** $\delta(\alpha_p\Delta) = (\alpha_p\Delta)$ at 950°C − $(\alpha_p\Delta)$ at 750°C.

band strengths of the isolated Si species, then one has $\delta[Si_{Ga}] = -\delta[Si_{As}]$ and thus

$$\beta = \delta(\alpha_p\Delta)_{384}/\delta(\alpha_p\Delta)_{399} = +b/a = +1.27$$

Table IV gives the values for β calculated from Table III and Fig. 4 gives β as a function of n_e. At the lower values of n_e most of the change is indeed accounted for by Si site transfer. However, as n_e and [Si] increase the value of β decreases and the change becomes progressively less due to $Si_{Ga} \rightarrow Si_{As}$. Since the other Si defect concentrations do not appear to change significantly, the large increases in $(\alpha_p\Delta)_{399}$ must be due to transfer of Si to Si_{As} from some state or states not detected by the LVM measurements made after 750°C Li diffusion. For the samples of largest [Si] this latter process dominates the change. From the TEM measurements mentioned previously it is known that there are no precipitates, inclusions, or extrinsic stacking faults in the prediffused samples. Later, TEM measurements will be presented of both 750° and 950°C Li-diffused samples which show that Si-rich loops form at 750°C and disappear at 950°C for the more heavily Si-doped material. Also GaAs:Si samples which were annealed at 900° and 1000°C and then e^- irradiated showed no evidence for the Si site transfer process. The large Li donor concentration present under the conditions of the high temperature saturation diffusion apparently enhances the formation of Si_{As} acceptors. One may thus conclude that site transfer of Si from Ga to As sites is indeed observed for the high temperature Li diffusion. The site transfer is not simply a thermal process, *i.e.*, the presence of the Li is required. Comparisons between low and high temperature Li-saturated samples indicate that at the low [Si] almost all of the $[Si_{As}]$ gain for the high temperature case is the result of Si_{Ga} site transfer while at the highest [Si] almost all the $[Si_{As}]$ gain results from some other source of Si.

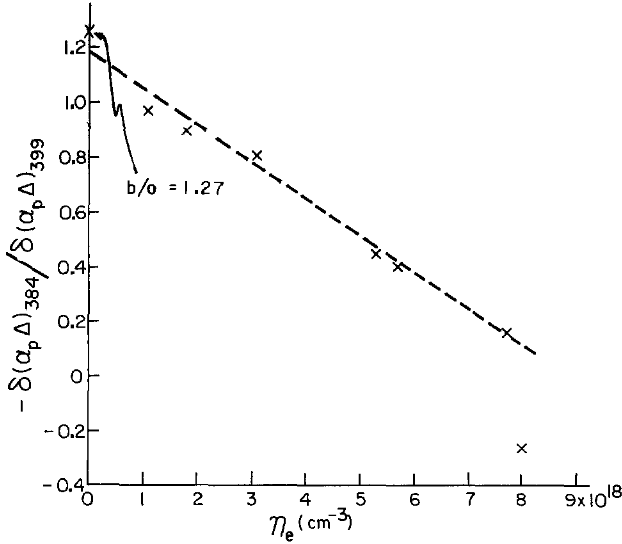

Fig. 4. A plot of $\beta = -\delta(\alpha_p\Delta)_{384}/\delta(\alpha_p\Delta)_{399}$ vs. initial n_e for all of the samples of Table IV. For site transfer only $\beta = 1.27$.

Possible role of Li-native defect complexes in Si site transfer.—From the preceding section we concluded that the presence of the Li was required to produce the site transfer and increase in $[Si_{As}]$. It is of interest to inquire whether one can detail in any way how the Li is instrumental in producing this effect and why the higher diffusion temperature is required.

The strengths of the Li-lattice defect complex bands induced by ^{6}Li diffusion of pure GaAs are very small for a low diffusion temperature (21), *i.e.*, at $T_D \lesssim$ 750°C, and they increase monotonically with T_D. The 389 cm^{-1} (acceptor) and 406 cm^{-1} (donor) bands are known to be the only two bands induced by Li-lattice defect complexes which are electrically active. For pure GaAs the ratio $(\alpha_p)_{406}/(\alpha_p)_{389}$ is approximately 2 at higher diffusion temperatures, $T_D \gtrsim$ 800°C (21, 22).

Examination of all absorption curves for ^{6}Li-diffused, Si-doped GaAs samples with different initial n_e and [Si] which were diffused at lower temperatures, *i.e.*, $T_D \lesssim$ 750°C, indicates that the 389 cm^{-1} acceptor band is the only Li-lattice defect band observed with significant strength and it increases in samples with higher n_e and Si values as shown in Table V. This indicates that the growth of the 389 cm^{-1} Li-native defect acceptor band may be a significant factor in the compensation of Si-doped GaAs for the lower temperature diffusions. As a comparison this result is quite different from that of Li-diffused p-type GaAs for a similar diffusion temperature. In this latter case, no Li-lattice defect bands are observed. In particular the 389 cm^{-1} band is absent. The compensation is completely accomplished (28) by forming Li_i-Mg_{Ga} (or -Zn_{Ga}, or -Cd_{Ga}, or -Mn_{Ga}) neutral pairs.

For the high temperature diffusion, $T_D \simeq$ 950°C, the Li-lattice defect complex bands in the present samples have increased substantially. To illustrate this Fig. 3 shows the absorption curves for four GaAs:Si samples having a common origin and identical n_e values but ^{6}Li diffused or outdiffused at different temperatures. Comparisons between these curves indicate that the saturation concentration of Li increases due to a higher diffusion temperature, the 389 and 406 cm^{-1} Li-lattice defect bands both increase, however, the growth rate of 406 cm^{-1} Li-lattice donor band is much larger than that of the 389 cm^{-1} acceptor band. It is this donor formation which likely provides the mechanism producing Si acceptor formation by the transfer of Si to As sites from other defects. When Li is outdiffused at a lower temperature the absorption curve tends to return to the curve it would have if indiffused at that temperature; see curve IV of Fig. 3. In particular, the site transfer produced in a 900°C diffusion has reversed and the 406 cm^{-1} band has disappeared. Furthermore, a 950°C ^{6}Li rediffusion after a 750°C diffusion produces Si site transfer with similar LVM curves as a sample diffused initially at 950°C.

Table V. Comparison of the $(\alpha_p)_{389}$ values for all 750°C ^{6}Li-diffused samples

Sample No./ T_D of ^{6}Li (°C)	n_e* (cm^{-3})	$(\alpha_p)_{389}$ (cm^{-1})

6-b/950	7.7×10^{18}	14.2	99.1	~7
7-b/950	8.0×10^{18}	14.6	53.4	~4

* Measured values.

Table VI shows that the $(\alpha_p)_{406}/(\alpha_p)_{389}$ ratio in general increases with increases of n_e for samples which are ^{6}Li diffused at 950°C for 2 hr. This observation is consistent with the result that in more heavily doped samples more Si transfers to As sites producing more acceptors.

The conclusion here is that the primary Li defect responsible for the enhancement of the Si_{As} concentration is the Li donor responsible for the LVM band at 406 cm^{-1} (for ^{6}Li). The increase in the concentration of this Li defect with temperature as measured by the LVM absorption is the reason why the site transfer requires the high diffusion temperature. The concentration of this Li defect and the Si_{As} both increase with the total [Si].

Absorption cross sections of Li-native defect complex bands.—From the discussion in the previous section we see that the electrically active defects in the Li-saturated samples are the Si_{Ga} donor, the Si_{As} acceptor, the Si-related donor responsible for the 367 cm^{-1} band, the Li donor responsible for the 406 cm^{-1} band, and finally the Li acceptor giving the 389 cm^{-1} band. One can now use this information to obtain the absorption cross sections for the Li bands. For all of the 750° and 950°C ^{6}Li-diffused samples of Table III one can use the fact that the samples are highly compensated after diffusion to obtain

$$n_e = 0 = a(\alpha_p\Delta)_{384} - b(\alpha_p\Delta)_{399} + c(\alpha_p\Delta)_{367} + E(\alpha_p\Delta)_{389} + F(\alpha_p\Delta)_{406}$$

where a, b, and c have been previously given. If the two Li defects are singly charged then E and F are the reciprocal cross sections for the Li defect bands. If either Li defect is a doubly charged donor or acceptor then the corresponding coefficient contains a factor of 2. For the 389 and 406 cm^{-1} bands our best estimated values of Δ are 2.4 ± 0.2 and 3.4 ± 0.2 cm^{-1}, respectively. Both of these bands overlap other bands which frequently made determinations of Δ difficult. Figure 5 shows a plot of $(\alpha_p\Delta)_{406}/\eta$ *vs.* $(\alpha_p\Delta)_{389}/\eta$. Here

$$\eta = -[a(\alpha_p\Delta)_{384} - b(\alpha_p\Delta)_{399} + c(\alpha_p\Delta)_{367}] = E(\alpha_p\Delta)_{389} + F(\alpha_p\Delta)_{406}$$

where all samples of Table III except sample 2-b are included. Sample 2-b was omitted because η was orders of magnitude smaller than for the other samples. Also note that $d(\alpha_p\Delta)_{369}$ is omitted as that band does not occur in Li-diffused samples. The line in Fig. 5 is a least squares fit which gives values for E and F of

$$E = -9.7 \times 10^{16} \, cm^{-1}$$

$$F = +2.8 \times 10^{16} \, cm^{-1}$$

where the signs indicate the 389 cm^{-1} band is an acceptor and the one at 406 cm^{-1} is a donor as expected from previous assignments. Application of these values for E and F and the n_e equation given above to the

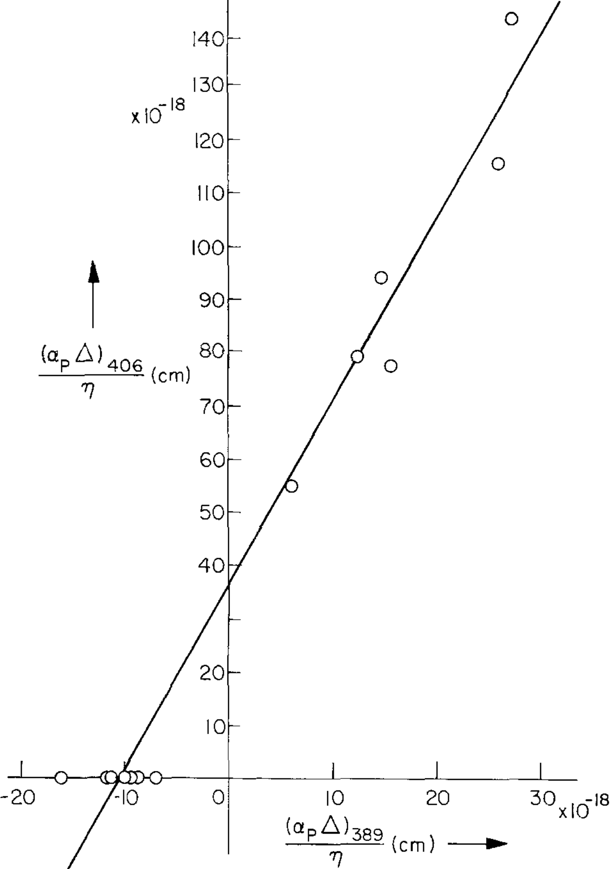

Fig. 5. $(\alpha_p\Delta)_{406}/\eta$ vs. $(\alpha_p\Delta)_{389}/\eta$ for the samples of Table III. The line is a least squares fit which yields values of $E = -9.7 \times 10^{16}$ cm^{-1} and $F = +2.8 \times 10^{16}$ cm^{-1} (see text).

samples of Table III yields n_e values for all cases save one which are <6% of the sum of all the defect concentrations used in the n_e equation. The single exception is sample 2-a where the figure is 11%.

When ^{7}Li is used as the diffusant in place of ^{6}Li then the Li bands have an isotope shift (22) with the 389 $cm^{-1} \rightarrow$ 364 cm^{-1} and the 406 $cm^{-1} \rightarrow$ 379 cm^{-1}. For the same Li concentrations there is also a change in α_p with $(\alpha_p)_{389}/(\alpha_p)_{364} = (\alpha_p)_{406}/(\alpha_p)_{379} = 1.30$. Since the Δ shows almost no change with Li isotope one has

$$E(^7\text{Li}) = 1.30E(^6\text{Li}) = -12.6 \times 10^{16} \, cm^{-1}$$

$$F(^7\text{Li}) = 1.30F(^6\text{Li}) = +3.6 \times 10^{16} \, cm^{-1}$$

As a test of the validity of these values they can be applied to the LVM results previously published (22) for ^{7}Li saturation diffusion in pure GaAs for 700°C $\lesssim T_D \lesssim$ 950°C. Near 700°C the E and F values with the previous data indicate almost exact compensation in agreement with experiment. However, at 900°C the estimated n_e is approximately 10% of the total Li donor and acceptor charge concentration if one still assumes that the 389 (364) and 406 (379) cm^{-1} defects are the only electrically active ones. Experimentally the samples are highly compensated and high resistivity.

One can also use the above values of E and F to estimate the total [Li] in the saturated pure material. From previous work (22) it is known that the 389 (364) cm^{-1} acceptor complex has 2 Li per defect and the 406 (379) cm^{-1} donor defect has 3 Li. Therefore the total [Li] due to these two defect centers only is

$$N = 2|E(^7\text{Li})|(\alpha_p\Delta)_{364}/n + 3|F(^7\text{Li})|(\alpha_p\Delta)_{379}/m$$

where n and m are the acceptor and donor defect charge states, respectively. Assuming $n = m = 1$ the calculated values for N are the points in Fig. 6 and they can be compared with the total [Li] which is

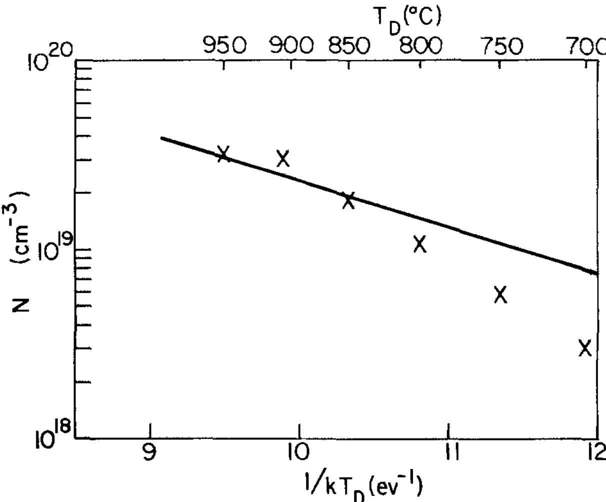

Fig. 6. A plot of ln$N$ vs. $1/kT_D$ for the ^{7}Li diffused pure GaAs samples in Ref. (22). Here $N = 2\,|E(^7Li)|\,(\alpha_p\Delta)_{364} + 3\,|F(^7Li)|\,(\alpha_p\Delta)_{379}$ which is the total [Li] due to these two defect centers (assuming $n = m = 1$, see text). A straight line is the total [Li] measured by Fuller and Wolfstein [see Ref. (18)].

given by the straight line determined by the flame spectrophotometric analysis measurements of Fuller and Wolfstirn (18). While there is reasonable agreement between the calculated points and the line there are several difficulties. First, there is no independent evidence that $n = m = 1$. Second, the LVM measurements show additional bands due to the other Li defects and they are not included in the calculated N values. Third, the determination of E and F depends on the prior knowledge of a, b, and c which means that the value of N involves a number of parameters known with only limited accuracy. In view of the uncertainties the qualitative agreement in Fig. 6 is considered to be very satisfactory. Therefore the reciprocal cross sections for the Li-donor and Li-acceptor defects are consistent with the data for the compensation of Li-saturated GaAs:Si, the compensation of Li-saturated pure GaAs and the total [Li] in the Li-saturated pure GaAs.

Microstructures of ^{6}Li-diffused samples.—The extent and nature of the microstructure of ^{6}Li-diffused samples depend both on the starting material, particularly the [Si], and on the temperature of the diffusion. It will help to clarify the results if they are discussed by groups of samples as follows:

(*i*) As previously mentioned nondiffused, nonannealed, HT + Q samples had no significant observable microstructure even for the highest [Si] used in this study.

(*ii*) Pure GaAs samples ^{6}Li diffused at $T_D \simeq 750°$, 900°, and 950°C were measured and showed Li precipitates and some dislocations which tend to be pinned by the precipitates. Some extrinsic stacking faults on {111} planes which may be related to the Li metastable phase were also observed in the 750°C diffusion. The size and density of Li precipitates decrease with decreases in diffusion temperature. In the case of the 950°C diffused samples, the average size of Li precipitates is approximately 1000Å and their density is approximately 9.5×10^{12} particles/cm^3. These observations are in agreement with those reported previously (24).

(*iii*) ^{6}Li-diffused samples at $T_D = 750°$C with low [Si] and $n_e \lesssim 3.0 \times 10^{18}$ cm^{-3}, as in sets No. 1 to 3 of Table III, have a microstructure which is similar for the 750°C ^{6}Li-diffused pure GaAs material described in case (*ii*). There were however, no extrinsic stacking faults observed. Thermal annealing with $T_D \gtrsim 400°$C of nondiffused samples with [Si] $\simeq 1.5 \times 10^{18}$ cm^{-3}, *i.e.*, set No. 1, resulted in no observable microstructure as in the HT + Q state.

(*iv*) ^{6}Li diffusion at $T_D = 750°$C for the samples with high [Si] $\gtrsim 2 \times 10^{19}$ cm^{-3} and $n_e \gtrsim 5.0 \times 10^{18}$ cm^{-3}, as in sets No. 4 to 7 of Table III, induces a high concentration of defects. Samples 4-a and 5-a with [Si] $\simeq 2 \times 10^{19}$ cm^{-3} show a microstructure with primarily triangular-shaped faulted loops, as shown in Fig. 7a. The loops are on four {111} planes of a tetrahedron and have the displacement vector $\vec{R}_F = a/3$ [111]. To the best of our knowledge this kind of defect has not been reported previously. Similar defects are also observed in the material with similar [Si] $\simeq 2 \times 10^{19}$ cm^{-3} when annealed at 750°C without ^{6}Li diffusion, and their density is similar to that of 750°C ^{6}Li-diffused samples, but they are about three time smaller in linear dimension. By using two different and independent TEM analyses (37, 38) we have established that these triangular loops are extrinsic faults and microanalysis with a scanning electron microscope (SEM) shows that they have a large Si content. We therefore conclude that these triangular loops are due to Si precipitation from GaAs:Si solution, however, the mechanism of their formation is unknown as is the reason for the observed morphology. The microstructure of samples 6-a and 7-a which have the highest [Si] $\simeq 5 \times 10^{19}$ cm^{-3} show primarily circular loops which are also on four {111} planes of a tetrahedron as shown in Fig. 7b. The TEM analysis (38) has established that these circular loops are also of the extrinsic type. As seen in Fig. 7b the loops here are much smaller than those in Fig. 7a making the SEM measurement difficult. However it seems reasonable to assume that the circular loops are due to Si precipitation from GaAs:Si solution as in the case of the triangular loops. Typical dimension of these loops is ~2500Å for the sample with [Si] $\simeq 2 \times 10^{19}$ cm^{-3} (Fig. 7a), decreasing to ~450Å for the sample with the largest [Si] $\simeq 5 \times 10^{19}$ cm^{-3} (Fig. 7b). The loop density in the former case is $\sim 8.0 \times 10^{12}$ cm^{-3} and is roughly thirty-five times higher or $\sim 2.9 \times 10^{14}$ cm^{-3} in the latter case. This indicates that the amount of Si precipitation through the formation of these triangular or circular loops increases with increasing [Si] in the 750°C ^{6}Li-diffused samples. Assuming that these extrinsic triangular or circular loops are forming completely by Si with double interstitial layers on {111} planes, one can estimate [Si] $\simeq 3.2 \times 10^{18}$ cm^{-3} for the triangular loops observed in sample 4-a (Fig. 7a) and [Si] $\simeq 6.6 \times 10^{18}$ cm^{-3} for the circular loops observed in sample 7-a (Fig. 7b).

(*v*) ^{6}Li-diffused samples at $T_D = 950°$C, all sets in Table III, all had similiar microstructure, *i.e.*, Li precipitates and some dislocations which tend to be pinned by the precipitates. This is similar to the 950°C ^{6}Li-diffused pure GaAs material. However, the size ~700Å and density $\lesssim 3.3 \times 10^{12}$ particles/cm^3 of precipitates is small compared to that of the pure GaAs. One previous study (18) concluded that the solid solubility of Li in doped GaAs is frequently larger than that in pure GaAs which can account for the reduction in precipitates in the Si-doped material. A few large dislocation loops are also observed in samples with high [Si] $\gtrsim 2 \times 10^{19}$ cm^{-3} as in sets No. 4-7 in Table III. The character of these large loops is not known, however, they would account for only a very small amount of [Si] even if one assumes their origin is due to Si precipitation. As previously mentioned ^{6}Li rediffusion at 950°C of sample 7-a after it was ^{6}Li diffused at 750°C, also induces site transfer and shows a similar LVM curve as that of sample 7-b with only 950°C diffusion. After this double diffusion the microstructure does not show the high density of circular loops seen after the first lower temperature diffusion.

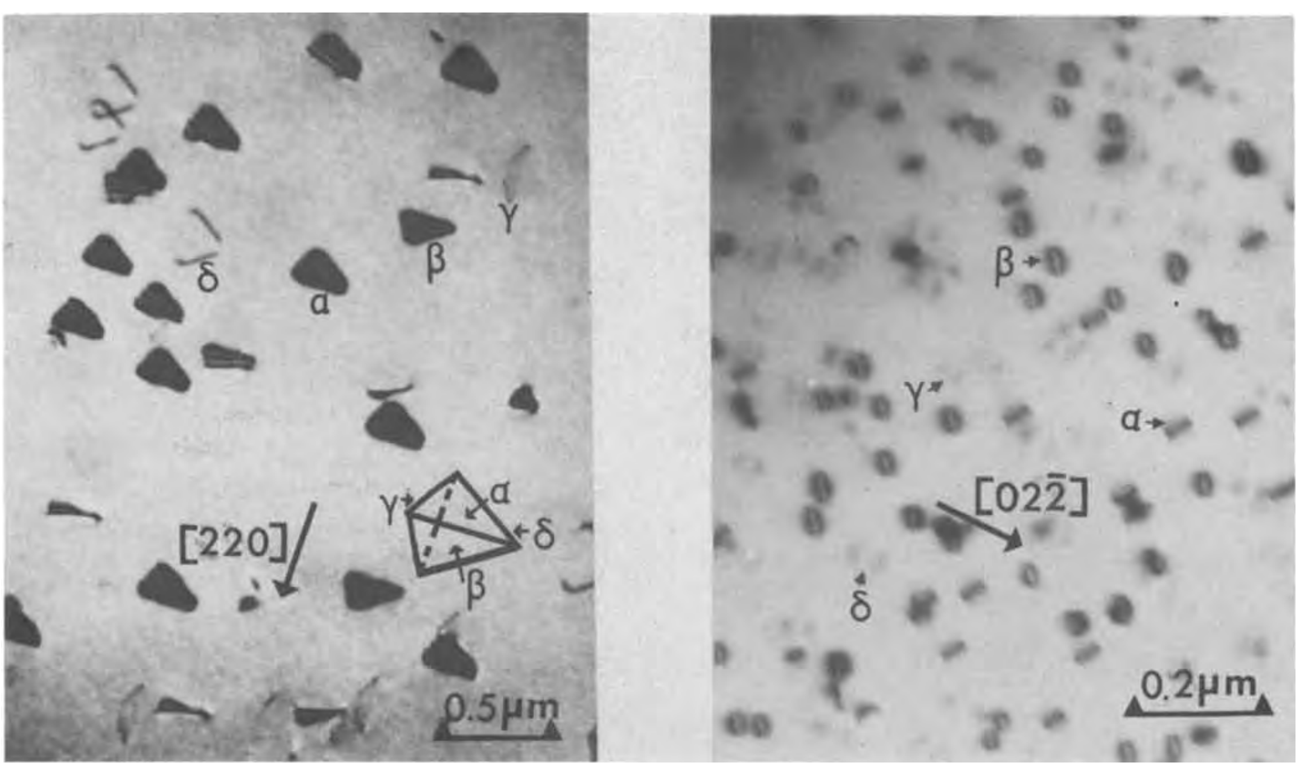

Fig. 7. Bright field micrographs showing the presence of a high concentration of loops which are extrinsic and on four {111} planes of a tetrahedron and observed after 750°C ^{6}Li diffusion. (a, left) Sample 4-a, $n_e \simeq 5.3 \times 10^{18}$ cm^{-3} shows triangular-shaped faulted loops with density $\sim 8.0 \times 10^{12}$ cm^{-3} and the displacement vector $\vec{R}_F = a/3$ [111]. Half of these triangular faulted loops (γ, δ) do not show fringe contrast under the deflection condition being used here. Foil orientation $\sim\langle\bar{1}14\rangle$. (b, right) Sample 7-a, initial $n_e \simeq 8.0 \times 10^{18}$ cm^{-3} shows circular loops with density $\sim 2.9 \times 10^{14}$ cm^{-3}. Foil orientation $\sim\langle\bar{1}12\rangle$.

The resulting final microstructure of sample 7-a is very similar to that of sample 7-b.

The microstructural results described above can be correlated with the LVM measurements and some of the results discussed in the four preceding sections. For the samples of lower [Si] no Si-rich loops are observed at any point in the study and the gain in $(\alpha_p\Delta)$ for the 399 cm^{-1} band for Si_{As} is largely the result of Si site transfer from Si_{Ga} defects, *i.e.*, β values of $+0.97$, $+0.89$, and $+0.81$ for sets No. 1-3 of Table IV as compared to the predicted value of $+1.27$. On the other hand, the higher [Si] samples show the Si-rich loops after the 750°C diffusion, but essentially none after a 950°C diffusion. These same materials have very low β values indicating that the increases in [Si_{As}] come largely from a source other than the Si_{Ga} defect concentration observed at 750°C. Since no other Si-related LVM bands show significant changes between the two temperatures it is reasonable to inquire into the possibility that the Si-rich loops could be the source of the high temperature increases in [Si_{As}]. By using the reciprocal cross sections a and b given earlier, one can estimate the net changes in [Si] in the 399 and 384 cm^{-1} band jointly from the data of Table IV. For sample 4-b the increase in [Si] is 2.7×10^{18} cm^{-3} and 5.7×10^{18} cm^{-3} for sample 7-b. These values are quite close to the estimated [Si] in the loops, 3.2×10^{18} cm^{-3} and 6.6×10^{18} cm^{-3}, respectively, obtained in the previous section. Therefore we conclude that the Si in the loops formed at 750°C is indeed the source of the additional Si observed after the 950°C diffusion.

There remains the fundamental question of the original source of the Si which appears as the Si-rich loops after a 750°C Li diffusion and as enhanced [Si_{As}] after 950°C Li diffusion. We know from the data of Table II that the 750°C Li diffusion causes a reduction of [Si_{Ga}], a reduction of both the 367 and 369 cm^{-1} Si-related defects and a substantial increase in the [Si_{Ga}-Si_{As}]. Also the Si_{Ga}-Li_{Ga} bands are created by the diffusion. The [Si_{As}] is unaffected. Since the cross sections of the Si_{Ga}-Si_{As} band and the Si_{Ga}-Li_{Ga} bands are not known one cannot quantitatively determine whether the total [Si] represented by the bands remains constant. It is conceivable that the Si in the loops and the enhanced [Si_{As}] comes from net decreases of Si in the Si bands observed in the prediffused samples. If this is the case then the source must be either the Si_{Ga} or the Si-related defects causing the 367 and 369 cm^{-1} bands and cannot be the Si_{Ga}-Si_{As} defect. Also the Si in the loops cannot come from the Si_{As} defects.

An alternate explanation for the original source of the Si in the loops or enhanced [Si_{As}] for the more heavily doped samples is the possibility that some of the Si dopant does not give rise to LVM spectra in the prediffused (e^--irradiated) samples. An indication of this possibility comes from a comparison of the measured total [Si] with that calculated from LVM spectra by using the known absorption cross sections. It is reasonable to estimate Si concentration by assuming $[Si]_{calculated} \simeq [Si_{Ga}] + [Si_{As}] + [Si_{Ga}\text{-}Si_{As}] + [Si]_{367} + [Si]_{369} \simeq a(\alpha_p\Delta)_{384} + b(\alpha_p\Delta)_{399} + 2a(\alpha_p\Delta)_{393} + c(\alpha_p\Delta)_{367} + d(\alpha_p\Delta)_{369}$ for e^--irradiated samples in Table II. The results for KM-16-3,4 and WA-Si-2-2,3 show that values for $[Si]_{calculated}$ account for only 60%-70% of the total [Si] values measured by electron microprobe analysis which were 2.3×10^{19} cm^{-3} and $\sim 5 \times 10^{19}$ cm^{-3}, respectively. In addition, Newman (37) and co-workers have recently studied irradiated samples simultaneously doped with Si and a group VI donor. The $(\alpha_p\Delta)_{384}$ band of Si_{Ga} is about the same as $(\alpha_p\Delta)_{399}$ for Si_{As}. Prolonged irradiation (31) can reduce the $(\alpha_p\Delta)_{399}$. They have found that after such an irradiation and upon annealing, [Si_{As}] recovers and $(\alpha_p\Delta)_{399}$ can overshoot its original value by as much as a factor of five even though the [Si_{Ga}] does

not change. Furthermore in a most recent communication, they have also observed that annealing Si-doped GaAs samples ([Si]$\simeq 2 \times 10^{18}$ cm^{-3}) after being irradiated with fast neutrons, the strength of the Si_{As} band also increases and may overshoot its original value by a factor of three but without any measurable change in the strength of other LVM bands involving silicon. They have also concluded that there is some silicon in as-grown crystals which does not give rise to LVM absorption.

Conclusions

The use of measurements of the carrier density, the LVM absorption, and the microstructure of GaAs:Si samples has provided information which allows one to describe in considerable detail the behavior of a number of defects in Li-saturated material. Specifically the conclusions which have been made from the present study are:

1. The effect of a saturation diffusion of Li at a temperature (750°C) which is below that at which Si transfers from Ga to As sites results in significant changes in the Si defect concentrations as compared to the prediffused state. These changes are: (*i*) a decrease in [Si_{Ga}]; (*ii*) an increase in [Si_{Ga}-Si_{As}]; and (*iii*) the creation of Si_{Ga}-Li_{Ga} defects. There is no change in [Si_{As}]. The changes increase with increases in [Si].

2. For samples of lower [Si], *i.e.*, [Si] $\lesssim 5 \times 10^{18}$ cm^{-3} and $n_e \lesssim 3 \times 10^{18}$ cm^{-3}, saturation diffusion of Li at a temperature of 950°C does result in $Si_{Ga} \rightarrow Si_{As}$ and most of the increase in [Si_{As}] is attributable to the decrease in [Si_{Ga}]. The Li defect responsible for inducing the Si site transfer is the Li donor which has an LVM band at 406 cm^{-1} (for ^{6}Li). The microstructure of these lower [Si] samples includes some Li precipitates and some dislocations which tend to be pinned by the precipitates. There is no evidence of Si precipitation or extrinsic faults.

3. For samples of higher [Si], *i.e.*, [Si] $\gtrsim 2 \times 10^{19}$ cm^{-3} and $n_e \gtrsim 5 \times 10^{18}$ cm^{-3}, the comparisons of Li saturation diffusion at 750° and 950°C are more complicated. The [Si_{Ga}] generally decreases and [Si_{As}] increases for the higher temperature case, however, $Si_{Ga} \rightarrow Si_{As}$ site transfer is no longer the dominant process. After the 750°C saturation, TEM measurements show faulted {111} extrinsic loops which are Si rich. These loops are not present after a 950°C saturation diffusion. Semiquantitative comparisons indicate that the large increase in [Si_{As}] at the higher temperature could come from the Si content of these loops. The question of the origin of the Si in the loops could not be answered unambiguously although two possible sources were identified and discussed.

4. By using the fact that the Li-saturated samples are electrically compensated and using the known values of the absorption cross sections of the electrically active Si defects, the absorption cross sections of the bands for the principal Li-donor and -acceptor defects were determined. These cross sections were used with the knowledge that there are 3 Li per donor defect and 2 Li per acceptor and some previously published data for Li-saturated undoped GaAs to estimate the total [Li] as a function of saturation temperature. The results are in reasonable agreement with earlier quantitative analysis data.

Acknowledgments

This work was supported by the Air Force Office of Scientific Research (AFSC) under Grant/Contract 76-2990. The authors wish to express their gratitude to Dr. G. H. Narayanan for his helpful advice on the TEM results and to Professor D. B. Wittry for useful discussions during the electron microprobe analysis. The authors would also like to thank L. Lowe and D. Morris for their help with the electron irradiations and their hospitality to one of the authors (W.G.S.) during his stay at Hanscom Field, Massachusetts. The authors also wish to express their appreciation to Professor R. C. Newman and his co-workers for their comments and communication of their results prior to publication.

Manuscript submitted Oct. 29, 1979; revised manuscript received Feb. 13, 1980. This was Paper 578 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the University of Southern California.

AES and PES Studies of Semi-Insulating Polycrystalline Silicon (SIPOS) Films

T. Adachi[1] and C. R. Helms

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

SIPOS (semi-insulating polycrystalline silicon) films with 40 atomic percent oxygen have been studied with Auger electron spectroscopy (AES) and photoelectron spectroscopy (PES). The comparison of the Si LVV Auger spectra with the Si 2p lines suggests that the as-grown SIPOS film contains large amounts of SiO_x ($x < 2$) as well as SiO_2. Annealing at 1100°C causes crystal growth of Si and the change of SiO_x towards SiO_2. An additional peak at 83 eV is found in the Si LVV Auger spectra, which has been reported to exist at the Si-SiO_2 interface, and can be attributed to SiO.

SIPOS (semi-insulating polycrystalline silicon) films have been extensively studied (1-6) because of their practical importance as a passivation layer on silicon devices (7, 8). The SIPOS films, prepared by chemical vapor deposition (CVD), have a macroscopic chemical composition expressed as SiO_x ($0 < x < 2$). The films contain polysilicon grains after annealing at temperatures higher than 850°C, whereas as-deposited films are reported to be amorphous (2).

In the present work, we used Auger electron spectroscopy (AES) and photoelectron spectroscopy (PES) to characterize the SIPOS films with 40 atomic percent (a/o) oxygen. We have found that the as-grown films investigated in this study were composed of SiO_x phases and Si as well as SiO_2 and that annealing at 1100°C induced a change of SiO_x towards SiO_2.

Experimental

SIPOS films were deposited on p-type (100) Si wafers by atmospheric pressure CVD at 650°C (7). The reactant gases and their flow rates were SiH_4 (30 cm^3/min), N_2O (93 cm^3/min), and N_2 (carrier gas, 25 l/m), which yielded about 40 a/o oxygen concentration. Films 300Å thick were prepared for the measurements reported here in order to prevent any charging effects in the electron spectroscopies used. Annealing effects were also examined for samples annealed in N_2 at 1100°C for 30 min. However, the experimental results indicate that the N_2 gas used for the annealing may have contained enough O_2 for a thin oxide layer to grow on the surface of the annealed films.

We used a Varian Auger microprobe with a cylindrical mirror analyzer (CMA) for AES measurements. A primary electron beam energy of 4.5 keV was employed at a beam current of 2 μA scanned over ~200 μm square area. Both derivative [$d(E \cdot N(E))/dE$] and nonderivative [$E \cdot N(E)$] spectra were examined. Argon ion beam sputtering with 0.5 keV ions at ~10 $\mu A/cm^2$ was used for sputter profiling of the films.

[1] Present address: Sony Corporation Research Center, Hodogaya, Yokohama 240, Japan.

Key words: films, interfaces, spectra.

As-grown films were also examined with PES. The radiation source at the Stanford Synchrotron Radiation Laboratory (SSRL) was employed. Photon energies of 180 and 100 eV were used for measurements of Si 2p lines and valence electronic structure, respectively. These photon energies were selected so that photoelectrons would have approximately the same kinetic energy as the Si LVV Auger electrons. Photoelectrons were analyzed with a PHI double-pass CMA, and the energies were referred to the valence band maximum of Si.

Results

Chemical depth profiles.—Figure 1 shows survey Auger spectra of SIPOS films prior to argon ion sputtering. Major elements detected at the surface are Si, O, and C, both for the as-grown and the annealed films. Most of the Si at the surface is so heavily oxidized that the 91 eV peak (in derivative mode) characteristic of pure Si was barely observed in Fig. 1, especially for the annealed film.

Figure 2 shows the chemical depth profiles of the films. Carbon, probably due to surface contamination after deposition, disappears very rapidly. A heavily oxidized surface layer was removed by 5 and 15 min sputtering for the as-grown and the annealed films, respectively. The thicker surface layer of the annealed film may be due to the presence of ppm concentrations of oxygen in the annealing system.

The interface between the SIPOS film and the Si substrate exhibits a peak in oxygen concentration after annealing. This effect may be due to the redistribution of oxygen in the SIPOS film and indicates that the SiO_x in the as-grown film may be unstable at high temperature, with an SiO_2 layer growing both at the Si/SIPOS interface and the SIPOS surface.

Si LVV Auger spectra.—Close examination of the Auger spectra was performed using the nonderivative mode. Figures 3 and 4 show the Si LVV spectra of the as-grown and the annealed films, respectively, at various depths. The positions where these spectra were taken are indicated in Fig. 2. At the surface, Si is almost completely oxidized after annealing [Fig. 4(f)].

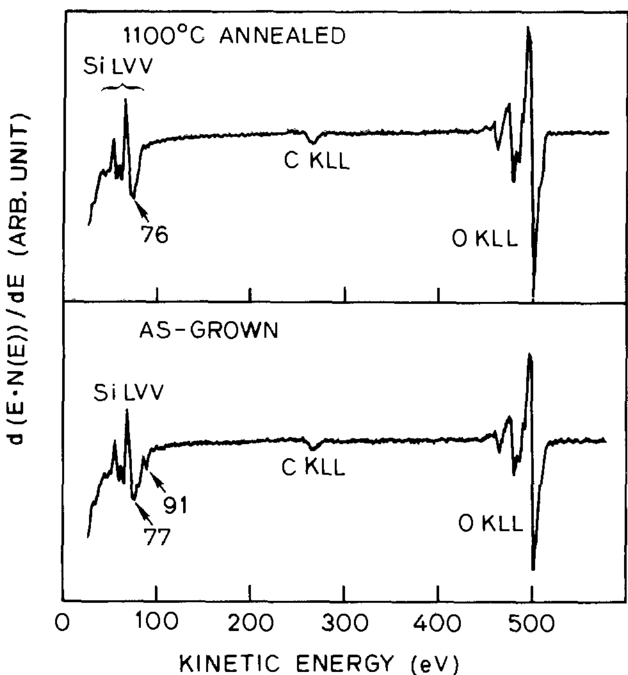

Fig. 1. Auger spectra of as-grown (lower panel) and 1100°C-annealed (upper panel) SIPOS films prior to argon ion sputtering.

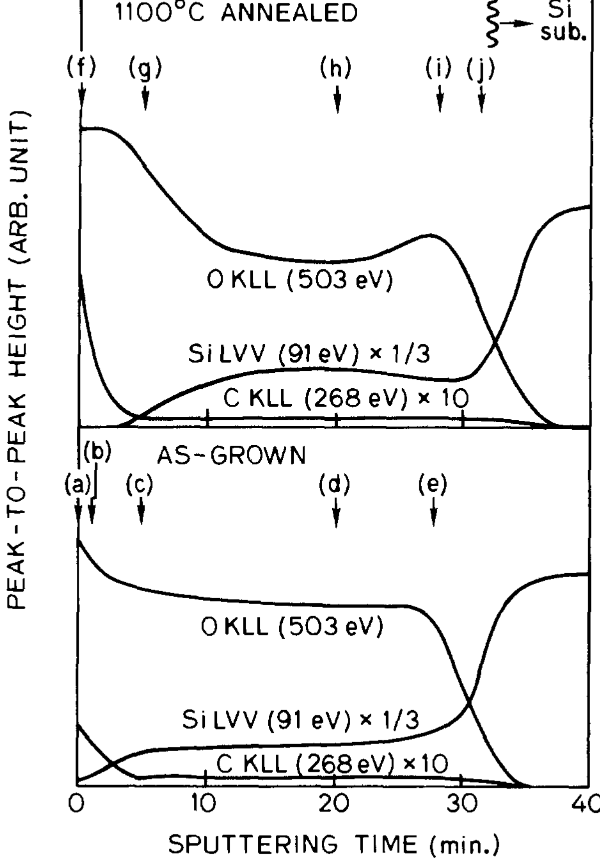

Fig. 2. Chemical depth profiles of as-grown (lower panel) and 1100°C-annealed (upper panel) SIPOS films. The profiles of Si are those of pure Si at ~91 eV in the *d(E · N(E))/dE* mode spectra. Small letters, (a) through (j), in the figure indicate the positions where the Si LVV spectra (Fig. 3 and 4) and/or photoelectron spectra (Fig. 5 and 6) were examined.

Even the as-grown film is heavily oxidized at the surface [Fig. 3(a)], and the Si LVV spectra of both samples are almost identical to that of SiO_2. A small peak at 88 eV in the as-grown film is probably due to

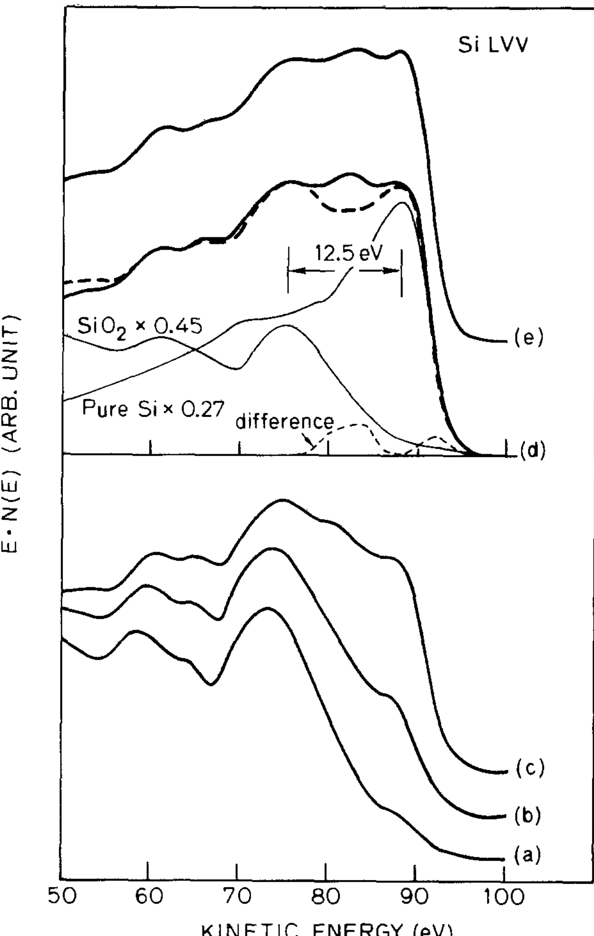

Fig. 3. Si LVV Auger spectra in the *E · N(E)* mode at various depths of the as-grown SIPOS film. Each spectra corresponds to the position in Fig. 2 indicated by the same letter. The thick solid line in (d) is the measured Si LVV spectra, and the dashed line is the composed spectra using pure Si and (shifted) pure SiO_2 spectra (thin solid lines) as basic components. The dotted line is the difference curve between the measured and the composed spectra. The intensity ratios of the two basic components relative to the intensities of pure spectra are also indicated.

the pure Si which is one of the components of SIPOS film (2, 5).

As shown in Fig. 2, 5 min of argon ion sputtering removes the surface contamination of carbon and the Si LVV spectra at this point [Fig. 3(c) and 4(g)] have at least two components—that is, pure Si and Si in SiO_2.

In another 15 min of sputtering, spectra were recorded that represent the bulk of the films in an as-sputtered condition [thick solid lines in Fig. 3(d) and 4(h)]. The spectra of the as-grown film [Fig. 3(d)] is quite different from that of the annealed film [Fig. 4 (h)]. It shows an Si LVV spectra composed of pure Si and SiO_2, while the spectra of the as-grown film has an extra peak at 83 eV. Another difference is that only the SiO_2 component in the Si LVV spectra of the as-grown film is shifted towards higher kinetic energy. In order to make these differences clear, we tried a semi-empirical fit of the Si LVV spectra of SIPOS films using spectra of pure Si and thermally grown SiO_2 as basic components. These two spectra were added to get the best fit to measured spectra with proportional coefficients as parameters determined by the least squares method. Since we know, by visual examination, that there is a contribution of the extra peak near 83 eV in the spectra, the data points near this peak were excluded intentionally. As a result, the difference between the measured and the composed spectra gives an estimate of the contribution of the 83 eV peak. Furthermore, to obtain a good fit, the SiO_2 component was

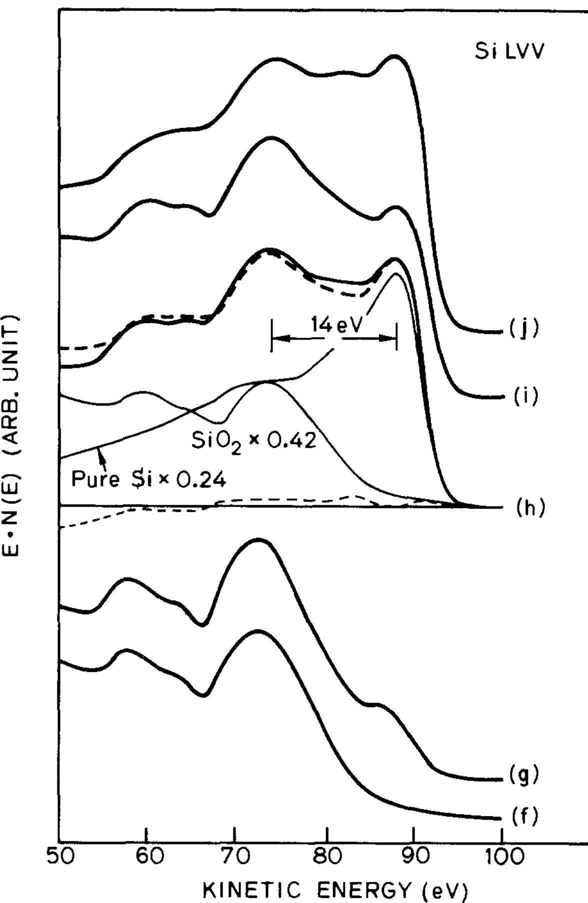

Fig. 4. Si LVV spectra in the $E \cdot N(E)$ mode at various depths of the 1100°C-annealed SIPOS film. Each spectrum corresponds to the positions in Fig. 2 indicated by the same small letter. The thick solid line in (h) is the measured Si LVV spectra, and the dashed line is the composed spectra using pure Si and (shifted) pure SiO_2 spectra (thin solid lines) as basic components. The dotted line is the difference curve between the measured and the composed spectra. The intensity ratios of the two basic components relative to the intensities of pure spectra are also indicated.

shifted towards higher kinetic energy to obtain minimum error. The results are illustrated in Fig. 3(d) and 4(h), where the solid thick lines are the measured spectra of the films, the dashed lines are the composite spectra by the method described above, dotted lines are the differences between the two, and the solid thin lines are the basic components (pure Si and shifted pure SiO_2) used in the calculations. The as-grown film has a large contribution from the 83 eV peak, whereas the 1100°C annealed film has almost none. The shift of the SiO_2 component necessary for the best fit is larger for the as-grown film, and the energy difference between the most prominent peaks of the Si and the SiO_2 components are 12.5 and 14.0 eV for the as-grown and the annealed films, respectively. (Note that the difference is about 15 eV when pure Si and pure thermal SiO_2 are measured separately.) The intensities of the two components are indicated in the figures relative to the intensities of the pure standards.

Another 8 min of sputtering of the annealed film reaches the region where the oxygen concentration is increased with respect to the "bulk value." The spectrum at this point [Fig. 4(i)] contains no new features, but the intensity ratio of the SiO_2 component increases relative to that of the "bulk spectra."

At the interface between the SIPOS film and the Si substrate, the Si LVV spectra of both the as-grown [Fig. 3(e)] and the annealed [Fig. 4(j)] films are similar; that is, the 83 eV peak appears also in the spectra of the annealed film. However, the position of the SiO_2 component in the spectrum of the annealed film remains at the position found in the bulk spectrum.

Photoelectron spectroscopy.—An as-grown film was examined also with PES. Figures 5 and 6 show the results of the Si 2p spectra and the valence electronic structures, respectively. Although these experiments were done separately from the AES experiments, each spectrum shown in Fig. 5 and 6 were taken at the same depths as the Si LVV Auger spectra in Fig. 3(a), 3(b), and 3(d).

The Si 2p spectrum of the surface prior to sputtering [Fig. 5(a)] has the highest energy peak with the smallest FWHM. About 1 min of sputtering induces a slight shoulder at the right-hand side of the main peak, which is shifted towards lower energy [Fig. 5(b)]. In the bulk of the film, the shoulder observed in the surface region becomes a resolved peak [Fig. 5(d)].

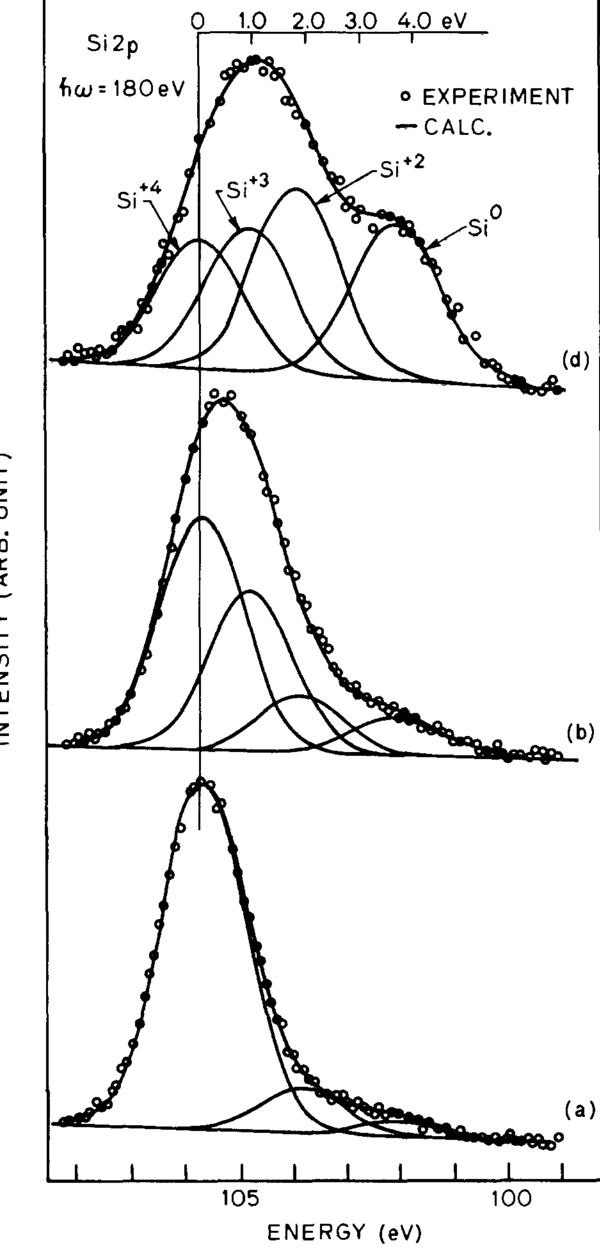

Fig. 5. Si 2p spectra of the as-grown SIPOS film at various depths indicated by the same small letters as in Fig. 2. The measured spectra (dots) are ftted by the five Gaussian peaks (solid lines) corresponding to five possible charge states of Si. Note that some of the five possible Gaussians do not contribute to the spectra. Energy scale refers to the valence band maximum of Si.

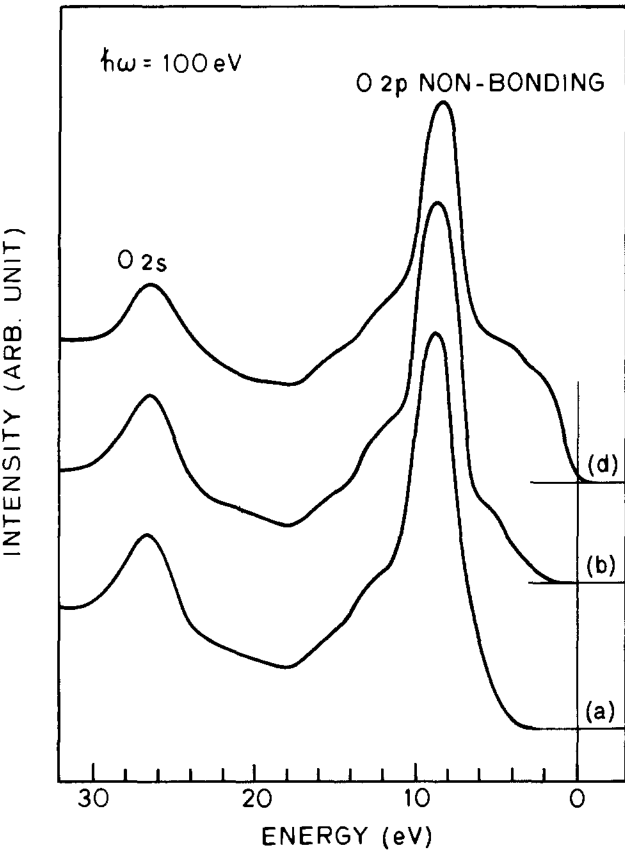

Fig. 6. Valence electronic structure of the As-grown SIPOS film at various depths indicated by the same small letters as in Fig. 2. Energy scale refers to the valence band maximum of Si.

The interpretation of the Si 2p spectra is complicated and a matter of considerable controversy (6, 9, 10, 11). In this paper, we have used a least squares method to fit the measured spectra by five Gaussians corresponding to five possible charge states of Si atoms. The same linewidth was assumed for all five charge states, and the energy differences between adjacent charge states were selected following the bond charge model of Ref. (12). We tried several different values for the chemical shift to minimize the error for all three spectra in Fig. 5. The results are shown with solid lines. We obtained 3.75 eV for the chemical shift of SiO_2 (Si^{+4}), referred to the energy of the pure Si peak. This value is very close to that reported for thin SiO_2 layers formed in the ultrahigh vacuum on Si surfaces (3.8 eV) (11) and "near interface" SiO_2 as reported by Grunthaner and Maserjian (3.9 eV) (10). One interesting result is that there is no contribution of an Si^{+1} charge state (corresponding to Si_2O) in any of the three spectra in Fig. 5. The shift and the broadening of the main peak in the bulk spectra are explained by the appearance of Si^{+2} and Si^{+3} charge states in addition to the Si^{+4} state.

The valence structure at the surface [Fig. 6(a)] is almost identical to that of SiO_2, consistent with the results of the Si 2p and Si LVV Auger spectra. Although 1 min of sputtering induces a shift of the major Si 2p peak, the O 2p nonbonding orbital in the valence band (the peak at ~9 eV in Fig. 6) does not appear to shift. Only the structure near the valence band maximum of SiO_2 appears in addition. In the bulk of the film, the valence structure [Fig. 6(d)] has a contribution from pure Si corresponding to the appearance of the Si^0 state in the Si 2p spectrum.

Discussion

As shown in Fig. 3(d), the Si LVV spectrum of the as-grown SIPOS film is composed of pure Si, shifted pure SiO_2, and the extra peak near 83 eV. The Si component in the bulk was found to be about one quarter as intense as pure Si. If the oxide in the film is SiO_2, the intensity of the Si component should be as large as 60% of pure Si since the average oxygen concentration of the film is about 40 a/o. This result indicates that the SiO_x in the film has an average stoichiometry with $x < 2$. In fact, the Si 2p spectra [Fig. 5(d)] indicate that the oxide is a mixture of SiO_2, Si_2O_3, and SiO. The fact that the Si LVV Auger spectra of the film can be fitted with the spectra of shifted pure SiO_2 could be interpreted as that some SiO_x phases give the same spectral shape of the Si LVV spectra as SiO_2, but that spectra is shifted due to the different chemical environment.

The 83 eV peak in the Si LVV Auger spectra has recently been reported at the Si-SiO_2 interface of MOS structures by several researchers (13, 14), and this peak has been attributed to the chemical structure characteristic of the connective layer between Si and SiO_2. The same idea might be applicable to the case of the SIPOS films because both AES and PES data indicate the existence of both Si and SiO_2 in the film, and there must be some connective species between them. Since the appearance of the 83 eV peak in the Si LVV Auger spectra is accompanied by the growth of the SiO peak in the Si 2p spectra, the 83 eV peak can probably be associated with the SiO bonding configuration.

Annealing at 1100°C causes two changes in the Si LVV spectra: disappearance of the 83 eV peak and a reduction in the shift of the SiO_2 component. The latter effect is probably due to the change in the oxide from SiO_x ($x < 2$) towards SiO_2. This is consistent with the recent report by Maxwell and Knoll (15) concerning the change of infrared absorption spectra of SIPOS films by annealing. They observed the shift of the 9 μm absorption band (represents Si-O-Si vibration) by the annealing from the considerably long wavelength position of as-grown SIPOS film towards the shorter wavelength corresponding to SiO_2.

The disappearance of the 83 eV peak by annealing can be understood in terms of the growth of polysilicon grains and larger SiO_2 particles in the film. Since 1100°C annealing causes crystal growth of Si in the film from less than 10 to ~40Å in diameter (2), the volume fraction of the connective layer between Si and SiO_2 particles in the escape depth of Auger electrons is reduced by annealing and the contribution to the 83 eV peak in the Si LVV spectra is reduced.

The "pile-up" of oxygen near the interface between the SIPOS film and the Si substrate can also be explained by the growth of an SiO_2 film at that interface in which case the intensity of the 83 eV peak in the Si LVV spectra at the SIPOS-Si substrate interface [Fig. 4(j)] would be reduced.

We used an argon ion beam for profiling in these experiments. Ion sputtering has been reported to create an additional peak at ~91 eV in the $dEN(E)/dE$ spectra of SiO_2 (16). Since the position of the peak corresponds to pure Si, the measured spectra of SIPOS films might contain additional contributions from ion-induced components. To minimize these effects, a low ion beam energy (0.5 keV) was used.

Even so, it is surprising that ion beam effects are not more severe than have been observed. For example, Thomas and Goodman (6) have performed profiling experiments both with chemical etches as well as sputter profiling; there are differences in these PES spectra, but the major features are still present. We therefore feel that the ion-induced artifacts in the spectra presented do not alter the conclusions presented.

In their work, Thomas and Goodman (6) studied 900°C annealed SIPOS films with AES and XPS using chemical etching with buffered HF to remove the surface layer. Although their samples were prepared by low pressure CVD, the Si 2p spectra with about the

same oxygen concentration as those reported here have two major peaks separated by 3.7 eV. This is close to the value we derived for the chemical shift of SiO_2. Based on a 4.4 eV for the chemical shift of SiO_2, they interpreted their data as indication of the existence of Si^{+3} and Si^0 (pure Si), as well as Si^{+1} as a connective layer.

This interpretation is not consistent with other recent work. Garner *et al.* (11) reported a 3.8 eV shift for a thin SiO_2 layer on the Si surface. Grunthaner and Maserjian (10) have reported that the SiO_2 peak in the Si 2p spectra shifts by 0.45 eV towards lower binding energy as the Si-SiO_2 interface is approached from the bulk SiO_2. They interpreted this effect as due to the change in the Si-O-Si bond angle caused by stress at the interface which is not accompanied by a stoichiometry change. Since it is reasonable to believe that as-grown SIPOS films are a mixture of small Si regions and small SiO_x regions, it is likely that the structure of the SiO_2 in the film is very strongly distorted and that the chemical shift of the SiO_2 phases is much smaller than the value reported for bulk SiO_2. We therefore believe that the major features in the data of Williams and Goodman are not due to Si^{+3} and Si^0 but Si^{+4} (SiO_2) and Si^0, as in the present work.

One can speculate about the effects of annealing on the SIPOS films using the foregoing arguments. The as-grown film contains very small or amorphous Si grains surrounded with "SiO_x" which is a mixture of SiO_2 and Si_2O_3. These two regions are connected with an SiO bonding configuration. Annealing at 1100°C causes crystal growth of Si, and mixed SiO_x stabilizes to become SiO_2.

Conclusions

40 a/o oxygen SIPOS films have been studied with AES and PES. The Si LVV Auger spectra of the as-grown films were found to be composed of the spectrum of pure Si and SiO_2 and a third peak at ~83 eV. The SiO_2 component was found to be significantly shifted towards higher kinetic energy. The data were interpreted to indicate the existence of an SiO_x phase rather than pure SiO_2 by comparing the Si 2p PES spectra with the Si LVV Auger spectra. The shift of the SiO_2 component is reduced by the 1100°C annealing at the same time the 83 eV peak disappears. These effects are explained by the growth of polysilicon grains and the change in the oxide from SiO_x phases towards stoichiometric SiO_2.

Growth and Microstructure of α-Al_2O_3 on Ni-Al Alloys: Internal Precipitation and Transition to External Scale

H. M. Hindam[1] **and W. W. Smeltzer***

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Oxidation properties of Ni-2 and 6 w/o Al alloys were investigated in 1 atm oxygen at temperatures in the range 1273°-1573°K. Ni-2 w/o Al oxidized parabolically, one order of magnitude more rapid than pure nickel, to a duplex scale by metal diffusion consisting of outer and inner layers of Al-doped NiO and NiO-$NiAl_2O_4$, respectively, and an internal zone of rodlike Al_2O_3 precipitates by oxygen diffusion through the Al-depleted alloy. Oxidation kinetics of Ni-6 w/o Al alloy were irreproducible due to early-stage formation of an imperfect Al_2O_3 scale containing NiO nodules. Impingement of favorably oriented rodlike Al_2O_3 precipitates growing beneath the NiO nodules accompanied with lateral diffusion of aluminum to react with oxygen at the precipitation front eventually led to transition from internal oxidation to development of a multilayered NiO|$NiAl_2O_4$|Al_2O_3 scale.

Nickel superalloys are used as construction materials for gas turbine engines, combustion furnaces, and high temperature reactors. These alloys, consisting of a Ni-Al γ-solid solution matrix to which several elements are added to impart desirable mechanical properties by solution and precipitation hardening (1), are often protected by nickel aluminide coatings containing Ni_3Al, NiAl, and Ni_2Al_3 intermetallic phases (2). The Ni-Al system, nonetheless, has been the subject of only few oxidation studies (3-9). The conditions under which Al_2O_3[2] is precipitated internally or is formed as a scale are well established (3), but the growth mechanisms of Al_2O_3 in both cases are not yet understood. The present paper defines the mechanism of internal precipitation and transition to growth of a continuous Al_2O_3 film beneath NiO | $NiAl_2O_4$ layers.

Experimental

Alloys of nominal compositions 2 and 6 weight percent (w/o) Al were prepared by electric arc melting of nickel (99.99 w/o pure) and aluminum (99.95 w/o pure) in an argon atmosphere gettered of oxygen by titanium chips. Actual compositions of the γ-solid solution phase alloys were 2.1 and 5.9 w/o Al corresponding to 4.4 and 12.0 atomic percent (a/o) Al, respectively. After homogenization at 1473°K for 24 hr in ultrapure grade argon, slices 1 mm thick were electric spark cut from the 1 cm diameter alloy buttons. These slices were subjected to metallographic polishing finishing with 1 μm diamond paste.

Oxidation runs were carried out in ultrapure flowing oxygen at 1 atm in the temperature range 1273°-1473°K. The reaction kinetics were determined using an assembly equipped with a semiautomatic balance as described elsewhere (10). Several Ni-6 w/o Al specimens were also oxidized in static 1 atm oxygen at 1573°K. Oxide phases were identified by x-ray diffraction powder analyses using Ni filtered Cu-Kα radiation. Light and scanning electron microscopy (SEM) were used to study the morphologies of reaction products. Specimens were mounted in room-setting epoxy resin and, whenever etching was difficult, fracture cross-sections were prepared. Electron probe micro-analyses (EPMA) were used to determine composition profiles within the reaction zone. It was necessary to vapor deposit carbon on the specimens to avoid electrical charge buildup during SEM and EPMA analyses.

Results

Ni-2 w/o Al Alloy

Oxidation kinetics.—These kinetics obeyed a parabolic relation during the intervals investigated (up to 50 hr). Arrhenius plots of the parabolic oxidation rate constants of this alloy and those for pure nickel are shown in Fig. 1. The values of the activation energy for oxidation of the alloy and nickel are 146 and 193 kJ/g mole, respectively.

Scale morphology and structure.—Oxidation led to growth of an internal duplex scale consisting of outer dark gray and inner light green layers and an internal oxide precipitation zone in the alloy. The scale was fractured along the interface between these layers to obtain separate samples for x-ray analyses. The internal precipitates, which were extracted by dissolving the alloy in 10% bromine-methanol, were also subjected to x-ray analyses. According to these determinations, the outer layer was NiO, the inner layer was mainly NiO containing $NiAl_2O_4$ as a second phase and the internal precipitates were α-Al_2O_3.

Different regions of the duplex scale and internal precipitation zone are shown in Fig. 2. Figure 2 (a) is an overall cross section and (b) is a scale fracture cross section illustrating the coarse grained columnar NiO layer. Well-defined closed pores, 1-5 μm, were located in the vicinity of its interface with the inner layer. The scale surface adjacent to the gas phase exhibited a terraced structure and grain size of ~30 μm [Fig. 2(c)]. The structure of the inner oxide layer [Fig. 2(d)] consisted of rod-shaped $NiAl_2O_4$ growths embedded in a NiO matrix. The rods lay parallel to the scale growth direction and extended completely across this inner layer as extensions of the Al_2O_3 rods but their relatively small extension beneath the alloy surface could not be experimentally determined.

Morphologies of Al_2O_3 precipitates were not completely revealed by mechanical polishing [Fig. 2(d)] or chemical etching [Fig. 2(e)], but an appropriate relief was obtained by "deep etching" [Fig. 2(f)]. It is seen here that the precipitates extend across the precipitation zone as cylindrical rods. SEM images in Fig. 3 further document these structural features. Their population and size were relatively uniform through the precipitation zone [Fig. 3(a)] except at alloy

Key words: oxidation Ni-Al alloys, Al_2O_3, $NiAl_2O_4$, NiO.

[2] Al_2O_3 is used in the text to designate α-Al_2O_3.

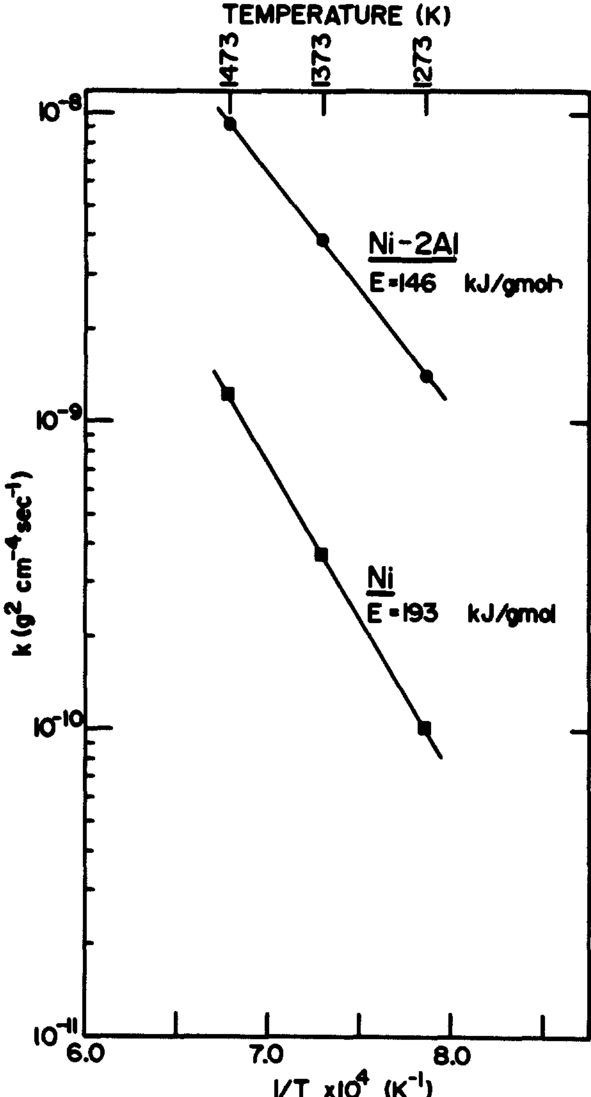

Fig. 1. Arrhenius plot of the parabolic rate constants for Ni and Ni-2 w/o Al oxidation.

grain boundaries where they are more dense without forming a continuous layer [Fig. 3(b)]. These parameters depended on temperature and alloy composition: the precipitates formed at 1473°K were coarser and have a wider spacing, 3 and 10 μm, respectively, than at 1273°K. This former precipitate size and spacing corresponded to a fractional surface coverage of 0.07. The cylindrical shape of the precipitated rods was further ascertained by examining a transverse section [Fig. 3(c)]. It was not possible to establish if a boundary existed at the precipitation front [Fig. 3(d)].

Nickel and Al x-ray scans across the scale and internal oxidation zone are shown in Fig. 4. The alloy was depleted of aluminum ahead of the precipitation front. Amounts of nickel dissolved in Al_2O_3 precipitates or the composition of $NiAl_2O_4$ growths could not be determined because their lateral dimensions were only ~5 μm. The outer NiO layer was doped with aluminum but quantitative determination of its amount was not possible because Al x-ray counts were only slightly above those of background.

Layer thickness measurements.—It was possible to determine rates of growth for both oxide layers and penetration of the internal oxidation zone. The latter was measured by optically examining etched cross sections while SEM was used to locate the interface between the two oxide layers by following Al x-ray counts using an energy dispersive analyzer in this instrument. The internal oxidation zone grew most

rapidly and the inner NiO-$NiAl_2O_4$ two-phase layer grew most slowly. All layers thickened according to a parabolic relation (Fig. 5), and values of the growth rate constants are given in Table I.

Ni-6 w/o Al Alloy

Oxidation kinetics.—These kinetics which were irreproducible due to a phenomenon of nodular growth are shown in Fig. 6. Furthermore, oxygen uptake during initial stages was dependent on alloy surface preparation since specimens polished to 1 μm diamond exhibited smaller uptake and formed fewer nodules than specimens abraded on coarse SiC papers. In this latter case, NiO formed rapidly as an almost complete scale rather than as scattered nodules. The oxidation kinetics when represented by parabolic plots (Fig. 7) exhibited an initial fast stage subsequent to which the kinetics declined to ultimately approach a second slower parabolic rate. At 1473°K, the value of the rate constant during the first parabolic stage was $k_1 = 2.5 \times 10^{-1}$ g² cm⁻⁴ sec⁻¹, and its value during the second parabolic stage was $k_2 = 8 \times 10^{-11}$ g^2 cm^{-4} sec^{-1}. The balance sensitivity did not permit accurate measurement of reaction kinetics beyond this stage since the specimens oxidized at an extremely low rate.

Scale morphology and structure.—As illustrated in Fig. 8, a thin Al_2O_3 film through which scattered NiO nodules protruded grew in early exposure periods.

Nodules formed preferentially at alloy grain boundaries [Fig. 8(a) and (b)] and at surface imperfections induced by polishing. In the region of a nodule, the scale was of the morphology observed for the Ni-2 w/o Al alloy consisting of an outer coarse grained NiO layer having a terraced surface, an inner NiO-$NiAl_2O_4$ layer and an internal Al_2O_3 precipitation zone [Fig. 8(a)-(d)]. Lateral growth of the nodules led to regions of duplex structured scale over an internal oxidation zone. In this alloy, nevertheless, a continuous Al_2O_3 film developed at the internal oxidation front [Fig. 8(d)].

This alloy underwent a long transient stage extending up to 150 hr during which initially formed reaction products transformed to continuous $NiAl_2O_4$ and Al_2O_3 layers. Light micrographs in Fig. 9 and SEM images taken from larger areas of specimens in Fig. 10 illustrate oxidation behavior during this transient stage. It can be observed that an Al_2O_3 film was formed at several regions of the precipitation front [Fig. 9(a) and Fig. 10(a)]. Lateral growth of these film sections eventually led to development of a complete film along the highly irregular alloy interface which separated the internal oxidation zone from the alloy substrate [Fig. 9(b) and Fig. 10(b)]. Subsequent reaction within this isolated alloy and Al_2O_3 precipitates resulted initially in formation of an NiO-$NiAl_2O_4$ conglomerate [Fig. 9(c)-(d), Fig. 10(b)] which was finally converted to a homogeneous $NiAl_2O_4$ layer laying between the outer NiO and inner Al_2O_3 layers [Fig. 10(c)].

Initiation of continuous Al_2O_3 film formation, which is indicated by arrows in Fig. 9 and 10, occurred at random sites within the alloy grains where the rodlike precipitates impinged. Confirmatory evidence for this mechanism for impingement of particles and lateral growth of Al_2O_3 film at the internal oxidation front is depicted in Fig. 11. Figure 11(a) illustrates that the rodlike precipitates tend to impinge while Fig. 11(b) shows a section of the Al_2O_3 film at the internal oxidation front. Formation of Al_2O_3 depleted the aluminum alloy concentration at precipitate tips but led to insignificant aluminum depletion from the alloy beneath the film since it acted as a diffusion barrier for reactants. This was verified by determining the aluminum profile in these two alloy regions as shown in Fig. 12. It is evident that the alloy is more significantly depleted of aluminum in vicinity of the precipitates (line A-A) than in the region where a continuous film was formed (line B-B). This lateral concentration gradient gave rise to aluminum diffusion in the alloy from beneath the discontinuous film to neighboring precipitates where it reacted with oxygen migrating inward to cause continual lateral film growth [Fig. 11(b)].

A fully developed scale at the highest investigated temperature of 1573°K was of duplex structure consisting of outer and inner $NiAl_2O_4$ and Al_2O_3 layers, respectively. This scale morphology is illustrated in Fig. 13 in conjunction with the Al and Ni x-ray maps.

Discussion

Ni-2 w/o Al Alloy

A schematic model depicting parabolic growth of the oxidation products on and in the alloy is illustrated in Fig. 14. The Al_2O_3 rod precipitates beneath the duplex scale are shown to extend perpendicularly to the alloy surface through the internal oxidation zone independent of alloy grain orientation. There is ~7 v/o increase accompanying formation of Al_2O_3 in the alloy and its growth in the form of continuous rods rather than as isolated precipitates decreases the oxide surface area and consequently total interfacial energy.

Growth of the columnar coarse-grained NiO layer is interpreted by predominant outward nickel diffusion since its diffusivity is at least two orders of magnitude larger than the oxygen diffusivity (11). The small density of fine pores found in the intermediate region of the scale [Fig. 2(b)] did not form a continuous network and they are not regarded as effectively contributing to an inward oxidant flux. Formation of these pores possibly arise from ~6 v/o decrease accompanying formation of $NiAl_2O_4$ from its parent oxides. Partial dissolution of Al_2O_3 into NiO results in alteration of its defect structure according

to the following equation

$$Al_2O_3 = 2Al_{Ni}^{\cdot} + V_{Ni}'' + 3\,O_o^{x} \qquad [1]$$

where the symbols $Al_{Ni}^{\cdot}$, V_{Ni}'', O_o^{x} refer to aluminum dissolved in a nickel site, a nickel vacancy, and oxygen in an oxygen site of NiO, respectively. This increase in vacancy concentration enhances the nickel diffusivity and combined with the larger oxygen activity gradient across the NiO scale due to the presence of $NiAl_2O_4$ in its inner region enhances the oxidation rate of the alloy in comparison to pure nickel (Fig. 1). The $NiAl_2O_4$ particles in the two-phase inner scale

layer, nevertheless, offer a high resistance to outward nickel flux and therefore mask the complete effect of aluminum as a dopant in NiO on scale growth.

Oxygen for growth of Al_2O_3 precipitates resulted from a solid-state displacement reaction between NiO and aluminum present in the alloy since the following equilibrium exists at the two-phase scale/alloy interface

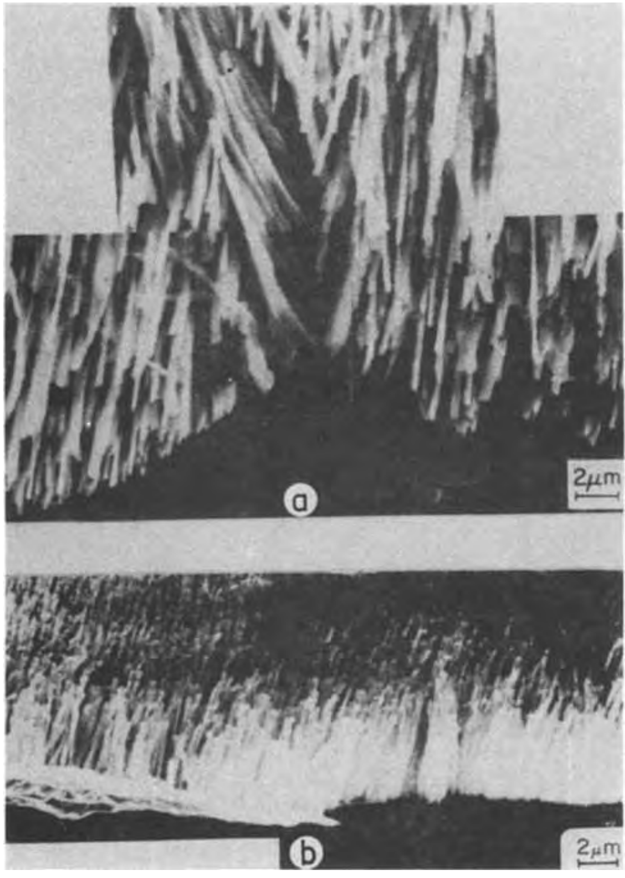

Fig. 11. Development of a continuous Al_2O_3 film on Ni-6 w/o Al alloy. (a) Impingement of Al_2O_3 rodlike precipitates, (b) lateral growth of Al_2O_3 film.

$$NiO_{(scale)} = Ni_{(alloy)} + O_{(alloy)} \quad [2]$$

Inward oxygen diffusion through the alloy in the internal oxidation zone to react with oxygen at the precipitation front can be represented as

$$2Al_{(alloy)} + 3\,O_{(alloy)} = Al_2O_{3(alloy)} \quad [3]$$

The net displacement reaction then becomes

$$3NiO_{(scale)} + 2Al_{(alloy)} \rightarrow Al_2O_{3(alloy)} + 3Ni \quad [4]$$

where the resultant nickel diffuses outward through the scale to react with atmospheric oxygen. If inward growth of the Al_2O_3 rod precipitates was controlled by oxygen diffusion in the aluminum depleted alloy matrix of the internal oxidation zone, the penetration depth, X, of this zone is given to a first approximation by

$$X^2 = 2\left(\frac{1-f}{f}\right)\left\{\frac{\text{M.W.}(Al_2O_3)}{1.5\,\text{M.W.}(O_2)}\right\} V_{Al_2O_3} D_o \Delta c_o t = kpt \quad [5]$$

where f is the fractional area covered by the Al_2O_3 rods, V is the molar volume, D_o is the oxygen diffusivity, Δc_o is the oxygen concentration difference across the alloy precipitation zone, t is time, and kp is the parabolic penetration rate constant (Table I). Oxygen concentration in the alloy at the alloy/scale interface is assumed equal to its solubility in pure nickel since only trace amounts of aluminum, few ppm, remain in solution upon precipitation of Al_2O_3 (12). Due to the high oxygen affinity for aluminum, the oxygen concentration at the precipitation front is considered as nil. At 1273°K, c_o in nickel $= 0.051$ a/o, D_o in Ni $= 4 \times 10^{-9}$ $cm^2 \cdot sec^{-1}$ (14), $f = 0.07$ from measurements in this investigation. Substituting these values in the above equation gives $k_p = 18.7\ \mu m \cdot hr^{-1/2}$ which is in close agreement with the experimentally determined value, $k_p = 19.8\ \mu m \cdot hr^{-1/2}$. Based on the temperature dependence of k_p (Table I), the activation energy for oxygen diffusion in the alloy of the internal oxidation zone is 128 kJ/g·mole.

The $NiAl_2O_4$ part of a rod precipitate was mainly confined to the inner conglomerate layer of the NiO scale. Al_2O_3 in the region of the alloy/scale interface can be converted to $NiAl_2O_4$ by solid-state reactions.

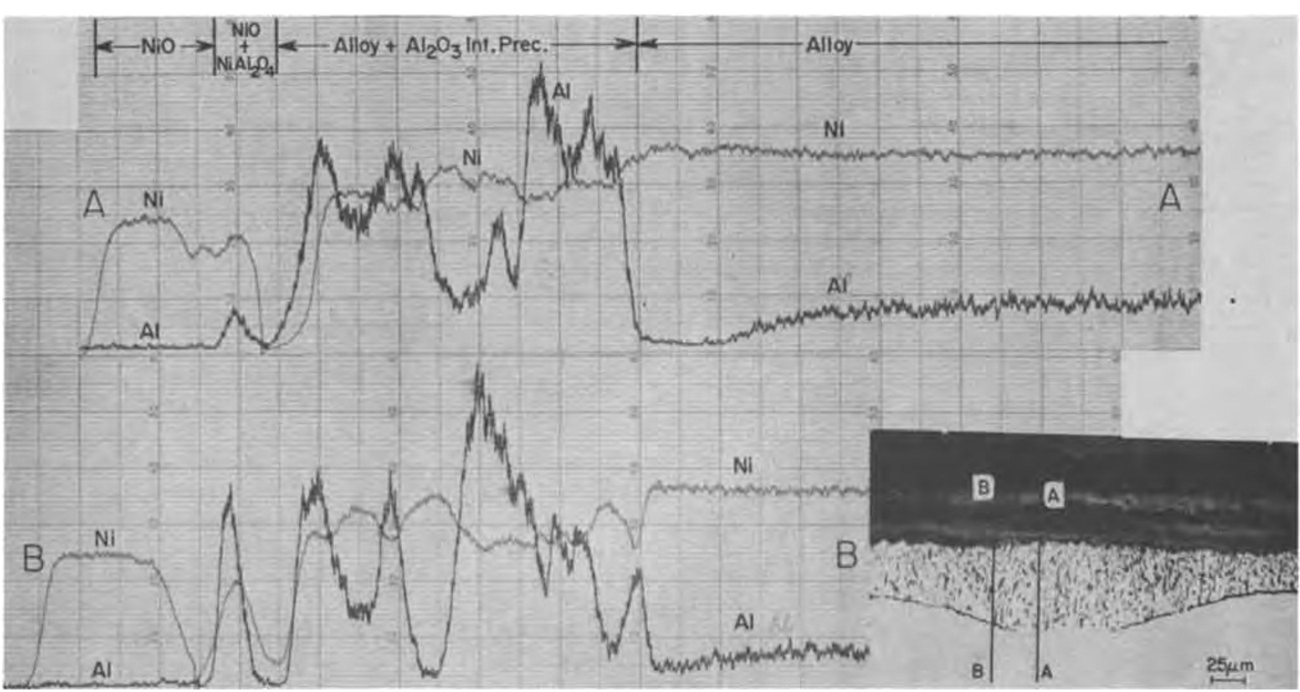

Fig. 12. Ni and Al electron microprobe x-ray scans across a scale formed on Ni-6 w/o Al alloy

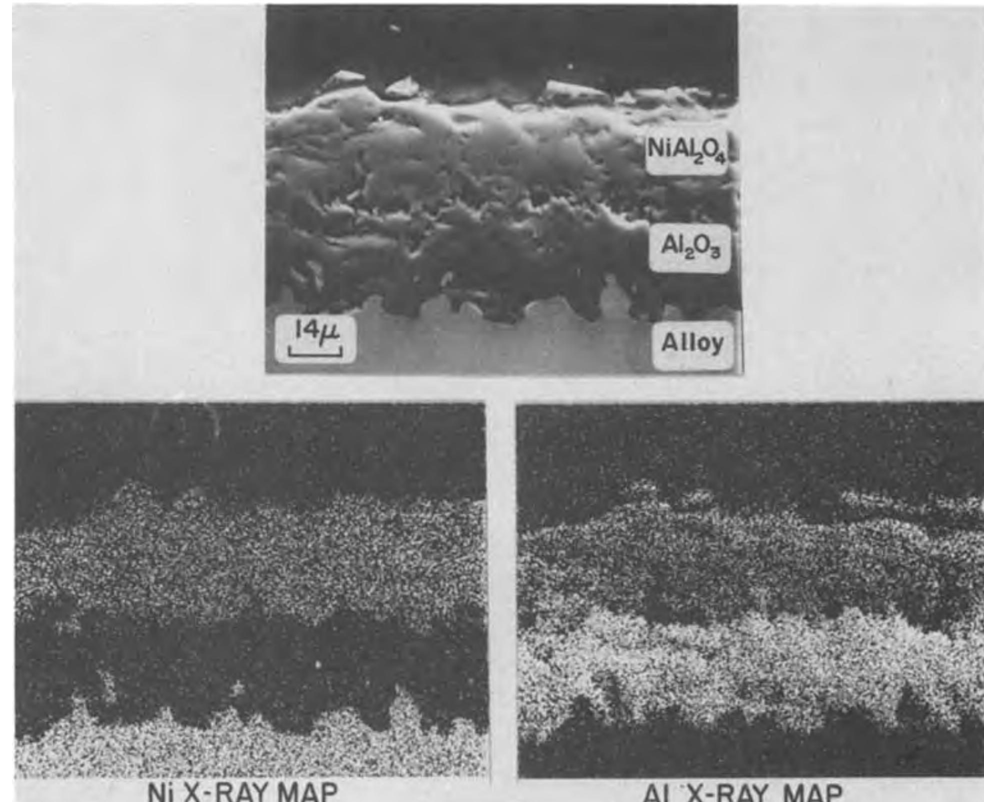

Fig. 13. Ni-6 w/o Al alloy steady-state morphology at 1573°K.

Since the scale retained intimate contact with the receding alloy surface during all stages of oxidation, these reactions involved diffusion processes. In NiO/ Al_2O_3 diffusion couples (15), counter diffusion of aluminum and nickel ions give rise to growth of $NiAl_2O_4$ by means of the following reactions which occur at the $NiO/NiAl_2O_4$ and $NiAl_2O_4/Al_2O_3$ interfaces, respectively

$$2Al_{(Al_2O_3)}^{3+} + 4NiO = NiAl_2O_4 + 3Ni_{(NiO)}^{2+} \quad [6]$$

$$3Ni_{(NiO)}^{2+} + 4Al_2O_3 = 3NiAl_2O_4 + 2Al_{(NiAl_2O_4)}^{3+} \quad [7]$$

For growth of the $NiAl_2O_4$ rods during the scaling reaction, it would be expected that the Ni^{2+} ions released by reaction [6] would diffuse outward through the scale under the influence of the oxygen activity gradient to form additional NiO. In order, therefore, for the $NiAl_2O_4$ rods to continually penetrate inward in the absence of a backward Ni^{2+} ionic flux, a solid-state reaction of Al_2O_3 with nickel and dissolved oxygen in the alloy would proceed as follows

$$Ni_{(alloy)} + O_{(alloy)} + Al_2O_3 = NiAl_2O_4 \quad [8]$$

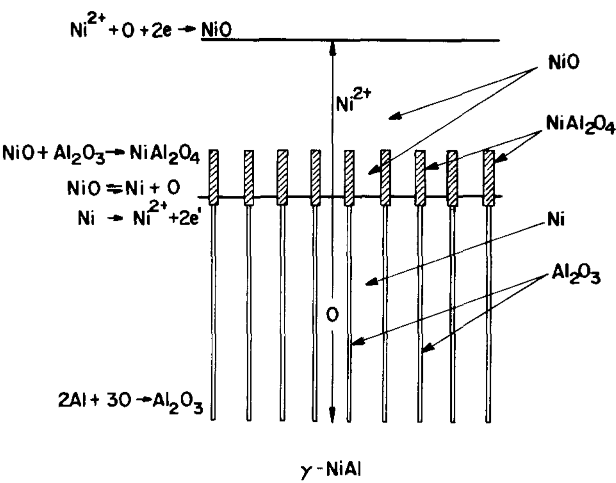

Fig. 14. Schematic model for scale growth on Ni-2 w/o Al alloy

At 1273°K, the $NiAl_2O_4$ growth rate in a diffusion couple at constant oxygen activity (15) is only ~0.1 of the observed advance rate of $NiAl_2O_4$ in the scale ($k = 0.6$ *vs.* $11.4\ \mu m \cdot hr^{-1/2}$). Hence, the growth rate of $NiAl_2O_4$ as rods in the conglomerate layer of the scale and beneath the alloy surface according to reactions [6] and [8] is probably determined by both boundary and lattice diffusion of the reactants under the influence of the oxygen and metal activity gradients.

Ni-6 w/o Al Alloy

Growth of nodules is a common transient phenomenon of alloy oxidation when large differences exist in diffusion and thermodynamic properties of the oxides. As examples, nodules of less stable and usually less protective oxides have been observed in films of more stable and protective oxides formed on Ni-Al(6,7), Ni-Cr(16,17), Co-Cr-Al(18), Fe-Cr(19,20), Fe-Al(21), and Fe-Si(22) alloys. In the present investigation, the oxidation kinetics decreased continuously with time suggesting that fracture of the oxide film did not occur. The relatively rapid oxygen uptake, however, rather suggests that Al_2O_3 does not form initially as a perfect continuous film but permits NiO to form as a transient phase at alloy grain boundaries and surface imperfections. This oxide subsequently develops as nodules exhibiting a circular base due to isotropic nickel diffusion. As reactant diffusion in NiO(23,24) is several orders of magnitude faster than in Al_2O_3(25,26), the former overgrows and partially converts the Al_2O_3 film into $NiAl_2O_4$.

A mechanism can now be advanced for the transition from scale growth with concurrent internal oxidation to solely external scale growth under these above early stage conditions. This oxidation behavior is interpreted by the schematic model illustrated in Fig. 15. In the region of nodules, the scale grew by a mechanism similar to the case of the Ni-2 w/o Al alloy [Fig. 15(a)]. The value of the parabolic rate constant during this initial oxidation stage, $k_1 = 2.5 \times 10^{-9}\ g^2\ cm^{-4}\ sec^{-1}$ at 1473°K was the same order of magnitude as that for the latter alloy. As oxidation proceeded, impingement of the Al_2O_3 rod precipitates at random sites of the oxidation front led to the formation of more protective film sections [Fig. 15(b)] and to the observed decline in reaction rate (Fig. 6 and 7). Complete development of an irregular Al_2O_3 film resulting from aluminum lateral diffusion from impingement sites to neighboring precipitates [Fig. 15(c) and (f)] isolated the internal oxidation zone from the alloy substrate. This behavior led to the onset of the second slower parabolic oxidation stage with $k_2 = 8 \times 10^{-11}\ g^2\ cm^{-4}\ sec^{-1}$ which is one order of magnitude less than $k_1 = 2.5 \times 10^{-9}\ g^2\ cm^{-4}\ sec^{-1}$. During this oxidation stage, nickel from the aluminum depleted alloy in the isolated internal oxidation zone diffused outwards to the scale surface. Simultaneous plastic deformation of the scale and continued incorporation of Al_2O_3 and NiO to form $NiAl_2O_4$ [Fig. 15(d)] ultimately led to development of the multilayered $NiO|NiAl_2O_4|Al_2O_3$ scale [Fig. 15(e) and 10(c)].

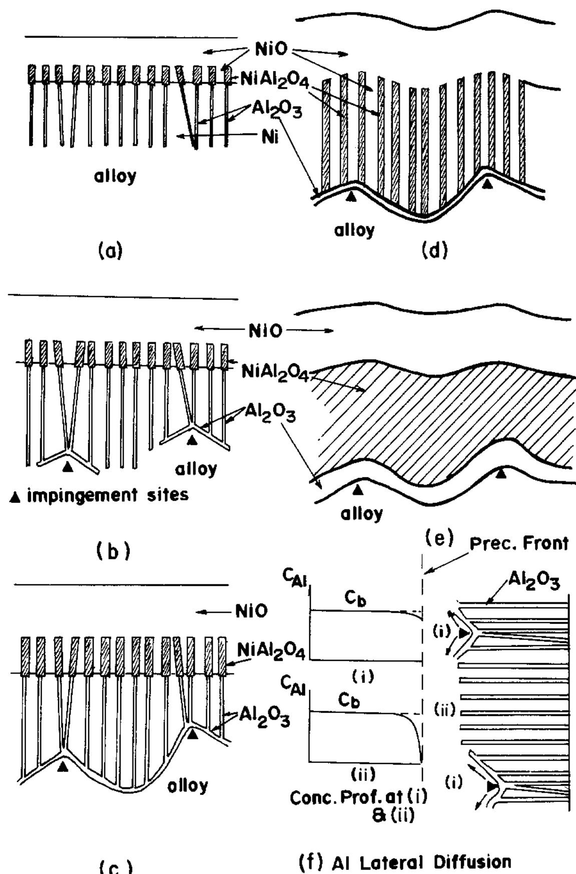

Fig. 15. Schematic model for scale growth on Ni-6 w/o Al alloy

Summary

High temperature oxidation properties of dilute Ni-Al alloys were investigated with special interest given to the microstructures and growth kinetics of α-Al_2O_3.

The alloy of low aluminum concentration, Ni-2 w/o Al, oxidized parabolically. α-Al_2O_3, which was precipitated internally in the alloy beneath a duplex $NiO|NiO$-$NiAl_2O_4$ layered scale, grew as rods extending through the internal oxidation zone parallel to the growth direction and independent of alloy grain orientation. Rod growth, which was controlled by oxygen diffusion in the aluminum depleted alloy of the internal oxidation zone, arose from a displacement reaction between NiO and aluminum in the alloy. A solid-state reaction between NiO and Al_2O_3 accounted for the continual growth of $NiAl_2O_4$. A rate-controlling step was not assigned to the reaction because the scale and internal oxidation precipitates grew in a cooperative diffusion mode.

The alloy of higher aluminum concentration, Ni-6 w/o Al, exhibited transient irreproducible oxidation before ultimate development of a $NiO|NiAl_2O_4|Al_2O_3$ layered scale. In the early stages of this transient period, NiO-$NiAl_2O_4$ nodules accompanied with an internal oxidation zone of Al_2O_3 precipitates grew through an imperfect Al_2O_3 film. Three distinct reaction stages could be discerned: a stage during which a duplex $NiO|NiO$-$NiAl_2O_4$ layered scale and an internal oxidation zone containing Al_2O_3 rod precipitates grew by a mechanism similar to that for the Ni-2

w/o Al alloy, a second and slower stage coinciding with the formation of an Al_2O_3 film at the precipitation front resulting from impingement of the Al_2O_3 rods at random sites and conversion of alloy in the isolated internal oxidation zone to $NiO|NiAl_2O_4$, and a third stage, the kinetics of which are not reported here, controlled by reactant diffusion through the Al_2O_3 film.

Scales formed on both alloys exhibited extraordinary resistance to spalling upon cooling. Scale adherence appeared to be improved by a pinning effect of the rodlike Al_2O_3 precipitates and, in the case of the high aluminum content alloy after long exposures, by the highly irregular inner Al_2O_3 film.

Growth and Microstructure of α-Al_2O_3 on β-NiAl

H. M. Hindam*,[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Growth of α-Al_2O_3 films and scales on β-NiAl (Ni-32 w/o Al) was investigated in oxygen at 1 atm over the temperature range 1273°-1573°K. An initial sub-microcrystalline oxide film recrystallized during its growth to a textured α-Al_2O_3 film containing polycrystalline ridges. Inert marker measurements demonstrated that the initial film grew by inward diffusion of oxygen. Fully developed α-Al_2O_3 scales contained dissolved nickel (0.5 w/o at 1473°K). Metallographic evidence indicated that these scales grew by counter-current aluminum and oxygen boundary diffusion and aluminum lattice diffusion. Cavities, which were generated at the alloy/Al_2O_3 interface, did not influence scale growth since aluminum was transported at a sufficient sustaining rate by evaporation from the alloy substrate. The square of the average oxide grain size in a growing scale increased proportional to time. The nonparabolic growth kinetics of the α-Al_2O_3 scales were interpreted by a short-circuit diffusion model.

Mechanisms for growth of internal Al_2O_3 precipitates in dilute Ni-Al alloys and transformation of these precipitates to a continuous layer in alloys at intermediate aluminum concentrations were defined in the preceding paper (1). Growth of Al_2O_3 scales on Ni-Al alloys has been the subject of only a few investigations (2-4) but more intensive research has been carried out on the growth mechanisms of these scales on other aluminum-containing alloys (5-12). The purpose of this investigation was to obtain detailed information on the growth kinetics and morpho-

logical development of α-Al_2O_3 on the intermetallic β-NiAl phase at high temperatures in order to advance a growth model.

