte.—Sulfuryl chloride was refluxed over Li ribbon for several hours and then distilled under a positive pressure of argon, retaining the middle fraction. Lithium aluminum chloride was prepared by fusion of the salts as described previously (5). The 1.5M solutions were prepared in an argon atmosphere, in a glove box, and were stored in a tightly stoppered bottle. Electrolyte was used within a day of preparation or argon-degassed just before use.

Preparation of cathodes.—"Uncompressed" cathodes were prepared as described previously (5) by wet-blending of du Pont TFE-30 emulsion, carbon powder, and a sufficient amount of water to yield a stiff paste. The latter was then applied to a 2.5 × 2 cm Exmet (Exmet Corporation) support. The latter support was prepared by welding two thicknesses of (Type 5 Ni7-2/0) screen together, wth the mesh out of registration so as to provide maximum tortuosity for good anchoring of the Teflon-carbon mixture and to provide high electronic conduction. While still moist, the electrode was pressed to whatever thickness (depending on the particular carbon powder used) required for a final thickness of 0.89 ± 0.05 mm after vacuum drying for approximately 24 hr at 99°C. All cathodes were trimmed to the 2.5 × 2 cm dimensions of the Exmet support.

"Compressed" (the fabrication procedure finally developed for United Carbon) cathodes were prepared as described above, but compressed to an intermediate thickness of 1.56 mm while still moist. After vacuum drying the electrode was pressed in a 0.635 mm frame and after re-expansion (due to electrode resilency) had a final thickness of 0.89 mm. The "uncompressed" electrodes made with Shawinigan black or Darco G-60 were of good, uniform appearance and possessed good adherence after the vacuum drying step. The uncompressed electrodes made of Columbia or United Carbon were badly cracked and fragile after the drying stage. The compressed United Carbon electrodes presented a good appearance and were sturdy.

Preparation of cells.—Cells were assembled in an all-Teflon jig with the planes of the electrodes parallel to the bottom of the jig. The cathode was placed between two Li anodes. An Li foil electrode placed in the same plane as the cathode served as reference. A 0.30 mm thick glass "filter-paper" provided mechanical separation between the cathode and the Li counterelectrodes facing it on each side. The lithium anodes were fabricated by pressing nickel Exmet into a 1.3 mm thick lithium foil and trimming to the same (2.5 × 2 cm) length and width as the cathodes. After assembling the cell and adding electrolyte, a Teflon weight was applied to the cell to help maintain good contact between the cell components. Unless otherwise specified, the electrolyte volume was 5 cm^3. Electrical connections were made to Pt wires sealed in the cap of a glass outer container having a standard taper ground glass joint, and the cell assembly was then

Key words: polarization curves, discharge curves, cathode polarization.

enclosed in the outer container. All assembly steps were accomplished in the glove box.

Electrochemical meaasurements.—Discharge and polarization curves were recorded on a Moseley Strip Chart Recorder at 22° ± 2°C. The discharge curves were obtained while applying constant current from a power supply. The polarization curves were measured by applying predetermined constant currents (starting from 0.02 mA/cm^2) for a period of 3 min before recording each cathode potential.

Cathode porosity determination.—The percent porosity is defined as the percent of wet cathode volume available for absorption of SO_2Cl_2. The volume of SO_2Cl_2 absorbed was determined by weighing a cathode before and after immersion in SO_2Cl_2 and "blotting" on a glass surface. The wet volume of the cathode was determined by measuring its lineal dimensions with calipers. The porosity measurements were conducted in the glove box.

Chemical analysis.—The solubility of lithium chloride at 25°C in SO_2Cl_2 was determined by preparing a saturated solution at 30°C, allowing equilibration/precipitation to proceed for several days at 25°C, and then weighing the LiCl residue after taking 10 cm^3 of solution to dryness.

Determination of sulfuryl chloride-insoluble chloride in discharged cathodes was accomplished as follows. The cathode was extracted with five 20 cm^3 volumes of SO_2Cl_2 (with vigorous magnetic stirring) during a 24 hr period. The cathode was then vacuum-dried, first at room temperature and then at 100°C. The cathode was then extracted with a total volume of 100 cm^3 of water and aliquots of the extract titrated potentiometrically with standardized silver nitrate solution.

Aluminum was determined quantitatively to correct for occluded lithium aluminum chloride in the sulfuryl chloride-insoluble (lithium) chloride cathode product residue. The aurintricarboxylate colorimetric method (6) was employed, and aluminum concentrations were read off from a Beer's law plot at the absorption maximum of 525 mμ.

Volumetric determination of (SO_2) gas release during cell discharge.—The cell was prepared for discharge as described above. Before use, a volume of electrolyte was presaturated with SO_2 for 45 min by bubbling the gas through the solution. To minimize gas-supersaturation effects, only 2 cm^3 of the presaturated electrolyte were inserted in the cell. After assembling the cell and closing the gas-tight glass outer envelope, the latter was flushed with SO_2 through its two stopcocks. The glass envelope was then connected to a manifold and gas burette assembly by means of standard taper joints. Before opening the stopcock separating the cell from the manifold-burette assembly, the latter was evacuated and backfilled with SO_2. Measurements were made more or less frequently depending on observed rate of change of volume, and a rate of gas release was derived from each pair of adjacent volume determinations.

Determination of solubilities of SO_2 and Cl_2 in SO_2Cl_2.—In an alkaline aqueous solution, SO_2 or Cl_2 when individually dissolved can be titrated through iodimetry or iodometry, respectively (7). If both gases are introduced into an alkaline solution, they will react, resulting in quantitative oxidation of the SO_2, by Cl_2, to SO_4^{--} and Cl^- plus the balance of the component present in higher normality. Therefore, only the excess of equivalents may be determined iodometrically/iodimetrically for such a mixture. Pure sulfuryl chloride can be expected to behave like a stoichiometric mixture of SO_2 and Cl_2 when dissolved in alkaline solution as was confirmed.

Solutions of either gas in SO_2Cl_2 were prepared by bubbling the gas through the liquid for ½ hr. A 1 cm^3 aliquot of either of the solutions was then placed in an ampul which was supported above 40 cm^3 of 1-5M aqueous KOH solution in a flask with a gas-tight stopper. The ampul was dropped into the KOH solution and the latter shaken vigorously. A sample of argon-saturated SO_2Cl_2 gave a negligible iodimetric or iodometric blank determination. Iodimetric/iodometric determinations were conducted on the saturated solutions of the pure gases.

Results and Discussion

Dependence of cathode polarization and discharge capacity on cathode physical properties.—A Teflon content of 16% was chosen for preliminary comparative evaluation purposes, because it was found to provide adequate coherence of the Teflon-carbon mixtures and adherence to the screens even though this is not the optimum Teflon loading for each individual carbon powder.

Table I identifies the carbon powders used in formulating cathodes, along with their BET surface areas. Shawinigan black possesses the lowest area of the entries listed, but has been a frequent choice of lithium battery technologists because of its good mechanical working properties and porosity. The latter quality is due in part to its extensive chain-like microstructure. Darco G-60 is a relatively high-area activated charcoal. The United and Columbia carbon blacks listed possess particularly high surface areas and were originally produced for use in experimental aqueous primary cells (8, 9).

The cathodes were compared at the same thickness (0.89 mm) (rather than at the same weight) since that allows the best comparison with respect to overall performance of a practical cell. The carbon loadings obtained reflect the different packing tendencies of the Teflon-carbon mixtures when accommodating to the same volume. Previous studies revealed that the BET surface area of such electrodes is approximately the same as that of the original carbon utilized (10). On that basis, Table I presents the BET areas for the electrodes computed from the powder areas and the carbon loadings (of representative electrodes). Because the variations in carbon loadings of the electrodes tend to compensate for the variations in surface areas of the powders, the only large variation in electrode BET area is that for Shawinigan black when compared with the other three carbons.

The electrode porosity or, more precisely, the ability to absorb SO_2Cl_2 depends on the original microstructure of the powder and its interaction with the Teflon

Table I. Teflon-bonded carbon cathodes (16% TFE)

Type of carbon	Derivation	Carbon loading* (g/cm^2)	BET surface area of carbon: meter^2 — Per gram of carbon powder	BET surface area of carbon: meter^2 — Per cm^2 of electrode geometric area*	% electrode porosity
Shawinigan—50% compressed	Decomposition of acetylene	0.0194	66	1.28	87
Darco-G60	Steam-activation of charcoal	0.0048	301	14.4	64
United XC-6310-4	Decomposition of oil	0.0146	1000	14.6	81
Columbia HR 1670	Decomposition of oil	0.0104	1200	12.5	75

* Based on (length × width) area of electrode, one side.

binder. As already mentioned above, the latter properties are particularly favorable for Shawinigan black and probably account for the higher than average cathode porosity listed in the table and the fact that the electrodes have a sturdy and uniform appearance. The Darco cathodes have the lowest porosity and fair mechanical integrity. The Columbia and United carbon cathodes prepared by this method are cracked and fragile, but possess medium porosity. When swollen with electrolyte, the latter electrodes acquired a more uniform appearance.

Figure 1 shows the polarization curves obtained for the four different carbon samples, with the recorded current density based on the geometric cathode area (length × width, one side). From the practical point of view, it can be concluded that the United carbon would provide the best and Shawinigan black the poorest initial voltage in a practical cell.

The results of Fig. 1 are replotted in Fig. 2 but with the current densities computed from the total currents and the BET carbon areas of the electrodes. It is now apparent that polarization for three of the carbons (covering more than an order of magnitude's spread in BET area) is very similar in the range of currents where "activated" processes predominate. The Darco cathode shows significantly more polarization than the other three in that range. This may possibly be attributed to the fact that Darco G-60 is an "activated charcoal" with part of the BET area intragranular in nature and consequently not readily accessible to solid/liquid reactions. The steep decline of cathode potential at high current densities may be attributed [as applies also to the similar thionyl chloride cathode (10, 11)] to transport limitations in pores partially blocked by a solid product of cell discharge.

Cathodes made from the four different carbon samples were discharged at a constant current density of 5 mA/cm^2 in cells containing the "standard" 1 mm of electrolyte/cm^2 of cathode geometric area. The "full discharge capacities" were determined from the discharge curves by drawing the appropriate tangents near the "knee" of the curves. In Fig. 3, the capacities are plotted against the percent porosity values taken from Table I. The relationship is approximately linear for the particular current density employed. The slope can be conceptualized as incorporating a pore "choking coefficient" as proposed by Marincic (11) for the thionyl chloride cathode. The similarity exists because the same major product of cathode reaction (LiCl) is involved in both cases as discussed below. It may also be anticipated, as observed for the thionyl chloride cell (12), that the distribution of LiCl in the cathode, and its effect on the discharge curve, will vary with the current density.

From Fig. 1 and 3 it can be concluded that Shawinigan black affords the best cathode capacity, but the poorest cathode voltage. United Carbon black, which affords the highest cathode voltage performance, provides second-best capacity. The latter carbon black was selected for further experimentation.

Improvement of the United Carbon cathode.—Figure 4 presents discharge curves for experimental modifi-

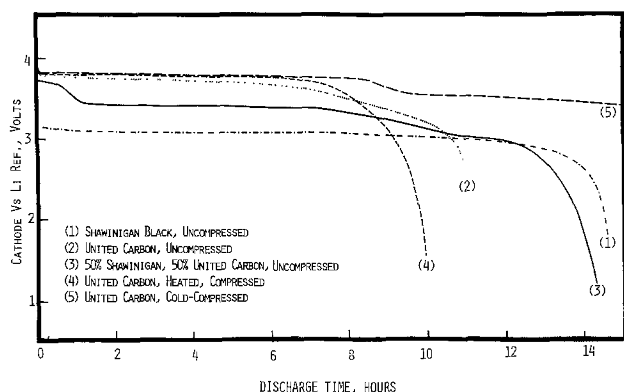

Fig. 4. Discharge curves (I = 5 mA/cm^2) for differently formulated cathodes.

cations of the cathode fabrication process (16% TFE) for comparison with those obtained by the original ("uncompressed") process (curves 1 and 2). All cathodes were constructed to the same final thickness (0.89 mm), but incorporated different amounts of carbon. Admixture of the two carbons (curve 3) results in the high capacity associated with Shawinigan black, but only part of the increased voltage associated with United Carbon black. Also, the physical integrity of the electrode is not good. Heat-compression of the United Carbon cathode at 300°C (curve 4) greatly improves its sturdiness and slightly improves the voltage, but causes decreased capacity. The "cold-compression" process (curve 5) results in a cathode of highest discharge voltage and longest life. This cold-compressed United Carbon formulation was therefore selected for further optimization.

Figure 5 shows the discharge curves obtained, at a current density of 5 mA/cm^2, for different concentrations of TFE in the dried United Carbon-Teflon mixtures. A maximum in cathode life ("full discharge capacity") is obtained for a TFE concentration of 10.7%. Duplicate runs for 9.7% and 10.7% are presented to show typical variation of results attributable to fabrication technique variability.

The 10.7% formulation was selected for the further investigations reported below. A typical electrode had a carbon loading of 0.024 g/cm^2 and a porosity of 87%. The electrode swelled 11% when immersed in electrolyte.

Solubilities of LiCl, SO_2, and Cl_2 in sulfuryl chloride.—The solubility of LiCl in sulfuryl chloride at 25°C was determined to be less than 0.009M. This corresponds to a solubility product of less than 8×10^{-5} and leads to the conclusion that LiCl is, practically speaking, insoluble in the 1.5M lithium chloroaluminate concentration of our electrolyte.

The solubilities of Cl_2 and SO_2 at 24° were determined to be 0.62 and 1.09 molal, respectively, when individually dissolved in pure SO_2Cl_2. The analysis for SO_2 correlates well with published results (13) for other temperatures.

Analysis of cell discharge products.—A discharged cathode, after rinsing in sulfuryl chloride and drying, was crushed and analyzed with an x-ray spectrometer. Diffraction lines were obtained for LiCl only. Two cathodes, A and B (formulated with 6.7% and 10.7% TFE, respectively), were discharged to a cut-off potential of 2V, treated as described in the Experimental section above, and analyzed for both Cl^- and Al^{+3}. Table II presents the results of the analyses, assuming that all chloride in the cathode is either LiCl or $LiAlCl_4$. It can be seen that agreement between the equivalents of charge passed and LiCl formed is within 2%, which is taken as evidence that LiCl is the only ionic product of cathode discharge for the predominant discharge reaction. Quantitative precipitation of the LiCl in the cathode is a result of its insolubility as already noted above. In this respect the situation is identical to that for thionyl chloride cells (14).

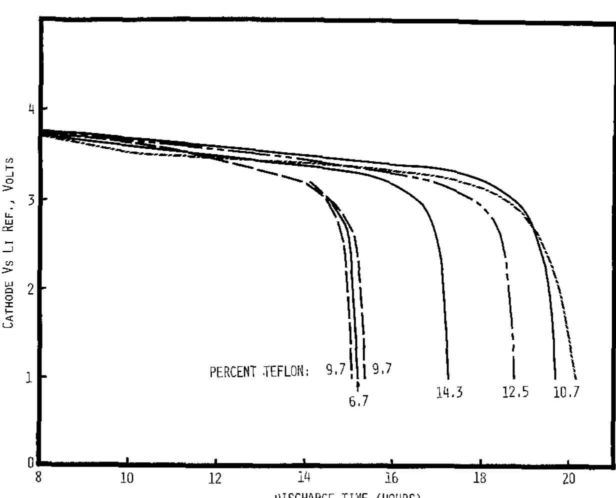

Fig. 5. Discharge curves ($I = 5$ mA/cm^2) for cathodes formulated with varying amounts of TFE (uncompressed).

Table II. Chloride determination for discharged cathodes

	Cathode A	Cathode B
Total equivalents of Cl- determined argentimetrically	0.0146	0.02035
4 × equivalents of Al^{+3} determined colorimetrically	0.00093	0.00103
Equivalents of Cl- as LiCl	0.0137	0.0193
Equivalents of electricity consumed in cathode discharge	0.0141	0.0189

One of the possible non-ionic products of cell discharge is elemental sulfur, as proposed previously (2). A cathode was fully discharged (20 hr) at a current density of 5 mA/cm^2. Extraction of the vacuum-dried cell components with CS_2 yielded only 15 mg of a yellow waxy substance with no distinct melting point. The substance dissolved in benzene and, therefore, was apparently not sulfur.

The simplest cell discharge reaction involving LiCl as the ionic product would produce SO_2 as the neutral product. Cells were always observed to develop positive pressure during discharge. The resulting gas phase contained SO_2 and Cl_2 which are, in any case, present above an SO_2Cl_2 volume (15). To avoid the difficulty of analyzing for SO_2 released in the presence of Cl_2, volumetric determination of gas release during discharge was made after saturating the solution with SO_2. This procedure has the benefit of suppressing Cl_2 release while forcing electrochemically produced SO_2 into the gas phase. The results of a determination appear in Fig. 6. The figure compares the observed rate of gas production with that anticipated based on the reactions

anode:

$$2[Li \rightarrow Li^+ + e^-] \qquad [1]$$

cathode:

$$SO_2Cl_2 + 2e^- \rightarrow 2Cl^- + SO_2 \qquad [2]$$

cell:

$$2Li + SO_2Cl_2 \rightarrow 2LiCl + SO_2 \qquad [3]$$

$$E^\circ = 3.909V\ (30^\circ C)$$

A "background" production of gas of approximately 0.06 cm^3/min was measured at open circuit. That "background" may, for instance, correspond to initial reaction (corrosion) of the fresh lithium electrode

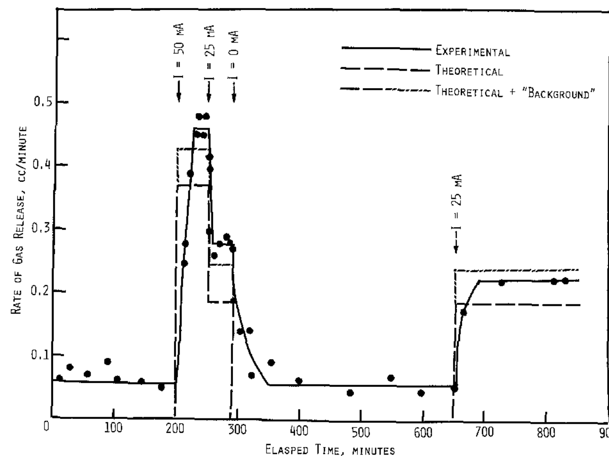

Fig. 6. Gas release during cathodic reduction of SO_2Cl_2

surface with the solvent. When the "background" and theoretical rates are added, they compare fairly well with the experimental rates eventually established when the current is increased or decreased. The results imply that the cell reactions proceed, at least largely, according to Eq. [1] and [2].

Effect of dissolved gases on cathode discharge.—Sulfuryl chloride dissociates readily into SO_2 and Cl_2 (15), and that reaction may be suspected of playing a role in the cell electrochemistry. The equilibrium constant at 30°C is 0.0288 for the reaction

$$SO_2Cl_2 \rightleftharpoons SO_2 + Cl_2 \quad [4]$$

The chlorine produced by reaction [4] could then be consumed as follows
cathode:

$$Cl_2 + 2e^- + 2Li^+ \rightarrow 2LiCl \quad [5]$$

The standard potential, $E°$, for reaction [5] *vs.* an Li reference electrode is 3.979V (30°C). However, the activity of Cl_2 in solution will always be equal to or less than dictated by the equilibrium constant of Eq. [4] and, therefore, always lower than unity. Correspondingly, the cell potential can never exceed that of Eq. [3] unless molecular Cl_2 is introduced from an external source.

Reaction [4] could proceed either homogeneously or heterogeneously. However, for pure SO_2Cl_2, the homogeneous reaction is slow, while the heterogeneous decomposition is relatively rapid at a carbon surface (15).

Figure 7 compares the polarization curves obtained when the electrolyte is saturated with either argon, SO_2, or Cl_2. Results for solutions prepared in the glove box and stored for a few days resemble the "argon-saturated" example. Clearly, Cl_2 and SO_2 serve to enhance or diminish the current, respectively, at any particular cathode potential. The effect of Cl_2 saturation demonstrates that molecular Cl_2 is kinetically more active than SO_2Cl_2 in this electrolyte, although reduction occurs well below the appropriate thermodynamic cell potential (3.979V). Since SO_2 is itself not reduced at these high potentials, and since it could not produce any significant decrease in Cl_2 bulk concentration over that in the argon-saturated solution, it is proposed that it exerts its effect on the polarization curve by decreasing the surface concentration of the chlorine which (at moderate currents and high potentials) normally serves as an intermediate in the reduction of SO_2Cl_2. In practical situations, (small volume of electrolyte, extended periods of discharge) the electrolyte will become SO_2 rich and the tendency for the results for the argon and SO_2-saturated electrolytes to converge (at higher currents) is also apparent from the figure.

Discharge curves (constant current of 5 mA/cm²) appear in Fig. 8. The results for the SO_2-saturated, argon-saturated, and "aged" electrolytes are almost

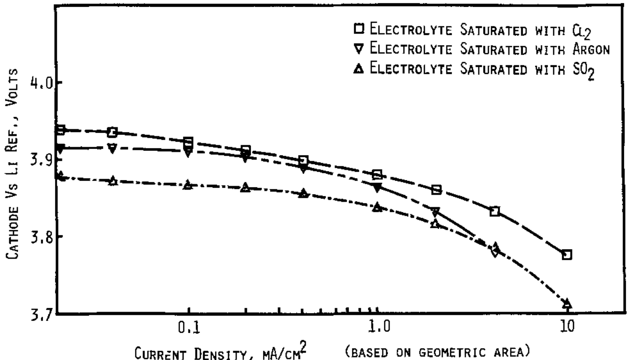

Fig. 7. Cathode polarization curves for optimized cathode electrolyte presaturated with different gases.

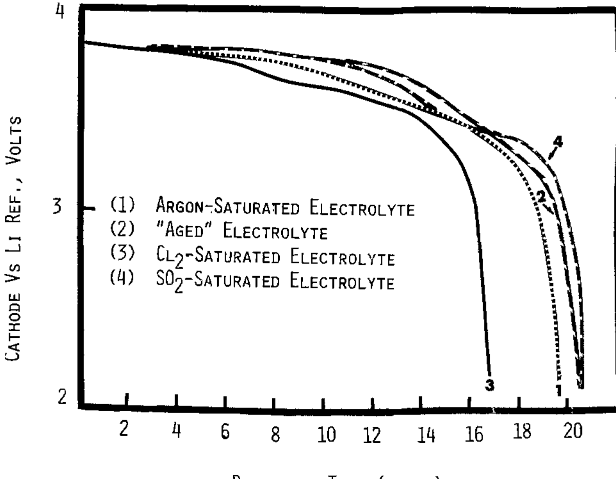

Fig. 8. Cathodic discharge curves (I = 5 mA/cm²). Electrolyte saturated with different gases.

indistinguishable in the first few hours (as might be expected due to buildup of product SO_2) in the first two cases. The variations during the later period of discharge are within the normal span for any particular (*e.g.*, argon-saturated) starting condition. The significantly shorter discharge for Cl_2 saturation was found reproducible. A possible explanation is that the direct reduction of chlorine from the bulk of the solution occurs near the outer surface of the electrode and has a greater tendency to clog pores than the heterogeneously produced Cl_2 intermediate which would be produced and consumed throughout the electrode volume.

The discharge curves for cells with either argon/SO_2-saturated or "aged" electrolyte exhibit an intermediate voltage decline suggesting a two-step reduction. This is probably analogous to the two-wave reduction observed by Behl (16) during voltage-sweep studies of carbon microelectrodes. Behl attributed the first and second waves to reduction of Cl_2 and undissociated SO_2Cl_2, respectively. A similar interpretation for the second transition in the discharge curve is tentatively adopted here. The transition to reduction of molecular SO_2Cl_2 might come about as the available surface area available to catalyze SO_2Cl_2 dissociation is diminished through coating with product LiCl.

Dependence of discharge curves (optimized United Carbon cathodes) on electrolyte volume and current density.—Figure 9 presents discharge curves for several current densities at the "standard" ratio of electrolyte volume to cathode geometric area of 1 ml/cm².

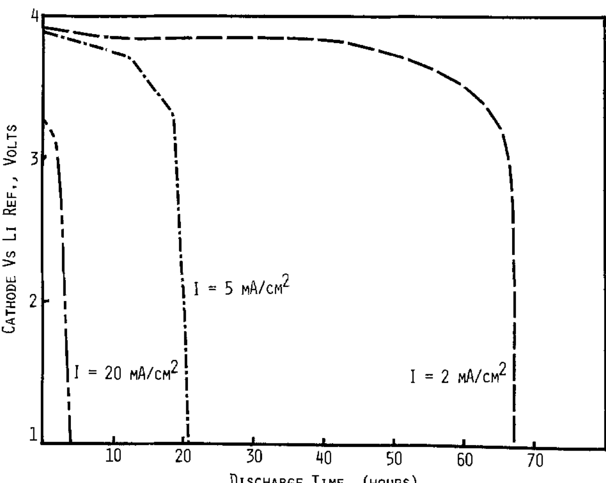

Fig. 9. Discharge curves for optimized cathode

As for thionyl chloride cells, the efficiency of cathode utilization tends to drop off with increased current density. The relatively efficient discharge current density of 2 mA/cm² was selected for exploring the effect of varying the electrolyte volume. Curves for several different volume/area ratios appear in Fig. 10. From such curves, a charge Q was estimated for "full discharge" and for discharge to a first "high voltage" transition point and the results plotted in Fig. 11. Based on Eq. [3], the values of charge, and the volume of solution in the cell, a "percent solvent utilized" was derived and plotted in Fig. 11. For volume/area rates of 0.14 or less, cell components are visibly incompletely wetted at the beginning of the experiment. No attempt has yet been made to analyze the rather sharp dependence on electrolyte volume/area ratio. Maximum solvent utilizations at "high voltage" and for "full discharge" were not observed to exceed 20% and 30%, respectively.

Let us consider how the 20% "high voltage" efficiency compares with the percentage of equivalents of Cl_2 available from the dissolved phase only. Corresponding to the Cl_2 (0.62 molal, as reported above) in a saturated solution at 24°C, 7.8% of the reducible equivalents are available from predissolved Cl_2. For degassed sulfuryl chloride, allowed to dissociate to equilibrium with the gas phase, the partial pressure of Cl_2 is approximately 0.05 atm [based on the vapor pressure of SO_2Cl_2 and dissociation constant of SO_2Cl_2 at 30°C (15)]. The corresponding percentage of equivalents available from Cl_2 can be as low as 0.4% (if Henry's law is obeyed). Hence the "high voltage" solvent utilization reported above cannot be attributed to a "reservoir" of Cl_2 resulting from dissociation of the solvent before cathodic discharge is begun, but must be supplied during the cathodic process.

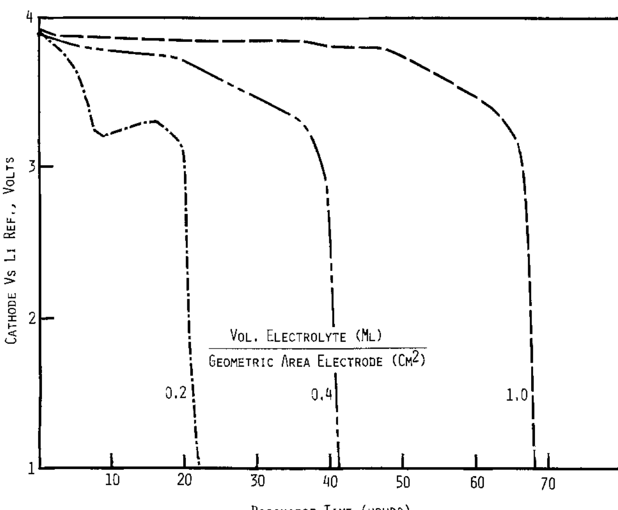

Fig. 10. Discharge curves for optimized cathode using various volumes of electrolyte.

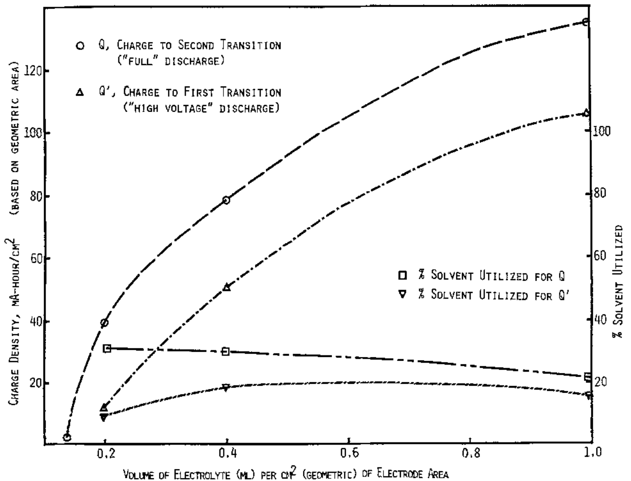

Fig. 11. Dependence of cathodic charge and solvent utilization on electrolyte volume.

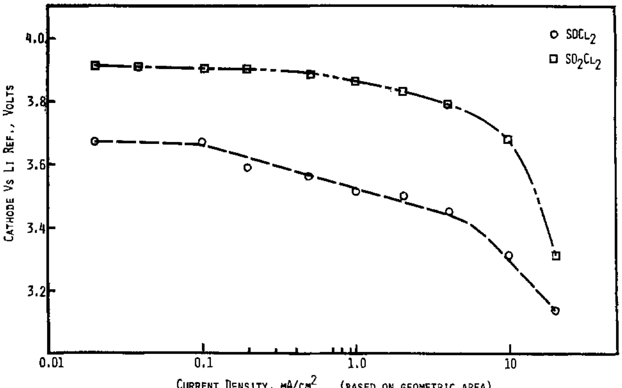

Fig. 12. Comparison of cathodic polarization curves for SO_2Cl_2 and $SOCl_2$.

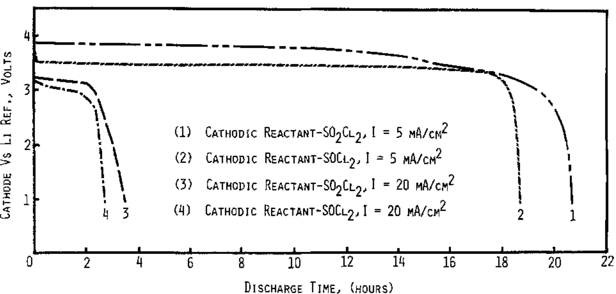

Fig. 13. Comparison of cathodic discharge curves for SO_2Cl_2 and $SOCl_2$.

Comparison of SO_2Cl_2 with $SOCl_2$ cathodes.—The polarization and discharge curves are compared in Fig. 12 and 13, respectively, for cathodes utilizing $SOCl_2$ and SO_2Cl_2 and an electrolyte volume/cathode geometric area of 1 ml/cm². Shawinigan black cathodes were used as representing the "state-of-the-art" for $SOCl_2$ and the optimized United Carbon cathodes were utilized for SO_2Cl_2. It can be seen from the figures that SO_2Cl_2 appears to offer an advantage in terminal voltage over $SOCl_2$ at high current densities, if the optimized cathodes are utilized. The comparison may be expected to vary, of course, for different proportions and concentrations of electrolyte, different temperatures, etc.

Manuscript submitted Oct. 19, 1979; revised manuscript received Feb. 8, 1980. This was Paper 33 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the U.S. Army Electronics Technology and Devices Laboratory (ERADCOM).

ABSTRACT

A model of the air diffusion electrode used in fuel cells was developed which accounts for the diffusion of oxygen in the gas-filled pores as well as diffusion into the liquid-filled pores, electrochemical reaction, and electrical conduction. The model was applied to a PTFE-bonded, platinum-on-carbon cathode in acid electrolyte to evaluate the relative contribution of these effects. Gas diffusion contributed 38% and ohmic loss in the electrolyte contributed 48% to the voltage loss other than activation. Knudsen diffusion was found to be as important as molecular diffusion. Diffusion of dissolved oxygen and ohmic conduction produced small voltage losses. Diffusion contributes to the utilization loss, especially at high oxygen utilizations, but ohmic effects do not.

The purpose of this study was to evaluate the importance of all of the sources of polarization in a polytetrafluoroethylene-bonded fuel cell cathode. In order to accomplish this purpose, a complete mathematical model of the electrode was required.

The type of electrode under consideration is shown in Fig. 1. The porous backing of the electrode consists of an inert, electronically conducting material which holds the catalyst layer. The catalyst layer consists of platinum supported on carbon powder which is sintered with du Pont Teflon. Air flows past the porous backing material and concentrated phosphoric acid electrolyte is present in the catalyst layer of the electrode. A microscopic view of a small region of the catalyst layer (also shown in Fig. 1) shows some pores filled with gas and other regions filled with electrolyte. The latter regions are referred to as agglomerates and consist of platinum crystallites (shown as dots), carbon (shown as grains) with electrolyte between the grains of carbon. The agglomerates can also be covered by a film of electrolyte.

The basic processes occurring in the electrode are shown in Fig. 2. In the first step, oxygen diffuses through the porous backing. Next, it diffuses into the catalyst layer, where it is transported through the gas filled pores. The oxygen then dissolves in the outer layer of the film of electrolyte which covers the agglomerates. The dissolved oxygen diffuses across the film and then diffuses into the pores of the agglomerates. By electrical conduction, electrons move through the carbon and hydrogen ions migrate through the phosphoric acid which is in the pores of the agglomerates. Finally, the oxygen reacts with the hydrogen ion and the electron. The resulting water evaporates into the gas pores and diffuses through the catalyst layer and the porous backing into the gas stream.

[1] Deceased.

Key words: fuel cells, mathematical models, polarization.

Mathematical Model

For each of these transport processes, there is a physical law and a mathematical equation which describes that process quantitatively.

Diffusion in the porous backing.—Fick's law was not used for diffusion in the porous backing because it applies only to the interdiffusion of two gases. In the present case, there are three gases: oxygen, water and, since the oxygen comes from air, nitrogen is also present. Therefore, the Stefan-Maxwell equations (1) for multicomponent diffusion were used

$$\frac{d\mathbf{P}}{dz} = \frac{RT}{P} A_s \mathbf{P} \qquad [1]$$

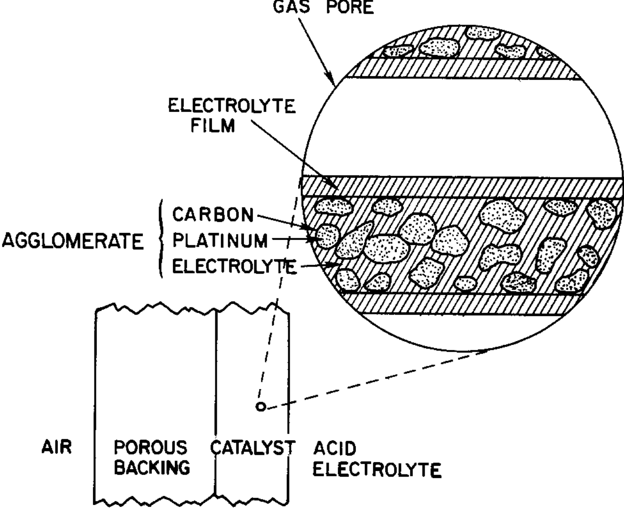

Fig. 1. Fuel cell cathode and its microstructure

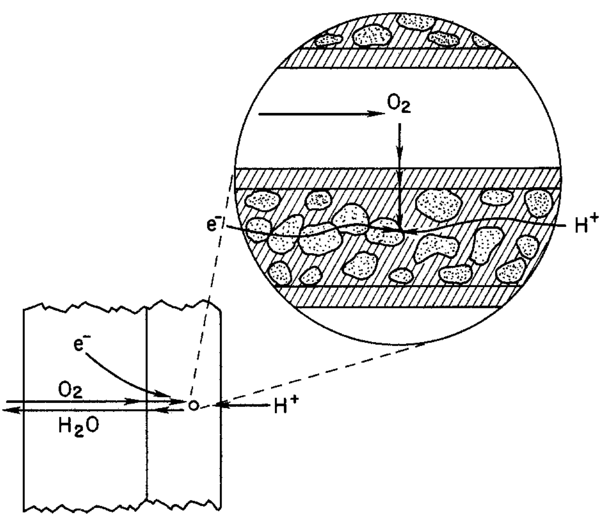

Fig. 2. Basic processes occurring in the cathode

where P represents the total pressure, $\mathbf{P}$ is the n-tuple (P_1, P_2, P_3) whose components represent the partial pressures of oxygen, P_1, water vapor, P_2, and nitrogen, P_3. The distance inside the porous backing is given by z, where the origin is at the gas stream-porous backing interface. The matrix A_s is given by

$$A_s = \begin{bmatrix} \frac{N_{20}}{D_{12p}} + \frac{N_{30}}{D_{13p}} & -\frac{N_{10}}{D_{12p}} & -\frac{N_{10}}{D_{13p}} \\ -\frac{N_{20}}{D_{12p}} & \frac{N_{10}}{D_{12p}} + \frac{N_{30}}{D_{23p}} & -\frac{N_{20}}{D_{23p}} \\ -\frac{N_{30}}{D_{13p}} & -\frac{N_{30}}{D_{23p}} & \frac{N_{10}}{D_{13p}} + \frac{N_{20}}{D_{23p}} \end{bmatrix} \quad [2]$$

The effective binary diffusion coefficients at pressure, P, are given by D_{12p} for oxygen and water, D_{13p} for oxygen and nitrogen, and D_{23p} for water and nitrogen.

The rate of diffusion of oxygen through the porous backing, N_{10}, can be found from the current density of the electrode, I_m, and is equal to $I_m/(4\mathbf{F})$. Water generated by the electrochemical reaction in the catalyst layer diffuses in a direction opposite to that of the oxygen at a rate N_{20}. Since nitrogen is neither produced nor consumed, the flux of nitrogen is zero: $N_{30} = 0$.

The effective diffusion coefficients in the porous backing, D_{ijp}, are equal to the gas-phase diffusion coefficients times a porosity-tortuosity factor, E_p, which is characteristic of the particular porous backing used. Furthermore, the gas-phase diffusion coefficients are, to a good approximation, inversely proportional (1) to the total pressure, P. Therefore

$$D_{ijp} = D_{ij}^{o} E_p / P \quad [3]$$

where D_{ij}^{o} is the gas phase diffusion coefficient at ordinary pressures extrapolated to unit pressure. With these substitutions, the multicomponent equations simplify to

$$\frac{d\mathbf{P}}{dz} = \frac{RTN_{10}}{E_p} A\mathbf{P} \quad [4]$$

where A is the matrix

$$A = \begin{bmatrix} m/D_{12}^{o} - 1/D_{12}^{o} - 1/D_{13}^{o} \\ -m/D_{12}^{o} \quad 1/D_{12}^{o} - m/D_{23}^{o} \\ 0 \quad 0 \quad 1/D_{13}^{o} + m/D_{23}^{o} \end{bmatrix} \quad [5]$$

and where $m = N_{20}/N_{10} = -2$.

The solution of this equation is

$$\mathbf{P}(z) = e^{ARTN_{10}z/E_p}\mathbf{P}_m \quad [6]$$

where $\mathbf{P}_m$ is the n-tuple (P_{1m}, P_{2m}, P_{3m}) whose components are the partial pressures of oxygen, water, and nitrogen, respectively, at the interface between the flowing gas stream and the porous backing. The fundamental matrix can be computed from the formula

$$e^{ARTN_{10}z/E_p} = \sum_{i=1}^{3} e^{\lambda_i RTN_{10}z/E_p} \prod_{j(\neq i)=1}^{3} \frac{A - \lambda_j I_u}{\lambda_j - \lambda_i} \quad [7]$$

where I_u is the unit matrix and the λ_i are the eigenvalues of A, which are 0, $(m+1)/D_{12}^{o}$, and $1/D_{13}^{o} + 1/D_{23}^{o}$.

The purpose of solving these multicomponent diffusion equations is to obtain $\mathbf{P}_c$, whose components (P_{1c}, P_{2c}, P_{3c}) are the partial pressures of oxygen, water, and nitrogen at the interface between the porous backing and the catalyst layer. This value of $\mathbf{P}_c$ is obtained by setting z equal to z_p in Eq. [6], where z_p is the thickness of the porous backing. This value of $\mathbf{P}_c$ then serves as the boundary condition for the next step, which is diffusion in the catalyst layer.

Gas diffusion in the catalyst layer.—The diffusion in the porous backing material was entirely molecular diffusion, in which the retardation of the flow of oxygen was due to collisions with other molecules. The diffusion in the catalyst layer is also partly molecular diffusion, but the pores in the catalyst layer are very narrow. The walls of the gas pores are so close together that their distance apart is nearly equal to the mean free path of the molecules. Therefore, oxygen molecules are slowed up by collisions with the walls of the pores as well as by collisions with other gas molecules. This added component of diffusion is called Knudsen diffusion. Therefore, for the catalyst layer, the Stefan-Maxwell equations must be modified (2) by adding a term for Knudsen diffusion

$$\frac{dP_1}{dz} = RTN_1 \left[\frac{1}{P_T} \left(\frac{m}{D_{12p}} P_1 - \frac{1}{D_{12p}} P_2 - \frac{1}{D_{13p}} P_3 \right) - \frac{1}{D_{k1e}} \right] \quad [8]$$

$$\frac{dP_2}{dz} = RTN_1 \left[\frac{1}{P_T} \left(-\frac{m}{D_{12p}} P_1 + \frac{1}{D_{12p}} P_2 - \frac{m}{D_{23p}} P_3 \right) - \frac{m}{D_{k2e}} \right] \quad [9]$$

$$\frac{dP_3}{dz} = RTN_1 \frac{1}{P_T} \left(\frac{1}{D_{13p}} + \frac{m}{D_{23p}} \right) P_3 \quad [10]$$

where P_T is the total pressure, $P_1 + P_2 + P_3$, inside the catalyst layer and N_1 is the flux of oxygen. The porous-backing, catalyst-layer interface is chosen for $z = 0$ and the catalyst-layer, electrolyte interface is at $z = z_l$. For a given flux ratio, m, the total pressure will not remain constant inside the catalyst layer, as was the case for entirely molecular diffusion in the

porous backing, but will vary from point to point in accordance with the above equations.

These equations can be simplified in a manner similar to that used for the porous backing. The molecular diffusion coefficients are approximately inversely proportional to the total pressure and are equal to the gas phase values times a porosity-tortuosity factor, E_T, which is characteristic of the catalyst layer

$$D_{ijp} = D_{ij}^{o} E_T / P_T \quad [11]$$

The Knudsen diffusion coefficient for the ith component, D_{kie} is similarly approximated by the Knudsen diffusion coefficient for a straight cylindrical tube, D_{kis}, corrected with the porosity-tortuosity factor

$$D_{kie} = E_T D_{kis} \quad [12]$$

and D_{kis}, in turn, as given in Ref. (1), is related to the radius of the tube, R_t, by

$$D_{kis} = 0.97\, R_t (T/\mu_i)^{1/2} \quad [13]$$

where μ_i is the molecular weight of the diffusing molecule. With these substitutions,the equations become

$$\frac{d\mathbf{P}}{dz} = \frac{RTN_1}{E_T} (\mathbf{C} + A\mathbf{P}) \quad [14]$$

where A is the same matrix as was given previously for diffusion in the porous backing and $\mathbf{C}$ is equal to $(-1/D_{k1s}, -m/D_{k2s}, 0)$.

The partial pressures of oxygen, P_1, and water vapor, P_2, can be expressed in terms of the partial pressure of nitrogen, P_3, by dividing the equations for dP_1/dz and dP_2/dz by the equation for dP_3/dz. The resulting equations are independent of N_1

$$\lambda_3 P_3 \frac{d\mathbf{p}}{dP_3} = B\mathbf{p} + P_3\mathbf{b} + \mathbf{c} \quad [15]$$

where $\mathbf{p}$ and $\mathbf{c}$ are the vectors formed from the first two components of $\mathbf{P}$ and $\mathbf{C}$. B is the matrix formed from the first two rows and columns of A and $\mathbf{b}$ is the vector formed from the first two components of the third column of A. The solution is

$$\mathbf{p} = Y(P_3)[Y^{-1}(P_{3c})\mathbf{p}_c + G(P_3) - G(P_{3c}) + H(P_3) - H(P_{3c})] \quad [16]$$

where

$$Y(P_3) = I_u + (P_3^{\gamma} - 1)B/\lambda_2 \quad [17]$$

$$Y^{-1}(P_{3c}) = I_u + (P_{3c}^{-\gamma} - 1)B/\lambda_2 \quad [18]$$

$$G(P_3) = \{I_u + [P_3^{-\gamma}/(1-\gamma) - 1]B/\lambda_2\}P_3\mathbf{b}/\lambda_3 \quad [19]$$

$$H(P_3) = \{(\ln P_3)I_u - [P_3^{-\gamma}/\gamma + \ln P_3]B/\lambda_2\}\mathbf{c}/\lambda_3 \quad [20]$$

$$\mathbf{p}_c = (P_{1c}, P_{2c}) \quad [21]$$

$$\gamma = \lambda_2/\lambda_3 \quad [22]$$

Only one of the three original differential equations for gas diffusion remains to be solved.

$$\frac{dP_3}{dz} = \frac{RTN_1\lambda_3}{E_T} P_3 \quad [23]$$

Diffusion of dissolved oxygen and electrochemical reaction.—As oxygen diffuses through the electrode, some of the oxygen reacts along the way. The flux of oxygen diffusion past any point in the electrode diminishes in proportion to the rate of reaction per unit volume of electrode, N_R, at that point

$$\frac{dN_1(z)}{dz} = -N_R \quad [24]$$

Before the oxygen can react, it must first dissolve in the outer surface of the film covering the agglomerates, diffuse across the film, and diffuse through the agglomerates. The oxygen dissolved in the outermost layer of the film may be taken to be in equilibrium with the oxygen in the gas pores at that point and therefore has a concentration, $P_1(z)C_1^o$, where C_1^o is the concentration of dissolved oxygen in equilibrium with oxygen at a partial pressure of one atmosphere. If the film is thin in comparison with the radius of the cylindrical agglomerates, the equation describing this diffusion can be approximated by Fick's law for a flat film

$$N_R = aD \frac{P_1(z)C_1^o - C_1(r_a, z)}{\delta} \quad [25]$$

where $C_1(r_a, z)$ is the concentration of oxygen at the film-agglomerate interface, a is the area of the film per unit volume of electrode, δ is the thickness of the film, D is the diffusion coefficient of oxygen in the electrolyte, and r_a is the radius of the agglomerate.

After the oxygen has diffused across the film, it diffuses radially into the pores of the agglomerates. Some of the oxygen reacts along the way. The current density has been found to be first order in the oxygen concentration from experiments at constant potential. The rate of reaction in the agglomerate can be obtained (3) by multiplying the rate constant, K_e, for the reaction by the concentration of dissolved oxygen, $C_1(r_a, z)$, at the surface of the agglomerate and by an effectiveness factor, ϵ_c, which depends on the relative rates of diffusion and reaction

$$N_R = \epsilon_c K_e C_1(r_a, z) \quad [26]$$

The formula for the effectiveness factor (3) is

$$\epsilon_c = I_1(2M_c)/[M_c I_0(2M_c)] \quad [27]$$

where I_0 and I_1 are modified Bessel functions of the first kind and

$$M_c = \frac{r_a}{2}\left(\frac{K_e}{E_n E_a D}\right)^{1/2} \quad [28]$$

where E_a is the porosity-tortuosity factor for the agglomerates and E_n is the volume fraction of the agglomerates in the electrode. The effectiveness factor can be approximated (3) by the formula

$$\epsilon_c \approx \frac{3M_c \coth(3M_c) - 1}{3M_c^2} \quad [29]$$

from which it is more easily computed.

The variable $C_1(r_a, z)$ can be eliminated between the two different equations [25] and [26] for N_R above. Since diffusion in the film and diffusion and reaction in the agglomerates occur in series, the resulting expression is the reciprocal of the sum of reciprocals of terms relating to diffusion in the film and diffusion and reaction in the agglomerates alone. The result is substituted into the differential Eq. [24] for N_1 to yield the final differential equation for the effect of diffusion of dissolved oxygen and electrochemical reaction

$$\frac{dN_1}{dz} = -\frac{P_1(z)}{\dfrac{\delta}{aDC_1^o} + \dfrac{1}{\epsilon_c K_e C_1^o}} \quad [30]$$

The rate constant, K_e, can be expressed in terms of $I_T(E)$, the current density which the electrode would have if activation were the only source of voltage loss

$$K_e = \frac{I_T(E)}{4\mathbf{F} z_l P_{1m} C_1^o} \quad [31]$$

For current densities greater than 10 A/m², I_T can be represented by

$$I_T(E) = I_T(E_r) \exp_{10}[(E_r - E)/T_s] \quad [32]$$

where E_r is some reference potential, usually 0.9V, and $I_T(E_r)$ is the current density at that potential. T_s is

the Tafel slope which is approximately 90 mV/decade at 190°C (4).

Electrical conduction.—Ohm's law governs the current of electrons through the catalyst layer

$$\frac{dE_e}{dz} = -\frac{I_e(z)}{\sigma_c} \quad [33]$$

and the current of hydrogen ions in the electrolyte

$$\frac{dE_i}{dz} = -\frac{I_i(z)}{\sigma_i} \quad [34]$$

where I_e and I_i are the electronic and ionic current densities and σ_c is the electronic conductivity of the catalyst layer material. The effective conductivity of the electrolyte in the pores, σ_i, is equal to the porosity-tortuosity factor for the agglomerates, E_a, times E_n, the volume fraction of agglomerates, times the conductivity of the electrolyte. E_e and E_i are the potentials in the catalyst layer and the electrolyte. The flux of oxygen flowing through the plane at z is consumed in producing the electronic current density at z, flowing in the opposite direction

$$I_e(z) = -4\mathbf{F}N_1(z) \quad [35]$$

The ionic current density $I_i(z)$ is equal to the difference between the total electronic current density through the plane at $z = 0$ and the electronic current density at z

$$I_i = I_e(0) - I_e(z) \quad [36]$$

The rate of electrochemical reaction, N_R, depends only on E, which is the difference between the potentials in the electrode and in the electrolyte

$$E(z) = E_e(z) - E_i(z) \quad [37]$$

Therefore, the two differential equations for E_c and E_i can be combined into a single differential equation for E

$$\frac{dE}{dz} = \frac{I_e(0)}{\sigma_i} + 4\mathbf{F}\left(\frac{1}{\sigma_c} + \frac{1}{\sigma_i}\right) N_1 \quad [38]$$

The above equations constitute a model which accounts for gas diffusion, diffusion of dissolved oxygen, and ohmic effects. Previous models considered only diffusion of dissolved oxygen and ohmic loss in electrolyte (5, 6), or only gas diffusion and diffusion of dissolved oxygen but not ohmic resistance (7).

Solution of the equations.—The electrode behavior can be characterized by solving the three simultaneous equations [23], [30], and [38]. For a given value of $E(0)$, the value of $N_1(0)$ must be varied by trial and error to give a solution of the equations for which the flow of oxygen through the catalyst layer-electrolyte interface, $N_1(z_1)$, is equal to zero. [Alternatively, $N_1(0)$ could be fixed and $E(0)$ varied.] The result is N_1, E, and P_3. From P_3, the values of P_1 and P_2 can be obtained using Eq. [16]. I_e and I_i can be obtained from N_1 using Eq. [35] and [36]. E_e and E_i can be obtained by quadrature from either Eq. [33] or Eq. [34] together with Eq. [37]. Since E_e and E_i are not independently observable, the boundary condition for E_i is arbitrary and $E_i(0)$ is conveniently chosen as zero. The experimentally measurable potential corresponds to the difference between the potential in the catalyst layer at the point of current collection, $z = 0$, and the potential of the reference electrode in the solution at the catalyst layer-electrolyte interface, $z = z_1$ or $E_e(0) - E_i(z_1)$. The experimentally observed performance curve corresponds to a plot of $E_e(0) - E_i(z_1)$ *vs.* $I_e(0)$. In the present case, the above equations were substituted into the IBM CSMP program to obtain the solution.

Approximate equations.—The partial pressure of water in the gas phase varies with the position between the two surfaces of the catalyst layer. The concentration of the electrolyte at various points in the catalyst layer will be determined by equilibrium with the water vapor present at that point. Therefore, the concentration of electrolyte will vary inside the catalyst layer. The conductivity of the electrolyte, σ_i, the solubility of oxygen, C_1^o, and the diffusion coefficient of oxygen in the electrolyte, D, are functions of the concentration of electrolyte and therefore, they will also vary with position. The diffusivity and solubility do not occur independently, but only as the product, DC_1^o, in the above equations. This product varies less rapidly with concentration than either the diffusivity or the solubility alone. The variation of diffusivity-solubility and conductivity were taken into account in calculations made with this model.

If the dependence of the conductivity σ_i on position is ignored, the number of simultaneous differential equations can be reduced from three to two. This can be done eliminating N_1 between Eq. [23] and [38] for P_3 and to yield

$$\frac{dE}{dz} = \frac{I_e(0)}{\sigma_i} + 4\mathbf{F}\left(\frac{1}{\sigma_c} + \frac{1}{\sigma_i}\right)\frac{E_T}{RT\lambda_3}\frac{d\ln P_3}{dz} \quad [39]$$

By integrating this equation, P_3 can be expressed in terms of E

$$P_3 = P_{3c}\exp\left\{\frac{RT\lambda_3}{4\mathbf{F}E_T\left(\frac{1}{\sigma_c}+\frac{1}{\sigma_i}\right)}\left[E - E(0) - \frac{I_e(0)}{\sigma_i}z\right]\right\} \quad [40]$$

In this case, only two simultaneous differential equations, [30] and [38], remain to be solved.

Application to a Particular Electrode

In order to apply this model to a particular electrode, parameters which are characteristic of that electrode must be substituted into the model equations. The rate constant for the electrode can be determined from its behavior at low current densities, where only activation losses are important and diffusion and ohmic losses are negligible. The observed Tafel slope, T_s, and the current density $I_T(E_r)$ at a reference potential, E_r, of 0.9V can be substituted into Eq. [32] to give the electrode behavior, I_T, with only activation losses. I_T can then be substituted into Eq. [31] to yield the rate constant. The Knudsen diffusion coefficient, D_{kis}, can be estimated from Eq. [13] and the average pore radius, R_t, can be estimated to be 70 nm, using electron micrographs of the catalyst layer. In a similar way, most of the parameters used in the model such as the conductivity of the carbon, the effective diffusivity in the porous backing, etc., can be evaluated experimentally.

Four parameters exist which cannot be determined directly: (*i*) the radius of the agglomerates, r_a (*ii*) the thickness of the electrolyte film covering the agglomerates, δ, (*iii*) the porosity-tortuosity factor for gas diffusion in the catalyst layer, E_T, and (*iv*) the product of the porosity-tortuosity factor for diffusion and electrical conduction in the pores of the agglomerates times the fraction of the electrode consisting of agglomerates, E_nE_a. These four parameters were determined by adjusting their values until the solution of the model equations agreed with four experimental performance curves over the range of current densities from one to 3700 A/m^2. These performance curves were obtained using four different humidified gas mixtures: (*i*) air, (*ii*) pure oxygen, (*iii*) 4% oxygen in nitrogen, and (*iv*) 4% oxygen in helium. By changing from air to pure oxygen, the diffusion losses are practically eliminated and only ohmic and activation losses remain. Therefore, this change of gases is effective in separating the ohmic losses from the diffusion

losses. Changing from pure oxygen to 4% oxygen in nitrogen reverses the situation. Diffusion losses predominate to such an extent that they cause a limiting current. This limiting current can be caused by the porous backing or by the electrolyte film covering the agglomerates. Therefore, changing to 4% oxygen in nitrogen is helpful in obtaining the effect of the backing and the film. The effect of the backing alone is obtained from the measured effective diffusivity of the backing material. Changing from 4% oxygen in nitrogen to 4% oxygen in helium changes only the molecular diffusion coefficient for gas diffusion in the porous backing and in the gas pores of the catalyst layer. Other factors remain the same. In particular, the Knudsen diffusion coefficient remains the same, since it is independent of the other gases in the mixture. Therefore, changing from 4% oxygen in nitrogen to 4% oxygen in helium is effective in separating the effect of ordinary molecular diffusion from that of Knudsen diffusion.

Calculation of Voltage Losses

This model is useful to evaluate how much voltage loss is caused by each of the basic transport processes, such as gas diffusion, diffusion of dissolved oxygen, ohmic losses, etc. Identification of the most important sources of voltage loss allows research and development efforts to be directed toward the minimization of these voltage losses.

A given loss was evaluated mathematically by calculating the performance curve with one parameter changed in such a way as to make its contribution to the total voltage loss equal to zero. For example, an ohmic loss would be made equal to zero by setting the electrical resistance equal to zero in the calculation. Figure 3 gives an example of a performance curve calculated with the diffusion loss in the agglomerate made equal to zero by making the diffusion coefficient for diffusion into the liquid filled pores of the agglomerates very large in Eq. [28]. The voltage loss corresponding to the parameter which was changed (in this case, diffusion in the agglomerate) is equal to the difference between the voltage calculated in this way and the base line curve in which all parameters have their normal values. Voltage losses for all of the transport processes were calculated in this way for an air cathode at a current density of 2000 A/m².

The total ohmic and diffusion losses are represented by the distance from the base line to the activation only Tafel line. The activation loss is represented by the distance from the Tafel line to the theoretical equilibrium potential.

The relative contributions of diffusion and ohmic losses to the total voltage loss for transport processes are summarized in Fig. 4 for a typical electrode made in 1974 at the Power Systems Division of United Technologies Corporation (4). Activation loss is not shown, being much larger than the losses for the transport processes. The conclusions are that, for the electrode studied, 54% of the voltage loss due to transport processes was due to ohmic resistance in the catalyst layer. Most of this ohmic loss occurred in the acid electrolyte and only a small part was due to the resistance of the catalyst material. Next most important was diffusion in the gas phase which accounted for 38% of the voltage loss for all the transport processes. Both the porous backing and the catalyst layer are important for gas diffusion. For the catalyst layer alone, Knudsen diffusion is slightly more important than molecular diffusion. Least important were the losses due to the diffusion of dissolved oxygen which accounted for only 8% of the total voltage loss due to transport processes. The very small voltage loss calculated for the electrolyte film indicates that such films are very thin or nonexistent at the cathode.

The voltage loss caused by Knudsen diffusion can be reduced by operating the cell at higher total pressure. However, the loss caused by molecular diffusion is practically unchanged because the benefits of the increase in oxygen concentration outside the electrode are compensated for by the decrease in the molecular diffusion coefficient with pressure shown in Eq. [3] and [11].

Optimum Electrode Thickness

The catalyst is composed of platinum particles dispersed among particles of noncatalytic conducting filler. For a fixed amount of platinum, increasing the amount of filler increases the thickness of the catalyst layer. As shown in Fig. 5, the gas diffusion and electrical conduction paths are longer for a thicker electrode than for a thinner electrode, resulting in larger gas diffusion and ohmic losses. On the other hand, reducing the amount of filler reduces the thickness of the catalyst layer and decreases the total surface area of the agglomerates. Since, from Fick's law, the gradient of oxygen concentration is inversely proportional to the area across which the diffusion is occurring, a reduction of the surface area of the agglomerates reduces the concentration of oxygen in the interior of the agglomerates (at constant overall current) and therefore increases the voltage loss due to the diffusion of dissolved oxygen. The fact that the voltage losses become large if the electrode is very thick or very thin indicates that there is an optimum amount of filler

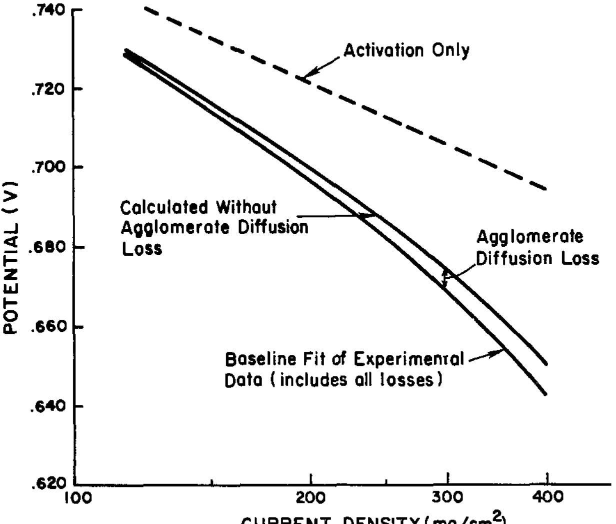

Fig. 3. Method of calculating the voltage loss due to diffusion in the agglomerates.

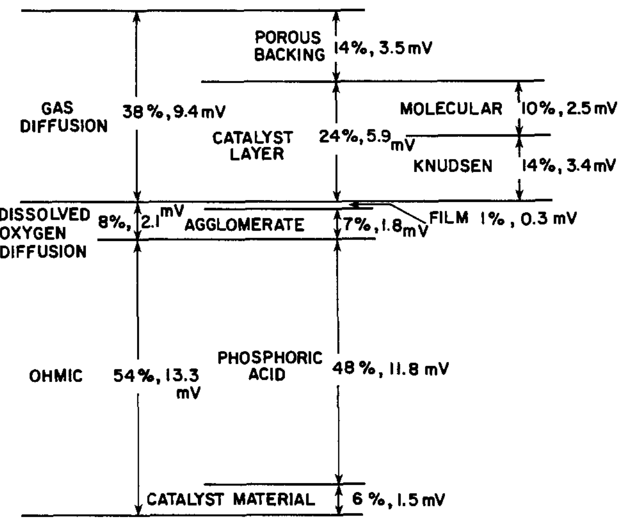

Fig. 4. Relative voltage losses for transport processes at 200 mA/cm².

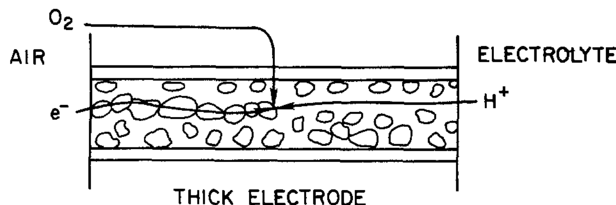

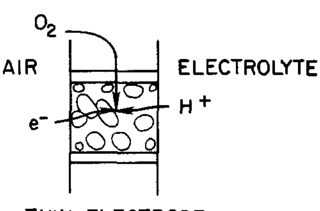

Fig. 5. Comparison of path lengths for gas diffusion and electrical conduction, and agglomerate surface areas for thick and thin catalyst layers.

and an optimum thickness for which the total voltage loss is a minimum.

Utilization

The losses given above are the only ones that apply in the laboratory situation, in which much more oxygen is made to flow past the electrode than is used to produce current. In a practical fuel cell, a substantial part of the oxygen in the air flow past the porous backing is consumed along the electrode. The parts of the electrode which are downstream operate on air which has less oxygen than the parts which are upstream. This depleted air increases the activation and diffusion losses in the electrode. Also, the downstream parts of the electrode carry a lesser than average current, while the parts nearer the inlet carry a greater than average current. The cell voltage, which is kept constant across the face of the cell by highly conductive current collectors, is less than it would be if all parts have access to the concentration of oxygen at the inlet and all parts were operating at the average current density.

The fraction of the input flow of oxygen, which is consumed to produce current, is called the air utilization. The distribution of partial pressures of oxygen in contact with the electrode at a given value, U, of the utilization can be obtained by first relating the partial pressure of oxygen to the utilization and then relating the utilization to position between the inlet and outlet. The partial pressure of oxygen, P_1, at any point across the face of the electrode is related to the molar flow of oxygen M_1 by

$$P_1 = PM_1/M_t \qquad [41]$$

where P is the total pressure and M_t is the total molar flow of all components, oxygen, water, and nitrogen. Since the molar flow of oxygen decreases in direct proportion to the utilization, it is given by

$$M_1 = P_{10}(1 - U)M_{t0}/P \qquad [42]$$

where P_{10} and M_{t0} are the partial pressure of oxygen and the total molar flow, respectively, at the inlet. For every mole of oxygen consumed, two moles of water are formed, which enter the gas stream to produce a net increase in the molar flow

$$M_t = [1 - (1 + m)P_{10}U/P]M_{t0} \qquad [43]$$

where $m = -2$ for the case where all of the product water is removed by evaporation into the oxidant gas stream. By eliminating M_1 and M_t, the utilization can be expressed in terms of the partial pressure of oxygen

$$U = \frac{1 - P_1/P_{10}}{1 - (1 + m)P_1/P} \qquad [44]$$

The utilization can be related to the position, x, along the electrode between the inlet at $x = 0$ and the outlet at $x = l$. The overall utilization, $U(l)$, is the value of U at the outlet. The utilization at any point is related to the distribution of current densities across the electrode, I, by

$$U(x) = \frac{h \int_0^x I\,dx}{4FM_{10}} \qquad [45]$$

where h is the height of the electrode. Introducing the overall utilization, $U(l)$, yields

$$U(x) = \frac{U(l) \int_0^x I\,dx}{lI_m} \qquad [46]$$

where I_m is the average current density produced by the electrode. Eliminating U between the above equations yields

$$\frac{1 - (1 + m)(1/P)}{[1 - (1 + m)(P_1/P)]^2 I}\,dP_1 = -\frac{U(l)}{I_m}\,d\left(\frac{x}{l}\right) \qquad [47]$$

For the range of current densities in which the electrochemical effects are much larger than ohmic effects, the current density, I, is related to the oxygen partial pressure by

$$I \approx I(P_{10})P_1/P_{10} \qquad [48]$$

where $I(P_{10})$ is the current density at the inlet, or at zero utilization. The distribution of partial pressures of oxygen is obtained by substituting for I in Eq. [47] and integrating. The resulting expression with x set equal to the width of the electrode, l, is used to eliminate the quantity $U(l)I(P_{10})/I_m$ in favor of P_{1l}, the partial pressure of oxygen at the outlet of the cell to yield

$$\frac{P_1}{P_{10}} = \left\{ s_p + \exp\left[\frac{x}{l}\ln\left(\frac{1}{r_p} - s_p\right) + \left(1 - \frac{x}{l}\right)\ln(1 - s_p) - \frac{1 - x/l}{1 - s_p} + \frac{1}{1 - s_pP_1/P_{10}} - \frac{x/l}{1 - s_pr_p}\right]\right\}^{-1} \qquad [49]$$

where $s_p = (1 + m)P_1/P$, $r_p = P_{1l}/P_{10}$, and P_{1l} is calculated from Eq. [44] using the known value of the utilization, $U(l)$. This equation can be solved numerically to obtain the oxygen partial pressure, P_1, as a function of position, x, in the cell. The oxygen partial pressure, in turn can be integrated numerically to obtain the average partial pressure of oxygen flowing past the electrode, P_{1m}. If the increase in the volume of reacting air caused by the formation of water had been neglected in the above derivation, the expression for the average partial pressure of oxygen would have reduced to

$$\frac{P_{1m}}{P_{10}} = \frac{(P_{1l}/P_{10}) - 1}{\ln(P_{1l}/P_{10})} \qquad [50]$$

The partial pressure of water vapor, P_2, is related to the partial pressure of oxygen by using the fact that two moles of water are produced for every mole of oxygen consumed

$$P_2 = \frac{P_{20}[P - (1 + m)P_1] - m(P_{10} - P_1)}{P - (1 + m)P_{10}} \qquad [51]$$

where P_{20} is the partial pressure of water at the inlet.

When P_{1m} is substituted for P_1 in this formula, then the average water partial pressure, P_{2m}, is obtained. The average partial pressure of nitrogen, P_{3m}, is the difference between the oxygen and water partial pressures and the total pressure, P

$$P_{3m} = P - P_{1m} - P_{2m} \quad [52]$$

The average partial pressures of oxygen, water vapor, and nitrogen found in this way serve as the boundary conditions for diffusion into the porous backing for the model of electrode behavior described above in Eq. [6], from which the performance curve can be calculated.

Calculations made in this way involve the approximation to the current density distribution in Eq. [48]. This approximation can be removed by dividing the cell into rectangular regions. From an initial assumed current density distribution, the flows of gases into and out of each of the nodes and the partial pressure distributions were calculated. Diffusion of water across the matrix was also considered. These partial pressures serve as the boundary conditions for diffusion into the porous backing for the above model of cathode behavior. The cathode potential was calculated at each node. A similar model was used to find the anode potential at each node. The voltage drop across each rectangular region was found from the anode and cathode potentials and the potential drop across the matrix. The difference in voltage from the average voltage is a measure of how much the current density at each node should be changed in order to improve the currrent density distribution. Successively more accurate distributions were calculated and the process was repeated until the potential difference was the same across each rectangular region. The cell voltage obtained in this way using 144 nodes differs by less than 2 mV from the approximate treatment of utilization given above when the current density was 2610 A/m^2 and the air utilization was 70%.

The utilization loss can be broken down into contributions from separate effects. The air activation component is the amount by which the activation Tafel line is shifted to lower potentials due to the decrease in oxygen partial pressure caused by utilization. Air activation is the largest component of the utilization loss. It depends only on the Tafel slope and the partial pressure of oxygen and is equal to $- T_s \log (P_1/P_{10})$. Its value averaged over all the nodes of the cell is 20 mV at 60% utilization and 31 mV at 80% utilization.

The diffusion loss in the porous backing and catalyst layer increases as the partial pressure of oxygen in the air decreases as a result of utilization. Unlike the activation component, the diffusion component of the utilization loss is different for different electrodes. This diffusion component is small at low utilizations but increases steeply at high utilizations amounting to about 14 mV at 90% utilization.

As the oxygen partial pressure decreases due to utilization, the partial pressures of water and nitrogen increase because the total pressure remains essentially constant. In addition, water from the fuel stream migrates and diffuses from the anode across the matrix to the cathode and water is produced at the cathode by electrochemical reaction. When dry air is used, a drying effect occurs which is confined to a small neighborhood around the inlet for all but very low utilizations. The ohmic component of the utilization loss increases by 6 mV when the utilization of dry air is reduced from 10%to nearly zero. This effect is eliminated by using humidified air at low utilization. As the utilization is varied under practical operating conditions the concentration changes in the electrolyte are small, and since the electrical resistance of the acid does not change much with concentration, the ohmic loss in the cathode and matrix does not change significantly. Except for dry air at very low utilization, the ohmic component is not an important factor in the utilization loss.

Manuscript submitted Nov. 5, 1979; revised manuscript received Jan. 18, 1980. This was Paper 32 presented at the Las Vegas, Nevada, Meeting of the Society, Oct. 17-22, 1976.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

The Effect of Ammonia on Hydrogen-Air Phosphoric Acid Fuel Cell Performance

United Technologies Corporation, Power Systems Division, South Windsor, Connecticut 06074

ABSTRACT

Laboratory experiments and tests conducted on phosphoric acid fuel cells have indicated that ammonia, when present as an impurity in either the fuel or oxidant streams, will react with the electrolyte to form $(NH_4)H_2PO_4$. Ammoniation of the acid to greater than 0.2 mole percent resulted in a loss in performance due primarily to a lowering in the rate of O_2 reduction on the the cathode catalyst. Complete recovery of the performance loss was achieved after the removal of the contaminant source. The degree of electrolyte conversion and, hence, steady-state performance loss were found to be dependent on the rate of ammonia addition to the cell relative to the rate of ammonium ion oxidation at the cathode. This oxidation process was found to be potential dependent, with an increase in cathode potential resulting in the ability of the cell to tolerate higher NH_3 concentrations in the reactant gas streams.

Small amounts of ammonia may be present as a contaminant in the processed fuel or oxidant streams of hydrocarbon-air fuel cell systems. The ammonia might be formed in a reformer used to convert a hydrocarbon fuel into a hydrogen-rich gas if nitrogen is present. Ammonia might also be introduced into the fuel because of its use as a tracer gas in natural gas distribution systems. It is also present at low concentrations in the air. Although the ammonia concentration will be on the order of a part per million, the presence of the ammonia is of concern to long-term operation of acid electrolyte fuel cell systems, since the ammonia will react with the electrolyte. This potential problem is an analog of carbon dioxide in the fuel and oxidant reacting with the electrolyte in alkaline fuel cell systems. An experimental and theoretical study was undertaken to define the severity of the performance loss associated with ammonia and the tolerance level of acid cells to ammonia.

Ammonia reacts with phosphoric acid electrolyte to form ammonium dihydrogen phosphate. Electrochemical experiments were performed with stationary and rotating electrodes to determine the effect of ammonium dihydrogen phosphate concentration on the per-

* Electrochemical Society Active Member.
Key words: cathode catalyst, electrolyte conversion, oxidation.

formance of fuel cell cathodes in phosphoric acid electrolyte. Post-test chemical analyses were performed on subscale fuel cells, which had operated for various periods of time, to determine the rate at which the electrolyte was converted in tests in which no ammonia was intentionally added to the reactants. Other subscale cell tests were performed with controlled ammonia injection in the fuel gas. The transient performance data of these subscale cell tests were compared with the results of a mathematical model that was derived to describe the cell behavior. This approach provided the definition of the effect of ammonia on the subscale fuel cell performance.

Experiments

Half-cell tests.—In order to determine the effect of $(NH_4)H_2PO_4$ concentration in the H_3PO_4 electrolyte on the performance of fuel cell cathodes, floating electrode experiments were performed using the experimental apparatus and electrodes described in Ref. (1). Electrode performance for the reduction of oxygen was measured as a function of current density under both oxygen and air. The electrodes contained about 0.5 mg Pt/cm^2 supported on Vulcan XC-72 with a concentration of 10 weight percent (w/o) Pt on the carbon support. The electrolyte in the working electrode chamber was maintained at 191°C and the water vapor pressure above the electrolyte maintained constant at a level in equilibrium with pure 99 w/o H_3PO_4. Data were obtained when various quantities of $(NH_4)H_2PO_4$ were added to the electrolyte in the working electrode chamber.

Additional half-cell experiments were conducted to determine the rate of oxidation of $(NH_4)H_2PO_4$ from H_3PO_4 electrolyte containing 1, 3, and 10 w/o $(NH_4)H_2PO_4$. The temperature and water vapor pressure of the electrolyte were maintained the same as in the previous half-cell tests. Oxidation currents were measured under N_2 over the potential range of 0.650-0.900V with respect to the hydrogen reference electrode in uncontaminated H_3PO_4 electrolyte. This potential range was selected since it is the operating potential range of fuel cell cathodes. The electrode used in this experiment consisted of a platinum-black-Teflon-bonded electrode supported on a gold-plated tantalum screen. The surface area of the Pt was determined electrochemically by hydrogen adsorption at room temperature in 50% H_3PO_4. Experiments were performed both with the electrode stationary in the electrolyte and rotating at 2100 rpm.

Subscale cell tests.—Tests were performed on 2 × 2 in. active area fuel cells to determine the effect of the presence of ammonia in the fuel gas on the cell performance and decay. Some tests were performed with no ammonia introduced into the fuel and oxidant streams. Post-test chemical analyses were performed on the cells to determine the amount of $(NH_4)H_2PO_4$ present in the cell after various periods of operation. Reactant gas analyses and chemical analyses of untested cell components were also performed to determine the source of any $(NH_4)H_2PO_4$ found after the cell tests.

Other cell tests were performed with about 1 mole percent (m/o) $(NH_4)H_2PO_4$ added to the electrolyte prior to the commencement of the test. Tests were performed at two different cell voltages, 0.616 and 0.750V, to determine the effect on cell operating voltage on the cell performance history. Two cells were tested at each cell voltage. One of each pair was tested for about 150 hr and the other for about 350 hr to determine the effect of operating time on the final $(NH_4)H_2PO_4$ content in the cell. A control cell in which no $(NH_4)H_2PO_4$ was initially added was also tested for about 350 hr at 0.616V and analyzed for post-test $(NH_4)H_2PO_4$ content.

In addition, cell tests were performed on the subscale cells with controlled quantities of NH_3 introduced into the fuel stream. The ammonia was introduced using permeation tubes which were placed in a dead-ended and thermally controlled branch to the inlet fuel line. The ammonia contents were set at 1, 2, and 6 ppm in the dry fuel gas in three separate cells by controlling the temperature of the permeation tubes. A control cell in which no NH_3 was introduced was also tested.

All subscale cell tests were performed at 191°C, atmospheric pressure, and 215 mA/cm^2. The fuel contained 80% H_2, 18.3% CO_2, and 1.7% CO and was provided at a flow rate such that 80% of the H_2 was consumed by the electrochemical reaction at the anode. The air flow was set at 40% O_2 utilization. Water was added to the cells using a saturator on the cathode gas stream.

Finally, three additional cell tests were performed. One test was conducted using a mixture of 20% H_2 and 80% N_2 as the fuel to determine whether NH_3 could possibly be formed within the cell. The other two tests were performed with 167 ppm NH_3 added to the fuel gas and NH_4OH injected into the fuel stream to obtain additional data on the effect of high levels of electrolyte ammoniation on cell performance.

All cells were constructed of the same materials. Both anode and cathode were Teflon-bonded electrodes of Pt supported on Vulcan XC-72. The electrode Pt loadings were nominally 0.25 and 0.50 mg/cm^2, respectively. The electrode spacing was approximately 125 microns.

Theory

Since some of the experimental data indicated that $(NH_4)H_2PO_4$ was oxidized at fuel cell cathode potentials, the mathematical model conceived was based on the conservation equation for $(NH_4)H_2PO_4$. This species was considered to be introduced by NH_3 present in the reactant gases and consumed by the oxidation of $(NH_4)H_2PO_4$ in the cell. All NH_3 entering the cell was assumed to react. In equation form

$$\text{input} - \text{output} + \text{generation} = \text{accumulation}$$

or

$$\Sigma C^*_{NH_3} \cdot F - 0 - kA_{Pt}C_{NH_4^+} = \frac{V(dC_{NH_4^+})}{dt} \quad [1]$$

where $\Sigma C^*_{NH_3} \cdot F$ is the sum of the products of ammonia concentrations and reactant flow rates for the two reactant streams (g moles NH_3/hr), k is the oxidation rate constant (cm^3 acid/hr cm^2 Pt), A_{Pt} is the real Pt area of cathode (cm^2 Pt), $C_{NH_4^+}$ is the concentration of NH_4^+ in the cell at any time, (g moles/cm^3 acid), V is the volume of acid in the cell at 191°C (cm^3), and t is the time (hr). In Eq. [1] the rate of consumption of NH_4^+ within the cell was assumed to be controlled by the rate of its electrochemical oxidation at the cathode and to be proportional to the Pt surface area.

The solution to this equation is

$$C_{NH_4^+} = \frac{\Sigma C^*_{NH_3} \cdot F}{kA_{Pt}} \left[1.0 - \exp\left(\frac{-kA_{Pt}t}{V} \right) \right] + C^\circ_{NH_4^+} \exp\left[\frac{-kA_{Pt}t}{V} \right] \quad [2]$$

where $C^\circ_{NH_4^+}$ is the initial value of $C_{NH_4^+}$.

The oxidation rate constant was calculated from subscale cell data on preammoniated electrolyte. The resulting expressions were

$$k = \exp\left[\frac{E_c - 1.034}{0.0273} \right] \text{ for } E_c \leqq 0.673 \quad [3]$$

and

$$k = \exp\left[\frac{E_c - 2.625}{0.1474} \right] \text{ for } E_c \geqq 0.673 \quad [4]$$

where E_c is the cathode potential.

Results

The performance loss due to electrolyte ammoniation was found to be a function of the amount of ammonium ion found in the electrolyte. The data obtained in both the half-cells and full cells are shown in Fig. 1. All of the experimental data indicate that 10 m/o conversion of H_3PO_4 to $(NH_4)H_2PO_4$ results in a performance loss of about 70 mV at 215 mA/cm². Only about 0.2 m/o conversion can be tolerated without a significant performance loss. The performance loss was found to be due to loss of cathode performance as can be seen by the good agreement between cathode half-cell data and full cell results. An inspection of the cathode Tafel plots from the half-cell tests indicated that the primary mode of performance loss is a reduction in the rate of the O_2 reduction on the cathode catalyst. Figure 2 shows the relative cathode catalyst activity for ammoniated electrolyte compared to the pure electrolyte. A loss of 84% in activity results with only 1% conversion of the H_3PO_4.

The data from the cell which was tested with an H_2/N_2 mixture as the fuel is also shown in Fig. 1. This test resulted in no performance loss due to ammoniation and only a small degree of ammoniation which was typical of a cell in which no ammonia was introduced. Therefore, N_2 does not react with H_2 in a cell to form $(NH_4)H_2PO_4$.

The results of the electrolyte analyses for cells which were endurance tested without NH_3 deliberately added to the fuel or NH_4^+ added to the electrolyte are shown in Fig. 3. The $(NH_4)H_2PO_4$ content in the cell did not increase linearly with time as might be expected if NH_3 were in the reactants, completely reacted within the cell, and not rejected. The $(NH_4)H_2PO_4$ content reached a constant value after about 1000 hr, indicating that the cell has a capacity to reject the $(NH_4)H_2PO_4$. Analyses of the reactant gases for NH_3 and of the pretest cell components indicated that much more $(NH_4)H_2PO_4$ was introduced in the cell than was found by post-test analyses, again indicating rejection capability.

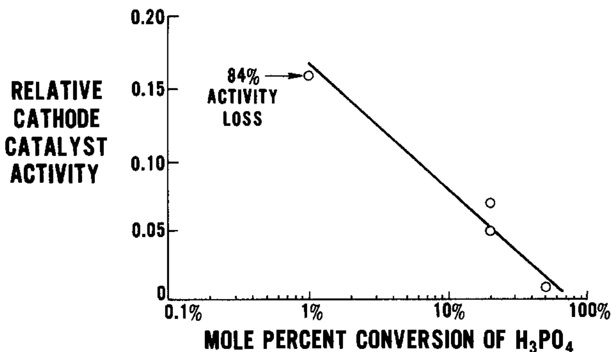

Fig. 2. Relative cathode catalyst activity as a function of percent H_3PO_4 conversion to $(NH_4)H_2PO_4$.

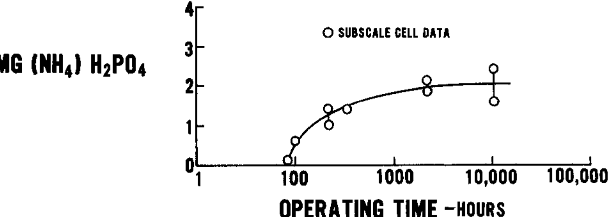

Fig. 3. Post-test analysis of subscale cell for $(NH_4)H_2PO_4$

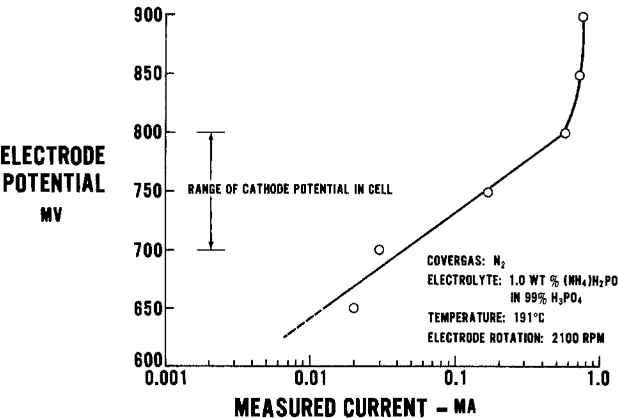

Fig. 4. Effect of electrode potential on ammonium phosphate oxidation current.

The results of the experiments to investigate the electrochemical oxidation of $(NH_4)H_2PO_4$ are shown in Fig. 4 for 1 w/o $(NH_4)H_2PO_4$ at a rotation rate of 2100 rpm. Significant oxidation currents were found for the probable reaction

$$NH_4^+ \rightarrow \frac{1}{2} N_2 + 4H^+ + 3e^- \quad [5]$$

The reaction rate for this reaction was found to be strongly potential dependent, increasing by a factor of about 60 in the potential range from 0.65 to 0.85V. Results at other electrolyte concentrations at 0.75V are shown in Table I. These results show that the rate of oxidation increases with the concentration of ammonium ion in solution and the rate of rotation.

Because of this strong effect of cathode potential on the oxidation rate of $(NH_4)H_2PO_4$, the rate of electrolyte purification for the cells containing preammoniated electrolyte would be expected to be dependent on the cathode operating potential in the cells. These results are shown in Fig. 5. In all cases, the initial concentration of $(NH_4)H_2PO_4$ in the electrolyte was about 1 m/o. For the two cells which were tested at 0.616V, the $(NH_4)H_2PO_4$ content decreased to 0.342 m/o in 141 hr for cell D and to 0.068 m/o in 334 hr for cell E. For the two cells tested at 0.750V, the $(NH_4)H_2PO_4$ content decreased more rapidly to 0.034

Table I. Summary of half-cell data

Measured current (mA) at mV RHE

Concentration w/o ammoniation	1st Experiment		2nd Experiment	
	With rotation	Without rotation	With rotation	Without rotation
0	0.0	−0.10	+0.27	0.0
1	−0.37	−0.30	−0.25	−0.38
3	—	—	−0.68	−0.66
10	−1.20	−0.75	−1.08	−0.80

Notes:
1. Electrode (Pt black, screen electrode) surface area = 11,407 cm².
2. Minus sign indicates anodic current (oxidation), plus sign indicates cathodic current (reduction).

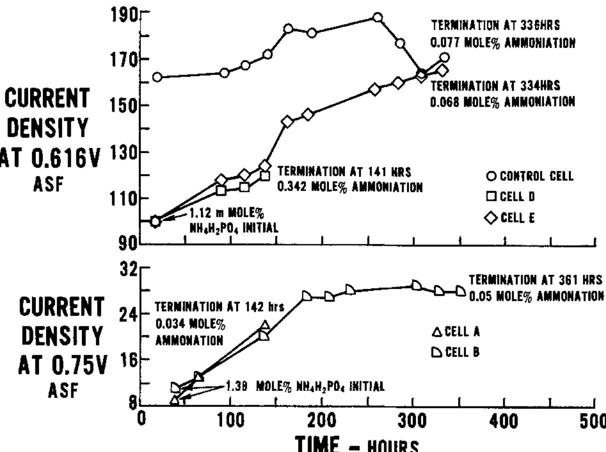

Fig. 5. Subscale cell current density at constant voltage vs. operating time.

m/o in 142 hr for cell A and 0.050 m/o in 361 hr for cell B. For cells E and B, the concentration after about 334 and 361 hr, respectively, was about the same as that of the control cell (0.077 m/o) after 336 hr. The amount of ammonium ion in the preammoniated cells had therefore been reduced to the low level of $(NH_4)H_2PO_4$ content of the control cell. Figure 5 shows also that the currents of the cells had also reached that of the control cell at the same potential. It is assumed that the performance had been improved by electrolyte purification provided by the cell cathodes. The data from these tests are summarized in Table II. This table shows that the percent of ammonium ion oxidized is a function of operating time, initial concentration, and the potential of the cell.

Experimental data for the subscale cells in which NH_3 was injected into the fuel stream is shown in Fig. 6. Introduction of 2 ppm NH_3 into cell G at about 150 hr resulted in a decay in performance. After about 560 hr, the ammonia injection was stopped and a gradual restoration of performance resulted until it reached that of the control cell at about 1500 hr. At this time, 1 ppm NH_3 was added to the fuel gas and a smaller decay again began. Analysis of the NH_3 content in the fuel gas of the control cell indicated 0.08 ppm. For cell H, introduction of 6 ppm was started at about 150 hr and removed after performance decay to about 560 hr. Again, restoration in performance to that of the control cell resulted. These results clearly show the ability of cells in which NH_3 is introduced to self-restore performance.

Figure 7 shows the loss in performance at 215 mA/cm² of cells G and H due to the introduction of NH_3 as a function of the NH_3 content. Two lines are shown since the initial performances of the three cells were slightly different. Less than 10 mV performance loss at 215 mA/cm² results if 1 ppm NH_3 is present in the fuel gas.

The results obtained using the mathematical model are compared with the results of cells G, H, and their control in Fig. 8 and 9. In applying the mathematical model, the relationship between $(NH_4)H_2PO_4$ content in the electrolyte and cell performance shown in Fig. 1 was used. In all three cases, agreement between the predicted and measured performance changes was found to be satisfactory.

The experimental data and mathematical analysis show that H_3PO_4 fuel cells can become contaminated due to NH_3 present in the reactants and be seriously

Table II. Test results from preammoniated electrolyte cells

Cell	Voltage	Operating time (hr)	m/o Ammoniation Initial	m/o Ammoniation Final	Final estimate of performance loss (mV)	% NH_3 oxidized

affected in performance. However, they have the ability of self-purification because of the oxidative capability of the cathodes. Therefore, the performance loss depends on the relative rates at which NH_3 enters the cell and is removed by oxidation. This means that the performance loss would be strongly dependent on the operating load profile of the fuel cell.

Conclusions

This study indicates that NH_3 present in the fuel or oxidant gases supplied to an H_3PO_4 fuel cell will react with the electrolyte to form $(NH_4)H_2PO_4$ and could have a severe detrimental effect on the cell performance. The conversion of the electrolyte must be limited to less than about 0.2 m/o to avoid a significant performance loss. This performance loss is due primarily to a reduction of the rate of O_2 reduction on the cathode catalyst. The cell has the capacity to reject $(NH_4)H_2PO_4$ by oxidation at the cathode. Therefore, a cell can tolerate sustained low levels of NH_3 in the reactants with little performance loss. Also the performance lost due to ammoniation can be restored if the NH_3 supply to the cell is stopped. The self-cleaning feature is dependent on the operating potential of the cathode. Therefore, the tolerance of H_3PO_4 cells to NH_3 in the reactants is dependent on the load profile that the cell is following. A mathematical model was developed to predict the loss in performance for any load profile.

Voltammetric Studies at Glassy Carbon Electrodes in Sulfuryl Chloride Solutions

Wishvender K. Behl*

U.S. Army Electronics Technology and Devices Laboratory (ERADCOM),

Power Sources Division, Fort Monmouth, New Jersey 07703

ABSTRACT

The electrochemical reduction and oxidation of sulfuryl chloride in 1M $LiAlCl_4$-SO_2Cl_2 solutions were studied at glassy carbon electrodes using the technique of cyclic voltammetry. It was found that the reduction of chlorine, which is formed by the decomposition of sulfuryl chloride, precedes and obscures the reduction of sulfuryl chloride. Thus, in chlorine-rich solutions, sulfuryl chloride reduction peak in the cyclic voltammograms is completely masked by the chlorine reduction peak. However, in solutions saturated with sulfur dioxide, the chlorine reduction peak is relatively smaller than the sulfuryl chloride reduction peak. The reduction of both chlorine and sulfuryl chloride leads to the deposition of insoluble lithium chloride at the electrode surface and results in its passivation. The electrochemical oxidation of $LiAlCl_4$-SO_2Cl_2 solutions leads to the formation of chlorine, first by the oxidation of $AlCl_4^-$ ions followed by the oxidation of sulfuryl chloride.

During the past few years, a number of studies have been reported on the ambient temperature lithium-inorganic electrolyte battery systems. However, only a few of these studies have been devoted to the lithium-sulfuryl chloride system. The scarce literature includes studies of the discharge characteristics (1-4) and discharge reaction stoichiometry (4) of lithium-sulfuryl chloride cells, conductivities (5), and voltammetric reduction of sulfuryl chloride (6) in $LiAlCl_4$-SO_2Cl_2 solutions. The electrochemical reduction and oxidation of sulfuryl chloride in 1M $LiAlCl_4$-SO_2Cl_2 solutions and in solutions containing excess of chlorine or sulfur dioxide were also investigated in this laboratory employing the technique of cyclic voltammetry. This paper summarizes our results.

Experimental

The preparation and purification of lithium tetrachloroaluminate have been described elsewhere (7). Sulfuryl chloride (Matheson, Coleman and Bell Company) was refluxed over lithium metal and distilled as colorless liquid. However, on storage, the color slowly changed to light yellow. Solutions of lithium tetrachloroaluminate in sulfuryl chloride were light yellow in color.

A three electrode system was used for all measurements. The reference (1 × 5 cm) and counter (3.5 × 6 cm) electrodes were both made by pressing lithium ribbon (0.38 mm thick; Foote Mineral Company) onto a nickel screen. The reference electrode was contained in a Pyrex tube (10 mm diam) with a coarse porosity fritted glass bottom. Both the reference and the counterelectrodes were thoroughly washed with carbon tetrachloride before use. The working electrode consisted of a 3.18 mm diam glassy carbon rod (Beckwith Carbon Company) heat-sealed in a shrinkable Teflon tubing and the end ground flush with the seal so as to expose the cross section of the rod. The glassy carbon electrode was then polished to a mirror finish using a 0.3 μm size powdered alumina and had an area of 0.079 cm^2.

All experiments were performed inside a Dry-train, Dry-lab (Vacuum Atmosphere Corporation) in a pure dried argon atmosphere. Other experimental details (8-10) were similar to those used for the voltammetric studies in phosphorous oxychloride and thionyl chloride solutions.

* Electrochemical Society Active Member.
Key words: electrolyte, battery, voltammetry.

In order to obtain reproducible voltammograms, the passivating lithium chloride film on the working electrode was dissolved, after each scan, in acidic $AlCl_3$-SO_2Cl_2 solution followed by washing with sulfuryl chloride and carbon tetrachloride. The electrode was then wiped clean and mechanically polished. The electrode could also be cleaned, *in situ*, by holding the electrode potential[1] at ~ 4.5V for 1-2 min. However, this procedure was not employed since it led to the contamination of the solution by the oxidation products, namely, chlorine, aluminum chloride, etc. (see Discussion).

Results

Typical cyclic voltammograms obtained in 1M $LiAlCl_4$-SO_2Cl_2 solution, through which pure dried argon was bubbled for 16 hr, at a scan rate of 0.1 V/sec, are presented in Fig. 1. Voltammogram A was obtained by scanning the electrode from 4.0 to 0.25V and voltammogram B by scanning the electrode from 4.0 to 5.0V. Cyclic voltammogram A shows a large increase in cathodic current beginning at ~ 3.6V with a shoulder (peak I) at ~ 3.05V and peak (peak II) at ~ 2.85V. A minor peak (peak III) is observed at ~ 2V before a rapid increase in reduction current is observed at ~ 0.75V. On reversing the direction of polarization at 0.25V, only one small anodic peak (peak IV) is observed at ~ 1.0V. The anodic peak IV is not observed if the direction of polarization is reversed at potentials positive to 0.75V. Similar cyclic voltammograms were observed at scan rates of 0.01 to ~ 0.2 V/sec. At higher scan rates peaks I and II merged together and peak III was slightly more discernible. The peak currents increased with increasing scan rate and peak potentials shifted to less positive potentials.

Cyclic voltammogram B shows a small anodic peak (peak V) at ~ 4.6V before a sharp increase in anodic current is observed at ~ 4.75V. Cyclic voltammograms did not show any reduction peak during the reverse scan. Similar cyclic voltammograms were obtained at scan rates of 0.01-2 V/sec.

In $LiAlCl_4$-SO_2Cl_2 solutions containing excess of chlorine or sulfur dioxide, cyclic voltammograms for the anodic processes were similar to the voltammogram B presented in Fig. 1. However, voltammograms for the cathodic processes were distinctly different from voltammogram A.

Thus, in saturated solutions of chlorine in 1M $LiAlCl_4$-SO_2Cl_2, cyclic voltammograms (Fig. 2) showed only one major reduction peak at scan rates of 0.01-2 V/sec. The peak potential for this reduction peak was closer to the peak potential for peak I in the cyclic voltammograms shown in Fig. 1. While peak II was not observed at all scan rates, the minor peak III became discernible only at scan rates greater than 1 V/sec.

[1] All potentials are reported with respect to lithium reference electrode.

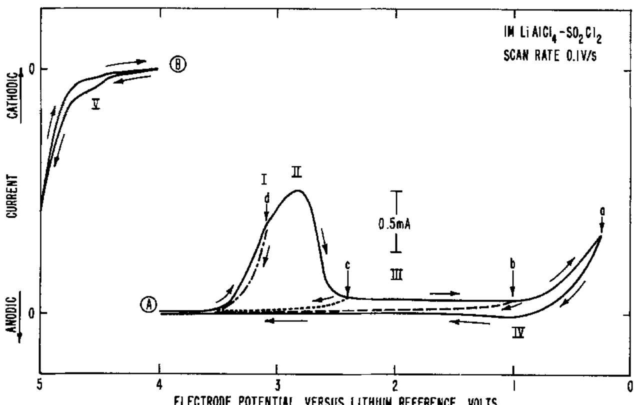

Fig. 1. Typical cyclic voltammograms at glassy carbon electrodes in argon purged 1M $LiAlCl_4$-SO_2Cl_2 solutions at a scan rate of 0.1 V/sec. Roman numerals refer to the different peaks and letters a-d indicate the potential of scan reversal of different sweeps.

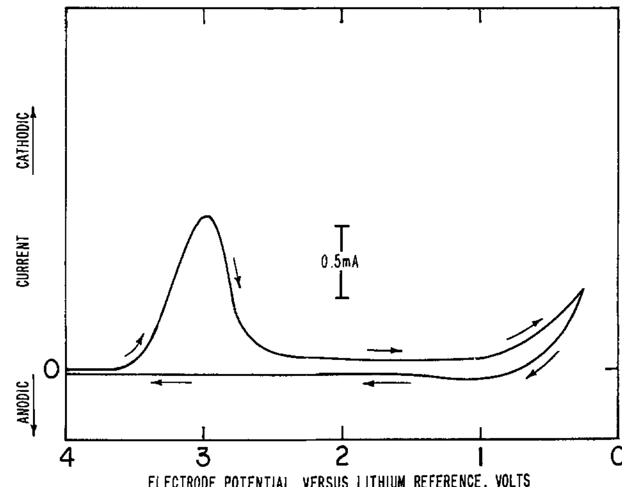

Fig. 2. Typical cyclic voltammograms at glassy carbon electrodes in saturated solutions of chlorine in 1M $LiAlCl_4$-SO_2Cl_2 at a scan rate of 0.1 V/sec.

Typical cyclic voltammograms obtained in 1M $LiAlCl_4$-SO_2Cl_2 solutions, through which sulfur dioxide was bubbled for 16 hr, at a scan rate of 0.1 V/sec are shown in Fig. 3. In these solutions, peak I appears as a small step at ~ 3.3V and peak II is the major peak at ~ 2.75V. Peak III appears as a wide peak beginning at ~ 2V. Again no anodic peak corresponding to reduction peaks I, II, and III is observed on the reverse scan. Similar cyclic voltammograms were observed at scan rates of 0.01-2 V/sec. Again the peak heights for peaks I, II, and III increased with increasing scan rate and peak potentials shifted to less positive potentials. Addition of chlorine to sulfur dioxide saturated $LiAlCl_4$-SO_2Cl_2 solution caused an increase in peak height for peak I (Fig. 4) and a corresponding decrease in peak height for peak II.

Discussion

Sulfuryl chloride is known (11) to decompose to sulfur dioxide and chlorine according to the equation

$$SO_2Cl_2 \rightleftharpoons SO_2 + Cl_2 \quad [1]$$

Both sulfur dioxide and chlorine are soluble (11) in sulfuryl chloride and remain in solution. While solu-

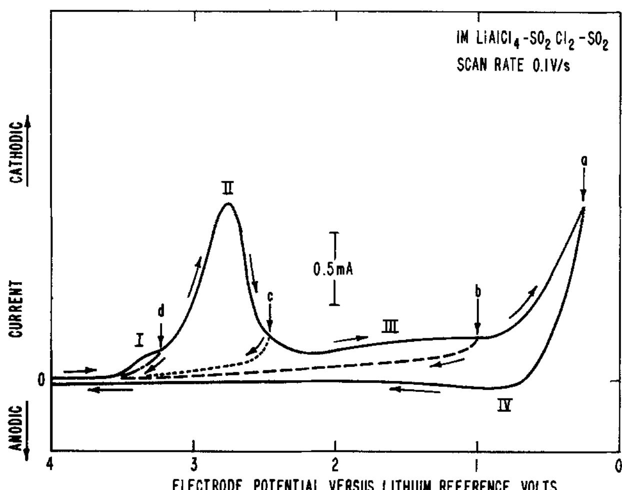

Fig. 3. Typical cyclic voltammograms at glassy carbon electrodes in saturated solutions of sulfur dioxide in 1M $LiAlCl_4$-SO_2Cl_2 at a scan rate of 0.1 V/sec. Roman numerals refer to the different peaks and letters a-d indicate the potential of scan reversal of the different sweeps.

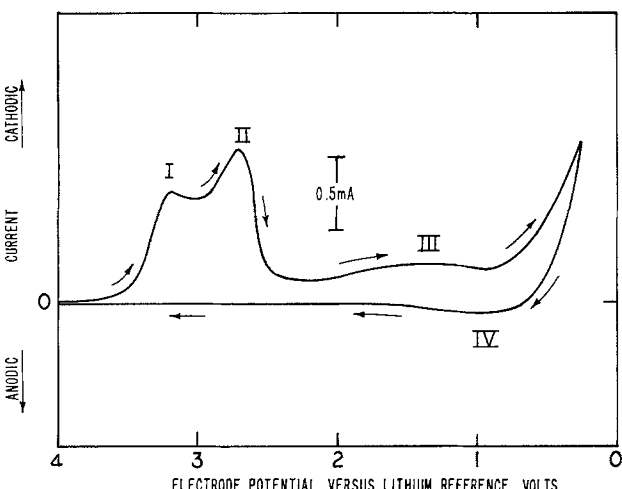

Fig. 4. Typical cyclic voltammograms at glassy carbon electrodes at a scan rate of 0.1 V/sec in 1M $LiAlCl_4$-SO_2Cl_2-SO_2 solutions to which a small amount of chlorine is added.

tions of sulfur dioxide in freshly distilled sulfuryl chloride are colorless, solutions of chlorine are light yellow in color. Solutions of lithium tetrachloroaluminate in freshly distilled sulfuryl chloride were always found to be light yellow in color. Both sulfuryl chloride and its solutions containing lithium tetrachloroaluminate became dark yellow in color on long storage. The yellow color in these solutions is attributed to chlorine which is formed by the decomposition of sulfuryl chloride according to Eq. [1]. It was not possible to completely remove the dissolved chlorine and the yellow color by purging the $LiAlCl_4$-SO_2Cl_2 solutions with argon, especially in the presence of lithium electrodes. It was, however, possible to shift the equilibrium in Eq. [1] to the left by bubbling sulfur dioxide and remove the dissolved chlorine. Thus, the $LiAlCl_4$-SO_2Cl_2-SO_2 solutions were almost colorless.

Electrochemical reduction of sulfuryl chloride.—Cyclic voltammograms (Fig. 1, voltammogram A) obtained in $LiAlCl_4$-SO_2Cl_2 solutions show three reduction peaks before a rapid increase in cathodic current is observed at $\sim$ 0.75V due to the deposition of lithium metal at the electrode surface. On the reverse scan only one anodic peak (peak IV) is observed at $\sim$ 1.0V. Since peak IV is not observed if the direction of polarization is reversed prior to lithium deposition, it may be regarded due to the dissolution of the deposited lithium metal. Similarly, the rapid increase in the cathodic current at $\sim$ 0.75V and the anodic peak IV at $\sim$ 1.0V in $LiAlCl_4$-SO_2Cl_2-Cl_2 (Fig. 2) and $LiAlCl_4$-SO_2Cl_2-SO_2 (Fig. 3) solutions may also be regarded due to the deposition and dissolution of lithium metal, respectively.

In order to identify the other reduction peaks, let us first consider the cyclic voltammograms in $LiAlCl_4$-SO_2Cl_2-SO_2 solutions (Fig. 3). Peak height for peak I in these voltammograms is strongly dependent on the concentration of dissolved chlorine as demonstrated by the addition of chlorine to $LiAlCl_4$-SO_2Cl_2-SO_2 solutions (Fig. 4). Further, if these solutions are allowed to stand for a few hours or if argon is bubbled through the solutions to remove sulfur dioxide, the equilibrium in Eq. [1] is shifted to the right resulting in an increase in the chlorine concentration and a corresponding increase in peak height for peak I. Thus, peak I may be regarded as due to the reduction of chlorine

$$\frac{1}{2}Cl_2 + Li^+ + e \rightarrow LiCl \quad [2]$$

The main reduction peak (peak II) in $LiAlCl_4$-SO_2Cl_2-SO_2 solutions may be regarded as due to the reduction of sulfuryl chloride. From a study of the discharge products in lithium-sulfuryl chloride cells, Gilman and Wade (4) have identified lithium chloride as the only solid reaction product. The reduction of sulfuryl chloride may, therefore, be represented as

$$SO_2Cl_2 + 2Li^+ + 2e \rightarrow 2LiCl + SO_2 \quad [3]$$

The reduction of both chlorine (Eq. [2]) and sulfuryl chloride (Eq. [3]) leads to the deposition of insoluble lithium chloride at the electrode surface and causes its passivation. Since it would require a fixed amount of lithium chloride, at a fixed scan rate, to cover the electrode surface, the combined peak height for peaks I and II remains constant and independent of the chlorine concentration in the solution. Thus, the peak heights for peaks I and II are interdependent and an increase in chlorine reduction peak (peak I) due to increased chlorine concentration results in a corresponding decrease in sulfuryl chloride reduction peak (peak II).

Similarly, peaks I and II in $LiAlCl_4$-SO_2Cl_2 solutions (Fig. 1) may be attributed to the reduction of chlorine and sulfuryl chloride, respectively. Since the chlorine reduction peak appears as the major reduction peak even in $LiAlCl_4$-SO_2Cl_2 solutions purged with argon for 16 hr, it seems likely that chlorine is supplied to the glassy carbon electrode not only by the migration of bulk chlorine but also by the decomposition of sulfuryl chloride at the electrode surface. Thus, at more catalytic surfaces such as platinum (12), the decomposition of sulfuryl chloride at the electrode surface is facilitated and the electrochemical reduction of sulfuryl chloride proceeds mainly through chlorine even in sulfur dioxide saturated $LiAlCl_4$-SO_2Cl_2 solutions.

The minor reduction peak III (Fig. 1 through 4) in the cyclic voltammograms may be assigned to the reduction of sulfur dioxide

$$2SO_2 + 2Li^+ + 2e \rightarrow Li_2S_2O_4 \quad [4]$$

While peak III is hardly discernible in $LiAlCl_4$-SO_2Cl_2 and $LiAlCl_4$-SO_2Cl_2-Cl_2 solutions, it is easily distinguishable in $LiAlCl_4$-SO_2Cl_2-SO_2 solutions. Since the electrode is already passivated due to the deposition of lithium chloride, the reduction of sulfur dioxide does not occur significantly in these solutions and results in only a very small peak in the cyclic voltammograms.

In order to further differentiate between peaks I, II, and III in the cyclic voltammograms, a small amount of aluminum chloride was added to the $LiAlCl_4$-SO_2Cl_2 solutions previously purged with argon. Since the excess of aluminum chloride increases the corrosion of lithium counterelectrode by dissolving the protective lithium chloride film and eventually results in its complete disintegration, the cyclic voltammograms were recorded immediately after the addition of aluminum chloride and are shown in Fig. 5. The excess of aluminum chloride in $LiAlCl_4$-SO_2Cl_2 solutions also partially dissolves the lithium chloride film on the glassy carbon electrode surface due to complex formation

$$LiCl + AlCl_3 \rightleftharpoons Li^+ + AlCl_4^- \quad [5]$$

Thus, the electrode surface continues to be partially regenerated during the life of the voltage scan and results in distinct reduction peaks for the reduction of chlorine (peak I), sulfuryl chloride (peak II), and sulfur dioxide (peak III). The peak heights are also slightly higher than those obtained in neutral $LiAlCl_4$-SO_2Cl_2 solutions. Further, due to the partial regeneration of the electrode surface, a small cathodic current is observed during the reverse scan of the cyclic voltammograms (Fig. 5) in contrast to almost no current in neutral $LiAlCl_4$-SO_2Cl_2 solutions (Fig. 1).

In $LiAlCl_4$-SO_2Cl_2-Cl_2 solutions (Fig. 2), the reduction of chlorine completely obscures the reduction of sulfuryl chloride so that only one major reduction

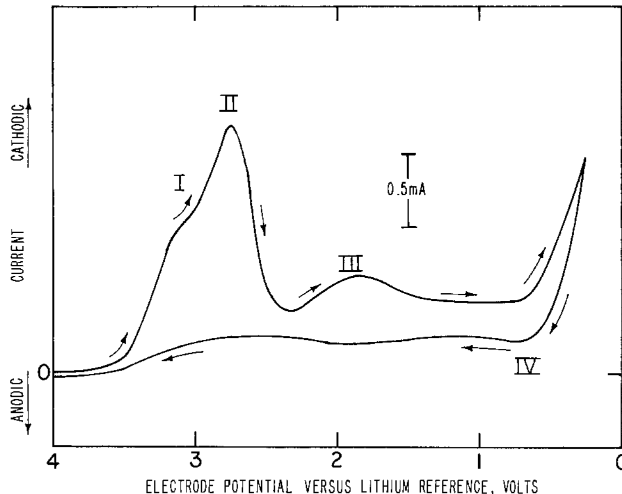

Fig. 5. Typical cyclic voltammograms at glassy carbon electrodes at a scan rate of 0.1 V/sec in 1M $LiAlCl_4$-SO_2Cl_2 solutions containing slight excess of aluminum chloride.

peak is observed in the cyclic voltammograms. Thus, in these solutions, the electrode surface is completely covered by lithium chloride produced as a result of chlorine reduction (Eq. [2]) and is not available for the reduction of sulfuryl chloride and sulfur dioxide. Cyclic voltammograms similar to those presented in Fig. 2 are also obtained in aged $LiAlCl_4$-SO_2Cl_2 solutions. The chlorine concentration in the aged solutions is rather large due to the decomposition of sulfuryl chloride and thus the chlorine reduction peak completely masks the sulfuryl chloride reduction peak. If the excess of chlorine in aged $LiAlCl_4$-SO_2Cl_2 or $LiAlCl_4$-SO_2Cl_2-Cl_2 solutions is removed by bubbling argon, cyclic voltammograms similar to those presented in Fig. 1 (voltammogram A) are obtained.

The total charge passed under peaks I and II of the cyclic voltammograms in $LiAlCl_4$-SO_2Cl_2, $LiAlCl_4$-SO_2Cl_2-Cl_2, and $LiAlCl_4$-SO_2Cl_2-SO_2 solutions was measured as a function of scan rate by integrating the area under the peaks. From the total charge passed, the thickness of the lithium chloride film on the glassy carbon electrode was then calculated taking the density of lithium chloride to be 2.068 g/cm^3 at 25°C. These results are plotted in Fig. 6. The total charge passed and hence the thickness of the lithium chloride film in all three solutions was found to decrease with increasing scan rate. However, at all scan rates, the film thickness in $LiAlCl_4$-SO_2Cl_2-SO_2 solutions was found to be slightly higher than that obtained in $LiAlCl_4$-SO_2Cl_2 or $LiAlCl_4$-SO_2Cl_2-Cl_2 solutions.

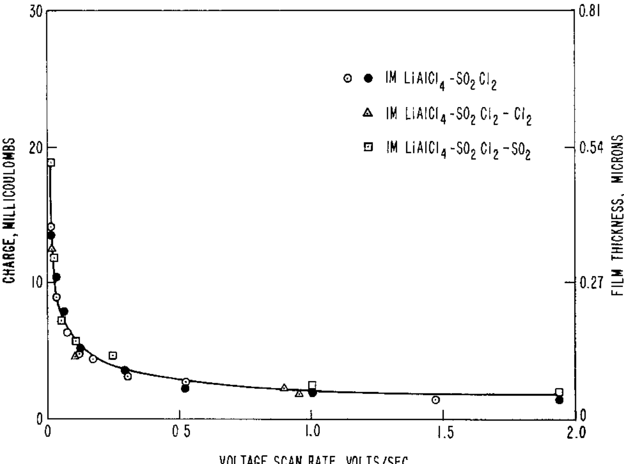

Fig. 6. Total charge passed under peaks I and II of the cyclic voltammograms and the thickness of lithium chloride film as a function of scan rate.

Electrochemical oxidation of sulfuryl chloride.— Cyclic voltammograms (voltammogram B, Fig. 1) for the oxidation of $LiAlCl_4$-SO_2Cl_2 solutions at glassy carbon electrodes were similar to those obtained in $LiAlCl_4$-$SOCl_2$ solutions (9, 13). Thus, analogous to $LiAlCl_4$-$SOCl_2$ solutions, anodic peak V at ~ 4.6V and the sharp increase in anodic current at ~ 4.75V in these voltammograms (Fig. 1) may be regarded as due to the oxidation of $AlCl_4^-$ ions and SO_2Cl_2, respectively

$$AlCl_4^- \rightarrow AlCl_3 + \frac{1}{2} Cl_2 + e \quad [6]$$

$$SO_2Cl_2 + AlCl_4^- \rightarrow SO_2Cl^+AlCl_4^- + \frac{1}{2} Cl_2 + e \quad [7]$$

Thus, if the potential of the glassy carbon electrode is held at ~ 5V for few minutes before scanning it in the cathodic direction, the formation of chlorine at more positive potentials (Eq. [6] and [7]) causes an increase in peak height for the chlorine reduction peak (peak I) in the cyclic voltammograms. At the same time, aluminum chloride formed in Eq. [6] partially dissolves the lithium chloride film on the electrode surface and causes an overall increase in combined peak heights for peaks I and II.

Manuscript submitted Oct. 15, 1979; revised manuscript received Feb. 14, 1980. This was Paper 31 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the U.S. Army Electronics Technology and Devices Laboratory (ERADCOM).

General Electric Company, Lamp Business Division, Cleveland, Ohio 44112

ABSTRACT

Several mixed aqueous electrolytes have been characterized for zinc oxide solubility, ionic conductivity, density, and nickel hydroxide utilization. These electrolytes were made by reducing the usual potassium hydroxide concentration and by adding the salts such as potassium fluoride or potassium phosphate to partially compensate for the lower ionic conductivity. These mixed electrolytes may be useful in prolonging the cycle life of the zinc electrode in secondary batteries.

Secondary batteries wth zinc anodes and alkaline electrolytes offer the promise of high energy density and high rate capability. Zinc-nickel oxide batteries under development for electric vehicles have higher energy density than lead-lead dioxide and nickel-cadmium batteries. If the cycle life of zinc-nickel oxide batteries can be substantially improved, they could be cost effective in electric vehicles. However, present state-of-the-art zinc-nickel oxide batteries do not meet the cost-life-energy density goals.

The zinc electrode is responsible for the limited cycle life of zinc-nickel oxide batteries. During cycling, zinc tends to concentrate in the center of the electrodes (shape change), thicken and lose porosity (densification), and grow tree-like structures (dendrites) on charge which cause internal shorting. General discussion of the secondary zinc electrode can be found in Ref. (1) and (2). References (3), (4), and (5) specifically address zinc electrode shape change. Zinc electrode thermodynamics and electrolyte properties are found in Ref. (6), (7), and (8).

Shape change, densification, and dendrite growth on secondary zinc electrodes are all results of the high solubility of zinc hydroxide in strong KOH and NaOH electrolytes. Uneven current distribution, electroosmotic pumping in separator membranes, diffusion, and natural convection can combine to cause migration of dissolved zinc hydroxide. Supersaturation of dissolved zinc hydroxide during discharge also aggravates these problems with zinc electrodes. One approach to improving the life of rechargeable zinc electrodes would be to utilize an electrolyte in which zinc hydroxide would be substantially less soluble. Such an electrolyte must satisfy several requirements. Ionic conductivity must be high enough to give a reasonable cell resistance. Both the zinc and nickel hydroxide active materials must have good utilization at practical discharge rates. The self-discharge rates of both electrodes must be low. Preferably the cost of the electrolyte should be not much more than that of the normally used KOH and should not contain any toxic material.

Considerable research has been done on the solubility of zinc oxide and hydroxide in aqueous potassium hydroxide and sodium hydroxide solutions and on the nature of the dissolved species. Good summaries of this work are found in (1), (2), and (6). The species present in alkaline solutions is the zincate ion, $Zn(OH)_4^{=}$ (7).

The concentration of zincate in alkaline solutions depends on the solid species in contact with the solution, the method used to introduce the dissolved zinc, and the history of the solution. Data from P. R. Mallory Company reported in (8) include for 31% KOH

Solid Species	Solubility mg(Zn)/ml
ZnO	54
$ZnO \cdot \frac{1}{2} H_2O$	92
$Zn(OH)_2$	114

Solutions prepared by electrochemically discharging zinc into solution can be substantially supersaturated, and the decay of these solutions to saturation can be very slow (9). Solutions saturated with $Zn(OH)_2$ also age, and eventually the dissolved zinc content reaches that of ZnO saturation. The $Zn(OH)_2$ decomposes to ZnO releasing water (8, 9). Aging of solutions can be accelerated by introducing finely divided ZnO and agitating the solution (9).

Experimental

Solutions were made using reagent grade chemicals and distilled water. Components were weighed to within ½%. Care was taken to minimize the amount of carbonate buildup from absorption of CO_2 from the air. The actual amounts of carbonate in the solutions were not measured.

Specific conductivities of solutions were measured using a Beckman Model RC16B2 conductivity meter at 1000 Hz and a conductivity cell with platinized electrodes. The cell constant was 0.90 ± 0.01 cm^{-1}. Densities were measured by weighing the amount in a 25 or 50 ml volumetric flask. Accuracy is probably $\pm$ 0.1%. A Fisher pH meter was used to measure the pH of some of the solutions, but these values are approximate because of the high alkalinity.

Dissolved zincate was produced in two ways: (*i*) by dissolution of ZnO powder, New Jersey Zinc USP12; and (*ii*) by electrochemical discharge of zinc metal into solution. The former solutions were agitated constantly with magnetic stirring bars while heat from the stirring plates warmed the solutions. After stirring was discontinued, the solutions sat at room temperature for at least one day. The latter method was accomplished by mixing 1g of nickel powder (made by the carbonyl process) and an amount of zinc metal powder, New Jersey Zinc 1223, sufficient to more than saturate the solution with zincate. The powder mix was added to 50 ml of solution and allowed to stand with occasional mixing until a white precipitate appeared. Zinc was discharged according to

$$Zn + 4\,OH^- \rightarrow Zn(OH)_4^{=} + 2e^-$$

* Electrochemical Society Active Member.

Key words: conductance, solubility, electrolyte.

while water decomposed on the nickel surface and hydrogen was evolved

$$2e^- + 2H_2O(Ni) \rightarrow H_2 + 2\,OH^-$$

The appearance of the precipitate indicated that saturation had been reached or exceeded and that solution aging had begun. To accelerate aging of these solutions, ZnO (NJZ USP12) was added and the solutions agitated continuously. Aliquots of clear supernatant were taken at various times for zinc analysis.

Separation of solutions from solids was accomplished by settling, centrifuging, or filtering through 0.6 micron pore polyvinyl chloride filter media. The last method is the most rapid and least troublesome.

Determination of the dissolved zinc content was done by an EDTA-Cu back titration method (10). Zinc solutions, diluted and buffered with NH_4Cl-NH_4OH buffer, were complexed with an excess of EDTA and then back titrated with copper sulfate using PAN indicator. The method was reproducible to within ± ½% and accurate to the larger of ± 3% or ± 0.03 mg/ml. The concentrations of KOH, KF, etc., reported are the starting values, uncorrected for zinc oxide dissolution or zinc discharge.

The effects of the electrolytes on the capacities of nickel hydroxide electrodes were tested in small flooded cells. A test electrode 15 cm^2 in area was placed in a 30 ml cell with a counterelectrode on each side. Test electrodes were cut from standard sintered nickel hydroxide electrodes, and the capacity was about 0.5 A-hr at 0.6A discharge. The test cells were automatically cycled using a 150 mA (5 mA/cm^2 on each side) charge for 4.2 hr followed by a discharge at 600 mA (20 mA/cm^2 on each side) to a cutoff of 0.22V *vs.* an Hg/HgO reference. After a test electrode had been cycled in 31% KOH several times, the cell was cleaned and refilled with a test electrolyte, and cycling was continued.

The open-circuit potentials of Zn/ZnO electrodes and of Zn/NiOOH cells were measured in the various electrolytes. A pasted zinc oxide electrode was charged in a test electrolyte and then partially discharged. A nickel electrode was fully charged in the same electrolyte. The electrodes were then transferred to another cell containing fresh electrolyte saturated by dissolution of zinc oxide. Mercury/mercuric oxide reference electrodes were prepared and vacuum filled, some with the test electrolytes and some with 31% KOH. Two reference electrodes were used for a test, one filled with the test electrolyte in the cell with the nickel and zinc electrodes, and one filled with 31% KOH in a side compartment isolated from the cell with a salt bridge. Nitrogen was bubbled through the cell to deaerate the electrolyte. Open-circuit voltage measurements were made after a 16-20 hr stand in an incubator set to 26.5°C.

Results

Electrolyte compositions, densities, conductivities, and nickel hydroxide electrode utilization are shown in Table I. The data are for zincate-free solutions. Electrolyte specific conductivities fall in the range of 0.1-0.64 $(\Omega\text{-cm})^{-1}$ with 31% KOH the highest. Adding KF or K_3PO_4 to 5% KOH significantly increases the ionic conductivity.

The nickel hydroxide utilizations are reported as a percentage of the discharge capacity of the same electrode in 31% KOH. Physical degradation of the nickel electrode did not seem to be a problem except with electrolyte O. The electrode in this test blistered and shed active material. The cause for the increase in utilization in electrolytes C, I, and K is unknown.

The effect of most of the electrolytes on the charge and discharge voltages of the nickel electrodes was small, less than 20 mV. In the 26.8% KF + 4.8% KOH, F, and in the 30% KF + 21% KOH, G, electrolytes, the spread between the mid-charge and mid-discharge voltages increased by about 30 mV relative to the spread in 31% KOH, A, electrolyte. In the 32.7% K_3PO_4 + 4.3% KOH, L, electrolyte, the mid-charge voltage increased 50-70 mV. In the 30% K_3PO_4, M, in the 20% K_3PO_4, N, in the 16.1% K_2HPO_4 + 19.6% K_3PO_4, O, and in the 30% KF adjusted to *p*H 13.5, H, electrolytes, the depression of the discharge voltages and the elevation of the charge voltages were unacceptably large.

Zinc solubility data are shown in Table II. Many of these values are not equilibrium values because of the slow dissolution rate of ZnO or the slow aging of solutions saturated with respect to $Zn(OH)_2$. The actual ZnO solubility is bracketed by the highest value obtained by ZnO dissolution and the lowest value obtained by zinc discharge and solution aging. Because the purpose of the study was screening and comparison of electrolytes for secondary zinc cells, tests were not continued until equilibrium had been definitively attained. The test results for electrolyte A, 31% KOH, fall within the range of the data (8) shown in the first section. The 104 mg/ml found in the freshest solution saturated by discharge is close to the reported value for equilibrium with $Zn(OH)_2$, and the aged solution, 88 mg/ml compares with the reported value of 92 mg/ml for equilibrium with $ZnO \cdot \frac{1}{2}\ H_2O$. The 46

* Solution stirred, no ZnO added, solution contained Ni powder and precipitate.
** ZnO added after * and stirring continued.

mg/ml produced by ZnO dissolution compares with the reported value of 54 mg/ml equilibrium with ZnO.