Experimental Methods and Results

Specimen preparation procedures of the β-NiAl button containing 32.2 weight percent (w/o) Al [50.8 atomic percent (a/o)] were identical to those adopted in the case of alloys with low aluminum contents (1). A horizontal mullite tube furnace closed at one end was used for oxidation runs in static oxygen at 1 atm pressure. Specimens were suspended in a recrystallized alumina boat made by cutting a cylindrical crucible parallel to its axis. Alumina rods resting on grooves in the boat walls were used to support Pt-Rh hooks for the specimens. Oxygen was admitted to the evacuated tube after the furnace was brought to the desired temperature. The boat containing the β-NiAl disk shaped specimens, 1 cm diam and 0.1 cm thick, was then moved from the cold end of the tube to the hot zone by means of a quartz rod sliding through a stainless steel swagelock fixed to the tube by O-ring seals. Thin oxide films were stripped from the alloy substrate using 10% bromine-methanol solution; thick films and scales were fractured from the alloy.

Oxide films formed at exposures less than 5 min at temperatures as high as 1473°K did not exhibit distinct morphological features. Figure 1(a) is a TEM image and selected area diffraction pattern of an ~120 nm film formed at 1273°K in 5 min. The image exhibits poor contrast and the pattern consists of halos which can arise from sub-microcrystallites <10 nm in size. Heating this stripped film in the microscope to 1123°K for ~30 min led to formation of crystallites having a wide size range, 50-250 nm, as shown in Fig. 2(b). This structure gave rise to a definite electron diffraction ring pattern, which could be indexed as γ-Al_2O_3.

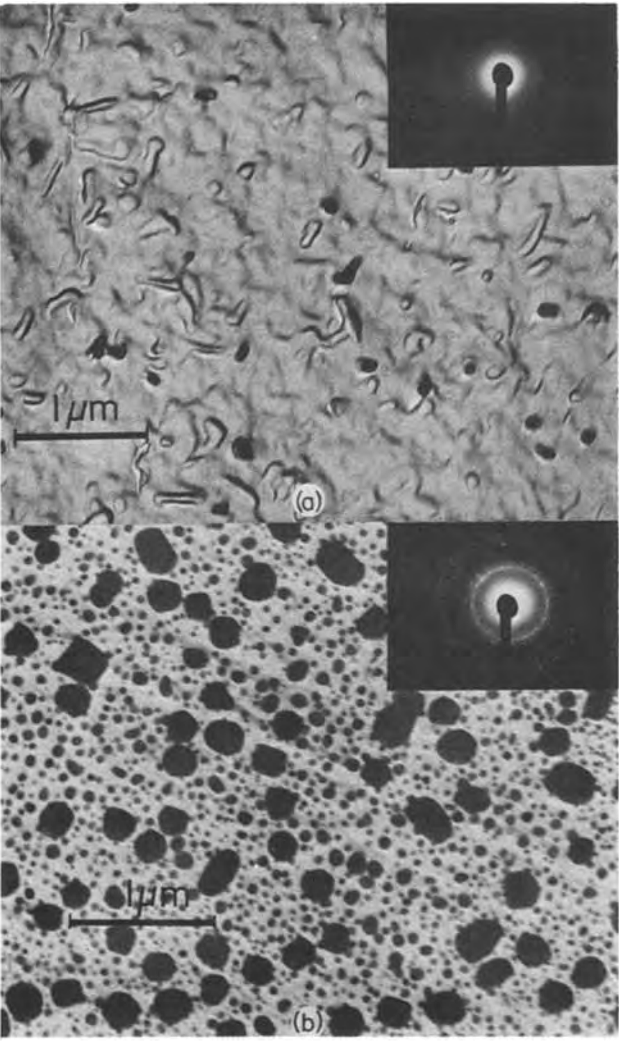

Fig. 1. TEM images and selected area diffraction patterns of oxide films formed on Ni-32 w/o Al alloy: (a) initial sub-microcrystalline film (5 min at 1273°K), (b) film shown in (a) after reheating *"in situ"* to 1123°K.

Thicker oxide films became nonuniform due to ridges extending outward and inward at spacing distances dependent on alloy grain orientations. The structure of this type of film (1 μm thick) formed after 30 min at 1473°K and the corresponding reflection electron diffraction pattern are shown in Fig. 2. The pattern exhibits sharp diffraction rings corresponding to those for α-Al_2O_3, Fig. 2(b). Faceted cavities were consistently observed at the alloy/film interface, Fig. 2(c), which tended to coalesce and form extended troughs between the film and alloy substrate. The oxide film in the vicinity of an alloy grain boundary is shown in Fig. 2(d) where the delineation between ridge spacings is evident.

Thicker scales spalled partially upon cooling which allowed close examination of their structure. Figure 3 illustrates SEM images at different regions of a scale formed after 15 days at 1473°K. It is apparent that the scale fractured intergranularly, Fig. 3(a). Electron probe microanalysis demonstrated that ~0.5 w/o Ni was dissolved in this scale. The ridge persisted after this long oxidation period as evidenced by micrographs of the scale outer surface, Fig. 3(b), and scale underside, Fig. 3(c). The total length of the ridges extending from both interfaces by means of the oxide grain boundaries, nevertheless, accounted for <10% of the scale thickness. Few whiskers were formed at the scale outer surface, Fig. 3(b). The alloy interface exhibited imprints from the scale corresponding to the ridges in its underside, Fig. 3(c), and oxide-free faceted cavities revealing crystallographic arrangements, Fig. 3(d). Spiral steps on the alloy surface were also evident in some cavities, Fig. 3(e). Though the degree of cavitation varied over different alloy grains, the total volume increased as oxidation was prolonged [compare Fig. 2(c) and 3(d)].

Oxidation kinetics of the recrystallized α-Al_2O_3 scales were determined at 1473° and 1573°K by layer thickness measurements of polished scale cross sections using SEM images at 8000× magnification to an accuracy corresponding to 0.1 μm. The reaction kinetics are shown in Fig. 4; each data point represents the average of 15 readings taken from three samples oxidized in a batch.

In light of the above evidence for reactant transport being dependent on the Al_2O_3 scale structure, the grain size was determined from fracture cross sections of partially spalled scale flakes. The grain diameter was measured parallel to the scale interfaces with the same accuracy as the thickness measurements. In each case, 100 grains chosen at random from different parts of the scale were used to determine the grain size distribution. The average grain size increased with continued oxidation as shown in Fig. 5.

It was feasible to employ inert Pd markers to identify the relative mobilities of the diffusing species during growth of the thin uniform oxide films. As has been described elsewhere (13), AES in combination with depth profiling by Ar ion sputtering can be employed to determine the location of extremely thin (3-5 nm) markers. In this case, a specimen was oxidized at 1273°K for 5 min to form a sub-microcrystalline oxide film. AES analyses of the oxidized specimen prior to and during sputtering of the film are shown in Fig. 6. The Pd marker, which resided at the external film surface, was sputtered completely away in less than 10 min. Disregarding Pd, the film

consists of pure Al_2O_3 since Ni could only be detected in the vicinity of the alloy/oxide interface.

Discussion and Conclusions

An initially formed sub-microcrystalline film consisting of Al_2O_3 grew by inward migration of oxygen even at temperatures as high as 1473°K under the conditions of experimentation. Reheating to 1123°K of a stripped film caused its "recrystallization" to γ-Al_2O_3. It is therefore conceivable that the sub-microcrystalline films, which transformed to α-Al_2O_3 during their growth under isothermal conditions at temperatures exceeding 1273°K, involved the transient formation of the γ-Al_2O_3 allotropic phase. This transformation could lead to the occurrence of faulted regions in the recrystallized film since the conversion of γ to α-Al_2O_3 is accompanied by a reduction of 14.3% in volume (14). The α-Al_2O_3 films were nonuniform exhibiting growth of polycrystalline oxide extending inward and outward which implies that these regions contained a large density of boundaries acting as easy diffusion paths for both reactants. The presence of these polycrystalline ridges between the oriented thinner oxide film regions, Fig. 2(c), could be induced by faults as discussed above or by the influence of the alloy substructure.

Origin of cavities at the alloy/Al_2O_3 cannot be unequivocally defined. These cavities have also been observed in other investigations on Al_2O_3 forming alloys (2-10, 15). We conjecture that in the presence of a few vacancy sinks, as in the case of coarse-grained alloys or foils having large surface/volume ratio (16-19), the concentration of the vacancies injected to the alloy substrate during oxide growth exceeded the supersaturation limit and led to void formation by vacancy coalescence. Transport of aluminum across the voids by evaporation is given by

$$\frac{dW}{dt} = P_{Al}\left(\frac{M}{2\pi RT}\right)^{1/2}$$

where P_{Al} and M are the vapor pressure and atomic weight of aluminum, respectively, and R is the gas constant. At $T = 1473$°K, vapor pressure of pure aluminum $= 10^{-5}$ atm (20) and aluminum activity in β-NiAl $= 10^{-3}$ (21), the calculated aluminum evaporation rate is 0.2×10^{-8} g cm^{-2} sec^{-1}. This rate, which is equivalent to 1.7×10^{-7} gO cm^{-2} sec^{-1},

is much larger than the maximum observed oxygen uptake rate by the specimen equal to 1×10^{-9} gO cm^{-2} sec^{-1}. An aluminum evaporative mechanism accompanied with outward aluminum migration through the growing scale leads to the conclusion that void formation does not interfere with scale growth and explains the development of relatively uniform thick scales. Aluminum evaporation from the substrate with limited inward boundary oxygen diffusion through the α-Al_2O_3 scale can also lead to the observed spiral steps, faceting, and enlargement of voids, Fig. 3(d) and (e).

The experimental evidence offers support to an oxidation mechanism for growth of the α-Al_2O_3 scales involving counter diffusion of aluminum and oxygen. Growth of polycrystalline ridges extending inward, Fig. 2(c) and 3(c), indicates that oxygen inward migration is mainly limited to regions of a large density of grain boundaries in the scale. Metallographic observations by previous investigations and those in this investigation suggest outward aluminum diffusion via grain boundaries: outward extension of the above polycrystalline oxide ridges (4, 11), Fig. 2(a), (c), and 3(b); the spacing of these ridges at the scale/gas interface is less than at the scale/alloy interface, Fig. 3(b) and (c), consistent with scale growth predominantly at its outer interface when nucleation of new grains and their subsequent growth are taken into account; growth of Al_2O_3 whiskers (3, 5, 10), Fig. 3(b), which can result from metal transport through the scale by a type of line or surface defect (22-24). These considerations are consistent with measurements of tracer diffusivities (25, 26) which demonstrate that at temperatures exceeding 1923°K aluminum diffuses approximately at a rate one order of magnitude higher than oxygen in polycrystalline Al_2O_3 and that the ratio of these diffusivities D_{Al}/D_o decreases with decreasing grain size (27). Oxygen diffusion in single crystal Al_2O_3 compared to the above aluminum diffusion rate is about two orders of magnitude less. This latter consideration and the continual growth of voids beneath the scales lead to the conclusion that the oriented Al_2O_3 grains between the polycrystalline ridges grow by aluminum lattice diffusion to react with oxygen at the external scale surface. The findings from the comprehensive studies on the defect properties of high purity α-Al_2O_3 single crystals (28, 29) are consistent with a point defect model involving aluminum interstitial ions and electrons as the major mobile species. This type of aluminum diffusion, moreover, would be enhanced by the doping effect of nickel since the thick scales contained ~0.5 w/o Ni. Consequently, enhanced aluminum lattice diffusion accompanied with oxide grain growth led to development of the observed relatively uniform thick scales, Fig. 3(a). As illustrated by the linear plots in Fig. 7, square of oxide average grain size *vs.* time, the Al_2O_3 average grain size during growth of the scales followed a general grain growth relationship. The activation energy for grain growth determined from these measurements at two temperatures is 133 kJ/g mole.

The oxidation kinetics for scale growth can be interpreted to a first approximation by a short-circuit diffusion model similar to that advanced to interpret NiO growth on nickel (30, 31). An effective diffusion coefficient for aluminum and oxygen migration along grain boundaries and aluminum via lattice sites in polycrystalline alumina is expressed as

$$D_{eff} = D_L + f\bar{D}_B$$

where D_L is the aluminum lattice diffusion coefficient, $\bar{D}_B$ is an average diffusion coefficient for counter migration of aluminum and oxygen along grain boundaries in a scale, f is the fraction of grain boundary diffusion sites represented by $f = 2d/D$ where d is

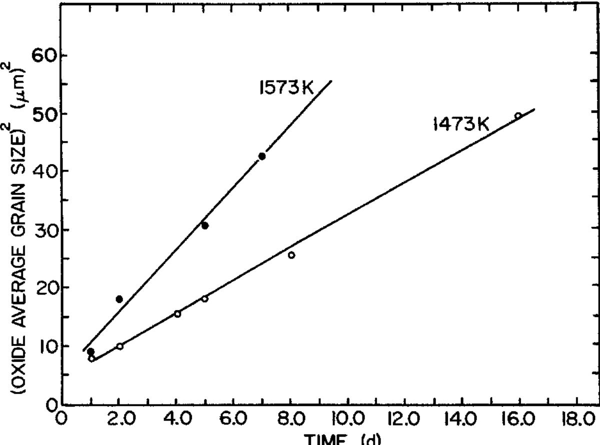

Fig. 7. α-Al_2O_3 scale grain growth: parabolic presentation

the grain boundary width and D is the average oxide grain diameter which was shown to obey the relationship $D^2 - D_o^2 = Gt$ where G is the grain growth rate constant. A modified parabolic rate equation

$$x^2 = 2\Omega D_L \Delta c \int_0^t \left(1 + f\frac{D_B}{D_L}\right)dt$$

where Ω is the equivalent volume of alumina represents the oxidation kinetics upon utilizing the approximation of a linear compositional gradient to define the flux of reactants across the oxide layer. This equation is placed on differential form

$$\frac{dx^2}{dt} = k_L + k_B d/D$$

where $k_L = 2\Omega D_L \Delta c$ and $k_B = 2\Omega D_B \Delta c$ to test the obeyance of the oxidation kinetics and alumina grain growth to this simple short-circuit diffusion model. The linear plots of dx^2/dt *vs.* $1/D$ in Fig. 8 demonstrate the validity of the above relation. Assuming an Arrhenius relationship for k_B and an independence

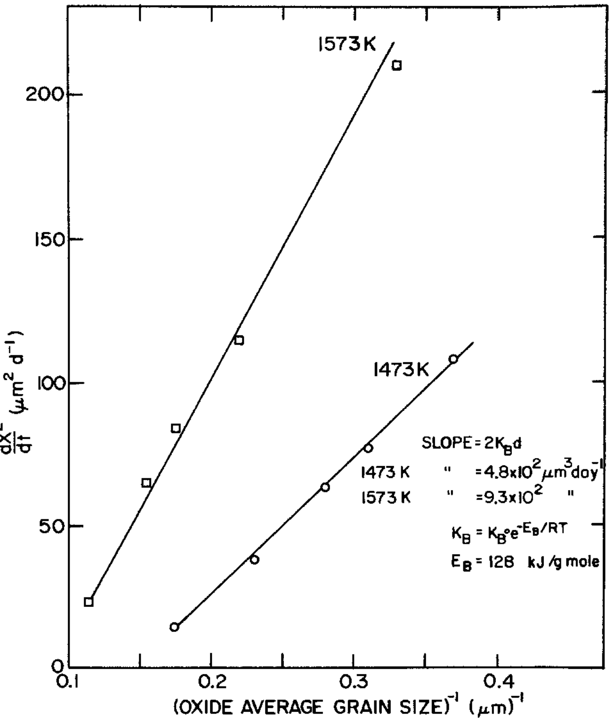

Fig. 8. Verification of short-circuit diffusion model: plot of dx^2/dt *vs.* D^{-1}.

Table I. Comparison of observed and calculated grain size in the α-Al_2O_3 scale formed at 1573°K

Oxidation time (days)	Average oxidation grain size (μm)	
	Observed	Calculated
2	3.2 ± 0.6	3.8
3	3.6 ± 0.8	4.7
5	4.5 ± 0.6	6.8

of boundary width on temperature, the effective activation energy for aluminum and oxygen boundary diffusion is 128 kJ/g mole. This value is much smaller than the activation energies for aluminum diffusion in high purity polycrystalline (130-200 μm) α-Al_2O_3, 475 kJ/g mole, and oxygen diffusion in single α-Al_2O_3 crystals, 635 kJ/g mole (25, 26).

Since $k_B >> k_L$, the scale grain growth rate can be predicted from the above equation using the oxidation kinetic data and knowing the average grain size at a given time. The calculated and measured grain size are given in Table I. The agreement between the observed and calculated values is reasonable when one considers the simple approximations utilized to describe scale growth by a short-circuit diffusion model.

The model schematically represented in Fig. 9 summarizes the present findings for growth of the α-Al_2O_3 scale on β-NiAl. Initially, a submicrocrystalline film was formed containing a large density of boundaries along which oxygen diffused inward. Film recrystallization led to development of an oriented α-Al_2O_3 film containing regions of disarrayed oxide induced by oxide faulting or by the influence of the alloy substructure. Boundaries in this disarrayed oxide for counter diffusion of aluminum and oxygen resulted in the development of ridges extending inward and outward. Based on the recent findings on the defect properties of alumina, it is assumed that oxide within grains grew by outward migration of aluminum ions via an interstitial mechanism. Voids were formed at the NiAl/Al_2O_3 interface by coalescence of vacancies

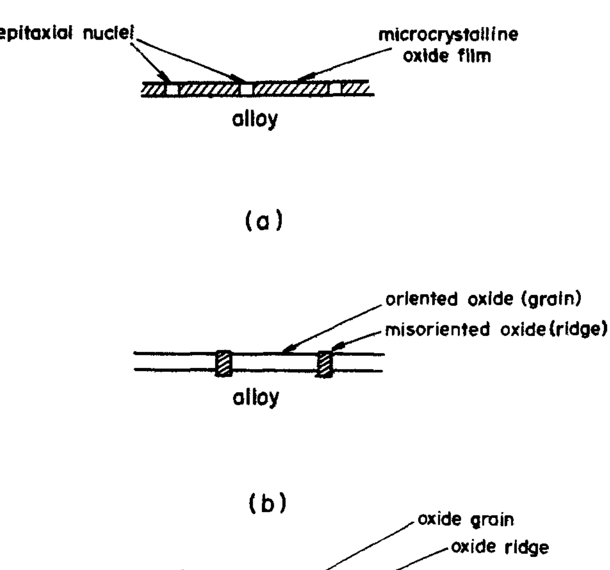

Fig. 9. Schematic model for Al_2O_3 growth on Ni-32 w/o Al alloy

generated by film growth. Aluminum evaporation from these voids in the presence of limited inward boundary oxygen migration in the α-Al_2O_3 scale led to development of faceted cavities. Eventually, counter diffusion of aluminum and oxygen through the boundaries present in the ridge and oxide grain growth coupled with aluminum outward diffusion partially enhanced by nickel doping led to uniform scale growth.

Relationship Between Deposition Conditions and Physical Properties of Sputtered ZnO

James O. Barnes,[1] David J. Leary,* and A. G. Jordan

Department of Electrical Engineering and Center for the Joining of Materials, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

ABSTRACT

Characteristics of the deposition process and properties of the resultant films have been determined for undoped and gallium-doped sputtered zinc oxide. The properties of interest are film growth rate, resistivity of the as-sputtered film, optical transmission, grain size, and carrier concentration and mobility as determined by the Hall effect. The goal of the investigation has been to establish how these properties depend on sputtering conditions, specifically sputtering ambient composition, sputtering power, and substrate temperature. The principal findings are: (*i*) the dependence of film deposition rate on applied power and ambient composition suggests a complex deposition process involving the transport of several types of aggregates of atoms; (*ii*) films sputtered in an oxygen-free ambient show strong optical absorption in the visible region and a high concentration of carriers, while films sputtered in a partial pressure of oxygen show absorption similar to that reported for ZnO powder; (*iii*) substrate temperature has a marked influence on the electrical properties of Ga-doped films, with films sputtered at certain temperatures showing behavior suggesting the existence of intergranular potential barriers.

Past investigations have shown that zinc oxide properties are significantly dependent on sample thermal history and method of preparation, particularly in the case of sintered specimens. The importance of surface effects in this material, due primarily to chemisorbed oxygen, has also been demonstrated. Therefore, measurements of properties of single crystal or sintered samples are not applicable to sputtered films. Because of the recent practical interest in ZnO sputtered thin films for surface acoustic wave (1) and solid-state gas sensing devices (2), and the unavailability of data for these films, the present investigation has been carried out.

Zinc oxide is an n-type ionic wide bandgap semiconductor ($E_g = 3.2$ eV) having a wurtzite crystal structure. It is generally agreed that a nonstoichiometric excess of interstitial zinc which occurs in undoped material is responsible for the free electrons. The temperature dependence of the excess zinc concentration for ZnO in an ambient of air (3) and zinc vapor (4) have been determined by chemical analysis. Early electrical measurements on sintered specimens (5) indicated the importance of heat-treatment in determining conductivity and Hall mobility. Another study of sintered ZnO (6) revealed that a single shallow donor model was unable to describe the temperature dependence of the carrier concentration and suggested the possibility of deep-lying acceptor states. Hutson (7) was the first to report comprehensive single crystal electrical measurements. For most of his zinc-, lithium-, and hydrogen-doped samples, the data could be fitted by a single shallow donor model. The mobility temperature dependence could be described well by a combination of polar optical mode, acoustic mode, and ionized impurity scattering, with the fit being best between 200° and 300°K. Later studies (8) revealed donor band conduction at low temperatures (below about 50°K).

In contrast to the extensive literature for single crystal and sintered specimens, few studies of the electrical properties of sputtered ZnO films have been reported (9, 10). A number of authors have described characteristics of sputtered ZnO films in connection with surface acoustic wave applications (11). However, the emphasis has been on film morphology, which is important for these devices, and not electrical properties. Of particular interest in the present work have been the influence of applied sputtering power, sputtering ambient composition, and substrate temperature on film properties. Film growth rate, optical transmission, grain size, resistivity, and Hall mobility were examined

Experimental Methods

For gas sensor applications, conductive ZnO films having well-controlled carrier concentration and grain size are required. A number of film deposition techniques, such as vacuum evaporation of ZnO source material, post-deposition oxidation of zinc thin films, and firing of an aqueous suspension of zinc oxide powder have been investigated by us. However, none allows incorporation of dopants and process reproducibility of the radio frequency sputtering process. Targets for this study were fabricated by pressing and sintering high purity powders; both an undoped and gallium-doped target (1% Ga: Zn ratio) were used. Fused quartz substrates were used for electrical measurements, while Pyrex microscope slides were used for optical and growth rate studies. The substrates could be maintained at 500°C during deposition by radiant heating.

Optical measurements were performed with a Cary 14 Double Beam Spectrometer. Film thickness was determined with a commercial stylus profile measuring device. For resistivity and carrier concentration measurements, six-arm Hall specimens were produced by sandblasting through a metal mask. Pressure contacts were then made to evaporated aluminum pads. Measurements at other than room temperature were made in a metal Dewar with the sample surrounded by a vacuum. Except near 100°C, the maximum temperature employed, no changes in electrical properties due to desorption of chemisorbed ions were detected. For Hall effect and conductivity measurements, a conventional d-c technique was used.

Effect of Composition of Sputtering Atmosphere on Growth Rate, Electrical, and Optical Properties

Film growth rate.—The nature of the sputtering process for compound materials has not been well

* Electrochemical Society Student Member.

Key words: zinc oxide, sputter deposition, electrical properties, optical transmission.

characterized, but it is believed that both individual atoms and aggregates of atoms are sputtered (12). In order to maintain stoichiometry in the deposited film, it has been found necessary to mix a small percentage (~10%) of oxygen with the argon sputtering gas. Properties of films sputtered in less than this percentage of oxygen are sensitive to atmosphere composition, while films sputtered in a greater percentage are not sensitive. The importance of ambient composition in determining film properties has been discussed previously (10).

Figure 1 shows film growth rate *vs.* ambient composition and applied rf power. Addition of 10% oxygen is seen to reduce growth rate by 36%, while further increase to 100% oxygen results in an additional 13% reduction. This behavior is not due simply to the mass difference of the argon and oxygen atom, since a linear relationship between growth rate and percentage oxygen would then be expected. One possible explanation is that, in atmospheres containing less than 10% oxygen, individual zinc and oxygen atoms are sputtered, while in greater than 10% oxygen larger aggregates are sputtered in addition to individual atoms. Ignoring differences in binding energy, the energy transfer from the sputtering ion to the ejected target material is greatest when the mass of the ejected particle equal that of the ion. This would result in a greater sputtering rate in the absence of oxygen.

Figure 1(a) shows the dependence of growth rate on applied rf power. In both 0% and 10% oxygen, an apparent threshold in power is seen below which sputtering does not occur. This behavior has been reported for d-c sputtered SnO_2 (13). Nonlinearity is seen in both curves; however, it is most pronounced in the 10% oxygen curve. This would be expected if (as conjectured above) the 0% sputtering process involved transport only of individual atoms, while the 10% oxygen process involved sputtering of atoms and aggregates in various proportions depending on applied rf power.

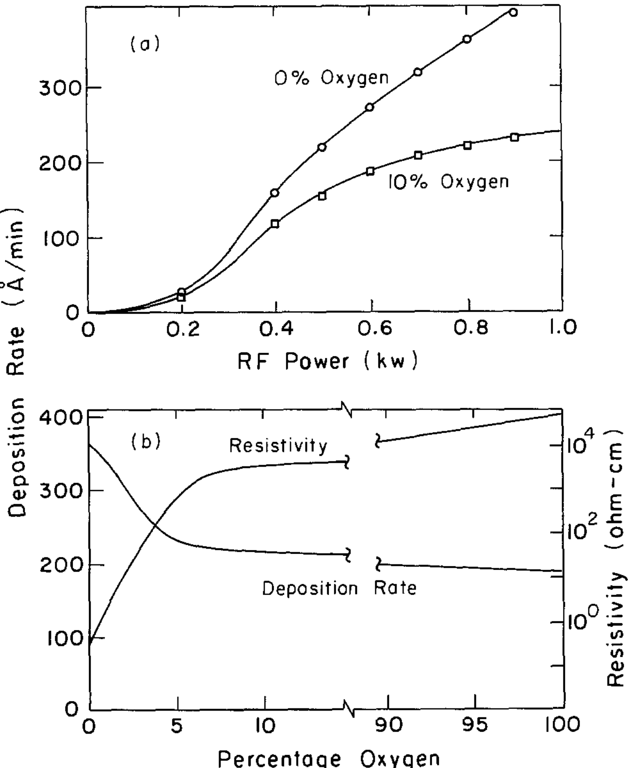

Fig. 1. (a) Dependence of deposition rate of undoped ZnO on applied rf sputtering power; (b) dependence of deposition rate and resistivity of undoped as-sputtered ZnO on argon-oxygen ratio of the sputtering gas. RF deposition power was 0.75 kW.

Resistivity of undoped films.—Films sputtered in less than 10% oxygen contain a high concentration of electrically active defects, as shown in Fig. 1(b). Assuming singly ionized shallow donor defects and a conductivity mobility of 5 $cm^2/Vsec$, typical of values found in Hall measurements, films sputtered in pure oxygen have a carrier concentration of about 4×10^{18} cm^{-3}, or 100 ppm atomic. Hagemark and Toren (4) studied the solubility of interstitial zinc for single crystals in equilibrium; the solubility was found to exceed 100 ppm for temperatures in excess of 1050°C. The degree of vibrational disorder of the surface of the growing film should in fact be equivalent to a very high temperature, since the mean energy of the impinging particles is several eV; therefore, the defect density seen in the sputtered films could be of the order of magnitude measured.

The conductivity of as-sputtered undoped films was found to be due in part to defects which annealed rapidly at 400°C. Films sputtered in pure argon and in a partial pressure of oxygen both showed a rapid resistance increase upon heating in air. The high final resistance values made quantitative study of this effect difficult, but an increase of greater than three orders of magnitude occurred for the pure argon films. The rate of diffusion of interstitial zinc at 400°C is too low to account for this annealing; in the solubility study (4), two weeks were required to reach equilibrium between a millimeter size crystal and zinc vapor at 700°C. A more likely explanation for the 400°C resistivity increase is chemisorption of oxygen at surface oxygen vacancies.

Optical transmission.—Figure 2 shows the optical absorption spectrum for single crystal, powder, and sputtered ZnO. The 3700Å absorption edge for the single crystal corresponds to a bandgap of 3.2 eV. Powder and sputtered samples show absorption at photon energies below the bandgap. Van Craeynest *et al.* (3) attribute the behavior of powder samples to F-centers associated with interstitial Zn, which is singly ionized below 750°C and doubly ionized at higher temperatures. Curve 2 of Ref. (3) represents powder cooled slowly in air from 1100°C and presumably containing a minimal amount of excess Zn. Curve 1 shows a sample quenched from 920°C containing excess Zn^{2+} centers. The sputtered films 1 and 2, sputtered in greater than 10% oxygen, show the same absorption band as powder specimen 1, although stronger in magnitude. The slight shift (~0.08 eV) to lower photon energies in the curve for the Ga-doped film (No. 2) is due to photo-excitation of carriers to the Ga levels as opposed to the conduction band in the undoped sample. The film sputtered in pure Ar, however, shows a spectrum markedly different from the other sputtered or pow-

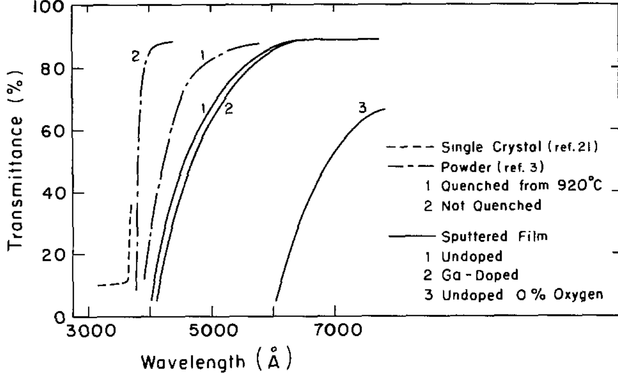

Fig. 2. Optical transmission spectrum of as-sputtered ZnO compared with single crystal and powder ZnO data. Sputtered film thickness is 1000Å. Data for single crystal and powder samples have been normalized to transmittance of sputtered films 1 and 2 at 7000Å.

der samples. The absorption edge at 6000Å is associated with the electrically active defects which anneal at 400°C, since the transmittance in the visible is increased with heat-treatment at 400°C. It is reasonable that the surface oxygen vacancy concentration, responsible for the high conductivity and strong optical absorption, should be largest in this film.

Effect of Deposition Temperature on Electrical Properties

The results described in the following section are restricted to Ga-doped films, since these were found to have stable characteristics and resistivities which facilitated measurement of the electrical properties. Substrate temperature can influence electrical characteristics through effects on grain size and doping concentration. Many polycrystalline films, including ZnO, are known to contain a high concentration of acceptor states in the grain boundary region; these states arise from point defects and departures from stoichiometry. In films of small grain diameter, the effective free carrier concentration n_{eff} can become significantly smaller than the doping concentration because of trapping of carriers by grain boundary defects. This behavior has been termed autocompensation (14), and has been modeled by simultaneous solution of Poisson's equation and the charge neutrality relationship in small spherical crystallites (15). The trapped carriers in the grain boundary region give rise to potential barriers and mobility values which are much lower than single crystal values (16, 17). Change in carrier concentration with deposition temperature may be due to loss of volatile dopant during sputtering, as has been reported for Sn_2CdO_4 (18), or annealing of defects during deposition.

Figure 3 shows that both grain size and doping concentration vary with substrate temperature. Grain size is seen to increase fourfold between 120°C (no radiant heating) and 480°C. A decrease in free carrier concentration of almost two orders of magnitude between 270° and 480°C is found. Since the amount of charge trapped in the grain boundary region is smallest at highest deposition temperatures, the loss of dopant at high temperatures is seen to be the predominant effect of substrate heating.

Figure 4 shows the temperature dependence of carrier concentration and mobility in Ga-doped films,

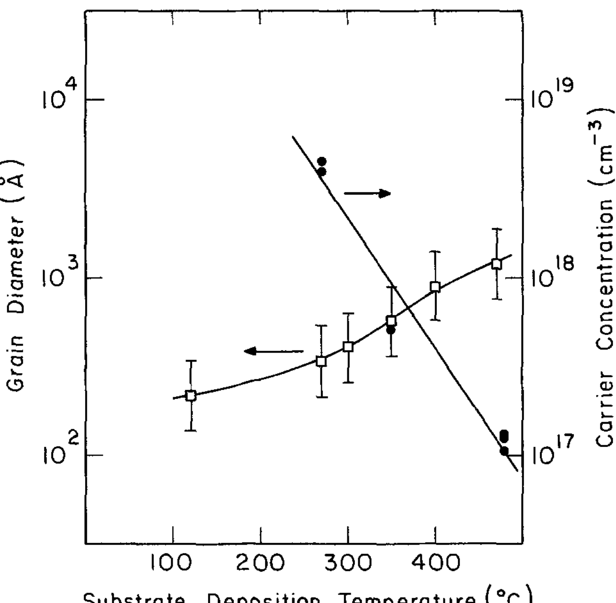

Fig. 3. Grain diameter as determined by scanning electron microscopy and carrier concentration of as-sputtered Ga-doped ZnO vs. substrate deposition temperature.

compared with single crystal and sintered sample measurements. Evidently the variation in doping level and grain size results in quite different behavior for samples deposited at different temperatures. The 270°C sample most closely approximates single crystal behavior in temperature dependence of n_{eff} and μ_H, as well as magnitude of mobility in this temperature range.

In Fig. 5, the n_{eff} *vs.* $1/T$ data are analyzed by plotting

$$\ln \frac{n_{eff}}{(N_D - n_{eff})N_C} \quad [1]$$

vs. $1/T$, as was done by Hutson (7). Here N_C is the conduction band density of states, calculated using an effective mass of 0.3 m_o. N_D was estimated from the carrier concentration above room temperature. Although previous authors have varied N_D from this estimate to produce the best straight line fit to the data, such a procedure is not warranted here. The present discussion is concerned mainly with the slopes of the curves, which are insensitive to order-of-magnitude changes in the value assumed for N_D. The heavily doped 270°C sample shows a considerably lower slope than the other two samples and additionally a possible break in slope near room temperature. Although onset of degeneracy can lead to such a slope change, the 270°C sample is at most weakly degenerate. Modification of Eq. [1] to reflect weak degeneracy (19) does not significantly alter the curve. From the data, the level scheme shown in Fig. 5 is inferred, with the Fermi level in this temperature range lying between the upper two donor levels from the 270°C sample and just above the third donor level for the 350° and 480°C samples. One or both of the upper two donor levels is due to Ga. The optical spectra of Fig. 2 indicate a shift toward lower energy of the absorption edge of the Ga-doped sample compared with the undoped sample. The shift could be due to transitions to the middle donor level, since the magnitude (~80 meV) is close to the 60 meV donor level measured. Regarding the lower donor level, it is not possible from the present data to establish whether it is due to Ga or is present in the undoped film. The deep-lying acceptor levels which pull the Fermi level down in the less heavily doped samples are probably due to chemisorbed oxygen, which forms acceptor states 0.72 eV below the conduction band (20).

In the mobility plot [Fig. 4(b)], the 270°C sample shows mobility values approaching that of sintered specimens, as well as a decrease with increasing temperature similar to the single crystal and sintered specimens. The mobility fall off near room temperature in single crystal ZnO is due to the predominance of polar optical mode scattering (7). That the mobilities of the sintered and 270°C sputtered samples are similar to the single crystal curves apart from an approximately constant factor suggests that the current flow in the first two is through material having the same electrical behavior as single crystal ZnO. The scaling of the mobility in sintered and 270°C sputtered ZnO implies that the cross-sectional area of the current path in these specimens is smaller than the measured cross-sectional area of the specimen. This would be expected if the current flow is through narrow necks between adjacent grains, with the electrical properties of the necks and material within the grains being essentially the same as single crystal ZnO.

The 350° and 480°C samples have considerably lower mobilities at any temperatures than any of the other samples and moreover have strongly increasing mobilities with temperature. The slope cannot be due to ionized impurity scattering, since this process is of comparable or larger magnitude in the heavily doped sample (270°C). Rather, the slope is indicative of a mobility controlled by intergranular potential barriers due to trapped impurities. From the ther-

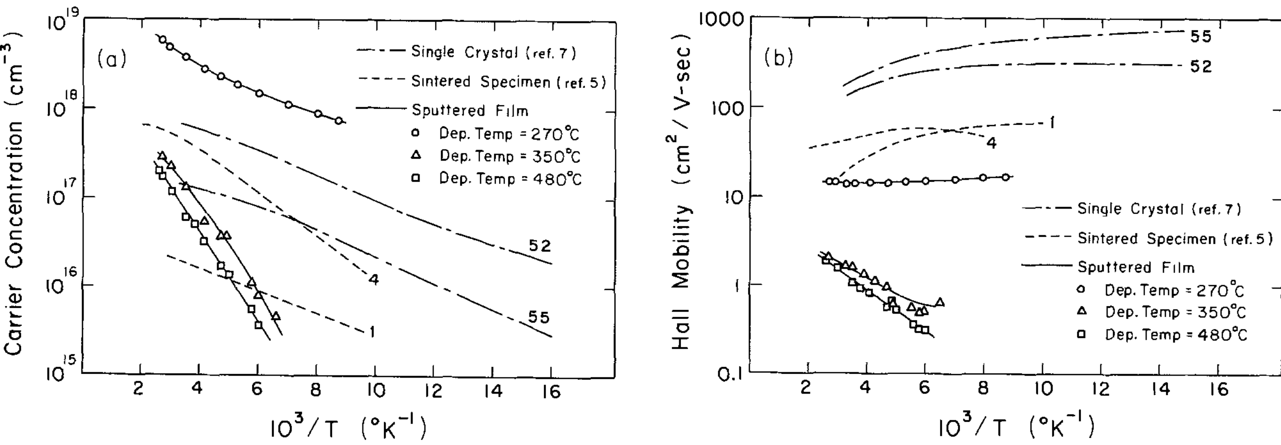

Fig. 4. (a) Carrier concentration of as-sputtered Ga-doped ZnO films vs. reciprocal temperature compared with representative data for single crystal and sintered specimens. mionic emission formula, the barrier mobility may be written (16)

$$\mu = \frac{e<v>}{N_1 kT} e^{-\phi_b/kT} \quad [2]$$

where $<v>$ is the mean thermal velocity of carriers, N_1 is the number of barriers per unit length along the current path, and ϕ_b is the potential barrier height. The exponential temperature dependence of μ_H is seen for both lightly doped samples, the slightly greater slope of the 480°C sample indicating a larger barrier height. Seager and Castner (17) have theoretically and experimentally studied potential barriers in epitaxially grown polysilicon films. It was found that at low doping levels, the barrier height approaches $(E_C - E_A)$, the acceptor energy with respect to the conduction bandedge. Above a certain doping level which depends on the trap density, the potential barrier was found to go to zero. This is evidently the case for the 270°C film. The barrier height for the 480°C sample is 0.14 eV, which is considerably less than $(E_C - E_A)$ for chemisorbed oxygen. Possible reasons for this difference are: (*i*) the carrier concentration of the 480°C film is not low enough to reach the limiting value for ϕ_b; (*ii*) the donors are nonuniformly distributed throughout the grains, giving rise to an electric field in opposition to the field due to the grain boundary charge. The latter possibility was avoided in Ref. (17) by doping the silicon through neutron transmutation. Further experiments using less heavily doped films are in progress.

Conclusions

The properties of sputtered zinc oxide films can in certain cases be strongly dependent on deposition conditions. In particular, as-sputtered films deposited in less than 10% oxygen show increased growth rate, markedly increased optical absorption in the visible region, and a higher free carrier density than films sputtered in greater than 10% oxygen. The optical absorption and donor defects which anneal at 400°C in the oxygen-deficient films were attributed to surface oxygen vacancies. Films sputtered in greater than 10% oxygen possess optical absorption similar to that seen in zinc-rich powder ZnO and attributed to F-centers formed by zinc interstitials. For films sputtered in an adequate oxygen concentration, properties are insensitive to precise ambient composition.

Gallium doping was found to produce a slight shift in the absorption edge.

Substrate temperature affects grain size and doping concentration of the Ga-doped films, with the latter effect being of primary significance. Substrate temperature control provides a convenient means for varying the carrier concentration by more than two orders of magnitude for films sputtered from one target. Analysis of the temperature dependence of the carrier concentration revealed at least three donor and one acceptor levels. The trend in the mobility data is similar to that reported for polysilicon. The mobility in samples doped in the range 10^{18} cm^{-3} appears to be controlled by intergranular potential barriers, while samples doped to greater than 10^{19} cm^{-3} do not have barriers. The latter films, as well as sintered samples, show a mobility temperature dependence similar to single crystal ZnO but scaled down by a constant factor.

Interpretation of Hall Measurements

R. D. Larrabee

National Bureau of Standards, Washington, D.C. 20234

ABSTRACT

The temperature dependence of the Hall coefficient is the usual parameter measured to determine dopant energy levels and densities in semiconductors. However, this interpretation of Hall measurements is not necessarily unique. An example of current interest is indium-doped silicon, where a new acceptor level has been reported. It was found that the Hall data for an indium-doped silicon sample could be interpreted in two ways: one including, and the other without, the new level. A donor addition experiment was performed that clearly distinguished between these alternative explanations by supporting the new level interpretation and denying the alternative. It is suggested that donor addition is one example of a variety of techniques that can be used to supplement Hall measurements in order to resolve ambiguities of interpretation.

The temperature dependence of the Hall coefficient is the usual parameter measured to determine dopant energy levels and densities in semiconductors. However, the interpretation of Hall measurements in terms of dopant parameters is not necessarily unique. An example of an ambiguity in the interpretation of Hall data is observed with samples of indium-doped silicon. Evidence regarding the existence of a new acceptor level has been reported by some observers (1-4). Since the apparent activation energy of this level (about 0.11 eV) does not correspond to any known elemental dopant or dopant complex, its nature is not immediately apparent, and it has been called the "X"-level. One of the important applications for indium-doped silicon is in monolithic infrared imaging arrays (5); such arrays can be seriously degraded by the presence of "X"-levels. Therefore, it became important to determine if what is being seen is really due to a new acceptor level, or just an artifact of the measuring techniques used.

Key words: analysis, impurity, semiconductor, transport.

Alternative Interpretations of the Same Hall Data

Figure 1 shows the results of some Hall measurements on a sample of Czochralski-grown indium-doped silicon that exhibits the behavior attributed to "X"-levels. The apparent hole density (*i.e.*, $1/qR$, where q is the electronic charge and R is the measured Hall coefficient) is plotted as a function of $1000/T$ on the assumption of equal Hall and drift mobilities [*i.e.*, assuming unity Hall scattering factor (6)]. These experimental points were fitted with a theoretical curve

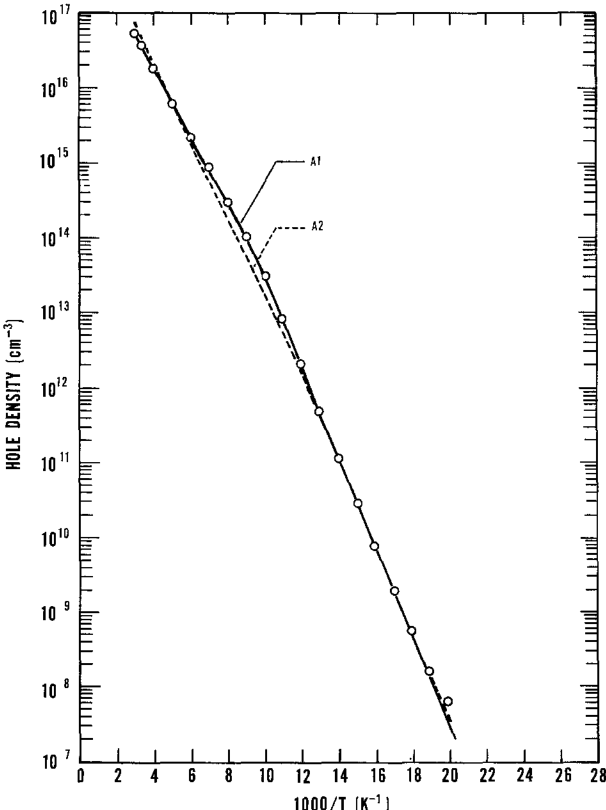

Fig. 1. Hole density vs. 1000/T for an indium-doped silicon van der Pauw sample. Points: calculated from the measured Hall coefficients assuming a unity scattering factor. Curve A1: computed curve with "X"-levels. (The five dopant parameters given in Table I were adjusted to fit this curve to these points.) Curve A2: computed curve without "X"-levels. (The two dopant parameters given in Table I were adjusted to fit this curve to these points.)

(A1) derived on the assumption that "X"-levels may be present.[1] The apparent dopant parameters so derived are listed in Table I. These results give the large indium acceptor concentration (expected because the material was intentionally doped with indium), and also indicate the presence of another acceptor level at 0.109 eV above the valence band (*i.e.*, the "X"-level).

There is, however, one other interpretation of these data that does not involve "X"-levels, but requires very close compensation of the omnipresent shallow acceptors (*e.g.*, boron) by donor states. A theoretical curve based on this interpretation was fitted to the experimental points, and the result is shown as curve A2 in Fig. 1 with the corresponding dopant parameters given in Table I. Although this close compensation interpretation does not appear to fit the experimental points quite as well as the new acceptor level interpretation (compare curves A1 and A2 in Fig. 1), it has only two adjustable parameters (see Table I), whereas

[1] The theoretical curves in this paper were generated by computing the carrier density as a function of specimen temperature and the density, energy, and degeneracy of the dopant states assumed to be present. The dopant parameters were determined by a trial-and-error fitting of the computer-generated curves to the experimental data.

Table I. Two possible interpretations of the Hall data in Fig. 1

Curve	Indium density (cm^{-3})	Indium energy (eV)	"X"-level density (cm^{-3})	"X"-level energy (eV)	Compensation* (cm^{-3})
A1	2.3×10^{17}	0.164	1.9×10^{15}	0.109	1.2×10^{14}
A2	5.0×10^{17}	0.176	0	—	—

* Compensation = (Density of donors) − (Density of shallow acceptors). The degeneracy of the indium and "X"-level states was assumed equal to 4 in computing the curves in Fig. 1.

curve A1 has five adjustable parameters. The question then arises whether the better fit of curve A1 is significant, or just an artifact of the larger number of parameters available for fitting it to the experimental data. Further, the measurement of the Hall coefficient is not a direct measure of carrier concentration without *a priori* knowledge of the ratio of Hall-to-drift mobilities as a function of temperature (6). The points in Fig. 1 represent the case where this ratio was taken to be unity at all temperatures. Since this is not strictly true, these points are not really at their correct positions. Finally, the theoretical curves were computed on the assumption that the activation energy of the dopant states relative to the nearest bandedge was not a function of temperature. Therefore, the theoretical curves may not truly correspond to the actual dopant situation in the sample. In view of uncertainties of this kind, the curve which appears to fit the points best may not necessarily be based on the correct interpretation.

Identifying Invalid Interpretations

One approach to identifying the invalid interpretation(s) would be to estimate the error of measurement of the Hall coefficient, any additional errors introduced in the computation of carrier density, and the errors introduced by the assumptions made in the computation of the theoretical curves. These errors could then be combined into an estimated rms error of fit between the measured points and the corresponding theoretical curve. A necessary condition for the acceptance of an interpretation would be that its rms error of fit be smaller than this value, and the error of fit of the alternative curve(s) be larger than this value. The fit of curve A1 in Fig. 1 is very good, but the error of the fit of the alternative curve (A2) is not clearly outside the estimated net total error. Therefore, in the present case, the close-compensation interpretation cannot be rejected on this basis alone.

Another approach to resolving this interpretation problem would be to perform some additional measurement that would experimentally resolve the ambiguity. A sensitivity analysis of the two interpretations shows that the close-compensation interpretation is much more sensitive to the introduction of additional donors or shallow acceptors than is the "X"-level interpretation. Donors can be added to silicon samples by several techniques: by neutron transmutation of silicon to phosphorus (2, 7); by indiffusion of interstitial lithium at 300°-500°C (8); or, if sufficient oxygen is present, by annealing in an inert atmosphere at 450°C for a short time (9, 10). Since the material of Fig. 1 had a measured oxygen content of about 2×10^{18} cm^{-3} (deduced from its 9 μm absorption), the last technique was used to introduce donors. Based on this measured oxygen content, it was estimated that the 450°C anneals would activate oxygen donors at a rate in the low 10^{13} $cm^{-3} \cdot min^{-1}$ range (10). Therefore, annealing times of about 100 min would activate sufficient donors to completely compensate any "X"-level acceptors this sample might contain. The temperature dependence of the Hall coefficient was measured after annealing for 16, 32, 128, and 256 min at 450°C and the results compared with that predicted on the basis of the two alternative interpretations. Prior to these 450°C anneals and the measurement of the initial Hall data in Fig. 1, this sample was annealed at 650°C for 30 min to inactivate any oxygen donors that it might have initially contained (10).

Results of the Oxygen-Donor Addition Experiment

"X"-level interpretation.—Figure 2 shows the experimental points and fitted theoretical curves before annealing (curve A), after annealing for 16, 32, 128, and 256 min at 450°C (curves B through E), and after annealing at 650°C for 30 min to remove the activated oxygen donors to see if the initial preanneal conditions

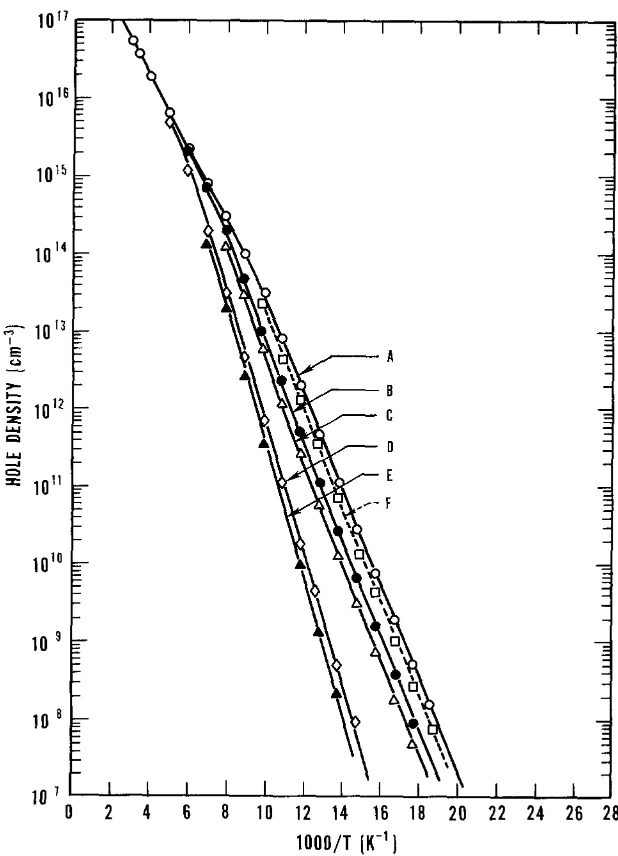

Fig. 2. Donor addition experiment—"X"-level interpretation. Experimental points and fitted theoretical curves of hole density vs. 1000/T as the compensation in the sample of Fig. 1 is changed.

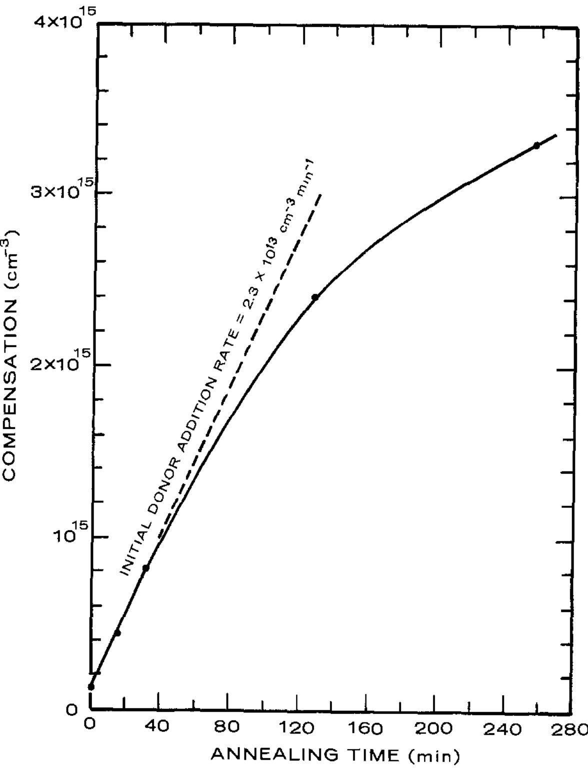

Fig. 3. Addition of donors by 450°C anneals as determined in Fig. 2 and listed in Table II.

could be restored (curve F). Curve A is a copy of curve A1 from Fig. 1 and has the dopant parameters listed for curve A1 in Table I. Each of the other curves in Fig. 2 was fitted by varying only the compensation (*i.e.,* donor concentration), and thus represents a one parameter fit to the corresponding experimental points. The remaining four parameters were held constant at their preanneal values given in Table I for curve A1. The values of compensation deduced in this way are given in Table II and plotted as a function of time in Fig. 3. The initial rate of donor activation agrees with the earlier estimate based on the measured oxygen content of this crystal. The tendency to saturate at the longer annealing times is also expected (10). This, plus the fact that the theoretical curves of Fig. 2 fit the measured points quite well, leads to the conclusion that the "X"-level interpretation provides a satisfactory model for explaining these results with added oxygen donors.

Close-compensation interpretation.—The dominant feature of the original Hall data that suggested "X"-levels was the linear portion of Fig. 1 at low temperatures (*i.e.,* high 1000/T) that has a slope corresponding to an apparent activation energy of about 0.11 eV. Any alternative explanation without "X"-levels must also be capable of exhibiting a linear region with this slope at these temperatures. The close-compensation interpretation achieves this as a transition between the lower slope of omnipresent shallow acceptors such as boron (undercompensated case) and the larger slope of indium (overcompensated case). Therefore, the close-compensation interpretation would be expected to predict this slope to increase as donors are added to overcompensate the shallow acceptors. The theoretical curves of Fig. 4 illustrate this behavior. Curve A of Fig. 4 is identical to curve A2 of Fig. 1 and has parameters for curve A2 in Table I. Notice that it does exhibit a linear region at low temperatures that agrees well with the experimental data points in this temperature region (open circles). Curves B through E were computed using the same parameters as curve A, but with added compensation levels of 10^{12}, 10^{13}, 10^{14}, and 10^{15} cm^{-3}, respectively. Notice that as few as 10^{12} cm^{-3} additional donors are sufficient to change the slope significantly, and that the slope is relatively insensitive to further donor addition. Experimentally, however, the slope did not change for the first two anneals (see Fig. 2), so it becomes impossible to achieve an acceptable fit for these two cases. This is illustrated in Fig. 4 by plotting the 16 min anneal data (solid-circle data points) and noting that they are not well represented by any of the theoretical curves in the family of close-compensation curves of this figure. In addition, based on the measured oxygen content in this crystal, it is expected that 16 min of anneal would add a few times 10^{14} additional donors. This would be equivalent to a curve between curves D and E in Fig. 4. Actually, the change produced by the 16 min anneal was much smaller than this. Consequently, these theoretical curves do not adequately describe the changes or the slopes for short annealing times. Therefore, there seems little doubt that the close-compensation interpretation is unable to explain the observed behavior with added oxygen donors.

Table II. Compensation produced by the anneals of Fig. 2

Curve	450°C annealing time (min)	650°C annealing time (min)	Compensation* (cm^{-3})
A	0	0	1.2×10^{14}
B	16	0	4.4×10^{14}
C	32	0	8.2×10^{14}
D	128	0	2.4×10^{15}
E	256	0	3.3×10^{15}
F	256	30	3.0×10^{14}

* Determined by fitting curves to the experimental points in Fig. 2.

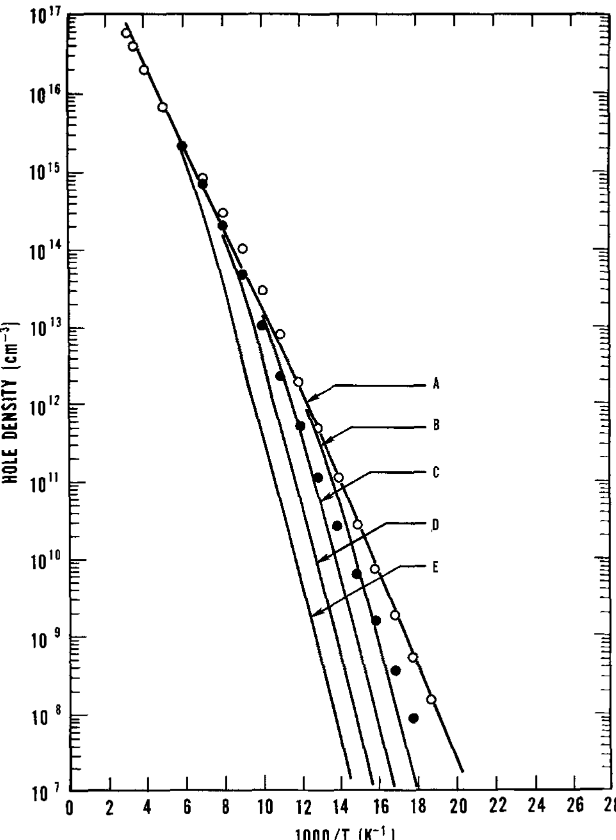

Fig. 4. Donor addition experiment—Close-compensation interpretation. Theoretical curves of hole density vs. 1000/*T* as the compensation in the sample of Fig. 1 is changed. The curve labeled A (and the open data points) correspond to the initial conditions before annealing and are taken from Fig. 1. The theoretical curves labeled B through E correspond to added compensation levels of 10^{12}, 10^{13}, 10^{14}, and 10^{15} cm^{-3}, respectively. The closed circles are the experimental data points after 16 min of anneal at 450°C. Notice that it is impossible to find a value of compensation (*i.e.*, theoretical curve) that will pass through these points.

Conclusions Drawn from the Donor Addition Experiment

The oxygen donor addition experiment has resolved the ambiguity in the interpretation of the Hall data of Fig. 1. As shown in Fig. 2 and 3, this sample exhibits behavior that is well described by the assumption that it contains an acceptor state at about 0.11 eV above the valence band. The only known alternative interpretation that does not involve this new acceptor level was unable to explain the behavior with added oxygen donors (Fig. 4). Therefore, in the absence of any data indicating otherwise, one is forced to accept the "X"-level interpretation of the Hall data for this sample. More fundamentally, however, it has been shown that despite the assumptions made in the analysis of these Hall data, the best fitting curve is based on the correct interpretation. Therefore, the foundation has been laid for a similar treatment of the Hall data from other samples of heavily indium-doped silicon.

Discussion

Donor addition is one example of the variety of ancillary techniques that can be used to supplement Hall measurements in order to resolve ambiguities of interpretation. Annealing to activate oxygen donors is a very convenient and relatively straightforward technique that can utilize the same sample used in the original Hall measurements. However, its use is limited to silicon crystals with comparatively large oxygen content (greater than about 20 ppm atomic), thus ruling out all float-zoned and some Czochralski crystals. Lithium indiffusion and neutron transmutation doping were mentioned earlier as alternative donor addition mechanisms. Looking for the presence (or absence) of infrared absorption or detector spectral response from suspected dopant states provides a fundamentally different type of approach to this interpretation resolution problem. The fields of thermally stimulated current and capacitance or capacitance transient spectroscopy might also be used to resolve interpretation ambiguities. With so many alternative approaches, it is suggested that one first attempt to appreciate the nature of any alternative interpretations and, armed with this insight, devise some simple measurement technique that will distinguish between them.

Acknowledgments

The author would like to thank M. G. Buehler, W. M. Bullis, K. F. Galloway, and W. R. Thurber for many helpful discussions during the course of this work, and Robert Baron, Hughes Aircraft Company, for the suggestion that oxygen donor addition could be used as a test of the validity of the "X"-level interpretation. This work was conducted as part of the Semiconductor Technology Program at NBS. The work was supported by the Defense Advanced Research Projects Agency (Order No. 2397).

Method for Determination of Diffusion Coefficients from Carrier Concentration Depth Profiles in Silicon

A. Bakowski
Institute of Electron Technology, 02-668 Warsaw, Poland

ABSTRACT

A method for the determination of diffusion coefficients from carrier concentration depth profiles is presented. Carrier profiles created during diffusion from ion-implanted sources were determined by differential conductivity measurements. The experimentally obtained distribution has been fitted for each sample by a smooth spline function approximation. Then applying the modified version of the Boltzmann transformation, diffusion coefficients of boron, phosphorus, and arsenic in silicon were determined. A full agreement between the measured and the calculated distribution was obtained when the concentration-dependent diffusion coefficient was inserted into the numerical solution of the diffusion equation. The temperature dependence of the diffusion coefficient of boron was also calculated and the activation energy value $E_a = 3.31$ eV was obtained.

For process control, device, and circuit characterization in silicon semiconductors, an accurate knowledge of the diffusion profiles is essential. The use of ion implantation in semiconductor device manufacture makes it possible to achieve the desired impurity distribution with great accuracy (1-6). As the implant concentration profiles of common dopants are fairly well known, knowledge of the diffusion and oxidation process parameters becomes most important. The diffusion coefficient has an especially great influence on impurity profile shape. The exact diffusion process simulation can be made if one knows the concentration-dependent diffusion coefficient (7-14).

Using the Boltzmann-Matano method, an effective diffusion coefficient as a function of carrier concentration can be calculated. This method may be applied when the surface concentration of the diffused impurity is invariant with time. A convenient formula obtained by the Boltzmann transformation has previously been used for determining the diffusion coefficient of phosphorus (15-19) and arsenic (14, 20, 21) as a function of concentration.

When the diffusing dopant of fixed total amount is redistributed, the Boltzmann transformation may not be applied because the surface concentration decreases with time, which implies a time dependence of the concentration separate from the ratio of penetration depth to square root of diffusion time postulated by Boltzmann. In this case the Boltzmann transformation can be replaced by a suitable modification proposed by Ghezzo (22, 23). This modification leads to a dependence of diffusivity on the ratio of concentration to surface concentration. This modified analysis was used by Fair and Tsai (3) for determining the diffusivity of arsenic from implanted, diffused As profiles.

In this paper a simple method of diffusion coefficient determination is presented. Drive-in diffusion occurred from an ion-implanted source. Diffusion coefficients were determined numerically using a modified Boltzmann-Matano transformation. Dependence of the diffusion coefficients on the concentration for boron. phosphorus, and arsenic and on the diffusion temperature for boron were found. Then, using finite difference techniques, the diffusion equation with concentration-dependent diffusivity was solved and a comparison made between experimental and calculated redistributions of the implanted ions.

Key words: ion implantation, diffusion coefficient, diffusion in silicon, spline function.

Experimental

The samples used for electrical measurements were (111) oriented, 4-5 Ω-cm phosphorus-doped silicon wafers for the boron implantations, and 10-12 Ω-cm boron-doped silicon wafers for arsenic and phosphorus implantations. All boron implantations were performed in the energy range 60-100 keV and in the dose range $3.6 \cdot 10^{15}$-$4.8 \cdot 10^{15}$ cm^{-2}. All P and As implantations were performed in the energy range 60-150 keV and in the dose range $2.5 \cdot 10^{15}$-$5 \cdot 10^{15}$ cm^{-2}. Wafers were tilted 7° during implantation in order to avoid channeling. Drive-in diffusion was carried out in a dry nitrogen atmosphere. Annealing of B-implanted samples was performed in the temperature range 1000°-1200°C. Arsenic-implanted samples were annealed at 1070°C and phosphorus-implanted samples at 920°C. Concentration profiles of electrically active impurities were obtained using sheet resistivity measurements combined with an anodic sectioning technique. Anodizations were performed in a mixture of 900 ml of ethylene glycol, 10 ml of water, and 10g of potassium nitride. Oxide layers were stripped in dilute HF and slices were rinsed in deionized water. The sheet resistance was read using a four-point probe with light probe pressure.

After several trials it was found that the variation in thickness of the removed Si layers in the case of different impurity concentrations did not exceed 10%. The concentration profiles were measured by removing 500 ± 50Å of Si in each step (300 ± 30Å in the case of shallow As and P profiles). The distance between the original silicon surface and the stripped region was measured for each sample with a stylus, after the concentration profile measurements had been finished, to check the etching depth.

Resistivity vs. carrier concentration.—Resistivity data from incremental sheet resistivity analysis were converted to impurity concentrations through the use of the expression for carrier concentration dependence of mobility from the work of Coughy and Thomas (24). The hole mobilities given by Wagner (25) and the electron mobilities given by Plunkett, Stone, and Leu (26) were used. The use of these mobility values resulted in calculated dose, Q_{PS}, 5-10% lower than the actual dose Q for boron and 10-20% lower for arsenic and phosphorus. Similar results were obtained for calculated and measured sheet resistances, R_{sPS} and R_s, respectively. The actual and calculated dose as

well as measured and calculated sheet resistances are compared in Tables I, II, and III.

The p-n junction depths were also measured for each sample using groove and stain techniques.

Analysis

Impurity concentration redistribution from an ion-implanted source can be treated as diffusion from a δ function source placed at a depth equal to the projected range of the implanted ions, R_p, from the Si surface. It can be shown that the expression for the determination of the concentration-dependent diffusion coefficient which is applicable to a redistributing impurity of fixed total amount in the case of an ion-implanted source is given (6, 11) by

$$D\left\{\frac{N(x_o,t)}{N(0,t)}\right\} = -\frac{N(x_o,t)\cdot(x_o - R_p)}{2\cdot t\cdot \left.\frac{\partial N}{\partial x}\right|_{x_o}} \quad [1]$$

where D is the diffusivity at a depth x_o from the surface. It must be emphasized, however, that because the initial profile after ion implantation is Gaussian, Eq. [1] is valid only when

$$\frac{\Delta R_p^2}{2} << D_i \cdot t$$

where ΔR_p is the range straggling of the implanted ions.

Results and Discussion

Spline function and Chebyshev polynomial approximation.—The results of the experimental determinations of carrier concentration depth profiles in Si are shown in Fig. 1-3.

The experimental points for all samples were fitted by a smoothed third degree spline function (27). The way of fitting a smooth spline function to a set of experimental points is shown in the Appendix. Computations were performed using an algorithm published by Reinsch (28, 29). The spline function approximation fidelity was evidenced by comparing the spline function integral Q_{SPLINE} with the experimental points integral Q_{pp}. These integral values are combined in Tables I, II, and III. The spline functions approximating

experimental carrier concentration profiles are shown in Fig. 1-3. Excellent fitted curves for all samples were obtained.

The carrier concentration profiles were also approximated by Chebyshev polynomials (30). Polynomials

from the 2nd to the 10th degree were tried. The best fitted curves were obtained with a fifth degree polynomial. Higher degree polynomials gave better fit but worse smoothness. For some samples the results were not satisfactory, it being impossible to produce smooth curves that fit the experimental values well. It is a common observation that a polynomial of moderately high degree fitted to a fairly large number of given data points tends to exhibit more numerous and more severe undulations than a curve drawn with a spline.

The Chebyshev polynomial approximation and spline function approximations are compared in Fig. 1.

Diffusion coefficient.—Equation [1] has been used to determine the diffusion coefficient as a function of the carrier concentration from the spline function approximation to the profiles. These results are shown in Fig. 4, 5, and 6. There are two concentration ranges where determined diffusion coefficient values are not confident.

Due to the use of an electrical measurement technique, a large degree of inaccuracy can occur near a p-n junction since the sheet resistance approaches infinity at the junction asymptotically. The drop of boron diffusivity for low concentrations ($< 10^{17}$ cm^{-3}) probably arises from an experimental error in this region (31). A large error can be also made at depths close to the projected range of implanted ions (*i.e.*, close to the maximum of the carrier distribution).

Two factors in Eq. [1], for $x \rightarrow R_p$, tend to zero simultaneously, $(x - R_p) \rightarrow 0$ and $\partial N/\partial x \rightarrow 0$. Thus, diffusion coefficient values, determined from a Boltzmann-Matano analysis in this region, will show a sharp decrease or increase depending on which factor reaches zero more rapidly.

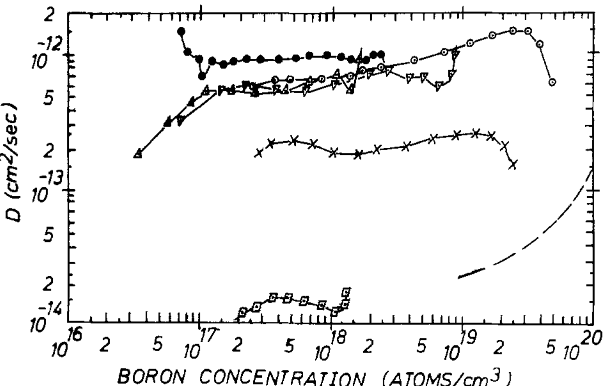

Fig. 4. Boron diffusion coefficient *vs.* impurity concentration. The data points shown are from this work (1000°C ⊡), (1100°C ×), (1180°C ▽ △ ⊙), (1200°C ●), and the dashed curve for 1000°C is from Crowder *et al.* (33).

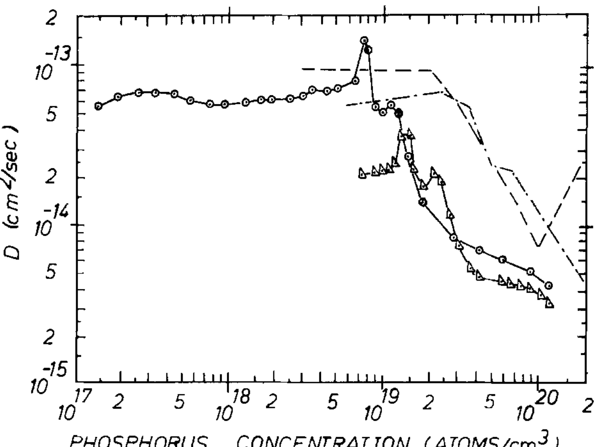

Fig. 5. Phosphorus diffusion coefficient *vs.* impurity concentration. The data points shown are from this work (920°C, $2.4 \cdot 10^{15}$ cm^{-2}, 60 keV △), (920°C, $5 \cdot 10^{15}$ cm^{-2}, 150 keV ⊙); Lee (900°C -·-·-·-) Ref. (15); and Fair and Tsai (900°C - - - - -) Ref. (34).

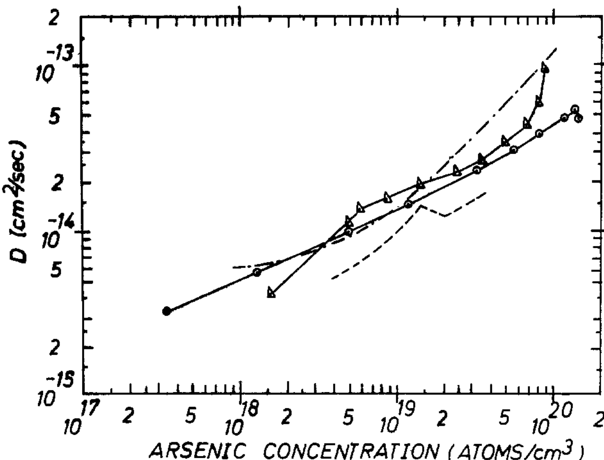

Fig. 6. Arsenic diffusion coefficient vs. impurity concentration. The data points shown are from this work (1070°C, 2.5 · 10^{15} cm^{-2}, 60 keV △), (1070°C, 5 · 10^{15} cm^{-2}, 150 keV ⊙); Fair and Tsai (1050°C -·-·-·-) Ref. (3); and Wang and Ghezzo (1050°C - - - -) (Ref. (20).

Although the boron diffusion coefficient tends to decrease for high dopant concentrations, as was reported by Brown and Kennicott (32), in our case this effect is a result of analysis error.

It is very difficult to define how reliable are results obtained from a modified Boltzmann-Matano analysis. Only the accuracy of the profile measurements method is known. Because the form of the underlying function is not known *a priori*, accuracy of the spline function approximation and spline function differentiation is almost impossible to estimate.

Thus, the reliability of the technique is demonstrated by the fit of the theoretical profiles to experimental data. Boron, phosphorus, and arsenic concentration-dependent diffusivities are also compared with previously published results (33, 20, 21, 3, 15).

In order to compute the impurity distribution it was necessary to find a function which describes the concentration-dependent diffusivity data for each impurity. It is well known that the diffusivity of phosphorus has three characteristic concentration regions. It was shown that in the high concentration region $D \propto n^2$, in the transition region $D \propto n^{-2}$, and in the low concentration region (tail region), D = const. (34). Through combination of earlier published results (15, 34) with the results presented in this paper, an empirical function which best describes the experimental points was formed.

In the tail region

$$D = D_{\mathrm{TAIL}} = \text{const.} \qquad [2]$$

In the surface and transition region at 920°C

$$D = h\left[3.59 \cdot 10^{-16} + 3.2 \cdot 10^{-18}\left(\frac{N}{n_i}\right)^2\right] + 3.65 \cdot 10^{-13}\left(\frac{N}{n_i}\right)^{-2} \qquad [3]$$

where

$$h = 1 + \frac{N}{2n_i}\left[\left(\frac{N}{2n_i}\right)^2 + 1\right]^{-1/2} \qquad [4]$$

is the electric-field enhancement factor.

A quantitative model of phosphorus diffusion in silicon was proposed by Fair and Tsai (19). But to obtain, based on the Fair and Tsai model, the theoretical dependence of $D(N)$ in the case of phosphorus diffusion from an ion-implanted source required further investigation.

The expression which best describes the concentration-dependent diffusivity of arsenic and boron is

$$D = D_i \cdot h \cdot \left(1 + A\frac{N}{n_i}\right) \qquad [5]$$

with $A = 0.1$ for boron and $A = 0.25$ for arsenic

The intrinsic arsenic diffusivity D_i.—From Eq. [5] the value of the intrinsic diffusion coefficient D_i, for arsenic was obtained which best describes the data in Fig. 6.

Phosphorus diffusivity in the tail region, D_{TAIL}.—The results obtained from Boltzmann-Matano analysis for phosphorus show the constant tail region diffusivity (see Fig. 5). However, a strong diffusion coefficient dependence on implanted dose is observed in this low concentration region. It was reported that tail diffusivity is influenced by the highly doped region near the surface (34, 35). By the way, the initial impurity concentration profile maximum was almost the same for both implanted samples. The increase in tail diffusivity observed for the high energy (150 keV) implanted P profile is not a result of channeling as could be supposed. A strong increase in phosphorus tail diffusion coefficient was also observed for low energy implanted P profiles in the dose range 2.5 · 10^{15}-7.5 · 10^{15} before a rapid decrease for higher dose (36). As can be seen in Fig. 2, the computed and experimental profiles coincide, meaning that a Boltzmann-Matano analysis error is not playing a significant role here either.

To explain the dependence of D_{TAIL} on ion dose, more experiments must be done.

The intrinsic boron diffusivity D_i.—In order to determine values of D_i from boron, experimental $D(N)$ curves of the samples in which the maximum concentration after drive-in dose did not greatly exceed the intrinsic carrier concentration at the diffusion temperature (in this case the factor $\left(1 + A\frac{N}{n_i}\right)$ in Eq. [2] is equal to ~1) were approximated by the least squares method as

$$D = D_i \cdot h \qquad [6]$$

With D_i values obtained from Eq. [6], Eq. [5] describes the boron diffusivity experimental points very well.

Values of D_i as a function of diffusion temperature are shown in Fig. 7. An activation energy of 3.31 eV with a preexponential factor of 0.205 cm^2/sec is found to describe boron diffusivity in (111) crystal orientation silicon in the temperature range 1000°-1200°C, in inert ambients. Also shown in Fig. 7 are examples of the boron intrinsic diffusion coefficient as determined by other workers (7, 37-39). The differences are mainly due to different ambient atmospheres. Prince and Schwettmann's diffusion was performed in steam (7). Massetti *et al.* (37) used dry O_2.

The results of the present work are in excellent agreement with the data recently published by Antoniadis *et al.* (40). They diffused boron from an ion-implanted source under intrinsic conditions in a non-oxidizing atmosphere. Although their technique of diffusivity determination was quite different from the one presented in this paper, the results over the range of common diffusion temperatures coincide.

Computations of impurity profiles.—The diffusion equation was solved by computer by finite difference techniques using a Crank-Nicolson type approach. The nonlinearity engendered by the concentration dependence of diffusivity required the use of a two-step iterative solution algorithm, the so-called predictor-corrector method of Douglas (7, 41, 42).

The initial implanted profiles were taken to be Gaussian with projected range R_p and range straggling ΔR_p according to earlier calculations (43) based on a method described by Winterbon (44).

The boron segregation coefficient was taken from the Colby and Katz paper (45). Although they used dry O_2 oxidations, their data are in general agreement with

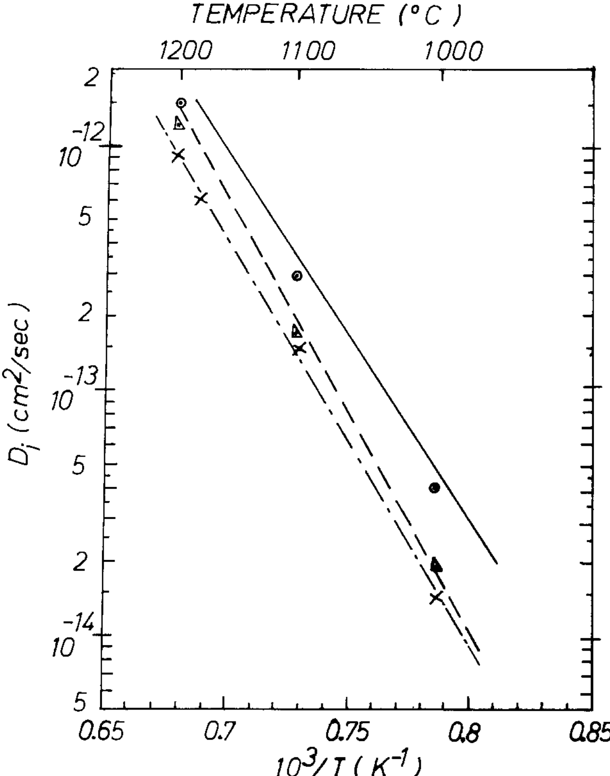

Fig. 7. Boron intrinsic diffusion coefficient vs. inverse temperature. The data points shown are as follows: this work (× -·-·-); Masetti et al. (△) Ref. (37); Kurtz and Yee (- - - - -) Ref. (38); Prince and Schwettmann (⊙) Ref. (7); and Huang and Wellivier (———) Ref. (39).

our earlier results obtained by a fitting technique (46). When the segregation coefficients of phosphorus and of arsenic were changed during the computations from 0.01 to 0.1, no differences in calculated curves were observed.

The concentration dependence of the diffusion coefficient was assumed for boron and arsenic to be given by Eq. [2] with $A = 0.1$ for boron and $A = 0.25$ for arsenic. Calculated B and As profiles are shown in Fig. 1 and 3. The empirical expression for phosphorus concentration-dependent diffusivity was obtained from the best fit of Eq. [2] and [3] to the experimental data. Calculated P profiles are shown in Fig. 2.

It is shown in Tables I, II, and III that the differences between the dose remaining in the silicon calculated from the experimental points Q_{pp} and the integral of the computed profile Q_{PS} do not exceed 10% for boron and 15% for phosphorus and arsenic. The same differences are observed between the sheet resistance calculated from the experimental points R_{spp} and from the computed profile R_{sPS}.

The Boltzmann-Matano analysis presented gives diffusion coefficients that can be successfully used for calculations of impurity diffusion profiles.

Comparing the calculated boron or arsenic or phosphorus profiles to experimental profiles, it is seen that the agreement is satisfactory.

Summary

1. A method was presented for the determination of the diffusion coefficient from the experimental impurity concentration depth profile. This method is valid only when: (*i*) the total impurity per unit area remains constant during drive-in and (*ii*) the diffusion length is much longer than the straggling range of the implanted ions.

2. A spline function is most useful for the approximation of measured doping profiles.

3. Activation energy obtained for boron diffusion is $E_a = 3.31$ eV.

4. The diffusion profile from ion-implanted layers after drive-in can be successfully predicted by numerical solution of the diffusion equation when the concentration dependence of the diffusion coefficient is well known. The use of a modified Boltzmann-Matano analysis for diffusivity determination leads to excellent profile calculations.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

APPENDIX

Spline functions.—Spline functions are a class of piecewise polynomial functions that have highly desirable characteristics for approximating, interpolating, and curve-fitting.

Let us define spline functions and natural splines.

Definition of a spline function (27).—Given a strictly increasing sequence of real numbers, $x_1, x_2, \ldots, x_n$, a spline function $S(x)$ of degree m with the knots $x_1, x_2, \ldots, x_n$ is a function defined on the entire real line having the following properties: (*i*) in each interval (x_i, x_{i+1}) for $i = 0, 1, \ldots, n$ (where $x_0 = -\infty$ and $x_{n+1} = +\infty$), $S(x)$ is given by some polynomial degree m or less and (*ii*) $S(x)$ and its derivatives of orders $1, 2, \ldots, m-1$ are continuous everywhere.

Definition of natural splines (27).—A spline $s(x)$ of odd degree $2m - 1$ with the knots $x_1, x_2, \ldots, x_n$ is called a nautral spline if it is given in each of the two intervals $(-\infty, x_1)$, (x_n, ∞) by some polynomial of degree $m - 1$ (rather than $2m - 1$) or less (in general not the same polynomial in the two intervals).

Thus, a spline function is a piecewise polynomial function satisfying certain conditions regarding continuity of the function and its derivatives.

Smoothing by natural splines (28, 47).—In our problem of fitting a smooth curve to a set of experimental points, (x_i, y_i) $i = 1, \ldots, n$, we have to determine the smooth curve $g(x)$ from the condition that

$$\int_{x_1}^{x_n} [g^{(m)}(x)]^2\, dx \qquad \text{[A-1]}$$

is minimized for all $g(x)$ satisfying the smoothing constraint

$$\sum_{i=1}^{n} w_i[y_i - g(x_i)]^2 \leq S, g \epsilon C^m(x_1, x_n) \qquad \text{[A-2]}$$

where $w_i > 0$, $i = 1, 2, \ldots, n$, and $S \geqq 0$ are given numbers.

The choice of $\{w_i\}_1^n$ and S for smoothing depends on the confidence we have in the data $\{y_i\}_1^n$. The S constant is redundant and is introduced only for convenience. It allows for an implicit rescaling of the quantities w_i which control the extent of smoothing. Recommended values for S depend on the relative weights w_i.

It has been suggested (28) that w_i should be chosen as δy_i^{-2}, where δy_1 is an estimate of the standard deviation of the ordinate y_i. In this case, natural values of S lie within the confidence interval corresponding to the left-hand side of Eq. [A-2] (28)

$$N - (2N)^{1/2} \leq S \leq N + (2N)^{1/2} \qquad N = n + 1$$

Small values of $\{\delta y_i\}_1^n$ and/or S emphasize fidelity to the observed data at the expense of smoothness, while large values do the opposite.

For many problems a choice of a small m is desirable, *e.g.*, $m = 2$ leads to cubic splines. Cubic splines are easily evaluated and give in general satisfactory results. The solution of Eq. [A-1] and Eq. [A-2] may be obtained by the standard method of the calculus of

variations. Thus, by introducing the auxiliary variable z together with the Lagrangian parameter p, we have to look for the minimum of the function

$$\int_{x_1}^{x_n} [g''(x)]^2 dx + p \left\{ \sum_{i=1}^{n} \left[\frac{y_i - g(x_i)}{\delta y_i} \right]^2 + z^2 - S \right\} \quad \text{[A-3]}$$

It was shown in (28) that the extremal function $g(x)$ is composed of cubic parabolas

$$g(x) = a_i + b_i(x - x_i) + c_i(x - x_i)^2 + d_i(x - x_i)^3 \qquad x_i \leq x < x_{i+1} \quad \text{[A-4]}$$

which join at their common endpoints such that g, g', and g'' are continuous. Hence the solution is a cubic spline. The procedure that permits the computation of the spline coefficients and the evaluation of the splines can be found in Ref. (28, 47, or 18).

LIST OF SYMBOLS

D	diffusion coefficient, $cm^{+2}\ sec^{-1}$
D_i	intrinsic diffusion coefficient, $cm^2\ sec^{-1}$
N	impurity concentration, cm^{-3}
E	implantation energy, keV
Q	implanted dose, cm^{-2}
Q_{DD}	implanted dose remaining in Si, calculated from experimental points, cm^{-2}
Q_{SPLINE}	spline function integral, cm^{-2}
Q_{PS}	theoretical profile integral, cm^{-2}
R_s	sheet resistance, measured, Ω/□
R_{sDD}	sheet resistance calculated from experimental points, Ω/□
R_{sPS}	sheet resistance calculated from theoretical profiles, Ω/□
xj	p-n junction depth, μm
N_B	bulk concentration, cm^{-3}
t	drive-in diffusion time, sec
R_p	projected range of implanted ions, μm
ΔR_p	straggling range of implanted ions, μm
n	free carrier concentration, cm^{-3}
n_i	intrinsic free carrier concentration, cm^{-3}
k	Boltzmann constant, $eV \cdot K^{-1}$

Technical Note

Carrier Concentration and Hall Mobility in Heavily Arsenic-Diffused Silicon

Satoru Matsumoto and Tatsuya Niimi

Department of Electrical Engineering, Keio University, Hiyoshi, Yokohama, 223, Japan

and Junichi Murota and Eisuke Arai

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino, Tokyo, 180, Japan

The electrical characteristics in high concentration arsenic-diffused silicon layers are an important factor in the design of silicon device structures. It is well known (1, 2) that electrically inactive arsenic atoms such as clusters are formed when arsenic atoms are diffused heavily into silicon and so the total arsenic concentration (C_T) differs from the electron concentration (n) at room temperature for C_T above 10^{20} cm^{-3}. The relationship between C_T and n is usually determined using the data of resistivity (ρ) *vs.* n, which are varied in many investigations (3-5) for n above 10^{20} cm^{-3}. Assuming that the electrically active arsenic concentration (C_A) at the diffusion temperature is equal to n, the relationship between C_T and C_A has been also discussed (6). However, the diffusion temperature dependence of the ρ-n curve and the relationship between C_A and n are not clear.

In this note, the dependences of Hall mobility μ_H and ρ on n for various diffusion temperatures are obtained from sheet Hall measurements at room temperature, and the relationships among C_T, n, and C_A are also determined.

Heavily arsenic-doped polycrystalline silicon was deposited as a diffusant on p-type silicon wafers of 1-2 Ω-cm with mirror polished (111) surface. The experimental conditions of the deposition of arsenic-doped polycrystalline silicon have been described in detail previously (7). Diffusions were performed at 900°, 950°, and 1000°C in nitrogen atmosphere where the surface of polycrystalline silicon was covered with CVD silicon dioxide. The polycrystalline silicon on the diffusion layer was removed by anodic oxidation in a solution of N-methylacetamide and 0.04*N* potassium nitrate and HF stripping. To obtain profiles of ρ, n, and μ_H in the diffused layers, measurements of sheet resistivity and sheet Hall coefficient by the van der Pauw method at room temperature and the removal of a thin layer of silicon by anodic oxidation method were repeated (8). The strength of the magnetic field was 6000G and the applied constant current was 1 mA. Also, profiles of total arsenic concentration were obtained by neutron activation analysis (7).

Typical profiles of C_T, n, and μ_H, which were obtained from the sample diffused at 900°C for 2020 min, are shown in Fig. 1. The ρ-n and μ_H-n curves, which are obtained from the data presented in Fig. 1 and the data obtained at the diffusion temperatures of 950° and 1000°C, are shown in Fig. 2. The C_T-n curves for several diffusion temperatures were also obtained simultaneously and are shown in Fig. 3. It is found from Fig. 2 that ρ and μ_H are almost independent of the diffusion temperature for any n specified. On the other hand, the neutral arsenic concentration ($C_T - n$) depends on the diffusion temperature. For example, ($C_T - n$) at $n = 2.6 \times 10^{20}$ cm^{-3} for 950° and 1000°C are 1.3×10^{20} cm^{-3} and 4.5×10^{19} cm^{-3}, respectively, which are estimated from Fig. 3. This fact means that the effect on μ_H of the scattering of carriers due to neutral atoms is negligibly small in the present concentration range. Results of the ρ-n and μ_H-n curves are somewhat different from Irvin's curve and are similar to Fair's and Müller's, which were obtained from the arsenic-implanted samples assuming $C_T = n$. On the other hand, the ρ-C_T and μ_H-C_T curves differ from their data on arsenic-implanted samples because neutral arsenic atoms exist in the present arsenic-diffused sample.

Key words: semiconductor, diffusion, resistivity.

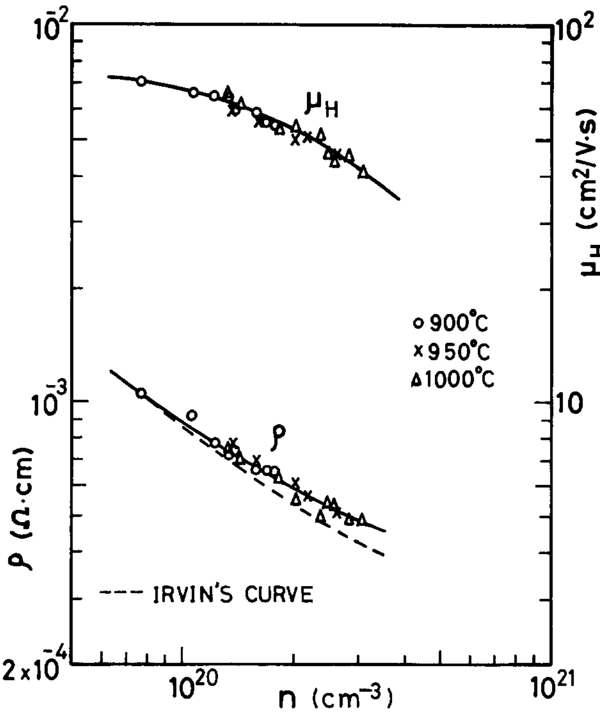

Fig. 2. ρ-n and μ_H-n curves in diffused layer for several diffusion temperatures.

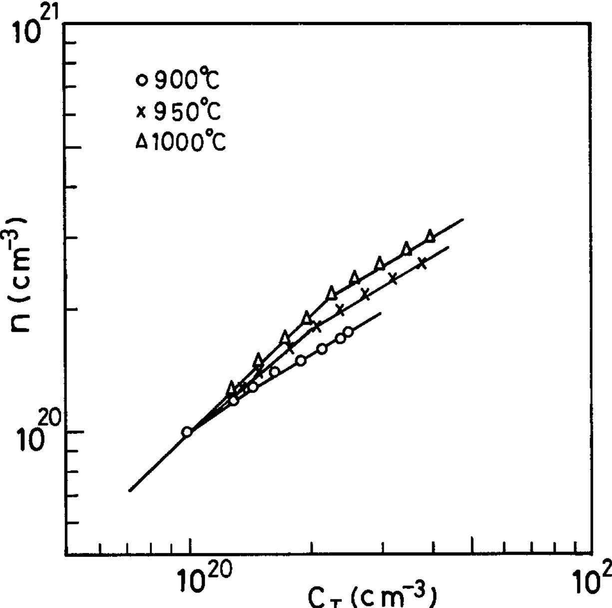

Fig. 3. C_T-n curves for several diffusion temperatures

The relationship between $(C_T - n)/n_i$ and n/n_i, which is obtained from the data presented in Fig. 3, is shown in Fig. 4, where n_i is the intrinsic carrier concentration at the diffusion temperature. From Fig. 4, the relationship between C_T and n for concentrations above 10^{20} cm^{-3} can be approximated by

$$(C_T - n)/n_i = 9.0 \times 10^{-6} (n/n_i)^4 \quad [1]$$

The deviations of experimental values from Eq. [1] are large for n/n_i below about 25.

Usually, the electrically active arsenic concentration at the diffusion temperature (C_A) has been determined by resistivity measurements using the ρ-n curve obtained at room temperature. That is, C_A has been tacitly supposed to be equal to n. On the other hand, Murota *et al.* (7) obtained the relationship between C_T and C_A from the concentration dependence of the

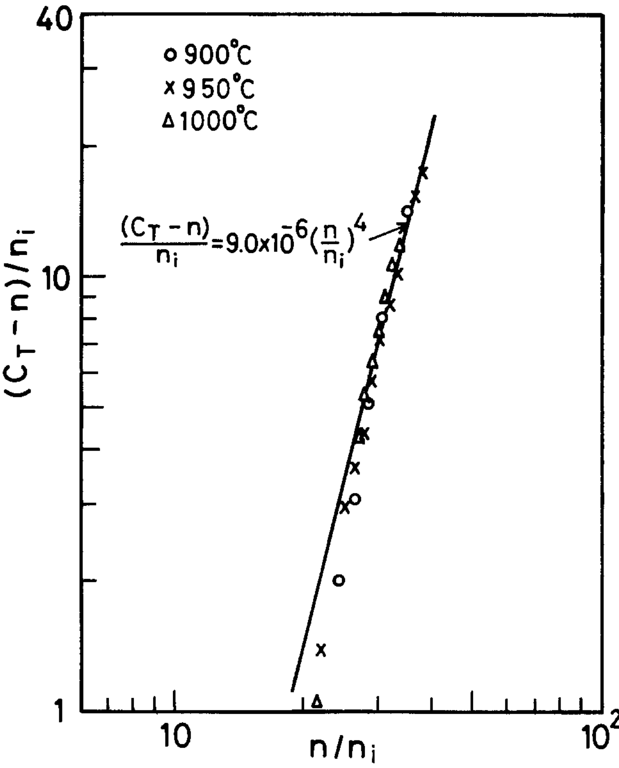

Fig. 4. Relationship between $(C_T$-$n)/n_i$ and n/n_i obtained from the data presented in Fig. 3.

arsenic diffusion coefficient without using the ρ-n curve

$$(C_T - C_A)/n_i = 3.2 \times 10^{-6} (C_A/n_i)^4 \quad [2]$$

From the comparison between Eq. [1] and Eq. [2], it is found that C_A is not equal to n for concentrations above 10^{20} cm^{-3}. The relationship between C_A and n may be obtained using Eq. [1] and Eq. [2]. However, this method for determining the C_A *vs.* n amplifies the error, since both Eq. [1] and Eq. [2] are approximate equations. We determined the relationship between C_A and n using the ρ-n curve of Fig. 2 and ρ-C_A curve of Ref. (7). The C_A-n curve thus obtained is shown in Fig. 5. The relationship between C_A and n approxi-

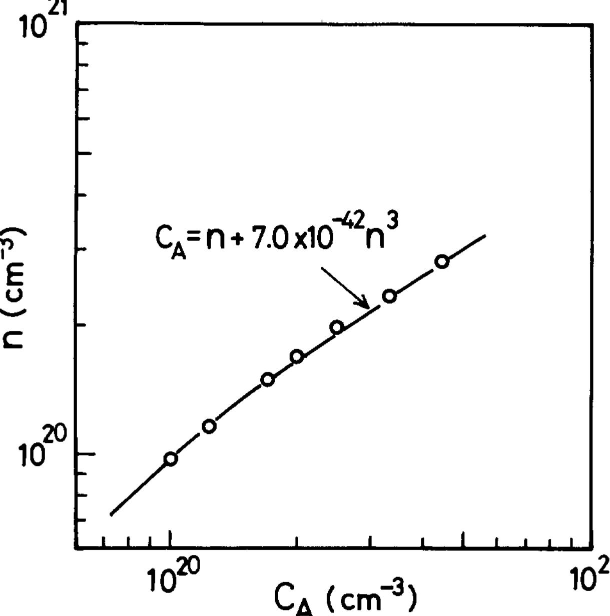

Fig. 5. Relationship between C_A and n obtained from the ρ-n curve of Fig. 2 and the ρ-C_A curve of Ref. (7).

mated by

$$C_A = n + 7.0 \times 10^{-42}n^3 \quad [3]$$

Recently, Fair *et al.* (9) have obtained the relationship between the total phosphorus concentration (C_{TP}) and n in diffused layer. Here, no electrically inactive phosphorus atoms such as cluster in phosphorus-diffused silicon is considered to be formed at diffusion temperature, differing from arsenic-diffused silicon. Replacing C_A with C_{TP} in Eq. [3], the C_{TP}-n curve obtained by Fair *et al.* is approximated within their experimental error by Eq. [3]. It is very interesting for the relationship between electrically active impurity concentration at diffusion temperature and n at room temperature to be given by Eq. [3] in spite of the kind of impurity (As or P). The above result cannot be explained at present. For the analysis of the difference between C_A and n, further investigation should be done.

Lithium Closoboranes as Electrolytes in Solid Cathode Lithium Cells

Jack W. Johnson and M. Stanley Whittingham*

Exxon Research and Engineering Company, Corporate Research, Linden, New Jersey 07036

Ambient temperature secondary lithium cells are presently limited by low rates and limited lifetimes caused by stability problems at the lithium-electrolyte interface. Often chemical reactions of lithium with the non-aqueous solvent and the electrolyte salt lead to reduced lifetimes of secondary lithium cells. Minimization of these chemical reactions is an important goal in the development of ambient temperature secondary lithium batteries. Herein we report the results of some studies of lithium salts of closoborane anions dissolved in ethereal solvents as electrolytes.

Closoborane anions are closed polyhedra of boron atoms bearing terminal hydrogens or halogens. $B_{10}Cl_{10}^{2-}$ (Fig. 1) is a typical closoborane anion. In contrast to many boron compounds, salts of closoborane anions exhibit an extraordinary degree of kinetic stability to oxidation, reduction, and thermal decomposition. These properties have been exploited for use in electrolytes in $Li/SOCl_2$ liquid cathode cells (1,2). In preliminary attempts to use $Li_2B_{10}H_{10}$, $Li_2B_{10}Cl_{10}$, $Li_2B_{12}H_{12}$, or $Li_2B_{12}Cl_{12}$ as electrolyte salts in lithium-solid cathode cells, we were frustrated by problems of low solubility.

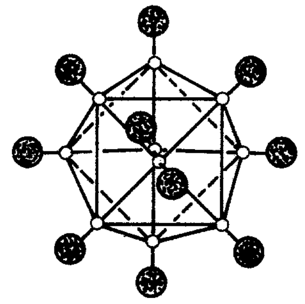

Fig. 1 Structure of $B_{10}Cl_{10}^{2-}$ Anion

Keywords: closoborane, lithium, electrolyte battery

The salts are soluble in high polarity solvents such as water, methanol and acetonitrile. These solvents are unsuited for secondary lithium battery applications because of their reaction with lithium metal. The lithium closoborane salts are very poorly soluble in ethereal solvents such as tetrahydrofuran, dimethoxyethane, diglyme, and dioxolane which are more desirable for secondary lithium cell applications. However, by using suitable mixtures containing the chelating ether dimethoxyethane and the cyclic ketal dioxolane, stable solutions containing high concentrations of $Li_2B_{10}Cl_{10}$ and $Li_2B_{12}Cl_{12}$ can be formed.

$Li_2B_{10}Cl_{10}$, obtained by modification (3) of the reported procedures (1,4,5) can be recrystallized from dioxolane/DME mixtures as the solvate $Li_2B_{10}Cl_{10}\cdot 6DME$. This solvate is soluble in pure dioxolane in concentrations from 32 to 50 wt%. At concentrations below this range, two clear liquid layers form, and if dilution is continued, a dioxolane solvate of the salt precipitates. $Li_2B_{12}Cl_{12}$ behaves in a similar fashion.

When the electrolyte is suitably purified it demonstrates good chemical stability in the presence of both lithium metal and titanium disulfide, a common cathode material. When a shiny piece of lithium metal was sealed in tubes containing $Li_2B_{10}Cl_{10}\cdot 6DME$/dioxolane no visible reaction was observed after one month at 70°C. Similar tests with high purity TiS_2 also demonstrated the electrolyte's inertness. The resistance of the electrolyte to electrochemical oxidation was demonstrated by voltammetric scans on inert electrodes. On a Ta working electrode, scanning positive from a Li reference electrode leads to an oxidation wave at 3.8 V. On a Pt working electrode, there is no significant oxidative current, as the electrode surface passivates at potentials above 4.0 V.

Preliminary cell tests of the lithium closoborane electrolyte in lithium-titanium disulfide cells have demonstrated its

utility. The first discharge curve is shown in Figure 2. It closely resembles that obtained with $LiClO_4$ in similar cells (6). The total cathode utilization at 2 ma/cm^2 was greater than 85% based on the reaction Li + $TiS_2 \longrightarrow LiTiS_2$. On reducing the current to 1 ma/cm^2, 92% of the theoretical capacity was obtained. The cell was then recharged at 1 ma/cm^2, followed by discharge at 1 ma/cm^2. More than 90% of the first discharge capacity was obtained on this second discharge. The charge-discharge cycle could be repeated more than twenty times. In contrast, at electrode concentrations where two liquid phases were present, cathode utilization was low, <10%.

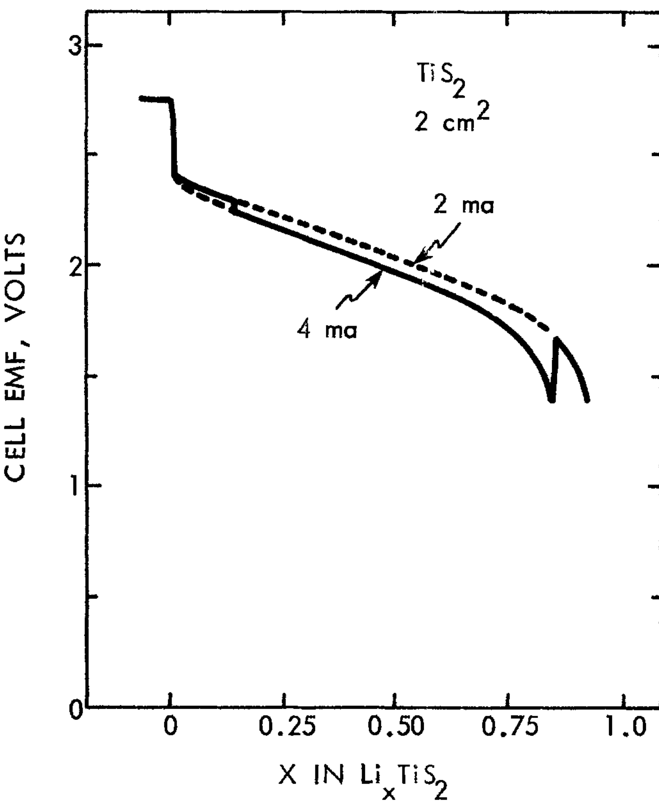

Fig. 2 First discharge curves of Li/TiS_2 cell at 1 and 2 ma/cm^2. ——— measured and ---- extrapolated area.

In summary, we have found that by use of a suitable mixed ethereal solvent system, lithium closoborane salts can be dissolved to form useful non-aqueous electrolytes that exhibit chemical stability to the components of a lithium titanium disulfide cell and show promise as electrolytes in those cells.

Solubilities of Oxygen and Carbon Monoxide in Carbonate Melts

A. J. Appleby*,[1] and C. Van Drunen

Institute of Gas Technology, Chicago, Illinois 60616

ABSTRACT

Physical CO solubilities and total O_2 solubilities (as chemically formed O_2^- and $O_2^=$ ions) have been determined for a comparatively wide range of carbonate melt compositions, and some restricted data on nitrogen and CO_2 solubilities have also been obtained. In general, the Uhlig-Blander equation in its simple form (without a correction term for gas molecule-melt interaction) does not apply to these melts. Care should be taken in interpreting hydrogen solubilities measured by chemical titration due to the formation of large amounts of chemically bound CO via the shift reaction.

Previous work in this laboratory (1) determined the dissociation pressure of the ternary alkali carbonate melt [43.5 mole percent (m/o) Li, 31.5% Na, 25% K, mp 397°C], both to verify results of previous authors (2), and to establish the minimum pressure to maintain the melt in equilibrium with CO_2, so that gravimetric measurements of the solubility of this gas could be performed using a microbalance. Attempts were made to determine oxygen solubilities at various partial pressures at 700°C, maintaining P_{CO_2} equal to the dissociation pressure of the melt. However, continuous weight losses were experienced, indicating loss of CO_2 (*i.e.*, change of CO_2 dissociation pressure) on absorption of oxygen. This behavior is discussed in detail in this paper. In view of the uncertainty in determining the absolute gas solubility under these conditions, it was decided to use an alternative quenching or melt-chilling method for solubility determination. This method is applied for a variety of carbonate melt compositions for oxygen and carbon monoxide solubility, and for nitrogen and CO_2 solubility in the ternary melt.

Experimental

Since gas solubilities in molten salts increase with temperature, quenching methods may be conveniently used to determine solubility by measurement of the quantity of dissolved gas released on freezing of the melt. Further advantages of such methods include rapid measurements, the possibility of determining solubilities of several gases simultaneously using analytical techniques, and the possibility of absolute measurements if displacement of one gas by another occurs.

The apparatus used is shown in Fig. 1. It was connected to the gas-mixing train and vacuum system described earlier (1), modified by the addition of a low permeability india rubber balloon linked with the main line via a vacuum stopcock to maintain atmospheric pressure during the periods of rapid temperature and gas volume change occurring with melt cooling. All gas mixtures studies were introduced into the apparatus at atmospheric pressure, in the form of nitrogen mixtures where necessary. P_{CO_2} was maintained somewhat above the melt dissociation pressure for each measurement (see below).

Melt preparation was as follows: (*i*) Mixed salts were melted, allowed to solidify, and then were maintained under vacuum at temperatures just below their

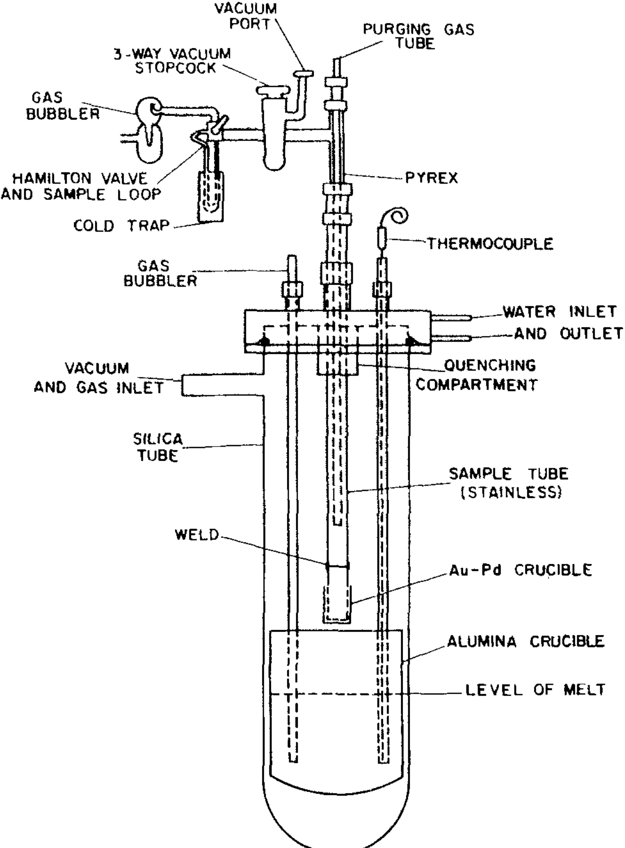

Fig. 1. Apparatus used for solubility measurements

* Electrochemical Society Active Member.
[1] Present address: E.P.R.I., Palo Alto, California 94303.

melting points for approximately 90 hr for preliminary drying and outgassing. (*ii*) The salt was isolated and slowly heated to about 820°-850°C. (*iii*) The melt was evacuated until a stable pressure of about 8 mm Hg was obtained. It was then allowed to reach equilibrium at 120 mm pressure with "Mattheson Research Grade" CO_2. This was followed by solidification. (*iv*) Steps (*ii*) and (*iii*) were repeated three times in sequence.

Preliminary experiments showed that saturation of the melt contained in the alumina crucible with each gas mixture was complete after 2-3 hr maximum under bubbling conditions. After saturation, a melt sample was withdrawn in the small Au-Pd crucible shown in Fig. 1 and introduced into the upper quenching compartment by vertical translation of the support tube in its sliding seal attached to the water-cooled stainless steel header. The internal sample tube (an Au-Pd extension of a long stainless steel tube) containing a helium atmosphere, which trapped a prescribed volume of melt, that liberated its dissolved gas on chilling. The quench rate was relatively slow to allow all the gases to escape. This gas was flushed by a stream of helium into the U-tube containing a small amount of activated Linde 5A molecular sieve closed by a Hamilton 4-way gas sample valve. The entire contents of the tube, after being allowed to reach room temperature, were flushed with a stream of carrier gas into a Fisher-Hamilton gas partitioner with Linde 5A column and Katharometer detector for analysis. This gas represented the whole of the solute in the melt aliquot. In earlier work, only a fraction of the atmosphere above the melt was examined (1), which led to some irreproducibility.

Preliminary experiments established that best results were obtained by slowly cooling the sample to 300°C by positioning the melt in the correct part of the upper zone of the furnace. This prevented cracking of the solidified electrolyte and leakage from the remainder of the solid carbonate and the atmosphere above the melt around the end of the sample tube, so that a frozen melt plug seal was produced. Very reproducible results were obtained by maintaining the sampling crucible, which contained a small amount of solid carbonate to isolate the sample tube and external gas systems, in the cooler part of the furnace. This was followed by plunging the crucible into the melt and withdrawing a sample. The volume of carbonate withdrawn was estimated by measuring its upper level with the sliding gas purge tube with a cathetometer. Care was taken to ensure that equilibrium was attained in each case. A number of independent determinations (typically 8-10) were carried out for each gas mixture. Henry constants and standard deviations were thus determined, and Henry's law verified.

Results and Discussion

CO_2 solubilities (ternary melt).—The majority of CO_2 solubility determinations in the ternary melt were carried out using dynamic weighing (1). However, in some cases the quenching method was used to obtain supplemental data to serve as a confirmation of those obtained by weighing. At 700°C, a mean solubility (six separate readings) of 3.60×10^{-3} mole-dm^{-3}-atm^{-1} was obtained by this method in good agreement with the value obtained by weighing [2.84×10^{-3} mole-dm^{-3}-atm^{-1} (1)].

Nitrogen solubilities.—Nitrogen solubilities were determined only in the ternary eutectic. The purpose of these measurements was to allow a standard of comparison with conventional theories (3-5) of solubilities of noninteracting gases in molten salts, since nitrogen may be expected to possess little affinity for the melt and certainly no chemical solubility. Results obtained, including standard deviations, are given in Table I, and these are expressed in the form of an Arrhenius plot in Fig. 2.

According to the so-called Uhlig-Blander theory of gas solubilities in molten salts (4) the free energy of solution is related to the creation of new melt surface in the form of cavities in the liquid, each of which is on the order of the dimensions of a gas molecule. For gases that interact with the melt by physical forces, a further free energy of solution term is required, representing the energy of association of the gas molecule with the surrounding melt ions. Overall, this theory proposes the following relationship

$$\Delta G_s^\circ = 4\pi N r^2 \gamma + \Delta G_a^\circ$$

where ΔG_s° and ΔG_a° are the standard free energies of solution and association, respectively, r is the radius of the gas molecule, γ is the "microscopic" liquid surface tension, and N is Avogadro's number. In general, correlations based on the above equation give a reasonably good agreement (to within about one order of magnitude) with experiment, assuming γ to be equal to the measured value of the melt surface tension. Results often are of a satisfactory order of magnitude agreement for gases of larger molecular radius, but correlations between measured and estimated ΔH_s (heat of solution) values are poor in most cases (5, 6). While modifications of the Uhlig-Blander theory which assume that gas molecules occupy holes already present in the melt rather than create holes for solution (5) may give more consistent agreement between theory and experiment for a wide range of solute radii, the expressions are complex and difficult to use, and they differ from the values given by the Uhlig Blander expression only by preexponential terms (5).

* 825°C.

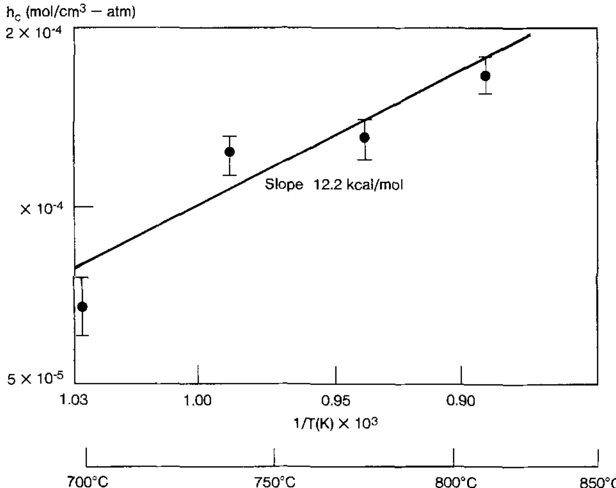

Fig. 2. $\log_{10}$ nitrogen solubility as a function of $1/T(K)$, ternary melt.

Considerations based on the simple Uhlig-Blander theory can still be used in first approximation correlations.

If we use the Uhlig-Blander equation and assume that for nitrogen ΔG_a^o is equal to zero, then for the ternary eutectic at 1000°K, $\gamma \sim 0.215$ j – m² (7), and using a value of 0.190 nm for the Lennard-Jones radius of N_2 (8), we obtain a calculated solubility of 1×10^{-5} mole-dm^{-3} atm^{-1}. This is about a factor of 7 lower than the value obtained experimentally (Table I and Fig. 2). We therefore conclude that the physical solubility of nitrogen in molten carbonates involves a small negative ΔG_a^o.

Carbon monoxide solubilities.—Carbon monoxide solubilities were obtained for the ternary, binary 42.7: 57.3 m/o Li/K, 53.3:46.7 m/o Li/Na, 58:42 m/o Li/Na, 58:42 m/o Na/K, and pure Li carbonate compositions. Results obtained, indicating standard deviations, are given in Table I. Arrhenius plots for all melts are given in Fig. 3. In all cases, a number of different CO partial pressures were used to determine the Henry constants, nitrogen being used to bring the total pressure to one atmosphere to avoid carbon deposition (8). In the ternary eutectic, the experimental solubilities are close to those of nitrogen. This is reasonable in view of their molecular radii.

An immediate problem observed is that the CO solubilities measured above are appreciably lower than those calculated from potential sweep electrochemical data (9) assuming a reasonable value of the diffusion coefficient (1×10^{-8} m²-sec^{-1}) [*cf.* Cl^- ion at similar temperatures (10)]. These data showed that two CO species accounted for the total solubility, one corresponding to CO physically dissolved in the melt ($\sim 1.1 \times 10^{-4}$ mole-dm^{-3} for 0.318 atm CO/0.682 atm CO_2 at 800°C in the ternary eutectic melt), the other being CO in the form of a chemically dissolved species, $CO_2^{=}$ (concentration about 1 times 10^{-3} mole-dm^{-3} under the above conditions, or ~9 times the physically dissolved CO concentration). This implies a Henry constant of *ca.* 3×10^{-4} (mole-dm^{-3}-atm^{-1}) for physically dissolved CO in the ternary melt at 800°C, in quite good agreement with the data derived from the slow cooling experiments (Table I). Hence, in the method used only physically dissolved CO is detected. Presumably the chemically dissolved part ($CO_2^{=}$) is sufficiently stable to remain in the salt during the chilling and pumping operation. Reducible material has indeed been detected in chilled melts (11). On the basis of the results obtained in the ternary melt it is reasonable to assume that results in other melts also refer to physical solubility.

Some data were obtained, though at only two temperatures, in the Na/K and pure Li melts (see Table I). These results appear to be distinctly anomalous. In the Na/K melt, much higher solubilities were recorded than in the lithium-containing melts. This perhaps implies that in the absence of lithium ion the $CO_2^{=}$ ion decomposes during the quenching operation so that both physical and chemical solubilities are detected. In the pure lithium melt the very low solubility detected at 800°C and the apparently large temperature coefficient of solubility (*cf.* that for oxygen, see below) may show that CO solubility detected, like the oxygen solubility, is entirely chemical in this case, with the stability of the $CO_2^{=}$ rapidly increasing with temperature (see discussion of peroxide ion, below). No electrochemical data on CO oxidation are currently available in these two melts, so the above conclusions must be regarded as tentative.

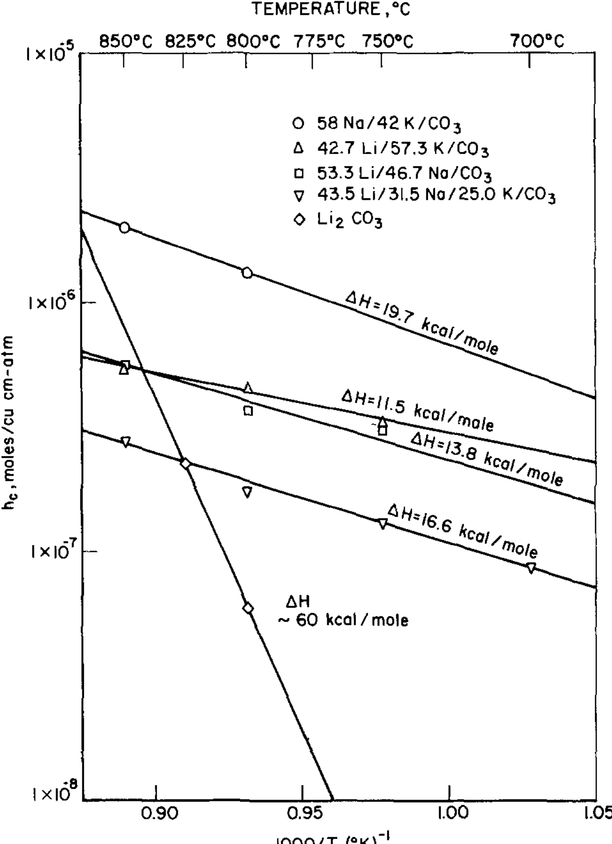

Fig. 3. $\log_{10}$ CO solubility as a function of $1/T(K)$ (Henry constants in mole-cm^{-3}-atm^{-1} units. 1 kcal = 4.184 kJ).

Oxygen solubility.—Determination of O_2 solubility by the weighing method proved unsatisfactory due to displacement of CO_2 during melt saturation. As shown below, this implies chemical solubility of oxygen in the melt, but at the same time introduces a further interpretive difficulty concerning the stability of the compounds formed by association of molecular oxygen and the carbonate melt, so that complete displacement of oxygen is ensured on cooling of the melt to lower temperatures. A comparison of electrochemical and quenching data indicates that reasonable certainty of the relative reversibility of the oxygen dissolution process may be inferred for a number of the carbonate melts, so that the oxygen solubility figures refer to both chemically and physically dissolved oxygen. The nature of the equilibria involved make the chemical species predominant.

Oxygen solubilities were obtained in a number of carbonate compositions by the quenching method (ternary alkali eutectic, 53.3/46.7 m/o Li/Na eutectic, 42.7/57.3 m/o Li/K eutectic, 58/42 m/o Na/K eutectic, pure Li_2CO_3, and 60 m/o Na_2CO_3/40 m/o NaCl). Results are given in Table II and Fig. 4. In

all cases, CO_2 partial pressures equal to or somewhat greater than the dissociation pressures were used (Table II). Several oxygen partial pressures in the 0.4-0.8 atm range were examined at each temperature and for each melt, so that apparent Henry constants and standard deviations could be determined.

Electrochemical data in the pure Li and Na/K melts show that oxygen is present as peroxide and superoxide ion in molten carbonates, superoxide being absent in the pure lithium melt (12-14). Calculations assuming a diffusion coefficient of 10^{-8} m^2-sec^{-1} using the diffusion peak height/square root sweep rate relationships and data generated in Li (13) and Na/K (14) melts give oxygen solubility (mole-dm^{-3}-atm^{-1}) of $7 \cdot 10^{-4}$ and $1.5 \cdot 10^{-3}$, respectively. Comparison of the data indicates good agreement between the electrochemical calculations and the quenching method, which suggests that all the peroxide and superoxide decompose on cooling. Calculations based on the Uhlig-Blander equation predict physical solubility values at least an order of magnitude lower than the chemical values measured. Attempts to calculate the solubility of oxgen as peroxide and superoxide based on thermodynamic data [JANAF, Ref. (15)] are probably not meaningful due to the approximate nature of the ΔG^o values and the probable stabilizing influence of the carbonate ion on $O_2^=$ and O_2^- [for discussion see Ref. (16)]. The high solubility values in Na_2CO_3-NaCl eutectic (Table II) are of great interest, but no electrochemical data are available at present to confirm the makeup of the species present in the melt. Results in Li_2CO_3 are comparable with those for CO given above, and suggest that the comparative stabilities of $CO_2^=$ and $O_2^=$ change in the same way with temperature. A very high activation energy for O_2 dissolution (175 kJ-mole^{-1}) was estimated from electrochemical data in a previous paper (13). The present results suggest an even greater value, but it must be pointed out that all the oxygen solubility data given here are for the processes

$$O_2 + 2CO_3^= \rightarrow 2\,O_2^= + 2CO_2$$

and

$$3\,O_2 + 2CO_3^= \rightarrow 4\,O_2^- + 2CO_2 \quad \text{(except pure } Li_2CO_3\text{)}$$

so that ΔH values will contain a component varying from 1.0-0.5 ΔH_d, where ΔH_d is the heat of decomposition of the melt, depending upon which of the above reactions predominates. This results from the fact that the CO_2 pressure above the melt was not held constant, but was maintained slightly over the dissociation value in each case. This effect is most marked for the pure Li melt.

A number of experiments were conducted in the ternary eutectic at 800°C to determine the effect of p_{CO_2} on oxygen solubility. Since the predominant species is superoxide ion in this melt, solubility should be approximately proportional to $p_{CO_2}^{-1/2}$. Changes were difficult to detect on increasing p_{CO_2}, since this required a decrease in p_{O_2} and consequent fall of sensitivity. In addition, it is possible that there is a partial compensation in that physical O_2 solubility may replace chemical solubility as the melt is neutralized: however it is significant that physically dissolved O_2 was not detected experimentally in the previously reported electrochemical sweep work (12-14). Large changes in oxygen content of the melt were only detected at low p_{CO_2} and high p_{O_2}: these are the conditions of the present work.

Due to the chemical solubility of oxygen, the typical first-order Henry's law should not be obeyed. This was first pointed out by Andresen (17), who determined oxygen solubility in sodium carbonate melts in a higher temperature range than that studied here. In all melts except pure lithium carbonate, the electrochemical results (12-14) indicate that the predominant

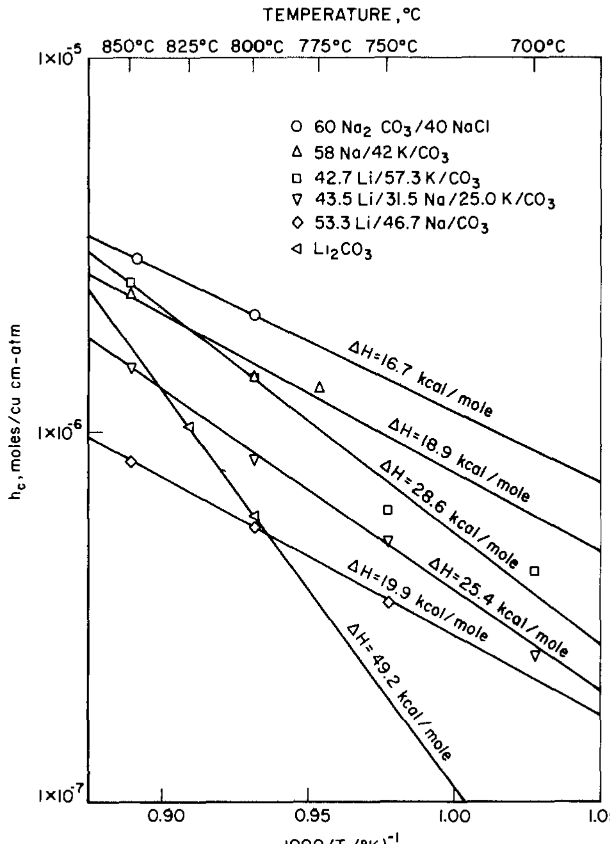

Fig. 4. $\log_{10}$ O_2 solubility as a function of $1/T$(K) (units as Fig. 3)

chemical species should be superoxide ion. For this species, the solubility reaction order should be 0.75. The present results do not permit a test of this relationship over only a twofold partial pressure change. In lithium carbonate, the corresponding order should be 0.5, with -1 for p_{CO_2}. Again, these were not detectable within the scatter of the data points at the low solubility levels observed for this melt. However, in calculating oxygen solubilities at other O_2 or CO_2 partial pressures, the reaction orders given above should be used.

It is interesting that results obtained by Broers (18) for oxygen solubility by an amperometric titration method (which will detect both physically and chemically dissolved oxygen) agree well with the values determined here. They are shown for comparison in Fig. 5, which includes total CO value obtained in the ternary eutectic. As expected, this value is several times higher than that for purely physical CO determined in the present work (Table I and Fig. 4). Broers' work (18) shows that hydrogen solubilities may be also high, but he did not distinguish between hydrogen and chemically bonded CO produced via the shift reaction. Work reported in Ref. (9) show that a nonlinear pressure-concentration relationship appears to apply in the case of the chemically bonded CO species. Results for H_2 and CO solubility obtained by amperometric titration therefore require careful interpretation.

Alternate Synthesis of Electrolyte Matrix for Molten Carbonate Fuel Cells

R. H. Arendt* and M. J. Curran

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

A process is presented for the preparation of the electrolyte matrix, a poorly bonded assemblage of $LiAlO_2$ crystallites, based on the use of a fugitive reaction medium, a molten mixture of alkali chlorides. Data on the characteristics of both the reaction and the product are presented.

The electrolyte structure, or tile, used in molten carbonate fuel cells consists of a mixture of liquid alkali metal carbonates retained by capillarity in the interstices of an array of chemically inert inorganic crystallites. At cell operating temperatures, the carbonates form an ionically conducting fluid held in place by capillarity. The selection of the carbonate composition is governed by consideration of, and balance between, proper liquid temperature range, ionic conductivity, reactant/product gas solubilities, volatility, etc. The most commonly used composition is 62 mole percent (m/o) Li_2CO_3-38 m/o K_2CO_3, having a liquidus temperature of ~764°K, and represents a judicious balance of the critical factors (1). The present matrix material is lithium metaaluminate, $LiAlO_2$, which may exist as one, or all, of three crystallographic modifications (2).

The electrolyte-$LiAlO_2$ matrix composite is most commonly prepared as an intimate mixture using either anhydrous techniques (3) or an initial aqueous solution/slurry of the components (4, 5). It is a characteristic of these preparations that either the electrolyte phase, or its precursor, is present throughout the synthetic sequence. The presence of the electrolyte phase precludes the presence of additional chemical species which could beneficially modify the matrix characteristics during its formation, since the matrix is not separated from these other species. The inclusion of the hygroscopic electrolyte also mandates that care be taken to maintain its chemical composition and purity throughout the required processing operations.

The product of this preparation is a mixture of $LiAlO_2$, average spherical equivalent crystallite size ranging from ~0.05 μm to more than 1.0 μm, and the mixed carbonates. It is generally recognized that minimization of the matrix crystallite size will maximize the volume fraction of molten electrolyte that can be properly retained, as well as produce matrix porosity which properly complements that of the fuel cell electrodes. However, the stability of small crystallites in the highly aggressive environment of the molten electrolyte is open to question, and will be more fully addressed in a companion paper.

The electrolyte-matrix composite is fabricated into the electrolyte structure by hot-pressing at temperatures 5°-15°K below the electrolyte liquidus, and at pressures ranging up to 60 MPa (6). Densities ranging up to 99% of theoretical have been achieved in this fabrication process.

An alternate preparation, the "chloride" synthesis, has been developed for the $LiAlO_2$ matrix which does not involve the presence of the electrolyte or its precursors. This preparation involves the use of a fugitive molten ionic solvent to promote the formation of the product from the reactants. This approach is predicated on the assumption that the interaction of the reactant and product species with the molten solvent are small compared with the free energy of the product-forming reaction. Under these circumstances, the product will have a smaller molten solvent solubility than will the reactants. Reaction proceeds by saturation of the solvent by the reactants, resulting in precipitation of the product species until all reactants are consumed to a level consistent with the product's melt solubility. The presence of one reactant in excess will effectively reduce all other reactant final concentrations to zero.

A requirement of the ionic solvent is that it provide a small solubility for the reactants. This solubility need not be great since the reaction "flux" is governed by the high mobility of the dissolved species in ionic melts, coupled with the small diffusion distances required in an intimate mixture of finely particulate reactants. The quantity of solvent required for complete reaction is a function of both the reactant and product crystal sizes. Sufficient solvent is required to provide access of the reactants to each other, providing the required reaction pathways.

A further requirement of the molten solvent is that it can be separated from the products under conditions which do not degrade the product. In general, product compounds of interest are relatively water insoluble. Therefore, water-soluble salts, such as the alkali and alkaline earth halides (except fluorides) are suitable. It has been found that the alkali chlorides, and their mixtures, satisfy these requirements. A number of technologically significant compounds have been prepared in this manner (7, 8).

"Chloride" Synthesis of $LiAlO_2$

The synthesis of $LiAlO_2$ was achieved by the reaction of $Al_2O_3 \cdot 3H_2O$ (ALCOA C-33) with excess $LiOH \cdot H_2O$ (J. T. Baker, reagent grade) in the presence of 50 m/o NaCl-KCl (J. T. Baker reagent grade) at 935°-945°K. $Al_2O_3 \cdot 3H_2O$ represents the least expensive, commercial Al^{+3} source available; alpha and gamma-Al_2O_3 were also suitable reactants. The reaction mixture was prepared by briefly ballmilling (α-Al_2O_3 system) together the reactant and solvent components to both homogenize and comminute any large agglomerates present in these materials. A 2 weight percent (w/o) excess of $LiOH \cdot H_2O$ was required to reliably achieve complete $Al_2O_3 \cdot 3H_2O$ conversion without resorting to extreme homogenization procedures. A solvent content of $\gtrsim 50$ w/o was empirically determined as necessary to achieve quantitative conversion of the $Al_2O_3 \cdot 3H_2O$ used in these experiments.

The homogenized reaction mixture was placed in dense α-Al_2O_3 crucibles and heated to 935°-945°K at 100°K hr^{-1}, maintained at temperature for 1 hr, then cooled to room temperature. An ambient air atmosphere was maintained throughout. The reacted mass was noticeably compacted and hardened, and had lost mass consistent with the appropriate dehydration reactions.

The product $LiAlO_2$ was retrieved from the chloride solvent and excess Li_2O/LiOH by dissolution of the

* Electrochemical Society Active Member.
Key words: electrolyte, fuel cell, fused salts, synthesis.

latter in distilled H_2O, assuming a salt solubility of ~250 kg meter^{-3}, a process requiring ~30 min with constant stirring. The dispersed, small crystallite sized powder was flocculated using an aqueous solution of an organic anionic flocculating agent (Hercofloc 821, Hercules Chemical Company). The supernatant solution was decanted and retained for chloride solvent recycle. The product was filtered to retrieve the remaining salt solution, washed sparingly with distilled H_2O, then 95 volume percent (v/o) ethanol to facilitate drying, and partially air dried on the filter. After more complete drying in a Teflon vessel at 473°K, the $LiAlO_2$ was briefly heated to 773°-873°K to destroy traces of organic material as well as reverse any hydration that had taken place in previous processing. The mass loss observed during this latter heating was typically 0.70 w/o. It was also determined that $LiAlO_2$ (β-, γ-) possessed an effective H_2O solubility of ~1.0 kg meter^{-3} within this processing scheme.

The retained alkali chloride solutions from MSLA-93, . . . , 98, containing the excess LiOH and dissolved $LiAlO_2$, was recycled into the synthesis of MSLA-99 and 100 by simply reducing it to dryness. The crystalline material was briefly comminuted to reduce its crystal size to that of the virgin chloride salts. The proper quantities of $Al_2O_3 \cdot 3H_2O$ and $LiOH \cdot H_2O$ (no excess) were added to the solvent and homogenized. The synthesis was then completed as described above.

Product Characteristics

During the development of "chloride" synthesis for $LiAlO_2$, the effects of maximum reaction temperature and excess concentration of $LiOH \cdot H_2O$ were investigated. Although the binary chloride melt had a liquidus temperature of 931°K, the addition of LiOH (mp = 723°K) to the chloride was anticipated to result in an effectively ternary solvent with liquidus below 931°K. Minimizing the reaction temperature was expected to minimize the product crystal size. The results for a constant composition reaction mixture containing 2 m/o excess $LiOH \cdot H_2O$ are shown in Fig. 1. Similar plots were generated for 6 and 10 m/o excess $LiOH \cdot H_2O$ content mixtures, the curves being displaced toward lower surface areas ($\lesssim$20%) with increasing excess $LiOH \cdot H_2O$.

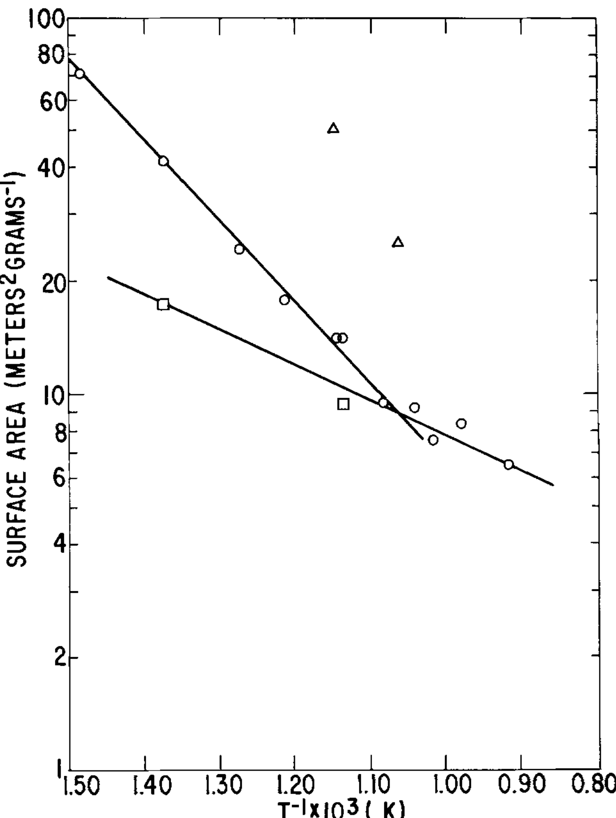

Fig. 1. Product surface area vs. inverse reaction temperature

Consider first the circle data, which follow the broken linear relationships indicated. The material corresponding to the highest temperature point was analyzed to be pure γ-$LiAlO_2$. The remaining samples were found to be predominantly β-$LiAlO_2$, with a small amount of α- and γ-$LiAlO_2$. The two lowest temperature samples also showed the presence of poorly crystallized γ-Al_2O_3. In a separate set of experiments, omitting the $LiOH \cdot H_2O$, γ-Al_2O_3 with a surface area in excess of 120 m^2 g^{-1} resulted. It was concluded from these data that the change in slope, which occurs very near the binary chloride liquidus temperature, resulted from the admixture of small sized, poorly crystalline γ-Al_2O_3 to a predominantly $LiAlO_2$ product. The poor crystallinity of the γ-Al_2O_3 rendered it detectable only at major concentrations.

This conclusion was confirmed with the square data which resulted from samples prepared from a fine $Al_2O_3 \cdot 3H_2O$ reactant, wet mixed with the chlorides and $LiOH \cdot H_2O$. These samples were determined to be predominantly β-$LiAlO_2$, with no γ-Al_2O_3 in evidence. They correspond well with the high temperature segment line. Therefore, to obtain quantitative conversion of $Al_2O_3 \cdot 3H_2O$ to $LiAlO_2$, either special care in reaction mixture preparation was required, or the reaction must be conducted above the chloride liquidus. The latter is the preferred route from an applications point of view. An additional benefit is possible in that the chloride liquidus temperature is very near the fuel cell operating temperature, thereby giving a matrix material more nearly in equilibrium with the conditions expected in operating fuel cells.

Variation of the lithium reactant anion was also explored. The triangle data in Fig. 1 were for samples in which Li_2CO_3 was equivalently substituted for $LiOH \cdot H_2O$. Both samples were composed of α-$LiAlO_2$ and γ-Al_2O_3. No β- or γ-$LiAlO_2$ were detected. Similar results were obtained with substitution of $LiNO_3$ for for $LiOH \cdot H_2O$ in that pure, high surface area α-$LiAlO_2$ resulted, although conversion was apparently complete in that case. These data indicated that the anion species can greatly effect the $LiAlO_2$ allotrope stability in an otherwise constant environment.

The effects of increasing excess of $LiOH \cdot H_2O$ in an otherwise constant composition reaction mixture are shown in Fig. 2. The reaction temperature was in the interval 923°-973°K. All products were predominantly β-$LiAlO_2$, with no unreacted Al_2O_3 detected by x-ray. Although the product surface areas decreased with increasing excess, the effect was relatively minor. Based on these data, it was decided to use a 2 m/o $LiOH \cdot H_2O$ excess in scaled-up preparations of a predominantly β-$LiAlO_2$ matrix material. This was done in order to compensate for expected compositional inhomogeneities in the larger lots of reaction mixture.

Eight 1.5 kg lots of $LiAlO_2$ were prepared using the "chloride" synthesis, the characteristics of which are given in Table I. The first six lots were prepared using virgin chloride solvent components. The last two lots used the recycled chloride solvent and excess LiOH generated by the first six lots. As indicated, there is no difference between the two groupings. The materials are predominantly β-$LiAlO_2$ with an average spherical equivalent crystallite diameter of 0.34 μm, as determined by BET surface area measurements. The material is, however, composed of crystallites of widely varying morphology and size, as shown in Fig. 3 and 4.

This mixture of crystallite sizes and morphologies was expected to yield matrix compacts which possessed small sized, narrow porosity distributions. It was found, however, that the as-prepared material contains suffi-

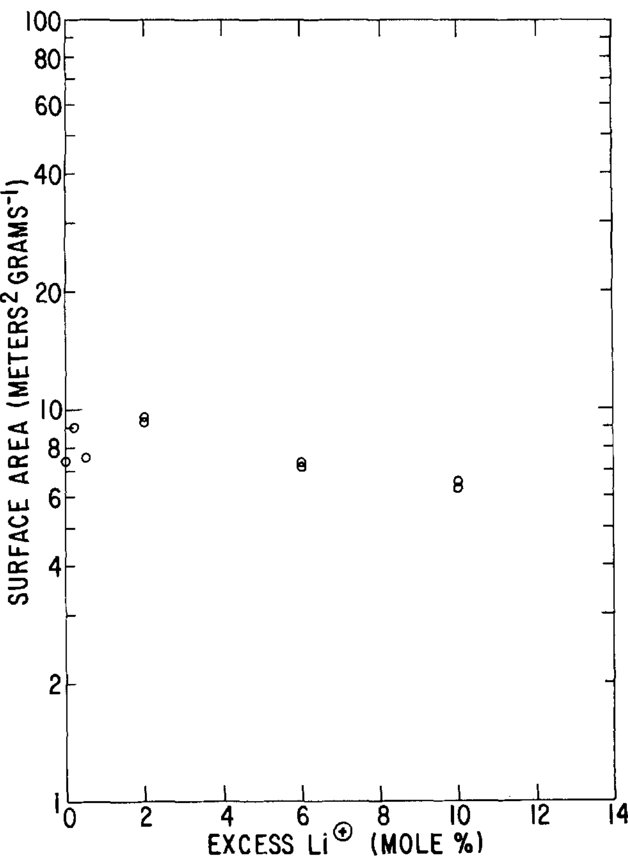

Fig. 2. Product surface area vs. excess LiOH in reaction mixture

cient synthesis-generated agglomerates to yield a broadened, ill-defined porosity distribution. This topic is covered in detail in the companion paper. The appropriate porosity distribution was developed by wet comminuting the as-prepared $LiAlO_2$ for 8 hr in an α-Al_2O_3 mill using absolute CH_3OH as the fluid. Although the average spherical equivalent crystal size of the milled sample changes little, from 0.31 to 0.26 μm, the porosity distribution was markedly altered. It became well defined about a maximum in the distribution located at 0.50-0.60 μm. It should be noted that a similar situation probably exists in conventionally prepared matrix-electrolyte composite mixtures. The deagglomeration of such mixtures is, however, made more uncertain by the presence of the relatively soft, hygroscopic electrolyte component.

Conversion to Matrix-Electrolyte Composite

The deagglomerated "chloride" synthesis $LiAlO_2$ was converted into a matrix-electrolyte composite by simply dry blending the $LiAlO_2$ with the requisite quantities of Li_2CO_3 and K_2CO_3. This mixture was heated to 873°K for 1 hr in an air atmosphere using a dense α-Al_2O_3 crucible. The resultant cake was briefly dry comminuted to produce a powder suitable for fabrication into electrolyte structures by hot-pressing.

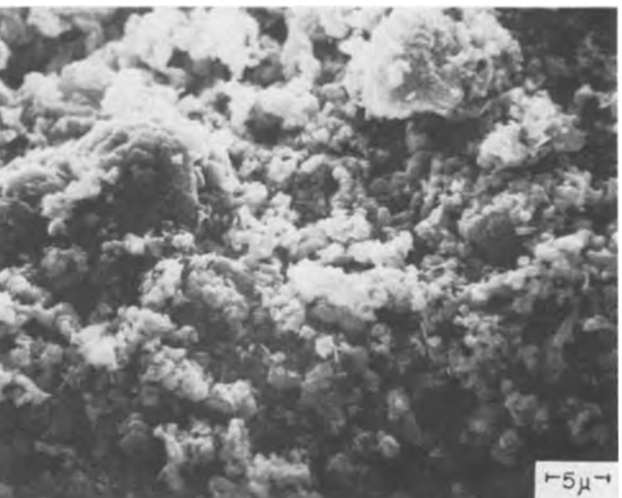

Fig. 3. SEM micrograph of MSLA-95, 2000×

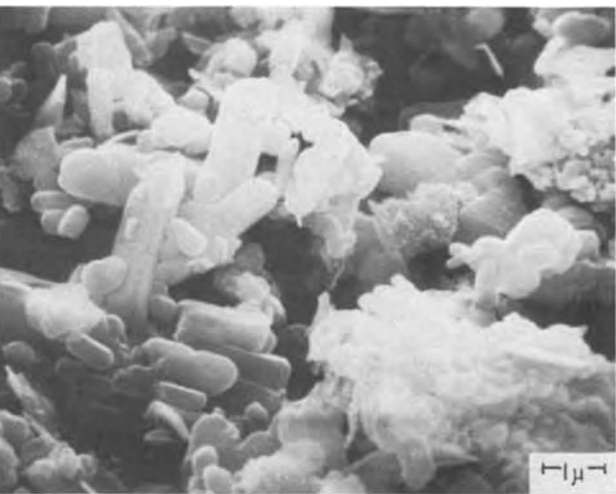

Fig. 4. SEM micrograph of MSLA-95, 10,000×

The behavior of this alternately prepared material during fabrication and subsequent fuel cell evaluation was equivalent to that experienced with conventionally prepared materials.

Conclusions

An alternate, relatively rapid process for the preparation of $LiAlO_2$ matrix material for molten carbonate fuel cells has been developed. The reaction conditions and processing operations required to generate fuel cell quality material have been defined.

Alternate Fabrication Process for Molten Carbonate Fuel Cell Electrolyte Structures

R. H. Arendt* and M. J. Curran

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

A process is presented for the preparation of reinforced molten carbonate fuel cell electrolyte structures which does not involve a hot-pressing operation. This process is based on the use of an electrolyte-free $LiAlO_2$ matrix material of predetermined, tailored characteristics. The matrix is fabricated into a "blank" using conventional ceramic techniques. The "blank" is subsequently infiltrated under controlled conditions with molten electrolyte.

The electrolyte structure, or tile, used in molten carbonate fuel cells consists of a mixture of alkali metal carbonates contained in the interstices of an array of chemically inert inorganic crystallites. The nature and preparation of the components of the electrolyte structure were discussed in a companion paper (1). The subject of the present paper is an alternate method for the fabrication of the matrix (presently $LiAlO_2$) and electrolyte (typically 62 mole percent (m/o) Li_2CO_3-38 m/o K_2CO_3) into the electrolyte structure.

The structure is conventionally fabricated by hot-pressing (2) a finely particulate, intimate, matrix-electrolyte composite mixture. The processing involves heating the die and mixture to temperatures 5°-15°K below the electrolyte liquidus (~764°K for the 62:38 composition) and applying pressures of up to 60 MPa for 15-120 min. The entire cycle, including heating and cooling of the apparatus, requires a minimum of 4 hr. Structures in excess of 0.30 m^2 have been successfully prepared in this fashion. However, commercial application of molten carbonate fuel cell will require tens of thousands of square meters of electrolyte structure in unit sizes exceeding 1 m^2. These size requirements may result in significant lengthening of the unit production time. The capital intensive nature of the present hot-pressing fabrication process indicates a need for an alternate fabrication process.

One possible approach to an alternate fabrication process is to decompose the present simultaneous application of pressure and temperature into two distinct processes. In such an alternate approach, all pressure applications are conducted at ambient temperatures, while high temperature processing is conducted at ambient pressure. With a process decomposition, it should be possible to both reduce unit process cycle times and introduce continuous processing operations. The development of such a fabrication process is the subject of this paper.

Impregnation Fabrication Process

The alternate process consists of fabricating the matrix material, in the absence of the electrolyte phase, into a particle array of appropriate porosity characteristics at ambient temperatures. This array is then impregnated with molten electrolyte at ambient pressure, using capillarity to draw the molten phase into the matrix interstices. There is, in principle, no limitation on the nature of either the matrix or the electrolyte.

The process was developed using the deagglomerated "chloride" synthesis $LiAlO_2$ previously reported (1). Any chemically stable matrix source is suitable, provided it contains substantially no second phase content which would preclude the establishment of the appropriate pore size distribution during the matrix fabrication operation. In the present case, cold-pressing of the matrix was used as a matter of convenience. More continuous, high volume fabrication processes, such as tape casting, slip casting, or electrophoretic deposition, are even more attractive. What is required of the matrix forming process is the attainment of a stable, close-packing of the matrix crystallites.

The deagglomerated "chloride" synthesis $LiAlO_2$ possessed insufficient self-binding character to allow pressing of sufficiently strong thin (~1-2 mm) slabs to permit handling. This condition was remedied by the addition of an organic compound as a fugitive

* Electrochemical Society Active Member.
Key words. electrolyte, fuel cell, fabrication.

binder. Initial experiments with the aqueous addition of polyvinyl alcohol (du Pont Chemical Company, 51-05) showed that partial hydration of the $LiAlO_2$ resulted. The hydrate formation led to a detrimental reagglomeration of the initially monodispersed crystallites, which in turn resulted in an inappropriate porosity distribution in the pressed body. This point will be considered more fully below.

A suitable binder system was developed based on polyvinyl butyral (Monsanto Chemical Company, BUTVAR B-74 resin) dissolved in absolute methanol. The $LiAlO_2$ was dispersed in the binder solution [1 weight percent (w/o) resin on a dry basis] using intensive, high-shear blending. The methanol was evaporated by infrared heating, with constant stirring of the mixture to avoid segregation of the binder. The drying process was halted before complete methanol removal, *i.e.*, at a point where a soft, apparently dispersed powder mass resulted. Complete removal of the methanol resulted in a rock-hard mass which could not be pressed into an appropriate porosity body due to binder generated agglomerates of exceptional strength. Such material could, however, be regenerated by the reintroduction of methanol through the vapor phase. The resin: methanol content ratio required is 1:1-1:3 on a mass basis. The binder containing powder was screened −40 mesh before use.

The matrix blanks were cold-pressed in a steel die at 14-35 MPa. The die was loaded with half the required powder charge and leveled. A single layer of pressure-flattened 20 mesh Kanthal® A-1 screen (0.127 mm wire diameter) was placed on the leveled powder and the remaining $LiAlO_2$ added and leveled. The pressed bodies, reinforced, measuring 165.1 × 76.2 × 2.3 mm, were cut in half to give two blanks suitable for fuel cell experiments in this laboratory. The blanks were transferred to suitable substrates for molten carbonate impregnation.

The nature of the substrate was important to the impregnation process. Since it contacted liquid electrolyte during the process, the substrate had to be chemically inert toward molten carbonate. Another requirement was that the blank-substrate interface be poorly mated to allow atmosphere displaced from the matrix interstices to escape ahead of the advancing liquid electrolyte front which originated at the opposite blank face. Failure to observe these conditions resulted in the generation of liquid envelope-bounded gas bubbles which, in the course of the impregnation, led to physical disruption of the nonbonded matrix crystal array with attendant loss of physical shape and dimension control in the finished electrolyte structure. It was found that porous Al_2O_3 plaques covered with wrinkled, and partially flattened, gold foil satisfied these requirements.

The reinforced matrix blanks were impregnated with molten electrolyte by loading the solid electrolyte, premelted and ground, on top of the blanks in an evenly distributed pattern. The majority of experiments conducted during this development used agglomerated matrix material so that the blanks possessed broad, poorly defined pore size distributions, as will be documented below. These distributions precluded adding the entire electrolyte charge with a single impregnation since no effective, practical means could be devised to throttle the rate of introduction of molten material to the blank. It was found that the rate-controlling step was the absorption and distribution of molten electrolyte within the matrix crystal array. Attempts to introduce the entire electrolyte charge resulted in dilation of the matrix array to the point where the crystallites rearranged themselves physically. This action disrupted the physical shape and dimensions of the blank and rendered the product useless for fuel cell experiments. The problem was eliminated by impregnating with only 50-75% of the required electrolyte. The remaining electrolyte was added in a second impregnation. Further, it was found necessary to limit the rate of heating to $\leq 40°K\ hr^{-1}$ near the electrolyte liquidus temperature. Adherence to these requirements resulted in electrolyte structures which were suitable for fuel cell experiments.

When a deagglomerated matrix material was used, and the reinforcing mesh omitted, the entire electrolyte charge could be added in a single impregnation. Further, there was no limitation on the rate of liquid addition to the blank. The finer porosity present with a deagglomerated matrix, and the attendant uniform capillarity of the array, provided for more rapid and uniform absorption of the liquid phase.

Incorporating a reinforcing mesh into a deagglomerated matrix crystal array resulted in a previously unobserved problem. The pressure-flattened mesh was used without preconditioning it with molten electrolyte since it was felt that such treatment would render the mesh too fragile for the fabrication. When the reinforced blank was impregnated with the entire electrolyte charge, it was observed that the mesh interacted with the molten electrolyte, both oxidizing and "lithiating" of a surface layer on the mesh, generating CO_2. This gas was trapped in liquid-bounded envelopes at the mesh plane and caused separation of the electrolyte structure at this plane. The problem was not observed using agglomerated matrix since the wide pore size distribution in that case likely provided electrolyte-void channels to vent the gas generated.

The effects of the mesh-molten electrolyte interaction were ameliorated by using two impregnations. The first impregnation added 50% of the required electrolyte. Since uniform, fine porosity was present with the deagglomerated matrix, the liquid electrolyte was substantially restricted to the regions of the blank bounded by the top surface, the point of electrolyte introduction, and the midplane where the mesh resided. The lower half of the blank remained substantially electrolyte-free and provided an escape path for the CO_2 generated during the *in situ* mesh conditioning. The remaining electrolyte was added using a second impregnation, yielding electrolyte structures suitable for fuel cell evaluation.

Fuel Cell Evaluation

The first fuel cell experiment (CRD-027) was conducted using a reinforced electrolyte structure containing agglomerated $LiAlO_2$ matrix material. The electrochemical performance of this $0.44 \times 10^{-2} m^2$ active area cell is shown in Fig. 1. This experiment involved more than 20 thermal cycles of the cell between 923°K, the cell operating temperature, and ~650°K, a temperature below the electrolyte solidus, at cycle rates of 50°-75°K hr^{-1}. The cell was maintained at the lower temperature for periods randomly

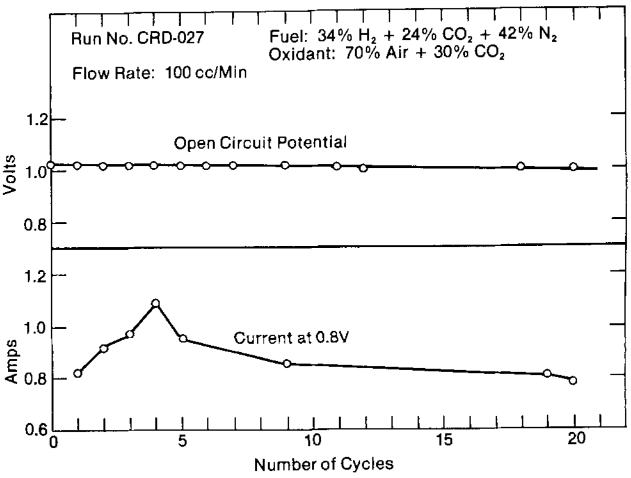

Fig. 1. Electrochemical performance of cell CRD-027

ranging from 2 to 18 hr before returning to the operating temperature. It was assumed that the major impact of thermal cycling was involved with the electrolyte phase transformation. The electrochemical performance of the cell was below (by a factor of 2-3) that achieved in this laboratory using selected, conventionally prepared electrolyte structures in the same hardware. The factors responsible for this behavior are considered below.

The gas management characteristics of this cell are shown in Table I. The wet seal performance was determined from measurement of inlet and outlet gas flow rates. The cross-leakage was determined using an argon-doped cathode stream and mass spectrometric analysis of the anode exit stream. These data indicate excellent anode seal performance from the start of the experiment, while the cathode seal took several days to establish. Both seals maintained integrity over the ~2000 hr of the experiment. The cross-leakage behavior was somewhat more variable. The initial behavior was good. Thermal cycling increased the cross-leakage, and there is indication that the magnitude of leakage is proportional to the frequency of cycling. Further, cessation of cycling, when coupled with steady cell operation, appeared to allow the cycling-induced damage to at least partially reverse itself.

Electrolyte Structure Diagnostics

The maintenance of electrochemical performance is dependent, in part, on the constancy of matrix material characteristics in the functioning electrolyte structure. The effects of cell operating conditions on the matrix were examined by measuring the crystallite surface area, hence average size, before and after use in a fuel cell. Three different electrolyte structures were examined. The first was from the previously discussed experiment (CRD-027). The material used was "chloride" synthesis $LiAlO_2$ with a surface area of 6.43 $m^2\ g^{-1}$, and the experiment duration was more than 2000 hr. The other two structures (DECP-010, CRD-028) were prepared by conventional techniques (3), the matrixes having surface areas of 11.42 and 9.09 $m^2\ g^{-1}$, respectively. Their cell environment exposures were ~700 and ~192 hr, respectively. The matrix was separated from the electrolyte by dissolution of the latter in an equal volume mixture of glacial acetic acid-acetic anhydride, followed by filtration, a wash with absolute methanol, and drying at 393°K. The samples analyzed represented quadrants of the electrolyte structures.

The results of this analysis are given in Fig. 2. These data show that the average crystallite size has increased as a result of cell exposure. The initial

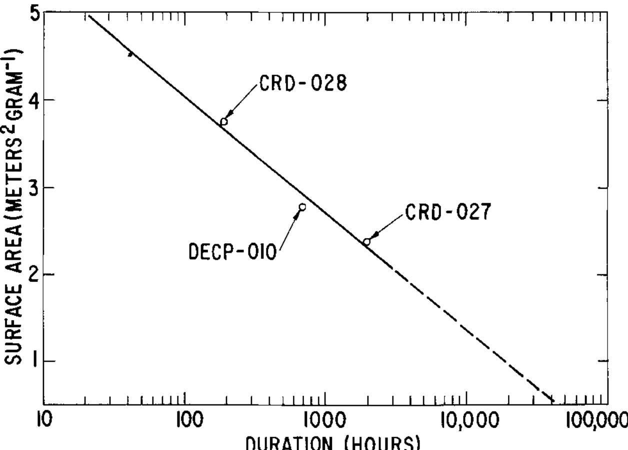

Fig. 2. Matrix crystal growth in fuel cell environment

crystal size difference has given way to one dependent on time of exposure. In addition, there is no indication that the crystal growth process has terminated at 2000 hr. These data indicate an instability of the matrix, hence the electrolyte structure, under cell operating conditions.

Measurement of the matrix crystallite pore size distribution in conventionally prepared materials involves the removal of the electrolyte phase. There is the attendant assumption that the freed material can be reassembled into an array representative of that which would have existed had the electrolyte been present. Such an assumption is unecessary in impregnation fabrication structure in that measurements can be made directly on the matrix blanks prior to impregnation. Such measurements were made in an effort to determine reasons for the failure of cell CRD-027 to give optimum electrochemical performance.

Figure 3 shows the cumulative pore volume fraction *vs.* pore diameter, as measured by mercury intrusion porosimetry, for both the matrix blank and the virgin Ni electrode used in the fuel cell experiment. The steepness of the electrode curve is indicative of the well-defined pore size distribution existent in that body. The matrix blank, in contrast, has a shallower slope, indicative of its poorly defined, broad pore size distribution. The distribution overlap between matrix and electrode indicated that at worst ~10% of the electrode pores would be electrolyte-filled. This condition should not have precluded satisfactory electrochemical performance of the cell.

Figure 4 shows that same matrix distribution along with the measured distributions for the anode and

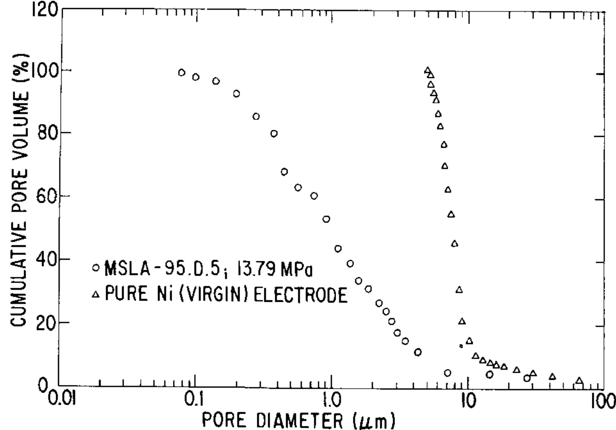

Fig. 3. Porosity distributions of agglomerated matrix and virgin Ni electrode.

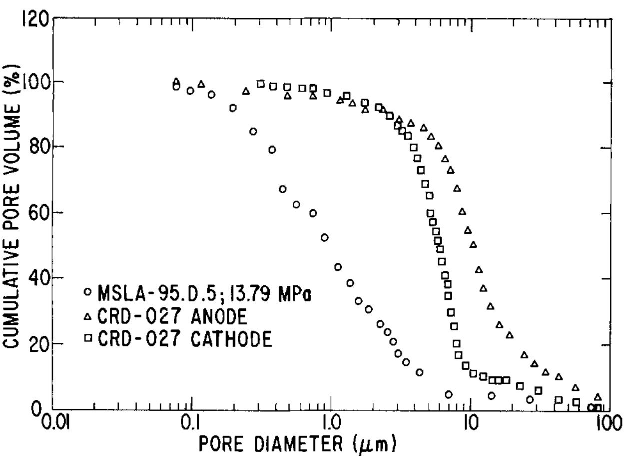

Fig. 4. Porosity distributions of agglomerated matrix and used electrode materials.

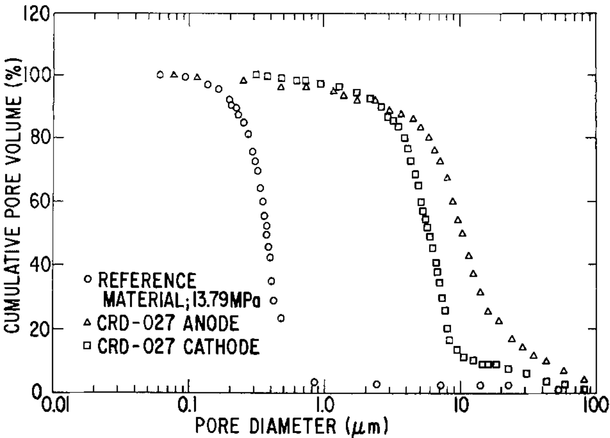

Fig. 5. Porosity distributions of monodispersed "reference" crystalline material and used electrode materials.

cathode retrieved from the cell experiment. The used electrode distributions are somewhat broadened relative to the virgin electrode material, resulting in an increased overlap with the matrix curve. The situation in an operating cell would be worse in that matrix crystal growth would have increased the average pore diameter, thereby further increasing the distributions' overlap. It was concluded from these data that the failure of the cell to perform properly was due in large measure to flooding of the electrodes with molten electrolyte resulting from excessive overlap of the matrix and electrode pore size distributions.

The cause of the poor matrix pore size distribution was determined with the aid of a "reference" material. An alkaline earth titanate, synthesized by a variant of the "chloride" synthesis previously discussed, was pressed into a matrix blank and its pore size distribution measured. This material possessed an average spherical equivalent crystal diameter, as measured through the BET surface area, of 0.31 μm, compared with 0.36 μm for the $LiAlO_2$. However, the "reference" material crystallites were more symmetrically shaped and uniformly sized than those of the $LiAlO_2$. Further, the "reference" crystallites were known to be substantially monodispersed, a characteristic unevaluated in the $LiAlO_2$.

Figure 5 shows the pore volume *vs.* size comparison of the "reference" with the electrodes from the cell experiment. Unlike the $LiAlO_2$ blank, the "reference" blank had a well-defined pore size distribution which produced only minor overlap with the electrode distributions, a condition which should result in proper electrode wetting. It was concluded from these data that agglomeration in the "chloride" synthesis $LiAlO_2$ was the source of the poor pore size distribution in the matrix blanks. To assess this conclusion, a sample of "chloride" synthesis $LiAlO_2$ was deagglomerated, as previously reported (1). The average spherical equivalent diameter was reduced from 0.30 to 0.26 μm. More strikingly, a blank prepared from the deagglomerated material possessed a pore size distribution indistinguishable from that of the "reference" material, confirming the interpretation.

The anticipated effect of the documented $LiAlO_2$ crystal growth under cell operating conditions is to move the pore size distributions of the matrix and electrodes closer together, increasing their overlap. However, the deagglomerated matrix should be more tolerant of this change than was the agglomerated matrix. Experiments are underway to assess the near and long-term performance of cells incorporating deagglomerated "chloride" synthesis $LiAlO_2$, both as conventionally and impregnation fabricated electrolyte structures.

Conclusions

A fabrication process for molten carbonate fuel cell electrolyte structures has been developed which eliminates the need for a hot-pressing operation. The requirements and conditions required to prepare structures suitable for fuel cell application have been defined.

Alkaline Aqueous Electrolyte Cells for Biomedical Implantable Applications

Paul Ruetschi*

Leclanché S.A., 1400 Yverdon, Switzerland

ABSTRACT

Technological advances, latest state of the art, and ultimate achieved performance of primary mercuric oxide-zinc cells for biomedical implantable applications are reviewed. The data presented in this review should serve as a basis against which long-term performance data of lithium batteries could be compared in the future. The different cell-internal and cell-external self-discharge processes are analyzed as to their relative importance in causing capacity loss. Other aqueous electrolyte, alkaline primary cells, such as the HgO-Cd cell, and secondary NiOOH-Cd batteries are also briefly discussed regarding biomedical implantable applications.

In recent years, more and more cardiac pacemakers have used as a power source a lithium battery of some sort. In the past, however, aqueous electrolyte, alkaline primary batteries of the mercuric oxide-zinc type were used extensively. Fester *et al.* (1) estimate that 99% of the 350,000 cardiac pacemakers implanted during the period 1969 to 1974 were powered by mercuric oxide-zinc cells. By the end of 1976 over 700,000 implanted cardiac pacemakers contained mercuric oxide-zinc cells as the power source (2). The first long-term use of mercuric oxide-zinc cells in pacemakers goes back to about 1960.

The present review describes the improvements made in mercuric oxide-zinc batteries over the past years, ultimate performance reached with this system, and finally some novel means to further optimize the system for long-term use.

The results on long-term testing of mercuric oxide-zinc cells reported in this review should serve as a basis of comparison with performance of various newer lithium batteries.

The major self-discharge processes occurring in HgO-Zn cells are evaluated as a function of temperature, and an estimation of the activation energy is attempted for each individual reaction. In analyzing self-discharge it is of importance to distinguish between cell-internal and cell-external processes.

The two main cell-internal side-reactions leading to capacity loss are: (*i*) Solubility of mercuric oxide in alkaline electrolytes and diffusion of dissolved mercuric oxide species towards the zinc electrode. (*ii*) Hydrogen evolution at the zinc electrode. Reactions occurring externally to the cells which may contribute substantially to self-discharge are: (*iii*) External electrolysis in moisture films on cell surfaces or leads, including anodic oxygen evolution or anodic corrosion of metal parts, and cathodic hydrogen evolution. (*iv*) External oxygen cycle, due to electrochemical reduction of oxygen on negative terminal parts and oxygen evolution on positive terminal parts.

Reliability, longevity, and uniformity of mercuric oxide-zinc primary batteries are determined by the construction of the inter-electrode separation, in particular the prevention of edge passage ways for mercury droplets, the type of separator material and number of separator layers, the conception of the seal, and the precision of metering anode, cathode, and electrolyte weights.

Besides mercuric oxide-zinc cells, some other aqueous electrolyte alkaline primary battery systems as well as rechargeable types have been proposed for implantable application, in particular the primary HgO-Cd and the secondary NiOOH-Cd system. So far, these have been of limited practical utilization (3, 4). Their behavior during long-term use is also briefly discussed in the present review.

Mercuric Oxide-Zinc Batteries for Biomedical Application

Primary mercuric oxide-zinc batteries for biomedical use are illustrated in Fig. 1 and 2. The Mallory RM 1 cell, shown to the left of Fig. 1 and 2, was for many years the only available power source (5, 6). It makes use of a cylindrical, ring-shaped electrode structure. The positive mercuric oxide electrode lines the inside can wall. The negative zinc electrode is contained in a centrally located separator tube. With this design it was very difficult to achieve ultimate safety against short circuits around the separator edges.

In the period 1960-1970 pacemakers had to be replaced typically after 18-24 months of service. Since the nominal capacity of RM 1 cells was 1 A-hr, and typical current requirements in a pacemaker at that time were in the order of 30 μA, only about 50% of the theoretically available capacity could be realized in practice prior to premature failures occurring due to internal short circuits (1, 7).

In order to immobilize the mercury droplets formed during discharge, silver powder was added to the positive electrode mix. The mercury droplets readily form with silver a solid amalgam. However, even though an improvement was noted, the shorting problem was still not solved satisfactorily.

Fig. 1. Medical-grade HgO-Zn cells. Left, Mallory RM1 cell; right, Leclanché MR 81 cell. Dimensions and characteristics are given in Table I.

Key words: alkaline primary cells, mercuric oxide-zinc cells, mercuric oxide-cadmium cells, nickel-cadmium cells, biomedical power source.

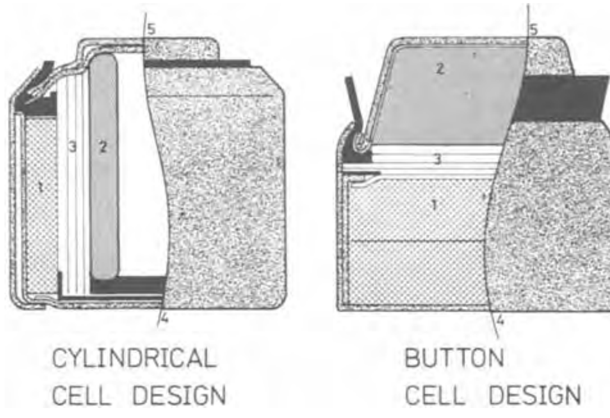

Fig. 2. Construction of RM1 (left) and MR 81 (right) cells. 1, Positive electrode; 2, negative electrode; 3, separators; 4, positive terminal (can); 5, negative terminal (cover) [from Ref. (9)].

In the beginning of the seventies, a further improvement was made by introducing the "double wrap" separator barrier. Better than 5 years longevity has been achieved with cells incorporating this improved separator design (4).

In the MR 81 (Leclanché) button cell design, shown to the right of Fig. 1 and 2, the electrodes are pellets, rather than cylinders (8). The separators are tightly locked at the edge between the grommet seal and a supporting steel ring. This cell construction is characterized by extreme reliability against internal short circuits. Long term performance data achieved with this cell have been reviewed recently (9). MR 81 cells have been available in an absolutely unaltered construction since 1970.

Dimensions and electrical data of RM 1 and MR 81 cells are listed in Table I. Obviously, for modern pacemaker designs, cells of lower height would be desirable. However, the basic design of the MR 81 cell lends itself to the construction of flat button cells, as used, for instance, in watches.

Most pulse generators have used 4 or 5 mercuric oxide-zinc cells of the RM 1 size connected in series. The cells were cast into the epoxy resin together with the electronic circuit. As will be discussed later, cell packaging, and in particular its effectiveness in preventing moisture and oxygen access to the cell surfaces, is of great importance for long-term use. One must remember that the body presents an atmosphere of high humidity and relatively high temperature (37°C).

A third type mercuric oxide-zinc cell, developed for biomedical use, was a relatively large 3.4 A-hr unit (General Electric). Data reported on this cell, (10, 11) indicated a self-discharge rate of about 1.5% per year at 37°C and 15% per year at 65°C. After storage for 24 weeks at 72°C, capacity on an accelerated six months discharge test was 3.0 A-hr, which corresponds to 25%/yr (3). The longest discharge tests reported so far were 5 yr at 37 μA, that is to only about 50% depletion of cell capacity.

Since internal short circuits tend to occur only when approaching complete exhaustion of anode capacity, it is not yet possible on the basis of the published material to judge reliability near the end of discharge.

In the following, life-limiting factors of mercuric oxide-zinc batteries are analyzed by using as a test vehicle the MR 81 cell.

It should be understood that data reported here on this cell could be extended suitably to other mercuric oxide-zinc cells when taking into account relevant geometric and other design features.

Long-Term Performance of Mercuric Oxide-Zinc MR 81 Cells

Typical performance achieved with MR 81 cells are illustrated in Fig. 3-7 and Table II. It should be noted that these data refer to the original MR 81 cell construction, as finalized in 1970.

Mercuric oxide-zinc cells are characterized by their constant discharge voltage (Fig. 3). Initial higher voltage is due to the MnO_2 addition to the positive electrode mix. It may serve as a safety indicator for absence of internal shorts (Fig. 4). Internal impedance remains low to the very end of discharge (Fig. 5). The initial hump in internal resistance, shown in Fig. 3, is due to an electrolyte redistribution phenomenon, which cannot be discussed here in detail. Extremely good uniformity was achieved with this cell by very precise metering of anode material (Fig. 6).

Long-term storage and discharge data are presented in Table II and Fig. 7.

Analysis of the Cell-Internal Self-Discharge Processes Occurring in HgO-Zn Cells

Solubility of mercuric oxide.—A major cause of internal self-discharge is the solubility of mercuric oxide in alkaline electrolytes (12, 13). Solubility may be suppressed, as will be discussed later, by using a very high electrolyte concentration (9). Only scarce data is available concerning dependence of HgO solubility on temperature. From one single literature value, reported for 100°C (14), the heat of dissolution for HgO in water can be estimated approximately at 6 kcal/mole. Solubility of HgO at different temperatures, as evaluated from a $1/T$ plot, using an integrated Clausius-Clapeyron equation with $\Delta H = 6$ kcal, is listed in Table III. Mercuric oxide dissolves in alkaline electrolytes probably in form of undissociated $Hg(OH)_2$ (9).

Self-discharge caused by mercuric oxide solubility may be measured experimentally by analyzing the amount of mercury present in the anode after known periods of storage at a given temperature. For such studies, it is preferable to use HgO-Cd cells, rather than HgO-Zn cells. The cadmium sponge anode is initially mercury-free, and its mercury content can be determined with good precision whereas with amalgamated zinc anodes, the diffused mercury must be determined as the difference between two large numbers.

Mercuric oxide diffusion may be expressed in terms of a self-discharge current. The surface available for diffusion is determined by the separator interface between positive and negative electrode. In

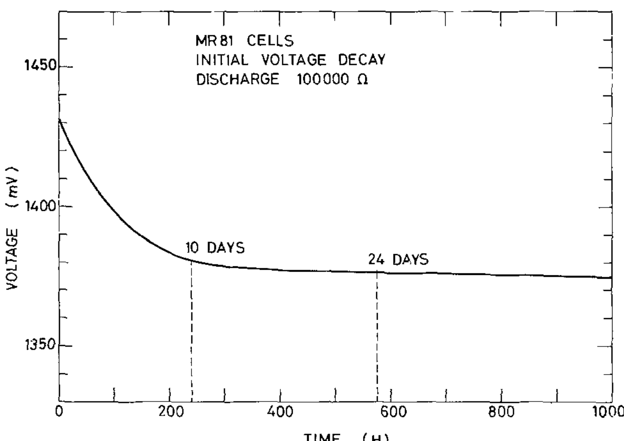

Fig. 4. Initial voltage decay of MR 81 cells during 100 kΩ discharge.

RM 1 cells, this surface amounts to about 2.4 cm^2. In the MR 81 cell it is restricted to the opening in the sealing grommet and amounts to only 0.8 cm^2. Rate of $Hg(OH)_2$ diffusion depends also on the type of separator, number of separator layers (distance between electrode surfaces) and on quantity and concentration of alkaline electrolyte in the cell.

Self-discharge current densities in the order of 0.1-0.3 $\mu A/cm^2$ at 22°C have been reported (15) for cells with radiation-grafted and cross-linked polyethylene (Permion® 2291-40/60) and an electrolyte of 30% KOH.

Self-discharge due to $Hg(OH)_2$ diffusion increases rapidly with temperature. At 71°C, for two layers of Permion®, a value of 2.4 $\mu A/cm^2$ has been reported (16). Measurements, carried out in our laboratories using HgO-Cd cells, are included in Table III. Using these values one can calculate the theoretical self-discharge due to $Hg(OH)_2$ diffusion in an MR 81 cell (theoretical anode capacity 1230 mA-hr, diffusional area 0.8 cm^2). Results are given in the last column of Table III. An Arrhenius plot with these values indicates an activation energy of 12 kcal/mole (Fig. 8, curve A). Self-discharge due to $Hg(OH)_2$ diffusion is particularly low in cells of the MR 81 design because of the restricted diffusional area, the wide electrode separation, and the high electrolyte concentration used in these cells. Various novel means to reduce mercuric oxide diffusion are discussed in a later chapter.

Hydrogen-evolution.—Hydrogen evolution on zinc in alkaline electrolytes according to $Zn + H_2O \rightarrow ZnO + H_2$ may be decreased to extremely small values by careful amalgamation and by using very pure zinc.

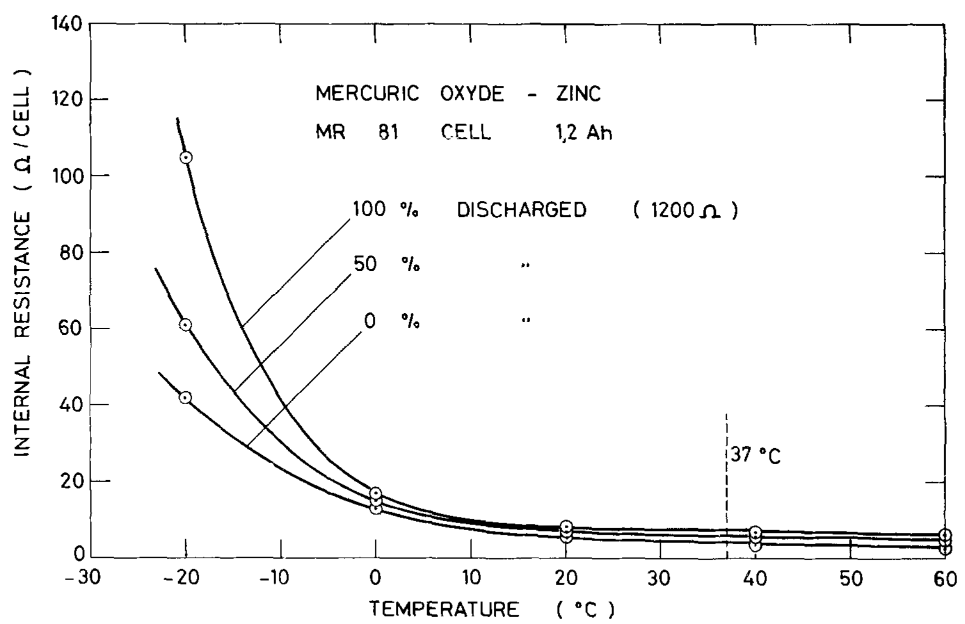

Fig. 5. Dependence of internal impedance (as measured at 40 Hz with a Keithley Milliohm-Meter) on temperature and depth of discharge. (Each point average of 5 cells)

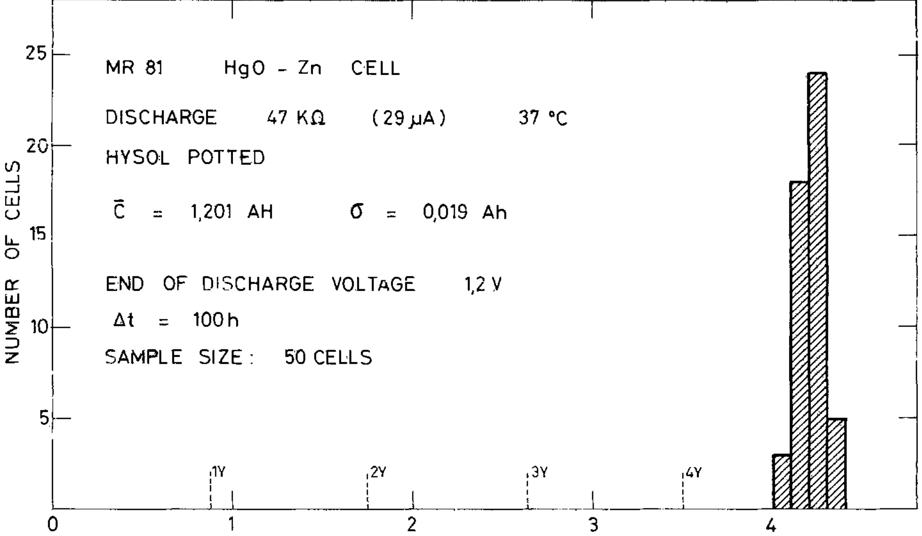

Fig. 6. Capacity distribution for discharge of 50 MR 81 cells at 47 kΩ.

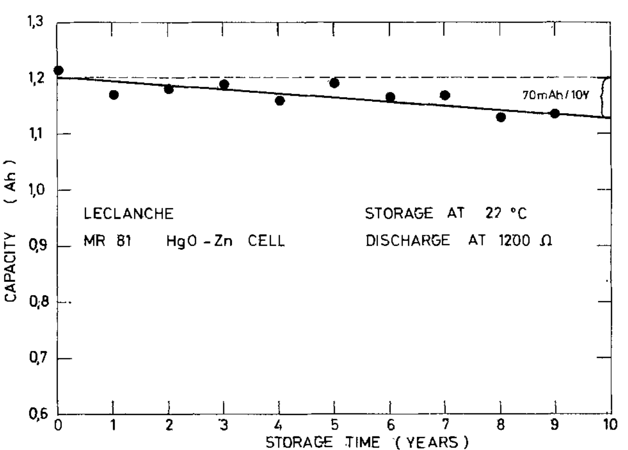

Fig. 7. Capacity of MR 81 cells, measured under 1200Ω load, as a function of storage time at 22°C. Each point average of 5 cells. (Cells stem from several different lots manufactured in 1970.)

Gassing rates of zinc powder containing 10% Hg, as measured in a Pyrex glass cell in 50% KOH, are given in Table IV. From a plot of log H_2 evolution rate *vs.* $1/T$ an activation energy of 19 kcal/mole is derived (Fig. 8, curve B). It is apparent from a comparison of the data in Table III and Table IV and from Fig. 8 that self-discharge due to H_2 evolution becomes increasingly important in relation to self-discharge by $Hg(OH)_2$ diffusion as the temperature increases.

In the MR 81 cell the zinc powder is in contact with an amalgamated copper or bronze surface, lining the inside of the cover (Fig. 2). It may be shown experimentally that the presence of a clean amalgamated copper or bronze surface, in contact with zinc powder, does not increase H_2 evolution significantly. On the other hand, if impurities, which would lower the hydrogen overvoltage, are present within the cell, self-discharge due to H_2 evolution may be increased drastically.

In the RM 1 cell (Fig. 2), the inside wall of the cover consists of tin plated steel. H_2 evolution in RM 1 cells, particularly when partly discharged, appears to be considerably larger than in MR 81 cells. Gassing is increased in partly discharged cells if the zinc anode has insufficient porosity such that electrolyte depletion occurs locally within certain sections of the electrode (17). The amount of hydrogen escaping through the seal of RM 1 cells at 37°C has been reported to be 7.3 cm^3 per cell and per yr (2). This would represent 1.5% self-discharge per year.

In RM 1 cells the seal is constructed as to allow hydrogen venting. Means to increase hydrogen venting through the neoprene seal have also been proposed (18). In this latter reference, H_2 evolution in RM 1 cells is reported to be about 5.5 cm^3/yr. For aged and partly discharged RM 1 cells gassing rates of up to 17 cm^3/yr at 37°C have been measured (9).

The MR 81 seal does not provide for H_2 venting. The only way of escape is by diffusion through the nylon grommets. Hydrogen escape from MR 81 cells, measured with an apparatus as shown in Fig. 10, is only 0.35 cm^3/H_2/yr at 37°C (9), representing only 0.07% self-discharge per year. (To avoid effects of Pyrex leachants on gassing, it is of advantage to repeatedly clean the cell with hot conc. KOH solution for several days.) However, actual H_2 production within the cell is probably higher, as discussed below, with a large portion of the hydrogen being re-absorbed (oxidized) in the positive electrode.

Total cell-internal self-discharge.—Self-discharge of MR 81 HgO-Zn cells was measured experimentally by long-term storage tests (2-9 yr, depending on temperature) at different constant storage temperatures (22°-75°C). After storage, the cells were discharged at low rates (1.2 kΩ load, 40 day test, or 10 kΩ load, 360 day test). Results are shown in Fig. 9 and Table V. Plotting log of percent capacity loss per year against $1/T$ yields a straight line (Fig. 8 curve C), from which a formal activation energy for the

overall self-discharge process of 19 kcal/mole may be calculated.

This value is very close to the value found for H_2 evolution *in vitro* (curve B), which suggests that H_2 production in the actual cell is strongly enhanced over that measured in a glass cell, and is actually a major, if not dominant, cause of cell-internal self-discharge (catalyzed H_2).

The fact that self-discharge follows a simple Arrhenius equation was also found for HgO-Cd cells (19). From the data reported in this latter reference a formal activation energy of 12 kcal/mole may be derived, indicating that $Hg(OH)_2$ diffusion is the only self-discharge process of importance in this type of cell.

Cataldi (11) has reported an activation energy of 15 kcal/mole for the self-discharge process in HgO-Zn cells. However, his self-discharge rates are somewhat questionable since they were based on the assumption that capacity loss per unit time is proportional to remaining capacity. Experimentally, one finds that self-discharge rates tend to be constant over very long periods of time and are finally increasing rather than decreasing, due to separator and seal degradation (9).

Cataldi's results indicate that at low temperatures a process of lower activation energy (9 kcal/mole) becomes dominant. This is in agreement with Fig. 8.

Microcalorimetric measurements.—Recently, the use of microcalorimeters has been proposed to determine self discharge of batteries for biomedical implantable applications (20-22). Using this technique, Untereker (22) estimated self-discharge loss of an RM 1 cell at 7 μW, which would correspond to a self-discharge current of 5 μA, or about 4% capacity loss/year. It should be pointed out that microcalorimetric measurements are not easy to interpret, mostly because true steady-state conditions in a cell are difficult to achieve, even on open circuit, and still more so during discharge. Many very slow processes take place in the cell which are not directly related to ca-

pacity, such as electrolyte equilibration in micropores of anode, cathode, and separators, buildup of soluble zincate concentration gradients, nucleation, crystallization and growth of ZnO crystals, and so on. Probably the largest unknown side reactions producing or absorbing heat are due to the addition of MnO_2 in the HgO cathode. Electrolyte penetration into micropores of MnO_2, uptake of K^+ or Na^+ ions into the lattice (23) dehydration, recrystallization and equilibration of its oxidation state, are slow, capacity-unrelated processes. Furthermore, it is known that for all chemical reactions involving solids of high surface area, the surface free energy can contribute noticeably to the overall free enthalpy change (24).

All the above-mentioned phenomena are more or less unrelated to cell capacity, but will contribute thermal effect. For this reason one must be careful in making any predictions on self-discharge, based on microcalorimetric measurements, carried out over periods of days or weeks only.

Cell-External Processes Influencing Self-Discharge

External electrolysis.—Electrolysis in moisture films surrounding the cells and bridging the grommet area becomes theoretically possible at cell voltages above about 1.23V.

In most pacemakers, used in the past, mercuric oxide-zinc cells were potted in epoxy resin. Moisture films could form between the epoxy casting and external cell walls. Considerable concern existed with manufacturers and users as to the possible effect of the presence of such moisture films, particularly when these latter would contain KOH, stemming from a defect seal (25, 26). However, Fester *et al.* have shown (27) that with properly encapsulated cells (Hysol or Scotchcast No. 15) external electrolysis does not contribute significantly to self-discharge.

In order to study the maximum self-discharge external electrolysis could possibly provoke, MR 81 HgO-Zn cells were placed into a volumetric glass apparatus (Fig. 10) which was then filled with 50% KOH solution (oxygen-free). Groups of 2 cells each were separated by insulating Teflon spacers, in order to avoid series connection of cells. Gas evolution, could be measured to a precision of 0.001 cm^3 by observing the displacement of the meniscus in the capillary. Gas evolution rates, measured at different temperatures, are given in Table VI. Assuming that external electrolysis produced O_2 and H_2 in stoichiometric ratios, the corresponding self-discharge was calculated. (Hydrogen stemming from the cell interior is negligible with respect to gassing by external electrolysis). As seen from Table VI, self-discharge due to external electrolysis even under these extreme conditions, is still surprisingly small. This must be due to passivation phenomena on pure nickel surfaces

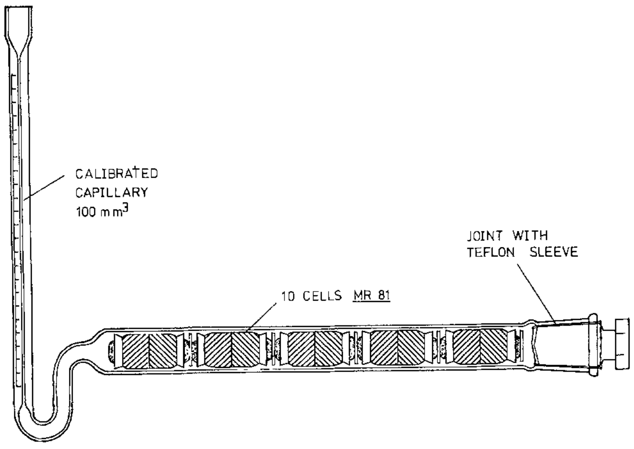

Fig. 10. Volumetric apparatus for measuring external electrolysis on HgO-Zn cells when submerged in KOH solution [from Ref. (9)].

Table VI. External electrolysis on MR 81 HgO-Zn cells submerged in 50% KOH solution

in 50% KOH solution, causing a high overvoltage for O_2 evolution.

With epoxy-encapsulated cells only very thin bridging films could be present, and the resulting self-discharge from external electrolysis should be smaller than that given in Table VI due to higher electrolytic resistance.

External electrolysis is enhanced, however, when a continuous liquid film forms over the surface of two or more cells, connected in series. A voltage of 2.7 or more volts is then available for electrolysis. In a pacemaker package, individual cells should therefore be separated from each other by long, well-embedded, welded connections, having surfaces which inhibit electrolyte creepage. (See section on cell-packaging.)

Finally, it should be mentioned that the presence of liquid films of NaCl solution, rather than KOH, provokes severe can corrosion, accompanied by a correspondingly increased capacity loss (9).

External oxygen cycle.—This type of self-discharge mechanism was described for the first time only very recently (9). It involves oxygen reduction on the negative cell terminal or lead, and oxygen evolution on the positive cell terminal or lead.

For this mechanism to take place, a liquid medium film, surrounding the cell, and oxygen must both be present.

The magnitude of self-discharge due to this process depends on the rate of oxygen diffusion to the negative terminal, as given by the geometry of the liquid medium surrounding the cell, by the solubility of oxygen in this medium, and by oxygen access to the medium. Even the low voltage of an HgO-Cd cell (0.9V) would be sufficient to drive an "oxygen cycle."

Oxygen diffusion at 37°C through a 2 mm thick epoxy encapsulation may not be entirely negligible (neither is H_2O diffusion). Only in hermetically sealed pacemakers could, of course, the described "oxygen cycle" not occur.

In order to study the contribution of the "oxygen cycle" to self-discharge, MR 81 cells were submerged in air-saturated KOH solution. The electrolyte level was 1 cm above the cell covers. Capacity loss, as measured by discharge tests after given storage times under these conditions, is shown in Fig. 11. After deduction of the loss due to external electrolysis, assumed independent of KOH concentration (Table VI) and total internal self-discharge (Table V), the approximate contribution due to the oxygen cycle was estimated in Table VII.

With increasing KOH concentration, oxygen solubility decreases strongly due to salting-out (28) which explains why the contribution of the "oxygen cycle" to self-discharge decreases with increasing KOH concentrations.

Long-lasting cell-seals.—Much progress has been realized over the past years in sealing alkaline cells. The use of a one-piece cover, (Fig. 1 and 2, right-hand side) in place of the earlier double-top construction (Fig. 1 and 2, left-hand side), which was spurred by the development of miniature cells for watches, has resulted in a more reliable long-term

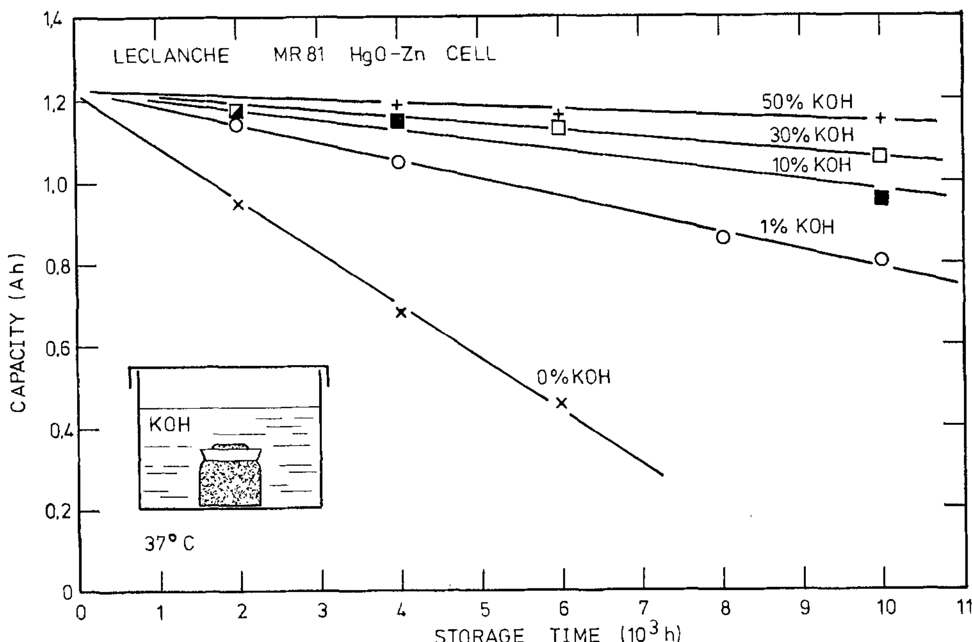

Fig. 11. Self-discharge of MR 81 cells submerged in KOH solutions of different concentrations at 37°C. Each point average of 5 cells [from Ref. (9)].

seal, based on the resiliency of the cover material (29).

Factors affecting the creepage of alkaline electrolytes along metallic parts have been the subject of several recent investigations (30-32). The presence of moisture and oxygen accelerate creepage and must thus be excluded from the cells as much as possible. Electrolyte concentration and viscosity, the nature of the metallic surface and the electric potential applied thereto are other factors affecting creepage rate.