Precipitates from some of the solutions saturated by discharge and partially aged were gently dried and analyzed for major phases by x-ray diffraction. Table III lists the results.

Open-circuit potentials of zinc electrodes and Zn/NiOOH cell voltages in the various electrolytes are presented in Table IV. Stable voltage readings were obtained from all the zinc electrodes but one. In electrolyte O, the zinc electrode corroded and disintegrated overnight. The potential readings in this electrolyte were taken within a few minutes of immersion of the electrodes. Zn/NiOOH cell voltages all fall in the range 1.72-1.80. Most of the variation is in the nickel positive electrode whose potential is a function of state of charge.

The *p*H's of the test electrolytes were calculated using the potential differences between Hg/HgO reference electrodes in 31% KOH and in the test electrolytes. From Pourbaix (11) $E_o = 0.926 - 0.0591\ p\text{H}$ for the Hg/HgO electrode in alkaline electrolyte. The *p*H of the 31% KOH at 25°C was calculated to be 15.26 using the mean molal activity coefficient, 1.93, the dissociation constant for water, 1.008×10^{-14}, and the activity of water in 31% KOH, 0.575. In the calculations of *p*H of test electrolytes, junction potentials were ignored, and the assumption was made that the presence of anions in addition to hydroxyl ions did not interfere with the Hg/HgO reaction mechanism. The potential differences and calculated *p*H values are shown in Table IV. The zinc electrode potentials measured at 26.5°C would be within 1 mV of those at 25°C because $(\partial E/\partial T)_p$ for the Zn/HgO cell is +0.033 mV/°C. The overall uncertainty in the calculated *p*H values is about ± 0.2. For the electrolytes in which *p*H could be measured, the agreement with calculated values is within the uncertainty.

Table III. X-ray diffraction results

Electrolyte	Species found in dried precipitate
C	ZnO
G	ZnO
I	ZnO
K	ZnO
M	ZnO and $KZnPO_4$
O	$KZnPO_4$

The measured zinc electrode potentials were adjusted by 0.025V (the potential of Hg/HgO at *p*H 15.26 *vs.* the NHE) to their values *vs.* the NHE. The adjusted values are listed in Table IV and are plotted against the calculated *p*H in the Pourbaix diagram (11) in Fig. 1. The points fall within or close to the band of potentials calculated by Pourbaix for various forms of ZnO and $Zn(OH)_2$. Because solid discharge product was present in all of the test electrodes, only the potential-*p*H curves for zinc-solid zinc oxide reactions were plotted.

Discussion

The goal of this study was to screen a number of electrolyte mixtures and select a few that appeared promising for use in nickel-zinc batteries.

The ideal additive to an electrolyte would be one which combines with the dissolved zincate ion to form insoluble species in analogy to the silver chloride precipitation. Ceneck *et al.* (12) used this approach by adding up to 10 weight percent potassium fluoride to the electrolyte or by using zinc oxalate or zinc fluoride in the anode. Their assertion that zinc fluoride is insoluble in the electrolyte is not consistent with the analysis in this study showing that ZnO is the solid species in equilibrium with 30% KF + 2% KOH. The reduction in solubility of ZnO in these electrolytes is apparently a function of the available hydroxyl ions. Note that the ZnO solubility in 5% KOH is close to that in 26.8 KF + 4.8% KOH and in 32.7% K_3PO_4 + 4.3% KOH. In phosphate-containing solutions with

low enough KOH concentrations, $KZnPO_4$ appears, but in these electrolytes, nickel hydroxide electrolyte utilization is undesirably reduced.

Borate-based electrolytes were studied by Schneider and Dominiczak (13) for a bipolar Ni/Zn battery. The conductivity and zinc solubility results of this work are roughly consistent with theirs. The analysis of the precipitate from the K_3BO_3 solution again showed that ZnO is the stable species and that compounds like $KZnBO_3$ are not preferentially precipitated. There is an apparent anomaly in the test results for the two borate-based electrolytes, I and J. Although the compositions are substantially different, the zinc electrode potentials and calculated *p*H values are essentially equal, and zincate solubilities are close. This may be a manifestation of a buffering action in the borate-based electrolytes.

No anions were found which form insoluble zinc compounds at *p*H values compatible with nickel hydroxide electrodes. Therefore the most promising electrolytes are those in which the KOH concentration is minimized, and a highly soluble salt added to raise the conductivity. The three salts found most suitable are potassium borate, phosphate, and fluoride. Other salts such as potassium aluminate, sulfate, and chloride do not have sufficient solubility to be interesting. The mixed sodium hydroxide-silicate solutions combined low conductivity with low zincate solubility and therefore did not appear as desirable. Silicate is also reported to stabilize supersaturated zincate solutions (14.)

Because of the slow approach to equilibrium in these systems, experiments could not be continued until equilibrium was established with certainty. However, the equilibrium value for the solubility of zinc oxide is bounded below by the maximum value found by ZnO dissolution and is bounded above by the minimum value found after saturation by zinc discharge into solution. These data can serve as guidelines for selection of electrolytes for secondary cells.

There is good agreement, illustrated in Fig. 1, between the potential-*p*H values for zinc electrodes in the test electrolytes and the theoretical relationship for zinc electrodes in alkaline media. This agreement indicates that the presence of fluoride, borate, or phosphate anions do not alter the reaction mechanism. The x-ray diffraction data which found ZnO in most discharge products confirm this for all points except N and O.

Plots of the log of ZnO solubility (mg Zn/ml) against calculated pH are shown in Fig. 2. The values plotted were the highest obtained by direct dissolution of ZnO. For comparison, the dotted line shows the solubility-*p*H relationship presented by Pourbaix for ϵ-$Zn(OH)_2$. The experimental data tend to parallel this line except for the electrolytes M, N, and O which contain phosphate with little or no KOH. The data suggest that above a *p*H of 14, hydroxyl ion activity controls the zinc solubility. The phosphate electrolytes below a *p*H of 13.5 show evidence of zinc complexing.

When the nickel hydroxide electrode utilization is plotted against the calculated *p*H some trends appear. Fluoride and phosphate both reduce the electrode utilization below a *p*H of 14.5, but at lower *p*H phosphate has an apparent buffering action.

Figures 2 and 3 provide a means for preliminary selection of which electrolytes might be tested in zinc-nickel oxide cells. Electrolytes with a *p*H greater than

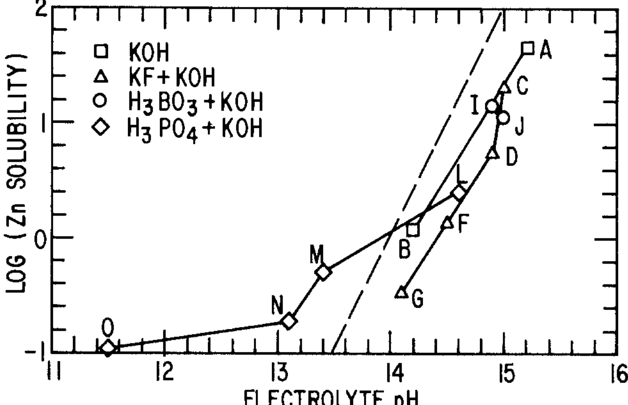

Fig. 2. Solubility of ZnO in various electrolytes

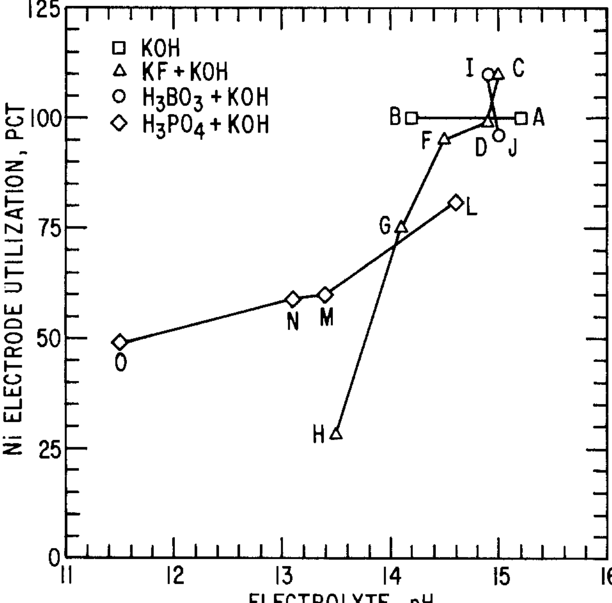

Fig. 3. Utilization of the nickel oxide electrode in various electrolytes.

14 are required for acceptable functioning of the nickel electrode. If one chooses only those electrolytes with more than a factor of 3 reduction in zinc oxide solubility, the electrolytes would be in the composition ranges represented by

D 10% KOH + 22% KF

E 7.5% KOH + 24.3% KF

G 2% KOH + 30% KF

I 24% K_3BO_3

J 32% K_2HBO_3

L 4.3% KOH + 32.7% K_3PO_4

P 7.5% KOH + 16% K_3PO_4 + 12% KF

One might also consider somewhat more acidic borate-based electrolytes than I and J.

Cycling tests of zinc-nickel oxide cells using some of these electrolytes will be described in a later report.

Conclusions

Several mixed electrolytes have been selected as promising for use in secondary cells with zinc electrodes. Alkaline electrolytes containing major amounts of potassium fluoride, phosphate, or borate show low solubility for zinc oxide and conductivity reduced in most cases by less than a factor of two. These electrolytes should suppress shape change, slumping, and dendrite growth during cycling of cells with zinc electrodes. Cells using these electrolytes may show higher cell resistance and lower electrode utilization. This compromise between energy or power density and cycle life could be adjustable by varying the ratio of KOH to other salts in the electrolyte.

The Behavior of the Zinc Electrode in Alkaline Solutions

IV. The Effect of Ionic Strength in the Tafel Region

T. P. Dirkse*

Calvin College, Grand Rapids, Michigan 49506

ABSTRACT

Potentiostatic pulses have been used to obtain information about the behavior of the zinc electrode in the Tafel region. The form of the current transients obtained has been analyzed and an interpretation of it is given. Changes in the current density of zinc at a given potential have been noted as the ionic strength of the electrolyte is altered. This has been done for solutions containing high and low concentrations of OH^- ion. The current density values are only slightly affected by changes in ionic strength except that as the ionic strength increases, the results tend to become more erratic.

For some time work in this laboratory has dealt with the kinetics and the mechanism of the zinc electrode in alkaline solutions. The exchange current density for this process has been measured by different methods (1-3). However, the experimental information was all obtained within 10 mV of the equilibrium potential. Attempts to get overpotential-current information beyond this equilibrium potential region were unsuccessful because of the unusual shapes of the transients obtained. Consequently, no information was obtained in the Tafel region.

* Electrochemical Society Active Member.
Key words: electrolyte, electrode, potentiostatic pulses, Tafel slope.

Our earlier work has also shown that the exchange current density is influenced by the ionic strength of the solution (4-6). This observation appeared to resolve the unexpected result that the exchange current density does not increase monotonically with increasing KOH concentration, but reaches a maximum in about 3-8M KOH and then decreases.

While much work has been reported on the kinetics of the zinc electrode processes, most of this has been concerned with the cathodic rather than the anodic part of the process. As a result, the cathodic or electrodeposition process is fairly well understood. This is not so true of the anodic process. There still is a difference of opinion, *e.g.*, as to whether the cathodic and anodic

paths are the reverse of each other. There is also the problem of whether the process is the same in the Tafel region as in the vicinity of the equilibrium potential. A good review of the present understanding of the zinc electrode reactions has appeared recently (7).

There were several reasons for undertaking the present work. First of all, an attempt was made to shed some light on the anodic part of the process. In doing so, an attempt was made to gather information in the Tafel region. It was suggested earlier (1) that the "peculiar" shapes of the transients might be due to metallurgical effects, *i.e.*, lack of sufficient active sites on the zinc metal. It was also shown that a cathodic prepulse overcomes these difficulties. With this in mind, attempts were made to provide sufficient such sites. This was accomplished in part by a cathodic pretreatment and in part by the use of repetitive pulses. With this experimental approach we were able to get information in the Tafel region for solid polycrystalline zinc electrodes. No work was done with amalgam electrodes.

The second purpose of this work was to attempt to explore more systematically the effect of ionic strength on the anodic process in the Tafel region and to compare this with information obtained in the equilibrium potential region. A later article will deal with the determination of reaction orders in the Tafel region.

Much of the work dealing with the behavior of the zinc electrode in the Tafel region has been obtained galvanostatically. Very little has been reported on the use of potentiostatic pulses in studying the behavior of the zinc electrode. Potentiostatic pulses were used in this work. The intent was to add the results of this approach to the literature already available on the study of the zinc electrode.

Experimental

Stock solutions of KOH, KOH + Zn(II), and KF were prepared by using analytical reagent grade solids and doubly distilled deionized water. The Zn(II) was introduced by dissolving ZnO in a KOH solution. These stock solutions were then used to prepare the working solutions. This was done by taking prescribed volumes of the stock solutions and quantitatively diluting them. The ionic strength of the solutions was controlled by the addition of KF. Three solution variables were considered: KOH concentration, Zn(II) concentration, and total ionic strength. Two series of solutions were prepared. In each series the OH^- ion and Zn(II) concentrations were held constant while the ionic strength was varied. These two series represented OH^- ion concentrations on either side of the maximum in the i_o *vs.* OH^- ion concentration plots.

The Tafel region information was obtained by subjecting the electrode to repetitive potentiostatic pulses from a Tacussel GATP Function Generator. These pulses were fed into the electrode by way of a Wenking Potentiostat. The pulse sequence consisted of a cathodic prepulse, an equilibrium pulse, followed by the working pulse. This series of pulses is shown on Fig. 1. All work was done at room temperature, 21° ± 1°C.

Results

The effect of repetitive pulses is shown on Fig. 2. Trace "a" was obtained from one of the first pulses. It is similar to the transients obtained with single potentiostatic pulses (3). It does not show the characteristic spike for such pulses. Trace "b" was obtained after pulsing repetitively for a few seconds. During this time a form of spike developed on the trace. Longer pulsing did not alter the shape of trace "b." Consequently, all the data were taken as soon as the trace stabilized. These were then extrapolated to zero time in the usual way. Changing the amplitude of the cathodic prepulse did not change the transient obtained during the working pulse. The change in shape of the transients suggests that the electrode needs to be worked (or cycled) before the so-called normal effects appear. A single cathodic prepulse alone is not sufficient to bring this about—see trace "a" on Fig. 2.

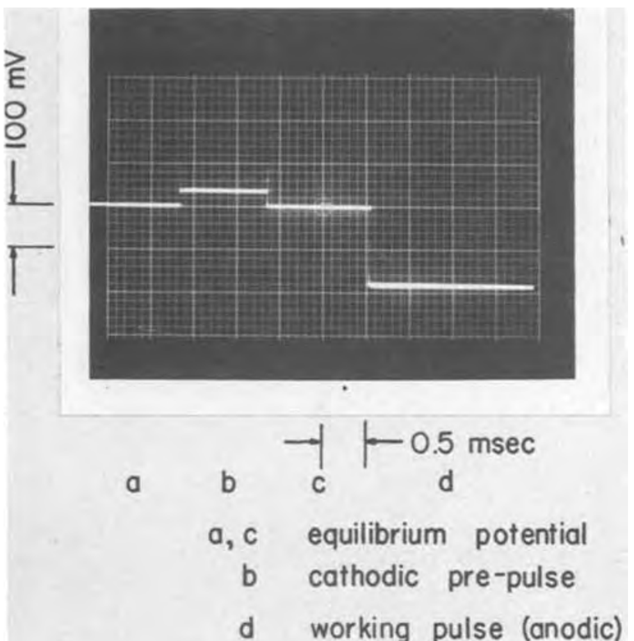

Fig. 1. Typical potentiostatic pulse sequence

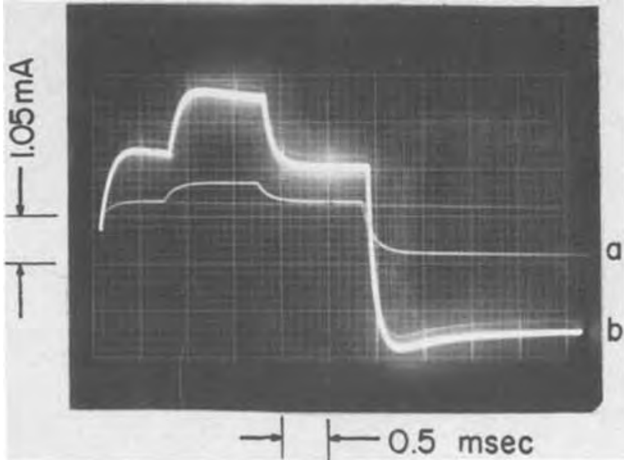

Fig. 2. Current-time transients from potentiostatic pulses in 2.04M KOH.

Repetitive pulsing has at least two effects: (*i*) the amplitude of the current is increased; and (*ii*) the leading edge of the current transient undergoes a change in shape. In addition to this there is another fact that should be noted. When the pulsing is terminated after the shape of the transient has stabilized (trace "b", Fig. 2), then during open circuit the electrode undergoes some sort of change so that when pulsing is resumed the sequence of transients obtained is again the same as that shown on Fig. 2.

On Fig. 3 are shown two of the Tafel plots obtained in a series of solutions whose ionic strengths ranged from 2.05 to 6.55M. The plots are all very similar. Apparently, the change in ionic strength has little, if any, real effect on the Tafel plots. All of these plots showed a tendency to level off at overpotentials greater than 140 mV. This has also been observed by others (7) and it was suggested that this is due to the attaining of full surface coverage by the anodic univalent intermediate which was considered to be strongly adsorbed.

Figure 4 shows a Tafel plot for a solution in which the OH^- ion concentration was 6.27M, *i.e.*, the solu-

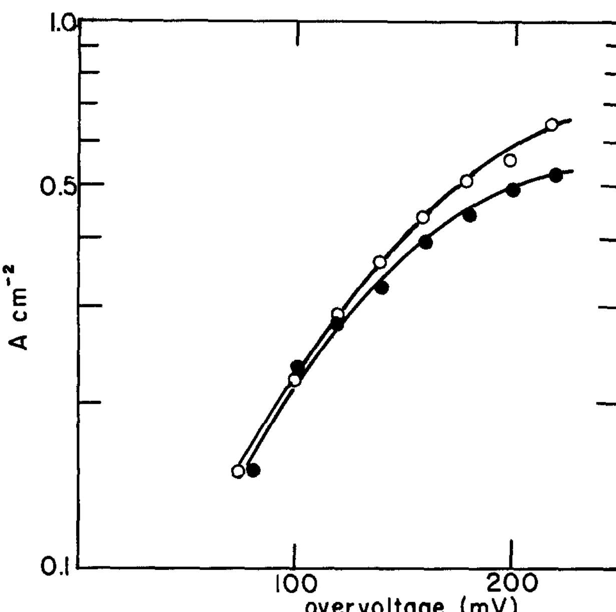

Fig. 3. Tafel plots for solutions containing 2.0M OH^- and 0.01M Zn(II). Ionic strength is 2.05M for the open circles and 6.55M for the closed circles.

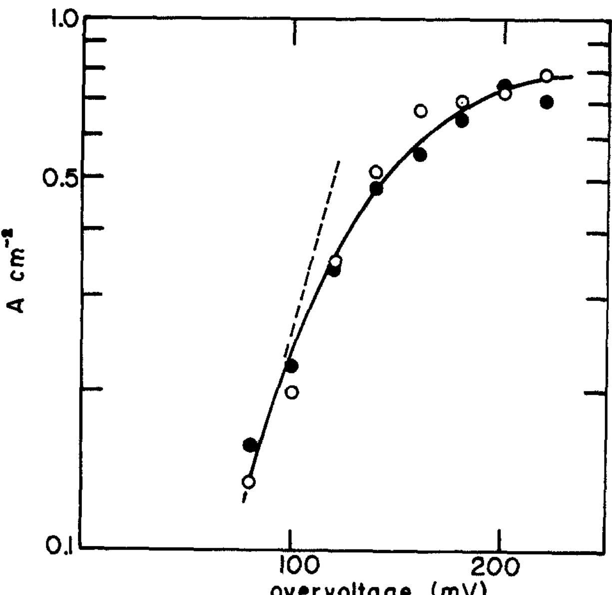

Fig. 4. Tafel plot for a solution containing 6.27M OH^- and 0.023M Zn(II). Total ionic strength is 8.65M. The open and closed circles refer to results obtained from two different cells.

tion was on the high side of the maximum in the i_o *vs.* KOH concentration plot, while the OH^- ion concentration in the solutions of Fig. 3 was on the low side of this maximum. Again, a change in the ionic strength from 6.38 to 8.65M has very little effect on the shape of the Tafel plot on Fig. 4. As on Fig. 3, the plots have a tendency to level off at the higher overpotentials.

The effect of changing ionic strength on the zinc electrode process is shown on Fig. 5. The potential in each case is chosen as 100 mV anodic to the equilibrium potential. Earlier work (8) has shown that the equilibrium potential of the zinc electrode is fairly insensitive to changing ionic strength. Consequently, selecting current densities at a given overpotential is equivalent to the selection of current densities at a given electrode potential, provided the concentrations of the OH^- and Zn(II) ions remain constant.

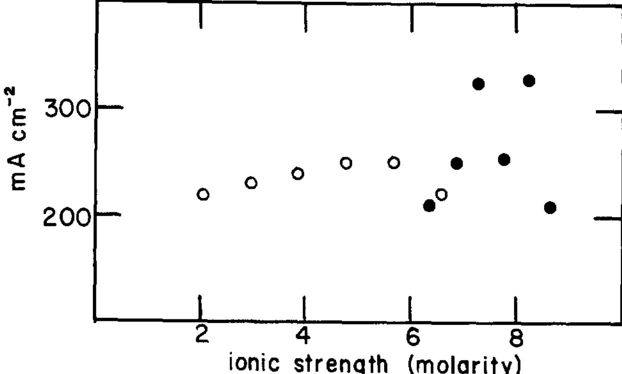

Fig. 5. Effect of ionic strength on current density in the Tafel region. Open circles, 2.0M OH^-, 0.01M Zn(II); closed circles, 6.27M OH^- and 0.023M Zn(II). The potential is 100 mV anodic to the equilibrium potential.

Discussion

Shape of transients.—The stabilized transients (trace "b" on Fig. 2) do not have the classical shape of a current transient resulting from a potentiostatic pulse. Although they do have a maximum at the leading edge of the transient, they do not have the sharp spike characteristic of double layer charging. Therefore it is necessary to analyze the transients further to determine what sort of information they do contain.

The first transient (trace "a," Fig. 2) appears to be the result of increasing surface area. The current increases with time which suggests that the initial potentiostatic pulses are altering the surface condition of the electrode. There are several possible explanations for this. First, it is possible that the surface area is increasing due to the formation of etch pits (9). However, the i *vs.* t relationship for trace "a" does not agree with that developed for each pit formation (9). Another objection to this explanation is that it would not readily account for the fact that on open circuit the electrode surface loses its increased area, *i.e.*, the etch pits disappear or fill in. Ordinarily, when etch pits are formed they tend to grow and thus increase the surface area (and the current) further.

A second explanation is related to the observation that the zinc electrode equilibrium potential is a mixed potential (10). As a consequence, the surface of a zinc electrode at its equilibrium potential may have hydrogen atoms adsorbed on it. The cathodic prepulse would then serve to reduce any oxide present as well as cause the adsorbed hydrogen to be evolved from the surface. This explanation would account for the fact that when the active surface is allowed to rest at the equilibrium potential the surface again becomes inactive, *i.e.*, it would again be covered with adsorbed hydrogen. However, as noted earlier, changing the amplitude of the cathodic prepulse had no effect on the shape of the stabilized pulse. If this explanation were correct then it would seem that increasing the amplitude of the cathodic prepulse would cover the surface with still more hydrogen and reduce the activity of the surface during the anodic working pulse, unless all the hydrogen so produced would be evolved.

A third explanation assumes that the anodic pulse produces active sites or centers on the zinc surface. These would disappear during the cathodic prepulse but during a series of repetitive cycles more anodic than cathodic charge is given to the electrode and so the net result is an increase in the number of active sites with time, causing an increase in current until a stabilized or equilibrium (or steady-state) condition is reached. On open circuit these active sites would be the first ones destroyed and hence the electrode would again revert to its relatively inactive form. This explanation appears to be the most likely

one of those presented here, especially since polycrystalline (rather than amalgam) zinc electrodes were used.

The discussion above had to do primarily with the shape of the first transient ("a" on Fig. 2) and the fact that during repetitive pulsing the current increases. However, this still does not account for the changes in the shape of the leading edge of the transient during cycling. An explanation for this is that both traces on Fig. 2 are composites of at least two processes occurring simultaneously. One of these processes is that discussed above, *i.e.*, the increase of reactive area on the electrode during repetitive cycling. This is the dominant process in trace "a" on Fig. 2. The other process(es) is the one associated with a classical potential step experiment, *i.e.*, the double layer charging spike followed by the charge transfer process and then tapering off as concentration polarization sets in. A combination of such a classical transient with one such as "a" will give a transient having the shape of "b" on Fig. 2.

This means that extrapolation of the current transients in the usual way to time zero is not really straightforward and may include a bit more information than that of charge transfer. However, as will be indicated below the information obtained by using the usual method is consistent with that obtained by other techniques.

Effect of ionic strength.—For the more dilute solutions with respect to the OH^- ion, Fig. 5, the ionic strength has no effect on the electrode process. For solutions more concentrated in OH^- ion the results are not so clear-cut. There is a good deal of scatter in the results and no particular trend is apparent. This is likely due to the excessive ionic crowding in these solutions. The increase in ionic strength of these solutions was done by adding KF, and this increases the viscosity of the solutions markedly (11).

The results of Fig. 5 may be compared with those reported earlier for the zinc electrode processes in the vicinity of the equilibrium potential (5). There the increasing ionic strength had no effect on the processes at the lower OH^- ion concentrations but caused a decrease in i_o at the higher OH^- ion concentrations. This latter effect is not observed here, Fig. 5 (closed circles). The difference in behavior is likely due to the fact that here an overpotential is applied which offsets the effect of increasing ionic strengths. This is borne out by considering data from these same Tafel plots but at a higher overpotential, Fig. 6. On Fig. 6 the current density is definitely higher for the solutions more concentrated in OH^- ion (closed circles) while at the lower overpotential, Fig. 5, there is no marked difference in current density between the different OH^- ion concentrations.

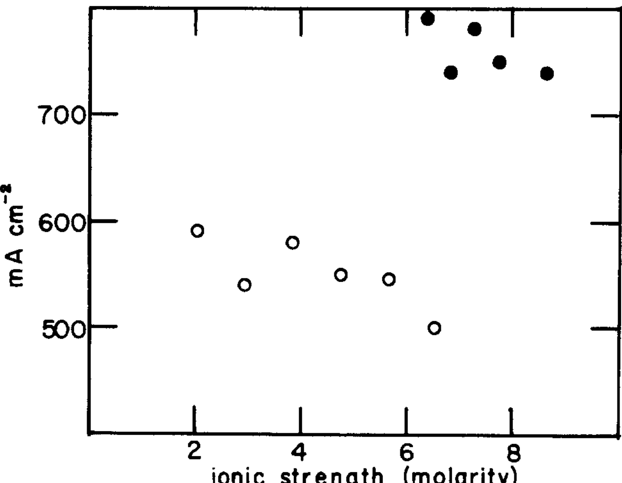

Fig. 6. Effect of ionic strength on current density in the Tafel region. Symbols the same as for Fig. 5. The potential is 200 mV anodic to the equilibrium potential.

Tafel slopes.—Although there probably is no really linear portion to these Tafel plots, slopes were measured as shown on Fig. 4 and extrapolated to zero overpotential to determine i_o. The results are given in Table I. The slopes for the solutions that were more dilute in OH^- ion concentration are fairly constant, and are larger than the others. The exchange current densities also are substantially constant for the solutions that are more dilute in OH^- ion and are in fairly good agreement with the results obtained by other methods (5, 6).

The Tafel slopes in Table I are almost double those obtained by Despic, *et al.* (7). Those authors obtained their Tafel information from galvanostatic pulses. It has been noted before that the values obtained for the parameters of the zinc electrode processes are dependent on the method used for obtaining the information (3). The exchange current densities obtained by Despic and co-workers by extrapolation of Tafel slopes are at least an order of magnitude smaller than the values measured in the region of the equilibrium potential (3).

For the solutions that have a higher OH^- ion concentration, (B) in Table I, the Tafel slopes show some variation but this is likely due more to difficulties in determining the slopes than to any real effect. The exchange current densities, likewise, show more scatter and are much lower than those obtained by other methods.

No significant kinetic information will be deduced from these Tafel slopes for two reasons: (*i*) the difficulty in determining the slopes; and (*ii*) the intention here is merely to note the effect of ionic strength on the process and to ascertain whether it is as important to control this variable in the Tafel region as it is in the region of the equilibrium potential. In a subsequent article the effect of changing OH^- and zincate ion concentration on the Tafel slopes will be used to extract kinetic and mechanistic information.

Conclusions

Changes of ionic strength have little effect on the zinc electrode processes in alkaline solutions in the Tafel region. However, at concentrations of OH^- ion above the maximum in the i_o *vs.* KOH concentration plot, *i.e.*, above about 3-6M, increasing the total ionic strength of the solutions causes the results to be rather erratic. A likely reason for this is that at these higher ionic strengths normal hydration numbers of the ions cannot be satisfied and the physical nature of the solution is changing. There may be significant ion pair formation as well as other accommodations to the increasing dearth of solvent molecules.

and Kenneth Peters*

Chloride Technical Limited, Swinton, Manchester, M27 2HB, England

ABSTRACT

The effect of alloying bismuth on the electrochemical behavior of lead has been investigated at three levels of bismuth. Linear sweep voltammetry and potential step experiments have been carried out in sulfuric acid solution of battery strength. The results show that bismuth additions accelerate the rate of corrosion of the lead and confirm that the relationship between the extent of the anodic attack and bismuth content is not linear but goes through a minimum value. From the potential step behavior it appears that bismuth differs in effect from that of antimony, the most obvious difference being the absence of a second current peak in the step response for the development of PbO_2 with the bismuth-containing electrodes.

Despite recent concentrated efforts toward the development of small, light-weight secondary electrochemical power sources, the lead-acid battery, first introduced in 1859, remains unsurpassed at the forefront of major battery systems today. Numerous attempts have been made, however, to replace antimony as the grid alloying ingredient for reasons we outlined in a previous publication (1), not least of these being the deleterious effect of the alloy on the hydrogen overvoltage of the cell. Materials suggested as a substitute include alloys of Ca, Sn, Mg, Al, and Ti, and several workers have considered the effect of alloying lead with various amounts of bismuth (2-7). Recent work carried out in this laboratory by Casson (8) in which a whole range of alloys were subjected to extensive cycling conditions has suggested that alloying with bismuth produces favorable recharge characteristics which are worth further investigation.

Small quantities of Bi ($<0.3\%$) do not seem to have any significant effect on the metallurgical properties of lead; as the quantity of Bi is increased the lead is found to harden, its bending strength being considerably reduced. The effect of Bi on the hydrogen evolution reaction has been studied by Kilimnek *et al.* (9) who found that the kinetic constants a and b in the equation $\eta = a + b \log_{10} i$ depend on the magnitude of the charge on the electrode surface. The values given in Table I for Bi in 1M H_2SO_4 (9) indicate the slow rate of hydrogen gas formation.

It has been reported that the stability of bismuth-containing alloys to corrosive attack passes through a minimum at approximately 3.5 weight percent (w/o) Bi (10). These curves were based on studies of the weight loss of a corroding anode, the amount of sludge formed, and the cathode weight gain over a period of 70 days. The authors offer no explanation for the effect of bismuth in promoting the corrosion of the lead lattice. A detailed study of the effect of bismuth on battery performance (11) has shown that the presence of bismuth results in an increase in the amount of positive shedding (*i.e.*, loss of active material as sludge in the cell case) and promoted grid growth. These increases, however, do not appear to be linear with increasing bismuth content.

There seems to be some discrepancy in the literature concerning the tolerable level of Bi, with one set of workers reporting that as little as 0.01% Bi in Pb increases its corrodability (12). For this reason it was decided to carry out our own investigation using vari-

ous levels of Bi in the form of binary weight alloys with pure lead.

This paper records the LSV and potential step measurements and compares the data obtained with that from our previous work on the Pb/H_2SO_4 and Pb-Sb/H_2SO_4 systems.

Experimental

The electrolytic cell, electrode pretreatment, and electrical circuitry have all been adequately described in a previous publication (1). Linear sweeping and potentiostatic pulse experiments were made with bismuth/lead binary alloys in 5M H_2SO_4 using a Kemitron PS-40 potentiostat and function generator, the output being monitored on an (X-Y-T) recorder (Bryans, Series 26000). The rods used in the preparation of the disk electrodes were precast and aged for a month in an attempt to simulate the industrial situation as far as possible. "Stabilized" electrodes were obtained by cycling to a constant response between the limits[1] 400 and 1520 mV for approximately 1½ hr. As before (1), it was found necessary to "initiate" the reaction by sweeping to a positive limit of 2000 mV[1] in the first cycle; this provides the considerable initial overpotential first emphasized by Fleischmann *et al.* (13), otherwise negligible product lead dioxide was formed with a positive limit set at 1520 mV. The three binary alloys used in the experiments contained, respectively, 0.063%, 0.127%, and 0.267% Bi.

Results and Discussion

Linear sweep experiments.—Rate of attainment of constant response.—Noticeable features of the early cycle pattern were the two anodic current peaks obtained during the negative-going sweep with the positive potential limit set at 2000 mV. This was to be expected from our previous work on lead and antimonial lead alloys (1), and we have attributed this to lead sulfate formation at a surface previously passivated by oxygen. The quantity of charge contained in the integrated anodic area of these peaks was independent of bismuth concentration in the range studied, confirming our findings that the response is due to the base metal (Pb) itself and is also connected with oxygen and other related species because of the upper limit required.

The extent of formation of product lead dioxide showed a large variation with bismuth content such that as the Bi level was increased the corresponding alloy required a large number of cycles to give a constant response (negligible change in peak current values).

Constant response curves.—Stabilized potential curves for each alloy under test are shown in Fig. 1. The intermediate Bi concentration (0.127 w/o) appears to produce the stablest alloy with peak current values (i_p in PbO_2 formation peak) appreciably less than those for electrodes containing higher (0.267 w/o) and lower (0.063 w/o) levels of bismuth. The position of this current maximum also changes with varying Bi content, the intermediate alloy having an i_p value at the more negative potential. This suggests that the kinetic barrier to the oxidation of $PbSO_4$ varies with the quantity of Bi in the test electrode. The form of the maximum current (corrodibility) and peak potential variation with bismuth concentration is interesting; a maximum stability to anodic attack occurs within the range studied here. Figure 2 depicts this trend as a plot of i_p *vs.* Bi content for stabilized electrodes. A possible explanation for this can be given in terms of grain refinement caused by the incorporation of Bi into the lead lattice. As the amount of Bi is increased, the quantity of lead available for surface reaction is depleted, hence the stability of the alloy initially rises with increasing Bi levels. Zener (14)

[1] All potentials were measured against the Hg_2SO_4/Hg electrode in the same solution.

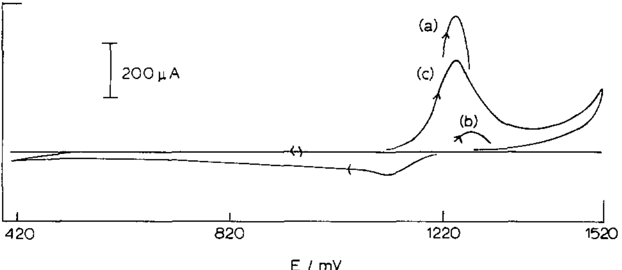

Fig. 1. Stabilized potential curves for (a) 0.063% Bi, (b) 0.127% Bi, (c) 0.267% Bi. (400-1520 mV; 50 mV/sec^{-1}, $A = 0.0707$ cm^2.)

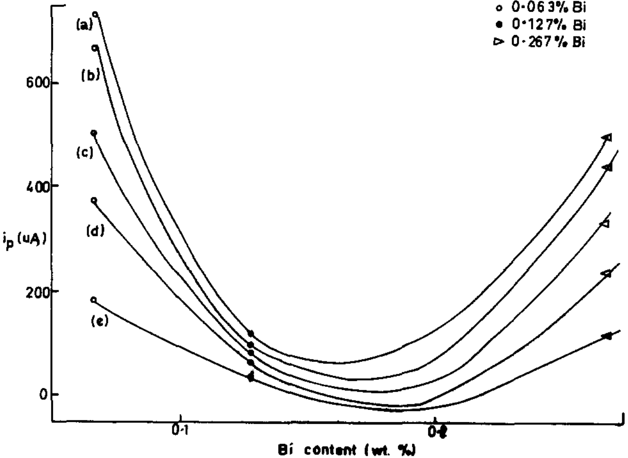

Fig. 2. Plot of i_p vs. Bi content for electrodes cycled to constant response: (a) 100 mV sec^{-1}, (b) 80 mV sec^{-1}, (c) 50 mV sec^{-1}, (d) 30 mV sec^{-1}, (e) 10 mV sec^{-1}.

has shown that grain growth should cease when the average grain size *Dm* is given by Eq. [1]

$$Dm = \frac{d}{F} \quad [1]$$

where *d* signifies the average diameter of an inclusion and *F* the fraction of the volume in the alloy. It is possible that this condition applies when the concentration of Bi in the alloy lies between 0.14 and 0.19 w/o and so accounts for the minimum in Fig. 2. These results contrast with those of Bryntseva (10) and Gonzales (15); Bryntseva has reported an increase in the electrochemical corrosion of lead anodes containing concentrations of Bi up to 2% and Gonzales has claimed that the corrosion rate can be doubled by increasing the Bi content from 0.01% to 0.1%. The latter author emphasized that the precise increase depended on the conditions of the test which greatly differ from those used here and probably account for the difference between their results and ours.

The relationship between peak potential (E_p) and sweep rate (v) is shown in Fig. 3 as a plot of E_p *vs.* $\log_{10} v$ for each alloy under test. This data is in agreement with that obtained by Canagaratna *et al.* (16) and us (17) (for both pure and antimonial lead) for the growth of a single layer on an electrode surface. Figure 4 shows the relationship between the peak current (i_p) and sweep rate (v) in the form of a plot of i_p *vs.* $\sqrt{v}$. In each case (three bismuth concentrations) the peak current values are much larger than corresponding data on Pb and Pb-Sb (5%) electrodes (1) indicating that concentrations as low as 0.06% Bi in lead result in the formation of an alloy which is much more susceptible to anodic attack than one containing a relatively high proportion of antimony.

A summary of the integrated anodic charge for stabilized electrodes is given in Table II. An interesting feature here is the similarity between Pb-Sb and

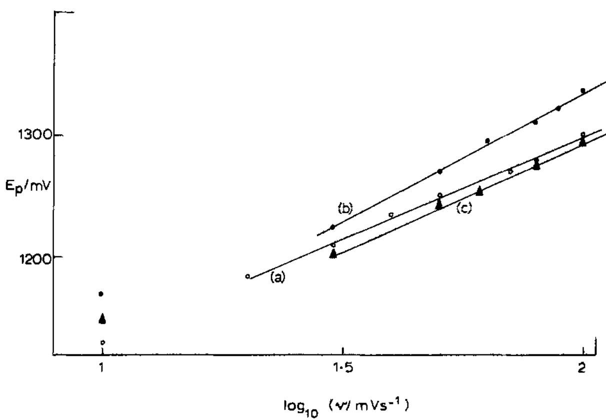

Fig. 3. Plot of peak potential vs. $\log_{10}$ sweep rate for (a) 0.063% Bi, (b) 0.127% Bi, (c) 0.267% Bi. (Electrodes cycled to constant response.)

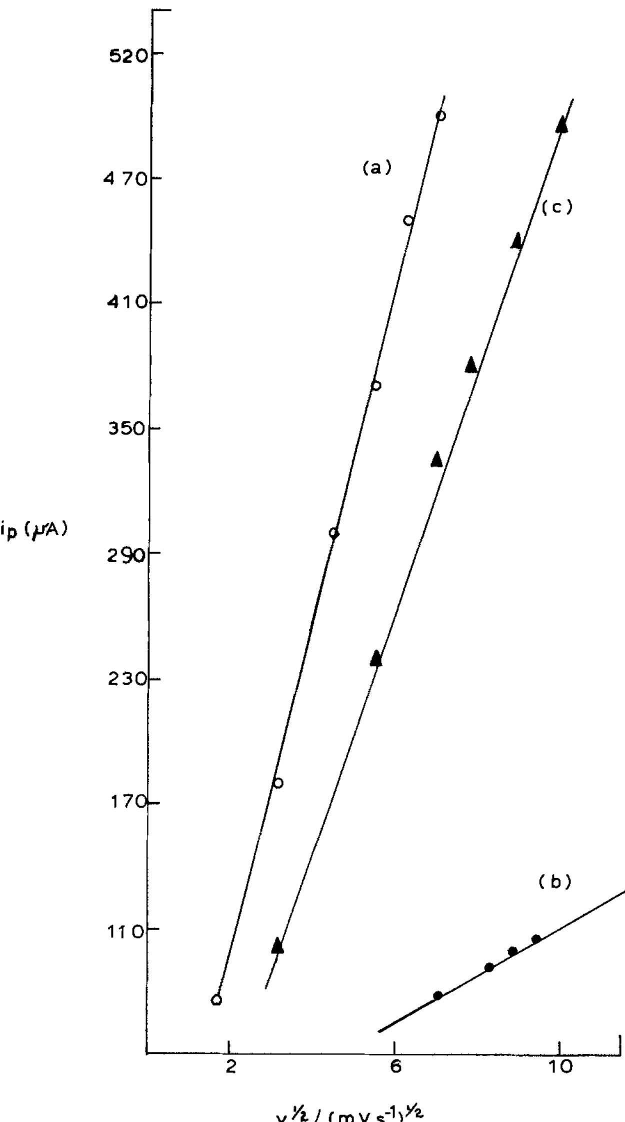

Fig. 4. Plot of peak current vs. (sweep rate)$^{1/2}$ for stabilized electrodes containing (a) 0.063% Bi, (b) 0.127% Bi, (c) 0.267% Bi.

Pb-Bi electrodes, both exhibiting a much larger sweep-rate dependency of charge than pure lead. As before (1) this can be attributed to the constant thickness of the oxidized layer on pure lead which discharges to approximately the same extent throughout. The Pb-Sb and Pb-Bi alloys, on the other hand, form a layer which is more porous than that on pure lead, and so the reaction is driven deeper into the spongy mass at

Table II. Calculated anodic charge during positive-going sweep (400-1520 mV) for stabilized electrodes

Sweep rate (mV sec^{-1})	Anodic charge (mC cm^{-2})		
	0.063% Bi	0.127% Bi	0.267% Bi
10	35.4	6.2	32.2
30	23.0	4.9	20.5
50	18.0	3.9	16.0
60	16.7	3.2	14.5
80	15.3	2.9	12.7
100	14.1	2.9	11.7

lower rates of sweeping. The lack of any rotation speed dependence during the electrochemical cycling indicates that the diffusion of species through the electrode occurs via a solid-state process similar to that for Pb and Pb-Sb electrodes.

Potential sweep experiments.—These were performed after formation of $PbSO_4$ by cyclic potential sweeping and a stabilizing period at 400 mV when the current became negligible (≤ 1 μA). We have already shown (17) that the length of time the electrodes are held in the sulfate region has a significant effect on the oxidative behavior of the lead sulfate deposit and have suggested this is due to the removal of nucleation sites formed during the stabilizing sweep. For this reason the reductive period prior to potential stepping was kept constant at approximately 20 min.

Figure 5 shows a typical current response curve when a lead sulfate deposit (formed by continuous cycling on a Pb-Bi base) is stepped into the lead dioxide region. The form of the transient is similar to that for pure lead (17) where the initial double layer charging spike is followed by an increase in current due to the formation and growth of nucleation centers. The presence of a single oxidation peak is indicative of a completely passivated film (PbO_2) with most of the residual current flow due to the oxygen evolution reaction because of the high overpotential used. These observations contrast with our previous work on antimonial lead when a thickening of the oxidized deposit does occur and a second rise in transient is obtained as a further layer of product PbO_2 is formed.

Although at the start of the transient response (Pb/Bi) the current did not rise from zero (indicating the presence of some growth centers) we were able to identify a two-dimensional growth process by the residual linear i-t correlation represented by Eq. [2]

$$i = (ZF\pi M/\rho) N o k^2 t \exp(-\pi M^2 N o k^2 t^2/\rho^2) \quad [2]$$

We have concluded (17) that the cycled electrode contains sufficient nuclei for electrocrystallization to proceed at a speed sufficient to change the process from

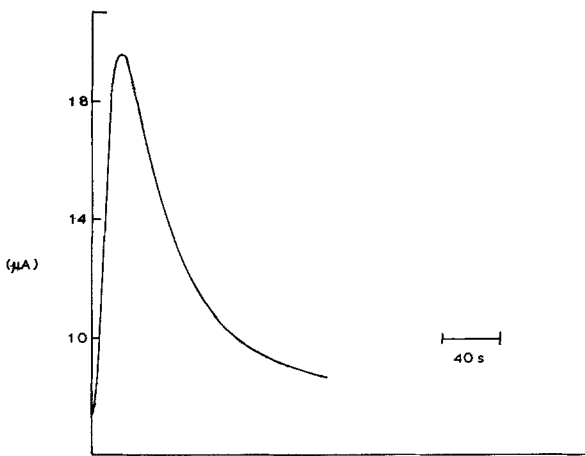

Fig. 5. Potential step experiment (400-1100 mV) on stabilized Pb-Bi (0.127%) electrode ($A = 0.0707$ cm^2).

the relatively slow three-dimensional one reported by Fleischmann and Thirsk (13) and later by Casson (8) to the faster two-dimensional process.

Figure 6 shows a typical series of current-time curves for the rise in transient as a cyclically formed $PbSO_4$ deposit is stepped to various overpotentials in the PbO_2 region. The slopes of these lines are seen to increase with increasing overpotential which is to be expected from Eq. [2] ($di/dt \alpha k^2No$ at short times). The potential dependency of k^2No is shown in Fig. 7 as a plot of overpotential *vs.* $\log_{10}$ (di/dt). It is interesting to note that as the electrodes are stepped to a series of increasing overpotentials the peak current values rise to a limiting value then start to fall. It can be shown (18) that for instantaneous nucleation

$$i_m = (2\pi No)^{1/2} nFkhe^{-1/2} \quad [3]$$

which, when compared with the data in Fig. 7, shows that for a simple two-dimensional process the value of i_m should not decrease. This fall-off in peak current values is accompanied by a corresponding fall in the charge contained in the oxidation peak (calculated by a simple integration process). A possible explanation for this can be given in terms of a reduction in effective surface area of the electrode due to partial coverage of the surface by gaseous oxygen (again because of the high overpotentials used): surface area before potential step $= A$, surface area after potential step $= A(1 - \theta)$, where θ represents the area of the electrode covered with oxygen. (As the overpotential is increased the value of θ will also increase and i_m subsequently falls). Figure 8 confirms the presence of oxygen on the electrode surface with a reduced plot of i/i_m *vs.* t/t_m. The current values at the tail end of the curve ($t/t_m > 1.5$) are larger than expected due to the contribution of the oxygen evolution current. A further proof that the reaction studied here follows a simple two-dimensional growth mechanism is provided in Fig. 9 with a typical plot of ln $(i - i_r)/t$ *vs.* t^2 with a correction for the oxygen evolution current being made. The straight lines obtained are in good agreement with Eq. [2].

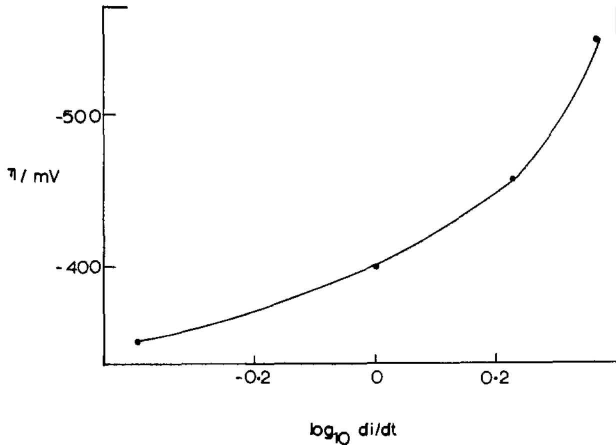

Fig. 7. Plot of overpotential *vs.* $\log_{10}$ (di/dt) for 0.127% Bi

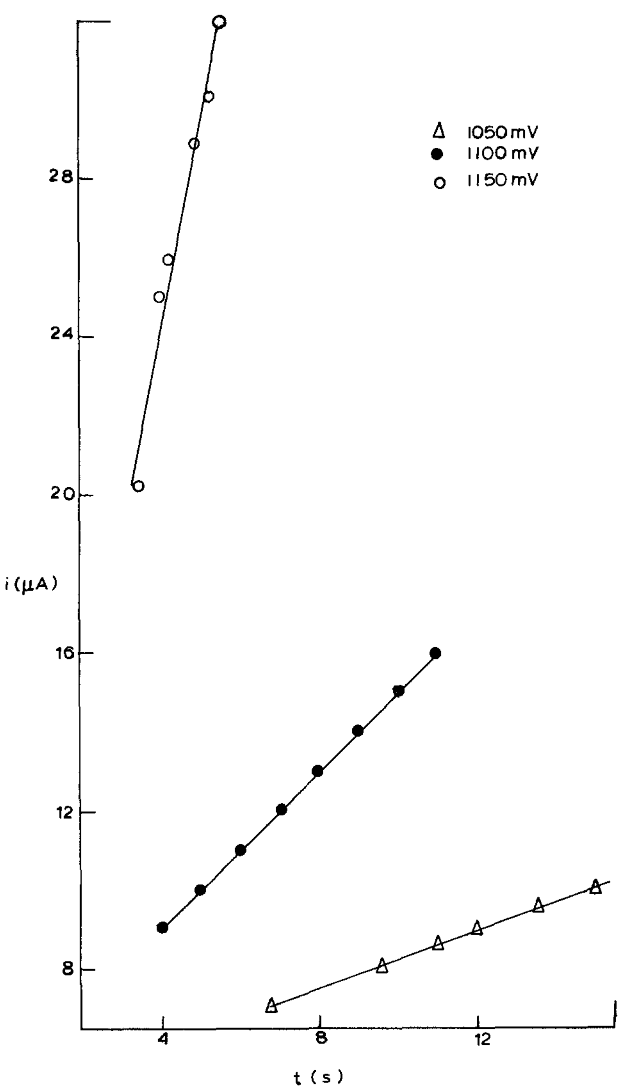

Fig. 6. Current-time plots (rise in transient) for potential step experiments on Pb-Bi (0.127%) stabilized electrodes.

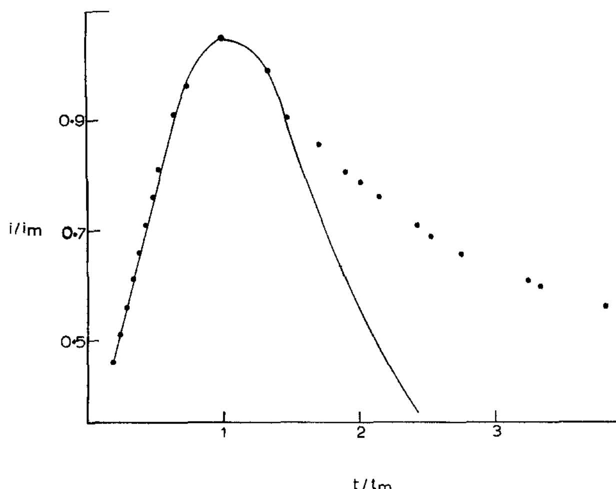

Fig. 8. i/i_m *vs.* t/t_m for potential step transient (0.127% Bi, 400-1100 mV).

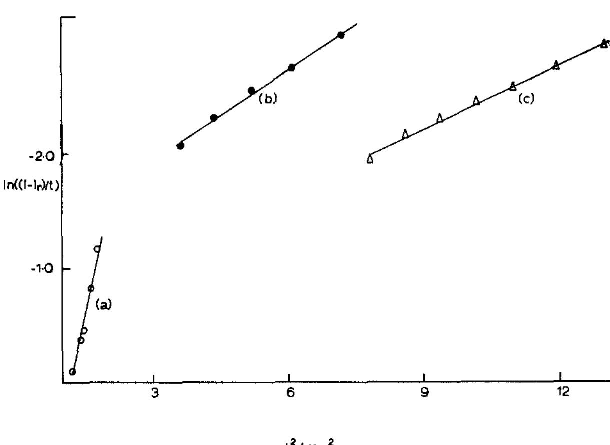

Fig. 9. ln $(i - i_r)/t$ *vs.* t^2 for (a) 0.063% Bi, (b) 0.127% Bi, (c) 0.267% Bi at long times ($t/t_m > 1$).

These results are of great importance to industry and battery manufacturers in particular since they give the optimum level of bismuth for use as a grid alloying ingredient in the lead-acid battery system. They do not, however, provide any information concerning the reacharge characteristics of such an alloy. Dewitt and Myers (19) found Bi to have a less harmful effect than Sb on self-discharge and gassing rates. These beneficial properties of bismuth if combined with the optimum level of the alloy (minimum anodic corrosion) in the positive battery grid could go a long way in promoting Bi as a replacement for Sb in the lead-acid system today.

Conclusions

1. The incorporation of bismuth into lead does not produce an alloy with the same electrometric behavior as antimonial lead (*viz.*, the second current peak in the step response for the development of PbO_2 is absent).

2. The oxidation of $PbSO_4$ to PbO_2 on a lead-bismuth electrode results in the formation of a completely passivating layer.

3. Concentrations as low as 0.06% Bi in lead render the alloy much more susceptible to anodic corrosion than a pure lead or antimonial (5%) lead electrode.

4. The relationship between bismuth content and depth of corrosive attack is not linear but parabolic.

5. A maximum stability concentration of bismuth in lead was found in the range studied.

Structure-Reactivity Relationships of Methylated Tetrahydrofurans with Lithium

J. L. Goldman,* R. M. Mank, J. H. Young, and V. R. Koch*

EIC Corporation, Newton, Massachusetts 02158

ABSTRACT

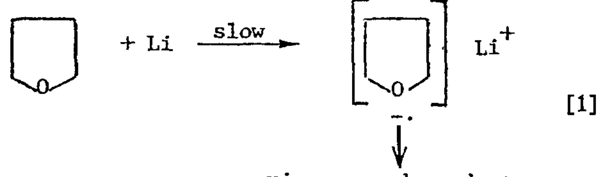
Tetrahydrofurans methylated in the α-position manifest remarkable chemical and electrochemical stability toward Li. While tetrahydrofuran (THF) distilled off benzophenone ketyl and stored with Li at 71°C reacts in two days, 2-methyltetrahydrofuran (2-Me-THF) treated similarly was stable for over 10 months. Electrolytes comprising either 2-Me-THF or 2,5-dimethyltetrahydrofuran (2,5-di-Me-THF) were subjected to cycling studies in half-cell configurations. Average Li on Li cycling efficiencies exceeded 96% for $Q = 1$ C/cm^2. Unlike the α-methylated ethers, 3-methyltetrahydrofuran (3-Me-THF) was as reactive towards Li as THF. Thus, the position of the methyl substituent with respect to the cyclic ether's oxygen atom is critically important, and several mechanisms are considered.

Ambient temperature Li secondary battery technology has been actively pursued for more than 20 years (1-4). Potential applications of such batteries run the gamut from vehicular propulsion to power sources for digital watches. Transition metal chalogenides such as TiS_2 (5-7) and $V_{1-x}M_xS_2$ (M = Fe or Cr) (8, 9) have proved to be suitable cathode materials for ambient temperature cells. More recently, transition metal oxides with perovskite-related structures such as V_6O_{13} show promise as rechargeable cathode materials (10). Yet, as is generally agreed, the key technical problem preventing the realization of such batteries is the cycling behavior of the Li electrode.

While Li may be plated onto a conducting substrate from a variety of aprotic organic electrolytes with 100% efficiency (2, 11). subsequent anodic dissolution is invariably less (11-14). The difference reflects Li metal electrically isolated from the substrate by passivating, albeit Li^+ conducting films (3, 14-18). These films arise from the reduction of impurities at high rate, and electrolyte itself at a lower rate by freshly deposited Li. The underlying metal is thereby protected from further attack. The presence of such filmed or "encapsulated" Li particles results in an irregular surface which seriously distorts the morphology of subsequent plates. On the second plate, for example, Li nucleation and growth proceed irregularly forming dendrites; the surface area of the plate correspondingly increases, the rate of reaction with electrolyte increases, and more Li is isolated. Thus, the effect of a small morphological perturbation on the first cycle becomes compounded over several cycles, leading to ultimate electrode failure.

Our approach to electrolyte development has been to choose solvents expected to manifest low reactivity toward Li, and then refine electrolytes based on these solvents via stringent purification procedures. In selecting a solvent, one may be guided by Selim and Bro who have pointed out that polar solvents are necessarily reactive with Li due to the presence of a molecular dipole (11a). The dipole results from an unequal distribution of electron density about a carbon-heteroatom bond which facilitates electron transfer from Li into the bond. More recently, a thermodynamic analysis of the possible direct interaction between Li and a variety of aprotic organic solvents demonstrated that all may be reduced by Li (19). We suspected, therefore, that cyclic ethers afforded the best chance of retarding Li/solvent reactivity, since the C—O bond is far less polar than C=O (methyl acetate, methyl formate, and propylene carbonate), or S=O (dimethylsulfite and dimethylsulfoxide), other solvents in which the Li electrode has been cycled. Lower Li/solvent reaction rates should permit more uniform Li plate morphology on charge, and smooth, nondendritic plates are a prerequisite for discharge with high efficiency. Accordingly, tetrahydrofuran (THF)/Li reactivity was investigated in depth (14, 20). We found that while $LiAsF_6$/THF electrolytes outperformed $LiAsF_6$/propylene carbonate (PC) (12, 13) and methyl acetate (21) in terms of Li electrode cycling efficiency, THF media were nonetheless too reactive for use in a practical secondary battery.

On the basis of isolated reaction products and earlier mechanistic work, we postulated a reduction mechanism involving an initial transfer of an electron from Li to the lowest unfilled molecular orbital (LUMO) centered on the oxygen atom of THF (20) (Eq. [1])



[1]

If Eq. [1] accurately describes the rate-determining step in the reduction of THF by Li, one can envisage modifying reaction kinetics by raising the activation energy of the slow step. This may be accomplished by perturbing the energy of the LUMO upward. Thus, locating an electron donating group, *e.g.*, alkyl, in the 2-position adjacent to the oxygen atom raises the activation energy required to form the anion-radical by localizing additional electron density on the oxygen atom. In a recent patent (22) and paper (23), we showed that 2-Me-THF and 2,5-di-Me-THF were less reactive toward Li than THF itself. In this paper, we elaborate upon these findings and present data indicating that 3-Me-THF is as reactive as THF toward Li.

Experimental

General.—All purification procedures subsequent to distillation and the electrochemical experiments were conducted at ambient temperature under an Ar atmosphere in a Vacuum-Atmospheres Corporation dry box equipped with a Model HE-493 Dri-Train.

* Electrochemical Society Active Member.
Key words: organic, electrolyte, lithium, electrode.

Materials.—Tetrahydrofuran (THF) (Burdick and Jackson, distilled-in-glass), lithium hexafluoroarsenate ($LiAsF_6$) (U.S. Steel Agri-Chemicals, electrochemical grade), and lithium perchlorate ($LiClO_4$) (Anderson Physics, highest purity) were used as-received. Lithium foil (15 mil) was obtained from Foote Mineral Company sealed under Ar. 2-Methyltetrahydrofuran (2-Me-THF), 3-methyltetrahydrofuran (3-Me-THF), 2,5-dimethyltetrahydrofuran (2,5-di-Me-THF) *cis/trans* mixture, tetrahydropyran (THP), 2-methyltetrahydropyran (2-Me-THP), 2,5-dimethyloxy-tetrahydrofuran (2,5-di-OMe-THF), and 1,3-dioxolane (Aldrich) were distilled off CaH_2 under Ar from a Perkin-Elmer Model 251 Auto Annular Still. The reflux ratio was 5:1; only the middle 60% fraction was collected. For some experiments, solvents were distilled off sodium benzophenone ketyl, and details regarding this procedure may be found elsewhere (20).

Activated neutral alumina (Woelm 200 neutral, activity grade Super 1) was used as received, and exposed only to the dry box atmosphere. Approximately 1g desiccant per 5 ml solvent was used in a given purification procedure. The first 10% of solvent eluting through the column was discarded.

Details regarding electrolyte preparation and purification and subsequent storage at elevated temperatures with Li may be found elsewhere (14, 20).

Cells and electrodes.—Glass rectangular cells (10 × 40 × 60 mm, Vitro Dynamics) were used for the galvanostatic cycling of Li in a half-cell configuration. The working electrode was a 5.5 cm × 3.8 cm × 5 mil strip cut from Ni 200 sheet (Roblinger). The counterelectrode was fabricated from 15 mil Li ribbon. Details regarding cell assembly, Li cycling experiments, and the galvanostatic preelectrolysis technique may be found elsewhere (14).

Linear sweep experiments employed a 5 mm diam vitreous carbon disk working electrode (Tokai) sealed in Pyrex. Li counter and reference electrodes dipped into the electrolyte under investigation, and these experiments were accomplished in an undivided cell.

Chronopotentiometric plating and stripping of Li were conducted with a constant current power supply and an automatic cycler (both constructed in-house). The latter allowed plating for a given period of time, then stripped to a preset potential (1.0V anodic of the stripping potential). Upon reaching this potential, stripping was terminated and the cell reverted to open circuit until plating again commenced.

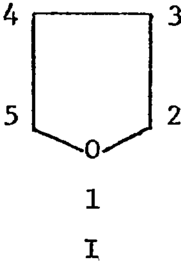
Linear sweep experiments were accomplished with a Pine Potentiostat Model RDE2 equipped with a triangle wave generator and a Houston Model 2000 Omnigraphic X-Y recorder.

Conductivity measurements were performed with a YSI Model 31 bridge in a medium range Jones-type conductance cell equipped with Pt electrodes. The cell constant was determined with standard 0.1D KCl solution.

NMR measurements.—^{13}C NMR spectra of the cyclic ethers with and without $LiAsF_6$ were run neat with an external reference tube comprising 75% D_6 acetone and 25% ^{13}C enriched TMS on a JEOL FX-60 spectrometer (Northeastern University). Spectra were recorded at ambient temperature (~30°C) in pulse/Fourier transform quadriture mode and were proton decoupled. Spectral resolution was greater than ±0.3 Hz (±0.02 ppm). Chemical shifts are reported as ppm downfield from TMS.

Results and Discussion

Methylated tetrahydrofurans.—The numbering scheme of the oxolane ring is shown in I. On the basis of the LUMO argument, 2-Me and 2,5-di-Me-THF are predicted to be more stable to Li than THF. 3-Me-THF, on the other hand, should



I

be about as stable as THF, since the inductive effect of the methyl group is rapidly attenuated through saturated C-C bonds (24). To test this hypothesis, a series of methylated-THF's were obtained and exposed to Li under static and dynamic conditions. Static tests involved the incubation of Li foil with electrolyte at 71°C. The onset of Li-electrolyte reaction visually manifests itself in terms of corrosion on the Li foil and concurrent yellowing of the electrolyte. Dynamic conditions were achieved by galvanostatically cycling Li to and from Li and Ni substrates at 25°C. A fresh Li surface, therefore, came into contact with electrolyte on every cycle. Li-electrolyte reactivity was noted in terms of a loss of cycling efficiency (Li stripped/Li plated) with increasing cycle number.

Li storage experiments.—Tables I and II summarize the results of the static tests. It is readily apparent that those solvents and electrolytes comprising 2-Me-THF or 2,5-di-Me-THF are markedly superior to THF or 3-Me-THF on exposure to Li at elevated temperature. We see that purified 2-Me-THF itself, as well as electrolyte prepared from it, require months before any sign of reaction with Li is noticeable. In fact, the ampul containing Li and 2-Me-THF off benzophenone ketyl was deliberately opened after 10 months of storage prior to the onset of reaction. The u.v. spectrum of this solvent was essentially superimposable with freshly distilled 2-Me-THF. The Li corrosion observed for unpurified 2-Me-THF and 2,5-di-Me-THF was due to the reaction between Li and BHT (butylated hydroxytoluene) added to the cemmercial product as a stabilizer. On the other hand, THF is quite reactive towards Li, regardless of purification procedure. Solvent distilled off benzophenone ketyl is effectively free

of H_2O and O_2—substances that can form protective films on Li (14). Yet even this extremely pure THF reacts with Li. Electrolyte prepared from THF is more stable, reacting after 25 days of storage. Presumably, impurities introduced in the electrolyte form protective films, or the salt itself can to some extent scavenge reactive intermediates. The major reduction product in the reaction of THF with Li was found to be n-butanol from lithium n-butoxide after hydrolysis (20).

Electrolyte conductivities.—The specific conductivities of the methylated cyclic ethers were determined at varying concentrations of $LiAsF_6$. These data are plotted in Fig. 1 and compared with literature values for the $LiAsF_6$/THF system (25). We see that the introduction of methyl groups on the oxolane ring lowers electrolyte conductivity. With 3-Me-THF, loss of molecular symmetry may inhibit the ability of these molecules to solvate Li^+ relative to that of THF resulting in a higher ratio of contact ion pairs to solvent separated ion pairs. With 2-Me and 2,5-di-Me-THF, the conductivity is more seriously attenuated. An attractive rationalization involves steric crowding of the oxygen atom by the α-methyl group(s), and this model has been advanced by us (23) and others (26). However, recent carbon-13 NMR measurements by us (vide infra) discount this explanation. In fact, from α-carbon chemical shift data we infer that Li^+ interacts more strongly with the oxygen atoms of 2-Me and 2,5-di-Me-THF than THF, as would be predicted on the basis of alkyl group inductive effects. It is therefore likely that α-methyl substituents simply perturb the efficient packing of solvent molecules about Li^+ leading to an increased number of contact ion pairs, as has been observed earlier (27).

Because $LiAsF_6$/2,5-di-Me-THF electrolytes have much lower conductivity than $LiAsF_6$/2-Me-THF, most of our electrolyte development effort was focused on the latter system.

Li cycling experiments.—A more stringent test of electrolyte inertness involves the dynamic cycling of Li to and from a conducting substrate. As indicated earlier, good cycling efficiency can only be achieved if the reactivity of electrolyte with Li is minimal. This requires the absence of reactive impurities as well as the chemical compatibility of salt and solvent with Li. In Fig. 2, the cycling efficiencies of THF and 2-Me-

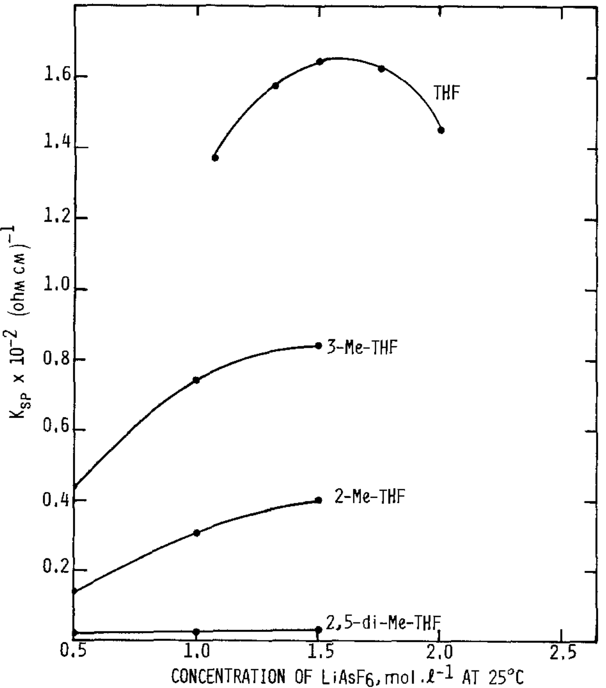

Fig. 1. Specific conductance of several tetrahydrofurans at various $LiAsF_6$ concentrations.

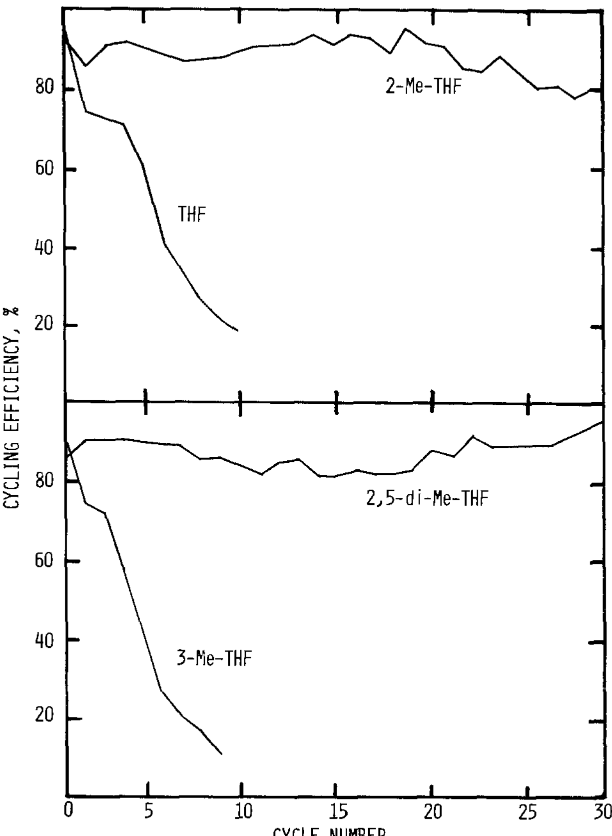

Fig. 2. Efficiencies of cycling Li on an Ni substrate. 1M $LiAsF_6$/cyclic ethers; $Q_p = 1.1$ C/cm²; $i_p = i_s = 1$ mA/cm² (2,5-di-Me-THF), and 5 mA/cm² (other ethers).

THF electrolytes (1M $LiAsF_6$) are presented as a function of cycle number for 1.1 C/cm² Li on Ni plates. On the 10th cycle run in THF-based electrolyte, 80% of the Li plated is encapsulated by films and lost to anodic dissolution. By comparison, only 7% of Li plated from 2-Me-THF based electrolyte is electrically isolated. This electrolyte nevertheless does degrade with cycle number, as evidenced by the slow decay in cycling efficiency. Either reactive impurities and/or a very slow reaction of 2-Me-THF with Li yield products which perturb the morphology of subsequent plates.

Figure 2 also compares the cycling efficiency of 2,5-di-Me-THF and 3-Me-THF, 1M in $LiAsF_6$. There is a striking similarity between these curves which is in qualitative agreement with the static storage tests, *i.e.*, that methyl groups α to the oxygen atom improve the electrolyte's stability.

Our experimental work with cyclic ether electrolytes attempts to mimic the charge and discharge characteristics of the secondary Li electrode in a practical battery. A key experiment employed by us to evaluate electrolyte stability involved cycling Li to and from a Li rather than Ni substrate in a half-cell configuration. This was accomplished by plating a known amount of Li onto a Ni electrode, and then sequentially stripping and plating a lesser charge of Li. The amount of excess Li determines, in part, the number of "100%" cycles to be achieved. For example, a typical Li on Li cycling experiment consists of plating 4.5 C/cm² Li onto a Ni electrode; 1.1 C/cm² are then stripped leaving 3.4 C/cm² of the excess Li. Subsequent plating and stripping cycles employ 1.1 C/cm². Were each cycle 100% efficient, the cell would cycle indefinitely with a 3.4 C/cm² reserve of Li (efficiency = Q stripped/Q plated). Of course, each stripping cycle is <100% efficient which means that each strip cuts into the Li reserve yielding an apparent "100%" cycle until the Ni substrate is reached. At this point the excess Li is exhausted and one may calculate the

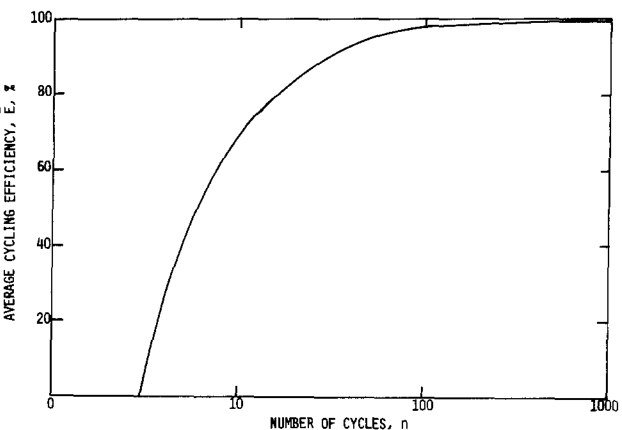

Fig. 3. Functional dependence of $\overline{E}$ on n, where $Q_s = 1.1\ C/cm^2$ and $Q_{ex} = 3.4\ C/cm^2$.

average efficiency per cycle, $\overline{E}$ (Eq. [2])

$$\overline{E} = \frac{Q_s - \frac{Q_{ex}}{n}}{Q_s} \quad [2]$$

where Q_s is the charge of Li stripped, Q_{ex} is the amount of excess Li, and n is the number of "100%" cycles. Beyond 100 "100%" cycles, large increases in n provide only a fractional increase in $\overline{E}$ as seen in Fig. 3.

Li on Li cycling efficiencies for $LiAsF_6$/THF and 2-Me-THF were determined at three salt concentrations. The cycling results and conductivity measurements are summarized in Table III. Electrolytes containing 2-Me-THF significantly outperformed those prepared with THF, even though the conductivities of the former were much less than the latter. In addition, Li plates from 2-Me-THF electrolyte were much less dendritic than those from THF electrolyte. Thus, good conductivity and throwing power alone do not necessarily insure regular Li plate morphology.

The average cycling efficiency of 1.5M $LiAsF_6$/2-Me-THF electrolyte was also assessed as a function of current density. As seen in Table IV, $\overline{E}$ increases to 97.4% as i is lowered to 0.9 mA/cm^2 presumably due to better Li plate morphology at lower current densities.

In an earlier paper (20), we noted the formation of a brown film on the surface of the Li electrode when it was cycled in $LiAsF_6$/THF media. Elemental and ESCA analyses suggested that the film was composed of LiF and a (—As—O—As—)$_n$ polymer formed from the reaction of THF and AsF_6^- reduction products (20). This film was also observed to form on the Li electrode after cycling in $LiAsF_6$/2-Me-THF electrolyte. However, the rate of formation in 2-Me-THF is substantially lower than that in THF again indicating that 2-Me-THF is less reactive toward Li than THF.

Anodic limits of cyclic ethers.—We believe Li-ether reactivity to be determined by the ease with which a solvent molecule acccpts an electron from Li (Eq. [1]). Data presented in earlier sections of this paper show that cyclic ethers incorporating methyl group(s) α to the oxygen atom resist reduction in consonance with the LUMO argument. If the electrophore (that part of a molecule accepting or giving up an electron) is involved in both one-electron oxidation and reduction, one would predict that those ethers more difficult than THF to reduce should be correspondingly easier to oxidize. In Scheme I, for example

III $\xleftarrow{-e^-}$ II $\xrightarrow{+e^-}$ IV

R = H, Me

Scheme I

the oxidation potential of II → III (R = Me) should be less than II → III (R = H). Accordingly, the reduction potential of II → IV (R = Me) should be greater than II → IV (R = H).

Now oxidation of the ether electrophore ensues at the highest occupied molecular orbital (HOMO). And, for aliphatic ethers, the HOMO comprises an orbital including the nonbonding electrons on oxygen as has been determined earlier (28).

In order to verify the anodic side of Scheme I, a variety of cyclic ether/$LiAsF_6$ electrolytes were subjected to linear sweep voltammetry. Starting from the rest potential (typically + 2V *vs.* Li), the working electrode was anodically polarized. Potentials at which the anodic current density reached an arbitrary value of 100 $\mu A/cm^2$ were recorded and are tabulated in ascending order (Table V). Although only 300 mV separate the extremities of this scale, it is clear that those compounds with electron-donating α-methyl groups oxidize more readily than unsubstituted THF or THP. Conversely, ring systems with electron-withdrawing substituents (—OMe) or with an electronegative oxygen atom in place of a methylene group (1,3-dioxolane) are more difficult to oxidize.

These data support the LUMO concept of cyclic ether reduction whereby transfer of an electron from

[b] Potential *vs.* Li at which the current density reached 100 $\mu A/cm^2$ on a vitreous carbon working electrode; $A = 0.196\ cm^2$, $v = 100$ mV/sec.

Li to an orbital approximated by a linear combination of sp^3 C and 2p O places excess electron density in the C—O bond (20). The excess electron density, formally a radical-anion, predisposes the C—O bond to cleavage, or ring-opening as in the case of cyclic ethers.

Knowledge of a solvent's anodic limit is critically important to Li battery technology, as has been noted previously by Dey and Rudd (29). They found that at +4.0V *vs.* Li THF rapidly underwent anodic oxidation with subsequent polymerization. Thus, the potential at which an electrolyte oxidizes determines the maximum charging potential as well as influencing the choice of the positive electrode for secondary Li batteries.

When 1M $LiAsF_6$/2-Me-THF was potentiostated at 4.15V *vs.* Li for several hours, no polymeric material was observed to form on the Ni working electrode surface. This is consistent with earlier work which demonstrated that 2-Me-THF and 2,5-di-Me-THF do not polymerize under conditions which readily polymerize THF (30). Nevertheless, α-methylated THF's oxidize irreversibly at potentials lower than THF, and this must be taken into account in setting battery charging limits.

Alternative mechanisms for cyclic ether reduction.—While the LUMO argument is consistent with the chemical and electrochemical results, other possible reaction mechanisms require consideration.

Bates and co-workers found that n-butyllithium (BuLi), a strong base, abstracted the α-proton from THF (Eq. [3]) (31). Accordingly, a methyl

[THF] + BuLi → [THF anion], Li^+ + BuH ↑
↓
ring-opened products [3]

group in the 2-position might effectively shield one side of oxolane ring from attack. At best, this halves the number of abstractable protons which in turn retards the observed reaction rate. This effect is typically accounted for by multiplying the rate expression by the statistical factor (0.5 for 2-Me-THF) (32). However, on the basis of the storage and cycling data presented earlier, it appears that the reaction rate of 2-Me-THF with Li is much more than halved compared to that of THF.

Szwarc and co-workers have suggested that a proton in the 3-position of 2-Me-THF may be sufficiently acidic so as to be abstracted by a strong base (Eq. [4]) (33)

[2-Me-THF] + ~S⁻, Na^+ → [ring-opened alkoxide O^-Na^+, CH_3] + ~SH [4]

where ~S^- ≡ polystyryl carbanion. Under the same conditions, however, Szwarc found that THF is inert to polystyryl carbanions (33). This indicates that a proton abstraction mechanism is not in force when these solvents are reacted with Li.

Another possibility is that the observed reaction rate differences are due to variations in the physicochemical properties of films on the Li surface. In the case of the cyclic ethers, such films are expected to be composed of Li alkoxide salts from solvent reduction by Li, *e.g.*, lithium n-butoxide from THF (20). Propylene carbonate (PC) is "stable" toward Li due to a coherent, insoluble Li_2CO_3 film which protects the underlying Li from PC (34). Unlike Li_2CO_3, however, lithium n-butoxide is soluble in hydrocarbon solvents at ambient temperatures—0.66M in n-hexane (25°C) (35). Now, Li-solvent reduction products from alkylated oxolane rings are expected to yield either longer or branched-chain alkoxide salts. These compounds have been shown to have even higher solubilities in alkane and cyclic ether solvents than lithium n-butoxide (35). Therefore, the chemical stability of the α-methylated THF's cannot be due to the intervention of protective alkoxide films. It is also difficult to invoke other, as yet unisolated reduction products or intermediates from 2-Me-THF which passivate Li, since structurally similar 3-Me-THF affords reaction products which clearly do not passivate Li.

It is known that corrosion rates generally accelerate with increasing electrolyte conductivity (36). And we have shown earlier that $LiAsF_6$/THF media are significantly more conductive than $LiAsF_6$/α-methyl THF's. In order to demonstrate that solvent reactivity with Li (corrosion of Li) is not simply an artifact of electrolyte conductivity, we have cycled the Li electrode in electrolytes composed of $LiAsF_6$/THF and $LiAsF_6$/2-Me-THF with identical conductivities, *i.e.,* $1.4 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$. With a 3.4 C/$cm^2$ excess, only seven "100%" 1.1 C/cm^2 plating and stripping cycles (i = 5 mA/cm^2) were obtained with the THF electrolyte ($\bar{E}$ = 57.1%); while 31 "100%" cycles were obtained with the 2-Me-THF electrolyte ($\bar{E}$ = 90.3%). These sizable variations in cycling efficiencies reflect changes in the reactivity of the oxolane rings on going from THF to 2-Me-THF, and not in a conductivity effect.

A recent paper (37) and patent (38) suggest that the addition of a macroheterocycle (such as a crown ether) to an organic electrolyte retards the rate of solvent-Li reaction. According to the authors, this phenomenon involves the selective complexation of Li^+ by the macroheterocycle rather than by the solvent's electronegative heteroatom (oxygen, in the case of THF). On the basis of this interpretation and in the absence of a macroheterocycle, one would predict that Li^+ should be more strongly associated with THF than with either of the α-methylated THF's since THF electrolytes are more reactive towards Li than 2-Me and 2,5-di-Me-THF electrolytes.

Now the affinity of Li^+ for a heteroatom is largely related to the basicity of that heteroatom in a homologous series of compounds, as calculated by Hinton and co-workers (39). Thus, the computed interaction between Li^+ and an ether's oxygen atom increases with alkyl substitution. However, experimentally determined basicity orders of cyclic ethers vary with the experiment. Sisler and Perkins, for example, deduced that the oxygen atom of 2-Me-THF and 2,5-di-Me-THF was much more basic than the oxygen atom of THF on the basis of the reaction of these ethers with N_2O_4 (40). Alternatively, Arnett and Wu found THF to be a slightly more basic molecule than either of the α-methylated THF's when these ethers were reacted with $H_3{}^+O$ (41). Nicholls and Szwarc measured the change in α-proton chemical shifts ($\Delta\delta$) of THF and 2-Me-THF on going from 0 to 10 mole percent Li^+ (42). They obtained $\Delta\delta$ values of 5.0 Hz for 2-Me-THF and 3.7 Hz for THF indicating a stronger interaction of the former ether with Li^+. We have measured the chemical shift of α-carbon atoms in THF, 2-Me, 3-Me, and 2,5-di-Me-THF on going from 0 to 1M Li^+. The chemical shift data, presented in Table VI, clearly indicate that Li^+ more strongly perturbs the electronic environment of the α-methylated THF's.

On the basis of Hinton's ab initio calculations (39) and the NMR work, we conclude that Li^+ interacts more strongly with α-methylated THF's than with THF. In addition, the nature of this interaction has been established as being ionic rather than covalent (39, 43). These results cast doubt on the proposed mechanistic role played by macroheterocycles in staving off electrolyte reduction by Li. More importantly, the NMR work coupled with ab initio calculations of Li^+-solvent interactions illustrate the importance of funda-

mental studies in helping to elucidate the complex chemistry of Li-electrolyte reactivity.

Summary and Conclusions

In this paper, we have shown that α-methylated oxolane rings are more resistant to reduction by Li compared to THF itself. With regard to the secondary Li electrode, cycling efficiencies in excess of 96% can be routinely achieved in $LiAsF_6$/2-Me-THF electrolytes for thin (1 C/cm^2) plates. On the basis of storage results at elevated temperatures, cycling data, linear sweep voltammetry, and a consideration of alternative reaction mechanisms, we believe that our results may be rationalized as follows: cyclic ether reduction is initiated by a rate-determining one-electron transfer from Li to the LUMO of the solvent molecule. Raising the activation energy of that initial step retards the rate of reduction of solvent by Li. Methyl groups bonded to α-carbon atoms inductively donate additional electron density into the LUMO making electron transfer from Li to the solvent molecule more difficult.

The use of methylated THF's as solvents in practical ambient temperature Li secondary batteries requires that high cycling efficiencies be maintained for thick (>50 C/cm^2) plates. While these anode efficiencies have not been reported in the open literature, it is nevertheless encouraging to note that $LiAsF_6$/2-Me-THF has found use as an electrolyte in a variety of Li/TiS_2 cells. Thus, Holleck and co-workers have indicated that 500 mA-hr Li/TiS_2 batteries may be designed for 100-200 deep cycles (44). Malachesky reported obtaining 25 deep cycles in a 90 mA-hr Li/TiS_2 button cell (45). Finally, Jet Propulsion Laboratory has tested 4.5 A-hr Li/TiS_2 D cells supplied by EIC Corporation (46). The major problem limiting cycle life was found to be short circuits, presumably caused by Li dendrite growth through the separator.

Although more work is needed to better understand Li-solvent-salt interactions, we believe that a practical secondary Li electrode is at hand. Problems associated with the design and manufacture of ambient-temperature rechargeable Li batteries appear to be ones of optimization and engineering, rather than a problem with the electrochemistry itself.

The A-C Response of Iridium Oxide Films

S. H. Glarum* and J. H. Marshall

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The dependence of the a-c response of iridium oxide films upon thickness, potential, and *p*H was explored in sulfuric and perchloric acid solutions. For concentrations greater than 0.1M, the response function closely resembled that for an injection process diffusively spreading from one interface throughout the film. The response time shifted by a factor of 10^5 with the potential drop across the film. A porous film model is suggested in which response is determined by the mobility of reduced lattice sites, the diffusion coefficient being controlled by a hydrogen ion exchange current within the pores.

Metal oxide films which shift color with applied potential are attractive possibilities for electrochromic display applications. Tungsten oxide has received much attention (1-4), and the discovery of analogous behavior in iridium oxide films has prompted several recent studies of their properties (5-8). At present the electrochemical kinetic response of these films is poorly understood. Most kinetic experiments have dealt with responses to large potential excursions, a property readily measured and important from a device-oriented viewpoint, but one difficult to interpret mechanistically. Analysis requires the assumption of an explicit model, such as the space-charge limited bleaching process described by Faughnan, Crandall, and Lampert for WO_3 (9).

In contrast to large potential transient studies, small amplitude modulation experiments, such as a-c impedance measurements, may be analyzed in considerable detail through complex-plane representations without recourse to any assumed model. With sufficient relaxation data it is possible to determine the requisites of a suitable model. The only a-c measurements on electrochromic films of which we are aware is a recent brief examination of WO_3 (10). We would emphasize that there need be no unique correspondence between large and small signal measurements. The former may introduce nonlinear effects absent in the latter. As one example, large perturbations could introduce nonuniform film states, whereas with small perturbations one always deals with states infinitesimally displaced from uniform, equilibrium configurations.

Figure 1 shows a cyclic voltammogram of an iridium oxide film grown in H_2SO_4. On passing from $0.1V_{SCE}$ to $1.1V_{SCE}$ the electrode's appearance shifts from metallic to dark blue. In this study we shall examine changes in the electrode's response function across this potential region, its dependence upon film thickness and solution *p*H, and "aging" or slow changes which take place when a film is moved between different solutions. Our computerized instrumentation facilitates the rapid acquisition and analysis of large amounts of a-c data, allowing a more systematic study than is feasible with manual procedures.

This paper encompasses a vast amount of experimental data, and it may be helpful to the reader to outline its course and content. Our philosophy for the interpretation of a-c measurements is somewhat unconventional. Rather than starting with a proposed kinetic scheme, deriving an equivalent circuit, and evaluating its parameters from the data, we prefer first to deduce an equivalent circuit description from the data and then proceed to possible interpretations. Our section on results is therefore largely a phenomenological presentation, while the discussion examines physical interpretations.

The most expedient path to find an equivalent circuit is through examination of the shape of complex-plane plots. Thus Fig. 2 indicates a series *R-C* circuit at low frequencies and a $\sqrt{i\omega}$ response at high frequencies. Empirical parameters can then be defined, and their dependence upon film thickness and potential determined (Fig. 3 and 4). A finite *R-C* transmission line is shown to have a response function close to that of the film (Fig. 5), and this simple two parameter function satisfies a test in which the characteristic relaxation time varies by a factor of 10^5 (Fig. 6). With the response function established, it is then feasible to

Key words: impedance, anodic films, electrochromism.

make continuous studies *vs.* potential to illustrate solvent and aging effects (Fig. 7, 9, and 10). In dilute acid solutions the response function changes (Fig. 8). The dominant dispersion is characterized by a Warburg element which varies with concentration as expected if the supply of solute H^+ ions is rate determining.

Our discussion focuses upon the interpretation of the response function. A simple model in which a neutral species is in electrochemical equilibrium at one film interface, but spreads diffusively through the film until blocked by the other interface, leads to the equivalent circuit previously deduced. In a more complex calculation we consider the influence on the relaxation process of finite diffusion constants for both species in a double injection process. In the space-charge-free limit, justified by injection densities and measured capacitances, a more complicated relaxation function is found, which reduces to observed behavior when one species is much more mobile. Whether electron or ion motion in the film is rate determining cannot be deduced wholly from the data. Because the limiting diffusion coefficient shifts with potential by a factor greater than 10^5, we favor a "slow" electron interpretation, and speculate upon a mechanism in which electron motion is blocked by hydroxyl groups whose lifetime is controlled by an electrochemical exchange process with electrolyte in film pores.

Experimental

Materials.—Sulfuric and perchloric acids were obtained from J. T. Baker (Ultrex). The end of a 20 mil iridium wire (0.002 cm^2) embedded in epoxy resin formed the working electrode. Use of a very small electrode was mandated by the large surface capacitance of an oxide film (0.05 F/cm^2). With larger surfaces the response is dominated by the combination of this capacitance with electrolyte resistance.

Even with such a small surface the latter resistance leads to a nonuniform current distribution which is manifest in complex plane plots at kilohertz frequencies. For each experiment the previous film was removed by abrasion with SiC paper. The electrode was then briefly polished with 15, 5, and 1 micron alumina. Extensive polishing tended to raise the metal above the resin surface. The response then appeared intermediate between that of a disk and a hemisphere. This ambiguity was eliminated by the above procedure. Films were grown on the electrode by pulsing as described by Gottesfeld and McIntyre (8).

Cell.—Details of the cell have been previously described (11). The cell was thermostated at 25°C, and all solutions were sparged with argon. All data were taken and are referenced with respect to a saturated calomel electrode.

Measurements.—Apparatus for this work has also been described previously (11). For sweep-frequency admittance measurements taken at a fixed potential, $Y_\eta^*(\omega)$, combinations of three decade sweeps covered the range between 150 kHz and 0.1 Hz. Below 1 kHz a calibrated capacitor shunted by a 1M resistor was used as a reference admittance. This led to greater accuracy over a wider frequency range, for the reference then better matched the unknown admittance.

Modifications of the phase-detector and the sweep circuitry expedited acquisition of data below 100 Hz. To avoid prolonged time constants, pulses at 0°, 90°, 180°, and 270° triggered four sample-and-hold circuits fed by the unfiltered phase detector outputs. Analog combination of these signals gave the required voltages for admittance computation. These pulses were also used to control the sweep rate, so that most time was spent at the low frequency end of the sweep. A single sweep from 100 to 0.1 Hz took 35 sec, and four such sweeps provided sufficient signal averaging for each run.

Prior to each series of experiments electrolyte resistance was determined from high frequency measurements, preferably at a high anodic potential. Following each measurement, the 500+ data points were corrected for the current distribution pattern of a disk electrode, electrolyte resistance was subtracted, and results plotted as a complex capacitance, $C^* = Y^*/i\omega$. Fifty points were listed for later identification and numerical analysis. Typically measurement, corrections, and output required 8-10 min per run.

In alternative experiments, admittance was measured *vs.* potential at a fixed frequency, $Y_\omega^*(\eta)$. Data were taken on the anodic traces of 50 mV/sec cyclic sweeps. At this sweep rate the lowest usable frequency was 5 Hz. After current distribution corrections and electrolyte resistance subtraction, data were plotted and listed in terms of an equivalent series capacitance and conductance. Each such run required a total period of about 10 min.

All reported data have been normalized with respect to the geometric electrode area.

Results

The relaxation function.—Figure 2a shows a composite complex-plane plot of measurements between 100 kHz and 0.2 Hz on an iridium oxide film charging 0.02 C/cm^2 between 0.0 and $1.2V_{SCE}$. Data were taken at $0.70V_{SCE}$ in 0.5M H_2SO_4, *i.e.*, at the reversible capacitance maximum (Fig. 1). An enlargement of the high frequency branch appears in Fig. 2b. Empirically this linear behavior is described by

$$C^* = C_\infty + W(i\omega)^{-\alpha} \qquad [1]$$

where W is a constant and C_∞, the intercept, equals

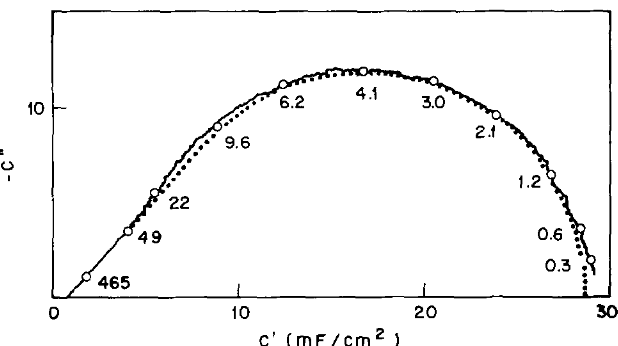

Fig. 2a. Composite complex-plane plot of C^* taken at $0.7V_{SCE}$ in 0.5M H_2SO_4. Frequencies are in hertz. The dotted curve is a theoretical function.

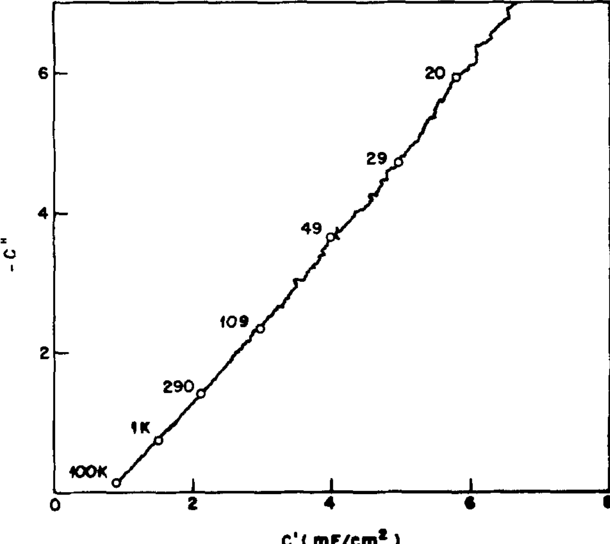

Fig. 2b. High frequency branch of the plot in Fig. 2a

750 μF/cm². From the angle of 47.5°, $\alpha = 0.53$. Below 20 Hz the plot shifts towards a semicircle, and one may formally define a relaxation time, $\tau = \frac{1}{2}\pi f_{max}$, a capacitance $2C_{max}''$, and a conductance $2C_{max}''/\tau$. At low frequencies the plot approaches an intercept on the real axis which roughly equals the capacitance inferred from cyclic voltammetry.

Measurements on this film at 0.1 V_{SCE} yielded much smaller capacitance values. Between 100 kHz and 100 Hz we find a broad C^* plot, indicative of a wide distribution of relaxation times, with measured values for C' ranging between 90 and 225 μF/cm², and an extrapolated value for C_∞ of 60-70 μF/cm².

The variation of τ with thickness was followed by subjecting the electrode to a number of 1 Hz pulses between −0.25 and 1.25V_{SCE}, cycling 10 min between 0.0 and 1.1V_{SCE} to minimize a slight drift in the response function following film growth, measurement, further pulsing, etc. Cyclic voltammograms had similar shapes as the film thickened, and the height of the reversible peak was proportional to the number of pulses. The position of the irreversible anodic peak shifted anodically with increasing thickness, while that of the reversible peak remained unchanged. Figure 3 plots τ and $2C_{max}''$ *vs.* the peak capacitance of the cyclic voltammogram. Assuming the latter to be proportional to film thickness, the dispersion amplitude is seen to be proportional to the first power, while the relaxation time increases as the second power of thickness.

In a separate series of experiments data were taken at 50 mV intervals. Between 0.4 and 1.0V_{SCE} the shape of C^* plots resembled that seen in Fig. 2. The amplitude of the dispersion paralleled the cyclic voltammogram, but the relaxation times varied substantially. Below 0.4V_{SCE}, f_{max} was less than 0.2 Hz, while above 1.0V_{SCE} the equivalent resistance was more than an order of magnitude less than the electrolyte resistance, and could not be accurately determined. Results for τ and $G = 4\pi f_{max}C_{max}''$ are plotted in Fig. 4. Both anodic and cathodic portions of the plot show exponential variations with potential, ~120 mV/decade, with an inflection near 0.7V_{SCE}.

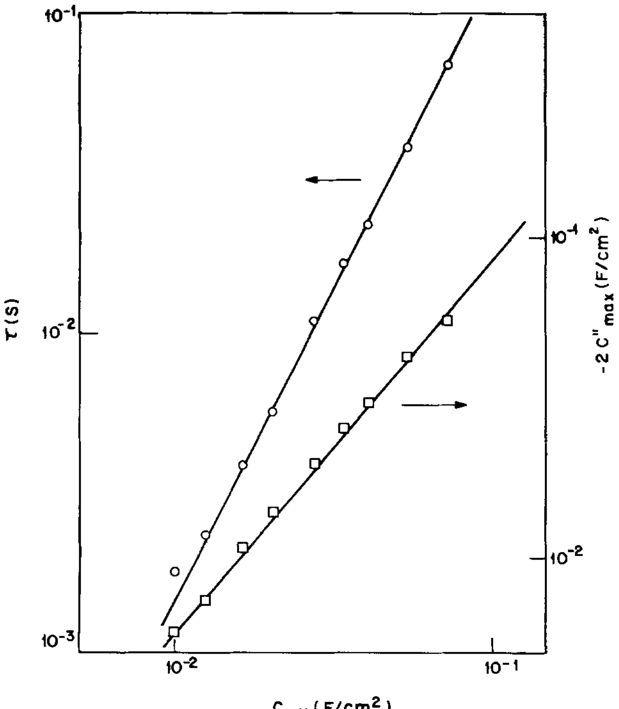

Fig. 3. Log-log plot of τ and $2C_{max}''$ vs. the peak capacitance found from a cyclic voltammogram. The respective slopes are 1.9_5 and 1.1_6. Data were taken at 0.7V_{SCE} in 0.5M H_2SO_4.

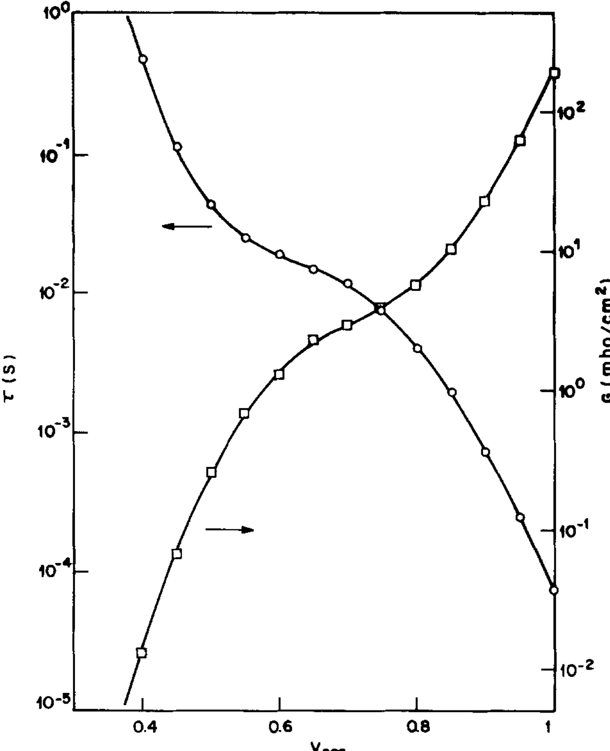

Fig. 4. Potential dependence of τ and G calculated from maxima in C^* plots. Data were taken in 0.5M H_2SO_4.

The shape of the dispersion in the complex plane (Fig. 2) is reminiscent of the response function for a finite R-C transmission line of length l

$$C^*/C_0 = \tanh\sqrt{i\omega\tau}/\sqrt{i\omega\tau}$$
$$C_0 = l\cdot\partial C/\partial x$$
$$\tau = l^2(\partial R/\partial x)(\partial C/\partial x) \quad [2]$$

This function is plotted in Fig. 5. At the maximum $\omega\tau = 2.54$, $2C_{max}''/C_0 = 0.834$, and $C_{max}'/C_0 = 0.582$. Although this shape is a good approximation to the experimental function, it is not exact as shown by the dotted plot in Fig. 2a. This difference may reflect a nonuniformity in the film, for the film was grown in a matter of minutes and its thickness is believed to be several thousand angstroms. Immediately after formation the angle of the high frequency branch exceeded 50°, and it gradually decreased to the cited value after an hour of cycling.

The tanh function may be tested by a comparison of W, derived from high frequency data using Eq. [1], with $\omega_{max}^{1/2}C_{max}''$. This comparison in Fig. 6 shows good agreement over several orders of magnitude and supports the hypothesis that the distinctive high and low frequency regimes reflect a common relaxation func-

tion and are not the fortuitous superposition of independent semicircular and circular-arc dispersions. Theoretically, $W/\omega_{max}^{1/2}C_{max}''$ should equal 1.50. The actual ratio appears closer to 1.0 over most of the potential range. In view of the much larger variations seen in these parameters, however, it appears that the tanh function furnishes a meaningful representation for film response.

Figures 7a and 7b show the results of experiments in which data were taken at a fixed frequency during the anodic portion of a cyclic, linear potential sweep. The admittance was resolved into series G and C components, and results are plotted *vs.* potential. At low frequencies the capacitance plot follows the cyclic voltammetric curve, but the irreversible peak is noticeably absent. With increasing frequency the amplitude of the plot decreases, first at cathodic potentials and then spreading across the plot. The equivalent series conductance shows an exponential variation with potential similar to that found in Fig. 4, but with a dispersion in values over most of the potential range.

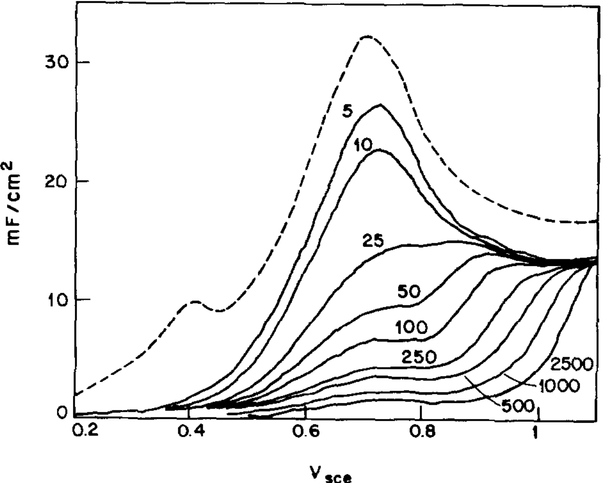

Fig. 7a. Equivalent series capacitance for a film in 0.5M H_2SO_4. Data were taken at a fixed frequency indicated in hertz. The dashed curve was derived from the cyclic voltammogram.

Some caution is required in interpreting such plots, for the dispersion appears only because plots such as Fig. 2a are not semicircles. The frequency at which the capacitance is half its equilibrium value does not reflect the relaxation time, but rather a frequency at which deviations from a series R-C circuit are significant. For this data at $0.7V_{SCE}$, a complex capacitance plot would have a maximum near 7 Hz, whereas Fig. 7a shows a 50% drop at 25 Hz.

At more anodic potentials the frequencies are comparable or less than the relaxation frequency, and one is in the low frequency regime where C^* plots are semicircular. Correspondingly, the dispersions in Fig. 7a and 7b decrease. In principle, at low frequencies Fig. 7a should reveal the reversible portion of the film capacitance and Fig. 7b should correspond to the conductance plot in Fig. 4. At cathodic voltages, however, relaxation frequencies are less than 5 Hz, the minimum frequency which could be used in these experiments, and G values exceed those found by a proper complex-plane analysis. At the anodic extreme, the relaxation frequency exceeds 1 kHz, and the deviation of 5 Hz values from asymptotic behavior seen at higher frequencies is related to the minor deviations from a normal low frequency intercept in Fig. 2a.

Solute effects.—In unbuffered dilute acid solutions C^* plots alter their form. To study this change, a film was grown in 0.1M $HClO_4$ and examined in various mixtures of 1M $HClO_4$ and 1M $NaClO_4$. Cyclic voltammogram waveforms indicated no major changes in the desorption isotherm other than a 60 mV/pH shift for 10^{-3} to 1M $[H^+]$ solutions. At the lower concentrations slow sweeps (10 mV/sec) and stirring were necessary to determine the potential of the capacitance maximum where these measurements were carried out. Figure 8 shows our results for a 5 mM solution. The plot has clearly shifted from a semicircular function at low frequencies to a 45° circular-arc function indicative of a Warburg admittance ($\sqrt{i\omega}W$). This

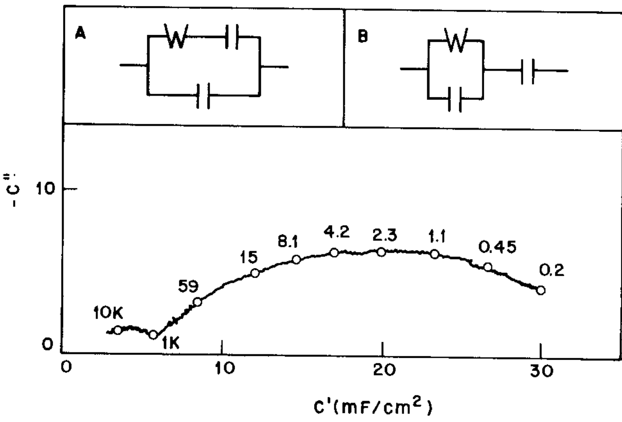

Fig. 8. Complex capacitance for a film in 1M $NaClO_4$/5 mM $HClO_4$. Frequencies are given in hertz. Insets A and B are two electrically indistinguishable equivalent circuits fitting the major dispersion.

may, in turn, be related to a bulk diffusion coefficient

$$W = (e\mathbf{F}/kT)\sqrt{D}\,[c] \qquad [3]$$

Two distinct equivalent circuits reproduce the observed dispersion and they are identified in the inserts in Fig. 8. Using either circuit for analysis, one finds a linear relationship between W and $[H^+]$ for 1-50 mM solutions. Circuit A gives $D = (3.8 \pm 0.4) \times 10^{-5}$ cm²/sec, while B yields $(6.5 \pm 0.4) \times 10^{-5}$. The error indicates the spread in results obtained for 1, 2, 5, 10, 20, and 50 mM solutions. A separate measurement of H^+ diffusion in a 1M $NaClO_4$/1.5 mM $HClO_4$ solution with a platinum rotating disk electrode gave $D = 6.5 \times 10^{-5}$ cm²/sec. Circuit B is therefore favored, and it seems clear that in these dilute acid solutions the response is primarily determined by the diffusion of H^+ ions in the electrolyte phase. For concentrations greater than 50 mM, C^* plots reverted to a semicircular low-frequency shape. From the frequency of the maximum we find $\tau = 1.1$ msec for 0.1M, and 0.6 msec for 0.2, 0.5, and 1.0M H^+ concentrations.

Parallel studies in H_2SO_4/Na_2SO_4 solutions also showed a diffusion controlled response in dilute acids, although the rate-determining ion appears to be HSO_4^-. In more concentrated acid sulfate solutions response is significantly slower and much more dependent upon $[H^+]$ than in corresponding perchloric acid solutions. Figure 9 shows data for a film grown and measured in 0.5M $HClO_4$. Direct comparison with Fig. 7a suggests a response time 20 times greater for the H_2SO_4 film.

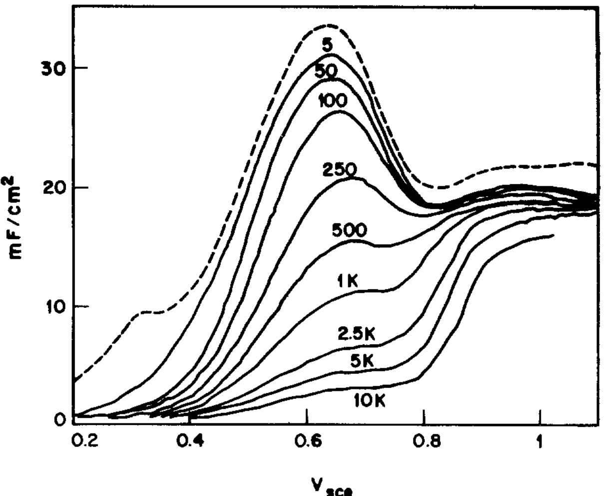

Fig. 9. Equivalent series capacitance for a film in 0.5M $HClO_4$. Frequencies are given in hertz. The dashed curve was derived from the cyclic voltammogram.

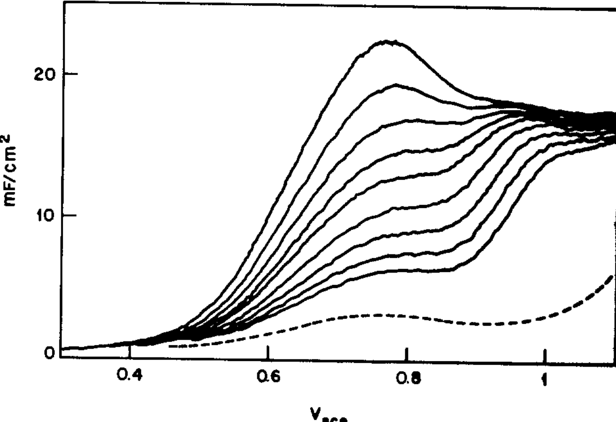

Fig. 10. Aging curves of equivalent series capacitance taken at 100 Hz after transferring a film from 0.1M H_2SO_4 to 2M H_2SO_4. The solid curves span a 2 hr period. The dashed curve was taken after 18 hr.

While in Fig. 7a the peak response is halved at 25 Hz, in 0.1 and 2.0M H_2SO_4 the corresponding frequencies are 250 Hz and <5 Hz. Figure 10 shows series capacitance results at 100 Hz for a film transferred to 2M H_2SO_4 after being grown in 0.1M H_2SO_4. A steady deterioration in response at all potentials is evident, and after 18 hr the electrode appears quite inactive. The level of response is quite similar to that of a film directly grown in 2M H_2SO_4. Nevertheless, upon replacement in 0.1M acid the original response curve was resurrected, although its amplitude had uniformly decreased 50%. The solubility of these films in concentrated H_2SO_4 has been noted by Gottesfeld and McIntyre (8).

Discussion

Cyclic voltammograms (Fig. 1) exhibit three distinct features: an irreversible prepeak at $0.4V_{SCE}$, a reversible maximum at $0.7V_{SCE}$, and a reversible plateau between 0.8 and $1.1V_{SCE}$. A-C measurements (Fig. 7a and 9) show no indications of the prepeak. One cannot decide from Fig. 1 whether the reversible features represent the superposition of two uncoupled processes or a common process with a free energy dependent upon the level of oxidation. Admittance data favor the latter interpretation. Complex-plane plots show no signs that the capacitance can be resolved into two components with differing response functions. Throughout the potential range where overlap would be anticipated, 0.7-$0.9V_{SCE}$, these plots maintained the functional form seen in Fig. 2. Correspondingly, $C_\omega(\eta)$ plots (Fig. 7a and 9) do not exhibit the clustering of traces at a nonzero capacitance value expected for a superposition of different processes. The a-c results in fact suggest that the response is controlled by a single, potential-dependent parameter. Even the aging curves in Fig. 10 follow the behavior seen in Fig. 7a for an "active" electrode, implying that aging is the time-dependent variation of this parameter.

Although low frequency capacitance measurements are closely correlated with cyclic voltammograms (Fig. 7a and 9), differences beyond the bounds of systematic errors are discernible above $0.7V_{SCE}$, a region where the response is sufficiently rapid to preclude the dominant relaxation process from being too slow. Quantitative comparison of cyclic voltammograms shows a slight asymmetry between anodic and cathodic currents, and together these facts may indicate a degree of irreversibility in the redox process. The discrepancy between a-c and voltammetric capacitances is reduced in more dilute solutions, and is less in perchlorate solutions than in sulfate solutions of the same concentration.

An explanation for the response function is naturally the prime object of a kinetic analysis. The thickness de-

pendence of τ (Fig. 3) rules out charge-transfer processes as rate determining. Should such a process be limiting at either the metal/oxide or oxide/electrolyte interface, the resulting resistance would be independent of thickness, and τ would then be directly proportional to film thickness. If, alternatively, limiting were due to charge-transfer occurring uniformly throughout the film, τ would be independent of thickness.

We have noted that the response function closely resembles that for a finite R-C transmission line, and a direct interpretation would be that the dispersion resistance arises from either the conductance of ions or electrons within the film. The possibility that it might reflect electrolyte conductivity within a porous film may be discounted, for increasing $[H^+]$ in sulfate solutions increases both electrolyte conductivity and the dispersion resistance, and it is rather difficult to rationalize a porous resistance change with potential by five orders of magnitude (Fig. 4).

Optical studies of films with comparable charging currents indicate thicknesses of order 10^{-5} cm (6). The maximum value of G measured then corresponds to a bulk conductivity of order 10^{-2} mho/cm. The conductivity of 0.5M H_2SO_4 is 0.3 mho/cm, while crystalline IrO_2 displays a metallic conductivity of 10^4 mho/cm (12, 13). Whether metallic behavior is expected for electrochemically formed iridium oxide films is questionable, for the structure of these films may be quite different from that of crystalline IrO_2 (14, 15).

Electronic conductivities of amorphous hydrogen tungsten oxide films, H_xWO_3, removed from electrolyte, show ambient conductivities of 10^{-3} to 10^1 mho/cm, with a transition to metallic behavior near $x = 0.3$ (16). Although this injection level approximately equals the fraction of the iridium oxide film oxidized at $0.7V_{SCE}$, our results cannot be directly interpreted in terms of such a transition because of the continued increase in conductivity with increasing film oxidation. Recent experiments by Zeller and Beyeler utilizing an amorphous WO_3 film with separated metallic and H_2SO_4 contacts suggest that the electronic conductivity of this film is small in comparison with its ionic conductance and that electron mobility is strongly dependent upon the degree of film reduction (3). Should this situation also prevail in iridium oxide films, it could account for the changes in relaxation time found with potential.

An alternative, but closely related interpretation for the function represented by Eq. [2] is a model involving diffusion through a layer of finite thickness. Let us assume the current to be a function of the concentration of a reduced species, c, formed at the interface $x = 0$ and the overpotential, η, at this interface

$$I^* = (\partial I/\partial\eta)\eta^* + (\partial I/\partial c)c^*(0) = -FD(\partial c^*/\partial x)_{x=0} \quad [4]$$

Solving the basic diffusion equation

$$i\omega c^* = Dd^2c^*/dx^2 \quad [5]$$

with a reflecting boundary at $x = l$, one obtains as a solution for the film impedance

$$\begin{aligned} Z^* &= G^{-1} + [i\omega C \tanh\sqrt{i\omega\tau}/\sqrt{i\omega\tau}]^{-1} \\ G &= \partial I/\partial\eta \\ C &= -\mathbf{F}l\ (\partial c/\partial\eta)_I \\ \tau &= l^2/D \end{aligned} \quad [6]$$

The second term is identical with the R-C transmission line response function. The quadratic dependence of τ upon l fits our findings, and assuming $l \sim 10^{-5}$ cm, values for D vary with potential from 10^{-10} to 10^{-6} cm²/sec.

Applied to iridium oxide films, this model does not tell us where the interface is or to what species c refers. In acid solutions we believe electrons enter across one interface and hydrogen ions across the other. Our simple calculation does not take into consideration the complications of a double-injection process involving charged species, save possibly as a limiting case.

For a more realistic analysis of our films let us therefore consider a film containing positive and negative carriers with unit charge, p and n. In addition we shall assume a certain density, c, of immobile, neutral traps formed by the 1:1 combination of p and n. We further assume that species p may pass across the interface $x = l$ without hindrance, but encounters a reflecting boundary at $x = 0$. Converse boundary conditions apply to species n. Local equilibrium between $c(x)$, $p(x)$, and $n(x)$ is also assumed, so that the model contains no kinetic constants and is wholly diffusive. The linearized kinetic equations we shall employ are

$$\begin{aligned} \frac{dp}{dt} &= D_p \frac{\partial}{\partial x}\left[\frac{\partial p}{\partial x} - \left(\frac{\partial p}{\partial \phi}\right)_e \frac{\partial \phi}{\partial x}\right] - \frac{dc}{dt} \\ \frac{dn}{dt} &= D_n \frac{\partial}{\partial x}\left[\frac{\partial n}{\partial x} - \left(\frac{\partial n}{\partial \phi}\right)_e \frac{\partial \phi}{\partial x}\right] - \frac{dc}{dt} \\ c(x) &= K(c)p(x)n(x) \end{aligned} \quad [7]$$

The subscript e denotes a derivative following local equilibrium configurations and $\phi(x)$ is the potential within the film. $\phi(x)$ satisfies Poisson's equation

$$\frac{\partial^2\phi}{\partial x^2} = (4\pi e/\epsilon)[n(x) - p(x)] \quad [8]$$

Before attempting a calculation of the small signal a-c response for these equations, we must first examine the nature of the equilibrium configurations to be perturbed. Their solution leads to an antisymmetric function for $\phi(x)$, with equal polarizations at each interface localized within a Debye length, λ (17). When $\lambda << l$ the interior of the film becomes an equipotential, space-charge free region ($\bar{p} = \bar{n}$) and $\phi = \eta/2$, η being the total metal-electrolyte potential difference.

High frequency capacitance measurements indicate that this approximation is valid for iridium oxide films. At a potential of $0.1V_{SCE}$, a nominally bare iridium surface exhibited a capacitance of 40 μF/cm². Repeating this experiment after a film had been grown on the surface gave 60 μF/cm². Both values indicate a potential drop localized within a short distance of a planar interface and require a large concentration of mobile charges.

We shall therefore consider the solution of Eq. [7] and [8] for a small a-c perturbation, taking the limit as $\lambda \to 0$. The narrow regions of polarization at $x = 0$, l are excluded, and we shall redefine $x = 0$, l to be the boundaries of the space-charge free region. The relevant modulation equations become

$$\begin{aligned} \frac{d^2p^*}{\partial x^2} &= \left[\frac{i\omega}{D_p}\left(1 + \frac{\kappa_2}{2}\right) + \frac{1}{\lambda^2}\right]p^* - \left(\frac{1}{\lambda^2} - \frac{i\omega\kappa_2}{2D_p}\right)n^* \\ \frac{d^2n^*}{\partial x^2} &= \left[\frac{i\omega}{D_n}\left(1 + \frac{\kappa_2}{2}\right) + \frac{1}{\lambda^2}\right]n^* - \left(\frac{1}{\lambda^2} - \frac{i\omega\kappa_2}{2D_n}\right)p^* \\ \frac{d^2\phi^*}{dx^2} &= (1/\lambda^2\kappa_1)(n^* - p^*) \end{aligned} \quad [9]$$

where

$$\begin{aligned} \kappa_1 &= (\partial n/\partial\phi)_e = -(\partial p/\partial\phi)_e \\ \kappa_2 &= (\partial c/\partial p)_e = (\partial c/\partial n)_e \\ 1/\lambda^2 &= (4\pi e/\epsilon)\kappa_1 \end{aligned} \quad [10]$$

At $x = 0$ three boundary conditions are given by

$$\partial p^*/\partial x + \kappa_1 \frac{\partial \phi^*}{\partial x} = 0 \qquad x = 0 \quad [11]$$
$$p^*(0) = n^*(0) = -\kappa_1[\eta^* - \phi^*(0)]$$

while the remaining three are set at $x = l$

$$\frac{\partial n^*}{\partial x} - \kappa_1 \frac{\partial \phi^*}{\partial x} = 0 \qquad x = l \quad [12]$$
$$p^*(l) = n^*(l) = -\kappa_1 \phi^*(l)$$

The total current across the metal/oxide interface is the sum of that injected and that charging surface polarization at this interface

$$I_{mo}^* = eD_n \left(\frac{\partial n^*}{\partial x} - \kappa_1 \frac{\partial \phi^*}{\partial x} \right)_{x=0} + i\omega\sigma^*(0)$$
$$= eD_n \left(\frac{\partial n^*}{\partial x} \right)_{x=0} - \left(eD_n\kappa_1 + i\omega \frac{e\lambda^2}{\kappa_1} \right) \left(\frac{\partial \phi}{\partial x} \right)_{x=0} \quad [13]$$

Similarly, at the oxide/electrolyte interface

$$I_{oe}^* = -eD_p \left(\frac{\partial p^*}{\partial x} \right)_{x=l} - \left(eD_p\kappa_1 + i\omega \frac{e\lambda^2}{\kappa_1} \right) \left(\frac{\partial \phi}{\partial x} \right)_{x=l} \quad [14]$$

The preceding differential equations automatically lead to the equivalence of these currents.

A formal solution for Eq. [9] yields

$$p^* = A \sinh \mu_1 x + B \sinh \mu_1 (l - x) - \gamma_2 C \sinh \mu_2 x - \gamma_2 D \sinh \mu_2 (l - x)$$
$$n^* = \gamma_1 A \sinh \mu_1 x + \gamma_1 B \sinh \mu_1 (l - x) + C \sinh \mu_2 (x) + D \sinh \mu_2 (l - x) \quad [15]$$
$$\phi^* = \alpha x + \beta(l - x) - (1 - \gamma_1) \frac{\lambda^2}{\mu_1^2} [A \sinh \mu_1 x + B \sinh \mu_1 (l - x)] + (1 + \gamma_2) \frac{\lambda^2}{\mu_2^2} [C \sinh \mu_2 x + D \sinh \mu_2 (l - x)]$$

A, B, C, D, α, and β are the integration constants.

In the limit $\lambda \rightarrow 0$

$$\mu_1^2 = (2/\lambda^2) + (i\omega/2)(1/D_p + 1/D_n)$$
$$\mu_2^2 = (i\omega/2)(1 + \kappa_2)(1/D_p + 1/D_n)$$
$$\gamma_1 = -1 + (i\omega\lambda^2/2)(1/D_p - 1/D_n) \quad [16]$$
$$\gamma_2 = -1 + (i\omega\lambda^2/2)(1 + \kappa_2)(1/D_p - 1/D_n)$$

After a stretch of thoroughly tedious algebra fitting boundary conditions to the integration constants, one finds

$$Y^* = I^*/\eta^* = e\kappa_1(D_n + D_p)\mu_2 \Bigg/ \left(\mu_2 l + \frac{D_n^2 + D_p^2}{D_n D_p} \coth \mu_2 l + 2 \operatorname{csch} \mu_2 l \right) \quad [17]$$

At low frequencies

$$Y^* = i\omega e l (\partial(n + c)/\partial\eta)_e \quad [18]$$

which is the required differential isotherm capacitance. If one diffusion coefficient is much greater, *i.e.*, $D_p >> D_n$

$$Y^* = eD_n(\partial n/\partial\phi)_e \mu_2 \tanh \mu_2 l \quad [19]$$

This expression is essentially identical with our previous result, less rigorously derived. The effect of traps, aside from increasing the low frequency capacitance, is to reduce the effective diffusion coefficient by a factor $(1 + \kappa_2)$.

When $D_n = D_p$ the normalized admittance is given by

$$Y^*(i\omega)/Y^*(0) = (\mu l/2)^{-1}(\mu l/2 + \coth \mu l/2)^{-1} \quad [20]$$

A complex-plane plot of this function lies very close to the full semicircle. Not finding such behavior at any potential in our experiments, we conclude that over the potential range studied either $D_p >> D_n$ or $D_p << D_n$, with no transition between these limits taking place. Equation [17] predicts deviation from a 45° slope towards a normal intercept at high frequencies in C^* plots when

$$\omega/\omega_{max} \simeq (D_1/D_2)^2 \quad [21]$$

Figures 2a and 2b show no break below 10 kHz, and as f_{max} is 4 Hz, the diffusion coefficient ratio must exceed 10^2.

This model leads to two physically distinct pictures of film oxidation and reduction. If hydrogen ions are the more mobile species, then following a potential change, a density change of electrons, free and trapped, first occurs at the metal/oxide interface and spreads diffusively through the film. An ample supply of hydrogen ions is available to neutralize any incipient space charge. Conversely, if the film is a good electron conductor, changes will first appear at the oxide/electrolyte interface. The Zeller-Beyeler experiments with WO_3 films show the former situation prevails there (3). Repetition of that experiment with an iridium oxide film could resolve this choice.

A serious problem with the double-injection model just analyzed is the potential dependence of the diffusion coefficient or the relaxation time (Fig. 4) which shows slopes at high and low potentials temptingly close to a value of 120 mV/decade. This is perplexing since, according to this model one is dealing with the diffusion of charges in a field-free region, and the only influence of potential is indirectly through the density of charges in the film. One might simplistically assume that $n \propto \exp(-e\phi/kT) = \exp(-e\eta/2kT)$ and that $c \propto n^2$. When $c >> n$, the trapping coefficient, κ_2, conveniently leads to the correct potential dependence for the effective diffusion coefficient, but the requisite exponential decrease of c with η is in no way compatible with the cyclic voltammogram. An additional difficulty with this model is the reversible change found when a film is transferred between dilute and concentrated acid solutions. It does not explain why, at corresponding points on the desorption isotherm, corresponding presumably to equivalent injection levels, the diffusion coefficient of the slow species is so greatly affected.

Both difficulties may be circumvented if one postulates a model of a highly porous film with essentially all oxide sites accessible to an electrolyte phase. At equilibrium this phase, containing both anions and cations, is electrically neutral and adopts the potential of the external electrolyte. The electrochemical potential of oxide sites is determined at the metal/oxide interface. In contrast to the preceding model, the total applied potential is felt by all sites within the film. Consider the process idealized in Fig. 11 as the path by which redox changes propagate. With a stationary transition state approximation

$$db/dt = k_a(a + c) - 2k_c b = 0$$
$$da/dt = k_c b - k_a a = k_a(c - a)/2 \quad [22]$$

where k_a and k_c are anodic and cathodic electrochemical rate constants for the interfacial release and uptake of hydrogen ions. Let Δ represent the distance the reduced site moves in this transition, so that its effective diffusion coefficient is $k_a\Delta^2/2$. If only nearest neighbor transitions are allowed, Δ will be of the

Fig. 11. Hypothetical electrochemical mechanism to describe the motion of a reduced lattice site.

order of a metal-metal distance in the oxide. The potential dependence of diffusion will be dominated by k_a, and is in accord with the observed 120 mV/decade slope.

The slow, but reversible, aging effects observed suggest that structural changes are taking place within the film which alter reduced site mobilities. To rationalize these changes we must speculate on the nature of the film. Indications are that they differ from crystalline IrO_2 in being amorphous and having a high water content (6, 14, 15). The IrO_2 rutile-like lattice can be described in terms of linear chains of edge-sharing octahedra, with adjacent, parallel chains coupled at triply coordinated oxygen vertices (13, 18). Direct hydrolysis of these interchain connections would lead to a structure $Ir(OH)_4$ which might rearrange to $IrO_2 \cdot 2H_2O$

Structures of this form have been proposed for polynuclear iridium complexes (19). We may further speculate that, during the process of film growth, octahedra are created at the metal/oxide interface and combine to form chains, not necessarily linearly connected. Random crosslinking between chains with a local bonding structure of triply coordinated oxygen atoms similar to that found between chains in the IrO_2 lattice will probably occur.

The aging seen in strong acids may reflect the further hydrolysis of this structure by the introduction of additional H_2O or H_2SO_4. This would reduce the connectivity of the network and thereby decrease the mobility of reduced sites restricted to motions along the chains. The reversibility of the aging process shows that a dynamic equilibrium exists, and the interconnections must be continually forming and breaking, even in a stable film. Under such circumstances one should be wary of direct comparisons between measurements made on dessicated films in high vacuum experiments and measurements made on "live" films. Both structure and physical properties may be significantly altered by dehydration.

One aspect of our measurements which remains unexplained are the values for C_∞. For the data in Fig. 2 this value, 750 $\mu F/cm^2$, is substantially larger than the double-layer capacitance, although but a fraction of the total film capacitance. For 1-10 mM solutions, *c.f.* Fig. 8, a capacitance of 5200-5800 $\mu F/cm^2$ is seen to characterize a high frequency relaxation process. With the dimensional expression, $C = Ne^2/kT$, the equivalent number of charges is $6 \times 10^{14}/cm^2$. The equivalent circuit (Fig. 8) requires that these charges correspond to an H^+ reservoir within the film. Qualitative observations of an unbuffered $NaClO_4$ solution show a rapid partial response despite the absence of a significant number of hydrogen ions. The cyclic voltammogram is comparatively featureless, as expected for a sluggish reaction, but upon stopping or reversing the sweep in the redox potential region one sees the superposition of a very rapid and a very slow relaxation. The optical response of an unbuffered dilute acid solution also indicates this composite behavior (8). We must conclude that, although in acid solutions, pH $\sim$ 3, the dominant relaxation is governed by the supply of hydrogen ions, an additional mechanism arises in neutral solutions. Rapid kinetics in alkaline solutions have been found (20), but in a nominally neutral solution both hydrogen and hydroxide ion concentrations are too low to support rapid and reversible kinetics. We have postulated two structures which might result from the hydrolysis of an IrO_2 lattice, and it is conceivable that the balance between these configurations is pH dependent. Further studies are needed to reconcile the properties of films in neutral and alkaline solutions with the effort herein reported for acidic media.

Acknowledgments

We gratefully thank Shimshon Gottesfeld for attracting our attention to this interesting system, and for many discussions of our findings.

Porphyrin Modified Tin Oxide Semiconductor as Photocathode

H. Ti Tien and John Higgins

Department of Biophysics, Michigan State University, East Lansing, Michigan 48824

ABSTRACT

A new sensitized semiconductor photoelectrochemical cell is described. The semiconductor is n-type SnO_2, a wide-band material inherently less susceptible to anodic dissolution. When sensitized by a thin layer of tetraphenylporphyrin (TPP), the SnO_2 electrode acts as a photocathode. The TPP layer is considered as a p-type organic semiconductor whereas the interface between the TPP layer and redox solution is likened to that of a Schottky barrier with the aqueous solution playing the role of a metal. Under illumination, the TPP-SnO_2 electrode *vs.* Pt (or SnO_2) displays a potential of 400 mV and a current density of 20 $\mu A/cm^2$.

One of the major problems for photoelectrochemical (PEC) cells using narrow bandgap n-type semiconductors such as CdS is anodic decomposition. The wide bandgap semiconductors such as TiO_2 and $SrTiO_3$ are stable against photoanodic decomposition (1-4), but unfortunately are poor absorbers of the solar spectrum (5). These semiconductors may be sensitized to enhance their absorption characteristics either by incorporating impurities into the semiconductors (6) or by absorbing dyes onto the semiconductor surface (7, 8). The latter approach has the advantages of simplicity of construction and modification and the availability of a wide range of dye absorption bands, but a PEC so sensitized has a low energy conversion efficiency because only the molecular layers near the semiconductor can inject charge into the semiconductor, the more distant molecules losing most of their energy of excitation in other ways (9, 10). Thus dye or pigment in a thick layer generally has a high electrical resistance and low quantum yield.

We report here a new sensitized semiconductor PEC cell which shows promise of overcoming the above problems. The semiconductor is n-type SnO_2, a wideband material ($Eg = 3.5 - 3.8$ eV) inherently less susceptible to anodic dissolution, and previously studied as a photoanode for possible application to solar cells (11-13). We have found that, when sensitized by a layer of the pigment *meso*-tetraphenylporphine (herein abbreviated TPP), the SnO_2 electrode acts as a photocathode, thereby obviating the anodic dissolution problem of the sensitized photoelectrode. By depositing only the small amount of pigment that can be electroactive, the electrode remains essentially an optically transparent electrode. This permits stacking of cells (or diodes) to form a battery capable of high absorption of visible light, and thereby overcomes the weakness of low absorption of the individual cells.

In addition to its potential for conversion of solar energy, our coated electrode may be of interest in the study of the electrochemical properties of porphyrins (and other pigments) owing to the direct chemisorption of the photoactive compound itself to the electrode without the need for linking molecules or modification of the pigment.

Experimental

A piece of window glass coated on one side with heavily doped SnO_2 (Nesa glass, PPG Company, Pittsburgh, Pennsylvania) with a resistance of 60 Ω/square. This is cleaned in acid, rinsed successively in water and chloroform, and heated to 80°-90°C before being dipped into the coating solution of *meso*-tetraphenylporphine (TPP, from Strem Chemicals, Danvers, Massachusetts) in $CHCl_3$. The normal concentration is 0.65% (w/v), but we have experimented with concentrations ranging from 0.2% to 3.25%, reported here. After 10 sec (not critical) of immersion, the electrode is quickly and smoothly withdrawn. The TPP solution dries to a smooth, hard film that does not noticeably dissolve into the aqueous electrolyte (at $pH < 7$) if the coat is given sufficient time to dry, usually 2-5 min at room temperature in air. The preheating of the glass appears only to decrease the required drying time, as Nesa glass dipped at room temperature works about as well if given longer time to dry. The electrolyte is 10^{-4}M $Fe_2(SO_4)_3$, 10^{-2}M $FeSO_4$, and 10^{-2}M H_2SO_4 (pH 2.0). For counterelectrodes we have tried platinum, glassy carbon, and SnO_2 (Nesa glass). SnO_2 was used for the data reported here. The electrical power of the cells with Pt or glassy carbon was about the same as for SnO_2. Electrical connection was made by tinned aligator clips, which also held the electrodes in a glass container of electrolyte. The electrodes were 2.5 by 5.0 cm, with the immersed, illuminated area being 3.2 cm^2. Illumination was from a 500W tungsten projector lamp, with spectral measurements made by a Bausch and Lomb High Intensity Monochromator (Model 33-86-02, grating 1350 grooves/mm, 350-800 nm). Both white-light and monochromatic irradiation were measured by the photocurrent from a silicon solar cell through a 1.0Ω load, whose response was calibrated by a radiometer (Yellow Springs Instruments, Incorporated).

Results

From the current-voltage (I/V) curves of two cells (Fig. 1), it can be seen that under irradiation of 200 mW cm^{-2} from tungsten lamp the cell is equivalent to a potential of 0.35-0.40V in series with a resistance of 7-15 kΩ-cm^2 with a short-circuit current density of $1.6\text{-}2.0 \times 10^{-5}$ A-cm^2. The fill factor is 0.2-0.3, and typical power is $1.0\text{-}2.0 \times 10^{-6}$ W cm^{-2}. Total power conversion efficiency (maximal power delivered divided by irradiation) is a maximum of 10^{-5} in tungsten white light and 4×10^{-3} at 420 nm. Due to differences between energy spectra, conversion efficiency is expected to be somewhat higher in sunlight than that in tungsten light. The photovoltage risetime is related to the exchange current density and the physical limits on the power such a cell can deliver. The time course of the photopotential exhibits three exponential time constants: 11 sec risetime and two decay constants of 38 and 100 sec. These were measured at 420 nm, but the values of all three are independent of wavelength within our error of measurement (1 sec). All the above data are for SnO_2 counterelectrode, 0.65% TPP:$CHCl_3$ coating solution, and no external potential. In the dark the same cell has zero potential and current (on the

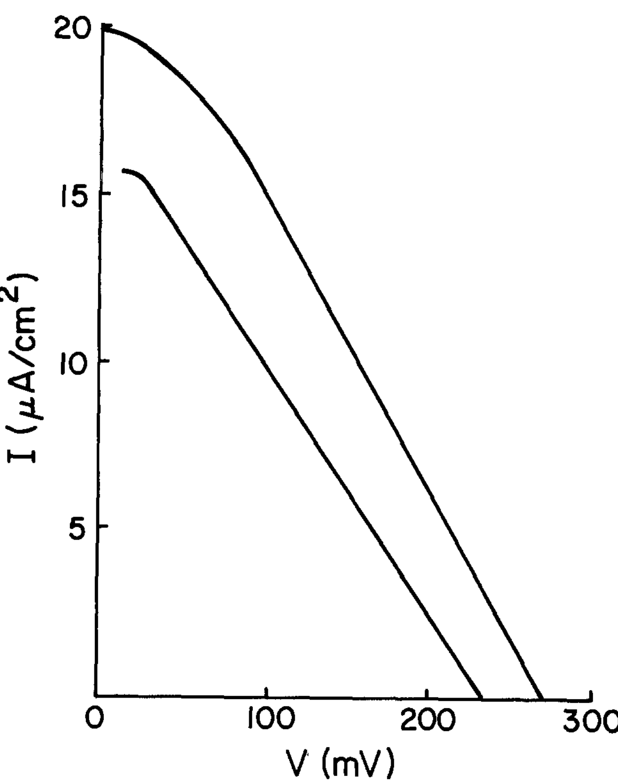

Fig. 1. Current-voltage characteristic of cell at 200 mW cm^{-2} irradiation of tungsten white light. The abscissa shows voltage difference between the electrodes when the cell is loaded by a resistor.

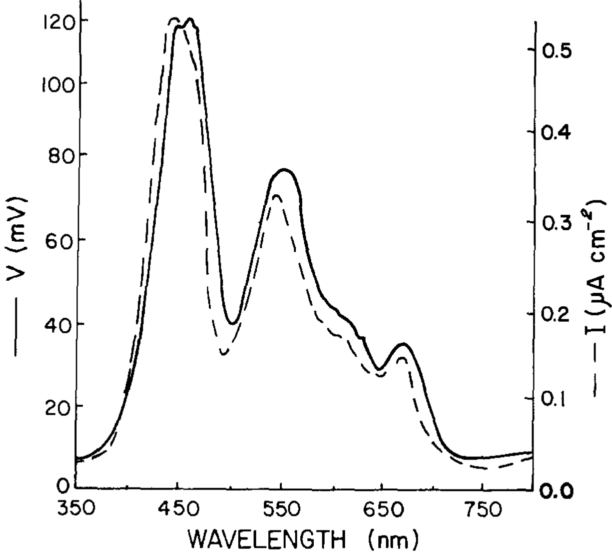

Fig. 2. Spectral photoresponse of TPP-SnO_2 electrode. Irradiation varies as described in the text. Photopotential (solid line) of electrode was measured by the voltage across the open-circuit cell after the absence of a photopotential from the clean SnO_2 counter-electrode or from the electrolyte was determined. Photocurrent (dashed line) through 100Ω, essentially a short circuit.

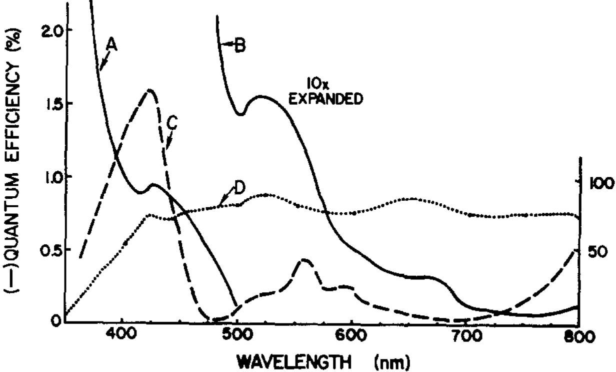

Fig. 3. Quantum efficiency (*QE*) spectrum (A and B) of cell and absorption spectra of TPP: $CHCl_3$ solution (C) and dry TPP film on SnO_2 (D, in % on right-hand scale). Note that beyond 500 nm the *QE* curve (B) has been expanded tenfold with respect to the illustrated scale. The scale for the solution absorption is relative.

scale of Fig. 1) with resistance of 2-5 times that in the light. Both the photovoltaic and photoconductive effects arise solely from the sensitized electrode. Thus, the currents of Fig. 1 are a combination of a photovoltaic effect (which is the source of overpotential driving the current) and a photoconductive effect, whose presence was shown by measurement of the dark TPP-SnO_2 electrode, which passed about 50% less current at the same overpotentials (provided by an external potential source). In both cases, overpotential was measured against a saturated calomel electrode. If excited TPP is considered the dominant electroactive species, electrochemical theory shows that a photopotential generally leads to increased exchange current density, equivalent to photoconductivity.

The open-circuit photovoltage and the short-circuit photocurrent spectra are shown in Fig. 2. They exhibit the strong violet absorption (Soret band) typical of all porphyrins. The spectra are uncorrected for the spectral distribution of irradiation so that the structure below 450 nm can be seen easily. The combined tungsten lamp-monochromator spectrum rises in three nearly linear segments, from 0.05 to 1.29 mW cm^{-2} over 375 to 550 nm, peaking to 1.78 mW cm^{-2} at 750 nm, and falling to 1.71 mW cm^{-2} at 800 nm. Therefore the light source does not introduce any structure. The quantum efficiency (electron flux divided by absorbed photon flux) and absorption spectra are shown in Fig. 3. The peak positions of the action spectrum are those of the corrected voltage and current spectra. The absorbance peaks of the absorption spectrum of a dilute TPP: $CHCl_3$ solution differs from the peaks of relative absorption of the porphyrin film on an SnO_2 electrode. The electrode was coated exactly as that for which the action spectra were measured. The absorption of the TPP film was measured by subtracting from the incident radiant energy flux the amounts transmitted and reflected by the coated electrode as well as the amount absorbed by the SnO_2-glass substrate (measured separately).

With respect to electron transfer, Fig. 4 shows the importance of a thin layer of pigment in maximizing the photovoltage and photocurrent, both of which increased as the concentration of the TPP in the coating solution decreased, and they had not reached apparent maxima even at 0.2% (w/v), at which concentration the cell was not stable for more than a few hours. We have not examined closely the relationship between the concentration of the coating solution and the mass of TPP deposited onto the electrode, although at all concentrations studied it was less than 10^{-4} g/cm² and there was a visible increase of pigment density with concentration.

We observed that the electrical output of batteries of 2-6 cells added approximately in series or parallel for corresponding electrical connection. That is, for a battery of cells connected in series, the observed battery voltage was close to the theoretical value predicted by the potentials and internal resistances of the individual cells. Similarly, the total current from a battery of cells connected in parallel was the sum of currents measured in isolated cells and the battery voltage was close to the average of cell voltages. These observations were made on batteries whose cells were physically arranged behind one another along the optical axis, so that a single beam of light passed through each cell in sequence, thus increasing the amount of electrical power extracted per beam area. This battery arrangement was permitted by the optical transparency

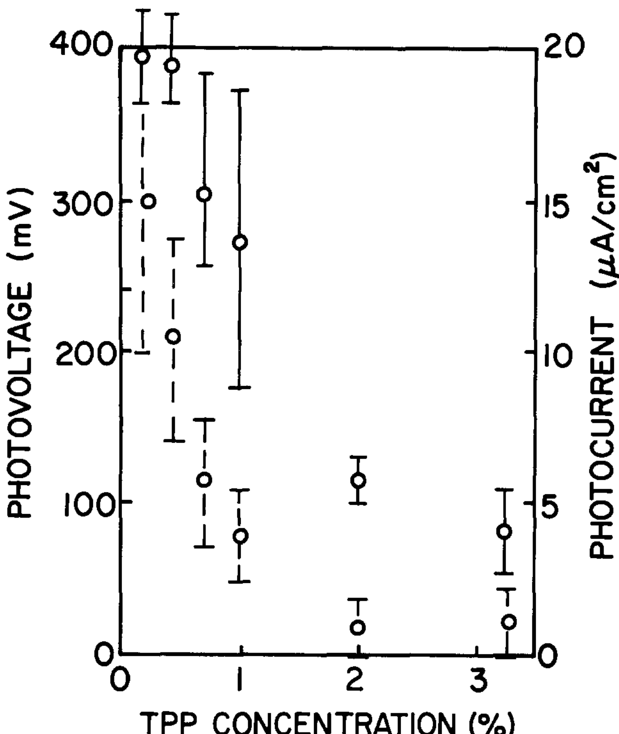

Fig. 4. Cell photopotential (filled circles) and photocurrent (open circles) *vs.* concentration of TPP coating solution. Bars indicate standard deviations (4-10 samples).

of the SnO_2 and the incomplete absorption of light by the films of TPP.

Discussion

We have described a new photosensitive electrode, SnO_2 coated with an insoluble film of tetraphenylporphine, that can function as a photocathode under its photopotential, in contrast to the more common anodic behavior of sensitized semiconducting electrodes. It has a quantum efficiency of 1% at 425 nm, 0.31 mW cm^{-2} irradiation. Explanation of the positive potential of the TPP-SnO_2 electrode with respect to three apparently inert electrodes, clean SnO_2, platinum, and glassy carbon, in the iron sulfate electrolyte solution requires more information on the relative energy levels. It is presumably due to the injection of a hole by excited TPP into the semiconductor's valence band, while the excited electron is blocked by the bandgap. The actual mechanism probably involves the bandgap because the photoresponses reported here are very much greater than those of various metals coated with TPP (16).

Regarding spectral characteristics of the electrode, the solution absorption (curve C of Fig. 3) changes and broadens upon depositing the TPP as a coat of pigment on SnO_2 (curve D of Fig. 3). Band broadening is expected in the condensed state. Quantum yield decreases with wavelength faster than does absorption of radiant energy by the film. This may be due to the higher probability for electron transfer from the valence band of SnO_2 to the lowest vacant levels of the energy band of a given ground-state valence orbital of TPP, the availability of more excited-state TPP orbitals to the electrons of higher excitation energy, and the ability of the higher energy charge carriers generated in TPP by the shorter wavelengths to migrate or diffuse through molecular layers of TPP. The dependence of QE on wavelength was reported for monolayers of chlorophyll on SnO_2 (13).

As the spectral intensities used to measure quantum efficiency (QE) of Fig. 2 approach the intensities present in 200 mW cm^{-2} of tungsten light used to measure I/V curves (Fig. 1), we estimate upper limits of 40% to 50% decrease in QE as follows. The theoretical current density is proportional to both QE and irradiation distributions, although both are unknown at the higher intensities, the fact that the irradiation distribution of the monochromatic source has the shape of a typical tungsten spectrum (at most 17% deviation) suggests that the intensity scaling factor (S) is approximately independent of wavelength. Also, our monochromator's bandwidth (BW) is independent of wavelength for fixed geometrical arrangement. Consequently S can be evaluated by numerically integrating the irradiation spectrum, to give

$$S = (0.40 \pm 0.04)\ BW(\text{nm}) \quad [1]$$

Because BW cancels in the final equation for current, it need not be known, but Eq. [1] provides a check on our approach if we use a value 5 nm for BW, estimated by the change in wavelength reading to make the same hue appear successively at the two edges of the electrode (2.0 cm across). We find $S = 2.0 \pm 0.2$, in agreement with the monochromator's specified efficiency of 55% at the blaze wavelength (*i.e.*, of maximal efficiency) of 550 nm (an exact check depends upon the unknown efficiency spectrum, but efficiency is specified as high throughout the visible spectrum). The intensity scaling factor is then multiplied by the value of numerical integration over wavelength of the product of irradiation (described in text) times absorption (curve D of Fig. 3) times quantum efficiency (Fig. 3) divided by the energy quantum. The result is multiplied by the electronic charge to give a theoretical current density of $34 \pm 8 \times 10^{-6}$ A-cm^{-2}, compared with measured values of 16 and 20×10^{-6} A-cm^{-2} from Fig. 1. Assuming all the difference is due to a decrease in QE upon doubling irradiation permits calculation of the QE decrease. Although we expect most of the decrease in current to be accounted for by QE, the absorption percentage should also decrease a little, so the calculated QE decrease is only an upper limit.

We compare the quantum efficiency results with those of a structurally analogous electrode: chlorophyll-lecithin monolayers on SnO_2 (13). For a given photon flux at the relevant sensitive wavelengths (420 and 673 nm) of each electrode, the TPP-SnO_2 electrode has factors of 406 more photons absorbed, 7.4 more electrons per incident photon, and 0.018 as many electrons per absorbed photon. The greater number of photons absorbed simply reflects the greater thickness of our film. The low ratio of electrons to photons absorbed is due to the inability of excited pigment molecules too far from the semiconductor to inject a charge (9, 10). From Fig. 3 and knowledge of the radiant energy absorbed by the substrate (approximately 4% at 425 nm), it is seen that 77% of the incident photon flux reached the molecular layers near the semiconductor. If only the adjacent pigments can inject charge, the efficiency of TPP must be ten times that of chlorophyll. Lower charge injection efficiency implies that charge carriers migrate or diffuse from regions of pigment near, but not adjacent to, the semiconductor.

Previously we have used Mg-*meso*-tetraphenylporphrin and metal-free tetraphenylporphyrin (TPP) to coat vitreous (glassy) carbon electrodes for use in a photogalvanovoltaic cell (15, 16). The photoactive TPP-electrode behaves as a photocathode. Owing to its opaqueness, cells made of glassy carbon electrodes cannot be stacked for better light utilization. Therefore, for the construction of a battery, electrode materials must be as transparent as possible in the visible region of the solar spectrum and have good conductivity.

On the basis of obtained data, the following mechanism may be given to account for the observed photocathodic current of the TPP-coated SnO_2 electrode. The doped SnO_2 serves as a conducting substrate with the appropriate bandgap for the TPP layer which is considered as a p-type organic semiconductor. The interface between the TPP layer and redox electrolyte is likened to that of a Schottky barrier with the aqueous solution playing the role of a metal. Upon excita-

tion by light, charge carriers are generated in the TPP layer. The excited TPP most likely decays first to the lowest singlet state and then crosses to the triplet state, at which the triplet state exciton transfers an electron to an acceptor in the bathing solution. The vacant hole left in the TPP layer is filled by an electron from the doped SnO_2 substrate, thereby giving rise to the observed direction of photocathodic current.

The present study has been restricted to inert counterelectrodes, but the behavior of this TPP-coated SnO_2 as a photocathode rather than a photoanode makes possible the use of a photoanode as the counterelectrode to increase power output. It should also be possible to sensitize this optically transparent cell to other visible bands by adding electroactive dye to the electrolyte solution. This is the photogalvanovoltaic concept and has been observed from porphyrin-coated glassy-carbon electrodes with thionine in solution (15-17). Thionine did not work well in the TPP-SnO_2 cell. We are currently searching for other dyes and pigments that (*i*) also bond tightly to SnO_2 to produce a photocathode of different spectral sensitivity or a photoanode and/or (*ii*) make use of dye solution to construct a photogalvanovoltaic cell. We will look at more quantitative methods of coating the SnO_2 electrode with porphyrin using Langmuir-Blodgett molecular layers, or by evaporating a known amount of TPP onto the SnO_2, a technique successful with surface active porphyrin (8).

In summary, we feel that our tetraphenylporphine-tin oxide electrode is a good candidate for further investigation as the photocathode for a solar cell. Chemical attack on the sensitized electrode appears to be negligible. One problem common to sensitized semiconductors, low absorption of the incident radiation, can be alleviated by the battery design discussed above, which is made possible by the transparent substrate. No component of our cell presents an obvious cost or production limitation. Pyrolitic deposition of polycrystalline tin oxide onto glass does not require the stringent control of purity required by single crystals or some other types of polycrystalline materials; and metal-free porphyrin can be readily synthesized (14).

Ammonia High Temperature Solid Electrolyte Fuel Cell

Roger D. Farr and Costas G. Vayenas*

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

A study was made of the overpotential and product selectivity characteristics of the high temperature solid electrolyte fuel cell

$NH_3,NO,N_2,Pt/ZrO_2(8\%Y_2O_3)/Pt,air$

It was found that NO is the primary oxidation product, although significant amounts of by-product N_2 are also formed due to the catalytic reaction between NH_3 and NO on Pt. The influence of this side reaction can be minimized under optimal operating conditions and yields of NO exceeding 60% can be achieved. Two dimensionless numbers have been identified which govern product selectivity and power output. The cell is a promising candidate for the cogeneration of electric energy and nitric acid.

The oxidation of ammonia to nitric oxide over a Pt-Rh alloy is the basic step for the manufacture of nitric acid (1). It is a highly exothermic reaction with $\Delta G = -64.5$ kcal/mole NH_3 at 1000°K. More than $7 \cdot 10^6$ tons of HNO_3 are produced annually in the U.S. alone. Due to the high exothermicity of the reaction large amounts of thermal energy are generated. It has been a long sought goal to obtain this

Key words: solid electrolyte, fuel cell, ammonia, nitric oxide.

energy as electric rather than thermal energy by oxidizing ammonia to NO in a fuel cell (2).

Low and intermediate temperature ammonia-air cells have been investigated using strong KOH solutions (3, 4) or fused KOH in an MgO matrix (5) as the electrolyte. However N_2 was found to be the only oxidation product.

High temperature solid electrolyte fuel cells operating on H_2, CO, or CH_4 as the fuel have been tested for years (6, 7). With Pt electrodes and H_2 as the fuel, pure resistance polarization has been observed, but with CO some activation overpotential also appears (7).

Stabilized zirconia cells have been used to monitor the activity of oxygen on metal oxidation catalysts (8) and to dissociate oxygen-containing compounds, including NO (9, 10).

Although the catalytic NH_3 oxidation is highly efficient and, under industrial conditions, mass transfer controlled (1), there have been several interesting recent studies of the intrinsic NH_3 oxidation kinetics on Pt (11, 12).

In this research NH_3 was used as the fuel in a high temperature stabilized zirconia fuel cell with Pt electrodes in order to examine the product distribution of the cell and explore the possibility of NO and electric energy cogeneration.

Experimental Apparatus

A schematic diagram of the experimental apparatus is shown in Fig. 1. It consists of a gas feed system, the fuel cell, and the analytical system. The fuel cell design is shown in Fig. 2. It consists of an 8 mole percent (m/o) yttria stabilized zirconia tube with an ID of 16 mm and 1.8 mm wall thickness. Platinum electrodes were deposited inside and outside to the dimensions given in Fig. 2 using Englehard Pt ink A3788 followed by air drying and calcining at 1300°K for 4 hr. This procedure was repeated twice with Englehard Pt ink A3788 and once with Englehard Pt 6926. Scanning electron micrographs showed electrodes prepared in this manner to be evenly applied and porous. Each electrode had a resistance of 0.24Ω and BET area of 300 cm^2/cm^2 of superficial catalyst area. Thickness was estimated to be 3 μm. The anode was extended to one end of the tube in order to ensure good contact with the Pt wire lead. All power

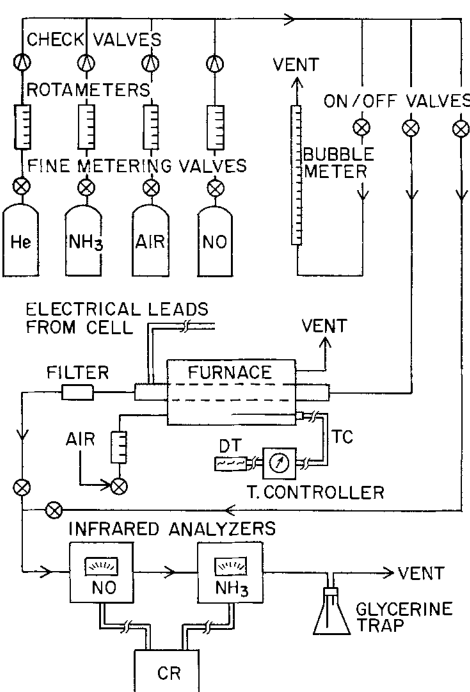

Fig. 1. Experimental apparatus

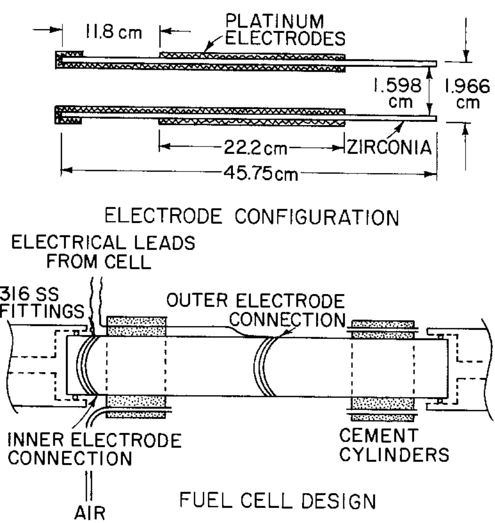

Fig. 2. Fuel cell design and electrode configuration

values reported here are based on the cathode length of 22.2 cm.

To complete the cell assembly and support the weak zirconia tube, Dylon C-3 cement cylinders were cast around the zirconia tube where it entered and exited the furnace. Thermocouple and cathode leads as well as air supply and removal tubes were set into the cylinders as shown in Fig. 2. The fuel cell temperature was held constant within 2°K by means of an on-off type controller. Stainless steel fittings with Viton O-rings were adapted to fit the ends of the zirconia tube. The assembly passed a helium leak test to 4.46×10^5 Pa. All tubing and fittings were 316 stainless steel. The product gas from the cell was immediately cooled by the exit fitting to 298°K for analysis.

Reactants and products were analyzed using Beckman 864 and 865 infrared analyzers for NH_3 and NO, respectively. The feed and exit streams were sampled as shown in Fig. 1. Cell voltage and current were measured by two digital multimeters (Fluke 8600A). A decade resistance box was used to vary cell load. In addition to this load a residual resistance of 0.873Ω was present at all times in the circuit due to connecting wires and multimeters. Additional details of the apparatus appear elsewhere (13).

Reactants used were Matheson certified standards of 4.59% ammonia in helium and 8550 ppm NO in helium. They could be further diluted with Matheson zero gas standard helium. The fuel cell was operated at atmospheric pressure.

Constant potentials could be applied to the cell, when necessary, using an AMEL 549 Potentiostat.

Results

Close agreement was observed (±0.5%) between measured and theoretical emf values when O_2, N_2, or He mixtures of known P_{O_2} were fed through the zirconia tube. This verified the pure ionic conductivity of the solid electrolyte.

Cell resistance.—With both Pt electrodes exposed to air, the potentiostat was used to apply to the cell voltages between −2 and 2V. In agreement with previous work (7) it was found that current is linear in voltage and therefore only resistance polarization appears. The cell resistance was thus determined from the slope of the voltage-current lines which have been shown to coincide with the a-c resistance of the cell (7). Results obtained in this manner are shown in Fig. 3. The dashed line between 1000° and 1200°K corresponds to single point d-c resistance measurements. Over the temperature range investigated (700°-1200°K) the cell resistance R can be approximated by the expression

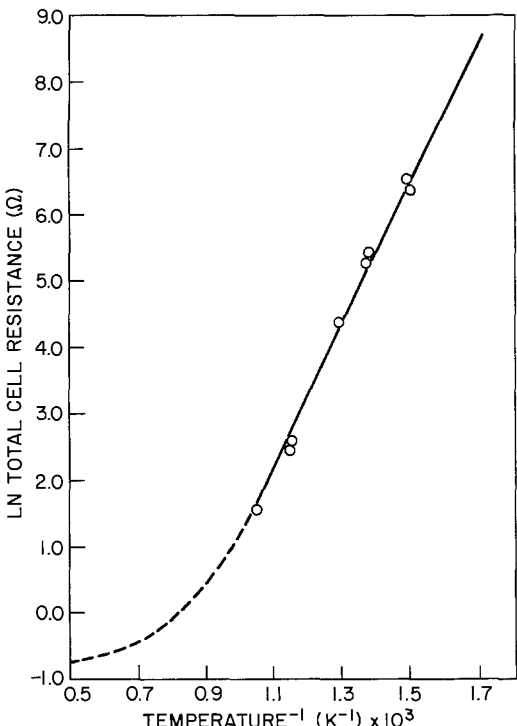

Fig. 3. Fuel cell resistance

$$R = 0.48 + 7.7 \cdot 10^{-5} \exp(10{,}600/T)\Omega$$

The first term roughly corresponds to the resistance of the electrodes, and the second is due to the solid electrolyte.

Fuel cell performance.—Typical current-potential plots at constant feed composition (4.59% NH_3 in He) are given in Fig. 4a and b. The current I_L corresponding to 100% ammonia conversion to N_2 is also shown for comparison. It is defined by $I_L = 3\mathbf{F}G_{NH_3,F}$, where $\mathbf{F}$ is the Faraday constant and $G_{NH_3,F}$ is the feed molar ammonia flow rate. Clearly the current I_M corresponding to 100% ammonia conversion to NO equals 1.67 I_L.

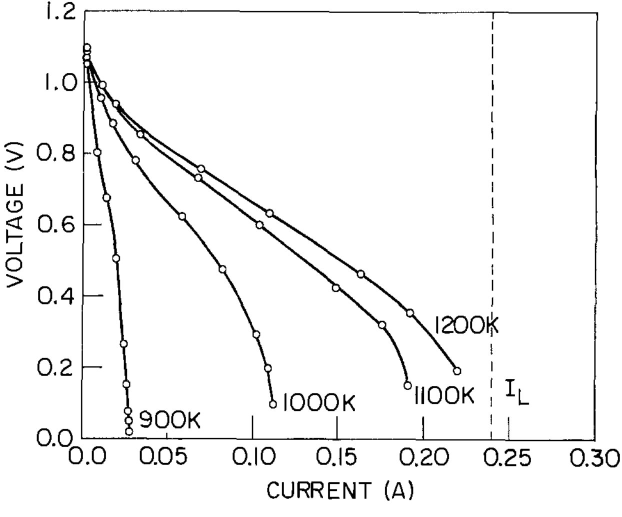
The current-potential plots indicate strongly that above 1000°K ohmic overpotential is the dominant source of polarization. Taking into account the residual resistance of connecting wires (~0.87Ω) one finds that the straight line portions of these curves correspond within 30% to the cell resistance. The initial nonlinear decrease in the cell potential can be accounted for by the "Nernst loss" due to increasing conversion to products with increasing current. This gradually increasing "Nernst loss" with increasing current causes the slopes of the quasi-linear portions of the curves to be systematically higher (10%-30%) than the cell resistance.

The potential values observed (Fig. 4), including the open-circuit emf value, would indicate that NO is the primary anodic product according to the reaction

$$2NH_3 + 5\,O^{2-} \rightarrow 2NO + 3H_2O + 10e^- \quad [1]$$

Assuming [1] to be the dominant anodic reaction and using the cell resistance values one can approximate fairly well the potential-current behavior. If O^{2-} or oxygen adsorbed on Pt were involved in N_2 formation, then the absolute emf value would be at least 250 mV higher than what is observed. This is further discussed below.

Using ammonia feed molar flow rates $G_{NH_3,F}$ in excess of $7 \cdot 10^{-7}$ mole NH_3/S, *i.e.*, roughly 20 cm^3 STP/min of 4.59% NH_3 in He, resulted in power outputs on the order of 10^{-3} W/cm^2 of electrolyte and almost zero selectivity to NO, nitrogen being the only oxidation product. However, a decrease in $G_{NH_3,F}$



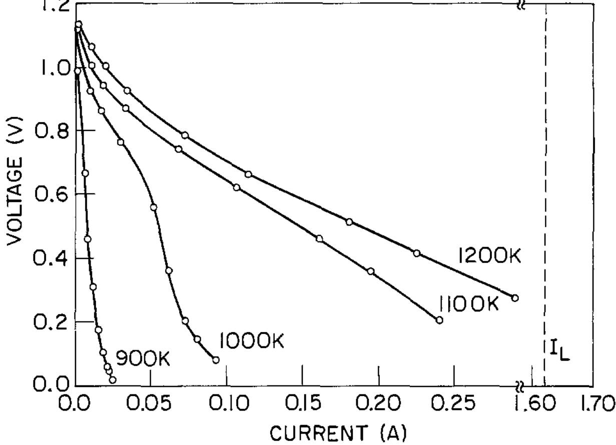


Fig. 4. Current-voltage behavior of the cell with $y_{NH_3,F} = 0.0459$. a (top). Flow rate 26 cm^3 STP/min. b (bottom). Flow rate 176 cm^3 STP/min.

below that value, by either increasing dilution or decreasing total flow rate, resulted in a dramatic increase in selectivity (moles NO formed/mole NH_3 reacted).

Accordingly, the fuel cell selectivity and power output were studied extensively at temperatures between 900° and 1200°K, NH_3 feed mole fractions $y_{NH_3,F}$ between 0.01 and 0.0459, and total flow rates between 5 and 25 cm^3 STP/min. At 1100°K, $y_{NH_3,F} = 0.02$ and with a total flow rate of 5 cm^3 STP/min the maximum selectivity was obtained (97%), although the power output had dropped to $7 \cdot 10^{-6}$ W/cm^2 due to the very long residence time employed. Under these low flow rates the fuel cell, although tubular in shape, behaves almost exactly as a continuous flow stirred tank reactor (CSTR). This was predicted on the basis of the axial and radial Peclet numbers, but was also verified experimentally (Fig. 5).

Although the dependence of selectivity on temperature, $y_{NH_3,F}$, and flow rate initially appears complicated, it was found that selectivity is almost uniquely defined at any T, $y_{NH_3,F}$, and flow rate by a dimensionless parameter M defined as

$$M = \frac{G_{O_2}}{G_{NH_3,F}} = \frac{I}{4\mathbf{F}G_{NH_3,F}}$$

where G_{O_2} is the molar oxygen flux, in the form of O^{2-}, through the electrolyte (Fig. 6). For M values below 0.75 the selectivity is very low but with $M = 1.0$, up to 97% selectivity can be obtained.

In light of this no distinct trend exists on plotting selectivity *vs.* conversion (13), *i.e.*, selectivity does

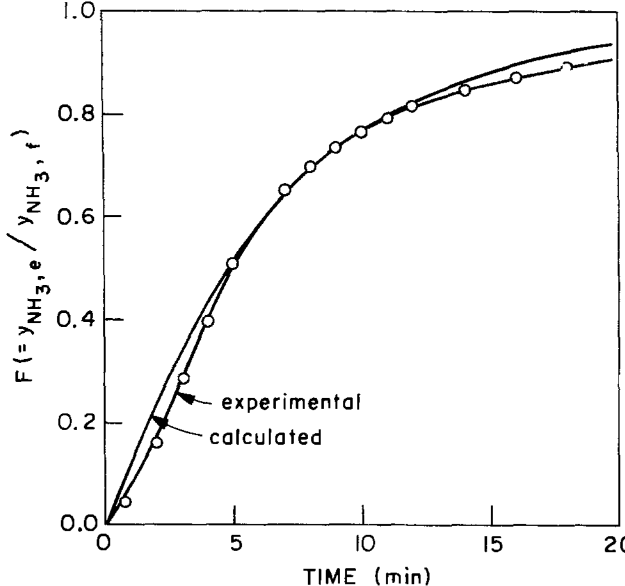

Fig. 5. Response to a step-function change in the feed concentration of ammonia and comparison with ideal CSTR response. Flow rate 18.6 cm³ STP/min, volume of reactor and associated tubing 126 cm³.

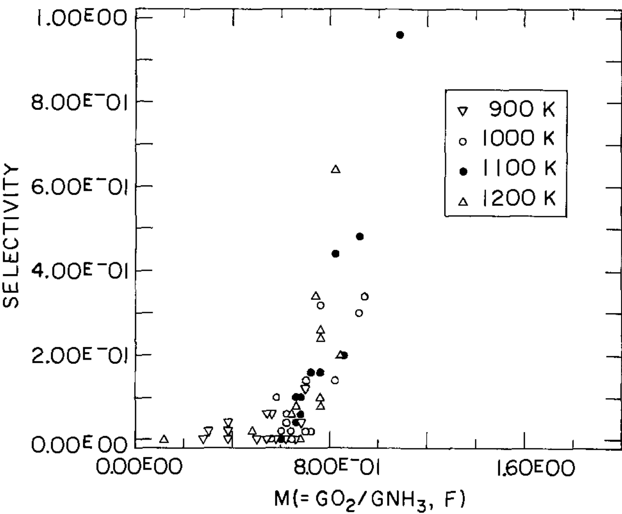

Fig. 6. Selectivity vs. dimensionless group M

not decrease with increasing conversion, and this is an attractive feature of the cell.

In order to examine if the dramatic dependence of selectivity on M is characteristic of NH_3 fuel cell only or if it is a general characteristic of the NH_3 oxidation on Pt, the following experiment was made. Small concentrations of oxygen were admixed with NH_3 fed in the cell. It was observed that when the ratio

$$M' = G_{O_2,F}/G_{NH_3,F}$$

is below 0.75 again the selectivity is practically zero, but increases sharply when $M' > 0.75$ (Fig. 7). It was thus verified that the origin of O_2 (through the zirconia or from the gas phase) plays no role on the selectivity of the cell.

With long residence times (several minutes) and with M values near 0.7 it was observed that the fuel cell voltage, current, and product concentrations exhibit self-sustained oscillations. This is shown in Fig. 8 for $M = 0.7$, $T = 1100°K$, and 8 min residence time. An extended study of this phenomenon will be presented in a later communication. Only steady-state data have been presented here.

The platinum electrodes performed well over long periods of time (~500 hr). Scanning electron micro-

Discussion

Pignet and Schmidt (11) have studied the kinetics of NH_3 oxidation on Pt wires and found the main reactions occurring to be

$$NH_3 + 5/4\,O_2 \rightarrow NO + 3/2\,H_2O \quad [2]$$

$$NH_3 + 3/2\,NO \rightarrow 5/4\,N_2 + 3/2\,H_2O \quad [3]$$

$$NH_3 \rightarrow 1/2\,N_2 + 3/2\,H_2 \quad [4]$$

$$NO \rightarrow 1/2\,N_2 + 1/2\,O_2 \quad [5]$$

The relative importance of reactions [4] and [5] in the fuel cell was examined by passing separately NO and NH_3 through the cell under open-circuit conditions. Decomposition of NO, as reported by Chilton (1), was found to be negligible at the temperatures and residence times employed in this study. In agreement with previous work by Mason and Huggins (9, 10) we found that the rate of NO decomposition can be enhanced dramatically by application of an external voltage. Decomposition of NH_3 was found to be significant only above 1100°K, therefore, the major source of by-product N_2 is reaction [3]. This is futher supported by the magnitude of the observed emf which would be considerably higher if O^{2-} or adsorbed oxygen were directly or indirectly involved in N_2 formation. That NO rather than N_2 is the primary anodic oxidation product is not surprising in view of the fact that Pt catalysts convert almost quantitatively NH_3 to NO at temperatures between 700° and 1200°K (1).

On the basis of these observations it is safe to conclude that the dominant anodic reaction is

$$2NH_3 + 5\,O^{2-} \rightarrow 2NO + 3H_2O + 10e^- \quad [1]$$

while N_2 is mostly formed by the catalytic side reaction

$$NH_3 + 3/2\,NO \rightarrow 5/4\,N_2 + 3/2\,H_2O \quad [3]$$

Because of the predominantly ohmic nature of the overpotential, the rate of reaction [1] is controlled by the rate of O^{2-} diffusion through the zirconia electrolyte.

The observed selectivity behavior can be explained in terms of these two reactions in a quantitative manner: mass balances of the three components NH_3, NO, and N_2 in the CSTR yield

$$Gy_{NH_3,f} = (4/5)\,(i/4F) + kSy_{NH_3,e}y_{NO,e} + Gy_{NH_3,e} \quad [6]$$

$$O = (-4/5)\,(i/4F) + (3/2)\,kSy_{NH_3,e}y_{NO,e} + Gy_{NO,e} \quad [7]$$

$$O = (-5/4)\,kSy_{NH_3,e}y_{NO,e} + Gy_{N_2,e} \quad [8]$$

where k is the specific constant of reaction [3], assumed first order in both NH_3 and NO, S is the Pt anode surface area, G is the total molar flow rate, and the y's represent mole fractions in the feed (f) and exit (e) streams. Writing these in terms of dimensionless variables and solving for the exit concentration gives

$$O = x_D^2 + (1/N - 2M + 3/2)x_D - (4/5)\,(M/N) \quad [9]$$

$$x_A = \frac{(4/5)M - x_D}{(3/2)Nx_D} \quad [10]$$

$$x_F = (5/4)Nx_Ax_D \quad [11]$$

where $x_A = y_{NH_3,e}/y_{NH_3,f}$, $x_D = y_{NO,e}/y_{NH_3,f}$, $x_F = y_{N_2,e}/y_{NH_3,f}$, $M = G_{O_2}/G_{NH_3,f}$, $G_{O_2} = i/4F$, and $N = k \cdot S \cdot y_{NH_3,f}/G$.

In terms of these dimensionless parameters, the selectivity is defined as

$$S' = x_D/(1 - x_A) \quad [12]$$

For very large values of N the selectivity is equal to x_D, and Eq. [9] and [10] yield

$$S' = 0 \quad \text{for} \quad M < 0.75$$

$$S' = 2M - 3/2 \quad \text{for} \quad 0.75 < M < 1.25$$

$$S' = 1 \quad \text{for} \quad 1.25 < M$$

The solution of Eq. [9], [10], and [11] for various finite values of N are shown in Fig. 10 where the predicted selectivity is compared with the experimental results. At constant M, Eq. [9], [10], and [11] predict a decrease in selectivity with increasing N. This is shown in Fig. 11 where the model prediction is compared with the observed selectivity at constant $M = 0.75$.

The excellent agreement between experimental results and model prediction shows that the cell performance can be adequately described in terms of the two dimensionless groups M and N. The group M has a much more pronounced effect on selectivity than N. Due to the large thickness of the solid electrolyte employed in the present fuel cell design, maintaining values of M above 0.75 was difficult and required low values of G_{NH_3} since G_{O_2} was limited to a low value because of the high electrolyte resistance. Power production from this cell was also greatly limited due to the high electrolyte resistance.

Thinner electrolyte walls must be employed to maintain high selectivity at higher NH_3 molar flow rates. This would also increase the power output proportionally to the reduction in the electrolyte wall

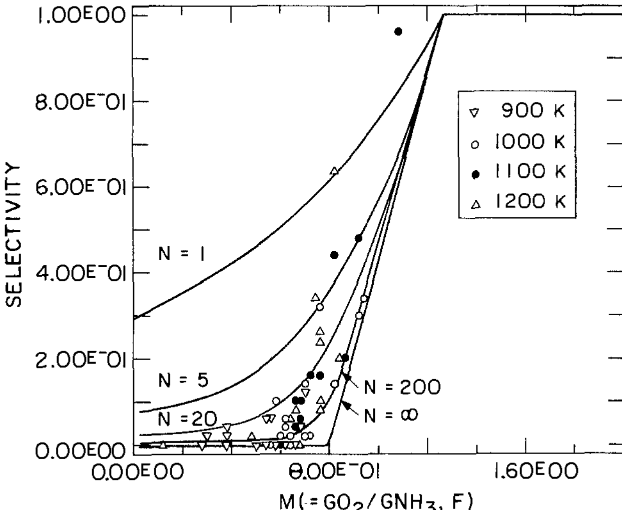

Fig. 10. Selectivity *vs.* *M* solid lines correspond to kinetic model prediction.

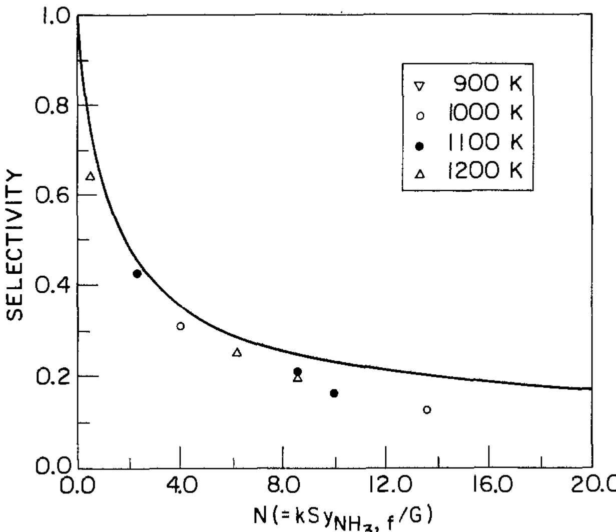

Fig. 11. Selectivity *vs.* *N* at constant $M = 0.75$ line corresponds to model prediction.

thickness. Work is currently being conducted in this direction.

Conclusions

Nitric oxide is the primary electro-oxidation product of the ammonia high temperature stabilized zirconia platinum electrode fuel cell. However the yield of NO can be severely decreased due to the undesirable catalytic side reaction between NH_3 and NO on the Pt anode. The product selectivity is completely determined by the values of two dimensionless groups that can be used as a guide for design and operation of this fuel cell. Improving the existing technology of thin stabilized zirconia film deposition on mechanically strong cathodes has a high probability of making the high temperature NH_3 fuel cell a commercially attractive means for nitric acid and electric energy cogeneration.

The Reaction of Electrogenerated Superoxide Ion with Nitroaromatic Amines

C. L. Hussey,* T. M. Laher, and J. M. Achord

Department of Chemistry, University of Mississippi, University, Mississippi 38677

ABSTRACT

The reaction of electrogenerated superoxide ion with 2-, 3-, and 4-nitroaniline and N,N-dimethyl-4-nitroaniline was studied as a function of temperature in N,N-dimethylformamide containing tetra-n-butylammonium perchlorate as the supporting electrolyte. Techniques used for the investigation were cyclic voltammetry, chronoamperometry, and absorption spectroscopy. The results obtained indicate that superoxide ion behaves as a strong base, effecting proton transfer from the amino group of 2- and 4-nitroaniline. No reaction of superoxide ion was observed with 3-nitroaniline or N,N-dimethyl-4-nitroaniline on the time scale of voltammetry. Pseudo-first-order rate constants for the chemical step in the ECE mechanism involving deprotonation of 2- and 4-nitroaniline by superoxide ion were estimated from chronoamperometric data to be 0.14 and 0.13 sec^{-1}, respectively, at 25.0°C and 0.46 and 0.30 sec^{-1}, respectively, at 40.0°C.

Electrochemical studies (1-7) have established that molecular oxygen undergoes a one-electron quasireversible reduction in aprotic solvents to the stable superoxide ion, $O_2^{\cdot-}$. Electrogeneration of this species by reduction of molecular oxygen in aprotic solvents provides a convenient method for producing it in high concentrations without accompanying reactive species. In addition, various electrochemical techniques can be used advantageously to study the kinetics of the reaction of $O_2^{\cdot-}$ generated in this fashion with substrates of interest.

The chemical reactivity of this unusual oxygen species, including its effective nucleophilicity, reducing power, and propensity to act as a strong base effecting proton transfer from organic substrates, recently was summarized (8). The latter property was postulated as the initial step in the "oxidation" of organic substrates by $O_2^{\cdot-}$ (8).

Reactions of $O_2^{\cdot-}$ with various organic substrates have been reviewed (9). Relatively few investigations have been concerned with reactions between $O_2^{\cdot-}$ and aromatic hydrocarbons substituted with basic nitrogen functional groups. Chern and San Filippo (10) used chemically introduced $O_2^{\cdot-}$ to oxidize hydrazines, hydrazones, and related compounds to azo compounds, N-nitrosoamines, and azines. In a recent study Crank and Makin (11) examined the reaction of $O_2^{\cdot-}$ with aromatic amines substituted with electron donating functional groups. These workers found that the 2- and 4- isomers of phenylenediamine and aminophenol were converted by $O_2^{\cdot-}$ to their diaminoazobenzenes and dihydroxyazobenzenes, respectively. The reaction process was postulated to involve hydrogen abstraction from the amino group of these compounds by $O_2^{\cdot-}$.

In order to obtain additional information about the reaction of $O_2^{\cdot-}$ with aromatic amines, particularly those substituted with electron withdrawing functional groups, reactions of electrogenerated $O_2^{\cdot-}$ with 2-, 3-, and 4-nitroaniline and N,N-dimethyl-4-nitroaniline were studied. The results of this investigation are reported in this paper.

Experimental

Chemicals.—2-Nitroaniline (Eastman), 3-nitroaniline (Eastman) 4-nitroaniline (Eastman), and N,N-dimethyl-4-nitroaniline (Pfaltz and Bauer) were recrystallized twice from 95% ethanol and dried in a vacuum for several days. Spectrophotometric grade N,N-dimethylformamide, DMF (Burdick and Jackson), with a specified water content of less than 0.004% was used without further treatment. *Tetra*-n-butylammonium perchlorate, TBAP, was prepared and purified using established procedures. Potassium superoxide, KO_2 (Pfaltz and Bauer), potassium hydroxide, KOH (Fisher, certified A.C.S.), and 18-crown-6 ether (Aldrich) were used as received. Dry grade oxygen gas (Linde) was passed through a laboratory gas drying unit (Ace Glass) containing Drierite before it was introduced into DMF-TBAP solutions. Solvent, supporting electrolyte, and solutions for study were stored in a dry box in a dry nitrogen atmosphere prior to use.

Instrumentation.—Cyclic voltammetry, chronoamperometry, and controlled potential electrolysis were performed using an AMEL Model 551-MWR ultrafast potentiostat equipped with a positive feedback *IR* compensation circuit. The potentiostat was programmed by means of an AMEL Model 566 function generator during cyclic voltammetric and chronoamperometric experiments. Cyclic voltammograms and potentiostatic current-time transients were recorded using a Houston Model 100 X-Y recorder or photographed from the display of a Tektronix Model 7844 dual beam oscilloscope. Resistance compensation was employed during all electrochemical experiments according to the procedure described by Whitson *et al.* (12).

Ultraviolet-visible absorption spectra were recorded on a CARY-17 UV-VIS spectrophotometer (Varian Associates). Gas chromatographic analysis was performed using a Beckman GC-45 gas chromatograph equipped with 6 ft × 1/4 in. columns packed with 12% OV-101 on Gas Chrom-Q, operated over a temperature range of 150°-250°C, using helium carrier gas.

Electrodes and cells.—A glassy carbon working electrode was constructed by forcing a small length of 0.5 cm Tokai GC-30 grade glassy carbon rod (Continental Ore) into an undersized, heated Teflon sleeve. A male 14/20 standard taper joint was machined into the opposite end of the Teflon sleeve. Electrical contact with the glassy carbon was accomplished by inserting a small spring into the sleeve and forcing an oversized brass rod into the sleeve until contact was established. The end of the Teflon rod containing the glassy carbon was cut flush and polished to a final mirror finish with 0.1 μm metallographic polishing alumina. The geometrical area of the electrode was 0.22 cm^2.

The counterelectrode was a platinum wire spiral held in a 14/20 standard taper Ace Glass mini-electrode

* Electrochemical Society Active Member.

Key words: free radicals, organic, kinetics.

adapter. Potentials were measured against a saturated calomel electrode, SCE, isolated from the bulk solution by means of a Vycor-tipped bridge tube equipped with a 14/20 standard taper joint.

Cyclic voltammetric and chromoamperometric experiments were conducted in a sealed Metrohm titration vessel. In addition to the working electrode, counterelectrode, and reference electrode bridge tube, gas dispersion and outlet tubes were provided. The cell and reference electrode bridge tube were filled inside the dry box, removed, and thermostated in a constant temperature bath to within ±0.2°C of the desired temperature before electrochemical measurements were made.

Results and Discussion

Voltammetry.—A representative cyclic voltammogram, illustrating the reduction of oxygen to $O_2^{\cdot-}$ at a glassy carbon electrode in DMF containing 0.1M TBAP, saturated with oxygen gas at 25.0°C, is shown in Fig. 1. Oxygen reduction at glassy carbon exhibits a degree of reversibility comparable to that of oxygen reduction at mercury or mercury-coated platinum. Use of glassy carbon to study oxygen reduction in aprotic solvents, for the most part, appears to have been ignored.

Cyclic voltammograms corresponding to the reduction of oxygen in DMF containing 2-, 3-, and 4- nitroaniline and N,N-dimethyl-4-nitroaniline are shown in Fig. 1, 2, 3, and 4, respectively. As can be seen in these figures, cyclic voltammograms representing the $O_2/O_2^{\cdot-}$ couple appear notably different in the presence of 2- and 4-nitroaniline (Fig. 1 and 3), but virtually unchanged in the presence of 3-nitroaniline and N,N-dimethyl-4-nitroaniline (Fig. 2 and 4). At slow scan rates the peak potential for O_2 reduction is shifted positively in DMF-TBAP containing 2- or 4-nitroaniline (Fig. 1 and 3). The cathodic current due to O_2 reduction is significantly increased compared to the current observed for the O_2 reduction process in DMF-TBAP which does not contain these nitroanilines. The positive shift of the O_2 reduction half-peak potential in the presence of 2- or 4-nitroaniline averaged about 29 ±2 mV at a scan rate of 0.020 V/sec at 25.0°C. The potential shift decreased in value as the scan rate was increased. Although relatively small in magnitude, this potential shift was always observed at slow scan rates when 2- or 4-nitroaniline was present, but was not observed in the presence of 3-nitroaniline or N,N-dimethyl-4-nitroaniline. In Fig. 1 and 3 the current corresponding to $O_2^{\cdot-}$ oxidation is greatly diminished and a small peak representing the oxidation of a product formed during the initial O_2 reduction process can be seen at potentials positive of the peak representing $O_2^{\cdot-}$ oxidation. The product peaks did not exhibit corresponding reduction peaks as ascertained from repetitive cyclic voltammetric scans. When the scan rate was increased above *ca.* 5-10 $Vsec^{-1}$, voltammograms for the O_2 reduction process in the presence of 2- or 4-nitroaniline were identical to those observed for O_2 reduction with no nitroaniline present and no product peaks were observed.

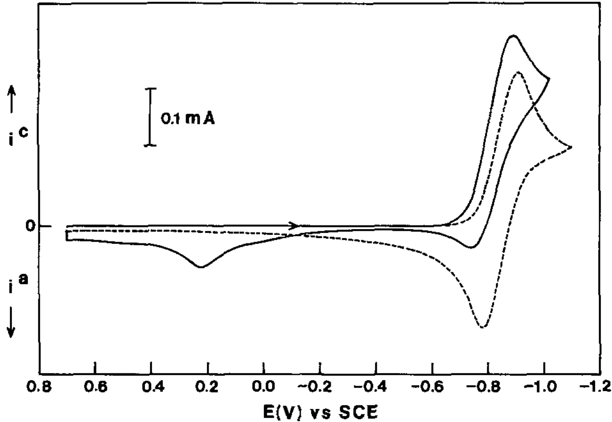

Fig. 1. Cyclic voltammograms at a glassy carbon electrode in DMF + 0.1M TBAP at 25.0°C; (dashed line) saturated with O_2 at 1 atm, (solid line) saturated with O_2 at 1 atm and 0.05M in 2-nitroaniline. Sweep rates were 0.02 $Vsec^{-1}$.

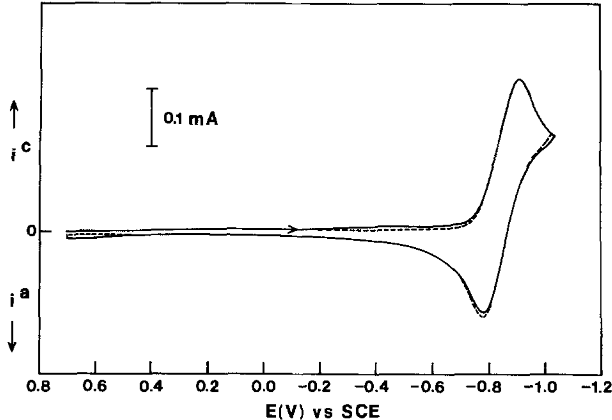

Fig. 2. Cyclic voltammograms at a glassy carbon electrode in DMF +0.1M TBAP at 25.0°C; (dashed line) saturated with O_2 at 1 atm, (solid line) saturated with O_2 at 1 atm and 0.05M in 3-nitroaniline. Sweep rates were 0.02 $Vsec^{-1}$.

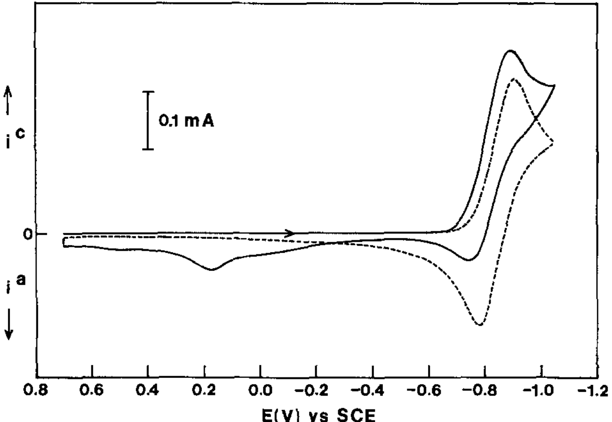

Fig. 3. Cyclic voltammograms at a glassy carbon electrode in DMF + 0.1M TBAP at 25.0°C; (dashed line) saturated with O_2 at 1 atm, (solid line) saturated with O_2 at 1 atm and 0.05M in 4-nitroaniline. Sweep rates were 0.02 $Vsec^{-1}$.

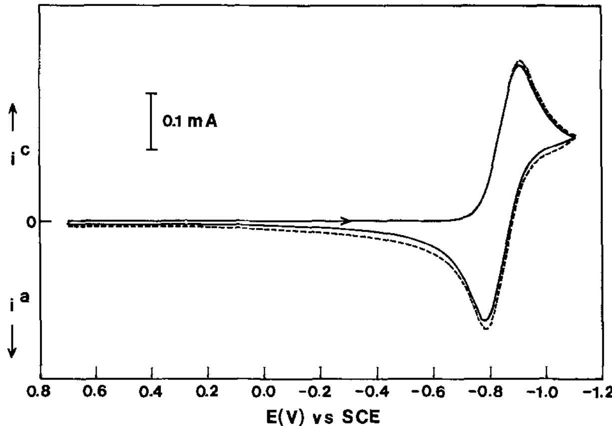

Fig. 4. Cyclic voltammograms at a glassy carbon electrode in DMF + 0.1M TBAP at 25.0°C; (dashed line) saturated with O_2 at 1 atm, (solid line) saturated with O_2 at 1 atm and 0.1M in N,N-dimethyl-4-nitroaniline. Sweep rates were 0.02 $Vsec^{-1}$.

The effect of changing the scan rate on the value of n_{app} for O_2 reduction, where n_{app} is calculated from the ratio of the voltammetric peak current for O_2 reduction with added nitroaniline to the respective voltammetric peak current without added nitroaniline at the same scan rate, for solutions containing 2- or 4-nitroaniline is shown in Fig. 5. At slow scan rates n_{app} increases toward a value of 2.0 for O_2 saturated DMF-TBAP solutions containing 2- and 4-nitroaniline. This is especially evident for data obtained at 40.0°C where the rate of reaction between $O_2^{\cdot-}$ and added nitroaniline is enhanced and indicates that the O_2 reduction process in the presence of 2- or 4-nitroaniline may involve two electrons.

The cyclic voltammetric behavior observed for the O_2 reduction process in the presence of 2- or 4-nitroaniline suggests that the process may proceed via an ECE mechanism (13). In this particular type of ECE process the charge transfer arising from the product of the coupled chemical step involves one electron and occurs at a potential positive of the original charge transfer step (13).

Addition of KO_2 and 18-crown-6 ether.—The failure of N,N-dimethyl-4-nitroaniline to react with $O_2^{\cdot-}$, unlike 4-nitroaniline, suggests that the hydrogens attached to the amine nitrogen of 2- or 4-nitroaniline may be important in the reaction of $O_2^{\cdot-}$ with these compounds. To deduce the nature of the products formed as a result of the reaction of $O_2^{\cdot-}$ with 2- or 4-nitroaniline, large quantities of $O_2^{\cdot-}$ were introduced into DMF solutions *ca.* 0.1M in these nitroanilines. Superoxide ion was most conveniently added using KO_2 and 18-crown-6 ether. Solutions containing 2-nitroaniline, initially yellow, turned red when $O_2^{\cdot-}$ was added. Greenish-yellow solutions of 4-nitroaniline became orange when treated with $O_2^{\cdot-}$. Colors identical to these also could be observed to form in the electrode diffusion layer in DMF-TBAP solutions saturated with O_2 containing 2- or 4-nitroaniline upon application of a potential step of sufficient magnitude to form $O_2^{\cdot-}$. Examination of both solutions using thin layer and gas-liquid chromatography revealed no detectable product species, only the starting material. However, the quantity of starting material was greatly diminished in $O_2^{\cdot-}$ treated solutions. It could be restored simply by the addition of a small amount of proton donor (water or acetic acid).

Absorption spectra were recorded for dilute solutions of 2- and 4-nitroaniline in DMF both before and after the addition of KO_2 and 18-crown-6 ether. Figures 6 and 7 show the spectra that were obtained. The absorption peaks which appear at 516 nm (Fig. 6) and

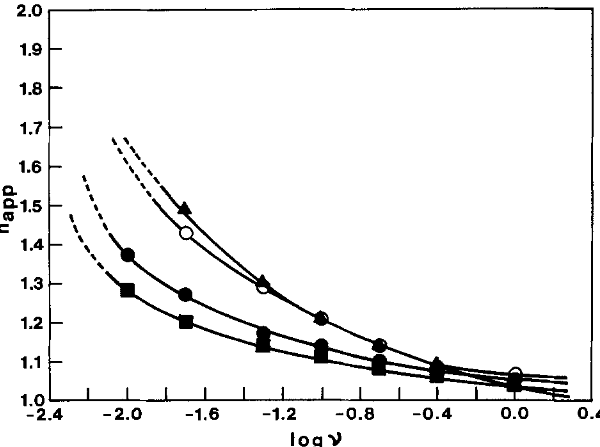

Fig. 5. Variation of n_{app} as a function of sweep rate for the voltammetric reduction of O_2 at a glassy electrode in DMF + 0.1M TBAP, saturated with oxygen at 1 atm; 0.05M in 2-nitroaniline, 25.0°C ●; 0.1M in 2-nitroaniline, 40.0°C ○; 0.05M in 4-nitroaniline, 25°C ■; and 0.1M in 4-nitroaniline, 40.0°C ▲.

Fig. 6. The initial concentration of 2-nitroaniline in each solution was 1.0×10^{-4}M.

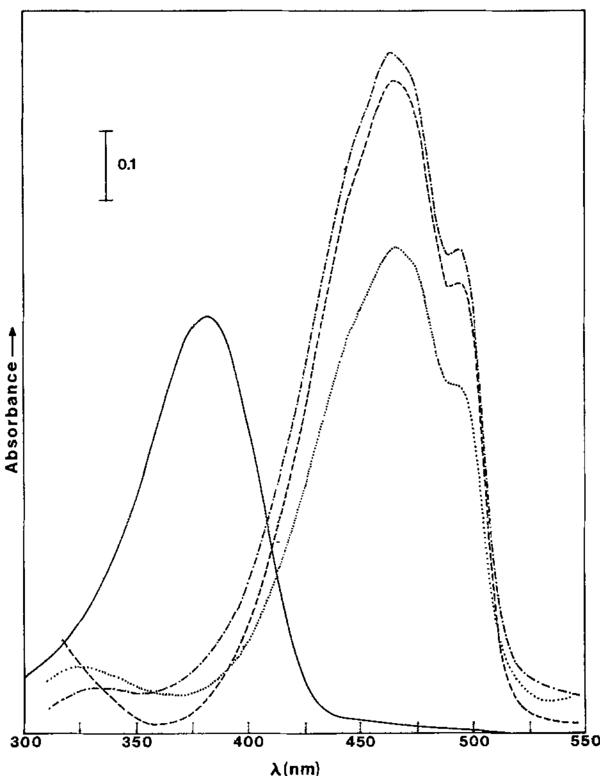

Fig. 7. Absorption spectra for 4-nitroaniline in DMF; (solid line) no base, (dashed line) addition of excess KO_2 + 18-crown-6 ether, (dotted line) addition of excess CH_3ONa, and (dashed-dotted line) addition of excess KOH + 18-crown-6 ether. The initial concentration of 4-nitroaniline in each solution was 2.8×10^{-5}M.

464 nm (Fig. 7) after the addition of $O_2^{\cdot-}$ are in excellent agreement with literature values (14) of λ_{max} for the anions of 2- and 4-nitroaniline, respectively, as shown in Table I. Unfortunately, published spectra for the 2- and 4-nitroanilide ions do not appear to be available. Values of ϵ_{max} were calculated from the spectra shown in Fig. 6 and 7 for both the neutral and ionized nitroanilines. It was assumed that the addition of excess $O_2^{\cdot-}$ to dilute solutions of 2- or 4-nitroaniline

Table I. Summary of spectroscopic data

Compound	Neutral molecule λ_{max} (nm)	ϵ_{max} (M^{-1} cm^{-1})	Anion λ_{max} (nm)	ϵ_{max} (M^{-1} cm^{-1})	Base added	Ref.
2-Nitroaniline	413	5400	516	8700	$O_2^{\cdot -}$	This work
	410	4500	515	8400	OH^-	(14)
4-Nitroaniline	382	19,000	464	32,800	$O_2^{\cdot -}$	This work
	378	16,900	467	32,300	OH^-	(14)

resulted in complete ionization of the nitroaniline. The values of ϵ_{max} calculated, summarized in Table I, also are in good agreement with values of ϵ_{max} reported in the literature (14) for the neutral and ionized nitroanilines.

Additional support for the $O_2^{\cdot -}$ induced generation of the anions of 2- and 4-nitroaniline was obtained from experiments in which CH_3ONa or alternately KOH + 18-crown-6 ether were added to dilute solutions of 2- or 4-nitroaniline. Both CH_3O^- and OH^- have been used extensively to generate the anions of weakly acidic organic compounds (14-16) in aprotic solvents. Absorption spectra for these solutions (Fig. 6 and 7) are identical to those obtained after the addition of $O_2^{\cdot -}$. Thus, the products of the reaction of the three bases, $O_2^{\cdot -}$, CH_3O^-, and OH^- with 2- or 4-nitroaniline appear to be equivalent for each aniline.

Mechanism of the reaction of $O_2^{\cdot -}$ with 2- and 4-nitroaniline.—The results obtained from experiments employing the addition of $O_2^{\cdot -}$ and other bases to solutions of 2- or 4-nitroaniline in DMF suggest that 2- and 4-nitroaniline undergo proton transfer to $O_2^{\cdot -}$ in DMF to form their respective stable nitroanilide ions. An overall reaction sequence for the reaction of $O_2^{\cdot -}$ with these nitroanilines can be written on the basis of the reaction of $O_2^{\cdot -}$ with other proton donors (8) and is represented by Eq. [1]

$$2O_2^{\cdot -} + RNH_2 \rightleftharpoons O_2 + HO_2^- + RNH^- \quad [1]$$

The overall process for oxygen reduction in the presence of these nitroanilines can be obtained by combining the O_2 reduction half-reaction with Eq. [1] to give

$$O_2 + RNH_2 + 2e^- \rightleftharpoons HO_2^- + RNH^- \quad [2]$$

The ECE process observed for O_2 reduction in the presence of 2- or 4-nitroaniline must therefore correspond to a stepwise series of reactions whose overall sequence involves two electrons and is represented by Eq. [2]. A series of reactions that would produce an ECE response and yet meet other criteria imposed by Eq. [2] are represented by Eq. [3]-[5]. An ECE process, similar to that represented by Eq. [3]-[5], has been postulated to account for the electrochemical behavior observed during the reduction of oxygen in nonaqueous solvents in the presence of organic and inorganic acids (4, 7, 17).

$$O_2 + e^- \rightleftharpoons O_2^{\cdot -} \quad E_1^\circ \quad [3]$$

$$O_2^{\cdot -} + RNH_2 \xrightarrow{k} HO_2^\cdot + RNH^- \quad C \quad [4]$$

$$HO_2^\cdot + e \rightarrow HO_2^- \quad E_2^\circ \quad [5]$$

An additional equilibrium involving homogeneous electron transfer also must be considered for an ECE mechanism of this type (18) since E_2° is positive of E_1°

$$O_2^{\cdot -} + HO_2^\cdot \overset{K}{\rightleftharpoons} O_2 + HO_2^- \quad [6]$$

The homogeneous electron transfer reaction represented by Eq. [6] is rapid with a k_2 value of 9×10^7 M^{-1} sec^{-1} (8). Estimation of the rate constant, k, for the chemical step represented by Eq. [4] and the equilibrium constant K, for the process represented by Eq. [6] is reported below.

The product peaks observed at 0.23 and 0.19V in Fig. 1 and 3, respectively, most likely correspond to the oxidation of the respective nitroanilide ions. Oxidation peaks were observed at the same potentials in degassed DMF-TBAP containing 2- or 4-nitroaniline to which KO_2 was added. Oxidation of nitroanilide ion should occur more readily than oxidation of the parent nitroaniline. Oxidation of peroxide ion, HO_2^-, was not considered in the reaction represented by Eq. [5] since no voltammetric peak attributable to HO_2^- oxidation was observed. This finding is in good agreement with a previous study (19) in which oxidation of HO_2^- was not observed in 1M NaOH at gold, glassy carbon, or pyrolytic graphite electrodes. It also was found to rapidly decompose in aprotic solvents (19).

Proton transfer rate measurements.—In order to estimate rate constants for the chemical step represented by Eq. [4] and equilibrium constants for the process described by Eq. [6], chronoamperometric measurements were employed. The resulting data were analyzed according to the procedure described by Hawley and Feldberg (18). Chronoamperometric experiments were run under pseudo-first-order conditions, *i.e.*, with a large excess of nitroaniline present. The amount of nitroaniline necessary to impose pseudo-first-order conditions was determined by observing the increase in voltammetric peak current for O_2 reduction at a fixed scan rate of 0.010 $Vsec^{-1}$ with increasing concentrations of nitroaniline. Concentrations of nitroaniline greater than 0.05M produced no measurable increase in the peak height at 25.0°C while concentrations greater than 0.10M produced similar results at 40.0°C. No change in potentiostatic current-time transients could be detected either, as the nitroaniline concentrations were increased above these values. The 2- and 4-nitroaniline were reduced to their respective radical anions at peak potentials of −1.30 and −1.45V. It was possible, however, to observe the foot of these reduction waves at potentials slightly negative of −1.05 and −1.10V, respectively, especially when the nitroanilines were present in high concentrations. To avoid any possibility of the simultaneous reduction of the nitroaniline to its radical anion during these rate measurements, potential steps of 1.00 to −1.05V were employed for 2-nitroaniline and 1.00 to −1.10V for 4-nitroaniline. Studies of O_2 reduction without added nitroaniline using potential steps of 1.00 to −1.05V showed the O_2 reduction process to be diffusion controlled at elapsed times greater than 0.1 sec, whereas significant effects due to convection were noticeable at times exceeding 8 sec. For this reason, chronoamperometric experiments were restricted to a time window of 0.1-8 sec.

Plots of n_{app} *vs.* log t for the reduction of O_2 in solutions containing 2- and 4-nitroaniline are shown in Fig. 8 and 9, respectively. Chronoamperometric values of n_{app} were calculated according to Hawley and Feldberg (18). These plots were matched to n_{app} *vs.* log kt working curves calculated using various values of K and the best fit was determined on the basis of similarity of shape. The best fit was generally obtained for curves generated with values of K less than 0.1. This is most vividly demonstrated for data acquired at 40.0°C (Fig. 8 and 9). Unfortunately, the method used to estimate K in the present investigation is too imprecise to allow determination of a more exact value for K or to study the effect of temperature on K. However, the available evidence tends to support a value of K for Eq. [6] which is close to 0 for the present systems. Values of log kt corresponding to experimental values of log t from Fig. 8 and 9 were obtained and used to calculate the pseudo-first-order rate constant, k, for the proton transfer reaction represented by Eq. [4]. Values of k estimated in this fashion are given in Table II. Using the estimates of k given in Table II, plots of n_{app} *vs.* log t were generated for values of

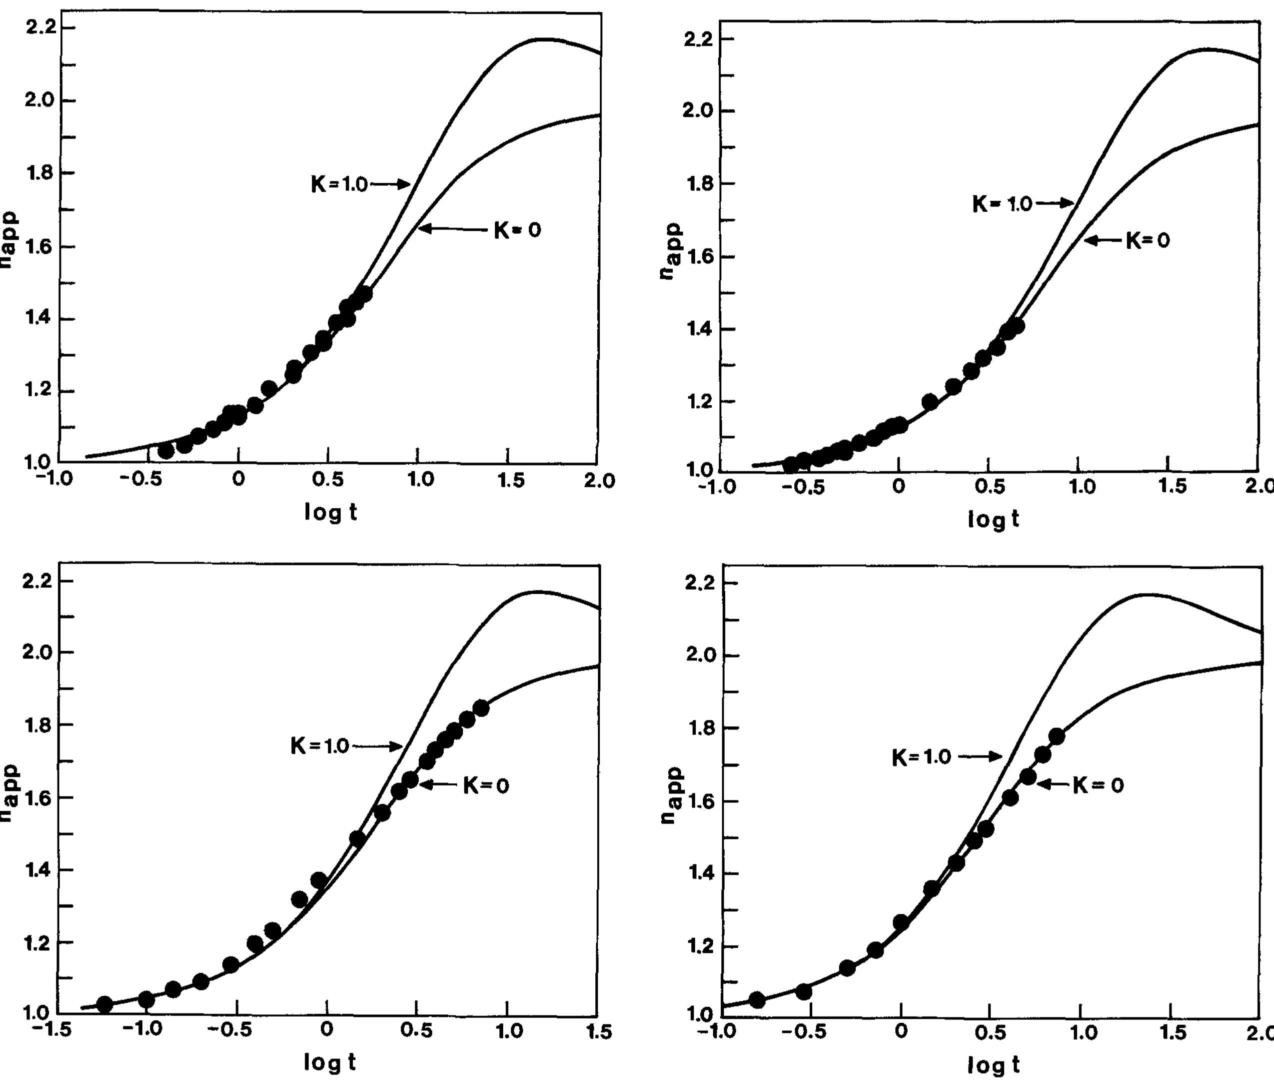

Fig. 8. Dependence of n_{app} on log t for O_2 reduction at a glassy carbon electrode in DMF + 0.1M TBAP, saturated with O_2 at 1 atm for a potential step of 1.00 to −1.05V vs. SCE. Upper figure: 0.05M in 2-nitroaniline, 25.0°C. Lower figure: 0.1M in 2-nitroaniline, 40.0°C.

Fig. 9. Dependence of n_{app} on log t for O_2 reduction at a glassy carbon electrode in DMF + 0.1M TBAP, saturated with O_2 at 1 atm for a potential step of 1.00 to −1.10V vs. SCE. Upper figure: 0.05M in 4-nitroaniline, 25.0°C. Lower figure: 0.1M in 4-nitroaniline, 40.0°C.

$K = 1.0$ and are shown in Fig. 8 and 9 for comparative purposes.

Examination of the data given in Table II reveals that the rate of deprotonation of the respective nitroaniline correlates well with the pK_a of the compound in the two cases studied. The failure of 3-nitroaniline to react with O_2^- is not surprising since it should be much more basic than the 2- and 4-isomers. The results of the present investigation also are in good agreement with the calculations of Sawyer *et al.* (8), who predict that superoxide ion solutions can promote proton transfer from substrates with pK_a values as large as 23.

The Electrochemical Oxidation of Substituted Catechols

Michael D. Ryan,* Alice Yueh, and Wen-Yu Chen

Department of Chemistry, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The oxidation of substituted catechols was studied by cyclic voltammetry, chronoamperometry, rotating ring-disk electrode, and coulometry. The results showed that the quinones that were formed from the oxidation of substituted catechols reacted with the basic forms of the starting material to yield the dimeric product. These products were generally unstable and rapidly polymerized or underwent some other irreversible reaction to form an electroinactive product. For 3,4-dihydroxyacetophenone and propriophenone, the intermediate was stable long enough to be observed in cyclic voltammetry. The rate of the coupling reaction was found to correlate well with the Hammett ρ-σ parameters and indicated that there was substantial negative charge in the transition state. Finally, an analysis of the coulometric n-values along with the $i_a t^{1/2}/C$ values indicated that the initial coupling product was a diphenyl ether. Analysis of the coulometry products showed extensive polymerization.

Many workers have shown that o- and p-diphenols can be oxidized electrochemically to o- and p-quinones, respectively. The quinone that is formed is quite reactive and can be attacked by a variety of nucleophiles. Adams and co-workers (1-3) have shown that 4-methyl-o-benzoquinone can react with nucleophiles such as ammonia, chloride, and sulfhydryl compounds to form the addition products. In addition, Adams (4, 5) has shown that p-benzoquinones with electron-withdrawing substituents can be nucleophilically attacked by water to yield a trihydroxy compound, which can be further oxidized to the hydroxyquinone. Several other workers (6-9) have investigated the reactions of o-quinones from Dopa, catechol, and 4-methyl catechol in aqueous solutions, but the emphasis has been mostly on acidic solutions and at low concentrations, which significantly suppress the coupling reaction. Outside of the work by Stum and Suslov (10), there has been little electrochemical work done on the coupling reactions of quinones.

By contrast, there have been extensive chemical studies on the oxidative coupling reactions of phenols, and this area has been reviewed in a book by Musso (11). The ultimate products of catechol oxidations is a melanin-type product (12-14), but it is very difficult to characterize the material or to understand its coupling mechanism. There are several possible reactions which the o-quinone can undergo. The first possibility is the reaction of the o-quinone with water (reaction [1])

o-quinone + H_2O ⟶ 1,2,4-trihydroxybenzene [1]

Because a p-quinone is formed when 1,2,4-trihydroxybenzene is oxidized, trihydroxybenzene is easier to oxidize than catechol. Thus, reaction [2] will occur when the trihydroxybenzene is formed

1,2,4-trihydroxybenzene ⟶ hydroxy-p-quinone + 2 e$^-$ + 2H$^+$ [2]

This species may then undergo a polymerization reaction (15). Alternatively, the o-quinone can react with the starting material, as shown in reaction [3]

o-quinone + catechol ⟶ diphenyl ether (OH, OH, OH) [3a]

⟶ HO, HO-biphenyl-OH, OH [3b]

* Electrochemical Society Active Member.

Key words: cyclic voltammetry, chronoamperometry, rotating ring-disk electrode, coulometry.

Both of these products can be further oxidized to form o-quinones. In the above reaction, the reactive phenol may also be one of the anionic forms of catechol, which is formed by the acid dissociation reaction. Finally, the coupling reaction may occur by way of a semiquinone intermediate.

Electrochemical methods are uniquely suitable to provide information on the kinetics of the coupling reaction. The rate of disappearance of the o-quinone can be monitored by the use of double-step chronoamperometry or the rotating ring-disk method. The identity of new electroactive species can be monitored by cyclic voltammetry. By this approach, it is possible to understand the initial steps that are involved in the coupling reaction.

Experimental

Equipment.—Most of the electrochemical experiments were performed on a homemade three-electrode potentiostat of conventional design. Some of the cyclic voltammetric experiments were done on a Princeton Applied Research Corporation (PAR) Model 174A polarographic analyzer. The reference electrode was a saturated calomel electrode (SCE) and the working electrode was a carbon paste electrode. A platinum wire was used as an auxiliary electrode. The chronoamperometric and cyclic voltammetric data were recorded on a Hewlett-Packard 7045A X-Y recorder or a Tektronix Model D15 storage oscilloscope. The u.v.-visible spectra were recorded on a Cary 14 spectrometer. The coulometry was performed on a PAR Model 173 potentiostat with a Model 179 integrator. The ring-disk electrode rotator was a Pine Instrument Company Model ASR, the ring and disk were platinum, and a homemade bipotentiostat was used as described in Ref. (16).

Catechol (CAT), 3,4-dihydroxacetophenone (DHAP), 3-methyl catechol (3MC), 4-methyl catechol (4MC), 3,4-dihydroxybenzoic acid (DHBA), and 3,4-dihydroxyphenylacetic acid (DHPA) were purchased from Aldrich Chemical Company. 3,4-Dihydroxypropriophenone (DHPP) was obtained from ICN Pharmaceutical Incorporated. 3,4-Dihydroxybenzoic acid, ethyl ester (DHBE) was obtained from Pfaltz and Bauer, Incorporated. Catechol and 3-methyl catechol were purified by sublimination. DHBE was recrystallized from hot water, and pale yellow crystals were obtained with a melting point of 198°-200°C. 3,3',4,4'-Tetramethoxy biphenyl (TMBP) was synthesized by the Ullmann reaction, as described in Ref. (17), and the TMBP was reacted with boron tribromide (18) to yield the 3,3',4,4'-tetrahydroxybiphenyl (THBP).

All solutions were prepared from deionized water. The *p*H 1 solutions were made with sulfuric acid. The solutions that were buffered around *p*H 5 were made from acetic acid/acetate mixtures, while phosphate buffers were used for solutions above *p*H 6.

Results

Cyclic voltammetry.—Only one oxidation peak was observed for all the catechols studied except for THBP, DHAP, and DHPP. With the same exceptions, only one reduction peak was seen, except in basic solutions where the quinone was unstable. In that case, the reduction peak disappeared. The quasi-reversibility of the electron transfer reaction makes it difficult to obtain quantitative kinetic data from the cyclic voltammograms but one can see qualitatively that the quinone becomes progressively less stable as the *p*H is raised. The effect of *p*H on the cyclic voltammetry of catechol is shown in Fig. 1. In addition. the second-order nature of the reaction process can be seen by the decrease in the peak current ratio, i_{pc}/i_{pa}, as the concentration is increased at a given *p*H and scan rate. A quantitative measurement of this effect is described later in this work.

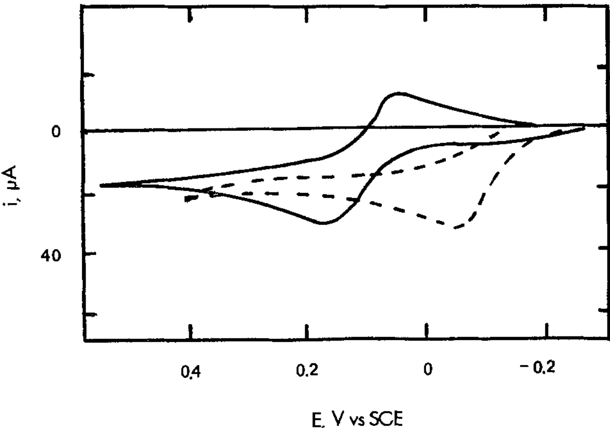

Fig. 1. Cyclic voltammetry of 0.3 mM catechol. Solid line *p*H 2. Dashed line *p*H 8. Scan rate 10 mV/sec.

The oxidation of DHAP and DHPP gives additional features that are instructive in understanding the reaction process. In solutions with a *p*H less than 5, the cyclic voltammetry of these two compounds is similar to the other catechols. But, for *p*H values between 5 and 7, a new redox couple is seen in the voltammograms, as shown in Fig. 2. For DHPP, the new oxidation wave is not seen until the second scan because its peak potential is less than the peak potential for catechol, while the new oxidation peak for DHAP is more positive than the catechol peak and hence is seen in the first scan. In Fig. 2, curve C, one can see that this new peak is reduced relative to the first peak as the scan rate is increased. At first glance, this behavior looks similar to the behavior seen for 2,5-dihydroxyacetophenone (4), where water adds to

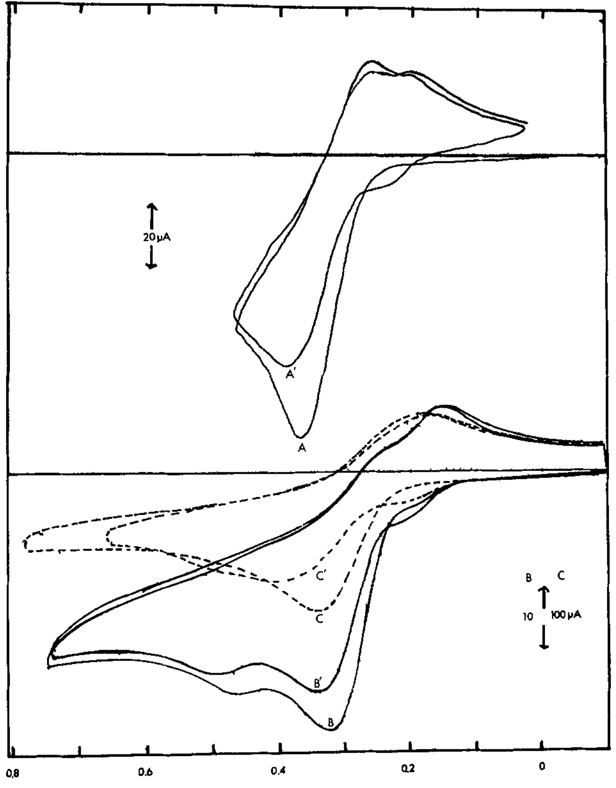

Fig. 2. A (first scan) and A' (second scan): cyclic voltammetry of 1.0 mM dihydroxypropiophenone, *p*H = 5.8; scan rate 30 mV/sec. B (first scan) and B' (second scan): cyclic voltammetry of 1.0 mM dihydroxyacetophenone (DHAP), *p*H = 6.0; scan rate 10 mV/sec. C (first scan) and C' (second scan): cyclic voltammetry of 1.0 mM DHAP; *p*H = 6.0; scan rate 100 mV/sec. Solid lines are the zero current for each voltammogram.

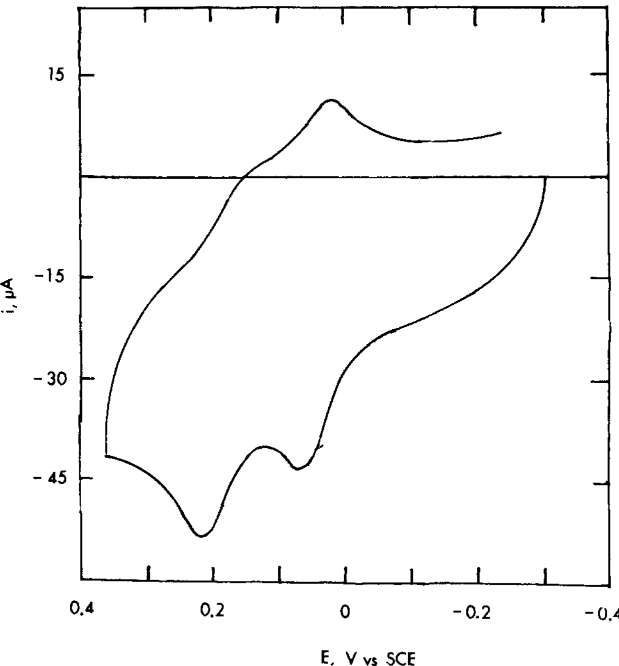

Fig. 3. Cyclic voltammetry of 0.1 mM 3,3′, 4,4′-tetrahydroxybiphenyl; pH 7.0; scan rate 100 mV/sec.

the quinone. But, on quantitative examination, the peak current function, $i_{pa}/v^{1/2}C$, does not increase but remains constant at the value for two electrons. This will be examined in more detail later by chronoamperometry. In more basic solutions, both reduction waves and the new oxidation wave disappear.

The oxidation of THBP is shown in Fig. 3. Two oxidation waves occur, and on the basis of previous work, the following scheme can be proposed

First Wave

I ⇌ II $+ 2e^- + 2H^+$ [4]

Second Wave

II ⇌ III $+ 2e^- + 2H^+$ [5]

The peak potential of the second wave is approximately at the same potential as the peak potential of catechol at the same pH. It should be noted that, except for catechol and 3-methyl catechol, none of the other biphenyls formed from their respective catechols can form structure II because of the repulsion of the 4-substituents on the rings. As a result, it is impossible for the biphenyl to form the planar configuration needed for the extended p-quinone structure.

Chronoamperometry.—In order to calculate the rate of reaction of the electrochemically generated quinone, double-potential step chronoamperometry (DPS) was used to eliminate the effect of the electron transfer rate. The chronoamperometric behavior of catechol was typical of all the substituted catechols where no new peaks were observed in the cyclic voltammograms. The current decay of the oxidation current for catechol obeyed the Cottrell equation for all the pH values studied ($1 < pH < 12$). The value of the current constant, $i_a t^{1/2}/C$, was equal to the value expected for a two-electron oxidation, even for times when there was substantial reaction of the quinone. The current ratio i_c/i_a, was dependent on the step time, τ, the concentration of catechol, and the pH. The first two

	20	148	221	0.037	0.127

effects can be seen in Table I for three different concentrations of catechol at pH 8. In all cases, the current ratios are divided by 0.2928 to normalize the values. This new parameter is called R_I. These data demonstrate the second-order nature of the reaction process. The current ratio data from Table I can be correlated with the theoretical working curve for the following coupling mechanism

$$A \rightleftharpoons B + 2e^- + 2H^+ \quad [6]$$

$$B + A \xrightarrow{k_d} D \quad [7a]$$

$$D \rightarrow D' + 2e^- + 2H^+ \quad [8]$$

$$D + B \rightleftharpoons A + D' \quad [9]$$

It is assumed that reaction [8] is irreversible because no new wave is seen for the D/D′ couple. Since reaction [8] is favorable, reaction [9] must also be occurring and may very well be the most probable means of forming D′. The current ratio data from Table I is shown in Fig. 4, along with the theoretical lines. It should be pointed out that an alternate coupling scheme could be

$$2B \xrightarrow{k'_d} D' \quad [7b]$$

The chronoamperometric working curve for R_I as a function of τ is somewhat different for this case, but the difference is not large. As will be seen later, though, the pH variation of the rate constant is more consistent with reaction [7a].

The variation of the coupling rate constant, k_{obs}, with pH is shown in Table II, along with the $i_a t^{1/2}/C$ values. This variation was consistent with the following coupling mechanism

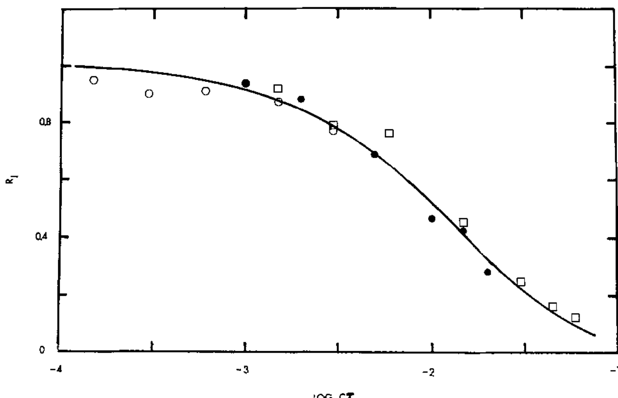

Fig. 4. Chronoamperometry of catechol at pH 8. Concentration of catechol: (○) 0.30 mM, (●) 1.00 mM, and (□) 3.00 mM. Line is theoretical line for a second-order coupling mechanism with a rate constant of 30 $M^{-1}sec^{-1}$.

Table II. Variation of the rate of the coupling reaction as a function of pH

pH	k_{obs} (M^{-1} sec^{-1})	α_1*	k_1 (M^{-1} sec^{-1})	α_2*	k_2 (M^{-1} sec^{-1})	k_{calc}† (M^{-1} sec^{-1})
8.0	30	0.059	507	1.18×10^{-5}	—	29
9.0	158	0.387	410	7.71×10^{-4}	—	188
10.0	456	0.848	537	1.69×10^{-2}	—	411
11.0	1398	0.823	802	0.164	4500	754
12.0	1610	0.333	(485)‡	0.666	2175	1605

* $pK_1 = 9.2$, $pK_2 = 11.70$, Ref. (20).
† Calculated value of k_{obs} from the best fit of the data.
‡ Calculated from the pH 8-11 data.

$$\text{o-quinone} + \text{catechol monoanion (OH, O}^-) \xrightarrow{k_1} D \quad [10]$$

$$\text{o-quinone} + \text{catechol dianion (}^-\text{O, O}^-) \xrightarrow{k_2} D \quad [11]$$

The value of k_{obs} is then

$$k_{obs} = \alpha_1 k_1 + \alpha_2 k_2 \quad [12]$$

where α_1 and α_2 are the fraction of the catechol in the first and second ionized forms, respectively, as defined in Eq. [13] and [14]

$$\alpha_1 = K_1[H^+]/([H^+]^2 + K_1[H^+] + K_1K_2) \quad [13]$$

$$\alpha_2 = K_1K_2/([H^+]^2 + K_1[H^+] + K_1K_2) \quad [14]$$

where K_1 and K_2 are the first and second acid dissociation constants, respectively. If k_2 is not much larger than k_1, then, when the pH $< pK_2$, $\alpha_2 k_2$ is negligible compared to $\alpha_1 k_1$, as a result, k_1 is then

$$k_1 \approx k_{obs}/\alpha_1$$

The calculated values of k_1 are shown in Table II, along with the k_2 values calculated from the best values of k_1 and Eq. [12]. In Table II, the best values for k_1 and k_2 are used with Eq. [12] to calculate the value of k_{obs} at each pH, and this will be called k_{calc}. The values of k_{obs} as a function of pH are shown in Fig. 5 along with the theoretical line based on the known α values and the measured rate constants.

This same procedure can be used to calculate the values of k_1 and k_2 for other catechols, except for DHPP and DHAP. The values of k_{obs} are small enough so that k_1 and k_2 can be calculated for 3MC, 4MC, and DHPA. The coupling reaction is too fast to measure the values of k_{obs} in very basic solutions which are necessary to calculate k_2 for DHBA, DHAP, DHPP, and DHBE. The variation of k_{obs} as a function of pH for these compounds are shown in Fig. 5 and 6. The values of k_1 and k_2 are given in Table III for all the catechols studied, along with the literature values for pK_1 and pK_2.

Table III. Values of k_1 and k_2 for substituted catechols

Compound	k_1 (M^{-1} sec^{-1})	k_2 (M^{-1} sec^{-1})	pK_1	pK_2

The measurement of k_{obs} for DHAP and DHPP must take into account the electroactivity of the reaction product. The working curve for an electroactive D/D′ couple was derived by the use of the finite-difference approach (19). The following reaction mechanism was numerically solved

$$A \rightleftharpoons B + 2e^- + 2H^+ \quad [6]$$

$$B + A \xrightarrow{k_d} D \quad [7a]$$

$$D \rightleftharpoons D' + 2e^- + 2H^+ \quad [15]$$

$$D + B \rightleftharpoons A + D' \quad [9]$$

$$D' + A \xrightarrow{k_t} T \quad [16]$$

$$T \rightarrow T' + 2e^- + 2H^+ \quad [17]$$

where T and T′ are the reduced and oxidized forms of the trimer, respectively, and k_t is the rate of the trimer reaction. Qualitatively we can see from cyclic voltammetry that the stability of the dimer peak depends on the concentration of the catechol. The working curve for this mechanism for different ratios of k_d/k_t is shown in Fig. 7.

The analysis of the DHPP data is illustrated in Fig. 8 for the chronoamperometric data at pH 6.8 for three different concentrations. For $R_I > 0.5$, the value of k_{obs} depends mostly on the dimerization rate while the value of k_t can be calculated most accurately for R_I values less 0.5. From this information, it was found that k_d was $1.0 \times 10^3\ M^{-1}\ sec^{-1}$ and k_t was $1.0 \times 10^2\ M^{-1}\ sec^{-1}$. One must remember that both k_d and k_t depend on pH and are observed rates that depend on α_1 and α_2. Data for different pH values are shown in Fig. 9, and the variation of k_d with pH is shown in Fig. 6. From this, k_1 was found to be $6.6 \times 10^4\ M^{-1}\ sec^{-1}$ and $k_{1,t}$ or k_1 for the trimer reaction was $1.3 \times 10^4\ M^{-1}\ sec^{-1}$. Similar data were obtained for

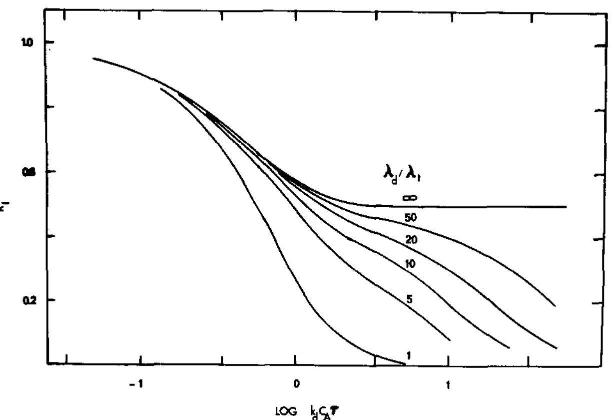

Fig. 7. Theoretical working curve for a dimer-trimer coupling reaction. $\lambda = k_dC\tau$, where k_d is the rate of dimerization reaction. $\lambda_t = k_tC\tau$, where k_t is the rate of the trimerization reaction.

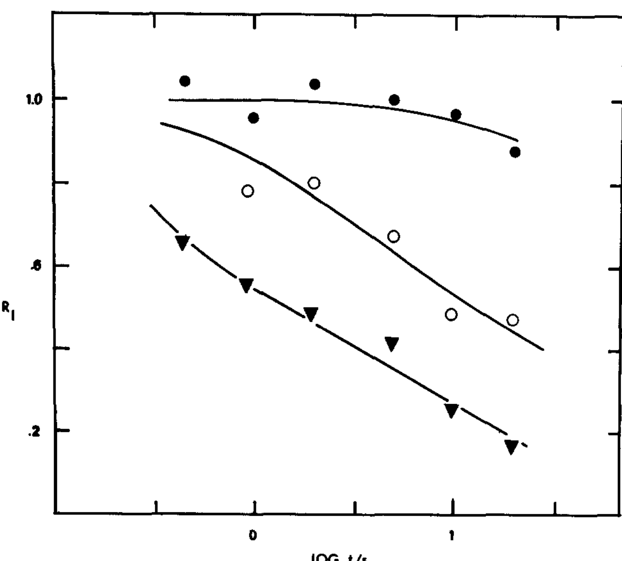

Fig. 9. Double potential step chronoamperometry of 1.0 mM dihydroxyproprophenone. (●) pH = 5.8, (○) pH = 6.2, (▼) pH = 6.8.

DHAP. The potential for the anodic step was always chosen positive of the second peak. It is interesting to note that the value of $i_at^{1/2}/C$ remained at the value indicative of two electrons even when there was substantial reaction for the quinone.

Rotating ring-disk experiments (RRDE).—4MC was studied by RRDE in order to verify that surface filming or other such effects were not occurring. The appearance of steady-state currents (especially for the ring) and the obtaining of kinetic data consistent with the chronoamperometry were a further verification that the homogeneous reactions were being monitored.

Only one oxidation wave was observed on the disk as the disk potential was scanned (Fig. 10). If the ring potential was held at a potential where the quinone is reduced, a reduction wave was seen as the disk potential was scanned through the oxidation wave (Fig. 10). In addition, if the disk potential was held in the limit-

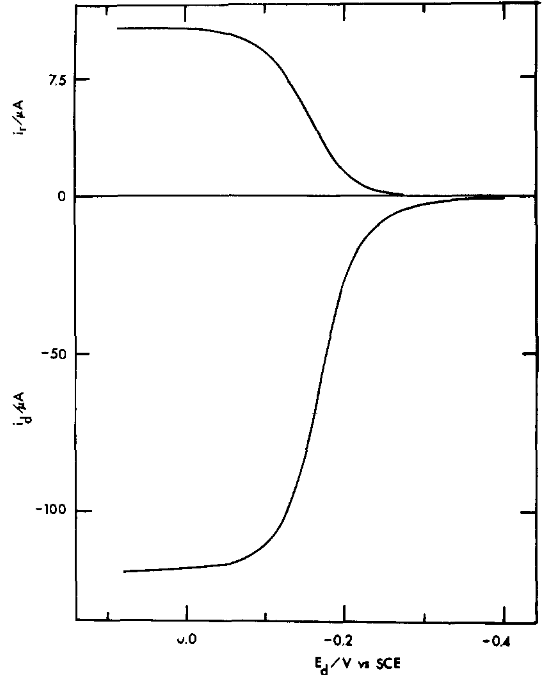

Fig. 10. Rotating ring-disk voltammogram of 0.93 mM 4-methyl catechol. i_r = ring current. i_d = disk current. pH = 12. ω = 10.5 sec^{-1}.

ing current region and the ring potential was scanned, only one wave corresponding to the quinone reduction was observed. For all pH values studied, the disk limiting current, i_D, was proportional to the square root of the rotation rate, $\omega^{1/2}$. For $n = 2$, the diffusion coefficient, D, for 4MC was calculated to be 4.64×10^{-6} cm^2/sec.

In acidic solutions, the collection efficiency, N_k, was independent of the rotation rate, ω, and was equal to 0.17, which was the maximum collection efficiency. In neutral and basic solutions, the collection efficiency decreased and was dependent on rotation rate. A typical set of data is shown in Fig. 11, along with the theoretical curve for the coupling mechanism. The second-order rate constant was calculated for different pH values and the results are shown in Fig. 5. These results were quite consistent with chronoamperometry.

Coulometry.—The coulometric oxidation of 4-methyl catechol was studied most extensively with less work being done on catechol, DHBA, and DHPP. All of these compounds gave similar results. The oxidation of these compounds leads to extensive polymerization as has been seen by previous workers (11). In particular, in this work the products of the oxidation of DHBA and DHPP were isolated and were found by mass spectrometry to be highly polymerized. Fragments were seen in the mass spectra for monomers, dimers, and trimers and the high melting point (>200°C) indicated even larger polymers. This is consistent with the chronoamperometric work which showed the poor stability of the dimer.

The current decay curve for the oxidation of 4MC depended somewhat on pH. In very basic solutions such as pH 11.2, the coulometric n-value was 2.12 which is consistent with the voltammetric and chronoamperometric data. An analysis of the log i-t curve at this pH also gave a slope with an n-value of 2.07. In less basic solutions, the log i-t curve tended to flatten out at long times and the overall coulometric n-value rose to 3.03 at pH 9.42. Still, for the first 10-15 min of the electrolysis, the slope of the log i-t curve yielded a value of 2.05. This indicated that in less basic conditions and at longer times an electroactive product was slowly being formed. This is at much too long a time scale to be observed in chronoamperometry or voltammetry and is probably related to the polymerization reaction. During the time scale for the chronoamperometric work, though, an overall $n = 2$ process occurred. Similar results were observed for DHBA where an n-value for the log i-t curve was initially 2.13 while the overall n-value was 2.91 at pH 10.62. Once again, the increased n-value was due to some slowly formed electroactive product which occurred during further polymerization.

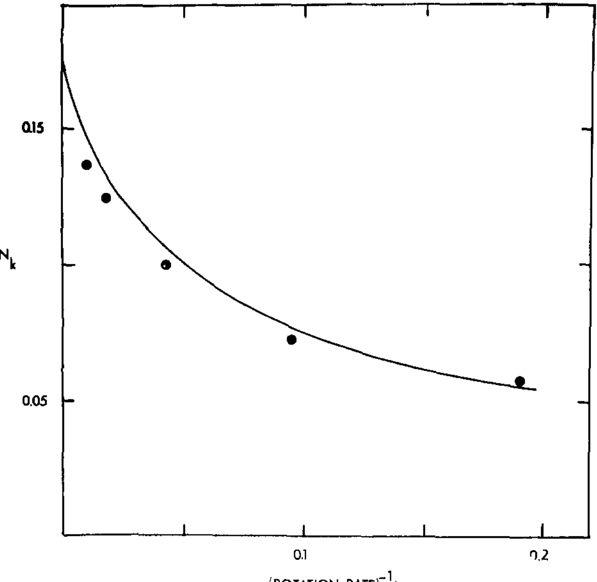

Fig. 11. Variation of the collection efficiency, N_k, as a function of the reciprocal of rotation rate for 0.93 mM 4-methyl catechol. pH = 12. Points are experimental points and solid line is the theoretical curve for $k_f = 620$ M^{-1} sec^{-1}.

Discussion

The oxidation of all the catechols studied involved initially the oxidation of the catechol to the o-quinone

$$+ 2e^- + 2H^+ \qquad [18]$$

The next step was the coupling between the starting material, catechol, and the quinone

$$\xrightarrow{k_1} D \qquad [19]$$

$$\xrightarrow{k_2} D \qquad [20]$$

The identity of D can only be inferred because of its poor stability and the great tendency of the quinones to polymerize. Two general types of D, which are formed by C-O or C-C coupling, can be visualized

D_1 $\qquad$ D_2

There are also several other isomers that can be formed by coupling at other positions. Dimer D_1 can be further oxidized as shown in reaction [21]

$$+ 2e^- + 2H^+ \qquad [21]$$

and D_2 can be oxidized as follows

$$+ 4H^+ + 4e^- \qquad [22]$$

There is an intermediate two-electron oxidation state for these catechols such as D_2' for catechol (R_2 = H) or 3-methyl catechol ($R_2 = CH_3$) or D_2'' for the other catechols

D_2' $\qquad$ D_2''

Since D_2 can be oxidized by four electrons at the potential that the oxidation occurred the overall oxidation of catechol by the C-C coupling is given in reaction [23]

$$\longrightarrow 1/2 \qquad + 3H^+ + 3e^- \qquad [23]$$

Conversely, the overall oxidation of catechol to D_1' is

$$\text{(OH, OH, } R_1, R_2 \text{ catechol)} \longrightarrow 1/2\ \text{(} R_1, R_2, \text{OH diphenyl ether quinone)} + 2H^+ + 2e^- \quad [24]$$

Thus, if reaction [23] were occurring, the $i_a t^{1/2}/C$ values should increase by 50% when the coupling reaction occurs to a significant extent. But if reaction [24] were occurring, the $i_a t^{1/2}/C$ values should remain constant, as was observed. In addition, the coulometric n-values were consistent with an $n = 2$ oxidation process. It is only when the coupling process is slow (low pH) and when the catechol concentration is depleted (long electrolysis time) that the coulometric n-value increases. In those cases, extensive polymerization is occurring and the decreases in the catechol may cause changes in the polymerization mechanism. In general, though, the formation of dimer D_1 is the most probable step in initiating the polymerization process for catechol. The electroinactivity of the product is probably due to the rapid polymerization or some yet uncharacterized irreversible reaction. Dimer D_2 has been shown in this work to be electroactive and, in all probability, dimer D_1 should also be electroactive. It is only for DHAP and DHPP that the reaction of the dimer is slow enough to be observed in voltammetry.

The coupling reaction is quite sensitive to substituent effects as was seen in Table III. The rate of the coupling reaction, k_1, can be related with the Hammett ρ-σ parameters, where the Hammett equation is

$$\log k_i = \log k_o + \rho\sigma$$

where k_i is the rate constant for the substituted catechol, k_o is the rate constant for catechol, σ is a constant characteristic of a given substituent group, and ρ is the slope of the log k_i-σ graph. The Hammett plot is shown in Fig. 12. The ρ value was 6.2. This positive ρ value means that the transition state has a substantial negative charge because the reaction rate is increased significantly for electron-attracting substituents. This result is consistent with the attack of the catechol anion on the quinone. The only exception is the coupling of DHBE, which deviates significantly from the log k_i-σ line. This deviation may be due to steric effects.

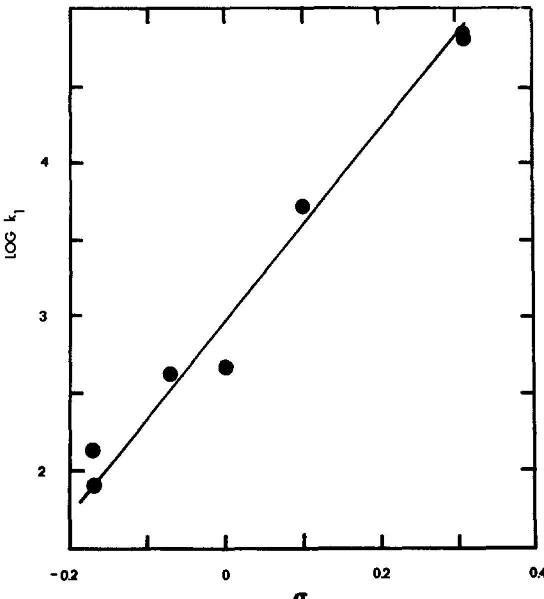

Fig. 12. Hammett σ-ρ plot for the catechols studied

The best fit was obtained for σ_m values, although σ_p gave similar results but with somewhat more scatter. This may be a reflection of the point of attack by the anion, although it is difficult to make any firm conclusions on this basis alone.

Conclusions

The results of this work show that substituted catechols are oxidized to their respective quinones. The quinone is then attacked by the various anionic forms of the catechol to form a diphenyl ether. The overall oxidation is a two-electron process, but the coulometric n-value increases at long electrolysis times due to some slowly formed polymeric products and also changes in the reaction mechanism due to the depletion of catechol. Finally, the Hammett ρ-σ plot is consistent with a substantial negative charge in the transition state.

The Electrochemichromic Properties of 4-Benzoylpyridinium Derivatives

Nobuyuki Yoshiike, Shigeo Kondo, and Masakazu Fukai

Central Research Laboratories, Matsushita Electric Industrial Company, Limited, Moriguchi, Osaka, 570 Japan

ABSTRACT

The electrochemistry and electrochemichromism of a number of 4-benzoylpyridinium derivatives (BpX) have been studied in aqueous electrolyte. Cyclic voltammograms demonstrate that the first reduction wave is reversible and controlled by diffusion. The radical compound ($\dot{B}p$) formed at the first reduction is fairly stable in the absence of oxygen. The second reduction peak potential is irreversible and it has a *p*H dependence. A linear relation between the first reduction potential of substituted 4-benzoylpyridines and the number of carbon atoms in normal alkyl substituents is found. The first reduction wave is shifted to positive region by using longer alkyl substituents increasing the separation from the second wave. The possibility of an electrochromic display based on BpX is also discussed.

Several electrochromic displays (ECD) have been studied in the last ten years. In general they differ from other display devices in that they are based on an electrochemical reaction which brings about a reversible color change. They have been demonstrated having a memory effect, good contrast, low switching voltage, low mean power consumption, and no viewing angular dependence.

They can be classified into two main groups; one using organic materials (1-5) such as viologen

$$(R-\overset{+}{N}\langle\rangle-\langle\rangle\overset{+}{N}-R\cdot 2X^{-})$$

and the other using inorganic materials (6-13) such as WO_3.

For the studies of application to ECD, it is very important to make clear the electrochemical properties of these electrochromic materials. Polarography and/or cyclic voltammetry are useful methods for this purpose. For example,the polarographic behavior of methyl viologen (MVX_2) was examined (1) in an aqueous solution. The first reduction wave of MV^{++} has been reported to be reversible and *p*H independent while the second wave is irreversible. In another example, the cyclic voltammetry of WO_3 has been reported (9) to be used for the investigation of electrochemical properties.

In this paper, the cyclic voltammetry of 4-benzoylpyridinium derivatives (BpX) was studied and BpX were found to give a purplish blue colored stable radical deposit by reduction reaction. The electrochemical and electrooptical behaviors of BpX for a new electrochromic material are described.