The seal of MR 81 HgO-Zn medical grade cells, as shown in Fig. 2, is constructed in a manner such as to take into account these parameters.

Separators for long-life cells.—Separator degradation has in the past been of concern as a life limiting factor. A recent investigation (9) has shown, however, that cellophane separators become extremely stable against hydrolysis and oxidation when highly concentrated alkaline electrolytes are used. (See below under "Water-starved Cells.")

In addition to cellophane, radiation-grafted and cross-linked methacrylic acid polyethylene (33, 34) and Teflon-based separators (35) are available which show very good stability in highly concentrated alkaline solutions. The results of Fig. 9 indicate that no deterioration of (cellophane) separators leading to accelerated self-discharge, is taking place in MR 81 cells even after prolonged storage at elevated temperatures.

In MR 81 cells the multilayer cellophane separator package is protected against the positive electrode by a nonwoven polypropylene fabric. The separators are tightly clamped at the edge between supporting steel ring and grommet (Fig. 12), which assures that no internal short circuit can occur.

The relative importance of the cell-external self-discharge processes as measured under the extreme conditions shown in Fig. 10 and 11, are compared to cell-internal self-discharge in Fig. 13.

Importance of cell packaging.—In spite of the fact that external self-discharge processes appear to be of little importance in properly engineered pacemakers, many failures have occurred in the past precisely because of cell-external electrochemical phenomena, in particular electrochemical corrosion processes occurring in moisture films. It is interesting to note that not the cells themselves, but primarily electronic components in proximity thereto, had to suffer from such electrochemical corrosion processes.

In some early pacemaker designs thin liquid films, present between epoxy encapsulation and cell components, became exposed to excessive voltage gradients. Corrosion processes then would occur in these films, causing destruction of electronic components, or producing shorts (current interruptions).

Figure 14 shows a pacemaker (Vitatron) in which the print plate touched three mercury cells in series. Moisture films present on the print plate were ex-

posed to high voltage (4.6V), causing severe corrosion of electronic components. The fact that this phenomenon occurred only in pacemakers exposed to high humidity (implanted or water-bath tested units) makes it likely that the moisture film stemmed from body fluid. Had the cells been separated from the print plate, early failures due to corrosion would not have occurred. It is unfortunate that in this instance the mercury cells were made the scapegoat for the failure, rather than packaging design.

Another corrosion phenomena, known under the name of "dendrite formation" also occurs as the result of moisture films creeping along electronic circuit parts and voltage drops occurring therein. An electrostatic field present in the film provokes anodic dissolution at the positively polarized part, and cathodic deposition of metal at the negatively polarized part of the interface. A critical area, where this can occur, is for instance at the lead exit.

An important observation concerning corrosion in thin water films on electronic components was made recently by Koelmans and Kretschman (36). These authors found that, in the presence of sodium ions at impurity levels, concentrated sodium hydroxide would form at the negatively polarized portion of the film, causing heavy corrosion. This proved for the first time very clearly that alkalinity in the moisture film does not need to stem from the cells, but could form *in situ* by electrolysis.

These examples show that the electronic circuit must be protected as much as possible against water intrusion. Hermetically sealed packaging of the circuit is thus a necessity. Moisture does more harm to electronic parts than it does to electrochemical cells. It should be mentioned in this connection that the good start lithium batteries have been able to make in pacemaker application was probably aided by the fact that the pacemakers were hermetically sealed and their electronic circuits better protected against moisture effects.

Also mercuric oxide-zinc batteries could be hermetically encapsulated, as shown in the experimental model of Fig. 15. For safety reasons, the hermetic enclosure should also contain a hydrogen absorber capsule, along with the cells. The hydrogen absorber can consist for instance of silver oxide (37) or manganese dioxide (38).

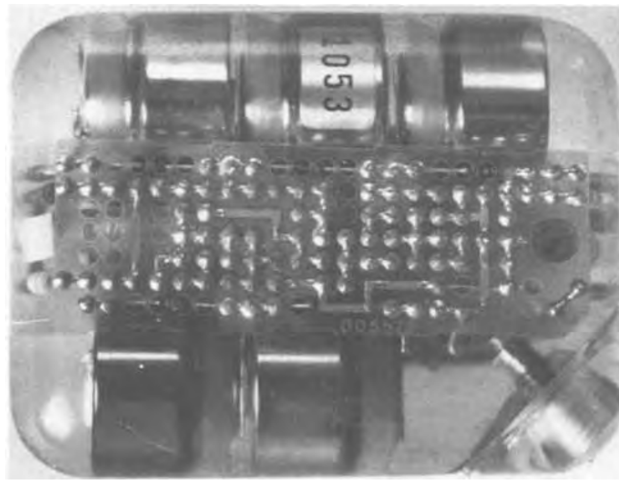

Fig. 14. Pacemaker package with epoxy-encapsulated print-plate touching three (plus 2) MR 81 cells in series.

Newest Innovations in Mercuric Oxide-Zinc Batteries for Long-Term Use

Cells with "filter electrodes."—Under the term "filter electrode" is understood a porous, electronically conducting layer placed on top of the positive electrode surface in contact with the separator layers (9). The filter electrode may, for instance, consist of a bed of graphite particles or of a sintered nickel matrix. Filter electrodes should have a thickness of at least 0.1 mm and should have a high tortuosity factor.

The purpose of the "filter electrode" is to decrease $Hg(OH)_2$ diffusion to the negative electrode by prolonging the diffusion path. The electronically conducting material in the filter electrode should be chemically inert and corrosion resistant in alkaline electrolytes at the potential of the positive electrode. It has been found to be of advantage to incorporate into the filter electrode finely divided substances of

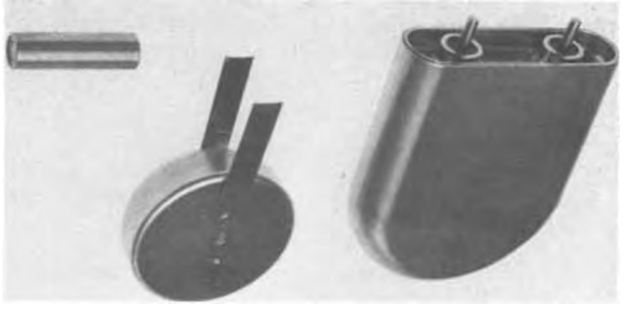

Fig. 15. Hermetically double-sealed HgO-Zn cell with glass feed-throughs. The cell package contains a round button cell and a small cylindrical H_2 absorber.

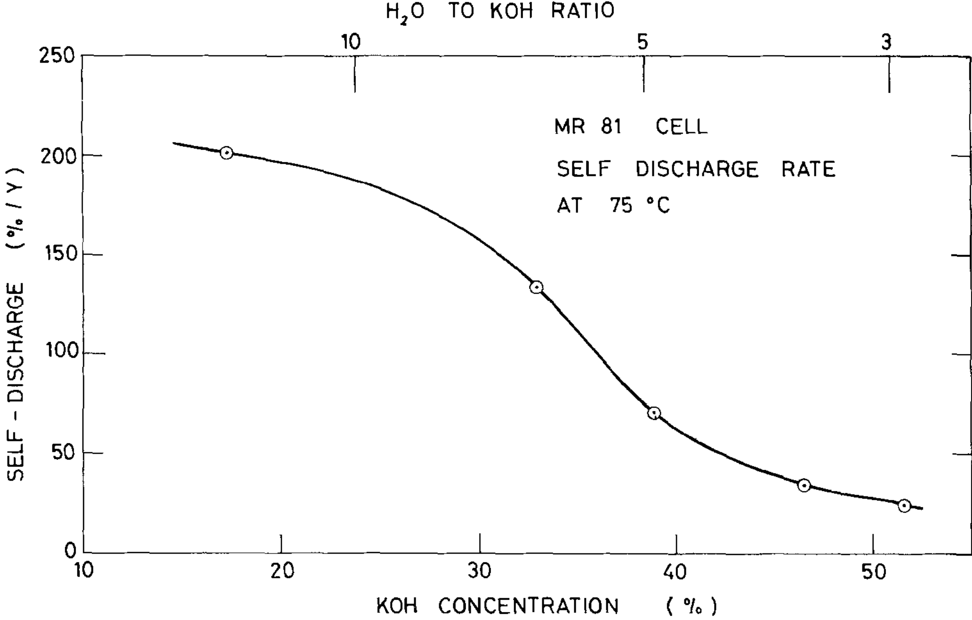

Fig. 16. Self-discharge of MR 81 HgO-Zn cells as a function of cell electrolyte concentration. Each point average of 50 cells.

high surface area which are insoluble in alkaline electrolytes. One substance of this type which has been found to be effective is, for instance, manganese dioxide. In addition, the filter electrode may contain inert binders and thickening agents for the alkaline electrolyte.

In spite of the fact that in MR 81 cells the dominant cell-internal self-discharge process is apparently due to H_2 evolution (Fig. 12), filter electrodes have been found to have a noticeable effect in reducing self-discharge (9). The reason for this could be, that not only the self-discharge loss by $Hg(OH)_2$ diffusion, but also "catalyzed H_2 evolution" (due to "impurities" or "local action cells") is decreased in presence of a filter electrode.

Diffusion of $Hg(OH)_2$ probably leads to localized discharge of the Zn electrode, just as partial high-rate discharge does. It is known that under such conditions hydrogen evolution (17) and associated self-discharge (39) is increased.

"Water-starved" cells.—With increasing NaOH or KOH concentration more and more water is tightly held in the inner ionic hydration shells. Once a molar ratio of water to alkali hydroxide of about 3 is reached, all the water molecules are bonded directly to the solute (40). Concentrated electrolytes have a very low water vapor pressure (41), which is of advantage when it comes to reducing the humidity level in a package containing also electronic components.

Solubility of HgO does not decrease as strongly with increasing electrolyte concentration as one would expect for completely nonionic solutes, such as H_2 (42), or O_2 (28), where the salting-out effect is very pronounced. Due to increased viscosity and decreased swelling of the cellophane or Permion barrier membranes, less $Hg(OH)_2$ will, nevertheless, diffuse to the Zn electrode at high electrolyte concentration.

Experimentally, one finds that self-discharge of HgO-Zn cells decreases drastically with increasing KOH concentration (Fig. 16). This decrease cannot be explained solely by a decrease in $Hg(OH)_2$ diffusion. Rather, at very high electrolyte concentration "catalytic H_2 evolution" on the zinc electrode must also be decreased. One of the reasons why the self-discharge of RM 1 cells is higher than that of MR 81 cells must also be the more dilute electrolyte used in the former. Capacity of RM 1 cells begins to decrease for discharge times greater than 10^4 hr (42).

"Catalytic hydrogen evolution" is apparently occurring when Zn electrodes are being locally and nonuniformly discharged by the reaction $Zn + Hg(OH)_2 \rightarrow ZnO + Hg + H_2O$ leading to a local dilution of the electrolyte. This then results in $H_2O + Zn \rightarrow ZnO + H_2$. At high electrolyte concentration this reaction mechanism is suppressed.

In order to take full advantage of the principle of a "water-starved" cell, separators, positive electrode, and grommet must be dried prior to cell assembly in order to avoid possible dilution of the electrolyte with water contained in these components.

"Water-starved" cells have a somewhat higher internal impedance than standard cells. For "water-starved" MR 81 cells internal resistance at 37°C was found to be about 20Ω. It should be remembered, however, that "water-starved" cells cannot be utilized at low temperatures, because of the high freezing point of the electrolyte.

"Punctured membrane" current focusing.—Another approach to reduce diffusion of mercuric oxide is depicted in Fig. 17. A very thin, inert membrane is tightly clamped at the edge, between grommet and support, but contains centrally one or more mechanically produced pinholes of controlled diameter. All the ionic current flow is focused across the pinholes.

At first sight it appears that such an extreme compartmentalization would drastically increase internal resistance of a cell.

However, when using an ultrathin "punctured membrane" this is not the case. For a membrane thickness of $l = 0.005$ cm, a pinhole diameter of $r_1 = 0.01$ cm, and a specific electrolyte resistance of $\rho = 2$ Ω-cm, one calculates, for instance, a pinhole electrolyte resistance of

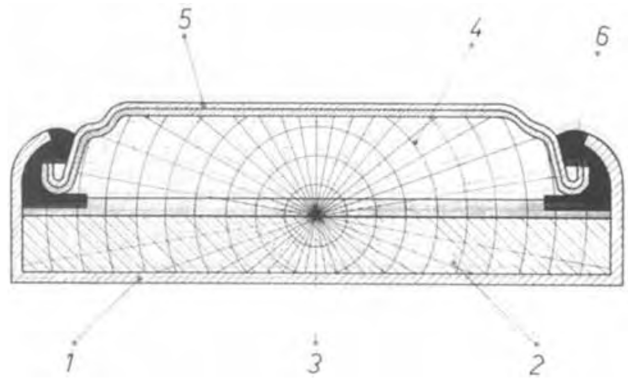

Fig. 17. Schematic illustration of current distribution in a cell with "punctured membrane."

$$R_i = \frac{\rho \cdot l}{\pi r_i^2} = 32\Omega$$

Electrolyte resistance outside the pinhole may be estimated at

$$R_e = \rho \int_{r_e=0.01}^{r_e=\infty} \frac{d(r_e)}{4\pi r_e^2} = 16\Omega$$

Thus, total electrolyte resistance associated with the use of the "punctured membrane" would still be below 50Ω.

"Mechanically punctured membranes" are reproducible means to prolong the average length of the diffusion path of dissolved $Hg(OH)_2$. On the other hand, reproducible manufacture of microporous membranes of very low porosity are technologically much more difficult to achieve. Mercuric oxide diffusion measured experimentally in cells having membranes with mechanically punctured holes of different diameters are shown in Fig. 18. These results were obtained with HgO-Cd cells, containing Permion 2291 40/60 separators in addition to the punctured membrane. Increase of mercury content of the Cd anode during storage at 75°C was determined by atomic absorption. The results are expressed in terms of anode capacity loss per year (mA-hr/yr). Capacity loss is not exactly proportional to diffusion surface probably because of edge effects (spherical diffusion).

Obviously, capacity loss through $Hg(OH)_2$ diffusion is greatly minimized in presence of a "punctured membrane."

Other Aqueous Alkaline Electrolyte Systems for Biomedical Implantable Applications

Primary batteries.—Mercuric oxide-cadmium primary batteries have been of interest for some time as ultrastable power sources for long-term military applications, because of their capability to perform well at low temperature even after prolonged hot storage.

Cadmium electrodes are entirely stable in alkaline electrolytes and do not evolve hydrogen. This is of importance when it comes to storage of cells at very high temperatures. On the other hand, at low temperatures and for cell designs with a large separator interface between positive and negative electrode, self-discharge of HgO-Zn and HgO-Cd cells become rather similar.

That diffusion of dissolved $Hg(OH)_2$ is the only self-discharge process of importance in HgO-Cd cells is demonstrated in Fig. 19. Capacity loss as determined from mercury analysis of the anode, and as determined from discharge tests after storage, agree within the experimental error limits.

Boden (44) and Weiss and Pearlman (19) report for HgO-Cd cells at 21.1°C (70°F) a self-discharge rate of 1.3%/yr. Klein and Eisenberg (45) give for

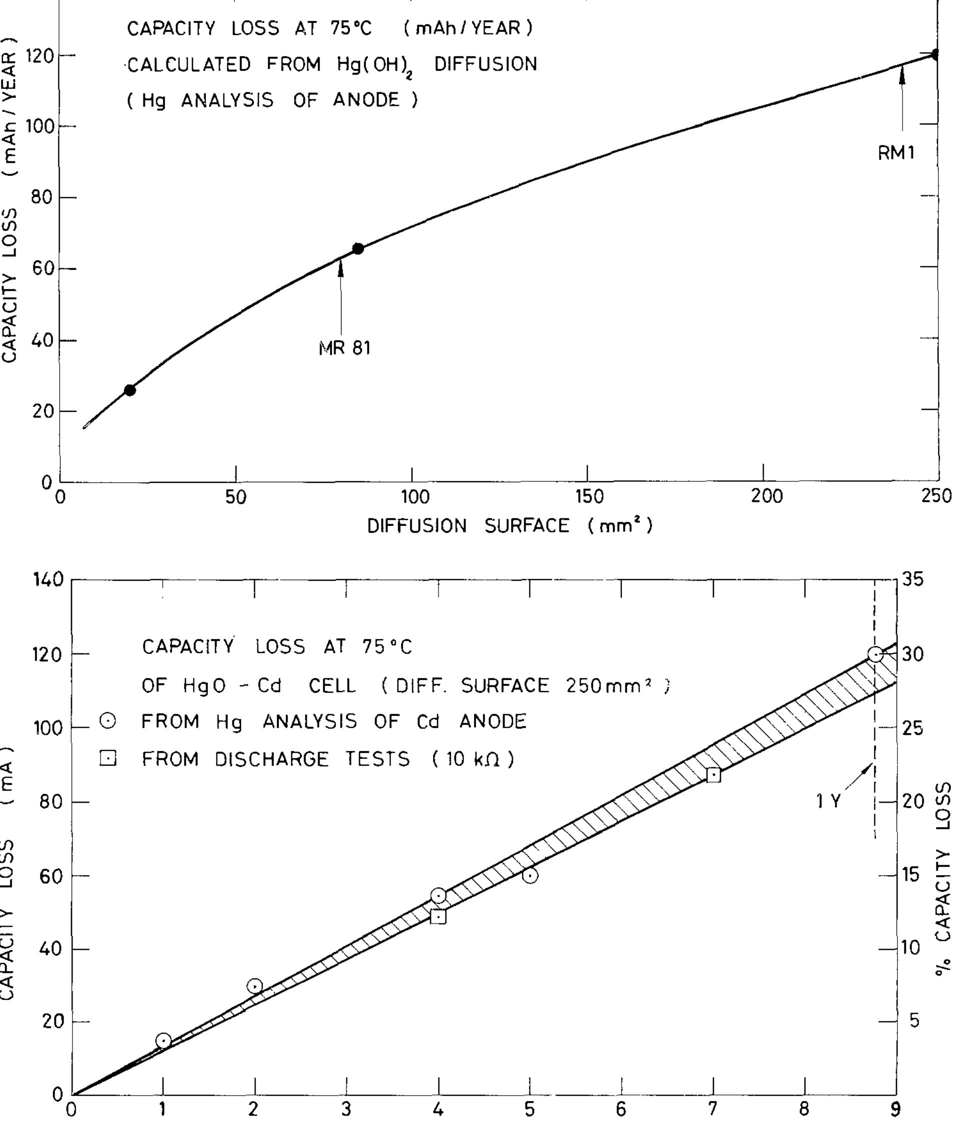

Fig. 18. Capacity loss (mA-hr/yr) due to $Hg(OH)_2$ diffusion at 75°C, as measured experimentally with HgO-Cd cells by Hg analysis of the anode, as a function of diffusion surface. Each point average of min. 5 determination.

Fig. 19. Self-discharge of HgO-Cd cells (initial cell capacity 400 mA-hr) at 75°C. Each point average of 5 cells.

74°C (165°F) a figure of 21%/yr. Self-discharge depends strongly on design (interelectrode area) and could be kept extremely small for cells requiring only low discharge rates.

Performance data of HgO-Zn and HgO-Cd cells are compared in Table VIII. The lower self-discharge rate of HgO-Cd cells does not offset the advantage of the higher initial energy density for the HgO-Zn cells, when it comes to long-term use at 37°C.

Silver oxide-zinc and manganese-dioxide zinc cells, optimized for long-term use at 37°C, would have similar self-discharge rates as HgO-Zn cells. Their volumetric energy density would, however, be inferior.

Silver oxide-cadmium and manganese dioxide-cadmium cells would have very low self-discharge rates, but again much smaller energy densities. One argument in favor of these cells could be that their safety is higher since no internal or external electrolysis is possible.

Rechargeable cells.—Nickel-cadmium secondary batteries have made their appearance in implantable devices for some time (46). In recent years, the space programs have spurred technical progress in nickel-cadmium batteries.

The nickel-cadmium battery used in the Johns Hopkins Pacemaker resembles a standard 225 mA-hr button cell (diameter 25 mm, height 8.6 mm). Deliverable capacity at the 6 hr rate was 280 mA-hr (3). Self-discharge was found to be 50 mA-hr/week at 37°C (3). Normally, the battery would be recharged 1 hr a week (4). The capacity of the battery is potentially sufficient to operate the pacemaker approximately 8 weeks. It is hoped that it will be possible to develop the system further and that, eventually, it will be possible to charge the cells at less frequent intervals (47). By the end of 1977, about 3100 "Pacesetter" units had been implanted (48, 49).

One problem, which must be given careful consideration when using nickel-cadmium batteries in a mode, involving relatively quick charge and subsequent slow discharge at 37°C, is growth of large Cd and $Cd(OH)_2$ crystallites (Fig. 20) and resulting charge and discharge inefficiency. $Cd(OH)_2$ crystallites can also grow into the separator, causing short-circuit failures (50-55).

It has been suggested that a Teflon treatment could retard migration. Pressed-powder type cadmium electrodes appear to resist the described crystallization phenomena somewhat better than sintered electrodes. Many additives have been studied to decrease crystal growth, without entire success, however.

The so-called "memory effect" in nickel-cadmium batteries is also a phenomenon related to the negative electrode. With repetitive partial discharge cycling, the same portion of the electrode keeps being called to work all the time while the rest of the (active)Cd becomes slowly insulated by resistive $Cd(OH)_2$ layers. These latter can only be broken down again by deep-discharge cycling with heavy overcharge. The relatively shallow cycling, at relatively high temperature, present in pacemaker application, would be ideally suited for causing a strong "memory effect" which could reduce reserve capacity to an unacceptably low level. It appears that more progress is needed in this area to improve long-term

Table VIII. Comparison of HgO-Zn and HgO-Cd long-life batteries

Property	HgO-Zn	HgO-Cd
Discharge voltage (V)	1.35	0.90
A-hr/cm³	0.4	0.2

use of nickel-cadmium cells in a rechargeable pacemaker.

Rechargeable nickel-cadmium batteries will thus have to fight a long uphill battle if large-scale use should ever become a reality.

Rechargeable mercuric oxide-zinc batteries (56) would have the advantage of very low self-discharge. This would hopefully necessitate recharge only once every few years. However, zinc electrodes are, after deep discharge, notoriously difficult to recharge. It also appears with this system that considerable technological advance is still needed. Present resistance to the use of rechargeable battery systems could possibly be overcome some day if recharge were carried out at the hospital, and not by the patient, at intervals of several years.

Summary

Self-discharge of alkaline primary HgO-Zn batteries is reduced to 1-2 %/yr at 37°C, when using an appropriate design. It appears that operating life spans of 10 years at 37°C are possible, with total cell-internal self-discharge of less than 20%. Cell-external self-discharge by electrolysis and oxygen cycle must be avoided by careful, hermetic packaging.

Lead-Acid Battery Expander

I. Electrochemical Evaluation Techniques

B. K. Mahato*

Globe-Union Incorporated, Milwaukee, Wisconsin 53201

ABSTRACT

The role of lignosulfonate constituent of the lead-acid battery expander on the negative electrode performance is analyzed. Two quantitative electrochemical techniques have been developed to monitor the expander activities on constant current discharge and capacity maintenance behavior of the electrode during cycling. Both these techniques are based on small electrodes and proved effective in evaluating expander candidate materials outside the test battery. Test results agree closely with the reported expander's influence on the pasted electrode. The plausible mechanisms of expander action during high rate discharge and deep discharge cycling are elucidated.

The lead-acid battery is presently being considered for the near term electric vehicle application. Its future dominance in the EV market in relation to the newly developing high energy systems such as Ni-Zn, Na/S, Li-Al/FeS_2, and Zn/Cl_2 will depend upon significant performance improvement while maintaining a relatively low cost per kilowatt hour. An effort is underway to improve energy density of the lead-acid battery by optimization of structural parameters and improved faradaic efficiency of the active materials (1). Under deep discharge cyclic operation the cycle life of this system is largely controlled by the active material shedding and the grid corrosion of the positive electrode (2, 3). However the lead or negative electrode represents a potentially significant area for improvement in specific energy of the system due to its relative small decline in capacity with cycling and underutilized active mass.

The material utilization of the lead electrode which has to date been greatly influenced by the expander incorporated in the paste during electrode preparation (2-16) has remained close to 40% at the 3 hr rate (1). This leaves behind 60% unutilized mass of this electrode to account for, at least partly, the low energy density of the lead-acid system. Any reduction of this nonutilized (or underutilized) mass without a loss in existing performance requires a proportionate increase in the effective surface area of the electroactive mass. The inclusion of expander in the paste is noted to increase the active mass surface area from 0.23 m^2/g to 0.50 m^2/g (7). This suggests that an additional increase in the active material surface area and its material utilization is possible by improving the quality of expander material.

The conventional expander is a mixture of a lignin compound, barium sulfate, and carbon black (2, 3). Out of these the lignin compound brings out the most beneficial influence (or expander action) to the lead active mass by altering its structure during formation (4-6) and by suppressing the growth of large lead crystals during repeated charge/discharge cycling (7); the barium sulfate and carbon black have very limited and sometimes questionable influence on the electrode characteristics (4-6). Thus the improvement in expander quality relies heavily on obtaining an improved lignin compound. The word "expander" is used here (as elsewhere in the paper) to mean the lignin constituent of the expander.

A significant difficulty exists in improving the quality of the expander. This is primarily due to its ill-defined chemical nature, lack of analytical means in monitoring its concentration, and our limited knowledge of the expander action, *i.e.*, how the presence of expander modifies the electrode performance. To date the expander evaluation has been attempted by measuring its influence on the overall electrochemical performance of a pasted plate or the battery (4-13, 15, 16). These test results being influenced by the electrode preparation parameters have rendered very limited understanding of the expander action. It is therefore suggested that a mechanistic understanding of the expander action and means of quantitative measurement of expander activity be developed to aid in the selective evaluation of expander candidates. The objective of this work has been to define expander activity and develop techniques for quantitative determination of expander type and concentration.

Mechanism of Expander Action

The negative electrode of a lead-acid battery consists of a high surface area reactive lead mass and is characterized by its material utilization during discharge (Eq. [1]) and the maintenance of the electrode structure or the capacity during repeated charge/discharge cycling (Eq. [2])

$$Pb \rightarrow Pb^{2+} + 2e \xrightarrow{HSO_4^-} PbSO_4 + H^+ + 2e \qquad [1]$$

($PbSO_4$ deposits on lead surface)

$$\left.\begin{array}{l} Pb \rightleftharpoons Pb^{2+} + 2e \underset{}{\overset{HSO_4^-}{\rightleftharpoons}} PbSO_4 + H^+ + 2e \\ \begin{pmatrix}\text{Electrode}\\ \text{structure}\end{pmatrix} \underset{\text{charge}}{\overset{}{\not\rightleftharpoons}} \begin{pmatrix}\text{Electrode}\\ \text{structure}\end{pmatrix} \quad \text{discharge} \end{array}\right\} \qquad [2]$$

The discharge process of the lead electrode in sulfuric acid solution is controlled by the formation of a lead sulfate passivating layer on the electrode surface (2, 3, 17-19). During repeated charge/discharge cycling the lead electrode active mass, *i.e.*, the high surface area lead particles, experiences a tendency to coalesce and thereby lose its specific surface area. This in turn reduces cycling ability of the electrode. Presence of expander in the system influences both the discharge behavior (Eq. [1]) as well as the capacity maintenance behavior of the electrode during cycling (Eq. [2]). No significant difference in electrode performance was observed with the mode of inclusion of expander in the system (9). The mechanistic understanding of expander action on the electrode performance has to date remained highly speculative.

The conventional expander is a lignosulfonate, a naturally occurring polymer with ill-defined structure (20). Its molecular weight varies from a few hundreds to several thousands. It is anionic and has surfactant properties (21). It adsorbs on solids (lead

* Electrochemical Society Active Member.

Key words: lead electrode, voltammetry, additive.

and lead sulfate) (22, 23) and has decreased solubility with increasing acid concentration (7). A reasonable understanding of the expander action is anticipated from a greater understanding of the expander material and its influence on the basic electrode kinetics (Eq. [1] and [2]).

Expander action on discharge.—The discharge process of the lead electrode as represented by Eq. [1] involves the dissolution of lead metal to Pb^{2+} ion controlled by the gradual coverage of the electroactive surface by resistive lead sulfate film. The anodic passivation of the lead electrode by the formation of a permselective lead sulfate membrane which limits the transport of reacting species and changes the interfacial *p*H has been discussed by Pavlov (17), Ruetschi (18), and Winsel *et al.* (19). The kinetics of this passivation process, *i.e.*, the dissolution process ($Pb \rightarrow Pb^{2+} + 2e$) as well as the lead sulfate precipitation (resistive film formation) process are affected by the presence of the expander, either in the electrode matrix or in the surrounding electrolyte.

The expander adsorbs on lead (22) as well as on lead sulfate (23). During anodic dissolution, besides the concentration of dissolved species, the *p*H of the interfacial layer increases (17, 18). This brings the adsorbed expander into solution, promotes the formation of Pb(II) or "lead-lignin" complex intermediate, and possibly alters the saturation concentration of Pb^{2+} ion at the interface. The adsorption of the expander on the freshly precipitated lead sulfate affects the particle size and the ion permeability of the product layer. The decomposition of transient Pb(II) intermediate upon the termination of discharge and acid diffusion provides a mechanism of formation of a compact lead sulfate layer as well as occlusion of the expander in the discharge product matrix. The presence of a labile quinoid structure in the expander molecule (24) also indicates a possibility that it might act as an electron transfer medium when adsorbed in the lead sulfate matrix. All the abovementioned effects of the expander on the oxidation behavior of the lead electrode result in an increased intensity of discharge or the longer constant current discharge period. The delayed passivation of the lead electrode in the presence of the expander has been reported (2, 3, 5, 7, 9-13, 15, 16) and explained in terms of the expanders contribution in decreasing the resistivity of the lead sulfate layer (10), in altering the morphology of the passivating discharge product matrix (5, 6, 10-12, 15, 16), in commencing the solid-phase reaction between the Pb and $SO_4^{=}$ or HSO_4^- anions under the influence of anodic potential (7, 12), and in the formation of Pb(II) soluble intermediate (25).

Expander action on charge.—The charging or the cathodic reduction of the lead electrode involves the electroreduction of the lead sulfate to a metallic lead. The conventional reduction process occurs through the chemical dissolution of $PbSO_4$ to Pb^{2+} ions followed by the electroreduction of Pb^{2+} to a metallic lead. The observation of Popova and Kabanov (26) that the lead electrode has limiting current close to 2000 A/cm² in 3-5.5M H_2SO_4 solution suggests that the dissolution process may not be rate limiting. The electroreduction of lead is very efficient, particularly in a pure system, due to high hydrogen overpotential on lead. For the same reason, the cathodic reduction of the pasted-type lead electrode is known to progress from the external surface to the interior of the plate matrix (17).

The obvious disadvantages of the high electroreduction efficiency are the tendency of the highly energized, freshly deposited lead particles to coalesce forming a low surface area deposit and to cause incomplete conversion of lead sulfate particles to metallic lead by sheathing the lead sulfate particles with impervious metallic lead (3). The latter is occasionally observed at high temperature formation and/or in a highly sulfated electrode (2).

The presence of the expander in the lead electrode matrix or in the surrounding electrolyte influences the overall electroreduction kinetics. This is caused by adsorptive surface coverage of lead sulfate and the lead deposition sites by expander molecules. The former controls the dissolution of $PbSO_4$, inhibits the complete sheathing of lead sulfate particles by electrodeposited lead, and helps the overall electroconversion efficiency. The latter, by blocking coverage of activation sites, prevents the sintering of the electrodeposited lead mass and helps to maintain or increase the surface area of the electrode after charging operation. Mahato (7) has noted that the expander present in the pasted lead electrode increases the specific surface area of the active mass and 150A, 0°F capacity after formation and hinders the agglomeration of the lead active mass during SAE-J240 type cycling. Expander in the paste has also been shown to alter the lead crystal structure after formation and to improve the cycle life behavior of the lead electrode (4-7).

Definition of Expander Activity and Evaluation Techniques

It has previously been noted that the expander influences both the discharge and the charge behavior of the lead electrode. During discharge it alters the morphology of the lead sulfate film and the interfacial electrode kinetics. During charge it restricts the lead adatom deposition sites and the lead sulfate dissolution process. Upon cycling the integral influence of expander on both discharge and charge will dominate the electrode behavior. Considering the complex functioning of the expander on the electrode performance an unambiguous definition of the expander activity which could truly reflect its influence on the electrode performance has been extremely difficult. However, as the intensity of discharge and the maintenance of the electrode structure are dominantly influenced by the expander, a quantitative estimation of expander effect is possible by determining its effect on the electrode performance, *i.e.*, the discharge behavior and the capacity maintenance characteristics during repeated charge/discharge cycling.

The dischargeability of a well-defined lead electrode under constant temperature and acid concentration can be expresssed in terms of the effective capacity, K_o as shown in Eq. [3]

$$I^n t_o = K_o \qquad [3]$$

Where I, t_o, and n are current density, duration of discharge, and an empirical constant, respectively. In the presence of the expander in the system the duration of discharge (t) and effective capacity (K) will change and the expander activity can be monitored by following the absolute value of K and its relative change as defined in Eq. [4]

$$\eta_{disch} = \left(\frac{K - K_o}{K_o} \right)_{T,C} \qquad [4]$$

T and C being temperature and acid concentration, respectively. The η_{disch} can be termed as high rate index also.

Likewise the cycling ability or the cycle life index of the expander (η_{cycle}) can be defined as the relative capacity change of the electrode cycled in acid electrolyte with and without the expander as shown in Eq. [5]

$$\eta_{cycle} = \left(\frac{Q_f - Q_o}{Q_o} \right)_{T,C,S,\phi,m} \qquad [5]$$

where Q_o is initial electrode capacity, Q_f is electrode capacity at mth cycle, C is electrolyte concentration,

S is concentration of expander in the electrolyte, T is temperature, and ϕ is mode of cycling.

The precise determination of the expander activities (K, η_{disch}, η_{cycle}) primarily depends upon the reliability of the electrode preparation. The conventional pasted electrodes as used in the lead-acid battery has a high degree of uncertainty of being reproducible because of the complexities associated in its preparation. The expander activity evaluation by such pasted electrodes as used by Ritchie (8), Willihnganz (10), Pierson *et al.* (4, 5, 6), Mahato (7), Simon (9), Zachlin (11), and Gillibrand *et al.* (15, 16) has remained highly qualitative. These observations suggest that the precise expander activity determination must involve a well-defined electrode and should preferably be carried out outside the test battery. For simplicity we have selected small electrodes with surface areas close to 1.57 cm^2 for high rate index determination. For cycle life index determination we felt the need of having a geometrically well-defined porous high surface area electrode at the start. This we have achieved by cycling the well-defined lead electrode in low gravity sulfuric acid solution similar to "Plante-type electrode" preparation as will be outlined in the experimental section. To simulate the conditions which approximate the expander action in a practical battery operation the electrode potential range for anodic process of −960 to −500 mV (*vs.* Hg/Hg_2SO_4) was selected. For cyclic operation the potential range between 100 mV anodic and 200 mV cathodic overpotential was selected.

Experimental

The test electrodes were made out of 2-2.2 mm diam cast wire of 99.999% pure lead (Cominco). The electrode length was 2 cm made from a 4 cm long section of the cast wire by isolating remainder with a coating of hot wax followed by two layers of heat-shrinkable Teflon tubing. An electric connection was made to this end. A 1.27 cm diam cast rod was made from 99.999% pure lead and used as the counter-electrode. The electrodes were degreased by rubbing with acetone soaked tissue paper followed by chemical cleaning in glacial acetic acid/hydrogen peroxide mixture as outlined by Burbank (27). The test electrode, counterelectrode, and an Hg/Hg_2SO_4/"*m*" H_2SO_4 reference electrode were assembled in a test cell with 50 ml of "*m*" sulfuric acid electrolyte. The reference electrode was isolated from the bulk electrolyte by establishing a small crack at the capillary of the reference compartment through a soft glass bead melted in it. This was very effective in maintaining the electrolyte purity and the reliability of the reference potential. The sulfuric acid electrolyte was prepared from reagent grade sulfuric acid and deionized distilled water. The test expander was Reax 80C lignosulfonate obtained from Westvaco Incorporated, Charleston, South Carolina. This was prepared from Kraft lignin and had a wide molecular size distribution. The exact composition of this polymeric material was not known. Limited evaluation and information obtained from Westvaco suggested that it contains 11.4% Na, 33.7% ash, 2.9% organic sulfur, and 92% sodium sulfonated lignin.

A "Precision Current Source, Model CS-120, North Hill Electronics, Incorporated" with ±0.1 μA precision was used to determine the constant current oxidation behavior of the lead electrode. The discharge time to −500 mV (*vs.* reference) was monitored by an electric timer and the half-cell potential was monitored by a Soltec recorder, Model VP-6232S in conjunction with a Keithley electrometer Model 616. The cycle life index determination was carried out by cycling a test electrode using a linear potential sweep cycling described elsewhere (28). The sweep was regulated by a function generator (PAR™ 175/99) at 0.5 mV/sec between −1160 to −860 mV (*vs.* reference). The current was supplied to the electrode by a PAR™ 173 potentiostat equipped with a Model 179 digital coulometer. During cycling, the peak cathodic current, peak anodic current, cathodic charge, and anodic charge were monitored by interfacing the Model 179 digital coulometer output to a PDP-11 data acquisition system (Digital Equipment Corporation) through a KIM-I microprocessor. The PDP-11 was also interfaced with the Honeywell 66/40 and a "graphic display system" for graphic print out. The duration of the experiment for cycle life index determination was four days involving approximately 290 cycles. Initially the electrode was cycled in 1.050 sp gr H_2SO_4 for 2 days (~145 cycles), in order to prepare a porous electrode. This was followed by cycling the electrode in test solution, acid electrolyte with or without the expander, for 145 cycles. The current and electrode potentials were also monitored by an Esterline Angus Model L1102S two channel recorder. The voltammograms during cycling were recorded by a Hewlett Packard/Moseley Autograph Model 7000AM X-Y recorder.

Results and Discussion

The effect of lignosulfonate expander in sulfuric acid solution on the constant current discharge profile of a lead electrode is shown in Fig. 1. It is in every respect similar to the constant current discharge profile of the pasted electrode (7, 10, 15, 16) and substantiates the fact that barium sulfate and carbon black present in the conventional expander contributes very little on the discharge behavior of the lead electrode. Nonetheless, the long term stabilizing effect of barium sulfate and/or carbon black on the lead electrode, particularly in the industrial-type cell which uses an appreciable amount of barium sulfate and a small amount of expander may be significant but has not been thoroughly investigated. The presence of the expander in the system has caused higher polarization at the start, but a greater depth of discharge. The latter is noted from the longer discharge time. The adsorption of expander on the lead electrode surface is responsible for higher electrode polarization (22). The delay in the passivation process in the presence of expander is associated in part with its ability to modify the morphology and resistivity of the discharge product layer and in part to its influence on the interfacial electrode kinetics.

Figure 2 exemplifies the influence of expander on the morphology or the particle size of the lead sulfate layer. The lead sulfate particle size is significantly smaller in presence of expander than that obtained in

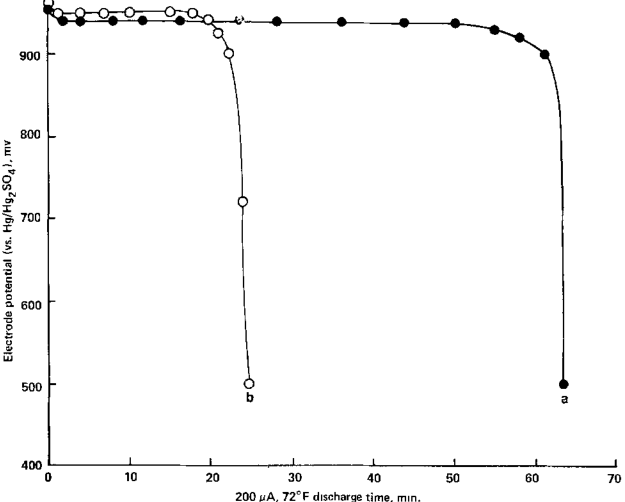

Fig. 1. Discharge characteristics of a lead microelectrode in 1.250 sp gr H_2SO_4 with (a) and without 10 ppm Reax 80C lignosulfonate (b) at 200 μA.

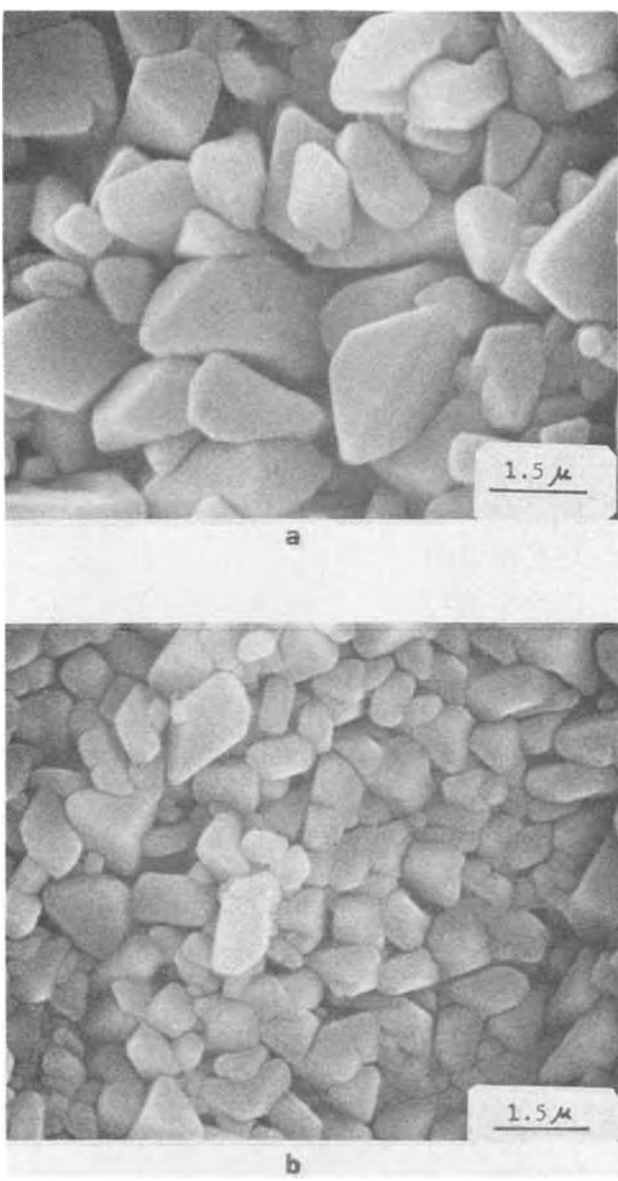

Fig. 2. Influence of expander on the discharge product morphology. 1.57 cm^2 lead electrode was discharged at 200 μA in 1.250 sp gr H_2SO_4 without (a) and with 10 ppm Reax 80C expander (b).

absence. The smaller particle size is the result of the surface adsorption of expander on the growing lead sulfate crystals. In the absence of the expander the growth of lead sulfate crystals remains unhindered and results in a larger size (Fig. 2). This is in agreement with Yampol'skaya *et al.* (29) who observed the chemically precipitated lead sulfate to be long and coarse, but in the presence of lignin fine leaflets were formed. The decreased resistivity of the lead sulfate product layer as observed by Willihnganz by the polarization measurement appears to be related to the increased ionic permeability of the lead sulfate matrix in presence of expander. The presence of a labile quinoid structure in the expander molecule (20) indicates a possibility that it might act as an electron transfer medium (24) when present in the lead sulfate matrix and reduce its electronic resistivity.

The lead electrode voltammograms in sulfuric acid solution without additive (Fig. 3) show a normal behavior, namely the oxidation at potential > -960 mV, passivation at ~ -860 mV, and reduction at < -960 mV, all with respect to the $Hg/Hg_2SO_4/m\ H_2SO_4$ reference electrode. These voltammograms indicate that the oxidation kinetics of this electrode is influenced by the dynamic growth of the passivating lead sulfate layer on the reacting surface whereas the reduction kinetics is controlled by the dissolution of lead sulfate and the lead adatom deposition sites. In the presence of the expander in solution (dotted line in Fig. 3) the conventional electrode kinetics is altered due to its affinity to adsorb on both the metallic lead and lead sulfate surface of the electrode. During anodic sweep or discharge an increase in the discharge overpotential is caused by the surface blocking effect of the expander; the increased intensity is caused by the expander's influence on the lead sulfate product morphology and on the nature of the reactive interface. On reverse scan the expander in solution severely inhibits the cathodic reaction as indicated by a reduction in cathodic peak current and by maintaining a considerable reduction rate at higher cathodic potential (long tail between −1100 to −1160 mV). The reduction in cathodic peak current is associated with the lack of deposition sites controlled by adsorptivity of expander on the lead surface whereas the reduction process at the extended potential range is controlled by the availability of Pb^{2+} species or the dissolution kinetic of the lead sulfate. The overall influence of expander on the cyclic voltammogram agrees well with the recent observation of Barradas *et al.* (30) who reported the effect of lignosol C-16 (Lignosol Chemical Limited, Quebec) on the cyclic voltammogram of Pb-Hg amalgam in $PbCl_2$ solution. In agreement with the present observation, a decreased charge acceptance of the lead electrode in the presence of the expander has been reported (2, 3, 31).

Figure 4 shows that the presence of the expander in the test solution influences the morphology of the lead electrodeposit and increases the reactive surface area after charge. This agrees with the reported increased surface area of the lead electrode in the presence of the expander (5, 7). This increase, as hypothesized earlier, results from the blocking coverage of deposition sites and dynamic adsorptive behavior of the expander on the electrode surface. Figure 5 shows that the capacity and peak discharge current buildup of the lead electrode is faster when cycled in the presence of expander than in absence. Both the capacity and the peak discharge current reflect the increased electrode surface area upon cycling and suggest that the electrode capacity would be better maintained in the presence of expander in the electrode in agreement with the reported observation (7).

Table I shows the reproducibility of the lead electrode discharge data obtained at varied acid concentration with and without 10 ppm Reax 80C expander. A good repeatability of the test data is apparent. The value of effective capacity, K, and exponential, "n", as obtained from the curve fitting of test data in $I^n t = K$ equation as well as the value of K' equivalent to $I^{1.5}t$ are included in the table. The exponential "n" is seen to vary from 1.45 to 1.64 with no apparent dependency to either acid concentration or the expander content in it. The K' values agree fairly well with the K indicating the possible use of K' for the design of the application-oriented cell. Further correspondence of the K' to the test data is shown in Fig. 6 in which the solid line is drawn based on $n = 1.5$. It notes that the presence of the expander in solution shifts the $\log t - \log I$ line upwards and increases the K' value almost twice that of the control electrode. It also suggests the use of either K' or its relative ratio (Eq. [4]) as a quantitative measure of the expander activity on discharge.

The discharge activity of the lead electrode decreases almost linearly with increasing acid concentration and nonlinearly in the presence of expander in the electrolyte are also shown in Table I. The expander activity on discharge is highly pronounced in 1.050 sp gr H_2SO_4 but not so in 1.350 sp gr H_2SO_4.

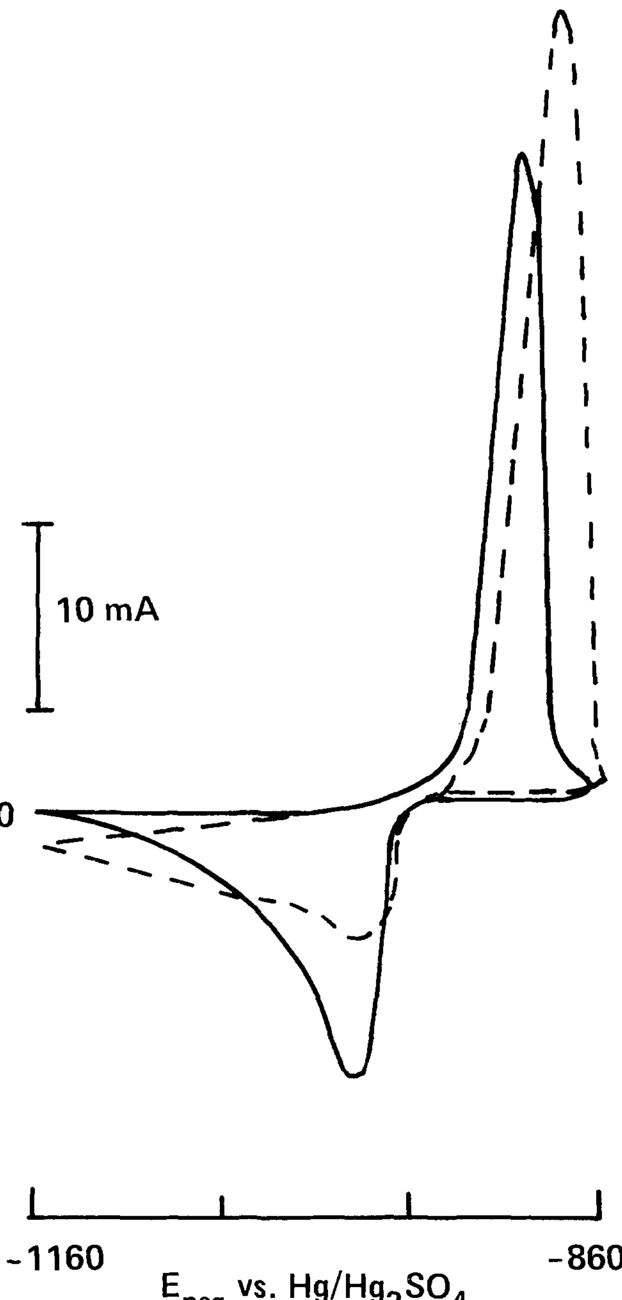

Fig. 3. Effect of 10 ppm lignosulfonate expander on the lead electrode voltammogram between —1160 to —860 mV (vs. Hg/Hg_2SO_4) in 1.250 sp gr H_2SO_4. ——— pure H_2SO_4; - - - H_2SO_4 solution with expander.

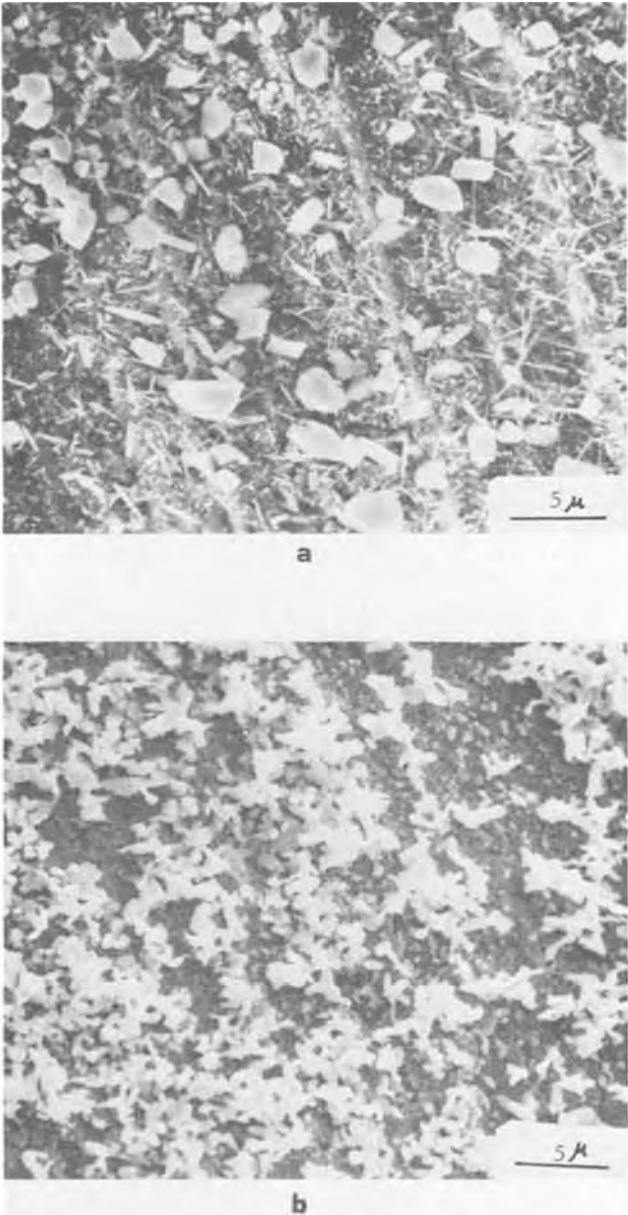

Fig. 4. Morphology of electrodeposited lead on the lead electrode at —1160 mV (vs. Hg/Hg_2SO_4) in 1.250 sp gr H_2SO_4 without (a) and with 10 ppm Reax 80C expander (b). Deposition period was 4 hr.

The K' values were found to increase over the no expander in solution by factors of 3.24, 1.97, 1.94, and 1.18 for 1.050, 1.150, 1.250, and 1.350 sp gr H_2SO_4, respectively. The exact cause of the decreased expander activity on the electrode dischargeability with increasing acid concentration is not known. It might be related to the acid concentration dependent precipitation kinetics of the lead sulfate and the adsorption-desorption behavior of the lignosulfonate on the lead and lead sulfate particles. Furthermore, Table I shows a continuous increase in K' values with increasing expander concentration up to 10 ppm with no significant changes between 10 and 40 ppm concentration in the test solution. The lack of increased expander activity with increasing expander concentration appears to be caused by supersaturation and/or by the formation of partial inactive electrode surface by multilayer surface adsorption.

Table II shows the reproducibility of the cycle life test data. It indicates a poor reproducibility of the initial capacity of the test electrode obtained after 2 days cycling in 1.050 sp gr acid and a good reproducibility of the cycle life index value as defined in Eq. [5] and noted in the last column of Table II. The variation in initial capacity is associated with electrode preparation, *i.e.*, our inability to control the initial electrode surface area which is influenced by the microroughness and the precision of the length of the cast lead wire electrode. However, this variation in initial capacity does not affect the sensitivity of this technique in determining the capacity maintenance behavior of the electrode during cycling. This is evident from the reproducibility of the cycle life index data. This table also notes a decreased electrode capacity when cycled in pure acid but increased electrode capacity when cycled in electrolyte with 10 ppm expander. This closely agrees with the reported observation of the expander's influence on the cycle life of the pasted negatives (5, 7) and validates the use of cycle life index as determined here in quanti-

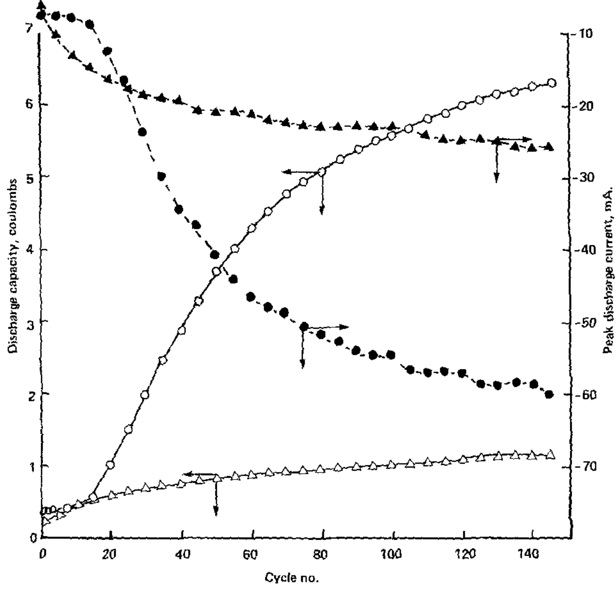

Fig. 5. Capacity and anodic peak current behavior of the lead electrode during linear potential sweep cycling between −1160 to −860 mV (vs. Hg/Hg_2SO_4) at 0.5 mV/sec in 1.050 sulfuric acid solution without (△-▲) and with 10 ppm expander (○, ●).

tative monitoring the expander activity on the cyclic performance of the lead electrode. It appears that this technique, being free from the complexities of the pasted electrode preparation, will offer unbiased information on the quality of expander in altering the lead electrode cyclic performance.

The effects of acid concentration and the influence of 10 ppm expander in an acid solution on the cycling ability of the lead electrode are illustrated in Fig. 7. It indicates that the capacity maintenance behavior of the lead electrode significantly decreases with increasing acid concentration. However, in the presence of 10 ppm expander in 1.250 sp gr H_2SO_4, a threefold increase in capacity is observed. The cycle life index (CLI) values for 1.050, 1.150, 1.250, and 1.350 sp gr H_2SO_4 are 0.25, 0.10, −0.30, and −0.68, respectively (Fig. 7). The presence of 10 ppm Reax 80C lignosulfonate in 1.250 sp gr has increased the CLI from −0.30 to +0.69. The decreased cycle life index with increasing acid concentration appears to be the result of an increasing tendency of the electrode for

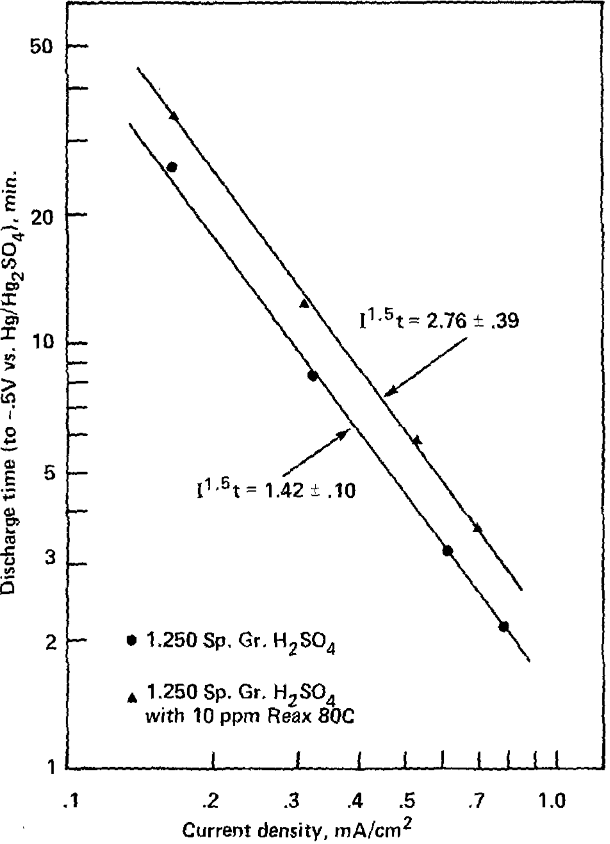

Fig. 6. Effect of 10 ppm Reax 80C lignosulfonate in 1.250 sp gr H_2SO_4 on the log-log relationship between discharge time and current density.

lead sulfate passivation and the greater loss of surface area caused by sintering of lead particles during electroconversion of lead sulfate to metallic lead. This is illustrated from the linear potential sweep voltammograms taken at the end of the test cycles (Fig. 8). The gradual diminishing pattern of the voltammograms reflects the change in passivation behavior and/or the loss of effective surface area with increasing acid concentration during cycling. In the presence of the expander in the test solution, however, the shape of the voltammogram is changed as

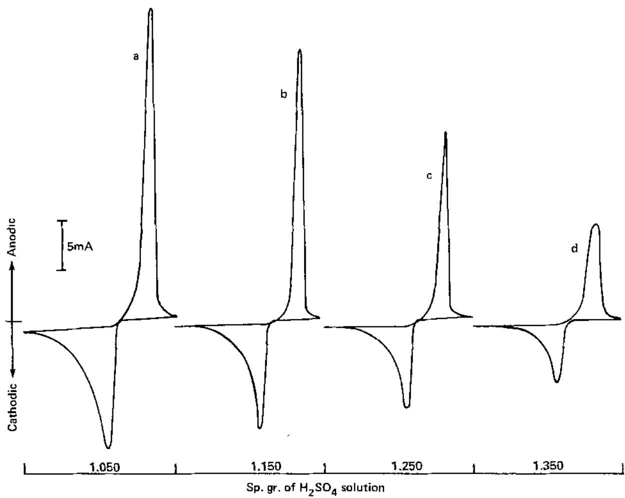

Fig. 8. Effect of sulfuric acid concentration on the lead electrode voltammograms carried out at 0.5 mV/sec between −1160 to −860 mV (vs. Hg/Hg_2SO_4) after 145 cycles. (a) 1.050 sp gr, (b) 1.150 sp gr, (c) 1.250 sp gr, and (d) 1.350 sp gr.

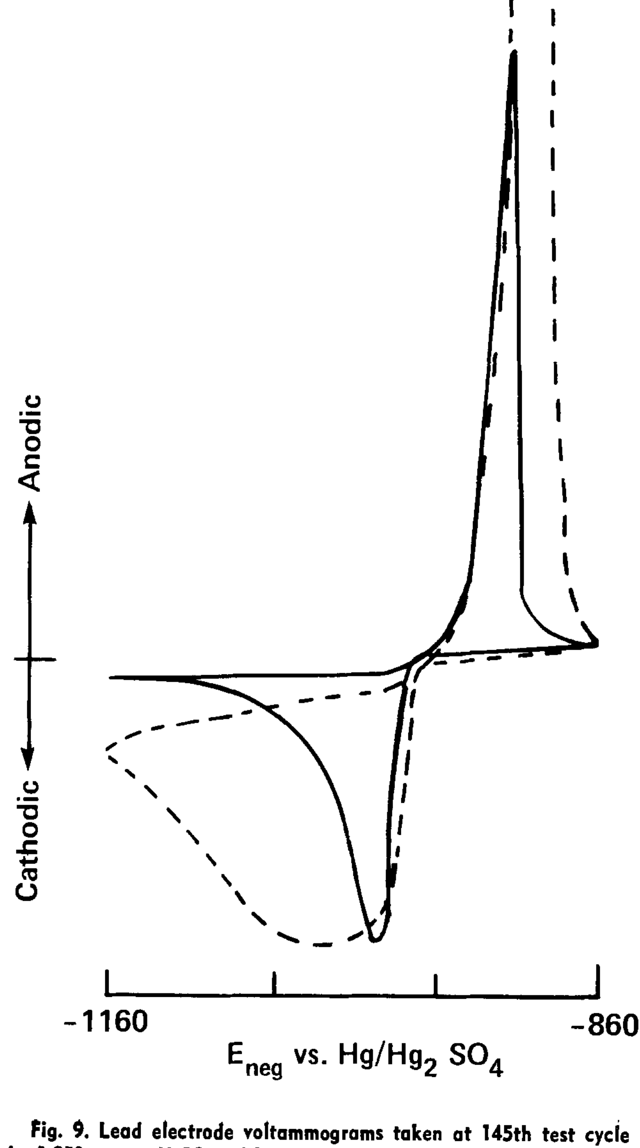

Fig. 9. Lead electrode voltammograms taken at 145th test cycle in 1.250 sp gr H_2SO_4 without (———) and with (- - -) 10 ppm Reax 80C lignosulfonate illustrate the role of expander on the cyclic performance.

which in turn has resulted in a significant gain in capacity and in mode of cathodic reduction behavior.

Expander added to the test solution causes charge inhibition during cathodic reduction (Fig. 3). This is

caused primarily by blocking of the lead adatom deposition sites through dynamic adsorptive coverage. Such electrodeposition hindrance favors the formation of an electrodeposit with increased surface area (Fig. 4). During repetitive charge/discharge cycling the growth of surface area and subsequent discharge behavior intensify and result in an electrode as typified in Fig. 9.

SEM micrographs of electrodes cycled in 1.250 sp gr H_2SO_4 with and without 10 ppm expander are shown in Fig. 10. The formation and maintenance of the high surface area electrode in the presence of expander is exemplified here. The size of the lead particles of the test electrode are much finer compared to the control electrode cycled in pure acid solution. This micrographic observation agrees well with the reported expander's influence on the pasted electrode morphology after electroformation and to a limited extent after cycling (4-7) and signifies the pertinence of the present technique in quantifying the expander activity on the electrode performance during cycling service.

The effect of expander concentration in 1.250 sp gr H_2SO_4 on the lead electrode cycle life index is shown in Fig. 11. It notes a continuous increase in CLI with increasing expander concentration up to 10 ppm; no significant difference between 10 and 20 ppm; and concentration in excess of 20 ppm decreases sharply the CLI values. The apparent presence of an optimum expander concentration in test solution for a maximum cyclic electrode performance indicates the sensitivity of the overall electrode kinetics on the expander concentration in the test solution. The expander when present in test solution at concentration >20 ppm loses its effectiveness in rendering beneficial influence and starts degrading the electrode performance. This is apparently related to the excessive adsorption of the expander on the electrode surface causing a significant deviation in the normal electrochemical behavior of the electrode. This is clearly illustrated from the voltammograms of the test electrodes cycled in 1.250 sp gr H_2SO_4 solution with 40, 60, and 100 ppm expander as shown in Fig. 12. The critical examination of voltammograms given in Fig. 9 and 12 indicates that the higher expander concentration in the test electrolyte primarily dominates the reduction kinetics of the lead electrode. This reduction process is in part controlled by the available deposition sites and in part by the Pb^{2+} concentration or the dissolution rate of lead sulfate particles. The greater adsorption of expander on lead rather than on the surface of lead sulfate (22) suggests that the overall cathodic process is to be solely controlled by the availability of the deposition sites. The gradual decrease of the deposition site area of the lead elec-

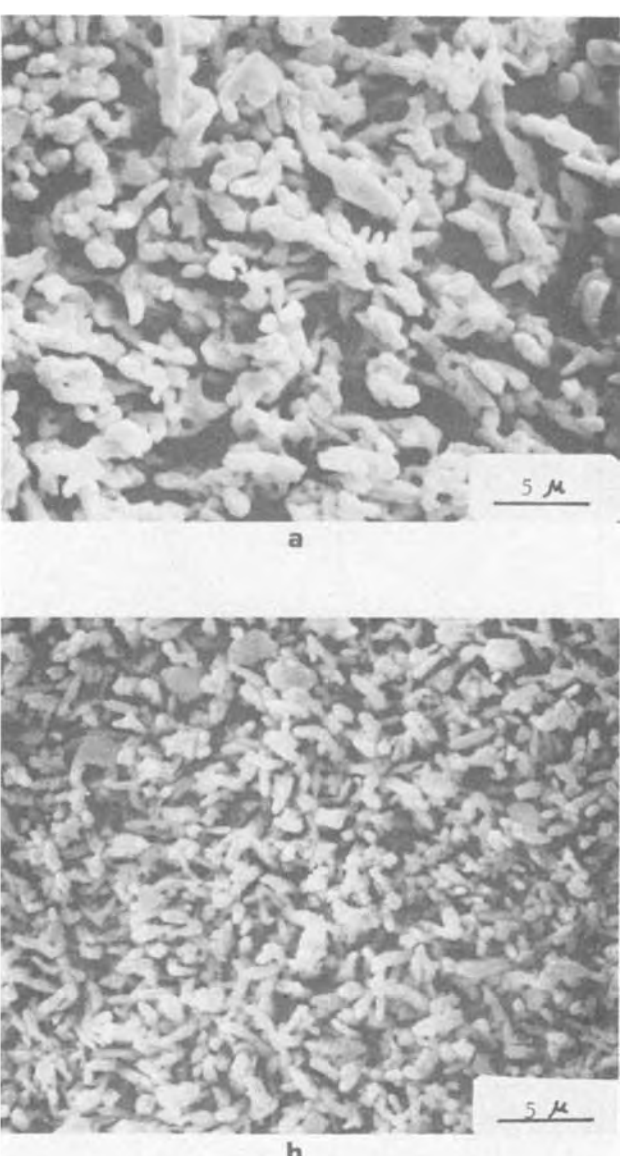

Fig. 10. Morphology of the linear potential sweep cycled lead electrode at 145th cycle in 1.250 sp gr H_2SO_4 without (a) and with 10 ppm Reax 80C (b).

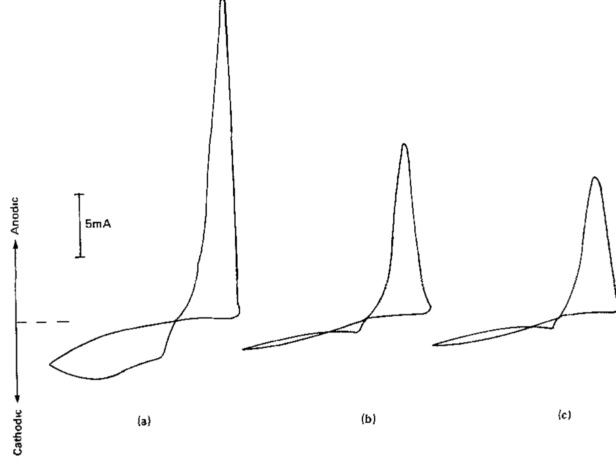

Fig. 12. The effect of higher Reax 80C lignosulfonate concentration in 1.250 sp gr H_2SO_4 on the lead electrode voltammograms obtained at 145th cycle point. (a) 40 ppm, (b) 60 ppm, and (c) 100 ppm.

trode with increasing expander concentration in test solution is qualitatively noted from the decrease in cathodic peak current at the onset of the cathodic sweep (Fig. 9 and 12). The follow up cathodic process is complex and appears to be controlled by the generation of lead nuclei, coverage of the freshly formed nuclei with expander, and possibly the potential dependent adsorption-desorption process of the expander on the electrode material.

In view of the limited information on the physical and chemical nature of the expander material which is known to have a highly complex polymeric structure, more work is needed for a thorough definition of the structure-dependent expander action on the charge and discharge processes of the lead-acid battery negative.

Conclusions

1. The expander action on the lead electrode performance has been defined in terms of its influence on the high rate discharge and capacity maintenance behavior during cycling.

2. Two electrochemical techniques have been developed for measuring expander activities outside the test battery. These techniques based on small electrodes are simple, free from the complexities of the pasted electrode, and provide unbiased information of expander activities. The test results agree well with the reported expander's influence on the pasted electrode performance.

3. Expander influences the high rate discharge of the lead electrode by modifying the lead sulfate passivating layer which decreases with increasing acid concentration.

4. The capacity maintenance behavior of the lead electrode is influenced by the presence of expander as it prevents the sintering of the lead mass during repeated charge/discharge cycling process. An optimum expander concentration exists for a maximum cyclic performance of the lead electrode.

5. The charge inhibition of the lead electrode in the presence of expander is caused by the blocking coverage of lead adatom deposition sites.

6. In view of the structural complexities of the expander material, a considerable difficulty exists in correlating the electrochemical activities of the expander to that of the molecular structure of this polymeric material.

ABSTRACT

A preliminary study was made of the effect of certain elements implanted in iron on the absorption of hydrogen by Ferrovac-E iron. Using the permeation technique, it was found that the location of implanted Pt, as modified by selective dissolution of iron from the surface, affects the kinetics of the hydrogen evolution reaction and, hence, of the hydrogen absorption process. The rate of hydrogen absorption decreased with increase in Pt concentration on the surface in both 0.1*N* NaOH and 0.1*N* H_2SO_4. A catalytic mechanism is proposed to explain the marked reduction in hydrogen permeation. There are no significant differences in the permeation behavior of unimplanted and helium- or iron-implanted iron membranes in 0.1*N* NaOH. The experimentally observed Tafel slope, the permeation-(charging) potential relationship, and the permeation-(charging) current relationship indicate a coupled discharge-recombination mechanism of hydrogen evolution on He-, Fe-, or Pt-implanted iron. At higher cathodic overpotentials in 0.1*N* NaOH, corresponding to potentials more negative than −1.0V (SHE), another mechanism of hydrogen evolution is indicated. Selective dissolution of iron from the Pt-implanted Fe surface layer may involve some platinum and iron interdiffusion according to Rutherford backscattering analyses.

Hydrogen absorption greatly reduces the mechanical properties of structural alloys. A number of investigators have studied the possibility of reducing hydrogen absorption by coatings (1-4). Besides functioning as barriers to hydrogen entry, coatings may also reduce hydrogen absorption through their effect on the kinetics of the hydrogen evolution reaction and, hence, of the hydrogen absorption process. Chatterjee *et al.* (4) provided experimental evidence for the catalytic mechanism of decreasing hydrogen entry into iron. They found that discontinuous electrodeposited coatings of Pt, Ni, or Cu on iron are effective in reducing hydrogen entry into the membrane. The ion implantation technique is another method for altering the surface chemically and, thus, the mechanism and kinetics of the hydrogen evolution reaction, without affecting bulk physical or mechanical properties.

Ashworth and co-workers (5) were among the first to report the effect of implantation on the polarization behavior of iron. They found that there are no significant differences between the polarization behavior of unimplanted and argon-implanted iron beyond that due to changes in surface roughness associated with the implantation process. Other implanted elements in iron, such as chromium and lead, were shown to influence the polarization behavior (6, 7).

This paper reports the results of initial studies directed at evaluating the effect of implantation on hydrogen permeation. No other studies of hydrogen permeation of implanted membranes are known to be reported in the literature. Specifically, the results provide insight on:

1. Whether, and to what extent, implanted platinum, helium, or iron reduce hydrogen permeation through iron.
2. The effect of the nature and proximity to the surface of the implanted species on the mechanism and kinetics of the hydrogen evolution reaction and, hence, of the hydrogen absorption process.
3. The effect of implantation on (effective) hydrogen diffusivity which may be related to trapping characteristics.

The rationale behind choosing Pt for implantation is that Pt is one of the best electrocatalysts for the hydrogen evolution reaction. In order to sort out any effects due to the implantation process, itself, the inert element, He, and the substrate element, Fe, were also chosen for comparison.

Experimental Procedure

The hydrogen permeation measurements were carried out on Ferrovac-E iron. The Fe membranes were prepared by cold-rolling wafers cut from a master ingot to the required thickness (0.365 mm). After polishing to 600 grit, they were degreased using benzene and methanol in a soxhlet apparatus, and then annealed for 2 hr at 1273°K (1000°C) in an argon-filled silica capsule. The latter treatment produced an etched surface. One side of some of these membranes was exposed to beams of Fe^+, He^+, or Pt^+ ions at fluences and energies given in Table I. The samples were implanted in a vacuum of 10^{-4} Pa (10^{-6} Torr) and were in close proximity to a cold surface at liquid nitrogen temperatures (77°K) which minimized carbon contamination. The temperature of the samples during implantation did not exceed 323°K. The implanted samples were stored in an evacuated desiccator. Prior to the permeation runs, the Pt content on the surface of the Pt-implanted membranes was increased by selective dissolution of iron via immersion in 1M H_2SO_4 for 20 sec. This amount of etching produced no change in surface morphology observable by light or

Key words: ion implantation, hydrogen evolution, Fe-Pt, Tafel slope, catalyst.

scanning electron microscopy. Permeation measurements were also made after subsequent 10 sec immersions in $0.1N$ H_2SO_4. Sulfuric acid is known to selectively remove iron from a Fe-Pt solid solution (8).

Electrolyte solutions were prepared from conductivity water (doubly distilled) prepared by the method of Powers (9) and reagent grade chemicals. Final purification was made by pre-electrolyzing the solutions in an external cell prior to admitting them to the permeation cell.

The technique of Devanathan and Stachurski (10) was used to measure the permeability of hydrogen through a membrane while evolving hydrogen off the implanted surface. In this method, a thin metallic membrane is electrolytically charged with hydrogen on the implanted side, while on the other exit side the hydrogen, which has diffused through the membrane, is anodically oxidized. The orifice of the cell and, thus, the charging area was 0.785 cm^2. The measured anodic current is a direct measure of the hydrogen flux through the membrane for conditions at the exit surface, which included a thin palladium coating and an oxidizing potential of 0.018V (SHE). These are the same conditions found previously to be suitable for oxidizing all of the hydrogen arriving at the anodically polarized surface (4). The reported values are the measured values after correction for the residual current which is typically less than 1 $\mu A\ cm^{-2}$. The potential of the charging surface was measured using an Hg/Hg_2SO_4 reference electrode in 0.1N H_2SO_4 and an Hg/HgO reference electrode in $0.1N$ NaOH, and that of the exit surface using an Hg/HgO reference electrode in $0.1N$ NaOH. Both chambers of the cell were deaerated by bubbling oxygen-free nitrogen through the solutions. The permeation measurements were performed under conditions of cathodic protection. Details of the cell and circuitry are reported elsewhere (4).

The permeation data were obtained as follows. The Fe- and He-implanted iron membranes were precharged at $i_c = 0.10$ mA cm^{-2} for 45 min by which time a quasi-stationary permeation current was established. The Pt-implanted membranes were similarly precharged at 1 mA cm^{-2} ($\sim$15 min in $0.1N$ NaOH and $\sim$7 min in $0.1N$ H_2SO_4). The membranes were then charged galvanostatically in 0.02 mA cm^{-2} steps in $0.1N$ NaOH or in 0.2 mA cm^{-2} steps in $0.1N$ H_2SO_4 in descending and then ascending directions. Each charging current was maintained for about 4 min by which time a quasi-stationary permeation current was established. This procedure has been found to give constant and reproducible permeation transients dependent only on the charging conditions for a given specimen.

Some of the concentration profiles after implantation were measured by means of high resolution Rutherford backscattering of alpha particles with a depth resolution of 4 nm. For this measurement, the surface to be implanted was first polished to a mirror finish with 6 μm diamond paste. Details of this method may be found elsewhere (11, 12).

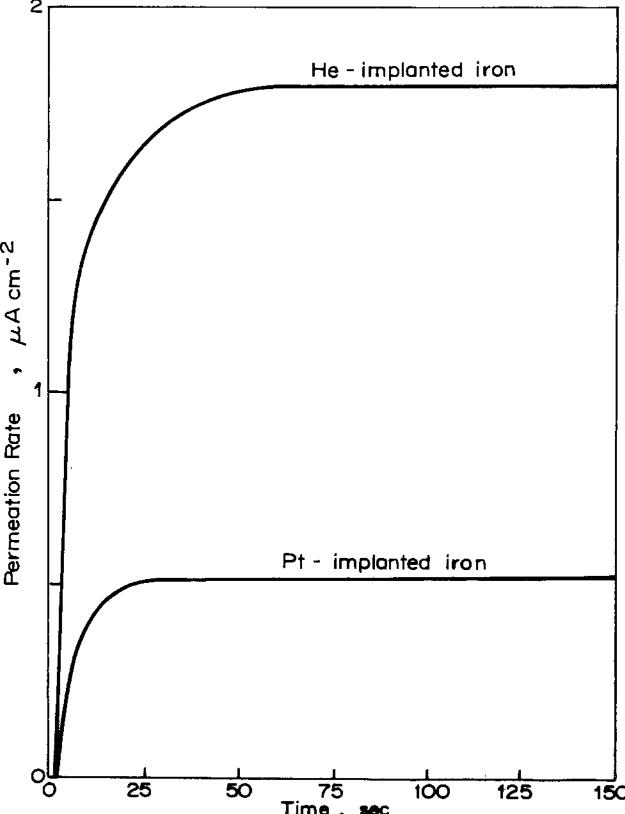

Fig. 1. Hydrogen permeation transients for an He-implanted Fe membrane and for a Pt-implanted Fe membrane after a 20 sec dissolution in 1M H_2SO_4. $i_c = 0.1$ mA cm^{-2} in $0.1N$ NaOH.

Results

Table II shows that the steady-state hydrogen permeation fluxes, i_x, and electrode potentials at the charging side, E, in $0.1N$ NaOH are the same for unimplanted Fe membranes and identical membranes implanted with He or Fe. These values and the transients themselves are also typical for these samples after various periods of immersion in sulfuric acid.

The permeation transients prior to steady state were also the same within the experimental error for these membranes; the half-rise time ($t_{1/2}$) was 5.5 $\pm$ 1.0 sec. Typical permeation transients are shown in Fig. 1. The effective diffusivity, calculated using the expression (13, 14)

$$D = \frac{0.138\, L^2}{t_{1/2}}$$

where L is the membrane thickness, is $D = 3 \times 10^{-5}$ $cm^2\ sec^{-1}$. This value is in good agreement with literature values for well-annealed iron (15) and is also essentially the value obtained by extrapolation of high temperature diffusion data to room temperature (16). The experimentally observed Tafel slope is -122 ± 5 mV (Fig. 4). This value is the same as that re-

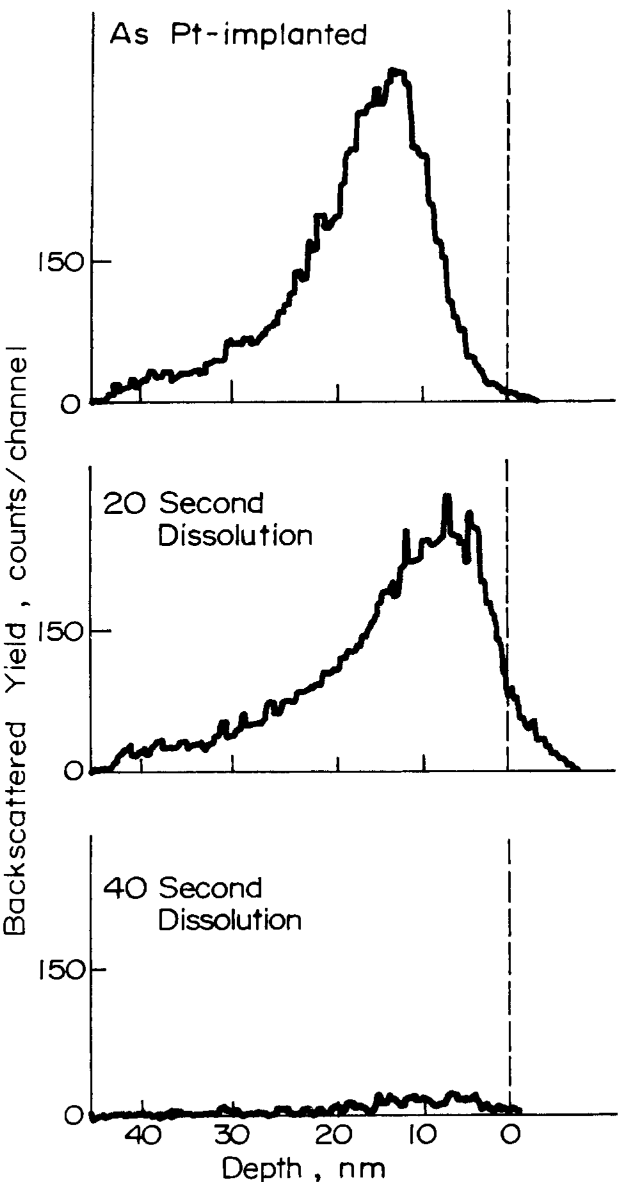

Fig. 2. Rutherford backscattering profiles of implanted Pt in Fe as a function of time of immersion of the implanted sample in 1M H_2SO_4 at room temperature. Depth of resolution is 4 nm (40Å).

ported for hydrogen evolution on Fe in 0.1*N* NaOH (17).

Figure 2 shows distribution profiles of Pt implanted in Fe after different amounts of dissolution in 1M H_2SO_4 at room temperature. After 20 sec immersion in the acid, the peak concentration of Pt is closer to the surface and the area under the curve is essentially unchanged, indicating that only iron is dissolved during this initial dissolution period; and the tail of the profile extends further into the alloy as measured from either the peak or the original surface position (not shown), suggesting Pt diffused into the alloy (during and/or following dissolution) to a distance roughly equal to the distance the surface has receded.[1] The (average) Pt concentration within a surface region of about 4 nm thickness as measured by Rutherford backscattering is significantly higher (~3% by weight) than in the as-implanted case ($\lesssim$0.1%).

Profiles obtained after a second 20 sec dissolution period in 1M H_2SO_4 show that the Pt content is much less and nearly at background levels (Fig. 2), which indicates that most of the Pt is lost from the membrane during this second dissolution process. Permeation measurements were mainly done, therefore, after an initial 20 sec exposure of the Pt-implanted membranes to 1M H_2SO_4.

Figure 3 shows a linear dependence of the steady-state permeation current density on the square root of the charging current density with the curve passing through the origin for an unimplanted Fe membrane and for a Pt-implanted Fe membrane following a 20 sec immersion in 1M H_2SO_4. This is taken as an indication of a diffusion-controlled hydrogen permeation process (17, 19). The permeation transient for the latter membrane is shown in Fig. 1. The hydrogen permeability is less at all charging currents for the Pt-implanted, than for the unimplanted, iron membranes. Pt profiles which were not modified by selective iron dissolution were found to have an insignificant effect on the hydrogen evolution and permeation kinetics.

The electrode potentials for hydrogen evolution on the Pt-implanted membrane (after immersion in acid) are invariably more noble than those on the unimplanted membrane, Fig. 4. The Tafel slope is -122 ± 5 mV for both unimplanted and Pt-implanted iron. The relations between permeation and the electrode potential of the charging surface for unimplanted and Pt-implanted Fe membranes are given in Fig. 5 for the 0.1*N* NaOH charging solution. The slopes of the straight segments of the curves of both the unimplanted Fe and Pt-implanted Fe membranes are -255 ± 5 mV. About the same slope is also obtained in the 0.1*N* H_2SO_4 charging solution over a wide range of overpotential for both charging surfaces, Table III.

As with the Pt content of the surface (Fig. 2), both the measured electrode potential of the Pt-implanted surface and the permeation rate of hydrogen through the Pt-implanted membrane during hydrogen charging are functions of the pretreatment immersion time in, and concentration of, sulfuric acid. Figure 6 shows variations in potential and permeation as a function of additional 10 sec immersion periods (following the initial 20 sec immersion) in a diluted sulfuric acid. The trends of i_∞ decreasing and E increasing in a more oxidizing direction hold for an additional 40 sec immersion in 0.1*N* H_2SO_4. Then, a reversal of the electrochemical parameters occurs.

Discussion

The electrocatalytic activity of a surface for the hydrogen evolution reaction can be estimated from the overpotential required to evolve hydrogen at a given current density—the lower the overpotential or the more noble the electrode potential, the more catalytic the surface. Figure 4 and Table III show the electrode potentials measured in alkaline- and acid-charging solutions. It is seen that the electrode potential for the hydrogen evolution reaction is more noble on Pt-implanted than on unimplanted surfaces. It follows

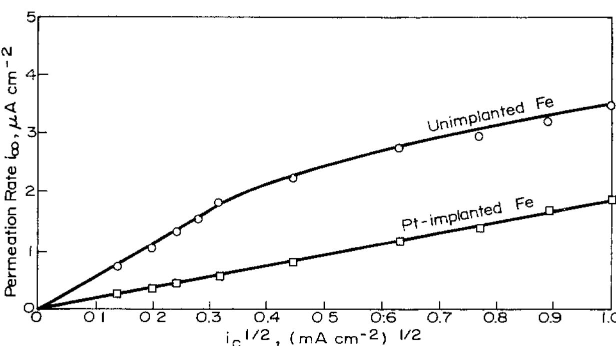

Fig. 3. Steady-state permeation rate i_∞ as a function of the square root of the charging current density i_c for an unimplanted Fe membrane and a Pt-implanted and acid-treated Fe membrane. Charging solution was 0.1*N* NaOH.

[1] This follows since the profile width is about the same before and after the initial 20 sec immersion. An estimate is 10 nm after 20 sec based on published corrosion rates (>10^{-3} A cm^{-2} at 298°K) of steel in sulfuric acid (18).

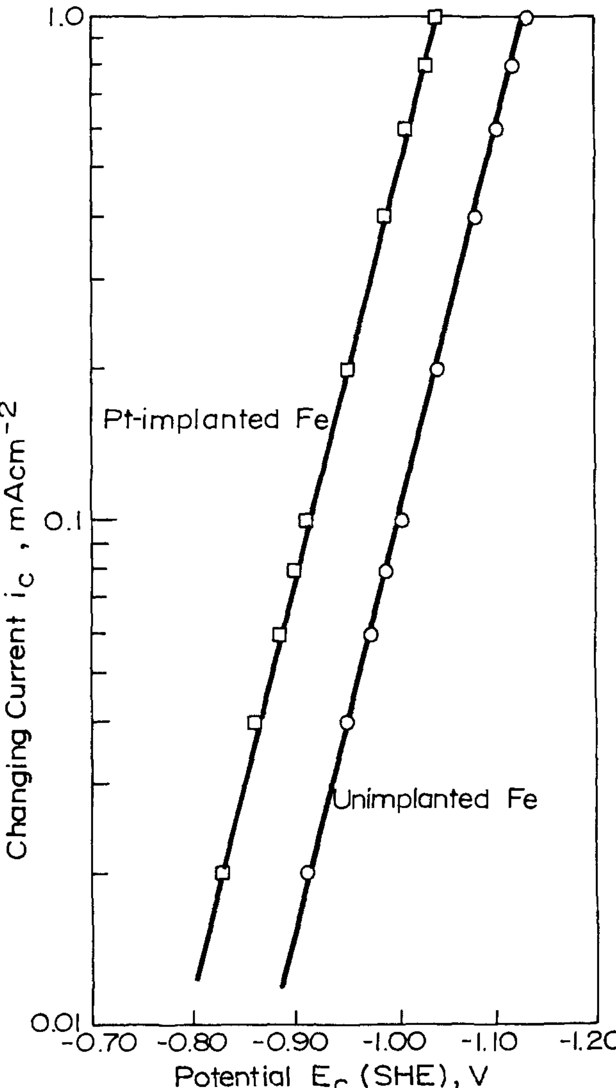

Fig. 4. The polarization curve in the Tafel region for hydrogen evolution in 0.1N NaOH on an unimplanted iron (○) and a Pt-implanted Fe membrane following a 20 sec immersion in 1M H_2SO_4 (□).

that the degree of hydrogen coverage, θ, and the permeability of hydrogen should be less for Pt-implanted, than for unimplanted, iron membranes (20, 13, 4) in accord with the permeation results in Fig. 3 and 5.

The above reasoning also explains the decrease of the steady-state permeation and the more positive electrode potential with increasing pretreatment immersion time (Fig. 6), *i.e.*, acid attack initially increases the Pt content of the surface as was shown by Rutherford backscattering (Fig. 2). A correspondence of the electrochemical and the backscattering data also holds at longer pretreatment immersion times when a reversal in the trends of E_c and i_∞ corresponds to a loss of Pt from the surface. Thus, it would seem

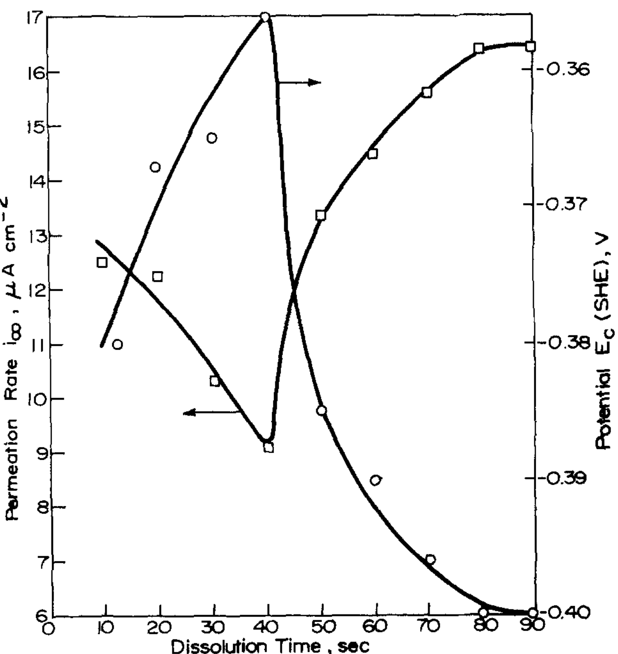

Fig. 6. Steady-state permeation rate (□) and charging potential (○) as a function of additional immersion periods in 0.1N H_2SO_4 beyond the initial 20 sec immersion in 1M H_2SO_4 of the Pt-implanted surface. Charging current was 0.6 mA cm^{-2} in 0.1N H_2SO_4.

that as the surface recedes and overtakes the Pt profile, the Pt concentration on the surface reaches a level for which accumulation of Pt into particles, followed by detachment, occurs. Such is known to happen when an alloy contains low percentages ($\lesssim 1\%$) of a noble metal in solid solution (21), and is in accord with industrial experience, especially during electrolytic refining of copper containing small amounts of gold. The reversal in the trends of E_c and i_∞ occurs at shorter immersion times for higher concentrations of sulfuric acid (Fig. 2 *vs.* Fig. 6). This is in accord with a faster rate of attack in the more concentrated acid, and thus a faster rate of recession of the surface. That continued dissolution of the membrane eventually leads to Pt loss from the surface (Fig. 2) is supported by the approach after long times of the i_∞ and E_c values to those for unimplanted Fe membranes.

In summary, the mechanism by which implanted Pt reduces hydrogen absorption by iron is related to the different catalytic tendencies of Pt and Fe for the hydrogen evolution reaction. In this case, the hydrogen evolution reaction occurs more readily (lower overvoltage required) on Pt than on Fe (sites); thus, the coverage of hydrogen on the composite Pt-Fe surface is lower and, consequently, so also is the absorption rate. Thus, these results indicate that for implantation in iron to be effective for reducing hydrogen absorption, implants should have a higher exchange current density for hydrogen evolution than that for the substrate metal. The data also show for Pt implants that modifications of the implantation profile, which increase the concentration of the implant in the outermost surface layer, increase evolution and decrease absorption of hydrogen.

The Rutherford backscattering data here and elsewhere (11) give some indication that a limited amount of interdiffusion of the alloy components occurs during (and/or after) selective dissolution (of the iron). While this has yet to be shown to be the actual explanation of the backscattering profiles obtained before and after the initial (20 sec) dissolution period (Fig. 2), the explanation itself is reasonable for certain conditions of anodic dissolution which generate vacancies as analyzed elsewhere (21-25).

The data in Table II for He- and Fe-implanted iron show that there are no significant differences in the polarization or permeation behavior between unimplanted and He- or Fe-implanted iron. Furthermore, the Tafel slopes are also the same. Thus, the implantation process, itself, does not modify the mechanism of, or the catalytic character of the surface for, the hydrogen evolution reaction. Ashworth *et al.* (5), also found that once the air-formed oxide is removed, the polarization behavior of unimplanted and argon-implanted iron is nearly the same. A delay in the permeation-kinetics, on the other hand, might have been expected for the implanted membrane since the implantation process, itself, introduces defects to about the depth of the profile. In recent ion beam studies of deuterium-implanted iron, Myers *et al.* (26) found that the activation energy of a deuterium trap produced by the implantation process is 0.81 eV, that slow release from the traps occurs between 300° and 400°K, and that either implanted deuterium or iron creates the traps. The presence of effective hydrogen traps can, in principle, be indicated by a comparison of the permeation rise times for unimplanted and implanted membranes. That the half-rise times in the present measurements were the same within the experimental error may be attributed to (*i*) modifications of the nature or density of the traps during the long (~9 month) delay between the implantation process and the permeation measurements, (*ii*) filling of the traps with hydrogen from other sources during the above-mentioned delay, and/or (*iii*) a lack of sensitivity in the measurement. Experiments are currently underway in an attempt to resolve this issue.

Some of the data obtained in this work are of the type normally used for evaluation of the mechanism of the hydrogen evolution reaction. It has been shown elsewhere (13, 19, 20) that if hydrogen evolution occurs via a coupled discharge-recombination mechanism, as is the case for iron, the following relations are obtained at low hydrogen coverages, Θ, for rate-controlling diffusion through the membrane

$$i_\infty \propto i_c^{1/2} \quad [1]$$

$$\frac{\partial \eta}{\partial \ln i_c} = -\frac{2RT}{\mathbf{F}} = -120 \text{ mV} \quad [2]$$

$$\frac{\partial \eta}{\partial \ln i_\infty} = \frac{\partial \eta}{\partial \ln \Theta} = -\frac{4RT}{\mathbf{F}} = -240 \text{ mV} \quad [3]$$

where η is the overpotential for hydrogen evolution, $\mathbf{F}$ the Faraday, R the gas constant, and T the temperature. In this investigation it was found that the steady-state permeation current is directly proportional to the square root of the charging current density (Fig. 3 and Table II) for Fe-implanted, He-implanted, and unimplanted iron membranes in accord with Eq. [1]. Furthermore, the Tafel slope (Fig. 4) is -122 ± 5 mV and $\partial\eta/\partial \ln i_\infty = -255 \pm 5$ mV (Fig. 5) in reasonably good agreement with Eq. [2] and [3], respectively. At higher cathodic overpotentials in 0.1*N* NaOH, corresponding to potentials more negative than -1.0V (SHE), there appears to be a change in the mechanism of hydrogen evolution for the unimplanted and Fe- and He-implanted membranes to slow discharge-fast electrochemical desorption, as indicated by an increase in $\partial\eta/\partial \ln i_\infty$, Fig. 5 (17, 20).