Experimental

Apparatus.—The electrochemical cell is shown in Fig. 1(a). The working electrode was a platinum plate (1.0 cm^2), the counterelectrode was a platinized platinum plate (15 cm^2) and a saturated calomel electrode (SCE) was used as the reference electrode. The cell (made of Teflon) used for electrooptical studies is shown in Fig. 1(b). The working electrode was a transparent In_2O_3 electrode coated with a thin Pt layer (*ca.* 20 Ω/cm^2, 0.79 cm^2). The electrochemical and/or electrooptical measurements were made with the assembly shown in Fig. 2. The optical measurements fitted for luminosity factor were made with a filter (Hoya Glass Works, LB-200), a gelatin filter (Kodak No. 106), and others as in Fig. 2. Test electrolytes were degassed with nitrogen to remove oxygen before each measurement.

Reagent.—4-(p-alkylbenzoyl) pyridine derivatives

$$(N\langle\rangle-\overset{O}{\overset{\|}{C}}-\langle\rangle-R_1)$$

were prepared by the following general procedure (14).

(*i*) $N\langle\rangle-COOH + SOCl_2 \longrightarrow N\langle\rangle-COCl$

(*ii*) $N\langle\rangle-COCl + \langle\rangle-R_1 \longrightarrow N\langle\rangle-\underset{\underset{O}{\|}}{C}-\langle\rangle-R_1$

yields, and boiling points of prepared materials are shown in Table I. 4-Benzoylpyridine was supplied by Tokyo Kasei Kogyo Company, Limited. The 4-(p-alkylbenzoyl) pyridines were distilled under vacuum, and then refluxed with n-alkyl halide (R_2X) in alcohol. The solid obtained by filtration was washed thoroughly with acetone until washings were colorless and extracted with water. The aqueous solution was evaporated to dryness in a rotary evaporator. The solid

obtained from aqueous solution was recrystallized twice from ethanol, confirmed by elementary analyses and used in the experiments.

The data of analyses are shown in Table II. Potassium bromide (guaranteed reagent) was used as the supporting electrolyte.

Results and Discussion

Electrochemical properties.—A typical cyclic voltammogram for N-heptyl-4-benzoylpyridinium bromide is shown in Fig. 3. It has two well-defined reduction waves. A purplish blue deposit was formed on the working electrode at the first reduction wave. It was fairly stable in the absence of oxygen and reverted to the initial state by an electrochemical oxidation; however, the deposit formed at the second reduction wave was not returned to the initial state and remained on the working electrode. The anodic current peak corresponding to the first reduction wave was sharp as shown by the dotted line in Fig. 3(a), on the other hand, the anodic peak corresponding to the second wave was not observed. In order to determine the reversibility of each reduction wave, current-potential characteristics were examined by cyclic voltammetry.

Cyclic voltammograms of N-heptyl-4-benzoylpyridinium bromide were measured at various scan rates and are shown in Fig. 3(b) and (c). The scan rate (v) dependence of the first peak potential (E_p^1), the second peak potential (E_p^2) and the first peak current (i_p^1) are obtained from the results as shown in Fig. 4 and give the following

$$\Delta E_p^1/\Delta \log (v) = 0, \qquad \Delta E_p^2/\Delta \log (v) \neq 0 \qquad [1]$$

$$i_p^1/v^{1/2} = 9.9 \times 10^{-3} \qquad [2]$$

In the case that the reduction process is reversible and the activity of the deposit is equal to unity, the peak potential (E_p) is given by Delahay (15) as

$$E_p = E_O + \frac{RT}{nF} \ln f_O C - (0.942)^2 \frac{RT}{nF} \qquad [3]$$

where E_O is the standard potential, R is gas const., T is

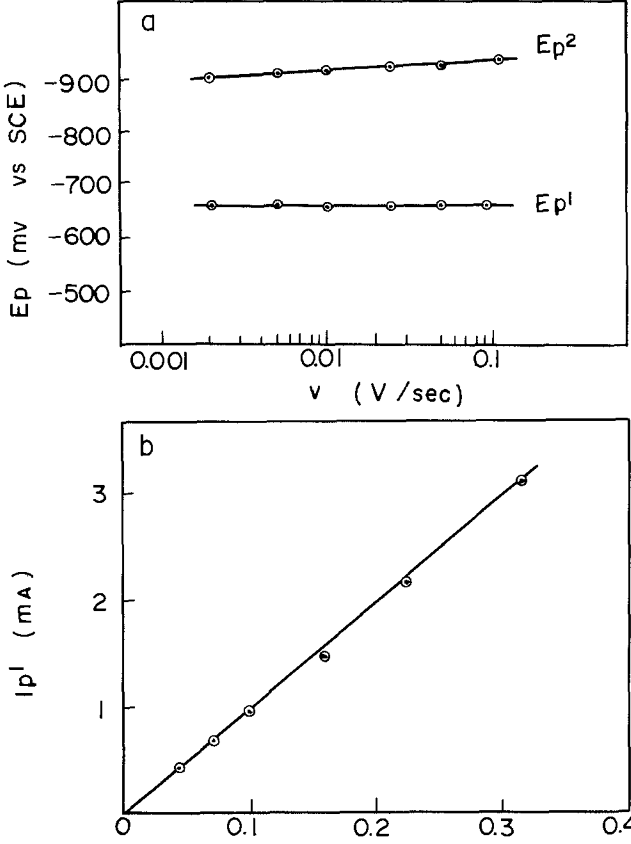

Fig. 4. Scan rate (v) dependence of the peak potential (E_p) and the first peak current (i_p^1) for

C_7H_{15}-$\overset{+}{N}$(pyridine)-C(=O)-(phenyl)$\cdot Br^-$

Data as in Fig. 3, E_p^1, the first peak potential, E_p^2, the second peak potential.

absolute temperature (°K), n is the number of electrons involved, F is Faraday's constant, f_O is the activity coefficient of the reactant, and C is the bulk concentration. The peak current (i_p) is given by

$$i_p = 3.67 \times 10^5 n^{3/2} S C D^{1/2} v^{1/2} \qquad [4]$$

where S is the area of working electrode, D is the diffusion coefficient and v is the scan rate (V/sec).

Empirical relations, [1] and [2] relating to the first reduction wave agree well with the theoretical equations, [3] and [4], respectively, so that the first reduction wave is reversible and controlled by diffusion. The reversibility of the first reduction is supported by other experimental data that show that the anodic-cathodic peak potential difference for the redox couple involved is independent of scan rates of cyclic voltammetric behavior [Fig. 3(c)] and that it is small (about 35 mV). The sharp anodic peak may indicate film stripping during the anodic process. The same results were obtained with other 4-benzoylpyridinium derivatives. The tabulation of these results, E_p^1, E_p^2, $E_p^1/\log(v)$ and $i_p^1/v^{1/2}C$ ($A\cdot sec^{1/2}\cdot cm^3/V^{1/2}\cdot mole$) is made in Table III.

The number of electrons involved at the first reduction wave may be calculated from theoretical Eq. [4] and an empirical relation between E_p^1 and log C. For instance, Fig. 5 shows the E_p^1 − log C plot of N-heptyl-4-benzoylpyridinium bromide and Eq. [5] the following

$$E_p^1 = 0.055 \log C + K \qquad [5]$$

where K is constant, and $n = 1.06 \simeq 1$ is calculated from Eq. [3] and [5]. Therefore the first reduction

C_7H_{15}-$\overset{+}{N}$(pyridine)-C(=O)-(phenyl)$\cdot Br^-$

in 0.3M KBr solution at 20°C.

waves of these derivatives proceed with one-electron reduction process. The same relations were obtained on others.

The second reduction process is irreversible, because the second reduction wave had the scan rate dependence of the peak potential (E_p^2) and the anodic current peak corresponding to the second reduction wave was not observed clearly as shown in Fig. 3.

The pH dependences of reduction waves were measured in various H_3BO_3-KCl-Na_2CO_3 buffer solutions and Na_2HPO_4-NaOH buffer solutions. The representative result of N-heptyl-4-benzoylpyridinium bromide is shown in Fig. 6.

The peak potential of the first reduction is independent of pH over a pH range of 8-12, and the second reduction wave varies 43 mV per pH unit. Therefore the first reduction,

R_2-$\overset{+}{N}$(pyridine)-C(=O)-(phenyl)-R_1 + e ⇌ R_2-N(pyridinyl radical)-C(=O)-(phenyl)-R_1

is not affected by protons in the electrolyte system. The structure of the first reduction product is actually a resonance structure with the radical delocalized over both the aromatic rings and the carbonyl group; such resonance contributes to the radical stability. The extraction of proton from the electrolyte follows presumably the second reduction and the process is irreversible.

Consequently, to use BpX as an ECD material, it is necessary to use only the first reduction reaction during writing time for the purpose of reversible color change. Therefore, it is desirable to separate the first reduction potential from the second irreversible reduction potential as much as possible.

The apparent standard potential (E_O) for the couple $Bp^+ - \dot{B}p$ was obtained from the experimental data, where each activity coefficient is equivalent under the experimental conditions. For example, for the 4-(p-methylbenzoyl) pyridinium derivatives

$(R_2\text{-}\overset{+}{N}C_5H_4\text{-}C(=O)\text{-}C_6H_4\text{-}CH_3 \cdot X^-,$

R_2 = n-alkyl group), the linear relation between m, the number of carbon atoms in the N-alkyl substituents, and the standard potential, E_O^1, is given by $E_O^1 = 28\,m + b$ (mV), where b is a constant, and is shown in Fig. 7.

The effect of p-alkyl substituents

$(R_2\text{-}\overset{+}{N}C_5H_4\text{-}C(=O)\text{-}C_6H_4\text{-}R_1 \cdot X^-,$

R_1 = n-alkyl group) on the apparent standard potential is the same as the effect of N-alkyl substituents. For N-pentyl-4-(p-alkylbenzoyl) pyridinium derivatives, the relation between m', the number of carbon atoms in p-alkyl substituents, and E_O^1 is almost linear and given by $E_O^1 = 15\,m' + b'$ (mV) where b' is constant and shown in Fig. 8.

These results demonstrate that the standard potential E_O of the first reduction shifts to more positive potentials with increasing carbon atoms in the alkyl substituents and that it is more efficient to use long alkyl groups, *i.e.*, n-hexyl, n-heptyl, for N-substituents than using these groups for p-substituents. They are supported by the fact that the reduction potential shifts to a more positive region with decreasing nucleophilic effect of the substituents (16-18). The substituent effect on the second reduction potential is not clear (see Table III).

The first reduction potential may be shifted to positive potential regions and separated from the second reduction potential by using large alkyl substituents, for example, the potential difference between E_p^1 and E_p^2 is more than 200 mV for N-heptyl substituents, so

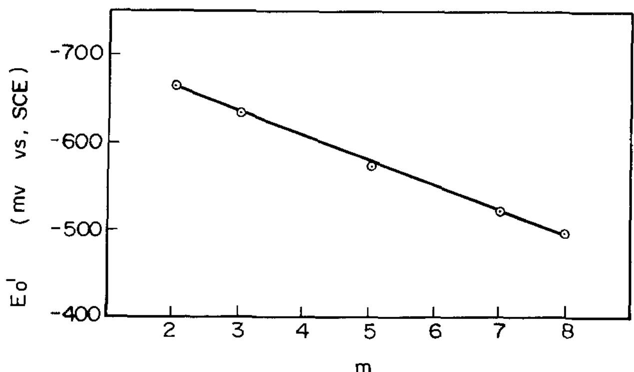

Fig. 7. The relationship between the standard potential and m for

$C_mH_{2m+1}\text{-}\overset{+}{N}C_5H_4\text{-}C(=O)\text{-}C_6H_4\text{-}CH_3 \cdot X^-.$

Table IV. Quasi-extinction coefficients which were obtained from the luminous transmittance (Tl) and the following equation, $K = -(FS/q) \log (Tl)$

	1	2	3	4
R_1	H	C_2H_5	CH_3	H
R_2	C_7H_{15}–	C_5H_{11}–	C_6H_5–CH_2–	C_2H_5–C_6H_4–CH_2–
K	5800	6230	5240	7420

it is easier to use the first reduction reaction during writing time, and possible to use BpX as an ECD material by using long alkyl groups for substituents.

The optical properties of BpX.—The electrooptical properties were measured by a potentiostatic pulsed mode with cell 2 of Fig. 1 and the assembly of Fig. 2. The reduction potential for the writing state was controlled within the first reduction peak potential ($E_p{}^1$).

The writing state of ECD is achieved by the deposition of reduced electrochromic materials on the working electrode. Absorption spectra of the deposit were obtained from the transmittance (Tr) at each wavelength (λ) and the following equation. $A = -\log \text{Tr} = kq/FS$ where A is the absorbance at each wavelength, k is the extinction coefficient, q is the amount of charge consumed for writing, and S is the area of the working electrode. The absorption spectra of Bp show broad bands around 5800Å as shown in Fig. 9.

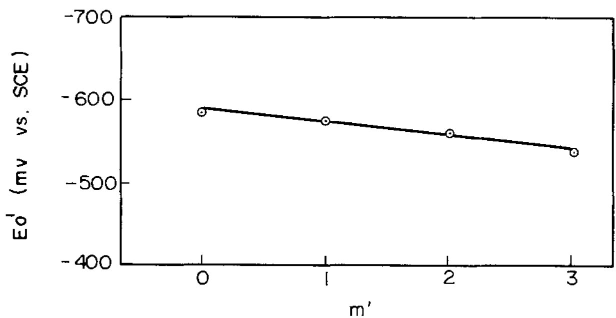

Fig. 8. The relationship between the standard potential and *m'* for

$$C_5H_{11}-\overset{+}{N}C_5H_4-\underset{\underset{O}{\|}}{C}-C_6H_4-C_{m'}H_{2m'+1}\cdot X^-.$$

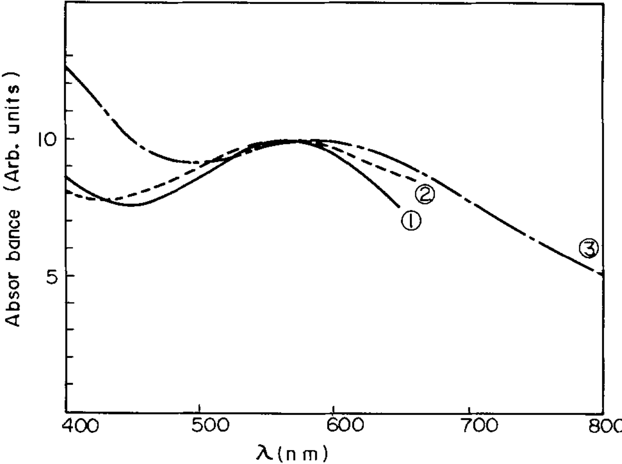

Fig. 9. Absorption spectra of radical states of

$$R_2-\overset{+}{N}C_5H_4-\underset{\underset{O}{\|}}{C}-C_6H_5\cdot X^-,\quad \mathbf{1},\ R_2 = C_7H_{15}-;$$

$$\mathbf{2},\ R_2 = C_2H_5-C_6H_4-CH_2-;\quad \mathbf{3},\ R_2 = C_6H_5-CH_2-.$$

Light absorption of Bp is based on π-electron resonance of benzoylpyridine ring, so that a small amount of adsorption spectrum shift may be achieved by changing the substituents R_1 and R_2 in

$$(R_2-\overset{+}{N}C_5H_4-\underset{\underset{O}{\|}}{C}-C_6H_4-R_1\cdot X^-)$$

A 0.11 eV shift was observed between $R_2 = C_7H_{15}$ and

$$R_2 = (C_6H_5-CH_2-)$$

The contrast at writing state is directly determined by absorbance fitted for a luminosity factor. For convenience, constants (K) which correspond to a quasi-extinction coefficient fitted for luminosity factor were obtained from the luminous transmittance (Tl) and the following equation, $K = -(FS/q) \log (Tl)$ and shown in Table IV for a comparison of the absorbance fitted for luminosity factor.

Absorption spectra of the radical state of BpX are mainly fitted for luminosity spectrum having peak at 5550Å, hence great contrast changes at write-erase cycles can be expected, so that absorption spectra of writing states of BpX are suitable for a display device.

From the above-mentioned results, BpX has a possibility as a new electrochromic material for ECD.

Photoanodic Dissolution Reaction of an n-Type Gallium Phosphide Electrode and Its Effect on Energies of the Electronic Bands at the Surface

Yoshihiro Nakato, Akira Tsumura, and Hiroshi Tsubomura*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560, Japan

ABSTRACT

Mott-Schottky plots obtained at dark and under weak illumination have shown that the energies of the electronic bands at the surface of an n-GaP electrode are sifted downward, toward more negative, by illumination under anodic polarization. The magnitude of the shift for the $(\bar{1}\bar{1}\bar{1})$-face of the electrode was somewhat smaller than that for the (111)-face. The results are explained by taking account of photoanodically formed surface intermediates, causing a change in the potential difference at the semiconductor-solution interface. These intermediates were found to decay in several minutes at dark under anodic polarization. It is suggested that these intermediates also act as effective surface recombination centers.

The flatband potential (U_{FB}) is the electrode potential of a semiconductor electrode, at which the electrostatic potential inside the semiconductor is flat. The quantity, $-eU_{FB}$, reflects the Fermi level of the semiconductor at the flatband condition, in the sense that the Fermi level of the semiconductor is given with respect to the electron energy (the Fermi energy) of a reference electrode. The lower energy limit of the conduction band of an n-type semiconductor, designated as E_c, is slightly higher (less negative) than the Fermi level. Therefore, at the flatband condition we can express E_c^s, by taking a small value Δ

$$E_c^s = -eU_{FB} + \Delta$$

where E_c^s is the E_c value at the surface of the semiconductor, E_c^s and $-eU_{FB}$ being measured with respect to the same reference electrode.

It is often tacitly assumed that E_c^s is a constant independent of the electrode potential. Under such an assumption, E_c^s is virtually equal to $(-eU_{FB} + \Delta)$. So, U_{FB} can be determined from the so-called Mott-Schottky plots (1, 2). In the case of p-type semiconductors, the upper energy limit of the valence band at the surface, designated as E_V^s, is in a situation similar to E_c^s in the above.

If E_c^s takes different values at electrode potentials (U) different from U_{FB}, it should be distinguished from $(-eU_{FB} + \Delta)$. In this case, we can define U_s as $E_c^s = -eU_s + \Delta$ (Fig. 1). If U_s (or E_c^s) remains nearly constant in a certain range of U, a Mott-Schottky plot should give a straight line in this potential range, from which U_s (or E_c^s) can be determined.

Gerischer and co-workers reported that the "flatband" potential of an intrinsic germanium electrode changes with either anodic or cathodic prepolarization (3). They explained the result as due to a chemical change at the surface from hydroxide- to hydride-like structure. This means that the energies of the electronic bands at the surface change with U in an intermediate potential range between the anodic and cathodic polarization.

Measurements of the Mott-Schottky plots under illumination have so far been reported only for a few semiconductors under limited conditions (4, 5). It was reported that the "flatband" potential of an n-TiO_2 electrode was not shifted by illumination (5). For an $MoSe_2$ electrode in an iodide-containing solution, the shift of the surface band energies by illumination was suggested from capacitive phase-shift measurements (6). The photo-shift of the surface band energies was also suggested from analysis of current-potential curves for a CdS electrode in a low concentration sulfide solution (7). Capacitance changes by illumination were also reported for an $SrTiO_3$ electrode (8).

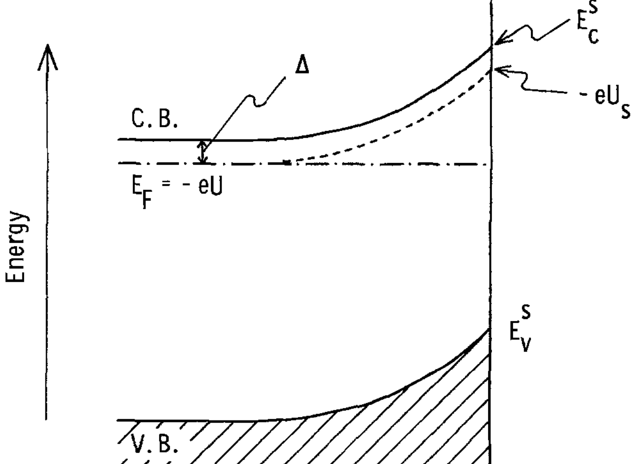

Fig. 1. A schematic figure showing a relation between U_s and E_c^s.

* Electrochemical Society Active Member.

Key words: semiconductor, photoelectrochemistry, reaction intermediate.

It is sometimes found that the onset potentials of anodic photocurrents for n-type semiconductors deviate from the "flatband" potential or above-mentioned U_s at dark to the positive. These results were explained in terms of electron-hole recombination via a preexisting surface state within the bandgap (9).

We have found that the band energy at the surface of an n-GaP electrode is shifted by weak illumination under anodic polarization. In the present paper, we will report on these experimental results and discuss the effect of electron or hole density at the surface on the surface chemical structure and band energies.

Experimental

The n-type GaP used was a single crystal in the form of wafers, 99.999% pure, doped with sulfur at the concentration of 2-3 $\times$ 10^{17} cm^{-3} obtained from Yamanaka Chemical Industries Limited. The p-type GaP used was doped with zinc at 3.7 $\times$ 10^{17} cm^{-3}, obtained from Sanyo Electric Company, Limited. Both were cut perpendicular to the [111]-axis. The electrodes were prepared in the same way as reported elsewhere (10). Before the experiment, they were polished and etched with warm aqua regia in order to remove oxide layers at the surface. The (111)-face (Ga face) and the $(\overline{1}\overline{1}\overline{1})$-face (P face) were distinguishable by microscopic inspection of the etched surfaces, the former very rough and the latter smooth, as reported in the literature (11).

The current-potential curve was obtained with a Hokutodenko HA-101 potentiostat. The differential capacitance was measured mostly with a Yokogawa-Hewlett-Packard Universal Bridge 4265B, having a modulation frequency of 1 kHz and a modulation amplitude of 20 mV (peak to peak). The frequency dependence of Mott-Schottky plots were checked by connecting a function generator with this bridge. The electrode was illuminated through a quartz window, with a 250W high pressure mercury lamp. The light intensity was attenuated by use of neutral density filters made of metal nets.

Solutions were prepared from deionized water by using reagent grade chemicals, in most cases, without further purification. They were deaerated by bubbling nitrogen and stirred with a magnetic stirrer. The *p*H of the solutions in the range of 3-11 was controlled by using buffer mixtures; acetate, phosphate, borate, or carbonate, each at about 0.01M, where M means mole/dm^3. This abbreviation is used throughout the present paper.

Results

Figure 2 shows the current-potential (*i-U*) curve for the (111)-face of the n-GaP electrode in an alkaline solution. Dark anodic currents were less than 0.1 $\mu A/cm^2$. The *i-U* curve under illumination shows hysteresis in the potential range between -2.0 and -1.0V *vs.* SCE. The hysteresis is quite strong at low illumination intensities or at high potential sweep rates. As the cathodic current observed in the range below -2.0V *vs.* SCE corresponds to hydrogen formation (12, 13), the electrode surface in this range is thought to have a reduced (hydride-like) structure. The photoanodic current in the range above -1.0V corresponds to the oxidative dissolution of the electrode (12-16), and therefore the electrode surface is expected to have an oxidized structure. Accordingly, the anodic and cathodic currents observed in the intermediate potential range can partly be attributed to oxidation of cathodically formed surface hydride and reduction of photoanodically formed surface hydroxide or oxide, respectively (12). Similar hysteresis was reported in the case of Ge and GaAs electrodes (17).

Based on the above interpretation, the *i-U* curve obtained by scanning from the anodic to the cathodic potential arises from the n-GaP electrode covered with the photoanodically formed surface hydroxide or oxide. Its shape and position can be characterized by two potentials: U_{sat}^a, at which the anodic photocurrent begins to deviate from the saturation value, and U_o^a, at which it is zero, as is shown in Fig. 2. It is to be noted that these potentials shift largely from U_s at dark [U_s (dark)], determined from the Mott-Schottky plot in the present work.

Figure 3 shows the *p*H dependence of U_o^a and that of U_{sat}^a for the (111)-face of the n-GaP electrode, as compared with that of U_s (dark) described in detail later. U_o^a and U_{sat}^a were measured at a low illumination intensity, with the anodic saturation currents kept at 15 $\mu A/cm^2$. It is seen that U_{sat}^a and U_o^a shift largely from U_s (dark) in the range of *p*H $\geqq$ 4. The difference between U_o^a and U_{sat}^a increases at around *p*H 4, conceivably due to the formation of a hydroxide or oxide layer, probably exceeding one-monolayer coverage because of its low solubility around this *p*H. It is thought that no such thick hydroxide or oxide layer is formed except weakly acidic solutions under weak illumination, because such layers dissolve easily in solution (13, 14).

The large deviations of U_o^a and U_{sat}^a from U_s (dark) suggest that E_c^s (or U_s) of the n-GaP electrode is shifted by illumination. We therefore determined the U_s values under illumination at various *p*H. Figure 4 shows some examples of Mott-Schottky plots for the n- and p-type GaP electrodes at dark, and Fig. 5 those under illumination. The electrode was illuminated at a low intensity, so as to avoid disturbance in the space charge layer by the flow of photocurrents. Very good straight lines were obtained both at dark and under illumination, showing applicability of the Mott-Schottky method to weakly illuminated electrodes. As

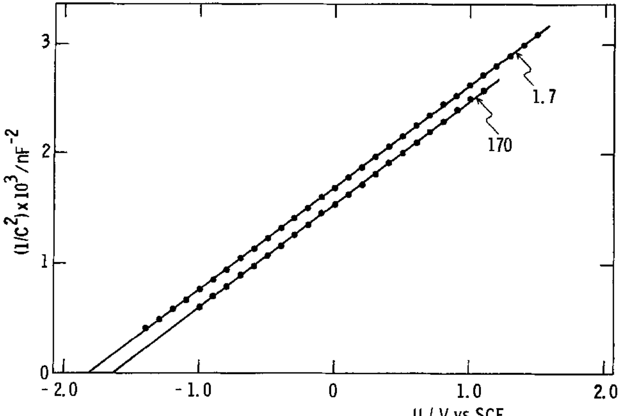

Fig. 5. Mott-Schottky plots for the (111)-face of an n-GaP electrode under illumination. The anodic photocurrents flowing under measurements are shown in unit $\mu A/cm^2$. Electrolyte: 0.1M NaOH. The modulation frequency: 1 kHz.

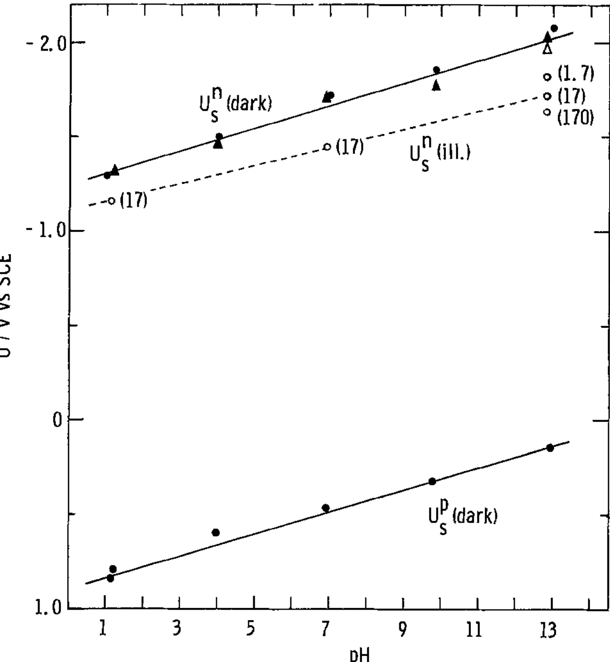

Fig. 6. U_s for the (111)-face of n- and p-GaP electrodes: (●) measured at dark after chemical etching, (▲) at dark in 10 min after the flow of cathodic currents, (△) at dark in 10 min after the flow of anodic photocurrents, and (○) under illumination. The anodic photocurrents flowing under measurements are shown in parenthesis in $\mu A/cm^2$. Electrolyte: the same as in Fig. 2.

seen in Fig. 4 and 5, the lines have slopes slightly different from each other, due probably to variations in the roughness factor of the electrode surface, caused by the mechanical polishing.

The values of U_s for the (111)-face of the GaP electrodes, determined by extrapolating the inverse square of the differential capacitance to zero, are shown in Fig. 6. Firstly, it is seen that the U_s values of the n- and the p-type GaP electrodes at dark, called U_s^n (dark) and U_s^p (dark), change linearly with pH with a slope of *ca.* −60 mV/pH. The onset potential of the dark cathodic currents changes with pH in parallel with U_s^n, showing the validity of the U_s^n values determined from the Mott-Schottky plots. Secondly, it is seen that the difference between U_s^n (dark) and U_s^p (dark) is about 2.1V throughout the pH range, nearly equal to the bandgap of the GaP semiconductor (2.26 eV). This is a reasonable result, which means that E_c^s and E_v^s are nearly the same in the n-GaP electrode under anodic polarization and the p-GaP electrode under cathodic polarization. The U_s values in the present work are also in good agreement with the values reported as the "flatband" potential at dark (18), lying very close to the U_s *vs.* pH lines drawn in Fig. 6.

The values of U_s for the n-GaP electrode under illumination, U_s^n (ill.), shift definitely from U_s^n (dark) to the positive (Fig. 6). The magnitude of the shift increases with the illumination intensity, reaching about 0.4V at the photocurrent density 170 $\mu A/cm^2$ at pH 13. The values of both U_s (dark) and U_s (ill.) were confirmed to be independent of the modulation frequency in the range of 1-10 kHz for the measurements of the differential capacitance.

Figure 6 also shows that the value of U_s (dark) of the n-GaP electrode at each pH is constant irrespective of whether it was measured after the chemical etching, after the flow of anodic photocurrents, or after the flow of cathodic currents. This means that both the photoanodically formed oxides or hydroxides and the cathodically formed hydrides at the surface disappear at dark under anodic potentials, through reaction with the electrolyte solution. The surface of the n-GaP electrode at dark under anodic polarization is then thought to be in an equilibrium state in the electrolyte solutions, irrespective of pretreatments of the electrode.

We can roughly estimate the average decay rate of the photoanodically formed oxides or hydroxides from the shift of the *i-U* curve under illumination in a way described below. In Fig. 7, broken lines show the *i-U* curves under illumination after 10 min preillumination at 0V *vs.* SCE, while solid lines are those obtained by 10 min preillumination at 0V *vs.* SCE, followed, after a certain period of dark time, by a potential sweep at 10 sec/V to the negative at dark, and reillumination at −1.0V *vs.* SCE. Although few examples are shown in Fig. 7 for simplicity, the *i-U* curve shifts to more negative, the longer the dark period, t_d, and beyond 660 sec no shift was observed. This result shows

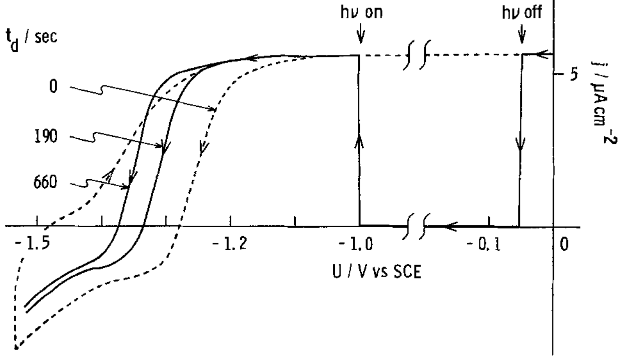

Fig. 7. The *i-U* curves for the (111)-face of an n-GaP electrode in a 0.1M NaOH solution, obtained under various illumination conditions.

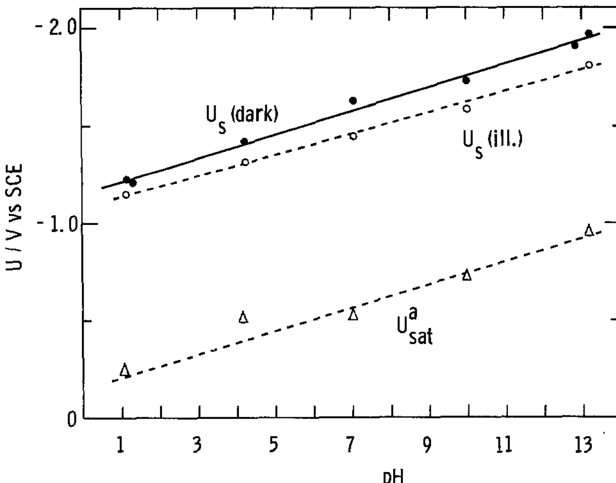

Fig. 8. U_s (dark), U_s (ill.), and $U_{sat}{}^a$ for the $(\bar{1}\bar{1}\bar{1})$-face of an n-GaP electrode. U_s (ill.) and $U_{sat}{}^a$ were obtained at a constant illumination intensity, with the photoanodic saturation currents kept at 17 $\mu A/cm^2$.

that the photoanodically formed oxides or hydroxides decay at dark in several minutes.

Figure 8 shows U_s (dark), U_s (ill.), and $U_{sat}{}^a$ for the $(\bar{1}\bar{1}\bar{1})$-face of the n-GaP electrode. Values of U_s (dark) for this face are in agreement with the reported ones (2), and are nearly equal to (or only slightly more positive than) those for the (111)-face. U_s for the $(\bar{1}\bar{1}\bar{1})$-face is also shifted to the positive by illumination, similar to the (111)-face, but the magnitude is somewhat smaller than that for the (111)-face.

Discussion

The position of $E_c{}^s$ and $E_v{}^s$ of semiconductor electrodes are determined not only by the electron affinity (EA) and the bandgap (E_g) of semiconductors but also by the potential difference (ψ_i) at the semiconductor-solution interface, arising from electric double layers formed by adsorbed ions and/or polar bonds at the surface (19, 20). The change of ψ_i, designated as $\Delta\psi_i$, should therefore cause the change of U_s equal to $-(\Delta E_c{}^s/e)$.

As described before, the Mott-Schottky plots observed at dark showed good straight lines in the range of U where the band bending is large (Fig. 4). This indicates that $E_c{}^s$ (or U_s) of the GaP electrodes remains unchanged in this potential range. This is understood as follows. For the semiconductors with the size of the bandgap of GaP, the surface densities of electrons in the conduction band and holes in the valence band are both quite small at dark when the band bending is large. Also, the surface intermediates such as oxides or hydrides, which may be formed by the electrons or holes at the surface, decay relatively fast through reactions with the electrolyte solution, as mentioned in the preceding section (Fig. 6 and 7). Therefore, the concentration of such surface intermediates is negligibly small at dark under large band bending. This means that the chemical structure of the electrode surface and therefore ψ_i are kept nearly the same, independent of U under the above condition. The accumulation of oxide- or hydride-type intermediates (and therefore the change of ψ_i) is expected only when the electrons or the holes come to the surface faster than the decay of these surface intermediates, as can be the case for small band bending or electrode illumination.

From the above consideration, we can also expect that the positions of $E_c{}^s$ and $E_v{}^s$ for the n-type GaP electrode under anodic polarization are almost the same as those for the p-type GaP electrode under cathodic polarization. This is really observed experimentally (Fig. 6). The pH dependence of U_s (dark) of the GaP electrodes can be attributed to an acid-base equilibria on the surface, as pointed out in the case of metal oxides (21) or germanium electrodes (3).

On illumination of the n-GaP electrode under anodic polarization, a number of photogenerated holes come to the surface, and induce photoanodic dissolution reaction of the electrode. Many kinds of oxide- or hydroxide-type reaction intermediates may be formed at the surface, but are thought to be in a stationary state in the range of U under which the constant saturation photocurrent is observed. This means that ψ_i (or U_s) remains constant in this potential range. Very good straight lines observed for the Mott-Schottky plots under illumination (Fig. 5) show that this is actually the case.

It was reported that six holes are consumed per a pair of Ga and P atoms in the photoanodic dissolution reaction at both the (111)- and $(\bar{1}\bar{1}\bar{1})$-faces, probably producing $Ga(OH)_3$ and H_3PO_3 or their analogues (11, 13-15). Also, the formation of a layer of hydroxides or oxides of Ga and P is often assumed for explaining quite hysteretic photocurrent-potential curves or production of white films on the electrode surface, especially in the intermediate pH range (10, 13, 14, 16). As to the reaction mechanism, Gerischer proposed that the first step is a nucleophilic attack of bases like OH^- or H_2O on the holes at the surface (1, 22, 23). Therefore, the following reaction intermediates, I, II, III, etc., are expected to exist at the electrode surface under illumination

I II III IV

Then the shift of ψ_i (or U_s) is expected by the accumulation of either the charged species like I or the highly polar Ga-O or P-O bonds present in II, III, and IV. The latter mechanism is essentially the same as proposed in the case of the Ge electrode (3). The positive shift of U_s can be attributed to the positively polarized Ga or P atom being more or less directed toward the inside of the semiconductor. The magnitude of the shift is thought to depend on the nature and the concentration of the intermediates.

In the discussion made so far, the large deviations of $U_o{}^a$ and $U_{sat}{}^a$ from U_s(dark) (Fig. 3 and 8) were mainly attributed to the shift in ψ_i (or U_s) by illumination. However, as is seen from comparison of Fig. 3 and 6, the differences between U_s(dark) and $U_o{}^a$ are much larger than those between U_s(dark) and U_s(ill.), that is, $U_o{}^a$ still deviates considerably from U_s(ill.) to the positive. The photoanodically formed surface intermediates are thought to capture effectively electrons in the conduction band when the band bending is small (12, 17, 24). This means that they act as effective recombination centers for electrons and holes. The large shifts of $U_o{}^a$ from U_s(ill.) for the n-GaP electrode can therefore be attributed to accumulation of such intermediates at anodic polarization under illumination.

Acknowledgment

The authors wish to express their gratitude to Sanyo Electric Company, Limited for the kind donation of GaP semiconductor single crystals.

A Mechanistic Study of O_2 Reduction on Water Soluble Phthalocyanines Adsorbed on Graphite Electrodes

J. Zagal,*,[1] P. Bindra,* and E. Yeager*

Case Laboratories for Electrochemical Studies and the Chemistry Department,

Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

Co and Fe tetrasulfonate phthalocyanines (M-TSP), adsorbed at monolayer levels on graphite surfaces, have been found to have a pronounced catalytic effect on the O_2 reduction process in both acid and alkaline solutions. The kinetics have been examined with the rotating ring-disk electrode technique. Co-TSP promotes the O_2 reduction process via two electrons to give peroxide whereas Fe-TSP promotes a four-electron reduction to give water.

The catalytic properties of metal phthalocyanines for the electroreduction of O_2 have been examined extensively in the literature (see *e.g.*, 1-10, 40). In general, macrocyclic transition metal complexes of this type have been found to have catalytic activity for the O_2 reduction process. A comprehensive review on this field has been published recently (1). Basic kinetic and mechanistic studies of the process, however, are less available. A direct correlation has been found (2-4) between the first oxidation potential of the metal phthalocyanine and its catalytic activity for O_2 reduction. Beck (4) has recently proposed a mechanism for the process based on data for O_2 reduction on Co tetraazaannulene (Co-TAA), which gives Tafel slopes of -60 mV/decade in acid solution. This author proposed that the metal complex reacts with oxygen according to the reaction

$$M^{II} + O_2 \xrightarrow{H^+} M^{III} - O_2H \quad [a]$$

* Electrochemical Society Active Member.
[1] On leave of absence from Universidad Technica del Estado, Santiago, Chile.

Key words: oxygen electrode, transition metal macrocyclics, oxygen electrocatalysis, phthalocyanines.

where O_2 undergoes partial reduction with simultaneous oxidation of the metal center. The O_2 adduct, according to Beck, then undergoes a two-electron reduction as the rate-determining step, regenerating the catalyst. For a transfer coefficient $\alpha = 0.5$, the Tafel slope could then be -60 mV/decade. Simultaneous two-electron steps, however, are unlikely on energetic grounds.

A mechanism has been recently proposed by Appleby and Savy (5, 8) based on studies of O_2 reduction on Fe phthalocyanines. According to these authors, the rate-determining step is the breaking of the O-O bond and the proposed mechanism in basic media is

$$O_2 \rightleftharpoons O_{2ads} \quad [b]$$

$$O_{2ads} + H_2O + e^- \rightleftharpoons O_2H_{ads} + OH^- \quad [c]$$

$$O_2H_{ads} + e^- \rightleftharpoons O_2H^-_{ads} \quad [d]$$

$$O_2H^-_{ads} + H_2O \rightarrow 2\,OH^-_{ads} + OH^- \quad [e]$$

Even though this mechanism explains the experimental data, it does not explain the specific involvement of the catalyst and particularly the valency state of the

transition metal in the reaction sequence. Further, it is unlikely that the superoxide species $(O_2H)_{ads}$ is protonated in alkaline electrolytes in view of the ionization constant (pK = 4.88) for the O_2H species in solution (41).

The present work has involved the catalytic properties of water soluble tetrasulfonated phthalocyanines adsorbed on graphite substrates. As previously reported (9, 11), considerable catalytic activity can be achieved by adsorbing these complexes from aqueous solutions. The redox properties of the catalysts can be determined using cyclic voltammetry under the same conditions (pH, solvent) at which the O_2 reduction experiments are carried out. This type of approach is facilitated by use of the basal plane of stress-annealed pyrolytic graphite (SAPG) with x-ray diffraction rocking angles as small as $\Delta\theta_{1/2} = 0.4°$. This material provides a near ideal surface for studying the redox properties of adsorbed species because of its low background currents (22) and very low catalytic activity for the O_2 reduction process (23).

Experimental Procedure

A disk electrode, exposing the basal plane of SAPG[2] (9-23) with an area of 0.20 cm², was used for most of the rotating disk measurements. For the ring-disk electrode measurements, the disk was constructed with ordinary pyrolytic graphite (OPG)[2] (radius = 0.250 cm) with gold (99.99% pure) as the ring (inner radius 0.272 cm, outer radius 0.357 cm). The OPG had an x-ray rocking angle of $\Delta\theta_{1/2} = 45°$. Unfortunately the fragile nature of the SAPG prevented its use as the disk in the ring-disk experiments. Unless otherwise indicated, all measurements on SAPG and OPG were on the basal plane.

The ring-disk electrode was calibrated with the ferrous/ferric couple using 10^{-2} and 10^{-3}M $Fe_2(SO_4)_3$ in 0.05M H_2SO_4. The value of the collection efficiency,[3] N, determined in this manner was 0.382. This value compared favorably with the calculated value of 0.38 obtained from the geometry of the electrodes using the tables of Albery and Bruckenstein (12). The Teflon cell had separate compartments for the reference [saturated calomel (SCE)] and counterelectrode (Au-foil) with an additional isolation compartment between the working and reference compartments. A Teflon Luggin capillary was used to minimize *IR* drop with its tip ~3 mm below the center of the rotating disk electrode. The polarization curves for the kinetic measurements were obtained by starting at the open-circuit potential and scanning toward more negative values at a rate of 10 mV/sec. The hysteresis on reverse of sweep was negligible at these scan rates. Small currents (i.e., $< 10\ \mu A$) were measured point by point by waiting at each potential for the drift rate to become negligible. All measurements were made at 20°-22°C.

The surface of the basal plane of SAPG was renewed by use of the adhesive tape technique with care to avoid contamination of the Teflon mounting with the adhesive of the tape (9, 21, 23). The OPG electrodes were polished using 0.3 μm alumina suspended in water with water on microcloth for the final polish. The M-TSP was adsorbed on the graphite surface by placing a drop of solution of the complex (10^{-5}M) on the electrode. Similar results were obtained when the adsorbed layer was applied by submerging the electrode in a 10^{-5}M solution of the complex. The electrode was subsequently washed with purified water (pyrolyzed over Pt/Rh at 800°C). For experiments in acid solution some of this complex was added to the electrolyte to preserve the adsorbed catalyst layer during the measurements. In the other electrolytic solutions the adsorption was sufficiently strong to render the loss of the adsorbed complex negligible over the duration of the measurements.

Basic (0.1M NaOH) and acid (0.05M H_2SO_4) solutions were prepared as described before (9). Other solutions of various pH were as follows: 1M NaOH, pH = 13.8; 0.1M NaOH, pH = 12.9; 0.1M Na_2CO_3, pH = 11.5; 0.005M Na_2CO_3 + 0.05M Na_2SO_4, pH = 10.8; 0.0015M NaOH + 0.05M H_3BO_3 + 0.05M Na_2SO_4, pH = 8.7; 0.10M NaOH + 0.05M H_3BO_3 + 0.05M Na_2SO_4, pH = 6.3; and 0.1M NaH_2PO_4, pH = 4.4. Special precautions were taken to minimize $CO_3^{=}$ in the alkaline electrolytes. The Co-TSP and Fe-TSP were prepared and purified by the procedures described by Weber and Busch (38).

[2] The SAPG and OPG were provided by the Union Carbide Corporation through Dr. A. Moore of the Parma Technical Research Center, Parma, Ohio.

[3] $N = I_R/I_D$, where I_R is the ring current and I_D is the disk current.

Results

Cyclic voltammetry measurements.—Figure 1 shows the cyclic voltammetry curves obtained at different potential scan rates for Co-TSP pre-adsorbed on the basal plane of SAPG. A Teflon hood, similar to that described by Randin and Yeager (39) was used to eliminate edge effects and leakage of the electrolyte between the Teflon and the side of the disk electrode, which otherwise cause a pronounced slant in the voltammetry curves. The peak currents are directly proportional to the scan rate, which is typical of a Faradaic process involving an adsorbed species. (For the adsorption of a diffusing species the peak currents are directly proportional to the square root of the scan rate.)

From the area under the peak, the charge involved in the process can be estimated. An experimental value of 3 μC/cm² has been determined, which corresponds to a surface concentration of 3×10^{-11} moles/cm² of adsorbed metal complex assuming that a one-electron transfer process is involved. Assuming that the surface redox couple obeys the Nernst equation, the peak current for the voltammetry is given by

$$i_p = \frac{n^2F^2\Gamma\nu}{4RT} \quad [1]$$

where Γ is the total surface concentration of the adsorbed complex in moles/cm², ν is the potential scan rate, and n is the number of electrons per adsorbed molecule. The charge under the peak is known and is equal to $Q = nF\Gamma$. Experimental values of Q and i_p give $n = 0.9$ or ~ 1, indicating that one electron is involved in the surface redox process, which is likely to involve the metal center (13-14); *i.e.*

$$(Co^{II}TSP)_{ads} \rightleftharpoons (Co^{III}TSP)_{ads} + e^- \quad [f]$$

The small deviation of n from unity is probably caused by the approximate nature of Eq. [1], which assumes

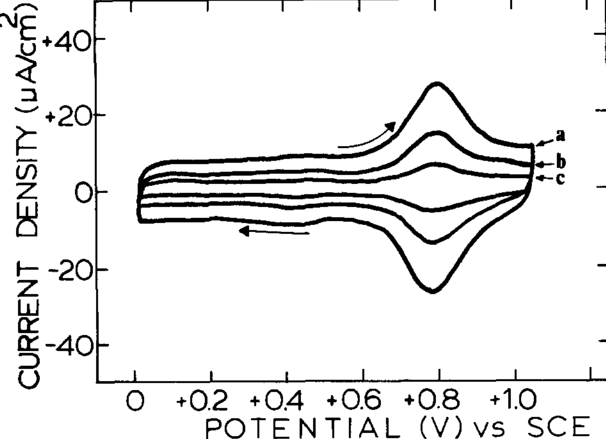

Fig. 1. Cyclic voltammograms at different scan rates for Co-TSP adsorbed on SAPG. Electrolyte: 0.05M H_2SO_4. Sweep rates: (a) 1 V/sec, (b) 0.5 V/sec, (c) 0.2 V/sec. (No Co-TSP in solution; obtained with hood to block electrolyte at edge of disk.)

that the Nernst equation is followed with the activities for the adsorbed species in the two different valence states replaced by the surface concentrations.

Co-TSP readily adsorbs on other carbon substrates including glassy carbon, the edge-orientation of SAPG, and ordinary pyrolytic graphite (OPG). Because of the high background currents of graphite surfaces other than the basal plane of SAPG, however, less well-defined cyclic voltammetry curves result. For Co-TSP adsorbed on the basal plane of OPG, the charge estimated from cyclic voltammetry is *ca.* 13 $\mu C/cm^2$ which is about four times that found on the basal plane of SAPG.

The iron derivative also readily adsorbed on the basal plane of SAPG as evidenced by the voltammetry curve shown in Fig. 2. From the scan rate dependence of both peaks 1 and 2, it was established that a one-electron transfer is involved in each case. The charge under each peak, estimated from the area between the solid and the dotted lines in Fig. 2, is ~3.0 $\mu C/cm^2$, which is the same as found for Co-TSP. This charge is independent of potential scan rate over the range investigated (50-1000 mV/sec). Even though this value is only approximate, it suggests that the surface coverages by Co-TSP and Fe-TSP species are essentially the same. For Fe-TSP adsorbed on the basal plane of OPG, the charge under both peaks 1 and 2 is 13 $\mu C/cm^2$ each, which is the value found for Co-TSP adsorbed on the same graphite material.

The voltammograms obtained at various *p*H indicate that the potentials of peaks 1 and 2 shift with *p*H. Peak 1 appears to involve the process $Fe^{III} + e^- \rightarrow Fe^{II}$. This process is *p*H dependent over a range of *p*H depending on pK_A of the M-TSP. The fact that macrocyclic complexes of transition metals in the oxidation state III undergo hydrolysis in water solutions is a well-known phenomenon [see, *e.g.*, Ref. (15 and 16)]. The redox reaction can be written as

$$S - \boxed{Fe}^{III}OH + H_2O + e^- \rightleftharpoons S - \boxed{Fe}^{II}OH_2 + OH^- \quad [g]$$

where S represents the graphite substrate.

The potential of the Fe^{III}/Fe^{II} redox couple, according to reaction [g], should shift with *p*H as $\Delta E/\Delta pH = -0.059$ V/*p*H. Figure 3 shows a plot of peak potential (peak 1) *vs.* pH. The slope of the linear region is -0.057 V/*p*H, suggesting that a process such as reaction [g] is involved.

The position of peak 2 shifts with *p*H only at low *p*H values. It is not clear what type of process is involved in this case. The voltammetry curves suggest that the

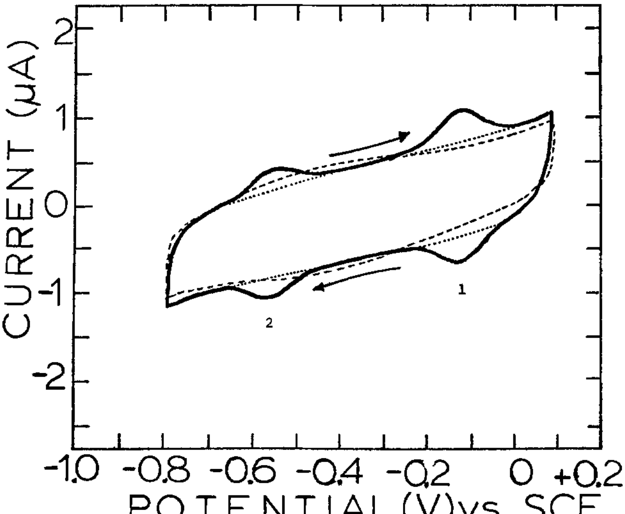

Fig. 2. Cyclic voltammograms with (solid line) and without (dashed line) Fe-TSP pre-adsorbed on SAPG. Supporting electrolyte: 0.1M NaOH, He saturated. Scan rate: 500 mV/sec. (Obtained without hood.)

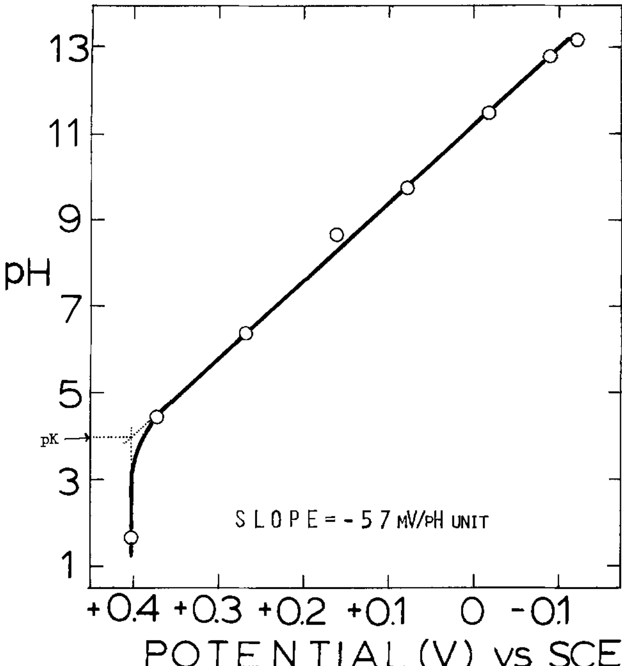

Fig. 3. pH dependence of the potential of peak 1 in the voltammetry (see Fig. 2) for Fe-TSP adsorbed on OPG.

process is reversible. Perhaps in the reduced form the transferred electron is delocalized in the π system of the macrocyclic ligand or alternatively the Fe is in the equivalent of the I valent state. Lever and Wilshire (17) have reported that iron (II) phthalocyanine ($Fe^{II}Pc$) can be electrochemically reduced in non-aqueous solvents to give $Fe^{I}Pc$ in which Fe has been shown to be five coordinated on the basis of its electron spin resonance spectrum.

O_2 reduction on graphite with adsorbed Co-TSP.—The O_2 reduction currents on graphite surfaces other than the basal plane of graphite in alkaline solution are large even in the absence of adsorbed transition metal macrocyclics. This makes the interpretation of the electrocatalytic properties of the Co-TSP adsorbed on these surfaces difficult. On all of these surfaces, the presence of the macrocyclic greatly increases the O_2 kinetic reduction current (i_k). The observed current-voltage curves are compared with and without the adsorbed Co-TSP in Fig. 4. The relatively low apparent limiting current for the basal plane of ordinary pyrolytic graphite is the result of combined diffusion and kinetic control with a potential insensitive chemical step (23).

For a process which is first order in a diffusing reactant, the disk current is related to the rotation rate f by the expression (28)

$$1/i = (1/i_k) + 1/(Bf^{1/2}) \quad [2]$$

where B is related to the diffusion limiting current by

$$i_L = Bf^{1/2} \quad [2a]$$

and is given by

$$B = 0.20\ (D_{O_2})^{2/3}\nu^{-1/6}n\mathbf{F}AC_{O_2} \quad [2b]$$

where D_{O_2} and C_{O_2} are the diffusion coefficient and solubility of O_2, ν is the kinematic viscosity, f is the rotation rate in radians, A is the area, $\mathbf{F}$ is the Faraday, and n is the number of electrons transferred per molecule of O_2 diffusing through the Nernst boundary layer. The plot in Fig. 5 for Co-TSP/SAPG in 0.1M NaOH clearly follows Eq. [2], thus confirming first-order dependence of the kinetics on O_2. Similar behavior has been observed in 0.05M H_2SO_4. This linearity also provides evidence for reasonable uniformity of the current distribution on the disk even at potentials other than

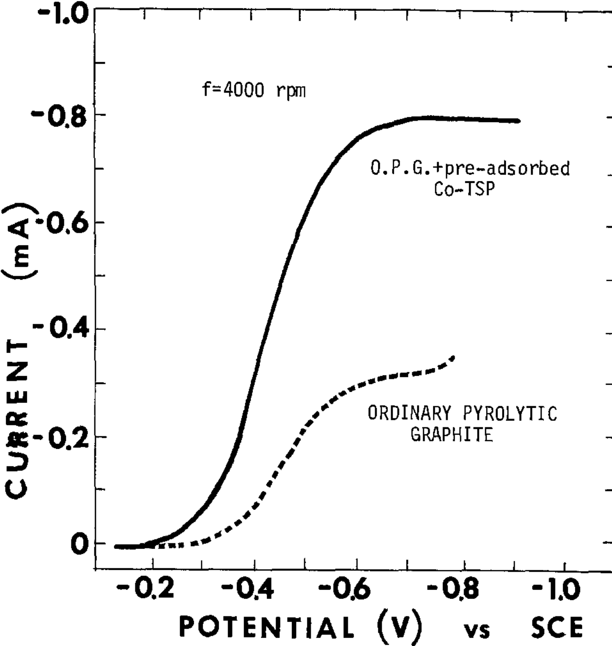

Fig. 4. O_2 reduction in 0.1M NaOH on the rotating disk electrode with (solid line) and without (dashed line) Co-TSP pre-adsorbed on OPG. Rotation rate: 4000 rpm; scan rate: 10 mV/sec.

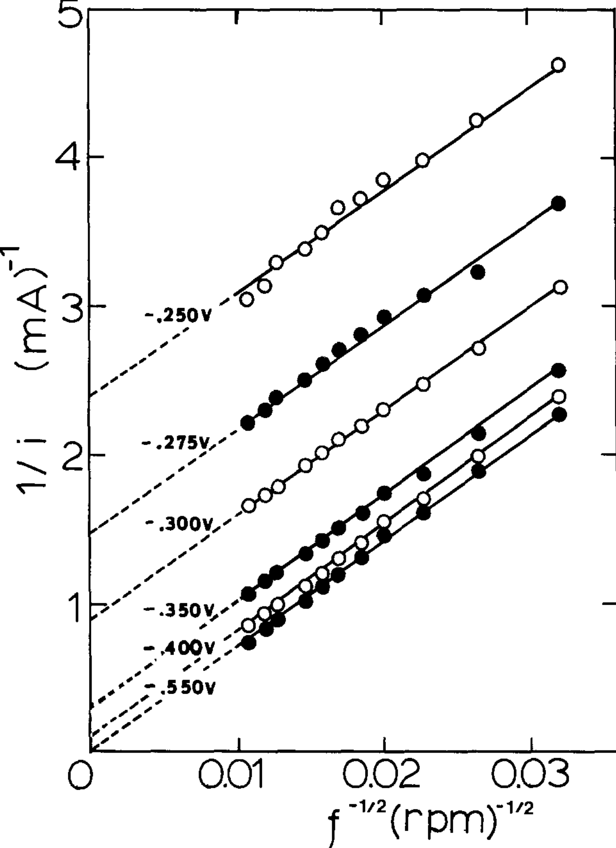

Fig. 5. Plots of $1/I$ vs. $1/f^{1/2}$ for Co-TSP adsorbed on SAPG in 0.1M NaOH + 10^{-6}M Co-TSP.

corresponding to the diffusion limiting value [see discussion in Ref. (29, 32)].

The B values evaluated from the slopes in these plots are 1.47×10^{-2} mA $(\text{rpm})^{-1/2}$, which compares well with the theoretical value of 1.42×10^{-2} mA $(\text{rpm})^{-1/2}$, calculated with Eq. [2b] for $n = 2$, using the following values for both 0.05 H_2SO_4 and 0.1M NaOH: $C_{O_2} = 1.38 \times 10^{-6}$ moles/cm² (24); the diffusion coefficient reported by Gubbins and Walker (25) at 25°C ($D_{O_2} = 1.90 \times 10^{-5}$ cm²/sec) corrected to 20°C ($D_{O_2} = 1.67 \times 10^{-5}$ cm²/sec), using the mean temperature coefficient estimated from the data of Davies, Horvath, and Tobias (26) [$d \ln D_{O_2}/dt = 2.4\%/°C$]; $\nu = 9.97 \times 10^{-3}$ cm²/sec, estimated from the viscosity of 1.002×10^{-2}g cm^{-1} sec^{-1} and density $\rho = 1.005$ g/cm³ (27); and $A = 0.196$ cm². This agreement confirms that the O_2 reduction catalyzed by adsorbed Co-TSP is the $2e^-$ reduction to the peroxide as the main product.

Kinetic data for O_2 reduction in 0.05M H_2SO_4 with Co-TSP adsorbed on various substrates using the rotating disk technique are summarized in Fig. 6. The kinetic current densities have been corrected for diffusion by multiplying by the factor $i_L/(i_L - i)$ where i_L is the diffusion limiting current density obtained directly from the i vs. E plots. The Tafel plots are essentially identical (−155 mV/decade) for all of the substrates except the basal plane of SAPG with a low rocking angle ($\Delta\theta_{1/2} = 0.4°$) for which the slope is −135 mV/decade. The lower slope on this surface may reflect the semiconductor properties (22) which influence the potential distribution at the surface or differences in the ionic double layer for the SAPG basal plane compared to other carbon surfaces.

Figure 7 indicates the Tafel-type plots for O_2 reduction on Co-TSP adsorbed on SAPG of $\Delta\theta_{1/2} = 0.4°$

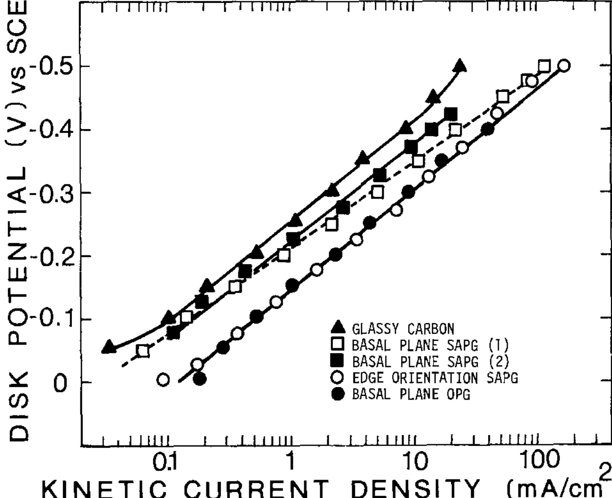

Fig. 6. Tafel plots for O_2 reduction on Co-TSP adsorbed on various carbon surfaces. Kinetic current densities corrected for diffusion. Electrolyte: 0.05M H_2SO_4 + 10^{-5}M Co-TSP; f = 2600 rpm.

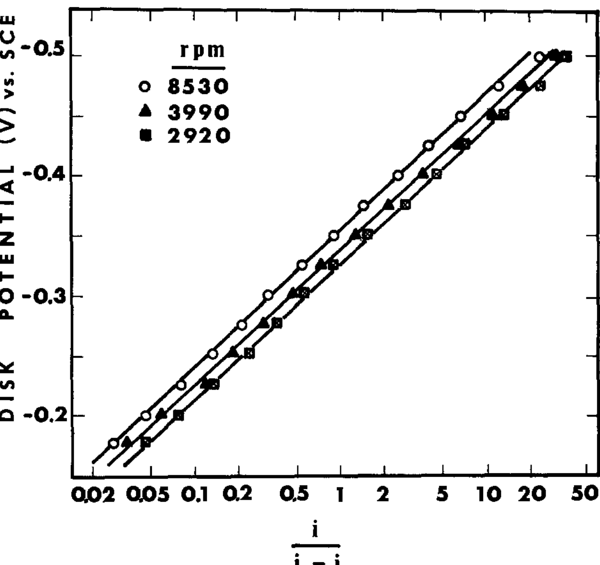

Fig. 7. Tafel plot of log $[i/i_L - i)]$ vs. E for O_2 reduction at various rotation rates for Co-TSP adsorbed on SAPG in 0.1M NaOH.

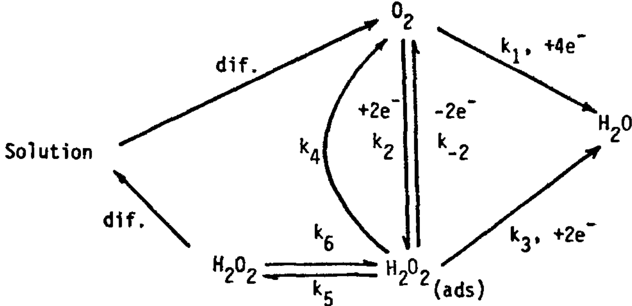
using the correction factor $(I/I_L - I)$ where I and I_L are the current and diffusion limiting current. This factor has been used rather than $[I_L/I_L - I]$ in order that the data for several rotation rates may be clearly represented. The slope is -120 mV/decade at 25°C, corresponding to an apparent $\alpha = 0.5$.

Rotating ring-disk data for Co-TSP adsorbed on OPG is shown in Fig. 8 for 0.1M NaOH. The gold ring was maintained at a potential in the diffusion limiting current range for the oxidation of peroxide (0.10V *vs.* SCE). Difficulty was encountered in obtaining well-defined diffusion limiting currents for peroxide oxidation on the Au ring in 0.05M H_2SO_4 and consequently ring-disk experiments are not reported for this electrolyte.

To analyze the rotating ring-disk electrode data (Fig. 8), consider the following series-parallel reaction scheme for O_2 reduction (19)



The disk-ring current ratio for the O_2 reduction process is as follows

$$NI_D/I_R = 1 + (2k_1/k_2) + X + [k_6/(Z_{H_2O_2}f^{1/2})]X \quad [3]$$

where

$$X = (2k_1/k_2k_5)(k_{-2} + k_3 + k_4) + [(2k_3 + k_4)/k_5] \quad [3a]$$

and

$$Z_{H_2O_2} = 0.62 D_{H_2O_2}{}^{2/3}\nu^{-1/6} \quad [3b]$$

If we assume that adsorption equilibrium exists between H_2O_2 on the electrode surface and in the solution, Eq. [3] becomes (18)

$$NI_D/I_R = 1 + (2k_1/k_2) + [1/Z_{H_2O_2}f^{1/2}]$$
$$[2k'_3 + k'_4 + (2k_1/k_2)(k'_{-2} + k'_3 + k'_4)] \quad [4]$$

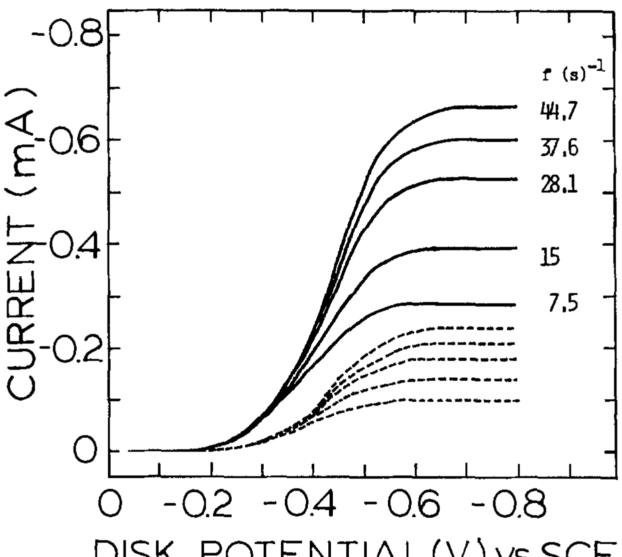


Fig. 8. Rotating ring-disk data for O_2 reduction on Co-TSP preadsorbed on OPG in 0.1M NaOH. Disk current indicated by solid lines; ring current by dashed lines. Scan rate: 10 mV/sec. Ring potential: +0.1V *vs.* SCE. Ring currents are anodic. Collection efficiency: $N = 0.38$.

where

$$k'_{-2} = K_{56}k_{-2}; \quad k'_3 = K_{56}k_3; \quad k'_4 = K_{56}k_4 \quad [4a]$$

with $K_{56} = k_6/k_5$.

The diffusion limiting current for a four-electron reduction of O_2 to yield OH^- or H_2O is given by

$$I'_L = 4AFZ_{O_2}C_{O_2}f^{1/2} \quad [5]$$

where

$$Z_{O_2} = 0.20 D_{O_2}{}^{2/3}\nu^{-1/6} \quad [5a]$$

It should be noted that I'_L is a theoretical value and not directly observed. Combining Eq. [4] and [5] yields (18), we obtain

$$\frac{(I'_L - I_D)N}{I_R} = 1 + \frac{2(k'_3 + k'_4 + k'_{-2})}{k_2} \cdot \frac{Z_{O_2}}{Z_{H_2O_2}} + \frac{2Z_{O_2}}{k_2} f^{1/2} \quad [6]$$

A plot of $(I_D/I_R)N$ *vs.* $f^{-1/2}$ is shown in Fig. 9. The scatter of the points is caused by the expansion of the ordinate, necessary as a result of the surprisingly low slope. This low slope and the closeness of the intercept to unity indicate that very little of the peroxide generated at the electrode is further reduced and that k_1 is small compared to k_2. Further analysis of the data can be done by plotting $(I'_L - I_D)N/I_R$ *vs.* $f^{1/2}$. This graph is shown in Fig. 10. The lines are straight as expected from Eq. [6]. From the slopes it is possible to evaluate k_2. The rate constant k_1 can be evaluated from the intercept in Fig. 9, using Eq. [4]. The scatter of the points in Fig. 9 is too great to permit the independently drawn straight lines through the data to be used to evaluate the intercepts. Consequently all of the lines in Fig. 9 have been drawn through the data with the same slopes. This assumption may not be fully justified and can influence the potential dependence of k_1.

The Tafel slopes evaluated from the E *vs.* log k plots (Fig. 11) are $dE/d \log k_1 = \sim -0.15$ V/decade and $dE/d \log k_2 = \sim -0.12$ V/decade, as compared with an apparent Tafel slope -0.12 V/decade from the E *vs.* log $i/(i_L - i)$ plots (Fig. 7). The slope of the $dE/d \log k_1$ plot, however, is based on the assumption that the slopes in Fig. 9 are not potential dependent. In addition, the uncertainties in the intercepts in this figure are substantial even with this assumption. Most likely the potential dependence of k_1 is essentially the same as that of k_2.

O_2 reduction on adsorbed Fe-TSP.—Figure 12 shows the polarization curves as solid lines obtained at different rotation rates on a ring-disk electrode with a pre-adsorbed layer of Fe-TSP on the OPG disk. The same figure shows the O_2 reduction currents observed on this graphite material without Fe-TSP adsorbed on

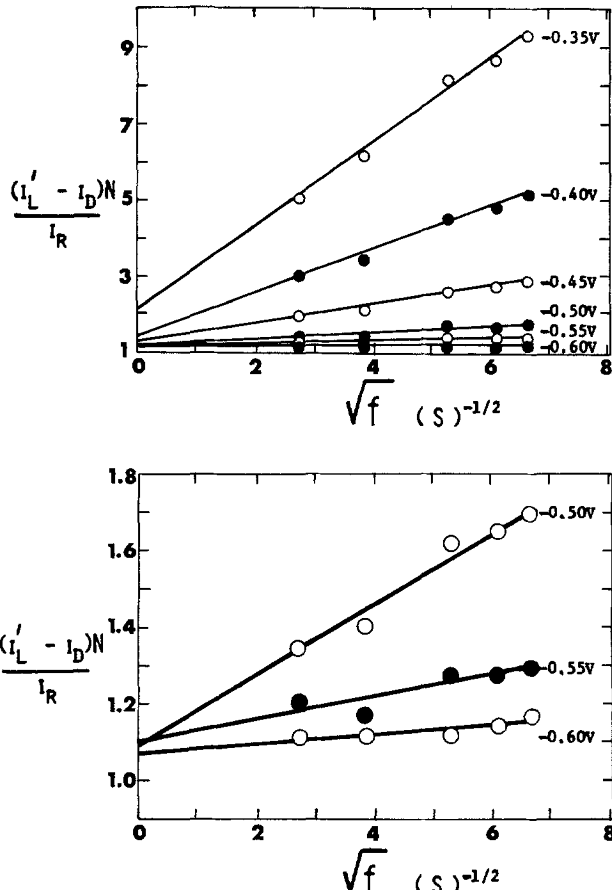

Fig. 10. Plots of $(I'_L - I_D)\ N/I_R$ vs. $1/f^{1/2}$ constructed from ring-disk data in Fig. 8.

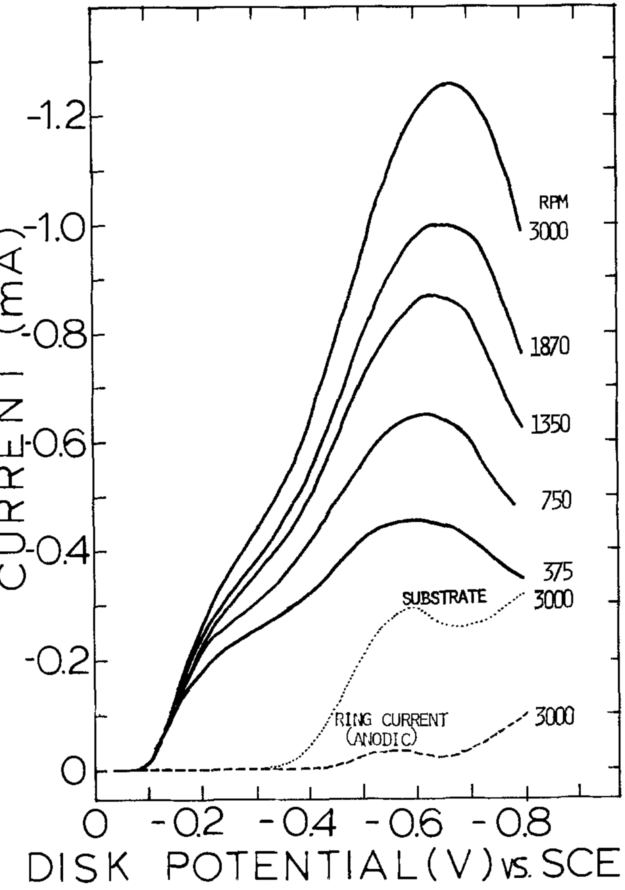

Fig. 12. Rotating ring-disk data for O_2 reduction on Fe-TSP preadsorbed on the disk for OPG. Disk currents in solid lines; ring currents in dashed lines; current on OPG disk without Fe-TSP in dotted line. Electrolyte: 0.1M NaOH. Scan rate: 5 mV/sec. Ring potential: +0.1V vs. SCE. Collection efficiency: $N = 0.38$.

the surface. Also shown is the ring current measured at the diffusion limiting HO_2^- peroxide oxidation condition on the Au ring.

The ring currents at disk potentials more positive than -0.32V are zero, which indicates that the O_2 reduction occurs via four-electrons with no detectable amount of peroxide at those potentials. The small amounts of HO_2^- detected at higher polarizations may be due in part to the O_2 reduction process on zones of the graphite uncovered by the Fe-TSP. The maximum in I_L for the OPG substrate occurs almost at the same potential as that for the Fe-TSP/OPG. On the other hand, the maximum in I_L for the latter is far too pronounced to be caused just by I_L for the substrate. This

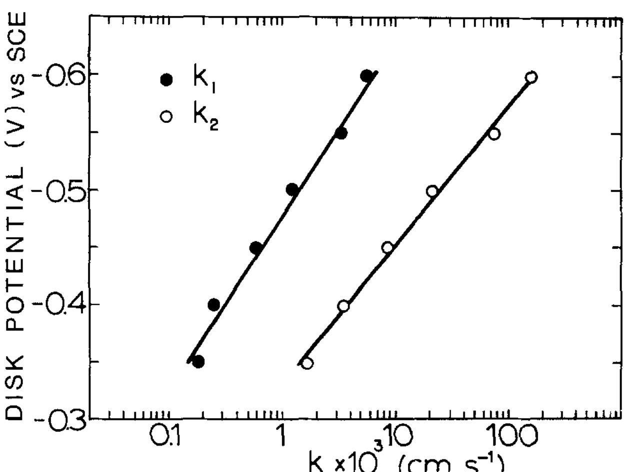

Fig. 11. Potential dependence of the heterogeneous rate constants for the $4e^-$ reduction (k_1) and $2e^-$ reduction (k_2) of O_2 on Co-TSP adsorbed on OPG in 0.1M NaOH.

maximum in I_L for Fe-TSP/graphite correlates well with the second peak in the voltammetry curve (see Fig. 2).

Plots of $1/I$ vs. $1/f^{1/2}$ (Fig. 13) yield parallel straight lines at potentials anodic to the maximum in Fig. 13 as expected for a first-order process on O_2. The currents at -0.6V correspond to pure diffusion control for the $4e^-$ reduction, based on the intercept and slope in Fig. 14 [$B(\text{exp}) = 2.4 \times 10^{-2}$ mA rpm$^{-1/2}$ as compared with $B(\text{theor}) = 2.8 \times 10^{-2}$ mA rpm$^{-1/2}$ for $n = 4$]. The deviation of the points at higher rotation rates and more anodic potentials on Fe-TSP/OPG is not fully explained but may be related to a change in rate-controlling step in this potential region as discussed later.

Plots of $1/I$ vs. $1/f^{1/2}$ for potentials cathodic to -0.6V (Fig. 14) have slopes which increase with potential; *i.e.*, B decreases indicating that the $4e^-$ process tends to revert to a $2e^-$ process. This correlates well with the sharp increase in the production of hydrogen peroxide at these potentials as indicated by the ring currents in Fig. 12 and with the second peak in the voltammetry curves (Fig. 2) which indicates a second reduction process at ~ -0.6V. This reduced form of the catalyst seems to be less effective for the $4e^-$ reduction process.

Figure 15 shows a plot of NI_D/I_R vs. $1/f^{1/2}$ for the potential range where some peroxide is detected. The marked deviation from linear behavior at low values of $1/f^{1/2}$ may be caused by shaft eccentricity, *i.e.*, wobble. Independent of whether the deviations at low values of $1/f^{1/2}$ are real or an experimental artifact, the data indicate a large potential dependent value of NI_D/I_R at infinite rotation rate. This suggests a parallel mechanism. Such behavior appears reasonable since a portion of the ordinary pyrolytic graph-

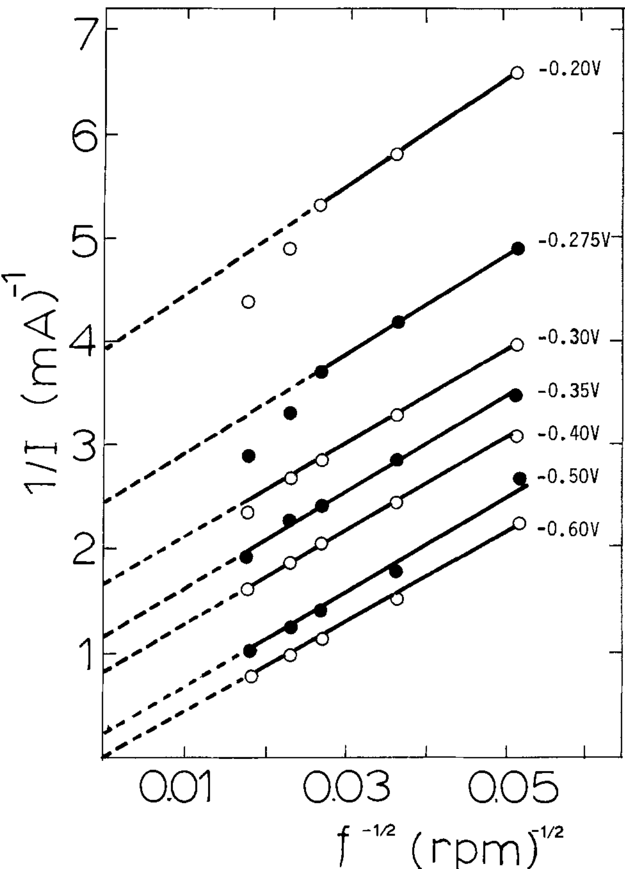

Fig. 13. $1/I$ vs. $1/f^{1/2}$ plot for currents in the potential region more anodic than −600 mV vs. SCE for conditions in Fig. 12.

ite surface is probably not blocked by the adsorbed Fe-TSP and will support the O_2 reduction principally to peroxide. The Fe-TSP may still support at least in part the overall $4e^-$ reduction.

The effect of pH on the O_2 reduction currents on Fe-TSP adsorbed on ordinary pyrolytic graphite was studied and the results are summarized in Tafel plots in Fig. 16. The solubility of O_2 in the different solutions varies slightly and is considerably smaller for the 1M NaOH solution according to the different I_L obtained for a given rotation rate. This will give different concentrations of O_2 for the different solutions used, which will be reflected directly in the currents since the process is first order in O_2. The plots in Fig. 16, however, include a correction for these differences since the parameter $I/(I_L - I)$ is independent of the

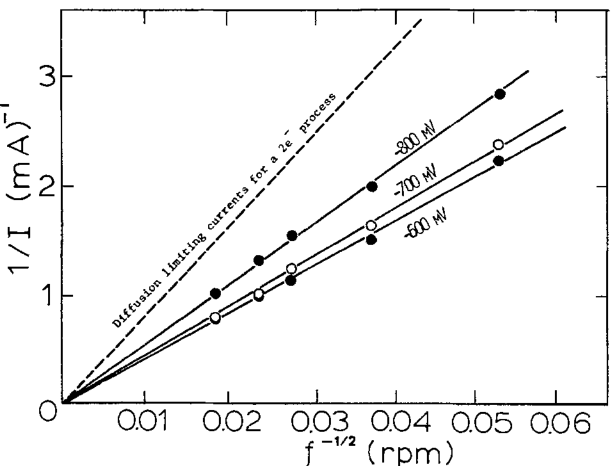

Fig. 14. $1/I$ vs. $1/f^{1/2}$ plot for currents in the potential region more cathodic than −600 mV vs. SCE for condition in Fig. 12.

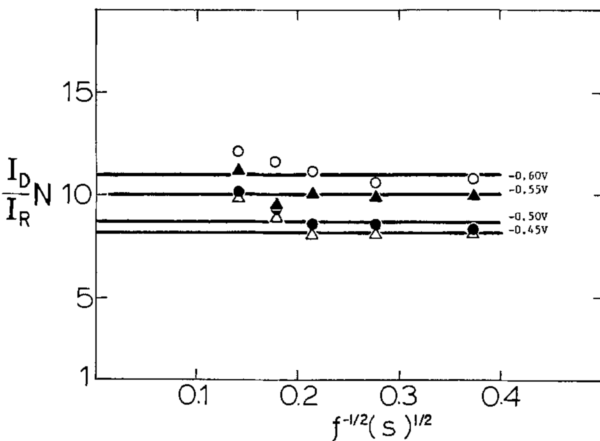

Fig. 15. Plot of NI_D/I_R vs. $1/f^{1/2}$ for various disk potentials for conditions indicated in Fig. 12.

O_2 concentration in solution for first-order kinetics. This is verified in Fig. 17 where data obtained in O_2 and air-saturated solutions also have been plotted in the form $I/(I_L - I)$ vs. E and superimposed.

The linear region of low polarization in Fig. 16 is strongly dependent on pH in contrast to the linear region of high polarization. The slopes of the lines in the pH range 13.8-10.8 are essentially the same and have values in the range −30 to −35 mV/decade. At lower pH values, these slopes increase reaching a value of −65 mV/decade at pH = 4.4. It was not possible to obtain reproducible data at pH values lower than 4.4 since the Fe-TSP complex decomposes when the potential of the electrode is scanned cathodically in acid media. This is accelerated by the presence of O_2 and produces a rapid decrease in activity with time.

Plots of log $[I/(I_L - I)]$ vs. the overpotential $\eta = E - E_{rev}$ (Fig. 18) show some features which are not clearly evident in Fig. 16. Figure 18 shows that the O_2 reduction process becomes more irreversible with decreasing pH (i.e., the process takes place at higher overpotentials in acid media). This is also observed on other carbon surfaces.

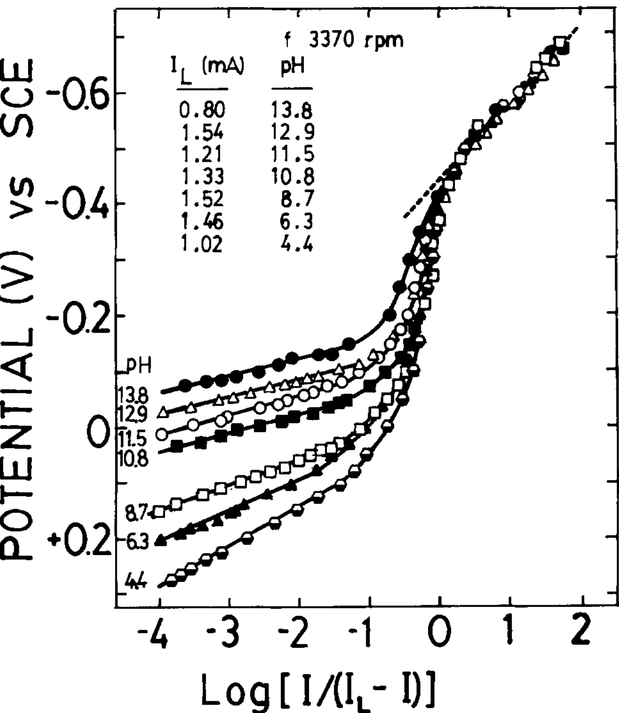

Fig. 16. Tafel plots for O_2 reduction on Fe-TSP adsorbed on OPG in solution of various pH values. Rotation rate: 3370 rpm.

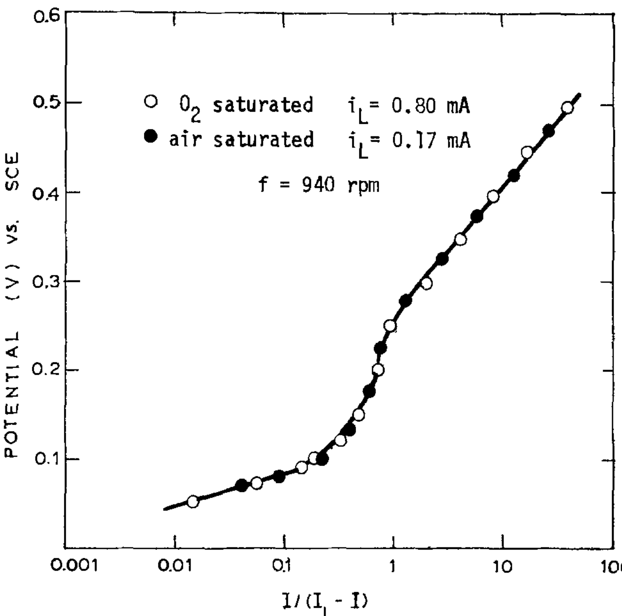

Fig. 17. Tafel plots of log $[I/(I_L - I)]$ vs. E for O_2 reduction on Fe-TSP on OPG using O_2-saturated and air-saturated 0.1M NaOH.

Another interesting feature that is clearly noted in this figure is that a limiting current is reached at log $[I/(I_L - I)] = \sim 0.1$. This limiting current is associated with the pre-wave observed in the polarization curves (see Fig. 12). This current is independent of pH for the whole range studied, and independent of potential and first order in O_2 concentrations. A chemical limiting process with essentially potentially independent kinetics appears to be involved.

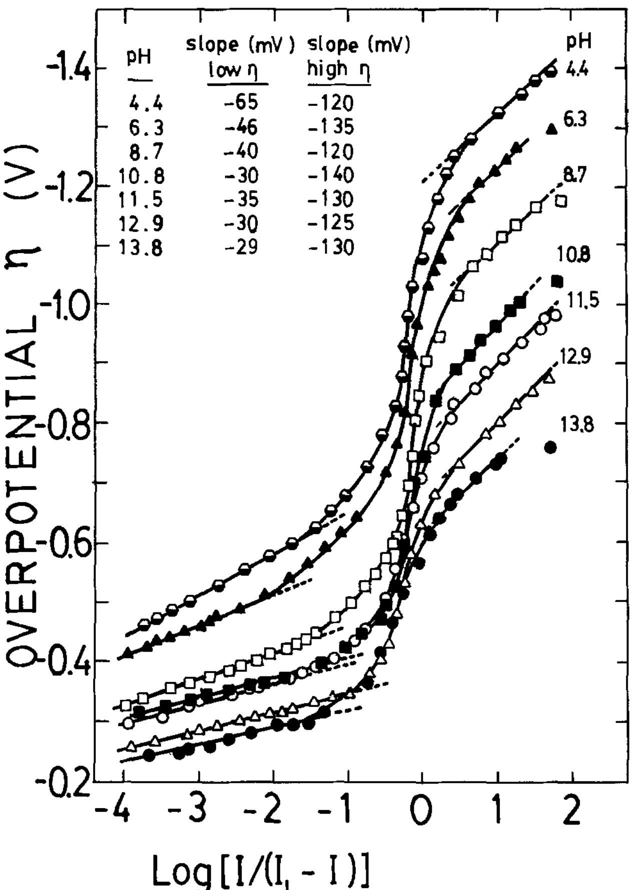

Fig. 18. Tafel plots of overpotential vs. log $[I/(I_L - I)]$. Conditions are the same as for Fig. 16.

Reaction order in OH^- at low polarization on adsorbed Fe-TSP.—Since the reaction is first order in O_2 concentration and the activity of water for the solutions of different pH is essentially constant, the rate of the reaction expressed as a kinetic current is

$$I_K = k[O_2][OH^-]^m \qquad [7]$$

with the back reaction negligible. From Eq. [7] the reaction order for OH^- is

$$m = \left(\frac{\partial \log I_K}{\partial \log [OH^-]}\right)_E = \left(\frac{\partial \log [I/(I_L - I)]}{\partial \log [OH^-]}\right)_E \qquad [8]$$

where I_K is given by

$$I_K = I_L \frac{I}{(I_L - I)} \qquad [9]$$

for a first-order reaction in O_2

The plots of log $[I/(I_L - I)]$ vs. log $[OH^-]$ for the low polarization-Tafel linear region in Fig. 18 yield straight lines in the pH range from 13.8 to 10.8 (Fig. 19). In some instances it was necessary to extrapolate the low polarization-Tafel linear region to lower and higher values of $I/(I_L - I)$ to obtain the data in Fig. 19.

The slopes of the linear portion of the curves in this figure range from -0.87 to -1.1 indicating a reaction order of -1 for OH^-. For pH values lower than 10.8 the order in OH^- decreases numerically. This correlates with an increase of the slope at low pH values in the Tafel plot of Fig. 16.

Plots of the potential vs. pH for constant $I/(I_L - I)$ values in the low polarization-Tafel linear regions yield straight lines for high pH values (13.8-8) with a slope of -30 mV/pH unit. This is compatible with a Tafel slope of -30 mV/decade and $m = -1$.

O_2 reduction on Fe-TSP adsorbed on SAPG.—Essentially the same behavior has been observed for the disk currents for O_2 reduction on Fe-TSP adsorbed on SAPG. On the basis of the observed B values, the O_2 reduction appears to proceed virtually entirely by the overall $4e^-$ process without any peroxide generation at potentials anodic to -0.5V. The B values indicate that peroxide generation becomes quite substantial at more cathodic potentials. O_2 reduction to peroxide or OH^- ion is grossly inhibited on the basal plane in the absence of the adsorbed complexes. Consequently this provides evidence that much of the peroxide is generated on the adsorbed Fe-TSP at more cathodic potentials and not just on the exposed graphite surface.

Tafel plots of log $[I/(I_L - I)]$ vs. E are given in Fig. 20 for Fe-TSP adsorbed on the basal plane of both SAPG and OPG. The chemical limiting currents are about eight times smaller for the SAPG than for

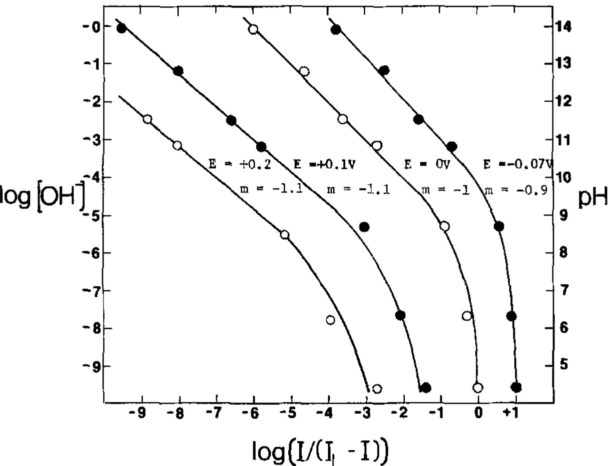

Fig. 19. Plots of log $[I/(I_L - I)]$ vs. log $[OH^-]$ for values of $I/(I_L - I)$ taken from the Tafel linear region of low polarization in Fig. 16, extrapolated, if necessary, at a constant potential.

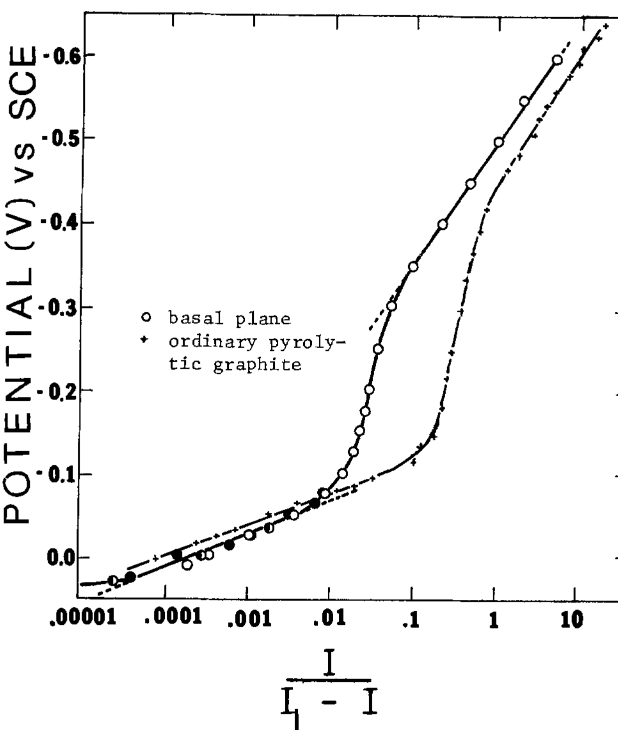

Fig. 20. Tafel plot of log $[I/(I_L - I)]$ vs. E for O_2 reduction in Fe-TSP adsorbed on SAPG and OPG at f = 3000 rpm in 0.1M NaOH.

the ordinary pyrolytic graphite and about twofold smaller for the high polarization-Tafel linear region, but almost the same for the low polarization Tafel linear region.

From the cyclic voltammetry curves for these two surfaces the surface concentration of Fe-TSP on the SAPG is about four to five times smaller than that observed on ordinary pyrolytic graphite, expressed in terms of superficial area.

Discussion

O_2 reduction on Fe-TSP.—On the basis of the experimental results for O_2 reduction on Fe-TSP adsorbed on the basal planes of SAPG and OPG, the mechanisms of O_2 reduction at low and high polarization are not the same. Evidence for this is the different Tafel slopes and pH dependence. The reaction at low polarization is strongly dependent on pH and has an order of −1 in OH^- ions over the pH range 13.8-10.8. In contrast, the process at high polarization is practically pH independent over the entire range studied (13.8-4.4). Both processes are first order in O_2.

The current potential data can be deconvoluted into two component processes as shown in Fig. 21. The experimental current density i corresponds to the sum of the values for each individual process, *i.e.*, i(total) $= i_a + i_b$. The process corresponding to i_b has been assumed to follow Tafel linearity only at more cathodic potentials and to approach zero current at potentials negative to the reversible value for the overall $4e^-$ reduction in order to fit the experimental data. Such behavior may occur if process b corresponds to a hydrogen peroxide producing reaction with the bulk peroxide concentration finite but very low (*e.g.*, 10^{-7}M). Small residual currents were observed on the ring after several cathodic potential sweeps, providing evidence for such peroxide. The curve corresponding to i_b then approaches the reversible potential for the O_2/HO_2^-, OH^- couple for whatever is the bulk concentration of HO_2^-.

Mechanism at low polarization at pH > 8 (mechanism I).—The more anodic peak in the voltammetry curves

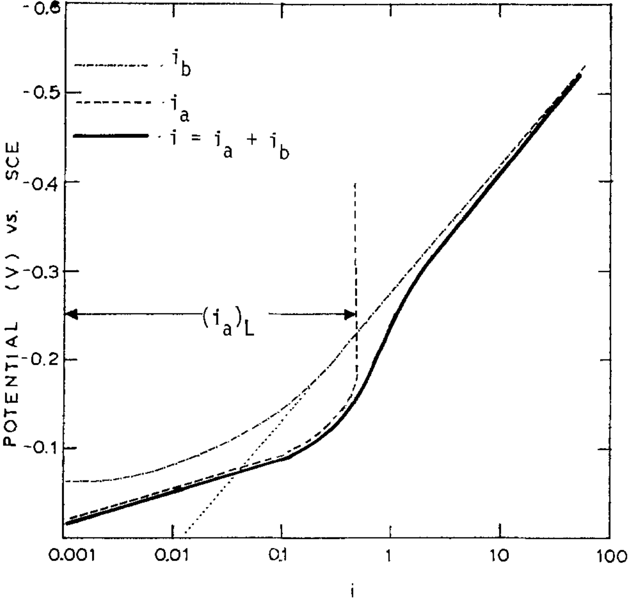

Fig. 21. Graphical representation of the combination of two processes for O_2 reduction on adsorbed Fe-TSP in basic media.

for Fe-TSP in Fig. 2 occurs at potentials in the low polarization region (Fig. 16) where deviations from Tafel linearly become evident. This suggests an involvement of the $[Fe(III)OH\,TSP]_{ads}/[Fe(II)\,TSP]_{ads}$ couple in the reaction mechanism responsible for this portion of the polarization curves. The following mechanism explains the O_2 reduction kinetics at pH > 8 for the region below the apparent chemical limiting current, corresponding to component i_a in Fig. 21

$$Fe^{III}OH_{ads} + e^- \rightleftharpoons Fe^{II}_{ads} + OH^- \quad \text{fast} \quad [i]$$

$$Fe^{II}_{ads} + O_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (Fe^{III} - O_2^-)_{ads} \quad \text{fast} \quad [j]$$

$$(Fe^{III} - O_2^-)_{ads} + e^- \underset{\text{rds}}{\overset{k_3}{\longrightarrow}} \text{intermediates} \quad \text{slow} \quad [k]$$

where the TSP groups have not been shown for simplicity. Reaction [k] would then be followed by further fast steps yielding finally OH^- as the product of the O_2 reduction with a total of $4e^-$ per O_2 consumed. For this reaction scheme, the rate of the reaction expressed as a current density is given by

$$i_a = 4Fk_3[Fe^{III} - O_2^-] \exp\left[-\frac{\alpha F}{RT}(E - E_o)\right] \quad [10]$$

where $[Fe^{III} - O_2^-]$ is the surface concentration of this adsorbed species, α is the symmetry factor, and k_3 is the rate constant at the standard electrode potential for reaction [k]; *i.e.*, at $E = E_o$.

Applying the Nernst equation to reaction [i] and assuming ideal behavior

$$E + E_o - \frac{RT}{F}\ln\frac{[Fe^{II}](OH^-)}{[Fe^{III}OH]} \quad [11]$$

where [ ] represents surface concentration and ( ) solution phase concentration. Brown and Anson (20) have called attention to the deviation of adsorbed complexes from Nernst behavior when using concentrations rather than activities or coverage-dependent standard free energies or E_o values (*i.e.*, non-Langmuir behavior). The deviations, however, should be small in the present work since the concentration of the adsorbed macrocyclic and, hence, the change in charge density are low.

The surface concentration of the Fe species can be expressed in terms of coverage θ, *i.e.*

$$[Fe^{II}] = \theta m; \quad 0 < \theta < 1 \quad [12]$$

$$[Fe^{III}OH] = (1 - \theta)m \quad [13]$$

where m is the total surface concentration of Fe-TSP species. Introducing Eq. [12] and [13] into Eq. [11] and solving for θ

$$\theta = \frac{(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)}{1 + (OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)} \quad [14]$$

Assuming steady state for step [j], the concentration of $[Fe^{III} - O_2^-]$ adsorbed species is given by

$$[Fe^{III} - O_2^-] = \frac{\vec{k}_2[O_2]\theta m - i_a}{\overleftarrow{k}_2} \quad [15]$$

Replacing $[Fe^{III}O_2^-]$ in Eq. [10] with Eq. [15], replacing k_3/k_{-2} by K and rearranging

$$i_a = 4\mathbf{F}k_2(O_2)\theta m \frac{K \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o)}{1 + K \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o)} \quad [16]$$

When $\theta \rightarrow 1$ and $K \exp \frac{-\alpha\mathbf{F}}{RT}(E - E_o) >> 1$, then i approaches a limiting value, given by

$$(i_a)_L = 4\mathbf{F}k_2(O_2)m \quad [17]$$

The coverage θ of Fe^{II}-TSP approaches one at potentials cathodic to E_o, *i.e.*, all Fe-TSP on the surface becomes Fe^{II}-TSP. For example, when $E - E_o = -0.1V$, $\theta = 0.93$; and when $E - E_o = -0.2V$, $\theta = 0.999$.

Combining Eq. [10]-[16] and rearranging

$$i_a = (i_a)_L \frac{(OH^-)^{-1}K \exp - \left[(1 + \alpha)\frac{\mathbf{F}}{RT}(E - E_o)\right]}{\left[1 + (OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)\right]\left[1 + K \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o)\right]} \quad [17a]$$

This equation predicts the essential features of the experimental data below the high polarization-Tafel linear region in the pH range from 8.7 to 13.8. The reaction rate is first order in (O_2), -1 in (OH^-), and predicts a limiting current density $(i_a)_L$ that is directly proportional to O_2 concentration and to Fe-TSP surface concentration and independent of pH. The quantity $(i_a)_L$ is not a diffusing limiting current density, but is due to a potential insensitive chemical process, reaction [j], which becomes rate controlling when the Fe^{II} species approach saturation and the cathodic polarization has increased the rate of reaction [k] to a relatively high value. According to this proposed mechanism, the Tafel slope for the linear Tafel region of i_a should be $-RT/[(1 + \alpha)\mathbf{F}]$. The value of the slope will depend on the value of α. For $\alpha = 0.5$ the slope is $-RT/(1.5\mathbf{F})$ or -40 mV/decade and for $\alpha = 1$ is $-RT/(2\mathbf{F})$, or -30 mV/decade as compared with an experimental value of ~ -35 mV/decade. A Tafel linear region of slope $-RT/[(1 + \alpha)\mathbf{F}]$ should be observed only if both terms $(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)$ and $K \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o)$ are small compared to unity. If either term becomes much larger than unity while the other is still very small compared to unity, a second Tafel linear region of higher slope should be observed. For $(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o) >> 1$ and $K \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o) << 1$, then the Tafel slope of $-RT/(\alpha\mathbf{F})$ or ~ -120 mV/decade would be expected while for the reverse situation, the slope should be -60 mV/decade. Neither of these slopes has been observed at high pH. The limiting current $(i_a)_L$ is achieved with a gradual change in the slope and an intermediate linear region is not observed. It is possible that the log linear region occurs only close to the limiting current $(i_a)_L$ over too small a potential range to be evident.

Acid-base equilibrium of Fe-TSP.—At more acid pH it is necessary to consider the acid-base equilibrium

$$Fe^{III}OH^- \overset{K_B}{\rightleftharpoons} Fe^{III} + OH^- \quad [l]$$

The redox process may be represented as

$$\begin{array}{ccc} Fe^{III}OH & \overset{e^-}{\rightleftharpoons} & Fe^{II} + OH^- \\ \Updownarrow K_B & \nearrow\!\!\swarrow e^- & \\ Fe^{III} + OH^- & & \end{array} \quad [m]$$

or alternatively

$$\begin{array}{ccc} Fe^{III} - OH^- + H^+ & \overset{+e^-}{\rightleftharpoons} & Fe^{II} + H_2O \\ \Updownarrow K_A & \nearrow\!\!\swarrow +e^- & \\ Fe^{III} + H_2O & & \end{array} \quad [n]$$

with

$$K_B = \frac{[Fe^{III}](OH^-)}{[Fe^{III}OH]} = \frac{1 - x}{x}(OH^-) \quad [18]$$

with x the fraction of the surface adsorbed Fe^{III} complex as $Fe^{III}OH$. Solving for x

$$x = \frac{(OH^-)/K_B}{1 + (OH^-)/K_B} \quad [19]$$

Expressing the concentrations as coverage, the Nernst equation for reaction [m] becomes

$$E = E_o - \frac{RT}{\mathbf{F}} \ln \frac{\theta(OH^-)}{(1 - \theta)x} \quad [20]$$

Solving Eq. [20] for θ

$$\theta = \frac{x(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)}{1 + x(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)} \quad [21]$$

Mechanism at low polarization in acid media (mechanism II).—It is possible that the uptake of O_2 by Fe^{II} becomes rate controlling when the pH of the solution is lowered. The following mechanism for acid media is proposed

$$[Fe^{II}] + O_2 \overset{k_2}{\rightharpoonup} [Fe^{III}O_2^-] \quad \text{slow} \quad [n]$$

$$[Fe^{III}O_2^-] + H^+ + e^- \rightarrow \text{intermediate} \quad \text{fast} \quad [o]$$

where Fe^{II} is generated by reaction [m]. The rate of the reaction expressed as a current is

$$i_a = 4\mathbf{F}k_2[Fe^{II}](O_2) \quad [22]$$

Expressing $[Fe^{II}]$ as coverage, using θ from Eq. [21], and replacing $4\mathbf{F}k_2m(O_2)$ by $(i_a)_L$ as before, the final expression becomes (21)

$$i_a = (i_a)_L \frac{x(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)}{1 + x(OH^-)^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)} \quad [23]$$

This mechanism predicts a Tafel slope of $-\mathbf{F}/RT$ or -60 mV/decade at 25°C. It also predicts a limiting current directly proportional to (O_2) and to the surface concentration of [Fe-TSP] species. This limiting current is independent of pH.

The terms x and $(OH^-)^{-1}$ are interdependent according to Eq. [19]. At alkaline pH values, $[OH^-] >> K_B$ and x in Eq. [19] becomes unity. At more acid pH values, the behavior of Eq. [19] will depend on the value of K_B. Figure 3 predicts an approximate value for the acid dissociation constant of $K_A \approx 10^{-4}$ and hence $K_B \approx 10^{10}$.

When $(OH^-) = \sim 10^{-10}M$, $x = 0.5$ and when $(OH^-) << K_B$, $x = 0$. According to this, at $pH < 4$ Eq. [20] becomes independent of (OH^-), and

$$x(OH^-)^{-1} = \frac{1/K_B}{1 + (OH^-)/K_B} = 1/K_B \quad [24]$$

Equation [23] becomes

$$i_a = (i_a)_L \frac{K_B^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)}{1 + K_B^{-1} \exp - \frac{\mathbf{F}}{RT}(E - E_o)} \quad [25]$$

Equations [19] and [23] fit the experimental observation (Fig. 19) that, at low pH, i_a has relatively little or no pH dependence.

Mechanism I and II are expected to be competitive in the pH range between 10 and 4. This would explain the gradual change in the Tafel slope over this pH range. Equations [19] and [23] do not include a correction for the mass transport of O_2 to the electrode surface. This correction is small in the current range where i_a is predominant. At high current densities the correction can be made with the equation

$$(O_2) = \frac{(i_L - i)}{i_L}(O_2)_{bulk} \quad [26]$$

where i_L corresponds to the diffusion limiting current density. At more cathodic potentials the fraction of the current corresponding to peroxide generation becomes quite substantial. Since this fraction is potential dependent, i_L also becomes potential dependent. The value at any particular potential can be evaluated from the B values calculated from the $1/I$ vs. $1/f^{1/2}$ plots (Fig. 14).

Mechanism at high cathodic polarizaztion (mechanism III).—Tafel slopes close to -120 mV/decade observed at high polarizations strongly suggest that a first one-electron transfer step becomes rate controlling at those potentials with mechanistic features analogous to those for Co-TSP. The process becomes practically pH independent as shown in the Tafel plots of Fig. 16. The rate of reaction can then be expressed by

$$i_b = 4\mathbf{F}km\theta(O_2) \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o) \quad [27]$$

or

$$i_b = 4\mathbf{F}km\theta(O_2)_{bulk} \frac{i_L - i}{i_L} \exp - \frac{\alpha\mathbf{F}}{RT}(E - E_o) \quad [27a]$$

where Eq. [27a] contains the correction for mass transport of O_2 from the data.

The pH independence of the process indicates that protons or OH^- ions are not involved before or in the rate-determining step.

A mechanism which explains the behavior at high polarization is as follows

$$(M^{II} - TSP)_{ads} \xrightarrow{O_2} [(M^{III} - TSP) - O_2^-]_{ads} \quad \text{fast} \quad [p]$$

$$[(M^{III} - TSP) - O_2^-]_{ads} \xrightarrow{e^-} [(M^{II} - TSP) - O_2^-]_{ads} \quad \text{slow} \quad [q]$$

$$[(M^{II} - TSP)] - O_2^-]_{ads} \xrightarrow[HOH]{e^-} (M^{II} - TSP)_{ads} + O_2H^- \quad \text{fast} \quad [r]$$

Reactions [p] and [q] may be either separate steps as shown or a single step. This same mechanism probably is also operative for O_2 reduction on $(Co\text{-}TSP)_{ads}$ and is to be preferred to the mechanism suggested earlier (9) since it accounts for the zero reaction order dependence on OH^- ion concentration.

A redox mechanism similar to mechanisms I and II is not observed on the adsorbed Co-TSP. This is probably related to the differences in the redox properties of Fe-TSP and Co-TSP. At pH 1, the Co^{II}/Co^{III}-TSP couple occurs at +0.78V vs. SCE and the Fe^{II}/Fe^{III} couple at +0.40V. Therefore it should be much easier for O_2 in binding to the transition metal of the TSP complex to oxidize Fe^{II} to Fe^{III} than Co^{II} to Co^{III}.

Some caution must be exercised in comparing the behavior of the adsorbed M-TSP at monolayer levels with that of thick layers of the corresponding phthalocyanine on carbon substrates or that of the bulk complex. Nonetheless, the experimental results of the present study may explain the different Tafel slopes found by various authors for O_2 reduction on metal chelates. For example, the Tafel slopes reported for O_2 reduction on iron complexes at ~25°C include -30 (6-8), -45 (30), and -60 (31) mV/decade. For cobalt chelates, slopes of -40 (37), -60 (4), and -120 (9, 10, 30, 33) mV/decade have been found. On the basis of the present work, this distribution of Tafel slopes appears to result from differences in the redox potentials and pK's of the couples and pH of the electrolytes. Despite the obvious importance of the redox properties of the surface species, relatively few authors have placed much emphasis on them in their studies (see, *e.g.*, 2-4, 34).

Manassen and Bar-Ilan (2) measured the redox potentials of metal phthalocyanines by solubilizing them in tetrabutyl ammonium perchlorate solutions. Randin (3) used the data for the homogeneous couple to rationalize the catalytic behavior of transition metal phthalocyanines in alkaline solutions. Aside from the question of the redox potentials for the heterogeneous vs. homogeneous Fe phthalocyanine couple, the difference in pH is expected to shift the potential very substantially. Similar behavior has been observed for iron porphyrins (35) and vitamin B-12 (36).

Appleby and Savy (6-8) have reported Tafel slopes of -30 mV/decade for O_2 reduction on layers of Fe phthalocyanine on carbon in alkaline media with an OH^- reaction order of -1. This is similar to the results found in the present work with Fe-TSP on graphite. It is very likely that the potential of the Fe^{II}/Fe^{III} phthalocyanine couple falls in the same range of potential where these slopes are observed. A recently reported value for the Fe^{II}/Fe^{III} phthalocyanine couple by Beck (4) at $pH = 0$ is +0.7V vs. SHE. If we assume that the pK_A of $Fe^{III}Pc\text{-}OH$ is approximately 4, then at $pH = 14$ the redox potential for iron phthalo-

cyanine should be approximately +0.10V, which is in the region of the −30 mV/decade slope.

In summary the present study provides an explanation for the different experimental results reported in the literature in terms of:

1. One mechanism is predominant for alkaline media with a Tafel slope close to $\mathbf{F}/2RT$ and another mechanism is predominant in acid media with a Tafel slope close to $\mathbf{F}/RT$. These two mechanisms can become competitive at intermediate *p*H values. This explains the gradual increase of the slopes at more acid *p*H values found by several authors (6-8, 37) and in the present work. These two mechanisms are controlled by the M^{II}/M^{III} couples and are only observed when the potential of these redox couples is close to that where O_2 reduction takes place. This is the case for Fe-TSP and on the basis of literature data also for Fe-Pc and Co-TAA (6, 8, 37).

2. At potentials far cathodic to those of the transition metal redox couple, a redox type of mechanism is not operative since all of the catalyst is in the lower valency state and the chemical step $M^{II} + O_2 \rightarrow M^{III}O_2^-$ does not occur because the formation of the M^{III} species is thermodynamically unfavorable even in the O_2 adduction. In this case a first one-electron transfer step becomes rate controlling via a different pathway, and the Tafel slopes are close to $RT/(\alpha\mathbf{F})$ (−120 mV/decade for $\alpha = 0.5$). This is the case for adsorbed Fe-TSP and Co-TSP in the present study and for Co-TAA, Co-Pc, Ni-Pc, and Cu-Pc reported in the literature (30, 33, 37).

The Nature of Surface States on Chemically Modified TiO_2 Electrodes

Micha Tomkiewicz*,[1]

Union Carbide Corporation, Tarrytown Technical Center, Tarrytown, New York 10591

ABSTRACT

Two important parameters which strongly influence the flatband potential of a semiconductor in electrolytic solutions are the electron affinity of the semiconductor and the net charge on the surface. An attempt to modify these parameters by chemical derivatization of the surface of the semiconductor will be described. When the surface of TiO_2 is modified with alkylsilanes, impedance and photocurrent measurements indicate that surface states are introduced at the semiconductor-electrolyte interface. These states have broad Gaussian distribution, with a maximum near the bottom of the conduction band. The states act as effective recombination centers for light-generated minority carriers. When the alkylsilane is derivatized with a phosphonate group, the Gaussian distribution of the states is retained but with reduced width, and the maximum is shifted considerably to more positive potentials. These states do not act as recombination centers. An attempt also was made to change the electron affinity of the surface by fluorination. The only measured result was an increase in surface recombination of minority carriers, which resulted in a decrease in the anodic photocurrent.

The position of the flatband potential of a semiconductor in contact with an electrolyte, relative to the oxidation-reduction potential of the solvent, is one of the key parameters determining the solar energy conversion efficiency of a photoelectrolytic cell (1).

According to Butler and Ginley (2) the electron affinity E_e and the flatband potential U_{FB} are related by

$$E_e = E_o - E_{FC} + e(U_{FB} + V_c) \quad [1]$$

where E_o is the difference between the vacuum level and the reference electrode (4.5 eV for SHE), E_{FC} is the energy difference between the Fermi level and the bottom of the conduction band in the bulk of the semiconductor, and V_c is a correction to the flatband potential due to absorption of charges on the surface. The last term vanishes if the measurements can be made at, or corrected to, the zero point of charge (ZPC). Butler and Ginley found very good agreement between the measured flatband potentials for oxides and the values calculated by Eq. [1] from electron affinities and measured ZPC values.

This paper describes our first effort at influencing the potential distribution at the semiconductor-electrolyte interface relative to the potential of the hydrogen electrode in the actual environment in which photoelectrolysis takes place. We chose TiO_2 as the semiconductor because its behavior in photoelectrochemical cells is the best understood; its bulk and surface properties have been extensively studied and its reported flatband potential is only a small fraction of a volt too positive for efficient photoelectrolysis under short-circuit conditions (1, 3). The strategy was to attach chemically functional groups on the surface and to monitor the effects of those groups on the potential distribution and on the light-induced anodic photocurrent.

A detailed study of the potential distribution at the unmodified TiO_2/aqueous electrolyte interface is reported separately (3, 4). For an effective improvement in the performance of a photoelectrolytic cell a modified surface has to meet the following conditions:

1. The modified surface has to be stable in the dark and under photoelectrolytic operation.
2. The oxidation-reduction potential of the attached group has to be significantly more positive than the potential of the oxygen electrode, so that light-generated holes will tend to oxidize water and not the functional groups.
3. It should not act as a surface recombination center for the light generated minority carriers.
4. The modified surface should not add a potential barrier or a resistive layer to the cell.
5. The modified surface should be negatively charged at a potential more positive than the oxygen potential.

Thus we seek a chemically attached monolayer of acidic groups with the pK much lower than water that will oxidize at potentials more positive than +1.23V *vs.* SHE and that will not form a recombination center.

Fortunately during the last few years an extensive research effort has been carried out aimed at derivatization of electrode surfaces by chemical modification (5-46). Some of the efforts in this area already have been applied to photoelectrochemical systems (40-46). Based on the expected stability we have limited our choice to silane derivatives (5, 6, 11, 12). A variety of functional groups can be synthesized and attached to the surface.

A demonstrative example of such an attachment is illustrated with the following reaction

$$TiO_2]\text{—}OH + (E_tO)_3 - Si\,CH_2\,CH_2\,\overset{\overset{\displaystyle O}{\|}}{P}\,(OE_t)_2$$

Y5727

↓ anhydrous conditions

$$TiO_2]\text{—}O - \underset{|}{\overset{|}{Si}} - CH_2\,CH_2\,\overset{\overset{\displaystyle O}{\|}}{P}\,(OE_t)_2$$

↓ H_2O

$$TiO_2]\text{—}O - \underset{|}{\overset{|}{Si}} - CH_2\,CH_2\,\underset{\underset{\displaystyle OE_t}{|}}{\overset{\overset{\displaystyle O}{|}}{P}} - O \left(\text{or} - CH_2\,\underset{\underset{\displaystyle O^-}{|}}{\overset{\overset{\displaystyle O}{\|}}{P}} - O^-\right) \quad [2]$$

The net result is the replacement of an —OH group by

* Electrochemical Society Active Member.

Key words: solar, impedance, semiconductor, interface.

$$\begin{array}{c} O \\ \| \\ -P-OH \\ | \\ OH \end{array}$$ group.

The ZPC for TiO_2 in the rutile form was reported to be at $pH = 5.8$ (47). The first pK_a of phosphoric acid is 2.12. If we assume that the ionization constant of phosphoric acid does not change with the substitution of the silane group and the attachment to the surface of the semiconductor, the result should be changed in the ZPC from 5.8 to 2.1 which will result in a negative shift of 225 mV in the flatband potential. Larger shifts can be expected from acidic groups with lower pK attached to semiconductors with a higher ZPC.

Alkylsilanes were used to investigate the interactions of the —Ti—O—Si— functional group with the minority and majority carriers in the semiconductor.

In addition, we will describe an attempt to change the electron affinity of the semiconductor at the surface by surface fluorination.

Experimental

TiO_2 single crystals were purchased from Atomergic and sawed perpendicular to the c axis. The resulting wafers (1 mm thick) were mechanically polished, etched in NaOH at 500°C for 1 hr, rinsed in running distilled water, boiling HCl, and washed again. The wafers were doped with an H_2/Ar mixture at 600°C for 30 min. The alkyl silanes were purchased from Petrarch Systems and distilled in vacuum. Toluene was distilled over Na in benzophenone. The diethyl [(β-triethoxysilyl) ethyl] phosphonate (Y5727) was kindly donated by Dr. K. G. Weinberg from the Chemical and Plastic Division of Union Carbide. The samples were reacted with silane derivatives in the apparatus shown in Fig. 1 which is based on a similar design by Cullen *et al.* (32). The procedure for electrode modification is similar to the one used by Murray *et al.* (6). Two samples were introduced into the modification apparatus and soaked in heptane overnight, then heated to 450°C for 4 hr in flowing Ar. One of the samples was soaked in 5% silane in toluene. Both samples were washed extensively with dry toluene, dried in flowing Ar for 30 min at room temperature, washed in distilled water, and dried with forced air.

The samples modified with alkylsilanes changed from hydrophylic to hydrophobic and the contact angle formed between the surface and a small drop of water served as the initial indication of the attachment of the alkylsilane to the surface.

ESCA-Auger analyses of the surfaces were performed using a Physical Electronics Model L 550 SAM-ESCA System spectrometer equipped with an Mg x-ray excitation source. All spectra were run at pressures less than 2×10^{-8} Torr. ESCA spectra signal averaging was performed using a Nicolet Model NIC-1072 computer.

Impedance measurements.—The electrochemical cell used for measurements of impedance and light-induced current-potential curves is shown in Fig. 2. Samples were held between two silicon gaskets pressed against the cell wall. The front gaskets had holes with an exposed area of 0.1 cm^2. The back side of the samples was rubbed with an In/Ga alloy for ohmic contact. A Pt wire attached to a thin Pt disk was pressed against the ohmic contact through a hole in the back gasket and through a hole in a pressure-fit Teflon piston to the outside measuring apparatus. The walls that were not fitted with electrode compartments were fitted with quartz windows. The cell was sealed and purged with N_2 or Ar. The two electrodes were connected to the network analyzer and to a d-c power supply as described previously (3, 4, 48). The potentials of the two electrodes, one modified, the other not, were monitored continuously against the SCE and kept identical. The network analyzer was switched from one sample to the other and the relaxation spectrum analysis, as a function of the electrode potential, was carried out using the same procedure as previously described (3).

The current-potential measurements were made with a PAR Model 173 potentiostat, Model 175 universal programmer, and 150W xenon lamp attenuated with neutral density filter to produce light intensity of 50 mW/cm^2. The light intensity was kept low to prevent bubble formation.

Surface fluorination.—Samples were fluorinated using a Union Carbide proprietary procedure (49).

Results and Discussion

Electrodes Modified with Alkylsilanes

In a set of preliminary experiments, no noticeable difference was found between alkyltrimethoxysilanes and alkyltrichlorosilanes. A detailed study was performed with methyltrimethoxysilane, hexyltrimethoxysilane, and eicosyltrichlorosilane. All three silane derivatives changed the surface of the electrode from

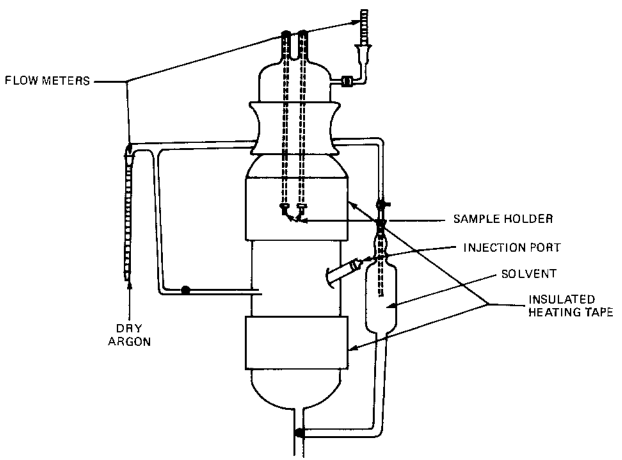

Fig. 1. The apparatus for surface derivatization of the electrodes

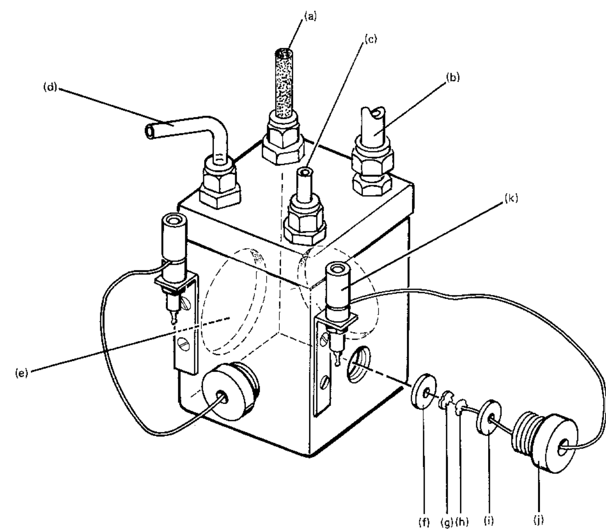

Fig. 2. The photoelectrochemical cell: a, counterelectrode; b, reference electrode (SCE); c and d, inlet and outlet for Ar; e, optical windows; f and i, silicon rubber gaskets; g, sample; h, platinum disk attached to Pt wire and is pressed against the ohmic contact on the sample; j, Teflon screw; k, electrical connector.

hydrophylic to hydrophobic. The modified surfaces retained their hydrophobic properties after exposure, for as long as 90 hr, to aqueous solution with pH values varying from 1 to 14. The derivatized surface was restored to its unmodified state by boiling the sample in 10M NaOH. ESCA results showed that the silane was attached to the surface. The Si was not present on unmodified surfaces. The Si(2P) peak with a binding energy (BE) of 102 eV was compared to Ti (3P) with a BE of 37 eV. The theoretical cross sections for ionization at these levels are 0.865 and 0.789, respectively (50). Typical molar intensity ratios of these two peaks were 1:1, but this ratio varied nearly 30% between different preparations. Analysis of the LMM and KLL Auger transitions showed that the Si is distributed within a layer of 10Å.

The variations in ESCA and Auger spectra, between various alkylsilane derivatives, were within the scatter for individual silanes.

Impedance and relaxation spectrum analysis (3, 4, 48).—The equivalent circuit of the derivatized TiO_2 was found to be the same as that of underivatized samples (3, 4). Over certain potential ranges, the capacitance values for the modified samples were found to be higher than those for the unmodified surface. Possible explanations that can account for different capacitive values in the derivatized surfaces are:

Formation of an insulating film on the surface.—This will introduce an additional capacitive element, smaller than the space charge capacitance and connected in series with it. This will result in reduction of the observed capacitance in the modified surface which is contrary to observation.

Different surface area and/or different doping level.—In spite of precautionary measures taken to ensure identical surface areas and doping levels, nevertheless these two parameters varied from sample to sample. If the difference in capacitance is due to this variation, the ratio of the two capacitances should be independent of potential, from the following argument:

The unmodified sample obeys the Mott-Schottky relation (51) over the potential range which is being measured

$$\frac{1}{C_u^2} = \frac{2}{A_u^2 \epsilon e N_D^u}\left(U - U_{FB} - \frac{kT}{e}\right) \quad [3]$$

where C_u is the capacitance of the unmodified sample, A_u its area, N_D^u the doping level, ϵ the dielectric constant, e the electronic charge, U the electrode potential, and U_{FB} the flatband potential. A similar expression will hold for the modified sample. If the flatband potential is the same, then

$$\frac{C_m}{C_u} = \frac{A_m}{A_u}\sqrt{\frac{N_D^m}{N_D^u}} \quad [4]$$

which is independent of potential. The experimentally observed potential dependence of the ratio indicates that this is not the primary reason for the difference in capacitance.

Surface states.—If derivatization of the surface does introduce surface states, their capacitance is in parallel with the space charge layer and an increase in the overall capacitance is expected (52). This increase in capacitance should be potential dependent according to the energy and energy distribution of the states, in agreement with our observations.

The ratio of the modified to unmodified capacitance was plotted as a function of potential, as shown in Fig. 3. The region of capacitance ratios which was found to be potential independent was subtracted from the ratio over the entire potential range and the result was multiplied by the capacitance of the unmodified sample. This procedure can be summarized in the following way

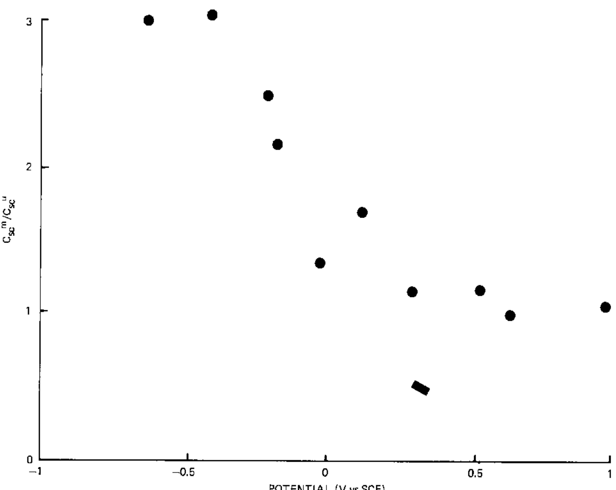

Fig. 3. The ratio of the capacitance of TiO_2 modified with hexyltrimethoxysilane and unmodified TiO_2, as a function of potential. (0.3M phosphate buffer, pH = 6.6.)

$$C^m = C_{sc}^m + C_{ss} \quad [5]$$

$$C^u = C_{sc}^u \quad [6]$$

and therefore

$$C_{ss} = C_{sc}^u\left(\frac{C^m}{C^u} - \frac{A_m}{A_u}\sqrt{\frac{N_D^m}{N_D^u}}\right) \quad [7]$$

The magnitude of C_{ss} as a function of potential, for TiO_2 which was modified with hexyltrimethoxysilane, is presented in Fig. 4.

The surface states are spread over a broad potential range near the bottom of the conduction band. The potential distribution of the capacitance fits a Gaussian line shape with the following parameters

$$C_{ss} = 5.4 \exp\left(-1.9\,(U + 0.9)^2\right) \mu F/cm^2 \quad [8]$$

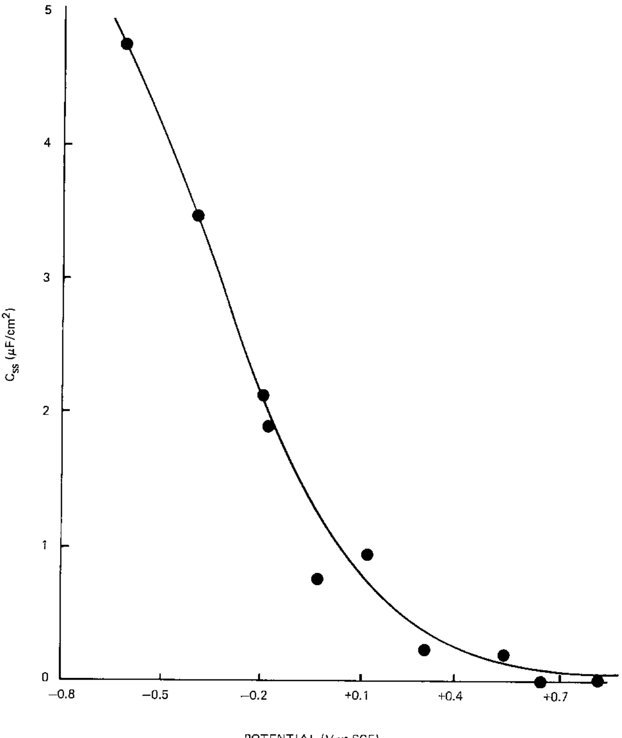

Fig. 4. The surface-states capacitance of TiO_2 which was modified with hexyltrimethoxysilane, as a function of potential. The experimental data were taken from Fig. 3 by using Eq. [7]. The solid line is the theoretical fit to Eq. [8].

This line shape can be interpreted as due to similar distribution of surface states at the semiconductor-electrolyte interface, which can be expressed in the following way

$$N_{ss}(E) = \frac{N_t}{e\sigma\sqrt{2\pi}} \exp\left[-(E_t - E)^2/2(e\sigma)^2\right] \quad [9]$$

where E is the energy, E_t is the most probable energy, $e\sigma$ the standard deviation in energy distribution, and N_t the concentration of surface states. Based on equivalent distribution, it was shown (3) that the number of positively charged donor states is given by

$$N_{ss}^+(E) = \frac{N_t}{2}\left\{\mathrm{erf}\left(\frac{U - U_t}{\sigma\sqrt{2}}\right) - \mathrm{erf}\left(\frac{U_{FB} - U_t}{\sigma\sqrt{2}}\right)\right\} \quad [10]$$

where U is the electrode potential, U_t the potential of the surface states, and U_{FB} the flatband potential.

The differential capacitance due to these states is given by

$$C_{ss} = \frac{edN_{ss}^+}{d\Delta\phi_s} = \frac{eN_t}{\sigma\sqrt{2\pi}} \exp\left(-(U - U_t)^2/2\sigma^2\right) \quad [11]$$

where

$$U = U_{FB} = \Delta\phi_s$$

From Eq. [8] and [11] we obtain the following parameters: $U_t = -0.9$V *vs.* SCE; $\sigma = 0.52$V; and $N_t = 4.4 \times 10^{13}/\mathrm{cm}^2$. This surface concentration of impurities corresponds approximately to 5% of a monolayer.

Photoactivity.—The modified semiconductors showed considerably reduced photoactivity compared to unmodified ones. A typical example of the ratio of the light-induced anodic current of an unmodified sample to one which was modified with hexyltrimethoxysilane, as a function of potential, is shown in Fig. 5. The modified and the unmodified electrodes are identical except for their surface composition. Therefore, the difference in the photoinduced anodic current is attributed to surface recombination. As with the surface-state capacitance, the surface recombination takes place in a broad potential range around the flatband.

Understanding these results requires invoking certain assumptions about the origin of the photoinduced anodic current and the mechanism of surface recombination due to the modified surface. The proposed mechanism for the surface recombination reaction is illustrated in Fig. 6. The energy diagram of TiO_2 is illustrated together with the normalized distribution of the surface states, obtained from the capacitance data which were described in the previous section. When light is absorbed by the semiconductor, holes in the valence band will be driven to the surface. Either electrons will be driven by the field to the interior of the semiconductor or, at potentials which are not too positive compared to the flatband potential, they will tunnel through the barrier to the surface states. We will assume that this process is very efficient and not rate limiting. The light-induced, minority-carrier current at the surface is given by (1e)

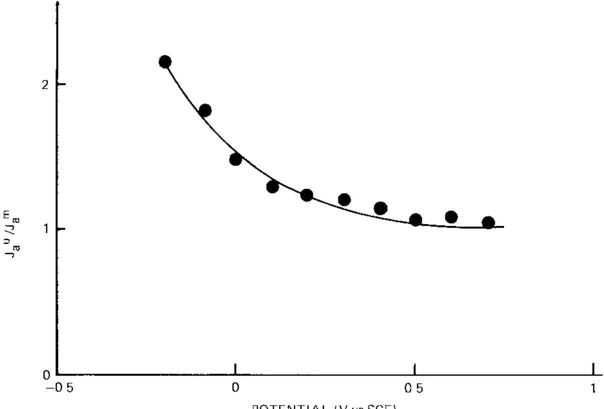

Fig. 5. The ratio of the light-induced anodic current of an unmodified TiO_2 to one which was modified with hexyltrimethoxysilane, as a function of potential. (Phosphate buffer, pH = 6.6.) The photocurrents were normalized to the same light intensity. The solid line is the theoretical fit to Eq. [31] with parameters given in the text.

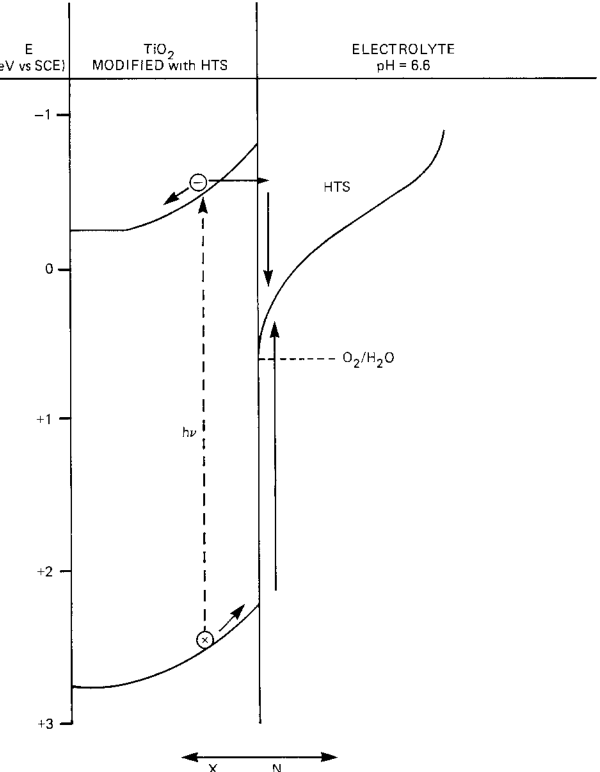

Fig. 6. The proposed mechanism for surface recombination on TiO_2 which was modified with hexyltrimethoxysilane (HTS). The distribution of the surface states was obtained from the capacitance data in Fig. 4.

$$J = eF(1 - R)\left[1 - \frac{\exp(-\alpha d)}{\alpha L_p + 1}\right] \quad [12]$$

where α is the absorption coefficient, R the reflectivity, F the photon flux, e the electronic charge, d the thickness of the space charge layer, and L_p the minority carrier diffusion length. This current will be divided into the anodic current, J_a, and a current, J_r, due to the recombination processes between the minority carriers and the occupied surface states.

If the anodic oxidation process involves only a single electron or hole the anodic current density may be expressed as (53)

$$J_a = ekp^*C_R \quad [13]$$

where C_R is the concentration of the reduced species that is being oxidized, k is the rate constant, and p^* is the steady-state excess concentration of holes at the surface. The reactions that occur at the anode, resulting in the evolution of oxygen from water, are more complex. Various mechanisms have been suggested (54). One series of reactions that has been proposed is (55)

$$h^+ + \mathrm{M} + e \xrightarrow{S} \mathrm{M} \quad [14]$$

$$h^+ + \mathrm{M} + \mathrm{OH}^- \xrightarrow{k_1} \mathrm{MOH} \quad [15]$$

$$h^+ + MOH + OH^- \xrightarrow{k_2} MO + H_2O \quad [16]$$

$$2MO \xrightarrow{k_3} 2M + O_2 \quad [17]$$

Reaction [14] represents the surface recombination with a rate constant S. MOH and MO are intermediate radicals involving the electrode material M. Since the anodic reaction is not limited by the dark reversed reaction we will neglect the latter. If reaction [15] is the rate-limiting step we may apply the steady-state method (55), by assuming that the concentrations of the intermediate species do not change with time. The steady-state concentration of the light-generated holes p^* at the surface is found from [12-17] to be

$$p^* = \frac{F(1-R)}{S + 2k_1[OH^-]}\left[1 - \frac{\exp(-\alpha d)}{\alpha L_p + 1}\right] \quad [18]$$

The anodic current J_a may be expressed as

$$J_a = 4e\frac{d[O_2]}{dt} = 2ek_1p^*[OH^-]$$

$$= \frac{2ek_1[OH^-]F(1-R)}{S + 2k_1OH^-}\left[1 - \frac{\exp(-\alpha d)}{\alpha L_p + 1}\right] \quad [19]$$

The ratio of the anodic currents of two identical samples, one with and the other without surface recombination, will be

$$\frac{J_a^o}{J_a} = \frac{S}{2k_1[OH^-]} + 1 \quad [20]$$

In complete analogy to Eq. [13] the hole recombination current is given by

$$J_r^h = ek_r^hp^*n_t^* \quad [21]$$

where n_t^* is the concentration of the occupied surface states given by

$$n_t^* = n_t + \delta n_t \quad [22]$$

where n_t is the equilibrium concentration of the occupied states and δn_t the nonequilibrium increment. The hole recombination current will be compensated by an electron recombination current given by

$$J_r^e = ek_r^ep_t^*n_s \quad [23]$$

where p_t^* is the concentration of the unoccupied surface states given by

$$p_t^* = p_t + \delta p_t \quad [24]$$

and n_s is the electron concentration at the surface.

The following relation will also hold

$$p_t^* + n_t^* = p_t + n_t = N_t \quad [25]$$

where N_t is the total surface state concentration.

For surface states with energies close to the flatband potential, the electron exchange between the surface states and the conduction band will be very efficient and the surface recombination current will be limited by the availability of holes, under those conditions

$$\delta n_t << n_t \quad [26]$$

and

$$S = k_r^hn_t^* = k_r^hn_t \quad [27]$$

From Eq. [10] we obtain

$$n_t = \frac{N_t}{2}\left\{\text{erfc}\left(\frac{U-U_t}{\sigma\sqrt{2}}\right) - \text{erfc}\left(\frac{U_{FB}-U_t}{\sigma\sqrt{2}}\right)\right\} \quad [28]$$

where erfc $(x) = 1 -$ erf (x). Substituting Eq. [28] into [27] will result

$$S = \frac{k_r^hN_t}{2}\left\{\text{erfc}\left(\frac{U-U_t}{\sigma\sqrt{2}}\right) - \text{erfc}\left(\frac{U_{FB}-U_t}{\sigma\sqrt{2}}\right)\right\} \quad [29]$$

For states which are situated very close to the bottom of the conduction band, such that

$$\frac{k_r^hN_t}{4k_1[OH^-]}\text{erfc}\left(\frac{U_{FB}-U_t}{\sigma\sqrt{2}}\right) << 1 \quad [30]$$

Equations [20] and [29] will yield

$$\frac{J_a^o}{J_a} \approx 1 - \frac{k_r^hN_t}{4k_1[OH^-]}\text{erfc}\left(\frac{U-U_t}{\sigma\sqrt{2}}\right) \quad [31]$$

The solid line in Fig. 5 demonstrates the fit of Eq. [31] to the experimental results which are marked by the dark circles. The experimental data were taken from the same samples used to obtain the capacitance data shown in Fig. 4. U_t and σ were taken from the capacitance data and the only adjustable parameter was

$$\frac{k_r^hN_t}{4k_1[OH^-]} = 6.6 \quad [32]$$

Equation [32] indicates that the minority carriers react with surface states more than six times faster than the rate of reaction of holes with water to evolve oxygen. This interpretation of the parameter which is described by Eq. [32] is as good as the approximation which is described by Eq. [30].

Electrodes Modified with Diethyl [β-(Triethoxysilyl) Ethyl] Phosphonate (Y5727)

Stability and coverage.—ESCA was used for characterization of the surface coverage and stability of the modified surfaces. The P(2P) transitions, with a binding energy of 134 eV, were used in addition to the Si and Ti transitions that were described in the previous section. The P(2P) transitions are close enough in energy to the Ti(3P) and the Si(2P) transitions so that differences in escape depth and geometrical factors can be neglected. The theoretical cross section for the photoionization of the P(2P) level is 1.25 (50). Based on this and the theoretical cross sections of the corresponding Si and Ti peaks, the molar ratio of the elements were calculated. These ratios varied considerably from experiment to experiment, but a few general trends became apparent. Typically, after derivatization the P/Ti ratio was found to be between 0.2-0.4; after exposure of the sample to phosphate buffer for 40 hr, this ratio was reduced by 50%. The ratio of Si/P also varied from experiment to experiment. This ratio was sometimes as high as 6/1 and as low as 1/1. When a sample with initial ratio of Si/P = 1/1 was exposed to 0.1M H_2SO_4 for 24 hr this ratio increased to 2/1. We do not have an explanation for these results. They can be caused by impurities or by chemical reactions on the surface which have yet to be elucidated. It is very probable that the reaction sequence which we described in Eq. [2] will have to be modified. Much more work is needed to understand the reactions which take place on the surface before any definite conclusions could be drawn. The results that will follow will have to be treated with this uncertainty in mind.

Surface state.—The capacitance of the surface states that were introduced due to the surface modification was measured using the same procedure that was described in detail in the section on alkylsilanes. A representative result of these measurements is shown in Fig. 7. The solid line is a theoretical fit of these results to Eq. [11] with the following parameters: $U_t = +0.85V$ *vs.* SCE; $\sigma = 0.13V$; and $N_t = 4 \times 10^{12}/cm^2$. The reproducibility in U_t and σ is much better than that which was obtained with the alkylsilanes but the coverage, as a rule, is order of magnitude smaller.

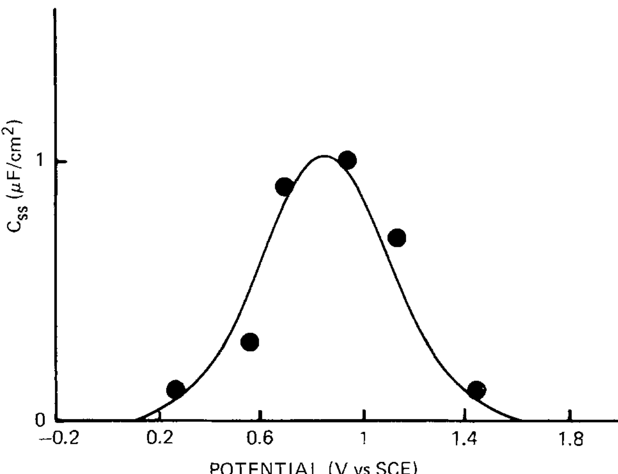

Fig. 7. The surface-states capacitance of TiO_2 which was modified with Y5727, as a function of potential. The solid line is the theoretical fit to Eq. [11] with parameters that are given in the text. (Phosphate buffer, pH = 6.6.)

Based on these results, the normalized distribution of the surface states relative to the position of the TiO_2 bands and the reversible oxygen electrode is shown in Fig. 8. The striking result which is evident in Fig. 8 is that the surface state energies, compared to alkylsilanes, were shifted to potentials even more positive than the reversible oxygen potential. This result indicates that a key requirement of a derivatized electrode was satisfied by the phosphonate derivative. The potential of the surface states ensures that in the competition between water and the silane, light-produced holes will tend to oxidize water. In agreement with this, the photoactivity of derivatized and underivatized electrodes shows no reproducible difference in photocurrent. The potential of zero photocurrent was also the same at both electrodes, under light of equal intensity.

In addition to the large positive shift in the potential of the surface states, compared to the surfaces that were derivatized with alkylsilanes, the energy distribution of these states is narrowed. In view of the uncertainties in the chemistry of the derivatized surfaces after prolonged exposure to electrolytes, a serious attempt to hydrolyze the phosphonate ester groups was not made. A few preliminary experiments, in which we have tried to hydrolyze the ester groups in various concentrations of H_2SO_4, resulted in irreproducible changes in coverage, but the potential and energy distribution of the states remained unchanged. Finally, the flatband potential of TiO_2 derivatized with Y-5727 remained unchanged.

Fluorinated Electrodes

To investigate the possibility of altering the flatband potential of TiO_2 by changing the electron affinity of the surface, we have fluorinated the doped TiO_2. The F (1S) ESCA peak was used for the surface analysis. It was found that the atomic ratio of F/Ti, at the surface, was 3.1. This ratio was reduced to 0.2 upon sputtering to a depth of 10Å and to 0.14 upon sputtering 60Å. Fluorine was observed on the surface after exposure to an electrolyte for a period in excess of 1 week, but in a greatly reduced amount. Only two samples were fluorinated; one was used for the initial ESCA measurement while the other one was used for the electrochemical measurements.

The impedance measurements showed identical behavior for fluorinated and unmodified samples. Both showed the same flatband potential and a linear Mott-Schottky plot over potentials exceeding 2/3 of the bandgap. The fluorinated sample showed considerably reduced photoactivity compared to that of the unmodified sample.

Figure 9 shows the ratio of the photoanodic current of an unmodified to a fluorinated sample, both normalized to the same light intensity. The solid line is a theoretical fit to Eq. [31]with the following parameters: σ = 0.64V; U_t = −0.6V *vs.* SCE; $(k_r^h N_t)/(4k_1[OH^-])$ = 2.7. These results are qualitatively similar to those obtained with alkylsilanes. This might be due to the close proximity of the semiconductor surface to the groups which directly participate in the electron transfer process. However, in view of the preliminary nature of these results further speculation is premature.

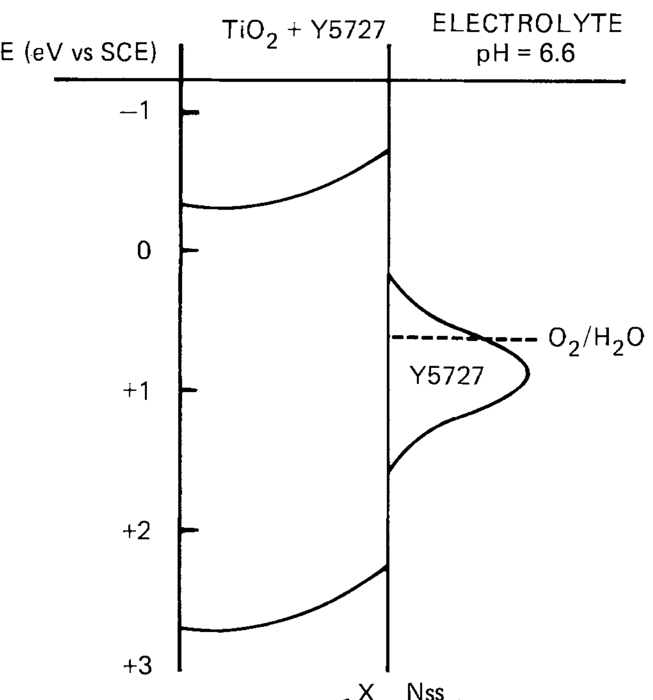

Fig. 8. Combined energy diagram of TiO_2 which was modified with Y5727 in phosphate buffer, pH = 6.6. The energy distribution of the surface states was taken from the data in Fig. 7.

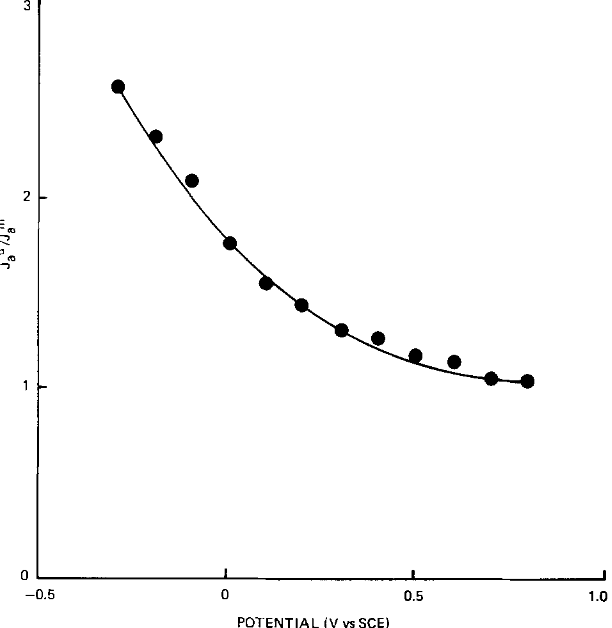

Fig. 9. The ratio of the light-induced anodic current of an unmodified TiO_2 to one which was modified by surface fluorination, as a function of potential. (Phosphate buffer, pH = 6.6.) The solid line is a theoretical fit to Eq. [31] with parameters given in the text.

Reproducibility

The results for the various surface treatments are qualitatively reproducible in the nature of the distribution of the density of states and the potential of these states. Procedures for reproducible coverage of the surface were not achieved and, even more disturbing, there was large irreproducibility in the standard deviation of the Gaussian distribution of the surface states. The standard deviation appears to increase with increasing coverage. The exact nature of this correlation is being further investigated.

Comment on the Origin of the Gaussian Distribution of the Density of Surface States

One possible interpretation of the energy distribution of the surface states is based on changes in the polarization of the solvent molecules near the derivatized surface, upon ionization of the functional groups at the surface. The broadening of surface energy states by this mechanism was described by Morrison (56), as the fluctuating energy level mechanism. According to this model, the probability that the energy levels of the species on the surface will have a value E less than the maximum probability is given by the Boltzmann factor

$$W(E) = (4\pi\lambda kT)^{-1/2} \exp[-(E_t - E)^2/4\lambda kT] \quad [33]$$

where E_t is the most probable energy and λ is the reorganization energy. Comparing this with Eq. [9] will yield

$$e\sigma = (2\lambda kT)^{1/2} \quad [34]$$

Based on this relation, the values of λ for the samples that were evaluated here are: λ hexyltromethoxysilane = 5.2 eV; λ Y5727 = 1.3 eV; and λ_{F_2} = 6.4 eV. These values of λ are larger than any comparable reorganization energies for ions in solution (57). This model also predicts that the standard deviation of the energy distribution will be independent of the coverage.

Based on these arguments we tend to rule out the fluctuating energy levels mechanism as the source of the surface-states line broadening, but we cannot yet offer an alternative model.

Conclusions

The results show no shift in flatband potential of chemically modified TiO_2 surfaces. Perhaps of greater importance is the observation that, in spite of the difficulties in obtaining reproducible surface coverage and the lack of understanding of the chemistry of the modified surface with the electrolyte, we could obtain qualitative and quantitative measurements of the effects of derivatization on the potential and charge distribution at the semiconductor-electrolyte interface and on the photoactivity of photoelectrochemical devices.

Of particular importance is the observation that introduction of a functional group which is removed from the surface can strongly influence the potential and potential distribution of the surface states. This should encourage utilizing organic chemistry in the design of functional groups on silane derivatives or other chemical backbones like phthalocyanines (58) which can be covalently attached with a stable chemical bond to the semiconductor surface in devices which are used either in solar energy conversion or in the semiconductor industry. We believe that, for the first time, methods have been demonstrated, that can tie together the chemistry and physics of surface states, in systems which are not under high vacuum. Th methods could help understanding and controlling surface properties of semiconductor devices.

ABSTRACT

Spectrophotometric and polarographic data demonstrate that the normal Sn(IV) and Ge(IV) chlorides are nonelectrolytes in the aprotic solvent acetonitrile. Both form the corresponding hexachloro species in the presence of chloride ion. Sn(IV) chloride is quantitatively converted to the hexachlorostannate ion while Ge(IV) chloride behaves as a weaker Lewis acid and exists in an equilibrium with the hexochloro ion in the presence of excess chloride. Each of the normal metal halides acts as a Lewis acceptor toward a test pyridine-N-oxide ligand in acetonitrile. Sn(IV) and Ge(IV) chloride are polarographically reduced in a $4e^-$ step at which the production of the corresponding hexachloro ion, reducible only at higher potentials, controls the plateau current.

Interest in the coordination chemistry of the group IV A metals has increased in recent years. However, this area remains one of the least characterized and understood segments of inorganic chemistry. The metals, germanium, tin, and lead may act as Lewis acids, much like transition metal ions. Examples of this behavior include the formation of halide adducts of tetravalent germanium (1, 2) and tetravalent and divalent tin (3, 4).

Polarographic and spectrophotometric data presented previously show that the two cathodic current plateaus observed in the reduction of Sn(II) chloride in acetonitrile (ACN) solvent containing *tetra*-N-propylammonium perchlorate (TPAP) are attributable to the $2e^-$ reduction of $SnCl_2$ at the lower potential wave and to the $2e^-$ reduction of the trichlorostannate ion ($SnCl_3^-$) at the higher potential (5, 6). The plateau current of the lower potential wave is controlled by the formation of the very stable $SnCl_3^-$ species which is only reducible at potentials of the second wave. Stannous chloride was found also to act as a Lewis acid toward various pyridine-N-oxide ligands; forming 1:1 adducts in ACN (5, 7, 8).

Even though the polarographic reduction of $SnCl_2$ occurs via irreversible steps, the importance of these data in determining its electrolyte and ligand acceptor properties in low basicity media has prompted similar studies of other chlorides of the group IV metals; specifically Sn and Ge in the +4 oxidation state. A portion of the work presented herein parallels that reported by Thomas and Kolthoff in their survey of the polarographic behavior of the group IV metal halides

Key words: polarography, hexachlorostannate ion, aprotic solvent.

in ACN (9). This work has been expanded with spectrophotometric and additional polarographic investigations. The results are reported herein.

Experimental

Apparatus.—The instrumentation and polarographic cells were of conventional design and have been described elsewhere (4).

Chemicals.—Spectroquality acetonitrile containing less than 0.03% water (Aldrich), polarographic-grade tetramethylammonium chloride (Southwestern Analytical Chemicals), and reagent-grade anhydrous Sn(IV) and Ge(IV) chloride were used. The supporting electrolyte, tetrapropyl-ammonium perchlorate (Eastman Organic Chemicals) was recrystallized from acetonitrile-water solution before use.

All polarographic and spectrophotometric solutions were prepared and transferred under a nitrogen atmosphere.

Results

Polarography.—Tin(IV) chloride, reduced in TPAP supporting electrolyte in ACN, exhibits a polarogram similar in appearance to that of $SnCl_2$ [Fig. 1(a)] (5). The total current of the two cathodic[1] plateaus appearing at +0.3V and −1.06V *vs.* saturated calomel (SCE) varies in proportion to the square root of the corrected mercury head height. The individual plateau currents deviate slightly from this behavior and are irreversible.[2] The current maximum associated with the positive potential plateau has been discussed by Thomas and Kolthoff (9). The diffusion current constants (I_d) measured at 25°C and 1.0 mM concentration are 3.90 and 9.25, respectively, for the positive and negative reduction plateaus.[3]

The anodic current [not pictured in Fig. 1(a)], apparently a double wave with an ill-defined point of separation, appears at +0.5V *vs.* SCE. The plateau current deviates from purely diffusion-controlled behavior.

Addition of controlled quantities of tetramethylammonium chloride (TMAC) to the test solution as a source of free (noncomplexed) chloride increases the current of the higher potential wave systematically at the expense of the lower (Fig. 1, Table I). At a ratio of 2/1 TMAC to Sn(IV) chloride a residue of the lower potential plateau remains and a weak anodic current attributable to the oxidation of free chloride is noted. The absence of detectable quantities of free chloride in Sn(IV) chloride or Sn(IV) chloride-chloride solutions of a lower ratio is noted and is a significant observation (5). The $E_{1/2}$ of the lower potential wave is shifted negatively *vs.* SCE and the higher potential wave positively upon addition of TMAC. The total cathodic current remains approximately constant at all TMAC concentrations (Table I).

Ge(IV) chloride also exhibits two cathodic and one anodic polarographic current plateau in the ACN-TPAP medium [Fig. 2(a)]. Similar to Sn(II) and Sn(IV) chloride behavior, the total cathodic current appears to be diffusion controlled and both cathodic processes are irreversible in nature. The higher potential plateau is extremely broad and the establishment of a reliable $E_{1/2}$ value is consequently difficult. At 1.0 mM concentration of Ge(IV) chloride the I_d of the low and high potential plateaus are 4.80 and 10.02, respectively.

Addition of TMAC to the test solution of Ge(IV) chloride brought about variations in the polarograms qualitatively similar to those noted in the cases of Sn(II) and Sn(IV) chloride. An oxidation current attributable to free chloride is not found in polarograms of 1 mM Ge(IV) chloride [Fig. 2(a)]. Addition of TMAC in a ratio of 0.5/1 TMAC to Ge(IV) chloride

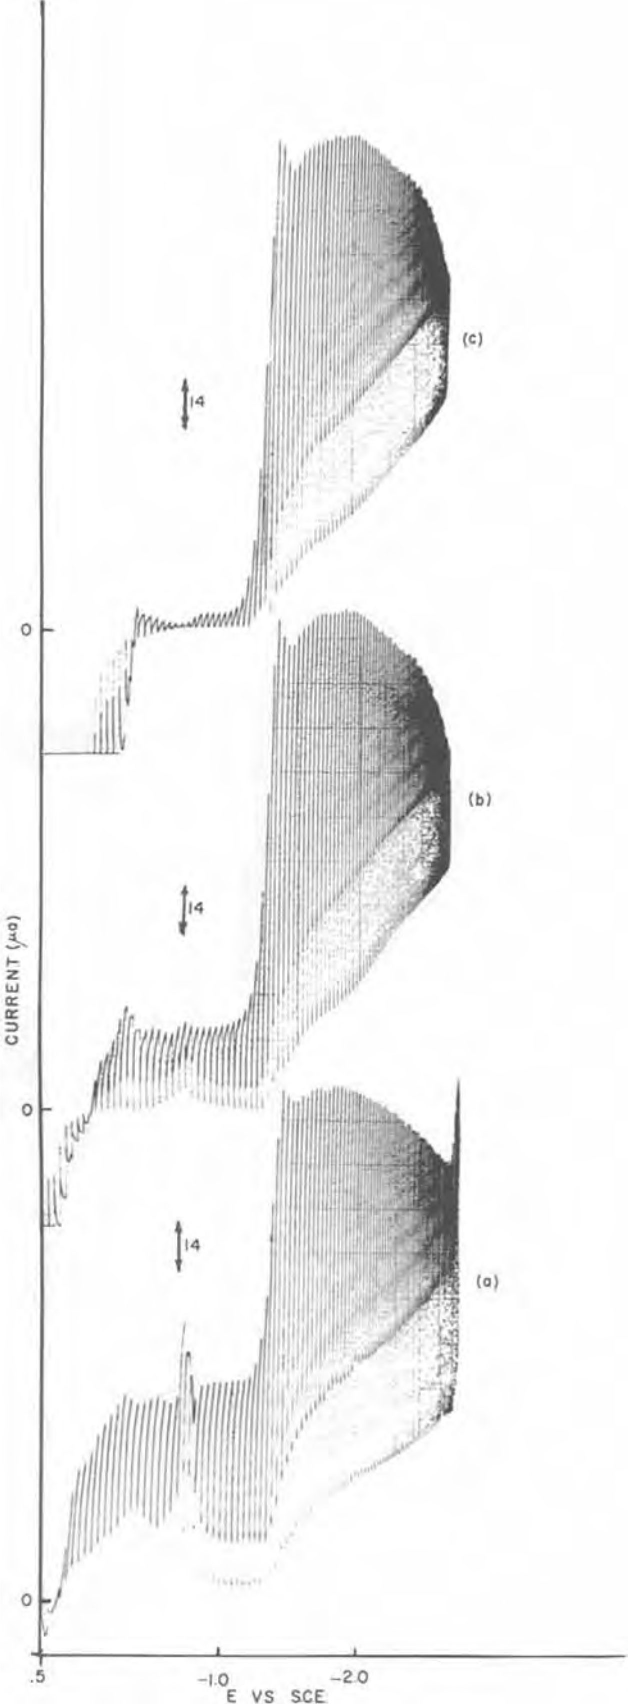

Fig. 1. Polarograms of ACN-TPAP solutions containing (a) 1 mM Sn(IV) chloride, (b) 1 mM Sn(IV) chloride plus 1 mM TMAC, and (c) 1 mM Sn(IV) chloride plus 3 mM TMAC.

diminishes the plateau current at the lower potential cathodic wave (Table I) without affecting the total cathodic current of both plateaus. The addition of TMAC concentrations higher than 2.0 mM to the 1 mM

[1] Cathodic is used throughout to signify a current response consistent with a reduction process.

[2] Slopes of log(id-i)/i *vs.* plots are 497 mV and 114 mV, respectively.

[e] Very broad wave.

Ge(IV) chloride solution did not significantly affect the current ratio of the two cathodic plateaus (Table I).

The role of Sn(IV) and Ge(IV) chloride as Lewis acids toward organic ligands in ACN solvent was investigated by adding 4-methoxypyridine-N-oxide (MPNO) to the polarographic test solution containing the metal species. Figure 3 summarizes the effects of increasing concenrtations of MPNO on polarograms of Sn(IV) chloride. An irreversible plateau appearing at −0.83V is attributable to the reduction of an Sn(IV) chloride-MPNO adduct. At concentrations of ligand in twofold excess of Sn(IV) chloride or greater the lower potential plateau is completely replaced by this current. The higher potential plateau is unaltered and the low intensity reduction plateau appearing at −2.08V in Fig. 3(d) corresponds to the reduction of uncomplexed MPNO. The polarographic behavior of Ge(IV) chloride in the presence of MPNO parallels that of Sn(IV) chloride.

Even though standard quantitative methods cannot be applied to an analysis of the irreversible current plateau, the concentration dependence of the polarographic wave attributed to the reduction of the metal(IV) chloride-MPNO adduct and the low potential reduction wave of the metal(IV) chloride suggests the formation of a neutral complex having the formula $MCl_4 \cdot 2MPNO$.

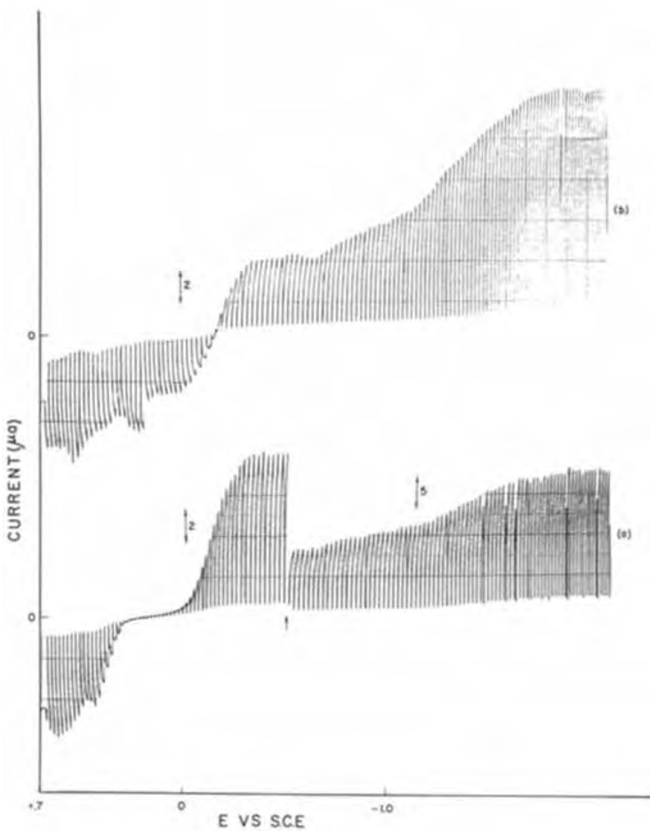

Fig. 2. Polarograms of ACN-TPAP solutions containing (a) 1 mM Ge(IV) chloride and (b) 1 mM Ge(IV) chloride plus 2 mM TMAC.

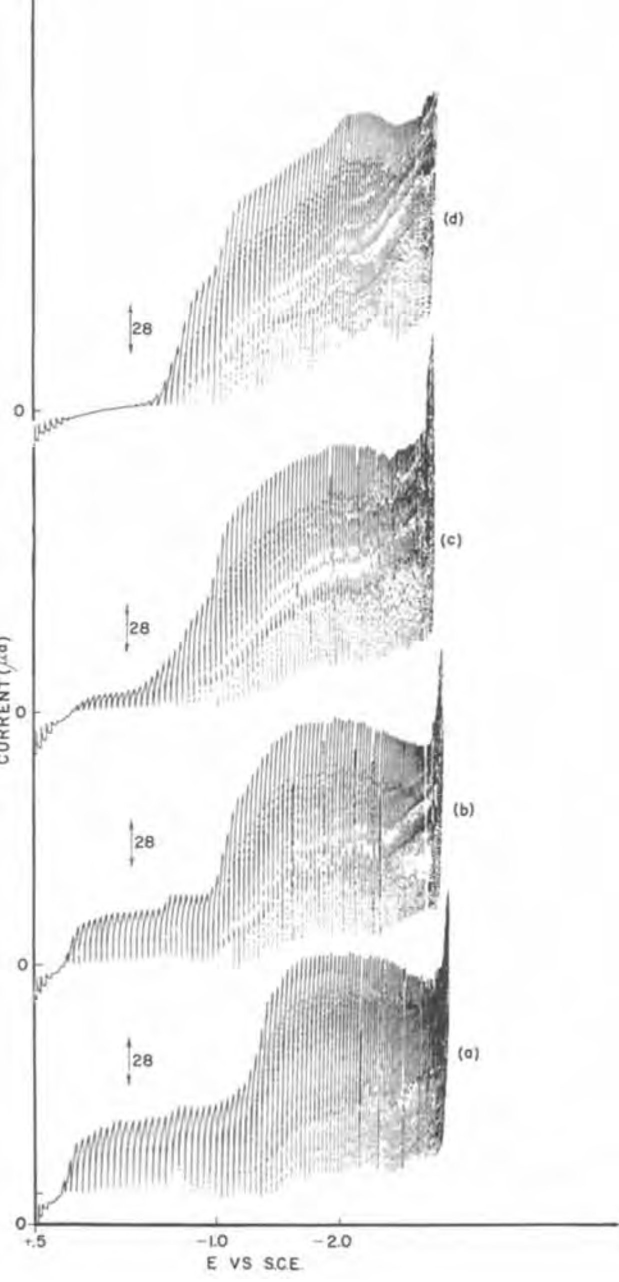

Fig. 3. Polarograms of ACN-TPAP solutions containing 1 mM Sn(IV) chloride plus (a) 0.3 mM MPNO, (b) 0.5 mM MPNO, (c) 1.0 mM MPNO, and (d) 2.0 mM MPNO.

Spectral observations: u.v. spectra of Sn(IV) chloride and Sn(IV) chloride-TMAC mixtures were recorded to establish data relatable to the electrolyte behavior of Sn(IV) chloride in ACN. The spectrum of a 0.8 mM solution of TMAC exhibits one absorption band centered at 198 nm [Fig. 4, curve (a)]. A 0.4 mM solution of Sn(IV) chloride in ACN consists of only one absorption band at 200.4 nm [Fig. 4, curve (b)]. Solutions containing TMAC and Sn(IV) chloride in varying ratios, but at a constant total concentration exhibit one absorption peak which shifts to longer wavelengths with increasing TMAC to Sn(IV) chloride ratios (Fig. 4). A standard continuous variation plot of these data is consistent with the coordination of two chloride ions per metal ion. These data and the absence of a polarographic wave and a u.v. absorption band attributable to chloride ion in Sn(IV) chloride solutions are consistent with the formation of the hexachlorostannate ion ($SnCl_6^{-2}$) via the complexation of free chloride with the neutral Sn(IV) chloride complex. Neither Ge(IV) chloride nor the products formed upon the addition of TMAC exhibits an absorption maximum detectable in ACN solvent.

The ligand MPNO exhibits absorption maxima at 206.3 and 281.0 nm in ACN solvent, Fig. 5, curve (b). The u.v. spectra of ACN solutions containing Sn(IV) chloride and MPNO exhibit an additional absorption maximum. The maximum appears at 270.4 nm when spectra of solutions containing a 2/1 ratio of ligand to metal are recorded, Fig. 5, curve (c). Continuous variation plots of u.v. data recorded at a total constant concentration (metal chloride plus ligand) of 1.2 mM reveal the formation of an adduct composed of two ligands per metal(IV) chloride.

Similar studies detail the effects of Ge(IV) chloride on the spectra of MPNO in ACN solvent. An absorption maximum[4] appearing between the bands associated with pure MPNO may be reasonably attributed to a Ge(IV) chloride-MPNO adduct. Continuous variation studies using the absorbance of this band do not conclusively reveal the presence of a single stable complex.

Discussion

The polarographic and spectrophotometric data show that Sn(IV) and Ge(IV) chloride are nonelectrolytes in ACN solvent. Previous studies have shown that Sn(II) chloride behaves in a similar manner (5). Each of these neutral complexes acts as a ligand acceptor. Data presented herein demonstrate that both metal(IV) chlorides form the hexachloride anion in the presence of free chloride. Tin(IV) chloride forms 2/1 complexes with pyridine-N-oxides in ACN solvent.

Kolthoff considered the first cathodic wave of both Sn(IV) and Ge(IV) to be two-electron reductions since the values of the diffusion current constants of the waves are in the range reported for two-electron reductions in ACN (10). It was noted that the somewhat "suppressed" current of the first reduction wave is analogous to the effect observed in acidic aqueous chloride solutions of Sn(IV) (11). Polarographic and spectrophotometric data presented herein and the similarity of the electrolyte properties and the polarographic behavior of Sn(IV) chloride and Sn(II) chloride in ACN (5, 6) suggest a different reduction mechanism. The polarographic and spectrophotometric behavior of Sn(IV) and Ge(IV) chloride in the presence of added chloride ion demonstrates conclusively that the most negative polarographic wave corresponds to the reduction of the hexachlorostannate ion of each. The direct conversion of the metal(IV) chloride into the hexachloro species by added chloride ion is confirmed by the spectrophotometric and polarographic data. These observations show that the low potential cathodic wave results from the reduction of the neutral tetrachloro species. It seems unlikely that the tetrachloro species would be reduced via a two-electron step and the hexachloro via a single four-electron step. Additionally, the behavior of Sn(II)

[4] 239.6 nm from solutions containing a 2/1 ratio of ligand to metal.

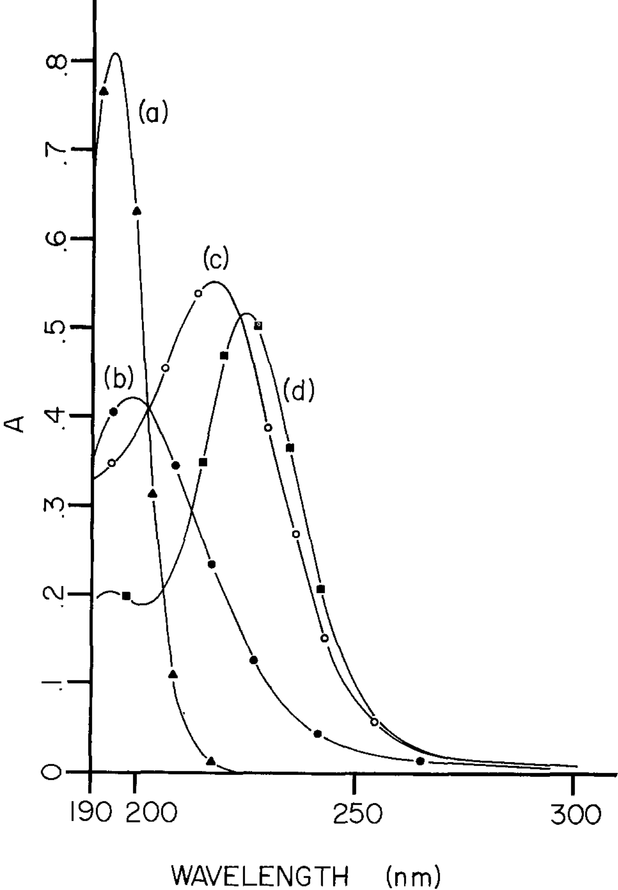

Fig. 4. U.V. spectra of ACN solutions containing: curve (a) 0.8 mM TMAC, curve (b) 0.4 mM Sn(IV) chloride, curve (c) 0.6 mM Sn(IV) chloride plus 0.6 mM TMAC, curve (d) 0.4 mM Sn(IV) chloride plus 0.8 mM TMAC.

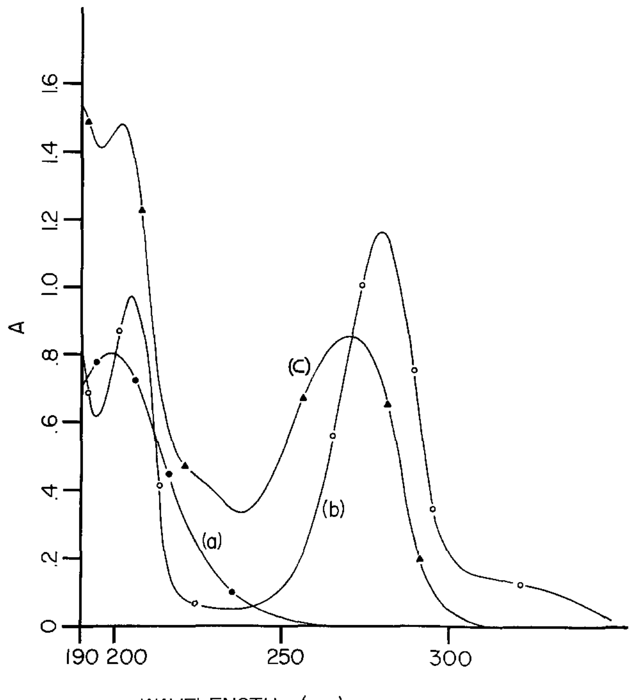

Fig. 5. U.V. spectra of ACB solutions containing: curve (a) 0.4 mM Sn(IV) choride, curve (b) 0.8 mM MPNO, curve (c) 0.4 mM Sn(IV) chloride plus 0.8 mM MPNO.

(5, 6) chloride suggest that a two-electron reduction of the tetrachloro species would generate the trichlorometal(II) anion at the electrode surfaces. No evidence of such species is detected in the polarograms of Sn(IV) and Ge(IV) chloride.

The behavior of the higher potential plateau is exactly analogous to the corresponding wave observed in polarograms of Sn(II) chloride in ACN at which formation of a higher chloride-coordinated species, reducible only at more negative potentials, controls the wave current of the lower potential plateau (5,6). This similarity and data presented herein suggest that the polarographic and complexation behavior of both Sn(IV) and Ge(IV) chloride may be best explained with the following reduction mechanism

First polarographic step

$$MCl_4(S) + 4e^- + Hg \rightarrow M(Hg) + 4Cl^-$$

$$MCl_4(S) + 2Cl^- \rightleftarrows MCl_6^{-2}(S)$$

Second polarographic step

$$MCl_6^{-2}(S) + 4e^- + Hg \rightarrow M(Hg) + 6Cl^-$$

In the presence of an organic ligand, the polarographic reduction process may be summarized

First polarographic step

$$MCl_4 \cdot 2L + 4e^- + Hg \rightarrow M(Hg) + 2L + 4Cl^-$$

$$MCl_4 \cdot 2L + 2Cl^- \rightleftarrows MCl_6^{-2} + 2L$$

Second polarographic step

$$MCl_6^{-2} + 4e^- + Hg \rightarrow M(Hg) + 6Cl^-$$

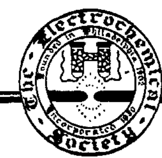
Technical Note



A Preliminary Investigation for an $Al/AlCl_3$-NaCl/FeS_2 Secondary Cell

N. Koura*

Faculty of Science and Technology, Tokyo University of Science, Yamazaki, Noda, Chiba 278, Japan

A secondary or rechargeable cell is an attractive energy storage device as well as an efficient electrical power source. Wide markets have already been established for several secondary cells, *e.g.*, lead-acid, nickel-cadmium, and nickel-iron. In recent years, according to the rapid growth rate in electric power demand, as well as the projected shortage and rising cost of petroleum, it has become very important to actively consider potential alternative energy sources. Secondary cells, among many potentially promising energy storage devices, are particularly attractive because their technical and economical feasibility appear to be within reach. Of the advanced secondary cells being developed in the world for application to utility load-leveling and electric-vehicle propulsion, major efforts are presently concentrated on the following five systems: Li-Al/LiCl-KCl/metal sulfide, Na/β-Al_2O_3/S, Zn/aq.$ZnCl_2$/Cl_2, Zn/aq.KOH/β-NiOOH, and so-called lead-acid. In the past several years, significant progress has been made in developing each of these systems, especially Li-Al/FeS_2 or FeS, lead-acid, and Na/S for both load-leveling applications and electric vehicles. However, these systems still possess many technical and economic problems (1).

The objective of this investigation is to develop an $Al/AlCl_3$-NaCl/FeS_2 cell as a potential candidate for the advanced secondary cells. Aluminum has a considerably negative potential, -2.08V *vs.* Cl_2/Cl^- at 450°C (2), in a molten salts system and a high theoretical capacity, 2.98 A-hr/g. The $AlCl_3$-NaCl system has a relatively low melting point (the lowest: 107.2°C (3)) and is stable as molten salt not in the presence of air or moisture. Therefore, material corrosion problems are not so severe because of the low operating temperature of the cell. FeS_2 is highly promising as

* Electrochemical Society Active Member.

Key words: Al/FeS_2 cell, high temperature cell, molten salt, secondary cell.

the active material for the positive electrode of a molten salts cell as investigated extensively with the Li-Al/LiCl-KCl/FeS_2 cell (4). Furthermore, FeS_2 as well as Al, $AlCl_3$, and NaCl are all inexpensive. In addition to these, an investigation for a secondary molten salt cell having an Al negative electrode is scarcely seen except Al/Cl_2 (5) and Al/S or oxidation states of S (6-9) systems.

$AlCl_3$ was reduced to fine powder in a glove box under an Ar atmosphere, and heated at 180°C for 10 hr *in vacuo*, then mixed in the glove box with NaCl dried at 180°C for 24 hr. The mixture was placed along with Al wire in a Pyrex tube ($\phi 60 \times 200$ mm) and heated at 250°C for 30 hr under a dry N_2 atmosphere in order to remove small amounts of impurities, *i.e.*, Fe^{2+}, Pb^{2+}, and H_2O. FeS_2 powder of 325 mesh, which has been kindly offered by C. E. Minerals (Pennsylvania) was purified 20 times by a sink-float separation with s-*tetra* bromoethane and the purity was checked by x-ray analysis. An Mo mesh current collector was surrounded with the FeS_2 powder (theoretical capacity: 3 A-hr),[1] covered with a SiO_2 cloth and then Ni mesh, as shown in Fig. 1. The FeS_2 electrode was degassed for 15 min and immersed for 15 min at 200°C in the molten salts bath *in vacuo* to wet both the FeS_2 powder and the current collector completely with the molten salts. The cell, as shown in Fig. 1, which had an Al negative electrode (a disk of 3 mm thick and 50 mm wide, 99.99% purity, theoretical capacity: 15 A-hr)[2] an $AlCl_3$ [54.5 mole percent (m/o)]-NaCl (45.5 m/o) molten salts electrolyte, an SiO_2 cloth separator, and an FeS_2 positive electrode (area: 7 cm^2), was placed in the thermostated furnace well located in the floor of the Ar atmosphere glove box. Cell performance was observed during repeated cycles of discharge (cutoff: 1.60 V)[3]—pause (30 min)—charge (cutoff: 0.35V)[3]—pause (30 min).

Discharge curves at various temperatures are presented in Fig. 2, where the cell voltage (*IR*-free, and so on) is shown as a function of discharge capacity. The cycle was repeated around 20 times. After several cycles the cell performance was steady, therefore, the data of each 10th cycle are presented. Although charge curves are not shown, the coulombic efficiencies were nearly 100%. The *IR* voltage during charge and discharge was 15-40 mV ($R = 0.2\text{-}0.6\Omega$).[4] The cell was first operated at 180°C. The discharge curve showed two plateaus, *i.e.*, a high plateau at about 0.9V and a low plateau (not shown in Fig. 2) at about 0.6V. The operating temperature was then increased to make the high plateau capacity spread. At 300°C it became 0.7 A-hr (including the higher plateau capacity), *i.e.*, about 23% of theoretical capacity, where it was assumed that FeS_2 was reduced to FeS. On the other hand, a higher plateau clearly appeared at temperatures above 270°C. The increase in temperature affects not only the reaction rate but also the diffusion rate of Al^{3+} ions in the cell. When the diffusion is slow, it is believed that a passivating salt layer forms at the Al electrode due to enrichment in $AlCl_3$ upon discharging and that an insoluble passivating salt layer forms due to a decrease in $AlCl_3$ upon charging (5). It might be the reason why the results in Fig. 2 showed significant effect of temperature on the cell performance. Moreover, when a spiraled Al rod ($\phi 10$ mm, 99.99% purity, 35 cm^2 area) was used as the negative electrode, the higher plateau capacity increased as seen in Fig. 2 curve D. Improvements of the Al electrode are under way.

[1] This capacity corresponds with the change from FeS_2 to FeS as mentioned later.

[2] The excess Al capacity allows the cell performance to be limited by the positive electrode.

[3] *IR* included value.

[4] The relatively high resistance should be reduced markedly by appropriate modifications of the cell design.

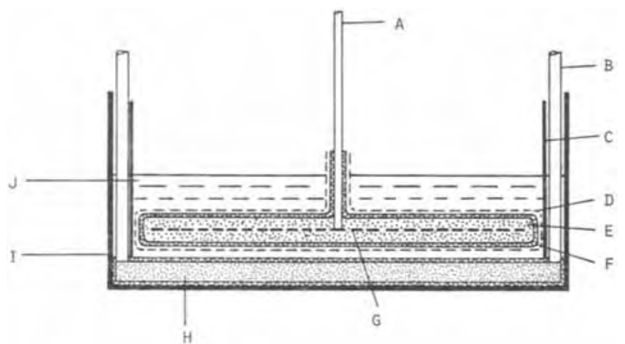


Fig. 1. Schematic diagram of experimental cell. A, positive lead (Mo); B, negative lead (Al); C, Pyrex tube; D, Ni mesh basket; E, FeS_2 electrode; F, SiO_2 cloth; G, Mo mesh current collector; H, Al electrode; I, stainless steel beaker; J, electrolyte ($AlCl_3$-NaCl).

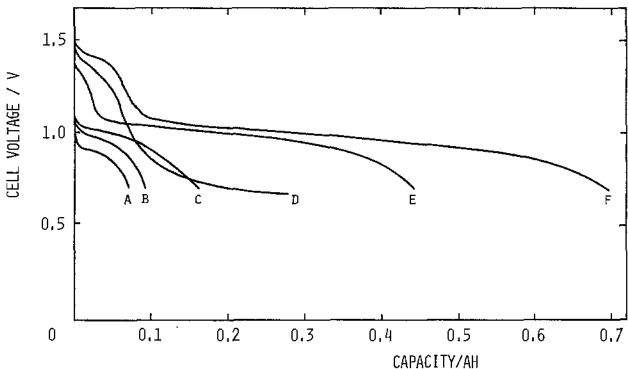

Fig. 2. Discharge curves (*IR*-free) at 10 mA/cm^2 and various temperatures. Lower cutoff voltage is 0.70V. Curve A, 180°C; curve B, 210°C; curve C, 240°C; curve D, 250°C and 15 mmϕ Al rod electrode; curve E, 270°C; curve F, 300°C.

Hereafter, data at 240°C will be discussed as a typical example.

Discharge curves at various current densities are shown in Fig. 3. The more the current density increased, the greater was the high plateau capacity. However, the current density could not be increased more than 30 mA/cm^2 due to a problem involving the Al electrode.

Sn^{2+}, Pb^{2+}, or Fe^{2+} was added into the molten salts electrolyte in order to improve the quality of Al deposition (10-13). As shown in Fig. 4, $SnCl_2$ additive showed significant effect on the cell performance. In the case of 1.0 m/o addition both high and low plateau capacities increased about 60%. Effects of the additive on reactions in the FeS_2 electrode are not clear now.

Additives to the FeS_2 electrode (14) were also investigated. It is known from Fig. 5 that an addition of CoS, CuS, or graphite was effective. In the case of CoS the high plateau capacity lengthened about twice.

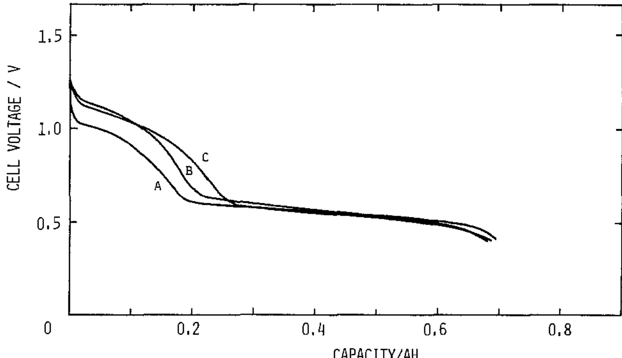

Fig. 3. Discharge curves (*IR*-free) at 240°C and various current densities. Lower cutoff voltage is 0.40V. Curve A, 10 mA/cm^2; curve B, 20 mA/cm^2; curve C, 30 mA/cm^2.

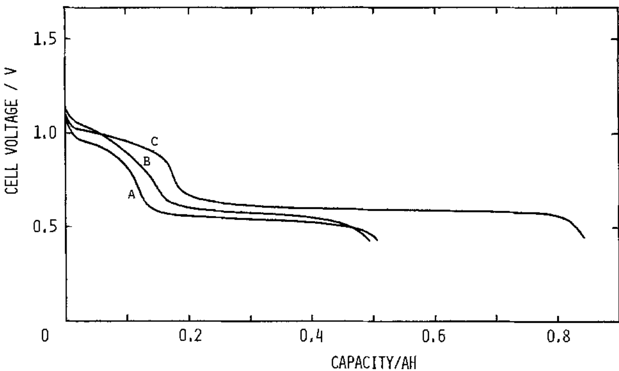

Fig. 4. Discharge curves (*IR*-free) at 240°C and 7 mA/cm² with $SnCl_2$ additive. Curve A, none; curve B, 0.4 m/o; curve C, 1.0 m/o.

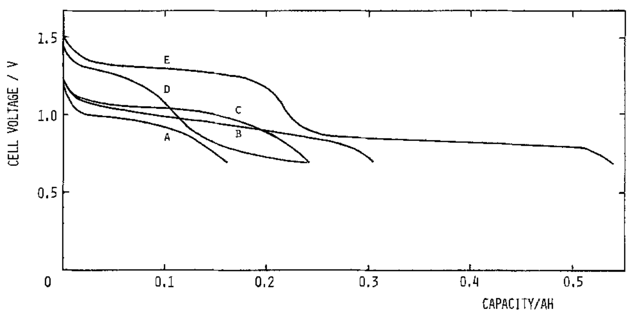

Fig. 5. Discharge curves (*IR*-free) at 10 mA/cm² and various additives. Lower cutoff voltage is 0.70V. The theoretical capacity value excludes that of additive. Curve A, none, 3.13 A-hr; curve B, 15 m/o CoS, 2.76 A-hr; curve C, 15 m/o CuS, 2.74 A-hr; curve D, 10 w/o graphite, 2.81 A-hr; curve E, 30 w/o graphite, 2.19 A-hr.

Moreover, the graphite additive strongly improved the cell performance at relatively low temperature as like 240°C. On the 30 weight percent (w/o) addition, the higher plateau capacity reached about 10% of theoretical, and the high plateau capacity included the higher capacity also reached about 25%.

On the other hand, three plateaus appeared in the discharge curve as known from above results. A stable compound of Al and S is only Al_2S_3 (15). Cell reactions concerned with FeS_2 and Al_2S_3 are considered to be primarily those shown below

$$FeS_2 + 2/3\ Al \rightleftharpoons FeS + 1/3\ Al_2S_3 \quad [1]$$

$$FeS + 2/3\ Al \rightleftharpoons Fe + 1/3\ Al_2S_3 \quad [2]$$

Namely, two plateaus should appear in the discharge (also charge) curve. Although there are few thermodynamic data for Al_2S_3 and these are somewhat indefinite, a theoretical electromotive force for Eq. [1] and [2] can be estimated according to the data of Elliot and Gleiser (16)

$$E_{calc}\ [1] = 1.18V\ (at\ 500°K)$$

$$E_{calc}\ [2] = 0.99V\ (at\ 500°K)$$

In addition to above facts, FeS was detected (but not Al_2S_3) from the FeS_2 electrode discharged up to 0.65V (*IR* included), while Al_2S_3 was detected up to 0.20V (*IR* included) by x-ray analysis. Moreover, open-circuit voltage of the cell charged up to 1.60V (*IR* included) increased strongly with temperature as seen in Fig. 2; however, that estimated from thermodynamic data decreases with temperature. These contradictions as stated above cannot be clearly explained. It should be considered that some complex compounds are formed in the positive electrode by the interaction of Al_2S_3 with iron-sulfur compounds such as in the Li-Al/FeS_2 cell (17).

ABSTRACT

The thermodynamics of aluminum nitride formation in the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems have been studied at 1200° and 1400°K. The nature of the condensed phase and the equilibrium gas phase composition have been determined. Aluminum nitride was the only condensed phase formed under the entire range of the gas phase composition investigated. With a gas phase composition in stoichiometric proportions ($P^{o}_{AlX_3} = P^{o}_{NH_3}$), the yield of aluminum nitride decreased rapidly when the halide or ammonia vapor pressure was higher than 10^{-3} atm. At high hydrogen concentration, the formation of monohalides always reduced the yield of aluminum nitride. Aluminum nitride films have been deposited on various substrates between 500° and 900°C, using an initial composition of the $AlBr_3$-NH_3-H_2 system corresponding to a thermodynamic yield of aluminum nitride higher than 90%. The films have been confirmed to be aluminum nitride by x-ray diffraction technique and by Rutherford backscattering spectroscopy. The deposition rate has been investigated with respect to the temperature and the gas phase composition. At an aluminum tribromide vapor pressure of 8×10^{-5} atm, the deposition rate of aluminum nitride decreased with increasing deposition temperature. At an aluminum tribromide vapor pressure of 2.3×10^{-4} atm, the deposition rate increased between 500° and 600°C. Above 600°C, the deposition rate decreased with increasing deposition temperature. A mechanism of the deposition process has been proposed.

Aluminum nitride has chemical, physical, and electrical properties suitable for several applications as active and passive components in semiconductor devices and for the fabrication of surface wave acoustic devices. Preparation, physical and chemical properties of aluminum nitride films have been reviewed lately (1). Aluminum nitride films have been prepared by chemical vapor deposition from the following starting materials: organo-metallic compounds, $Al(CH_3)_3$ and $Al(C_2H_5)_3$, adduct compound, $AlCl_3 \cdot NH_3$, and aluminum chloride, $AlCl_3$. The deposition temperatures were always higher than 800°C and the plasma activation of low pressure gas phase did not allow deposition at lower temperature. Hence, the chemical vapor deposition of aluminum nitride films could not be used with many semiconductor substrates unstable in this temperature range. Recently, using the $AlBr_3$-NH_3-H_2 system, aluminum nitride films could be deposited between 500° and 900°C and some properties of these films have been examined (2). A decrease of deposition rate was observed with increasing deposition temperature, and aluminum nitride films could not be deposited above 900°C.

In this work, thermodynamics and kinetics of chemical vapor deposition processes have been investigated in order to determine the origin of the decrease of the deposition rate. The nature of condensed phases and the equilibrium gas phase compositions have been determined as a function of the initial gas phase compositions at a given temperature for the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems. The thermodynamic yield of aluminum nitride has been calculated *vs.* the initial gas phase composition, and the domains of formation of aluminum nitride have been determined. Aluminum nitride films have been deposited on various substrates (monocrystalline silicon wafers, nickel and vitreous carbon plates) using an initial composition of the $AlBr_3$-NH_3-H_2 system corresponding to a thermodynamic yield of aluminum nitride higher than 90%. The aluminum nitride deposition rate was investigated with respect to the temperature and the gas phase composition. A mechanism of aluminum nitride film deposition is proposed in this paper.

Thermodynamic Calculations

Procedure.—The computation procedure is based on the minimization of the total Gibbs energy of the system. Assuming that the behavior of the gas phase and the condensed phases is ideal, the free energy of the system is given by the equation

$$\frac{G}{RT} \sum_{i=1}^{N} \left[q_i \left(\frac{\mu^o}{RT} \right)_i + a_i \log_e P_i \right] \qquad [1]$$

* Electrochemical Society Active Member.
Key words: equilibrium, film growth insulator, aluminum nitride.

where q_i is the number of moles of the constituent i, μ^o is the standard chemical potential of the constituent i, N is the total number of constituents, P_i is the pressure of the gaseous constituent i and a_i is a coefficient ($a_i = 1$ for an ideal gas and $a_i = 0$ for a condensed constituent).

The N chemical constituents considered in the equilibrium computation are given in Table I. The probability of existence of these constituents at equilibrium was estimated by considering the values of their free energy of formation, the temperature, and the pressure. The initial experimental parameters (temperature, total pressure, and initial gas phase composition) and the thermodynamic data (3) (free energy function and standard heat of formation of each constituent) were introduced in the computation program of minimization of Eq. [1] detailed in previous papers (4, 5) and used for other gaseous systems (6-8). The partial vapor pressure of each gaseous compound and the number of moles of each constituent present at equilibrium could be calculated. The equilibrium yield, η, of each aluminum compound (aluminum nitride and aluminum halides) with respect to the initial aluminum trihalide composition could be determined. The aluminum nitride yield is defined by the ratio

$$\eta_{AlN} = \frac{N_{eq}^{AlN}}{N^o_{AlX_3}} \times 100 \qquad [2]$$

where N_{eq}^{AlN} is the number of moles of aluminum nitride formed at equilibrium and $N^o_{AlX_3}$ is the initial number of moles of aluminum trihalide. The yield of aluminum halide is given by an analogous equation.

Results and discussion.—The calculations for the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems were carried out at 1200° and 1400°K and at a total pressure of 1 atm. These temperatures were chosen in order to compare the results of the theoretical analysis with the experimental data known for the $AlCl_3$-NH_3-H_2 system [using this system, aluminum nitride films were deposited between 1000° and 1600°K (1)]. For a total number of mole close to 1, at equilibrium, a compound can be considered absent when its number of moles is lower than 10^{-7}. That is the accuracy of calculation. The concentration of the constituents preceded by one dot in Table I has been found lower than the accuracy of calculation and, consequently, these constituents are not existing in the system at equilibrium. Aluminum nitride is the only condensed phase formed under the entire range of the gas phase composition investigated. The variation of the yield of aluminum nitride has the same aspect for both systems studied (Fig. 1). For a given initial gas phase composition and temperature, the chloride and bromide systems yielded similar values of the yield of aluminum nitride. The domain of initial compositions corresponding to a yield of aluminum nitride higher than 90% is located between the horizontal axis and curve (A). At 1400°K and at low aluminum trihalide and ammonia concentrations, curve (A) (dashed line) is slightly shifted away from the bisector because of the formation of other aluminum halides (Fig. 2 and 3). At 1200° or 1400°K, using initial concentrations located between curves (A) and (B), the yield of aluminum nitride decreases from 90 to 10%; between curves (B) and (C), the yield decreases from 10 to 1% and beyond curve (C), it is less than 1%.

With a high hydrogen concentration and a low aluminum trihalide concentration in the initial gaseous mixture, the yield of aluminum monohalide is high and increases with increasing temperature. For example, at 1200°K, the yield of aluminum monobromide is higher than 60% when the initial composition is located between the vertical axis and curve (D) in Fig. 1; between curves (D) and (E), this yield decreases down to 5% and beyond curve (E) it is less than 5%. At 1400°K, the surface area of these domains increases; the yield of aluminum monobromide is higher than 60% between the vertical axis and curve (F) and decreases down to 5% between curves (F) and (G).

The initial gas phase compositions of the $AlCl_3$-NH_3-H_2 system used by several investigators are represented in Fig. 1. The initial compositions used by Chu and co-workers (9) (striped area) and by Noreika and Ing (10) (dark area) correspond to a yield of aluminum nitride higher than 90%. The domains of initial compositions of Arnold and co-workers (11) and Bauer and co-workers (12) cannot be located exactly in the diagram because the vapor pressure values were not provided with accuracy. Nevertheless, from these investigators' data it is possible to locate the initial composition domains between curves (A) and (B) where the yield of aluminum nitride is between 90 and 10%. Assuming that the aluminum trichloride vapor pressure is equal to the saturation vapor pres-

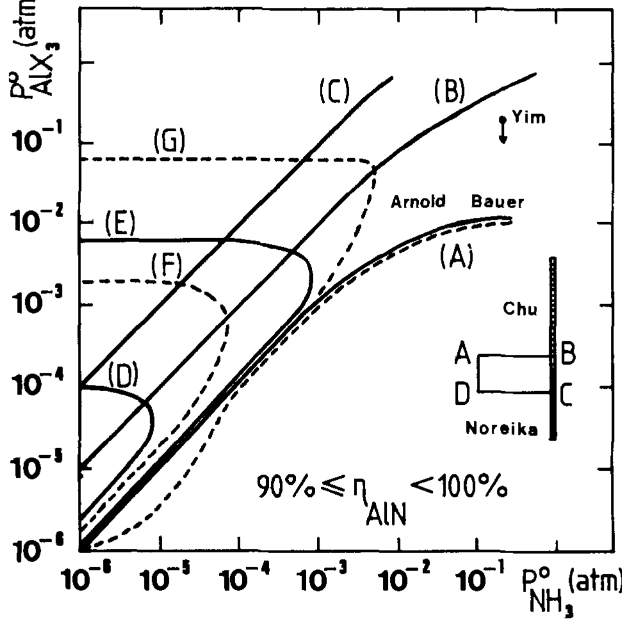

Fig. 1. Deposition domains of aluminum nitride in the initial gas phase composition diagram with the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems. Solid lines, T = 1200°K; dashed lines, T = 1400°K.

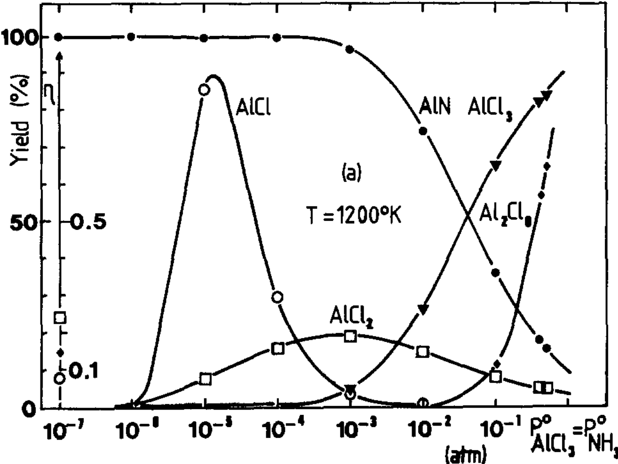
sure, the composition of gaseous mixture used by Yim and co-workers (13) is represented by one point in Fig. 1. The actual halide vapor pressure is certainly lower than the saturation vapor pressure, and then the yield of aluminum nitride is higher than 15%.

The yields of aluminum nitride and aluminum halides as a function of the trihalide vapor pressure or the ammonia vapor pressure are plotted in Fig. 2 and 3. The trihalide and ammonia vapor pressures are equal with an initial gaseous mixture carried out in stoichiometric proportions corresponding to the reaction of aluminum nitride formation. The value of the yield of aluminum monohalide reaches a maximum with an aluminum trihalide vapor pressure of about 10^{-5} atm and this maximum yield increases rapidly with increasing temperature. For chloride system, the abscissa of the maximum yield of aluminum monochloride shifts from about 10^{-5} to 2×10^{-3} atm of aluminum trichloride as the temperature changes from 1200° to 1400°K. The increase of the yield of aluminum monochloride (Fig. 2) or aluminum monobromide (Fig. 3) corresponds to the decrease of the yield of aluminum nitride. The yield of aluminum nitride decreases rapidly at an initial aluminum trihalide vapor pressure higher than 10^{-3} atm when the dissociation of ammonia at equilibrium is important. The yield of dimers (Al_2Cl_6 and Al_2Br_6) is always less than 1%. The yield of aluminum dichloride (Fig. 2) is also very low.

These thermodynamic calculations show that both systems studied are analogous with respect to the yield of aluminum nitride at equilibrium. The prevision of the thermodynamic analysis inserts with the experimental results obtained for the $AlCl_3$-NH_3-H_2 system (9-13). The thermodynamic estimations can be limited. Indeed, the condensed phases considered are only stoichiometric constituents and the thermodynamic equilibrium is not always established at high gas flow rate. Nevertheless, the thermodynamic calculations give an optimization of deposition conditions from the point of view of yields and condensed phase compositions.

Experimental Procedures

The deposition of aluminum nitride films by chemical reaction in the $AlBr_3$-NH_3-H_2 gas flow system was carried out by using an apparatus described in a previous paper (2). Briefly, the deposition was carried out in a horizontal reaction tube and the substrates (silicon, nickel, or vitreous carbon plate) were supported by a silicon carbide coated graphite susceptor heated by an rf generator. The composition of ammonia-hydrogen mixtures was adjusted and maintained at a constant value by means of flow meters and flow regulators. The total flow rate was always equal to 12 liters/min. The aluminum bromide was contained in a Pyrex evaporator maintained at a constant temperature and the vapor was carried in the reactor by a hydrogen stream at a constant flow rate of 50 cm³/min. The evaporator was weighed before and after each run. With the evaporator temperatures of 121° and 147°C. the molar flow rate of aluminum tribromide in the reaction tube was 4×10^{-5} and 1.1×10^{-4} mole/min and the aluminum tribromide vapor pressure was 8×10^{-5} and 2.3×10^{-4} atm, respectively. The kinetic study of deposition was carried out with gas



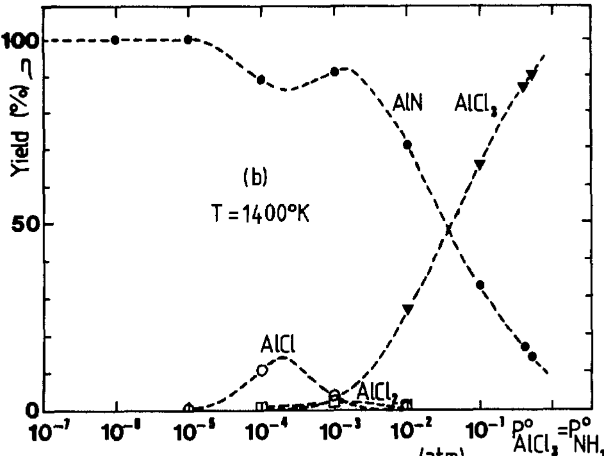


Fig. 2. Variation of equilibrium yields of aluminum nitride and aluminum chlorides using the $AlCl_3$-NH_3-H_2 system in the stoichiometric proportions ($P°_{AlCl_3} = P°_{NH_3}$) (a) at 1200°K and (b) at 1400°K.

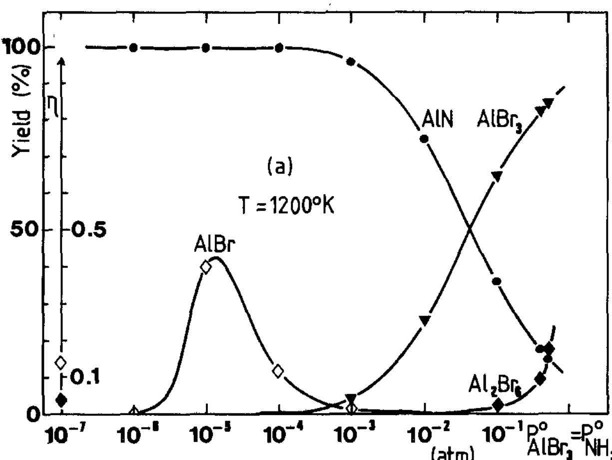

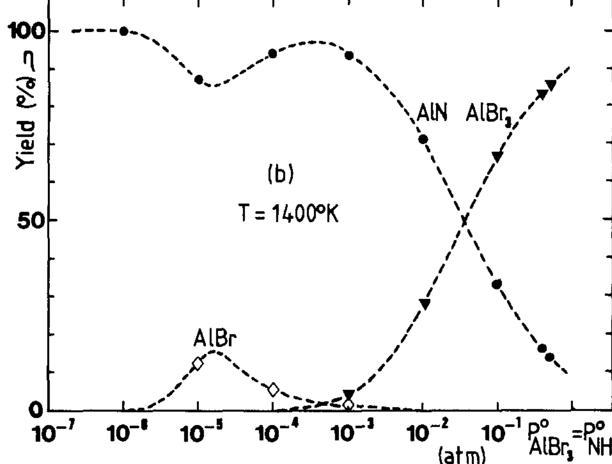

Fig. 3. Variation of equilibrium yields of aluminum nitride and aluminum bromides using the $AlBr_3$-NH_3-H_2 system in the stoichiometric proportions ($P°_{AlBr_3} = P°_{NH_3}$) (a) at 1200°K and (b) at 1400°K.

phase compositions located in the rectangle ABCD (Fig. 1) in the initial gas phase composition diagram where the thermodynamic yield of aluminum nitride is about 99%. The mixing zone between ammonia and aluminum bromide vapors was heated at 300°C in order to avoid the formation of solid adduct compounds, $AlBr_3 \cdot nNH_3$. Aluminum nitride films were deposited at substrate temperatures in the range 500°-900°C. Above 900°C, the deposition rate was low and the thickness of films was not uniform. The deposition time was determined by the time of hydrogen stream on aluminum bromide.

The crystallographic structure of deposited material was determined by removing the layer from the nickel plate substrate and identifying the x-ray patterns obtained by means of a Debye-Scherrer powder technique. In all the cases, the pattern revealed the presence of polycrystalline aluminum nitride. The films deposited on vitreous carbon substrates were analyzed by Rutherford backscattering spectroscopy (14). The accuracy on the aluminum atom numbers per square centimeter was 0.8%. The deposition rate of aluminum nitride was expressed by the number of aluminum atoms deposited per square centimeter per minute.

Kinetic Study

Results.—At an aluminum bromide vapor pressure of 8×10^{-5} atm, the deposition rate was low and almost independent of the ammonia-hydrogen composition. The measured values fall within the limits of reproducibility of the experiments. The deposition rate decreased with increasing deposition temperature (Fig. 4a). At an aluminum bromide vapor pressure of 2.3×10^{-4} atm, the deposition rate was higher and the reproducibility was better. The rate increased between 500° and 600°C; above 600°C, it decreased with increasing deposition temperature (Fig. 4b). The variation of deposition rate with the ammonia-hydrogen composition was not continuous. The decimal logarithm of the deposition rate *vs.* the reciprocal absolute temperature is plotted in Fig. 5. Below 600°C, the activation energy was about 9 kcal $mole^{-1}$. The dashed straight line (Fig. 5) represents the result obtained by Kelm (15) for the deposition of aluminum nitride films by pyrolysis of adduct compound, $AlCl_3 \cdot NH_3$. Using the $AlBr_3$-NH_3-H_2 gas flow system, the deposition rate of aluminum nitride films had the same value but in a lower temperature range.

Discussion.—Thermodynamic analysis has shown that the yield of aluminum nitride at equilibrium increased with increasing temperature; this yield was higher than 98% at 1200°K with an initial gas phase composition located in the rectangle ABCD (Fig. 1). Then, the decrease of deposition rate with increasing deposition temperature (Fig. 4) can be only attributed to the kinetic characteristics of the deposition process. This decrease is suggesting of a homogeneous reaction in the gaseous phase and can be analyzed using the model proposed by Sladek (16). Schematically, the deposition process can be represented under the following form

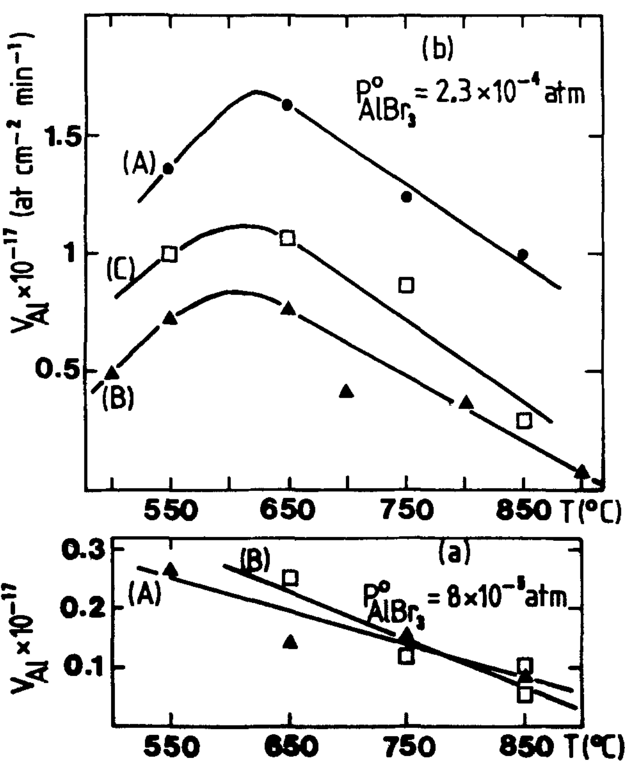

Fig. 4. Variation of AlN deposition rate in the $AlBr_3$-NH_3-H_2 system *vs.* the deposition temperature.

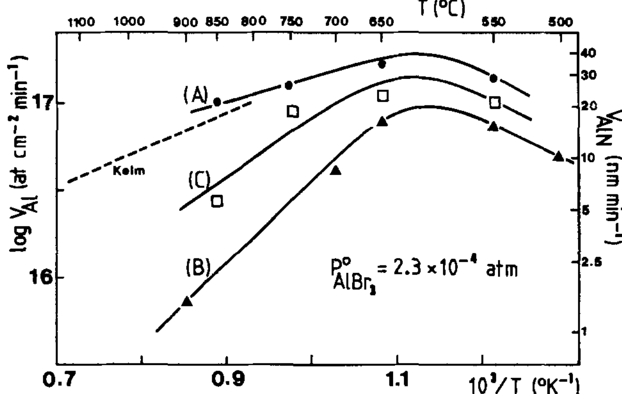

Fig. 5. Variation of the decimal logarithm of aluminum nitride deposition rate *vs.* the reciprocal absolute temperature at an aluminum bromide vapor pressure of 2.3×10^{-4} atm and an ammonia-hydrogen composition of (A) 1:9, (B) 2:1, and (C) 9:1.

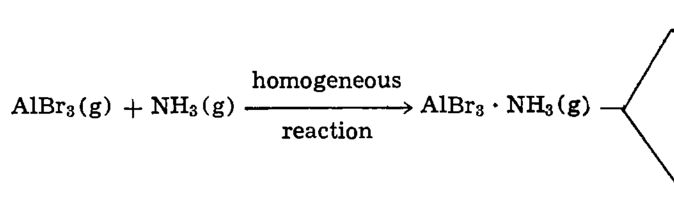

Under our experimental conditions, the gaseous adduct compound, $AlBr_3 \cdot NH_3$, was probably formed at 300°C in the mixing zone between ammonia and aluminum bromide vapor. Using the data given by Trusov and Suvorov (17), a thermodynamic calculation has shown that the aluminum tribromide vapor introduced into the reactor could be completely transformed into the adduct compound according to the following equilibrium

$$(i) \quad AlBr_3(g) + NH_3(g) \rightleftharpoons AlBr_3 \cdot NH_3(g)$$

and the concentration of the adduct compound at equilibrium was independent of the ammonia-hydrogen

composition used. The thermodynamic calculation has also shown that the reverse reaction was possible above 300°C, simultaneously with the reaction of aluminum nitride formation

(*ii*) $AlBr_3 \cdot NH_3(g) \rightarrow AlN(s) + 3HBr(g)$

At low deposition temperature, reaction (*ii*) occurred in an adsorbed phase on the substrate surface. The activation energy of the surface reaction was low (9 kcal mole^{-1}) probably because of the configuration of the adduct compound; aluminum and nitrogen atoms are already bonded in the molecule $AlBr_3 \cdot NH_3$. Simultaneously, a small part of the films could grow by the deposition of aluminum nitride powder formed by nucleation in the gaseous phase.

Under the experimental conditions used, the temperature gradient in the gaseous phase was high and the homogeneous reaction could only occur in a very thin layer located on the substrate surface. The high roughness of films deposited at low temperature [curves (A) and (D), Fig. 6] was probably due to this deposition of powder. The activation energy of homogeneous reaction is higher than that of surface reaction. With increasing temperature, the rate of homogeneous reaction increased more rapidly than the rate of surface reaction and the yield of homogeneous reaction also increased because the volume of gaseous phase where the reaction could occur was larger. At high temperature (above 700°C), the aluminum nitride powder was formed at a large distance from the substrate surface and could not be deposited. The films had a smooth surface [curves (C) and (F), Fig. 6]. The concentration of reactants close to the substrate surface was reduced and the growth rate of film by the surface reaction decreased.

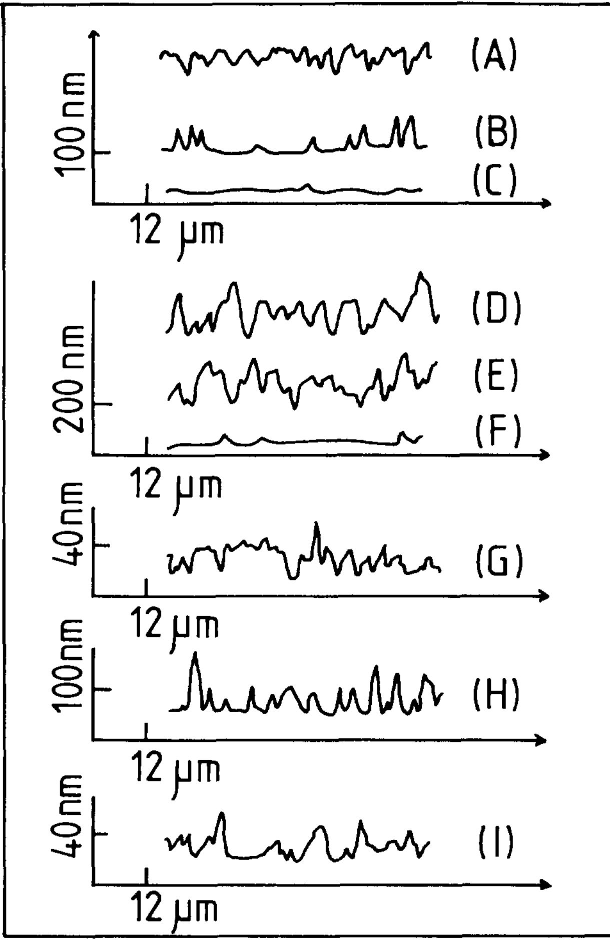

Fig. 6. Surface profiles of aluminum nitride films. Films deposited at (A) 550°C, (B) 750°C, and (C) 850°C with a 2:1 ammonia-hydrogen mixture and an aluminum bromide vapor pressure of 8 × 10^{-5} atm. Films deposited at (D) 550°C, (E) 750°C, and (F) 850°C with a 2:1 ammonia-hydrogen mixture and an aluminum bromide vapor pressure of 2.3 × 10^{-4} atm. Films deposited at 650°C with an aluminum bromide vapor pressure of 8 × 10^{-5} atm and an ammonia-hydrogen composition of (G) 1:9, (H) 2:1, and (F) 9:1.

The deposition rate dependence with ammonia-hydrogen composition at the higher aluminum bromide vapor pressure and the independence at the lower vapor pressure cannot be easily interpreted. At an aluminum bromide vapor pressure of 8 × 10^{-5} atm, the deposition rate (Fig. 4a) and the surface profiles of films [curves (G), (H), and (I), Fig. 6] were not affected by the variation of ammonia concentration in the gaseous phase probably because the concentration of the adduct compound remained constant. The nature of substrate can change some properties of deposit. The effect of the three substrates used (silicon, nickel, and vitreous carbon) could not be investigated because the nature of substrate was appropriated with the property of film studied. Sometimes, the effect of total flow rate might provide insight into the mechanism of deposition. This effect could not be studied because with a total flow rate lower than 10 liters/min, the thickness of films was not uniform and, then, the kinetic study of deposition was not possible.

Summary and Conclusions

The thermodynamics of aluminum nitride formation in the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems have been studied. The equilibrium gas phase composition and the thermodynamic yield of aluminum nitride have been determined. Aluminum nitride films were deposited in the $AlBr_3$-NH_3-H_2 system between 500° and 900°C. With the higher aluminum bromide vapor pressure (2.3 × 10^{-4} atm), the deposition rate increased with increasing substrate temperature up to 600°C; above 600°-650°C, the deposition rate decreased. With the lower aluminum bromide vapor pressure (8 × 10^{-5} atm), the deposition rate was decreasing in the entire temperature range studied. The deposition rate did not depend on the gas phase composition. The roughness of surface of aluminum nitride films deposited at lower temperatures was attributed to the deposition of aluminum nitride powder formed by gas phase nucleation. At higher temperatures, the growth of aluminum nitride films was only due to the adsorbed gas phase reaction on the surface of substrate. A model for the deposition mechanisms of aluminum nitride films was proposed. These results show the influence of homogeneous reactions in a chemical vapor deposition process. Using the $AlCl_3$-NH_3-H_2 system, Arnold and co-workers (18) have shown the effect of the gaseous adduct compound formation, $AlCl_3 \cdot NH_3$, on the kinetics of aluminum nitride deposition. The aluminum nitride deposition mechanisms in the $AlCl_3$-NH_3-H_2 and $AlBr_3$-NH_3-H_2 systems are very similar.

Deformation in Dielectric-Isolated Substrates and Its Control by a Multilayer Polysilicon Support Structure

Takaya Suzuki, Akio Mimura, Tatsuya Kamei, and Takuzo Ogawa

Hitachi Limited, Hitachi Research Laboratory, Hitachi, Ibaraki 319-12, Japan

ABSTRACT

Curved deformations in the dielectric-isolated substrate with a conventional, single polysilicon support structure occur mainly during two processes. One is deposition of the polysilicon support region and the other is thermal oxidation and diffusion for junction formation. The former is concave toward the polysilicon support layer side. The latter, however, has a tendency to bow convexly toward the polysilicon layer side and seems to be caused by expansion stress generated through penetration or diffusion of high concentrations of oxygen into the surface region of the polysilicon support region. These deformations can be successfully controlled by adopting a multilayer polysilicon support structure consisting of alternating polysilicon layers and silicon oxide films for the support region and also by providing a preventive film for oxide diffusion into the surface of the polysilicon support region. During the formation of the multilayer structure, it is proposed that contraction stress, caused by polysilicon deposition, and expansion stress, caused by silicon oxide deposition, are occurring alternately and are compensating each other to form a wafer with little deformation.

Dielectric-isolated (DI) substrates are used in high voltage power IC's and radiation-hardened devices because of their excellent characteristics, including high isolation voltages, isolation capability for an alternating current, diminished parasitic capacitances, and lessened photodiode currents in radiation environments (1, 2). One of the most serious problems in DI manufacture is complicated wafer deformation originating from the use of a relatively thick polysilicon layer as a support structure for single crystal silicon regions (3, 4). The deformation of the DI substrate takes place mainly during the deposition of the polysilicon support region and during the formation of junctions in the single crystal silicon regions, *i.e.*, the processes of thermal oxidation and diffusion. The former kind of deformation has been reported to be caused by the tensile growth stress generated through contraction of the growing polysilicon layer at high temperatures (5, 6). No investigation has apparently been reported as to the latter kind of deformation. These severe macroscopic deformations create undesirable effects in the subsequent grinding process for substrate fabrication and in the photolithography process for junction formation. Therefore, it is very important to control these deformations in order to improve process yield and accuracy. Although it has been reported that doping of a small amount of an impurity, such as oxygen into polysilicon, is effective in minimizing the deformation during polysilicon deposition (7, 8), a successful control method of deformation throughout the whole device fabrication process has not been reported.

Key words: dielectric isolation, polysilicon, deformation, support structure.

This paper first describes the deformations of the DI substrate with a conventional, single polysilicon support structure and then describes a novel method for controlling both kinds of deformation in which a multilayer polysilicon structure consisting of alternating polysilicon layers and silicon oxide films is adopted for use in the support region of the DI substrate.

Experimental

Preparation of DI substrates. —The DI substrates were fabricated by the conventional single poly method (1), as shown in Fig. 1. The single crystal silicon used was CZ type, (100) surface oriented, 50 mm in diameter, about 290 μm in thickness, n-type, and had 10-15 Ωcm resistivity. V-shaped isolation moats were formed by using anisotropic etch with KOH solution (9). Isolation oxide (about 1.7 μm) was grown by thermal

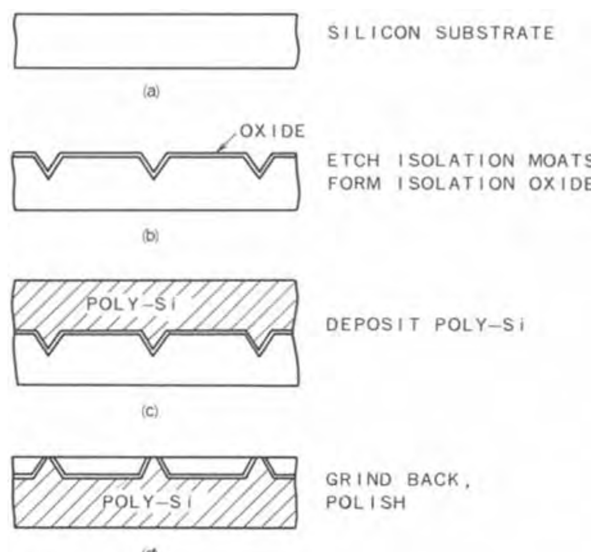

Fig. 1. Fabrication process for DI substrates

oxidation at 1100°C. Two different structures of polysilicon support region were formed in these experiments: a single layer polysilicon structure and a multilayer polysilicon structure. The polysilicon was deposited in a conventional epitaxial reactor with a growth rate of about 6 μm/min at 1200°-1250°C (optically observed) using an $SiHCl_3$-H_2 reduction process. After the polysilicon was deposited, the poly surface was ground. The slice was then inverted and the original single crystal substrate was ground back and polished until the silicon oxide isolation films on the grooves were exposed. The thickness of the single crystal silicon islands ranged between 60-80 μm. After polishing, the substrate was ready for conventional device processing (oxidation and diffusion).

Deposition of multilayer polysilicon structure.—Figure 2 shows cross-sectional examples of the multilayer polysilicon support structure. This support structure consists of an alternating laminate of polysilicon layers and silicon oxide films. The alternating depositions were carried out in a conventional, vertical-type epitaxial reactor having a rotating disk 300 mm in diameter. The deposition temperatures were 1200°-1250°C (optically observed). The $SiHCl_3$-H_2 reduction process was used for polysilicon and the $SiHCl_3$-CO_2-H_2 process, for silicon oxide. The deposition rates of the polysilicon layers and the silicon oxide films were about 6 and 0.3 μm/min, respectively. The quality of the oxide film was examined and found to be almost the same as that of the oxide film grown by thermal oxidation. The thicknesses of the silicon oxide films were the same through the structure, while various oxide thicknesses ranging from 0.3 to 1.4 μm were used in the experiments. The total thickness of the support region ranged about from 200 to 500 μm.

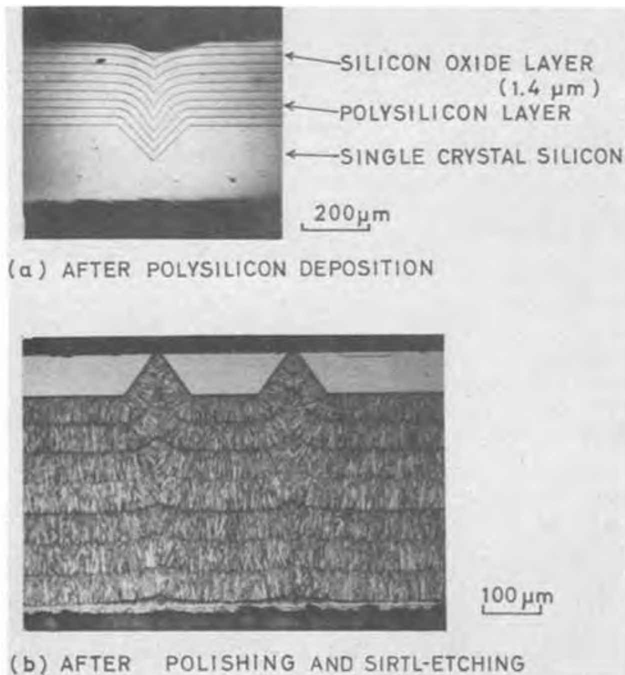

Fig. 2. Cross-sectional views of the multilayer polysilicon support structure.

The steps for producing such multilayer polysilicon support are as follows. Initially, a predetermined thickness of the first polysilicon layer was deposited by introducing trichlorosilane and hydrogen into the reactor. Then, the introduction of trichlorosilane was stopped and the reactor was purged with hydrogen for 5 min. Next, a silicon oxide film was deposited by introducing trichlorosilane and carbon dioxide together with hydrogen. After the deposition of the silicon oxide film, the reactor again was purged with hydrogen and the second polysilicon layer was deposited. In this way, the steps of polysilicon deposition, reactor purge, silicon oxide deposition, and reactor purge were repeated according to the number of layers required.

Degree of wafer bowing. —In the DI process, two types of deformation were observed. One is the type in which the polysilicon support layer side of a wafer is concave while the other is reversed. Therefore, the sign of the bowing direction is defined as "plus" for the former and as "minus" for the latter. The degree of bowing is expressed by the reciprocal of the radius of curvature R calculated from the deviation h from a flat plane 50 mm in length, assuming that the configuration of the deformation is almost spherical (5). The deviation was measured with a surface measuring instrument (Dektak). The value h is the average of the two values measured in the x and y directions on a wafer. The relation between $1/R$ and h is given as $1/R - (2/r^2)h$, where r is the radius of the wafer.

Results and Discussion

Deformation of substrates with single polysilicon support structure.—It was observed that the deformation of wafers took place mainly during the following two processes. One is the deposition of the polysilicon support region and the other is the formation of junctions in the single crystal silicon region, *i.e.*, the processes of thermal oxidation and diffusion.

Figure 3 shows the variation in the degree of deformation (bowing) during the various wafer processes. Results are shown for three different polysilicon thicknesses. The polysilicon deposition temperature was 1230°C. Thermal oxidation was performed at 1200°C in a wet oxygen atmosphere for 5.7 hr. Boron diffusion was carried out at 1200°C for 9 hr after a BN predeposited process at 1000°C. It can be seen that the wafers underwent curved deformations in the plus direction after the deposition of the polysilicon support layer and had a tendency to deform in the minus direction during the thermal oxidation process. The former kind of deformation has been discussed previously (5) and hence will not be described in detail. The degree of bowing after the deposition of the polysilicon layer increases with increasing thickness of the deposited polysilicon layer and tends to increase with lowering of the deposition temperature. It can be considered that this kind of bowing is caused by the tensile growth stress generated through the contraction of the growing polysilicon layer at high temperatures. This contraction of the polysilicon layer may be induced by a mechanism similar to sintering (5). The latter kind of deformation has apparently not been reported previously and hence is examined here in more detail.

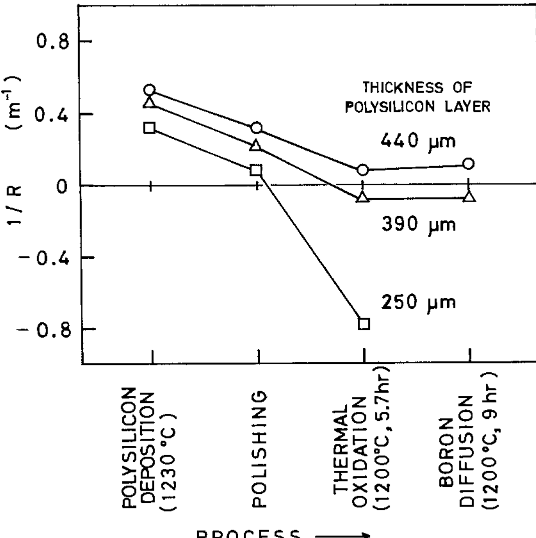

Fig. 3. Effect of process steps on wafer deformations

As seen above, the DI substrate has a tendency to deform convexly toward the side of the polysilicon support layer, *i.e.*, the minus direction, during the subsequent thermal oxidation process. The degree of bowing shows a remarkable change, especially in the case of the substrate with a thinner polysilicon support layer. The change in bowing is smaller as the thickness of the polysilicon support layer increases. It was also observed that the change in bowing during the thermal oxidation process was greater at higher temperature and for longer heat-treatment times. Figure 4 indicates the effect of the time of oxidation t on the amount of the change in the reciprocal of the radius of curvature $(1/R)$, where, $\Delta(1/R) = (1/R$ before oxidation$) - (1/R$ after oxidation$)$. It is seen that $\Delta(1/R)$ is approximately proportional to the square root of the oxidation time. This is very similar to the so-called parabolic relationship in the rate of thermal oxide growth. These deformations toward the minus direction did not change even if the oxide film formed on the polysilicon surface was removed by etching. In addition, it was found that this kind of deformation occurred only during the high temperature heat-treatment in an oxygen-containing atmosphere and not in atmospheres such as argon or hydrogen.

From the above results, it appears that the bowing which occurred during thermal oxidation may be caused by the expansion stress generated through penetration or diffusion of high concentrations of oxygen along the grain boundaries of polysilicon into the surface region of the polysilicon support region. The time dependence of $\Delta(1/R)$, see Fig. 4, can be qualitatively explained as follows. The reciprocal of the radius of curvature $1/R$ is proportional to the expansion stress in the polysilicon surface region. This expansion stress can be assumed to be proportional to the amount of oxygen penetrated or diffused into the polysilicon surface. Therefore, since the amount of oxygen which will reach and diffuse into the polysilicon surface region is controlled by the diffusion through the oxide film formed on the polysilicon layer and is proportional to the square root of the oxidation time (10), it may be considered that $\Delta(1/R)$ shows the same time dependence.

Figure 5 shows the profile of oxygen concentration in the polysilicon support layer of the DI substrate which has been subjected to the thermal oxidation process. The oxygen concentration was determined by successively etching the surface and measuring the ratio of $^{44}SiO^+$/total ion by secondary ion mass spectroscopy (Hitachi, IMA-2). Although the absolute values of concentration are not known, it can be seen that high concentrations of oxygen exist in the polysilicon support layer ranging from the surface to a depth of about 30-40 μm. Next, the change in bowing of DI substrates which had been deformed by thermal oxidation was measured by successively etching off the surface of the polysilicon layer side. These results are shown in Fig. 6. It was found that, by etching off the polysilicon surface of about 30-40 μm, bowing in the minus direction is almost restored to the initial bowing in the plus direction that had been observed before thermal oxidation. The etched thickness necessary to return to the initial bowing is roughly consistent with the range of high oxygen concentration.

As mentioned above, the DI substrates have a tendency to deform in the minus direction during heat-treatment in an oxygen-containing atmosphere. The change in this bowing can be reduced by increasing the thickness of the polysilicon support layer. However, the degree of bowing during the deposition of the polysilicon support layer becomes larger as the thickness of the polysilicon support layer is increased. Therefore, from the standpoint of practical use, it is necessary to establish a method for controlling deformation, even during thick polysilicon deposition, and also for minimizing deformation during thermal oxidation. In the next section, a novel fabrication method for DI substrates that meets such requirements is described.

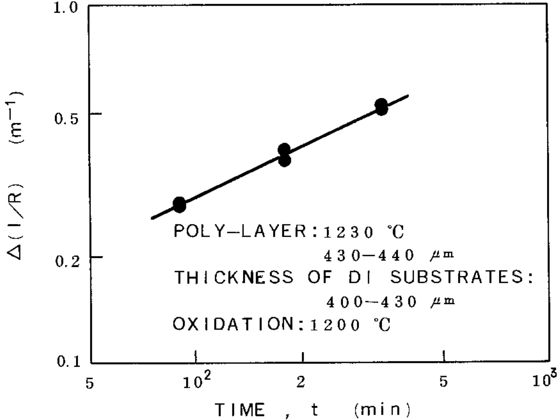

Fig. 4. Dependence of the amount of change in curvature on the time of thermal oxidation, where $\Delta(1/R) = (1/R$ before oxidation$) - (1/R$ after oxidation$)$.

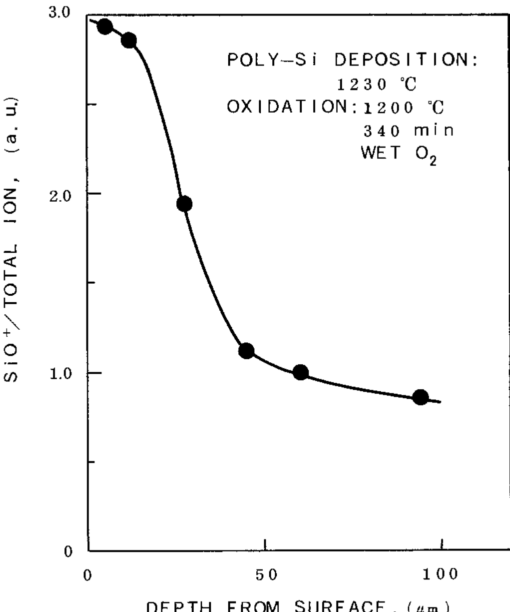

Fig. 5. Profile of oxygen concentration in the polysilicon support region of the DI substrate subjected to thermal oxidation.

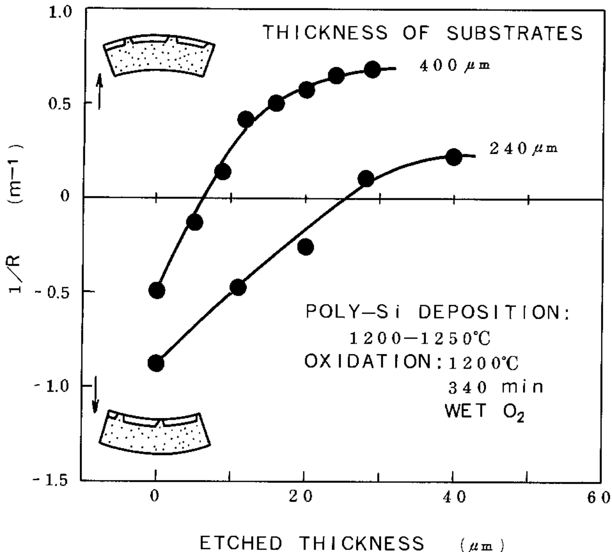

Fig. 6. Bowing recovery of DI substrates deformed by thermal oxidation as measured by successive etching of the surface of the polysilicon layer side.

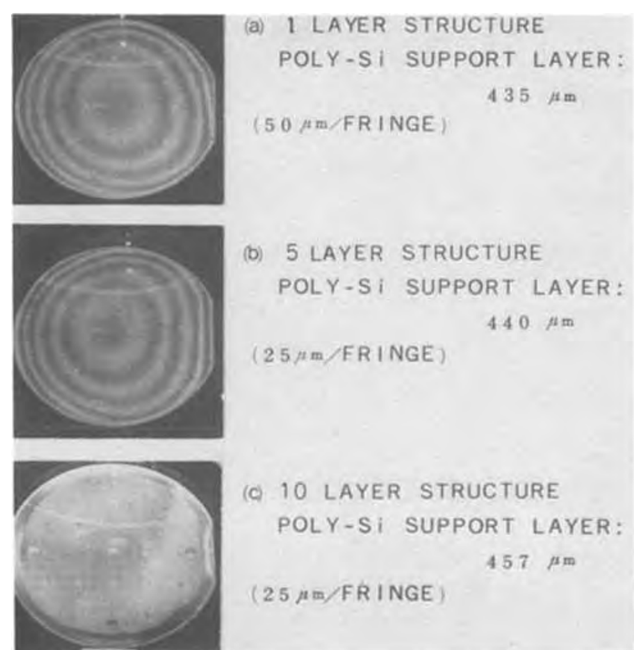

Fig. 8. Typical interference patterns of the deformation for wafers with different numbers of polysilicon layers.

Control of deformation by a multilayer polysilicon support structure.—Control of deformation during deposition of a polysilicon support structure.—It was found that the magnitude and direction of bowing due to the deposition of a polysilicon support layer can be controlled by applying the multilayer structure consisting of alternating polysilicon layers and silicon oxide films. Figure 7 shows a relation between the number of polysilicon layers in a multilayer structure and the magnitude of bowing of the substrate for two different total thicknesses of the support region. The degree of bowing decreases with increasing numbers of polysilicon layers. Above a certain number of layers, the direction of bowing is inverted so that the polysilicon support region side of the wafer begins to take the form of a convex surface. For the two cases in which the total thicknesses of the support regions are 210-260 and 430-480 μm, the thickness for one polysilicon layer when the degree of bowing is almost zero is about the same, *i.e.*, 40-50 μm. Figure 8 shows typical interference patterns of the deformation for three different numbers of polysilicon layers. The patterns were observed with a commercial flatness tester (Speedlap, Check Flat). The thicknesses of the polysilicon support regions of these samples were 430-460 μm. Figure 9 shows the effect of the thickness of the silicon oxide films between the polysilicon layers on the degree of bowing of wafers with a multilayer polysilicon structure. The degree of bowing was hardly affected by the thickness of the silicon oxide films in the range from 0.3 to 1.4 μm.

Next, in order to investigate the cause of the bowing reduction effect by the multilayer structure, the manner of changes in bowing during the deposition of the support region was indirectly observed by measuring the curvature of the wafers when taken out of the reactor at various deposition steps during the multilayer structure fabrication. The results are shown in Fig. 10. The curvature measurements were done at the first, second, fourth, and eighth depositions of polysilicon and silicon oxide. The dashed line indicates an approximation of the bowing variation. It is seen that the degree of bowing which occurred at the first polysilicon layer deposition decreases in the following deposition of the silicon oxide film. Although the magnitude of the bowing increases at the deposition of the second polysilicon layer, it again decreases with the following sili-

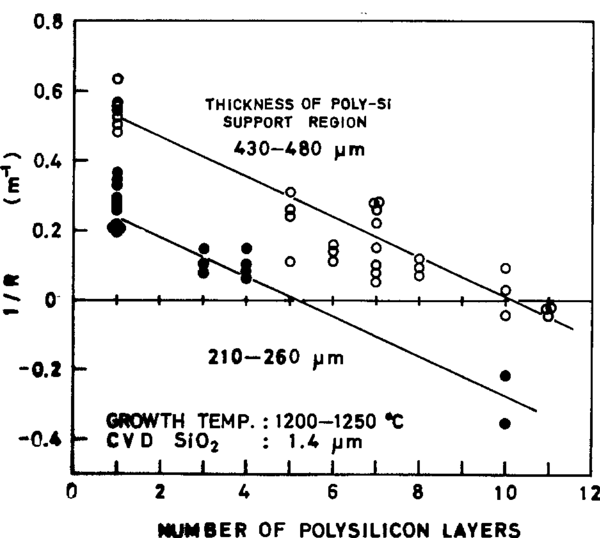

Fig. 7. Relation between the number of polysilicon layers in a multilayer polysilicon support region and the degree of bowing of wafers.

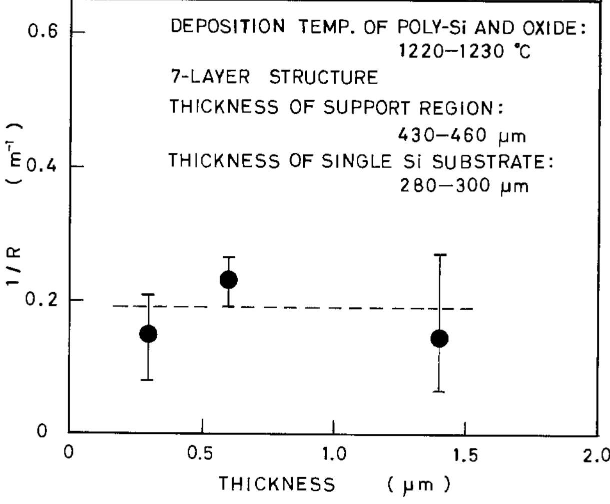

Fig. 9. Effect of the thickness of the silicon oxide films between the polysilicon layers on the degree of bowing of wafers with a multilayer polysilicon structure.

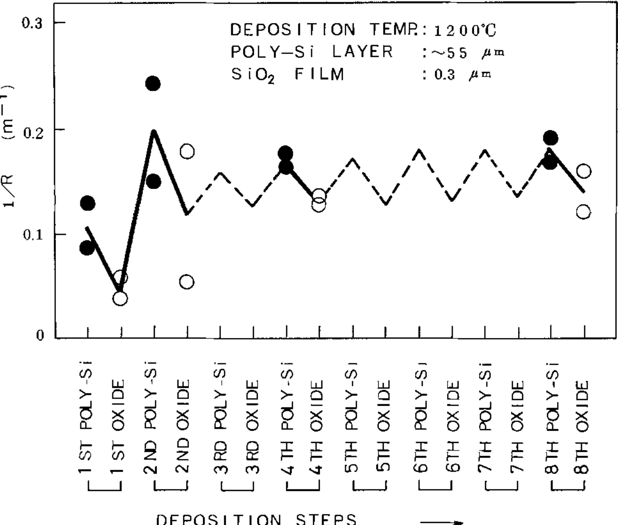

Fig. 10. Curvature variation of the wafers during the formation of a multilayer polysilicon support structure.

con oxide film deposition. The reduction in bowing, however, is somewhat smaller than that of the first deposition step. In this manner, the whole polysilicon support region seems to grow thicker with the repetition of increases and decreases in bowing, according to the alternating polysilicon layer and silicon oxide film depositions. It appears that the penetration or diffusion of high concentrations of oxygen into the polysilicon layer also takes place in the case of the chemical vapor deposition of silicon oxide film at high temperatures just as in the case of thermal oxidation. Therefore, it is proposed that during the formation of the multilayer polysilicon support structure, contraction stress, caused by polysilicon deposition, and expansion stress, caused by silicon oxide deposition, are occurring alternately, and these stresses of opposite direction are successfully compensating each other to form a wafer with little deformation.

Control of deformation during thermal oxidation.—The DI substrate with a multilayer polysilicon support structure was also deformed convexly toward the side of the polysilicon support region, *i.e.*, the minus direction, due to high temperature heat-treatment in an oxygen-containing atmosphere. It was observed, however, that the degree of this kind of deformation was affected by the thickness of the extreme outer polysilicon layer. Therefore, the magnitude of bowing change after thermal oxidation was measured using the sample wafers in which the thickness of the extreme outer polysilicon layer was intentionally varied by lapping. Figure 11 shows a schematic cross-sectional view of such a DI wafer used for the experiments.

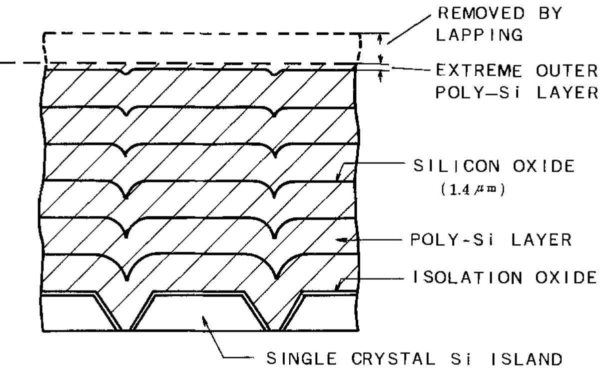

Fig. 11. Schematic cross-sectional view of the multilayer polysilicon support structure in which the thickness of the extreme outer polysilicon layer was thinned.

Figure 12 graphs the experimental results and shows the relation between the ultimate thickness of the extreme outer polysilicon layer after polishing and the change in the magnitude of bowing toward the minus direction, $\Delta(1/R)$, due to thermal oxidation. The thermal oxidation was performed at 1200°C for 340 min in a wet oxygen atmosphere. Although scatter in the measured values is seen, it is evident that the change in the magnitude of bowing $\Delta(1/R)$ decreases as the thickness of the extreme outer polysilicon layer is decreased. The scatter may be due to the uncertainty of the amount of lapping of the extreme outer polysilicon layer, which is caused by wafer bowing after the deposition of the polysilicon support region. Similar experiments, that is, the thermal oxidation of the DI substrates in which the whole extreme outer polysilicon layer was removed by etching and the silicon oxide film was exposed, showed little change in bowing toward the minus direction. Therefore, it is concluded that the deformation of the DI substrate with multilayer polysilicon support structure due to thermal oxidation and diffusion processes is caused by the same mechanism as in the case of the DI substrate with a single layer polysilicon support structure, and that the extreme outer silicon oxide film is acting as the preventive film for oxygen diffusion into the polysilicon support region.