For Pt-implanted Fe, as modified by the 20 sec acid immersion the Tafel slope is -122 ± 5 mV and $\partial\eta/\partial \ln i_\infty = -255 \pm 5$ mV, and the steady-state permeation varies linearly through the origin with the square root of the charging current density. Thus, it is concluded that the mechanism of hydrogen evolution for Pt-implanted Fe is also coupled discharge-chemical desorption in both the 0.1*N* NaOH and 0.1*N* H_2SO_4 solutions within the overpotential range studied. The Tafel slope reported in the literature for hydrogen evolution on Pt surfaces is in two different ranges, either -110 to -130 mV in NaOH solutions (27-30) or about -30 mV in H_2SO_4 solutions (29) for ultraclean systems. Tafel slopes greater than -30 mV in H_2SO_4 have, however, been observed in the presence of impurities (31).

Conclusions

Implantation by the ion beam technique can be used to reduce hydrogen entry into iron. This was shown using the (model) system of Pt implanted into Fe. Pt is known to greatly reduce hydrogen entry into iron via a catalytic effect of the hydrogen evolution reaction when the Pt is present on the surface (4). The effectiveness of implanted Pt was greatly increased by controlled selective dissolution of iron which increased the surface concentration of Pt. There are no significant differences in the permeation behavior of unimplanted and He- or Fe-implanted Fe specimens.

The experimentally observed Tafel slope, the permeation-charging potential relationship, and the permeation-charging current relationship indicate a coupled discharge-recombination mechanism of hydrogen evolution on Fe-, He-, or Pt-implanted Fe surfaces in 0.1*N* NaOH or 0.1*N* H_2SO_4 charging solutions.

ABSTRACT

The kinetics of the Fe/Fe^{2+} electrode have previously been explained on the basis of either a consecutive or a catalytic charge transfer mechanism including adsorbed intermediates. In order to obtain more exact kinetic information, pulse and frequency response measurements on polycrystalline Fe in acidic sulfate solutions at $T = 298°K$ have been carried out. The stationary current density-potential curves already allow a preselection of the proposed reaction models. Dynamic parameters were calculated from the measured electrode impedance. It is shown that the existing reaction models do not agree with the measured impedance behavior. However, the experimental results can be explained assuming a potential-dependent relaxation of the surface combined with a catalyzed dissolution mechanism. The mechanism of the iron electrode in the active, transition, and prepassive ranges can be described by the reaction scheme

$$Fe \rightleftharpoons (FeOH)_{ads} \rightleftharpoons [Fe^*(FeOH)]_{ads} \rightarrow FeOH^+ + (FeOH)_{ads}$$

$$\downarrow\uparrow \qquad\qquad\qquad\qquad \downarrow\uparrow$$

$$Fe^{2+} \cdot aq.$$

$$\downarrow\uparrow$$

$$[Fe(OH)_2]_{ads} \rightleftharpoons \{Fe^*[Fe(OH)_2]\}_{ads} \rightarrow FeOH^+ + (FeOH)_{ads}$$

The kinetic data of the anodic iron dissolution in acid solutions free of oxygen and surface active substances have been interpreted for the active range assuming a consecutive mechanism [Bockris (1)] or a catalyzed mechanism [Heusler (2)] which depend on the substructure of the electrode, *i.e.*, the surface activity (3-5). The kinetics of the iron dissolution processes in the transition, prepassive, and passive

Key words: iron dissolution kinetics, impedance measurements, surface structure, surface relaxation.

layer formation ranges have been explained taking into account different intermediates, $[Fe(OH)_n]_{ads}$ with $n = 1, 2, 3$, which are potential-dependently adsorbed at the metal surface (6-11). The proposed mechanism of iron dissolution in the different ranges is shown in Table I.

Nonstationary methods have been used to further clarify the electrode reaction mechanism, *e.g.*, pulse techniques or sine wave measurements (12-15). Single pulse measurements have been performed on the iron electrode (2, 16, 17). The galvanostatic double pulse (GDP) method has been applied only on the consecutive charge transfer reaction of the Cu/Cu^{2+} electrode (18). Impedance measurements of iron dissolution have been carried out extensively by Epelboin *et al.* (19-28).

Transfer Function Measuring Methods

The dynamic electrochemical electrode properties, *i.e.*, the transfer function or the two-pole function,[1] can be determined by analyzing the system response which can be measured either directly as a function of time (time domain) or as a function of the frequencies of the applied test signal (frequency domain). The system responses in both domains are connected by the Laplace transformation. The analysis of the system response is often more difficult in the time domain than in the frequency domain (29). Moreover, a greater resolution of the system response in the frequency domain can be achieved. Therefore, in many cases measurements in the frequency domain are more precise.

For frequency response measurements on electrochemical systems a large frequency range from mHz up to MHz may be necessary and the correlation technique[2] appears to be the most convenient one (23, 29).

Neglecting transport phenomena, the measured impedance of the system, as well as that calculated for the reaction model, can be represented by a broken rational function

$$Z(s) = \frac{\sum_{i=0}^{m} p_i s^i}{\sum_{i=0}^{n} q_i s^i} = k \frac{\prod_{i=1}^{m} (s - s_{0i})}{\prod_{i=1}^{n} (s - s_{\infty i})} \quad [1]$$

where p_i and q_i are the coefficients, while s denotes the Laplace variable and s_{0i} and $s_{\infty i}$ represent the zeros and poles of this function.

The impedance Z corresponds to a two-pole function and, therefore, the relation

$$m - 1 \leq n \leq m + 1 \quad [2]$$

must be valid. Moreover, the two-pole function must be stable having no singularities under both potentiostatic and galvanostatic control (30). The two-pole function can be determined graphically or analytically. In the case of more complicated electrode properties, analytical methods are to be preferred (29).

Experimental

The investigations were carried out in the systems Fe(polycrystalline)/$x \cdot$M H_2SO_4 + $y \cdot$M Na_2SO_4 $(x + y = 0.5)$, $0.3 \leq pH \leq 6$ at $T = 298°K$ using conventional three-electrode techniques. Additionally, a platinum probe was connected in parallel with the reference electrode (Hg/Hg_2Cl_2,KCl sat.) by a capacitor in order to achieve a reference system of low resistance which is important for avoiding phase shifts at high frequencies.

[1] The transfer function generally represents the correlation between input and output variables. In the case of electrochemical systems, the interest is mostly directed to the correlation between the current flux and the voltage across the electrode/electrolyte interphase. This special type of transfer function is called the two-pole function.

[2] The correlation technique gives directly the real and imaginary parts of the transfer function calculated via the cross-correlation functions between the test signal and the system response.

Table I. Mechanism of anodic iron dissolution and passivation in electrolytes free of oxygen and surface active substances at $0 < pH < 6$

Catalyzed charge transfer	Noncatalyzed charge transfer	No.
Active range		
$Fe + H_2O \rightleftharpoons (FeOH)_{ads} + H^+ + e^-$		[1]
	$(FeOH)_{ads} \xrightarrow{rds} FeOH^+ + e^-$	[2]
$Fe + (FeOH)_{ads} \rightleftharpoons [Fe(FeOH)]_{ads}$		[3]
$[Fe(FeOH)]_{ads} + OH^- \xrightarrow{rds} FeOH^+ + (FeOH)_{ads} + 2e^-$		[4]
$FeOH^+ + H^+ \rightleftharpoons Fe^{2+} \cdot aq. + H_2O$		[5]
Transition range		
$(FeOH)_{ads} + H_2O \rightleftharpoons [Fe(OH)_2]_{ads} + H^+ + e^-$		[6]
Prepassive range		
$Fe + [Fe(OH)_2]_{ads} \xrightarrow{rds} FeOH^+ + (FeOH)_{ads} + e^-$		[7]
$[Fe(OH)_2]_{ads} + H_2O \rightleftharpoons Fe(OH)_3$ − oxide phase $+ H^+ + e^-$		[8]
Passive layer formation range		
$2Fe(OH)_3$ − oxide phase $\rightleftharpoons Fe_2O_3 + 3H_2O$		[9]
$[Fe(OH)_2]_{ads} + Fe_2O_3 \rightleftharpoons Fe_3O_4 + H_2O$		[10]

A rotating disk electrode was used as the working electrode, the rotational speed could be varied between $5 \cdot sec^{-1} \leq \nu \leq 160 \cdot sec^{-1}$. The polycrystalline, highly pure iron samples[3] were recrystallized under vacuum ($p < 10^{-8}$ bar) at $T = 1400°K$ for 2 hr. The electrode was then embedded in polyethylene holders with an epoxy resin. After polishing and cleaning with acetone, the electrode was dipped in 0.5M H_2SO_4 for 10 min. Prior to each experiment, the electrode was polarized anodically by a current density of $i = 70$ mA $\cdot$ cm^{-2} for 5 min in the measuring cell in order to provide a reproducible initial state of the electrode surface.

The electrolytes with constant ionic strength of $c_{SO_4^{2-}} = 0.5M$ were prepared of sulfuric acid,[4] sodium sulfate,[4] and bidistilled water. The system was maintained under hydrogen atmosphere.

The experiments were carried out under potentiostatic as well as under galvanostatic conditions using a Wenking potentiostat, Type PCA 72 L, and a Megaphysik multichannel pulse galvanostat system MPI-IM 400, respectively. A Solartron Frequency Response Analyser 1172 was applied for transfer locus measurements. The pulse responses were registered by a Tektronix storage oscilloscope, Type 549 with plug-in unit W.

In the transition range, the iron dissolution is characterized by nonmonotonous current density-potential curves (7-9). Therefore, only potentiostatic measurements can be performed in this range in order to get defined stationary conditions.

Further experimental details are published elsewhere (31).

Results

The basic requirements of nonstationary low signal measurements is the stability of operating points of the system under investigation. First information about the reaction kinetics can be obtained by analyzing the stationary current density-potential curves.

Stationary measurements.—The stationary current density-potential curves were registered point by point. Under galvanostatic control, the stationarity was assumed when the condition $|\Delta\epsilon/\Delta t| < 1$ mV $\cdot$ min^{-1} was fulfilled. Under potentiostatic control, a variation of the current less than 1% $\cdot$ min^{-1} and an asymptotic current-time transient were required.

[3] Marz grade iron (Materials Research Corporation).

[4] Suprapur grade (Merck).

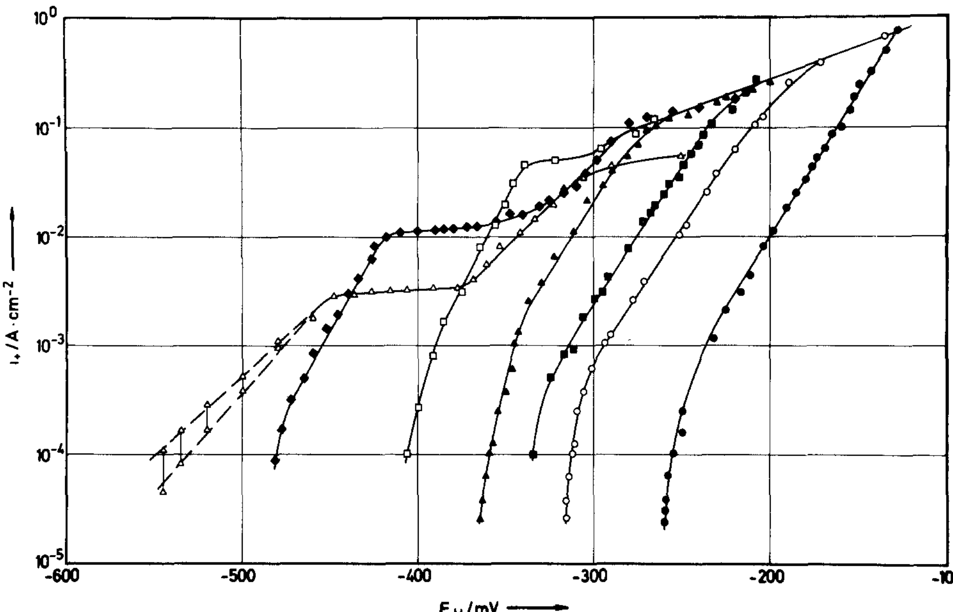

Fig. 1. Stationary anodic current density-potential curves of the systems Fe(polycrystalline, recrystallized)/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M); T = 298°K, galvanostatic and potentiostatic measurements. ν = 70 sec^{-1}: ●, pH = 0.3; ○, pH = 1.45; ■, pH = 2; ▲, pH = 2.9; □, pH = 4; ◆, pH = 5. ν = 70-150 sec^{-1}: △, pH = 6.

Longer waiting periods caused no significant changes of the stationary values. At higher pH values, the waiting time for stationarity in transition and prepassive ranges ($i > 10$ mA · cm^{-2}) was about 15 min.

Figure 1 shows the measured stationary current density-potential curves in the active, transition, and prepassive ranges. The given potentials are corrected for the ohmic drop, IR_Ω. The current density is related to the geometrical surface area.

In general, the rotational speed of the rotating disk electrode does not influence the anodic results (16, 17). Only at pH > 5.0 the current density in the active range decreased slightly with increasing rotational speed at constant electrode potential.

As can be seen from Fig. 1, the active range of iron dissolution at $0 < pH < 3$ is characterized by Tafel slopes of $b_+ = (\partial\epsilon/\partial \log i_+)_{a_i} = +40 \pm 2$ mV. The index a_i denotes constant activities of all species i, except $a_{Fe^{2+}}$ in the electrolyte. The iron dissolution kinetics, however, is independent of $a_{Fe^{2+}}$ (3). The standard deviation of the Tafel slopes was determined by averaging different current density-potential measurements at each constant pH value.

The pH dependence of the iron dissolution kinetics is characterized by the electrochemical reaction order

$$n_{+,pH} = \left(\frac{\partial \log i_+}{\partial pH}\right)_{\epsilon,a_j} \quad [3]$$

where the index a_j denotes constant activities of all species i except $a_{Fe^{2+}}$ and a_{H^+} in the electrolyte. It can be shown using the Jacobian representation of the partial derivatives that

$$n_{+,pH} = -\left(\frac{\partial \log i_+}{\partial \epsilon}\right)_{a_j,pH} \cdot \left(\frac{\partial \epsilon}{\partial pH}\right)_{i_+,a_j} = -\frac{1}{b_+} \cdot \left(\frac{\partial \epsilon}{\partial pH}\right)_{i_+,a_j} \quad [4]$$

Inserting the experimental results given in Fig. 2 and the measured Tafel slope of $b_+ = +40 \pm 2$ mV into Eq. [4], one obtains an electrochemical reaction order of $n_{+,pH} = 1.1 \pm 0.1$.

In contrast to earlier findings (7, 9), the transition range is characterized by a current density plateau I instead of the previously reported current density maximum I (7, 9-11). It can be shown that the current maximum I appears only under potentiodynamic polarization conditions using sweep rates $|d\epsilon/dt| \gtrsim 0.1$ mV · sec^{-1}. Obviously, the time constants of the reaction kinetics in the transition range are relatively high. The pH dependence of the current density plateau I (Fig. 3) was found to be

$$\left(\frac{\partial \log i_{+,pl\,I}}{\partial pH}\right)_{a_j} = -0.6 \pm 0.05 \quad [5]$$

The adjacent prepassive range is characterized by a Tafel slope of $b_+ = 60 \pm 8$ mV (Fig. 1) and a reaction order of $n_{+,pH} = 0 \pm 0.1$. This Tafel slope of about 60 mV contradicts previous results of $b_+ = +120$ mV (7-10). It can be shown clearly that this discrepancy is caused by the influence of the sweep rate on the anodic current density-potential measurements. A steady state of the iron electrode in the prepassive range can be achieved only at sweep rates $|d\epsilon/dt| \lesssim 0.1$ mV · sec^{-1}. However, this lower Tafel slope in the beginning of the prepassive range violates the reaction model given in Table I. In this model, the prepassive range is characterized by a dominating electrochemical equilibrium (step [8], Table I) and

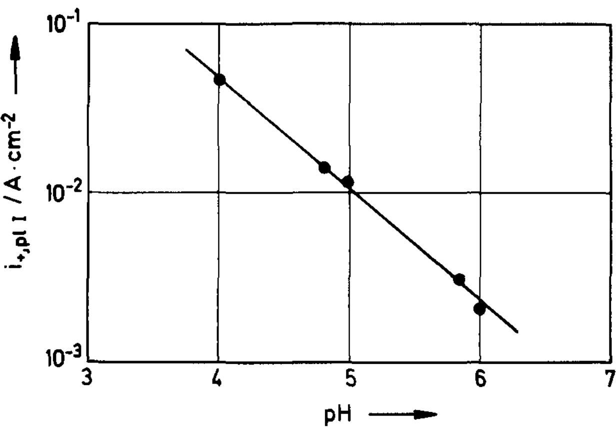

Fig. 3. pH dependence of the current density $i_{+,\mathrm{pl}\,\mathrm{I}}$ at plateau I. System: Fe/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M); T = 298°K; ν = 70 sec^{-1}.

by a rate-determining charge transfer reaction (step [7], Table I) which occur in parallel. The degree of coverage of the electrode surface with $[Fe(OH)_2]_{ads} \equiv \theta_2$ has been assumed to be nearly unity and constant. Under these conditions, the reaction model in Table I leads to a Tafel slope of $b_+ = 2.303RT/\alpha_7\mathbf{F}$ and an electrochemical reaction order $n_{+,\mathrm{pH}} = 0$ for the prepassive range (8-10).

Impedance measurements.—Frequency response measurements have been carried out in the frequency range $5 \cdot 10^{-3} \leq f \leq 10^4$ Hz. In order to get quantities independent of the geometrical surface area, a normalized and dimensionless impedance

$$Z_N = (Z_m - R_\Omega) \cdot \frac{I_s}{U_N} = R_N + jX_N \quad [6]$$

is used, where Z_m denotes the measured impedance, I_s is the stationary d-c current in the outer circuit, and the normalization voltage U_N is taken as 1 mV.

Normalized reaction impedances Z_N of the systems Fe(polycrystalline)/x · M H_2SO_4 + y · M Na_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M) are shown in Fig. 4-6 for the active, transition, and prepassive ranges. The impedance diagrams agree qualitatively with the results previously published by Epelboin *et al.* (19, 20, 22, 27, 28).

The steady-state value $Z_N(f = 0)$, which is identical with the polarization resistance R_{pN}, was calculated from the stationary current density-potential curves by

$$R_{pN} = R_p \cdot I_s/U_N \quad [7]$$

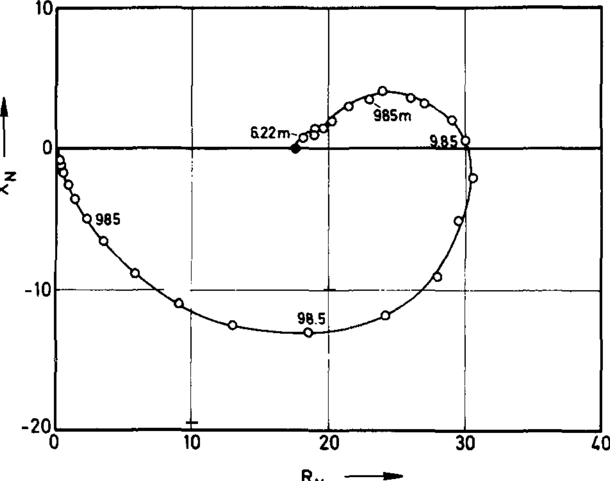
where

$$R_p \cdot I_s = \frac{d\epsilon}{dI_s} \cdot I_s = b_+ \cdot \frac{1}{2.303} \quad [8]$$

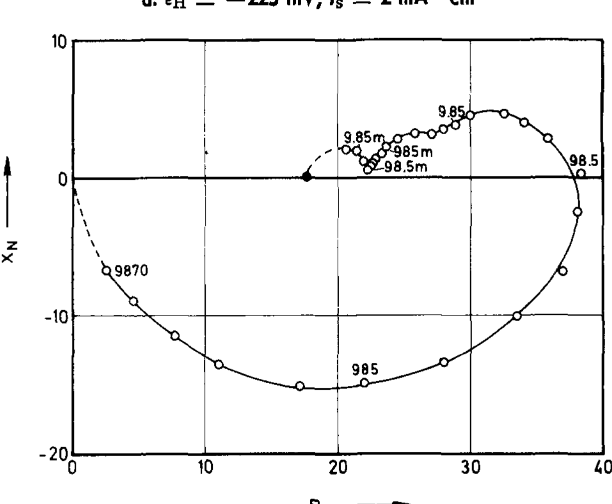
The transfer resistance R_t is defined as the real part of the impedance Z at infinite frequency after subtraction of the impedance arising from the double layer capacity C_D.

From the impedance diagrams, the following facts can be derived: (*i*) Several time constants exist in the inductive part. (*ii*) The capacitive part differs from a semicircle, *i.e.*, the frequency response in the capacitive half-plane is determined by more than one time constant. (*iii*) In the transition range, negative real parts of the electrode impedance were found. (*iv*) In the prepassive range, the extrapolation of the transfer locus $f \to 0$ yields a polarization resistance R_{pN} which corresponds to a Tafel slope of $b_+ = 60$ mV. This finding agrees well with the results of the stationary measurements.

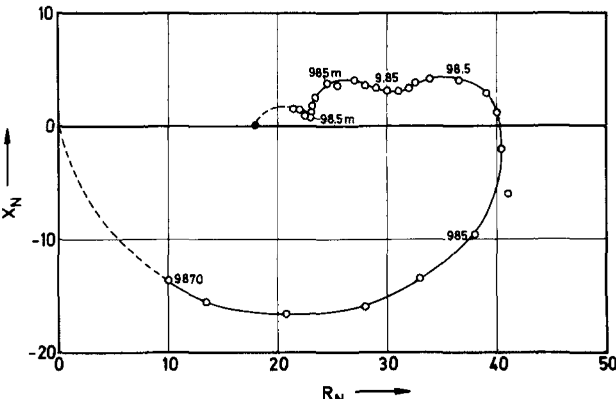
The broken rational function Eq. [1] under the restriction of Eq. [2] was fitted to the normalized impedance diagrams obtained for the iron dissolution in the active range at different pH values. A satisfactory fit for the degree $m/n = 4/5$ was obtained corresponding to the solid lines in Fig. 3. This result shows that one has to expect five time constants for the system studied in the active range. Two of these time constants determine the capacitive part of the transfer locus and three of them the inductive part. Obviously, one of the time constants in the capacitive part of the transfer locus represents the influence of the double layer capacity C_D.



a. ϵ_H = −225 mV; i_s = 2 mA · cm^{-2}



b. ϵ_H = −203 mV; i_s = 8 mA · cm^{-2}



c. ϵ_H = −160 mV; i_s = 100 mA · cm^{-2}

Fig. 4. Transfer loci of the electrode impedance in the active range of iron dissolution. System: Fe/0.5M H_2SO_4; pH = 0.3; T = 298°K; ν = 70 sec^{-1}; frequencies in Hz. ●, Stationary value Z ($f \to 0$) calculated from the Tafel slope.

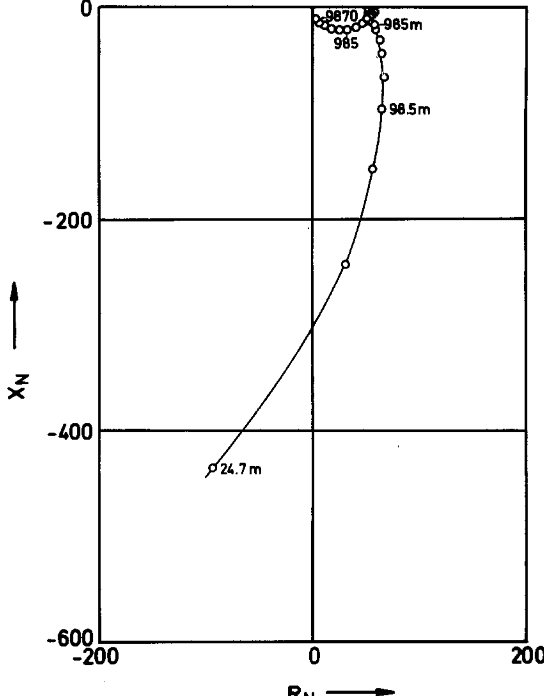


Fig. 5. Transfer locus of the electrode impedance in the transition range of iron dissolution. System: Fe/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5 M); pH = 5; T = 298°K; ν = 70 sec^{-1}; ϵ_H = −313 mV; i_s = 28 mA · cm^{-2}; frequencies in Hz.

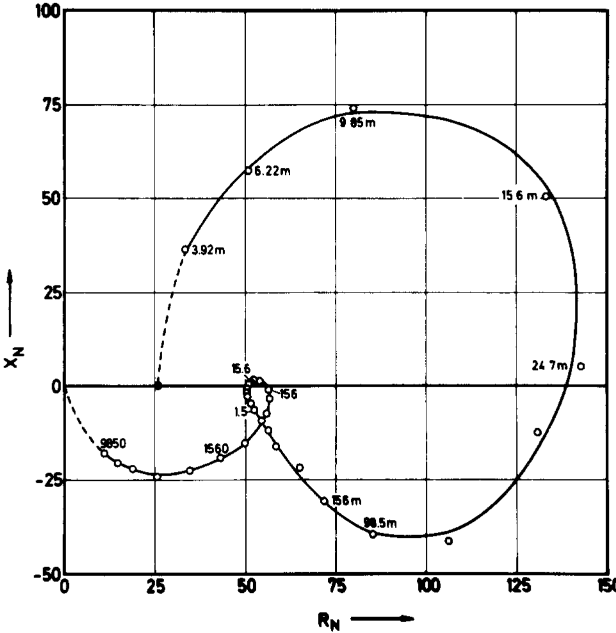

Fig. 6. Transfer locus of the electrode impedance in the 60 mV Tafel region of the prepassive range of iron dissolution. System: Fe/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M); pH = 5; T = 298°K; ν = 70 sec^{-1}; ϵ_H = −293 mV; i_s = 63 mA · cm^{-2}; frequencies in Hz. ●, Stationary value $Z(f \rightarrow 0)$; calculated from the Tafel slope.

Under the assumption that the double layer capacity is in parallel with the faradaic impedance Z_f, the values of C_D and $R_t \cdot I_s$ have been determined from the coefficients of the fitted broken rational function Eq. [1]) as well as by graphical analysis of the transfer loci after transformation of the impedance diagrams into the admittance plane (31). Both, C_D and R_t have been obtained additionally applying the GDP method (18).

Figures 7 and 8 show the results for the active dissolution of iron. At relatively low overvoltages, an apparent Tafel slope of

$$b_t = \left(\frac{\partial \epsilon}{\partial \log (R_t \cdot I_s)} \right)_{a_i} = 56 \pm 5 \text{ mV} \quad [9]$$

and a reaction order related to the pH value

$$n_{t,pH} = \left(\frac{\partial \log (R_t \cdot I_s)}{\partial pH} \right)_{\epsilon, a_j} = 0.81 \pm 0.05 \quad [10]$$

can be estimated from the results in Fig. 8. At relatively high overvoltages, R_tI_s becomes constant at about 30 ± 5 mV and the reaction order $n_{t,pH}$ reaches zero (Fig. 8).

Discussion

Kinetics with regard to previous models.—The experimental results of the iron dissolution in the active range are usually explained on the basis of the consecutive (Bockris) mechanism, corresponding to the reaction steps [1], [2], and [5] in Table I. Under the conditions (*i*) step [1] is in equilibrium, (*ii*) step [2] is the rate-determining one, and (*iii*) Langmuir adsorption behavior of the intermediate $(FeOH)_{ads}$ is valid at relatively low degree of coverage, a theoretical treatment of the consecutive mechanism yields a steady-state Tafel slope of $b_+ = 2.303RT/(1 + \alpha_2)F = +40$ mV at $\alpha_2 = 0.5$, $T = 298$°K, and an electrochemical reaction order of $n_{+,pH} = +1$ (32). These theoretical values agree well with the present data. For this mechanism, the theoretical frequency response of the electrode impedance must be capacitive in the whole frequency range (31, 33). However, this prediction is contradicted by the experimental inductive impedance characteristics of the iron electrode in the active range at lower frequencies [cf. Fig. 3, (19, 20, 22, 27, 28)].

Impedance measurements on active iron electrodes showing inductive parts were interpreted by Epelboin

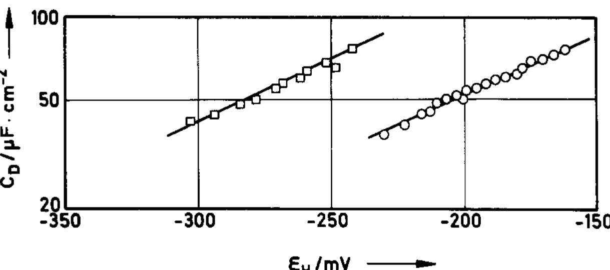

Fig. 7. Potential dependence of the double layer capacity as a function of pH. System: Fe/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M); T = 298°K; ν = 70 sec^{-1}. ○, pH = 0.3; □, pH = 2.

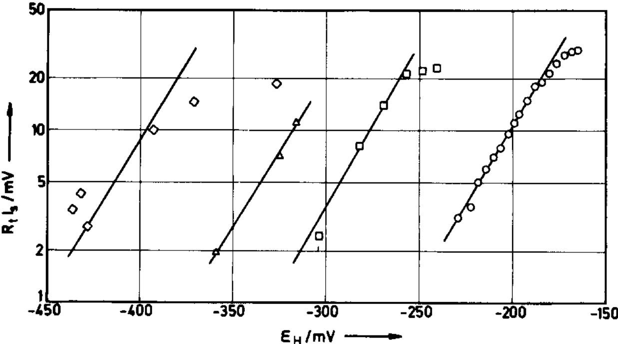

Fig. 8. Potential dependence of $R_t \cdot I_s$ as a function of pH. System: Fe/x · M Na_2SO_4 + y · M H_2SO_4 ($c_{SO_4^{2-}}$ = 0.5M); T = 298°K; ν = 70 sec^{-1}; ○, pH = 0.3; □, pH = 2; △, pH = 2.9; ◇, pH = 5.

et al. (22, 27, 28) using a modified consecutive Bockris mechanism. Their theoretical considerations are based on experimental steady state Tafel slopes of $b_+ = 63$ mV at low overvoltages and $b_+ = 220$ mV at high overvoltages with corresponding electrochemical reaction orders of $n_{+,pH} = 1$ and $n_{+,pH} = 0$, respectively. In the reaction model proposed, the reaction step [1] is assumed to be irreversible. This model is only able to explain anodic steady-state Tafel slopes of $b_+ \geqq 60$ mV at $T = 298°K$, leading to asymmetric charge transfer coefficients of $\alpha_1 = 0.96\text{-}0.99$ and $\alpha_2 = 0.18\text{-}0.27$, respectively. Obviously, the relatively high b_+ and α_1 values do not agree with the usual results and interpretations (3, 32-36).

Furthermore, because of the occurrence of capacitive reaction impedances, the disregard of all capacitive parts, as done by Epelboin *et al.* (22, 27, 28), seems rather doubtful.

Lorenz *et al.* (4, 5) had previously suggested iron dissolution to be caused by the simultaneous transfer reactions of the consecutive and the catalyzed mechanisms given in Table I. On the basis of this concept, the measured steady-state values $b_+ = 40$ mV and $n_{+,pH} = 1$ in the active range can only be explained by a dominating consecutive dissolution mechanism. However, a theoretical analysis of the corresponding impedance behavior (31) leads to the additional conditions $b_t = 60$ mV and $R_t \cdot I_s < 5.2$ mV. The experimental $R_t \cdot I_s$ values (Fig. 7) were much greater than 5.2 mV showing that the reaction cannot be described by a dominating Bockris mechanism only.

Consequently, all theoretical models including a consecutive Bockris mechanism are not appropriate to explain both the steady-state kinetic data and the dynamic electrode behavior.

Kinetics with regard to the surface state.—The existing reaction models have been based on the uniformity and potential independence of the electrode surface. However, it is well known that a polycrystalline metal surface is inhomogeneous and contains discontinuities such as grain boundaries, atomic step lines, etc. Such a surface is subdivided in different microregions with different electrochemical behavior depending on the crystal orientation, microroughness, and dislocation density. For this reason, the anodic metal dissolution process will take place preferentially at active surface sites. It has been demonstrated that kink sites are mainly responsible as active centers for the charge transfer process of metal ions (34, 37-47). Obviously, surface diffusion processes do not play an important role in the kinetics (40, 48). Kink sites are localized at monoatomic steps which can be produced by 2-D nucleation and growth processes as well as via screw dislocations. Emergency points of edge dislocations at the metal surface are inactive for the metal deposition processes, while they represent active centers for metal dissolution (49).

Recently, Harrison *et al.* (50, 51) assumed that structural surface effects have to be taken into account for explaining the time dependence of copper and gold electrode kinetics. Furthermore, morphological and electrochemical investigations on single crystal faces of iron electrodes showed a significant influence of the surface structure and the density of kink sites on the anodic dissolution process (44-47).

Consequently, a reaction model of the iron dissolution, the charge transfer of which is catalyzed by surface active Fe* centers, is proposed for the active, transition, and prepassive ranges. A relatively simple reaction scheme for a polycrystalline iron surface is given in Table II. Moreover, a time dependence, as well as a potential dependence, of the surface state may be assumed. This surface relaxation process will change both the number N of the adsorption sites and the number N^* of the active centers. The catalysts $[Fe^*(FeOH)]_{ads}$ and $\{Fe^*[Fe(OH)_2]\}_{ads}$ are assumed to be formed at N^* sites, only.

Table II. Modified mechanism of anodic iron dissolution

Reaction	No.
Active range	
$Fe + H_2O \rightleftharpoons (FeOH)_{ads} + H^+ + e^-$	[1]
$Fe^* + (FeOH)_{ads} \rightleftharpoons [Fe^*(FeOH)]_{ads}$	[3]
$[Fe^*(FeOH)]_{ads} + OH^- \xrightarrow{rds} FeOH^+ + (FeOH)_{ads} + 2e^-$	[4]
Transition range and the beginning of prepassive range†	
$(FeOH)_{ads} + H_2O \rightleftharpoons [Fe(OH)_2]_{ads} + H^+ + e^-$	[6]
$Fe^* + [Fe(OH)_2]_{ads} \rightleftharpoons \{Fe^*[Fe(OH)_2]\}_{ads}$	[7a]
$\{Fe^*[Fe(OH)_2]\}_{ads} \xrightarrow{rds} FeOH^+ + (FeOH)_{ads} + e^-$	[7b]
$FeOH^+ + H^+ \rightleftharpoons Fe^{++} \cdot aq. + H_2O$	[5]

† At higher overvoltages in the prepassive range, the increasing formation of $Fe(OH)_3$-oxide phase (Eq. [8] in Table I) causes the maximum II in the current density-potential curves (8-11). The present investigation does not regard this extended prepassive range.

Next, the following notations will be used

N_1 = number of adsorbed species $(FeOH)_{ads}$ [11]

N_2 = number of adsorbed species $[Fe(OH)_2]_{ads}$ [12]

N_{k1} = number of adsorbed species $[Fe^*(FeOH)]_{ads}$ [13]

N_{k2} = number of adsorbed species $\{Fe^*[Fe(OH)_2]\}_{ads}$ [14]

Clearly, the number of the free adsorption places on the electrode surface is given by $N\text{-}N_1\text{-}N_2\text{-}N_{k1}\text{-}N_{k2}$. Normalizing the different N values with respect to the corresponding equilibrium values, leads to

$$\frac{N}{N_o} \equiv \Phi \equiv \text{roughness coefficient} \quad [15]$$

$$\frac{N^*}{N_o^*} \equiv \Psi \equiv \text{active center coefficient} \quad [16]$$

$$\frac{N_i}{N_o} \equiv \theta_i \equiv \text{degree of coverage with } (FeOH)_{ads} \text{ or } [Fe(OH)_2]_{ads}, \text{ respectively} \quad [17]$$

$$\frac{N_{ki}}{N_o} \equiv \theta_{ki} \equiv \text{degree of coverage with } [Fe^*(FeOH)]_{ads} \text{ or } \{Fe^*[Fe(OH)_2]\}_{ads}, \text{ respectively} \quad [18]$$

The index o indicates the values at the equilibrium potential ϵ_o of the Fe/Fe^{2+} electrode.

Assuming (*i*) Langmuir adsorption behavior and (*ii*) the reverse reaction of the rate-determining steps [4] and [7b] in Table II to be negligible, the following reaction equations can be derived using the exchange flux densities, $v_{o,i}$ (cf. Table II)

$$v_1 = v_{o,1}\left\{\frac{\Phi - \theta_1 - \theta_{k1} - \theta_2 - \theta_{k2}}{1 - \theta_{10} - \theta_{k10} - \theta_{20} - \theta_{k20}} E_1 - \frac{\theta_1}{\theta_{10}} E_{-1}\right\} \quad [19]$$

$$v_3 = v_{o,3}\left\{\frac{\theta_1}{\theta_{10}}\Psi - \frac{\theta_{k1}}{\theta_{k10}}\right\} \quad [20]$$

$$v_4 = v_{o,4}\frac{\theta_{k1}}{\theta_{k10}} E_4 \quad [21]$$

$$v_6 = v_{o,6}\left\{\frac{\theta_1}{\theta_{10}} E_6 - \frac{\theta_2}{\theta_{20}} E_{-6}\right\} \quad [22]$$

$$v_{7a} = v_{o,7a}\left\{\frac{\theta_2}{\theta_{20}}\Psi - \frac{\theta_{k2}}{\theta_{k20}}\right\} \quad [23]$$

$$v_{7b} = v_{o,7b} \frac{\theta_{k2}}{\theta_{k20}} E_7 \quad [24]$$

with

$$E_i = \exp\left(\frac{z_i \alpha_i \mathbf{F}}{RT} \eta\right) \quad [25]$$

and

$$E_{-i} = \exp\left(\frac{-z_i(1-\alpha_i)\mathbf{F}}{RT} \eta\right) \quad [26]$$

where z_i = electrochemical valency and $\eta = \epsilon - \epsilon_o$.

The flux balances yield

$$N_o \frac{d\theta_1}{dt} = v_1 - v_3 + v_4 - v_6 + v_{7b} \quad [27]$$

$$N_o \frac{d\theta_{k1}}{dt} = v_3 - v_4 \quad [28]$$

$$N_o \frac{d\theta_2}{dt} = v_6 - v_{7a} \quad [29]$$

$$N_o \frac{d\theta_{k2}}{dt} = v_{7a} - v_{7b} \quad [30]$$

The surface functions Φ and Ψ are assumed to be simple exponential functions

$$\Phi = \exp\left(\frac{\alpha_\Phi \mathbf{F} \eta}{RT}\right) \quad [31]$$

$$\Psi = \exp\left(\frac{\alpha_\Psi \mathbf{F} \eta}{RT}\right) \quad [32]$$

where α_Φ and α_Ψ are formal parameters.

From Eq. [19-32], a general stationary current density-potential relation of the iron dissolution reaction in the active, transition, and prepassive ranges results

$$i_s = 2\mathbf{F}\Phi\Psi \frac{v_{o,4}E_4W_3 + v_{o,7b}E_7W_4}{\{(W_1K + \theta_{10})W_4 + \theta_{k10}\Psi\}W_3 + W_4(\theta_{20}W_2 + \theta_{k20}\Psi)} \quad [33]$$

where

$$K \equiv \exp\left(-\frac{\mathbf{F}}{RT}\eta\right) \quad [34]$$

$$W_1 \equiv 1 - \theta_{10} - \theta_{20} - \theta_{k10} - \theta_{k20} \quad [35]$$

$$W_2 \equiv 1 + \frac{v_{o,7b}}{v_{o,7a}} E_7 \quad [36]$$

$$W_3 \equiv K \cdot W_2 + \frac{v_{o,7b}}{v_{o,6}} \Psi \exp\left[\frac{(\alpha_7 - \alpha_6)\mathbf{F}}{RT}\eta\right] \quad [37]$$

$$W_4 \equiv 1 + \frac{v_{o,4}}{v_{o,3}} E_4 \quad [38]$$

From the Faraday admittance only, the general relation

$$R_t \cdot I_s = \frac{RT}{\mathbf{F}} \cdot \frac{2\Psi[v_{o,4}E_4W_3 - v_{o,7b}E_7W_4]}{[v_{o,1}E_{-1}W_4 + 4v_{o,4}\alpha_4E_4\Psi]W_3 + v_{o,6}\left[E_{-6} \cdot W_2 + (\alpha_6 + \alpha_7)\frac{v_{o,7b}}{v_{o,6}}\Psi E_7\right]} \quad [39]$$

can be calculated (31).

Restricting the iron dissolution reaction to the active range and assuming

$$v_{o,3} << v_{o,4}E_4 \quad [40]$$

one obtains the steady-state current density-potential relation

$$i_s = 2\mathbf{F}\Phi E_1 \cdot \frac{v_{o,4}E_4\Psi}{[(1 - \theta_{10} - \theta_{k10})E_{-1} + \theta_{10}E_1]\frac{v_{o,4}}{v_{o,3}}E_4 + \theta_{k10}E_1\Psi} \quad [41]$$

and

$$R_t \cdot I_s = \frac{RT}{\mathbf{F}} \cdot \frac{2\Psi}{\frac{v_{o,1}}{v_{o,3}}E_{-1} + 4\alpha_4\Psi} \quad [42]$$

Equations [41] and [42] can be compared with the experimental results of both the steady-state polarization measurements ($b_+ = +40$ mV and $n_{+,pH} \simeq 1.1$) and the impedance measurements ($b_t = 56$ mV and $n_{t,pH} = 0.81$ at low overvoltages as well as $R_t \cdot I_s \simeq 30$ mV and $n_{t,pH} \approx 0$ at high overvoltages) in the active range of iron dissolution. From this comparison result the values $\alpha_1 = 0.4$, $\alpha_4 = 0.4$, $\alpha_\Psi = 0.5$, and $\alpha_\Phi = 0$ [5]). A complete correspondence of all experimental results with the model proposed can be achieved for this set of parameters only. These adjusted α parameters seems to be more reasonable than those derived from the model by Epelboin *et al.* (22, 27, 28) as mentioned above. Therefore, the presented model is suitable for the interpretation of the steady-state as well as the dynamic electrode behavior for iron dissolution in the active range.

Furthermore, a fitting of the relation [33] to the steady-state current density-potential curve in the active, transition, and prepassive ranges at $0.3 \leq pH \leq 6$ was performed assuming (*i*) $v_{o,3} << v_{o,4}E_4$, (*ii*) $v_{o,7a} >> v_{o,7b}E_7$, and (*iii*) $\epsilon_{o,Fe/Fe^{2+}} = -560$ mV [6] and using the adjusted α values for the active range.

The computer simulation is demonstrated in Fig. 9. The simulation results agree well with the measured current density-potential curves in the overall potential range depending on the pH of the electrolyte as can be seen by comparing Fig. 1 and 9. At pH > 5, the measured Tafel slope in the active range of iron dissolution increases due to lateral interactions between the adsorbed intermediates at higher degrees of coverages, where the conditions for a simple Langmuir behavior are no longer valid (32). The general agreement between the simulated and the measured current density-potential curves shows that the model proposed does not contradict the experimental findings. It should be mentioned, however, that the computer simulation was carried out using several fitting parameters included in the kinetic Eq. [19-26]. Therefore, the agreement between simulation and experiment is only of qualitative nature.

A relaxation behavior of the active centers can be described by

$$\Delta\Psi(s) = \Delta\epsilon(s) \frac{\left(\frac{\partial\Psi}{\partial\epsilon}\right)}{1 + s \cdot \tau} \quad [43]$$

where τ represents the relaxation time constant.

[5] $\alpha_\Psi = 0$ implies the potential independence of the surface roughness.

[6] Assuming $a_{Fe^{2+}} \simeq 10^{-7}$ in the electrolyte.

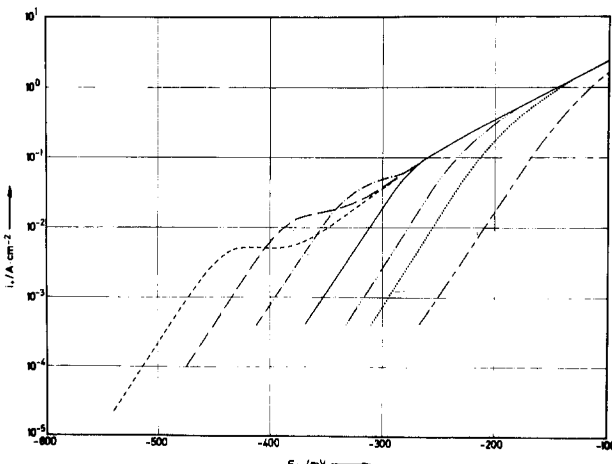

Fig. 9. Simulated current density-potential curves of anodic iron dissolution. —●— pH = 0.3; . . . . pH = 1.45; —. . .— pH = 2; ——— pH = 2.9; —·—·— pH = 4; – – – – – pH = 5; ‐‐‐‐‐‐‐ pH = 6.

For the reaction model proposed in Table II, the normalized impedance is a function of many variables

$$Z_{fN} = Z_{fN}\left(\eta, \alpha_1, \alpha_4, \alpha_\Psi, \frac{v_{o,4}}{v_{o,3}}, \theta_{10}, \theta_{k10}, \frac{v_{o,3}}{v_{o,1}}, \frac{N_o}{v_{o,3}}, \tau\right) \quad [44]$$

The values of α_1, α_4, α_Ψ, $v_{o,3}$, $v_{o,4}$, θ_{10}, and θ_{k10}, estimated above, and $v_{o,3}/v_{o,1} = 10^{-7}$, obtained by the analysis of $R_t \cdot I_s$, can be used for an impedance simulation in the active range of iron dissolution. Assuming $N_o/v_{o,3} = 10^8$ sec and $\tau = 1$ sec, the simulated transfer loci of the Faraday impedance are shown in Fig. 10 as a function of the overpotential $\eta = \epsilon - \epsilon_{o,Fe/Fe^{2+}}$.

This simple model of a surface relaxation and the proposed reaction mechanism given in Table II yield a Faradaic impedance with two time constants in the inductive region of the transfer locus and one time constant in the capacitive one. Taking into account the double layer capacity, the simulated curves in Fig. 10 are in reasonable agreement with the measured curves in Fig. 4. The additionally observed fifth time constant may be caused by cosorption phenomena and/or by surface nucleation and growth processes. However, a more precise analysis of such a complex dynamic electrode behavior requires the use of single crystal electrode surfaces.

Recently, Heusler and Allgaier (44-47) carried out electrochemical measurements on iron single crystal surfaces, assuming a catalyzed iron dissolution mechanism which is very similar to that in Table II. However, in order to explain the observed steady-state kinetic data $b_+ = 30$ mV and $n_{+,pH} \approx 2$ for the iron dissolution in the active range, the surface concentration of the kink sites was postulated by a different potential dependence of $\Psi = \exp(F\eta/RT)$. The deviations of the present experimental results and the modified theoretical assumption in Eq. [32] may be explained by a different crystal imperfection density of the electrode material used (3-5, 44-47). The kink sites at the iron surface are assumed to be preferentially covered by adsorbed OH^- ions which arise in acid solutions by deprotonation of adsorbed water dipoles (3). Thus, an energetically nonfavored two-electron charge transfer process starting from such covered kink sites seems to be possible in the active range of iron dissolution (52). On this basis, the electrochemical reaction order related to the bulk pH reflects the degree of "stabilization" of the kink site density at the electrode surface which may depend on the crystal imperfection density of the bulk metal.

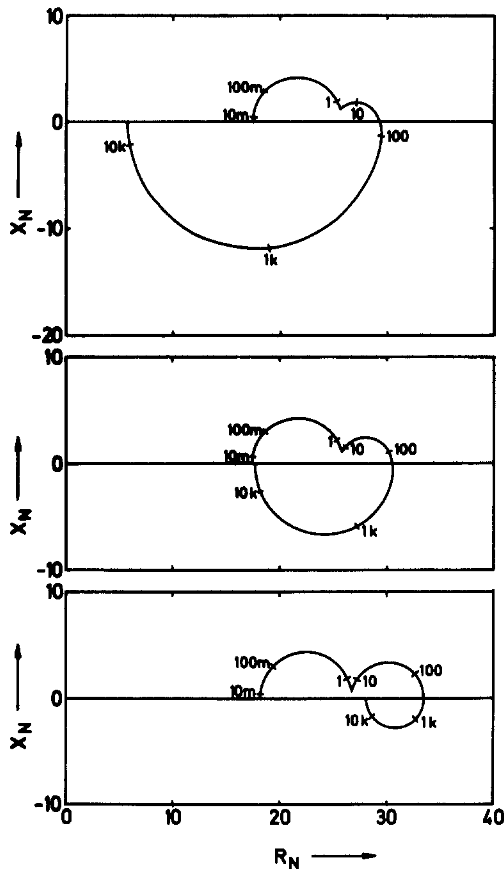

Fig. 10. Simulated transfer loci of the Faraday impedance of anodic iron dissolution (frequencies in Hz). (a, top) η = 330 mV; (b, center) η = 370 mV; (c, bottom) η = 410 mV (values of parameters cf. text).

Conclusions

The impedance measurements of the anodic iron dissolution reaction show clearly that the electrode behavior is determined not only by charge transfer steps including different adsorbed intermediates, but also by the influences of electrocrystallization steps and surface relaxation phenomena. The number of kink sites, which are responsible for the catalyzed dissolution reaction, were found to be strongly dependent on the electrode potential. Moreover, the time behavior of the electrode kinetics at low frequencies can be explained assuming surface relaxation processes. Both effects produce the observed impedance characteristics.

So far, the kinetics of cathodic metal deposition, as well as anodic metal dissolution of polycrystalline metal substrates containing a relatively high density of crystal imperfections, has been interpreted by charge transfer mechanisms only, disregarding electrocrystallization and surface relaxation processes as rate-determining steps. The present investigation shows, however, that these assumptions do not hold in the system studied. At this stage of the investigations, a reconsideration of the theory of polycrystalline Me/Me^{z+}-electrode kinetics with regard to electrocrystallization and surface relaxation processes seems to be necessary.

ABSTRACT

The Pb-H_2O-Cl Pourbaix diagram was investigated by examining potentiostatically oxidized lead samples using Raman and infrared spectroscopy. The surface films formed in 0.1M HCl solution were those predicted by the potential-*p*H diagram. In neutral and basic solutions, the film compositions were not as predicted by thermodynamic calculations, although potentiostatic results agreed very well with potentiodynamic polarization curves. Two polymorphs of PbO were found at different potentials in *p*H7 solutions, the orthorhombic form at low potentials and the tetragonal form above +0.18V *vs.* NHE. Infrared spectra gave indications that orthorhombic PbO is formed by deposition from solution while tetragonal PbO forms from the reaction of water with the metallic lead surface.

Laser Raman spectroscopy is an effective technique for analysis of aqueous corrosion product films on metal surfaces. It can identify insoluble aqueous corrosion products *in situ*, without removing a sample from its corrosive environment (1).

Raman spectra of relatively thin surface films (50Å) on metals can be observed (2). Since water is a very weak Raman scatterer, there is little difference between spectra of dry samples and of those immersed in a reactive aqueous solution (1, 3). Metal samples can be examined undisturbed in an electrochemical cell while oxidation proceeds under controlled conditions in different regions of a Pourbaix diagram. *In situ* Raman spectroscopy, in combination with the complementary and more sensitive technique, infrared reflection-absorption spectroscopy, can unambiguously identify insoluble films formed at specific conditions of potential and *p*H.

A previous report discussed investigations of the Pourbaix diagram for the Pb-H_2O system (1). The present report describes spectroscopic results from exposures of lead under similar conditions with 0.1M chloride ions added to the solutions in order to identify the effect of the chloride ion on lead oxide surface films.

Experimental

Raman spectra were recorded with a Spex Industries Model 1401 double monochromator using a photon counting detection system. A Coherent Radiation Laboratories Model CR-3 argon ion laser was used as the excitation source. Both the 488.0 and 514.5 nm wavelength laser lines were used and the power at the sample was approximately 500 mW.

Infrared reflection-absorption spectra were obtained with a Wilks Scientific Corporation Model 9 multiple specular reflection attachment in both the sample and reference beams of a Perkin-Elmer Model 521 infrared spectrophotometer equipped with a grating polarizer. The reflection apparatus was adjusted to give 2-4 reflections and a 65° angle of incidence of the infrared beam. Details of the exposure apparatus and instrumentation used in this research are contained in a previous report (1).

* Electrochemical Society Active Member.
Key words: spectroscopy, corrosion, films.

Lead foil (1.6 mm thick) supplied by Alfa Products, Incorporated, at greater than 99.9% purity was used for the investigation. It was cut into 2.8 × 5.7 cm rectangles to fit the sample holder of the electrochemical cell. This size was also required for the infrared reflection attachment. Prior to placing a lead sample in solution, it was immersed in warm, concentrated ammonium acetate solution for 5 min to dissolve the outer layer, leaving a clean, silvery surface. The clean sample was washed with distilled water and immediately placed in the exposure solution.

The solutions were sparged with dry nitrogen for 30 min before and throughout the electrochemical exposures. The potential of the working electrode, lead, was held constant relative to the saturated calomel reference electrode by a Wenking Model LT73 potentiostat for periods ranging from 1 to 24 hr. Upon completion of an exposure period, an *in situ* Raman spectrum was recorded. The sample was then removed from the cell, washed thoroughly with distilled water, and allowed to dry in air. The dry sample was returned to the Raman spectrometer for examination and then analyzed by the infrared spectrophotometer.

The solutions used were made from reagent grade compounds. The acid solution was 0.1M HCl. The *p*H7 buffer was KH_2PO_4-NaOH solution and that for *p*H10 was a $NaHCO_3$-NaOH mixture, both with KCl added to make the solution 0.1M in Cl^-. Buffer solutions were desired to maintain *p*H constant throughout periods of exposure as long as 24 hr, but no suitable buffer was available in the strongly acidic region.

Results and Discussion

The Pourbaix diagram for the Pb-H_2O-Cl system was calculated in the manner used by Appelt (4) but employing more recent thermodynamic data for some species (5). The newer free energy values used in the calculations are given in Table I. The positions of equilibria between species on the diagram depend strongly on the chloride concentration. A concentration of 0.1M was chosen for the exposures as a reasonable ionic concentration which should affect oxide film formation. The 0.1M Cl^- concentration was used in construction of the potential-*p*H diagram shown in Fig. 1.

In order to provide an experimental basis for choosing exposure potentials, as well as the theoretical,

Table I. Revised free energy values used to calculate Pourbaix diagram

Substance	NBS (5)	$\Delta G_f°$ (cal/mole) Used by Appelt (5)
OH^-	−37,594	−37,595
Cl^-	−31.372	−31,350
$PbCl_2$	−75,080	−75,040
$3PbO \cdot PbCl_2$	−224,686	−225,000

thermodynamic basis (the Pourbaix diagram), potentiodynamic polarization curves were recorded for lead in the three solutions selected for exposures. The polarization curves were run with a slowly changing potential, 40 mV/min, to allow the formation of a relatively thick oxide film, as would be encountered in potentiostatic oxidation.

It can be seen from the polarization curves, Fig. 2, that there is a definite relation between these curves and the Pourbaix diagram. The lower oxidative wave occurs at the approximate potential of the predicted $Pb/PbCl_2$ or $Pb/3PbO \cdot PbCl_2$ transitions and the wave at +0.96V (*vs.* NHE) in *p*H10 corresponds roughly to the $3PbO \cdot PbCl_2/PbO_2$ transition. The Pourbaix diagram offers no reason for the waves found at +0.17V in *p*H7 or at −0.07V in *p*H10, however.

Potentials to be used for lead exposures were chosen so that at least one was located in each region of the theoretical Pourbaix diagram and in all potential regions where the polarization curves indicated the possible formation of different species. The exposure conditions selected and the resulting spectra obtained from these potentiostatic oxidations are summarized in Table II. The current densities listed are those recorded after current became steady.

*p*H1 *exposures.*—In 0.1M HCl solution, lead is stable at low potentials while it is oxidized to $PbCl_2$ at higher potentials (3, 6). The Raman spectra of lead oxidized at potentials of +0.14V and higher indicated the presence of a $PbCl_2$ surface layer as shown in Fig. 3. The spectrum of the surface film is identical to that of a powder sample of pure $PbCl_2$ with bands at 62, 88, 126, 156, and 178 cm^{-1} (7, 8). No infrared spectra of these samples were obtained because lead chloride has no absorption bands in the infrared region examined by the spectrophotometer, 1500-250 cm^{-1} (9). Current densities for these samples were extremely high and the lead quickly became covered with a light gray crystalline coating.

In the region where immunity is predicted, net current flow was in the reducing direction and samples remained clean in appearance. *In situ* Raman spectra gave no indication of film formation but upon drying both Raman and infrared spectra indicated the presence of orthorhombic PbO on the lead surface. It is unlikely that the PbO was formed by oxidation of the lead under generally reducing conditions, but it is probably the result of dissolved lead being re-

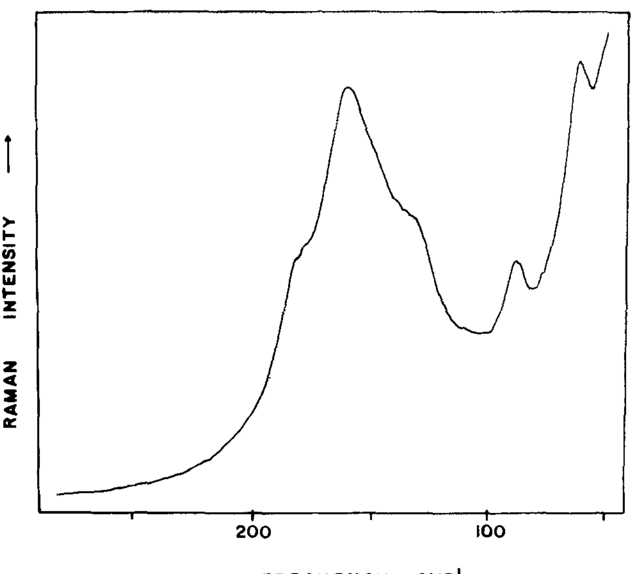

Fig. 3. Raman spectrum of the surface film on lead exposed to 0.1M HCl at +0.69V vs. SHE for 2.5 hr.

deposited from the solution as the oxide. It has been suggested (10) that orthorhombic PbO is formed from the plumbous ion by the reaction

$$Pb^{++} + H_2O \rightarrow PbO + 2H^+ \quad [1]$$

Due to the solubility of lead in 1.0M hydrochloric acid, sufficient quantities of Pb^{++} are present to form orthorhombic PbO films on lead undergoing exposure for several hours.

In the potential region where $PbCl_2$ was formed, a gray coating was deposited on the platinum cathode. After drying, the material gave the Raman spectrum of orthorhombic PbO. Apparently the oxide on the auxiliary electrode was formed by the same dissolution-deposition mechanism as that found on the working electrode.

Raman spectra of the dried cathode coating were recorded in two ways: as a powder in a glass capillary tube, or pressed into a KBr pellet. As shown in Fig. 4, the spectra are slightly different for the different sample preparation techniques. While both are spectra of orthorhombic PbO, the pellet spectrum shows impurity bands at 84, 149, and 344 cm^{-1}, the three strong bands of tetragonal PbO, litharge. The same results were obtained with spectra of reagent grade orthorhombic PbO. The grinding required to make a pellet transforms some of the orthorhombic PbO to the lower energy, tetragonal form. The crystal structures of the two oxides are very similar (11) and at room temperature the tetragonal structure is thermodynamically stable. Orthorhombic PbO is known to be stabilized by the presence of small quantities of various impurity anions (12), which allow it to remain indefinitely without reverting to the tetragonal structure. It is likely the the presence of chloride or some other ion in the solution stabilizes orthorhombic PbO so that it can remain in that form until intensive grinding brings about the transformation.

pH7 exposures.—According to the Pourbaix diagram in Fig. 1, controlled potential oxidations of lead in a pH7, 0.1M chloride solution should show immunity at potentials below −0.26V *vs.* NHE, formation of $3PbO \cdot PbCl_2$ between −0.26V and +0.75V, and formation of PbO_2 at higher potentials. The predicted compounds were not found experimentally.

In the region where immunity is predicted, *i.e.*, below −0.26V, the Pourbaix diagram, polarization curve, and spectroscopic results all agree. Potentiostatic exposure resulted in a reducing current, the sample remained shiny and silver in color, and no infrared or Raman bands could be observed.

Above the potential where Pb is the stable species, *i.e.*, −0.34V according to the polarization curve of Fig. 2, an insoluble oxidation product film was formed. Current flow, although small, was in the oxidizing direction. The sample surface darkened and, after a few hours, became dull gray in color. *In situ* Raman spectra and infrared reflection spectra of sample surfaces indicated that, at potentials between −0.11V and +0.18V, orthorhombic PbO was formed. At potentials above +0.18V, the film consists entirely of tetragonal PbO, whereas exposures at +0.18V showed both types present, as spectra show in Fig. 5. There was no difficulty in identifying which PbO polymorph was present. While the structures are similar, infrared and Raman spectra of the two polymorphs are markedly different (13, 14).

We have no explanation why the two types of PbO should be found at different potentials. The tetragonal form is thermodynamically favored under all conditions at room temperature. It is likely that the weak wave at approximately +0.16V on the polarization curve indicates a PbO (0) to PbO (+) transition, but such a transition is not reflected in the Pourbaix diagram which is based solely on thermodynamic equilibria.

Infrared spectra indicate that the orthorhombic PbO films may be formed by deposition from the solution. Reflection spectra of orthorhombic PbO films recorded using two different polarizations of the infrared beam were very similar, differing only in intensity (15). However, spectra of tetragonal PbO films had differing

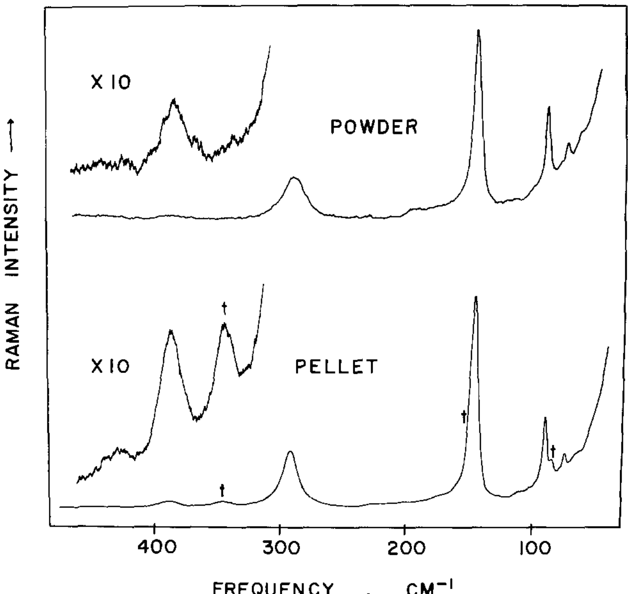

Fig. 4. Raman spectra of dried material from the Pt cathode after lead exposure at +1.09V in 0.1M HCl for 17 hr. Bands marked "t" are due to tetragonal PbO.

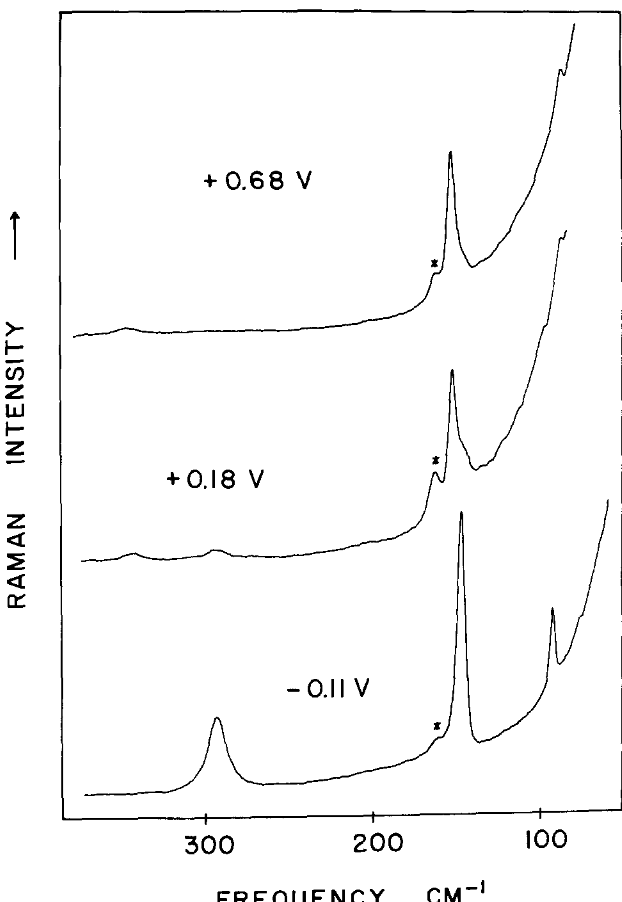

Fig. 5. *In situ* Raman spectra of lead surfaces exposed to pH 7, 0.1M chloride solutions for 18 hr at 0.68V, +0.18V, and −0.11V vs. SHE. The spectra indicate tetragonal, tetragonal plus orthorhombic, and orthorhombic PbO films, respectively. The feature marked with an asterisk is a grating ghost.

relative peak heights depending on polarization. This is shown in Fig. 6. This indicates that, while orientation of orthorhombic PbO crystals is probably random, there is probably some long-range order to the tetragonal films. Long-range order may be expected if the oxide is formed directly on the lead surface by the reaction

$$Pb + H_2O \rightarrow PbO + 2H^+ + 2e^- \quad [2]$$

Thus the tetragonal PbO layer may be aligned with the grain structure of the underlying metal while orthorhombic PbO, formed by a dissolution-deposition route, is random in orientation.

The effect of chloride ions was investigated by conducting exposures at −0.01V in pH7 solutions of different KCl concentrations: 0.01M and 0.1M. In 0.01M Cl^- solution, the oxidation product detected was tetragonal PbO, the same compound observed in nil chloride exposures (1). In 0.1M Cl^- orthorhombic PbO was formed. These results indicate that it is indeed the chloride present in solution which allows the formation of the thermodynamically unstable orthorhombic PbO layer.

pH10 exposures.—According to the Pourbaix diagram the results of potentiostatic exposures should be the same in pH10 solutions as in pH7 but, experimentally, they are not. The differences are due, in part, to the composition of the pH10 buffer used. They are also due to the behavior of soluble lead species in basic solutions.

The pH10 buffer, a bicarbonate solution, gave slightly different results from those predicted in the immunity region. As in nil chloride exposures (1), potentials in the region of Pb stability in the potential-pH diagram, but above −0.42V, gave oxidizing currents and a thin film of basic lead carbonate. The oxidation wave at −0.35V apparently corresponds to the Pb to $(PbCO_3)_2 \cdot Pb(OH)_2$ transition.

At potentials higher than the carbonate region, tetragonal PbO was found, between −0.07V and +0.96V. No trace of the orthorhombic form was detected. The dissolved lead species, Pb^{++} and $HPbO_2^-$, are in equilibrium at a pH of 9.34 (16). In more basic solutions only $HPbO_2^-$ is present, the Pb^{++} needed to make orthorhombic PbO according to the mechanism of reaction [1] is not present.

Although the transition to a higher oxidation state predicted by the Pourbaix diagram would give PbO_2, none could be detected. Instead a thick, nonprotective film of Pb_3O_4 was formed at potentials above the +0.96V wave. The Raman spectrum of this compound has not previously been reported but the composition of the film was confirmed by comparison of its Raman spectrum with that of the pure compound, as shown in Fig. 7, and by its infrared spectrum which agrees with a previously reported infrared spectrum of Pb_3O_4 (17).

Conclusions

In situ Raman spectroscopy and infrared reflection-absorption spectroscopy are excellent methods for the experimental investigation of Pourbaix diagrams. Examining two different potential-pH diagrams, we have found considerable difference in the oxidation of lead between nil chloride and 0.1M chloride solutions. Orthorhombic PbO and Pb_3O_4 were formed only in the presence of chlorides. The relationship between the tetragonal and orthorhombic PbO polymorphs is not well understood. Some potentials and chloride concentrations result in formation of one type while other potentials or concentrations give the other.

The experimental results of potentiostatic oxidations agree very well with slow potentiodynamic polarization curves but only partially with the calculated Pourbaix diagram. The major difference is that, where $3PbO \cdot PbCl_2$ is predicted, PbO was found. The compound $3PbO \cdot PbCl_2$, which probably exists as $3Pb(OH)_2 \cdot PbCl_2$ or $(Pb_8(OH)_{12})_n\ Cl_{4n}$, has a somewhat different spectrum (3) and should have been easily detected. In calculating the regions of the diagram, the presence of dissolved substances other than lead or chloride species was not considered. The presence of the buffer solutions may account for the discrepancies between experimental results and those predicted by the Pourbaix diagram. In 1.0M HCl, a simpler solution where no unaccounted for compounds were present, the Pourbaix diagram, polarization curve, and potentiostatic exposures all agreed.

Automatic Corrosion Rate Monitoring of Metals in Solution

Lindsay F. G. Williams

Materials Research Laboratories, Department of Defence, Ascot Vale, Victoria, 3032, Australia

ABSTRACT

The paper describes a versatile computerized method for automatic corrosion rate monitoring of metals in solution. Potentiostatic pulses of varying amplitude are applied to the metal and the current sampled after the initial decay has finished. These data are then computer fitted to the general equation for corrosion of metals in solution and the corrosion current calculated together with the anodic and cathodic Tafel parameters. The corrosion of zinc in an aerated ethylenediaminetetra-acetic acid solution at a pH of 8.5 has been used to demonstrate the method.

Previously, the corrosion rate of metals in solution has been monitored using potentiostatic pulse methods such as those described recently (1-3). The advances in microcomputer technology have enabled the economic extension of computer methods to the control of the potentiostat and data acquisition. This, together with computer fitting methods of calculating corrosion rates (4-6), opens up the possibility of automated corrosion rate measurements.

This paper describes a microcomputer system for automating electrochemical corrosion rate measurements. The system is fitted with two digital to analogue converters and one analogue to digital converter, and is programmed to produce a polarization curve around the corrosion potential and then fit the data to the equation originally derived by Wagner and Traud (7). The curve fitting programs are similar to those published by Mansfeld (4) and yield both the Tafel parameters and the corrosion current.

The corrosion of zinc in an ethylenediaminetetraacetic acid solution at a pH of 8.5 was chosen to demonstrate the computerized method for two reasons. The cathodic process is diffusion-controlled oxygen reduction as confirmed by rotating disk studies (8) and the current response to short duration potentiostatic pulses is ideally suited to these experiments (1).

Key words: corrosion, zinc, nonlinear polarization, microcomputer.

Experimental

Computerized system.—A block diagram of the system is shown in Fig. 1. The microcomputer was an Intel Microdevelopment system fitted with 32 kbits of memory, and an Input-Output Board (SPC 732) with one twelve bit analogue to digital (A/D) and two twelve bit digital to analogue (D/A) converters. The other periferals were an Intel Double Density Disc system, a Tektronix Oscilloscope, a Princeton Applied Research Model 174 Polarographic Analyzer (PAR 174), and a Teletype Model 43. The output from the

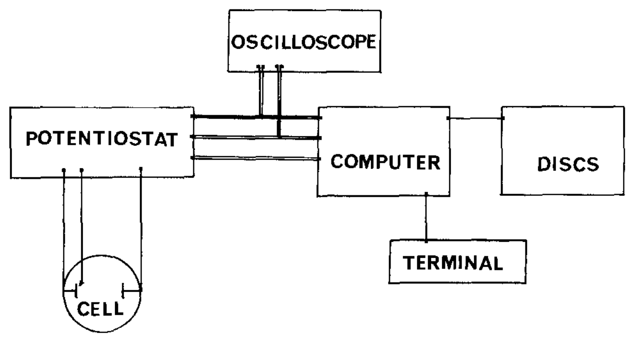

Fig. 1. Schematic diagram of the computerized system

D/A converters was reduced to ±50 mV and fed into the d-c external input on the PAR 174 while the current output on the PAR 174 was read by the A/D converter every 2 msec. The converters were calibrated according to the manual prior to use. After roughly setting the potentiostat at the corrosion potential, one of the D/A converters was used to adjust the current to as close as possible to zero. The second converter was then used to apply the pulses.

To check the system a dummy circuit consisting of a 100 μF capacitor across a 47Ω resistor in series with a further 100Ω resistor was connected across the working electrode terminal and both the auxiliary and reference terminals of the PAR 174. The current response to pulses of ±2, ±4 etc. mV can be seen in the oscilloscope traces in Fig. 2 and gave the expected values within 1%.

Programming.—Subroutines in assembly language for applying single pulses of varying amplitude were developed for each pulse length (60 msec to 10 sec). Control of the experiment was achieved from a Basic Program as shown in Fig. 3. After setting the system to the corrosion potential by zeroing the current output, pulses of ±2, ±4, ±6 etc. mV were applied to the corroding metal. In all experiments, the 10 current readings over the final 20 msec of each pulse were averaged and this was used in subsequent calculations. In this way 30 points on a polarization curve within ±30 mV of the corrosion potential were obtained.

Computer fitting of the polarization curves was achieved by the methods previously described (4), resulting in both Tafel parameters and the corrosion current. The program fits the polarization data to the equation

$$2.3\,R_p I = \frac{b_a b_c}{b_a + b_c}\left\{\exp\left(\frac{2.3\,\Delta E}{b_a}\right) - \exp - \left(\frac{2.3\,\Delta E}{b_c}\right)\right\} \quad [1]$$

where R_p is the polarization resistance, I the current at a potential ΔE from the corrosion potential, and b_a and b_c are the anodic and cathodic Tafel parameters, respectively. This equation can be reduced to a linear equation which enables a linear regression calculation. Programs were checked on theoretical data and on data obtained manually.

Cell and electrodes.—The cell was similar to that used in previous experiments (1) with a saturated calomel reference electrode (SCE) fitted in a Luggin probe. Cylindrical specimens of zinc (99.999%) with an exposed area 3.66 cm^2 were mounted in a standard holder and immersed in the solution at 20°C.

The solution contained 0.1 mole/liter ethylenediaminetetra-acetic acid (EDTA) (R grade) and adjusted to a pH of 8.5 by additions of NaOH (AR grade). Air was passed over the solution to avoid the slight changes in E_{corr} caused by bubbling through the solution.

Results

The current responses to the potential pulses were similar to those previously published (1). The polarization curves obtained using 60 msec pulses and averaging the currents over the final 20 msec of each pulse are shown in Fig. 4. The points are the experimental results while the line is the curve fit calculated by the computer. In all instances the percentage fit of the regression was greater than 99% and the mean square deviation of the individual points was typically 1%. For example, the precentage fit and the mean square deviation for the data in Fig. 4 were curve (i) 99.2% and 1.2%, curve (ii) 99.7% and 0.7%, curve (iii) 99.6% and 1.0%, and curve (iv) 99.9% and 0.2%, respectively.

Table I compares the anodic Tafel parameters with previously published experiments. A value of 80 ± 2 mV has been obtained from an *IR* compensated Tafel plot (1). However, values could be calculated from the previous work (1) by LeRoy's method (9) and assuming a diffusion-controlled cathodic process (8). These previous results for the first 9 hr of each experiment are compared with the present results in the table. The calculated error in the b_a in the present work was less than 1 mV. The cathodic Tafel parameter was always greater than 300 mV as would be expected for a diffusion-controlled process.

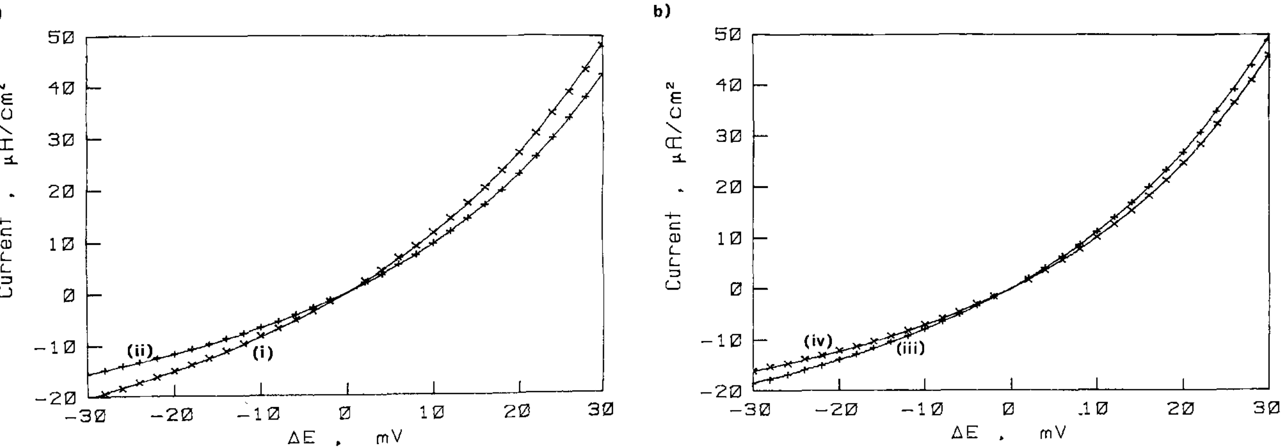

Fig. 4. Polarization data obtained at potentials ΔE mV from the corrosion potential for a zinc electrode after curve (i) 10 min, curve (ii) 1.5 hr, curve (iii) 10 min, and curve (iv) 2.5 hr immersion in a 0.1 mole/liter EDTA solution at pH 8.5; (a) from the first experiment and (b) from a duplicate run.

A plot of the calculated corrosion currents against time for duplicate experiments is shown in Fig. 5. The error calculated from the regression fit was less than 1 μA/cm^2 but results obtained 2 min apart gave values of 16.8 and 14.8 μA/cm^2 in the worst instance. Since this corrosion reaction is diffusion controlled (8), the current would be expected to remain fairly constant. Therefore, differences of 2 μA/cm^2 probably reflect the experimental errors rather than real changes in corrosion rates.

Discussion

Computerization of the method for obtaining polarization data has enabled a polarization curve to be generated very rapidly. The use of a 12 bit A/D converter means the currents are obtained very accurately and similarly the potential pulses are accurate to 0.03 mV. After the pulse is applied, the time at which the current is recorded can be altered to suit the type of current decay for individual experiments. For example, in the latest experiments on steel (10) pulses between 60 msec and 10 sec have been used. When the current is sampled, 10 consecutive readings are averaged to give one data point.

Once the data are obtained, curve fitting can be used to calculate the corrosion current and the electrochemical parameters. The microcomputer can also be programmed to plot the results as shown in Fig. 4. Automatic recording of corrosion rates over a period of time is now possible using appropriate timing subroutines or interrupts. The automation of data collection will improve the efficiency of experiments in the laboratory and can be used commercially to monitor the corrosion rates of metals in solution.

The present results for zinc in an EDTA solution at pH 8.5 confirm that the cathodic reaction is diffusion controlled as evidenced by the large cathodic Tafel parameters calculated from the curve fit. The b_a values as shown in the table are similar to those calculated at similar times from previous experiments where the values tend to a minimum value after 3-7 hr immersion and, thereafter, tend to increase. Slightly different b_a values result from only small, subtle changes in the shape of the polarization curve and these small changes in the curves are responsible for the spread of results observed in the I_{corr} values calculated (see Fig. 5). As mentioned above, two consecutive experiments 2 min apart resulted in a 2 μA/cm^2 difference between the I_{corr} values calculated. The R_p values, however, remained fairly constant at 1353 and 1317 Ω-cm^2 for the two sets of data but b_a varied from 57.0 to 60.2 mV. Thus, variations observed in the calculated corrosion current largely resulted from small variations in the shape of the polarization curve. The computer fitting method seems to be sensitive to small changes in shape which produce significant changes in b_a and b_c calculated from the current fit.

The effect of random and systematic errors on the calculated Tafel slopes and the I_{corr} values will be the subject of a later paper. In some instances, the b_c values were large negative numbers and this resulted from a very small uncompensated resistance overvoltage (*IR* drop). As the ohmic resistance was small compared with R_p it would not have affected the I_{corr} calculated.

Conclusions

Full computerization of electrochemical corrosion rate measurements by potentiostatic pulsing methods enables automatic monitoring not only of the corrosion rate but also the Tafel parameters which give kinetic information on the corrosion reactions. The corrosion of zinc in an aerated EDTA solution has been used to demonstrate the capabilities of the system.

High Speed Electrodeposition of Chromium from Low Concentration Chromic Acid Solutions

Mitchell A. LaBoda,* Arnold H. Holden, and James P. Hoare*

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

The presence of trichromate ions in the chromic acid solution is required to obtain a cathodic film from which metallic Cr may be deposited. With a high flow rate plating system, it was predicted from this proposed mechanism that bright, smooth, adherent deposits of Cr can be laid down on Cu or Fe substrates from solutions as dilute as 25 g/liter CrO_3 but no deposit from 1 g/liter CrO_3. A high speed plating process (HSP), based on an air pressure flow system (APFS) propulsion of electrolyte through a narrow gap between the cathode and anode separated by about 4 mm, was used to plate chromium metal on copper samples at rates up to 50 times faster from solutions 5 times as dilute as conventional chromium plating techniques. The HSP system, the APFS descriptions, and some selected results are presented.

During the conventional electrodeposition of chromium, the part to be plated is immersed in a properly catalyzed chromic acid bath under a low, d-c, applied voltage with a Pb anode, and the deposit is laid down at current densities ranging between 0.16 and 0.3 A/cm². Because of poor cathode current efficiency (12-15%), the process is slow, varying between 10 and 100 μm/hr. In most cases, particularly decorative plating applications, this system is satisfactory since it provides the required coating at a reasonable cost.

For industrial "hard" chromium used for wear and corrosion protection, the thickness of the coating may be about 25 μm. It is desirable, consequently, to develop a method to improve the efficiency, and hence, the rate of deposition of chromium.

A high rate process for the electrodeposition of chromium has been reported by Safranek and Layer (1) which indicated that both the limiting current and the deposition rate could be increased by increasing the rate of ion transport and reducing diffusion layer thickness by rapid flow of solution. No description of the cells or devices used for achieving the fast solution flow was given, however. Chin (2) has also studied the deposition of Cr at current densities from 1 to 70 A/cm² in a small flow cell using steel cathodes and a Pt anode at a flow rate of 2 liters/min (Re = 9000).

* Electrochemical Society Active Member.

Key words: coatings, cathode, current efficiency, kinetics.

A high speed plating (HSP) process consisting essentially of passing a stream of electrolyte under high air pressure (by reciprocating the flow between two tanks acting alternately as a reservoir and a sink) through the narrow gap (~4 mm) between the anode and cathode has been developed by LaBoda (3). With this air pressure flow system (APFS) (4), it is possible to deposit hard Cr from chromic acid solutions ranging from 1/10 to 1/25 of the conventional concentrations (250-300 g/liter). It is the purpose of this report to discuss the results of the deposition of hard Cr from dilute chromic acid solutions using APFS.

Theory

From an analysis of steady-state, galvanostatic, and potentiostatic polarization curves obtained (5) on Pt-bead cathodes in a Teflon cell in various chromate and chromic acid solutions, it was concluded for conventional Cr-plating: (*i*) that metallic Cr is deposited from a cathodic film without which a deposit is not formed, (*ii*) that a cathodic film is detected only if a polychromate is present, (*iii*) that polychromates are formed in strong solutions of chromic acid at low values of pH, (*iv*) that the cathodic film is required to protect the Cr^{+3} ion from forming the very stable complex with water, $Cr(H_2O)_6{}^{+3}$, from which metallic Cr cannot be deposited, (*v*) that the cathodic film is decomposed by an acid catalyzed hydrolysis, (*vi*) that the discharge of the chromous ion decomposition prod-

uct to metallic Cr is catalyzed by the HSO_4^- ion, and (*vii*) that the HSO_4^- also acts as a blocking agent so that the proper cathodic film is generated.

According to this model for conventional Cr plating, the cathodic film is composed of a mixture of various complexes between HSO_4^- ions and complex polychromates. Since these complexes can bond to one another by hydrogen bonding through water molecules, a viscous layer of hydrated complex polychromates is formed in the Nernst diffusion layer next to the cathode surface. This viscous layer may be identified with the blocking film of Müller (6), the colloidal film of the Russian workers (7-9), and the viscous film of Saiddington and Hoey (10, 11).

Because the complex trichromate ions from which metallic Cr is eventually deposited must diffuse through this viscous layer, the solution must be stirred well to reduce the thickness of the layer, and hence, shorten the diffusion path for high rate deposition of chromium. To reach HSP rates (high current densities) stirring alone is not enough because of the large *IR*-drop over the solution path between the anode and cathode (12). Consequently, this solution path between anode and cathode is reduced (to 3.8 mm, typically) permitting very high current densities (up to 15.5 A/cm^2 or 100 $A/in.^2$) to be passed. At such high current densities, the solution must be passed through the gap at very high rates (up to 6.3 m/sec) to (*i*) reduce the temperature of the solution in the gap (otherwise the solution would boil away); (*ii*) sweep out the viscous film so that the diffusion layer will be as thin as possible; and (*iii*) bring fresh solution into the gap so that depletion of the active material will not occur. To obtain this high solution flow the APFS system was invented (4).

With the APFS plating system, the viscous layer is made very thin and large quantities of fresh solution are transported to the cathode surface continuously. Successful high rate plating of hard Cr should be possible from solutions with concentrations of CrO_3 as low as 50 or 25 g/liter, since these solutions are red showing the presence of trichromate ion. Also, polarization studies show that cathodic films are formed in these solutions.

As a strong solution of chromic acid is diluted, the color of the solution changes, passing from deep red (250 g/liter) through red (100 g/liter) and orange (10 g/liter) to yellow (1 g/liter). From the polarization studies (5), it was found that the electrochemical behavior of the 10 g/liter solution of CrO_3 (orange) is similar to that of a solution of 1M $Na_2Cr_2O_7$. Here, the orange color is associated with the dichromate ion and a cathodic film was detected.

Similar behavior between the yellow solutions of CrO_3 (1 g/liter) and 1M Na_2CrO_4 was found. In these cases, the yellow color is associated with the monomer, $HCrO_4^-$ ion, and the presence of cathodic films on the electrode surface was not observed.

According to this mechanism, one should expect only a very thin deposit of metallic Cr to be laid down on the cathode from the 10 g/liter solution in the APFS system under the same experimental conditions used in the 50 g/liter case. Even though cathodic films are detected at cathodes in orange solutions of CrO_3, this behavior is predicted because the concentration of trichromate ions must be very low.

Since cathodic films were not detected at the electrode surface in the yellow 1 g/liter solution of CrO_3 and since the concentration of trichromate most likely is negligible, one should not expect to obtain a deposit of Cr metal under this given set of experimental conditions.

Experimental

The samples to be plated were copper tubes 7.6 cm long with an OD of 3.8 cm and a wall thickness of 0.17 cm (cathode area is 83.6 cm^2). Preparation of the Cu samples included polishing, buffing electrocleaning, acid dipping, and drying. Seventy-five liters of electrolyte were placed in tank No. 1 of the APFS plating system shown in Fig. 1 and the Cu sample was clamped into position in the fixture presented in Fig. 2. A detailed account of the operation of the APFS system may be found elsewhere (3). The electrolyte was heated by a steam heat exchanger. Samples were plated for 1 min.

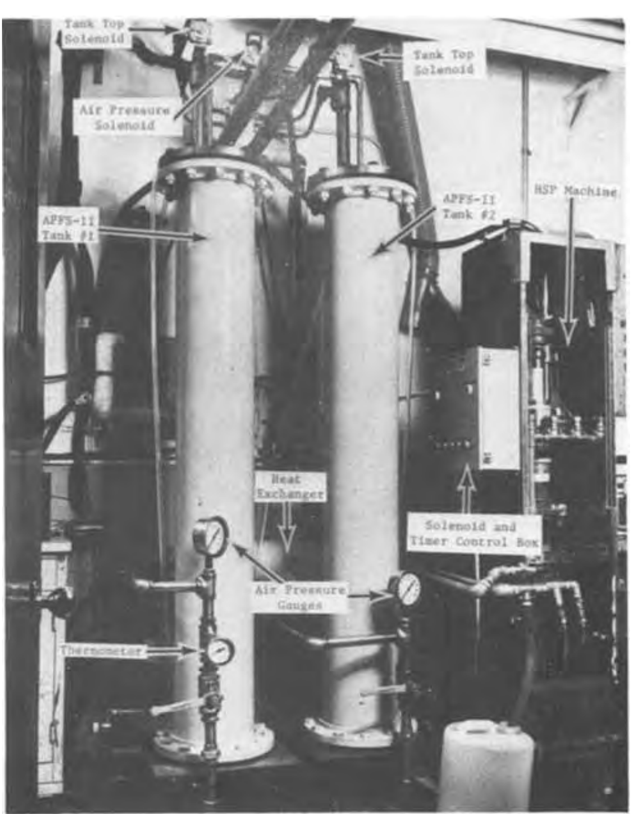

Fig. 1. HSP installation including APFS

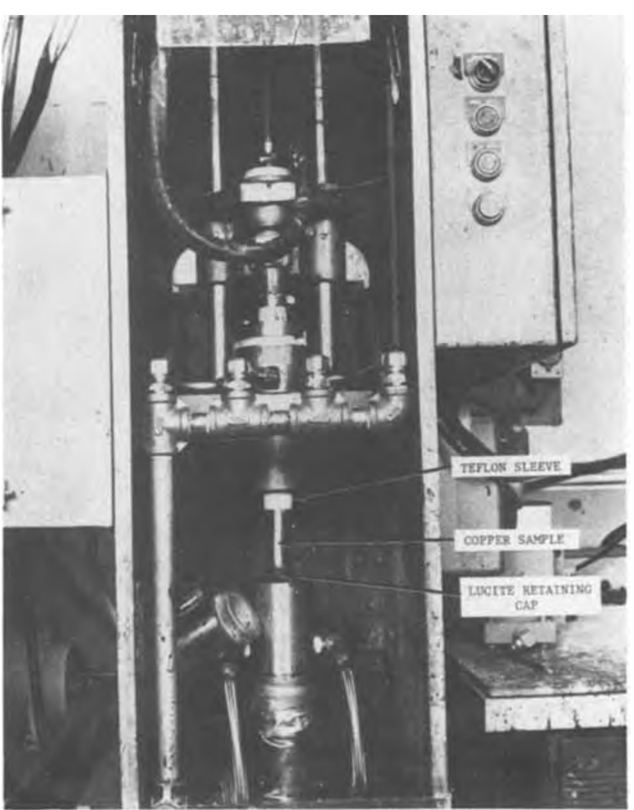

Fig. 2. HSP plating fixture open to load-unload position

Current efficiency measurements were obtained from weight-gain determinations of the sample and the total current passed which was determined by integrating under the current-time trace recorded on a strip chart. Integration was accomplished by cutting out the chart trace, weighing, and comparing that weight with the weight of a unit area of chart paper.

The outside surfaces of the Cu-tube samples were plated with Cr against a concentric 95% Pb-Sn alloy anode at temperatures ranging between 41° and 91°C with applied voltages ranging from 5 to 15V and solution flow rates up to 6.15 m/sec. In all cases, the chromic acid electrolyte was made up so that the ratio of CrO_3/H_2SO_4 was 100/1 since uncatalyzed CrO_3 electrolytes did not give deposits of metallic Cr.

Results and Discussion

According to the proposed model (5), bright Cr deposits should be obtained from solutions as dilute as 25 g/liter of CrO_3. In Fig. 3, typical results of Cr deposition on Cu tubes from a solution of 25 g/liter of CrO_3 and 0.25 g/liter of H_2SO_4 are given.

At this temperature and flow rate, the deposits were bright, smooth, and adherent between applied voltage of 7.5 and 12.5V (see Fig. 3B-D). Above 12.5V (Fig. 3E), the deposits became dull and were often blistered. In addition, a thin, adherent, yellow film was deposited along with partial coverage with bright Cr. This film was analyzed with the electron probe, Auger electron spectroscopy (AES), x-ray photoelectron spectroscopy (XPS), and the scanning electron microscope (SEM). The AES, XPS, and electron probe results indicate that the yellow film is almost completely composed of Cr_2O_3. SEM micrographs of the bright Cr surface are shown in Fig. 4 A-C and of the yellow film in Fig. 4 D-F at three different magnifications.

The proposed model states that the cathodic film from which Cr is eventually deposited, is a hydrated complex of HSO_4^- ion hydrogen bonded to a chromous dichromate species. By an acid catalyzed hydrolysis, this film is decomposed to form chromous hydroxide which complexes with HSO_4^- ion (5). The chromous bisulfate complex may then be discharged to metallic Cr with the transfer of two electrons. The result is the deposit shown in Fig. 4A. For very high deposition rates (Fig. 3E, 9 μm/min), some hydroxide may be codeposited with the metallic Cr. When the sample is removed from the plating machine and dried, the dehydrated hydroxide film decomposes to Cr and Cr_2O_3

$$3Cr(OH)_2 \rightarrow Cr + Cr_2O_3 + 3H_2O$$

as detected in Fig. 4D.

The highest plating rate obtained in the 25 g/liter electrolyte was 12 μm/min but was whitish gray; bright deposits were obtained only in the 3-5 μm/min range.

A plot of the cathodic current efficiencies as a function of the current density for three temperatures is given in Fig. 5. As the temperature is increased the current efficiency for Cr deposition decreases for a given current density. The reason for this is the fact that a parallel reaction, the reduction of H^+, can occur. Although the rate of Cr deposition increases with temperature, the rate of H_2 evolution also increases but at a higher rate of increase (Fig. 6). As a result, the current efficiency for Cr deposition falls off even though the actual amount of Cr deposited per unit time at a given current density may be greater at the higher temperature.

The voltage range over which bright Cr may be obtained is extended with higher temperatures. The deposit in Fig. 3E obtained at 79°C was greatly improved when deposited under the same conditions at 91°C.

To determine the optimum electrolyte for plating from low concentration chromic acid electrolytes, a 50 g/liter CrO_3 solution containing 0.5 g/liter H_2SO_4 was investigated. The deposition rate for bright deposits in this electrolyte ranged from 6 to 12 μm/min, over twice the rate obtained in the 25 g/liter solution. From the 50 g/liter electrolyte, deposit thicknesses of 18-20 μm were routinely achieved in 1.5 min, a thickness which is the present-day industrial specification for the chromium plating of MacPherson struts. Deposits up to about 12 μm were adherent, bright, and smooth (similar to Fig. 3B or C).

As a further test of the predictions made from the proposed model, Cu tubes were plated in the APFS system from very dilute electrolytes composed of 10 g/liter CrO_3 + 0.1 g/liter H_2SO_4 and 1 g/liter CrO_3 + 0.01 g/liter H_2SO_4.

Three copper samples plated in the 10 g/liter CrO_3 electrolyte at 85°C are shown in Fig. 7, since the best results were obtained at this temperature. At the high applied voltages (above 10V) the samples were covered with the yellow film. Although the deposits were thin (about 1 μm) they were smooth, and at the higher applied voltages, were bright. Since the concentration of trichromate ion from which the cathodic film is formed is very low in this electrolyte, one would expect to find the observed low deposition rate.

At a concentration of 1 g/liter CrO_3, Cr metal deposits were not detected at low applied voltages. Even at higher applied voltages, virtually no Cr deposits were observed as noted by a slight loss in weight of the copper sample indicating some dissolution of the copper tube in this electrolyte. This observation agrees well with the polarization curves obtained (5) in this solution showing no evidence for cathodic film formation. Consequently, a Cr deposit should not be expected.

Use of the 50 g/liter CrO_3 electrolyte in the APFS, HSP system offers one the opportunity of plating metallic Cr 30-40 times faster than that in conventional Cr plating (25 μm/hr from 250 g/liter CrO_3) from solutions containing only 20% of the CrO_3. Not only does the HSP have an obvious economic advantage, but since it is a closed loop system (opened only for load and unload), the chromic acid misting is contained in the APFS system providing a reduction in the corrosion of ventilating systems and in environmental pollution control.

Photoelectrochemical Investigation on Trigonal Selenium Film Electrodes

W. Gissler

Commission of the European Communities, Joint Research Centre, Ispra Establishment, 21020 Ispra (Varese), Italy

ABSTRACT

The photoelectrochemical properties of trigonal selenium films were investigated in view of a possible application in semiconductor liquid junction photo cells. A photo decomposition reaction of Se into hydrogen selenide was observed in acidic solutions. Only redox couples with a relatively anodic standard potential can prevent the decomposition process. The results are interpreted by a charge transfer process via interband states. Possible applications of Se-film electrodes are discussed.

The conversion of solar energy into electrical and storable chemical energy by semiconductor liquid junction solar cells is a potential low cost technique provided that cheap semiconductor materials of suitable photoelectrochemical properties can be found [see, *e.g.*, Ref. (1)]. So far only relatively few semiconductors have been investigated (2, 3) and an investigation of less known materials seems to be warranted. In this paper results of an investigation on photoelectrochemical properties of trigonal selenium are reported. Formerly selenium has been used for the production of solid-state photoelements and current rectifiers (4), but so far no attempts have been made to use it in semiconductor liquid junction solar cells. Measurements of the electrochemical behavior with and without illumination have been reported earlier (5).

In the solid state, selenium has several allotropic forms. At room temperature the only stable phase is that of trigonal selenium which is a p-type semiconductor with a bandgap energy of $E_g = 1.9$ eV (6) exhibiting a direct optical transition with a correspondingly high absorption coefficient. Polycrystalline selenium films can be easily produced either by evaporation or by dipping metallic substrates in the liquid phase (melting point 220°C). These properties make selenium an interesting candidate as photoelectrode for solar energy conversion.

Key words: semiconductor electrolyte, photocorrosion, electrode.

Experimental

Selenium film electrodes were made either by evaporation or from commercially available rectifiers. Evaporation was performed with 99.999 atomic percent (a/o) Se at 240°C onto a gold film covered aluminum substrate which was kept at 150°C. After the evaporation process the layers were annealed at 100°C for a period of 24 hr in order to assure a complete transformation of the film into the crystalline state. The gold selenium contact showed a pure ohmic behavior. The selenium film electrodes from rectifiers were made by removing the Cd film by etching. The thickness of both film electrodes was between 5 and 10 μm.

The electrodes were mounted in single compartment cells with a calomel reference and platinum counterelectrodes. An aqueous solution of 1F H_2SO_4 was used as an electrolyte. Potentiostatic measurements were performed with a PAR Model 173 potentiostat in conjunction with a PAR Model 175 Universal Programmer. For the measurement of the transient current behavior a PAR Model 4202 signal averager was used. Illumination was from a 500 W xenon lamp filtered by 10 cm of water, and the light was interrupted by either a PAR Model 192 chopper or a Spindler and Hoyer rapid manual shutter. As monochromator, a Spex Model Minimate was used. Capacity measurements were made by superimposing on the potentiostatically controlled d-c voltage an a-c volt-

age of approximately 100 mV amplitude at 20-100 kHz. The a-c amplitude and phase angle were measured in a circuit in which the cell was placed in series with a resistance (7). Gas analysis was performed with a Balzers quadrupol residual gas analyzer Type QMG 111 B.

Results

The photocurrent wavelength dependence of selenium was measured at an electrode potential of $U = -0.5V$ (SCE) and compared with the light source spectrum, from which the photoresponse spectrum (photocurrent/photon flux) was derived (Fig. 1). The spectrum is consistent with a direct optical transition for a bandgap energy of $E_g = 1.9$ eV.

Space charge capacity (C_{SC}) measurements were performed in a potential range U of -0.5-0.25V (SCE) where the electrodes showed only a small dark current ($i_d < 20\ \mu A/cm^2$). Frequency dispersion was observed below 50 kHz, indicating the existence of "slow" energy states (*e.g.*, surfaces states). Linear Mott-Schottky plots ($1/C_{SC}^2$ *vs.* U) were only obtained with the electrodes made from selenium rectifiers. Figure 2 shows such a plot at 100 kHz for a dark and an illuminated electrode (intensity ~2 sun AM2). From the slope of the plot for the dark electrode an acceptor density of 2.3 10^{17} cm^{-3} is obtained assuming a value of 13 (8) for the dielectric constant. For the flatband potential a value of $U_{FB} = 0.84V$ (SCE) is obtained by extrapolation of $1/C_{SC}^2 \rightarrow 0$. For the illuminated electrode, U_{FB} is only slightly increased. The obtained capacity values are about 2 times larger than for the dark electrode.

Current-potential (i *vs.* U) curves were measured with intermittent light (frequency ≈ 1 Hz) using a scan speed of 20 mV/sec. Figure 3a depicts normal behavior of p-type rotating disk semiconductor. The appearance potential of the photocurrent, however, is about 0.6V more cathodic than the flatband potential. Such a discrepancy has been observed also with other p-type semiconductors (9, 10). Measurements on a stationary electrode (Fig. 3b) revealed a quite anomalous behavior: with a positive potential scan direction and for potentials $U > 0.4V$ (SCE) an anodic photocurrent superimposed on a relatively large dark current was observed. The fact that this anomalous behavior could be observed only with the stationary electrode suggests that it is due to an electrochemical reaction of the product of the cathodic photo reaction. This hypothesis is also supported by the observation that the anomalous behavior disappears with reversed scan direction. Cyclic voltammograms (Fig. 4) elucidated this effect further.

The time response of the photocurrent to a trapezoidal light pulse has been measured with the stationary and the rotating electrode in the potential range $0.4 < U < 0.8V$ (SCE) (Fig. 5). Before every measurement the electrode was kept for 1 min at a potential of $-0.5V$ (SCE) and illuminated. Interestingly the rotating electrode, which does not exhibit a stationary photocurrent in this potential region, responds like a capacitor to a potential step. The photocurrent response of the stationary electrode resembles the response of a system where diffusion enters the kinetics.

The cathodic photocurrent causes a decomposition of the electrode. It is accomplished by a visible evolution of a gas of a strong unpleasant smell. A mass-spectrometric investigation revealed hydrogen selenide as decomposition product. It is therefore assumed that in acidic solutions the cathodic photocurrent is due to the reaction

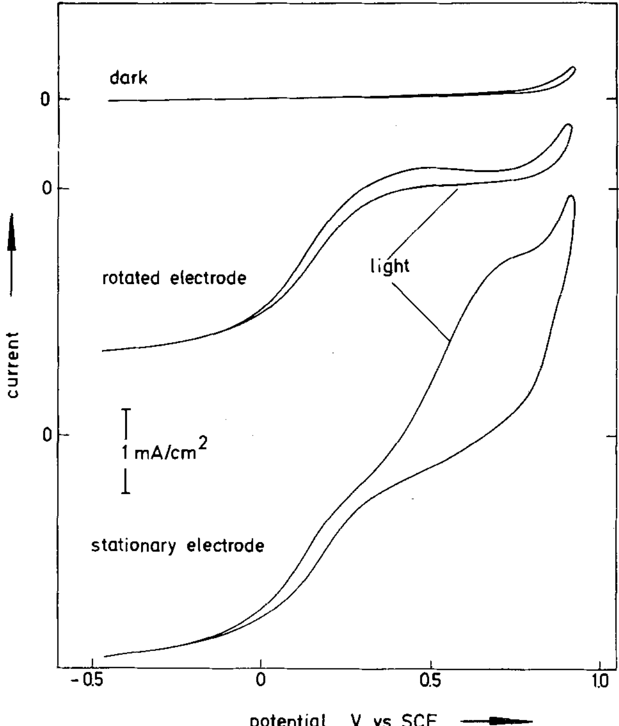

Fig. 4. Cyclic voltammograms of Se, scan rate 2 V/sec

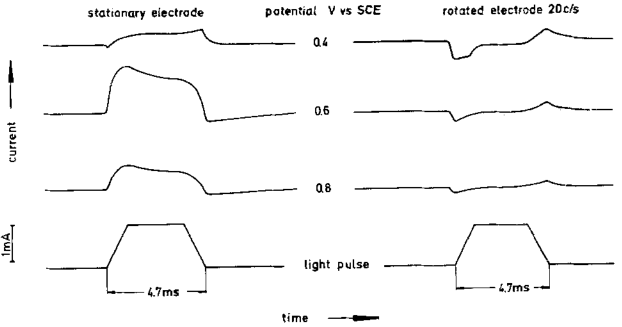

Fig. 5. Photocurrent response of a stationary and rotated (30 C/sec) electrode on a trapezoidal light pulse.

$$Se + 2H^+ + 2e^- \rightarrow H_2Se \quad [1]$$

From thermodynamic considerations (11) Se is expected to be decomposed into H_2Se for potential $U < -0.46V$ (NHE) and into H_2SeO_3 for potentials $U > 0.69V$ (NHE) at pH 1.

Experiments to stabilize the electrode by adding redox systems as $Eu^{2+/3+}$ and $Cr^{2+/3+}$ failed. The standard potentials of both couples are slightly more positive than the potential of the decomposition reaction [1], and the unoccupied levels of both couples can be assumed to overlap well with the conduction bandedge. Also the hydrogen evolution reaction can evidently not compete with the photodecomposition, although it cannot be completely excluded. With other p-type semiconductors, *e.g.*, GaP and GaAs, a photocurrent stabilization due to hydrogen evolution has been obtained (9).

Using redox systems of relatively positive standard potentials such as $Fe(CN)_6^{4-/3-}$, $Fe^{2+/3+}$, and $Ce^{3+/4+}$ the odor of H_2Se could no longer be detected and the photocurrent became stable within ±5% over the measurement period of 2 hr. Figure 6 shows the *i-U* curves in the dark (full line) and under illumination (broken line) obtained with a rotating electrode (30 C/sec) for the pure electrolyte of 1F H_2SO_4 (curve 1) and for solutions to which the following redox systems have been added: 0.1M $K_3Fe(CN)_6$ + 0.01M $K_4Fe(CN)_6$ (curve 2), +0.05M $Fe_2(SO_4)_3$ + 0.01M

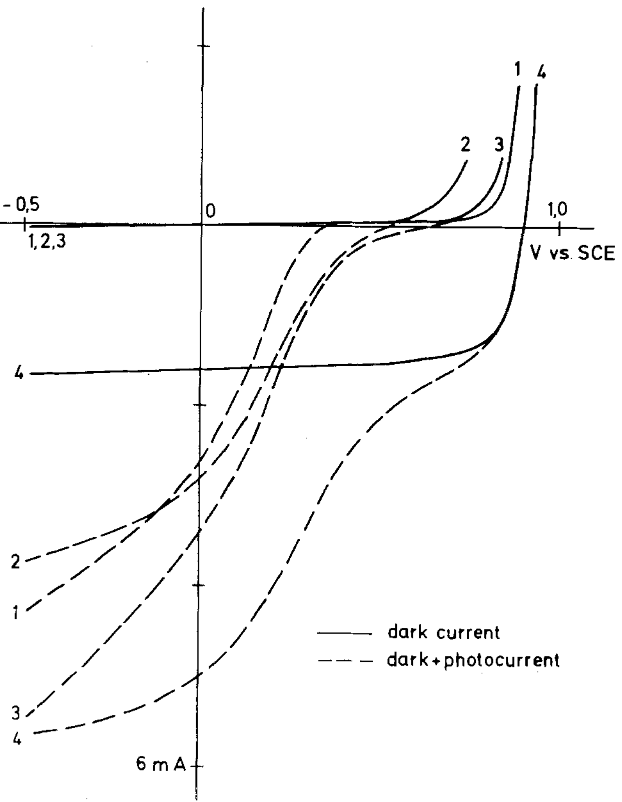

Fig. 6. Current-potential dependence of a dark (full) and illuminated (dashed) Se electrode for different redox electrolytes. Curve 1: 1F H_2SO_4; curve 2: 1F H_2SO_4 + 0.1M $Fe(CN)_6^{3-}$ + 0.01M $Fe(CN)_6^{4-}$; curve 3: 1F H_2SO_4 + 0.1M Fe^{3+} + 0.01M Fe^{2+}; curve 4: 1F H_2SO_4 + 0.1M Ce^{4+} + 0.01M Ce^{3+}.

$FeSO_4$ (curve 3), and 0.1M $Ce(SO_4)_2$ + 0.01M $Ce_2(SO_4)_3$ (curve 4). It is interesting to note that the more anodic the redox potential of the couple the more the appearance potential U_{ap} of the photocurrent is shifted towards the flatband potential. The cathodic dark current is large only in the case of the $Ce^{3+/4+}$ redox couple which is probably due to a direct charge transfer from the valence band. An estimation from the rearrangement energy (12) shows that the unoccupied levels overlap well with the valence band. Also an anodic dark current is observed. This is to be expected for $U > U_{FB}$. However, for the $Fe(CN)_6^{4-/3-}$ and $Fe^{2+/3+}$ redox couples an anodic dark current is also observed for $U < U_{FB}$.

Discussion

From thermodynamic considerations (14), it is expected that only those redox reactions can successfully compete with the photodecomposition of p-type semiconductors having more positive standard redox potentials. This is the case for all redox couples used in our experiments. However, only the redox couples with very anodic standard potentials seem to compete with the photodecomposition, although the oxidation levels in all cases are located within the bandgap of selenium [as estimated from the rearrangement energies (12)]. Corresponding observations have been made on n-type semiconductors (15). Whether the direct electron transfer model is an adequate description or surface states are involved is still an open question.

The observed difference between standard redox potential and appearance potential of the photocurrent can be understood by both types of transitions if large surface recombination rates (in comparison to the rate of charge exchange between semiconductor and solution) are assumed (13, 16).

It is difficult to estimate the kinetics of the charge transfer process via surface states for the redox couples

used in this experiment. However, the observed large values of ($U_{FB} - U_{ap}$) for the photodecomposition reaction might be indicative of slow kinetics for this reaction, compared to simple redox reactions.

Recently for n-type semiconductors it has been assumed that the decomposition proceeds in different steps and that the energy levels of the intermediate states are located within the bandgap (17). Only the last step is the virtual decomposition reaction, which can be prevented if suitable redox reactions can compete with it. If such a model is applied to selenium the decomposition might be assumed to consist of the two steps

$$Se + H^+ + e^- \rightarrow HSe \quad [2]$$

$$HSe + H^+ + e^- \rightarrow H_2Se \quad [3]$$

It is reasonable to assume that the rate constant for reaction [3] is smaller than for a competing redox reaction of the type

$$HSe + ox \rightarrow Se + H^+ + red \quad [4]$$

because the decomposition process according to [3] probably also involves some geometrical restraints in contrast to the redox reaction [4]. If the standard potential for reaction [3] is more positive than the reversible hydrogen electrode it also becomes clear that only the redox couples with more positive standard potentials prevent the decomposition process. The existence of interband states in hexagonal Se has been observed earlier by capacitance relaxation measurements (18).

The observation of an anodic dark current (Fig. 3a and Fig. 6) at electrode potentials $U < U_{FB}$ suggests either a tunnel mechanism or an avalanche breakdown (19). An estimation using the expression for the tunnel probability T given in (20) shows that this process is fairly probable even for the relatively low charge carrier density of $2.3 \ 10^{17}$ cm^{-3} if it is assumed that the occupied states are located only a few tenths of an electron volt above the valence bandedge. The anodic dark current assumes large values only during the anodic potential scan direction at the illuminated stationary electrode (Fig. 3b and Fig. 4). It might therefore be due to the product of the cathodic reaction which should be a solution species to be detected in the anodic reaction. A possible reaction is the back reaction of [3] which, however, can occur at $U < U_{FB}$ only assuming a hole injection process via tunneling.

The anomalous anodic photocurrent is always accompanied by a large anodic dark current. It might therefore be due to an increase of the tunneling probability under illumination: this is actually to be expected because the observed capacity increase under illumination (Fig. 2) can only be explained in a potentiostatic experiment by a reduction of the space charge layer, leading to an increase in the tunneling probability. In the absence of a reactant, a pure charging and discharging current of the space charge capacity should be observed. This is actually the case (Fig. 5).

Due to the fact that a stabilization can be reached only with redox couples of relative positive standard potentials, selenium electrodes seem to be unsuitable for use in regenerative solar cells: a large part of the energy which has been gained by band-band excitation is lost by transitions from the conduction band into the lower interband levels, and correspondingly, only small cell voltages can be obtained.

However, selenium photocathodes might be used in a novel way for hydrogen production: in contrast to direct photolysis, in a first step hydrogen selenide is produced by utilizing the photodecomposition reaction [1], and then in a subsequent reaction step hydrogen selenide is thermally dissociated in hydrogen and selenium, which has to be, however, regenerated for use as electrode. Since the fabrication of selenium electrodes from the melt is a well-established low cost technique (4) and the dissociation reaction occurs at relatively low temperatures (21) a more detailed investigation of the feasibility of such a cycle would seem to be worthwhile.

Acknowledgments

The author wishes to express his thanks to Dr. J. S. Curran and Dr. G. Schütz for valuable suggestions and discussions and to Messrs. A. Hoffmann and R. Schubert for very helpful technical assistance. The very stimulating discussions with Dr. R. Memming are particularly acknowledged.

The Measurement of Sulfur Chemical Potential Differences Using a Calcium Fluoride Solid Electrolyte

T. A. Ramanarayanan*,[1] and W. L. Worrell*

Department of Materials Science and Engineering, University of Pennsylvania, Philadlephia, Pennsylvania 19104

ABSTRACT

Calcium fluoride has been conventionally used as a solid electrolyte to measure fluorine chemical potentials in high temperature systems. However in this investigation, this electrolyte has been used as a sulfur sensor. Open-circuit emf measurements have been carried out with the following four galvanic cells

$$Cu, Cu_2S, CaS|CaF_2|Fe, FeS, CaS$$

$$Cu, Cu_2S, CaS|CaF_2|Ag, Ag_2S, CaS$$

$$Cu, Cu_2S, CaS|CaF_2|Mn, MnS, CaS$$

$$Cu, Cu_2S, CaS|CaF_2|Cr, CrS, CaS$$

The cells were investigated in the temperature range, 500°-900°C. Using Richardson and Antill's data for the standard Gibbs energy of formation of Cu_2S, the standard Gibbs energies of formation of FeS, Ag_2S, MnS, and CrS have been determined.

Several investigators have used a calcium fluoride solid electrolyte to determine the Gibbs energies of formation of metal fluorides (1, 2). This electrolyte has also been used to obtain Gibbs energy data for carbides and silicates (3, 4). Recently, calcium fluoride has been used to measure oxygen chemical potentials (5, 6). This paper reports measurements of the sulfur chemical potentials of solid electrodes using a CaF_2 solid electrolyte. Moriyama and co-workers (7, 8) and Jacob, Rao, and Nelson (9) have also used the CaF_2 solid electrolyte for sulfur chemical potential measurements at high temperatures.

Consider the electrochemical cell

$$M, M_xS, CaS|CaF_2|Me, Me_yS, CaS \qquad [A]$$

$$\mu_{S_2}', \mu_{F_2}' \qquad \mu_{S_2}'', \mu_{F_2}''$$

where M and Me are different metals. The equilibrium of the reaction

$$xM + \tfrac{1}{2} S_2 = M_xS \qquad [1]$$

establishes a sulfur chemical potential, μ_{S_2}', at the left-hand electrode of cell [A]. Further, consider the equilibrium

$$CaF_2(s) + \tfrac{1}{2} S_2 = CaS(s) + F_2 \qquad [2]$$

The equilibrium constant, K_2, of this reaction is given by

$$K_2 = p_{F_2}/p_{S_2}^{1/2} \qquad [3]$$

where p_{F_2} and p_{S_2} denote partial pressures of fluorine and sulfur, respectively. Since the chemical potential, μ_{S_2}', at the left-hand electrode is fixed, the fluorine chemical potential, μ_{F_2}', is also fixed in accordance with Eq. [3]. In a similar manner, the chemical potentials, μ_{F_2}'' and μ_{S_2}'' are fixed at the right-hand electrode.

Calcium fluoride is a solid electrolyte having anionic Frenkel disorder. Under conditions of negligible electronic conduction, the transport number of fluorine ions is unity. The open-circuit emf of cell [A] is then given by

$$E = \frac{1}{2F} [\mu_{F_2}'' - \mu_{F_2}'] = \frac{RT}{2F} \ln \frac{P_{F_2}''}{P_{F_2}'} \qquad [4]$$

with $\mu_{F_2}'' > \mu_{F_2}'$. According to Hinze and Patterson (10), electronic conduction in CaF_2 is negligible even at unit activity of calcium. Delcet, Heus, and Egan (11) have recently reported that at temperatures between 800° and 950°C n-type electronic conduction is present in single crystalline calcium fluoride at calcium activities higher than 10^{-3}. Combining this value with data for the Gibbs energy of formation of CaS (12) one calculates a value of 3.6×10^{-36} atm for the low p_{S_2} limit for predominant ionic conduction ($t_{ion} \geqq 0.99$) in CaF_2 at 1100°K. The lowest p_{S_2} investigated in the present work was only 4.3×10^{-20} atm at 1100°K. Thus no electronic contribution to the conductivity is expected. On combining Eq. [3] and [4]

$$E = \frac{RT}{4F} \ln \frac{p_{S_2}''}{p_{S_2}'} \qquad [5]$$

If p_{S_2}' is known, then p_{S_2}'' may be calculated from the measured open-circuit cell emf's using Eq. [5]. The standard Gibbs energy of formation of Me_yS is related to p_{S_2}'' through

$$p_{S_2}'' = \exp\left(\frac{2\Delta G_f^\circ (Me_yS)}{RT}\right) \qquad [6]$$

Similarly, p_{S_2}' is given by

$$p_{S_2}' = \exp\left(\frac{2\Delta G_f^\circ (M_xS)}{RT}\right) \qquad [7]$$

Thus if the standard Gibbs energy of formation of M_xS is known, then that of Me_yS may be determined.

In the present study, the standard Gibbs energies of formation of FeS, Ag_2S, MnS, and CrS were determined using the cells

$$Cu, Cu_2S, CaS|CaF_2|Fe, FeS, CaS \qquad [B]$$

$$Cu, Cu_2S, CaS|CaF_2|Ag, Ag_2S, CaS \qquad [C]$$

$$Cu, Cu_2S, CaS|CaF_2|Mn, MnS, CaS \qquad [D]$$

$$Cu, Cu_2S, CaS|CaF_2|Cr, CrS, CaS \qquad [E]$$

Materials and Experimental Procedure

Metal and sulfide powders of 99.99% purity were obtained from Cerac Incorporated. Optical grade high purity single crystals of CaF_2 (½ in. diam and 1 in. length) grown along the <111> axis were obtained

* Electrochemical Society Active Member.

[1] Present address: Exxon Research and Engineering Company, Corporate Research Laboratory, Linden, New Jersey 07036.

Key words: solid electrolyte, sulfur sensor, emf measurements.

from Harshaw Chemical Company. The electrolyte was cut into disks of ⅛ in. in thickness with a diamond wheel. The electrolyte faces were finely ground and polished with 1 μm diamond paste. The metal, metal sulfide, and calcium sulfide powders were mixed in roughly equal amounts by volume. The mixed powders were pressed in a 1 cm diam die into electrode pellets of approximately ¼ in. thickness at about 12 tsi. The electrodes were not presintered. The cell was assembled in an alumina cell holder as shown in Fig. 1. Light spring pressure was exerted to keep the electrode and electrolyte in intimate contact. Platinum disks spot-welded to Pt wires were used as electrical leads. A Pt-Pt(10% Rh) thermocouple, placed within ½ cm of the cell, was used to measure temperatures. The cell was placed in the constant temperature zone (±1°) of a Pt-Rh wound resistance furnace. A flowing inert atmosphere of purified argon was maintained around the cell. The argon was purified by first passing through anhydrous calcium sulfate, then through activated copper (BASF) maintained at 200°C and then through titanium sponge maintained at 800°C. Any final traces of oxygen were removed by having a tantalum foil around the alumina cell holder upstream from the cell.

After the cell was heated to the experimental temperature, the open-circuit emf was measured using a high impedance digital electronic voltmeter. The cell emf was considered steady if the random variation was within ± 0.5 mV over a 5 hr period. The emf's were independent of the argon flow rate. Cell reversibility was confirmed by passing a small current (10-20 μA) for a few minutes. After the current passage, the open-circuit emf's returned to the original values within 0.5 mV.

Cell [B] was assembled and heated in purified argon atmosphere to a temperature of 550°C. The cell emf reached the equilibrium value in about 15 hr. The cell temperature was then raised by 50° increments. After changing the temperature, the attainment of the new equilibrium cell emf took approximately 5 hr. The highest temperature used was 850°C. Open-circuit emf readings were also taken upon cooling at 50° intervals. Equilibration times for cell [C] were similar to those for cell [B]. The cell was investigated over the temperature range, 500°-750°C. Above 750°C, the silver-sulfide showed a tendency to decompose. Cell [D] was investigated in the temperature range, 700°-900°C. After heating the cell to 700°C, the initial equilibration took ~ 48 hr. Upon changing the cell temperature, equilibrium at the new temperature was attained in about 15 hr. The attainment of equilibrium was too slow at temperatures below 700°C. The initial equilibration with cell [E] occurred within 15 hr at 727°C; subsequent equilibrations occurred within 3 hr.

X-ray diffraction patterns of the electrode pellets were taken before and after the experiments. In all cases, only the metal, metal sulfide, and calcium sulfide phases were observed. No mutual solubility between calcium sulfide and the other metal sulfides was detected.

Results and Discussion

The open-circuit emf values obtained using cell [B] are shown in Fig. 2, in which the solid line fits the least squares expression

$$E\ (\text{mV}) = -128.29 + 0.159T\ (\pm 5\ \text{mV}) \quad [8]$$

The uncertainty indicated in brackets is twice the standard deviation of E about the regression line. Emf's calculated using Richardson and Antill's data (13) for the Gibbs energy of formation of Cu_2S and Rosenqvist's data (14) for the Gibbs energy of formation of FeS are also shown in Fig. 2. The uncertainty in this calculated line is estimated to be ± 14 mV, which corresponds to about 650 cal in the standard Gibbs energy change for the reaction

$$\text{FeS} + 2\text{Cu} = \text{Cu}_2\text{S} + \text{Fe} \quad [9]$$

The agreement between the two lines is excellent, within 5 mV at the lower temperatures and within 9 mV at the higher temperatures.

In the four cells investigated in the present study, the Cu-Cu_2S-CaS electrode was used as the reference electrode. The Cu-Cu_2S equilibrium has been investigated by Richardson and Antill (13) over the temperature range 800°-1313°K. The uncertainty in their data is ± 300 cal, and their data are in good agreement with other results in the literature (12, 15). The standard Gibbs energy of formation of Cu_2S according to Richardson and Antill is given by the expression

$$\Delta G_f^\circ\ (\text{Cu}_2\text{S}) = -31{,}390 + 7.33T\ (\pm 300)\ \text{cal/mole} \quad [10]$$

Using the Gibbs energy of formation for Cu_2S, the free energy of formation of FeS can be calculated using Eq. [5]-[7]. Such a calculation yields the following expression for the standard Gibbs energy of formation of FeS at temperatures between 550° and 850°C

$$\Delta G_f^\circ\ (\text{FeS}) = -37{,}310 + 14.66T\ (\pm 500)\ \text{cal/mole} \quad [11]$$

The standard Gibbs energy of formation of FeS obtained by various investigators are compared in Fig. 3. The data of Alcock and Richardson (16) and of Rosenqvist (14) were obtained from gas-equilibration

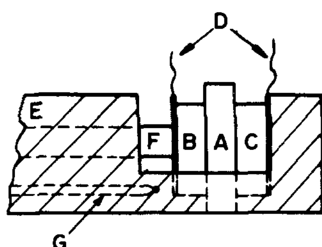

Fig. 1. Experimental cell arrangement

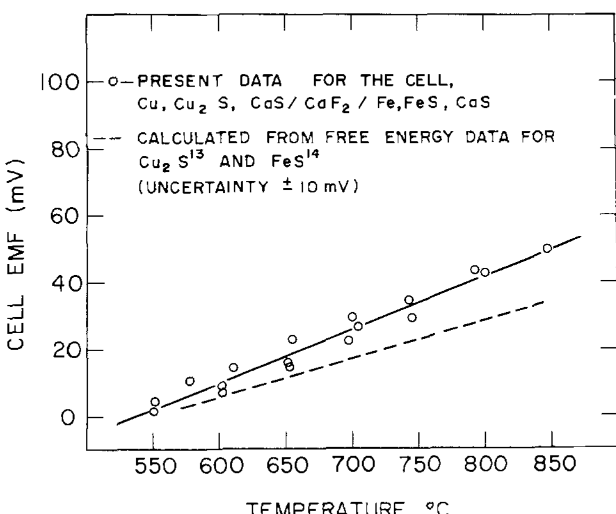

Fig. 2. Temperature variation of the open-circuit emf for cell [B].

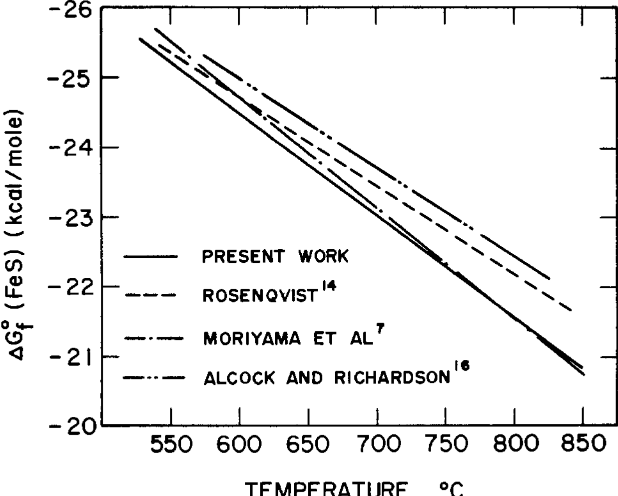

Fig. 3. Comparison of the standard Gibbs energy of formation of FeS determined in this study with results from earlier investigations.

studies using H_2-H_2S mixtures. Moriyama and co-workers (7) used an electrochemical cell based on a calcium fluoride solid electrolyte. Our values are in good agreement with those of Moriyama *et al.*, but are less negative than those of Rosenqvist by 200-500 cal and those of Alcock and Richardson bv 500-800 cal.

The emf values obtained using cell [C] are plotted as a function of temperature in Fig. 4. Also shown in Fig. 4 is the line calculated from the data of Richardson and Antill (13) for the Cu-Cu_2S equilibrium and of Rosenqvist (17) for the Ag-Ag_2S equilibrium. The solid line in Fig. 4 fits the least squares expression

$$E\ (\text{mV}) = 231.75 + 0.0126T\ (\pm 4\ \text{mV}) \qquad [12]$$

On combining Eq. [10] and [12], the standard Gibbs energy of formation of Ag_2S at temperature between 500° and 750°C is calculated to be

$$\Delta G_f^\circ\ (Ag_2S) = -20{,}700 + 7.91T\ (\pm 500)\ \text{cal/mole} \qquad [13]$$

The standard Gibbs energy of formation of Ag_2S has been plotted as a function of temperature in Fig. 5. Also shown in Fig. 5 are the results of Rosenqvist (17) and of Thompson and Flengas (18). Rosenqvist used a gas equilibration technique involving H_2-H_2S gas mixtures for his investigations whereas Thompson and Flengas used an electrochemical technique based on a KCl-NaCl molten salt containing AgCl and Ag_2S. Our results are in excellent agreement with those of Rosenqvist and agree with those of Thompson and Flengas within 500 cal.

The emf results of cell [D] are shown as a function of temperature in Fig. 6. The upper dotted line in

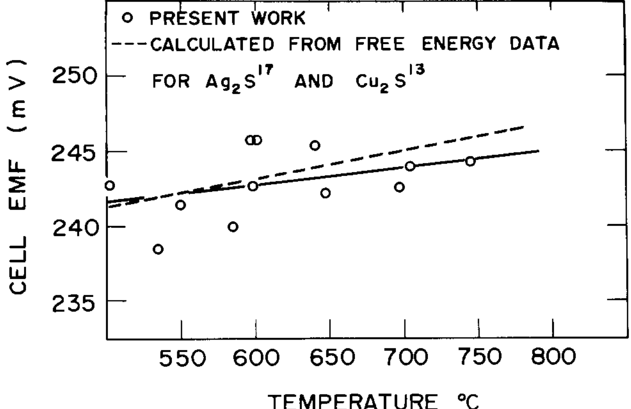

Fig. 4. Temperature variation of the open-circuit emf for cell [C]

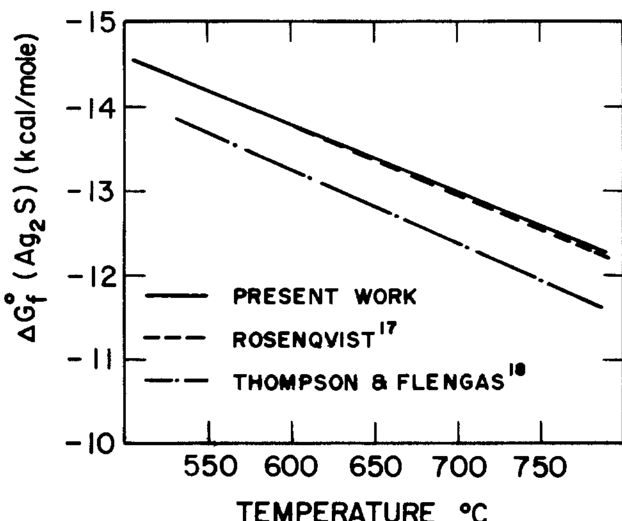

Fig. 5. Comparison of the standard Gibbs energy of formation of Ag_2S determined in this study with results from earlier investigations.

Fig. 6 is based on the Mn-MnS equilibrium data of Larson and Elliott (19). The lower line comes from the Mn-MnS equilibrium data reported by Richardson and Jeffes (20). Our data points in Fig. 6 fit the least squares expression

$$E\ (\text{mV}) = 720.65 - 0.155T\ (\pm 12\ \text{mV}) \qquad [14]$$

On combining Eq. [10] and [14], one calculates for the standard Gibbs energy of formation of MnS at temperatures between 700° and 900°C

$$\Delta G_f^\circ\ (\text{MnS}) = -64{,}635 + 14.46T\ (\pm 900)\ \text{cal/mole} \qquad [15]$$

The standard Gibbs energy of formation of MnS has been plotted as a function of temperature in Fig. 7. Shown also in Fig. 7 are the results of Larson and Elliott (19), of Moriyama *et al.* (8), of Richardson and Jeffes (20), and of Turkdogan *et al.* (21). Richardson and Jeffes quote an uncertainty of ± 1500 cal in their estimate for the free energy of formation of MnS. Larson and Elliott's values are based on electrochemical measurements of the MnO-MnS-SO_2 equilibrium using a stabilized zirconia solid electrolyte. Moriyama *et al.* (8) used an electrochemical technique based on a CaF_2 solid electrolyte. The values reported by Turkdogan and co-workers are derived from measurements of the MnO-MnS-H_2O-H_2S equilibrium. Our free energy values are less negative than those of Larson and Elliott by 500-900 cal, and of Turkdogan *et al.* by 1700-2500 cal and more negative than those of Moriyama *et al.* by 400-600 cal.

The emf values obtained using cell [E] at temperatures between 500° and 950°C are shown in Fig.

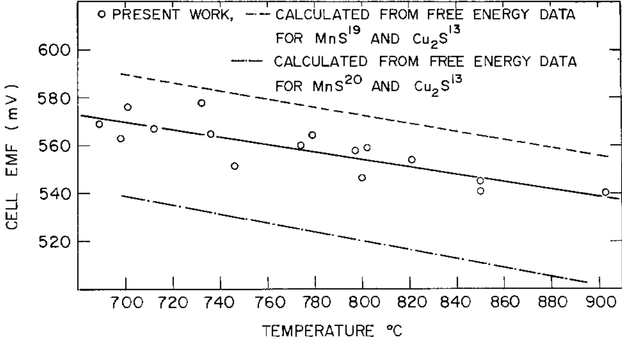

Fig. 6. Temperature variation of the open-circuit emf for cell [D].

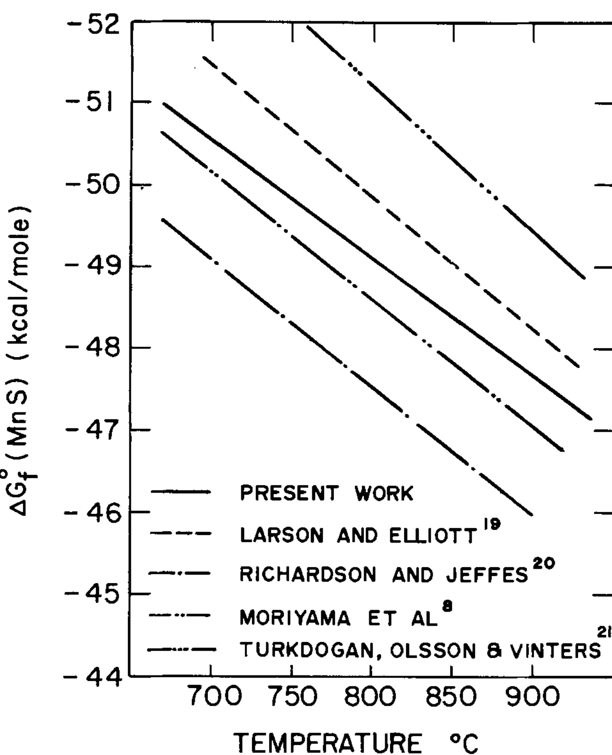

Fig. 7. Comparison of the standard Gibbs energy of formation of MnS determined in this study with results from earlier investigations.

8. The solid line in Fig. 8 fits the least squares expression

$$E\ (\text{mV}) = 368.72 - 0.13T\ (\pm 2\ \text{mV}) \quad [16]$$

On combining Eq. [10] and [16], one calculates for the standard Gibbs energy of formation of CrS at temperatures between 550° and 950°C

$$\Delta G_f^\circ\ (\text{CrS}) = -48{,}400 + 13.3T\ (\pm 400) \quad [17]$$

As shown in Fig. 9, the results for ΔG_f° of CrS are in excellent agreement (within 100 cal) with the extrapolated results of Hager and Elliott (22), who used an H_2/H_2S gas-equilibration technique at 1100°-1300°C. Our results are also within the quoted uncertainty (± 2000 cal) of a single gas-equilibration measurement at 700°C by Young *et al.* (23).

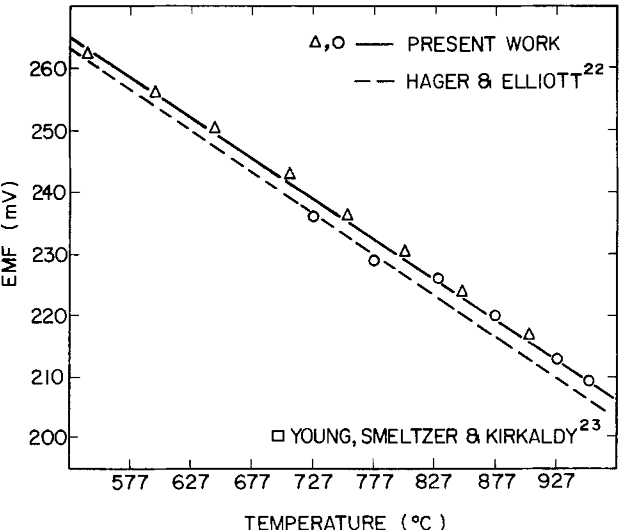

Fig. 8. Temperature variation of the open-circuit emf for cell [E].

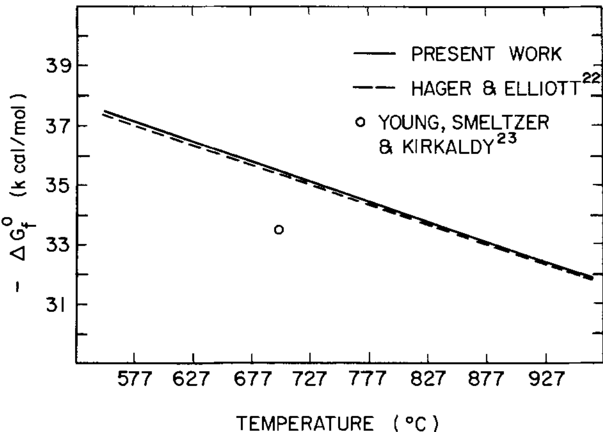

Fig. 9. Comparison of the standard Gibbs energy of formation of CrS determined in this study with results from earlier investigations.

Conclusions

The CaF_2 solid electrolyte is suitable for the measurement of sulfur chemical potentials in solid electrodes at temperatures between 500° and 950°C. Measurements with metal-metal sulfide electrodes have been used to determine the standard Gibbs energy of formation of FeS, Ag_2S, MnS, and CrS. The CaF_2 electrolyte has also been used to measure sulfur potentials in gaseous atmospheres (9). Further experimentation with this electrolyte in the measurement and control of sulfur potentials in melts seems worthwhile. However, the influence of dissolved oxygen in the melt would need to be established.

and Barton L. Houseman[1]

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico 87545

ABSTRACT

The activities of cadmium over alloys containing 0.0007-0.1454 mole fraction of palladium at 776°K have been determined from emf and from vapor pressure measurements. In the range of $N_{Cd} = 1$ to $N_{Cd} = 0.9648$ the equation

$$a_{Cd} = 1 - N_{Pd} - 2.538 N_{Pd}^2$$

fits the combined emf and vapor pressure results with a standard deviation of 0.00043. In the range of $N_{Cd} = 0.9648$ to $N_{Cd} = 0.8546$ a constant value of 0.9616 is observed for the activity, indicating the presence of a solid phase together with a saturated liquid phase.

This work forms part of a continuing investigation at this laboratory into the behavior of solvent activities in dilute alloys (1-11); it was undertaken in order to compare the activity of cadmium in dilute palladium-cadmium solutions as measured by emf with the same activity determined by vapor pressure measurements.

Cadmium activities were determined from stirred H-cell measurements using molten cadmium iodide as the electrolyte with cadmium and cadmium alloy electrodes. Earlier work has indicated that the value of n in the equation $-n\mathbf{F}(dE) = RT(d \ln a_{Cd})$ is nonintegral for the Cd-CdI_2 system (10, 16); this comparison of emf activity with vapor pressure activity, using Pd as the solute, verifies the earlier work.

Vapor pressure measurements of cadmium activity in solutions of the same concentration range were made using the isopiestic balance (1, 3, 4, 6, 7), which measures the temperature difference needed to establish a condition of zero transfer of vapor between pure cadmium and a cadmium alloy.

Procedures and Calculations

EMF measurements.—The H-cell shown in Fig. 1 has been described (8). The lower portion of the cell was attached to a Pt/Pt-10%Rh thermocouple and lowered into a furnace (2) designed to minimize temperature fluctuations and gradients. Cadmium of 99.999% purity, as analyzed by the United Mineral and Chemical Corporation, was melted and boiled, at 10^{-7} atm pressure, in intimate contact with cadmium iodide, so that any traces of electrochemically interfering elements (*e.g.*, zinc) would be oxidized by the CdI_2. Small, conveniently sized beads of Pd were created by melting the metal (99.95% pure by manufacturer's

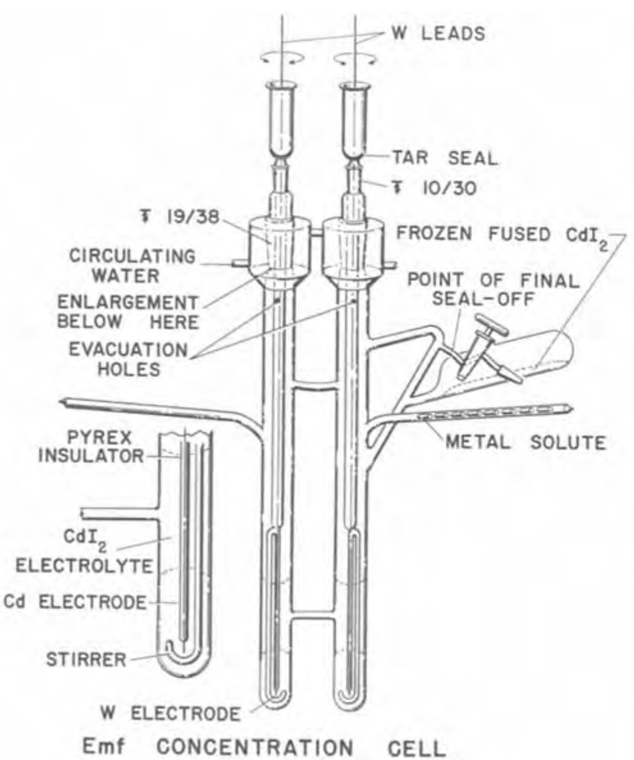

Fig. 1. EMF concentration cell

[1] Present address: Department of Chemistry, Goucher College, Towson, Maryland 21204.

Key words: metals, electrode, potential, activity coefficient.

analysis) in an rf-furnace. The tungsten electrodes were cleaned by using them as electrodes to pass alternating current through concentrated NaOH solution (thereby removing the tungsten oxide layer) and washing them with distilled water. Reagent grade CdI_2 was loaded into the side tube shown in Fig. 1, boiled under vacuum until the molten CdI_2 caused no higher pressure than 10^{-5} Torr to be registered on the pump side of the liquid nitrogen cold trap, then cooled. This was necessary to remove the substantial amounts of adsorbed gas in the commercially available CdI_2. The cell was backfilled to a pressure of 0.5 atm with argon which had been purified by distillation. The cell was loaded into the furnace, the cadmium in the legs melted, and the CdI_2 fused by torch and allowed to run into the H-cell legs and cross arm.

The liquid metal in each leg of the cell are relatively good thermal conductors compared with the glass of the cell, and the conduction area of the metal was large, relative to the cross-sectional area of the cell walls. Therefore, one can expect good temperature uniformity in each of the cell legs. However, because of the small diameter of the cross arm of the H-cell, thermal conductance between the two legs was not as good, and, in spite of the careful design of the furnace, evidence of a small temperature gradient between the two electrodes could be observed.

Thermodynamically, the emf arising from this cell may be considered as the sum of two emf's, one arising from $Cd(T_2)$ *vs.* $Cd(T_1)$, and the other arising from $Cd(T_1)$ *vs.* alloy(T_1). The second emf is required for determining the activity of the Cd at temperature T_1. Since initially no solute had been added to the alloy side, the second emf was initially zero, and the first was just the measured emf before the addition of the first piece of Pd. This value, which remains essentially constant, must be subtracted from emf readings obtained for the alloys to obtain that value which arises from the cell $Cd(T_1)$ *vs.* alloy (T_1).

After the cell was allowed to equilibrate for two days with occasional stirring, an initial emf bias between the two pure cadmium legs was recorded. For run 1 the cell was then tipped so that when the sidearm was tapped, a piece of palladium would slide down into the alloy leg. For run 2 a ground glass joint allowed the leg to be rotated to obtain the angle necessary for tapping a solute piece into the alloy leg. During run 2 the main cell body was fixed rigidly to the furnace so that the bias would remain more nearly constant.

After each piece was added, both legs of the cell were stirred and the emf was observed until no further change occurred. The thermocouple and cell emf's were then recorded.

For run 1, cell emf's were recorded to the nearest 0.1 μV and thermocouple emf's to the nearest μV. For run 2, cell emf's and thermocouple emf's were both recorded to the nearest 0.01 μV although the uncertainty in absolute temperatures was probably as much as ± 0.1°K. A correction factor of 1.37 μV was subtracted from the measured thermocouple emf to bring the equation (12)

$$E = -309.17 + 8.29558\,t + 0.00144103\,t^2 + 0.0000001634\,t^3 \quad [1]$$

into agreement with more recent reference tables (13). For Eq. [1], E is in microvolts and t is in degrees Celsius.

Cadmium was weighed to the nearest 0.1 mg and palladium to the nearest 0.01 mg. The CdI_2 over each leg was estimated to be about 35g. The uncertainty in cadmium added was less than one part in 100,000. For the most dilute palladium piece added, the uncertainty was approximately one part in 2000.

The experimental values of cell emf, temperature, and material added are known to a high degree of accuracy as well as precision. The calculated values for alloy composition, electrolyte composition, and activity are subject to further uncertainties, however, which result from the significant solubility of cadmium in CdI_2.

For cells containing cadmium alloys in the presence of molten CdI_2 electrolyte, the evaluation of cadmium activities from the emf data depends upon the value assigned to n in the equation $-n\mathbf{F}\,dE = Rt\,d\ln a_{Cd}$. The value of n, the average charge per mole of cadmium transferred, depends upon the solubility of cadmium in its iodide and upon the types, concentrations, and mobilities of the various chemical species present in the electrolyte.

When the solubility of cadmium in its iodide at 775°K is assumed to be 6.5 mole percent consistent with the cooling curve measurements of Topol and Landis (14) and when the mobilities of the various cadmium ion species are assumed to be about the same as is true for the chloride system investigated by Herzog and Klemm (15), emf data taken on the Ni-Cd system yield activities which agree with Raoult's limiting law (10). The value estimated for n from these assumptions is 1.87 at the limit of infinite dilution. This value agrees with a direct experimental determination of n by Houseman (16).

Consistent with these results, the cadmium activities for the cell

Anode	A	B	Cathode
Cd	Cd(sat) CdI_2	$Cd(N_{Cd}^{elec})$ $CdI_2(N_{CdI_2}^{elec})$	$Cd(N_{Cd}^{alloy})$ $Pd(N_{Pd}^{alloy})$

were calculated using the equation (10, 17)

$$\ln a_{Cd} = -\frac{2\mathbf{F}}{R}\int_0^{E/T} N_{CdI_2}^{elec}\,d\,\frac{E}{T} \quad [2]$$

where it was assumed for dilute alloy solutions that $N_{Cd}^{elec} = 0.065\ N_{Cd}^{alloy}$. A change in the coefficient 0.065 by an amount 0.001 will cause a change in the slope of the cadmium activity with concentration by approximately one part per thousand. The variation of $N_{CdI_2}^{elec}$ with E/T is so slight over the range of the measurements that the trapezoid rule may be employed between the actual experimental points instead of drawing a smooth curve through the data. As a consequence, the experimental uncertainty is essentially retained in the calculated activities.

Vapor pressure measurements.—The isopiestic balance (Fig. 2) consists of a quartz tube with two legs, one of which contains the alloy and the other pure cadmium condensate. When vapor equilibrium is established between the alloy and pure cadmium, measurement of the temperature difference between the two legs allows the reduction of cadmium activity over the alloy from that for pure cadmium to be determined.

The tube is suspended by a balance system and surrounded by a furnace. The leg and cross arm temperatures are separately controlled.

Palladium and cadmium of the same purities as used in the emf measurements were cleaned in the same manner as previously described except that the cadmium was not boiled with CdI_2.

The palladium metal was introduced directly into the balance tube. However, the cadmium was vaporized into the tube under an initial vacuum of 10^{-5} Torr from an attached U-tube. Half of the cadmium originally loaded into the U-tube remained in the tube after completing the evaporation.

The run started with all of the cadmium in the alloy leg. Lowering the temperature of the other leg then allowed cadmium to condense while simultaneously increasing the solute concentration of the alloy. The temperatures for equilibrium between a particular alloy and the reservoir were determined by slowly shifting the reservoir temperature until cadmium

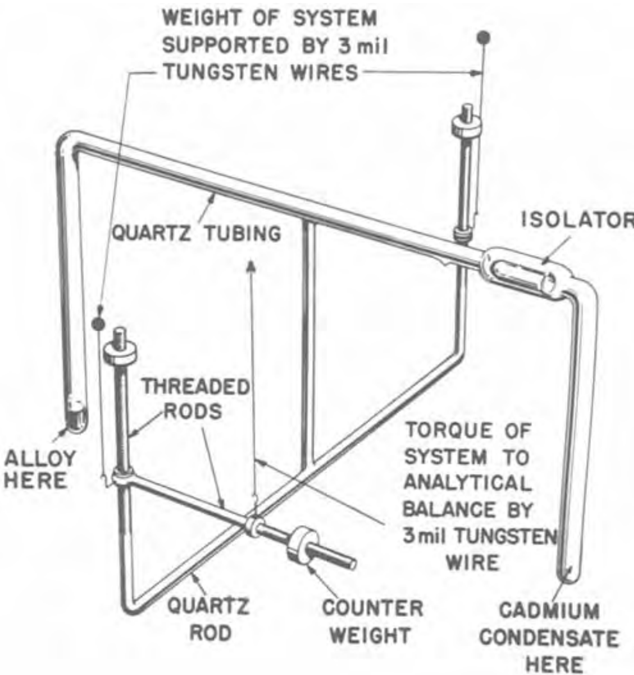

Fig. 2. Isopiestic balance (schematic)

transfer ceased, then reversed. Reversal points were approached from both higher and lower temperatures relative to the equilibrium temperature.

The balance system was adjusted to a sensitivity sufficient to detect weight shifts of 0.02 mg at the analytical balance for reversal detection. However, the accuracy of the analytical balance with its weights was probably only ±0.2 mg or less. Since the balance factor (the ratio between weight shift read at the analytical balance and weight shift occurring in the balance tube) is approximately six, the uncertainty in the weight of cadmium transferred is ±0.03 mg. For a 1g sample this gives an uncertainty of three parts in 100,000. The metals were weighed to 0.01 mg before introduction into and after removal from the balance tube.

A Leeds and Northrup galvanometer and Wenner potentiometer combination which had a sensitivity of 0.01 μV was used to measure the Pt/Pt-10% Rh thermocouple emf's. Temperatures were calculated in the same manner as for the H-cell measurements.

Because the thermocouple junctions below the legs of the tube are not at exactly the same temperatures as the tube legs, a correction factor must be added to the measured emf. This bias correction also varies with weight of cadmium transferred in the tube due to the fact that a small temperature gradient is present along the legs. When the amount of metal in a given reservoir increases, its height increases, changing the average metal temperature relative to the thermocouple junction below. This effect has been measured (9) to be

$$\Delta \text{ emf} = -(0.075 \pm 0.007) \times \text{bal. shift} + \text{const.} \quad [3]$$

where the emf is in μV and the balance shift is in grams. The additive constant is determined for a given run by extrapolating an activity *vs.* mole fraction plot to infinite dilution.

The activities are determined by dividing the solvent vapor pressure over the alloy by the vapor pressure of pure solvent at the same temperature. Activity is used because it varies slowly with allow temperature and is determined by the temperature difference between the alloy and pure solvent reservoirs.

The vapor pressure over pure cadmium was calculated using the equation

$$P_{Cd}^{\circ} = \exp[(-13\,119/T) + 19.950 - 1.05676 \ln T] \quad [4]$$

which is consistent with Hultgren's values (18). The 150 cal-per-mole uncertainty in $\Delta H_{v, 298°K}$ indicated by Hultgren corresponds to an uncertainty of one part in 200 in the slope of activity *vs.* mole fraction (1).

More extensive descriptions of the experimental apparatus, techniques, and uncertainties are available (1, 3, 4, 7, 9).

Results

For the palladium-cadmium systems, the results taken by emf are listed in Table I and those taken by vapor pressure are listed in Table II. Figure 3 is a plot of cadmium activity *vs.* cadmium mole fraction. In the range of $N_{Cd} = 1$ to $N_{Cd} = 0.9648$ the equation

$$a_{Cd} = 1 - N_{Pd} - 2.538\, N_{Pd}^2 \quad [5]$$

fits the combined emf and vapor pressure results with a standard deviation of ±0.00043. In the range of N_{Cd}

[a] 6.0650g balance shift = 1.00000g cadmium shift. Initial cadmium 2.19926g, palladium 0.00453g.
[b] Measured with Pt/Pt-10% Rh thermocouple against ice junction to nearest 0.1°K.
[c] Measured with Pt/Pt-10% Rh thermocouple to 0.001°K temperature difference between alloy and pure cadmium. Distinct reversal of cadmium transfer observed 0.010°-0.015°K beyond equilibrium values. ΔT calculated from millivolts using equation of Roeser and Wenzel, after subtracting a bias correction of [0.00266-0.000075 × balance shift (grams)] millivolts. The first constant is established by finding that correction necessary to make the data extrapolate to unit activity at pure solvent; the second constant is determined from measurements on pure cadmium runs.
[d] Vapor activity relative to that over pure liquid cadmium, using equation consistent with Hultgren's (17) value, namely $P_{Cd}^{o} = \exp[(-13\,119/T) + 19.950 - 1.05676 \ln T]$.
[e] Calculated using equations in text.

$= 0.9648$ to $N_{Cd} = 0.925$ the cadmium activity is 0.96157 with a standard deviation of ± 0.00035. Better fits can, of course, be obtained if the emf and vapor pressure results are each fitted individually to separate curves. In this case the separate curves do not agree. However, the discrepancy between the two curves is less than the absolute uncertainties associated with various aspects of the two methods of measurement.

Although the least squares fit to the three runs gives an indication of the accuracy of the results, the precision associated with the individual emf runs is much higher than is indicated by the above fit. However, because saturation occurs at such dilute concentrations, the palladium dissolved very slowly in the cadmium. As a result, days rather than hours were involved in obtaining individual emf measurements. Consequently, the emf results for the Pd-Cd system are less precise and less accurate than those obtained for the Ni-Cd (10) or Au-Cd (19) systems.

The scatter in the data for the vapor pressure measurements tends to remain constant with solute concentration whereas the emf scatter tends to be proportional to solute concentration due to the nature of the measurements taken.

The solution is evidently saturated at a composition corresponding approximately to $PdCd_{27}$ or $N_{Cd} = 0.9643$.

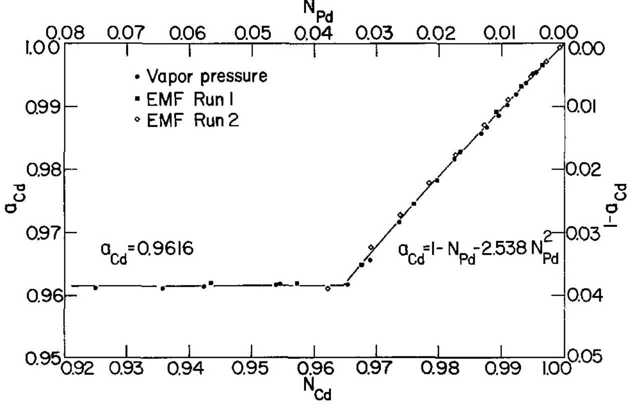

Fig. 3. Cadmium activities for solutions containing small amounts of palladium.

From the form of Eq. [5] it is apparent that the dilute palladium-cadmium solutions are in agreement with Raoult's limiting law within the uncertainty of the data. As a consequence, we have obtained further evidence that the assumption of 1.87 for the value of n at the limit of infinite dilution is justified.

The Coulostatic Method: Analysis of Error and Computation of Parameters

H. Reller and E. Kirowa-Eisner

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

Analysis of error has been carried out for the coulostatic method. The optimal time scale for the determination of i_o has been shown to be equal to $2\tau_c$. The determination of i_o is based on the computer curve-fitting of a set of points on the transients to the analytical equation of potential decay. The uncertainty in the determination of i_o depends only on the ratio τ_c/τ_d. Highest accuracy is otbained for $\tau_c/\tau_d > 500$, where the uncertainty in the determination of i_o is 3.3 times that for the measurement of the potential. Reasonable accuracy can be obtained for values of τ_c/τ_d not less than 0.5. An iteration method for the simultaneous determination of i_o and C_{dl} has been outlined.

The state of the art of the coulostatic method has been recently reviewed by van Leeuwen (1). Although the strength of this method is suited well for the study of fast electrode reactions, its use is rather limited.

In this work we have addressed ourselves to three problems encountered in the study of fast electrode reactions by the coulostatic method.

1. The optimal experimental conditions for undertaking coulostatic measurements and the estimation of the accuracy and the limits of the method must be determined. Some data on this subject are given in the work of Kooijman and Sluyters (2).

2. The common methods for determination of C_{dl} are not operative for fast electrode processes, where the faradaic current plays an important role from the very beginning of the measurements. However, it is necessary to know C_{dl} for the determination of i_o when diffusion corrections have to be made. In this work, we propose an iteration method for the simultaneous determination of i_o and C_{dl} based on measurements at different parts of the decay curve.

3. The complex form of the mathematical expressions impose difficulties on the evaluation of the experimental data. Methods based on approximation (3), nomograms (2), and transformation of the transients data into an impedance plane (4) have been proposed. Our approach is based on the use of a computer parameter fitting program, which permits straightforward evaluation of the kinetic parameters from Eq. [2], without the need to use any approximation other than those made in the derivation of the basic Eq. [2].

Discussion

Fast electrode processes are controlled by charge transfer and mass transfer simultaneously. Delahay (5) and Reinmuth (6) derived a potential-time expression for single step reactions, taking the diffusion into consideration (Eq. [2]). Reller and Kirowa-Eisner (7) treated the case of multi-step reactions of the type

$$\nu_O O + ne^- = \nu_R R \qquad [1]$$

where the stoichiometric coefficients ν_O and ν_R are different than unity.

The equation of the potential decay at small perturbations from equilibrium ($|\eta| << RT/\alpha\mathbf{F}$) is general for single step and multi-step reactions (7)

$$\eta = \eta_o \frac{1}{\gamma - \beta}\{\gamma \exp(\beta^2 t)\,\mathrm{erfc}(\beta t^{1/2}) - \beta \exp(\gamma^2 t)\,\mathrm{erfc}(\gamma t^{1/2})\} \qquad [2]$$

where η_o is the overpotential at the completion of the charge injection, and

$$\beta = \frac{\tau_d^{1/2} + (\tau_d - 4\tau_c)^{1/2}}{2\tau_c} \qquad [3]$$

$$\gamma = \frac{\tau_d^{1/2} - (\tau_d - 4\tau_c)^{1/2}}{2\tau_c} \qquad [4]$$

The parameters ν_O, ν_R, and ν (stoichiometric coefficients and stoichiometric number) which alone characterize multi-step reactions at small perturbations from equilibrium are incorporated in τ_c and τ_d

$$\tau_c = \frac{\nu}{n}\frac{RT}{\mathbf{F}}\frac{C_{dl}}{i_o} \qquad [5]$$

$$\tau_d^{1/2} = \frac{RTC_{dl}}{n^2\mathbf{F}^2}\left[\frac{\nu_O^2}{C_O^o D_O^{1/2}} + \frac{\nu_R^2}{C_R^o D_R^{1/2}}\right] \qquad [6]$$

τ_c and τ_d are the time constants for the charge-transfer and the diffusional relaxation, respectively.

Equation [2] is derived on the assumption that no faradaic current is flowing during the charging step.

The parameters i_o and C_{dl} are determined on the basis of Eq. [2]. The complexity of the equation has usually involved the use of approximations which introduce systematic errors. To avoid this type of error, we use a parameter-fitting program, in which equally weighted points along the transient are fitted into Eq. [2] (details at end of paper).

Optimal time scale and accuracy in the determination of i_o.—It is important to analyze the potential-time Eq. [2] in terms of the level of information and the accuracy in the determination of i_o as a function of the kinetic parameters of the reaction and the time scale on which the transient is observed.

The kinetic information content along the decay curve can be expressed by the absolute value of the first derivative of the potential $\partial\eta/\partial i_o$. The level of in-

Key words: coulostatic method, computer, decay.

formation is dependent on the kinetic parameters of the electrode reaction and on the time elapsed from the start of the transient. We define the instantaneous information content, I, as

$$I = \frac{i_o}{\eta_o} \left| \frac{\partial \eta}{\partial i_o} \right| \quad [7]$$

Zero value for I means that the measured parameter η is independent of i_o or in other words it does not provide information about i_o. Unity value for I indicates maximum information content in respect to a linear relationship between both parameters.

The expression for I, which is too long to be presented here, was analytically derived on the basis of Eq. [2] and calculated for specific values of exchange currents, concentrations, and time by a computer program. The instantaneous information content, I, is independent of η_o, while $\partial\eta/\partial i_o$ is proportional to η_o (Eq. [2]). The variations of the instantaneous information content with time, for different values of τ_c/τ_d are shown in Fig. 1. The potential decays for the conditions presented in Fig. 1 are given in Fig. 2.[1]

Three regions can be distinguished on the curves (Fig. 1): (*i*) for $t < \tau_c$, where the capacitance contribution is high, there is little instantaneous information, in spite of the small degree of diffusion control; (*ii*) for $t \sim \tau_c$, maximum instantaneous information; (*iii*) for $t > \tau_c$, where the measured signal has fallen to low values and where, in the case of fast reactions, the transient is largely controlled by diffusion, again little instantaneous information.

The shape of the information curve is similar to the one derived for discharge of a condenser through a constant resistance ($I = t/RC \exp [-t/RC]$). The maximum in this case is reached at a time equal to $RC \times 1$ or in terms of the charge-transfer time constant to $\tau_c \times 1$. The value of I at the maximum is

[1] The presentation of the potential decays in a scale of t/τ_c gives the wrong impression that the slowest decay belongs to the largest exchange current.

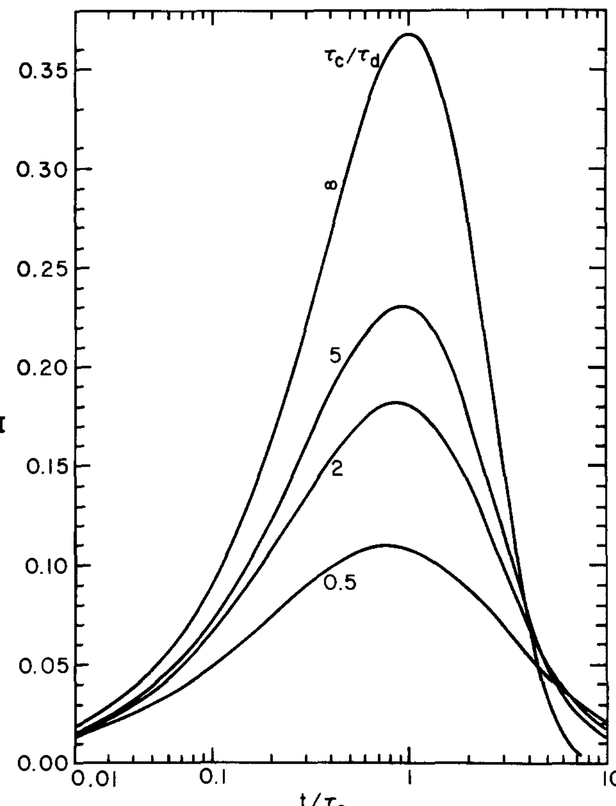

Fig. 1. Instantaneous information in respect to exchange current density, $I(i_o)$ along the potential transient, for a set of electrode reactions with different τ_c/τ_d.

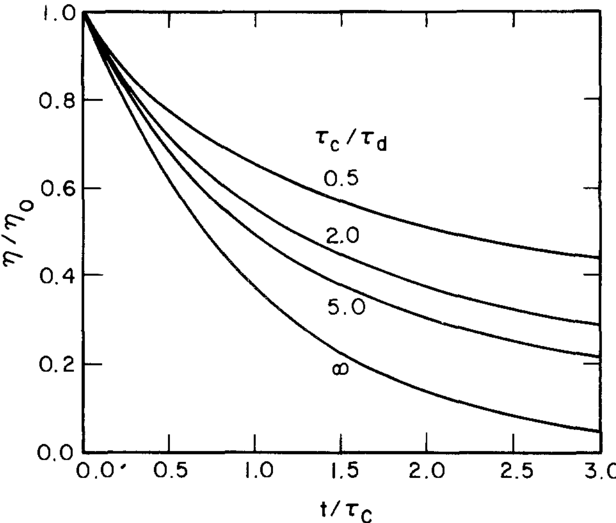

Fig. 2. Potential decays for a set of electrode reactions. Conditions as in Fig. 1.

e^{-1} (0.37). That will be the limiting value reached in an electrochemical system with negligible diffusion control. The higher the contribution of diffusion (lower τ_c/τ_d), the lower the maximal value for I (see Fig. 1).

This approach of presenting the instantaneous information content is similar to that used by Kooijman and Sluyters (2).

The aim of our work is to estimate the average information content over a certain measuring-time interval. This is of practical importance in computing parameters from a considerable section of the transient, rather than from a single point on it. The optimal time scale does not necessarily coincide with the occurrence of a maximum in the instantaneous information curve. For the method of determination of i_o we propose, based on fitting a set of points from the transient into Eq. [2], the average value of the information along the transient is of interest.

The average information $\bar{I}$ is expressed as

$$\bar{I} = \frac{1}{T}\int_0^T I dt = \left| \frac{i_o}{\eta_o T}\int_0^T \frac{\partial \eta}{\partial i_o} dt \right| \quad [8]$$

where T is the full time-scale reading at which the transient is observed.

The average information varies along different parts of the transient. The time scale at which the potential decay provides the highest value of average information is the optimal time scale from which data have to be used.

Curves with average information along the transient are shown in Fig. 3 (the data correspond to the potential decays shown in Fig. 2). For the purpose of determining the optimal time scale, the maximum in these curves is searched. Characteristic to all curves, the maximum is found at $t/\tau_c = 1.8$. Thus the time at which the maximum of the average information content is reached is about twice as long compared to the value for the instantaneous information content. This stems from the need to compensate for the low instantaneous information content at short times. The optimal time scale is determined solely by the value of the exchange current and the capacity as would be for a simple system of a capacitor discharged through a resistor. The diffusion rate has no effect on the optimal time scale. This was confirmed by determining the optimal scale for a large set of systems in which i_o was varied in the range of 10^{-4}-2 A/cm^2 and the concentration in the range of 0.1-100 mM.

One can further optimize the average information by limiting the time scale at its lower extreme (up to 0.2 τ_c) as well as at the upper end (near 2 τ_c), since

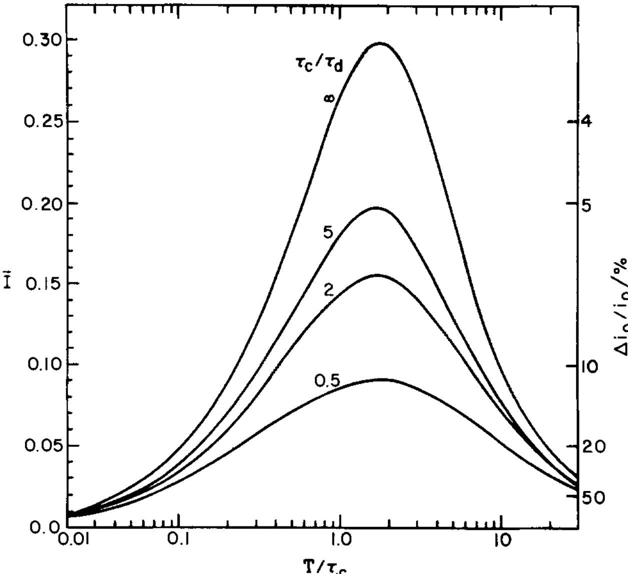

Fig. 3. Average information in respect to exchange current density, $\bar{I}(i_o)$, along the potential transient. Conditions as in Fig. 1. Right-hand axis is calibrated as $\Delta i_o/i_o$, calculated for $\Delta\eta/\eta_o N^{1/2} = 0.01$.

the data up to 0.2 τ_c contain a low level of instantaneous information (Fig. 1). This modification brings about some improvement in the value of the average information, $\bar{I}$ ($\bar{I}$ is increased by about 10%).

It is important to compute the accuracy by which i_o can be determined and to study the factors which determine it. Thus the potentiality and the limits of the coulostatic method can be estimated.

The accuracy in the determination of i_o is proportional to the average information content, $\bar{I}$. The error, Δi_o, is proportional to the reciprocal value of $\bar{I}$; before using this relationship, one has to ensure that the error, Δi_o, is determined solely by the first order derivative $\partial i_o/\partial\eta$. The error in the exchange current as a function of the uncertainty in the overpotential can be expressed by expanding the function $i_o = \mathbf{F}(\eta)$ into Taylor's series

$$\Delta i_o = \frac{\partial i_o}{\partial\eta}\Delta\eta + \frac{\partial^2 i}{\partial\eta^2}\frac{\Delta\eta^2}{2!} + \dots \quad [9]$$

We have calculated and compared the values of the first and second derivatives along the decay curve for a large set of systems in which τ_c/τ_d was varied between 10^{+2}-10^{-3}. In all cases, for a typical value of $\Delta\eta = 10^{-4}$V, the second term on the rhs of Eq. [9] was found to be only 7% of the first term. However, the simplified equation $\Delta i_o = \frac{\partial i_o}{\partial\eta}\Delta\eta$ cannot be used in its present form because (*i*) $\partial i_o/\partial\eta$ varies along the part of the transient used for the computation of i_o; its average value $\frac{1}{T}\int_0^T \frac{\partial i_o}{\partial\eta}\,dt$ has to be used instead; (*ii*) $\Delta\eta$, which is the uncertainty in the determination of a single point has to be replaced by its mean value over the set of N points used for computation of i_o, which is $\Delta\eta/N^{1/2}$.

The relative error $\Delta i_o/i_o$ is estimated by

$$\frac{\Delta i_o}{i_o} = \frac{\Delta\eta}{N^{1/2}}\frac{1}{T}\left|\int_0^T \frac{\partial i}{\partial\eta}\,dt\right| = \frac{\Delta\eta}{\eta_o N^{1/2}}\frac{1}{\bar{I}} \quad [10]$$

The relative error can be estimated from Fig. 3, where the right-hand side of the y-axis is calibrated in $\Delta i_o/i_o$ units for a typical case of $\eta_o = 5$ mV, $\Delta\eta = 0.15$ mV, and $N = 10$. The error decreases with the decrease of the exchange current (or the increase of τ_c/τ_d). This naturally is expected as kinetic control predominated with the decrease of i_o. The relative error, at the optimal time scale $T = 2\tau_c$, is shown in Fig. 4 and 5 as function of exchange current and concentration. The y-axis in these figures are calibrated as $1/\bar{I}$ and $\Delta i_o/i_o$.

The maximal value of the average information $\bar{I}$, has been computed for different combinations of i_o, C, and C_{dl}, for the purpose of correlating the error $\Delta i_o/i_o$ with the parameters of an electrode reaction. Large sets of systems have been tested (over a concentration range 0.1-100 mM; capacity range 5-40 μF/cm² and exchange current range 10^{-4}-5 A/cm²). It was found that systems with the same value for the ratio τ_c/τ_d (or C^2D/i_oC_{dl} in the case $C_O{}^o = C_R{}^o = C$ and $D_O = D_R = D$) provide the same average information, $\bar{I}$, at the optimal time scale. Kooijman and Sluyters (3) have pointed out (by expanding Eq. [2] in the form of power series) that the value τ_c/τ_d, and not i_o itself, determines the capability of the method. This knowledge permits us to generalize in a useful way, the dependence of the error on the parameters characterizing the system. An empirical equation, relating $\bar{I}$ with τ_c/τ_d, has been formulated (Eq. [11])

$$\ln\frac{\tau_c}{\tau_d} = 0.64 - 1.5\ln\frac{\bar{I}_{lim} - \bar{I}}{\bar{I}} \quad [11]$$

The relative error for any system complying with Eq. [2], can be calculated on the basis of Eq. [10].

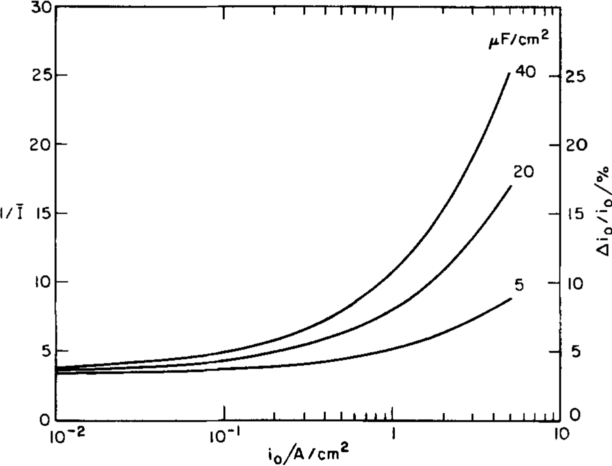

Fig. 4. Error curves as function of exchange current. Y-axis calibrated as $1/\bar{I}$ and $\Delta i_o/i_o$. $C_O{}^o = C_R{}^o = 5$ mM; $D_O = D_R = 10^{-5}$ cm²/sec; $T = 2\tau_c$; $\Delta\eta/\eta_o N^{1/2} = 0.01$.

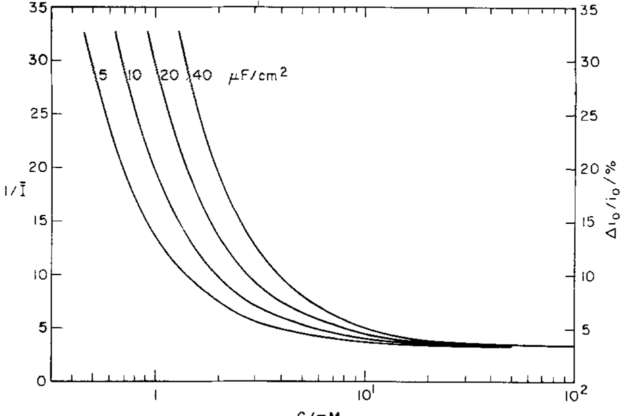

Fig. 5. Error curves as function of concentration. Y-axis calibrated as $1/\bar{I}$ and i_o/i_o. $i_o = 0.5$ A/cm²; $C_O{}^o = C_R{}^o$; $D_O = D_R = 10^{-5}$ cm²/sec; $T = 2\tau_c$; $\Delta\eta/\eta_o N^{1/2} = 0.01$.

$\bar{I}_{\text{lim}}$ is the value of the average instantaneous information, $\bar{I}$, reached for $\tau_c/\tau_d > 10^3$. Its numerical value is 0.30,which is identical to the average information calculated for discharge of a condenser through a resistor.

Equation [11] can also be expressed in terms of i_o, C_{dl}, and C, in view of Eq. [5] and [6]. For the simple case of $C_O^o = C_R^o = C$ and $D_o = D_R = 1.1 \times 10^{-5}$ cm²/sec, $\tau_c/\tau_d = C^2/i_oC_{dl}$ (C in mM i_o in A/cm², and D_{dl} in μF/cm²). The equation describes faithfully the correlation between $\bar{I}$ and the parameters τ_c and τ_d. This is demonstrated in Fig. 6, where the solid line of the $\bar{I}$ curve corresponds to the empirical Eq. [11] and the points are calculated according to Eq. [8]. The correlation coefficient of the individual points in relation to the line fitted to these points is −0.9996.

The error curve (calculated on the basis of $\bar{I}$ and Eq. [11] for $\frac{\Delta\eta}{\eta_o}\frac{1}{N^{1/2}} = 0.01$) is presented in Fig. 6, alongside the average information curve. Good accuracy can be reached only for values of τ_c/τ_d larger than unity; below unity the error strongly increases, although satisfactory results can be obtained for $\tau_c/\tau_d = 0.5$. Highest accuracy is obtained for $\tau_c/\tau_d > 500$, where the uncertainty in the determination of i_o is 3.3 times that for the measurement of the potential (Eq. [11]).

In addition, Eq. [11] was used to estimate the largest value of the exchange current that can be measured at a given concentration of reaction species within the limits of a predetermined error. These data are summarized in Table I.

Practically, the upper limit of the obtainable exchange current density is determined by (*i*) the instrumental problems of observing the potential decay at short time scale [$T_{\min} \sim 0.5$ μsec (8)]; (*ii*) the limitations dictated by Eq. [2], which requires that no faradaic current flows during the charging step. To fulfill this requirement the charge injection should be completed at a time shorter than 0.1 τ_c. Injection time of 50 nsec have been used (8). Thus, the smallest value of τ_c that can be experimentally determined is about 0.5 μsec, which in terms of i_o is 0.5-2 A/cm² (for C_{dl} 10-40 μF/cm²).

An increase in the concentration of reacting species causes an increase in τ_c/τ_d (decrease of $\Delta i_o/i_o$), while simultaneously decreasing τ_c. Thus, there is an upper concentration limit imposed by the experimental requirement of $\tau_c > 0.5$ μsec.

If the maximum values of i_o estimated above are combined with a value of $\tau_c/\tau_d = 0.5$, for which rea-

Table I. Maximal values of i_o measured with a predetermined error of 10% and 20%. $\Delta\eta/\eta_oN^{1/2} = 0.01$; $C_O^o = C_R^o$

1	0.1	0.03	0.5	0.1
5	3	0.8	5	3
20	>5	>5		>5

sonable accuracy in the determination of i_o can be achieved, it turns out that a standard rate constant, k_s, up to 3 cm/sec can be measured. (In the calculation of k_s we refer to a simple electrode reaction for which $k_s = i_o\,[n\mathbf{F}(C_O^o)^{\alpha_c}(C_R^o)^{\alpha_a}]^{-1}$, $C_O^o = C_R^o$ and $\alpha_a = \alpha_c = 0.5$.)

It should be stressed that the above treatment considers only the error resulting from the measurement of the potential. It gives a general information of the factors on which the accuracy of the method is dependent. It can be used only when the exchange current is the only parameter that has to be determined (C_{dl} is known from some other independent method).

Analysis of error for the single step and double step galvanostatic method is in preparation.

Simultaneous determination of i_o and C_{dl}.—In some cases there is no previous information about C_{dl} and its value has to be determined simultaneously with the exchange current density. But even when C_{dl} is known from some independent method, it is important to confirm that its value is constant along the coulostatic transient.

For the sake of simplicity, we shall consider first the hypothetical case in which C_{dl} is the only variable to be determined, while i_o is known without error. The error, $\Delta C_{dl}/C_{dl}$, is determined on the basis of Eq. [12] analogous to Eq. [10]. Only first derivatives are used in view of Eq. [9] (terms with higher derivatives have been found negligible)

$$\frac{\Delta C_{dl}}{C_{dl}} = \frac{1}{N^{1/2}}\frac{\Delta\eta}{T}\left|\int_0^T \frac{\partial C_{dl}}{\partial\eta}\,dt\right| = \frac{\Delta\eta}{\eta_oN^{1/2}}\frac{|1}{\bar{I}(C_{dl})} \qquad [12]$$

The variation of the average information, $\bar{I}(C_{dl})$, as a function of time scale T is given in Fig. 7. For pure kinetic control ($\tau_c/\tau_d \to \infty$), $\bar{I}(C_{dl}) = \exp(-t/\tau_c)$. When the time scale is short, $T << \tau_c$, the average in-

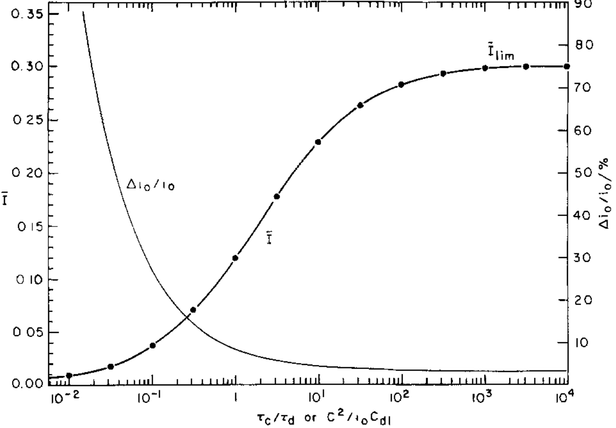

Fig. 6. Average information in respect to exchange current as function of τ_c/τ_d. Relative error as a function of τ_c/τ_d (calculated for $\Delta\eta/\eta_oN^{1/2} = 0.01$) X-axis calibrated also as C/i_oC_{dl} ($\tau_c/\tau_d = C/i_oC_{dl}$ for $C_O^o = C_R^o = C$; $D_O = D_R = 1.1 \times 10^{-5}$ cm²/sec; C[mM]; C_{dl}[μF/cm²]; i_o[A/cm²]).

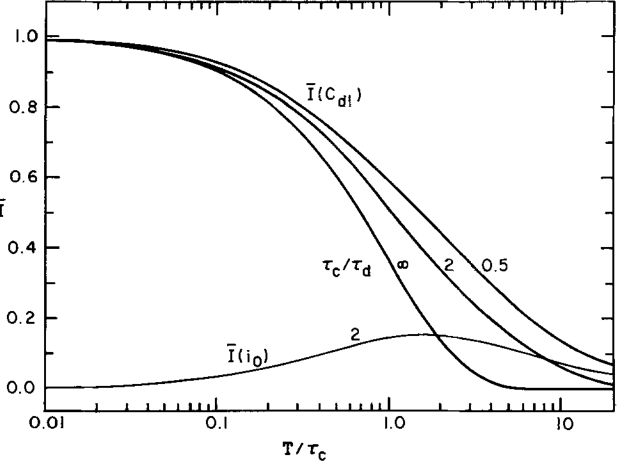

Fig. 7. Average information curves in respect to double layer capacity at different τ_c/τ_d. A curve with average information in respect to exchange current density is given for comparison purposes.

formation approaches unity, independently of τ_c/τ_d. For longer time scales, the information decreases with the rate of decrease depending on τ_c/τ_d.

Since the optimal time scales for the determination of the individual parameters differ appreciably, the simultaneous determination of i_o and C_{dl} for a particular time scale will entail a large error. Our approach to this problem is the use of an iteration method, combined with the parameter-fitting program. In principle, the complex-plane analysis used by Sluyters *et al.* (4) is another solution to the problem.

1. Preliminary computation of i_o and C_{dl}. Potential decays are recorded on several time scales. From the data of each decay the parameters i_o and C_{dl} are computed (with the use of the computer curve-fitting program). The mean and standard deviation of the two parameters are calculated.

2. Computation of C_{dl} as single parameter. The data from the shortest experimentally attainable time scale are used for the determination of C_{dl} with the predetermined value of i_o, obtained from 1. (At short times, the high value of $\bar{I}(C_{dl})/\bar{I}(i_o)$ ensures that C_{dl} can be determined quite accurately in the presence of large error in i_o.)

3. Computation of i_o as single parameter. Data from the optimal time scale, $T = 2\tau_c$, for the determination of i_o, are used (τ_c is estimated from step 1). i_o is computed with the predetermined value of C_{dl}, obtained from step 2.

4. Steps 2 and 3 are repeated until i_o and C_{dl} remain unchanged within the expected errors (estimated from the value of τ_c/τ_d).

The efficiency of the iteration method is demonstrated in Table II by a simulated experiment of a system with a large diffusion contribution ($\tau_c/\tau_d = 0.5$). The data in Table II were obtained as follows.

Potential decays with an initial potential of 5 mV were calculated according to Eq. [2]. Four time scales have been used. At each time scale six experiments have been simulated with different sequences of random errors. Sets of data for each decay were constructed as follows: 10 points were selected at equal time intervals, the first point at $0.1T$ and the last at T. A normally distributed random error with zero mean value and a standard deviation of 0.15 mV was added to the calculated value of the potential at each point.

We shall add that a two-indicator electrode cell proposed by Sluyters *et al.* (10) is suitable for the above outlined experiment. The cell provides an excellent solution for most of the nonlinearity problems which may arise when the initial potential is larger than 1 mV.

The value of i_o and C_{dl} were calculated according to the iteration method outlined above. The steps followed by the simulated experiment are summarized in Table II. First, i_o and C_{dl} were determined by two-parameter curve-fitting. The standard derivatives were large [$\sigma(i_o) = 50\%$ from the mean of i_o and $\sigma(C_{dl}) = 7\%$ from the mean of C_{dl}, both at $T \sim 2\tau_c$]. At subsequent recalculation i_o and C_{dl} according to the iteration procedure, the standard deviations decrease to 8% and 1%, respectively, in good agreement with the expected values as calculated from $\bar{I}(i_o)$ and $\bar{I}(C_{dl})$ at the respective time scales ($\sim 2\tau_c$ for i_o and $\sim 0.3\tau_c$ for C_{dl}).

The proposed method for computation of parameters is applicable to reactions controlled by charge transfer and by mass transfer. If a simple scheme is not operative, the use of complex-plane method (4) is advised.

Computation of parameters.—The evaluation of the parameters i_o and C_{dl} from the potential decay curves cannot be performed by a direct approach using Eq. [2]. Berzins and Delahay (3) proposed an approximation method. Kooijman and Sluyters (2) developed a numerical analysis based on the use of nomograms and van Leeuwen *et al.* (4) introduced a method based on transformation of the experimental relaxation curve into the impedance plane.

Our approach is based on the use of a parameter-fitting program [library program MINUIT (11)], in which the data from the experimental relaxation curve has been fitted to the analytical expression of the η-t curve (Eq. [2]). The kinetic parameters are computed on the basis of searching minimum for the chi-square, χ^2

$$\chi^2 = \sum_{i=1}^{n} \left(\frac{\eta_{i(\text{calc})} - \eta_{i(\text{exp})}}{\Delta\eta} \right)^2 \qquad [13]$$

where $\eta_{i(\text{exp})}$ is the measured potential at point i; $\eta_{i(\text{calc})}$ is the calculated value obtained from the curve-fitted parameters; and $\Delta\eta$ is the standard deviation of the measured potential.

The computer program supplies the following information: i_o, C_{dl}, τ_c, τ_d, $\eta_{i(\text{calc})}$; graphic comparison of experimental decay curve with calculated curve. A program for calculating the derivative $(\partial\eta/\partial i_o)_{\tau_c,\tau_d}$ is included for enabling the estimation of the error $\Delta i_o/i_o$. The input data are: the experimental points along the decay curve, the value of the injected charge, the concentration and diffusion coefficients of species O and R, and the value of n.

In respect to the output, it is suggested to perform a χ^2-test for the goodness of fit and to check if the experimental points of the decay curve are randomly distributed along the calculated potential decay curve.

The computer program is written in Fortran IV. The program is available upon request from the authors.

LIST OF SYMBOLS

C_{dl}	double layer capacity
$C_O^o, (C_R^o)$	bulk concentration of oxidized (reduced) form in bulk of solution
$D_O, (D_R)$	diffusion coefficient of oxidized (reduced) form
I	instantaneous information
$\bar{I}(\bar{I}(C_{dl}))$	average information in respect to the exchange current density (double layer capacity)
$\bar{I}_{lim}$	$\bar{I}$ at $\tau_c/\tau_d > 10^3$
i_o	exchange current density
Δi_o	error in the determination of i_o
N	number of points along the transient used for the computation of i_o
O,(R)	oxidized (reduced) form of reactive species
T	full time scale reading
t	time elapsed from the start of the potential transient
$\beta(\gamma)$	defined by Eq. [3] (4)
η	overpotential
η_o	the overpotential at the completion of the charge injection (at $t = 0$).
ν	stoichiometric number
$\nu_O(\nu_R)$	stoichiometric coefficient of O(R) in the overall electrode reaction
τ_c	charge-transfer relaxation constant
τ_d	diffusional relaxation constant

Electrochemical Analysis of Copper Oxides Present in Cuprous Sulfide

J. Vedel* and M. Soubeyrand[1]

Laboratoire d'Electrochimie Analytique et Appliquée (associé au CNRS), E.N.S.C.P., 75005, Paris, France

ABSTRACT

A titration method permitting the determination of the products of air oxidation of thin layers of cuprous sulfide containing copper or not is described. It consists of a cathodic reduction at constant current with potentiometric determination of the equivalent point (current density, 2 A m^{-2}; electrolyte, 0.1M aqueous solution of sodium acetate). Nonstoichiometric cuprous sulfide (Cu_xS) is reduced to Cu_2S at −0.7V (*vs.* Ag/AgCl/KCl 1M electrode) and Cu_2S to copper at −1.0V. When cuprous sulfide is heated in air, cupric oxide is formed which is reduced at −0.16V. If an excess of metallic copper is present, cuprous oxide is formed and reduced at −0.45V. The titration method may be used to characterize the cuprous sulfide from CdS-Cu_2S solar cells.

The active element in CdS-Cu_2S solar cells is the heterojunction which exists between the cadmium sulfide and a layer of cuprous sulfide formed on its surface. Most of the light is absorbed by the cuprous sulfide, whose properties strongly influence the output of photocells. The properties of cuprous sulfide are governed by its composition or, more precisely, the departure from the stoichiometric composition Cu_2S which is thus a very important parameter (1, 2).

A few years ago we developed a method of analyzing cuprous sulfide, which permitted the determination of the stoichiometric ratio, X, of Cu_XS (3), and which contributed to the manufacture of rather efficient CdS-Cu_2S solar cells (7.2%) (4).

This method consists of the cathodic reduction of the sulfide layer at constant current. The progress of the reduction is followed by recording the variation over time of the potential of the electrode formed by the layer of sulfide. With samples of sulfide which do not contain oxide, titration curves like the curve in Fig. 1 were obtained. These curves show two equivalent points. Analysis of layers of controlled composition and the determination, by chemical analysis, of the total quantity of copper involved has shown (3) that the first step in reduction corresponds to the reduction of nonstoichiometric cuprous sulfide, Cu_XS, to Cu_2S, thus

$$Cu_XS + (2 - X)e^- + \frac{2 - X}{2} H_2O \rightarrow \frac{X}{2} Cu_2S + \frac{2 - X}{2} HS^- + \frac{2 - X}{2} OH^- \quad [1]$$

The second step corresponds to the total reduction of cuprous sulfide to copper

$$\frac{X}{2} Cu_2S + Xe^- + \frac{X}{2} H_2O \rightarrow XCu + \frac{X}{2} HS^- + \frac{X}{2} OH^- \quad [2]$$

Finally the reduction of the water is observed.

This total reduction of thin layers of cuprous sulfide (the thickness existing on solar cells never exceeds 1 μm) is due to the great mobility of Cu^+ ions in the Cu_2S lattice as observed by Etienne (5). He studied

Key words: copper, oxide, sulfide, titration, solar cells.

the growth of copper sulfides on a copper anode in a saturated acidic solution of H_2S at constant current.

If t_1 and $t_1 + t_2$ are the values of time at the two equivalent points, the deviation from stoichiometry δ is given by

$$\delta = 2 - X = \frac{2t_1}{t_1 + t_2} \quad [3]$$

Certain treatments of solar cells involve heating the layers of Cu_XS, which can be overlaid with copper, in air (6). Upon analysis, the titration curves of the layers which are thus treated show new plateaus, no doubt linked to the presence of oxide. The aim of this work is to study the influence of these treatments on the form of the titration curves and to deduce from them a method for the determination of the quantities formed. Thus, samples of air-oxidized cuprous sulfide were analyzed. The quantities of oxide formed are very slight and cannot be identified by physical methods. In order to characterize the oxidation products, the samples were put in contact with solutions containing appropriate reagents and the titration curves obtained with the samples thus treated were compared with those of the untreated samples.

Experimental Section

The cathode reduction is carried out in a closed glass cell permitting the liberation of gas released from the electrolyte (0.1M sodium acetate solution). The auxiliary electrode, which serves as the anode, is a platinum wire placed in a separate compartment. The current density used is 200 $\mu A\ cm^{-2}$. The reference electrode is an Ag/AgCl/KClM electrode. The titration curves are obtained by means of a recording voltmeter with high input impedance.

The samples are obtained by depositing a layer of electrolytic copper on a platinum disk. This layer is then anodically oxidized in an aqueous solution of sodium sulfide. The sulfide obtained is generally nonstoichiometric. The samples are equilibrated by cathodically reducing the excess Cu(II). They are, for this purpose, placed in the titration cell and reduced, as in the analysis, until point A (Fig. 1) is attained. A known quantity of copper can be deposited on the sulfide by continuing the electrolysis beyond point A, for example point B (Fig. 1).

The oxidation consists of heating, in air, at 100°C, for 120 min. The quantities of oxide formed are reproducible at better than 1%. Layers of pure oxide were prepared by heating, the copper layer in air under the same conditions as above, for the cuprous oxide and by anodic oxidation of copper in an N solution of sodium hydroxide for the cupric oxide (7) (current density, $2A\ m^{-2}$).

The solutions used to characterize the products formed are a 10^{-3}M sodium sulfide solution (solution of sulfide) and a dilute perchloric acid solution, pH = 3.5 (acidic solution).

Results

Figure 2 summarizes the influence of oxygen on cuprous sulfide. Only the first part of the titration curve has been presented; the plateau at −1.0V corresponds to the potential observed during the reduction of Cu_2S to copper (reaction [2]). Equilibration gives the Cu_XS stoichiometric (curve 1). Upon treating in air again a plateau appears at a higher potential (−0.16V *vs.*Ag/AgCl) than that corresponding to reaction [1] (−0.70V *vs.* Ag/AgCl) (curve 2, Fig. 2). After immersion in the sulfide solution, a plateau of the same length as the preceding one is observed, but at the level of reaction [1] (−0.70V). Finally the reaction of the acid solution leads to a plateau at the same potential as the preceding one but half the length. The reduction of pure cupric oxide occurs at a different potential (−0.65V *vs.* Ag/AgCl) (curve 5, Fig. 2).

If a layer of copper-enriched cuprous sulfide is treated in the same way, the titration curves shown in Fig. 3 are obtained. For a sample which is only air-oxidized (curve 2), a plateau is observed at −0.45V, next to the plateau at −0.16V already observed after the heating, in air, of the cuprous sulfide alone, whose length is exactly equal to the time of reduction during which the reduction of equilibrated Cu_2S was carried out. The action of the sulfide solution (curve 3) and the action of the acid solution (curve 4) eliminate this plateau and the previous behavior as is observed. Cuprous oxide alone is reduced at −0.75V. When the proportion of reduced copper is increased, there is a decrease of reduction potential of the supplementary wave, which tends toward this same value of −0.75V. (Fig. 4).