As mentioned above, it is found that the bowing occurring during thermal oxidation or diffusion processes is able to be minimized by providing a film for preventing the penetration or diffusion of oxygen into the surface region of the polysilicon support region. For the DI substrate with a multilayer polysilicon structure, this preventive film is realized by lapping the extreme outer polysilicon layer to a thickness as thin as possible.

Summary

The DI substrate with a single polysilicon support structure is deformed during two processes. One is the deposition of the polysilicon support region and the other is the high temperature heat-treatment in an oxygen-containing atmosphere, *i.e.*, thermal oxidation and diffusion. The deformation after deposition of the polysilicon support region is bowing in a direction such that the polysilicon support region side of the substrate is concave, while the deformation after the thermal oxidation and diffusion is bowing in a direction such that the polysilicon support region side of the substrate tends to become convex. The former bowing seems to be caused by the tensile growth stress gen-

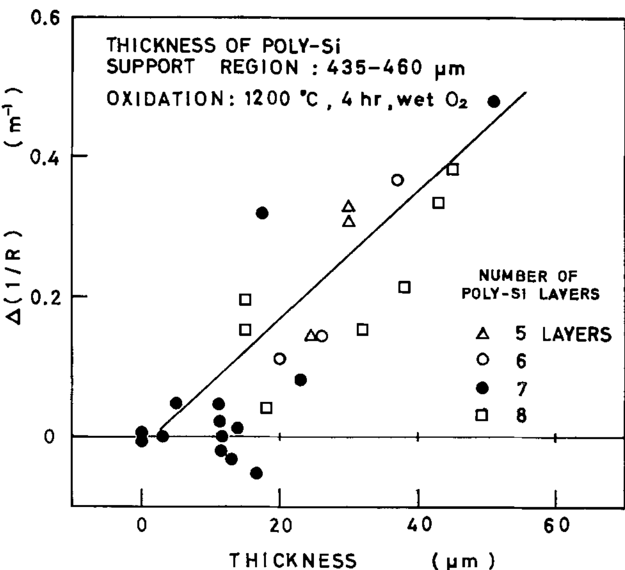

Fig. 12. Relation between the ultimate thickness of the extreme outer polysilicon layer after polishing and the change in the degree of bowing, $\Delta(1/R)$, due to thermal oxidation.

erated through contraction of the growing polysilicon layer at high temperatures. The latter bowing seems to be caused by the expansion stress generated through penetration or diffusion of high concentrations of oxygen into the surface region of the polysilicon support region.

The magnitude and direction of bowing due to the deposition of a polysilicon support layer can be controlled by applying the multilayer structure consisting of alternating polysilicon layers and silicon oxide films. The magnitude of bowing decreases with increasing the number of polysilicon layers for a given total thickness of the support region. The thickness for one polysilicon layer in which the magnitude of bowing is almost zero is about 40-50 μm. It is proposed that during the formation of the multilayer polysilicon support structure, contraction stress, caused by polysilicon deposition, and expansion stress, caused by silicon oxide deposition, are occurring alternately, and these stresses of opposite direction are successfully compensating each other to form a substrate with little deformation.

The DI substrate with a multilayer polysilicon support structure also tends to bow convexly toward the side of the polysilicon support region due to thermal oxidation and diffusion. This type of deformation can be minimized by providing a film for preventing the penetration or diffusion of oxygen into the surface region of the polysilicon support region. This preventive film was realized by lapping the extreme outer polysilicon layer to a thickness as thin as possible.

The deformations which take place during the DI process can be successfully controlled by adopting the multilayer polysilicon support structure and by providing a preventive film for oxygen penetration or diffusion into the surface of the polysilicon support region.

Electronic States of Ni-Silicides and Its Relation to Metal-Silicide/Si Interfaces

M. Iwami, K. Okuno, S. Kamei, T. Ito, and A. Hiraki

Department of Electrical Engineering, Osaka University, Suita, Osaka 565, Japan

ABSTRACT

Electronic states of Ni-silicides (Ni_2Si, NiSi, and $NiSi_2$) and potential barrier heights (ϕ_B's) of Ni-silicide/Si junctions were studied by nuclear magnetic resonance (NMR) and by capacitance-voltage (C-V) measurement, respectively. It was determined that the electronic state of silicon is metallic in all Ni-silicides and that at the site of Si-atom the 3s-electron density with Fermi energy [$\rho_s(E_F, \mathrm{Si})$] becomes larger with increasing Si concentration. From C-V measurements, all of three Ni-silicide/Si junctions showed almost the same barrier height (ϕ_B) of $\sim$0.7 eV. These and other experimental results are discussed, and a proposal is made on the nature of the Schottky barrier height at the transition-metal-silicide/Si interfaces.

Many investigations on metal-semiconductor (M-S) interfaces (contacts) have been done for a long period. Above all, so-called contact problems such as the formation of Schottky barriers or ohmic contacts are also practically very important from their role in semiconductor device technology. The metal-semiconductor potential barrier (Schottky barrier) can be classified into two groups whether the barrier height (ϕ_B) is metal dependent or not (1). Although the metal dependent case can be understood very clearly, the metal independent case has stimulated many experimental (2-5) and theoretical studies (6-9); the M-S interface problem is as yet unsettled.

Key words: interfaces, junctions, magnetism.

On the other hand, in transition metal-silicide (tmSi)/Si contact diodes, there is a proposal that the barrier height (ϕ_B) may be determined by the electronic state of tmSi (10). TmSi/Si junctions have been utilized for their reliability owing to the fact that they are formed through the low temperature solid-phase reaction of tm/Si contacts (11) and that the reaction removes impurities and defects existing at the original tm/Si interfaces to form new and clean tmSi/Si junctions. Because of their potential applicability, the mechanism of rectification in tmSi/Si diodes has been studied but has not yet been fully elucidated. However, it is natural to expect that the mechanism of rectification of a tmSi/Si junction depends upon the elec-

tronic state of tmSi. In order to clarify this possibility, including the proposal given in Ref. (10), direct and microscopic information is required on the electronic state of tmSi.

In this respect, we studied the electronic state of silicon in Ni-silicides (Ni_2Si, NiSi, and $NiSi_2$) and barrier heights (ϕ_B's) of Ni-silicide (Ni_2Si, NiSi, or $NiSi_2$)/Si junctions by means of nuclear magnetic resonance (NMR) and by capacitance-voltage (C-V) measurement, respectively.

Experimental

Crystals of Ni-silicides (Ni_2Si, NiSi, and $NiSi_2$) for NMR measurements were prepared by melting appropriate amounts of nickel powder and polycrystalline silicon in an induction furnace under an argon atmosphere (~1 atm). The crystals were identified by the x-ray diffraction method, and then they were filed or crushed into powder. The measurements of T_1 of ^{29}Si in Ni-silicides were carried out by spin-echo technique between 1.4° and 4.2°K at the resonance frequency of 10 MHz.

Schottky diodes of Ni-silicide/Si junctions were prepared as follows. A wafer of n-type silicon, phosphorus-doped with resistivity of ~10 Ω · cm, was cleaned by chemical process, and then an SiO_2 layer left on the surface of the wafer was removed by dipping it in dilute HF. Then an Ni-film (~1000Å) was deposited on the cleaned Si-substrate under oil-free vacuum (~10^{-8} Torr). Silicides of Ni_2Si, NiSi, and $NiSi_2$ on Si substrate were formed by heating the Ni(film)/Si(substrate) specimens under conditions given in Table I. Barrier heights (ϕ_B's) of the Schottky barriers, *i.e.*, Ni-silicide/Si junctions, were deduced from the measurements of diode capacitance as a function of bias voltage.

Results

Spin-lattice relaxation times (T_1's) of ^{29}Si in three Ni-silicides are shown in Fig. 1 as a function of Si-concentration. Two features are deduced from the figure: (*i*) T_1's of ^{29}Si in the silicides fall between 0.7 and 7 sec at 4.2°K, which are very short and comparable with those of pure metals (12); (*ii*) T_1 of ^{29}Si is shorter in Si-richer silicides—T_1 decreases along with the change of composition from Ni_2Si to $NiSi_2$. Another result obtained by NMR measurement which is not shown in the figure is that T_1's of these Ni-silicides satisfy the relation of $T_1 \cdot T \simeq$ const. within experimental errors between 1.4° and 4.2°K where T is absolute temperature. In general, T_1's of metals and nonmetallic semiconductors have characteristics as follows: (*i*) in metals, T_1 is very short ($\lesssim 1$ sec at 4.2°K) due to a high density of conduction electrons and proportional to $[\rho_s(E_F)]^2$ and T^{-1}; (*ii*) in nonmetallic semiconductors, T_1 is very long (~10^6 sec at 4.2°K) and proportional to N, the density of conduction electrons per unit volume, and $T^{-1/2}$ (13). Therefore, the above results for the Ni-silicides, T_1 is very short and $T_1 \cdot T \simeq$ const., demonstrate that the local density of 3s-electrons with the Fermi energy at the nucleus of silicon $[\rho_s(E_F, Si)]$ is so high that the electronic state of silicon can be concluded to be metallic.

The second result, T_1 becomes shorter with increasing Si concentration, indicates that $\rho_s(E_F, Si)$ is larger —we term in the present paper this tendency for silicon to be more metallic—in Si-richer silicides.

Table I. Conditions to prepare Ni-silicide/Si junctions by solid phase interfacial reaction

	Temperature (°C)	Time (min)
Ni_2Si	300	10
NiSi	550	10
$NiSi_2$	800	8

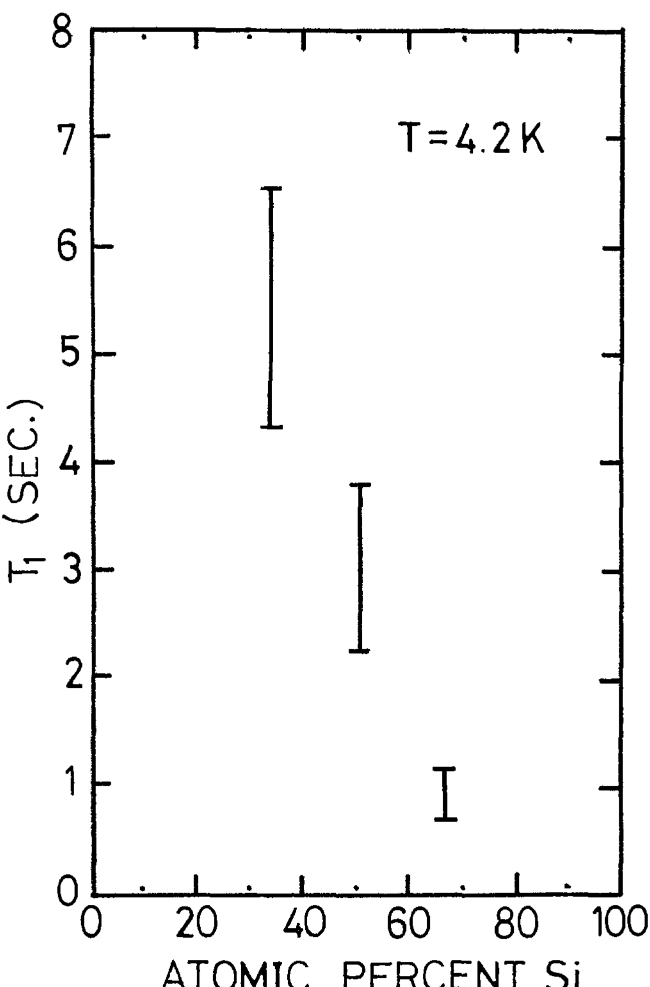

Fig. 1. Spin-lattice relaxation time (T_1) of ^{29}Si in Ni-silicides

As for Schottky barriers, a typical result of a C-V measurement is shown in Fig. 2 for a Ni_2Si/Si junction. ϕ_B's of Ni-silicide (Ni_2Si, NiSi, or $NiSi_2$)/Si diodes deduced from the C-V measurement are shown in Fig. 3 as a function of Si-concentration in Ni-silicides; the formation of the corresponding Ni-silicides by the heat-treatment (shown in Table I) was ascertained by

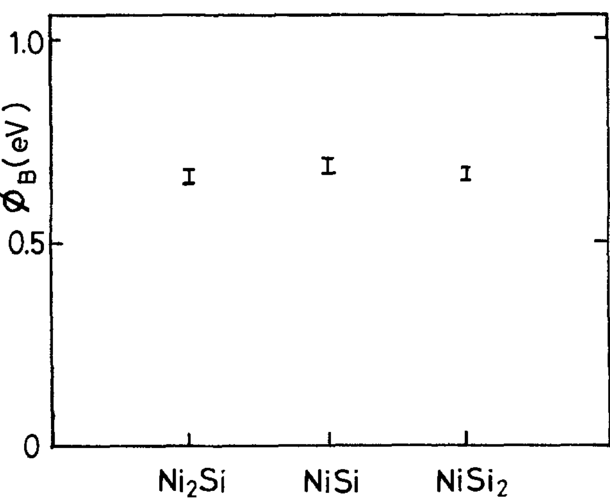

Fig. 3. Schottky barrier height (ϕ_B) in Ni_2Si/Si, NiSi/Si, and $NiSi_2$/Si junctions.

Rutherford backscattering spectroscopy (RBS). An example for $NiSi_2$-layer formation on a silicon surface is shown in Fig. 4. The ϕ_B values are distributed around 0.7 eV in all specimens irrespective of the difference in Si concentration in the silicide overlayers. There is no apparent functional relation between ϕ_B and x in $Ni_{1-x}Si_x$, which is a clear contrast for the NMR measurement, where T_1 decreases with increasing x.

Discussion

The present results by NMR measurement are summarized in Table II with data of previous works for comparison. Our data show that $\rho_s(E_F, Si)$ is so high compared with that of semiconductor silicon, not only that of pure silicon but also that of degenerate silicon, heavily doped with impurity atoms (14), that Si-atoms are concluded to be making metallic bonding (here we term such silicon as "metallic silicon") in the Ni-silicides. The electronic nature of silicon is metallic when Si atoms are dissolved slightly in the host 3d-metal (the concentration of silicon is so low that an Si atom is considered to be a single impurity), which has been explained theoretically in terms of the redistribution of 3s- and 3p-electrons at silicon sites

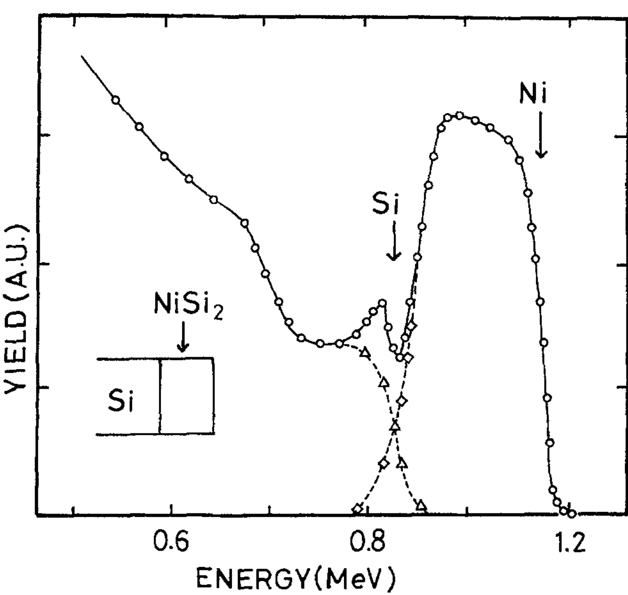

Fig. 4. Rutherford back-scattering examination of the formation of $NiSi_2$ layer on Si(substrate) by heating a specimen of Ni(film)/Si(substrate) for 8 min at 800°C. Dotted lines show the expected spectra for the distribution of nickel and silicon.

Table II. T_1 values and temperature dependence of T_1 of ^{29}Si in Ni_2Si, NiSi, and $NiSi_2$. Those of n-Si crystals doped with donor impurities are also shown for comparison

Specimen	T_1 at 4.2°K (sec)	Temperature dependence of T_1	Reference
Ni_2Si	5.5	T^{-1}	Present study
NiSi	3	T^{-1}	Present study
$NiSi_2$	0.7	T^{-1}	Present study
n-Si (n_D = 2.5 × $10^{19}/cm^3$)	6 × 10^2	T^{-1}	(14)
n-Si (n_D = 4 × $10^{13}/cm^3$)	5 × 10^6	$T^{-1/2}$	(13)

through the hybridization with 3d-electrons of host metals (15). Several experimental results have confirmed the above theory (16, 17). It is plausible that the metallic silicon in Si-deficient-Ni-silicides, for example, in Ni_3Si, is also explained in the same way (17). However, the metallic silicon in Si-richer-Ni-silicides, as in the present study, cannot be explained by the above theory because of extremely high Si concentration. Therefore, it is an interesting question which mechanism metallizes silicon in those Ni-silicides.

For the sake of discussion, we will refer to the data by soft x-ray spectroscopy (SXS) measurements. Figure 5 illustrates measured Si-K_β emission spectra from several Ni-silicides and pure silicon, which provide information on the electronic structure of 3p-electrons of silicon (18). One apparent point to be noted about the silicides is that each spectrum has a finite intensity at the Fermi energy, which indicates that the 3p-electron density of silicon $[\rho_p(E_F, Si)]$ is large to show that Si atoms have metallic bonding. Also

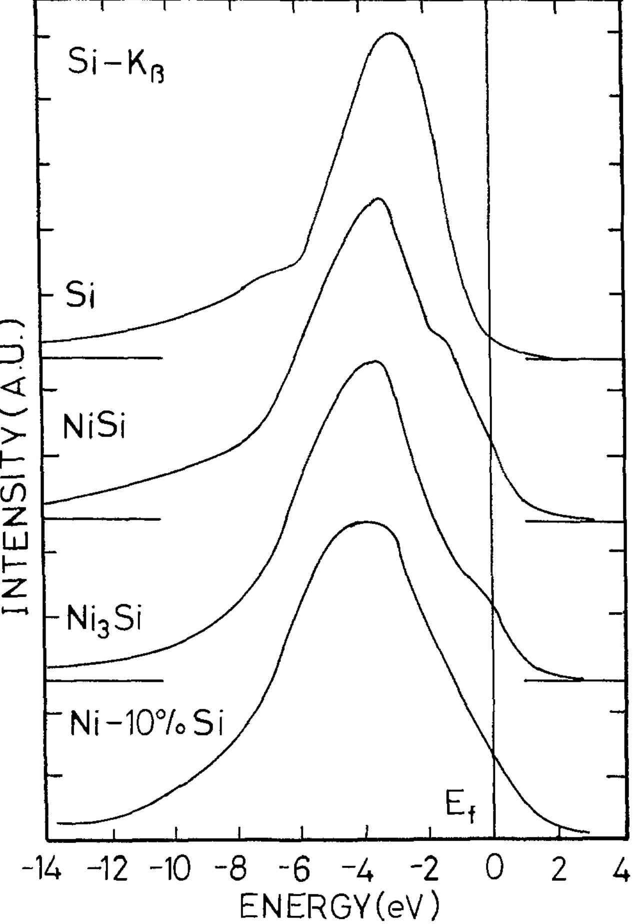

Fig. 5. Si-K_β emission spectra from Ni-silicides and from pure silicon (18). The date for NiSi is unpublished.

the increment of the intensity at E_F, which is roughly proportional to $\rho_p(E_F, Si)$, in Si-K_β emission spectra with increasing Si concentration from Ni_3Si to NiSi is observed to coincide with the results of T_1 measurement in Ni-silicides, *i.e.*, the increment of $\rho_s(E_F, Si)$ with the increase of Si concentration. Another feature of the results (Fig. 5) is that K_β-emission spectra gradually change their shapes from single peaked one of $Ni_{0.9}Si_{0.1}$ into the spectrum with a clear shoulder of NiSi. Similar spectral change of K_β-emission was reported for the Ni-Al system as shown in Fig. 6 (18). These results of the Al-K_β emission spectra in the Ni-Al system must be the reflection of the fact that the electronic structure of 3s-electrons of aluminum is approaching that of pure metal aluminum with increasing Al-concentration, i.e., the appearance of the shoulder in NiAl is considerd to be an appearance of the free electron nature of pure metal aluminum. The similar change in K_β-emission spectra of Ni-silicides (Fig. 5) to that of Ni-Al system (Fig. 6), *i.e.*, a clear shoulder appears in the spectrum of NiSi, is thought to be an indication of the appearance of metallic silicon, which can be observed only when silicon is either in a liquid state or exposed to an ultrahigh pressure ($\gtrsim$200 kb). There is a suggestive report about germanium being metallic, *i.e.*, the radial distribution function of germanium is almost the same as that of liquid (metallic) Ge, in the Ni-Ge system with Ge-rich alloys (19).

Next, we will discuss our present conclusion with the proposal given by Andrews and Phillips (10). They intended to explain the relation between ϕ_B and ΔH_f (heat of formation of tmSi per tm-atom) from the view point of the degree of sp^3-hybridization of d-electrons of tm-atoms with neighboring Si atoms. Namely, they assumed that tm-atoms in tmSi with higher ΔH_f value would have more sp^3-like covalent bondings. On the other hand, the present NMR study clearly indicates that Si-atoms in Ni-silicides have metallic bondings rather than sp^3-like covalent bondings. Therefore, the present conclusion suggests some different model is necessary for the electronic property of Schottky barriers in tmSi/Si interfaces, especially for Ni-silicide/Si junctions. On this point, the results in Fig. 3 can be a clue. Namely, ϕ_B's are almost constant for three different diodes, *i.e.*, in Ni_2Si/Si, NiSi/Si, and $NiSi_2$/Si junctions. Possible explanations for the results on the ϕ_B's are the existence of some kind of alloy phase at the interface region as with Au/Si contacts (2), the band closure of silicon at the tmSi/Si contact region (6-9), and others (3-5). Further studies will be necessary to decide which mechanism is applicable for Ni-silicide/Si junctions.

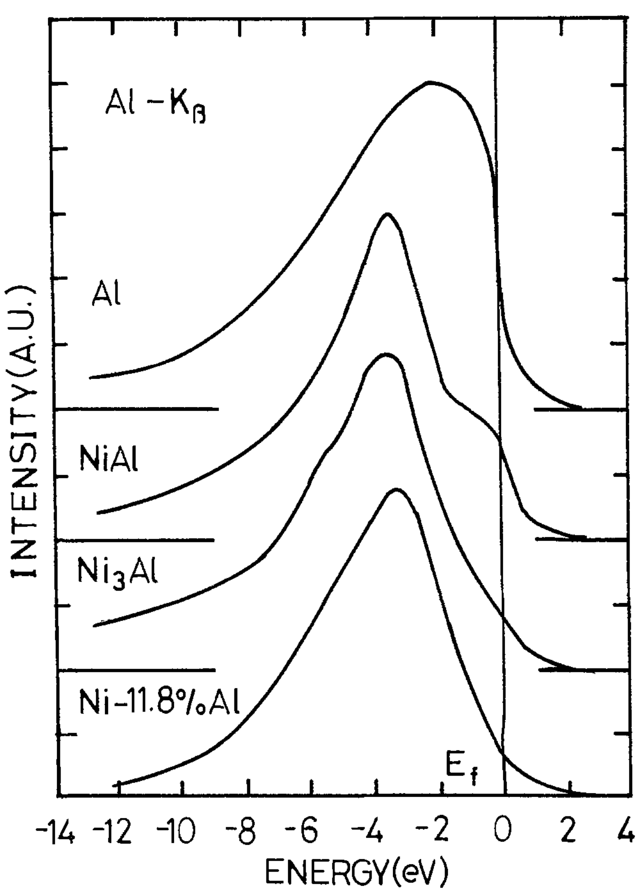

Fig. 6. Al-K_β emission spectra from Al-Ni alloys and from pure aluminum (18).

Conclusions

NMR measurements of the electronic structure of Ni-silicides (Ni_2Si, NiSi, and $NiSi_2$) show that Si atoms in the silicides are considered to have metallic bondings with surrounding atoms rather than to have sp^3-like covalent bondings and that Si-atoms are more metallic in Si-richer-Ni-silicides. Either this fact or the invariance of Schottky barrier heights (ϕ_B's) shows that some different explanation from previous ones must be considered for the electronic property of Ni-silicide/Si junctions, such as Fermi level pinning due to the band closure of silicon at the M-S contact.

Boron Diffusion into Si from CVD-BN Covered with Si_3N_4 and Application to Master Slice p-MOS IC

Katsufusa Shohno,* Tejin Kim,[1] and Chol Kim

Faculty of Science and Technology, Sophia University, Kioicho-7, Chiyoda-ku, Tokyo, Japan

ABSTRACT

A boron nitride (BN) film was deposited on an n-type Si wafer at about 500°C by the thermal reaction of diborane and ammonia in nitrogen. The boron diffusion into Si was performed in nonoxidizing ambients both during the deposition of the BN on the Si and the subsequent heat-treatment. To obtain the reproducibility of the boron surface concentration at its solid solubility at the diffusion temperature, the BN has to be covered with Si_3N_4, which is deposited at about 750°C in a silane-ammonia-nitrogen system. No silicon-boride formation at the interface of the BN and Si was confirmed. The resistivity of the BN was determined as $\rho = 10^{13}$-10^{14} Ω-cm. The BN can be used not only as a boron diffusion source but also as a surface passivation of integrated circuits when the BN and Si_3N_4 remained after the boron diffusion.

Boron diffusion into Si from CVD-BN films as a diffusion source was reported previously (1). The BN had been deposited in a hydrogen carrier gas at a high deposition temperature range of 700°-1250°C. When the BN was used in a practical integrated circuit process, the authors found that less reproducible boron surface concentrations were often observed due to the change of the BN during the boron diffusion heat-treatment in nitrogen. In addition, the writers also found that the low temperature deposition of the BN at about 500°C in nitrogen and the over-coat deposition of Si_3N_4 on the BN were effective in maintaining the reproducibility of the boron surface concentrations at its solid solubility.

Fair summarized the boron diffusion into Si from various diffusion sources (2). When the boron surface concentration exceeds the intrinsic carrier concentration at a diffusion temperature, the effects of electric field enhancement caused by the increase of donor-type vacancies have to be taken into account. Fair's analysis was employed in this work to determine the boron diffusion characteristics from BN in nonoxidizing ambients.

In the final section of this report an application of the BN to master slice p-MOS IC is shown, in which the resistivity of the BN was determined, and the BN was used not only as a diffusion source of boron but also as a surface passivation when it remained after the boron diffusion.

Experimental

The experimental apparatus for the BN and Si_3N_4 deposition has been described previously (1). A quartz reaction chamber used in this work had an internal width of 35 mm, a height of 20 mm, and a length of 400 mm. The reactant gases used for the BN deposition were high purity diborane (B_2H_6) diluted to 5% in nitrogen and ammonia (NH_3), and those gases for the Si_3N_4 deposition were high purity silane (SiH_4) diluted to 5% in nitrogen and ammonia. The carrier gas was high purity nitrogen.

First, the BN was deposited on the n-type (100) Si wafer with a resistivity of 3-5 Ω-cm ($N_D = 0.9$-1.5×10^{15} cm^{-3}). The deposition conditions were: (*i*) a wafer temperature of 500°C, and (*ii*) flow rates of the B_2H_6-N_2, the NH_3, and the N_2 carrier gases of 50, 70, and 2000 cm^3/min, respectively. Under those conditions the average deposition rate of the BN was about 300 Å/min.

The Si_3N_4 was then deposited on the BN after the wafer temperature was increased to 750°C. The flow rates of the SiH_4-N_2, the NH_3, and the N_2 carrier gases were 20, 70, and 2000 cm^3/min, respectively, and the average deposition rate of the Si_3N_4 was about 500 Å/min.

With heat-treatment in nitrogen for 10-300 min at 1200°C, the boron diffusion layer was formed in the Si wafer. To measure the diffusion depth and the sheet resistance, the Si_3N_4 was removed by etching in conc HF at room temperature and the BN was removed in hot H_3PO_4 (~160°C). After the complete removal of the films, the hydrophobic or hydrophilic nature of the wafer surface was observed.

The diffusion depth x_j (cm) was measured by spherical drilling and staining (3) and the sheet resistance R_s (Ω/□) was measured by four-point probe. The boron surface concentration C_s (cm^{-3}), the total amount of boron diffusing into Si Q (cm^{-2}), and the intrinsic diffusion coefficient D_i (cm^2/sec) were all determined by using the following relations given by Fair (2)

$$C_s = \frac{2.78 \times 10^{17}}{R_s x_j} \quad [1]$$

$$Q = 0.4 C_s x_j \quad [2]$$

$$x_j = 2.45 \left(\frac{C_s D_i t}{n_i} \right)^{1/2} \quad [3]$$

The effects of electric-field enhancement caused by the increase of donor-type vacancies were taken into account. The intrinsic carrier density is $n_i = 2 \times 10^{19}$ cm^{-3} at the diffusion temperature of 1200°C.

Results and Discussion

Uniformity and reproducibility.—The uniformity and reproducibility in a run-to-run of a boron diffusion layer in Si become important when the BN is used in a practical Si planar process as a boron diffusion source. After the heat-treatment for boron diffusion from the BN, the Si_3N_4 and the BN were removed, resulting in the hydrophobic nature of the Si surface. To obtain the distribution of the sheet resistance of the boron diffusion layer, a conventional four-point probe was moved from one point to the next at an interval of 2 mm for about 240 points over the entire surface of the Si wafer with a 40 mm diam.

Key words: boron diffusion, CVD-BN, p-MOS IC.

The measurements were repeated five times and the average values were obtained for each of the points. Representative examples of the distribution are shown in Fig. 1 for 29 representative points. The maximum value is 1.70, the minimum one is 1.55, the average is 1.63 Ω/□, and the distribution is within the range of ±4%. The run-to-run distributions are also satisfactory and within the same range.

Characteristics of boron diffusion.—Auger spectroscopic analysis of boron in the BN gives the boron an atomic density of about 2-3 × 10^{22} cm^{-3}. When the thickness of the BN was more than about 500Å, that is, when a sufficient amount of boron was given as a diffusion source, the boron diffusion characterisics are summarized in Fig. 2 for experimentally measured values and in Fig. 3 for calculated values from Eq. [1], [2], and [3].

The junction depth x_j increases in proportion to the square root of the diffusion time and reaches 10 μm for the diffusion time 80 min. The sheet resistance R_s decreases in proportion to the square root of the diffusion time. Consequently, the average resistivity $\bar{\rho}$, which is a product of the junction depth and the sheet resistance, becomes constant for the diffusion time and it is as low approximately as $\bar{\rho} = 1.2 \times 10^{-3}$ Ω-cm. The constant average resistivity corresponds to a constant boron surface concentration $C_s = 2.7 \times 10^{20}$ cm^{-3}, which is obtained from Eq. [1] and is almost in agreement with the solid solubility reported by Vick and White (4). The total amount of boron diffusing into Si given by Eq. [2] increases in proportion to the square root of the diffusion time and approaches to about 10^{17} cm^{-2}, with expectation of the continuous supply of a sufficient amount of boron from the BN. The intrinsic diffusion coefficient obtained from Eq. [3] becomes constant for the diffusion time, and the value is $D_i = 1.0 \times 10^{-12}$ cm^2/sec, which is almost in agreement with that already reported (4-6).

When the BN with a thickness of about 200Å was used as a boron diffusion source, the supply of boron from the BN becomes apparently poor in relation to the long-time diffusion, as shown in Fig. 4. For a diffusion time of less than 30 min the boron surface concentration is maintained at the solid solubility $C_s = 2.7$ × 10^{20} cm^{-3}, and the total amount of boron increases in proportion to the square root of the diffusion time. On the other hand, for a diffusion time of more than 30 min the boron surface concentration decreases, and the total amount of boron tends to saturate to 8 × 10^{16} cm^{-2}.

To determine the boron profile, the change of the sheet resistance is measured by repeated dry plasma etching of the boron diffusion layer. An approximately independent hole mobility of $\mu = 55$ cm^2/V sec was assumed for a boron concentration larger than 5 × 10^{19} cm^{-3}. Dry plasma etching was carried out in a gas mixture of CF_4 (98%) and O_2 (2%). The etching rate

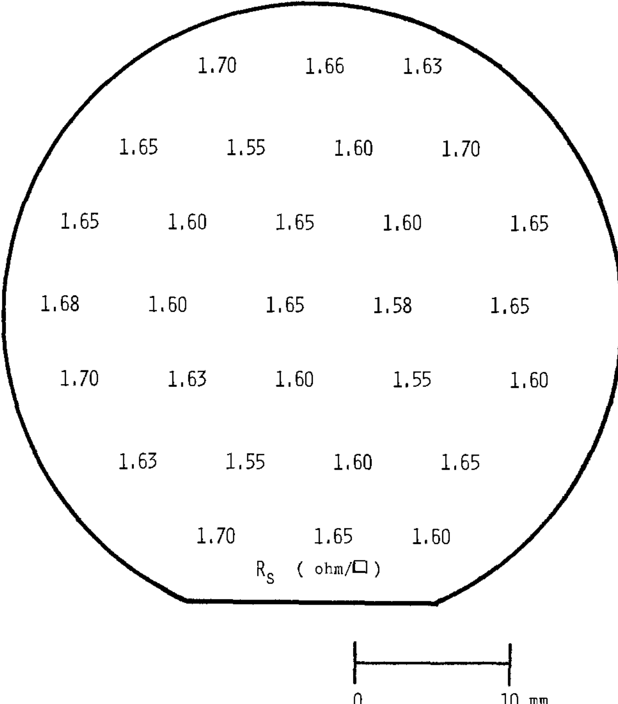

Fig. 1. Sheet resistance of boron diffusion layer. The diffusion temperature was 1200°C and the time was 50 min.

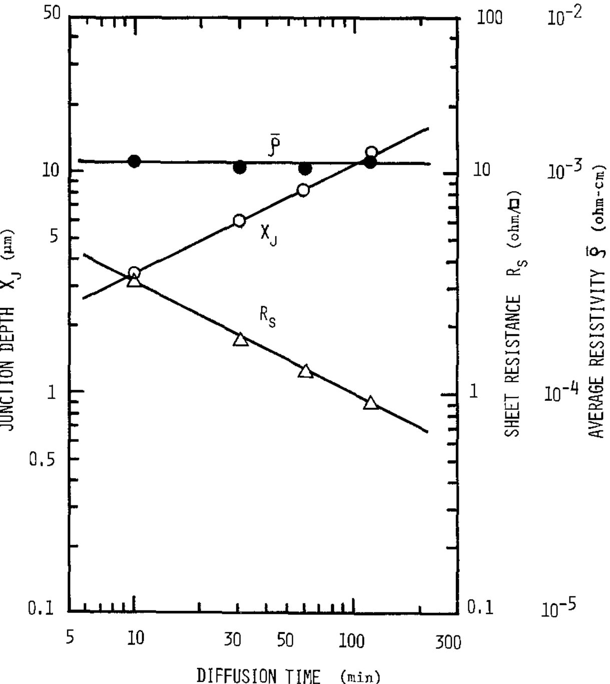

Fig. 2. Junction depth, sheet resistance, and average resistivity of boron diffusion layer of the BN when thicker than about 500Å.

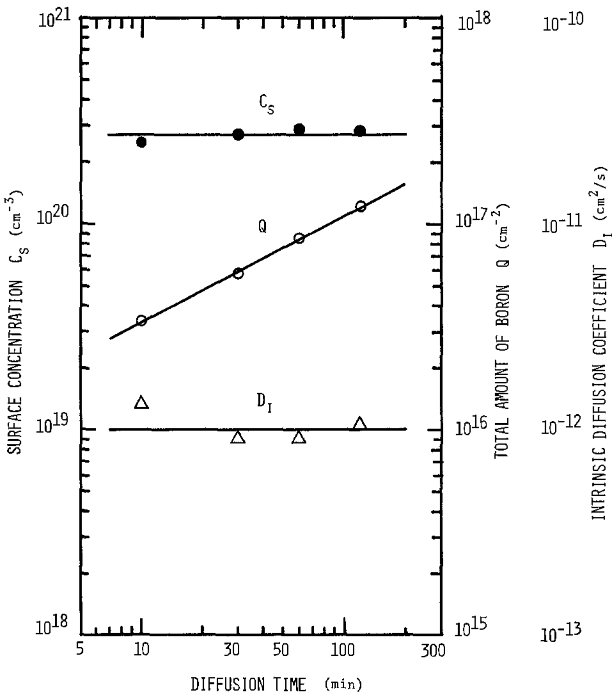

Fig. 3. Surface concentration, total amount, and intrinsic diffusion coefficient of boron diffusing into Si as a function of diffusion time.

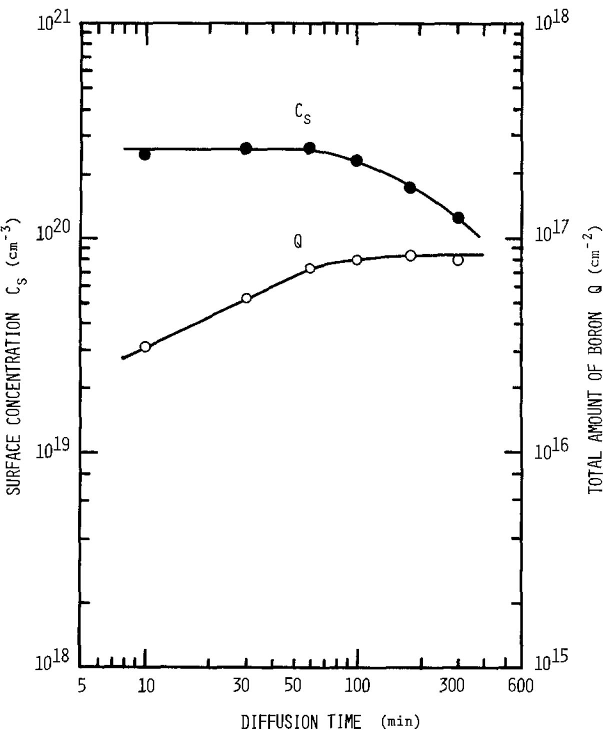

Fig. 4. Surface concentration and total amount of boron diffusing into Si from the BN when thinner than about 200Å.

was 1000 Å/min, and, after every etching cycle, a measurement was made of the sheet resistance. The thickness of the silicon removed was determined with an interference microscope.

The boron profile obtained is shown in Fig. 5. The black points show experimentally obtained values. For comparison, the well-known error function complement (erfc) curve is shown and the solid line is a curve of the form

$$C(x) = C_s(1 - (x/x_j)^{2/3}) \quad [4]$$

which was given by Fair, and in which the junction depth of 7.5 μm is measured at 10^{15} cm^{-3}. It is clearly seen that the boron diffusion was accelerated due to the effects of electric-field enhancement, compared with the erfc curve.

Interface of BN and Si.—To investigate the interface between BN and Si, diffusions involving two steps were performed. After the deposition of the BN and Si_3N_4, the prediffusion was done at a temperature between 750° and 1250°C for 10 min. For the samples of the boron diffusion at 750°C, the 10 min prediffusion had to be a total of the Si_3N_4 deposition time at 750°C for 2 min and the prediffusion time for 8 min. In Fig. 6 the solid line is an expected curve of the amount of boron which is calculated by Eq. [2], in which the boron surface concentration C_s is a solid solubility of boron at each of the temperatures (4), and the junction depth x_j is given by Eq. [3].

After the prediffusion, the Si_3N_4 and BN were successively removed. The hydrophobic nature of the Si surface was confirmed.

Before the postdiffusion, the Si surface was newly covered with Si_3N_4 at a deposition temperature of 750°C. The postdiffusion was the heat-treatment for the samples in nitrogen at 1200°C for 30 min. When the prediffusion was done at above 1000°C, the junction depth and sheet resistance could be measured and the amount of boron in Si was determined both after the pre- and postdiffusions. The same amount of boron was obtained for both measurements; the values are shown with black circles in Fig. 6. When the 10 min prediffusion was done below 950°C, the boron diffusion layer was formed of such shallow depth that the direct measurement of the junction depth was difficult. After the shallow boron profiles were extended out by postdiffusion at 1200°C for 30 min, the junction depth and sheet resistance could be measured and the amount of boron determined. The values are shown with white circles in Fig. 6.

The solid line in Fig. 6 is in good agreement with the experimental points, with the result that the amount of boron given in the prediffusion step can be maintained during the postdiffusion step. This result leads to the conclusion that by etching off the BN diffusion source an additional boron diffusion source

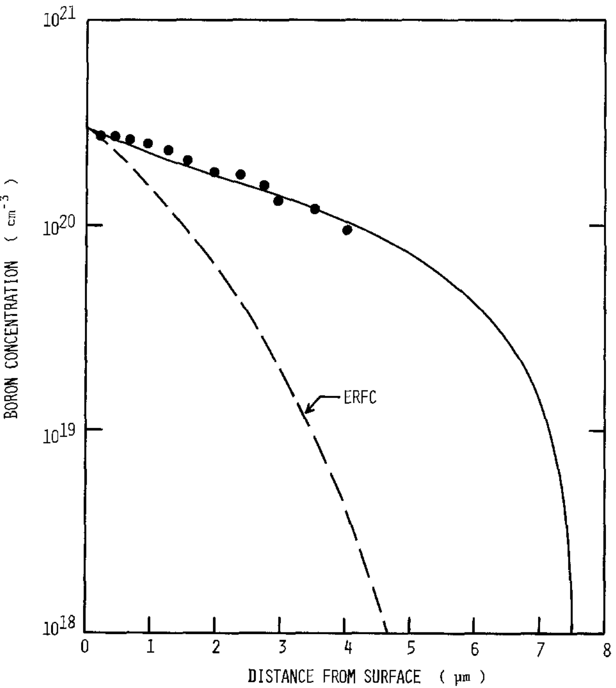

Fig. 5. Boron profile diffused from the BN. The diffusion temperature was 1200°C and the time was 60 min.

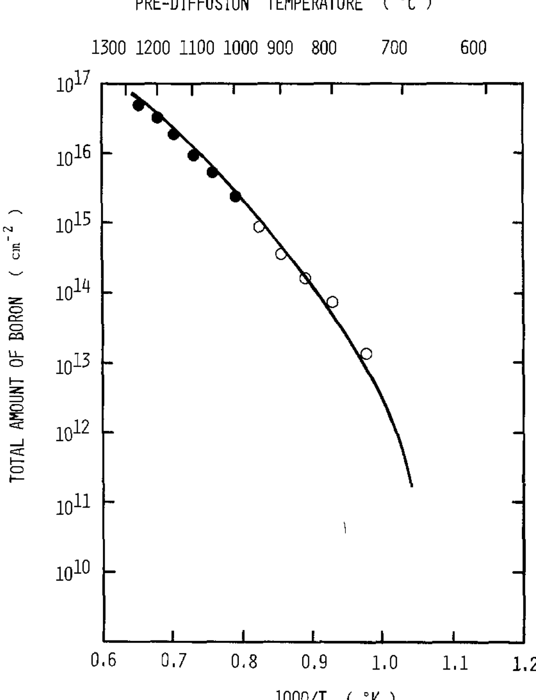

Fig. 6. Conservation of the total amount of boron with two-step diffusions.

did not remain on the Si surface and no silicon-boride (SiB_4) layer was formed at the interface between the BN and Si.

Resistivity of BN and application to master slice p-MOS IC.—The fabrication sequence of the polycrystalline Si-gate self-aligned p-MOS transistor is shown in the cross-sectional view of Fig. 7. The n-type Si wafer with a resistivity of 3-5 Ω-cm was thermally oxidized in dry oxygen at 1070°C for 50 min, resulting in a 700Å layer of SiO_2. A 300Å layer of Si_3N_4 and a 3000Å layer of polycrystalline Si were deposited at 750° and 650°C, respectively. This wafer is the starting material for us (A). The windows of both source and drain were opened in the first photolithographic step by successively etching the polycrystalline Si, the Si_3N_4, and the SiO_2 layers in a plasma of CF_4 (98%) and O_2 (2%) (B). A 200Å layer of the BN and a 3000Å layer of Si_3N_4 were deposited over the entire surface of the wafer. Boron diffusions in Si to a junction depth of 3 μm and also in polycrystalline Si gate were simultaneously accomplished by an 80 min heat-treatment at 1100°C in nitrogen. The boron surface concentration in Si is 2.5×10^{20} cm^{-3} and the resistivity of polycrystalline Si is 2.0×10^{-3} Ω-cm (C). The second photolithographic step is for the opening of the contact windows. Successive dry plasma etching was used to selectively remove the Si_3N_4 and BN layers. Slight attacks on the Si surface and the polycrystalline Si layer make it easy to form the ohmic contacts (D). A 5000Å layer of Al was evaporated over the wafer surface at a wafer temperature of 230°C. The third photolithographic step is for the delineation of the Al (E). The Al is etched in a solution of H_3PO_4 and DI-H_2O in equal parts at 55°C (F). In this fabrication process, the BN was used not only as a diffusion source of boron but as a surface passivation of MOS transistors.

The square-type inverter circuits are a unit of the master slice p-MOS IC's, and an overview microphotograph of a part of a chip including six inverter circuits is shown in Fig. 8. The inverter circuit layout has the load transistor at its center, surrounded by the inverter transistor. The source of the load transistor serves as the drain region of the inverter transistor and also as the output of the inverter circuits. The contact windows of Al interconnections are opened at each of the corners. In our practical device fabrication process of the master slice p-MOS IC's, two Al evaporations and delineations are employed. The first Al delineation forms the pads at each of the contact windows to measure the V_G-I_D characteristics of each of the MOS transistors in advance. The second Al delineation makes Al interconnections for the selected inverter circuits. The photomasks for the Al interconnections are designed for each of the chips using the authors' easy method of photomask fabrication (7).

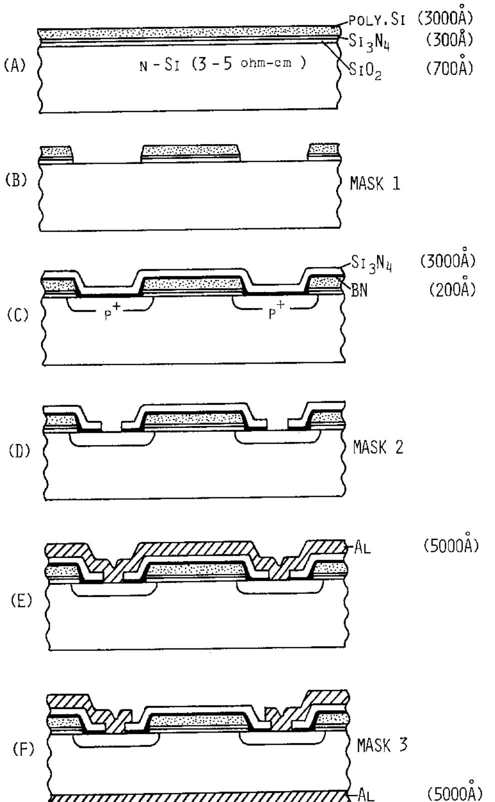

Fig. 7. Fabrication sequence of polycrystalline Si-gate self-aligned p-MOS transistor.

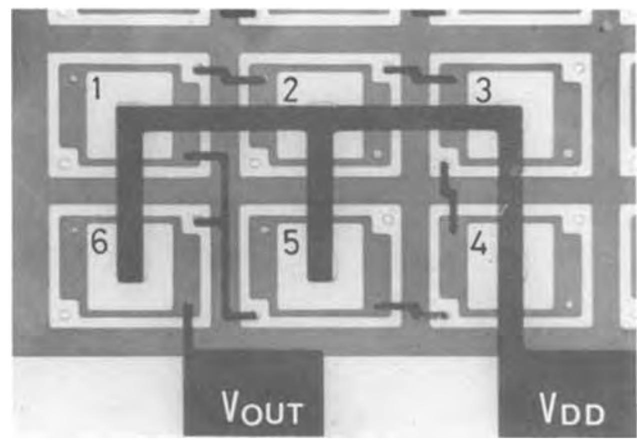

Fig. 8. Overview microphotograph of six inverter circuits. Five inverter circuits, 1-5, are connected to a ring oscillator with a buffer stage, 6.

A cross-sectional view of our fabrication process shown in Fig. 7 (F) has a structure showing that the BN covers the edge wall of the gate insulator, the double layers of SiO_2, and Si_3N_4 between the polycrystalline Si gate and the source or drain p-region. To determine the resistivity of the BN, once the amount of negative charge was given on the polycrystalline Si gate of the inverter transistors, the gate charge decay time τ was obtained from the decrease of the drain current. The decay time was simply given as

$$\tau = C_iR = \frac{\epsilon_0\epsilon_i l \rho_{BN}}{2d_{BN}} \quad [5]$$

where (*i*) the gate capacitance is $C_i = 4\epsilon_0\epsilon_i wl/d_i$, (*ii*) the resistance through the current path is $R = d_i\rho_{BN}/8wd_{BN}$, (*iii*) the average dielectric constant of gate SiO_2 and Si_3N_4 layer is $\epsilon_i = 4.4$, and (*iv*) the total thickness of gate SiO_2 and Si_3N_4 layer is $d_i = 1000$Å. The charge decay time and the resistivity of the BN are shown in Fig. 9 as a function of the deposition temperature of the BN. The current path was assumed through the BN along the edge wall of the gate insulator, as shown in the insertions of the figure. The resistivity of the BN was about 10^{13} Ω-cm for the deposition temperature of the BN at 500°C. This value can be compared with the resistivity of SiO_2 and Si_3N_4 of about 10^{15}-10^{16} Ω-cm (8).

An example of the application of the p-MOS IC device using the BN in the fabrication process is a ring oscillator circuit with several inverter stages, as shown in Fig. 8, where the output of the inverter circuit is directly connected to the input of the next inverter circuit stage. The V_G-I_D curve of each of the MOS load and inverter transistors is measured in advance. The inverter circuits are characterized by the threshold voltage V_T of the gate and the conduction factor k, which has a relation with the surface mobility μ, of each of the load and inverter transistors. The ring

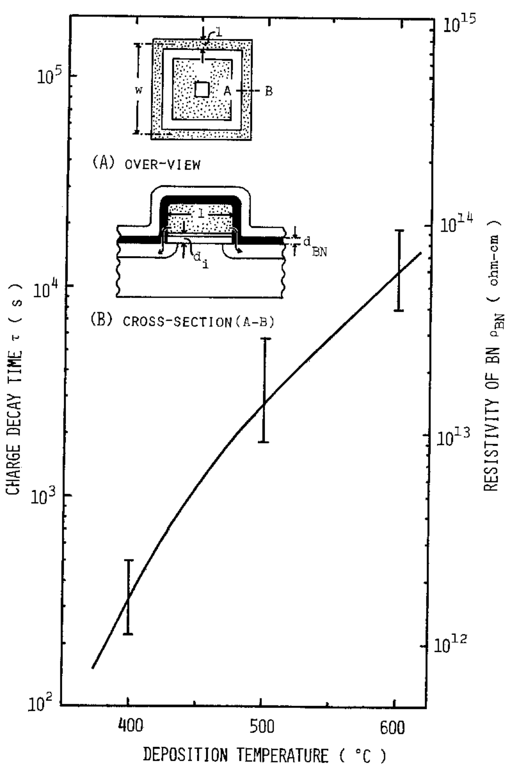

Fig. 9. Charge decay time and resistivity of the BN as a function of the deposition temperature of the BN.

oscillator circuit was formed and connected with the selected number of inverter circuits. Taking into account the load capacitance C_L between each of the inverter circuit stages, the oscillation wave forms are calculated and are compared with the observed ones. The observed frequencies are about 15% less in average than the calculated ones. The leakage current of the inverter transistor through the BN is as small as about 10^{-14}A for the design in Fig. 8, and the drain current under the ring oscillator operation is in the range of from 10^{-5}-10^{-4}A. No effect of the leakage current through the BN was observed in our practical device application. It can be concluded that the BN can be used as a surface passivation, except for the special devices which need a long charge holding time, such as the FAMOS memory devices.

Conclusion

The BN deposited at 500°C in the B_2H_6-NH_3-N_2 system and covered with Si_3N_4 acts as a reproducible diffusion source of boron in Si. The boron surface concentration was maintained at its solid solubility, when the BN thickness was above 500Å. After the boron diffusion no silicon-boride formation was observed at the interface of the BN and Si. An application example to the MOS IC device is a master slice polycrystalline Si-gate self-aligned p-MOS IC. The charge decay time on the gate gives the BN resistivity of 10^{13}-10^{14} Ω-cm, and the BN can be concluded to be useful as a surface passivation of the devices when the BN remained after the boron diffusion in Si.

The Systems Y_2O_3-P_2O_5 and Gd_2O_3-P_2O_5

Dinesh Agrawal and F. A. Hummel

Solid State Science Section, Department of Materials Science and Engineering,

The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

The systems Y_2O_3-P_2O_5 and Gd_2O_3-P_2O_5 each contain six intermediate compounds of 4:1, 3:1, 1:1, 1:2, 1:3, and 1:5 ratios. The systems were investigated by solid-state reactions and also by quenching methods in the glass-forming region between the 1:2 and 1:5 compounds. The 4:1, 1:2, 1:3, and 1:5 compounds in the two systems appear to have identical or similar structures, whereas the 3:1 and 1:1 compounds differ in structure. It was found that the 4:1 and 3:1 compounds in the refractory portion of the systems have lower temperature limits of stability. The newly discovered 1:2 compounds in each system are relatively stable, $Y_2O_3 \cdot 2P_2O_5$ decomposing to 1:1 and 1:3 near 1450°C and $Gd_2O_3 \cdot 2P_2O_5$ melting incongruently to 1:1 and liquid near 1305°C. The 1:3 compounds melt congruently and the 1:5 compounds melt incongruently to 1:3 and liquid.

It is already known that YPO_4, and the ultraphosphates YP_5O_{14} and GdP_5O_{14} are of interest for their luminescent behavior when activated by various rare earths, especially Eu^{3+}. Various other compounds in the systems have been reported such as 4:1, 3:1, and 1:3 but neither system has been completely explored and the exact thermal behavior of the known com-

Key words: inorganic, refraction, phases.

pounds has not been determined. Therefore, the purpose of this study was to determine the phase relationships in both systems, including the refractory portion between the oxide end member and the orthophosphate $R^{3+}PO_4$ and the glass-forming region between $R^{3+}PO_4$ and the 1:5 compound, thus providing a firm basis for further luminescence studies.

Literature

End member rare earth oxides.—The RE_2O_3 rare-earth oxides have been shown to exist in hexagonal (A), monoclinic (B), and cubic (C) forms (1-3). Many detailed studies have been made on the crystal structure, temperature and rate of transformation, and the effect of pressure on the temperature of transformation.

In this study, the cubic form of Y_2O_3 and the cubic and monoclinic forms of Gd_2O_3 were observed in the phase analysis. The high temperature hexagonal and another form of Gd_2O_3 observed by Foex and Traverse (4) above 2360°C were not relevant to this work.

The 4:1 and 3:1 compounds.—Kizilyalli (5) prepared $3Gd_2O_3 \cdot P_2O_5$ by reaction of $GdPO_4$ and Gd_2O_3 at 960°C, and claimed the compound to be orthorhombic with a = 11.35Å, b = 9.75Å, and c = 8.80Å. Serra, Coutures, and Rouanut (6) synthesized $3Y_2O_3 \cdot P_2O_5$ and $3Gd_2O_3 \cdot P_2O_5$ by heating the oxide and phosphoric acid in air between 800°-1200°C. During further research (7) they prepared the 3:1 and 4:1 compounds of both Y and Gd by reacting the orthophosphates with Y_2O_3 or Gd_2O_3 between 1200°-1400°C.

The orthophosphates.—The natural mineral xenotime (YPO_4) and many other rare earth orthophosphates have been known and examined for many years. Xenotime is structurally related to zircon, $ZrSiO_4$, which has been synthesized as a gemstone and used as a refractory ceramic material.

YPO_4 is tetragonal and optically positive with n_ω = 1.7207 and n_e = 1.8155 (8). $GdPO_4$ is hexagonal and isomorphic with $LaPO_4$, $CePO_4$, and $NdPO_4$. Above 500°C a transformation to a monoclinic form (isostructural with monazite) takes place (in the presence of H_2O). As in the case of the rare-earth oxides, the literature on the orthophosphates is very extensive and easily available, and it need not be repeated here.

The 1:2, 1:3, and 1:5 compounds.—The 1:2 compound was apparently unknown before the present study and therefore no literature was found. $Gd(PO_3)_3$ was reported (9) to undergo a polymorphic transition between 800°-850°C and melt incongruently to $GdPO_4$ and liquid.

Bagieu-Beucher and Duc (9) described the preparation of rare earth ultraphosphates of the formula LnP_5O_{14} (Ln = La − Lu, Y). Mixtures of rare earth oxides and diammonium phosphate were calcined at 500°C for one day. All of the ultraphosphates were reported to melt incongruently to metaphosphate and P_2O_5-rich liquid between 800°-900°C. They claimed that the ultraphosphates existed in three structural types in space groups: (*i*) $P2_1/a$, (*ii*) Cc or C2/c, or (*iii*) Pc2/n or Pcmn. YP_5O_{14} existed (9, 10) in orthorhombic and monoclinic forms, but the orthorhombic form was not isolated and occurred only in small quantities with the monoclinic form. GdP_5O_{14} exists only in the monoclinic form (9, 10).

Materials, Apparatus, and Experimental Procedure

Y_2O_3 (99.99%) from Apache Chemicals, Incorporated, Gd_2O_3 (99.9%) from Ventron ALFA Products, and $NH_4H_2PO_4$ from Fisher Scientific were used as starting materials. Ten compositions (Table I) in each system were thoroughly mixed in acetone in an agate mortar, heated to 300°-500°C for 24 hr in covered Pt crucibles to eliminate volatiles NH_3 and H_2O, and then given the final heat-treatment as shown. Solid-state reactions were done in SiC Globar furnaces. In the phosphate-rich, glass forming part of the system, glasses were melted in Pt crucibles for 20 min to avoid loss of P_2O_5 and then quenched to room temperature. The starting materials for preparation of glasses were prereacted crystalline compounds or mixtures of compounds, an-

other technique which was used to minimize or avoid loss of P_2O_5 during melting. A Pt-wound quenching furnace was used not only for quenching of compositions in the glass-forming region, but also for determination of upper and lower temperature limits of stability of compounds in the refractory region of the system. Samples for quenching studies were encapsulated in sealed Pt tubes (2.5 or 5 mm diam) and temperatures of solid-state and quenching studies were measured with Pt/Pt-10% Rh thermocouples.

Phase identification was made with Ni-filtered CuKα radiation from a Norelco diffractometer operated at 40 kV and 15 mA. For routine studies samples were run at 1°2θ/min, and for standard patterns of the various binary compounds, the speed was reduced at ¼°2θ/min. A polarizing microscope was used to measure the refractive indexes of the phosphate-rich glasses using the Becke line method.

Results and Discussion

General.—The phase diagrams shown in Fig. 1 were constructed from the data given in Table I. Both systems contained six (4:1, 3:1, 1:1, 1:2, 1:3, and 1:5) binary compounds, five of which were previously reported. The 1:2 compound in each system was discovered by careful analysis of compositions which had been prepared by solid-state reaction and by crystallization from glass. Both systems are divided into a refractory portion between the oxide and $REPO_4$ and a glass-forming portion between $REPO_4$ and the ultraphosphate, which is customary for many systems involving a refractory oxide and P_2O_5.

In the glass-forming region between the 1:2 and 1:5 compounds, it was easier to prepare the 1:2, 1:3, and 1:5 compounds by crystallization from glass, but they can also be prepared as phase-pure crystalline materials by solid-state reaction if sufficient time is provided at the required temperature levels.

The Y_2O_3-YPO_4 subsystem.—(i) Y_2O_3.—Up to 1450°C, Y_2O_3 was observed to exist only in the cubic form. The monoclinic to cubic transformation at 900°C was not observed, probably because yttrium carbonate or oxalate was not used as a starting material or because no H_2O was present during reaction.

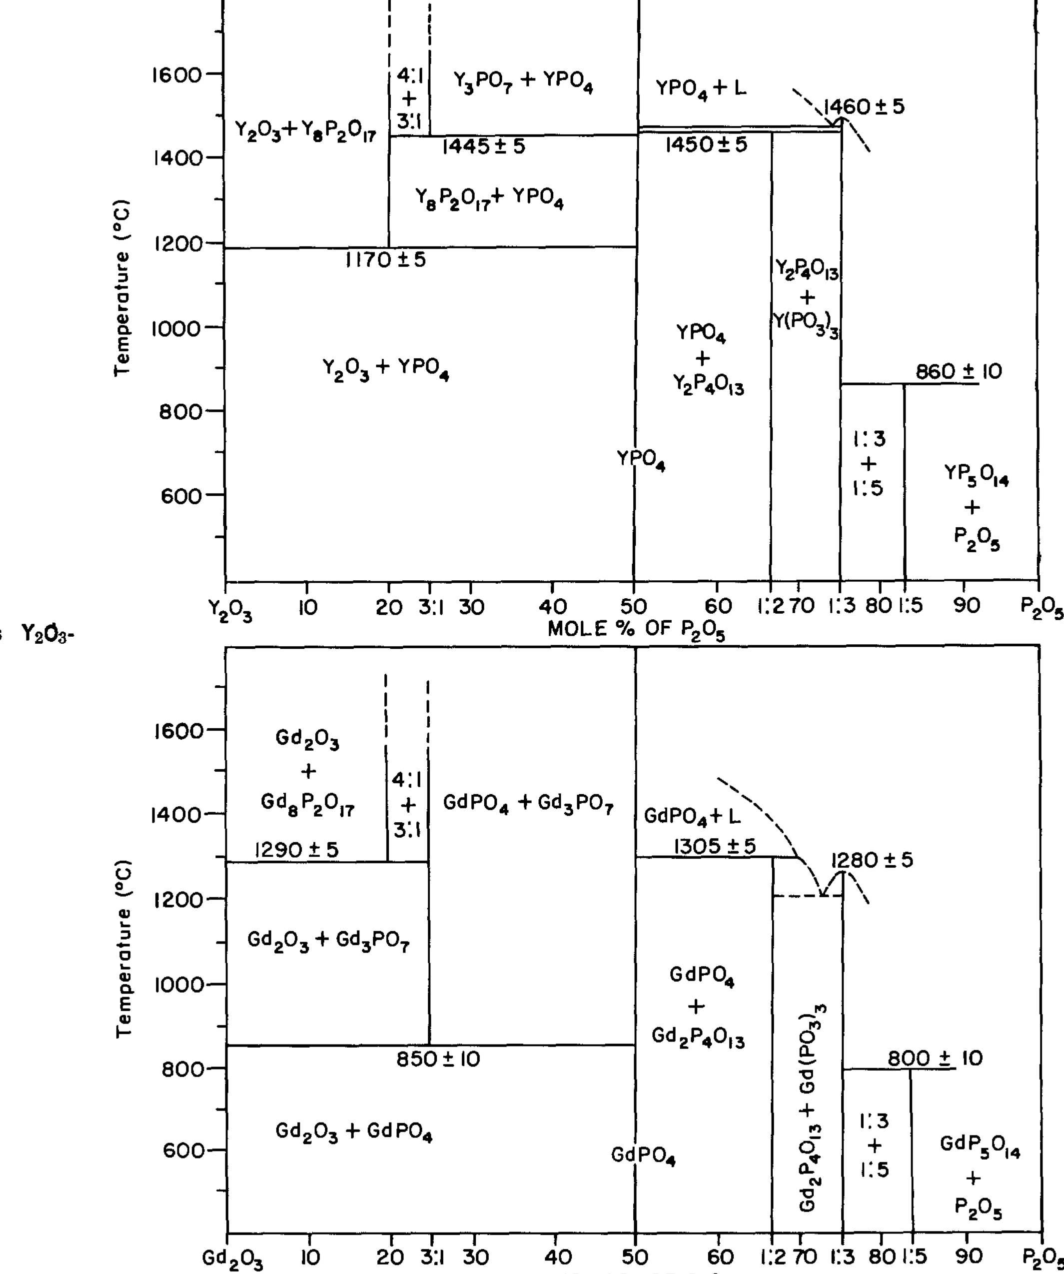

Fig. 1. The systems Y_2O_3-P_2O_5 and Gd_2O_3-P_2O_5.

(ii) $Y_8P_2O_{17}$ *(4:1)*.—The 4:1 compound was found to have a lower temperature limit of stability at 1170° ± 5°C. When a single phase 4:1 sample prepared at 1300°C was held at 1100° for 72 hr, it decomposed to Y_2O_3 and YPO_4.

(iii) Y_3PO_7 *(3:1)*.—The 3:1 compound has a lower temperature limit of stability at 1445° ± 5°C. Serra *et al.* (6) claimed it could be prepared by reaction of Y_2O_3 and $NH_4H_2PO_4$ between 1200° and 1400°C, but the present work shows that it would be metastable in that temperature range. A single-phase sample prepared at 1475°C decomposed to 4:1 and YPO_4 when held at 1300°C for 30 hr.

(iv) YPO_4.—The compound existed as the tetragonal zircon type structure from RT to 1400°C.

The YPO_4-P_2O_5 *subsystem.*—*(i)* $Y_2P_4O_{13}$.—Formation of the compound was very difficult by solid-state reaction and its existence could easily be overlooked if sufficient time was not allowed for reaction. It was prepared by holding for 800 hr at 1200°C. However, glass of the 1:2 composition melted at 1550°C crystallized to the 1:2 compound within 72 hr. Using the compound prepared by crystallization from glass, $Y_2O_3 \cdot 2P_2O_5$ was found to dissociate to 1:1 and 1:3 at 1450°C.

(ii) $Y(PO_3)_3$.—The 1:3 compound existed as a single structure from RT to its congruent melting point of 1460° ± 5°C. Earlier it had been reported (9) to melt incongruently to YPO_4 and a P_2O_5-rich liquid.

(iii) YP_5O_{14}.—The 1:5 compound was found to exist only in the monoclinic form and to melt incongruently at 860° ± 10°C to 1:3 and a P_2O_5-rich liquid. No orthorhombic phase was observed as previously reported (9).

The Gd_2O_3-$GdPO_4$ *subsystem.*—*(i)* Gd_2O_3.—The reported (1) polymorphic transformation was briefly investigated. Below 1100°C, only the cubic form could be detected. When heated at 1300°C for 500 hr, the monoclinic phase coexisted with the cubic phase. Perhaps longer times would produce a pure monoclinic phase.

(ii) $Gd_8P_2O_{17}$ *(4:1)*.—The 4:1 compound was found to have a lower limit of stability at 1290° ± 5°C. When a single phase 4:1 sample prepared at 1350°C was held at 1100°C for 50 hr, it decomposed to Gd_2O_3 and 3:1.

(iii) Gd_3PO_7 *(3:1)*.—The lower temperature limit of stability was 850° ± 10°C. Below 850°C, Gd_2O_3 and $GdPO_4$ coexist. A phase pure sample of 3:1 prepared at 1100°C for 72 hr decomposed to Gd_2O_3 and $GdPO_4$ when held at 800°C for 120 hr.

(iv) $GdPO_4$.—The compound was found to exist only in the monoclinic form and no phase transformation was observed, as had previously been reported (11). Samples were held at 1000°C for 100 hr. Kuznetsev *et al.* (11) reported a change from hexagonal to monoclinic near 500°C when gadolinium chloride and phosphoric acid were used as starting materials in aqueous solution.

The $GdPO_4$-P_2O_5 *subsystem.*—*(i)* $Gd_2P_4O_{13}$.—The compound behaved in a manner similar to the yttrium analogue as far as reaction rate was concerned. It was prepared by solid-state reaction at 1100°C for 800 hr, and from glass by crystallizing for 60 hr. The glass had been melted at 1500°C. Using the 1:2 compound which had been prepared by crystallization from glass, it was determined that it melted incongruently at 1305° ± 5°C into $GdPO_4$ and liquid.

(ii) $Gd(PO_3)_3$.—The 1:3 compound melted congruently at 1280° ± 5°C in contrast to the reported incongruent melting (9). In earlier literature (9), a transition was reported to take place between 800°-850°C. In the present work, the transition was detected when the sample was held near 750°C for 400 hr.

(9). The 1:5 compound melted incongruently to 1:3 and a P_2O_5-rich liquid at 800° ± 10°C.

Refractive index data.—The RI of the glasses between the 1:2 and 1:5 compositions are shown in Fig. 2. The relatively constant index between the 1:3 and 1:5 compositions is interesting. However, the error in measurement was ± 0.004 and it is unlikely that the index actually increased between the 1:3 and 1:5 compositions in the case of the Y_2O_3-P_2O_5 system.

X-ray diffraction data.—Patterns for the 1:2 compounds are given in Table II. Analysis of the data indicated that the 4:1, 1:2, 1:3, and 1:5 yttrium and gadolinium compounds had similar structures and would form either complete or partial solid solution systems, whereas the 3:1 compounds had different structures. To further confirm this analysis, 50:50 mixtures of the 4:1, 3:1, 1.2, 1:3, and 1:5 yttrium and gadolinium compounds were prepared and heated at 1400°/24 hr, 1475°/10 hr, 1100°/48 hr, 1100°/48 hr, and 700°/96 hr, respectively. The x-ray data confirmed the probable isomorphism of 4:1, 1:2, 1:3, and 1:5 and the coexistence of the $3Y_2O_3 \cdot P_2O_5$ and $3Gd_2O_3 \cdot P_2O_5$ structures.

Sulfur Substitution during Operation of CdSe Photoanodes and Mechanism of Surface Protection

K. T. L. De Silva and D. Haneman

School of Physics, University of New South Wales, Kensington, Australia, 2033

ABSTRACT

The concentrations of S, Se, and Cd during operation of a polycrystalline CdSe photoanode in 1M Na_2S, 1M S, 1M NaOH solutions were measured by x-ray photoelectron spectroscopy as a function of total charge passed. Sulfur had reached half the final concentration in the XPS probed layer after only 5 C cm^{-2}, although there was little change in cell output. These and other phenomena are analyzed to suggest that the Cd-S layer that forms does not establish a semiconductor heterojunction but merely a chemically protective layer which is of low semiconductor quality and has little barrier to current flow. At high current densites the layer thickens and becomes obstructive, requiring Se in solution to prevent its growth to obtrusive proportions. The XPS results also show that when the electrochemically deposited Cd-Se film is annealed, chemical shifts of the Cd and Se peaks occur, indicating formation of the compound CdSe during annealing, from codeposited but not reacted elements in the initial film.

Sustained, efficient conversion of solar energy to electricity has been demonstrated using photoelectrochemical (PEC) cells based on CdSe photoanodes (1-5). In these PEC cells, photogenerated holes oxidize the reduced component of the redox couple, after which these oxidized species migrate to the cathode to be reduced back again by electrons. The semiconductor CdSe which has many potential advantages as a solar energy conversion photoanode, can be stabilized against photocorrosion by adding sulfur ions to the electrolyte

$$CdSe \xrightarrow{h\nu} Cd^{2+} + Se + 2e^- \quad [1]$$

$$Cd^{2+} + S^{2-} \rightarrow CdS \quad [2]$$

Key words: solar cells, photoelectrochemical, cadmium selenide, photoanodic protection.

CdSe is oxidized under illumination in the PEC cell, to Cd^{2+} and Se. Cd^{2+} ions probably react to give CdS within a very short time of its formation, because of the high surface concentration of sulfide ions. This means that the surface of the CdSe electrode will be replaced by CdS during illumination. Sulfur was found to depths up to 10 nm from the surface in XPS studies by Cahen *et al.* (6) and by Noufi *et al.* (7). However, the rate at which the surface substitution of Se by S occurs, was not determined. This is of interest in checking the formation of a postulated heterojunction between the CdSe bulk and thin (6-12 nm) CdS layer, and how this affects operation of the electrode.

Experimental

Measurements were made with a Varian IEE-15 photoelectron spectrometer using MgKα radiation

(1253.6 eV), with a resolution of 1.8 eV FWHM (full width half maximum) on gold 4s peaks. The Mg x-ray source was operated at 8 kV and 80 mA. Scanning the spectrum was performed by varying the retarding voltage, with the analyzer set to detect retarded electrons of 100 eV (this gives the above resolution). Preliminary wide scans were carried out over a 90V region (500 channel and 12 sec per scan). The scans were then repeated with 30V scan width (200 channel and 40 sec per scan), so that peak positions could be measured accurately.

Various preparation methods of polycrystalline CdSe are given in the literature (1-4). The polycrystalline CdSe samples (ten) used in this study were prepared by electrolysis of 1M HCl solution containing 1M $CdCl_2$ and 1M SeO_2. The nickel substrate was cleaned with acetone in the ultrasonic cleaner, then etched in nitric acid and rinsed thoroughly with distilled water. A carbon plate was used as the anode, spaced 1 cm from the Ni substrate. The solution was stirred continuously using a magnetic stirrer. A thick film (about 40 microns) of Cd-Se was formed on the Ni substrate and then annealed in an N_2 atmosphere at 400°C for 1 hr and kept under N_2 until cool. CdSe and CdS single crystals were used as the XPS standards. They were polished and cleaned prior to analysis. Evaporated Se on an Al substrate was also used as a standard.

1M Na_2S, 1M S, and 1M NaOH solutions were used as the electrolyte in the PEC cell. The counterelectrode was prepared by applying aquadag and cobalt acetate on to a stainless steel gauze and subsequently heating it in an N_2 atmosphere. The short-circuit current of this cell, initially 4 mA cm^{-2}, was measured under illumination by a 250W tungsten filament quartz iodine lamp operated at 16V (rated for 24V). The photoanodes, after photolysis, were washed with 0.5M Na_2S solution, to prevent precipitation of elemental sulfur from the absorbed electrolyte. Then they were washed five times with distilled water to remove physically adsorbed electrolyte, before the analysis.

Results

Prior to annealing, Cd-Se films showed the presence of Cd and Se as shown in Fig. 1, curve I. Scans were made of the Cd-3d region, Se-3p region, S-2p region, and the S Auger peak at ~151 eV kinetic energy. There was no evidence for the presence of sulfur. The positions of Cd, Se, and S peaks obtained from XPS results are given in Table I. Figure 1 shows the spectra obtained from CdS single crystals and CdSe films under various conditions described in the caption. A reduction of the Se concentration on the CdSe surface occurred during the annealing process (curve II). At the same time an increase of the Cd peak intensity was observed. Quantitative analysis showed a reduction of the ratio Se/Cd by ~60%.

As shown in Fig. 1 curve III, after operation as an illuminated photoelectrode, a strong peak at 161.1 eV is observed, due to sulfur ($2p_{1/2}$ and $2p_{3/2}$) on the CdSe surface. This peak at 161.1 eV overlaps with the Se peak at 160 eV. The overlapping of the peaks is confirmed by the larger FWHM of this peak (~3.2 eV) compared with the FWHM of the Se-$3p_{3/2}$ peak (~2.6 eV) of a fresh CdSe film. The reduction of the Se-$3p_{1/2}$

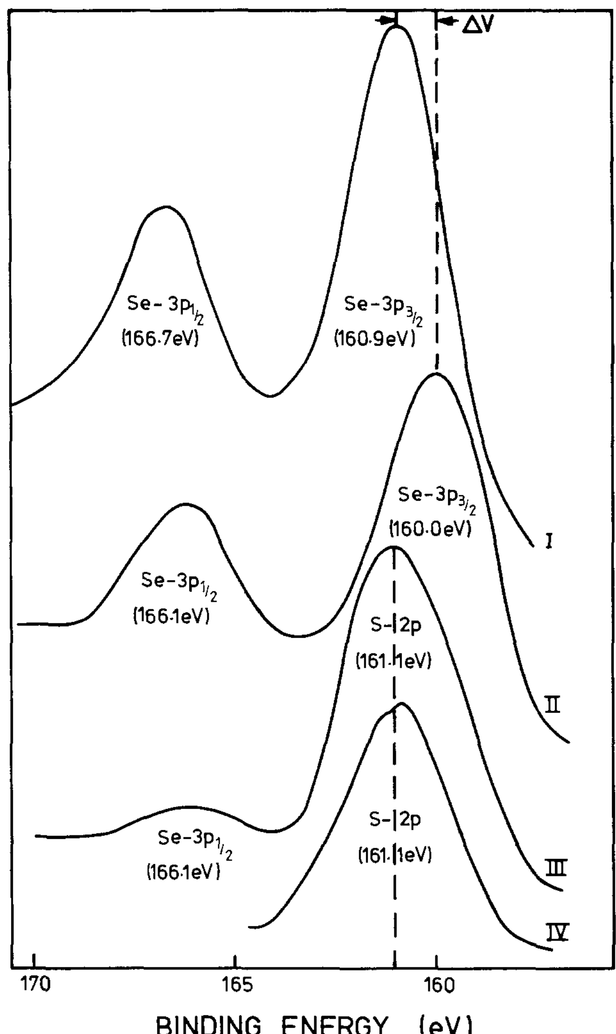

Fig. 1. X-ray photoelectron spectra of CdSe electrode: curve I, before heat-treatment; curve II, same film after heat-treatment; curve III, same film after illuminating as a photoelectrode in PEC cell (after passage of 60 C cm^{-2}); curve IV, CdS single crystals. The quantity ΔV represents the difference in position of the Se-3p peaks before and after annealing.

peak at 166.1 eV clearly shows the S/Se substitution. The position of the S-2p peak of CdSe is identical with the S-2p peak of pure CdS, as shown in Fig. 1 curve III and IV. The Cd peaks showed no significant change before and after photolysis.

The ratios of S/Cd and Se/Cd of the electrode surface were measured as a function of charge passed through the photoanode and are shown in Fig. 2. This graph was drawn using the peak heights of Cd-3d, Se-3p, and S-2p. The heights were adjusted for relative XPS sensitivities as given by Berthou and Jorgensen (9). The initial overall efficiency (~2%) of the cell was constant to within 5% during the S/Se substitution.

Solid lines are for the ratios Se/Cd and S/Cd; dashed line is for depth of S penetration, drawn using the 2 values in Ref. (7) and, when extrapolated, passing through the value of 10 nm at approximately 540 C cm^{-2} inferred from Ref. (6).

Discussion

After the annealing process we observed (*i*) a decrease of the ratio Se/Cd, (*ii*) a negative shift of the Se peak position by 0.9 eV, (*iii*) a positive shift of the Cd peak position by 0.5 eV. We also observed a very large improvement of the photocurrent after the heat-treatment, by a factor of about 100. Several reasons have been forwarded to explain this improvement (10). These include the liberation of excess Se and formation of crystallites of large sizes. The liberation of excess Se is confirmed by (*i*) above. The increase of photocurrent may be due to the formation of CdSe from Cd and Se, during the annealing process. A consistent explanation is that the electrolysis process deposits Cd and Se on the substrate but these do not form CdSe. During annealing the two materials react to form Cd-Se complexes. This is supported by the observed chemical shifts after annealing. Also the photocurrent wavelength response is characteristic of CdSe.

The reduction of Se/Cd occurred after a relatively small amount of charge had passed as shown in Fig. 2. The ratio S/Cd was increased at the same time. Because the Cd peak heights did not reduce, the increased sulfur peaks cannot be explained by a deposited sulfur or contaminant over layer (11). Furthermore the binding energy of the sulfur peak is the same as that in CdS (curves III and IV in Fig. 1). Therefore we conclude that the sulfur is present together with Cd, consistent with the conclusions of Heller *et al.* (11) that CdSe in the surface is replaced by CdS. Previous microprobe studies (12) have shown that the S/Se ratio of the CdSe surface, after photolysis for several hours, was about 1:1 in the top micrometer of the layer. Our measurements show that this ratio is about 1.8:1 in the thin layer (~2-3 nm) probed by XPS, showing that the sulfur concentration is highest at the surface itself.

An EIS (electrolyte-insulator-semiconductor) band scheme has been proposed by Cahen *et al.* (6) for the S/S^{2-}-CdS-CdSe system, by considering CdS as a thin insulating layer bonded to the CdSe. For insulating layers of $>$ ~2 nm thickness, a significant increase of series resistance has to be expected (13). The thickness of the CdS layer on the CdSe electrodes is very much larger than 2 nm (11). However, the constancy of photocurrent (~4 mA cm^{-2}) of our cells during substantial S/Se substitution, does not accord with an increase of such a series resistance, and indeed implies no significant change in mode of operation. Therefore we feel the evidence does not support the growth of an EIS structure over a substantial portion of the surface.

The deterioration of CdSe PEC cells can be prevented by working at low current densities (6, 10). At such densities, ($<$10 mA cm^{-2}) all holes are captured by the redox couple and a decrease in free Cd^{2+} concentration can be obtained because oxidation of CdSe by reaction [1] does not take place. Furthermore at large current densities, (10-40 mA cm^{-2}) the rate of deterioration can be decreased with addition of a small amount of Se solution, as shown by Heller *et al.* (10) for polycrystalline hot-pressed and single crystal CdSe photoanodes. This effect is due to the decrease of x in the series of compounds $CdSe_{1-x}S_x$ on the surface of CdSe. The barrier to hole transfer to the solution interface is said to be lowered as x decreases. Miller *et al.* (3) and Cahen *et al.* (6) have reported an increase in stability of sintered disk and single crystal CdSe electrodes with increasing S^{2-} concentration in solution. This minimizes the time that free Cd^{2+} can exist by precipitating CdS on the surface.

For electrodeposited polycrystalline electrodes the deactivation is much less (6). According to this explanation, decrease of photocurrent can be prevented by rapid formation of CdS on CdSe. This however appears to contradict the above proposal (10) that CdS causes a barrier to hole transfer and should be reduced by Se addition in order to prevent deterioration at high current densities.

Clearly the situation is complex and all phenomena cannot be accounted for by a single simple explanation. However the results reported here would show that during the initial states of cell operation, S rapidly enters the surface, mostly in the form of Cd-S, without much effect on cell output. We believe this can be accounted for if the Cd-S layer shows substantial leakage through to the underlying CdSe crystals; indeed it is highly unlikely that a high quality hermetic structure could form. A very schematic diagram is shown in Fig. 3. From a topography point of view, scanning microscope pictures of the surface of an electrode after operation show a very uneven surface, as also do those of a CdS electrode (7). The Cd-S layer is presumed to contain many defects and be very conductive, much more than a normal CdS semiconductor. There are impurity and defect levels which are sufficiently closely spaced in the approximately 6 nm Cd-S layer to form impurity bands and hence negligible potential barrier to carriers. Of course carrier recombination will be high, but not necessarily higher than that at the CdSe-electrolyte interface.

At high current densities, the Cd-S structure becomes sufficiently thick and pervasive to cause current obstruction, and also significant light absorption, and hence the addition of Se to the solution would help to keep any such structures to the lesser form that

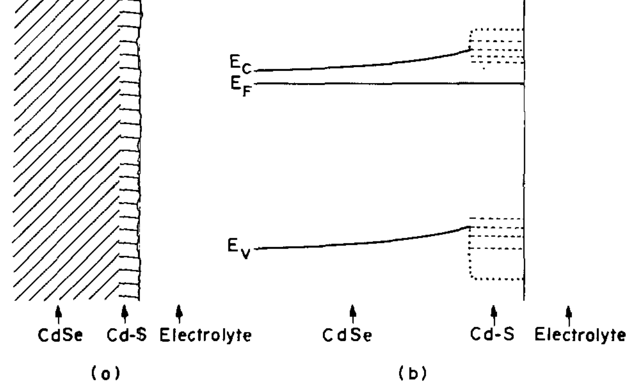

Fig. 3. Schematic diagram showing the CdSe:Cd-S electrolyte interface. The Cd-S layer, about 3-6 nm thick is of poor electrical quality and highly conductive via impurity-defect bands, shown dashed in (b). The "band edges" of the Cd-S are indicated by dotted lines.

develops at lower current densities. This lesser layer does not seal against current flow but reduces corrosion. Although this explanation is necessarily qualitative, it appears to be in accord with a number of phenomena.

Electrochemical Sectioning and Surface Finishing of GaAs and GaSb

C. R. Elliott and J. C. Regnault

British Post Office Research Centre, Martlesham Heath, Ipswich IP5 7RE, England

ABSTRACT

The characteristics of a new anodic dissolution process for sectioning and removing damage from monocrystalline GaAs and GaSb are described. Dissolution proceeds in the presence of a solid anodic film, which limits local variations in etch rate, so the flatness and microtopography of initially smooth surfaces are preserved. The high anodic efficiency permits accurate monitoring of material removal. Etch rates may be varied from below 0.01 μm hr^{-1} to over 10 μm hr^{-1} on GaAs and to 4 μm hr^{-1} on GaSb. Applications discussed include epitaxial layer thickness trimming and preparation of substrates for epitaxy and samples for crystallographic defect studies.

Smooth, flat, damage-free surfaces are often required for both growth and characterization of single crystal semiconductor materials. Furthermore, an ability to maintain such surfaces during removal of small, accurately known, thicknesses of material permits profiling and layer thickness trimming to be carried out. Initial flatness in cut slices is best achieved by mechanical lapping and polishing; thereafter, electrochemical polishing is potentially the best process for damage removal and for sectioning, because electrochemical dissolution may be monitored and controlled readily. However, although electropolishing of metals is well established (1) and electropolishing of semiconductors has been reported (2-6), the latter processes are limited in application to low resistivity materials, as relatively high current densities are required. Also, the complication of a scanned jet has been found necessary for producing extended flat areas (7). Compound semiconductor substrates are commonly chemo-mechanically polished (8-11) and then etched chemically to remove the residual damage (12). This process is not well suited to the removal of small, well-defined thicknesses of material and it tends to give beveled edges and "orange peel" type of surface topography, with the chemical etching quickly degrading surface flatness (13).

Key words: anodization, etching, defects, gallium arsenide, gallium antimonide.

Discontinuous processes are employed for profiling semiconductors accurately (14, 15). In these processes material is removed stepwise, by repeated growth and selective dissolution of anodic oxide films, whose thicknesses are determined by the applied voltage. Care is required in order to achieve a reliable thickness/voltage relationship (16) and the maximum thickness of each step is typically limited to a few hundred nanometers.

A novel approach to the problems of surface preparation and controlled removal of material was reported recently by Faktor and Stevenson (17), working on gallium arsenide. By anodizing in an oxide-forming phosphate electrolyte, to which a controlled addition of a chemical complexant (Tiron) had been added, they achieved continuous dissolution of GaAs in the presence of about 100 nm of anodic oxide, which, by transport limitation of the anodic current, ensured a uniform dissolution rate over the semiconductor surface. As the initial surface topography was preserved the process was described as replication etching. We have been concerned with the establishment of improved processes of this type, both for GaAs and for other compound semiconductors, for

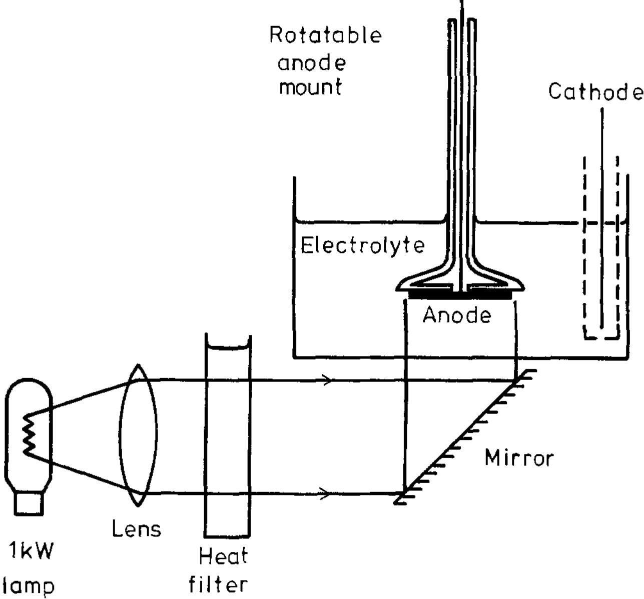

Fig. 1. Apparatus for anodic dissolution of n-type semiconductors of larger area.

the purposes of sectioning epitaxial layers and the removal of damage from mechanically polished slices. We report here the characteristics of a process which is applicable to GaAs and GaSb and has significant practical advantages over that introduced by Faktor and Stevenson for GaAs.

Table I.

pH	Charge transferred (C)	Weight loss (mg)	$x + y$
7.2	966	242.9	5.96
9.5	618	151.9	6.10

Experimental

The apparatus of Fig. 1 was employed for larger area specimens, such as substrates for epitaxial growth or whole wafers for microstructural evaluation. Because charge transfer in anodic dissolution of GaAs and GaSb is via holes (18), intense illumination (400 mW cm^{-2}) from a tungsten-halogen lamp was provided for generating a plentiful supply of holes at the surface of n-type materials. The anode was rotated at 50-500 rpm to establish a uniform diffusion layer in the electrolyte at the interface (19). A mercury back contact was usually satisfactory for n- and p-type materials, but any established contacting method may be used. The cathode was platinum foil and a porous membrane prevented any gas bubbles formed at its surface from reaching the anode. Anodizations were carried out at constant voltage, using a stabilized power supply which could provide up to 100V d.c. and had adjustable current limitation. The total charge passed was recorded by means of a digital integrator. The electrolyte consisted of 0.2M ethylene diamine tetraacetic acid disodium salt (EDTA), with ammonium hydroxide added for pH control. Small

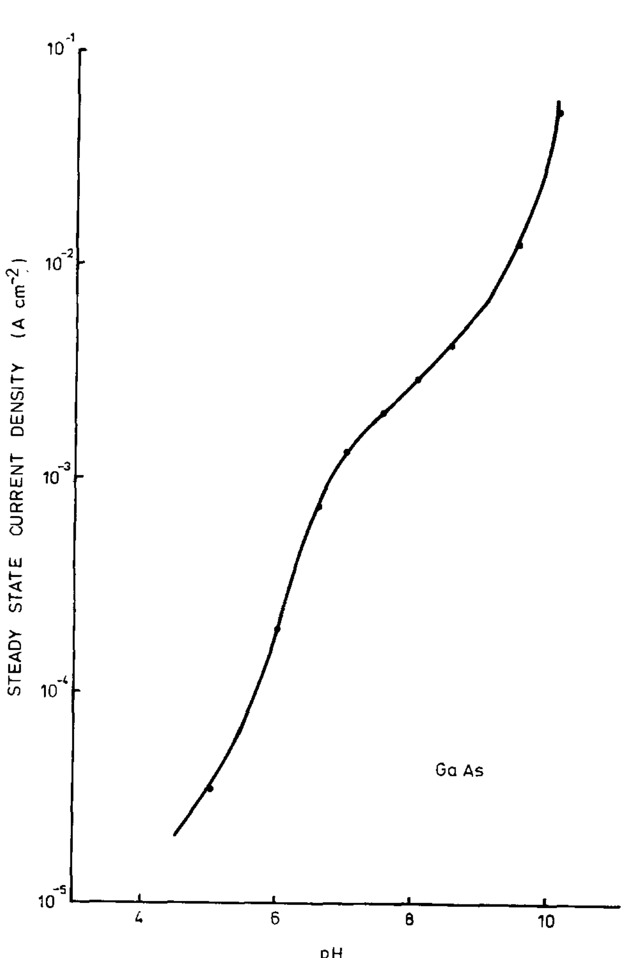

Fig. 2. Variation of steady-state current with pH for a GaAs anode in 0.2M EDTA/ammonium hydroxide.

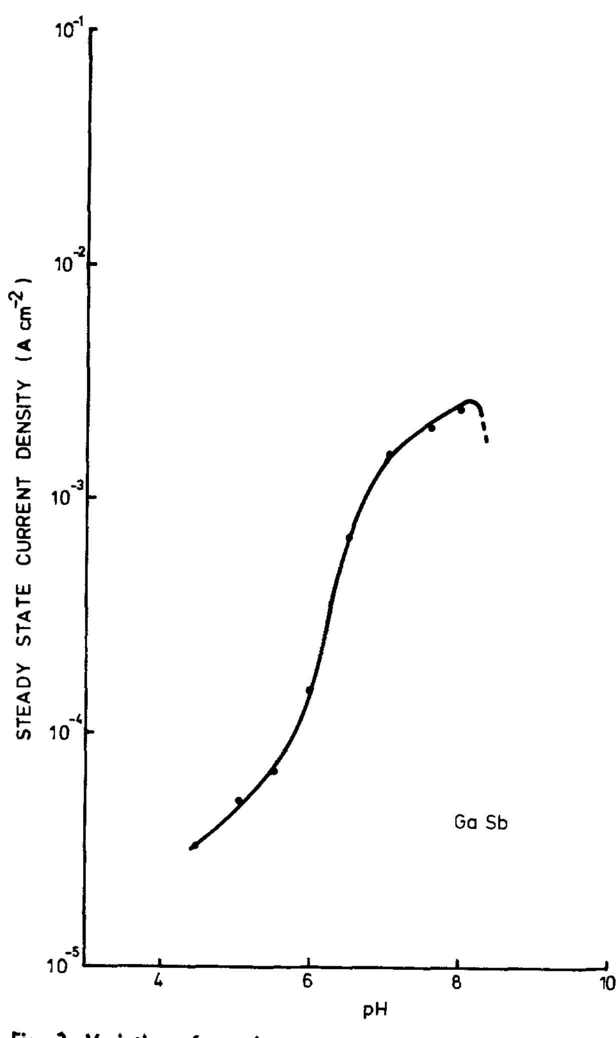

Fig. 3. Variation of steady-state current with pH for a GaSb anode in 0.2M EDTA/ammonium hydroxide.

selected areas were anodized using a microscope-mounted electrochemical cell of the type described by Faktor and Stevenson (17).

Results and Discussion

On applying about 50V between the electrodes a relatively large transient film-forming current flowed. As the thickness of the anodic oxide increased, this current decreased rapidly, reaching a steady value within a few seconds. Figure 2 shows the variation of the steady-state current with *p*H for a GaAs anode. At *p*H 4.5, the natural *p*H of 0.2M EDTA, the low current density of 20 μA cm^{-2} indicates negligible oxide solubility. Above *p*H 10 the current density could reach levels at which limitation by the semiconductor could occur, sometimes resulting in uneven dissolution of the anode. Between these values of *p*H the correlation of weight loss with charge passed (Table I) confirmed that the anodic reaction was of the form

$$GaAs + xe^{+} \rightarrow Ga^{3+} + As^{3+} + ye^{-}$$

where $x + y = 6$ and $x >> y$ (20, 21), corresponding with a dissolution rate of 1.69 μm mA^{-1} cm^2 hr^{-1}. Results for GaSb were similar up to *p*H 8, with a dissolution rate of 2.1 μm mA^{-1} cm^2 hr^{-1}, but above *p*H 8 the current density fell, as shown in Fig. 3, and the film became dull in appearance.

At *p*H values greater than 2.5 EDTA reacts with gallium ions at room temperature to form a strong complex (formation constant 10^{20}) (22). The increasing solubility of the anodic oxide with *p*H at near neutral *p*H's is thus associated with the increasing ionization of the EDTA with *p*H. At higher *p*H's the formation of soluble arsenite, antimonite, and gallate species will also be involved. The difference in behavior of GaAs and GaSb above *p*H 8 probably results from the different solubilities and stability regions of As_2O_3 and Sb_2O_3 (23).

Figures 4a-d are interference contrast micrographs of GaAs and GaSb surfaces before and after anodization in EDTA/ammonium hydroxide. Figure 4a shows a ¼ μm diamond polished n-type GaAs (100) surface and 4b the same, after anodic removal of a 20 μm thick layer at 2 mA cm^{-2}. Figure 4c shows a bromine/methanol polished GaSb surface and 4d the same, after anodic removal of 10 μm at 1 mA cm^{-2}. The topographies of the initial surfaces are still evident after anodization and no new surface structures are present, hence the process fulfills the essential requirements for damage removal and sectioning. Retention of flatness on a macro scale was confirmed by interferometry. Figure 5a shows the interference fringes obtained on a diamond polished GaAs (100) surface and 5b the same after removal of 20 μm anodically. Damage removal was confirmed by etching surfaces electrochemically in a defect-sensitive mode (17) before and after anodization in EDTA/ammonium hydroxide. Figures 6a and 6b show, respectively, defect revealed (100) surfaces of GaAs after bromine/methanol polishing and after an-

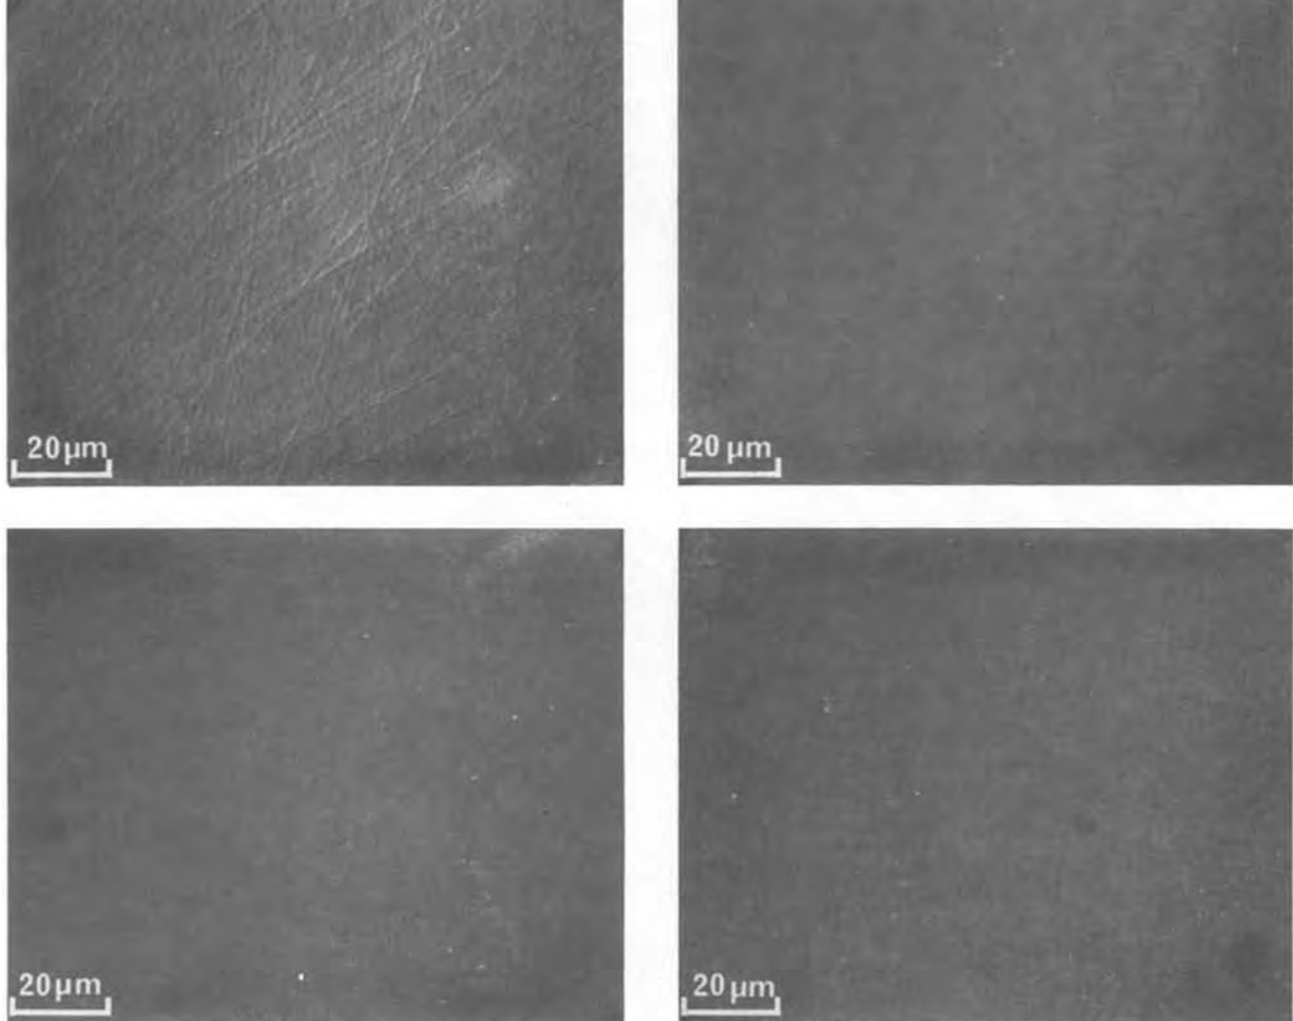

Fig. 4. Interference contrast micrographs of surfaces before and after anodization in EDTA/ammonium hydroxide: (a, top left) ¼ μm diamond polished n-type GaAs (100) surface, and (b, top right) the same after removal of 20 μm at 2 mA cm^{-2}; (c, bottom left) bromine/methanol polished undoped GaSb (100) surface, and (d, bottom right) the same after removal of 10 μm at 1 mA cm^{-2}.

odic removal of 20 μm from a ¼ μm diamond polished surface.

It was noted that the surface of Fig. 4b was slightly smoother than that of 4a. As this implied a possibility of substituting the simple anodization process for one or more of the final stages of mechanical polishing of substrates, which require great care, an additional experiment was undertaken to further evaluate the smoothing effect. A GaAs (100) surface lapped with 25 μm alumina was anodized at 2 mA cm^{-2} until 10 μm had been removed. Figure 7a shows the characteristic "cellular" surface obtained. Within each polygon boundary the surface was smooth and slightly concave. Although the average size of the "cells" increased with anodization time, the structure persisted, even after removal of 105 μm of material, Fig. 7b. An electron channelling pattern, Fig. 8, obtained in the scanning electron microscope, indicated that the surface at this stage was essentially free from damage. Figures 7a and 7b were obtained by interference contrast microscopy, which greatly accentuates the apparent surface irregularity. A Talystep profile, Fig. 9, of the surface shown in Fig. 7b confirmed that the vertical amplitudes of the features were no more than 1 μm, and mostly only ½ μm. The mechanism of formation of this interesting surface structure, under the conditions used here, is not yet understood. Similarly structured surfaces in other semiconductor-etchant systems have been reported (7, 24), but not investigated in detail. The relationship between anodized surface structure and polishing medium particle sizes between 25 and ¼ μm was not pursued in this investigation, but a vapor phase epitaxial layer 20 μm thick was grown on the surface shown in Fig. 7b. The morphology of this layer is shown in Fig. 10.

No electrical breakdown at specimen edges or at surface features was observed during anodization in EDTA/ammonium hydroxide, whereas, in our experience, this does tend to occur in the phosphate/Tiron electrolyte. A further significant practical advantage of the EDTA/ammonium hydroxide system over the latter is its considerably wider range of usable current densities, simply obtained by adjustment of pH.

Applications

The process described has been shown to be satisfactory for preparing diamond polished or chemomechanically polished GaAs substrates for liqud phase, vapor phase, and molecular beam epitaxy, no further etching being required before growth (25). Figure 11 is an interference contrast micrograph of an MBE layer 1 μm thick, grown on a GaAs substrate prepared by this process. It has also been used successfully for trimming n-type epitaxial layers to the desired thickness for device fabrication and for preparing surfaces for defect-sensitive etching. In the first of these

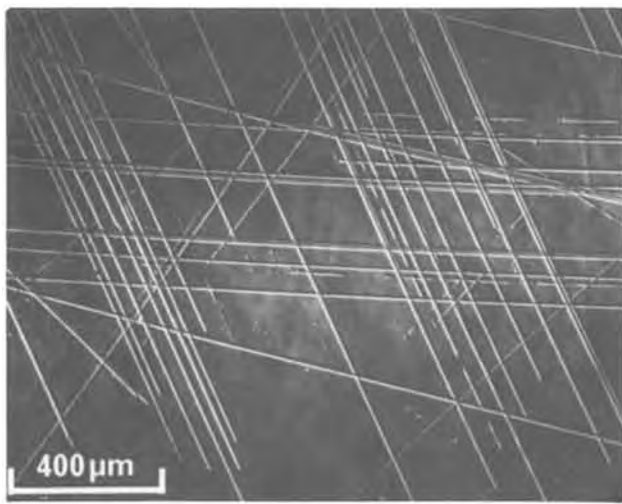

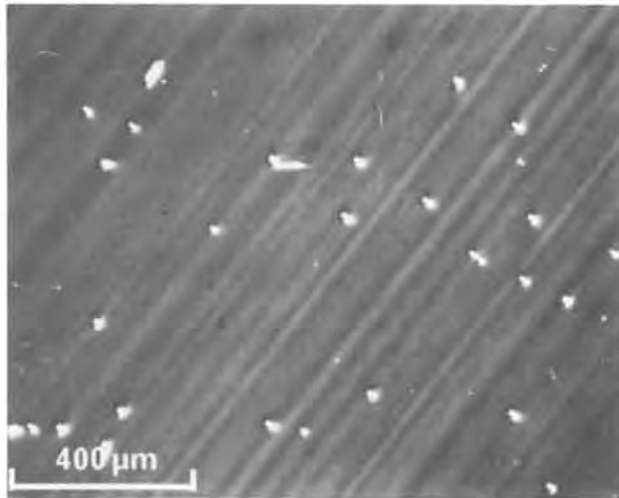

Fig. 6. GaAs (100) surfaces electrochemically etched to reveal defects; (a, left) residual abrasion damage after bromine/methanol polishing delineated, (b, right) damage-free surface after removal of 20 μm anodically following polishing with ¼ μm diamond.

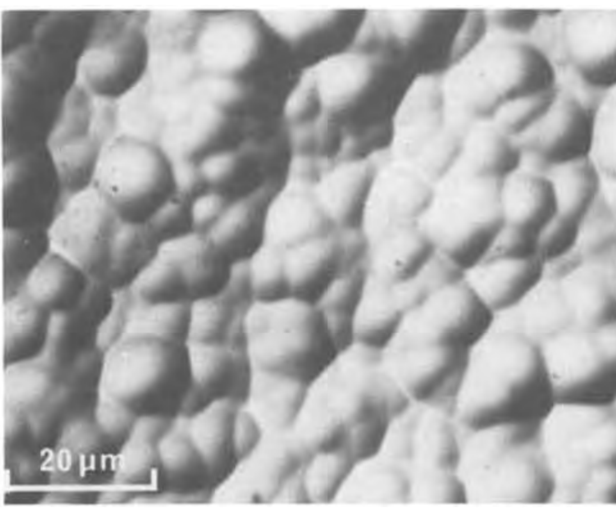

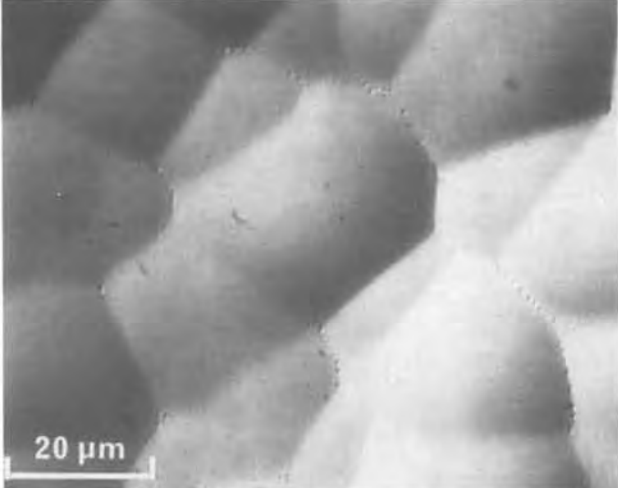

Fig. 7. Interference contrast micrographs of a GaAs (100) surface lapped with 25 μm alumina, after removal of (a, left) 10 μm and (b, right) 105 μm anodically.

applications one advantage of the technique is that the oxide may be left on the substrate as a protective film until immediately before growth. The oxide on GaAs is readily soluble in dilute hydrochloric acid or ammonium hydroxide, and that on GaSb is soluble in 2M aqueous potassium hydroxide. In the case of liquid phase epitaxy, where substrate thicknesses are critical and edge beveling is undesirable, the process has obvious advantages.

Summary

A technique is described for the smooth anodic dissolution of GaAs and GaSb. The process has the advantages of retention of surface flatness, easy and close control over the quantity of material removed, insensitivity to structural defects, and a variable dissolution rate. It has been shown to be satisfactory for trimming epitaxial layer thicknesses accurately and for preparing damage-free surfaces both for epitaxial growth and for crystallographic defect studies.

Lateral Definition of Monocrystalline GaAs Prepared by Molecular Beam Epitaxy

S. Hiyamizu, K. Nanbu, T. Fujii, T. Sakurai, H. Hashimoto, and O. Ryuzan

Fujitsu Laboratories Limited, 1015 Kamikodanaka, Nakahara-ku, Kawasaki, Japan

ABSTRACT

Using a thermal oxide of GaAs for masking, excellent planar structures of monocrystalline and polycrystalline GaAs were prepared on GaAs substrates by molecular beam epitaxy. Micron-sized monocrystalline GaAs of device quality with sufficient electrical isolation by semi-insulating polycrystalline regions were obtained. Planar-type MESFET's were successfully fabricated to confirm the application potential of this technique.

Selective epitaxial deposition of GaAs has been long investigated for application to integrated circuits by vapor phase epitaxy (VPE) (1-4), liquid phase epitaxy (LPE) (5-7), and molecular beam epitaxy (MBE) (8-16). MBE has an apparent advantage over VPE and LPE to achieve lateral definition because of its feature of crystal growth in high vacuum. Therefore, many attempts have been made to obtain two- or three-dimensional structures of GaAs and AlGaAs with various techniques, such as deposition with mechanical shadowing using tungsten (8), tantalum (9, 10), and silicon masks (11, 12), deposition on SiO_2 masked substrates (13, 14), and preferentially etched substrates (15, 16). One of the most promising methods among them is planar growth of monocrystalline and polycrystalline GaAs using SiO_2 masking (13, 14), since the well-established and developing technique of lithography can be used to obtain fine patterning with good reproducibility.

In this study we present another promising method, *i.e.*, selective growth of GaAs with the use of a GaAs thermal oxide for masking, which provides a similar, but superior planar structure of monocrystalline and polycrystalline GaAs. Thermal oxides of GaAs have been extensively investigated (17), but they have not been applied to practical devices due to their poor dielectric properties (18) and poor characteristics for surface passivation of GaAs (19). Notwithstanding, when a thermal oxide was used as a masking film for selective growth by MBE, it exhibited rather favorable features compared with SiO_2 masking, *e.g.*, extremely uniform and thin native oxide with a thickness of about 300Å could be easily obtained with high reproducibility over a large area of GaAs substrates, even up to a 2 in. diam or more, and consequently lateral definition with a micro-sized pattern could be accomplished with superior planar feature.

The electrical properties of high resistivity polycrystalline GaAs grown on the thermal oxide film and those of monocrystalline GaAs isolated by the polycrystalline regions were extensively studied to assess the application potential of this technique. Fabrication of planar-type MESFET's was demonstrated.

Key words: FET, isolation, mobility, polycrystalline GaAs, thermal oxidation.

Crystal Growth

A (100) oriented, Cr-doped semi-insulating GaAs substrate was chemically etched in a solution of H_2SO_4:H_2O_2:H_2O = 18:1:1 to remove any mechan-

ically damaged layer. After being rinsed in deionized water, the substrate was oxidized in a stream of oxygen (0.5 liter/min) at 550°C for 30 min. An oxide layer with a thickness of about 300Å and exhibiting excellent uniformity up to an area of 2 in. diam or more was formed with good reproducibility. This native oxide was dissolved in HF, but it was hardly attacked by H_2SO_4, HCl, and H_2O_2. The oxide film on areas of the substrate intended for growing monocrystalline GaAs, was removed selectively using a conventional photolithographic technique and HF. Subsequently, the As-rich layer, which inherently exists at the interface of the thermal oxide film and GaAs (20), was also etched off with H_2O_2 to expose the GaAs in the window areas. After photoresist removal the exposed areas of the substrate were lightly etched again with a solution of $H_2SO_4:H_2O_2:H_2O = 1:1:125$ to remove a ~300Å layer of GaAs and rinsed in deionized water to clean the GaAs surface. The substrate was then loaded in an MBE system described previously (21).

Immediately before MBE growth, the substrates were preheated to about 600°C for a few minutes in an As_4 ambient with 1×10^{-7} Torr. Auger electron spectra of the substrate after preheating are shown in Fig. 1. It can be seen that the exposed surface area [Fig. 1(a)] exhibits the cleanliness of nonmasked GaAs substrates. In a spectrum from a coated area [Fig. 1(b)], we can see large peaks for oxygen and gallium but none for arsenic, which is consistent with that previously reported in GaAs thermal oxides (20, 22). The thermal oxide layer still remained even after the heat-treatment.

GaAs was deposited on such a substrate at growth temperatures between 460° and 530°C. Monocrystalline and polycrystalline GaAs were deposited simultaneously on exposed GaAs areas and on the thermal oxide coated areas, respectively. Pure graphite cells were used for Ga, As, and Sn evaporation. Effusion cell temperatures were 1050° (Ga), 330° (As), and 800°-950°C (Sn). The growth rate was 0.3-0.5 μm/hr and the background pressure was about 1×10^{-6} Torr during growth.

Results and Discussion

Properties of polycrystalline GaAs.—Figure 2 shows a scanning electron micrograph of a cleaved cross section of a 1 μm thick deposited film, which includes the boundary between the polycrystalline and monocrystalline regions. The film thicknesses were measured with a Talystep. Surfaces of both regions were almost on the same level with each other, that is, the surface was nearly planar. Careful observation, however, revealed that polycrystalline films were about 5% thicker than the monocrystalline GaAs.

An electron micrograph of a platinum-shadowed carbon replica of a 1 μm thick polycrystalline GaAs film deposited at 460°C is shown in Fig. 3(a). The grain size of this film seems to be around 0.5 μm in diam at the surface. Figure 3(b) is a transmission electron micrograph (TEM) observed in the region near the surface of the same sample. Specimens for TEM, which have a 1-1.5 mm diam hole through the substrate and the oxide layer, were prepared by etching with the use of a solution of $NH_4OH:H_2O_2 = 1:10$ followed by Ar^+ sputtering. This figure shows that grain size of the film is 0.3-0.5 μm in the region near the surface, which agrees well with that of the carbon replica. The grain size did not depend on the growth temperature in the range of 460°-530°C.

The *I-V* characteristics shown in Fig. 4 were measured through polycrystalline GaAs deposited at 500°C. To measure the electrical resistivity of polycrystalline GaAs, we prepared samples with a planar structure as shown in the inset. The deposited films with 1.1 and 2.3 μm thickness were Sn-doped to a concentration of 1×10^{18} cm^{-3}, in which case the resistivity of the monocrystalline region became 2×10^{-3} Ωcm. The doping concentration in polycrystalline GaAs was supposed to be the same as that of monocrystalline regions prepared in the same wafer. Gold-germanium ohmic contacts with 20 μm width were applied to the monocrystalline stripes, and the *I-V* characteristics between these contacts were measured at room temperature (Fig. 4). Assuming that current flows uniformly and only through the polycrystalline film, we obtained resistivities of 2×10^6 Ωcm for the 1.1 μm thick film and 4×10^5 Ωcm for the 2.3 μm thick film from the gradient of the *I-V* curves in the ohmic range (≦10V) and the geometry of the samples. The resistivity decreased by a factor of 5 when the thickness increased from 1.1 to 2.3 μm, suggesting that the films are considerably inhomogeneous in the direction of the thickness.

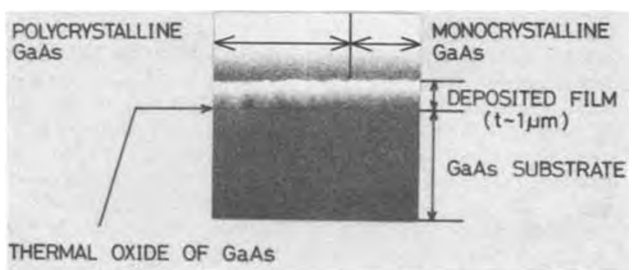

Fig. 2. Scanning electron micrograph of cleaved surface of a 1 μm thick film. The cleaved edge surface was lightly stain-etched. The boundary between polycrystalline and monocrystalline GaAs shows excellent planarity.

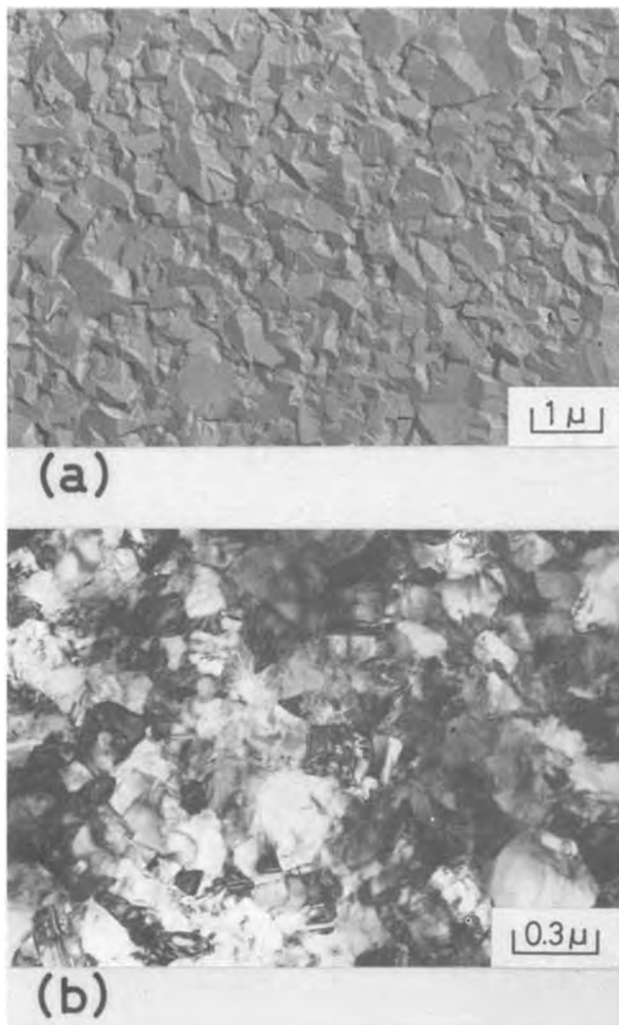

Fig. 3. (a) Electron micrograph of platinum-shadowed carbon replica of a 1 μm thick polycrystalline GaAs film deposited on the thermal oxide of GaAs at 460°C, showing grain size of about 0.5 μm. (b) Transmission electron micrograph of the surface region in the same polycrystalline GaAs, showing grain size of 0.3-0.5 μm.

The variation of resistivity in these polycrystalline films was then measured, by step-etching the samples, as a function of d, the distance from the interface of the thermal oxide and polycrystalline film (Fig. 5). In the 2.3 μm film the resistivity in the region near the surface ($d \sim 2$ μm) became more than one order of magnitude lower than that in the region within 1 μm from the interface. In the latter region, almost constant resistivities, about 2×10^6 Ωcm, were observed in both films. The above assumption on current flow seems to be correct for the 1.1 μm film.

Figure 6 shows electron micrographs of platinum-shadowed carbon replicas of the as-grown surfaces for four polycrystalline films with thicknesses of 0.2, 0.5, 1.1, and 2.3 μm and almost the same doping concentration of about 1×10^{18} cm^{-3}. A significant increase in grain size from 0.2 to 1 μm can be seen with increasing film thickness from 0.2 to 2.3 μm. It is likely, therefore, that such a variation in grain size might be realized in the direction of the thickness through the 2.3 μm film, and that this is the main cause of the rapid decrease in resistivity with increasing polycrystalline GaAs film thickness as seen in Fig. 5. The resistivity in polycrystalline silicon has been reported (23) to decrease with increasing grain size.

Resistivities at room temperature of about 1 μm thick polycrystalline films deposited at 480°-500°C are plotted as a function of doping concentration

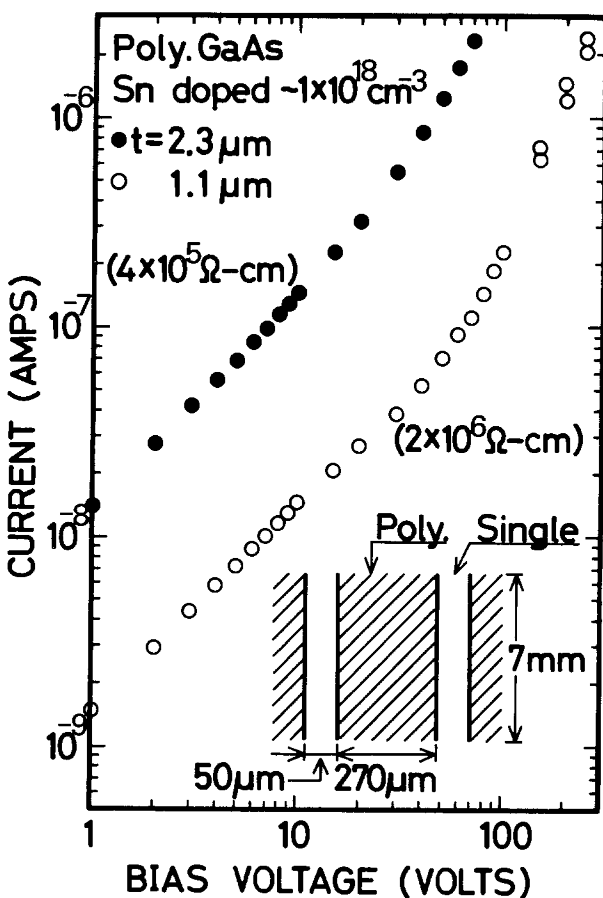

Fig. 4. I-V characteristics of Sn-doped polycrystalline GaAs films with thicknesses of 1.1 and 2.3 μm at room temperature. A sample for measurements is schematically illustrated in the inset. Ohmic relation was obtained over the range of bias voltage less than 10V in both films.