Finally, Fig. 5 represents titration curves recorded during the analysis of a copper sulfide obtained by ion exchange on a layer of vacuum deposited CdS [Shirland method (8)]. Curve 1 was obtained by

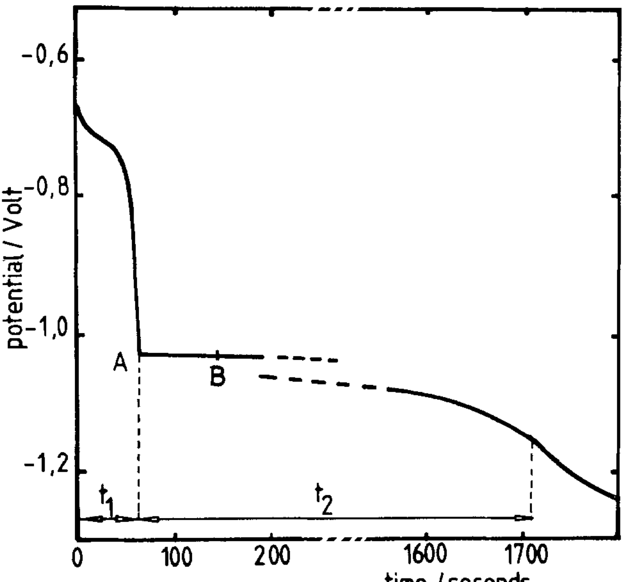

Fig. 1. Potentiometric titration curve at constant current of a layer of nonstoichiometric cuprous sulfide.

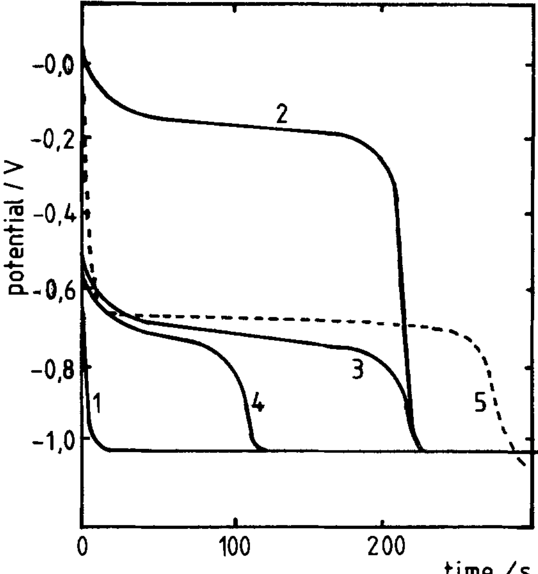

Fig. 2. Potentiometric titration curve at constant current of a layer of equilibrated cuprous sulfide. 1, After equilibration; 2, 3, and 4, after air oxidation. 2, Without treatment; 3, after contact with the sulfide solution; 4, after contact with the acid solution; 5, reduction of a CuO layer.

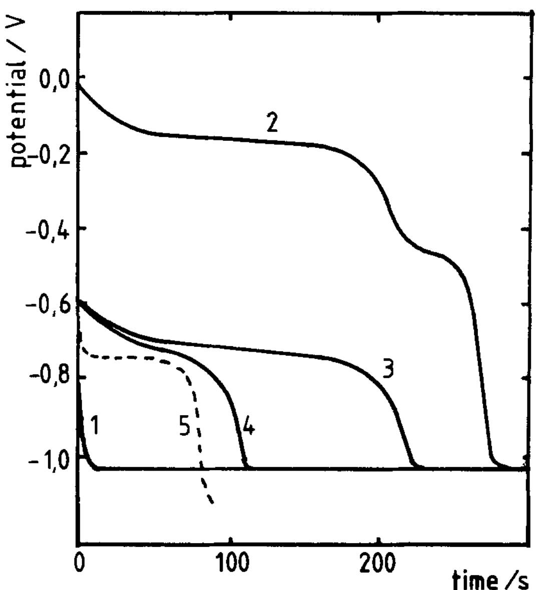

Fig. 3. Potentiometric titration curve at constant current of a layer of equilibrated cuprous sulfide containing an excess of copper. 1, After equilibration; 2, 3, and 4, after air oxidation. 2, Without treatment; 3, after contact with a sulfide solution; 4, after contact with an acid solution; 5, reduction of a Cu_2O layer.

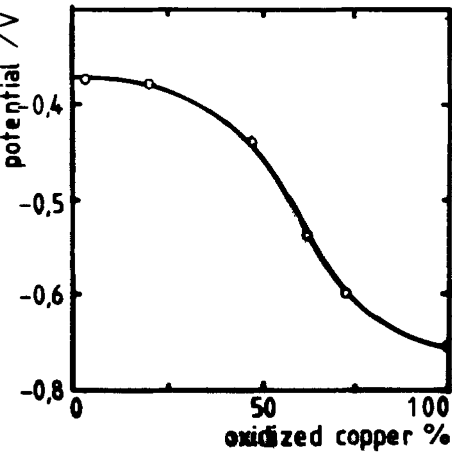

Fig. 4. Variation of reduction potential of the oxidation product of the excess copper (cf. Fig. 4) as a function of the proportion of transformed copper (oxidized copper/transformed copper/total copper).

carrying out the analysis just after the formation, and curve 2 after treatment in the sulfide solution. Curve 1 shows three plateaus, a, b, and c, of which the latter, which corresponds to reaction [2], is situated at a potential more negative than on the curve in Fig. 1. Likewise, plateau b, which corresponds to reaction [1], is displaced toward the more negative potentials. This variation of potentials of plateaus is frequently observed with samples of different origins and can be attributed to modifications of ohmic drop in the underlying layers.

Discussion

The action of oxygen on cuprous sulfide leads to the formation of cupric oxide and cupric sulfide

$$Cu_2S + \frac{1}{2}O_2 \rightarrow CuO + CuS$$

For low ratios of oxidation, this transformation can be accounted for by writing the reaction of the insertion of oxygen in the cuprous sulfide. As a result of its electronegativity, oxygen is fixed to a sulfur site, by the reaction

$$\frac{1}{2}O_2(g) \rightarrow O_S + 2V_{Cu}^x$$

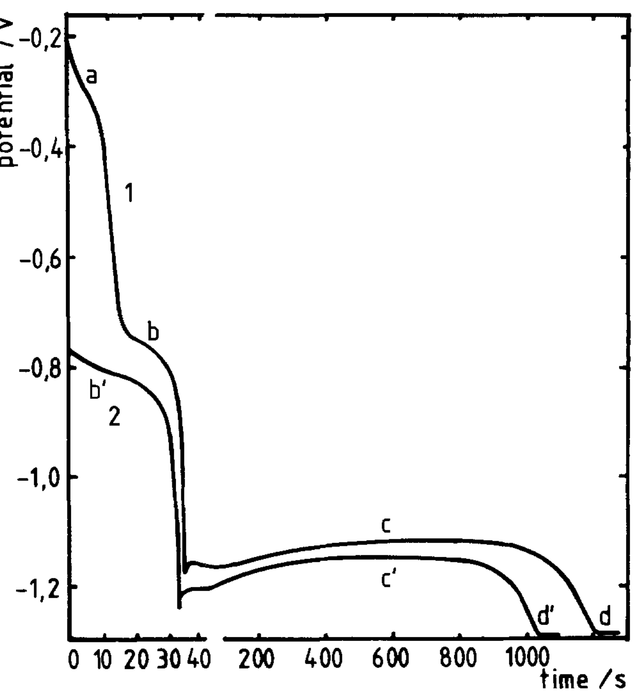

Fig. 5. Titration curve of a layer of cuprous sulfide obtained by ion exchange between a layer of vacuum-deposited CdS and a solution of cuprous salt. 1, After ion exchange; 2, after ion exchange and contact with the sulfide solution.

where, following the notation of Kröger, O_S represents an oxide ion occupying a sulfur site, and V_{Cu}^x, the neutral vacancy of copper which, as in the case of Cu_2O (9), can be considered as the association between a Cu^{2+} ion at a place normally occupied by a Cu^+ ion ($Cu_{Cu}^{\cdot}$) and a copper ion vacancy V_{Cu}' (*i.e.*, a Cu^+ ion is missing). Upon oxidation by an atom of oxygen two Cu^{2+} ions and two copper ion vacancies appear in the solid. The reduction reaction for ($O_S + 2V_{Cu}^x$) is written

$$O_S + 2V_{Cu}^x + 2e + H_2O \rightarrow 2\,OH^- \text{ (aq)} \qquad [4]$$

The copper sulfides are more insoluble than the corresponding oxides. The action of the sulfide solution thus leads to an exchange between the O^{2-} ions and the S^{2-} ions by the reaction

$$O_S + HS^- \text{ (aq)} \rightarrow S_S + OH^- \text{ (aq)} \qquad [5]$$

which leaves the copper ion vacancy V_{Cu}^x unchanged and available for a later reduction

$$S_S + 2V_{Cu}^x + 2e + H_2O \rightarrow HS^- + OH^- \qquad [6]$$

This is another way of writing reaction [1]. The action of the acid solution is written

$$O_S + Cu_{Cu} + V_{Cu}^x + 2H^+ \text{ (aq)} \rightarrow H_2O + Cu^{2+} \text{ (aq)} \qquad [7]$$

Reaction [7] consumes half the V_{Cu}^x vacancies formed during the oxidation by oxygen. Their subsequent reduction thus requires only half the amount of charge as was previously necessary. Thus, the plateau at -0.16 (*vs.* Ag/AgCl) is attributed to reduction of cupric oxide introduced into the cuprous oxide structure during the air-oxidation.

The oxidation of excess copper leads to the formation of cuprous oxide. Indeed, (*i*) as much electricity is necessary to reduce the oxidation product to copper as was necessary in preparing the copper from cuprous sulfide; (*ii*) when the proportion of Cu_2S in the analyzed mixture is decreased, the reduction potential of the material formed tends toward the reduction potential of pure Cu_2O; and (*iii*) the action of the sulfide solution and the action of the acid solution eliminate

Table I. Reduction potential of materials obtained after air-oxidation of copper-enriched cuprous sulfide

Material being reduced	Reduction potential (V) vs. Ag/AgCl	Reduction potential (V) vs. Cu_2S/Cu
CuO (in Cu_2S)	−0.16	+0.84
Cu_2O (in Cu_2S)	−0.45	+0.55
CuS (in Cu_2S, i.e., Cu_xS)	−0.70	+0.30
Cu_2S	−1.00	0
H_2O	−1.21	−0.21

the formation of the compounds formed by the following reactions

$$Cu_2O + S^{2-}\ (aq) + H_2O \rightarrow Cu_2S + 2\,OH^-$$

and

$$Cu_2O + 2H^+\ (aq) \rightarrow Cu_{aq}^{2+} + Cu + H_2O$$

To summarize, the reduction potentials of various materials present in cuprous sulfide are assembled in Table I. In order to eliminate the variations in potentials observed during the study of various samples, the table includes the values obtained by taking, as the reference potential, the potential corresponding to the reduction of Cu_2S to Cu for the sample being considered.

The potentials of the plateaus a, b, c, and d of the titration curve No. 1 in Fig. 5 are 0.84, 0.38, 0, and −0.14V, respectively. Comparing these values with those in Table I, the first plateau, a, can be attributed to the reduction of cupric oxide, the second to the reduction of Cu_xS to Cu_2S (reaction [1]) and the third to the reduction of Cu_2S to Cu (reaction [2]). This conclusion is confirmed by curve 2, Fig. 5, which was obtained after immersion of the sample in the sulfide solution. The first plateau disappeared following reaction [5] and a plateau b' appears whose length is equal to the sum of the lengths of plateaus a and b. If t_0, t_1, and t_2 are the times corresponding to the lengths of plateaus a, b, and c, it is shown, according to reactions [1], [2], and [4] that the fraction of cupric oxide present in the sample, in relation to the total quantity of sulfur, equals $t_0/(t_1 + t_2)$. The fraction of cuprous oxide would be calculated in a similar way.

Periodic Phenomena during Anodic Dissolution of Copper at High Current Densities

John F. Cooper,*[1] Rolf H. Muller,* and Charles W. Tobias*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Uniform and sustained anode potential oscillations (amplitude, 10-20V) have been observed in galvanostatic dissolution of copper in chlorate electrolyte. The oscillations occur in the current density range of 0.3-150 A/cm². Frequency increases with current density in this range from 10^{-3} to 10^3 Hz. Increases in electrolyte temperature, acidity, and flow rate were found to result in a decrease of oscillation frequency. Large amplitude oscillations were also observed in a narrower current density range and with less cycle uniformity, in a variety of mixed electrolytes containing small concentrations of halides. The rise and fall of potential reflects an alternate growth and destruction of an adherent cuprous oxide surface layer. A model for the oscillations is proposed based on resistive switching transitions within the anode surface film.

The anodic dissolution of copper in sodium chlorate electrolyte gives rise to a remarkable phenomenon. On applying a constant current to the cell, the anode potential fails to reach a steady level; rather, the potential undergoes a periodic rise and fall of about 10V, as shown by the sample oscillograph recording (Fig. 1). The individual cycles are impressively uniform in period and amplitude. Oscillations are found with galvanostatically controlled current densities in the range of 0.3 to over 150 A/cm². Above approximately 180 A/cm², random fluctuations accompanied by gassing and sparking were observed. Frequency increases with current density within this range from 0.003 Hz to over 1000 Hz. In a narrower current density range and with less cycle uniformity, large amplitude oscillations may also be produced with a variety of mixed electrolytes containing small concentrations of halide ions. In addition, the anodic dissolution of iron in the chlorate electrolyte occurs with similar potential oscillations.

The oscillations associated with the copper/chlorate system (1, 2) were first encountered during a study of electrolytes commonly used in electrochemical machining, the technique which employs anodic dissolution at current densities from 5 to 500 A/cm² to cut, shape, and polish metals (3, 4). The possibility that the oscillations were connected with the favorable results obtainable with the chlorate electrolyte (5)

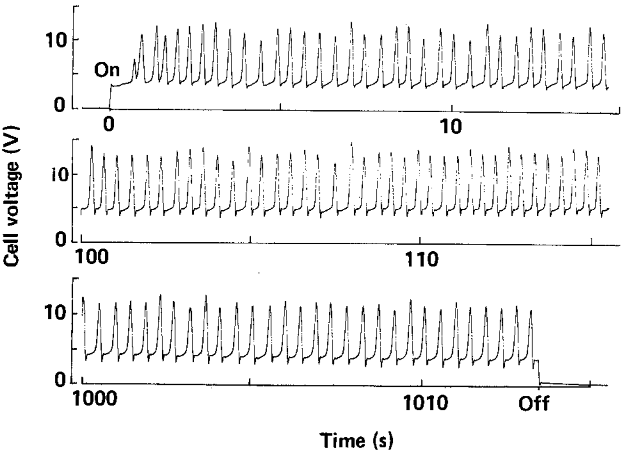

Fig. 1. Sustained cell voltage oscillations. Cell voltage recorded at three intervals during a dissolution experiment lasting over 1000 sec. Electrolyte composition, 2M $NaClO_3$; current density, 3 A/cm^2; electrode area, 0.32 cm^2; ambient temperature; stationary electrode, stirred electrolyte.

prompted the thorough investigation reported here. Large amplitude oscillations reflect the alternate growth and decline of the electrical resistance of passive or transpassive surface layers. An understanding of the periodic growth and breakdown of such layers should lead to a better general understanding of passive and transpassive electrode states.

Earlier Interpretations of Periodicity

Electrode reactions taking place with periodic changes in current or potential are by no means uncommon. A wealth of descriptive literature dates from the early nineteenth century. The preponderance of the over one hundred cases reported involves active-passive or active-transpassive transitions occurring during the anodic polarization of metals. The older literature has been reviewed by Hedges and Meyers (6) and by Indira *et al.* (7). Wojtowicz reviewed recent experimental work with emphasis on the relatively few cases where attempts at rational interpretations were made (8).

Numerous schemes have been proposed for the periodic growth and breakdown of electrode resistance. The models fall into perhaps five general categories: (*i*) Changes in local anolyte pH brought about by electrode reactions coupled with diffusion may shift the Flade potential for active/passive transitions. Franck developed a general theory along these lines (9, 10) and applied it to the Fe/H_2SO_4 system (11). (*ii*) The sequential deposition, oxidation, and chemical dissolution of a salt or oxide layer may induce the transitions (12). (*iii*) Active-passive transitions may reflect the exhaustion, followed by the diffusion-controlled replenishment, of an acceptor anion necessary for active dissolution (13, 14). (*iv*) Dielectric or mechanical disruption of the resistive layer may alternate with periods of film growth and repair (15, 16). (*v*) Changes in electrode state may reflect solid-state transformations within the resistive layer, such as recrystallization, transport, and accumulation of aggressive anions within the lattice, insulator-to-conductor "switching" transitions, etc.

In this last category, Indira and co-workers proposed that oscillations in certain instances may arise from subtle changes in the stoichiometry of solid anodically formed layers (7, 17). The gradual and uniform growth of the layer (by ionic conduction) was said to terminate in a nondestructive dielectric breakdown, which leaves behind a number of discrete filaments of highly defective and hence highly conductive material. The repair and buildup of the film then begins anew. The mechanism for restoring the high resistance state was not identified by the authors, nor was the existence of the filaments verified experimentally. Nevertheless, field-induced insulator-to-conductor transitions are known to occur in a wide variety of materials (18) including cuprous oxide (19, 20).

A theory of periodicity must first of all identify the individual processes dominant in each phase of the cycle. The models described above present reasonable mechanisms for the growth and destruction of current-restricting layers. As pointed out by Wojtowicz, however, many authors have assumed that (rather than explained why) growth and breakdown should occur in sequence and in phase over an extended electrode surface. The possibility must be ruled out that the same processes could occur simultaneously (but out of phase) on discrete sites on the electrode surface. With a sufficiently large number of such sites, the electrode potential might approach steady levels which reflect the mixed potential of a large number of sites in different stages of the growth/breakdown cycle. Thus, a second requirement of a theoretical model is that the processes involved must occur in phase over the electrode surface.

This paper reports an investigation into the potential oscillations associated with the copper/sodium chlorate system, which is treated as a model for a wider range of high amplitude, sawtooth oscillations observed in certain halide-containing electrolytes at high anodic current densities. For purposes of comparison, data on these other systems are reported in Appendix A.

Experimental Apparatus and Materials

The potential oscillations in the chlorate electrolyte occur over a broad and elevated range of current densities: 0.3-150 A/cm^2. Experimental studies under these conditions presented technical difficulties in the design of electrolysis cells. In our investigation (1), the primary factors considered were: (*i*) the provision of high rates of solution-side mass transfer under reproducible and reasonably well-defined hydrodynamic conditions, (*ii*) prevention of excessive ohmic heating of the electrolyte, and (*iii*) a reasonably constant cell geometry despite the rapid changes in the position and topography of the electrode surface during dissolution. No single experimental system met all of these requirements. At the lower end of the current density range a rotating disk electrode was employed. The disk was formed by casting an epoxy cylinder of diameter 3.5 cm around a 0.56 cm diam copper rod. The 0.25 cm^2 disk electrode was ground flush with the surface of the epoxy between experiments.

In an intermediate current density range (up to about 30 A/cm^2), a rectangular duct flow channel system was used. The flow system was designed for use under reproducible hydrodynamic conditions at Reynolds numbers up to 10,000. The copper electrodes, 3 mm square, were positioned opposite each other and flush with the horizontal walls of the flow channel. Electrode separation was 0.1 cm. The entrance length of 30 cm (200 hydraulic diameters) was sufficient to establish stable fluid velocity profiles in the vicinity of the electrodes. Electrode potentials were measured against a saturated calomel electrode by means of capillary openings drilled into the horizontal channel walls just 0.01 cm upstream of the leading edge of the electrodes.

An electrolyte jet apparatus provided the high rates of heat and mass transport needed for investigations in the high current density range. A 0.32 cm diam jet of electrolyte was directed against the anode surface; the circular end of a 1.6 mm diam copper wire was held in a Teflon plug. The electrolyte flows radially outward over the surface of the anode and plug and thence over a concentric cathode ring (area, 10 cm^2). The wire was periodically advanced such that the electrode surface remained flush with the floor of the cell.

We have chosen to investigate the oscillatory phenomena under galvanostatic conditions, thereby allowing an important experimental parameter to be fixed and accurately determined. The galvanostat (Electronics Measurements Power Supply, Model C618) delivered a maximum of 3A at 200V, with a rise time of 1 msec. Electrical measurements (cell or anode potential, current) were recorded either on a light beam oscillograph with a frequency response of 1 kHz or, when necessary, on an oscilloscope.

For the jet electrode system, zone-refined high purity copper (99.999+%) was used. Impurities quoted by the manufacturer (Materials Research Incorporated, Orangeburg, New York) were as follows (ppm, weight): Zn < 5; Sn < 1; Ni, P, Pb, < 1; O < 2; Mo < 5; rare earths < 1; Cl < 0.01. In all other experimental systems, oxygen-free, high conductivity copper (OFHC, 99.99+%) was used. Solutions were prepared from reagent grade sodium chlorate and doubly distilled water.

Experimental Results

Electrical properties of the oscillations.—Waveform, cycle uniformity, and persistence.—By separate measurements of anode and cathode potential against a reference electrode, it was determined that the oscillatory phenomena are associated with the anode. Once it had been established that polarization of the copper cathodes used in all three experimental systems was low and independent of time, the oscillations in anode potential could conveniently be monitored by measurements of cell voltage.

The oscillations are characteristically of a sawtooth waveform: an upward-sweeping potential terminates in a relatively sharp peak, followed by an abrupt fall to lowest potential of the cycle, *i.e.*, the trough (see Fig. 1-4). Considerable detail appears within each cycle at the lower end of the current density range for oscillations. Figure 2 depicts the first oscillation obtained following the start of dissolution of a rotating disk electrode. A low potential phase (V_1) and a high potential phase and peak (V_2-V_p) are evident and are separated by a short interval of random potential fluctuations of low (0.2-0.3V) amplitudes. For reasons which will become clear later (see discussion of morphology below), we shall refer to the low and high potentials phases as, respectively, "active" and "transpassive" dissolution.

Below the minimum current density at which the peaks are observed (for given conditions of flow rate, temperature, etc.), the electrode potential fluctuates randomly between the active and transpassive levels (Fig. 3a). As the current density is raised in the range 1-5 A/cm², however, the peaks appear and the duration of the transpassive phase increases at the expense of the active phase. Above approximately 5 A/cm², discrete active phase of the potential cycle is no longer evident, and the cycles assume the characteristic waveforms shown in Fig. 3c and d. Above about 100 A/cm², another waveform is found, which has the appearance of a spike of about 20V superimposed on the more rounded peaks as shown in the insets of Fig. 10.

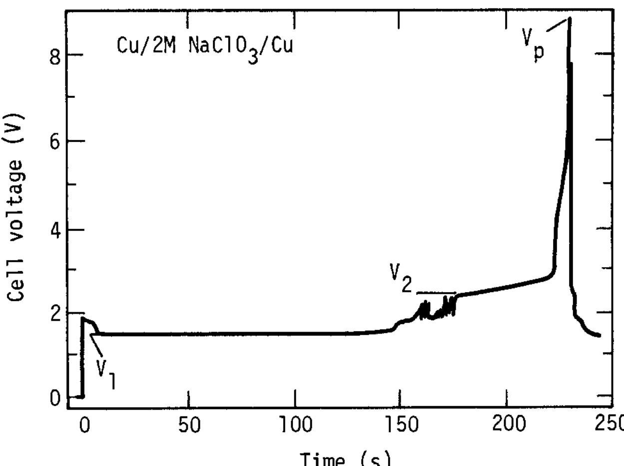

Fig. 2. Details of oscillation waveform produced at low current density. Rotating disk electrode system, 360 rpm, current density = 0.32 A/cm². V_1 = potential of active phase; V_2 = potential at onset of transpassive dissolution; V_p = peak potential.

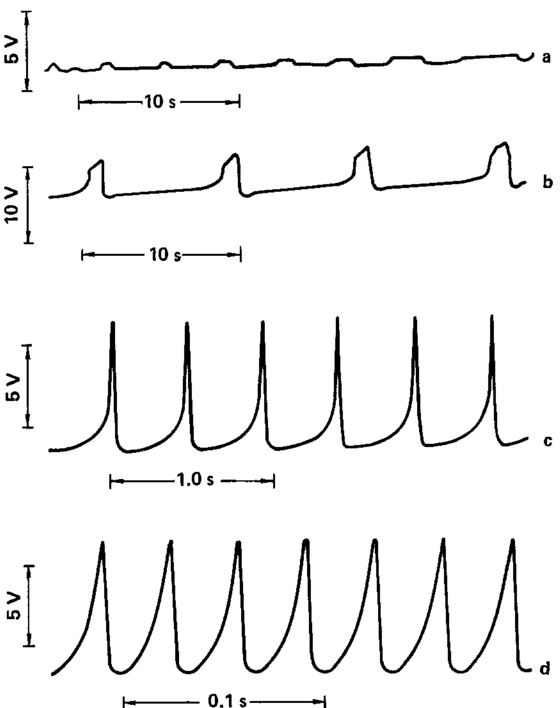

Fig. 3. Waveforms characteristic of different current density ranges. Channel flow system. 2M $NaClO_3$ electrolyte. (a) Low current density extreme, no potential peaks; i = 0.61 A/cm²; Re = 425; (b) active and transpassive dissolution, showing potential peaks; 1.83 A/cm², Re = 6810; (c) transpassive dissolution only; 6.57 A/cm², Re = 6810; (d) 33.4 A/cm², Re = 6810.

The oscillations observed in the chlorate electrolyte represent a sustained mode of dissolution and persist essentially unchanged as long as the experimental conditions (flow rate, current, cell geometry) are maintained. Recordings of potential against time in various intervals of single dissolution experiments are shown in Fig. 1 and 4. If the surface of the electrode is disturbed during dissolution (for example, with a glass pick), the oscillations first become disordered, then rapidly revert to a uniform period and amplitude (see Fig. 4a). The cycling shows no tendency to dampen permanently even after as many as 2500 cycles. The standard deviation in both peak amplitude and period over twenty consecutive oscillation cycles was less than 2%.

Dependence of period length on experimental parameters.—Period length shows a strong dependence on current density. This is shown in the composite plot of data (Fig. 5) taken with the rotating disk, channel flow, and jet systems over the entire range of mass transport conditions under which the phenomenon occurs. The relationship between period length and current density is linear on the double-logarithmic plot, with a change in slope from -2.5 to -1.5 occurring in the range 3-10 A/cm².

To a much lower extent than can be depicted on the scale of Fig. 5, the oscillation period also depends on flow rate. Below about 5 A/cm², the period is proportional to the 0.3 power of flow rate ($450 < \mathrm{Re} < 1500$) in the flow channel (Fig. 6). In the higher current density range investigated with the jet (above

10 A/cm²), the dependence of period on flow rate is comparatively weak (Fig. 7). Generally, the oscillation period increases with increasing electrolyte flow rate, and the effect of flow rate decreases at current densities above 10 A/cm².

The oscillation period increases with electrolyte temperature (Fig. 8) in the range of 4°-80°C. The effect of electrolyte pH was investigated using solutions of 2M $NaClO_3$ containing additions of sodium hydroxide or perchloric acid. The oscillation period increases with solution acidity over a pH range of 11.2-1.4, the influence of acidity being greatest at the lowest current densities (Fig. 9).

Dependence of oscillation amplitude and trough potentials on current density.—While the oscillation period length showed a strong dependence on current density, the oscillation amplitude was relatively independent of current density as shown in the plots of cell peak and trough voltages against current (Fig. 10). The right-hand inset in Fig. 10 indicates the high current density waveform found above about 100 A/cm². This waveform, having the appearance of a spike superimposed on the waveform of lower current densities, is probably the result of the formation of a thin gas layer on the electrode surface followed

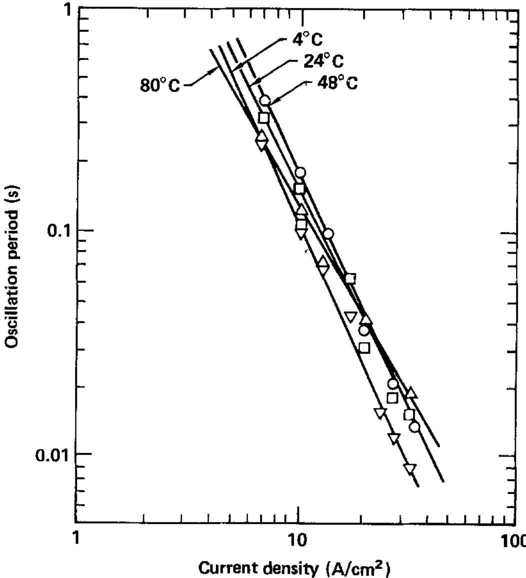

Fig. 8. Effect of temperature on period length. Channel flow, Re = 400; electrolyte, 2M $NaClO_3$.

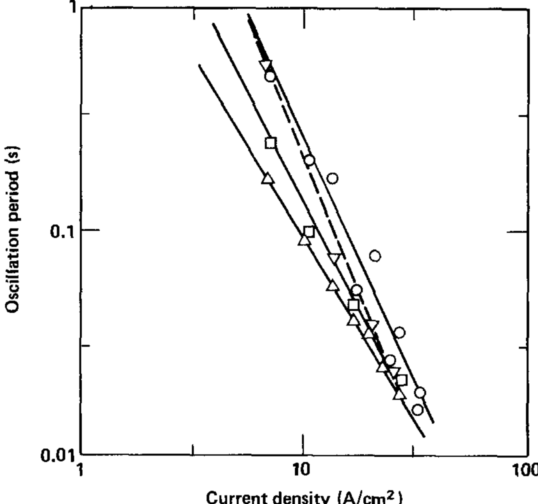

Fig. 9. Dependence of oscillation period on bulk electrolyte pH. Channel flow system, Re = 400. ▽, pH = 1.4; ○, 2.4; □, 4.6; △, 11.2. Electrolyte, 2M $NaClO_3$.

by an electrical discharge through it. Sparking and gas evolution are clearly evident whenever this waveform occurs. After falling from the peak, the potential pauses at the level extrapolated from the peaks of lower current density waveforms (indicated by triangle data points in Fig. (10). The potential spikes are probably unrelated to the periodic phenomena of interest and are not treated further in this paper.

The trough potentials (*i.e.*, the lowest potential of the cycle) plotted against current density in the range of 40-150 A/cm² extrapolate to 10V at zero current. This possibly indicates that the electrode is still covered with a resistive film, the resistance of which has a nonlinear dependence on current.

Chemical aspects of the copper/chlorate system. Apparent valence.—At the electrode potentials observed in this system, mono-, di-, and even trivalent copper oxidation states may be produced (21). The average apparent valence, $\bar{n}_a$, was determined from anode weight loss measurements using the following equation

$$\bar{n}_a = (It/\mathbf{F})/(\Delta W/M) \quad [1]$$

Here, I is current, t is dissolution time (at least ten times the period length, $\mathbf{F}$ is Faraday's constant, ΔW is weight loss, and M is the atomic weight of copper. Average apparent valence is plotted against current

density in Fig. 11 and is shown to approach a nearly constant level of 1.2 ± 0.04 above 10 A/cm².

The possibility that the stoichiometry of dissolution might change periodically made it necessary to measure the instantaneous apparent valence within a single cycle. To determine instantaneous apparent valence, a copper disk (9.6 cm²) was anodically dissolved with the electrode surface facing upward in a stationary electrolyte cell of low volume (20 ml). A number of experiments, conducted at 0.54 A/cm², were interrupted at successive points within the first cycle. Weight loss during each experiment was plotted against the quantity of charge passed through the cell, as shown in Fig. 12. The derivative of the curve obtained may be related to the apparent valence, n_a

$$d\Delta W/dQ = (M/n_a) \quad [2]$$

where Q is the quantity of charge passed (in equivalents). Although the precision of the technique is insufficient to allow detection of changes within intervals of less than 10^{-5} equiv./cm², it is apparent that the stoichiometry of dissolution is constant within both the active and the passive phase. The same result was obtained for dissolution at 1.33 A/cm².

Production of chloride.—In each instantaneous apparent valence determination at 0.54 and 1.33 A/cm², the anolyte was collected, filtered, and analyzed for chloride by means of potentiometric titration with a standardized solution of silver nitrate. The quantity of chloride in the anolyte was found to be proportional to the quantity of charge passed. The chloride is the product of the reduction of chlorate by the cuprous ion according to the net reaction

$$Cu^+ + 1/6\, ClO_3^- + 1/2\, H_2O = Cu^{++} + 1/6\, Cl^- + OH^- \quad [3]$$

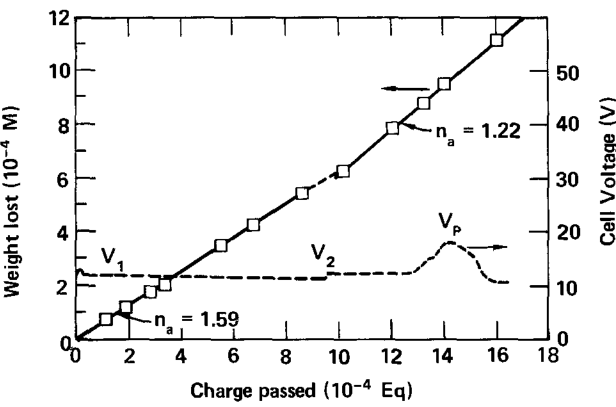

Fig. 12. Total copper dissolved as a function of charge passed. Stationary copper disk, 9.6 cm²; i = 0.54 A/cm²; instantaneous apparent valence indicated, showing distinct values for active and transpassive phases. Cell voltage is plotted against charge passed, with active (V_1), transpassive (V_2), and peak (V_p) cell voltages indicated.

Taking into account the nonintegral apparent valence, the quantity of chloride produced corresponded to roughly 60% of the quantity of monovalent copper produced. These results are consistent with those of Royer *et al.* (22), who studied the dissolution of copper in 1.2*M* $NaClO_3$ (at 15 mA/cm^2) and found an apparent valence of 1.0 at temperatures above 70°C and a quantitative reduction of ClO_3^- to Cl^-. It may be concluded that the electrolyte adjacent to the anode surface and within any pores in the solid surface layer contains a high concentration of the chloride ion.

Analysis of solid reaction products.—Solid reaction products adhering to the surface of the anode following dissolution were analyzed by x-ray diffraction. The copper substrate served as an internal reference. The water-insoluble phases of products resulting from active dissolution, as well as transpassive dissolution, showed only diffraction lines for cuprous oxide. Extraneous lines were absent, including those for other possible products such as $Cu(OH)_2$, CuCl, CuO, etc.

Morphological changes occurring within the potential cycle.—As shown in Fig. 2, the oscillation cycle at low current densities can be resolved into a succession of distinct potential plateaus and a potential peak. During the low potential phase of the cycle, the copper substrate becomes etched and in places pitted, while an adherent layer of a red-orange substance (identified as cuprous oxide) accumulates on the metal surface. The appearance of the electrode during the active phase with dissolution at 0.3 A/cm^2 is clearly shown in the photomicrograph of Fig. 13a. The term "active phase" has been given to this portion of the cycle because of the etched appearance of the substrate and the low overpotentials for dissolution. Active dissolution involves the passage of the metal cation directly from the metal lattice to an aqueous complex. Continued removal of cations from sites of lower free energy of dissolution gives rise to the formation of fine pits, the walls of which often consist of planes of low index numbers (23). Light scattered from the pitted surface accounts for the dull, matt appearance. A fraction of the cuprous ion precipitates from the aqueous complex to form the thick (10-20μm) porous layer of cuprous oxide.

Beginning with the onset of transpassive dissolution, the copper substrate becomes progressively smoothed and polished and attains a nearly specular appearance as peak potentials are approached. Solid reaction products in this low current density range are found in two distinct layers: (*i*) a thin adherent layer of submicron thickness, found to consist of cuprous oxide; and (*ii*) a thick (10-100 μm) loosely adherent layer consisting of cuprous oxide and water-soluble copper

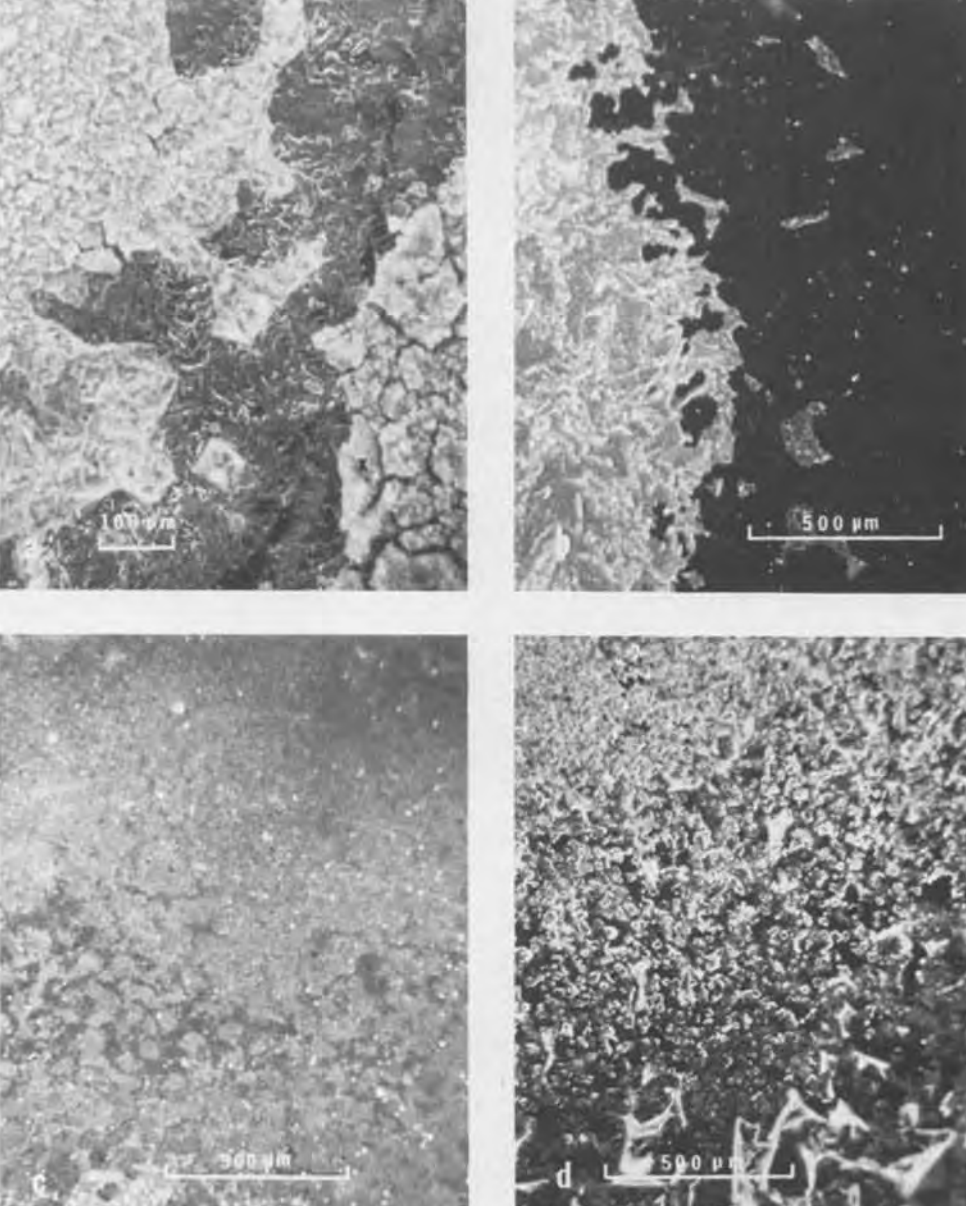

Fig. 13. Sequence of changes of surface morphology during a potential cycle. Rotating disk electrode, $i = 0.32$ A/cm^2, 360 rpm. (a) Appearance of active phase electrode showing thick Cu_2O layer (x) and roughened substrate (bright field illumination). (b) Progression (right to left) of transpassive film; thick film has been removed; dark field illumination. (c) Electrode surface at peak potential (bright field). (d) Beginning of active phase of second cycle (dark field).

oxychlorides. The formation of the thin layer begins at the periphery of the electrode and spreads progressively inward, undermining and dislodging the porous layer formed during the active phase. The advance of the transpassive layer is shown in the dark field photograph of Fig. 13b.

Immediately before the fall from peak potentials, the electrode surface loses its polished appearance, becoming dull and relatively uniform under intense bright field illumination (Fig. 13c). At the beginning of the active phase of the succeeding cycle, the thin film peels away from the surface (Fig. 13d), while crystals of a new thick phase of cuprous oxide are beginning to form.

The alternating periods of film growth and rupture/removal were recorded using motion picture photography for dissolution experiments at 3 A/cm². The rupture of the film and a rapid outward movement of solid reaction products were shown to coincide with the fall from peak potential within a time interval of less than 0.03 sec.

Observations of resistive switching transitions in the transpassive film.—Many electronic insulators and semiconductors are known to show an abrupt decrease in resistance on being subjected to a critical electric field strength. When the transition is accompanied by the destruction of the material (through spark discharge and local vaporization), the term "breakdown transition" is used. In other cases, called "resistive switching transitions," no readily perceptible change occurs in sample morphology as a result of the transition. Materials showing the latter behavior have been used in both monostable and bistable electronic switches. The subject of switching transitions has been reviewed by Klein (24).

Resistive switching transitions have been observed in samples of cuprous oxide produced by the high temperature oxidation of copper in air (19, 20, 25, 26). The schematic steady-state electrical characteristic is shown in Fig. 14A. The current-voltage plot consists of a stable high resistance, low current branch (H) and a low resistance, high current branch (L). The voltage (V_s) and resistance of the external circuit (represented by a load line) determine currents before and after transition. Although a low resistance state is formed immediately on the collapse of voltage, the stable, reproducible characteristic (L) is established only with the continued passage of charge. This phenomenon has been called "electroforming" (25). The threshold field strength for such transitions was found to be about $2 \times (10)^5$ V/cm by Morgan and Howes for 10^{-5} cm thick samples of Cu_2O (25). Resistive switching in cuprous oxide results in the formation of discrete channels of a low resistivity copper oxide which, when formed at sufficiently high currents, contains filaments of elemental copper (26).

Experiments were undertaken to determine whether the thin cuprous oxide films formed during transpassive dissolution could undergo resistive switching transitions at voltages comparable to the oscillation amplitudes. Sample electrodes were anodized at various points within the transpassive region. The electrodes were then removed from the cell, washed in distilled water, and dried in vacuum. Breakdowns were detected with a movable copper whisker probe using the electrical circuit depicted in Fig. 14B. The probe was brought to rest on the electrode surface and a potential step (1-10V) was then applied.

Resistive switching transitions occurred during which the resistance of the probe-electrode assembly fell from 10^7-10^8 to 1-10Ω within less than a microsecond. The observed time lag between voltage application and collapse (Fig. 15) depended inversely on the applied voltage. The time lag varied widely from point to point on the electrode surface; an order of magnitude spread in the data is consistent with the statistical nature of the phenomenon (25). Electroforming of the low resistance state was also observed. There is little doubt that the transitions observed are similar to those reported earlier (19). In addition, the applied voltages required for transitions in the dried samples are comparable to voltages occurring during transpassive dissolution.

Interpretation of Experimental Results

In this section we first use the results of solid-state ionic conduction theory to interpret the potential-time behavior during the growth phase of the cycle. Next, we offer an explanation for the near-constancy of the

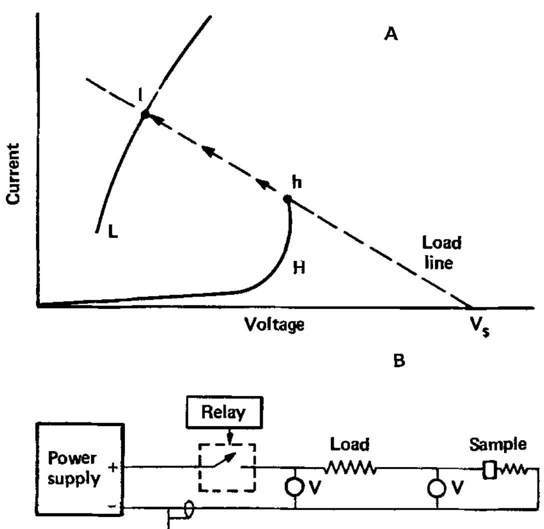

Fig. 14. (A) Current-voltage characteristics of materials showing resistive-switching transitions. H, high resistance state; L, low resistance state. V_s, voltage of power supply. (B) Testing circuit used in the study of electrical breakdown in transpassive surface films. A mercury-wetted relay and a dual beam oscilloscope (V, V) were used with a decade resistance load.

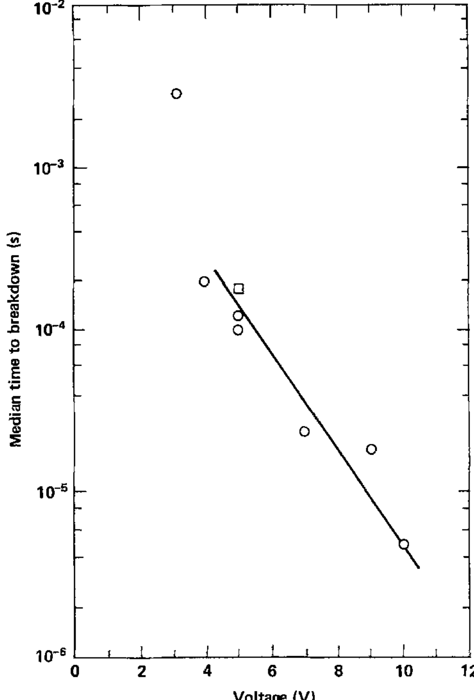

Fig. 15. Dependence of lag time for resistive switching transitions on applied voltage. Lag time is the interval between the application of voltage to the sample and voltage collapse. Transpassive film produced at 0.8 A/cm². Dissolution interrupted at a voltage of 5.9V above trough potential. Peak potential for these conditions is roughly 9V.

amplitude over a wide range of current densities, based on the assumption that the probability for a switching transition is proportional to the thickness of the film and to the field strength. Then a model is presented which attributes the oscillatory nature to the alternation of periods of film growth by high field ionic conduction and field breakdown resulting from switching transitions. A permanent mixed electrode state, allowing simultaneous ionic conduction through the film and electronic conduction through breakdown channels, is shown to be impossible because of the widely different field strengths required for the two processes. Finally, the possible roles of the chloride and chlorate ions are discussed.

Ionic conduction in transpassive surface films.—The copper substrate becomes progressively polished during the interval in which the potential rises from the lowest level to the highest level of the cycle. We refer to this interval as the "potential growth phase." As suggested by Hoar (23) and Novak (27), such electropolishing of copper results from (*i*) the generation of vacancies in the copper sublattice of the anodic oxide film at the film/electrolyte interface, (*ii*) the transport of vacancies through the film to the metal surface, and (*iii*) the annihilation of the vacancies by combination with cations from the metal phase. The flattening and polishing of the anode substrate during this phase is a consequence of the large resistance of the thin film to ionic conduction. With the onset of transpassive dissolution, the resistance of the thin film controls the distribution of current on a microscopic scale. If the thin film is of uniform properties (ionic conductivity and thickness), the current density will be uniform on the surface of any asperity having dimensions which are large compared to the thickness of the film. Continued dissolution under these circumstances will lead to a smoothing of an initially rough surface. The mechanism described here is similar to that which is widely held responsible for the electropolishing of copper in, for example, orthophosphoric acid solutions.

The vacancies reflect the nonstoichiometric nature of cuprous oxide. The material is a cation-deficient, p-type semiconductor, and the vacancies migrate within an electrostatic field as if they were negatively charged. The cation deficiency, indicated by y in the formula, $Cu_{2-y}O$, varies widely with sample preparation. [Values of $y = 10^{-3}$ (28), 0.5 (29), and 0.76 (30) have been reported for samples showing the same unit cell structure.] It is therefore not possible to predict *a priori* the properties of the surface film during high rate dissolution. Nevertheless, it is reasonable to conclude that the primary mode of ionic conduction during the transpassive phase of the oscillation cycle is the migration of negatively charged cation vacancies from the electrolyte to the metal substrate.

We can test the hypothesis of vacancy migration with the use of high field strength ionic conduction theory, as presented by Dignam (31). When diffusion can be neglected, and for a sufficiently high field strength, the current density i may be expressed as a function of field strength, E

$$i = 2A \sinh (BE) \quad [4]$$

$$\sim A \exp (BE) \quad [5]$$

where the approximation [5] is valid for $BE > 1$. A is proportional to the concentration of charged vacancies, while B is proportional to the width of the potential energy barrier encountered by the defect during migration through the periodic field. The physical meanings of A and B are discussed further in Appendix B.

In Fig. 16, we have plotted log (i) against the mean field strength, $\overline{E}$, estimated for the growth phase of the cycle. Mean field strength was obtained without an independent measurement of film thickness using the following equations

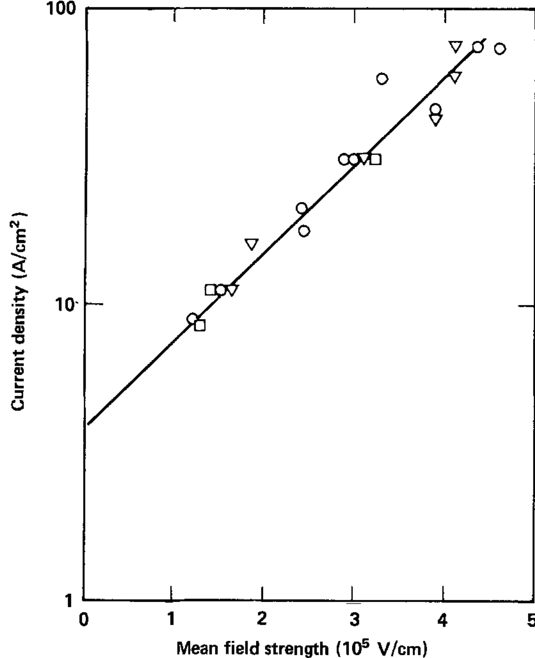

Fig. 16. Dependence of current density on mean field strength. Jet electrolyte flow system. Electrolyte, 2M $NaClO_3$. Flow rates: ○, 93; □, 160; ▽, 193 cm/sec.

$$\overline{E} = (V_p - V_2)/S \quad [6]$$

where V_p and V_2 are peak and trough potentials and S is the corresponding change in film thickness

$$S = \left[\frac{2 - \overline{n}_a}{\overline{n}_a} \right] \frac{i\tau M_{Cu_2O}}{2Fd} \quad [7]$$

Here τ is the oscillation period, and M_{Cu_2O} and d are the formula weight and density of cuprous oxide, respectively. The quantity in brackets is the fraction of current producing monovalent copper, if only Cu^+ and Cu^{++} are produced. Equation [7] results from the assumptions that all monovalent copper formed during dissolution is retained within the film as Cu_2O and that the film is pore free. The plot of log (i) against $\overline{E}$ shown in Fig. 16 is linear, with a slope of 6.8×10^6 cm/V for field strengths, 1.5×10^5-4.5×10^5 V/cm. This linearity and the greater-than-unity values of $B\overline{E}$ tend to support the high field strength ionic conduction mechanism proposed for the growth phase of the potential cycle. The slope is the same (6.8×10^{-6} cm/V) as that estimated by Kojima (32) from impedance data and a film thickness value of 60Å estimated by ellipsometry (27) for electropolishing films produced in the copper/phosphoric acid system. The proposed mechanism is further supported by the relative magnitudes of field strength, slope, and intercept, as discussed in Appendix B. We conclude that the predominant mode of charge transfer during the film growth phase is ionic conduction through a thin solid film.

The occurrence of resistive breakdown transitions.—The observations of voltage breakdowns in the dry films suggest that these can also occur in the transpassive films during anodic dissolution. In addition, the breakdowns occur at approximately the same voltage (or field strength) on dry and on immersed electrodes.

In general, resistive switching transitions begin to occur when the field strength is raised above a critical threshold. The threshold is inversely related to the sample thickness, measured in the direction of the applied field. The thickness dependence is said to arise from the increase in probability that an electron ini-

tiating an avalanche of a critical magnitude will be situated along a line of breakdown (24). The probability for a breakdown should then be proportional to sample thickness.

Assuming that it is the acceleration of an electron by the field that causes the critical avalanche, the probability for a transition should be proportional to field strength. The net probability of the breakdown should then be proportional to the product of film thickness and field strength, *i.e.*, the voltage drop across the film. We have already noted the weak dependence of amplitude on experimental parameters.

The experimentally established dependence of film thickness at breakdown field strength is shown in Fig. 17. The relation between S and E is given by

$$S \exp (K_1 \bar{E}) = K_2$$

where $K_1 = 3.2 \times 10^{-6}$ cm/V and $K_2 = 1.4 \times 10^{-4}$ cm. During the growth of the film, both S and maximum field strength (*i.e.*, as indicated by the slope of the potential-time curves) increase very rapidly as the peak potential is approached; therefore, the incidence of breakdown transitions should also increase.

A Model for the Potential Oscillations

The model presented below is based on three assumptions: (*i*) During the potential growth phase of the cycle, charge is passed through a growing nonporous film by ionic conduction. (*ii*) Channels of low electronic resistance exist in the film after the peak potential is reached. (*iii*) The passage of current through these channels causes the removal of adjacent film material such that the film becomes porous. The following sequence of film growth, channel formation, and partial or complete film removal is proposed.

During the potential growth phase of the cycle, a uniform, nonporous film increases in thickness and the charge carriers are predominately ionic. Above a threshold voltage (*i.e.*, above a critical product of field strength and thickness), resistive switching transitions begin to occur in parallel with film growth. These transitions result in the formation of channels of low electronic resistivity and provide alternate paths for the current. As film growth continues, the voltage rises and the incidence of such transitions increases. The accumulation of parallel current paths of low resistance causes a progressive decrease in electrode resistance and an eventual drop in voltage at constant current. With the drop in voltage, the flow of ionic current and the growth rate of the film is greatly reduced because of the exponential dependence of current on voltage at constant film thickness (see Eq. [4]). The formation of channels ultimately results in a shift of current from the bulk of the film to the channels and a change in charge carriers from ionic to electronic species. The continued flow of electronic current through the channels results in the removal of the channels and adjacent cuprous oxide by a mechanism described below. Following the complete removal of the low resistivity channels, the high field strengths can again be achieved as required for growth of a new nonporous film or for the repair of the existing film.

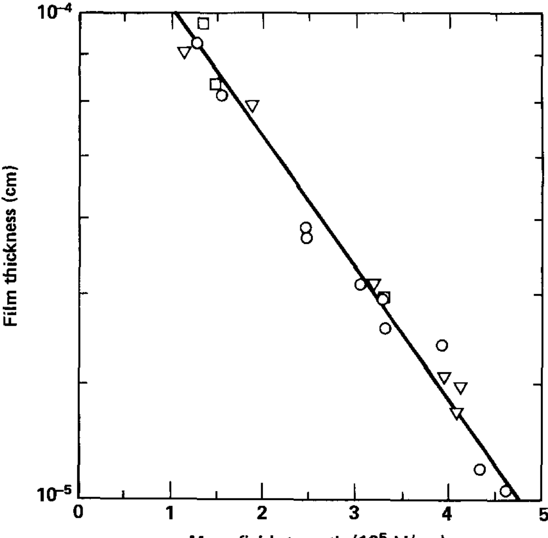

Fig. 17. Inverse relation between film thickness and mean field strength jet electrolyte flow system. Electrolyte, 2M $NaClO_3$. Flow rates: ○, 93; □, 160; ▽, 193 cm/sec.

It is an assumption of this model that the flow of electronic current in the channels effects the removal of the channels and the adjacent cuprous oxide. There are several likely mechanisms for promoting partial or complete film removal. With a means for electron transfer supplied, the film might undergo localized anodic oxidation in the presence of acceptor anions (Cl^- or ClO_3^-)

$$H_2O + Cu_2O + 4Cl^- = 2CuCl_2 + 2e^- + 2\,OH^-$$

Water could be oxidized at the trough potentials, producing a local drop in pH

$$2H_2O = O_2 + 4H^+ + 4e^-$$

The lowering of pH could accelerate the chemical oxidation and dissolution of Cu_2O

$$Cu_2O + 1/3\,ClO_3^- + 4H^+ = 2Cu^{++} + 1/3\,Cl^- + 2H_2O$$

It is also possible that during the potential growth phase of the cycle space charge accumulates near to the film/electrolyte interface and that the capacitor thus formed is rapidly discharged through newly formed channels causing the channels to be vaporized, as in dielectric breakdown. The upward sweeping potentials (*i.e.*, $d^2V/dt^2 > 0$) which are observed during film growth at constant current are supporting evidence for the existence of such space charge. Such a catastrophic breakdown, however, is not required by the model.

Once the channels are removed from the film, a process of film repair or film growth can resume. It is necessary to remove all of the conductive channels in order to polarize the film of a given thickness to the field strengths required for ionic conduction. At low current densities, the removal of the cuprous oxide film is complete, as evidenced by the resumption of active dissolution potentials, the restoration of an etched substrate, and the observed undermining and removal of the film. At current densities above about 10 A/cm², the removal of the film is partial, and the lowest potentials of the cycle (trough potentials) are roughly 10V above the potential for active dissolution.

The Inability of the Anode to Reach a Stable Potential

The widely different field strengths required for the two modes of current flow (ionic conduction through the bulk of the film and electronic conduction through channels) preclude the possibility that both mechanisms can occur simultaneously over extended periods of time on the same electrode surface to produce a steady state. As long as the field strength and thickness have exceeded a critical combination allowing the transitions, the transitions will occur and tend to lower the effective resistance of the electrode and ionic current will be effectively terminated. Nor can electronic current flow alone result in a stable state: the cuprous oxide film can only conduct electrons through electrochemical mechanisms which tend to destroy the film. Finally, no stable electrode state can be reached through ionic conduction mechanisms; as long as cuprous oxide is produced at a rate greater than it dissolves in the electrolyte, the film would

continue to thicken and the potential would increase without limit.

This model differs fundamentally from those citing dielectric breakdown and repair as mechanisms for potential oscillations in anodically formed films. Unlike the resistive transitions, the dielectric breakdown leaves behind no permanently conducting channels. Breakdown is followed by immediate field restoration and film repair. In this case, a stable potential is reached when the rate of film growth just equals the rate of film destruction.

The Role of Chloride and Chlorate Anions

Anode potential oscillations of the nature discussed here may be produced in various electrolytes by the addition of halide ions. The oscillations are particularly uniform and occur over an exceptionally wide range of current densities only in the chlorate electrolyte, which contains some chloride as a result of *in situ* reduction of chlorate. To understand the role of the chlorate or chloride we first examine two conditions of ionic conduction in thin cuprous oxide films: with the chlorate electrolyte and in phosphoric acid solutions. On the basis of impedance data collected from numerous publications, Kojima (32) showed that the thickness of cuprous oxide films in orthophosphoric acid was in the range of 15-125Å, with a most probable thickness of 60Å as determined by ellipsometry (27). For the typical voltage drop through such films of 1.0V, field strengths are in the range of 10^6-10^7 V/cm and, therefore, the high field ionic conduction Eq. [5] should apply. Parameters $B\overline{E}$ and A of the equation can be derived from experimental polarization curves. The experimentally accessible parameters for the two systems are compared in Table I.

The most striking difference between the polarization equations of the two cuprous oxide films is in the pre-exponential factor, A. As this factor is proportional to the concentration of mobile ionic defects, the difference between two electrolyte systems is the concentration of vacancies. Chloride and other "aggressive" anions have long been known to alter the resistance to corrosion of anodic oxide films, and incorporation of the anions into the crystal lattice of the film is a mechanism proposed to account for the phenomenon. If chloride displaces an oxygen ion from the lattice, the difference in the valences requires the removal of cation (formation of a vacancy) to maintain charge neutrality. The chlorate ion might contribute to an increase in vacancy concentration by the partial (nonstoichiometric) oxidation of cuprous oxide at the film electrolyte interface to form the divalent ion. Electroneutrality requires the formation of a vacancy in the copper sublattice for this mechanism as well.

For the chlorate system, the large value of A allows current densities of up to 150 A/cm^2 to be achieved with moderate field strengths (5×10^5 V/cm); above 150 A/cm^2, the increased field strength begins to effect destructive breakdown of the films. For the phosphoric acid electrolyte, not even current densities of 10 A/cm^2 can be achieved below field strengths of approximately 2.5×10^6 V/cm, at which level destructive breakdowns and stable mixed-electrode processes are encountered

The high current density oscillations in the halide-containing electrolytes are apparently the result of dissolution through thin films at field strengths which promote switching rather than destructive breakdown.

Table I. Comparison of parameters of high field ionic conduction for cuprous oxide films formed in chlorate and phosphoric acid electrolytes

	Cu/ClO_3^-	Cu/H_3PO_4
Film thickness, S (cm)	10^{-5}-10^{-4}	$1.3(10^{-7})$-$1.2(10^{-6})$; $6(10^{-7})$*

Exponential term, B (cm/V)	$6.8(10^{-6})$	$(1.5\text{-}14) \times 10^{-6}$; $6.8(10^{-6})$*
Exponential term, BE	0.7-3.4	11†
Pre-exponential factor, A (A/cm^2)	4	$2(10^{-7})$

* Most probable film thickness, based on ellipsometric measurements (27).

† Based on experimental data using an equation derived from [5]

$$BE = V_p / i(dV/di)_i$$

where V_p is voltage drop through the film and V is electrode potential (32).

Conclusions

The anode potential oscillations in the chlorate electrolyte are interpreted as sequential periods of film growth (by a high field ionic conduction mechanism), field collapse (following the onset of resistive switching transitions), and partial dissolution and removal of film material (at discrete sites adjacent to the breakdown channels). A stable electrode state with a constant potential is inaccessible in this model, because of the large differences in field strengths required for the separate processes of film growth and conduction through channels, and because each process acting alone results in conditions favoring the opposite process.

The role of the chlorate or chloride ion has not been firmly established. Comparisons of the dissolution of copper in phosphoric acid and in chlorate electrolytes leads to the conclusion that the latter electrolyte promotes a high concentration of mobile vacancies in the copper sublattice. Consequently, the conductivity of the film is higher, and dissolution at current densities from 10 to 150 A/cm^2 requires field strengths in the range giving rise to resistive switching transitions as opposed to dielectric breakdown. Although this hypothesis is consistent with the experimental results obtained, firm proof of its validity will require more detailed knowledge of the effects of chloride ions on the properties of growing oxide surface layers.

APPENDIX A

Large-Amplitude Anode Potential Oscillations in Electrolytes Containing Halide Ions

Large-amplitude oscillations in potential were found during the constant current dissolution of copper in a number of mixed electrolytes containing halide ions. In these electrolytes, the range of current densities over which the oscillations were observed was narrower than in the chlorate electrolyte. Also, the cycles tended to lack uniformity of amplitude and period length. Oscillation parameters are summarized in Table A-I, and sample oscillographs of the more uniform oscillations are shown in Fig. A-1 and A-2.

The anodic dissolution of iron in pure sodium chlorate electrolytes gave rise to uniform oscillations having the same waveform and uniformity as in the copper/chlorate system.

APPENDIX B

Ionic Transport and Space Charge in Crystalline Solids

Fundamental equations of ionic transport.—In crystalline solids, ionic conduction occurs through the movement of charge point defects: anion or cation vacancies and interstitial anions or cations. With a simple kinetic model, a transport equation may be derived which expresses the flux of a defect species

as a function of field strength and certain physical constants. A simplified derivation is given below. Detailed derivations and fuller discussion of transport theory in solids are found in Young [Chap. II, Ref. (33)] and Dignam (31).

For a solid free of any externally applied field, charged defects are pictured to diffuse through a field of identical potential energy barriers of height W and width $2a$. A defect will surmount a barrier if sufficient thermal energy is acquired. From Boltzmann statistics, the probability of a defect possessing a kinetic energy greater than W is proportional to exp $(-W/kT)$. When an electrostatic field is applied to the sample in direction x, the energy of the defect will be the sum of thermal energy and energy acquired by movement in the field. This situation gives rise to a skewing of the periodic potential profile such that the effective barrier height for a defect at x with charge q and in a field strength E, will be $(W + qaE)$ for diffusion with or against the direction of the applied field.

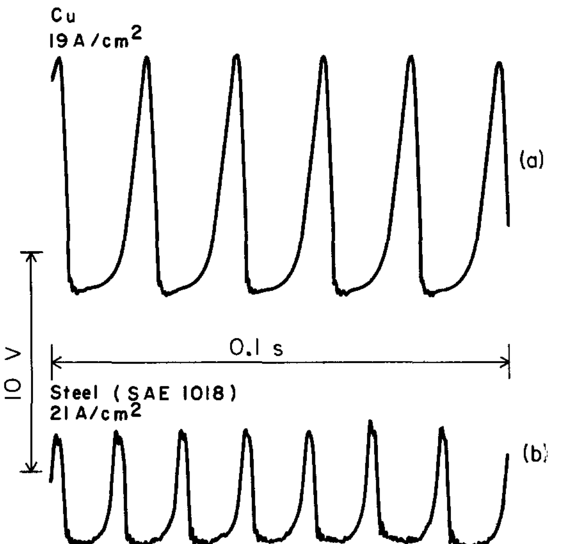

Fig. A-1. Oscillation waveforms for dissolution of Cu and Fe: cell voltage tracings. Current density = 19 A/cm^2; stationary electrolyte. (a) Cu/5M $NaClO_3$; (b) Fe/5M $NaClO_3$; anode metal, SAE 1018 steel.

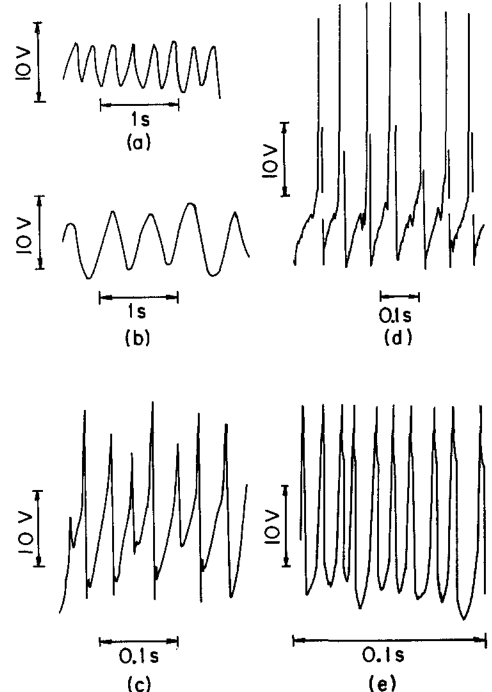

Fig. A-2. Oscillation waveforms in halide-containing electrolytes; stationary electrolyte; copper anodes. (a) 2M KNO_3, 1M KI; 3.2 A/cm^2; (b) 2M KNO_3, 0.3 MKCl; 3.1 A/cm^2; (c) 5M $NaNO_3$, 0.1M NaCl; 20 A/cm^2; (d) 4M NaOH, 1M KCl; 9.5 A/cm^2; (e) 2.5M H_3PO_4, 0.03M NaCl; 19.6 A/cm^2.

From elementary rate theory, the flux in the direction of the field (increasing x) is given by (30)

$$\vec{j} = 2ac\nu \exp(-(W - qaE)/kT) \quad \text{[B-1]}$$

The flux against the field is given by

$$\overleftarrow{j} = 2a(c + 2a(dc/dx))\nu \exp(-(W + qaE)/kT) \quad \text{[B-2]}$$

The net flux in the direction of the field is

$$j = \vec{j} - \overleftarrow{j} \quad \text{[B-3]}$$

$$j = 4ac\nu \exp(-W/kT) \sinh(qaE/kT) - 4a^2\nu(dc/dx)\exp(-(W + qaE)/kT)$$

High feld approximation.—As shown by Dignam [p. 142, Ref. (31)], the diffusion term may be neglected for space charge densities less than about $5 \times (10^9)$ e/cm^3 provided $qaE/kT \geq 1$. Under these conditions, Eq. (B-3) takes the simple form

$$j = 2ac\nu \exp(-W/kT) \exp(qaE/kT) \quad \text{[B-4]}$$

To convert the above expression into units of A/cm^2, we multiply by the factor, $q\mathbf{F}/N_a$

$$I = A \exp(qBE) \ (A/cm^2)$$

$$A \equiv qc(2a\nu\mathbf{F}/N_a) \exp(-W/kT)$$

$$B \equiv a/kT \quad \text{[B-5]}$$

Despite the simplicity of the model, the exponential dependence of current on field strength is well established by experiment with anodic oxide films formed on a variety of metals (23, 33, 34).

The Measurement of pH in Aqueous Systems at Elevated Temperatures Using Palladium Hydride Electrodes

Digby D. Macdonald,*,[1] Paul R. Wentrcek, and Arthur C. Scott

SRI International, Materials Research Laboratory, Menlo Park, California 94025

ABSTRACT

The use of palladium hydride electrodes (Pd black on Pd, Pt, and Au) for the measurement of pH in high temperature aqueous systems (298°-548°K) is described. The electrodes were calibrated against boric acid/lithium hydroxide buffer solutions, whose pH_T *vs.* temperature profiles have been calculated using known dissociation constants for the components. Linear potential *vs.* pH correlations are observed for all temperatures studied. However, the gradients of the correlations deviate from the predicted Nernstian values. Furthermore, thermodynamic analyses of the systems demonstrate that above 373°K the observed potential deviates significantly from the equilibrium values calculated on the supposition that the potential-determining reaction is $H^+ + e^- \rightleftarrows H(Pd, \alpha + \beta)$. Possible reasons for the observed deviation from ideal behavior are identified.

A major obstacle to the study of physiochemical processes in aqueous systems at elevated temperatures is the lack of a reliable and generally applicable method for measuring the activity of hydrogen ion in this hostile environment. Previous studies involving precise pH measurements in high temperature aqueous systems have employed concentration cells with transport to compare the activity of H^+ in the solution of interest with that in a standard solution for which the pH can be calculated. This technique has been used extensively by Mesmer *et al.* (1-4) and by Macdonald and co-workers (5-7) to study various hydrolysis reactions and transport processes in high temperature solution. Although the technique is very precise, it suffers two restrictive requirements: First, an overpressure of hydrogen is required for the proper operation of the cell. Accordingly, the technique is applicable only to those systems that are stable to reduction by molecular hydrogen. Second, due to a lack of reliable transport data for various ions in high temperature aqueous solution, it is usually necessary to suppress the isothermal liquid junction potential between the two electrode compartments. This has been accomplished by use of KCl as the supporting electrolyte in both the working and reference compartments, although it should be noted that the problem of junction potential is common to most electrometric techniques for the determination of pH.

In this paper we describe the use of palladium hydride electrodes for the measurement of pH ($= -\log a_{H^+}$) in aqueous systems at temperatures as high as 275°C. Previous work by Dobson and co-workers (8-11) on this system has indicated that palladium hydride electrodes exhibit Nernstian pH responses at elevated temperatures. However, their work was restricted to highly acidic and highly basic systems, and no data were obtained for the technologically important pH range from ~5 to ~13. In the present work, we have analyzed the pH response of palladized palladium, palladized platinum, and palladized gold electrodes in various lithium hydroxide-boric acid buffer solutions ranging in pH (25°C) between 5 and 13.

Experimental

Apparatus.—The high temperature recirculating loop used for these studies will be described elsewhere (12). Briefly, the aqueous solution was pumped from a reservoir through a preheater and into the measuring cell using a positive displacement diaphragm pump. The exiting solution was heat-exchanged with the input and then discharged back to the reservoir via a pressure control valve. The pressure in the circuit was maintained at 74.3 kPa (1100 psig) to maintain a single (liquid) phase within the loop. Both the preheater and the measurement cell were thermostated with electrical heaters and controllers. Adjustment of these heaters permitted the cell temperature to be controlled to within ±2°K at temperatures as high as 548°K (275°C).

Details of the measurement cell used in this study are shown in Fig. 1. The solution enters the bottom of the cell and passes over the three pH probes that protrude into the stream from insulated lead-troughs. The porous ziconia liquid junction of the reference electrode is located immediately downstream (~0.5 cm) from the three pH probes. The stainless steel

Key words: pH, acidity measurements, aqueous solution, elevated temperatures, palladium hydride electrodes.

counterelectrode is also located in this region so that electrolysis products generated at this electrode will not interfere with the operation of the pH probes. A thermocouple for temperature control and measurement also protrudes into the fluid stream.

The design of the pH probe assembly is shown in detail in Fig. 2. The fine wire pH probes (1 cm long × 0.0254 cm diam), were sealed between two PTFE sleeves that had been heat-shrunk onto a roughened central steel shaft. The shaft was then inserted through a standard CONAX fitting in the normal manner.

The palladium, platinum, and gold pH probes were initially cleaned in concentrated nitric acid and were then palladized cathodically in acidified $PdCl_2$ solution (2 weight percent $PdCl_2$ in 1M HCl) at a current of 23 mA for 60 sec. Microscopic examination of the surfaces showed that the palladium deposit was highly porous and had the characteristic structure of palladium "black." The probes were cleaned and repalladized prior to each run.

A major problem in any electrochemical study involving high temperature aqueous systems is choosing a suitable reference electrode as reviewed by Macdonald (13). In this work we have used a pressure-balanced external reference electrode, rather than the traditionally employed internal reference electrodes. The design of the external reference electrode is shown in Fig. 3; details of the construction and operation of the electrode have been given recently by Macdonald, Scott, and Wentrcek (14). Briefly, the external silver-silver chloride electrode (25°C) was calibrated against an identical internal electrode in various KCl solutions ranging in concentration from 0.005 to 0.505*M*. Thermodynamic analyses then permitted the evaluation of the correction parameter $\Delta E_{SHE}(T) - \Delta E_{obs}(T)$, where $\Delta E_{obs}(T)$ is the observed potential of the pH probe *vs.* the external reference electrode and $\Delta E_{SHE}(T)$ is the corresponding potential *vs.* the hypothetical standard hydrogen electrode at temperature *T*. Numerical values for this correction parameter for an internal 0.102*M* KCl solution in the reference electrode were found to be 0.287, 0.237, 0.185, 0.130, 0.069, and −0.001V for ΔT values of 0, 50°, 100°, 150°, 200°, and 250°K, respectively, where $\Delta T = T - 298.15°K$.

Method.—At the start of each run, the solution in the reservoir was purged with 99.99% nitrogen overnight to remove traces of oxygen. After pressurization and steady flow had been achieved, each of the pH probes was charged cathodically at a total current of 0.8 mA (1.6 A/cm^2 apparent surface area) for various times between 5 and 15 min; for most experiments, however, a standard cathodic charging time of 5 min was adopted, except for the Pd (black)-Pd system. In this case, the substrate also absorbs hydrogen so that a longer charging time of 15 min was adopted. We also found that brief anodization (15 sec for Pd(black)-Pd, 5 sec for Pd-Pt and Pd-Au at 0.8 mA) immediately after cathodization, or after the potential had decayed to an approximate steady state, frequently reduced the response time for the electrode, particularly if anodization was carried out without delay on interruption of cathodic deposition of hydrogen.

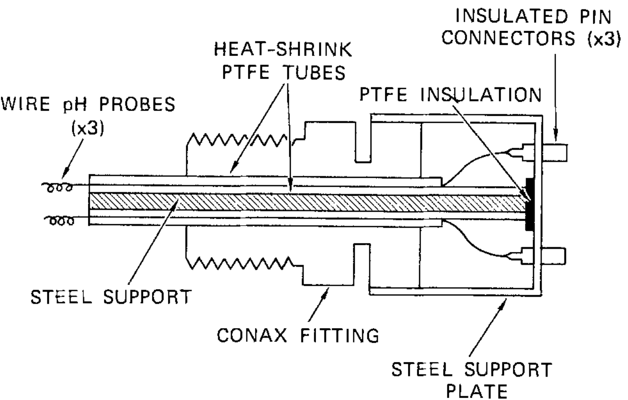

Fig. 2. pH probe assembly

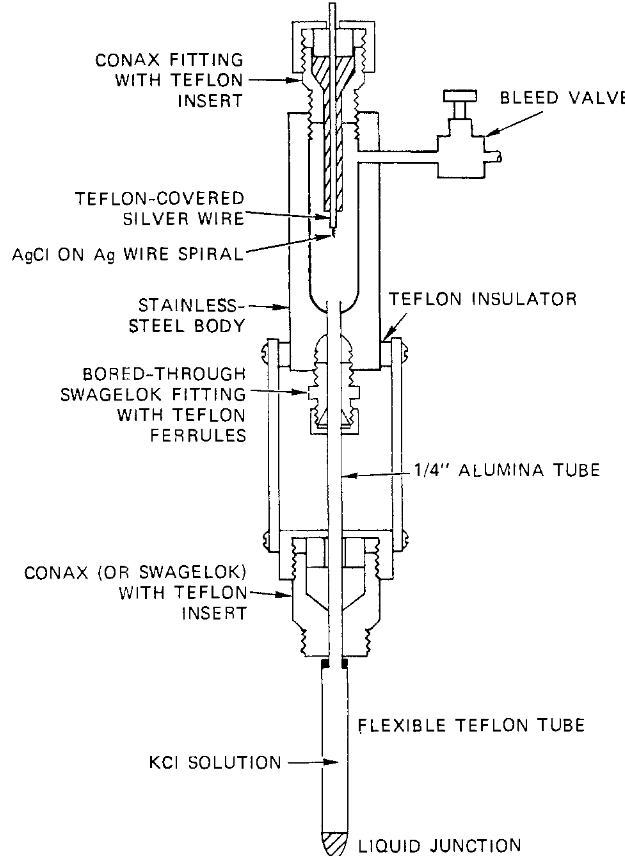

Fig. 3. Reference electrode assembly

Results and Discussion

Potential decay.—Typical potential decay curves for Pd-Pd, Pd-Pt, and Pd-Au electrodes in 0.1*M* LiOH at 298° and 548°K after cathodization and subsequent anodization are shown in Fig. 4. In all cases shown, the potential eventually decayed to a steady value that was found to be independent of the brief anodization that was applied after the initial decay to the plateau observed on cessation of cathodization. However, the decay times were generally much shorter at 298°K than they were at 548°K, and the plateau lifetimes were much greater at the lower temperature. Also, plateau lifetimes were found to be dependent on the pH of the solution. For example, in 0.1*M* LiOH at 548°K plateau lifetimes of several hours were observed, whereas in 0.1*M* $B(OH)_3$ the plateaus endured for generally less than 1 hr.

System composition.—The calibration of pH probes for the use in high temperature aqueous solutions requires calculation of the composition of the system and in particular the activity of hydrogen ion at the temperature of interest. For the system $B(OH)_3/LiOH/H_2O$, the composition of a dilute solution (<0.1*M*) can be calculated by considering the following equilibria

$$B(OH)_3 + OH^- \overset{Q_B}{\rightleftarrows} B(OH_4)^- \quad [1]$$

$$Li^+ + OH^- \overset{Q_L}{\rightleftarrows} LiOH \quad [2]$$

$$H_2O \overset{Q_W}{\rightleftarrows} H^+ + OH^- \quad [3]$$

where Q_B, Q_L, and Q_W are the ionic products for reactions [1], [2], and [3], respectively. Thus

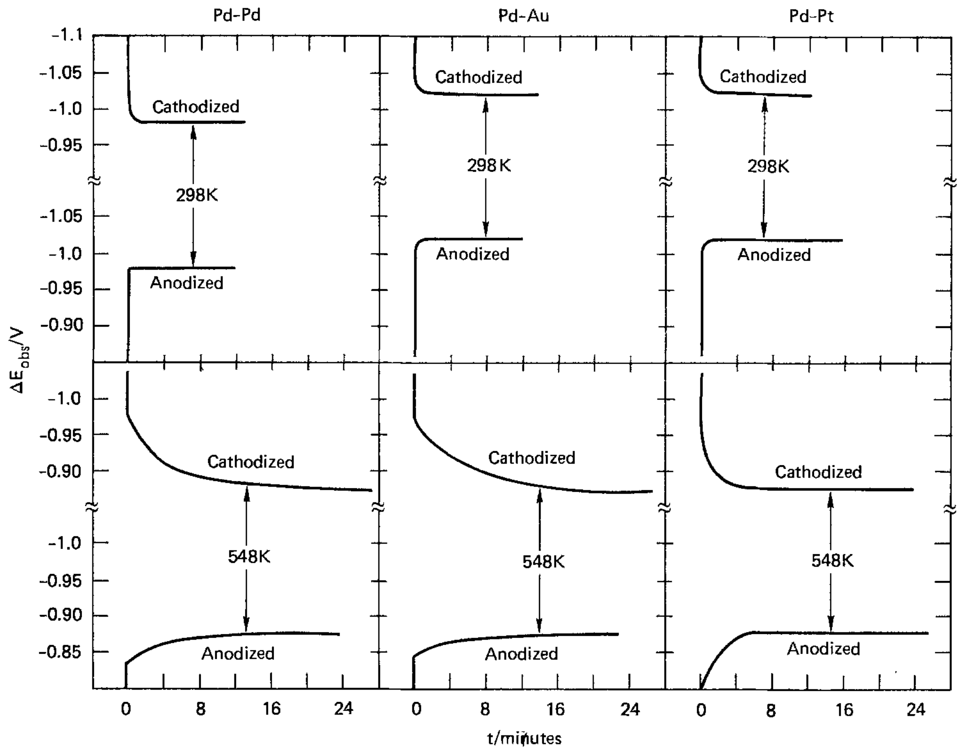

Fig. 4. Potential decay curves for bimetallic Pd-Pd, Pd-Au, Pd-Pt hydride electrodes in 0.1*M* LiOH at 298° and 548°K after cathodic deposition of hydrogen and subsequent anodization. ΔE_{obs} is the observed potential *vs.* the external Ag/AgCl, 0.102*M* KCl electrode (298°K). Cathodization and anodization parameters are given in the text.

$$Q_B = M_{B(OH)_4^-}/M_{B(OH)_3} \cdot M_{OH^-} \quad [4]$$

$$Q_L = M_{LiOH}/M_{Li^+} \cdot M_{OH^-} \quad [5]$$

$$Q_W = M \cdot M_{OH^-} \quad [6]$$

Mass and charge balance constraints provide three additional relationships

$$M_{B(OH)_4^-} = M^o{}_B - M_{B(OH)_3} \quad [7]$$

$$M_{Li^+} = M^o{}_{Li} - M_{LiOH} \quad [8]$$

$$M + M_{Li^+} - M_{OH^-} - M_{B(OH)_4^-} = 0 \quad [9]$$

where $M^o{}_x$ is the total molality of element x and M is the molality of hydrogen ions in the system. From Eq. [4] and [9] we obtain

$$M^4 + AM^3 + BM^2 - CM - D = 0 \quad [10]$$

where

$$A = Q_W(Q_L + Q_B) + M^o{}_{Li} \quad [11]$$

$$B = Q_W(Q_L Q_B Q_W + M^o{}_{Li} Q_B - 1 - M^o{}_B Q_B) \quad [12]$$

$$C = Q_W(Q_L Q_W + Q_B Q_W + M^o{}_B Q_L Q_B Q_W) \quad [13]$$

$$D = Q_L Q_B Q_W{}^3 \quad [14]$$

Equation [10] was solved iteratively using the Newton-Raphson technique. Data for Q_B, Q_W, and Q_L were taken from the work of Mesmer, Baes, and Sweeton (3), Sweeton, Mesmer, and Baes (15), and Tremaine (16), respectively. The first two quantities are given as functions of both temperature and ionic strength. Accordingly, a double iterative technique about both M and $I = \Sigma M_i Z_i{}^2$ (Z_i = ionic charge) was employed. Satisfactory convergence of both M and I (ΔM and ΔI per iteration <0.01%) was generally obtained in less than ten iterations for I. Satisfactory convergence was also judged from the value for the excess charge, defined here as

$$Z_{ex} = \Sigma M_i Z_i / \Sigma M_i |Z_i| \quad [15]$$

This quantity was found to be always less than 10^{-7}, thereby indicating excellent convergence for the solution of Eq. [10].

The activity coefficient for H^+ was calculated using Debye-Huckel theory

$$\ln \gamma_i = -AZ_i{}^2\sqrt{I}/(1 + Ba_o\sqrt{I}) \quad [16]$$

where A and B are the Debye-Huckel coefficients and a_o is the so-called "distance of closest approach." A value of 4.5×10^{-8} cm was adopted for a_o in accordance with the recommendation of Naumov *et al.* (17). Calculated activity coefficients for univalent ions in the systems employed are summarized in Table I. Combining these data with the calculated values for the concentration of hydrogen ion yields the *p*H data summarized in Table II.

The accuracy of these calculations is difficult to assess since the input data (Q_W, Q_L, and Q_B) were taken from three different sources (two laboratories) and complete statistical information on the precision of the data is not available. However, the data for Q_B and Q_W were obtained using highly precise *p*H titrations employing concentration cells with transference. Furthermore, errors in the parameter of lowest precision (Q_L) do not have a major effect on the computed values for M, at least for the relatively dilute systems (< 0.1*M* LiOH) of interest here. Finally, the calculated and measured *p*H values at 298°K agreed to within ± 0.05, and it is believed that this level of precision is typical for all temperatures considered.

Liquid junction potentials.—A complete thermodynamic analysis of the potentiometric data reported in this paper requires estimation of the liquid junction potential between the internal KCl solution of the reference electrode and the $B(OH)_3/LiOH/H_2O$ system at each composition and temperature. Formally, the junction can be represented as

Reference	$[H^+] = M_1$	$[H^+] = M$	Solution
	$[K^+] = 0.102$	$[OH^-] = M_{OH^-}$	
	$[Cl^-] = 0.102$	$[Li^+] = M_{Li^+}$	
	$[OH^-] = M_1$	$[B(OH)_4{}^-] = M_{B(OH)_4^-}$	

where M_1 is taken as $\sqrt{Q_W}$; that is the solution in the reference electrode is assumed to be neutral. According to the Planck-Henderson theory (18), the liquid

junction potential is given by

$$E_J \approx \left(\frac{2.303RT}{\mathbf{F}}\right) \left\{ \frac{\Sigma\lambda^o_i(M_{iS} - M_{iR})}{\Sigma\lambda^o_i Z_i(M_{iS} - M_{iR})} \right\} \log \left\{ \frac{\Sigma\lambda_i Z_i M_{iR}}{\Sigma\lambda^o_i Z_i M_{iS}} \right\} \quad [17]$$

where λ^o_i is the limiting equivalent conductance for ion i, and subscripts R and S designate the reference electrode and solution side of the junction, respectively.

Limiting equivalent conductances for the ions of interest at temperatures to 548°K (275°C) were interpolated from the estimated values given by Quist and Marshall (19). No data are available for $B(OH)_4^-$; instead values listed by Quist and Marshall (19) for bisulfate ion were assigned to this species.

Calculated liquid junction potentials for the reference electrode/solution interface for various solution compositions as a function of temperature are listed in Table III. The liquid junction potentials become significant from a practical viewpoint (*i.e.*, $E_J > 0.010$V) only at temperatures above 373°K (100°C), particularly for pure boric acid and pure lithium hydroxide solutions. Also, the sign of the liquid junction potential changes as the concentration of lithium hydroxide is increased. This change in sign reflects a change in the dominant charge carrier from H^+ for boric acid solutions to OH^- for the alkaline systems. Finally, it should be noted that the Planck-Henderson equation is derived assuming a uniform variation in concentration across the liquid junction. Since no techniques are currently available to examine the concentration profiles at the junction, particularly for high temperature systems, the values listed in Table III must be regarded as approximate only.

Potential-pH correlations.—Plots of the observed potential of the three palladized pH probes corrected for the calculated liquid junction potential against pH are presented in Fig. 5a and 5b. Correction of the observed potentials to the SHE scale using the calibration factors discussed earlier yields the $E_{SHE} + E_J$ *vs.* pH_T correlations summarized in Table IV. The least squares fits have been performed for each probe separately and for the combined set of data for a given temperature. The fitting coefficients, which are a measure of the success of the linear correlations, are also given in Table IV.

Both the data plotted in Fig. 5a and 5b and the correlations reported in Table IV demonstrate that the plateau potentials observed during desorption of hydrogen from palladium vary linearly with pH over the range of acidity considered in this study. Assuming that the potential-determining reaction is a one-elec-

* Correlation for the complete data set at each temperature.

tron process, then the slope of the $E_{SHE} + E_J$ vs. pH correlation should be equal to 2.303 RT/F. Comparisons of the observed and theoretical slopes are given in Fig. 6. Reasonable agreement between theory and experiment is observed, except at 548°K (275°C) where the difference between the theoretical and observed slopes is ~20 mV/pH. This is considered to be well outside the estimated error in the experimental data.

From a practical viewpoint, the correlations given in Table IV can be used to measure the pH of a solution at elevated temperatures, provided that the approximate composition is known so that the liquid junction potential can be estimated. Reproducibility of the measured plateau potentials from run to run was found to be better than ±10 mV which indicates that at 548°K (275°C) the pH of the solution can be determined to within ±0.1. This level of precision is sufficient for all but the most accurate acid-base titration work and is only slightly less than that available at ambient temperature using glass membrane potentiometry unless precautions are taken to ensure electrode stability and to compensate for "alkaline error."

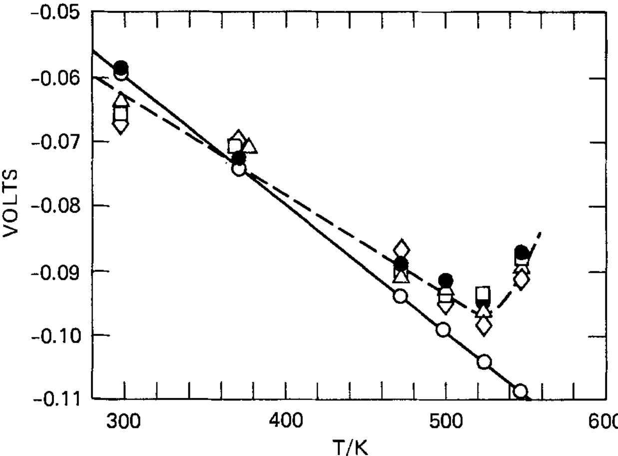

Fig. 6. Comparison of the measured dE/dpH values for the Pd-Pd (●), Pd-Pt (◇), and Pd-Au (□) hydride electrodes and for the total data set (△) with the theoretical value for a one-electron equilibrium. 2.303 RT/F (○).

Thermodynamic considerations.—It has been suggested (20) that the potential of the palladium hydride electrode in aqueous solution is due to the equilibrium

$$H^+ + e \rightleftarrows H\,(Pd) \qquad [18]$$

It is clear, therefore, that an understanding of the origin of the potential requires a brief analysis of the thermodynamic properties of the palladium hydride system.

The phase diagram for the Pd-H system as given by Lewis (21) is shown in Fig. 7. Each isotherm for $T < 310°C$ exhibits a plateau over which equilibrium exists between the α (solid solution of hydrogen in palladium) and the β (Pd_xH, $\bar{x}$ given by the boundary between the $\alpha + \beta$ and β regions) phases. By definition, the activity of Pd_xH is unity so that the activity of hydrogen in the lattice in the $\alpha + \beta$ region is given by

$$\ln a_{H,\alpha+\beta} = (\mu^o_{Pd_xH} - x\mu^o_{Pd} - \bar{\mu}^o_H)/RT \qquad [19]$$

where $\mu^o_{Pd_xH}$, μ^o_{Pd}, are the Gibbs energies per mole of Pd_xH and Pd, and $\bar{\mu}^o_H$ is the standard partial molal Gibbs energy for hydrogen in the lattice. These quantities are functions of temperature only (at constant pressure), so that the activity of hydrogen in the lattice is fixed for a given value of T.

In the present study, hydrogen was discharged cathodically onto the palladium surface such that the surface of the metal attains a composition that is assumed to lie well into the β region of the phase diagram. Following brief anodization that presumably oxidizes some of the hydrogen from the lattice and also oxidizes metal impurities that may have been electrodeposited during cathodization, the current is interrupted and hydrogen is allowed to desorb spontaneously into the solution (note that p_{H_2} in solution $<< p_{\beta\alpha}$). Consequently, the composition of the surface layer passes through the $\alpha + \beta$ region, during

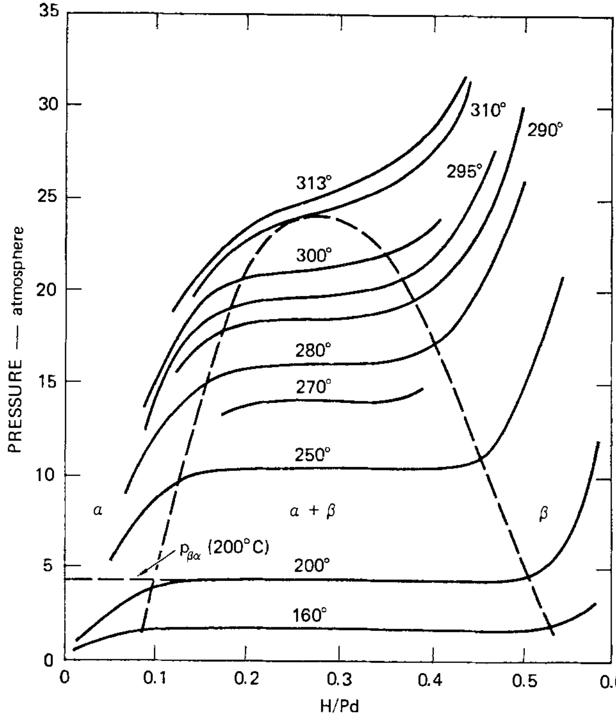

Fig. 7. Phase diagram for the palladium-hydrogen system

which time the potential should remain constant. This is precisely what is observed (Fig. 4).

Previous work (20) has shown that at 298°K the potential of the palladium hydride electrode is about 50 mV more positive than that for the hydrogen electrode $H_2(p_{H_2} = 1 \text{ atm})/H^+$ in the same solution. In the present work at pH = 8 this difference is found to be ~67 mV. The origin of this difference between the palladium hydride and the hydrogen electrode has been discussed by a number of authors (8-11, 20), and it is generally attributed to the difference in the "nature of the potential-determining reaction." However, if the palladium-hydride electrode were at equilibrium, the chemical potential of hydrogen in the lattice would be equal to the chemical potential of hydrogen in solution. That is, for the equilibrium

$$2H(Pd, \alpha + \beta) \rightleftharpoons H_2(p_{\beta\alpha}, \text{solution}) \quad [20]$$

the activity of hydrogen in the lattice is given by

$$\ln a_{H,\alpha+\beta} = [\bar{\mu}^o_{H_2,soln} + RT \ln p_{\beta\alpha})/2 - \bar{\mu}^o_{H,\alpha+\beta}]/RT \quad [21]$$

where $p_{\beta\alpha}$ is the partial pressure of hydrogen for the appropriate isotherm in the plateau region (see Fig. 7). Since the potential of the palladium hydride electrode is given by (see reaction [18])

$$E_{Pd\text{-}H} = -(\bar{\mu}^o_{H,\alpha+\beta} - \bar{\mu}^o_{H^+,soln})/\mathbf{F} - (RT/\mathbf{F}) \ln a_{H,\alpha+\beta} - (2.303RT/\mathbf{F})pH \quad [22]$$

then substitution of Eq. [21] for $\ln a_{H,\alpha+\beta}$ yields

$$E_{Pd\text{-}H} = -(\bar{\mu}^o_{H_2,soln}/2 - \bar{\mu}^o_{H^+,soln})/\mathbf{F} - (RT/2\mathbf{F}) \ln p_{\beta\alpha} - (2.303RT/\mathbf{F})pH \quad [23]$$

which is, of course, the expression for the hydrogen electrode for a hydrogen partial pressure equal to $p_{\beta\alpha}$ (by definition the first term is zero). The important point is simply that any meaningful thermodynamic comparison between the palladium hydride and hydrogen electrodes must be made at equivalent hydrogen partial pressures.