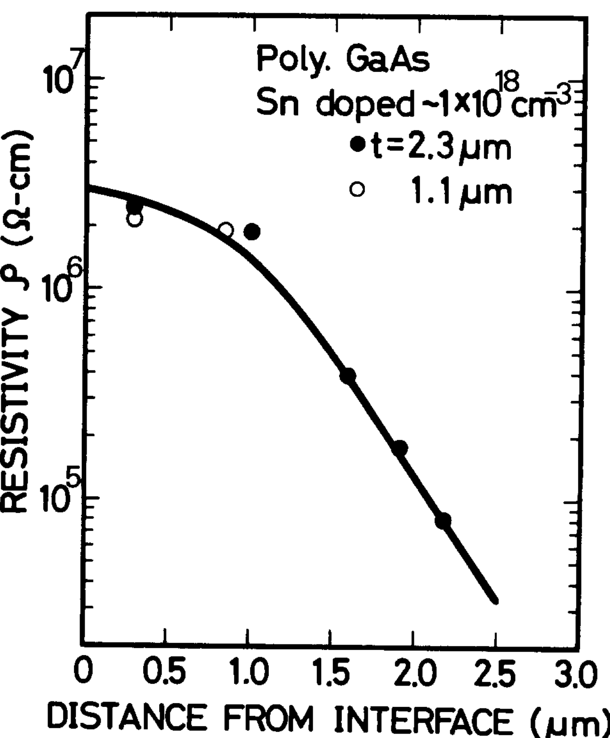

Fig. 5. In-depth profiles of resistivity in 1.1 and 2.3 μm thick polycrystalline GaAs with doping concentration of 1×10^{18} cm^{-3}, measured by step-etching at room temperature. The resistivity decreases considerably with increasing distance from the interface between thermal oxide and polycrystalline layer.

over a range of 2×10^{17}-1.2×10^{19} cm^{-3} in Fig. 7. The high resistivity of about 2×10^6 Ωcm was maintained up to the doping level of 4×10^{18} cm^{-3}, and above this point resistivity dropped sharply. This result suggests that this planar growth technique can be applicable for isolation between n^+ contact areas ($n = 3 \times 10^{18}$ cm^{-3}) employed in GaAs power FET's (24). In these films we could not find an appreciable increase in grain size with increasing doping concentration as seen in polycrystalline silicon (25).

Properties of monocrystalline GaAs.—Electrical properties of monocrystalline GaAs in small regions laterally defined by the semi-insulating polycrystalline GaAs were characterized by Hall measurements. A Hall bar-shaped monocrystalline region with a film thickness of 0.5 μm (prepared at 500°C) is shown in the inset of Fig. 8. The length of the narrow stripe region was 210 μm, and the width, w, was varied from 50 to 4 μm. Hall mobilities and carrier concentrations at room temperature are plotted as a function of stripe width in Fig. 8. Electron mobility remained at a constant 2500 cm^2/Vsec ($n \sim 1.4 \times 10^{18}$ cm^{-3}), even when the stripe width decreased to 4 μm. This suggests that high quality GaAs can be grown selectively with narrow stripe widths down to 4 μm. The quality of monocrystalline regions with lower carrier concentration is described in the next section.

Planar-type MESFET's.—In order to test application of this technique, planar-type MESFET's were fabricated. A 0.13 μm thick active layer with a carrier

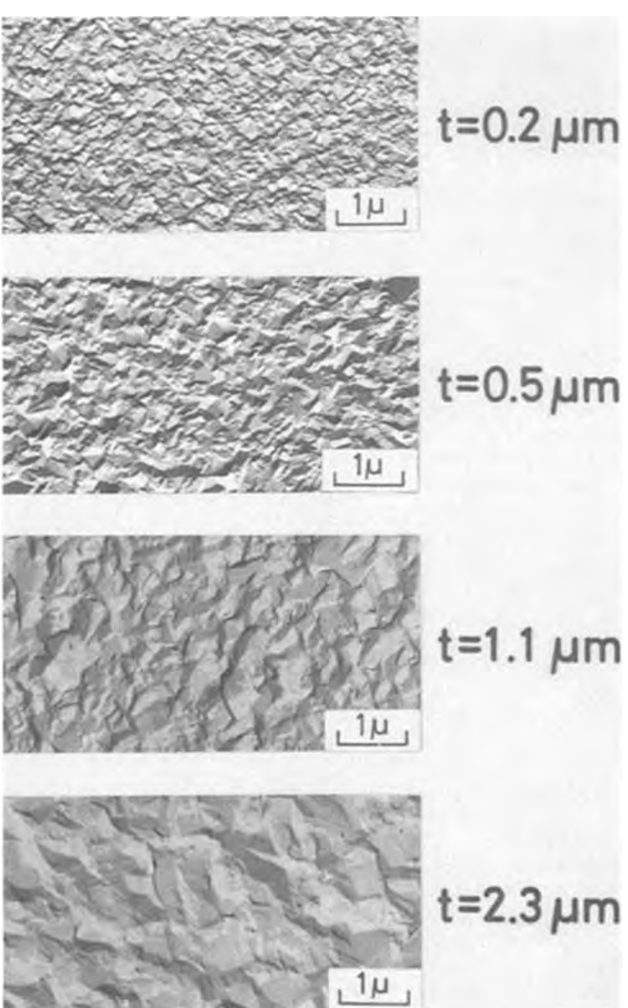

Fig. 6. Electron micrograph of platinum-shadowed carbon replicas of as-grown surface for polycrystalline GaAs films with thicknesses of 0.2, 0.5, 1.1, and 2.3 μm. The grain size increases with increasing film thickness.

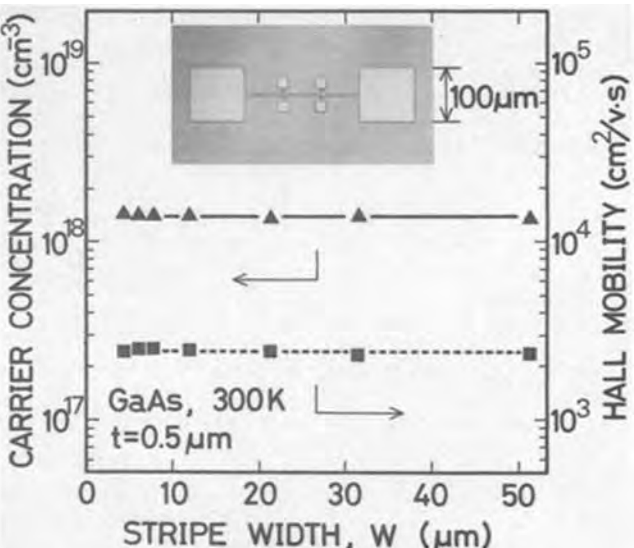

Fig. 8. Carrier concentration and Hall mobility as a function of a stripe width of monocrystalline GaAs region. The inset is a photomicrograph of a Hall-bar-shaped monocrystalline region with a stripe area of 4×210 μm. The film is 0.5 μm thick and Sn doped to a concentration of 1.4×10^{18} cm^{-3}. Electron mobility remained at a constant 2500 cm^2/Vsec, even when the stripe width decreased to 4 μm.

concentration of 2.4×10^{17} cm^{-3} was subsequently deposited on a 1.1 μm thick, unintentionally doped buffer layer at 520°C. The unintentionally doped monocrystalline layer showed p-type conduction with resistivity of 4×10^3 Ωcm at room temperature.

In-depth profiles of electron mobility and carrier concentration in this wafer were measured by a Schottky-barrier Hall technique (26) in a rectangular monocrystalline region with dimensions 400×50 μm surrounded by the polycrystalline GaAs (Fig. 9).

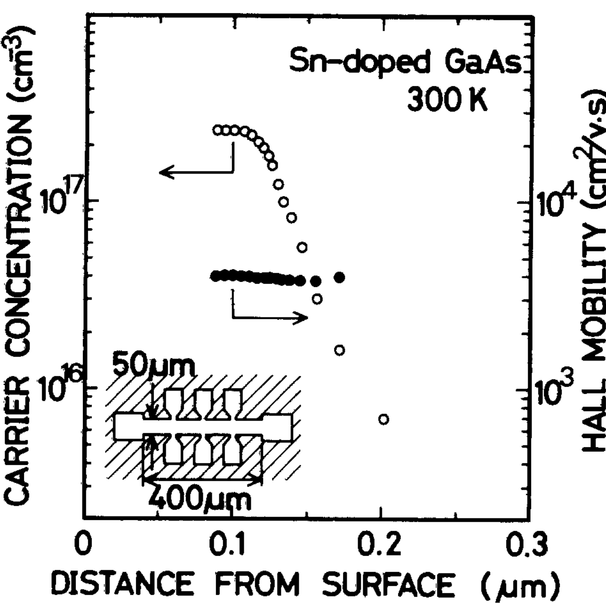

Fig. 9. In-depth profiles of carrier concentration and electron mobility in a rectangular monocrystalline GaAs region (400 × 50 μm), laterally isolated by the polycrystalline GaAs, showing that device quality of monocrystalline GaAs could be obtained in small region. A 0.13 μm thick, Sn-doped layer ($n = 2.4 \times 10^{17}$ cm^{-3}) was grown on a 1.1 μm thick unintentionally doped, high resistivity buffer layer.

The electron mobility remained almost constant, 4000 cm^2/Vsec at room temperature, through the active layer and also at the interface between the active and buffer layers.

Figure 10 shows an as-grown surface of an area for preparing MESFET's on the same wafer. Very clear boundaries and featureless surface of monocrystalline regions can be seen. Figure 11(a) shows the same area of the wafer after fabrication of devices. Resistance between two rectangular monocrystalline regions separated by 24 μm [Fig. 11(a) lower right], was $1.6 \times 10^9 \Omega$ at room temperature, *i.e.*, sufficient electrical isolation by the polycrystalline region in between them was obtained. Planar-type MESFET's were fabricated in the smallest, rectangular monocrystalline regions with dimensions of 150 × 18 μm, which is illustrated with greater magnification in Fig. 11(b). Source (S) and drain (D) contacts (with 5 μm separation) were formed by applying gold-germanium and gold. The Schottky gate (G) was made of aluminum. Gate length is 1.5 μm and width is 300 μm.

To test electrical isolation by the polycrystalline regions and their boundaries, over which the Schottky gate crosses, the current-voltage characteristics of the planar-type MESFET [Fig. 11(b)] were compared with those of a conventional ring MESFET, which was fabricated in the largest monocrystalline region [Fig. 11(a) upper left] and did not contain polycrystalline regions. Typical *I-V* characteristics of these FET's are shown in Fig. 12(a) and (b). Both are free from hysteresis. There seems to be no significant difference between them. In the planar-type MESFET, the drain-to-source current was readily controlled by the gate voltage and was pinched off at a gate bias of −3V. There existed no substantial leakage current between the source and drain contacts not only through the polycrystalline regions but also the boundaries. Consequently, we believe that this growth technique could be successfully applied to fabrication of planar-type FET's.

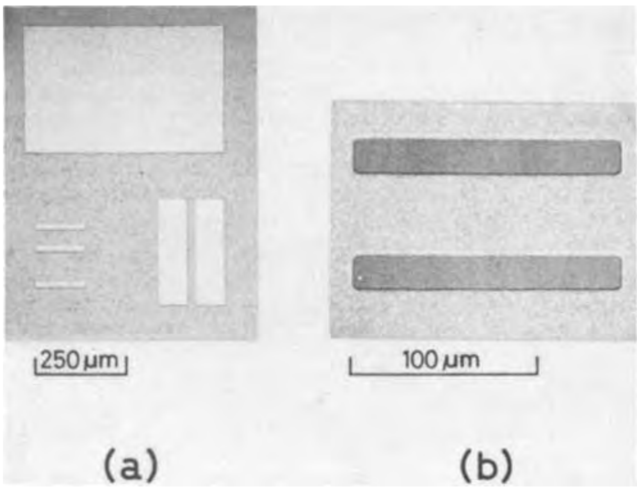

Fig. 10. (a) Photomicrograph of as-grown surface of an area for preparing MESFET's of a selectively grown 1.23 μm thick film, showing clearly defined monocrystalline regions with featureless surface. (b) Scanning electron micrograph of the smallest rectangular monocrystalline regions (150 × 18 μm) shown with larger magnification.

Conclusion

Using a thermal oxide of GaAs for masking, planar-type selective growth of polycrystalline and monocrystalline GaAs has been achieved by MBE. The polycrystalline GaAs was semi-insulating, and exhibited a resistivity of 2×10^6 Ωcm for 1 μm thick film with a doping concentration of less than 4×10^{18} cm^{-3} which is of same order as that of polycrystalline GaAs on SiO_2 mask (13). This resistivity is almost 9 orders of magnitude higher than that of a corresponding monocrystalline film, 2×10^{-3} Ωcm ($n = 1 \times 10^{18}$ cm^{-3}). It should be noted, however, that the resistivity of the polycrystalline film decreases considerably with increasing film thickness or with increasing dopant concentration above 4×10^{18} cm^{-3}. High quality monocrystalline GaAs, *i.e.*, GaAs having high mobilities (2500 and 4000 cm^2/Vsec for $n = 1 \times 10^{18}$ and 2.4×10^{17} cm^{-3}, respectively) were obtained in small regions isolated by the semi-insulating polycrystalline GaAs. In addition, planar-type MESFET's were successfully fabricated by this technique. Consequently, this planar growth by MBE can be considered to have promising features for application to the fabrication of GaAs integrated circuits, *i.e.*, excellent planar structure, sufficient electrical isolation provided by the polycrystalline GaAs, and device quality of monocrystalline regions.

LPE Growth of Misfit Dislocation-Free Thick $In_{1-x}Ga_xAs$ Layers on InP

Kazuo Nakajima, Satoshi Komiya, Kenzo Akita, Toyoshi Yamaoka, and Osamu Ryuzan

Fujitsu Laboratories Limited, Semiconductor Materials Laboratory, Nakahara-ku, Kawasaki, 211, Japan

ABSTRACT

The conditions for equilibrium LPE growth of exactly and nearly lattice-matched $In_{1-x}Ga_xAs$ epitaxial layers on InP (100) substrates were determined at 650°C by lattice constant measurements. It was found that the half-width of the diffraction peak of the ternary layer was much smaller than that of an $In_{1-x}Ga_xAs_{1-y}P_y$ layer, and that the composition of the ternary layer scarcely varied along the thickness. The threshold region for the formation of misfit dislocations into the ternary layers were experimentally determined by using an x-ray topograph. This region can be displayed by both the lattice misfit and the thickness. It was found that the layers thicker than 10 μm without misfit dislocations could be grown starting from 650°C only when the lattice misfit at room temperature was between -6.5×10^{-4} and -9×10^{-4}. It is most important for the growth of misfit dislocation-free thick layers that the layers should be lattice-matched to the substrates at the growth temperature and that tensile stress should not be incurred at the growth temperature. The relationships between the photoluminescence peak wavelength or solid composition and the lattice misfit were determined experimentally.

The growth of lattice-matched $In_{0.53}Ga_{0.47}As$ on InP substrates has been investigated mainly to fabricate avalanche photodiodes (APD's) for light whose wavelength lies between 1.0 and 1.65 μm. Several reports (1-4) were made on the ternary APD's. For the fabrication of optical devices such as APD's, thick and misfit dislocation-free epitaxial layers are required. The thin ternary layers without any misfit dislocations have generally been obtained by exact lattice-matching on the substrates at room temperature. However, we found that misfit dislocations appeared in the exactly lattice-matched thicker $In_{0.53}Ga_{0.47}As$ layers than 4 μm, which were grown by liquid phase epitaxial (LPE) method starting from 650°C. These misfit dislocations are introduced by the interfacial stress which is caused by the difference of thermal expansion coefficients between the epitaxial layer and the substrates. Therefore, the conditions for the growth of thick and misfit dislocation-free layers must be studied in order to fabricate APD's of $In_{0.53}Ga_{0.47}As$. Such conditions had ever been determined only for the $Ga_{1-x}Al_xAs_{1-y}P_y$ system on GaAs substrates (5).

In this work, the conditions for the growth of the misfit dislocation-free thick $In_{0.53}Ga_{0.47}As$ layers on InP(100) substrates were experimentally determined. Under these conditions, the misfit dislocation-free layers thicker than 10μm could be grown. These results were analyzed. In order to determine the accurate wavelength of the exactly lattice-matched $In_{0.53}Ga_{0.47}As$ on InP, the relationship between the photoluminescence peak wavelength and the lattice misfit was measured. The composition variations of the layers with distance from the surface of the substrate were also studied.

Experimental Procedure and Results

LPE growth conditions.—The previously determined liquidus isotherm at 650°C (6) was used to grow $In_{1-x}Ga_xAs$ on InP under equilibrium conditions. The conditions for equilibrium LPE growth of exactly and nearly lattice-matched layers on InP (100) substrates were found by lattice constant measurements of these layers grown from melts with compositions on the liquidus isotherms. Supersaturated melts were not used in this growth. Layers were grown starting from 650°C at a constant cooling rate of 0.5°C/min by the ramp cooling technique. Lattice constants were determined from the (400) reflection of the $CuK\alpha_1$ radiation by the double crystal x-ray diffraction technique. They are lattice constants of the epitaxial lattice perpendicular to the wafer surface.

Figure 1 shows the lattice misfit at room temperature, $\Delta a/a$ as a function of $X_{Ga}{}^{l}$. Where, Δa is equal to the lattice constant of $In_{1-x}Ga_xAs$ minus the lattice constant of InP, $a = 5.86875$Å (7), and $X_{Ga}{}^{l}$ represents the atomic fraction of Ga in the ternary melt. The melt compositions for the growth of layers with various $\Delta a/a$ can be determined from Fig. 1 and previously determined liquidus isotherm (6).

Composition variation along the growth direction.—The existence of composition variations along the growth direction is undesirable because it causes variations of the lattice constant and generates misfit dislocations. Uniform layers without composition variations are also necessary to determine accurately the lattice constant. Figure 2 shows the $CuK\alpha_1$ rocking curves for the (400) reflection of (curve a) $In_{0.7}Ga_{0.3}As_{0.64}P_{0.36}$ and (curve b) $In_{0.53}Ga_{0.47}As$ layers grown on InP (100) substrates. These layers were grown

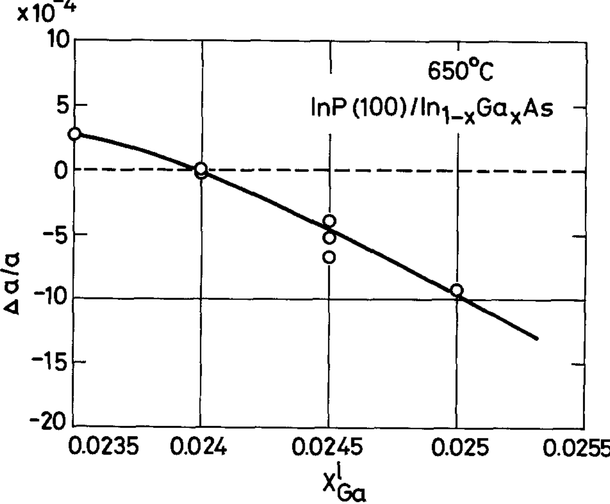

Fig. 1. Lattice misfit $\Delta a/a$ of the $In_{1-x}Ga_xAs$ ternary alloys grown on InP (100) substrates at 650°C as a function of $X_{Ga}{}^{l}$.

Key words: misfit dislocation, InGaAs, lattice-matching, photodiode.

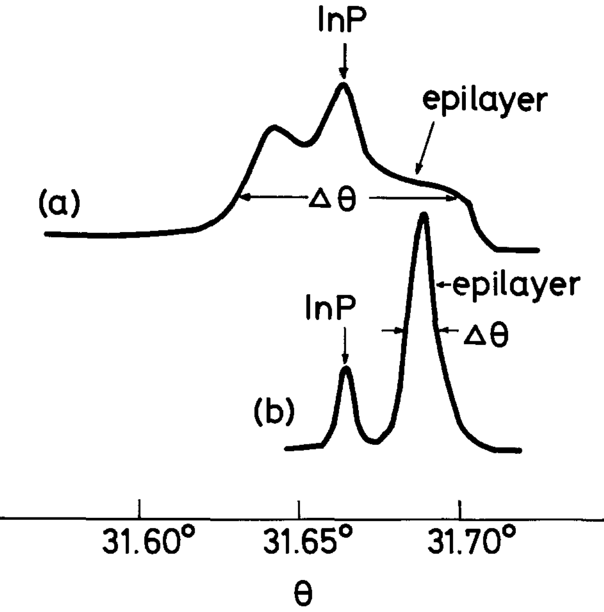

Fig. 2. CuKα_1 rocking curves for the (400) reflection of (curve a) $In_{0.7}Ga_{0.3}As_{0.64}P_{0.36}$ and (curve b) $In_{0.53}Ga_{0.47}As$ layers grown on InP (100) substrates at 650°C.

starting from 650°C at a constant cooling rate of 0.5°C/min by using just saturated melts at 650°C The thicknesses of the ternary and quaternary layers were 4.0 and 4.3 μm, respectively. The half-width of the diffraction peak of the ternary layer (about 34 sec) is much smaller than that of the quaternary layer (about 250 sec). This indicates, as also previously pointed out (8, 9), that the composition of the quaternary layer has the gradient of P concentrations as a result of the depletion of P in the quaternary melt near the growing interface, but this also indicates that the ternary layer does not have such a large composition variation. From results shown in Fig. 2, the lattice misfit, $\Delta a/a$ of the ternary layer was found to be -6.85×10^{-4}, but that of the quaternary layer were estimated between 6.2×10^{-4} and -9.9×10^{-4}.

Figure 3 shows how the photoluminescence (PL) peak wavelength of $In_{0.53}Ga_{0.47}As$ and $In_{0.77}Ga_{0.23}As_{0.5}P_{0.5}$ layers with the distance d (μm) from the interface between the layers and the InP substrate. PL measurements (8) were used to determine wavelengths on step etched surfaces at various distances of d (μm) from the substrates. The ternary and quaternary layers were grown from 650°C at constant cooling rates of 0.2° and 0.1°C/min, respectively. The thicknesses of the ternary and quaternary layers were 26.5 and 8.5 μm, respectively. As shown in Fig. 3, the wavelength of the ternary layer is almost constant with the layer thickness, but that of the quaternary layer varies largely despite its slower cooling rate. This indicates, as also shown in Fig. 2, that the composition of the ternary layer hardly varies with the layer thickness because the ternary system does not include elements like P. Therefore, the lattice constant of $In_{1-x}Ga_xAs$ layers can be determined accurately.

Misfit dislocation-free region.—It has been generally expected that thick layers without misfit dislocations can be obtained by exact lattice matching to InP at room temperature. It was found that this idea was not correct. In this work, (422) reflection x-ray topographs using CuKα_1 radiation and double crystals were used to determine whether misfit dislocations are generated or not in epitaxial layers. The generation of interfacial misfit dislocations depends on both the lattice misfit and the layer thickness under a fixed starting growth temperature (10). Therefore, a series of $In_{1-x}Ga_xAs$ layers with different $\Delta a/a$ and thicknesses were grown on InP (100) substrates in order to determine the conditions for the growth of misfit dislocation-free layers. In this growth, a constant cooling rate of 0.2°C/min, the starting growth temperature of 650°C, and just saturated melts at 650°C were used. The results are shown in Fig. 4. Open circles show the misfit dislocation-free layers and crosses show the layers with misfit dislocations. The samples are divided into two groups depending on whether misfit dislocations were present or not. Line forming these areas define the threshold for the formation of misfit dislocations. Thus, the area where misfit dislocations do not generate was determined. If the lattice constant of the ternary layer matches that of InP at room temperature, the thickness of the layer without misfit dislocations is less than 3.6 μm. In order to obtain misfit dislocation-free layers thicker than 3.6 μm, these layers must have a negative lattice misfit. It was found that misfit dislocation-free layers thicker than 10 μm could be grown starting from 650°C only when $\Delta a/a$ was between -6.5×10^{-4} and -9×10^{-4}. The surface morphology of these ternary layers was as good as that of layers with $|\Delta a/a| \leqq 1 \times 10^{-4}$.

The maximum attainable thickness in misfit dislocation-free region was not determined in this work. Thicker layers than 11.5 μm were not grown in this

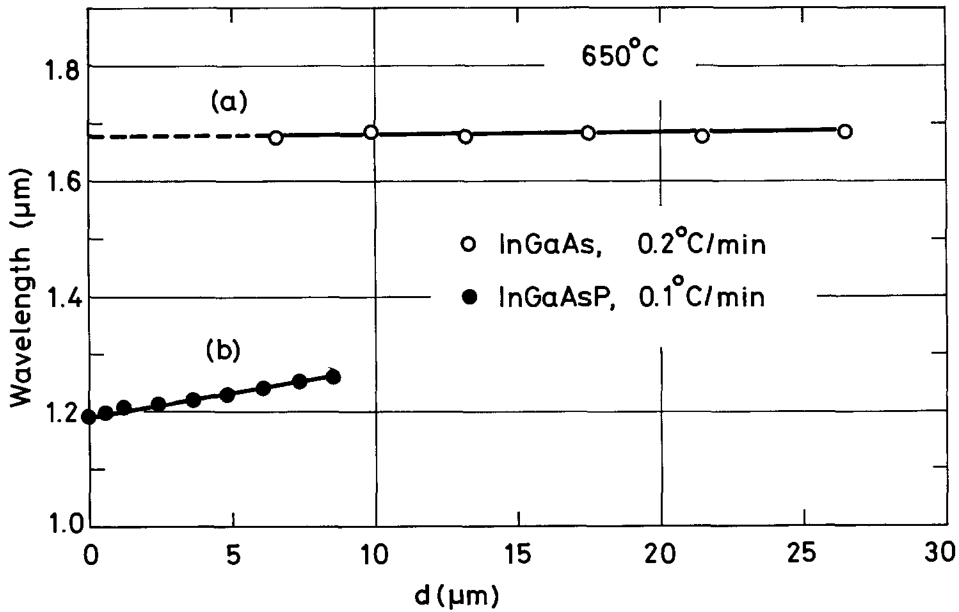

Fig. 3. Wavelength variations of (curve a) $In_{0.53}Ga_{0.47}As$ and (curve b) $In_{0.77}Ga_{0.23}As_{0.5}P_{0.5}$ layers grown at 650°C with distance d (μm) from the interface between the layers and InP substrates.

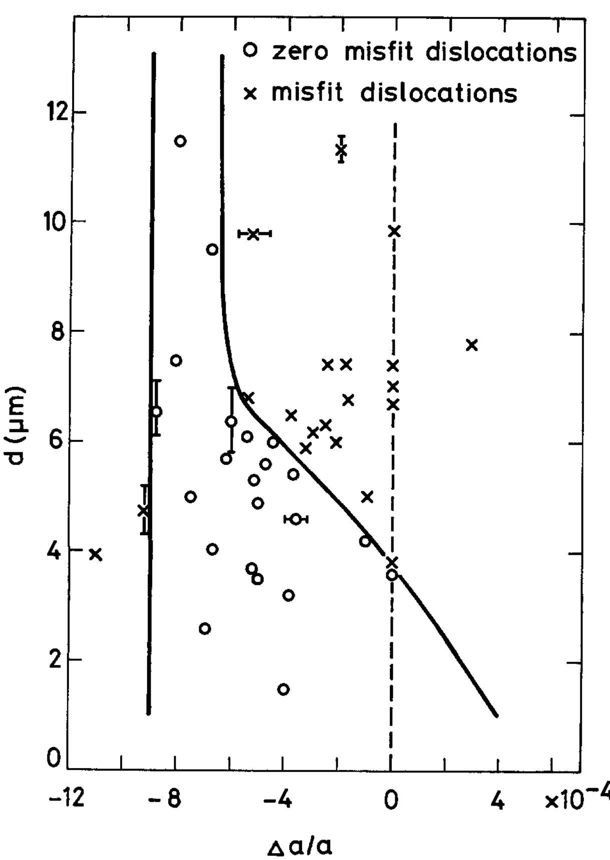

Fig. 4. Threshold region of both the lattice misfit $\Delta a/a$ and the layer thickness d (μm) for initiation of misfit dislocations into $In_{1-x}Ga_xAs$ layers on InP. ○ and × represent samples with no misfit dislocations and with misfit dislocations, respectively.

experiment, but there is a possibility of obtaining misfit dislocation-free and thicker layers than 11.5 μm. The misfit dislocation-free region for thinner layers than 1 μm is not shown in Fig. 4. For thin InGaAsP layers of 0.4 μm, it was reported that misfit dislocations were not found if $\Delta a/a$ was between 5×10^{-3} and -5×10^{-3} (11).

In ternary layers whose thicknesses are just above the demarcation lines for misfit dislocation generation, it was observed that the density of misfit dislocation was very low and generally less than several hundreds. Most of these misfit dislocations were introduced from edges of wafers in the early stage of their formation and formed unidirectional arrays. As farther from the demarcation lines to the outside of the region, a cross-grid of misfit dislocations was present.

Wavelength and solid composition vs. lattice misfit.—The wavelength and solid composition of $In_{1-x}Ga_xAs$ with lattice constants nearly matched to InP were determined. Figure 5 shows the wavelength λ (μm) of ternary layers as a function of the lattice misfit $\Delta a/a$. The wavelength was determined by PL measurements which were previously reported in detail (8). As shown in Fig. 5, the wavelength is approximately 1.685 μm when the lattice constant matches that of InP, and the wavelength is approximately 1.65 μm when the lattice misfit is -5×10^{-4}. The previously reported wavelengths of the lattice-matched ternary layer on InP were 1.65 (12, 13) and 1.68 μm (14, 15). The cause of the difference has not been explained. Degrees of the lattice misfit of samples used for wavelength measurements were not clearly described in most of these reports. In Fig. 5, it can be known that the difference of the reported wavelengths was caused by the difference of degree of lattice matching among them. Pollack *et al.* (13) reported that $\lambda = 1.656$ μm at $\Delta a/a = -5 \times 10^{-4}$. Their data is consistent with

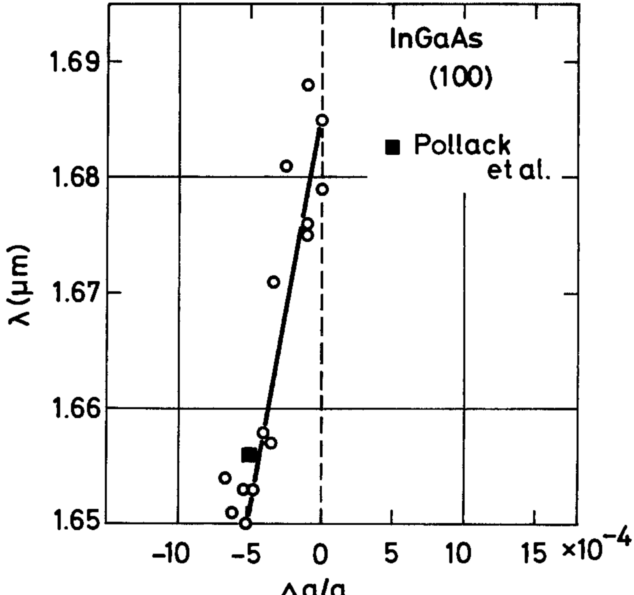

Fig. 5. Wavelength λ (μm) of $In_{1-x}Ga_xAs$ layers as a function of the lattice misfit $\Delta a/a$. ■ is the data reported by Pollack *et al.* (13).

present results. Figure 6 shows the solid composition x of $In_{1-x}Ga_xAs$ as a function of $\Delta a/a$. The solid composition was determined by electron-probe microanalysis (EPMA) (6, 16) performed on surfaces of $In_{1-x}Ga_xAs$ epitaxial layers grown on InP (100) substrates. Just saturated melts at 650°C were used in this growth. x is almost constant in the lattice misfit range from 3×10^{-4} to -1×10^{-3}, and it is about 0.47.

Discussion

The reason why the thickest layer without misfit dislocations have the negative lattice misfit at room temperature as shown in Fig. 4 can be explained by the difference of the thermal expansion coefficients of InP and $In_{0.53}Ga_{0.47}As$. The lattice constants of InP, InAs, and GaAs at 18°C are 5.86875 (7), 6.0584 (7) and 5.6535Å (17), respectively. The lattice constant of $In_{0.53}Ga_{0.47}As$ can be derived from these values on the

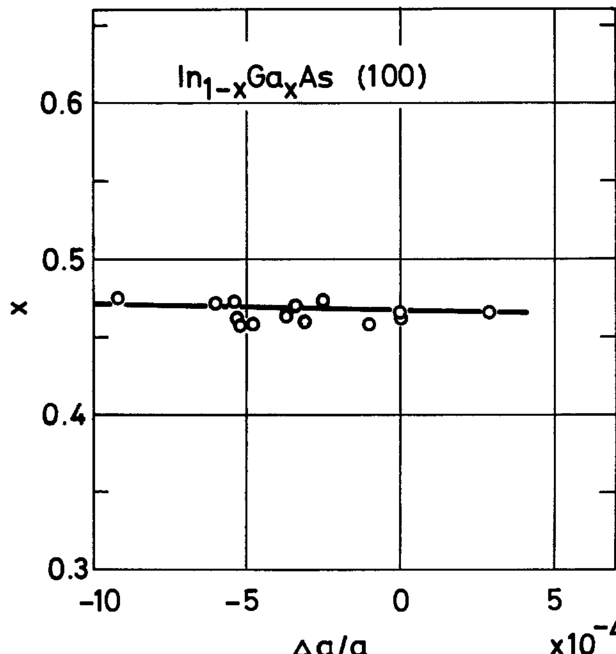

Fig. 6. Solid composition x of $In_{1-x}Ga_xAs$ grown on InP (100) substrates as a function of the lattice misfit $\Delta a/a$.

basis of Vegard's law, and it is 5.8681Å. (Strictly speaking, the composition of the ternary alloy which is exactly lattice-matched to InP at 18°C is $In_{0.5316}Ga_{0.4684}As$.) The thermal expansion coefficients of InP and $In_{0.53}Ga_{0.47}As$ reported by Bisaro *et al.* (18) are $(4.56 \pm 0.10) \times 10^{-6}/°C$ and $(5.66 \pm 0.10) \times 10^{-6}/°C$, respectively. Assuming the relation between the lattice constant and temperature to be linear, the formula for the thermal expansion is as follows

$$a_T = a_0(1 + \alpha T) \qquad [1]$$

where a_T is the lattice constant at any temperature T (°C), a_0 is the lattice constant at 0°C, and α is the thermal expansion coefficient. The calculated lattice constants of InP and $In_{0.53}Ga_{0.47}As$ at 650°C by using this formula are 5.8856 and 5.8891Å, respectively. The temperature dependence of the lattice constants of InP and $In_{0.53}Ga_{0.47}As$ calculated by Eq. [1] is shown by the lines (a) and (b), respectively in Fig. 7. $In_{0.53}Ga_{0.47}As$ has the positive lattice misfit equal to 6×10^{-4} at 650°C. ($In_{0.5316}Ga_{0.4684}As$ exactly lattice-matched to InP at room temperature has the positive lattice misfit equal to 7×10^{-4} at 650°C.) This shows that misfit dislocations are introduced in lattice-matched thick layers by the compressive stress due to the positive lattice misfit at the growth temperature. The thickest layer without misfit dislocations has the negative lattice misfit between 6.5×10^{-4} and -9×10^{-4} at room temperature as shown in Fig. 4, and such a layer almost lattice-matched to InP at the growth temperature, 650°C as shown by the broken line (c) in Fig. 7. Therefore, misfit dislocations are more easily introduced in a lattice-matched layer at room temperature than in a lattice-matched layer at the growth temperature, that is to say, they are easily formed at high temperature.

For the growth of thin layers within the misfit dislocation-free region shown in Fig. 4, it is desirable that the lattice misfit at room temperature should be as small as possible not to cause the large elastic stress at the interface of the heteroboundary. The line (b) in Fig. 7 shows such a case. As the layer thickness becomes large, the lattice misfit at room temperature must be larger in order to obtain misfit dislocation-free layers, that is to say, the growth condition must approach from the line (b) to (c) in Fig. 7. When the starting growth temperature is changed from 650°C to the lower temperature, the lattice misfit at which the thickest layer without misfit dislocations can be obtained as shown in Fig. 4 becomes smaller. This case is shown by the dotted line (d) in Fig. 7.

Several authors (10, 19) have reported expressions for h_c, the critical epitaxial layer thickness above which misfit dislocations are expected to generate. Jesser and Kuhlmann-Wilsdorf (10) gave the expression for cubic crystals and an infinitely thick substrate in the limit of small strains. For semiquantitative estimate, their rather formidable equation can be replaced by

$$h_c \cong \frac{b}{2|f|} \qquad [2]$$

where b is the magnitude of the Burgers vector, and f is the lattice misfit, $\Delta a/a$ (20). This is the simplified equation, but it keeps the essential characteristics of the original expression. h_c was calculated by using Eq. [2] for b = 4.15Å at room temperature and b = 4.16Å at 650°C as shown in Fig. 8. The solid line (a) and (b) are the calculated results at room temperature and 650°C, respectively. The line (b) was calculated on the basis of the fact that a layer lattice-matched to InP at 650°C has the negative lattice misfit,

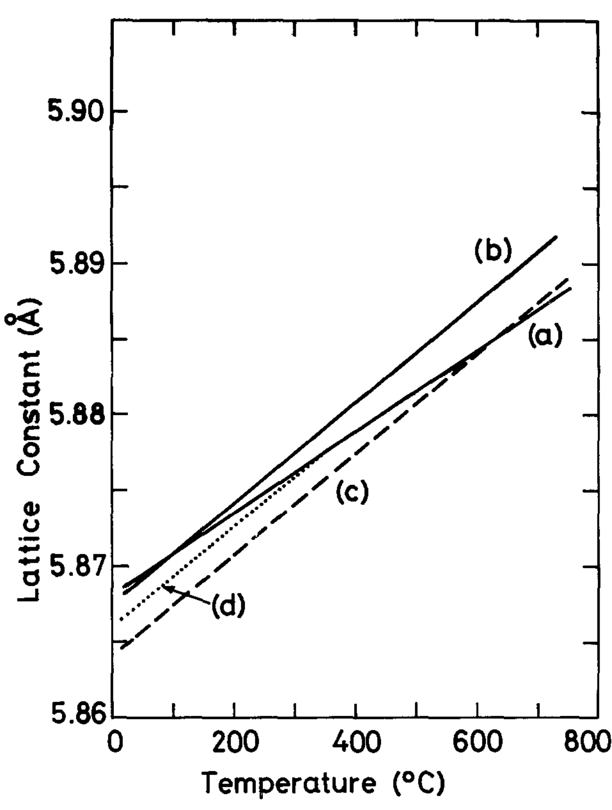

Fig. 7. Temperature dependence of lattice constant for representative heterojunction combinations. Solid lines (a) and (b) are the lattice constants of InP and $In_{0.53}Ga_{0.47}As$. Broken line (c) is a schematic representation of a layer almost lattice-matched to InP at 650°C. Dotted line (d) is a schematic representation of a layer lattice-matched to InP at lower temperature than 650°C.

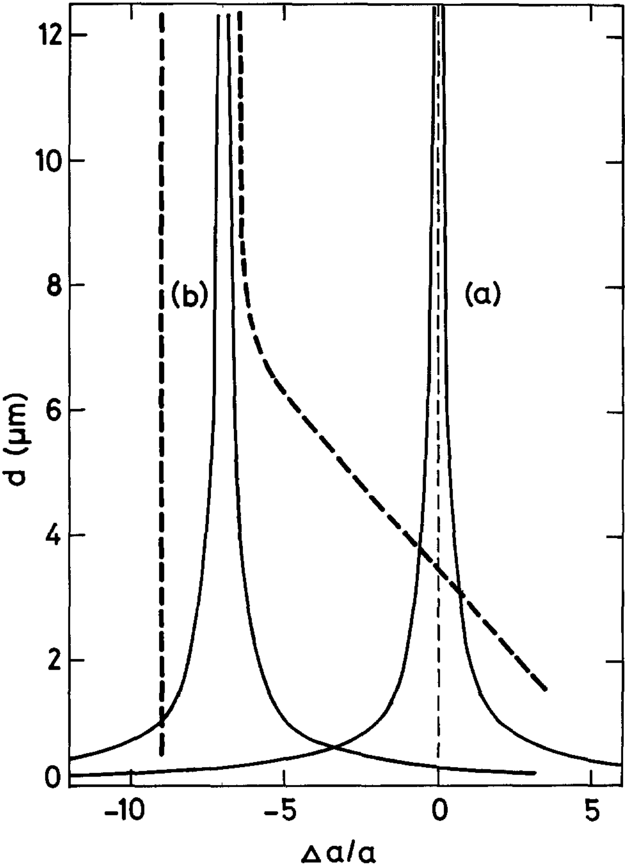

Fig. 8. Calculated threshold region for initiation of misfit dislocations into $In_{1-x}Ga_xAs$ layers on InP. Solid lines (a) and (b) are the calculated results at room temperature and 650°C, respectively. Broken line is the experimental threshold region as shown in Fig. 4.

-7×10^{-4} at room temperature. The broken lines are the experimentally determined demarcation lines for misfit dislocation generation as shown in Fig. 4. The experimentally determined region is asymmetric, but the calculated region is symmetric. In all equations to calculate the critical thickness, it was not considered that the mechanism of generation of misfit dislocations in tension and in compression are different from each other.

The experimentally determined misfit dislocation-free region has a perpendicular edge on the negative side as shown in Fig. 4. This shows that at the growth temperature, misfit dislocations were much more easily introduced by tension than by compression. This result is consistent with the previously reported results at room temperature for InGaP/GaAs (21) and InGaAs/InP (22) systems that layers in tension cracked at smaller misfit than those in compression. At room temperature, however, misfit dislocations were not formed in greater tension and the ternary layers yielded elastically even with a negative lattice misfit of -8×10^{-4}. It is most important for the growth of thick and misfit dislocation-free epitaxial layers that at the growth temperature, layers should be lattice-matched to the substrates and that tensile stress should not be incurred at the growth temperature.

Summary

The equilibrium conditions for the LPE growth of exactly and nearly lattice-matched $In_{1-x}Ga_xAs$ layers on InP (100) substrates were determined at 650°C by lattice constant measurements. The half-width of the diffraction peak of the ternary layer is much smaller than that of an $In_{1-x}Ga_xAs_{1-y}P_y$ layer, and the composition of the ternary layer scarcely varies along the growth direction. The threshold region for the formation of misfit dislocations into the ternary layers were experimentally determined. The conditions for the growth of misfit dislocation-free layers thicker than 10 μm were found. These layers can be grown starting from 650°C only when the lattice misfit is between -6.5×10^{-4} and -9×10^{-4} at room temperature. It is most important for the growth of thick and misfit dislocation-free epitaxial layers that the layers should be lattice-matched to the substrates and tensile stress should not be incurred at the growth temperature. The relationships between the photoluminescence peak wavelength or composition and the lattice misfit were determined experimentally.

Acknowledgments

The authors wish to acknowledge the crystal growth of Mr. T. Tanahashi and Dr. S. Yamazaki, and the microprobe and photoluminescence measurements of Mrs. T. Furusawa and A. Yamaguchi. We are grateful to Mrs. M. Ito and T. Kotani for their helpful discussions.

Electrical Defects in Silicon Introduced by Sputtering and Sputter-Etching

E. Grusell, S. Berg, and L. P. Andersson*

Institute of Technology, University of Uppsala, Uppsala, Sweden

ABSTRACT

Sputtering a gold contact on n-silicon or sputter-etching the silicon surface prior to deposition of gold results in a Schottky barrier which shows a barrier height which depends on the sputtering voltage and time, and is lower than a corresponding barrier obtained by evaporation of a gold contact. On p-silicon a sputtered gold contact also shows a barrier height influenced by the sputtering conditions. The modifications of the barrier height are caused by a thin positively charged layer formed in the semiconductor near the metal-semiconductor junction. During sputter etching the silicon surface is subject to bombardment by Ar ions with energies of about the sputtering voltage. If this voltage is high enough charged centers will be introduced. These centers are also observed after sputter deposition at high voltage. We found that damage is caused by etching at 500V but not at 100V. This indicates that the damage found after sputter deposition was caused by rebounded Ar atoms.

It is well known that the properties of a thin film strongly depend on the sputtering or evaporation deposition parameters as well as on the original substrate conditions. However, drastic changes of surface condition of the substrate during deposition may also be important (1-6). During the sputtering process the substrate is bombarded by several kinds of particles: low energy Ar ions from the plasma, sputtered metal atoms with energies up to 20 eV, electrons with energies up to twice the sputtering voltage, and neutral Ar atoms which have been neutralized at the target and backscattered without losing their energy. It has been found that in silicon the sputtering process creates damage which is electrically active at a few nanometers below the surface of the wafer (2, 4, 5). Of the particles mentioned above the electrons are unlikely to produce any damage because of their low mass. It is known that an electron needs more than 250 keV to displace a silicon atom (6). It is shown in this work and by other authors that the sputter-induced damage depends strongly on the sputtering voltage. Of the particles bombarding the substrate during the deposition, only the electrons and the rebounding neutral Ar atoms have energies proportional to the sputtering voltage. The energies of the low energy Ar ions from the plasma and of the sputtered metal atoms depend only weakly on the sputtering voltage. Therefore, we conclude that the rebounding neutral Ar atoms must be mainly responsible for the observed damage. The nature and extent of the defects produced in an n-type or p-type single crystal silicon wafer during deposition of a metal film or sputter-etching followed by deposition of a metal film have been investigated earlier by measuring the electrical characteristics of the resulting metal-silicon junction, *i.e.*, *I-V* (2, 4, 5), *C-V* (2, 3), and temperature activation measurements (4, 5). DLTS (3) (deep level transient spectroscopy) measurements have also been made.

In the DLTS studies of Andersson and Evwaraye (3) they showed that the sputtering-induced defects formed a band of defect states that are located from $E_c - 0.3$ eV to $E_c - 0.5$ eV. The measured capture cross section for majority carriers was $1.3 \cdot 10^{-19}$ cm^2. The *C-V* and *I-V* characteristics showed that the defects were donorlike. The concentration $N_t(x)$ of the sputtering-induced traps at a distance x from the surface was shown to be

$$N_t(x) = N_{ts} \exp\left(-\frac{x}{L}\right)$$

where N_{ts} is the trap density at the surface and L is a characteristic length. L and N_{ts} depend on the sputtering voltage and on the sputtering time. As found from the DLTS measurements L is of the order of 160Å and N_{ts} of the order of 10^{18} cm^{-3}. When the metal n-silicon contact is reverse biased we assume all the traps to be positively charged. On n-silicon, with L and N_{ts} as stated above this will give a significant probability for electrons to tunnel through the barrier (T-F emission) (7), so that a reduced effective barrier height will be observed. As the sputtering process creates donorlike traps also on p-type silicon, a sputtered metal contact will create a metal contact followed by an n-p junction close to the surface. This will affect the band bending so that the hole barrier will be higher than it would have been if there were no n-type layer. The band bending will also be dependent on the applied voltage so that the reverse current is not expected to saturate.

Experimental

N-type silicon of 50 Ωcm was used. A few samples were made on 350 Ωcm n-type silicon. The p-type silicon used was of 500 Ωcm resistivity. The silicon wafers were etched in CP-6 and on their back sides ohmic contacts were formed. On n-silicon this was done by sputter-etching followed by deposition of Al and Au, and on p-silicon by sputtering of Au at a low voltage. The sputtering was performed in an rf sputtering system using an Ar atmosphere of pressure 0.7 Pa. The target to substrate distance was 7 cm. Before initiating the plasma the vacuum vessel was evacuated to $6 \cdot 10^{-4}$ Pa by an oil diffusion pump. The use of rf sputtering means that the Ar ions have energies up to the peak rf voltage.

The contacts to be investigated were sputtered through a very thin gold-coated stainless steel mask with holes of 3 mm diam. The sputter-etching was also done through this mask. The forward and reverse characteristics of the diodes were measured at different temperatures ranging from $-35°$ to 60°C. *C-V* measurements were made with a capacitance bridge working at 500 kHz. The DLTS spectra were obtained with a setup similar to the one described by Lang (8).

Theory

As first suggested by Mullins and Brunnschweiler (2) and later verified experimentally by Andersson

* Electrochemical Society Active Member.
Key words: defects, sputtering, etching.

and Evwaraye (3), we assume the density of the sputtering-induced traps near the surface to be

$$N_t(x) = N_{ts} \exp\left(-\frac{x}{L}\right)$$

where N_{ts} is the trap density at the surface and L a characteristic length. L was estimated to 160Å in Ref. (3). The traps and the ionized donors give a space charge in the depletion region of

$$\rho(x) = q\left(N_{ts} \exp\left(-\frac{x}{L}\right) + N_d\right)$$

where N_d is the doping of the n-type semiconductor. When we integrate the Poisson equation

$$\frac{d^2\phi}{dx^2} = \frac{\rho}{\epsilon\epsilon_0}$$

where ϕ is the position of the conduction bandedge, assuming that the true barrier height is ϕ_{Bo}, we get

$$\phi(x) = \frac{qN_{ts}}{\epsilon\epsilon_0} \cdot L^2\left(\exp\left(-\frac{x}{L}\right) - 1\right) - \frac{qN_d}{\epsilon\epsilon_0} x\left(w - \frac{x}{2}\right) + \phi_{Bo}$$

where w is the width of the depletion region. For p-type material N_d is of course negative. (See Fig. 1 and 2). The condition

$$\phi(w) = \phi_{Bo} - V_{bi} - V$$

where V is the applied reverse bias and V_{bi} the band bending at zero bias gives

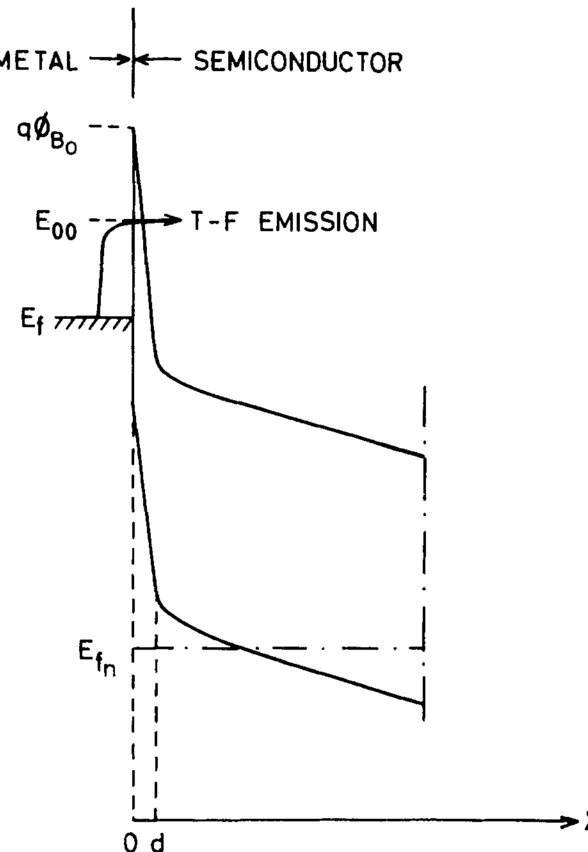

Fig. 1. Schematic energy diagram of a reverse biased sputter-damaged Schottky barrier. The damaged region is $0 < x < d$. The thermionic field emitted electrons are indicated by the arrow. E_f is the Fermi level in the metal and E_{fn} is the quasi-Fermi level for electrons in the semiconductor.

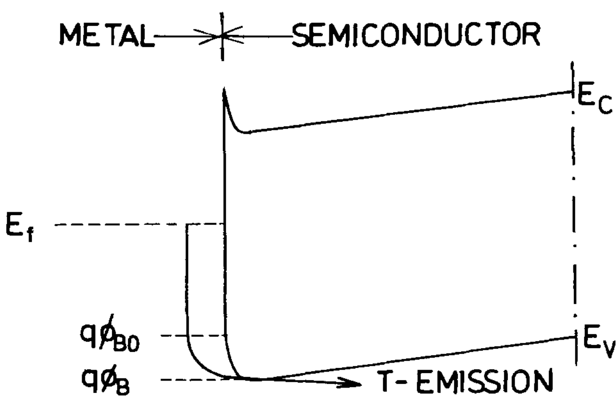

Fig. 2. Schematic energy diagram of a reverse biased sputter-damaged Schottky barrier formed on a p-type semiconductor surface. $q\phi_B$ — E_f is the effective barrier height for holes from the metal to the semiconductor.

$$w = \left\{\frac{2\epsilon\epsilon_0}{qN_d}\left[V_{bi} + V - \frac{qN_{ts}}{\epsilon\epsilon_0} L^2\right]\right\}^{1/2}$$

This formula gives the expected value of the junction capacitance C which is

$$C = \frac{A\epsilon\epsilon_0}{w}$$

The barrier height as estimated by plotting $1/C^2$ against V will thus for n-type material be given by

$$\phi_B = \phi_{Bo} - \frac{qN_{ts}}{\epsilon\epsilon_0} \cdot L^2$$

When N_{ts} has a high value there will be tunneling of carriers through the barrier both for reverse and forward bias. In Ref. (4) it is shown that this will give an apparent barreir as estimated from a reverse activation plot lower than ϕ_{Bo}, but not as low as $\phi_{Bo} - \frac{qN_{ts}}{\epsilon\epsilon_0} L^2$. On p-type material ϕ_{Bo} is heightened by $\frac{qN_{ts}}{\epsilon\epsilon_0} L^2$.

Results and Discussion

In Table I and Fig. 3 and 4 we summarize the results from the barrier height measurements. Corresponding measurements on Schottky barriers made by evaporation of Au onto n-type silicon show barrier heights of 0.7-0.8 (10).

It is clear that the contacts which were sputtered at 500V with or without being sputter-etched at 100V show a similar behavior with a barrier height of 0.70 eV. If there is any slight damage in these diodes one can at least say that the etch at 100V did not introduce an appreciable number of extra traps. The substrate temperature was estimated not to exceed 100°C. Depositing at 2.5 kV on the other hand lowers the barrier, and it is interesting to note that the depositing for 2 min results in a lower barrier than does depositing for 30 sec. This means that the particles responsible for creating the damage act through the gold layer which is already deposited after 30 sec. Sputter-etching of the surface at 500V gives a further lowering of the barrier and an increase of the etching voltage gives still lower barriers.

The contacts which were etched for 30 sec at 0.5, 1, and 1.5 kV showed a decreasing barrier height as measured by the forward I-V characteristics. The differences are not very large though. This shows that there is a tendency towards a saturation in the number of active traps.

As shown in the preceding section the expected lowering of the barrier as measured by a C-V plot is

Table I

Sample	Type	Etching voltage and time	Deposition voltage and time	Thermal activation reverse current (eV)	Barrier height I-V forward (eV)	C-V (eV)
1	n	—	500V, 15 min	0.70	0.70	0.70
2	n	—	2.5 kV, 30 sec 500V, 15 min	0.61	0.61	0.56
3	n	—	2.5 kV, 2 min	0.55	0.55	0.52
4	n	100V, 30 sec	500V, 15 min	0.70	0.71	0.70
5	n	100V, 10 min	500V, 15 min	0.70	0.71	0.68
6	n	500V, 30 sec	500V, 15 min	0.43	0.51	0.45
7	n	1 kV, 30 sec	500V, 15 min	0.47	0.49	0.48
8	n	1.5 kV, 30 sec	500V, 15 min	0.45	0.46	0.35
9	p	—	2.5 kV, 2 min	0.23	0.60	—
10	p	1.5 kV, 30 sec	500V, 15 min	0.23	0.74	—

proportional to $N_{ts}L^2$. This makes it possible to estimate this product, or if a value for L is known, to estimate N_{ts}. For $L = 160Å$, for example, a barrier lowering of 0.1 eV is given by

$$N_{ts} = 2.5 \cdot 10^{17}\ \text{cm}^{-3}$$

One result from a photoelectric measurement was obtained for a contact which was sputtered at 500V. The result was 0.73 eV, in agreement with the results obtained by the other methods. However, it proved impossible to use this method on the diodes which showed a large lowering of the barrier, because the photoelectric signal was then too small. This indicates a high recombination rate near the surface in these diodes.

The low values found for the thermal activation energies of the reverse currents in the contacts made on p-silicon can be explained by a generation current, which, when the barrier is high, will completely dominate the reverse current. The fact that the sputter etching of the samples at 100V did not give any appreciable damage shows that neither sputtered neutral metal atoms nor Ar ions from the plasma can cause the damage observed when depositing at 2.5 kV. The former have energies below 20 eV, and the latter have energies below 100 eV (9). Among the remaining possibilities are neutral Ar atoms which have been neutralized at the target and which rebound without losing much of their energy, and negative metal ions accelerated by the potential drop in the cathode dark space. It is not possible to make any conclusive statement about the relative importance of these two mechanisms from the experiments reported here.

The DLTS spectrum of the diode which was sputter-etched at 500V is shown in Fig. 5. There are two peaks near each other, corresponding to energy levels of 0.3 and 0.22 eV below the conduction band. The total concentration is $3 \cdot 10^{17}$ cm^{-3} at the surface. These peaks were observed also in spectra from samples 2 and 3, giving concentrations of about $5 \cdot 10^{16}$ cm^{-3} at the surface. The concentrations are computed according to the model presented above, *i.e.*, it is assumed that the traps are distributed so that their concentration decreases exponentially near the surface with a characteristic length of 160Å. The capture cross section was estimated to $6 \cdot 10^{-17}$ cm^2. These results are similar to the results reported by Andersson and Evwaraye (3), although the capture cross section reported here is larger.

It was not possible to obtain any DLTS spectra from the diodes which had been etched at higher voltages because of the high leakage currents. The concentrations measured by DLTS are low compared to the concentration of traps estimated from the barrier height data with the aid of the model mentioned above. One possible reason for this is that the traps near the junction can unload themselves by tunnel-

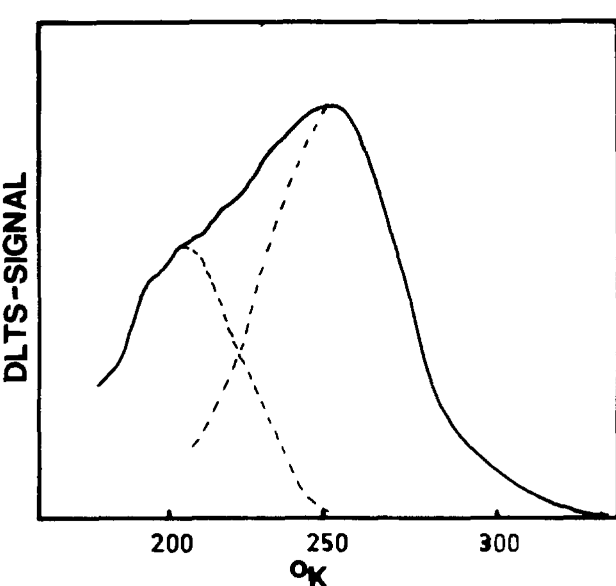

Fig. 5. DLTS spectrum of sample 6 with initial delay equal to 0.2 msec and the rate window equal to 1 msec.

ing, which is a fast process, and they are thus not seen in the DLTS spectrum.

Summary

It is shown that the defects found after sputter deposition of gold on Si at a sputtering voltage of 2.5 kV are not produced during sputter-etching of the Si surface at 100V. From this the conclusion is drawn that the defects are produced by particles more energetic than both the Ar ions accelerated by the plasma potential and the sputtered metal atoms. We suggest that the damage is produced by energetic Ar atoms rebounding from the target. As the difference in barrier height between the samples etched at 0.5, 1, and 1.5 kV is not very large it is clear that there is a saturation in the number of active traps produced. When the surface is more severely damaged the result is an amorphization of the surface with high generation and recombination rates of the surface. This explains the impossibility of photoelectric measurements on the sputtered contacts and also the insensitivity of DLTS when applied to the contacts made on heavily damaged surfaces.

Manuscript submitted May 31, 1979; revised manuscript received Feb. 25, 1980. This was Paper 148 presented at the Boston, Massachusetts, Meeting of the Society, May 6-11, 1979.

Photoelectrolysis of Water; Photoresponses of Nickel, Chromium and Zinc-Doped Polycrystalline TiO_2 Electrodes

Alain Monnier and Jan Augustynski

Département de Chimie Minérale, Analytique et Appliquée Université de Genève, Geneva, Switzerland

ABSTRACT

The effect of different dopants, chosen among transition elements, on the photoelectrochemical behavior of polycrystalline n-type TiO_2 electrodes was investigated. Except for Cd doping, all other impurities studied are shown to induce a drastic decrease of quantum efficiency of the photoanodes simultaneously with a shift of the photoresponse towards the visible light.

Impurity doping, which is known to induce substantial modifications in the physical properties of semiconductor materials, has been, up to now, only sporadically investigated in connection with semiconducting electrodes for liquid junction solar cells or for photoelectrolysis devices (1-6). The purpose of such studies was essentially to try to extend the photoresponse of some stable, wide bandgap electrode materials to the visible part of the solar spectrum with a view to increase the overall conversion efficiency of the photoelectrolytic process. This approach was mainly considered with regard to n-type TiO_2 photoanodes employed for the photoelectrolysis of water, which, due to a relatively large bandgap (~ 3.05 eV), can absorb only a small percentage of the solar light.

Thus, doping a single crystal of TiO_2 with tungsten has been found (7) to result in the shift of the photoresponse towards the u.v. region, while the addition of chromium has been reported (8, 9) to extend the absorption spectrum of TiO_2 from the fundamental bandedge at ~ 400 nm to near 550 nm. Recently we have shown (10) that doping polycrystalline TiO_2 electrodes

Key words: photoelectrochemistry, semiconductor electrodes, quantum efficiency.

with several atom percent (a/o) of cadmium extended their photoactive range into the visible light; these electrodes exhibited at the same time high quantum efficiencies in the photoelectrolysis cell.

In the present paper we discuss the effects of doping polycrystalline TiO_2 photoanodes with three different cationic elements: nickel, chromium, and zinc. We also report on results obtained when doping TiO_2 simultaneously with two foreign elements: nickel and beryllium or chromium and beryllium.

Experimental

The electrodes were prepared by depositing a 15-20 μm thick film of doped TiO_2 on the cross section (~0.28 cm^2) of 99.8% titanium rods obtained from Kobe Steel Limited. The iron content in the titanium was less than 0.024%. The films were formed by applying onto the Ti substrate, layer by layer (usually from 10 to 15 layers), and thermally decomposing in air at 400°-450°C the solutions of the salts of corresponding metals. All these compounds were reagent grade quality: $TiCl_4$ puriss. (from Fluka, containing less than 0.001% of Fe); $NiCl_2 \cdot 6\,H_2O$, $Cr(NO_3)_3 \cdot 9\,H_2O$, $ZnCl_2$-pro analysi, and $Be(NO_3)_2 \cdot 4\,H_2O$ extra pure (all from Merck). The solutions of dried salts were prepared with a pro analysi quality ethanol and methanol. In order to induce a partial reduction of the oxide by titanium metal from the substrate all the electrodes were finally heated during 40-60 min in argon at 550°-800°C.

The wavelength response of the electrodes was determined using a 450W xenon lamp (Osram) set in an Oriel Model 6141 housing, and a Jarrell-Ash Model 82-410 monochromator equipped with six Corning filters for the removal of unwanted orders of the spectrum. The absolute intensity of the incident light from the monochromator was measured with a Model 730 A radiometer/photometer from Optronic Laboratories, Incorporated. Photoelectrochemical measurements were performed with a 1M NaOH solution, a platinum counterelectrode, and a mercuric oxide/mercury (HgO/Hg) reference electrode. Photocurrents used to calculate the quantum efficiencies were determined, in all cases, at a potential of —0.1V *vs.* HgO/Hg, *i.e.*, at about 0.4V below the reversible potential for oxygen evolution in the dark.

Results and Discussion

The TiO_2 layers forming the photoanodes contained from 0.4 a/o[1] to 10 a/o of doping elements; these amounts were even higher for TiO_2-Be-Ni and TiO_2-Be-Cr electrodes. The choice of dopant concentrations was based on our previous results, particularly on those obtained for TiO_2-Al (11) and TiO_2-Be (12) electrodes, which have demonstrated that the optimum doping levels, in the case of the polycrystalline samples, were frequently much larger than equilibrium solubilities of the corresponding oxides. Since the characteristics of the TiO_2 electrodes were strongly dependent not only on the nature and the amount of dopant but also on the temperature of thermal treatment, the samples of a given composition were generally annealed in argon at two different temperatures: ~550°C and ~700°C. X-ray diffraction analyses of all the doped samples have shown essentially anatase structure except for the Be-containing electrodes which consisted of a mixture of rutile and anatase.

A perceptible shift of the photoresponse towards the visible light, with respect to the undoped TiO_2, was mainly observed for moderate doping levels (except, however, for Zn-doped electrodes) and the lower temperature (550°C) heat-treatment. The most pronounced effect was found for TiO_2-0.4 a/o Cr, TiO_2-5 a/o Zn, and TiO_2-0.4 a/o Ni photoelectrodes which displayed a measurable photocurrent up to 500-550 nm (Fig. 1), *i.e.*, 100-150 nm beyond the fundamental absorption edge of TiO_2. In this sense our results con-

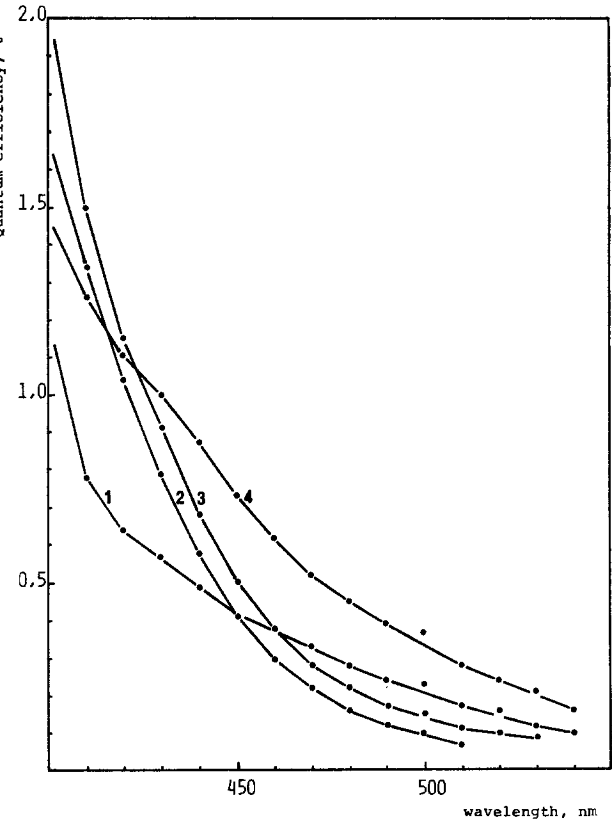

Fig. 1. Quantum efficiency vs. wavelength curves for curve 1, TiO_2-5 a/o Zn(560°C); curve 2, TiO_2-4 a/o Ni(560°C); curve 3, TiO_2-0.4 a/o Ni(560°C); and curve 4, TiO_2-0.4 a/o Cr(560°C) photoanodes.

firm previous observation of Ghosh and Maruska (8, 9) on the extended photoresponse of the Cr-doped rutile single crystal. However, as visualized by the expanded scale in Fig. 1, quantum efficiencies of the photocurrents corresponding to the wavelengths >400 nm were very poor and thus would contribute only in a negligible manner to the overall solar-to-chemical conversion efficiency. Moreover, the presence of dopants affected considerably also the response of the photoelectrodes to the wavelengths <400 nm, *i.e.*, located in the main part of the TiO_2 absorption spectrum. A particularly drastic decrease of the quantum efficiency was observed (Fig. 2) for heavily Zn and Ni-doped samples, but even for relatively well behaving TiO_2-0.4 a/o Ni photoanode η_q did not exceed the half of that of the undoped TiO_2 photoanode. In a general way the decrease of quantum efficiency was more pronounced higher the Ni, Cr, and Zn doping level; in the latter case, however, it was attenuated by the heat-treatment in argon at ~700°C. These trends are well represented by η_q *vs.* λ curves for a series of Ni-doped TiO_2 photoelectrodes, shown in Fig. 3. It is also interesting to note that for all the electrodes mentioned above the heat-treatment at ~700°C suppressed practically the photoresponse to the visible light ($\lambda > 400$ nm). These observations suggest that a possible interpretation of the effect of extended photosensitivity illustrated in Fig. 1 would involve the structural defects induced by the presence of dopants in TiO_2. However, since the moderately Ni, Cr, or Zn-doped photoelectrodes (as well as the undoped TiO_2) exhibited essentially anatase structure (12), one could consider at this point the decrease of the quantum efficiency, characterizing the doped samples, as inherent to the above form of TiO_2. In order to settle this question we have prepared a series of TiO_2 electrodes containing simultaneously two additives: beryllium and nickel or beryllium and chromium. In fact, the Be doping has recently been reported (12) as not only to enhance the quantum

[1] Given with respect to the total amount of metals.

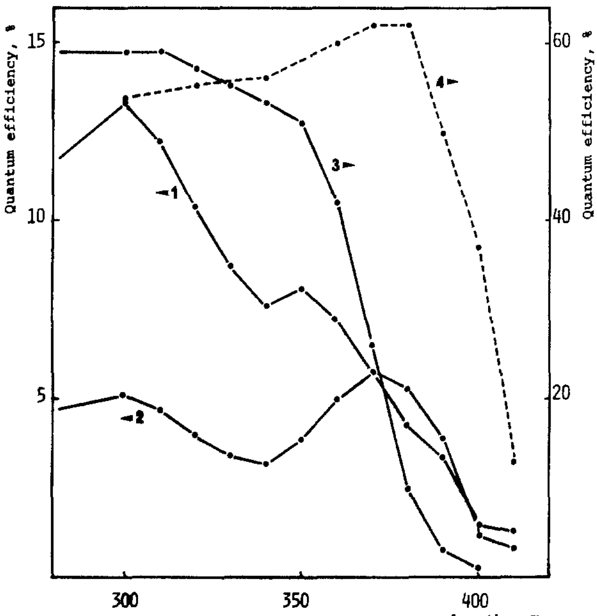

Fig. 2. Effect of the doping on the quantum efficiencies of TiO_2 photoanodes (wavelengths corresponding to the fundamental absorption spectrum of TiO_2): curve 1 TiO_2-0.4 a/o Cr(560°C); curve 2 TiO_2-5 a/o Zn(560°C); curve 3 undoped TiO_2(560°C); and curve 4 TiO_2-5 a/o Cd(710°C).

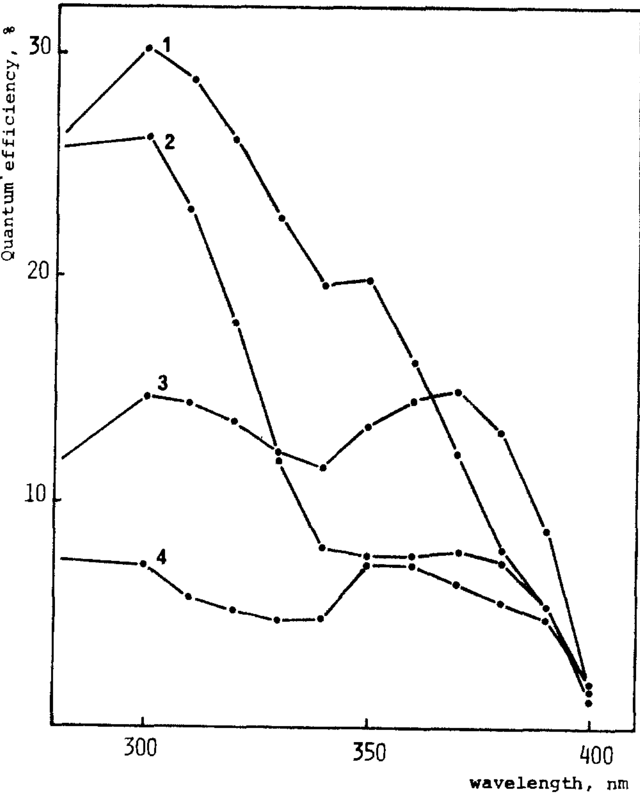

Fig. 3. Effect of the nickel content and of the temperature of the heat-treatment on the quantum efficiencies of TiO_2-Ni photoanodes: curve 1 TiO_2-0.4 a/o Ni(560°C); curve 2 TiO_2-0.4 a/o Ni(700°C); curve 3 TiO_2-4 a/o Ni(700°C); and curve 4 TiO_2-4 a/o Ni(560°C).

efficiency of the TiO_2 photoresponse but also to promote the anatase-rutile transformation. For testing the influence of Ni and Cr doping on the behavior of this kind of photoelectrodes we have chosen the optimum (from the point of view of the conversion efficiency) 15 a/o beryllium content. Principal results concerning TiO_2-Be-Ni electrodes are summarized in Fig. 4; those for TiO_2-Be-Cr samples were quite similar and are not shown separately. The only effect practically observed was a general decrease of the quantum efficiency which followed the same trends discussed above.

In conclusion, it appears clearly that the predominant result of doping the polycrystalline TiO_2 photoanodes with nickel, chromium, or zinc is a more or less marked loss of quantum efficiency of the photocurrent relative to the fundamental absorption region of TiO_2; this effect overcompensates the gain in overall optical-to-chemical conversion efficiency which would be expected from the extension of the photoresponse towards the visible part of the spectrum. This kind of behavior is very likely consistent with the formation of intermediate levels in the bandgap, which can originate from impurity cations or/and from defects induced by the doping, and which act as recombination centers in the depletion layer. Such effects have, for example, been previously observed for iron-doped TiO_2 photoelectrodes (10) and, in less drastic form, for copper, cobalt, and manganese-doped TiO_2 (13). It is interesting to note that the role played by the abovementioned dopants is basically different from that of the cadmium addition to TiO_2. The latter also produces a modification in the spectral photoresponse of TiO_2, consisting in its extension up to 430 nm and in the appearance of the photocurrent maximum at 390 nm (Fig. 2). Nevertheless, in contrast with other dopants from transition and post-transition series, the Cd doping results in a slight enhancement (instead of the decrease) of quantum efficiency with respect to the undoped TiO_2. Thus, for TiO_2-5 a/o Cd photoanode η_q exceeds 60%, the value quite comparable with those

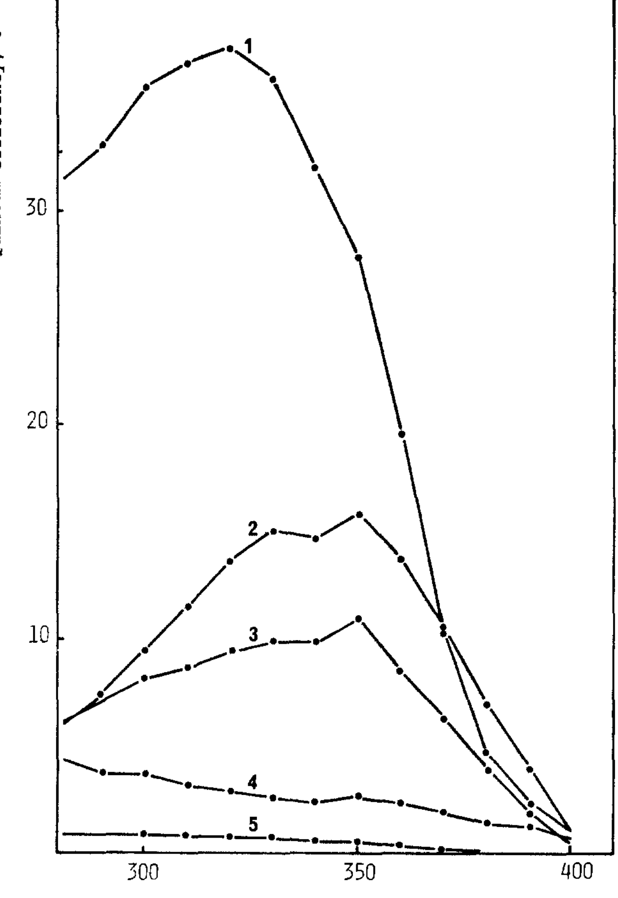

Fig. 4. Quantum efficiency vs. wavelength characteristics of a series of TiO_2-Be-Ni photoanodes: curve 1 TiO_2-15 a/o Be-4 a/o Ni(700°C); curve 2 TiO_2-15 a/o Be-0.4 a/o Ni(700°C); curve 3 TiO_2-15 a/o Be-10 a/o Ni(700°C); curve 4 TiO_2-15 a/o Be-0.4 a/o Ni(560°C); and curve 5 TiO_2-15 a/o Be-4 a/o Ni(560°C).

obtained for the best polycrystalline (Al- or Be-doped) TiO_2 electrodes.

Unfortunately, due to a partial decomposition of the coatings at the temperatures required for annealing, we were unable to prepare the electrodes containing more than 5 a/o of cadmium, and to establish whether the increase of its content in TiO_2 could lead to a further shift of the photoresponse. Actually, although using the TiO_2-Cd photoanode enables only limited improvement of the solar-to-chemical conversion efficiency (which is evaluated as twice that of an undoped TiO_2 photoanode) the qualitative result seems more promising than those obtained with chromium, nickel, and zinc dopants.

Lubrication and Pattern Improvement in Photolithography

D. L. Flowers* and J. N. Smith

Motorola Semiconductor Research and Development Laboratory, Phoenix, Arizona 85008

ABSTRACT

A photoresist overcoat formulation (SLI) has been developed which significantly reduces photolithographic, induced defects and produces improved definition. The overcoat is composed of a surfactant, lubricant, and free radical inhibitor in solvent. The surfactant and lubricant function to decrease photomask-photoresist interactions which decreases defect densities. The free radical inhibitor absorbs stray light energy under opaque mask areas. This improves fine line resolution and definition, with particularly beneficial results when used over reflective metal films. The interaction of the overcoat with the mask light energy are discussed and a mechanism is proposed. It was also found that the incidence of scum film formation (smog effect) in developed areas was reduced.

Photolithographic processing is one of the principle areas in semiconductor manufacture where major expense and yield loss occur. Some of these problems have been discussed in considerable detail by Kern and Schnable *et al.* (1, 2). Photodefects caused by mask and resisted wafer sticking due to chemisorption (3, 4) are of prime importance. On separation after exposure, pieces of photoresist are torn from the wafer and adhere to the photomask. This results in pinholes in the substrate when it is later etched. Additionally, opaque pieces of photoresist on the mask are responsible for latent pinholes on further mask use and result in limited useful mask life.

Recently reported work addressed these problems with lubricating mask coatings (5) and a resist protect coat (6) in which longer photomask life and significant pinhole reduction were demonstrated. The above resist protect coat formulation was polyvinyl alcohol-based and hence had to be removed from the exposed, negative photoresist by a water rinse and dry before normal pattern development. As such, it constituted a process inconvenience. Because of these considerations, attention was turned to developing a resist protect coat that would not change exposure times and would be quickly removable in the normal development cycle and solvent.

Other problems are also important factors controlling acceptable photolithographic processing. Fine line pattern definition with negative photoresist is frequently limited by reflected light closing narrow spaces and enlarging lines. Metal bridging adjacent runners in IC devices is often responsible for rework or low yields. This is due to reflection of incident light by the shiny metal surface. Using resist films as thin as possible has been common practice to solve this problem but film integrity may be compromised so that resist tears and the incidence of pinholes increase unacceptably. Using commonly accepted principles of free radical chemistry, additives to a new protect coat formulation were investigated to absorb the reflected light causing these problems. The same class of additives that can improve definition was expected to be effective in inactivating those ambient materials causing "smog" films periodically plaguing the industry. It is the purpose of this paper to present the results of the resist overcoat approach to minimize the above problems.

Key words: photolithography, resist overcoat, defect reduction, definition improvement, smog film.

Experimental

Materials.—Polished 7.62 cm silicon substrates were used for the definition improvement study. For metal bridging experiments, 1 Knm of Al (Si) was E-beam deposited on the oxide. To evaluate pinhole improvements, a gate circuit, 3.0 × 3.7 mm with 1 Knm of phosphosilicate glass, PSG, passivation over patterned first layer metal was used. For "smog" film reduction experiments, chips were 3.8 × 3.8 mm with a 0.25 mm grid. One lot of wafers was patterned for mesa (silicon) etch, one lot was patterned for metal (gold) etch.

The SLI, resist protect coat solution, applied by spinning at 3K rpm for 10 sec, contained a surfactant (S), a lubricant (L), and free radical inhibitor (I) dissolved in electronic grade isopropanol. Film thickness was estimated to be 5-10 nm. Typically, 0.03% w/v Triton X-100 (Rohm and Haas) surfactant, 0.1% w/v glyceryl monostearate (C. P. Hall Company, Illinois), and 0.1% w/v hydroquinone inhibitor were used. One protect coat, SL, containing only the surfactant and lubricant was tested to confirm the effect of the inhibitor.

Photoresist processing and evaluation.—Negative photoresist was applied by spinning to give a thickness of 1 Knm and soft baked for 30 min at 80° ± 2°C in nitrogen unless otherwise noted. Contact (5-6 psi) exposures were made for times noted in the text. A 20 sec xylene-20 sec butyl acetate spray development cycle was used. This was followed by a 60 min "hard" bake in nitrogen where necessary for subsequent etching.

To evaluate pinhole reduction with the SLI resist coat aluminum metallized wafers with PSG passivation were used. After photolithographic processing of the PSG glass, pinholes in the PSG layer were extended through the metal by etching for 2.5 min at 65°C in a standard, phosphoric acid-nitric acid, aluminum etch. Twenty selected die on each wafer were visually inspected and pinholes counted.

A high resolution test mask was used in the definition improvement experiments to determine the effect of the inhibitor in the SLI coating layer. This mask had a "checkerboard" pattern in the center of each die and ancillary bar and space patterns ranging down to 0.1 mil (2540 nm). Each mask was used for only six contacts. Twenty die per wafer were inspected after development and the percent of bars and spaces defined as a function of width is reported. It was found that a 10 sec exposure at 2500 μW/cm² was optimum. Exposures ranged from 11-15 sec to increase the amount of reflected light and emphasize the effect of the inhibitor in the SLI protect coat formulation.

Results and Discussion

Defect reduction studies.—Comparative pinhole results as a function of the process step and use of SLI are shown in Table I. Set A shows the pinholes present in the as-deposited PSG passivation. A 95% pinhole-free die yield was achieved on this large chip, one third of which is covered with patterned metal. Set B illustrates the number of pinholes introduced by twice contacting the photomask and photoresisted wafer. After photoresist was removed, the wafers were "aluminum" etched with no prior passivation etch to define pinholes caused by mechanical damage in the glass. This step gives an 87.5% pinhole-free die yield, thus a 10% yield loss is brought about by twice contacting the mask and wafer. In Set C, six photoresisted wafers were each contacted twice, exposed, developed, and given a standard passivation etch simulating normal device processing. After resist strip and aluminum etch to define a reference pinhole yield, the number of pinhole-free die was reduced to 5%. The average number of pinholes in the reject die had more than doubled due to resist damage. Set D shows the improvement achieved by using the SLI overcoat on the photoresist. The percentage of pinhole-free die has increased by more than a factor of three to 17.5%. In addition, the average number of pinholes in the reject die has decreased by more than a factor of three. This is a significant improvement compared to the results obtained from standard photolithographic processing.

Table I. Comparative pinhole formation in processing with and without SLI and 11.1 mm² die

Set	Wafer numbers	Pinhole-free die per 20	Average No. pinholes per reject die	Condition
A	1	19	3	PSG glass + "Al" etch, no photoresist
	2	19	1	
B	3	19	10	Resisted, 2 contacts and expose, strip photoresist—no PSG etch, just "Al" etch
	4	16	3	
C	5	2	10	Standard photo processing and etching. No SLI coat
	6	1	7	
	7	1	6	
	8	2	6	
	9	0	6

D	11	5	2	Same as (C) but with SLI spun at 3K rpm.
	12	4	2	
	13	4	2	
	14	2	3	
	15	5	2	
	16	1	2	

It should be pointed out that in the SLI formulation, the inhibitor is not necessary for the pinhole reduction achieved with this formulation. It was experimentally verified that only the lubrication composition and concentration in conjunction with the surfactant accomplished this improvement. It was also found during the course of this work that the soft bake cycle dramatically affects the results. That is, if the bake time is shortened or if the bake temperature is lowered residual solvent remains in the resist film and lubrication benefits are not achieved.

Inhibitor effect on resolution over thermal oxide.—The purpose of these experiments was to show that the presence of the inhibitor in the coating formulation does increase resolution limits even at various degrees of overexposure. Six sets of twelve wafers were used for this study. Six wafers from each set were controls and were processed in an identical manner as the experimental wafers except no coating was applied. Three of the experimental sets were coated with SLI and three with SL.

Results of each group of six wafers were averaged to give the values shown in Table II. A significant improvement in resolution is evident after develop inspection for the first three experimental sets which were coated with SLI. With an 11 sec exposure, set 1 Expt showed a 13% increase of 0.1 mil spaces open *vs.* the control set. With a 12 sec exposure a lower overall yield due to overexposure was observed, but with the inhibitor present the percent open spaces

Table II. Effect of SLI on resolution over PSG as a function of exposure time

Set	Exposure time (sec)	Coating formulation	Spaces 0.1 mil	Spaces 0.15 mil	Spaces 0.2 mil
1 Control	11	None	70	100	100
1 Expt	11	SLI	83	100	100
2 Control	12	None	40	90	100
2 Expt	12	SLI	70	100	100
3 Control	15	None	10	50	80
3 Expt	15	SLI	10	100	100
4 Control	11	None	75	100	100
4 Expt	11	SL	70	90	100
5 Control	12	None	38	96	100
5 Expt	12	SL	39	95	100
6 Control	13	None	32	74	92
6 Expt	13	SL	42	93	99

increased from 40% to 70% for 0.1 mil, and from 90% to 100% for 0.15 mil spaces. In the case of the 5 sec overexposure (15 sec exposure) the inhibitor action was overcome on the 0.1 mil spaces and no improvement was observed. However, in the case of 0.15 mil spaces a 50% increase was observed and with 0.2 mil spaces a 20% increase was observed. The relationship of percent open spaces to the linewidth and overexposure time is a logical one, and is confirmed by the data.

The last three sets of experiments were conducted without the inhibitor in the solution to confirm that the presence of the inhibitor in the coating formulation was indeed responsible for resolution improvement. The results, though scattered show no definition improvement without the inhibitor.

Inhibitor effect on resolution over aluminum.—Because the Al surface is highly reflective, greater problems with definition and "bridging" of fine lines and spaces would be expected. To evaluate the performance of SLI over Al, it was tested on wafers that had 1 Knm of E-beam Al(Si) on them. Variations in the bake cycle were also examined to optimize performance of the overcoat. As shown in Table III, the total bake time of 30 min was held constant while the order of the bake within the process was varied. That is, in Set 2 the overcoat was applied directly after photoresist and both were baked for 30 min, while in Set 4 the photoresist was baked 30 min prior to SLI coating, with no bake after coating; and in Set 3 the bake was split between the two layers. Within the reproducibility of reading the patterns ($\pm 5\%$), Sets 2 and 4 appear to be equivalent. Set 3 with 20 min bake after photoresist spin and a 10 min bake after SLI coating is not quite as satisfactory. Thus, from the results and process efficiency the procedure of Set 2 would be preferred.

Comparison of the control Set 1 to the SLI coated Sets, 2, 3, and 4 shows a very significant improvement in the fine line and space definition due to SLI. For example, considering 0.1 mil geometries with no overcoat, Set 1, all of the photoresist bars were bridged and only 17% of the spaces were open. With SLI overcoat however, Set 2, 26% of the bars and 35.4% of the spaces were clear. This represents an increase of 26% and 19% for 0.1 mil bars and spaces, respectively. The percentage improvement is considerably greater over aluminum than it is over oxide, *cf.*, Set 2, Table II, which is presumably due to the greater reflectivity of the aluminum surface. In general, these data indicate that the greatest improvement occurs in bar patterns which decreases the amount of bridging between adjoining stripes of photoresist. Shrinkage of space openings is also significantly improved, however. Similar but smaller improvements are noted for larger geometries up to 0.2 mil.

Inhibitor mechanism.—The mechanism for improved photoresist definition described above depends on reflected light being much less intense than the incident light and the presence of an inhibitor which absorbs (inactivates) reflected light under the opaque portions of the photomask. Thus, the presence of the inhibitor eliminates polymerization of photoresist due to reflected light and is not present in high enough concentration to effectively change the intensity of the incident light in the clear areas of the photomask.

The function of the inhibitor is readily explained if one considers the free radical chemistry of polymerization reactions. A general sequence for photochemical crosslinking of negative photoresist may be written

1. catalyst or sensitizer $C \xrightarrow[K_I]{h\nu} C\cdot$ Initiation
2. $C\cdot + R \text{ (resist)} \xrightarrow{K_A} C{-}R\cdot$ Addition
3. $C{-}R\cdot + R \xrightarrow{K_P} C{-}R{-}R\cdot$ Propagation (crosslinking)
4. $2C{-}R{-}R\cdot \xrightarrow{K_T} C{-}R{-}R{-}R{-}R{-}C$ Termination

Here, the rate constants K_A and K_P are much larger than K_I or K_T so that Steps 2 and 3 proceed a number of times for each time Step 1 or 4 occurs. Thus, a typical free radical chain reaction is involved. This is the reaction sequence that, in general, occurs when light of the proper energy exposes negative resist. If the light is not perfectly collimated or the underlying surface is not planar, light reflections between the mask and underlying surface are set up. These multi-reflections allow some light energy to reach under the opaque portions of the photomask which will cause crosslinking of photoresist in these areas. Any overexposure of the resist film will of course intensify this effect and cause lines in the pattern to enlarge and spaces to shrink. When the free radical inhibitor is placed as a very thin film on top of the photoresist, attenuation (absorption) of the reflected light can be achieved. That is, the inhibitor has a very high extinction coefficient for the wavelength of light used and does not itself produce active free radicals that produce crosslinking of the resist. Under these conditions, polymerization under opaque areas of the mask is decreased. Among those substances which act as inhibitors are those compounds that, on absorbing light energy form highly resonance stabilized free radicals. Their normal reaction mode is to stabilize by combination with another free radical, *i.e.*

5. $I \text{ (inhibitor)} \xrightarrow{h} I$
6. $I\cdot + I\cdot \text{ or } R \xrightarrow{K_6} I{-}I \text{ or } I{-}R$ (no crosslinking)
7. $I\cdot + R \xrightarrow{K_7} I{-}R$ Addition

with $K_6 >> K_7$

Table III. Effect of SLI on resolution over aluminum as a function of bake cycle

Set	Soft bake cycle (80°C, N_2) After photoresist (min)	Soft bake cycle After SLI coating (min)	Percent pattern open 0.10 mil Bars	0.10 mil Spaces	0.15 mil Bars	0.15 mil Spaces	0.20 mil Bars	0.20 mil Spaces

4	30	0	28	30	59	93	93	100

Exposure time constant at 12 sec.

That is, reaction 6 is much more probable than reaction 7. Some compounds used as free radical inhibitors include: a) hydroquinone, b) pyrocatechol, c) pyrogallol. Also, alkyl or amine substituted compounds of the above type materials may be used, *e.g.*, 2-methyl-4-ethyl hydroquinone or orthoamino phenol.

Summary and Conclusions

This study has resulted in a negative resist overcoat 5-10 nm thick which is readily removed in the develop cycle. The overcoat, composed of a surfactant, a lubricant, and a free radical inhibitor is applied by spinning from an alcohol solution. Use of the overcoat process has resulted in a more than threefold decrease in pinholes and a similar increase in pinhole-free die yields on large, 11.1 mm^2 chips over those obtained in standard, contact mode photoresist processing. Fine line and space definition, particularly in patterning reflective metal surfaces were significantly improved. A free radical mechanism to explain pattern definition improvement is proposed.

Acknowledgments

The authors wish to thank Mrs. Eileen Uravitch for the careful laboratory work done in these experiments as well as Drs. H. Hughes and K. Ritchie for many helpful discussions. They are also greatly appreciative to Mrs. Beth Gersitz for preparing the manuscript.

Photoelectrochromic Characteristics of Photoelectrochemical Imaging System with a Semiconductor/Solution (Metallic Ion) Junction

Tooru Inoue, Akira Fujishima,* and Kenichi Honda

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Tokyo 113, Japan

ABSTRACT

Photoelectrochemical reactions at semiconductor electrodes in solutions containing metallic ions have been applied to a reversible imaging system. Clearly visible images were formed on the surfaces of TiO_2, $SrTiO_3$, and ZnO (n-type) and GaP (p-type) semiconductor electrodes in solutions with metallic ions such as Tl^+, Pb^{2+}, Co^{2+}, and Ag^+ as image-forming agents. Image formation occurs under irradiation with light absorbable by the semiconductors, while semiconductor electrodes are polarized either anodically (for n-type) or cathodically (for p-type). Erasing can be accomplished only by polarizing the semiconductor electrodes cathodically (n-type) or anodically (p-type), or the image can be held if desired by opening the circuit after the image formation process. For example, a brown image pattern was formed on a sintered n-type ZnO photoelectrode in an aqueous solution containing Tl^+ when the electrode was anodically polarized (1.0V *vs.* SCE) under irradiation with absorbable light. The image was stable for more than 20,000 hr in air, but faded immediately when cathodic polarization of −0.5V *vs.* SCE was applied at a ZnO electrode. This imaging process has good reversibility during image formation and erasing. Electrochemical characteristics based on the semiconductor photoelectrode reactions were investigated and discussed focusing on charge transfer across the semiconductor/solution junction.

The photoelectrochemistry of semiconductors has been extensively studied in recent years, with the main interest focused on the establishment of heterogeneous charge transfer mechanisms, the development of radiant energy converters to the electrical energy and/or chemical energy, and the development of functional devices. Most recently, electrochemical photocells (EPC's) with a semiconductor/solution junction have been investigated in order to utilize solar energy in chemical and/or electrical form (1-14). The photoelectrocatalytic synthesis of fuels has been also carried out in semiconductor powder/solution or semiconductor powder/gas systems (15-18).

* Electrochemical Society Active Member.

Key words: photoelectrochemistry, semiconductors, photoelectrodes, reproducible imaging, display.

When, in such a photoelectrochemical system with semiconductors, the semiconductor is irradiated with an absorbable light of shorter wavelength than the bandgap frequency, electrons are excited from the valence band to the conduction band while positive holes are generated at the valence band. Thus it follows that these photogenerated carriers (electrons or holes) react with redox agents in solution at the semiconductor/solution interface.

If metallic redox agents (M^{n+}) are oxidized or reduced by the photogenerated carriers (e^-_{cond}, an elec-

tron in the conduction band or p^+_{val}, a hole in the valence band) and the species produced deposited on the electrode surface, as we have reported previously (19, 20), a photoimage can be obtained by the reaction

$$M^{n+}_{sol} + ne^-_{cond} \rightarrow M_{surf} \quad [1]$$

or

$$M^{m+}_{sol} + rp^+_{val} + kH_2O \rightarrow M_xO_{y\,surf} + zH^+ \quad [2]$$

where M^{n+}_{sol} and M^{m+}_{sol} denote metallic ions in solution, M_{surf} a metal deposited on the electrode surface, and $M_xO_{y\,surf}$ a metal oxide deposited on the electrode surface. When the deposited layer of metal or metal oxide is distinguished in color from the semiconductor substrate, a visible image can be recognized.

A variety of new image display methods (21-29) have recently been reported employing nonsilver halides, but silver halides (AgX) continue to be the most widely used as the light sensitive material in photographs. Their initial imaging reactions are (30)

$$AgX + h\nu \rightarrow AgX^* (e^-_{cond} + p^+_{val}) \quad [3]$$

$$Ag^+_{in} + e^-_{cond} \rightarrow Ag$$

$$AgX^* + p^+_{val} \rightarrow Ag^+_{in} + \tfrac{1}{2} X_2 \quad [4]$$

where AgX^* denotes a silver halide excited by light and Ag^+_{in} an interstitial silver ion. These photographic imaging processes are irreversible photochemical reaction, and it is thus impossible to erase an image and to reconstitute the silver halide. One method that gives promise of overcoming the irreversibility of imaging uses a semiconductor electrode/solution system in which one can control the reaction by shifting electrode potential.

McLeod (23) has reported the photographic process by the photocatalytic reduction of metallic ions on nonsilver halide semiconducting materials.

Memming *et al.* (24) have described the electrochemical characteristics on the photographic processes which took place by the action of the photocatalytic deposition of Pb on TiO_2.

In this report we have investigated semiconductor electrode reactions under light irradiation in the course of imaging processes by means of electrochemical techniques and we discuss them focusing on the charge transfer across the interface of the semiconductor/solution junction.

Experimental

The photosensitive semiconductor materials used in this experiment were n-type TiO_2 (single crystal from Fuji Titan Company, sintered polycrystal with 0.1% Nb as dopant, and evaporated thin film from Mitorika Company) which had donor densities of 10^{17}-10^{19} cm^{-3}, n-type ZnO (single crystal from 3M Company, sintered polycrystal) with donor density of *ca.* 10^{18} cm^{-3}, n-type $SrTiO_3$ (single crystal from Fuji Titan Company) with donor density of *ca.* 10^{18} cm^{-3}, and p-type GaP (single crystal with Zn as dopant from Mitsubishi Kinzoku Kozan Company) which had acceptor density of $3 \cdot 10^{17}$ cm^{-3}. For the ZnO polycrystal electrode, a ZnO substrate was prepared by pressing ZnO powder (1000-2000 mesh) at *ca.* 1.0 ton/cm^2 and then heating it at 1300°C for *ca.* 3 hr in air. Procedures for the preparation of electrodes, such as ohmic contact and connection with the copper lead, are described elsewhere (8-17). A semiconductor electrode was fixed in the aqueous electrolyte solution together with a Pt counterelectrode and a saturated calomel electrode (SCE). Electrode potentials were controlled using a potentiogalvanostat (Nikko Keisoku). Light was irradiated on the electrode surface through the standard test mask (Japan Electronic Photograph Society) from a 500W Xe lamp. Figure 1 is a schematic of the experimental image formation and measuring system. The supporting electrolyte was an aqueous solution of a 0.2 mole/dm^3 Na_2SO_4 or 0.5 mole/dm^3 KNO_3. The metallic ions used as image formation agents were obtained from Tl_2SO_4, $Pb(CH_3COO)_2$, $MnSO_4$, $CoSO_4$, and $AgNO_3$. Electrolyte solutions were deaerated before measurements by bubbling with purified N_2 gas. Identification of the images formed were carried out by x-ray diffraction.

Results

Figure 2 shows the current-potential characteristics of an n-type TiO_2 electrode in an electrolyte of 0.2 mole/dm^3 Na_2SO_4 + 0.01 mole/dm^3 $TlSO_4$. When the TiO_2 electrode is set in the supporting electrolyte (0.2 mole/dm^3 Na_2SO_4) solution, a positive photocurrent appeared under irradiation with wavelengths of 300-400 nm at the anodic polarization at potentials more positive than the flatband potential of TiO_2, where water in solution was oxidized by photogenerated positive holes (minority carriers) at the valence band, in accordance with equations

$$TiO_2 + h\nu \rightarrow TiO_2^* \; (e^-_{cond} + p^+_{val}) \quad [5]$$

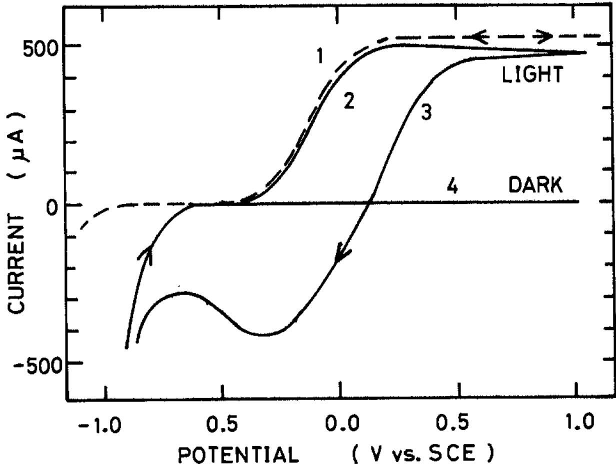

Fig. 2. Current-potential characteristics of an n-type TiO_2 single crystal electrode. 1, In 0.2 mole/dm^3 Na_2SO_4 aq. soln.; 2, 3, in 0.2 mole/dm^3 Na_2SO_4 + 0.01 mole/dm^3 Tl_2SO_4 aq. soln.; 4, in the dark.

$$H_2O + 2\,p^+_{val} \rightarrow \tfrac{1}{2}\,O_2 + 2H^+ \quad [6]$$

where h denotes the Planck constant, ν the frequency of light, while negligible current flows at TiO_2 during darkness (12, 16) (see 1 in Fig. 2).

When the metallic ion (Tl^+) was added to the electrolyte an anodic photocurrent (2 in Fig. 2) also appeared at potentials more positive than the flatband potential (the value of which was the same as when there was no Tl^+ in the solution, indicating that adsorptive interaction of Tl^+ against the surface of TiO_2 was very small), and during the appearance of this anodic photocurrent, the portion of the TiO_2 illuminated through the mask turned brown. Hence, it is possible to obtain an image through photo-oxidation at a semiconductor electrode. When after fixation of an image on the electrode surface, the electrode potential was swept to the negative side, cathodic current appeared even at potentials more positive than the flatband potential, and the brown image gradually disappeared with the surface of the TiO_2 electrode returning to the condition before image formation. Therefore, the imaging reactions are reversible and we can write the following equations: for an image formation

$$2Tl^+ + 3H_2O + 4p^+_{val} \rightarrow Tl_2O_3 + 6H^+ \quad [7]$$

and for an image erasing

$$Tl_2O_3 + 6H^+ + 4e^-_{cond} \rightarrow 2Tl^+ + 3H_2O \quad [8]$$

or

$$Tl_2O_3 + 3H_2O + 4e^-_{cond} \rightarrow 2Tl^+ + 6\,OH^- \quad [9]$$

The species oxidized from Tl^+ by the positive holes was identified as thallium oxide (Tl_2O_3) by x-ray diffraction. That is, the imaging step is the formation of a layer of Tl_2O_3 on the TiO_2 surface, and the decoloration step is the erasing of this layer from the TiO_2 substrate.

Figure 3 shows the current-potential characteristics of the ZnO electrode in electrolytes containing $PbSO_4$ at various concentrations. The ZnO electrode is photocorrosive in the course of the photoelectrode reaction in the supporting electrolyte (*e.g.*, a 0.2 mole/dm^3 Na_2SO_4 aqueous solution), resulting in the reaction (11, 13)

$$ZnO + 2p^+_{val} \rightarrow Zn^{2+} + \tfrac{1}{2}\,O_2 \quad [10]$$

When the metallic ion (Pb^{2+}) is dissolved in the solution as the imaging agent, both the anodic photocurrent, based on the image formation, and the reduction current, based on the image erasing, are obtained in a way similar to the case of TiO_2. As shown in Fig. 3, the electrode reactions are: for image formation

$$Pb^{2+} + 2H_2O + 2p^+_{val} \rightarrow PbO_2 + 4H^+ \quad [11]$$

and for image erasing

$$PbO_2 + 4H^+ + 2e^-_{cond} \rightarrow Pb^{2+} + 2H_2O \quad [12]$$

The limiting anodic photocurrent, for image formation, is constant because it is controlled by the supply of photogenerated holes in the valence band of the semiconductor to the electrode surface. The reduction current for the image erasing, on the other hand, varies with the Pb^{2+} concentration, which can be determined on the basis of competitive oxidation at the ZnO electrode. That is, in solutions containing Pb^{2+}, the image formation reaction [11] competes with the photocorrosion reaction of ZnO [10], and the current efficiency (competition ratio) of reaction [11] is enhanced over that of reaction [10] when Pb^{2+} concentration is increased (13). Hence, the quantity of PbO_2 formed on the ZnO electrode determines the total amount of electricity of the reduction current.

Figure 4 shows the current-potential curves when Mn^{2+} or Co^{2+} is dissolved in the solution as the imaging agent. The characteristics obtained were similar to those for Tl^+ and Pb^{2+}, but the reduction behavior of the oxides formed on the semiconductor electrodes

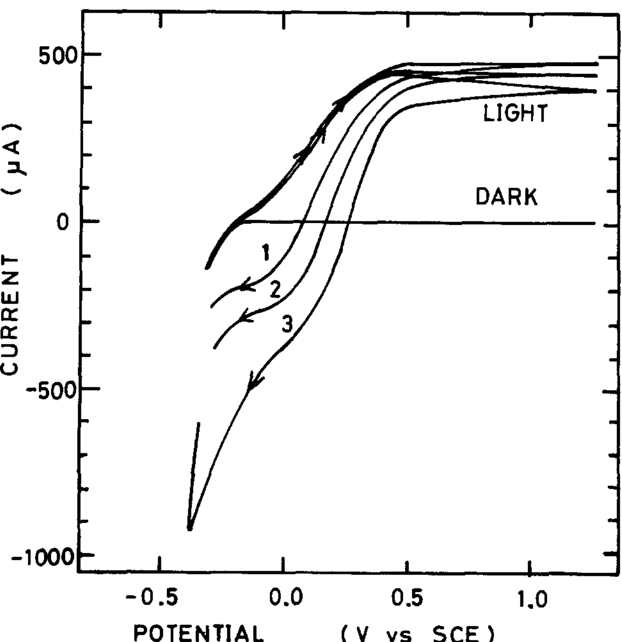

Fig. 3. Current-potential characteristics of an n-type ZnO polycrystal electrode. 1, In 0.2 mole/dm^3 Na_2SO_4 + 2 × 10^{-3} mole/dm^3 $PbSO_4$ aq. soln.; 2, in 0.2 mole/dm^3 Na_2SO_4 + 5 × 10^{-3} mole/dm^3 $PbSO_4$ aq. soln.; 3, in 0.2 mole/dm^3 Na_2SO_4 + 10^{-2} mole/dm^3 $PbSO_4$ aq. soln.

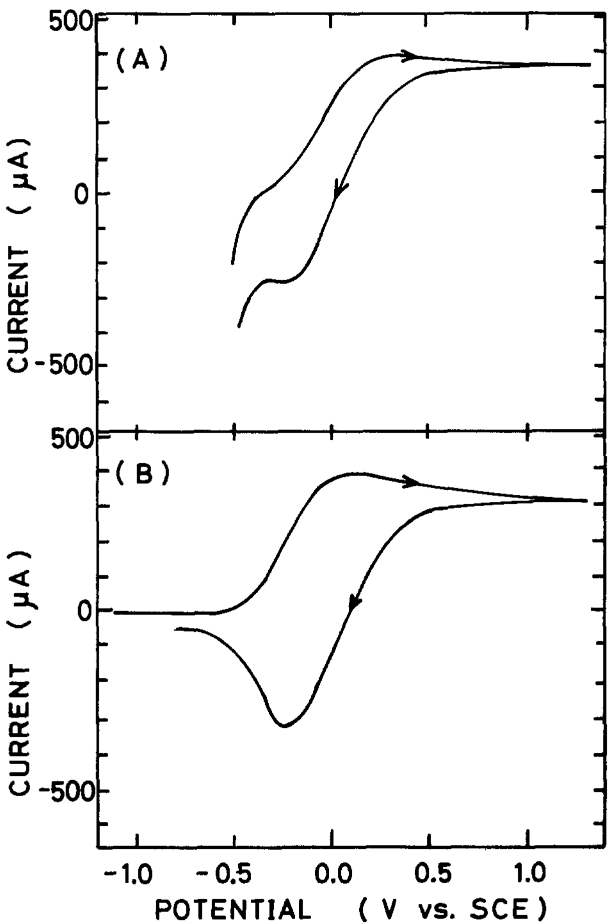

Fig. 4. Current-potential characteristics of an n-type ZnO polycrystal electrode under light irradiation, (A) In 0.2 mole/dm^3 Na_2SO_4 + 10^{-2} mole/dm^3 $CoSO_4$ aq. soln.; (B) in 0.2 mole/dm^3 Na_2SO_4 + 10^{-2} mole/dm^3 $MnSO_4$ aq. soln.

were slightly different, a fact that may be attributable to a junction of oxide on the semiconductor surface and on the reduction reactivity of the oxide layers.

Figure 5 shows the current-potential characteristics at a p-type GaP electrode in an electrolyte solution containing Ag^+. As this is a p-type semiconductor, the minority carriers are electrons in the conduction band, so that the photoelectrode reaction is reduction electrolysis by photogenerated electrons. In the supporting electrolyte water was reported to be reduced at the GaP electrode, resulting in the evolution of hydrogen

$$2H_2O + 2e^-_{cond} \rightarrow H_2 + 2\,OH^- \quad [13]$$

When metallic ions were present in the solution, they were also reduced by electrons during cathodic polarization of an electrode, resulting in metal deposition on p-type semiconductor electrodes. Hence, at a p-type GaP electrode the imaging reaction is

$$Ag^+ + e^-_{cond} \rightarrow Ag \quad [14]$$

When the image is formed on the surface of the GaP electrode, the illuminated part of the reddish brown GaP substrate turns white based on Ag deposition [14]. To erase the image, the Ag image layer on the GaP is oxidized to Ag^+ by the holes as the majority carrier in the valence band. Thus, the anodic corrosion reaction of Ag is a decoloration reaction

$$Ag + p^+_{val} \rightarrow Ag^+ \quad [15]$$

The formation and erasing characteristics and the color are listed in Table I for the images formed in the course of the current-potential measurements.

Figure 6 shows the time dependence of photocurrent at the TiO_2 electrode in solutions containing Tl^+ when the irradiation intensity and Tl^+ concentration is varied, where the electrode potential of TiO_2 is fixed at 1.0V *vs.* SCE. The phenomena of decreasing photocurrent depend upon the filtering effect that the image layers formed on the TiO_2 surface have against the incident light, and the fact that after sufficient electrolysis the surface is completely covered with image-making oxide. When irradiation intensity is varied and the Tl^+ concentration is kept constant, the photocurrent decreases with time and this decrease is more rapid at higher irradiation intensities [Fig. 6(A)]. And when the Tl^+ concentration is varied and the irradiation intensity is kept constant, the photocurrent again decreases more rapidly at higher concentrations of Tl^+ [Fig. 6(B)]. This indicates that the formation rate ($V(t)$) of an image-making layer becomes the larger under conditions of the increased irradiation intensity and Tl^+ concentration, and thus, we can assume that the initial formation rate ($V_{t=0}$) of an image may be approximately described as a function of the irradiation intensity (Q) and the metallic ion concentration (C), as follows

$$V_{t=0} = \lim_{t \to 0} V(t) = \lim_{t \to 0} r \cdot i(t) = k \cdot Q \cdot C \quad [16]$$

where k denotes the image formation rate constant, $i(t)$ the photocurrent depending on time, and r the competitive ratio of the image formation reaction.

Figure 7 shows the reproducibility of an imaging system with a ZnO electrode/metallic ion (Tl^+) in the solution, where the factors of light intensity, electrode potential (V *vs.* SCE), optical density (OD), and current are expressed as a function of a common time scale. The hatched areas on the optical density curve indicate the appearance of the image; the positive portions of the current curve correspond to image formation, and the negative portions to image erasing. The results in Fig. 7 for an n-type semiconductor electrode show that image formation requires both anodic polarization of the ZnO electrode and light irradiation, while image erasing needs only cathodic polarization of ZnO. The time response of current in both image formation and erasing is rapid. Image formation requires both cathodic polarization of the electrode and light irradiation, while image erasing needs only anodic polarization of the electrode, if a p-type semiconductor is used. Reversible characteristics analogous to those for an n-type semiconductor are obtained. The image can be held by opening the circuit after the image formation process, or erased by shorting the circuit with a reverse bias against image formation, as desired.

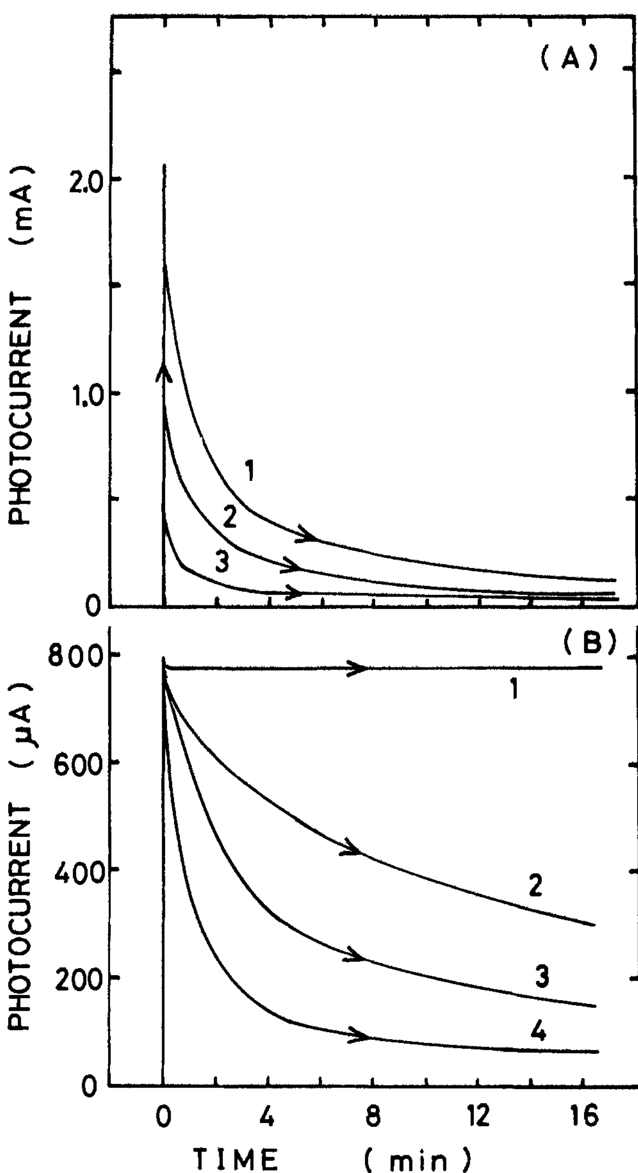

Fig. 6. Time-dependence of photocurrents at an n-type TiO_2 electrode in a 0.2 mole/dm^3 Na_2SO_4 aq. soln. with Tl_2SO_4. (A) At constant Tl_2SO_4 concentration (10^{-2} mole/dm^3) and light intensity (a.u.): curve 1 = 4, curve 2 = 2, and curve 3 = 1. (B) At constant irradiated light intensity and Tl_2SO_4 concentration (mole/dm^3): curve 1 = 0, curve 2 = 10^{-4}, curve 3 = 10^{-3}, and curve 4 = 10^{-2}.

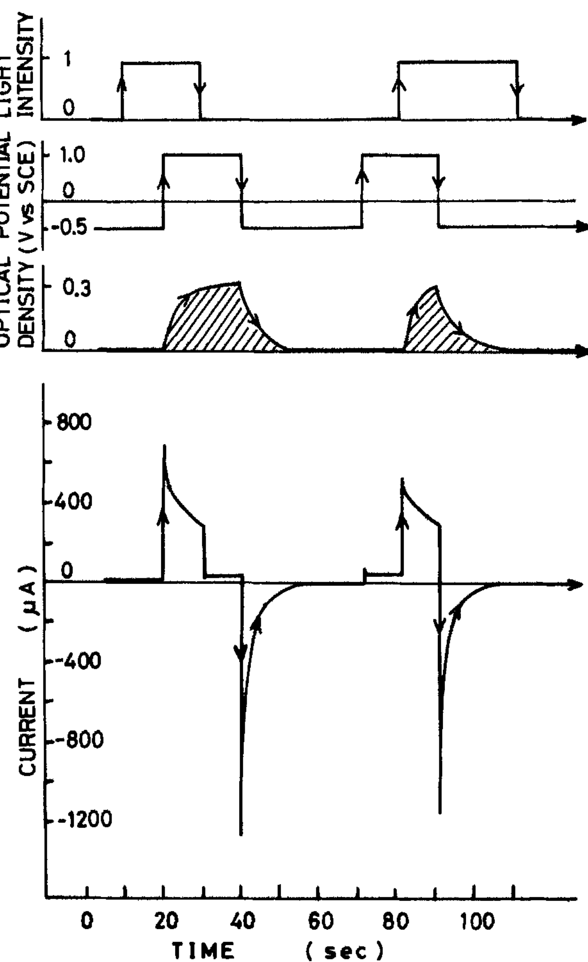

Fig. 7. Dependence of irradiated light intensity and electrode potential on currents at a ZnO electrode in a 0.2 mole/dm^3 Na_2SO_4 + 10^{-2} mole/dm^3 Tl_2SO_4 aq. soln. Light intensity and optical density are expressed in arbitrary units. Hatched portions denote the appearance of images.

Figure 8 shows a photograph of an image obtained on a sintered ZnO electrode with a diameter of 10 cm. The image is negative because the illuminated part of the electrode was colored brown by the formation Tl_2O_3. Illumination was carried out for 1 min through the standard testing mask with a resolution of *ca.* 15 lines per mm. As can be seen, a fairly clear image was obtained on the semiconductor substrate and stable for more than 20,000 hr in air, but erased immediately when cathodic polarization of −0.5V *vs.* SCE was applied at a ZnO electrode.

Discussion

The redox behavior of chemical species in solution at irradiated semiconductor electrodes depends upon the interfacial mode of the semiconductor/solution junction. The reactivity of solution species with photogenerated carriers (electrons and holes) in a semiconductor are due to the correlation between the energy levels of the semiconductor and the redox potentials of the species. Figure 9 shows the energy correlation of the imaging systems employed in this study. As previously reported in connection with competitive redox reactions at semiconductor photoelectrodes (8-13), the solution species with redox potentials within the bandgap potential region were oxidized at n-type semiconductor electrodes and reduced at p-type electrodes, and the current efficiency of the redox reactions of the solution species depended upon their standard redox potentials. In these imaging systems, the standard redox potentials of oxide-formation for n-type semiconductors, and of metal-deposition for p-type semiconductors lie within the bandgap potential region, analogous to the previous results (8-13), with the result that image-formation (reactions [7], [11], [14], [17], and [18]) proceeds in competition with the decomposition of water or of the electrode itself (reactions [6], [10], and [13]). As for the formation of images with respect to the difference of redox potentials of solution metallic ions, it was qualitatively recognized that an image was formed more favorably in the system with the more negative metallic redox potential than in the system with the more positive metallic redox potential, partly as shown at the term of Formation in Table I, where the systems with Tl^+ and Pb^{2+} have the faster reaction rate for the image formation. In a higher concentration of an imaging agent in a solution, as one can recognize from the result in Fig. 6 (B), when there are imaging agents in higher concentrations in the solution imaging reactions surpass the decomposition reactions. However, when a reducing agent such as hydroquinone (H_2Q) or potassium ferrocyanide ($K_4Fe(CN)_6$) was added to imaging systems using an n-type semiconductor, no image could be

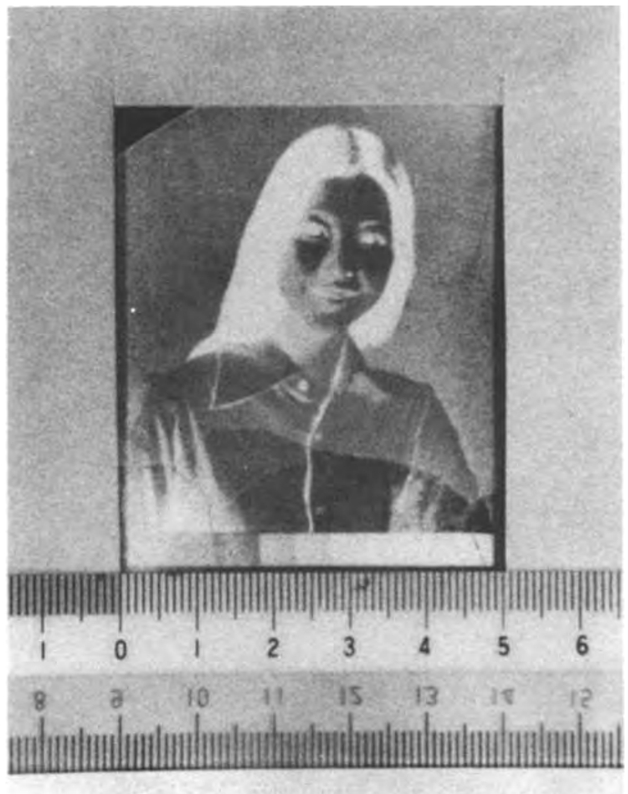

Fig. 8. Photograph of an image formed on a ZnO polycrystal electrode.

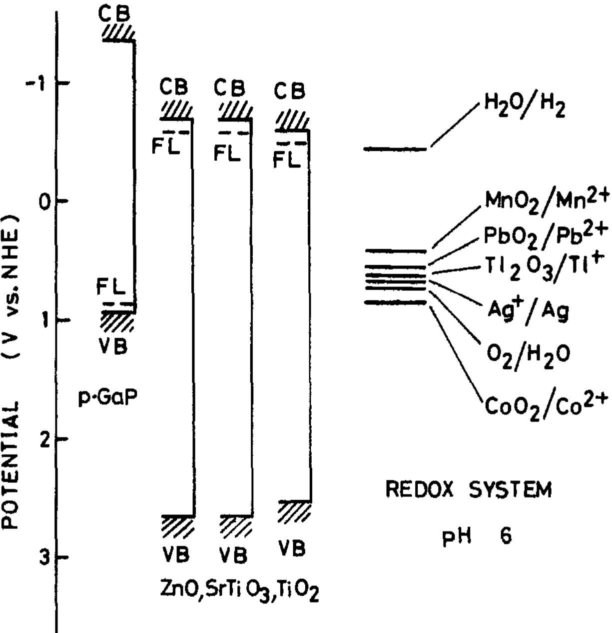

Fig. 9. Schematic correlation of energy levels between semiconductor electrodes and redox couples.

obtained. This can be attributed, with respect to the interfacial redox reactions, to the fact that the redox potentials of the oxidation of H_2Q and $K_4Fe(CN)_6$ are more negative than those of oxide formation reactions and to the fact that the oxidation of reducing agents surpasses any other reactions (imaging or the decomposition of water or the electrode itself), resulting in suppression of imaging reactions (12, 13).

Figure 10 (A) is a schematic presentation of image formation on a typical n-type semiconductor electrode (*e.g.*, ZnO) due to a photoelectrode reaction. The illuminated part alone is covered with an oxide layer.

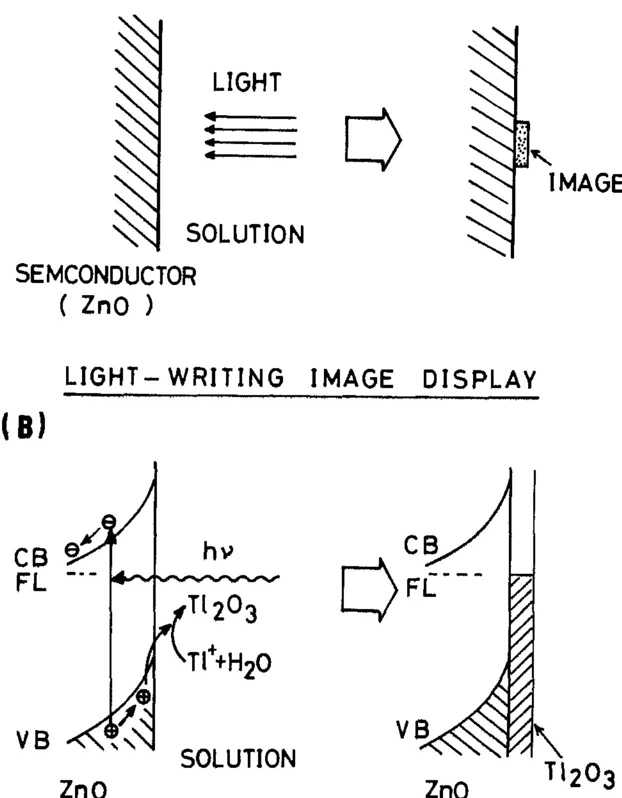

Fig. 10. Schematic of a typical light-writing image display process with a ZnO-Tl^{+} system. An image appears at an irradiated part of the ZnO electrode.

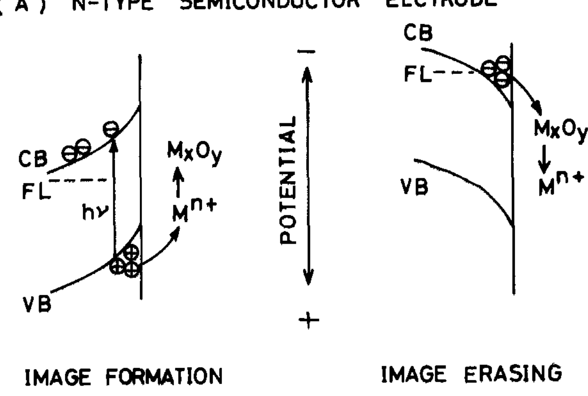

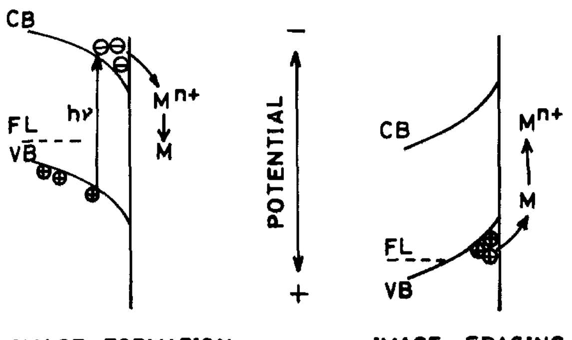

Fig. 11. Schematic of image formation and erasing processes in reversible photoelectrochemical imaging systems with a semiconductor/solution junction. (A) n-type semiconductor electrode, (B) p-type semiconductor electrode.

Figure 10 (B) simply shows the charge transfer across the interface.

Figure 11 is schematic summarizing the reversible photoelectrochemical imaging processes. For an n-type semiconductor electrode, the image formation process is the oxidation of metallic ions by photogenerated positive holes as minority carriers at the valence band under anodic polarization of the semiconductor, and the image erasing process is the reduction of the oxide layer by electrons as majority carriers at the conduction band under cathodic polarization. For a p-type semiconductor electrode, the polarization conditions of image formation and erasing are reversed, *i.e.*, image formation is by the reduction of metallic ions by photogenerated electrons as minority carriers, and erasing is by oxidation of the metal layer by valence band holes as majority carriers.

Image evaluations from the view of displaying points are dealt with in a subsequent report (31).

ABSTRACT

The aim of the work was to study the regrowth behavior of three different damage structures, namely, a buried amorphous layer, a continuous amorphous layer extending from the surface of the specimen, and a buried layer of clusters in P^+ implanted (111) Si. These structures were obtained by implanting P^+ at 120 keV to doses of 5×10^{14}, 10^{15}, and $5 \times 10^{15}/cm^2$ at implantation temperatures RT, 150°, and 350°C, respectively. A Q-switched ruby laser with a wavelength of 0.695 nm and at an energy either 0.7 J/cm² or 1.5 J/cm² was used for laser annealing. TEM was used to examine the damage in a 90° "cross-sectional" view. At 0.7 J/cm², two-thirds of the continuous amorphous layer regrew to give a polycrystalline layer. The buried amorphous layer regrew leaving dislocation loops and clusters and the buried layer of clusters remained unaffected. However, at 1.5 J/cm², dislocations and stacking faults extended from the surface for all the structures and were in direct contact with the deeper lying damage containing clusters. The density of dislocations, stacking faults, and deeper lying clusters progressively increased with the dose of the implanted phosphorus.

The potential applications of high energy pulsed laser beams for the regrowth of damage layers in ion-implanted semiconductors has drawn worldwide interest because of the simplicity of the process. By suitable choice of laser parameters, such as the energy, pulse length, etc., epitaxial regrowth of the damaged layers resulting from implantation can, in principle, be carried out either in the solid phase or molten phase (1-3). However, the mechanism of regrowth is not yet fully understood. The present study is therefore aimed at studying the regrowth behavior of three different types of damage structures, namely a buried amorphous layer, a continuous amorphous layer, and a buried layer of damage clusters in P^+ implanted Si on subsequent pulsed laser annealing at different energies. The origin of the formation of different damage structures has been explained elsewhere (4). For all of the work described here, TEM was used to examine the damage structures in 90° "cross-sectional" and "plan" views before and after the laser annealing. A mechanism for the regrowth has been suggested based on the observations made here.

Experimental

Implantation.—p-Type 17 Ω-cm (111) Si wafers of 5 cm diam were implanted in a nonchanneling direction with 120 keV P^+ ions using doses of either 5×10^{14}, 10^{15}, or $5 \times 10^{15}/cm^2$. The implantation energy of 120 keV corresponded to an LSS projected range of 1510 ± 690Å. The implantation time in all instances was 10 min. The implantation temperatures in the three cases were RT, 150°, and 350°C. The increases above RT in the latter two cases being due to ion beam heating.

Laser.—A Q-switched ruby laser operating at a wavelength of 0.695 nm was used. The multiple beam output was passed through a diffusing screen coupled to a light guide in order to achieve a flat and uniform intensity distribution (5). The laser energies of 0.7 and 1.5 J/cm² were used for each specimen. The pulse length for all the specimens was ~30 nsec.

TEM.—For TEM studies, 90° "cross-section" and "plan" view specimens were prepared. The "cross-section" specimens were obtained by cleaving the slices and then mechanically polishing followed by low energy ion beam thinning as described previously (6). The micrographs from these specimens correspond to the $(1\bar{1}0)$ plane perpendicular to the original (111) specimen surface plane. All of the TEM examinations described here were performed using bright field strong beam diffraction contrast conditions. Transmission electron diffraction (TED) patterns were also obtained to aid in the identification of the damage, using either the standard selected area method or microdiffraction techniques.

Results

Buried amorphous layer.—For the specimen implanted to a dose of $5 \times 10^{14}/cm^2$, the TEM "cross-section" micrograph showed an ~1150Å wide buried amorphous layer "A" located at a mean depth of ~850Å from the surface (Fig. 1a). The region between the surface and the top edge of damage layer "A" had sparsely distributed clusters.

After the specimen had been laser annealed at 0.7 J/cm², the region between the surface and ~1600Å depth, marked as "B" in Fig. 1b, consisted of dislocation loops (mean diameter ~100Å) and clusters. The density of dislocation loops obtained from "plan" view micrograph (not included in the text) was $\sim 6 \times 10^{10}/cm^2$. The regrown region "B" was followed by a second damage layer "C" ~250Å wide, consisting of dense fine structure and was located at a depth immediately below the bottom edge of layer "A" in the as-implanted specimen (Fig. 1b).

After the specimen had been laser annealed at 1.5 J/cm², the first damage layer "B" in the previous specimen was no longer present. The previous second layer "C" was much less in evidence and consisted mainly of small damage clusters in the layer "D"

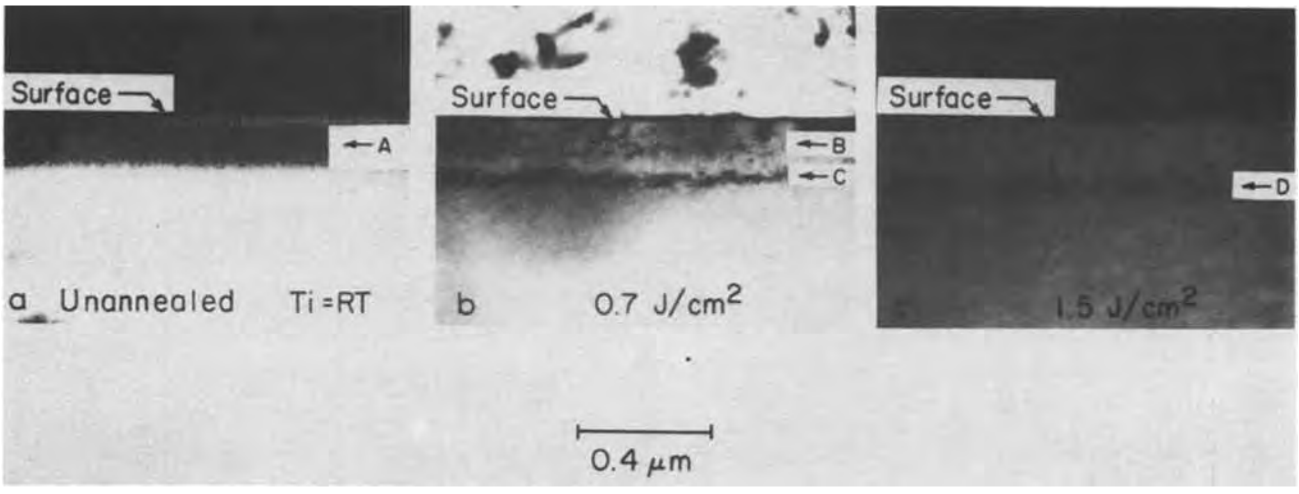

Fig. 1. TEM "cross-section" micrographs showing the laser annealing sequence for P^+ implanted (111) Si. (T_i = RT, $N_{P^+} = 5 \times 10^{14}/cm^2$, E_i = 120 keV).

(Fig. 1c). Occasionally, single dislocations extending from the surface to the clusters layer were observed.

Continuous amorphous layer.—For the wafers implanted to a dose of $10^{15}/cm^2$, the TEM "cross-section" micrographs showed a continuous amorphous layer "E" extending from the surface to a depth of ~1800Å. At the lower edge of this layer there was a narrow irregular zone ~250Å wide corresponding to heavily damaged but not amorphous material (the narrow dark layer in Fig. 2a).

After the specimen had been annealed at 0.7 J/cm², a first damage layer "F" comprising polycrystalline material with mean grain size ~1000Å extended from the specimen surface to a depth of 1500Å (Fig. 2b). A second damage layer "G" consisting of dense fine structure and ~500Å wide occurred and was in direct contact with the first damage layer (7).

After the specimen had been laser annealed at 1.5 J/cm², a first damage layer "H" comprising single crystal material containing mainly stacking faults but also dislocations extended from the surface to a depth of ~1800Å (Fig. 2c). The stacking faults density (from "plan" view micrographs) at the surface was ~10^9/cm². A second damage layer "I" consisting of dense fine structure and ~200Å wide occurred and was in direct contact with the first damage layer.

Buried clusters layer.—For the specimens implanted to a dose of $5 \times 10^{15}/cm^2$, the TEM "cross-section" micrographs showed a buried layer of clusters "J," ~1200Å wide, in single crystal material that was located at a mean depth of ~2000Å (Fig. 3a). There were "visible damage" free regions on either side of layer "J" (the term "visible damage" refers to the damage visible by TEM). After the specimen had been laser annealed at 0.7 J/cm², no noticeable change in the damage structure or distribution occurred (Fig. 3b).

However, for the specimen laser annealed at 1.5 J/cm², the results were similar to that of $10^{15}/cm^2$ except that the densities of dislocations and stacking faults (from "plan" view micrographs) were now ~$10^{10}/cm^2$ and ~$7 \times 10^{11}/cm^2$, respectively. The first damage layer containing stacking faults and dislocations is marked as "L" and the second damage layer containing small clusters is marked as "M" in Fig. 3c.

Discussion

A striking feature of the laser annealing is that two distinctly different annealing zones are sometimes present within individual specimens (Fig. 2b, 2c, and 3c). We suggest the following mechanism for the formation of the observed regrown structures.

For the as-implanted specimens with buried damage layers (Fig. 1a and Fig. 3a), the near-surface region, although damaged, is still single crystal as shown by TED's (not included in the text). However, for the 10^{15} P^+/cm^2 specimen, the near-surface region is amorphous. As a result, the energy absorption in the "buried layer" specimens occurred over a larger volume as compared to the "continuous amorphous layer" specimen. This is because of different absorption coefficients for amorphous and single crystal Si. There-

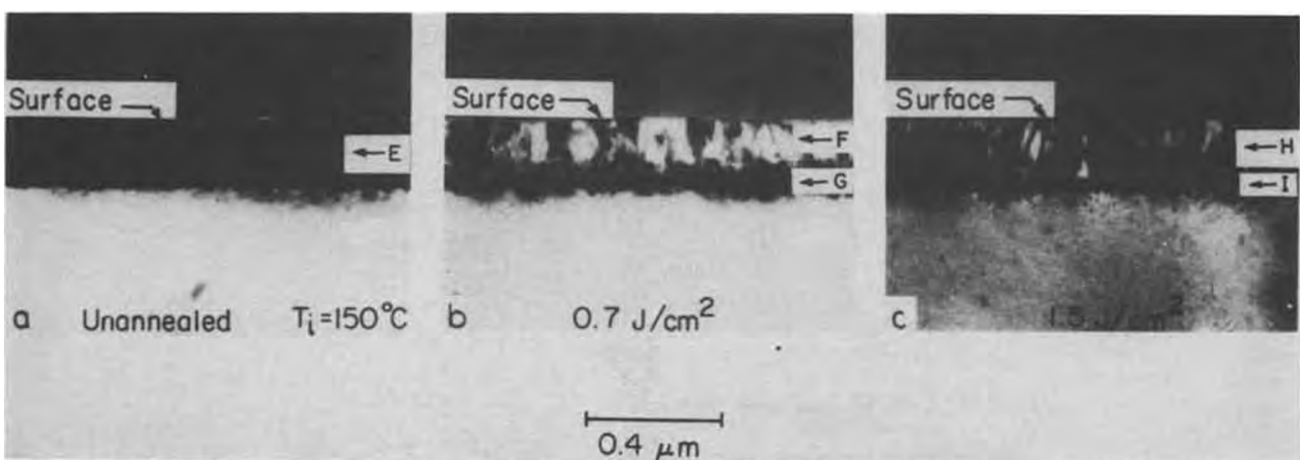

Fig. 2. TEM "cross-section" micrographs showing the laser annealing sequence for P^+ implanted (111) Si. (T_i = 150°C, $N_{P^+} = 10^{15}/cm^2$, E_i = 120 keV).

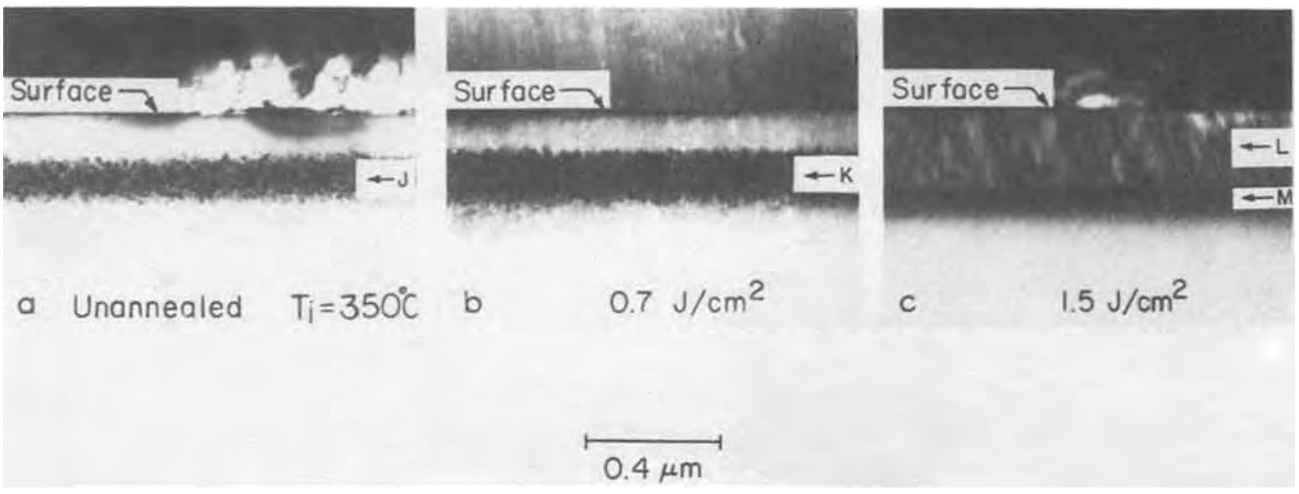

Fig. 3. TEM "cross-section" micrographs showing the laser annealing sequence for P^+ implanted (111) Si. (T_i = 350°C, N_{P^+} = 5 × 10^{15}/cm^2, E_i = 120 keV).

fore, at lower energies, *i.e.*, 0.7 J/cm^2 the "buried damage layers" either partially recover (Fig. 1b) or remain unaffected (Fig. 3b) depending on the thickness and the extent of damage in the near-surface region. However, for "continuous amorphous layers" strong absorption of energy nearer to the surface causes melting of the surface layer, but the deeper lying damage still remains amorphous or heavily damaged. The molten upper layer in this case regrows on a heavily damaged or amorphous substrate forming the polycrystalline layer.

At 1.5 J/cm^2, the laser energy absorption is high enough to melt the main damage layer in all three specimens but the solidification of the molten material on deeper lying clusters still gives rise to the formation of the dislocations and stacking faults. The density of these clusters increases progressively with the dose of the implanted P^+ ions. Consequently, the density of dislocations and stacking faults in the regrown layer also increases.

Conclusions

1. The regrowth structures from damaged layers in P^+ implanted Si resulting from laser annealing at 0.7 J/cm^2 critically depend on the crystallinity of the specimen in the near-surface region.

2. At a laser energy of 1.5 J/cm^2, the regrowth of the damage layer occurs via melting for all cases. The perfection of the regrown material then depends on the depth of melting relative to the depth of the original implantation damage.

The Effect of Phosphorus Doping on Tin Oxide Films Made by the Oxidation of Phosphine and Tetramethyltin

I. Growth and Etching Properties

Yar-Sun Hsu* and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

This paper describes the growth and etching characteristics of phosphorus-doped tin oxide films, prepared by the simultaneous oxidation of tetramethyltin (TMT) and phosphine gas in the 400°-500°C range. Both the growth and etch rates of these films are found to be relatively constant until the P/Sn ratio exceeds 3.2%, at which point they fall off and eventually become negligible. In addition, films grown by this technique are found to undergo a rapid transition from the polycrystalline to the amorphous state when their P/Sn ratio exceeds 3.2%. Possible mechanisms for this behavior are outlined, based on the relative strength of the P-O and Sn-O bonds and on the network former properties of P_2O_5. It is proposed that the mechanism of film growth and dopant incorporation is the direct (and independent) reaction of phosphine and TMT with oxygen adsorbed on the substrate surface. The transport properties of these films are discussed in a companion paper.

Tin oxide is a promising material for heterojunction solar cells, because it combines the unusual properties of high conductivity and excellent transparency in the visible spectrum. In addition, its large energy gap (~3.5 eV) and its suitable index of refraction (~1.9) make it not only an excellent upper window for solar cells, but also a good antireflection coating. An additional advantage is its durability under harsh environmental conditions. For example, tin oxide is not attacked at room temperature by either concentrated acids or bases.

Many techniques have been developed for its deposition. Among these, chemical vapor deposition or spray hydrolysis of tin tetrachloride-antimony chloride mixtures (1-5) are the commonly used methods. High substrate temperatures ranging from 500° to 750°C are usually required for these processes. In addition films tend to be unstable because of the incorporation of volatile chlorine in them.

In a previous paper (6), we have developed a simple preparation technique for phosphorus-doped tin oxide films formed by the simultaneous oxidation of tetramethyltin (TMT) and phosphine (PH_3), at relatively low temperatures (400°-500°C). TMT is a stable liquid with a relatively high vapor pressure (100 mm Hg) at room temperature. It can be readily transported to the reaction chamber in vapor form by bubbling argon gas through liquid TMT. Because of the absence of volatile chlorine, films made by this technique are more stable than those prepared by alternate methods.

Our past work has emphasized the kinetics of growth of undoped SnO_2 films, and shown that phosphorus doping results in a significant increase in their conductivity. The results were anomalous however, in that the conductivity fell off rapidly once a critical ratio of PH_3/TMT was exceeded.

This paper and its companion extend our work into this regime, and investigate both the growth and transport properties of these films as a function of dopant incorporation. All other process parameters (substrate temperature, argon and oxygen flow rates, and bubbler parameters) were held constant during the course of this work.

Experimental

Apparatus.—The deposition of tin oxide films was performed in an open tube vertical reactor. The reactants were introduced into a 130 mm ID, 160 mm long, vertically positioned reaction chamber containing a tungsten susceptor (50 mm diam) which was maintained at the deposition temperature by conventional resistance heating. UHP argon gas[1] was bubbled through the tetramethyltin[2] (TMT) at room temperature to transport its vapor to the heated substrate. Phosphine[3] gas, diluted to 500 ppm in argon, was used to dope these films. A baffle plate was used to mix the TMT vapor with phosphine and argon prior to their reaction with oxygen.[4] A separate inlet was brought in close to the substrate to introduce oxygen into this chamber, so that the reaction took place near the surface. All depositions were conducted using an argon carrier gas flow of 2.0 liters/min.

Deposition procedures.—Deposition of doped and undoped tin oxide films was carried out on oxidized silicon slices which were positioned on the susceptor. Prior to the deposition, the slices were degreased in trichloroethylene, acetone, and isopropyl alcohol, followed by a thorough rinse in deionized water. The substrates were further cleaned in Caro's etch [1:1 solution of H_2SO_4 (97%) and H_2O_2 (47%)] and given a final rinse in methanol. Subsequently, SiO_2 was grown on the wafer to a thickness of 5000Å in wet oxygen at 1090°C. Next, the chamber was pumped down and flushed with argon gas. Once the deposition temperature was reached, argon gas with flow rate of 16 cm^3/min was bubbled through the TMT bubbler at 25°C to transport its vapor to the substrate. At the same time, oxygen was also introduced at a flow rate of 50 cm^3/min, followed by phosphine gas. Immediately after SnO_2 growth, a 2000Å layer of SiO_2 was deposited on this film, at the same temperature. This was done by the oxidation of silane[5] which was used

in a 3% dilution in argon. The silica layer was patterned by conventional photolithographic techniques and used as a mask for etching the tin oxide.

A number of different types of substrates were used in this work. These included microscope cover slides (Corning No. 2940), semi-insulating Cr-doped GaAs, and thermally oxidized silicon. The results for these substrates were virtually identical, but are presented here for the oxidized silicon slices.

Thickness determination.—The silica layer was patterned by conventional photolithography, and served as a mask for the tin oxide film. Electrochemical etching (7) was used to remove exposed regions of highly conductive films. Etching was carried out in a bath of dilute hydrochloric acid [1 part of concentrated HCl (37%) in 5 parts of deionized water] with a platinum anode, and using the tin oxide as the cathode. In this system, nascent hydrogen is generated at the cathode by the passage of current, and probably reduces the SnO_2 to tin, which is continuously dissolved in the electrolyte as etching proceeds.

The electrochemical technique was found to be unsuited for low conductivity films, due to the formation of isolated unetched patches of tin oxide on the substrates. Therefore, an etching solution (8) was prepared by dissolving 1g of chromium metal into dilute HBr [20 ml of concentrated HBr (48%) with 20 ml of deionized water] at 98°C. In this system, it is believed that chromium is first dissolved to chromous ions which can be further converted to chromic ions by reaction with SnO_2. In this way, the SnO_2 is reduced to Sn which is removed by the hydrobromic acid. This solution was found to be satisfactory for etching the exposed tin oxide, if used as soon as it was prepared. During etching, the addition of extra chromium was sometimes necessary to maintain the chromous ion concentration when the action slowed down.

After etching, the silica mask was removed in hydrofluoric acid. The tin oxide film and substrate were next covered with evaporated aluminum, and the step measured by means of a multiple beam interferometer (Varian Model 980-4012).

X-ray diffraction.—Films were subjected to Cu-Kα radiation (λ = 1.5405Å) in a General Electric XRD-7 Diffractometer system, in order to study their crystal structure. The intensity *vs.* 2θ plots were directly obtained in a plotter attachment and compared to standard values available in the literature (9). All of these films were at least 1 μm thick so that the x-ray diffraction signals of sufficient intensity could be obtained.

Results and Discussion

The behavior of tin oxide films as a function of TMT, oxygen flow, and temperature, has been studied earlier (6). Here, we confine ourselves to a study of film behavior as the incorporation of phosphorus is increased. As a result, all data presented here are for films grown at 450°C with 16 cm^3/min flow rate of argon through the TMT bubbler held at 25°C. This corresponds to a partial pressure of 0.7 Torr, assuming that equilibrium transport is achieved. A flow rate of 50 cm^3/min of oxygen was used for these experiments. Film composition was varied by altering the PH_3/TMT mole ratio, while keeping a constant partial pressure of TMT and oxygen.

Composition.—The actual composition of the films was determined by microprobe analysis. Figure 1 shows the oxygen to tin atomic ratio as a function of PH_3/TMT mole ratio in the vapor phase. We note that, for low PH_3 concentration, the film is essentially in the form of SnO_2 with a small oxygen deficit. As the PH_3 concentration is increased, some of the phosphorus replaces the tin, so that there is a small increase of the O/Sn atomic ratio.

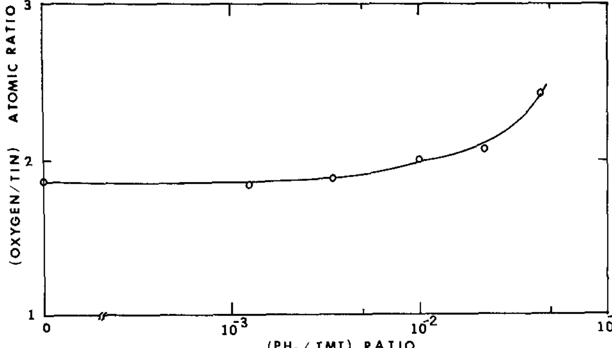

Fig. 1. Oxygen/tin atomic ratio vs. PH_3/TMT mole ratio

The P/Sn atomic ratio in the tin oxide films is plotted in Fig. 2 as a function of the PH_3/TMT mole ratio in the vapor phase, and is seen to be linear over the entire range of interest, with a proportionality factor of 3.2. This type of behavior would be expected if the incorporation of phosphorus and tin into the growing film is both by absorption of oxygen on the surface, and reaction with the incoming tin and phosphorus species at a rate which is directly proportional to their partial pressures. The adsorbed oxygen has a greater affinity for the phosphorus than for the tin, so that its effective sticking coefficient is larger.

Some phosphorus was found to be present in the undoped SnO_2 films. This is believed to be due to the residual impurity in the reaction chamber and the inlet lines.

Morphology.—All films grown with a PH_3/TMT mole ratio less than 0.01 showed x-ray diffraction peaks corresponding to those obtained for polycrystalline SnO_2. Some differences were observed for films grown under different conditions, as indicated by the change of relative intensity of those peaks. However, peaks were at the same reflection angle, and no new peaks were formed. Thus, the orientation of

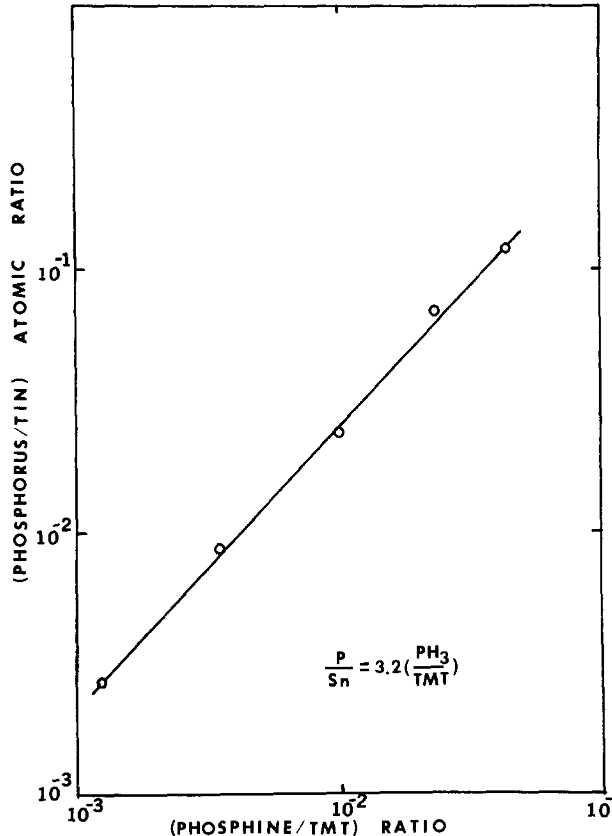

Fig. 2. Phosphorus/tin atomic ratio vs. PH_3/TMT mole ratio

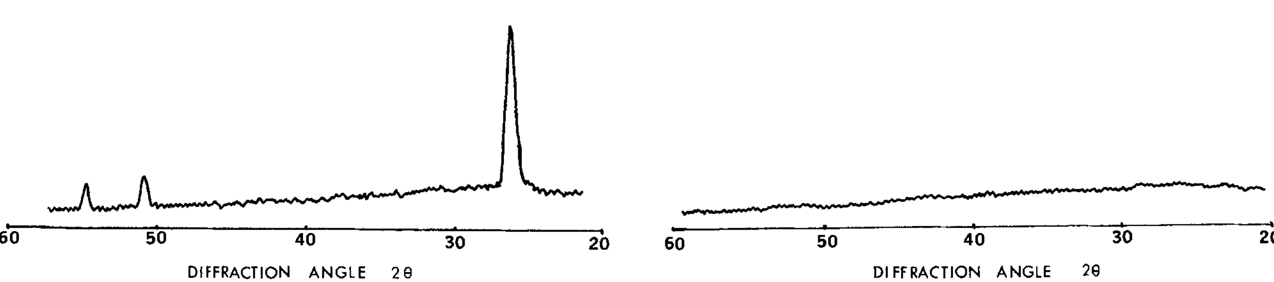

Fig. 3. X-ray diffraction plot for phosphorus-doped films (a, left) $PH_3/TMT = 0.01$ (b, right) $PH_3/TMT = 0.023$

crystals, as well as the lattice parameters, seemed to be independent of the variation of phosphorus content.

Figure 3a shows a typical diffraction pattern for a film grown with a PH_3/TMT ratio of 0.01. Peaks corresponding to 2θ values of 26.5° (110), 51.7° (211), and 54.7° (220) are clearly seen in this figure. Crystal size could not be resolved by scanning electron microscopy with a magnification of 20,000X. However, calculations based on the broadening of the (110) peak, using Scherer's formula (10) and Jones' conversion curves (11), gave an average grain size of 370Å. This grain size was relatively constant for PH_3/TMT ratios below 0.01, and was independent of the type of substrate used.

Neither SnO nor Sn_3O_4 peaks have been observed. This is in agreement with the result of microprobe analysis, namely that the films are essentially SnO_2 with some oxygen deficit. It is consistently found that the (110) peak was the strongest one. These results are quite different from those obtained for films grown by the pyrolytic decomposition and oxidation of $(CH_3)_2 SnCl_2$ (5), where the (200) peak was seen to be the strongest. It is interesting to note that this (200) peak was always missing in our samples.

The magnitude of the x-ray diffraction peaks fell off rapidly for PH_3/TMT ratios in excess of 0.01. In fact, no peaks were observed (see Fig. 3b) for $PH_3/TMT \geq 0.023$, so that films were essentially amorphous beyond this point. We believe that this comes about because of the large phosphorus-oxygen bond strength (88-111 kcal/mole). As a result, phosphoric oxide is a glass network former (12-13) having the unusual property of high viscosity, which increases rapidly at concentrations in the 1-2% range (14). Its introduction into the tin oxide greatly reduces the mobility of the reactant species on the surface, so that the "critical nucleus" required to form a crystalline film becomes increasingly hard to achieve. This favors the formation of amorphous tin oxide as the phosphorus content increases.

The incorporation of phosphorus and tin into these films remained linear with reactant mole ratios, even though the film structure went through a rapid change from the polycrystalline to the amorphous state. This would indicate that the incorporation mechanism outlined earlier is in effect over this full range, and that chemical compound formation is not the process for initiating the transition to the amorphous state.

Heat-treatment at high temperature was attempted to recover the crystallinity. Annealing the amorphous tin oxide films at 900°C in a nitrogen ambient for 20 hr was found to result in partial recovery as evidenced by the reappearance of x-ray peaks of SnO_2. However, their intensities were not as strong as those obtained for films grown with PH_3/TMT ratios below 0.01.

Growth rate.—Figure 4 shows the growth rate as a function of PH_3/TMT ratio at the deposition temperature (450°C). This is seen to be relatively constant until a PH_3/TMT ratio of 0.01 is reached, but falls off with increasing concentration until it becomes essentially zero for a mole ratio of 0.09. Comparable behavior has been noted for arsenic-doped tin oxide films (15), grown by the simultaneous oxidation of arsine gas and tetramethyltin.

A falloff in growth rate of polycrystalline silicon films as a function of arsenic doping has also been noted by other workers (16) and has been explained by using the concept of catalytic poisoning by Group VB elements. We do not believe that this is the case in our films since the high P—O bond strength would favor the presence of phosphorus in the form of tetrahedra where the normally toxic phosphorus atom is shielded by four oxygen atoms (17). We note, however, that the phosphorus is more strongly bound to the adsorbed surface oxygen than the tin (the Sn—O bond strength is 46 kcal/mole). As a result, an increasing phosphorus concentration should increasingly inhibit the attachment of tin to adsorbed oxygen atoms, resulting in the observed falloff in growth rate.

Etch rate.—Figure 5 shows the etch rate of phosphorus-doped films as a function of the PH_3/TMT mole ratio. The same etchant (Cr-HBr system described earlier) was used for all samples as a basis of comparison. Here, we note that the etch rate is relatively constant until a PH_3/TMT ratio of 0.01, and falls beyond this point, becoming essentially zero for a mole ratio of 0.05. This is quite similar to the growth rate behavior, and can also be explained in terms of the large P—O bond strength, as compared to that for the tin-oxygen bond. This is because the etching process essentially involves the rupture of these bonds, and the subsequent dissolution of the reaction products.

Conclusions

The growth and etching properties of phosphorus-doped tin oxide have been described, and explained

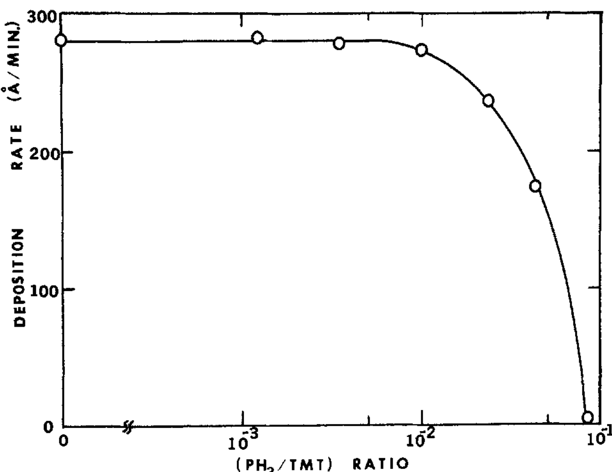

Fig. 4. Deposition rate vs. PH_3/TMT mole ratio

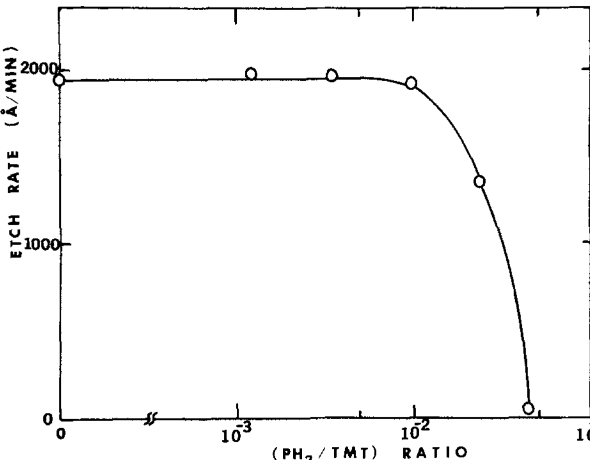

Fig. 5. Etch rate vs. PH_3/TMT mole ratio

on the basis of the relative strengths of the P—O and Sn—O bonds. These arguments also explain the rapid transition of these films from the crystalline to the amorphous state at low phosphorus incorporation levels. Finally, a relatively simple model for the film growth is proposed, based on the direction reaction of the phosphorus and tin species with the surface adsorbed oxygen.

The Effect of Phosphorus Doping on Tin Oxide Films Made by the Oxidation of Phosphine and Tetramethyltin

II. Electrical Properties

Yar-Sun Hsu* and Sorab K. Ghandhi*

Electrical and Systems Engineering Department, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The electrical properties of tin oxide films have been measured as a function of phosphorus doping. It is shown that the electron concentration increases monotonically with phosphorus doping, with about 7.7% of the incorporated phosphorus being active. An oxygen deficiency is also present in these films, and is found to be about 0.1 eV below the conduction bandedge. The mobility increases with phosphorus doping to a maximum of 26 cm^2/V sec, and then falls off with further doping, as the film undergoes a crystalline to amorphous transition. Film behavior in these two regimes can be explained by the established theories for current transport in polycrystalline and amorphous films, respectively.

A simple technique for the preparation of tin oxide films by the oxidation of tetramethyltin (TMT) has been reported in a previous paper (1). Although undoped, these films are conducting due to the deficiency of oxygen; typically, their undoped conductivity is on the order of 1.0 $(\Omega\text{-cm})^{-1}$. This conductivity can be further increased by doping with Group V elements, such as phosphorus (1), antimony (2-6), and arsenic (7).

This paper describes the effect of phosphorus doping upon the conductivity of tin oxide films. An anomalous feature of this doping behavior is that the conductivity

* Electrochemical Society Active Member.

Key words: doping, oxidation, films.

increases with phosphorus content until it reaches a maximum value, and then rapidly falls with further phosphorus doping. Similar behavior has been observed in Sb-doped (6-9) and As-doped SnO_2 (7). However, no detailed explanations have been previously given for this phenomenon.

Here, we show that the change in conductivity behavior of phosphorus-doped tin oxide films is related to their transition from the crystalline to the amorphous state, as demonstrated in a companion paper (10). The separate contributions of mobility and carrier concentration have been determined in this work, and the transport properties of the films related to the change in these parameters with phosphorus concentration.

Experimental

Tin oxide films were prepared on glass microscope slides, oxidized silicon, and on semi-insulating GaAs wafers. The results were essentially the same, and are presented here only with specific reference to films made on oxidized silicon substrates. Films were grown at 450°C with typical gas flow rates of 50 ml/min oxygen and 16 ml/min argon flow through a TMT bubbler. Phosphine gas, diluted in argon, was used to dope the films as described earlier (10).

The mobility and carrier concentration of these films were measured by using bridge samples in a Hall effect apparatus. These samples were obtained by coating the SnO_2 layer with silicon dioxide at 450°C, followed by conventional photolithographic delineation of the oxide. This oxide was used as a mask for etching the SnO_2 layer using either an electrochemical technique (11) or a hot HBr + Cr solution (10). Ohmic contacts were made to the arms with silver epoxy, followed by curing at 100°C for 1 hr. The temperature dependence of electrical conductivity. carrier concentration, and Hall mobility were studied between 96° and 373°K. Hall voltages were measured by applying a magnetic field of 4.5 KG.

Results and Discussion

A number of phosphorus-doped tin oxide films were made on this program with a variety of crystalline and amorphous substrates. The results that follow are outlined for one specific set of films, labeled A-H for ease of reference.

Conductivity.—Both undoped and phosphorus-doped tin oxide films were found to be n-type. Undoped SnO_2 with conductivity ranging from 0.5 to 5 $(\Omega\text{-cm})^{-1}$ could be obtained by varying the oxygen to TMT ratio. Increasing the oxygen flow while keeping constant TMT flow results in films with low conductivity. This suggests that conduction of undoped films arises from the lack of stoichiometry, *i.e.*, an oxygen deficiency.

The addition of Group V elements increases the conductivity of SnO_2 films. In this work, phosphine gas was introduced during the growth of SnO_2 for this purpose. Since the ionic radius of P^{5+} (0.35Å) is different to that of Sn^{4+} (0.71Å), the introduction of phosphorus into SnO_2 leads to the replacement of some Sn^{4+} ions by P^{5+} ions. This results in the formation of a new donor level, and enhances the conductivity of the films. The rest of the phosphorus is incorporated in the film in inactive form. In all probability, this takes the form of phosphorus-oxygen polyhedra, because of the strength of the P—O bond and the network former character of phosphoric oxide.

Figure 1 shows the change in conductivity as a function of PH_3/TMT mole ratio. The conductivity with no phosphine flow (film A) was 0.9 $(\Omega\text{-cm})^{-1}$. As mentioned in the preceding paper (10), microprobe analysis has indicated the presence of a small amount of residual phosphorus in the undoped films. This was always present, in spite of repeated flushing of the system with argon. Thus, this conductivity

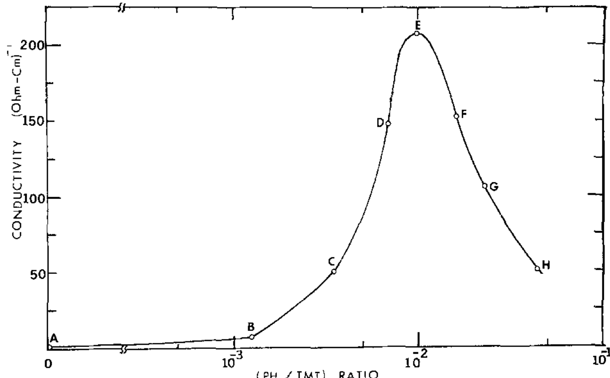

Fig. 1. Conductivity vs. PH_3/TMT mole ratio

value is partly due to the contribution of phosphorus, as well as the oxygen deficiency.

The conductivity of doped films increased with the introduction of phosphorus, reaching a maximum of 210 $(\Omega\text{-cm})^{-1}$ for a PH_3/TMT mole ratio of 0.01 (film E). Increasing the flow rate beyond this point resulted in a rapid drop in conductivity. This is contrary to what is expected from the controlled valency mechanism.

X-ray diffraction data showed that films A-E were polycrystalline, whereas films F-H were amorphous. Thus, the unusual behavior of conductivity is related to this change in film state.

Carrier concentration.—Figure 2 shows the carrier concentration as a function of the amount of phosphorus incorporated in the film. Note that the undoped SnO_2 film already has a high carrier concentration ($\simeq 1.5 \times 10^{18}/cm^3$). This has been attributed to the combined contributions of the residual phosphorus and the oxygen deficiency. The introduction of phosphorus leads to a further increase of this carrier concentration. At high phosphorus concentration, the carrier density approaches saturation. As a result, the rapid drop in conductivity is primarily due to changes in the electron mobility of these films.

It is important to note that a Hall effect measurement of a nonsingle crystalline sample only gives an effective value of carrier concentration, n_{eff}, which is at best a measure of the barrier to current flow through it. Nevertheless, an estimate of the actual carrier concentration can be made by consideration of the theory of current flow in polycrystalline films (12). Films of this type consist of small grains joined together at grain boundaries. These grain boundaries represent a transition region between crystallites of different orientation, and have a large defect density due to incomplete bonding. Current transport between crys-

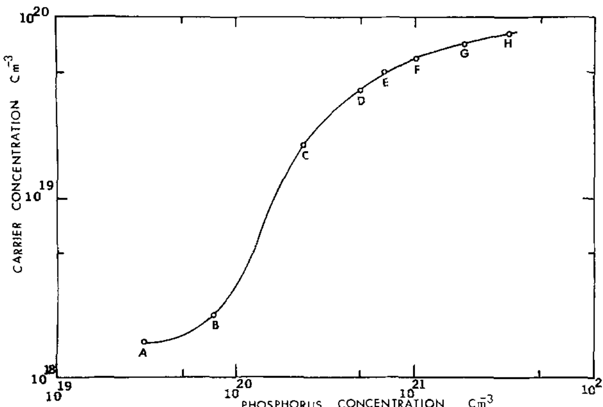

Fig. 2. Effective carrier concentration vs. phosphorus concentration.

tallites is impeded by these defects which capture mobile carriers. This creates a potential barrier between crystallites, and reduces the effective mobility. Using this model, it can be shown that the effective barrier height initially increases with doping concentration until all the traps are filled. Further increase in the doping concentration reduces the potential barrier height and therefore increases the mobility. At very high doping levels there is an additional (apparent) reduction of barrier height due to tunneling effects.

Figure 3 shows the temperature dependence of n_{eff}, from 96° to 373°K. We note that film E is the most heavily doped polycrystalline film and should have the lowest value of barrier height at the grain boundaries. Assigning (for the present) a value of $E_b = 0$ to this film, the actual carrier concentration within the grain is found to be $5 \times 10^{19}/cm^3$. The phosphorus content, however, is $6.5 \times 10^{20}/cm^3$. Thus, approximately 7.7% of this phosphorus is active for this film while the rest is probably incorporated in the form of phosphorus-oxygen polyhedra.

From Fig. 3 it is seen that there are two slopes for the lightly doped SnO_2 films (A and B), and donor levels can be associated with each. One level has been assigned to the oxygen vacancy, and has a slope corresponding to about 0.1 eV below the conduction band. The other level is assigned to the phosphorus impurity, which is at the conduction bandedge. As expected, the level attributed to oxygen was not observed in films grown at increasing phosphine flow rates.

Mobility.—Figure 4 shows the room temperature Hall mobility as a function of the phosphorus concentration. This mobility was found to increase as the ratio of PH_3/TMT was increased, while keeping TMT flow constant. The highest mobility value, 26 cm^2/Vsec, was observed for a phosphorus concentration of $6.5 \times 10^{20}/cm^3$. Note that films (A-E) were polycrystalline up to this point.

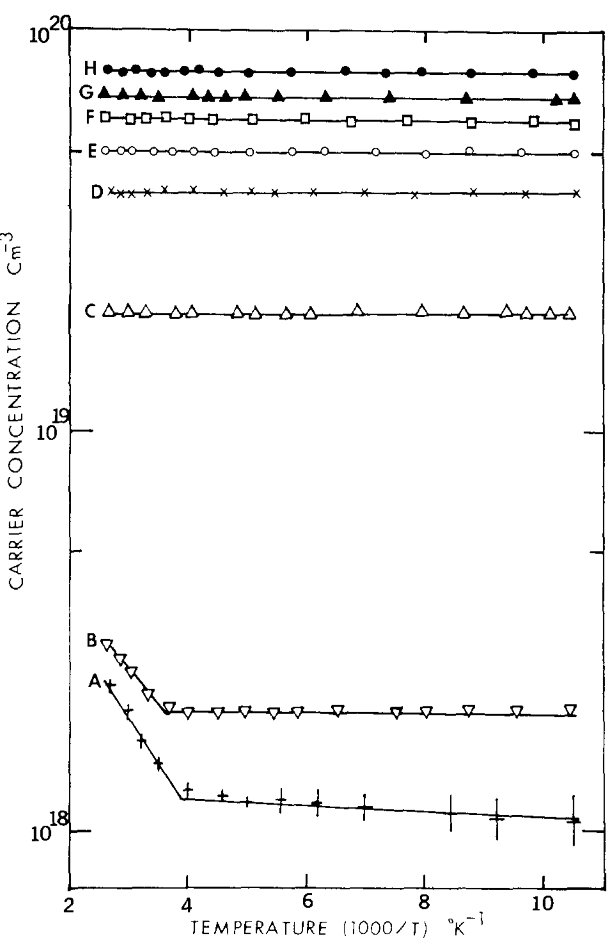

Fig. 3. Effective carrier concentration vs. temperature

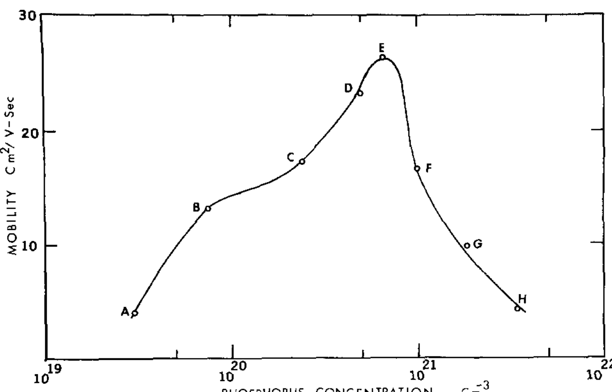

Fig. 4. Effective mobility vs. phosphorus concentration

Further increasing the phosphine flow rate produced a rapid drop in mobility as the films became amorphous (F-H). Since the carrier concentration increases monotonically with increasing phosphine flow rate, the drop in conductivity is primarily due to the fall of this parameter. The mobility behavior of these films can be explained by considering these two types of behavior separately and recognizing that the Hall effect measurements give only an effective value of mobility.

Films A-E.—These are polycrystalline with a grain size of about 370Å. Here, the conductivity increases monotonically with PH_3/TMT mole ratio. This increase is due to the enhancement of both the n_{eff} and μ_{eff}. Again invoking the model for current transport in polycrystalline material, this effective mobility can be expressed as

$$\mu_{eff} = A\, T^{-1/2} \exp\,(-E_b/kT)$$

where E_b is the potential barrier height and A is a function of the grain size and the effective electron mass. A plot of ln ($\mu_{eff}\, T^{1/2}$) *vs.* $1/kT$ should yield a straight line with a slope of E_b. Figure 5 shows that our experimental results fit this expression very well. Therefore, it is concluded that grain boundary trapping effects dominate carrier transport in the polycrystalline SnO_2 films.

From this figure, the barrier height for film E is obtained as 7 meV. Thus, the previous assumption that it was negligible is a reasonable one, in view of the crude nature of the calculation.

The model for current transport in polycrystalline films also predicts that

$$E_b = \frac{q\, N_t^2}{8\, \epsilon\, N}$$

where N is the doping concentration in the grain, and N_t the trap density per unit area at the interface between grains, and $\epsilon \simeq 9$ for tin oxide. For highly doped films with low barrier height, $n_{eff} \simeq N$. For these films, the $E_b\, n_{eff}$ product should be constant, and can be used to calculate the trap density per unit area. Results are shown in Table I, where the $E_b\, n_{eff}$ product is reasonably constant for films C-E, so that these assumptions are justified.

Films F-H.—In this region the films are amorphous and the above model is no longer applicable. We note that the carrier concentration is still high, and that the drop in conductivity at high PH_3/TMT ratio is due to the fall in electron mobility, and results from a transition to the amorphous state.

In noncrystalline material, the lowest states in the conduction band are "localized" because of fluctuations of potential due to disorder (13, 14). There is a con-

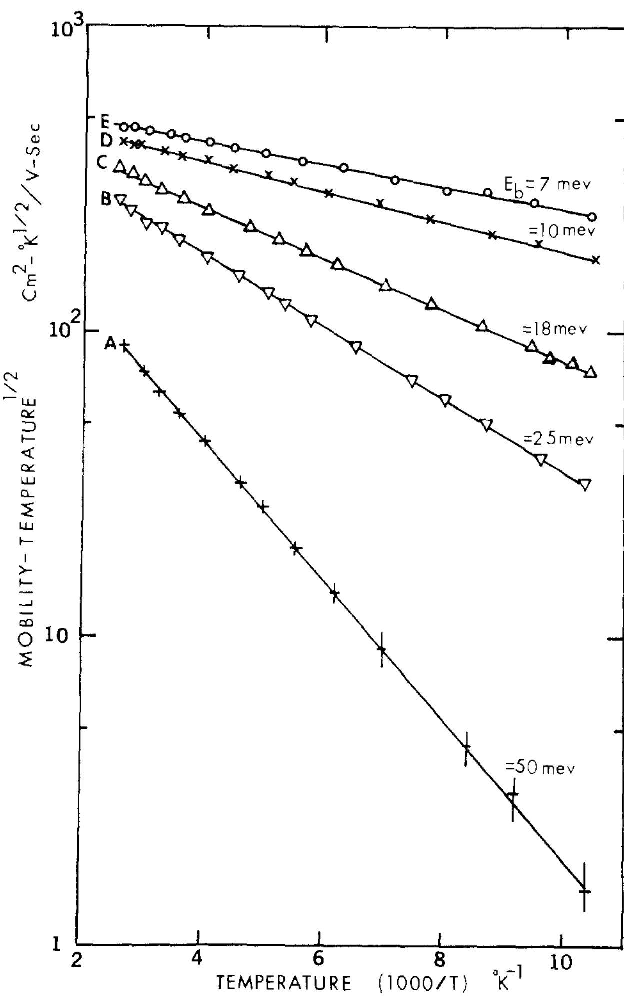

Fig. 5. $\mu_{eff}\ T^{1/2}$ vs. temperature

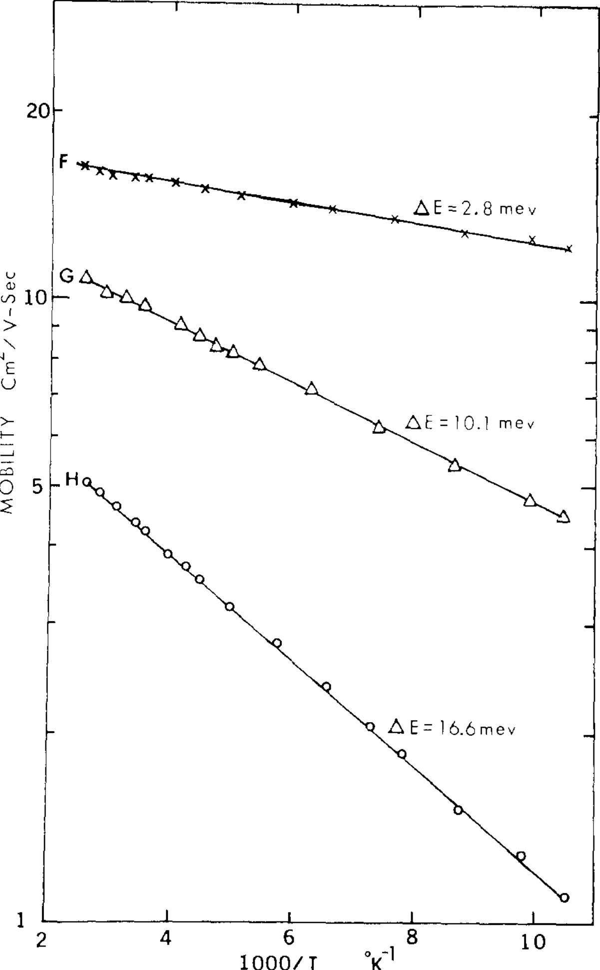

Fig. 6. μ_{eff} vs. temperature

tinuous range of such localized states from the bottom of the band up to a critical energy E_c' (the mobility edge), which separates the high mobility region in the extended states from the low mobility region in the localized states. What one expects for this situation is that charge transport is by "hopping" from one localized state to another at low temperatures. Typically, the range of operation of hopping behavior is between 1° to 20°K. At higher temperatures, current is carried by electrons excited to the mobility edge; to a first order, the effective mobility will vary as $\mu_0 \exp(-\Delta E/kT)$, where ΔE is the difference between E_c' and Fermi level E_F.

This model has been verified for amorphous doped SnO_2 in the higher temperature range. Figure 6 shows the effective mobility from 96°-373°K plotted as a function of $1/T$. The linear relation between $\ln \mu_{eff}$ and $1/T$ indicates that band conduction of electrons excited above E_c' dominates the contribution to the conductivity over this range.

Conclusions

In a companion paper, we noted that tin oxide films undergo a rapid transition from the polycrystalline to the amorphous state, once a critical level of phosphorus doping is exceeded. Here, it is shown that the transport properties of these films exhibit a correspondingly abrupt change in behavior. The behavior has been explained in terms of established models for polycrystalline and amorphous films, and is shown to fit these theories quite well. In addition, we have explained the anomalous, abrupt falloff in conductivity at high doping levels, as well as its temperature behavior. The barrier height to current flow has been shown to be small (~ 7 meV), in the heavily doped polycrystalline films, and about 7.7% of the incorporated phosphorus is shown to be electronically active. It is presumed that the rest is in shielded form as phosphorus-oxygen polyhedra.

Table I

Film	E_b (cm^{-3})	n_{eff} (cm^{-3})	$E_b n_{eff}$	N_t (cm^{-2})
A	0.05	1.6×10^{18}	8×10^{16}	?
B	0.025	2.3×10^{19}	5.75×10^{17}	?
C	0.018	2×10^{19}	3.6×10^{17}	3.78×10^{12}
D	0.01	4×10^{19}	4×10^{17}	3.99×10^{12}
E	0.007	5×10^{19}	3.5×10^{17}	3.73×10^{12}

ABSTRACT

The electrical time response of ion sensitive field effect transistors to an applied step change in bias voltage is examined. The results show that ISFET time response is determined by the ion selective membrane and the conditions at the associated interfaces. Lateral charge distribution at the membrane/insulator interface and its effect on time response is discussed. An understanding of the transient characteristics of ISFET's is advantageous in designing systems where bias voltages are switched, *i.e.*, multiplexing and telemetry.

The ion sensitive field effect transistor (ISFET) is one of the family of chemically sensitive semiconductor devices which has been the object of considerable research and development (1). Structurally, the ISFET is an insulated gate field effect transistor (IGFET) in which the metal gate is replaced by an electrochemical structure consisting of a reference electrode, electrolyte solution, and an ion sensitive membrane. A change in the chemical environment to which the membrane is exposed or in the applied electrical voltages will cause a change in the electrical potential at the membrane/transistor interface. This change is directly related to the charge distribution in the semiconductor, which is reflected in a change in current. The time required to reach equilibrium following a change in applied voltage is examined in this study.

The time response of an IGFET is determined by its gate impedance and the transit time of charge carriers in the channel. For a MOSFET, the small values of these factors give typical time constants of 10-100 nsec. The transient characteristics of ISFET's with various membranes depend on four processes: relaxation of the space charge of the membrane at the solution/membrane interface, the bulk impedance of the membrane, the relaxation of space charge at the membrane/insulator (or metal) interface, and the time response of the insulator/semiconductor structure (2). The time constant of the MOSFET indicates that the last impedance is the lowest and can be neglected. Therefore, the time response of an ISFET will be a function of the membrane and its associated interfaces, which can be modeled by a series of parallel combinations of capacitors and resistors.

A series of experiments has been conducted to provide initial data on the relaxation time of different ISFET's. A voltage step method was used in order to obtain a rapid survey of the transient behavior of the membranes used on our transistors. However, this technique is not readily suitable for the assignment of time constants to the appropriate physical processes. The measurement of the real and imaginary parts of the impedance at various frequencies (Cole-Cole plots) was found to be most suitable for that purpose (3).

The possible effects of potential variation along the channel of an ISFET on charge distribution at the membrane/insulator interface has been suggested by Zemel (4). By making step changes in both the drain and the gate voltages of ISFET devices, these effects were observed.

Experimental

Devices.—The fabrication and principles of operation of ISFET's have been described previously (1). The devices tested in this study can be divided into four groups according to their gate structure. The first type is the MOSFET. Second is the bare gate silicon nitride ISFET which has been shown to be *p*H sensitive (5, 6). The third group consists of ISFET's with homogeneous polymeric membranes. Calcium ion, K^+, and H^+ sensitive membranes of this type were used. The characteristics and method of fabrication of these devices have been reported (7).

The fourth group consists of ISFET's with heterogeneous membranes (8), sensitive to Cl^- and I^-.

The transistors were tested for their chemical response before they were used for transient electrical characteristic studies.

Other equipment.—A Tektronix TM-503/FG-501 function generator was used to produce a symmetrical square wave with variable amplitude, bias, and frequency. The rise time of this signal was on the order of 50 nsec.

A double junction Ag/AgCl (saturated KCl) reference electrode (METROHM EA-437) was used for solution (gate) biasing of the ISFET's. Distilled deionized water and reagent grade chemicals were used

in all experiments. All measurements were made at an ambient temperature of 22° ± 2°C.

The drain current was measured by connecting the source lead of the ISFET to the input of an OP AMP electrometer and tracing the output voltage on a Tektronix 7623-A storage oscilloscope. An oscilloscope camera was used to photograph the tracings. The apparatus used to measure transient response is illustrated in Fig. 1.

The Princeton Applied Research Electrochemistry System was used to obtain the steady-state *I-V* characteristics.

Results

The voltages which are applied to an ISFET device establish the equilibrium charge and potential distribution in the device. This distribution determines the measured drain to source current, I_D. The experimental procedure consisted of making step changes in either of the applied voltages (V_G or V_D) while measuring I_D as a function of time.

The ISFET's were biased as shown in Fig. 1 with the substrate and the source kept at zero volts. The gate voltage was maintained above threshold for all measurements to insure that the time response measured would not include the time required to form an inversion layer in the device. A square wave was used to generate the applied step changes in drain or gate voltage. To measure the response to changes in gate voltage (V_G) a square wave with an amplitude of approximately 500 mV was added to the gate bias voltage while holding the drain voltage constant at 2V. To measure the response to changes in drain voltage (V_D) a square wave with amplitude of approximately 1.5V was added to the drain bias voltage while holding V_G constant. The d-c biasing of the drain and gate were such that the value of I_D was always within the operating range generally used for these devices which is from 0.25 to 1.0 mA.

Typical applied voltage waveforms and the corresponding changes in I_D are shown in Fig. 2 with definitions of the measured parameters: τ_{V_G}, τ_{V_D}, and overshoot. The curves in Fig. 2 show the response to a voltage pulse applied to the drain (a) or to the gate (b), respectively.

As seen in Fig. 2, the current response to a step change in V_G is different than that to a step change in V_D. When V_G is stepwise increased, I_D increases monotonically to its final steady-state value with a time constant of τ_{V_G}. When V_D is increased stepwise, I_D increases to a value greater than its final steady-state value, thus producing an overshoot. It then decays with a time constant of τ_{V_D}. When these two time constants are compared they are found to be nearly identical for any one particular device (see Fig. 3). The time constants of each device are independent of

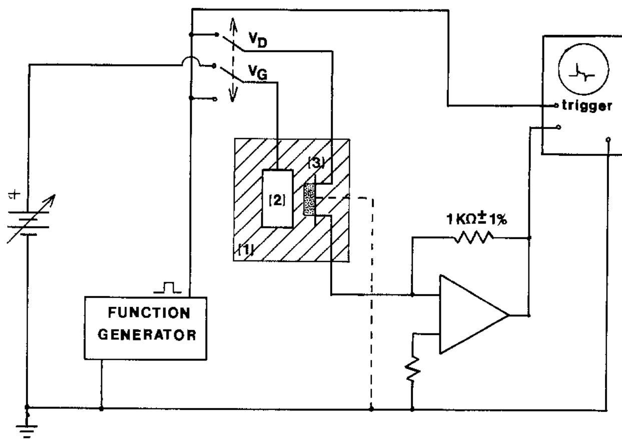

Fig. 1. ISFET biasing and measuring apparatus. (1) ionic solution, (2) reference electrode, (3) ISFET.

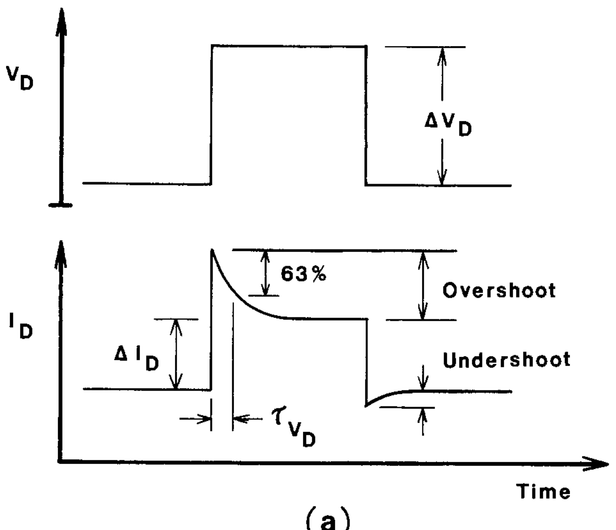

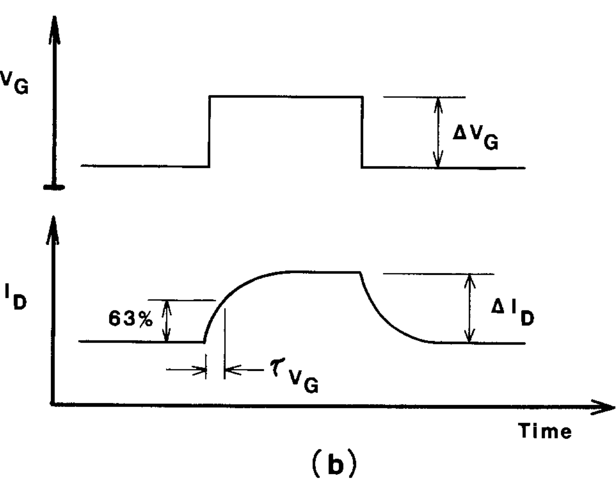

Fig. 2. Definition of terms. (a) ISFET current response to step changes in drain voltage; (b) ISFET current response to step changes in gate voltage.

whether an increasing or decreasing step change in voltage is made. The time response data for all devices is enumerated in Table I.

During the course of study it was found that a symmetrical pulse applied to V_D produced a nonsymmetrical degree of overshoot in comparison to undershoot of I_D. Since I_D is a nonlinear function of V_G and/or V_D, the degree of overshoot will be a function of initial bias, size, and direction of the V_D step. Evidence of this was seen in ISFET's when a train of pulses with increasing pulse height was applied to the drain of a Cl^- ISFET. The resulting I_D showed an increasing degree of overshoot with step size. The applied waveform and resulting drain current are shown in Fig. 4.

The interposition of an electrically floating layer between the insulator and membrane reduced the overshoot for all membranes and affected the time response of most. The results obtained from time response measurements made with gold gate devices provided some insight into the effects of interfacial conditions on the time response of ISFET's. The presence of gold drastically reduces the time response of the heterogeneous membranes (I^- and Cl^-) and slightly increases that of the homogeneous membranes (Ca^{++}, K^+, and H^+) (Table I).

The time response measured for bare gate and MOSFET devices were three to four orders of magnitude less than that measured for membrane devices. Comparing each type of membrane reveals a time constant hierarchy; the devices with homogeneous PVC

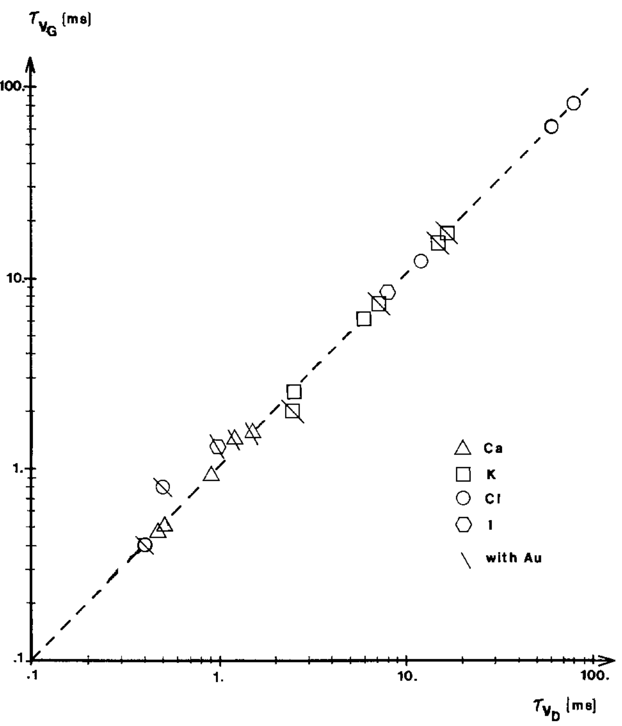

Fig. 3. Log-log plot of the time response to a step change in gate voltage (τ_{V_G}) *vs.* the time response to a step change in drain voltage (τ_{V_D}) of various ISFET's.

based membranes (Ca^{++} and K^{+}) were found to have the shortest time constants, followed by those with heterogeneous membranes and finally those with *p*H membranes.

Discussion

The characteristic current response to pulsed gate or drain voltages of ISFET's can be explained in terms of the lumped parameter model shown in Fig. 5. According to IGFET theory, the drain current is determined by the effective gate voltage (*i.e.*, the voltage at the insulator/membrane interface), the drain voltage, and the geometry of the semiconductor structure (9). The model represents a cross-sectional segment of an ISFET in which the drain voltage is assumed constant during steady-state conditions. When the applied gate voltage is increased stepwise, the effective gate voltage is also increased stepwise to a value determined by the capacitor divider network of C1, C2, and Cox while V_D remains constant. For ISFET's this increase is small due to the large value of Cox compared to C1 and C2. As the voltage across C1 and C2 decreases due to R1 and R2, the effective gate voltage continues to increase until the applied gate voltage appears across Cox. In response to the change in effective gate voltage, the drain current increases and reaches its final steady-state value with a time constant characteristic of the membrane and the interfacial impedances. From the V_G-I_D curve of a typical ISFET in Fig. 6(a), the magnitude of change in I_D can be estimated as a function of device parameters. If V_G is stepped from A to B, I_D will increase from A′ to B′. The time constant of the response measured was found to be independent of step size or direction which is further evidence that it is determined by the membrane and associated interfaces.

When the drain voltage is pulsed, the response in I_D is more complex. A step increase in V_D will be capacitively coupled through Cox to the gate resulting in a stepwise increase in the effective gate voltage of approximately the same amount. The resulting change in drain current will be a large stepwise increase to a value which can be estimated by the V_D-I_D curves of the device which are shown in Fig. 6(b). If V_D is stepped from C to D, and V_G also initially increases approximately the same amount, I_D will go from C′ to D′.

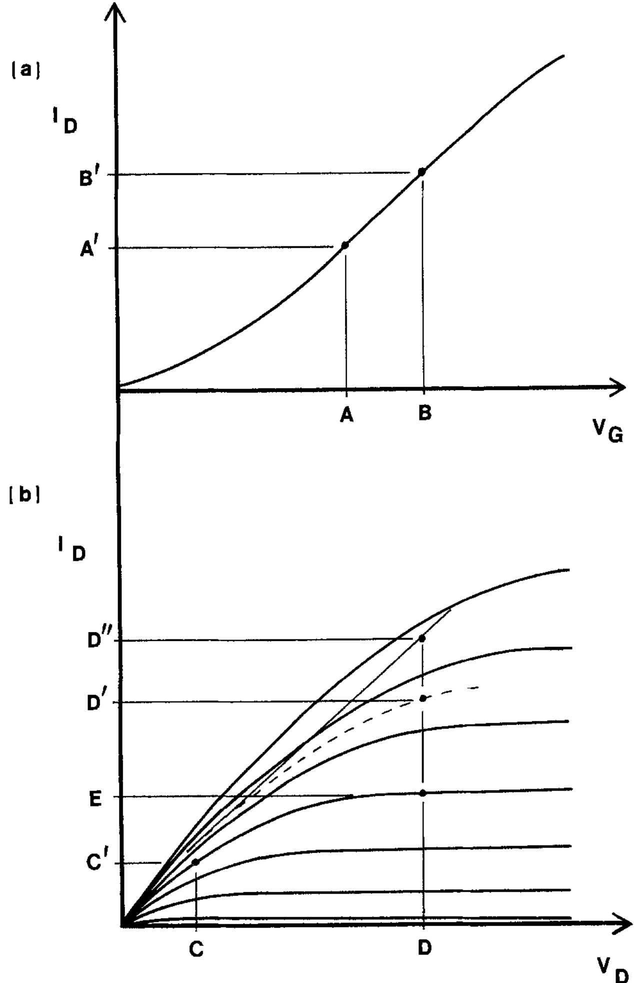

Fig. 6. Typical ISFET I-V characteristics. (a) I_D vs. gate voltage (V_G); (b) I_D vs. drain voltage (V_D).

As the increase in effective gate voltage is dissipated through the membrane model network of R_1C_1 and R_2C_2, and the effective gate voltage returns to the value of V_G which is applied, I_D decays with a time constant determined again by the membrane impedance. The final value of I_D is determined by the value of V_G applied and the new final value of V_D as indicated by E in Fig. 6(b). The difference between the values of I_D at D' and E is the overshoot defined in Fig. 2 (a).

We have found that interposition of gold between the membrane and the insulator of CHEMFET devices reduces the overshoot of the current response to a step increase in V_D (Table I, devices No. 8, 9, 12-15, 18, 22, 23, 25, and 26). The reduced overshoot of the gold devices cannot be explained solely by the CHEMFET model in Fig. 5. It should be remembered that the model is of an incremental section of the device and does not take into account the fact that V_D varies from drain to source as a function of y or distance from the source. A schematic diagram of the overall channel and the section (dy) considered in the model is shown in Fig. 7. From this figure, it can be seen that in order to represent the entire channel, a series of models could be connected by a lateral impedance with a different V_D at each node. The initial explanation of overshoot assumes an equipotential at the membrane/insulator interface in a lateral direction. This must be true in steady state for equilibrium conditions to be met at the interface. However, if the lateral impedance at the membrane/insulator interface is large, a lateral distribution in potential will be initially formed there in response to a step change in V_D. This potential distribution will match that which is formed along

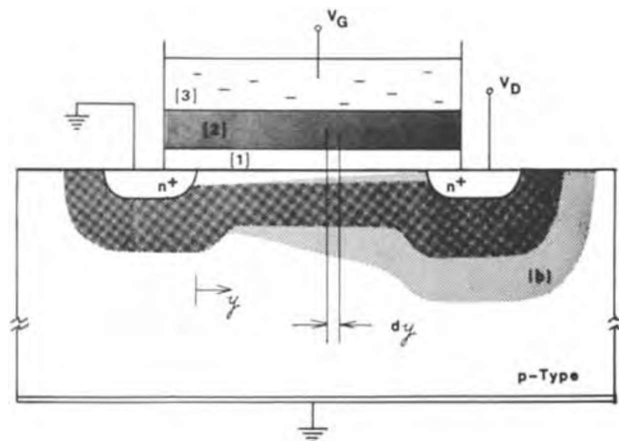

Fig. 7. An ISFET cross section indicating an incremental length along the channel (dy) where V_D may be assumed constant. The space charge and channel geometry for (a) $V_D < V_{Dsat}$ and (b) $V_D \geqq V_{Dsat}$ are shown. (1) insulator, (2) membrane, (3) solution.

the insulator/semiconductor interface. During this initial state, the field across the insulator does not change and therefore the channel resistance will remain approximately the same. The expected response in I_D will be a step increase which can be illustrated on the V_D-I_D curves if the slope of the curve is kept constant, as shown in Fig. 6(b) from C' to D''. From D'' I_D will decay back to E with a decay time determined by the longer of two relaxation times—one in the vertical direction and the other in the lateral direction. Assuming the membrane is an isotropic material, the impedance over any unit length will be the same in all directions. Therefore, the time response measured will be the same as that which was measured for a step change in V_G.

When a layer of gold or any conducting material is placed between the membrane and the insulator, the effect is to short out the lateral interfacial potential distribution. When a step increase is applied to V_D, the effective gate voltage will uniformly increase, independent of position along the channel. The field across the insulator then will not remain constant and the channel resistance will increase. The current overshoot will therefore be less, and can be estimated in the manner described for the sectional model.

This hypothesis was tested using a series of MOSFET's connected as shown in Fig. 8. Two tests were performed. In the first test, R_L was eliminated and the gates were shorted together. This corresponds to the devices with a gold layer as described above. In the second test, R_L was made very large (10 MΩ).

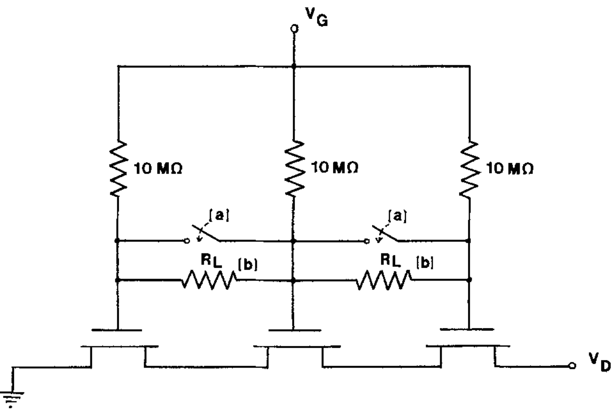

Fig. 8. Electrical circuit used to model effects of lateral potential distribution in the channel on time response of ISFET's (a) with and (b) without gold at the membrane/insulator interface.

When a step increase was made in V_D, an overshoot was observed which was approximately 40% larger than in the first test. This difference in overshoot is comparable to that which was measured on ISFET's (see Table I).

As stated earlier, current overshoot was reduced for all membrane devices when gold was introduced at the membrane/insulator interface. The time response, however, was not always reduced. Instead, it was membrane dependent (see Table I). This suggests that the effect on time response of the gold layer is not due to the change in lateral charge distribution but rather is dominated by the change in the vertical impedance at the interface. This change in impedance is represented by a change in the value of R_2 and C_2 in the lumped parameter model. Whether the impedance increases or decreases will depend on the properties of the gold/membrane interface.

Conclusion

The results of this study show that the time response of an ISFET is determined by membrane and gate structure. There are several applications of ISFET's where electrical time response information is important. Multisensor operation is one example. If several devices were to be operated in the same solution simultaneously, multiplexing of bias voltages may be necessary. The maximum rate of multiplexing would be determined by the number and types of membranes used.

Another application is in ISFET telemetry systems where power consumption is a major concern. To conserve power, switching of bias voltages to low values after sampling may be desired. The time response of the devices will then determine the maximum sampling rate possible.

Conduction Properties of Chemically Deposited Polycrystalline Silicon

T. Yoshihara, A. Yasuoka, and H. Abe

Mitsubishi Electric Corporation, LSI Development Laboratory, Itami, Hyogo 664, Japan

ABSTRACT

The relation between the conduction properties of the polycrystalline silicon films and process parameters such as the dose of implanted impurities, the deposition temperature, and heat-treatment were investigated. The doping concentration in polycrystalline silicon film was precisely controlled by ion implantation techniques. The trapping state density at the grain boundary which was the most important factor for the conduction properties of polycrystalline silicon was calculated using the doping concentration and experimentally obtained potential barrier height. It was found that the trapping state densities were $3.5 \times 10^{12}/cm^2$ for the boron-implanted polycrystalline silicon deposited at 700°C, and $5.2 \times 10^{12}/cm^2$ for the phosphorus-implanted polycrystalline silicon, respectively. The trapping state density was found to be reduced by increasing the deposition temperature or by the heat-treatment of the film at high temperature after the deposition of the polycrystalline silicon. It was also revealed that even a very small amount of oxygen caused the increase of the trapping state density.

Pyrolytic polycrystalline silicon has been widely used in silicon technology as gate electrodes, load resistors, and interconnections of silicon gate MOS devices, dielectric isolation, and polycrystalline silicon devices. Kamins (1) measured extensively Hall mobility of polycrystalline silicon films doped by a diffusion method and proposed the grain boundary trapping model in which the electrical conduction properties of the polycrystalline silicon were determined by the potential barrier of the space charge region originated from the trapping of carriers at the grain boundary of the films. Seto (2) measured the dependence of Hall mobility on temperature and reported the trapping state density of about $3.3 \times 10^{12}/cm^2$ for the boron-implanted polycrystalline silicon films. In this paper, the relation between the electrical conduction properties of the polycrystalline sili-

Key words: conduction, impurity, deposition.

con films and the dose of implanted impurities, the deposition temperature, heat-treatment and so on, will be described by observing the trapping state density.

Experimental

Polycrystalline silicon films of 0.5 μm in the thickness were deposited on silicon dioxide films thermally grown on silicon wafers by the thermal decomposition of silane diluted in hydrogen ambient at atmospheric pressure at a deposition temperature between 700° and 1050°C. The deposition of the polycrystalline silicon films was carried out using the vertical-type reaction system (Model AMV800), in which an rf heated carbon susceptor was used and gas was injected vertically. Boron (B) or phosphorus (P) impurities whose doses were from $4 \times 10^{13}/cm^2$ to $1 \times 10^{15}/cm^2$ were implanted into the as-grown polycrystalline silicon films at 50 keV and 80 keV in energy, respectively. In some experiments, the annealing of the as-grown polycrystalline silicon films was carried out in nitrogen ambient in the temperature range from 700° to 1180°C before ion implantation. B or P-implanted polycrystalline silicon films were annealed to activate these impurities in the films at 1100°C for 30 min in nitrogen ambient. The resistors were fabricated by a process flow shown in Fig. 1. The value of the resistivity was obtained from the Ohm's law region of *I-V* characteristics of the resistors, because, in the case of lightly doped polycrystalline silicon films, *I-V* characteristics deviated from the Ohm's law at the region of high electric field (3).

Experimental Results and Discussion

Trapping state density.—In Fig. 2 is shown the activation energy obtained from the slopes of logarithmic plot of resistivity *vs.* $1/kT$ for B or P-implanted polycrystalline silicon films as a function of the doping concentration N_d, whose value is calculated by dividing the total dose by the thickness of the polycrystalline silicon films. Since the thickness of the polycrystalline silicon is 0.5 μm, the value of the doping concentration N_d is from 8×10^{17} to $2 \times 10^{19}/cm^3$. It is noticed from Fig. 2 that the activation energy E_a is inversely proportional to the doping concentration N_d.

This experimental result can be interpreted by the grain boundary trapping model proposed by Kamins (1), Seto (2), and other authors (4) as described in the following.

The other model concerning the electrical properties of polycrystalline silicon is the segregation model (5), according to which the grain boundary acts as a sink for impurity atoms due to impurity segregation. It is described by Seto (2) and Baccarani *et al.* (5);

Sample Preparation

- o silicon wafer
- o oxidation (1um)
- o polycrystalline silicon deposition (0.5um)
- o (heat treatment)
- o ion implantation (B or P)
- o annealing (1,100°C or 1,000°C for 30 min. in N_2)
- o photolithography (polycrystalline silicon)
- o SiO_2 deposition (430°C, 0.8um)
- o photolithography (SiO_2 ething for contact window)
- o B or P diffusion (970°C for Ohmic contact)
- o metallization (Al)
- o photolithography (Al)

Fig. 1. Process flow chart of the sample preparation

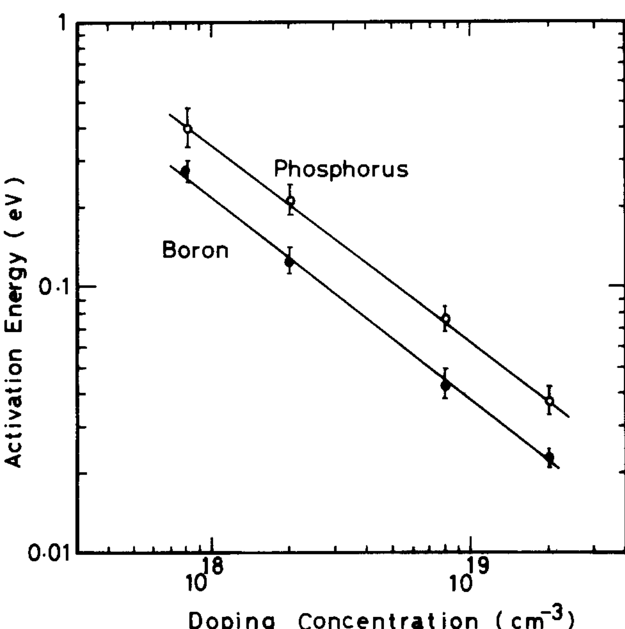

Fig. 2. The relation between the activation energy E_a of the B or P-implanted polycrystalline silicon and doping concentration N_d.

the limitation of this model is that it cannot explain the temperature dependence of resistivity of films which exhibit a negative temperature coefficient.

According to the grain boundary trapping model, there exist a large number of trapping states at the grain boundary in the polycrystalline silicon film. These trapping states are supposed to result from the incomplete atomic bondings. A space charge region is formed in the film by trapping free carriers, then a potential barrier is generated.

The height of this potential barrier can be obtained by solving the Poisson's equation under the appropriate boundary conditions. In our measurement of the resistivity of the films, as the applied voltage to the films is low, most of the measured current that flows across the grain boundary is expected to be caused by the thermionic emission over the potential barrier.

Seto (2) presented two kinds of the expressions for the resistivity due to the thermionic emission current across the grain boundary depending on the doping concentration.

In case I, in which the crystallite is partially depleted, that is, $LN_d > N_t$, where N_d is the doping concentration, N_t is the trapping state density, and L is grain size, the resistivity and the activation energy E_a can be written as follows

$$\rho = \frac{kT}{q^2 L N_d V_c} \exp (E_a/kT) \quad [1]$$

$$E_a = \phi = q^2 N_t^2 / 8\epsilon N_d \quad [2]$$

where ϕ is the potential barrier height at the grain boundary and equal to the activation energy E_a in this case, V_c is the collective velocity, and ϵ is the permittivity of silicon.

In case II, in which the crystallite is completely depleted the trapping states are partially filled, that is, $LN_d < N_t$, the resistivity ρ and the activation energy E_a are written as follows

$$\rho = \frac{2kT (N_t L N_d)}{q^2 L^2 N_c N_d V_c} \exp (E_a/kT) \quad [3]$$

$$E_a = \tfrac{1}{2} E_g - E_t \quad [4]$$

where E_t is the energy level of the trapping state referred to the intrinsic Fermi level, N_c is the effective

density of state, and E_g is the bandgap energy. In this case, the potential barrier height ϕ is given by

$$\phi = q^2L^2N_d/8\epsilon \quad [5]$$

which is proportional to the doping concentration N_d.

The experimental result that the resistivity depends exponentially on $1/kT$ can be interpreted by Eq. [1] or [3], because the temperature dependence of the term preceding the exponential term in the equations is small.

The result shown in Fig. 2 that the activation energy is inversely proportional to the doping concentration corresponds to Eq. [2], and then the crystallite is found to be partially depleted for the range of the doping concentration in our experiment. Thereafter, this experimental result is considered to mean that the activation energy E_a is equivalent to the potential barrier height ϕ at the grain boundary in the films.

Among the factors which relate to the potential barrier height as shown in the Eq. [2], the trapping state density is the most important one, because it determines the characteristics of polycrystalline silicon, while the doping concentration can be varied intentionally by changing the ion implantation dose.

The trapping state density at the grain boundary can be obtained from the Eq. [2] using the doping concentration N_d and the measured potential barrier height ϕ. In calculating the trapping state density, the amount of atoms which segregate at the grain boundary is assumed to be small for the range of doping concentration in this experiment (2, 4). The calculated trapping state density N_t are $3.5 \times 10^{12}/cm^2$ for B-implanted polycrystalline silicon and $5.2 \times 10^{12}/cm^2$ for the P-implanted one, respectively. The difference of trapping state density between the B and P-implanted polycrystalline silicon is considered due to the difference of the energy level of the trapping state density in the energy band (6). The value of N_t $3.5 \times 10^{12}/cm^2$ for the B-implanted sample is in good agreement with the value reported by Seto for the B-implanted sample deposited at 650°C (2).

Deposition temperature.—The electrical properties of the polycrystalline silicon film as well as the growth rate depend on the deposition temperature. In this experiment, the deposition temperature was varied from 700° to 1050°C. Figure 3 shows the dependence of the sheet resistivity on the deposition temperature.

The implanted dose of B is $1 \times 10^{14}/cm^2$. It is found that the sheet resistivity decreases as the deposition temperature is increased from 700° to 1050°C (7).

The potential barrier height can be calculated from the dependence of the sheet resistivity on the measuring temperature. In Fig. 4, the relation between the trapping state density N_t obtained by using the Eq. [2] and the deposition temperature is shown. In Fig. 4, the potential barrier height is also shown. It is found from Fig. 4 that the trapping state density N_t decreases when the deposition temperature is increased. In this experiment, the value of trapping state density varies from 3.5×10^{12} to $2.0 \times 10^{12}/cm^2$ for the range of the deposition temperature from 700° to 1050°C. These facts suggest that the incompleteness at the grain boundary of the grain boundary of the polycrystalline silicon can be improved by raising the deposition temperature.

It is probable the facts that the grain size becomes large (8) and the deposition rate is limited rather by the diffusion of the reactants than by the surface reaction (9) when the deposition temperature is increased are related to the decrease of the trapping state density.

Effects of heat-treatment.—In this experiment, the effects of the heat-treatment on the electrical characteristics of the polycrystalline silicon before ion implantation were investigated. The temperature of the heat-treatment of the polycrystalline silicon films was varied from 700°C (as-grown) to 1180°C.

The annealing after ion implantation was carried out at 1000°C in nitrogen ambient for 30 min to distinguish the effect of the heat-treatment before ion implantation from that of the annealing by lowering the annealing temperature from 1100°C. The implanted dose of B was $1 \times 10^{14}/cm^2$. Sheet resistivity decreases similarly as in the case of increasing deposition temperature when the temperature of the heat-treatment is increased. The dependence of the trapping state density and the potential barrier height ϕ on the temperature of the heat-treatment of the polycrystalline silicon is illustrated in Fig. 5.

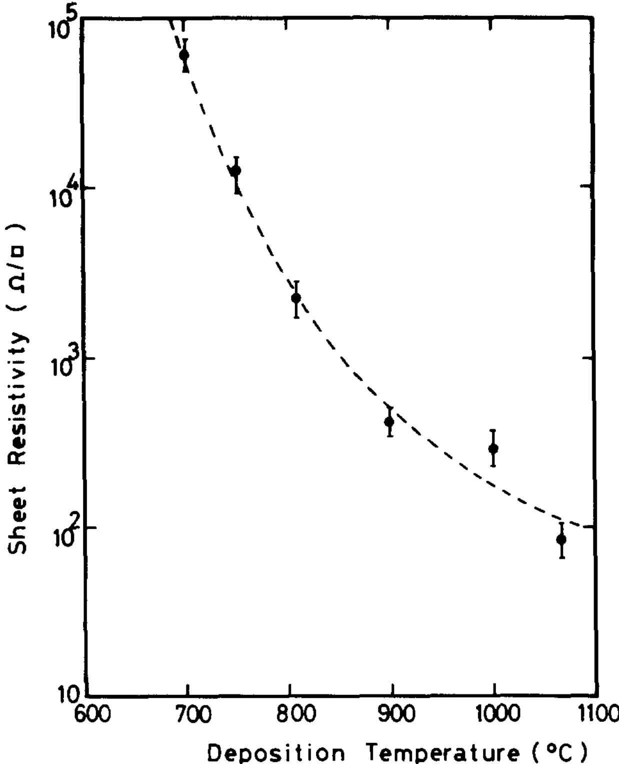

Fig. 3. Sheet resistivity of the B-implanted polycrystalline silicon as a function of deposition temperature. The implanted dose is $1 \times 10^{14}/cm^2$.

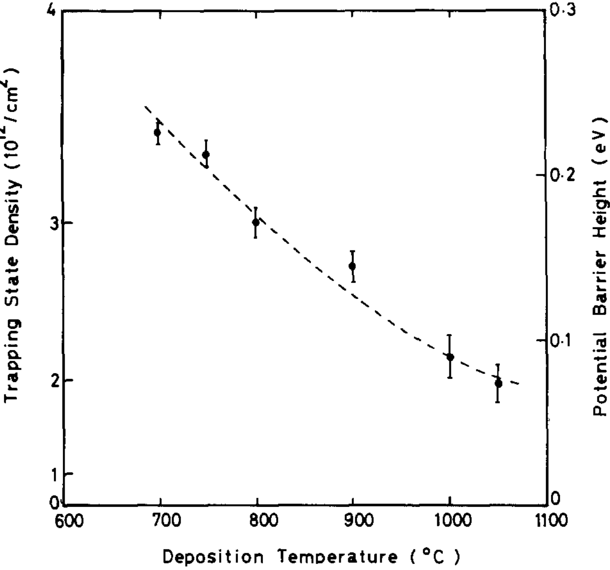

Fig. 4. Trapping state density and potential barrier height of the B-implanted polycrystalline silicon as a function of deposition temperature.

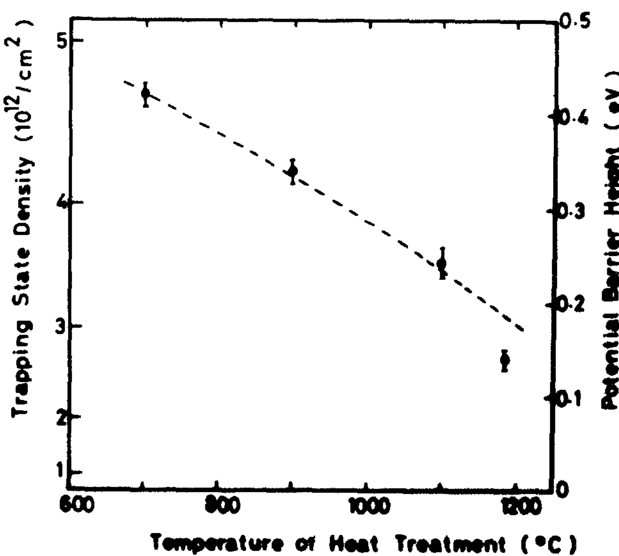

Fig. 5. Trapping state density and potential barrier height of the B-implanted polycrystalline silicon as a functon of temperature of heat-treatment before ion implantation. The deposition temperature is 700°C, and the dose is 1×10^{14}/cm^2. The annealing is carried out at 1000°C for 30 min in N_2.

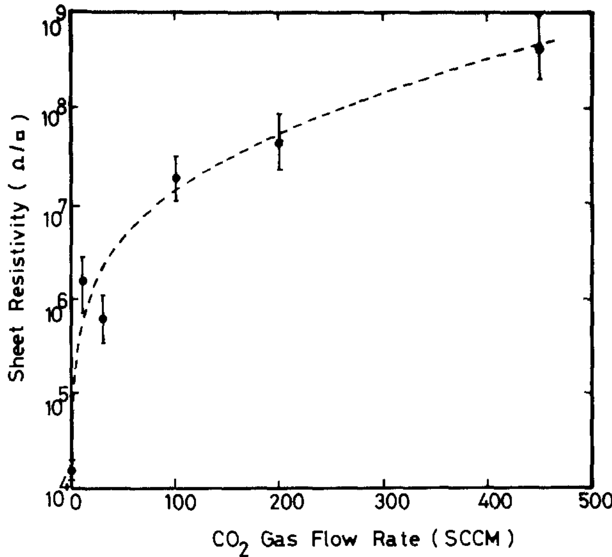

Fig. 6. The relation between sheet resistivity of the B-implanted polycrystalline silicon measured at 70°C and the flow rate of CO_2 gas mixed in reaction gas. The dose is 1×10^{14}/cm^2.

It is observed that the trapping state density N_t decreases from 4.5×10^{12} to 2.6×10^{12}/cm^2 with increasing heat-treatment temperature up to 1180°C. It seems that the rearrangement of the polycrystalline silicon at grain boundary occurs and causes the decrease of the trapping state density by heat-treatment before ion implantation as well as in the case of increasing deposition temperature.

Influence of oxygen.—The influence of oxygen on the crystallographical structure (10) and the electrical properties of the oxygen-rich polycrystalline silicon (11, 12) have been reported. In this experiment, CO_2 gas was mixed in reaction gas in order to investigate the influence of oxygen on the trapping state density.

CO_2 gas flow rate was changed up to 425 sccm while the flow rate of 5% silane diluted by Ar was 2500 sccm and that of H_2 carrier gas was 45 slpm, respectively.

In Fig. 6, the sheet resistivity of the B-implanted polycrystalline silicon is plotted as a function of the CO_2 gas flow rate. The dose of B is 1×10^{14}/cm^2. It is observed that the existence of a small amount of oxygen causes the abrupt increase of resistivity. In Fig. 7 are shown the relation between the trapping state density and the CO_2 gas flow rate. It can be seen that the trapping state density increases abruptly similarly with the case of sheet resistivity. In the range where CO_2 gas flow rate is small, as the initial state of polycrystalline silicon is pure, so even a very small amount of oxygen has a serious effect on the electrical properties of polycrystalline silicon. When CO_2 gas flow rate is increased, the electrical properties of the polycrystalline silicon is considered to change to that of semi-insulating materials. and then the rate of increase of trapping state is thought to become small.

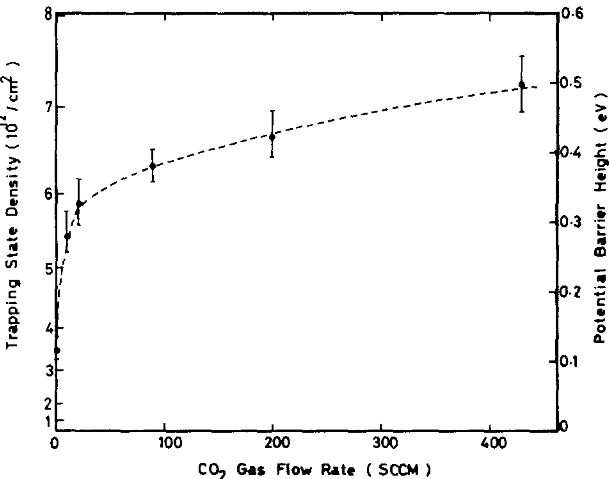

Fig. 7. Trapping state density and potential barrier height of polycrystalline silicon as a function of the flow rate of CO_2 gas.

Conclusions

The electrical conduction properties of the pyrolytic polycrystalline silicon have been investigated by observing the trapping state density at the grain boundary. The doping concentration in the film was precisely controlled by the ion implantation techniques, and its range was from 8×10^{17} to 2×10^{19}/cm^2. For this range of the doping concentration. it is revealed that the activation energy E_a obtained from the temperature dependence of resistivity is inversely proportional to the doping concentration N_d and therefore the activation energy E_a is found to be equivalent to the potential barrier height ϕ at the grain boundary of the film. The trapping state density estimated from the potential barrier height is about 3.5×10^{12}/cm^2 for the B-implanted film and 5.2×10^{12}/cm^2 for the P-implanted film, respectively.

The trapping state density is found to be reduced by increasing the deposition temperature of the polycrystalline silicon film or by the heat-treatment of the film after deposition, which seems to be attributed to the decrease of the incompleteness of the bondings of silicon at the grain boundary in the film. It is also found that even a small amount of oxygen caused the increase of the trapping state density. The P-doped polycrystalline silicon films also exhibit the same behavior as the B-doped films as functions of deposition temperature, heat-treatment, and oxygen.

Infrared Absorption and Microstructure of Li-Saturated Si-Doped GaAs

R. T. Chen* and W. G. Spitzer

Departments of Materials Science and Physics, University of Southern California, Los Angeles, California 90007

ABSTRACT

Infrared absorption, free carrier density, and transmission electron microscopy measurements have been correlated for n-type Si-doped GaAs samples with 1×10^{18} cm^{-3} $\lesssim$ [Si] $\lesssim$ 5×10^{19} cm^{-3}. The infrared absorption of the localized vibrational modes was measured after the samples were compensated by e^- irradiation or by ^{6}Li saturation diffusion. Comparisons of the results of the two compensation methods indicate that: (*i*) the Li-native defect acceptor complex is responsible in large part for the compensation after a 750°C Li diffusion; (*ii*) the degree of the Si site transfer from Ga to As lattice sites as a result of the Li saturation diffusion at 950°C is a function of [Si] and the Li-native defect donor is probably responsible for this transfer; (*iii*) samples that are heavily Si-doped have Si-rich faulted loops produced by a heat-treatment or Li diffusion at 750°C and this excess Si transfers to As sites if Li is diffused at 950°C; (*iv*) absorption cross sections of the Li-native defect donor and acceptor bands can be determined which account for the compensation of the Li-diffused Si-doped samples and also fit previously published data for Li-saturated pure GaAs. There is also the suggestion that, at least in the nondiffused, nonannealed more heavily Si-doped material, not all of the Si shows up in the localized mode measurements even though there is no observable microstructure.

Results are presented here of an investigation of the behavior of Si and Li when they are simultaneously present as impurities in GaAs. This system is a complicated one since the behavior of either Si or Li when individually present as an impurity in GaAs is complex. However, a combination of optical, electrical, and microstructural measurements yields considerable insight into the nature of this double-doped system. In this study one observes clearly the influence of Li saturation diffusions in GaAs:Si at various temperatures on the concentrations of both Li and Si defects for a variety of Si concentrations. The presence of the Si inhibits the formation of certain Li-native defect complexes while the presence of the Li can cause the transfer of Si from one type of lattice site (Ga) to another (As). The measurements of compensated samples permit an estimate of the infrared absorption cross sections of the prominent localized vibrational mode (LVM) bands previously attributed to the two most important electrically active Li-native defect complexes.

The Si site transfer effect in Li-diffused GaAs:Si has been observed previously but was not studied in any detail (1). The present investigation demonstrates that the site redistribution is a function of Si concentration. It also shows that the observed LVM absorption bands produced by Si-related defects in low temperature Li-diffused, heavily Si-doped samples do not account for all the Si. Transmission electron microscope (TEM) measurements of the heavily doped samples after Li diffusion reveal some microstructure which could account for the unobserved Si.

Background

Gallium arsenide doped with Si has been of particular interest in a number of studies because of the amphoteric behavior of the Si. Silicon substitution on a Ga site, Si_{Ga}, is a donor and on an As site, Si_{As}, is an acceptor. The distribution of Si on the two sublattices is known to vary with the Si concentration (2-4), the temperature of growth (2-7), the temperature and time of heat-treatment (8-12), the nature and concentration of other impurities (13-15), and the vacancy concentrations (1, 8-11). Electroluminescent (16) and photoluminescent (8-10) characteristics, LVM absorption band strengths (1-7, 11-15), and transport properties (17) of the GaAs:Si are dependent on the distribution of Si on the two lattice sites. Other Si defects such as Si_{Ga}-Si_{As} nearest neighbor pairs and Si_{Ga}-native defect complexes have also been proposed and studied.

Lithium is an electrically active impurity in semiconductors and has been the subject of many investiga-

* Electrochemical Society Active Member.
Key words: infrared absorption, microstructure, gallium arsenide, silicon impurity, lithium diffusion.

tions for both technological and scientific reasons. While lithium behaves as an interstitial donor in the elemental semiconductors Si and Ge, it is self-compensating in GaAs. Lithium can form either donor or acceptor defects in GaAs and can be used electrically to compensate either n- or p-type material. The relative concentrations of the different Li defects are controlled by the initial concentrations of electrically active impurities and by the tendency for self-compensation. There has been a considerable volume of literature (2, 18-29) dealing with the detailed behavior of Li in pure and doped GaAs, and as a result of these studies a number of specific defect species involving Li either with native defects or paired with other impurities have been identified.

The earlier studies of the GaAs:Si + Li system arose because of the Li behavior as an electrical compensator. In order to make infrared measurements of the LVM absorption bands in GaAs:Si it is necessary to reduce the free carrier absorption. The free carriers are present because heavily doped GaAs:Si is strongly n-type when grown from a nearly stoichiometric melt. One of the methods used for carrier removal was compensation by Li saturation diffusion at an elevated temperature. For reference Table I summarizes all LVM bands observed in GaAs:Si + Li as deduced from a number of studies (1-7, 11-14, 25, 29-31). Table I gives the peak absorption frequency for each band measured at liquid nitrogen temperature and the defect responsible for the band, where X_A refers to the species X on the A sites. According to the theory of localized vibrational modes the integrated absorption for each band is proportional to the volume concentration of the defect species responsible for the band. We refer to the constant of proportionality as the absorption cross section; $\int_{band} \alpha \, d\nu/[X_A]$, where α is the absorption coefficient and [ ] means concentration. The ν = 384 and 399 cm^{-1} bands in Table I are due to Si_{Ga} and Si_{As} and their absorption cross sections have been established (3, 4). The ν = 389 and 406 cm^{-1} bands are attributed to two electrically active ^6Li-native defect complexes, and the absorption cross sections for these bands are given in a later section of this work. These latter bands do not involve Si as they occur in Li-diffused undoped GaAs samples. The Si concentration does, however, play a significant role in determining the concentrations of these Li defect species. In Table I the band at ν = 367 cm^{-1} has not been assigned to a specific defect. It was previously assigned to the $^{28}Si_{Ga}$-$^{28}Si_{As}$ nearest neighbor pair defect, however, recent experimental evidence has lead to the conclusion that this assignment is not correct (4, 32).

The electrical compensation of GaAs:Si which is necessary for the infrared studies has been accomplished by saturation diffusions of either Li or Cu at elevated temperatures, *i.e.*, 700°C $\lesssim T_D \lesssim$ 1000°C, or by penetrating particle irradiation, *i.e.*, 1 to 2 MeV electrons or by neutrons (31). In a few cases partial compensation was achieved (6, 12) by counterdoping with a compensating impurity such as Zn during crystal growth. If one wants to study the distribution of Si among the various defects then a major difficulty of all the above procedures is that the compensation process may alter the Si distribution and even create Si-related defects which were not present in significant concentration prior to the compensation procedure. Ample evidence exists for such changes. Saturation diffusions of Li or Cu result in the formation of Si_{Ga}-Li_{Ga} or Si_{Ga}-Cu_{Ga} second neighbor pairs, and Li diffusion at $T_D \gtrsim$ 900°C can cause the transfer of substitutional Si from Ga to As sites (1). Also Li and Cu diffusions are done at temperatures, *i.e.*, $T_D \gtrsim$ 400°C, and times for which major aging effects have been observed (11, 33), and these effects are attributed to changes in Si defect concentrations as well as the formation of new defects. The compensation by electron irradiation is frequently done with the sample maintained near liquid nitrogen temperature during the irradiation to reduce thermal annealing. Subsequently the sample is allowed to warm to room temperature. There is the concern that native defects introduced by the irradiation might pair with some of the Si defects and thus alter the defect concentrations (31). In one study (3) the irradiation was continued to fluences approximately five times that necessary to render the samples transparent at frequencies where there is little lattice or LVM absorption. Essentially no changes were observed in the absorption at the Si_{Ga} or Si_{Ga}-Si_{As} LVM frequencies as a result of this extended irradiation fluence. Further measurements of the removal rate (31) for the Si_{As} band with increases in electron fluence indicate that for the total fluences used in the present study there should be no significant change produced in this band. As will be discussed the present measurements are in accord with this view. From the evidence available the e^--irradiation method of compensation appears to be the least disturbing to the precompensation distribution of Si defects and in the present work it is assumed that the Si defect concentrations are the same as the precompensated values.

The site transfer of substitutional Si from Ga to As sites in GaAs has been inferred in several studies. Two reports (8, 9) describe thermally related photoluminescence changes introduced in n-type Si-doped GaAs. In one case the change was by heating heavily doped crystals ($n_e \simeq 4 \times 10^{18}$ cm^{-3}) in hydrogen at 1050°C and the other case by heating lightly doped material ($n_e \simeq 3 \times 10^{16}$ cm^{-3}) in evacuated quartz ampuls at 900°C. These two studies indicate that Si atoms may transfer from Ga to As sites via an As vacancy mechanism. One more recent photoluminescence measurement (10) of lightly doped GaAs:Si ($n_e \simeq 3.3 \times 10^{16}$ cm^{-3}) which was annealed in vacuum at a temperature of 800°C has also resulted in the same conclusion. It was also reported (13, 15) that for heavily double-doped crystals of GaAs:Si + Te and GaAs:Si + Se, the effect of the Te or Se is to substantially enhance the fraction of the Si concentration, [Si], which resides on As sites and thus to reduce the [Si_{Ga}]. The effect of redistribution of Si between substitutional sites induced by the saturation diffusion of Li at elevated temperatures has been previously observed (1) only for Si-doped GaAs with $n_e \simeq 9.0 \times 10^{17}$ cm^{-3} and was not studied in any detail.

In the present study a comparison is made of the LVM absorption and microstructure for identically doped samples compensated either by ^6Li diffusion or by e^- irradiation as well as comparing the influence of different diffusion temperatures on the degree of Si site transfer. These comparisons are made by using sets of identical samples for the different treatments. Different sets of samples are used to cover a range of values for n_e and [Si].

Table I. A list of all observed LVM bands in ^6Li-diffused Si-doped GaAs

Mode frequency (cm^{-1})	Electrical character	Impurity	Defect
352

367	?	—	Si-related defect

Experimental Method

The samples were taken from several horizontal Bridgman-grown ingots which were doped with different Si concentrations. Some ingots were single crystals while others were polycrystalline but with very large single crystal sections, *i.e.,* typical dimensions of centimeters. The samples were always taken from the single crystal regions. The total Si concentration was $1 \times 10^{18}\ \mathrm{cm}^{-3} \lesssim [\mathrm{Si}] \lesssim 5 \times 10^{19}\ \mathrm{cm}^{-3}$ as estimated from the dopant added during crystal growth by using the known segregation coefficient and also from spectrochemical analyses. In a few cases the [Si] was also measured by using an electron probe microanalyzer.

All samples were first heat-treated at 1200°C for 1 hr and then quenched to room temperature, a process hereafter called HT + Q. The HT + Q treatment establishes a common thermodynamic background for all samples. It avoids some of the known and previously mentioned lower temperature aging effects for both the free carrier density, n_e and the Si defect concentrations. These aging effects are generally present in the as-grown material because of a cool-down cycle in the growth process. The carrier densities after HT + Q ranged from $1.0 \times 10^{18}\ \mathrm{cm}^{-3} \lesssim n_e \lesssim 8.0 \times 10^{18}\ \mathrm{cm}^{-3}$. The HT + Q procedure has essentially no effect on the n_e for material with $[\mathrm{Si}] \lesssim 1 \times 10^{18}\ \mathrm{cm}^{-3}$ but it substantially increases n_e for samples with $[\mathrm{Si}] \gtrsim 1 \times 10^{19}\ \mathrm{cm}^{-3}$. This procedure also significantly improves the microstructural quality of the material, particularly for the heavily Si-doped samples.

After the HT + Q treatment the free electron density of each sample was measured by determining the frequency of the free carrier plasma minimum observed in the infrared reflectivity. This method has been compared previously (34) with Hall measurement results and very good agreement was obtained. Before taking the measured n_e as the bulk value sufficient material was removed from the surfaces, ~0.1 mm, that the infrared reflectivity measurements of the plasma frequency indicated that further removal of material did not change the carrier density.

Several samples with nearly the same free carrier density were cut from the same section of each ingot and were divided into two groups. One group was compensated by e^- irradiation while the other group of samples was saturation diffused with ^{6}Li in an inert atmosphere, some at $T_D = 750°\mathrm{C}$ for 18 hr and others at $T_D = 950°\mathrm{C}$ for 2 hr. The diffusions were done with a "sandwich" arrangement in which the sample of interest was placed between two pure GaAs blocks which had previously been surface alloyed with ^{6}Li on the outer surfaces, *i.e.,* the surfaces not in contact with the sample to be diffused. This procedure substantially reduced the loss of material which occurs when the sample of interest is surface alloyed with Li directly. The details of the procedure used for the Li diffusions have been reported elsewhere (22). The samples of the first group were compensated by 1.4 MeV e^- irradiation while at temperatures $\lesssim 140°\mathrm{K}$ and with electron fluences of $\sim 1 \times 10^{19}\ e^-/\mathrm{cm}^2$.

The infrared absorption coefficient at liquid nitrogen temperature of the Li-diffused and the e^--irradiated samples was measured. The spectral range covered was $350\ \mathrm{cm}^{-1} \lesssim \nu \lesssim 500\ \mathrm{cm}^{-1}$ which contains the frequencies of all the absorption bands of interest in this study. The samples were generally about ~0.3 mm thick and had a wedge of ~0.2° to eliminate multiple reflection interference fringes. The absorption coefficient α was calculated from the transmission T by using the usual formula

$$T = I_{\mathrm{Sample}}/I_o = (1 - R)^2 \exp(-\alpha x)/1 - R^2 \exp(-2\alpha x)$$

where R is the reflectivity and x is the sample thickness.

After the infrared transmission measurements all Si-doped samples, as well as some pure GaAs samples which had been saturation diffused with ^{6}Li, were used to prepare specimens for transmission electron microscope measurements (35). The TEM specimens were examined by a Hitachi HU-125C microscope operated at 125 kV. Measurements were also made of the HT + Q, Si-doped materials before Li diffusion as well as undoped samples and they were free of microstructure except for an occasional dislocation loop. In particular the samples showed no stacking faults or precipitates while the Si-doped samples which had not been given the HT + Q treatment, *i.e.,* in the as-grown condition, were found to have frequent extrinsic stacking faults, particularly those samples having the larger [Si] (36).

Results and Discussion

In this section the results are presented in the following order:

1. The changes introduced by Li diffusion into GaAs:Si at 750°C are examined by comparison with e^--irradiated samples. Some of the irradiated samples will have no prior annealing while others were thermally aged at 700°C prior to the irradiation.
2. A comparison is made of samples which have been Li-diffused at two different temperatures and the Li-induced Si transfer from Ga to As sites is examined including the [Si] dependence of the transfer process.
3. The possible role of the known Li-native defect complexes in the Si site transfer process is explored.
4. The LVM absorption measurements of the Li saturation diffused GaAs:Si samples are used with other data to estimate the absorption cross sections of the two bands arising from the two electrically active Li defect complexes. These cross sections are then tested by applying them to previously reported LVM measurements of Li-saturated undoped GaAs.
5. TEM results for the microstructure of the Li-diffused samples are discussed and correlated to the LVM measurements and the Si site transfer observations.

Changes in defect structure and concentration resulting from ^{6}Li saturation diffusion at 750°C.—One of the primary purposes of the present study is to investigate the site transfer of Si in GaAs:Si which results from ^{6}Li saturation diffusions at an elevated temperature, *i.e.,* 950°C. This effect is demonstrated by direct comparisons with samples diffused at a lower temperature of 750°C where the transfer process is found to be negligible. However, before reviewing the data for the above comparison it is of interest to inquire first into the changes introduced by Li diffusion at 750°C as compared to the prediffused state. The LVM spectra of the prediffused state is taken to be that of the e^--irradiatea samples. As mentioned previously, the heavily doped GaAs:Si undergoes changes due to thermal aging at temperatures such as 750°C and therefore the effect of the diffusion on Si distribution could be the result of the 750°C diffusion temperature and/or the presence of a large Li concentration.

To demonstrate the changes three absorption curves are used, one for a sample which was Li saturated at 750°C, a second e^- irradiated, and a third annealed near 750°C and then e^- irradiated. These comparisons allow one to attribute the changes as due primarily to Li saturation or due to thermal annealing at the diffusion temperature.

Figure 1 shows the LVM absorption bands for three samples of nearly equivalent $[\mathrm{Si}] \simeq 5 \times 10^{19}\ \mathrm{cm}^{-3}$ and $n_e \simeq 8 \times 10^{18}\ \mathrm{cm}^{-3}$ after the HT + Q treatment. Sample 7-a, see curve I, was compensated by ^{6}Li saturation diffusion at 750°C and sample WA-2-3 was electron irradiated, see curve II. The data for these

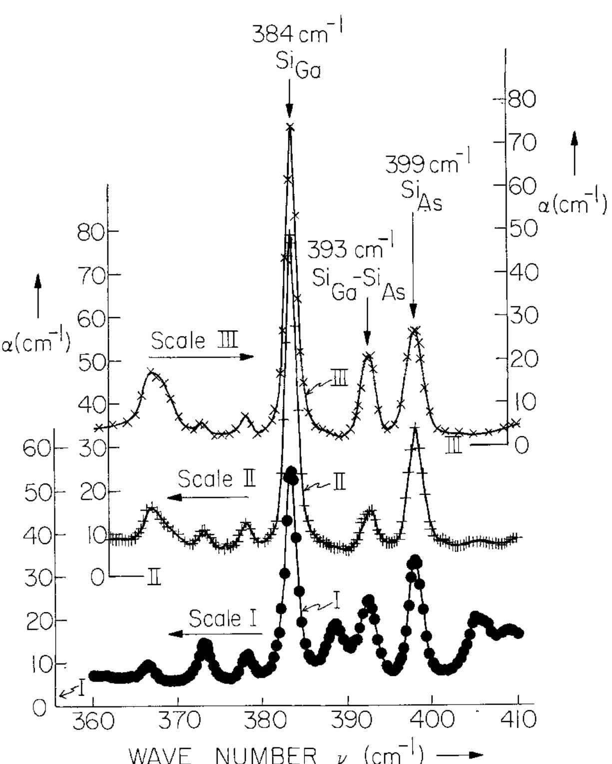

Fig. 1. Infrared absorption spectrum at liquid nitrogen temperature for three GaAs:Si samples having nearly equivalent [Si] $\simeq$ 5 $\times$ 10^{19} cm^{-3} and with initial $n_e \simeq 8 \times 10^{18}$ cm^{-3} after 1200°C/1 hr + quench (see Table II). Curve I: sample 7-a, 750°C ^{6}Li diffused. Curve II: sample WA-2-3, compensated by e^- irradiation. Curve III: sample annealed at 700°C then compensated by e^- irradiation.

two samples including the integrated absorption ($\alpha_p\Delta$) of the LVM are among those of Table II, where α_p is the peak LVM absorption coefficient with the background removed and Δ is the bandwidth at half-maximum. Curve III of Fig. 1 is for the third sample which was annealed at 700°C before being compensated by electron irradiation. The $(\alpha_p\Delta)_{399}$ is the same for the three samples indicating that the [Si_{As}] is independent of the compensation method or thermal aging as long as the temperatures involved are ~750°C. The Si_{Ga}-Si_{As} nearest neighbor pair band at 393 cm^{-1} is the same for the annealed sample and the diffused sample but they both are approximately twice the value for the nonannealed, nondiffused sample. This indicates that there is a substantial increase in [Si_{Ga}-Si_{As}] for the diffused and annealed samples, and this increase is clearly a thermal effect rather than the result of the presence of a large [Li]. The $(\alpha_p\Delta)_{384}$ for the Si_{Ga} band of the annealed sample is 102.5 cm^{-2} which is below the 117.3 cm^{-2} of the nonannealed sample, but significantly larger than the 78.3 cm^{-2} of the diffused sample. The decrease of [Si_{Ga}] in the diffused sample therefore appears to be largely a combination of thermal aging and the formation of (Si_{Ga}-Li_{Ga}) pairs which give rise to the bands at 374, 379, and 405 cm^{-1}, see Table I and Fig. 1-curve I. Several other bands are observed in the absorption spectra of Fig. 1. The weak bands near 374 and 379 cm^{-1} in the nondiffused samples are due to the LVM of the $^{30}Si_{Ga}$ and $^{29}Si_{Ga}$ and they superimpose upon two of the $^{28}Si_{Ga}$-Li_{Ga} bands, see curve I. The 367 and 369 cm^{-1} bands are poorly resolved and are related to unknown defects involving Si; see Ref. (4) for a discussion of these modes. The 389 cm^{-1} band in the diffused sample is due to a Li-native defect complex which is not Si related, see Table I.

These results necessitate a reinterpretation of some previously published data in which the samples were not given the HT + Q treatment prior to electron irradiation or ^{7}Li diffusion at 700°C (30). This prior comparison between Li diffusion and e^- irradiation was therefore between samples which had been thermally aged in an unknown temperature profile during the growth process. Therefore, the effective anneal temperature is unknown although a temperature zone of ~800°C was used after the growth zone.

A more complete comparison of the nonannealed, e^--irradiated, and 750°C ^{6}Li-diffused cases for different [Si] is given by the data of Table II. In all cases the absorption was measured at liquid nitrogen temperature. The data of Table II were taken from samples such as those in Fig. 1. The data for the irradiated samples were also used in Ref. (4) where they are discussed in detail. From Table II it is seen that the changes observed in Fig. 1 and the conclusions based on those changes appear to apply generally with larger changes being observed at higher [Si]. In particular, it can be concluded that the saturation diffusion of Li at 750°C produces no change in the concentration of Si_{As} acceptors, significant increases in the concentration of Si_{Ga}-Si_{As} nearest neighbor pairs, and decreases in the concentration of Si_{Ga} donors with all changes being measured relative to the prediffused state. With this information we may now examine the changes which occur when the saturation temperature is increased.

Si site transfer induced by Li saturation diffusion.—Figure 2 and curve I of Fig. 3 show the absorption coefficient of three samples having different [Si] which were ^{6}Li diffused at 950°C. Each of these samples is similar to one of those diffused with ^{6}Li at 750°C. The results of 750° and 950°C saturation diffusions of ^{6}Li are summarized quantitatively in Table III for pairs of initially similar samples. Comparisons indicate that the 384 and 399 cm^{-1} bands of the Si_{Ga} and Si_{As}, respectively, have changed their relative strengths while the other Si-related bands remain essentially unchanged. The 384 cm^{-1} band is reduced and the 399

All were ^{6}Li diffused and in one case subsequently outdiffused. Curve I: sample 4-b, 950°C/2 hr ^{6}Li diffused. Curve II: sample 4-c, 900°C/3 hr ^{6}Li diffused. Curve III: sample 4-a, 750°C/18 hr ^{6}Li diffused. Curve IV: sample 4-c′, 900°C/3 hr ^{6}Li diffused + 700°C/24 hr ^{6}Li outdiffused.

cm^{-1} band enhanced for the higher diffusion temperature suggesting site transfer of Si from Ga to As sites has been produced. This relative decrease of the 384 cm^{-1} band after the higher temperature diffusion decreases with increasing [Si] while the relative increase for the 399 cm^{-1} band increases. The Si_{Ga}-Si_{As} pair band strengths at 393 cm^{-1} are almost the same for two diffusion temperatures for each set of samples indicating that the large annealing-induced increase observed at 750°C does not continue with increased Li diffusion temperature. There is no consistent pattern of change and the observed changes are small between the two diffusion temperatures for all other bands.

One can examine site transfer hypothesis quantitatively if the absorption cross sections of the Si defect bands are known. In a recent study (4) the cross sections of Si_{Ga}, Si_{As}, and two other Si-related defect bands were measured for a number of melt-grown Bridgman, HT + Q samples having [Si] and n_e in the range of those used here. All samples were compensated by e^- irradiation. Assuming the $^{28}Si_{Ga}$ donor (384 cm^{-1} band), $^{28}Si_{As}$ acceptor (399 cm^{-1} band), and two other Si-related defects (367 and 369 cm^{-1} bands) to be electrically active defects then the reciprocal absorption cross sections were determined to be $a = 10.0 \times 10^{16}$ cm^{-1}, $b = 12.7 \times 10^{16}$ cm^{-1}, $c = 25.3 \times 10^{16}$ cm^{-1}, and $d = 19.0 \times 10^{16}$ cm^{-1}, where

$$n_e = a(\alpha_p\Delta)_{384} - b(\alpha_p\Delta)_{399} + c(\alpha_p\Delta)_{367} - d(\alpha_p\Delta)_{369}$$
$$= [Si_{Ga}] - [Si_{As}] + [Si]_{367} - [Si]_{369}$$

As indicated by the signs the charge status found for 367 and 369 cm^{-1} bands are donor and acceptor, respectively. For all of the Li-diffused samples shown in Table III the 369 cm^{-1} band is not observed and the 367 cm^{-1} band is always small and has almost no change in value at different diffusion temperatures. If one assumes that site transfer of Si_{Ga} to Si_{As} is the only mechanism responsible for the changes in the Si