Data for the equilibrium partial pressure of hydrogen in the plateau region of the isotherm for the Pd-H system are not in good agreement; indeed, the values quoted by various works (21, 22) appear to be somewhat dependent on the technique employed for their determination. Furthermore, hysteresis is frequently observed between the absorption and desorption isotherms and values for $p_{\alpha\beta}$ (absorption) and $p_{\beta\alpha}$ (desorption) frequently differ by as much as 50%. In the present study the plateau potentials were measured during desorption of hydrogen from the β phase so that the analysis given below employs values for $p_{\beta\alpha}$ as quoted by Mueller *et al.* (22)

$$\log p_{\beta\alpha} = 4.44698 - 1835.4/T \quad (0°C < T < 180°C) \quad [24]$$

$$\log p_{\beta\alpha} = 4.602186 - 1877.82/T \quad (200°C < T < 300°C) \quad [25]$$

Using the data for $p_{\beta\alpha}$ given above and Eq. [23] with our experimentally determined $E_{Pd\text{-}H}$ we have calculated values for the potential difference between the palladium hydride electrode and the hydrogen electrode at equivalent partial pressures of hydrogen ($p_{\beta\alpha}$) at pH_T = 5, 8, and 11, as a function of temperature (Fig. 8). For temperatures below 373°K (100°C), the potential difference is small indicating that the measured potentials are consistent with reaction [18] being the potential-determining process for the palladium hydride electrode. However, at higher temperatures, the difference is substantial and furthermore depends on the pH of the medium.

A number of hypotheses can be advanced to explain the apparent discrepancy between the observed potentials and those predicted at equilibrium for the palladium hydride system. First, it could be argued that the potential of the reference electrode deviates from that computed in a previous publication (14). For this to be so, the potentials for the thermocell (298) Ag/AgCl, KCl⁝KCl, AgCl/Ag(T) and/or the isothermal potential for the cell H_2/HCl, AgCl/Ag at 373°K < T < 548°K would have to be in error by as much as 0.2-0.3V. However, the potentials of both cells have been substantiated by a number of workers [see Ref. (14) and (23)], so that we do not believe that this is a realistic explanation for the observed behavior. Furthermore, this hypothesis does not offer an explanation for the lack of Nernstian behavior shown in Fig. 6 (at least at 548°K) or the pH dependence of the potential deviation shown in Fig. 8. A second hypothesis can be advanced to the effect that the brief anodization employed after the cathodic deposition of hydrogen results in the formation of surface oxide phases, and hence the establishment of a mixed potential. However, anodization appeared to merely result in a more distinct plateau and did not appear to shift the plateau potential itself significantly. Finally, it must be recognized that, overall, the electrode is irreversible in that hydrogen is continually being desorbed from the palladium lattice. Thus, the potential of an irreversible or quasi-reversible electrode is expected to be less negative than that for the reversible system (as observed), and the difference should become more apparent as the rate of desorption increases due to increasing temperature. Clearly, this explanation must be regarded as speculative in nature, and it is apparent that additional work is required if the potential-determining processes for the palladium hydride electrode in aqueous solution at elevated temperatures are to be understood.

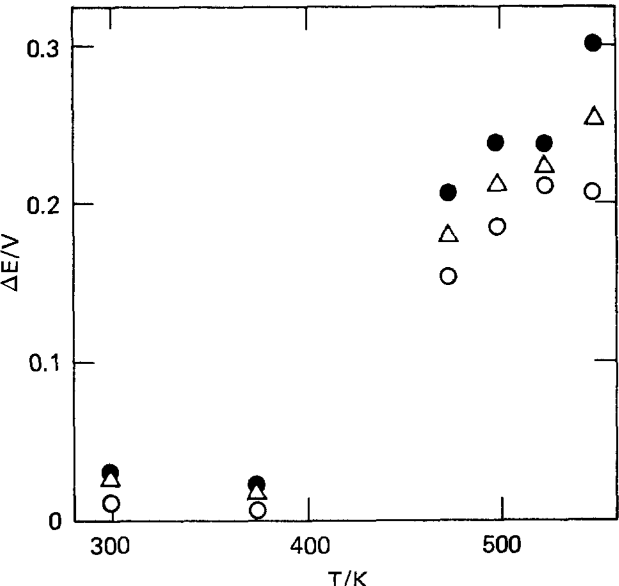

Fig. 8. Plot of $\Delta E = E[Pd/Pd_xH] - E[H_2(p_{\beta\alpha})/H^+]$ vs. T for pH values of 5 (○), 8 (△), and 11 (●).

Photoelectrochemical Compatibility of n-WSe_2 and n-$MoSe_2$ with Various Redox Systems

S. Menezes,* F. J. DiSalvo, and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Photoelectrochemical reactions at n-WSe_2 and n-$MoSe_2$ in several redox electrolytes have been resolved into hole transfer and photocorrosion components by hydrodynamically modulated rotating disk and ring disk electrode methods. Different n-WSe_2 specimens show a range of current-potential behavior, although parallel chemistry, with the better examples exceeding n-$MoSe_2$ in photopotential. Both semiconductors show the same selectivity to redox couples with optimum photoelectrochemical output in I^-/I_2 solutions. Surfaces exposed to I^-/I_2 have catalytic activity for Br^- oxidation. The rotating disk methods show examples (I^-, $Fe(CN)_6^{-4}$) of efficient solution hole transfer, mixed solution oxidation-photocorrosion (Cu(I)-NH_3, Br^-), and photocorrosion (Ti^{+3}, Fe^{+2}, Ce^{+3}) at these semiconductors. The photopotential-current characteristics indicate specific surface interactions strongly modify redox potential ordering.

A limiting problem with regenerative semiconductor-liquid junction cells is the extent of the competitive photodecomposition of the semiconductor surface. One of the more satisfactory efforts at surface stabilization, due to Tributsch, involves using transition metal dichalcogenides in which d-d photoexcitation does not break bonds (1). An extensive selection process for these compounds considering specific properties, such as maximum d-d splitting and smallest metal-metal distances, yielded MoS_2, WS_2, $MoSe_2$, and WSe_2 as the most promising (1).

In addition to bandgaps near the optimum for solar conversion, increased stability in these materials permits use of redox systems with more positive potentials. Photoelectrochemical cells so far developed are generally dependent on specific redox systems for stabilization (2-5) and are therefore affected by the restrictions of the solutions such as light absorption, toxicity, and air sensitivity. A wider range of redox couples with less limited properties would be expected to be open to inherently more stable semiconductors, if their flatband positions are also advantageous. These materials also allow investigating the influence of several redox systems on a particular semiconductor.

From photoelectrochemical studies on the transition metal dichalcogenides, the most efficient systems reported so far are based on the n-$MoSe_2$ or n-WSe_2/I^-/I_2 junctions, but the results are very sensitive to crystal selection and orientation (6-10). In the present work we have examined the photoelectrochemical reactions of n-$MoSe_2$ and n-WSe_2 in these and other electrolytes for a variety of specimens to gain further information on the factors which determine photoefficiency and stability in these systems.

Successful regenerative operation of a semiconductor-liquid junction solar cell requires no net change in either the electrolyte composition or the semiconductor surface. Thus in an n-type semiconductor, the light separated holes should oxidize the solution species rather than the crystal surface. The resolution of the various reaction paths occurring at photoanodes can

* Electrochemical Society Active Member.

Key words: photovoltaic, energy conversion, voltammetry, semiconductor.

be usefully studied with rotating disk electrode (RDE) methodology, particularly in its two extensions of the rotating ring-disk electrode (RRDE) technique (11-15), and sinusoidal hydrodynamic modulation (SHM) at the RDE (14, 15). The former provides quantitative and qualitative identification of the various reactants and products involved in photochemical reactions and the latter may be used to separate solution (*e.g.*, regenerative redox reactions) from surface processes (*e.g.*, photocorrosion). We utilize these methods to investigate compatibility of n-WSe_2 and n-$MoSe_2$ with several redox systems.

Experimental

WSe_2 and $MoSe_2$ crystals were grown by Cl_2 or $TeCl_4$ transport at temperatures ranging from 850°-1000°C (16). Approximately 0.1 cm^2 disks were punched out from thin crystals isolated from as-grown clusters and fabricated into RDE and RRDE (17) using silver-epoxy for electrical contact. Surface preparation or renewal involved peeling off the damaged and disrupted layers with an adhesive tape. Surface orientation is ⊥ to the C axis (van der Waals plane facing the electrolyte).

The RRDE's were provided with a Pt ring with inner radius of 0.24 cm and outer radius of 0.31 cm. Circuitry for RRDE voltammetry and SHM experiments has been previously described (17, 18). Electrochemical experiments were performed potentiostatically under an N_2 atmosphere in a three-electrode cell equipped with an optical flat window. Carbon rod counterelectrodes were used with either a saturated calomel electrode (SCE) or another carbon rod as reference electrodes. The disk was illuminated with a 100W tungsten-halogen lamp. Electrolytes were prepared with reagent grade chemicals and triply distilled water. Photocurrent spectra were taken as before (19).

A center rotation speed of 1600 rpm and scan rate of 5 mV/sec were maintained in all experiments except for spectra (stationary electrode). Peak to peak modulation $\Delta\omega^{1/2} = 2$ rpm$^{1/2}$ was superimposed on the rotation speed at a frequency of 1 Hz in SHM experiments.

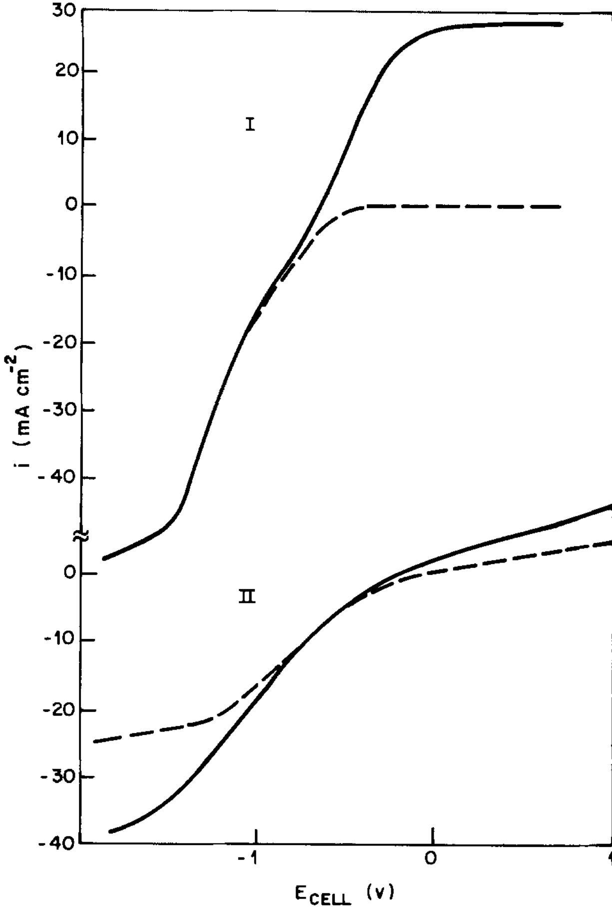

Fig. 1. Current-voltage characteristics of Type I and II n-WSe_2 in 1M I^- + 0.25M I_2 under illumination (——) and in dark (- - -). Potentials referred to carbon electrode measuring the solution redox potential.

Results

RDE voltammetry and photocurrent spectra.—Current-voltage curves for I^-/I_2 solution were recorded on several samples of n-doped WSe_2, with and without illumination. These crystals generally showed a negative shift in potential at open circuit when illuminated (n-type response) but the magnitude varied and that of the currents at different biases even more so. The current-voltage curves of the two samples shown in Fig. 1 illustrate the two extremes of photoresponse found in the n-WSe_2 crystals, labeled Types I and II. The anodic photocurrent and open-circuit photovoltage for the Type I electrodes of Fig. 1 exceeded 24 mA/cm^2 and 0.6V, respectively, under the circumstances for which Type II behavior included both n-and p-type photocurrents and as low as 0.1V photovoltage. Anodic dark current is virtually nil in Type I electrodes and the cathodic behavior is essentially independent of illumination, as expected for ideal n-type electrodes. Intermediate behavior variously includes lower photocurrents and photovoltage than Type I values, as well as more poorly defined steps for mass transport limited (MTL) reactions (observed when millimolar concentrations of electroactive species were employed with high light fluxes). At some specimens grouped into Type II, cathodic currents which decrease under illumination (n-direction) were seen, opposite to the Fig. 1 Type II behavior.

Current-voltage characteristics of different n-$MoSe_2$ crystals under Fig. 1 conditions were all similar and qualitatively like that of Type I n-WSe_2. The definition of the anodic steps for solution species on n-$MoSe_2$ was generally better than that of WSe_2. However, high dark currents in the anodic direction for $MoSe_2$ were sometimes observed.

In Fig. 1 with bias negative of the flatband condition, the cathodic current step ought to be limited by iodine mass transfer to the disk, unaffected by light, as is the case for the Type I sample. In this Type II specimen the step increases on illumination. Figure 2 contains Levich plots for a Type I (independent of illumination) and such a Type II electrode (with and without illumination) in the same iodine-containing electrolyte. The i_D-$\omega^{1/2}$ traces for Type I are linear with a slope of 45 μA-rpm$^{-1/2}$. With Type II, apparent Levich behavior is still attained, but the slope increases from 18 to 40 μA-rpm$^{-1/2}$ on illumination. The latter value is in accord with that of the Type I electrode, within experimental electrode geometry matching.

The photocurrent spectra of Types I and II n-WSe_2 in 1*M* iodide solution are shown in Fig. 3 [$MoSe_2$ spectra are available elsewhere (6)]. Type I has a normal response near the bandedge whereas phase shifts and oscillations occur in that region for Type II, and the output and sign above 850 nm are phase setting dependent. The apparent bandgap is otherwise the same for both types, 1.4 eV, in agreement with other measurements (20).

RRDE and SHM Measurements.—RRDE data on these materials have not previously been given. We present studies on n-$MoSe_2$, which resembles Type I WSe_2, and on Type II WSe_2, as representative of the range of chemical behavior that was encountered.

Redox processes in I^-/I_2 solution at an illuminated $MoSe_2$ disk with Pt ring are displayed in Fig. 4 for the disk potential range of −0.3 to +0.2V *vs.* SCE. Two separate scans with different fixed ring potentials, $E_R{}^+$

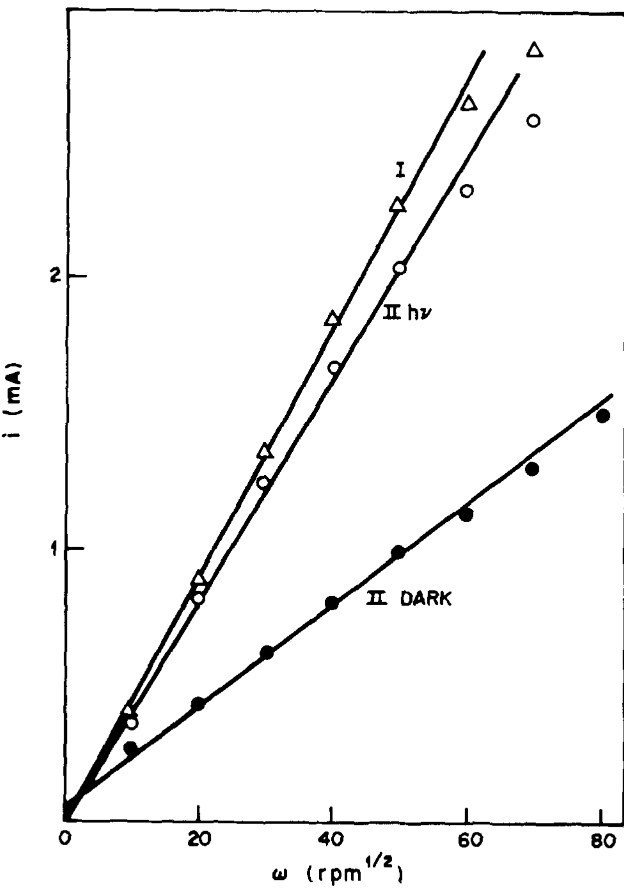

Fig. 2. Cathodic currents at −1.25V vs. carbon/I^-/I_2 at Type I(△), illuminated Type II(○) and unilluminated Type II(●) WSe_2 crystals in 1M I^- + 0.01M I_2 as a function of rotation speed.

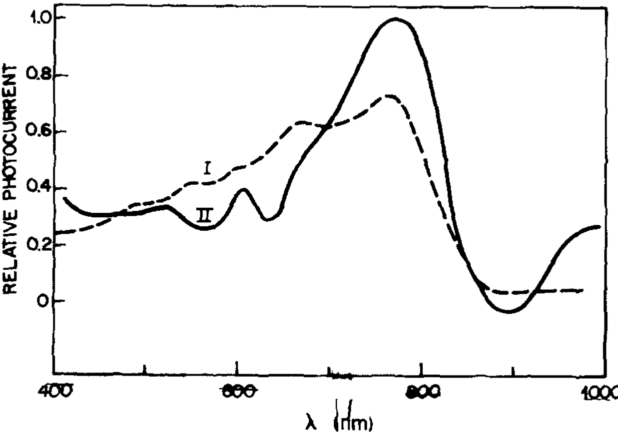

Fig. 3. Photocurrent spectrum under short-circuit conditions of Type I (- - -) and Type II (———) n-WSe_2 in 1M I^-.

and E_R^-, adjusted to oxidize I^- and reduce I_2, respectively, at MTL rates were used to construct the figure; the disk trace is reproducible. The disk and ring currents are i_D and i_R^+ and i_R^-, the latter corresponding to E_R^+ and E_R^-, respectively. Disk oxidation of I^- to I_2 causes an increase in i_R^-, Δi_R^-, and a concommitant decrease in i_R^+, Δi_R^+, as measured from the ring values at zero disk current and at the ring current plateaus at the positive extreme of the disk scan. In a similar fashion the changes in ring currents due to the cathodic reduction of iodine at the disk can be derived from the figure. In either anodic or cathodic case the disk current corresponding to the ring flux change is related by the collection efficiency, N (21). Since a conventional, perfectly circular, and concentric RRDE

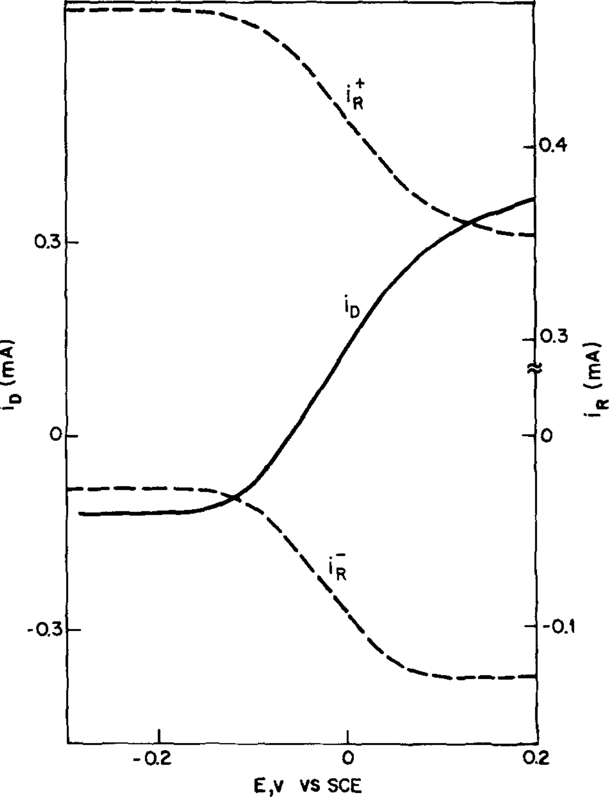

Fig. 4. Disk current i_D, ring oxidation i_R^+, and ring reduction i_R^-, for $MoSe_2$ disk potential scan in 2 mM I^- + 0.5 mM I_2 + acetate buffer (pH 5) under illumination. E_R^+ = 0.6V and E_R^- = 0.0V vs. SCE.

was difficult to fabricate from the punched out disks of the layered crystals, N cannot be accurately calculated. This factor was internally calibrated from the disk cathodic branch of the plot which was assumed to be totally due to iodine reduction.

Ring and disk current data from Fig. 4 are tabulated in the $MoSe_2$ column in Table I. The four values for N obtained from each of the Δi_R^+ and Δi_R^- pairs for the cathodic and anodic disk processes are identical and verify that the photoassisted oxidation of I^- at $MoSe_2$ proceeds quantitatively within the accuracy limits, estimated as ±0.02 in N.

Analogous experiments with a Type II WSe_2 disk-Pt ring electrode are displayed in Fig. 5 and the WSe_2 column in Table I. Because the waves are less well defined, the potential scale is wider than in Fig. 4. The disk current shows an inflection consonant with a transport limited current for I^- oxidation, and then increases sharply. The ring in either monitoring mode tracks the I^-/I_2 disk processes up to the inflection in i_D in a manner, from Fig. 5 and the Table I calculations, which leads to conclusions parallel to those given for $MoSe_2$. During the sharp increase in anodic current at the positive extremes of the disk scan, the levels of i_R^+ and i_R^- remain unchanged, thus implying that the additional disk current arises from surface processes occurring simultaneously with iodide oxidation. [Oxygen evolution would not be detected at the cathodic ring because of iodide poisoning of its reduction at Pt surfaces but there is no visible gassing or other evidence (1) for such occurring.] It is to be

Table I

	I^-	I_2	I^-	I_2
i_D, mA	0.33	0.12	0.70	0.20
Δi_R^+, mA	0.09	0.03	0.17	0.05
Δi_R^-, mA	0.08	0.03	0.20	0.06
N^+	0.27	0.25	0.24	0.25
N^-	0.24	0.25	0.28	0.30

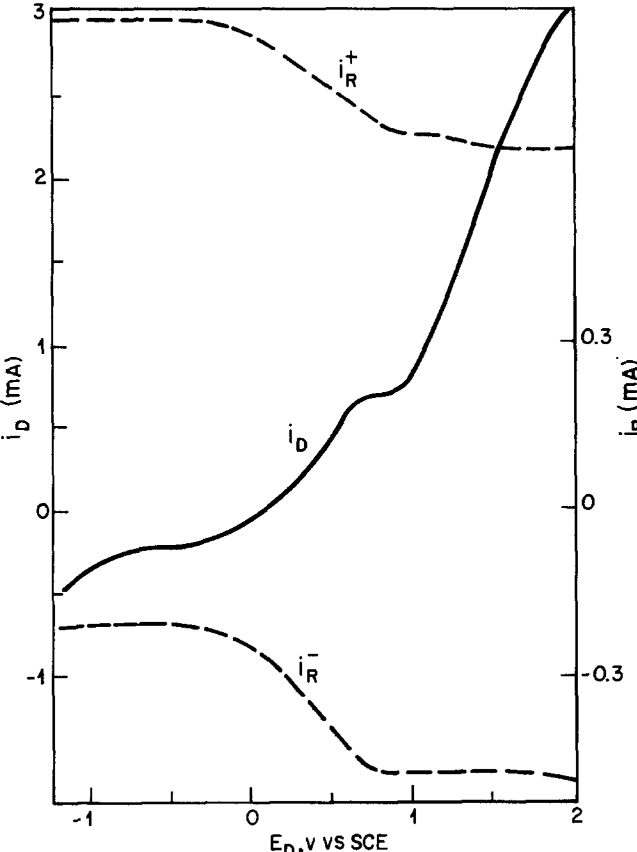

Fig. 5. Experiment of Fig. 4 at WSe_2 (II) RRDE in 10 mM I^- + 1 mM I_2 + 1M $HClO_4$.

noted that the apparent complication in the WSe_2 Type II case of light sensitivity in both directions (Fig. 1) will not affect the ring calibration for N since the mechanistic origin of I^- cathodic generation does not alter the ring collection characteristics as long as the only flux changing process at the disk is iodine reduction at 100% current efficiency.

Further data to distinguish among the processes occurring in the WSe_2 and $MoSe_2$ electrodes in I^-/I_2 solution was obtained with sinusoidal hydrodynamic modulation at the respective disk electrodes in Fig. 6. For the WSe_2 electrode the modulated current component, Δi_ω, wave shape resembles that of the ring responses in Fig. 5 in that it does not drop to zero level in the photocorrosion region as long as the total current, i_D, is not limited by photon flux (15); slight decrease in Δi_ω at positive potentials occurs as the disk current approaches light flux control. (The difference in the potentials for the Fig. 5 and 6 transitions arises from the use of a Type I crystal in the latter.) In these systems, noise and spurious responses at center speed related frequencies, caused by the imperfect circular symmetry of the disks rotating in a partially focused beam, are of more than usual significance. The $MoSe_2$ results are, however, closer to mass transfer control theory for which the Fig. 6 i_D and $\Delta i_\omega \times \omega^{1/2}/\Delta\omega^{1/2}$ traces would be coincident, within the small frequency effects (22) and electronic gain errors (18) which reduce the modulated part of the signal by about 5%.

Potential scan derived plots of i_D and Δi_ω in Fig. 7 from n-$MoSe_2$ and WSe_2 disks in Br^-/Br_2 solution show the expected behavior for the dark Br_2 reduction (well-defined waves) but an absence of anodic SHM response until high levels of total disk current, i_D. The anodic disk current shows no plateau for either semiconductor and must be dominated by surface corrosion above 0.4V. Although the anodic Δi_ω response is initially nil, it becomes evident positive of corrosion current appearance. Its magnitude, however, is much less than that seen for comparable iodide concentrations. A slightly narrower potential region of no SHM response is obtained with $MoSe_2$ under the same conditions, but corrosion is still the dominant process for the latter at any significant anodic current. Modulated response at both electrodes at the high anodic current appears not to be an artifact, as it is found experimentally to be a linear function of $\Delta\omega^{1/2}$ at the anodic SHM plateau. Additional confirmation that part of the disk current at $MoSe_2$ proceeds to Br^- oxidation was provided by RRDE experiments of Fig. 8 parallel to the one shown in Fig. 4. The ring traces in the Br^- case of Fig. 8 are similar to those for iodide in terms of their indications of halide/halogen flux change during the cathodic and anodic steps. The additional disk current component

at positive potentials is not accounted for by the bromide oxidation and thus is attributed to surface corrosion.

The power output characteristics of the n-$MoSe_2$-I^-/I_2 based cell have been ascribed to specific interaction between these solution species and the $MoSe_2$ surface layers (6). To test whether such effects can be used to activate the surface for other reactions, an $MoSe_2$ electrode was initially cycled in I^-/I_2 solution and the Fig. 7 scans repeated. The result is shown in Fig. 9. The iodide or iodine species adsorbed by n-$MoSe_2$ are still effective in Br^- solution as seen by the distinctly improved Br^- oxidation step and its separation from the surface photocorrosion. That the current in the region 0-0.2V is due to Br^- and not adsorbed I^- oxidation is shown by the SHM response and the fact that the current can be maintained for prolonged periods of time. However, scanning the electrode potential positive of the point of active corrosion destroys the catalysis due to the I^-/I_2 exposure, as indicated by a rapid decrease in SHM response above 0.4V *vs.* SCE in Fig. 9, not here due to photon flux control. The catalytic properties are completely lost after a few Fig. 9 scans (behavior reverts to that of Fig. 7) and can only be recovered by another immersion into I^-/I_2 solution.

Figure 10 shows i_D and Δi_ω plots as a function of linearly scanned disk potential at n-WSe_2 and n-$MoSe_2$ in an acidified $Fe(CN)_6^{-4}$ solution. The scaled SHM current follows the total current wave in the mass transfer controlled region and continues unchanged during the corrosion process at the sharp rise in i_D, until the light limited current region is approached in both cases. The onset of photocurrent is at a more positive potential for $MoSe_2$. Similar data, not shown, are obtained for the redox system Cu(I)-Cu(II)-NH_3 at these electrodes.

The results with three other redox couples in acid solution, Ti(III)-Ti(IV), Fe(II)-Fe(III), and Ce(III)-Ce(IV), were clearly different from those above. No evidence of Ti(III) or Fe (II) oxidation at n-WSe_2 was detected from SHM behavior, although such reaction was reported for p-WSe_2 (23). Cathodic reduction of Fe(III) gives the expected MTL current step and SHM response, whereas no anodic current appears until photocorrosion occurs. Large photocurrents and open-circuit photovoltage are observed with the Ce(III)-Ce(IV) couple at n-WSe_2, but no SHM response could be extracted on the anodic side indicating that the current was due to corrosion. In that case a dark open-circuit voltage exists, already reflecting a mixed corrosion process.

Redox potentials and photovoltages.—The relation of redox potentials to photovoltages in the above acid systems was investigated. A higher concentration (up to 1M) of redox species than in SHM experiments (low millimolar) was used. A set of four crystals each of n-WSe_2 and n-$MoSe_2$ were employed to average the cell potentials. The photopotentials, E_{cell}, are plotted *vs.* the measured redox potentials at a carbon electrode. No dark potentials were observed in any of the solutions outside of Ce(III)-Ce(IV), which had about 0.15V.

The photopotential plot in Fig. 11 is obviously not a smooth function of redox potentials, but the direction of scatter is consistent for both semiconductors, and suggests other systematic factors are of influence. To examine this more closely, current-voltage curves with n-WSe_2 and $MoSe_2$ in all these redox systems under illumination are shown in Fig. 12 and 13, respectively. (The slopes of the individual curves reflect the ap-

parent resistance, charge transfer, and otherwise, of the particular samples selected and are not important for the present purpose.) If the onset of the photocurrent is an approximate measure of the flatband potential and contributions of surface states thus ignored, the shift to most negative onset potentials is observed for the I^-/I_2 redox couple, in agreement with the high photovoltage in Fig. 11 and the other exceptional behavior earlier noted for this system. Correspondingly smaller shifts were observed in $Fe(CN)_6^{-3/-4}$, Cu(I)-Cu(II)-NH_3, and Br_2/Br^- solutions, all of which are less readily oxidizable to the extent earlier indicated by the respective SHM and RRDE results.

Anodic current for the Ti(III), Fe(II), and Ce(III) ions is essentially absent in the potential range of −0.4-0.4V *vs.* SCE. A sharp rise in current is common to all three at essentially the same potential when the semiconductor corrosion actively proceeds. This is consistent with SHM results where modulated current output was detected only for the (light or dark) cathodic processes of Fe(III) and Ce(IV).

Discussion and Conclusions

In general this examination of a range of n-WSe_2 and n-$MoSe_2$ samples suggests that crystal surface quality determines the quantitative current-voltage characteristics but not the fundamental occurrence of given electrochemical processes. For example, our data show that photo-oxidation of I^- proceeds in an identical manner at both Type I and Type II WSe_2. Thus physical imperfections of Type II crystals which limit their power conversion outputs do not alter the attainable interfacial chemical reactions but rather the potentials at which they occur at given rates.

From the RRDE and SHM data for WSe_2 and $MoSe_2$ in the seven redox couples investigated, the voltammetric characteristics can be classified into regions of potential dominated by the following:

(a) Cathodic MTL reduction wave

(b) Anodic MTL oxidation wave

(c) Anodic MTL oxidation and surface corrosion, in parallel

(d) Surface corrosion

The sequence a-b-c has been quantitatively identified for the systems I^-/I_2, $Fe(CN)_6^{-3/-4}$ and I^- surface-catalyzed-Br^-/Br_2. In the cases of Br^-/Br_2 and Cu(I)-Cu(II)-NH_3, the reactions basically proceed from a to c since, for the first, no MTL oxidation step and, for the second, only partial separation of such a step were observed. For the three multivalent cations only d is detectable in the anodic region.

Figure 6 shows a distinct photo-oxidation step a in I^-/I_2 before the onset of corrosion. The wider region of stability is consistent with its correlation to the most negative current onset potential shift, as estimate of flatband position, observed in Fig. 11-13, as well as the optimum photoconversion characteristics observed with this system for both semiconductors.

RRDE and SHM response at positive potentials in Fig. 5 and 6 illustrate that photo-oxidation and corrosion can occur competitively and concurrent surface dissolution of the electrode does not necessarily suppress its role in the hole transfer process even at high relative levels of corrosion. This feature complements the foregoing observations that diffusion-controlled photo-oxidation of I^- can still occur at Type II samples.

The redox potentials of Br^-/Br_2 appear too positive to restrain photocorrosion in the absence of a specific surface interaction reflected in a large negative flatband shift. Thus i_D-E_D curves of Fig. 7 and 8 show no diffusion-limited wave for oxidation of Br^-. Modulation and ring current response resemble the processes occurring positive of decomposition (indicated by the sharp rise in i_D) in Fig. 5 and 6, where surface corrosion and oxidation of I^- proceed simultaneously.

However, Fig. 9 shows that it is possible to attain well-defined separation of solution and surface processes in Br^-/Br_2 when the surface has been exposed to I^-/I_2 and has acquired the flatband shift characteristic of that medium. The loss of this activity after forced surface corrosion indicates that only surface layers undergo changes, possibly by I^- adsorption on Mo at the more reactive exposed edges (6).

Specific surface interaction can also occur in the larger, multiply charged $Fe(CN)_6^{-3/-4}$ ions which have redox potential close to that of the I^-/I_2 couple, and also a well-defined oxidation step, but less of a flatband potential shift at the solar equivalent levels investigated here.

Absence of photo-oxidation and flatband shifts in Ti(III)-Ti(IV), Fe(II)-Fe(III), and Ce(III)-Ce(IV) suggest that these multivalent cations do not participate in any type of complex formation or intercalation with either W or Mo selenides. In the case of the Cu(I)-Cu(II)-NH_3 couple, which is as negative in potential *vs.* SCE as Ti(III)-Ti(IV), but in alkaline medium, oxidation occurs at both WSe_2 and $MoSe_2$. However, the low photoactivity and nearly degenerate behavior of WSe_2 and $MoSe_2$, respectively, with this system implies that band bending is minimal with either crystal. Therefore the redox potential must be nearly coincident with the flatband level of $MoSe_2$ and only slightly positive of that of WSe_2.

It is well understood that 100% current efficiency for solution process b is essential for regenerative operation of a power conversion cell. Evidence of substantial photovoltages or photocurrents is of course possible with mixed corrosion/oxidation or exclusively corrosion. The overall corrosion reaction at $MoSe_2$ (as WSe_2) probably occurs via

$$MoSe_2 + 6H_2O + 14h^+ \xrightarrow{h\nu} Mo(VI) + 2SeO_3^{-2} + 12H^+$$

or other closely related multiple electron reactions which involve passage of a large number of coulombs before signs of crystal deterioration are evident (6, 7). Stability over long periods observed at $MoSe_2$ in redox systems such as Br^-/Br_2 may be misleading as the RDE methodologies show; 100% current efficiency in the uncatalyzed surface condition is unlikely.

Negative potential shifts of anodic current onset have been observed with the three anions investigated but the location of Br^-/Br_2 bandedges is not sufficiently favorable. The flatband shifts in I^-/I_2 and $Fe(CN)_6^{-3/-4}$ are large enough to produce a distinct oxidation wave before the onset of corrosion. Cell response curves with I^-/I_2, however show definite superiority to $Fe(CN)_6^{-3/-4}$ for power conversion efficiencies.

All experimental results indicate that semiconductor-electrolyte interfacial chemistry is similar for $MoSe_2$ and WSe_2. Two differences between the semiconductors are (*i*) negative potential shift of about 0.15V for WSe_2 relative to $MoSe_2$ under similar conditions, and (*ii*) voltammetric curves with steeper slopes and higher dark currents for $MoSe_2$. The former is consistent for all the redox couples investigated and implies that the conduction bandedges in WSe_2 are situated higher (negative) than $MoSe_2$. The second feature may relate to doping levels and morphological differences not well enough known in the individual exposed surfaces.

Photoelectrochemical performance of W and Mo dichalcogenides has already been shown to depend on the orientation of the crystal surface (8-10); rates of electron transfer vary for surfaces $\|$ and $\perp$ to the C-axis. Exposed edges have surface states that provide recombination sites for minority carriers and reduce photoresponse. The range of photoactivity observed at WSe_2 specimens (8) of the same origin as those examined here can be correlated to surface morphology of the crystals. The extent of Type II character is probably dependent on the fraction of the surface comprising exposed edges as opposed to the smooth van der Waals surfaces which ought to exhibit Type I behavior.

Surface orientation, however, does not account for the p and n character of Type II samples. To interpret these results we assume that inhomogeneous doping and occlusions (24), originating from the arbitrary growth process, result in crystals with p conducting areas interspread on an surface with dimensions $\geq$ diffusion layer thickness. In the absence of illumination, the p areas of the electrode are inactive under cathodic bias. Cathodic current contribution to the diffusion limited I_2 reduction is exclusively from the n area with $\omega^{1/2}$ dependence still dominant (25). Illumination photoactivates the p areas and the entire surface of the electrode then participates in the reduction process, yielding the expected geometric area diffusion-controlled currents. The latter is confirmed by Fig. 2 where the value of Levich slope at a Type II crystal under illumination, about twice as much as in the dark, is equivalent to that of a Type I crystal of comparable area.

Crystals with both types of carriers in low concentration have been found among naturally occurring MoS_2 samples (26). In the present synthetic procedure, the transport agent used empirically determines the carrier type (16), along with the stoichiometry of W(Mo) and Se. Although it may be possible to alter growth of n-WSe_2 to more reproducible Type I behavior of wafer segments, it is difficult to conceive of also attaining high area coverage quality electrodes for the purpose of solar conversion with these materials.

A Determination of the Oxygen-Content of Platinum-Oxygen Alloys

James P. Hoare

General Motors Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

Samples of Pt (99.97% pure) foil were converted to a Pt-O alloy either by anodizing at 16 mA/cm² (~2.0V) in 1M H_2SO_4 or by soaking in concentrated HNO_3. The gain in weight during the conversion process, determined gravimetrically with corrections for the amount of dissolved oxygen, corresponds to an O/Pt atomic ratio of about 0.03 in agreement with AES depth profile values, both of which are less by an order of magnitude than the value expected for a saturated Pt-O alloy. The results are discussed in terms of two absorption sites for dissolved oxygen: intergranular oxygen and interstitial oxygen in octahedral sites of an fcc lattice.

There is good evidence in the literature (1-9) that oxygen can be dissolved in bulk platinum. According to the model proposed (10) for a Pt/O_2 electrode at rest, a local cell is set up at the electrode surface such that oxygen is dissolved in the Pt by the driving force of the local cell potential. Consequently, the reversible potential cannot be observed because of the presence of this local cell. If, however, the Pt sample could be charged to saturation with dissolved oxygen, the adsorbed oxygen layer generated by the local cell would grow to a complete monolayer, the local cell would be eliminated, and the reversible oxygen potential would be observed (10-13).

Two ways to charge Pt with dissolved oxygen are: (*i*) strong anodization (~2.0V) for several hours (11, 12) and (*ii*) treatment with concentrated nitric acid (7, 13). Of these two methods, treatment with HNO_3 charges the Pt with dissolved oxygen to a greater extent (7, 11-13). Platinum charged with dissolved oxygen is referred to as a Pt-O alloy. When a Pt-O alloy diaphragm was formed by treating a Pt foil on the back side with HNO_3, the reversible oxygen potential was observed on the front side (13) and the foil was bulged by lattice expansion.

If enough oxygen can be dissolved in Pt to cause the Pt foil to bulge due to lattice expansion, it would seem possible that the dissolved oxygen could be detected by an increase in weight of the Pt sample. In this report, Pt-O alloys were made both by anodization and by immersion in concentrated HNO_3, and the oxygen content of the alloys was determined gravimetrically.

Experimental

Early work was carried out in Teflon cells but later work was done in glass beakers. In both cases the results were the same. All measurements reported here were obtained in cleaned 30 ml glass beakers over which inverted 150 ml beakers were placed. Platinum samples were cut from the same piece of Pt foil (0.0127 cm thick and 99.97% pure). To each of the 1 × 1 cm square Pt samples, a Pt lead wire was spot welded for handling. Each sample plus lead wire was weighed on an analytical balance (to ±50 μg). These samples were cleaned by heating to a white heat in a burning jet of H_2 gas and quenching in concentrated HNO_3. This procedure was repeated until the H_2 flame was colorless after which the white hot Pt was allowed to cool down in air.

In one 30 ml beaker, exactly 10 ml of 1M H_2SO_4 solution was pipetted, and in another, exactly 10 ml of concentrated HNO_3. The lead wires were bent into the form of a hook so that the Pt foil was suspended 1 cm below the surface of the electrolyte. The sample in 1M H_2SO_4 was anodized at 16 mA/cm² and ~2.0V against a large Pt gauze counterelectrode, and that in the HNO_3 was soaked in the air-saturated concentrated HNO_3 under open-circuit conditions. Each day the Pt samples were removed from the beakers, washed with triply distilled water, blotted with filter paper, and dried in a vessel with air drawn over the sample by a vacuum pump for at least 30 min. After the samples had been weighed again and the 10 ml solution samples collected in sample vials, the Pt samples were treated as before newly pipetted 10 ml portions of H_2SO_4 and HNO_3. This procedure was repeated each day until seven determinations were made (8 day run). The 14 electrolyte samples were analyzed for Pt in solution by atomic adsorption spectroscopy using a graphite furnace (flameless) (to ±0.5 μg).

Results

Nearly all of the change in weight occurred in the HNO_3-treated sample in the first 50-70 hr of treatment. During the first 48 hr, 0.8×10^{-6}g of Pt went into solution, but with further time of exposure to HNO_3, additional Pt was not detected in solution. In contrast to this behavior, the weight of the anodized sample changed each day and about equal amounts of Pt were found in solution. Over the 8 day period, 4.0×10^{-6}g of Pt went into solution.

The increase in weight of the sample had to be corrected for Pt dissolution by subtracting the weight of dissolved Pt from the initial sample weight to obtain a corrected weight gain value. As seen in Table I, this correction is negligibly small and affects only the estimated figures of the corrected values. It is of interest to note that very little Pt is dissolved in the HNO_3 because the Pt surface becomes passivated, whereas Pt is continuously dissolved during anodization. The weight of the initial sample must be corrected by subtracting the weight of the lead wire above the solution. It is assumed that the Pt lead

* Estimated figures are distinguished from significant figures by displaying them as subscripts.

wire above the solution level contributes negligibly to the determination of dissolved oxygen. Using 16.00 and 195.09 for the atomic weights of oxygen and platinum, respectively, the oxygen/platinum ratio in the anodized Pt sample was found to be 0.013, and in the HNO_3-treated Pt, 0.026 as outlined in Table I.

It is valid to assume that the increase in weight is due only to oxygen dissolved in the Pt metal since oxygen adsorbed on the surface contributes negligibly as demonstrated by the following calculations. The volume of Pt in the foil samples is 0.0127 cm^3 and the total area of the samples is 2.051 cm^2. Using values of 21.45 g/cm^3 and 195.09g for the density and molecular weight of Pt, one finds that there are 8.40×10^{20} atoms of Pt. Noting that a unit cell of face centered cubic (fcc) Pt contains 4 Pt atoms, one calculates that there are 2.10×10^{20} atoms of O atoms dissolved in the Pt metal at saturation if each oxygen occupies the octahedral hole of the unit cell. Assuming that 420 $\mu C/cm^2$ of adsorbed oxygen constitute a complete monolayer of adsorbed oxygen, one determines that this value represents 1.31×10^{15} O atoms/cm^2 (5, 11, 14). The number of oxygen atoms adsorbed on the surface of the Pt foil sample is 2.69×10^{15} atoms. The O/Pt ratio for dissolved oxygen is 0.25 and for adsorbed oxygen 0.37×10^{-5}. Whether the adsorbed layer is PtO or PtO_2, adsorbed oxygen is less by 4 orders of magnitude than the dissolved oxygen found in Table I.

Discussion

Since the Pt crystal is face centered cubic (fcc), there exists one octahedral hole in the center of each unit cube. It is possible for a dissolved oxygen atom to reside in the octahedral hole and produce the observed lattice expansion.

Since the O/Pt atomic ratio at saturation is 0.25, it is an order of magnitude larger than that found in the Pt-O alloy formed from HNO_3 passivation in Table I. To account for this observation, one concludes that O atoms dissolved interstitially in the octahedral holes are unstable in the dehydrated state. Consequently, when the Pt-O alloy sample is removed from the cell, washed, and dried for analysis, this interstitial oxygen escapes to the surroundings.

It was observed (7, 15) that the electrocatalytic properties of HNO_3-treated Pt-O alloys were retained even after application of strong reducing conditions to the alloy electrode (such as strong cathodization in a hydrogen atmosphere) if a source of oxygen dissolved in the electrolyte was restored to the system. An x-ray diffraction analysis of a Pt-O alloy shows (16) that the lattice is expanded compared to untreated Pt by shifts in the diffraction lines even though Auger (AES) spectroscopy depth profiling shows that only about 3 atomic percent oxygen is present in the interior of the sample (16). This oxygen concentration corresponds to an O/Pt atomic ratio of 0.031 which is in good agreement with the gravimetric analysis reported in this work. These observations indicate that oxygen can enter the expanded lattice of an HNO_3-treated Pt-O alloy interstitially from the oxygen-saturated electrolyte as easily as interstitial oxygen can escape from the dehydrated alloy without a collapse of the expanded lattice. To return the expanded Pt lattice to its original state, the sample must be heated white hot causing the collapse of the lattice (15).

Another absorption site for dissolved oxygen is in the grain boundaries. In a differential thermal analysis (DTA) study of Pt-O alloys (17), the data were interpreted in terms of two types of dissolved oxygen, intergranular oxygen occupying sites in the grain boundaries and interstitial oxygen occupying octahedral sites in the lattice. In the case of Pt-O alloys formed by moderate anodization, most of the dissolved oxygen is intergranular without expansion of the Pt lattice. Lattice expansion (interstitial oxygen) of anodized Pt-O alloys has been observed (18, 19) only in those instances where the Pt was anodized severely for extended periods of time.

Another source of evidence for intergranular oxygen is obtained from studies of the diffusion of oxygen through Pt foils. By anodizing Pt diaphragms on one side and detecting oxygen on the other, the diffusion coefficient for oxygen through Pt was determined (5, 18) to be about 10^{-11} cm^2 sec^{-1}. Such a value appears to be too high (20) for the diffusion of O atoms through lattice sites of bulk Pt. It is more likely that oxygen diffuses at these high rates along the grain boundaries of these anodized Pt foils.

The difference between Pt-O alloys made by anodization and by HNO_3 treatment rests in the amount and location of oxygen dissolved in Pt. This situation arises from the fact that anodization produces only general corrosion of the Pt surface whereas treatment with HNO_3 causes preferred etching of the Pt surface as seen in Fig. 1. This etched Pt surface approximates the stepped surfaces investigated by Somorjai and co-workers (21) which expose high index planes where oxygen can easily penetrate to the Pt lattice. As a result, the HNO_3-treated Pt-O alloy can dissolve more oxygen per unit time than the anodized Pt-O alloy which in the absence of exposed high index planes must dissolve oxygen by the slower place-exchange mechanism (22-24). It seems, then, that oxygen dissolves in Pt intergranularly without lattice expansion first, and after reaching a certain concentration, oxygen is dissolved interstitially accompanied by lattice expansion. It follows, therefore, that intergranular oxygen is more stable than interstitial oxygen. The oxygen-content of Pt-O alloys determined gravimetrically (Table I) and by AES depth profiling analysis (16) is probably mostly intergranular oxygen.

It is surprising that the expanded lattice of the HNO_3-treated Pt-O alloy does not collapse with the loss of interstitial oxygen. Yet, because it does not and because the surface is preferentially etched, the electrode can regain its catalytic activity by replacing it in the cell in contact with oxygen-saturated electrolyte. On the contrary, when dissolved oxygen is removed from an anodized Pt-O alloy by strong cathodization (11), the catalytic activity is not regained by exposure to O_2-saturated electrolyte, but must be reanodized.

This observation is in agreement with that of a number of electroanalytical chemists (25-28) who noted that the catalytic activity of Pt indicator electrodes for certain reduction processes was greater for freshly anodized Pt electrodes.

Cation Effects on the Electrode Reduction of Molten Nitrates

M. H. Miles* and A. N. Fletcher*

Naval Weapons Center, Chemistry Division, China Lake, California 93555

ABSTRACT

Cyclic voltammetric, potentiostatic, and galvanostatic methods were used to investigate the electroreduction of molten alkali metal nitrates at 350°C on a platinum electrode. The cation of the nitrate salt plays a major role in the reduction reaction as well as in determining the ultimate fate of the oxide ion produced. Nitrate reduction occurs most readily in $LiNO_3$ melts, and the Li_2O formed appears to be relatively stable. Overvoltages for nitrate reduction increase with increasing size of the metal cation involved and the oxide ions produced by the reaction become more prone to oxidation to form peroxides or superoxides. The rate of water removal by purging the nitrate melt with helium gas was monitored by the water-wave on platinum. Surprisingly, no water-wave was detected using a nickel electrode. The solubilities of several substances were determined in $LiNO_3$ and KNO_3 and compared with ideal solubility calculations.

The chemistry of alkali metal compounds depends greatly upon the nature of the metal cation involved. For example, the alkali metals burn in air to yield lithium monoxide, sodium peroxide, and potassium, rubidium, and cesium superoxides (1). The strong, positive electric field around the small lithium ion restricts the spread of negative charge from the oxygen anion towards another oxygen atom, making the formation of higher oxides difficult. The weaker electric field around the larger unipositive ions allows the formation of the peroxide, $O_2^{=}$, or superoxide, O_2^-, to take place.

Oxide ions are produced by the electrochemical reduction of molten alkali metal nitrates (2-5)

$$MNO_3 + 2e^- \rightarrow MNO_2 + O^{=} \quad [1]$$

The role of the oxide ion produced by this reaction has been a controversial ghost which has haunted the chemistry of fused nitrates (6, 7). A variety of studies (8-17), however, support the conclusions that the oxide ion in nitrate melts is an unstable species due to the following reactions

$$O^{=} + NO_3^- \rightleftharpoons NO_2^- + O_2^{=} \quad [2]$$

$$O_2^{=} + 2NO_3^- \rightleftharpoons 2NO_2^- + 2O_2^- \quad [3]$$

in which the oxide is converted to peroxide or superoxide (6, 18, 19).

Most of the previous studies were conducted in molten $NaNO_3$-KNO_3 mixtures at about 230°C with very little consideration given to the role of the metal cation. By considering the strength of the electric field of the cation, it seems that the electrochemical reduction of molten alkali metal nitrates would produce Li_2O, Na_2O_2, KO_2, RbO_2, and CsO_2 as stable products in molten $LiNO_3$, $NaNO_3$, KNO_3, $RbNO_3$, and $CsNO_3$, respectively. Thermodynamical data predict both solid Na_2O_2 and KO_2 to be stable in equimolar $NaNO_3$-KNO_3 and that with increasing K^+ content the formation of O_2^- ions will be favored at the cost of $O_2^{=}$ ions (14, 20). Studies in individual nitrate melts show the preferential formation of peroxide in $NaNO_3$ and superoxide in KNO_3 (21).

Just as the positive electric field of a cation near a reacting species can make it more difficult to remove electrons in anodic reactions such as

$$2O^{=} \rightleftharpoons O_2^{=} + 2e^- \quad [4]$$

$$O_2^{=} \rightleftharpoons O_2^- + e^- \quad [5]$$

the cation field can also make it less difficult to add electrons in cathodic reactions such as in Eq. [1]. The rate of the electrochemical reduction of molten nitrates is strongly dependent upon the cation radii and decreases in the order $LiNO_3 > NaNO_3 > KNO_3 \sim RbNO_3$ (22). Hills and Johnson (2) also noted that the presence of lithium ions facilitates the reduction of nitrates. The thermal stability of the nitrates themselves with regard to decomposition into nitrites and oxygen decreases with decreasing cation radius (20). Catalytic effects produced by small cations having large electric fields have also been observed for other electron transfer reactions (23, 24).

Our interest in molten nitrates is related to their possible use as an oxidizing electrolyte in thermal batteries (25-27). A previous "open-pan" study of thin Ca/MNO_3 cells exposed to the atmosphere reports the effect of varying temperature upon the cathodic potential during cell discharge at constant currents (22). The present study reports half-cell investigations of nitrate reduction at fixed temperatures under a dry helium atmosphere. In addition to individual investigations of molten $LiNO_3$, $NaNO_3$, KNO_3, and $RbNO_3$, studies were also made on the $LiNO_3$-LiCl-KCl system [50-25-25 mole percent (m/o), mp = 160°C] found to be promising in thermal battery cell tests (27).

Experimental

The electrochemical cell and electrodes were similar to a previous study of the calcium anode (25) except that platinum or nickel disks were used as the working electrode in place of calcium. Uncompensated solution resistance was minimized by positioning the working electrode within 1-2 mm of the Luggin capillary tip. A glass tube for bubbling helium gas through the nitrate melt to remove water was added to the cell. The helium gas was passed through tubes of anhydrous calcium sulfate (indicating Drierite) and P_2O_5 prior to entering the cell. During all studies in this cell, a blanket of flowing helium gas was maintained above the melt. An Ag/$AgNO_3$ (0.1m) reference electrode in KNO_3-$NaNO_3$ was used as before. Temperature control was maintained within ±5°C by the use of a fluidized sand bath (Tecam).

All electrochemical measurements were obtained with a PAR Model 173 potentiostat/galvanostat. For cyclic voltammetric measurements, a PAR Model 175 programmer was also used and results were recorded with an X-Y recorder (Houston 2000 or Hewlett-Packard 7047A). Results for potentiostatic and galvano-

static experiments were recorded using a strip chart recorder (HP 7100B).

Approximate values for the solubilities of several oxides, peroxides, and superoxides were obtained using the method of successive additions. Solutions were generally equilibrated overnight to insure that true saturation limits were obtained. These measurements were made in a glass tube equipped for helium bubbling through the melt to remove any water and to provide stirring action.

All of the nitrate salts used were reagent grade except for rubidium nitrate (from Pfaltz and Bauer). The cyclic voltammograms for this salt suggested considerable nitrite was present, and its melting point (291°-298°C) also indicated impurities. Since most studies showed that the cathodic behavior of $RbNO_3$ was quite similar to KNO_3, results for this salt will generally not be shown. All salts were used without further purification except for drying in a vacuum oven overnight at 130°C.

Results

The presence of dissolved water in nitrate melts can be readily detected on a platinum electrode using cyclic voltammetry. Figure 1 (solid line) shows the water-wave that occurs just prior to the main nitrate reduction wave in molten $LiNO_3$ despite using $LiNO_3$ that had been oven-dried as described above. This water-wave has been reported by other authors (3, 8, 28-31) and is not due to trivial electrolysis of water since no hydrogen or oxygen is formed (8). Preliminary studies indicate that the water-wave can also be detected in $LiNO_3$ on iridium, silver, and gold electrodes at about the same potential as on platinum.

Surprisingly, no water-wave was detected when a nickel electrode was substituted for the platinum electrode as shown by the dashed line in Fig. 1. In addition, the anodic peak at −0.36V due to the oxidation of insoluble Li_2O to Li_2O_2 became much more clearly defined on nickel. The absence of this water-wave on nickel greatly simplified the analysis of the "open-pan" studies reported previously (22).

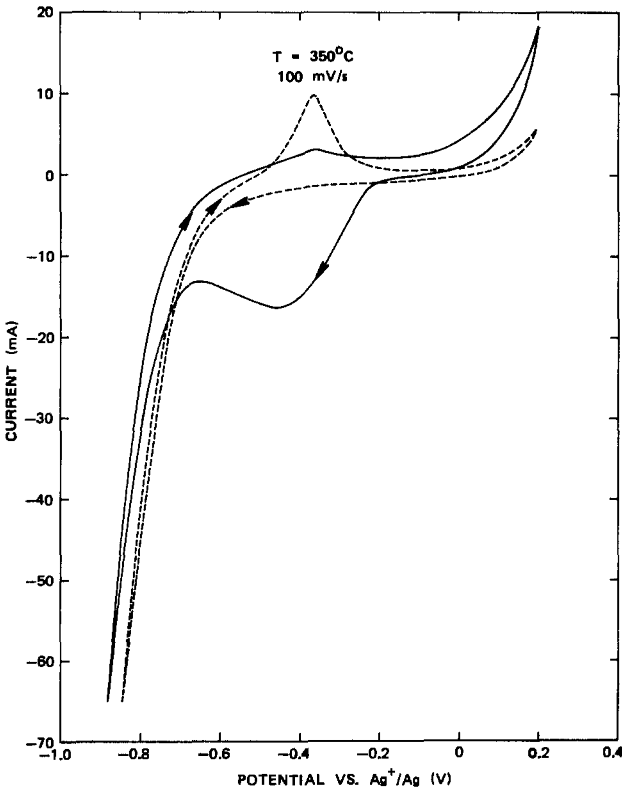

Fig. 1. Cyclic voltammograms showing the difference in the water-wave on platinum and nickel in molten $LiNO_3$ at 350°C. The solid line is the trace using a platinum electrode while the dashed line is the trace with a nickel electrode. Potential sweep rate was 100 mV/sec. Electrode area was 0.32 cm².

Studies of the water-wave on platinum at 350°C showed that the bubbling of dried helium gas through the molten $LiNO_3$ for about 1 hr was required to remove the water retained by this salt, whereupon the cyclic voltammogram became practically identical to the results shown for nickel in Fig. 1 (dashed line). In other alkali metal nitrates, the water-wave is smaller and tends to shift to more negative potentials as the size of the cation increases. The retention of water by the molten salt is much less a problem with $NaNO_3$ and KNO_3, since the small amounts of water present in these salts at 350°C can be removed within 5-10 min by purging the melt with the dried helium gas.

Figure 2 shows typical cyclic voltammograms for water-free melts of $LiNO_3$, $NaNO_3$, and KNO_3 obtained at 350°C using a platinum electrode and a potential sweep rate of 100 mV/sec. These results were obtained in quiet solutions (no stirring) under a helium atmosphere. The cathodic wave clearly shows the cation effect on the electrochemical reduction of molten nitrates. At 100 mV/sec, this major reduction wave represented by Eq. [1] reaches 70 mA (220 mA/cm²) at potentials of −0.90V, −1.36V, and −1.82V for $LiNO_3$, $NaNO_3$, and KNO_3, respectively. Neither the main anodic wave at about 1.1V resulting from nitrate oxidation (32-39)

$$NO_3^- \rightarrow NO_2 + \tfrac{1}{2}O_2 + e^- \quad [6]$$

nor the anodic process having a peak potential of about +0.5V reflecting nitrite oxidation (8, 18, 19, 38, 40, 41)

$$NO_2^- \rightarrow NO_2 + e^- \quad [7]$$

appear to be greatly affected by the nature of the cation. For $LiNO_3$, the anodic peak due to the oxidation of Li_2O to Li_2O_2 is again observed at −0.36V. Other peaks in Fig. 2 are more difficult to define, but they likely involve reactions of peroxides or superoxides (15, 19, 21). The addition of KO_2 to KNO_3 produced a large increase in the anodic current beginning at about −0.5V; however, gas evolution indicates that some decomposition of the KO_2 occurs at 350°C.

Cyclic voltammetric studies provide a means of detecting the presence of insoluble oxide on the electrode surface by use of the anodic reaction

$$2M_2O \rightleftharpoons M_2O_2 + 2M^+ + 2e^- \quad [8]$$

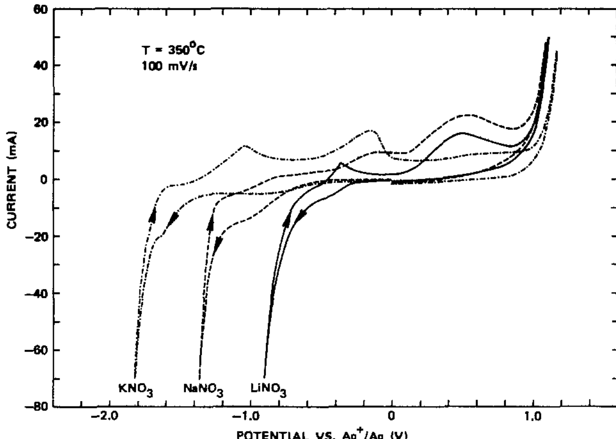

Fig. 2. Cyclic voltammograms for molten $LiNO_3$, $NaNO_3$, and KNO_3 obtained at 350°C in a helium atmosphere using a platinum electrode (A = 0.32 cm²). Potential sweep was begun at 0.0V and swept first cathodically, then anodically, and finally cathodically to the starting potential. Potential sweep rate was 100 mV/sec.

wherein the precipitated oxide is electrochemically oxidized to the more soluble peroxide. By gradually increasing the cathodic sweep limit, anodic peaks corresponding to this reaction are first observed at about −0.35V in $LiNO_3$ and at about −1.2V in $NaNO_3$. Fleeting evidence was also obtained for a slight anodic peak at about −1.6V in KNO_3. These results are consistent with the decreasing stability of the oxide with increasing radius of the alkali metal cation. In a voltammetric study on platinum using a thin Ca/$LiNO_3$ cell that generates Ca^{++} ions, a new anodic peak develops at about −0.1V indicating the oxidation of insoluble calcium oxide. Due to its higher charge, the electric field about the small Ca^{++} ion is even stronger than that about the Li^+ ion, hence a more stable oxide is to be expected. Cyclic voltammetric studies of the electrochemical reduction of $LiNO_3$, $NaNO_3$, $RbNO_3$, $Ca(NO_3)_2$, and $Sr(NO_3)_2$ mixtures with KNO_3 indicate that insoluble oxides form in the presence of all cations except K^+ and Rb^+ ions. These experiments suggest that the catalytic effect of the cation on nitrate reduction decreases in the order $Ca^{++} > Sr^{++} \sim Li^+ > Na^+ > K^+ \sim Rb^+$.

Cyclic voltammograms of $LiNO_3$ and $NaNO_3$ obtained using a small platinum working electrode (A = 0.006 cm^2) to minimize uncompensated IR effects are shown in Fig. 3. The usual relationship between peak current (I_p) and potential sweep rate (ν) was observed, *i.e.*, $I_p \alpha \nu^{1/2}$, while the peak potential (E_p) tended to vary with the rate of potential change. The greater stability of Li_2O compared with Na_2O is reflected by the more positive potential required for Li_2O oxidation. Despite the shorter potential excursions in $NaNO_3$, most of the Na_2O formed is apparently lost during the sweep cycle. At the slower sweep rates, the anodic peak in $NaNO_3$ disappears entirely. It is also interesting to note that the residual current following the cathodic peak is smaller in $LiNO_3$ where the more stable Li_2O is formed. The cyclic voltammograms in molten KNO_3 and $RbNO_3$ at 350°C do not show such interrelated peaks involving nitrate reduction.

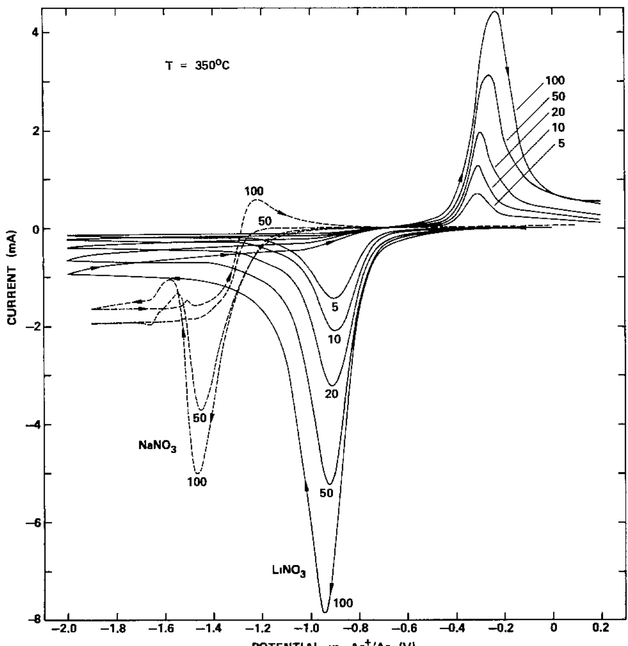

Fig. 3. Effect of the potential sweep rate on the cyclic voltammograms for molten $LiNO_3$ at sweep rates of 5, 10, 20, 50, and 100 mV/sec. Voltammograms for $NaNO_3$ at 50 and 100 mV/sec are shown for comparison (dashed lines). Results were obtained at 350°C in a helium atmosphere using a small platinum electrode (A = 0.006 cm^2). Potential sweep was begun at 0.0V and swept cathodically to −2.0V then anodically to 0.2V.

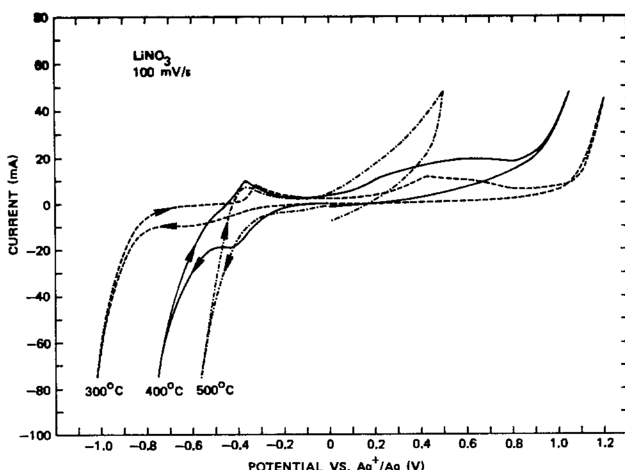

Fig. 4. Effect of the temperature upon the cyclic voltammograms in molten $LiNO_3$ under a helium atmosphere. Results were obtained at 300°, 400°, and 500°C using a platinum electrode (A = 0.32 cm^2).

Figure 4 shows the effect of temperature upon the cyclic voltammogram obtained in $LiNO_3$. In addition to the 300°, 400°, and 500°C results shown, experiments were also conducted at 350° and 450°C. The large shifts in potential for the nitrate reduction wave reflect the improved kinetics for this reaction at the higher temperatures. At a selected constant current of 50 mA for this reduction reaction, the potential, E, varies linearly with the temperature (correlation coefficient = 0.988) with $\partial E/\partial T = 2.31 \times 10^{-3}$ V/K. This shows good agreement with previous "open-pan" cathode studies obtained with Ca/$LiNO_3$ cells under conditions of varying temperature and constant current (22). The nitrate oxidation wave (Eq. [6]) also shows a large shift in potential between 300° and 400°C. The nitrite oxidation peak (Eq. [7]) increases with temperature such that it dominates the anodic reactions at 500°C. This is likely due to the nitrite formed by the increasing thermal decomposition

$$NO_3^- \rightarrow NO_2^- + \tfrac{1}{2} O_2 \quad [9]$$

with increasing temperature (7, 20, 42-44).

Chronopotentiometric studies of nitrate reduction on platinum in unstirred solutions are shown in Fig. 5. Sharp transition times were always observed in the $LiNO_3$ and $NaNO_3$ melts as well as in the mixed salt solution. The observed transition times are much shorter than expected for a reaction controlled by the diffusion and migration of nitrate ions, hence the

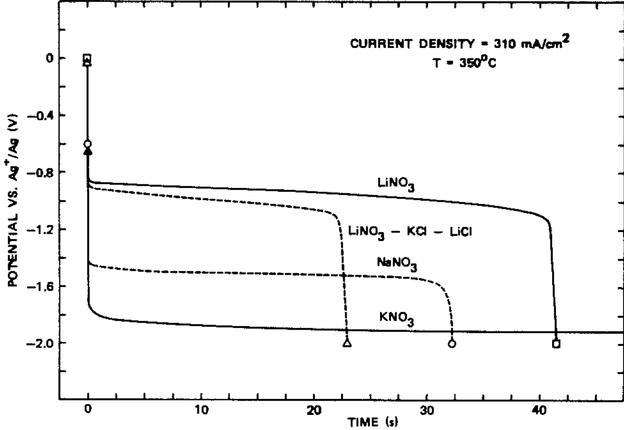

Fig. 5. Chronopotentiometric studies of nitrate reduction using a constant current of 310 mA/cm^2. Results were obtained at 350°C in a helium atmosphere using a platinum electrode (A = 0.32 cm^2).

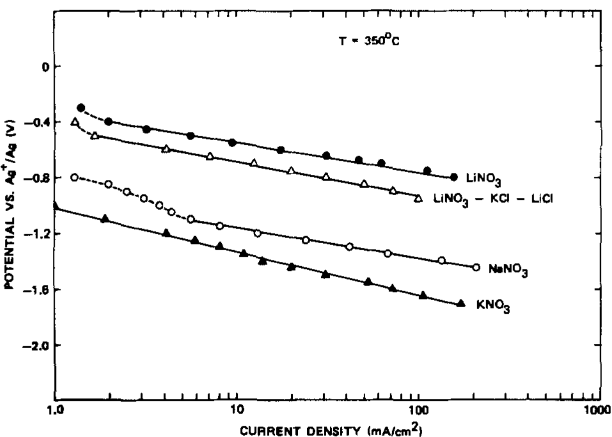

Fig. 6. Potentiostatic studies of the electrochemical reduction of molten nitrates at 350°C in a helium atmosphere using a platinum electrode ($A = 0.32$ cm²).

abrupt changes in potentials are likely caused by blocking effects of insoluble oxides. There were no abrupt changes in potential during the constant current reduction of KNO_3 even for time periods exceeding 100 sec.

Potentiostatic studies of nitrate reduction on platinum at 350°C are shown in Fig. 6. Measurements were made under conditions of a steady stirring action produced by bubbling helium through the melt. The experimental currents dropped when the stirring was stopped, suggesting concentration polarization due to the buildup of reaction products (13). Linear Tafel behavior was usually observed between about 2-100 mA/cm². Tafel and kinetic parameters calculated from these studies are given in Table I. Experimental current densities generally reached limiting values between 100-200 mA/cm²; even the studies in molten KNO_3 showed this limiting current effect under potentiostatic conditions. The limiting current is likely caused by blockage of the electrode surface by insoluble reaction products. A potentiostatic study of the reduction of molten $LiNO_3$ on nickel gave results very similar to those obtained with a platinum electrode.

Since oxides, peroxides, and superoxides are so entwined with the electrochemistry of molten nitrates, approximate values for the solubilities of a few of these compounds were measured. Results are given in Table II where solubility measurements of KCl are also included and show good agreement with published values. Data on solubility values in fused alkali metal nitrates reported in the literature are sparse (7, 45), hence in the absence of experimental data, ideal solubility calculations provide rough approximations for the solubility of substances that do not react with the molten nitrate. The ideal solubility given by

$$\ln X = \frac{\Delta H_{fus}}{R}\left(\frac{1}{T_M} - \frac{1}{T}\right) \quad [10]$$

demonstrates that the lower the melting point, T_M, and the lower the heat of fusion, ΔH_{fus}, of the substance concerned, the greater will be its ideal solubility in mole fraction, X, at any given temperature, T (46, 47). The phase diagram of the KNO_3-KO_2 system (20, 48) shows a high solubility for KO_2 as indicated by the ideal solubility calculated. The low experimental values shown in Table II suggest a low solubility for some reaction product formed. Insufficient oxygen concentration may cause KO_2 to decompose into K_2O_2 or even K_2O (17, 48). A decreasing stability of superoxide ions with rising temperature has been predicted (20). Experimental solubilities in molten KNO_3 are generally closer to ideal solubility values than are the measured solubilities in $LiNO_3$. Ideality in a solution requires uniformity of the intermolecular forces between the various components. In $LiNO_3$, interactions involving the small Li^+ ion are likely much stronger than interactions involving the NO_3^- ion whereas in KNO_3 the interactions involving K^+ and NO_3^- are more equal.

Discussion

The experimental transfer coefficient of about 0.5 found for the electrochemical reduction of molten nitrates (Table I) is in agreement with a previous study where the addition of the first electron to undissociated MNO_3 and breakage of the N—O bond was postulated to be the slow step (22). Cation effects for this reduction arise from the interaction of the positive metal ion with the nitrate ion that weakens the N—O bond and aids the electron transfer. The lack of obvious cation effects on the electrochemical oxidation of NO_3^- and NO_2^- (Fig. 2) could result from reaction mechanisms that do not involve bond rupture in the slow step. Nitrite oxidation may simply involve an electron transfer to form NO_2 as represented by Eq. [7].

Results shown in Fig. 2, 5, and 6 show a strong correlation between the experimental potential, E, for nitrate reduction and the radius, r, of the cation. Theoretically, the electric field of the cation acts to reduce the free energy of activation such that E will vary with r^{-1} of the cation (22). Using potentials taken at 100 mA/cm² in Fig. 2 and 6 and potentials taken at 10 sec in Fig. 5, $\partial E/\partial(r^{-1}) = 1.30$, 1.24, and 1.36 V·Å, respectively. The correlation coefficient is better than 0.99 in each case.

The rather low i_o values as well as the large temperature effect (Fig. 4) suggest the need for catalyzing the nitrate reduction reaction even at elevated temperatures. Open-pan cyclic voltammetric studies of molten $LiNO_3$ at 350°C on various metals suggest a catalytic order for nitrate reduction of Ag ~ Au ~ Ir ~ Ni ~ Pt > Mo > Ti >> Ta. For many metals, nitrate reduction for a given melt occurs at about the same potential (2, 3, 22). The large concentration

of added chloride in the $LiNO_3$-KCl-LiCl mixture (Table I) does not appear to greatly affect the reduction of $LiNO_3$.

Lovering *et al.* (31) propose that the electroreduction of water in nitrate melts is coupled with nitrite reduction

$$H_2O + NO_2^- + 2e^- \rightleftharpoons 2\,OH^- + NO^- \quad [11]$$

In agreement with their study, we found the water-wave to be smaller on the initial cathodic sweep but quickly increased as nitrite is produced by the main nitrate reduction wave. Cyclic voltammetric studies of the water-wave on platinum showed that $I_p \alpha v^{1/2}$ while E_p is not dependent on either the sweep rate or the concentration of water. This is the expected behavior for a diffusion-controlled reversible reaction with soluble reactants and products (49, 50) and is consistent with Eq. [11]. The fact that Lovering's reaction does not yield measurable currents on nickel electrodes could be related to the observed tendency of dark oxide films to form on nickel in molten nitrates. Such films could greatly restrict the involvement of chemisorbed water or hydrogen in the reaction mechanism. The dissolution of Li_2O by water adsorbed on platinum could also explain the smaller anodic peaks observed with this electrode in melts containing water.

The residual currents following the nitrate reduction peaks (Fig. 3) have been noted by other workers who propose that the limiting process is the rate of dissolution of the oxide precipitate (2, 13, 19) or that this current depends upon the permeability of the solid deposit (20). We suggest that the after-peak current may result from the oxidation of the metal oxide by the molten nitrate (Eq. [2]) followed by the electrochemical reduction of the peroxide formed. The smaller after-peak currents in $LiNO_3$ can then be correlated with the fact that Li_2O is more stable than Na_2O with respect to oxidation to the peroxide.

The lack of an observed reduction peak in molten KNO_3 is likely related to the rapid conversion of the unstable K_2O to K_2O_2 and KO_2 (19). In cyclic voltammetric experiments at high current densities, the current-potential trace becomes quite irregular suggesting rate-control by surface processes. The electrochemical reduction of the higher oxides formed on the surface helps to sustain the high cathodic currents observed when the potential is allowed to vary.

Other experimental results also show the important role of the cation in the electrochemistry of molten nitrates. During the cathodic reduction of nitrate melts on platinum, multilayer oxide films grow rapidly in KNO_3, slowly in $NaNO_3$, and not at all in $LiNO_3$ (13). We also observed a corrosive attack on platinum and nickel with the formation of black particles during the electroreduction of KNO_3 whereas any such attack was much less evident in $NaNO_3$ and $LiNO_3$. These results are consistent with the oxide stability order of $Li_2O > Na_2O > K_2O$ in the corresponding nitrate. Conversion of the oxide to peroxide and superoxide in $NaNO_3$ and KNO_3 gives remarkable oxidizing power and reactivity to the molten nitrate (8, 13) such that even corrosive attack of platinum can occur (13, 51). Cation effects were also readily apparent in the rate of attack of the nitrate melts upon the Pyrex glass cell used. Crazing and etching of the glass surface contacting the melt was much more rapid with $LiNO_3$ than with $NaNO_3$ or KNO_3.

Thermodynamic calculations support the conclusions regarding the important role of the cation in reactions involving molten nitrates. Considering, for example, the reaction

$$M_2O_{(s)} + MNO_{3(l)} \rightleftharpoons M_2O_{2(s)} + MNO_{2(l)} \quad [12]$$

the standard free-energy change, ΔG°, at 350°C is estimated to be about 10.2 kcal/mole in $LiNO_3$, 1.8 kcal/mole in $NaNO_3$, and −3.4 kcal/mole in KNO_3 from available data (14, 52-54). These values show that Li_2O is quite stable, thermodynamically, in $LiNO_3$ at 350°C, and that the stability of the metal oxide in its corresponding nitrate melt decreases with increasing size of the cation involved. Observations during solubility measurements (Table II) also support these cation effects. Li_2O appeared to be stable in both $LiNO_3$ and KNO_3 while Na_2O was stable in $LiNO_3$ but reacts in the KNO_3 melt.

Technical Notes

Testing of Sintered $LiAlO_2$ Structures in Molten Carbonate Fuel Cells

J. W. Sim,* R. N. Singh, and K. Kinoshita[1]

Argonne National Laboratory, Argonne, Illinois 60439

Molten carbonate fuel cells are under development for use in generating electricity for utility networks (1). The operating cycle of such cells will inevitably require that they be thermally cycled from the operating temperature (650°C) to ambient temperature. The electrolyte component of the cell must withstand the thermal cycling without developing large cracks, which would permit cross-mixing of the fuel and oxidant and lead to decreased operating efficiency. This note describes work on electrolyte structures containing sintered $LiAlO_2$; these structures resist cracking during thermal cycling and prevent cross-mixing of reactant gases.

Porous sintered structures of MgO infused with molten alkali carbonates were previously used by many investigators (2-6) as the electrolyte component in experimental fuel cells. Use of such structures was discontinued because the low porosities and coarse pores of the sintered bodies gave rise to high cell resistance and poor retention of the molten carbonates. Paste electrolytes formed by hot-pressing finely divided MgO powder and alkali carbonates were then used to overcome the problems associated with sintered MgO structures. The use of MgO in paste structures was subsequently abandoned in favor of $LiAlO_2$ because MgO proved to be soluble in the carbonate melt. In this study, electrolyte structures were fabricated by sintering $LiAlO_2$ powders and impregnating the resultant porous bodies with molten carbonates. One structure of this type was tested in a cell and sustained five thermal cycles with no cross-mixing of reactant gases. The high porosities (64%) and low mean pore size (0.1 μm) obtained with some sintered $LiAlO_2$ bodies suggest that the problems associated with sintered MgO structures can be minimized by using sintered $LiAlO_2$ structures instead.

The $LiAlO_2$ powders used to fabricate the sintered structures were prepared by heating mixtures of Li_2CO_3 and Al_2O_3, first at 600°C for 66-82 hr to form α-$LiAlO_2$, then at 900°C for 16-20 hr to convert the α-$LiAlO_2$ to γ-$LiAlO_2$. Porous bodies of γ-$LiAlO_2$ were formed by pressing the powders at 6895 kPa and firing the compacted powders at 1000°-1200°C for 0.5-4 hr. A screen (20 mesh) of Kanthal[2] wire (Type Al, 0.13 mm diam) was incorporated into some of the structures at midplane. A typical pore-size distribution

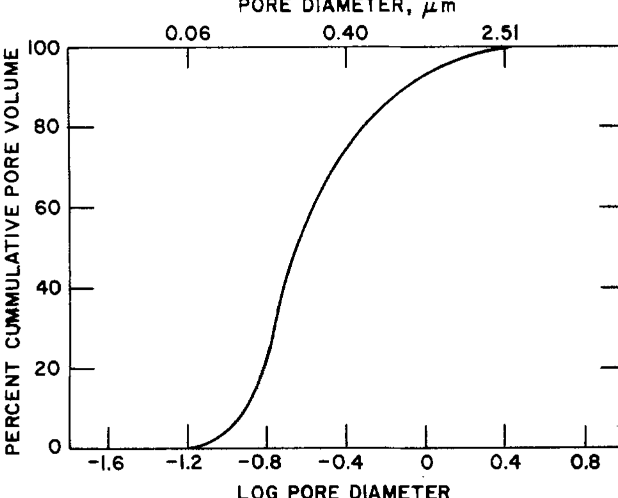

Fig. 1. Pore size distribution of sintered $LiAlO_2$

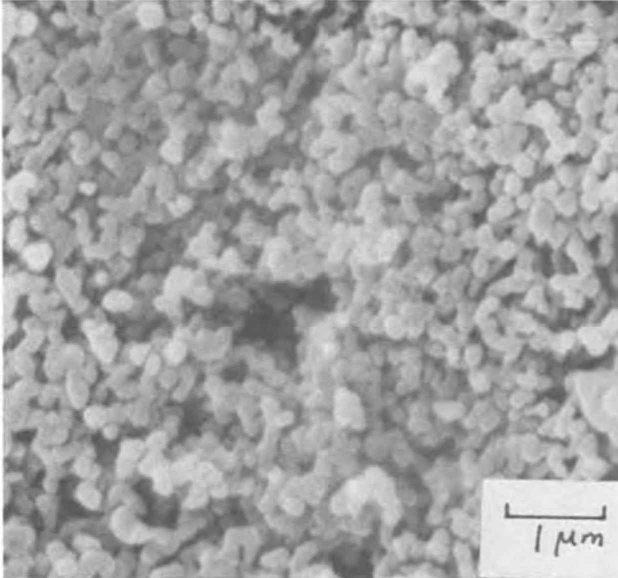

Fig. 2. Microstructure of porous sintered $LiAlO_2$

(determined by mercury porosimetry) for a structure prepared by this method is shown in Fig. 1, and a typical microstructure is shown in Fig. 2. The porosities of the structures tested in cells ranged from 52 to 57%, but porosities up to 64% were obtained in some specimens which were too small for cell testing. Impregnation by the carbonates was accomplished by evacuating the porous structures, and then dipping them into the molten carbonate eutectic [62 mole percent (m/o) Li_2CO_3-38 m/o K_2CO_3]. The entire fabrication process is described in more detail elsewhere (7).

The impregnated structures (nominally 70 × 70 × 1.8 mm) were examined for defects by x-ray radiography before cell testing. The cell hardware and reactant gases used are described elsewhere (8). Cross-leakage of reactant gases through the electrolyte structures was monitored by measuring the amount of nitrogen in the anode exhaust while varying the differential pressure between the cathode and the anode. Because the cathode gas contained ~57 volume percent nitrogen while the anode gas was pure helium during the cross-leakage measurement, any increase in nitrogen in the anode exhaust with increasing differential pressure was taken as an indication of cross-leakage. When the level of nitrogen did not increase with differential pressure, the nitrogen that was detected was caused by diffusion of air through imperfections in the "wet-seal" (8) formed between the anode housing and the electrolyte structure. This was verified by maintaining a constant differential pressure between the cathode and the anode while increasing the anode pressure; the level of nitrogen decreased with increasing anode pressure. Each thermal cycle consisted of cooling the cell from 650° to 25°C at a rate of ~3°C/min and reheating to 650°C at the same approximate rate.

Three structures were tested: two were reinforced with a Kanthal screen and one was not reinforced. One of the reinforced structures, which had no detectable flaws under radiographic examination, underwent five thermal cycles. After the second thermal cycle, 0.5% nitrogen was detected in the anode exhaust, with and without 6.9 kPa differential pressure between the cathode and the anode, clearly indicating the absence of cross-leakage. The anode wet-seal efficiency during these measurements was 99%, which is consistent with the low level of nitrogen detected. After the third and subsequent thermal cycles, the anode wet-seal efficiency increased to 100%, and the nitrogen levels, with and without 6.9 kPa differential pressure, were less than 0.03%. Thus, no cross-leakage was detected after five thermal cycles, when the cell was voluntarily terminated to inspect the cell components.

The second reinforced structure, which contained two small cracks (~0.01 mm wide) prior to cell assembly, was tested to determine whether such small cracks would permit cross-leakage. Two thermal cycles were performed before the cell was terminated, due to obstruction of the anode inlet tube. The level of nitrogen in the anode exhaust after the first thermal cycle increased from 1.2 to 2.7% when the differential pressure between the cathode and the anode was increased from 0 to 2.5 kPa, clearly indicating cross-leakage. The anode wet-seal efficiency was 96%. Similar levels of nitrogen (1.4 and 2.7% at 0 and 2.5 kPa, respectively) were detected after the second thermal cycle, indicating that the amount of cross-leakage was essentially unaffected by the second cycle. Thus, cross-leakage was detected with the second reinforced structure, possibly due to the small cracks observed under radiographic inspection prior to cell assembly.

The nonreinforced structure, which contained four larger cracks (~0.03-0.06 mm wide) before cell assembly, showed cross-leakage upon startup. At 0 and 2.0 kPa differential pressure, the nitrogen level was 0.3 and 1.4%, respectively, and the wet-seal efficiency was 99%. After two thermal cycles, however, severe failure of the structure occurred, as indicated by a drop in open-circuit voltage to less than 1V (1.096V theoretical). Examination of the sintered structure after cell testing indicated that the failure was caused by enlargement of one of the cracks present before testing.

In summary, this study demonstrated one of the advantages of using a sintered $LiAlO_2$ structure impregnated with carbonates as an electrolyte component in fuel cells. When the structure contained no cracks prior to cell assembly, cross-leakage of reactant gases through the structure was not detected, even at a differential pressure of 6.9 kPa and after five thermal cycles. When cracks were present in the structures before testing began, cross-leakage occurred during cell operation. Additional testing is necessary to fully demonstrate the feasibility of utilizing sintered $LiAlO_2$ structures in molten carbonate fuel cells, however.

Spectroelectrochemistry in Melts: Applications to Molten Chloroaluminates

G. Mamantov and V. E. Norvell

Department of Chemistry, The University of Tennessee, Knoxville, Tennessee 37916

and L. Klatt

Oak Ridge National Laboratory, Analytical Chemistry Division, Oak Ridge, Tennessee 37830

The use of spectroelectrochemistry as a tool for studying redox chemistry in solutions has developed rapidly over the last several years (1). This technique yields simultaneous spectral and electrochemical information useful in the elucidation of mechanisms of redox reactions. By using appropriate experimental designs, short-lived intermediate species, which may be undetectable electrochemically, can be studied.

The transmission mode spectroelectrochemical experiment involves the use of an optically transparent electrode (OTE), *i.e.*, an electrode which is transparent in the spectral region of interest. Radiation of the desired wavelengths is passed through the solution and the OTE where a portion is absorbed by the solute species. The attenuated radiation is then measured to give a spectrum. Spectroelectrochemistry most commonly involves the u.v.-visible-*IR* spectral regions, but it has been applied to ESR, NMR, and mass spectrometry as well (1).

We are currently developing u.v.-visible spectroelectrochemical techniques for studying redox systems in molten chloroaluminates (mixtures of $AlCl_3$ and alkali halides). Solute chemistry in these melts is quite dependent on the melt acidity (2-4). The acid-base properties of the chloroaluminate melts near the 1:1 $AlCl_3$-NaCl mole ratio can be described by the equilibrium (5-9)

$$2AlCl_4^- = Al_2Cl_7^- + Cl^-$$

$AlCl_4^-$ is the predominant anion in the equimolar $AlCl_3$-NaCl melt. As the acidity is increased, $Al_2Cl_7^-$ becomes more abundant (5-9).

To date we have examined by spectroelectrochemistry the reduction of niobium (V) and the oxidation of sulfur in chloroaluminate melts. The use of OTE's to study species in melts spectroelectrochemically has not been reported previously.

Experimental

A block diagram of the spectrometer/data acquisition system used to carry out spectroelectrochemical experiments is shown in Fig. 1. The spectrometer is a silicon-vidicon based rapid-scan spectrometer (RSS) which is controlled by the PDP-8/I minicomputer. To obtain an absorption spectrum of a sample, white light is passed through the sample and into a polychromator where it is dispersed by a grating. A 400 nm wide segment of this spectrum is directed across the face of the vidicon detector, where it is read as light intensity *vs.* wavelength by an electron beam. The sweep frequency of this beam can be adjusted so that spectra may be acquired at time intervals varying from 50 msec to 5 sec. Since the spectrometer operates in a single-beam mode, a 100% transmission spectrum (with no sample in the beam) is also acquired and the absorbance spectrum is calculated using the computer. Spectra are stored either on disk or cassette tape. An absorption spectrum can be viewed either on a CRT display, or displayed on an X-Y recorder. A potentiostat is also interfaced to the system; this makes it possible to synchronize the start of spectral data acquisition with the initiation of the electrochemical experiment as well as to simultaneously acquire and store both spectral and electrochemical data. A more detailed description of the spectrometer and the computer interface system is available (10).

A typical cell used to carry out molten salt spectroelectrochemical experiments is illustrated in Fig. 2. The optically transparent electrode consists of a piece of reticulated vitreous carbon (11) (RVC-4, 80 or 100 pores per inch porosity, the Fluorocarbon Company, Anaheim, California), a tungsten grid (Buckbee Mears Company, St. Paul, Minnesota), or a piece of 80 mesh platinum screen. The electrical contact to the tungsten

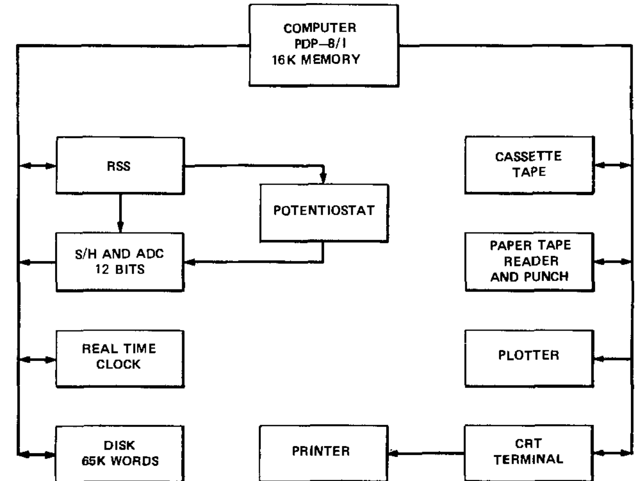

Fig. 1. Block diagram of the system used for spectroelectrochemical experiments.

Key words: spectroelectrochemistry, chloroaluminate melts, sulfur, niobium, molten salt electrochemistry.

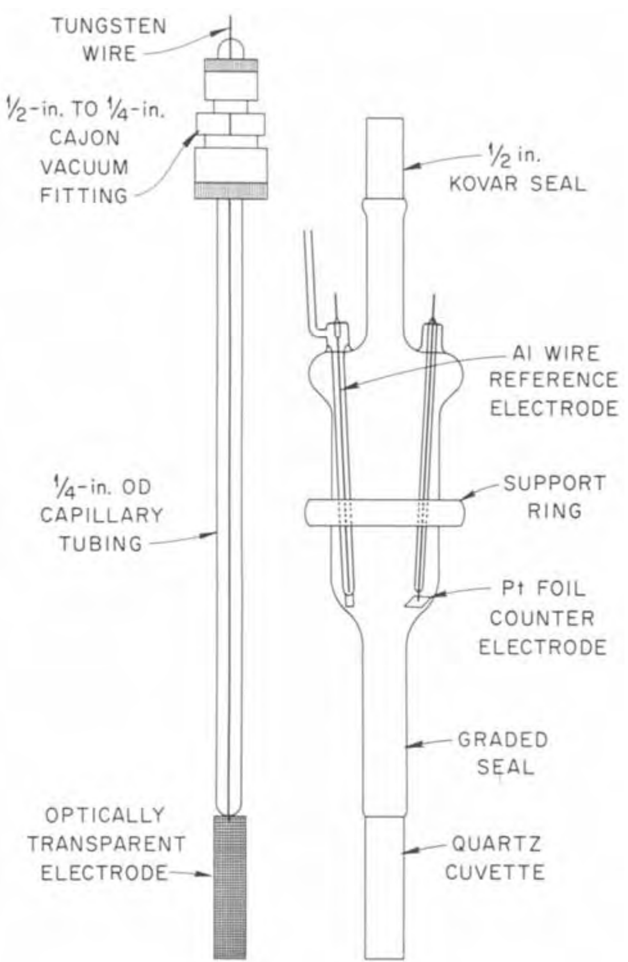

Fig. 2. Typical spectroelectrochemical cell used in the molten salt studies. The reference electrode is isolated from the bulk melt by a porous ceramic frit.

or platinum electrodes is made by spot welding to a platinum or tungsten wire which was previously sealed into ¼ in. OD capillary tubing. Electrical contact to the reticulated vitreous carbon electrode is accomplished by inserting a platinum wire approximately 1 cm into the top of the electrode and cementing it in place with carbon cement (UCAR C-34, Union Carbide Corporation, New York). The cement connection is carbonized by heating to approximately 900°C under vacuum. The platinum wire is then spot welded to a tungsten wire sealed in capillary tubing as described above. The OTE is inserted into the quartz cuvette, the pathlength of which ranges from 0.25 mm (for platinum or tungsten OTE's) to 2.00 mm (for reticulated vitreous carbon OTE's). The completed OTE assembly is held in place by a Cajon vacuum fitting. The counterelectrode is a platinum foil electrode and the reference electrode is an aluminum wire in a separate fritted compartment.

Other electrodes, not shown for clarity, include a platinum or tungsten wire working electrode for cyclic voltammetry, and an extra platinum foil electrode. The melt is added via a filling tube (not shown) in the top of the cell which is then sealed under vacuum. The cell is mounted in a suspension assembly by means of the support ring, and this assembly is then lowered into an optical furnace. The furnace consists of a glass tube wrapped with a Nichrome heating element, and contains two quartz windows through which spectra are taken. The furnace temperature is controlled by using a variable voltage transformer. A tungsten lamp and a xenon arc lamp serve as light sources.

Spectroelectrochemical Study of the Reduction of Niobium (V)

The redox chemistry of transition metals in Groups IVB-VIB in chloroaluminate melts is unusual because of the tendency to form metal clusters in which the metal exists in an unusually low oxidation state (2, 4, 12-14). The electrochemical reduction of Nb(V) in both acidic [mole percent (m/o) $AlCl_3 > 50$] and basic (m/o $AlCl_3 < 50$) chloroaluminates has been previously reported (4). Potentiometric and spectroscopic studies of Nb(V) in $AlCl_3$-KCl melts have also been performed (15). In basic melts the first step of the reduction of the bright-yellow Nb(V) results in the formation of purple Nb(IV). The spectroelectrochemistry of this reduction was studied at a Pt screen OTE in an NaCl-saturated (basic) melt at 225°C. Figure 3 illustrates the spectra obtained during the course of the reduction. At $t = 0$ sec, an absorption band at 300 nm due to Nb(V) is observed. Following a potential step to the diffusion plateau of the first reduction wave, two new absorption bands appear at 275 and ~350 nm. Previous spectra of Nb(IV) obtained in this melt (14), in solid phase (16), and in another solvent (17) show bands near 285 and 325 nm, plus other lower wavelength bands. The reported band positions vary by as much as 10-15 nm. Figure 4 shows a thin-layer coulogram of this reduction calculated from chronoamperometric data obtained simultaneously with spectral data. The charge value obtained from this curve yields an n value of 0.99, thus confirming a simple electrochemical reduction.

In acidic melts, the reduction of Nb(V) proceeds through an ECE mechanism to produce an Nb(III) species (4) as shown below

$$\mathrm{Nb(V)} + e \rightleftharpoons \mathrm{Nb(IV)}$$
$$2\mathrm{Nb(IV)} \rightleftharpoons \mathrm{Nb_2}^{8+}$$

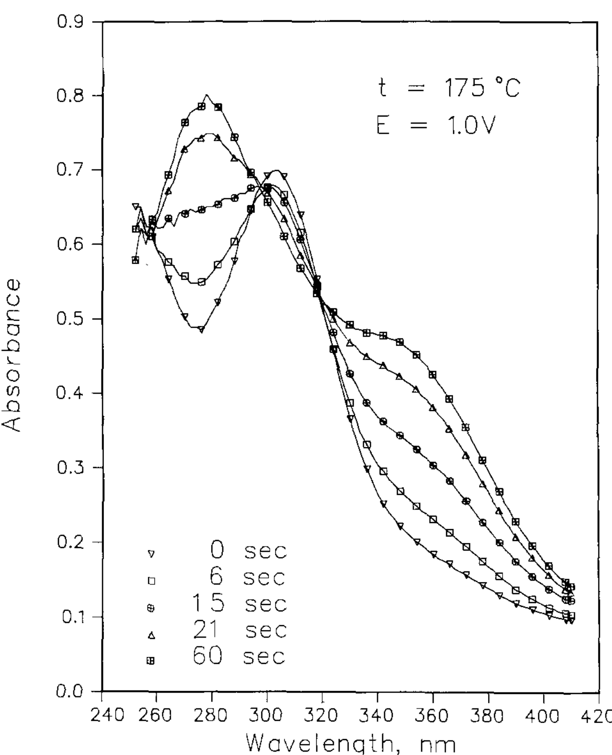

Fig. 3. Spectra obtained during the reduction of Nb(V) in the NaCl-saturated chloroaluminate melt. Potential stepped from 1.5V to 1.0V vs. the Al(III)/Al reference electrode in the NaCl-saturated melt. OTE: Pt screen; pathlength: 0.25 mm; conc. Nb(V): 0.0015M.

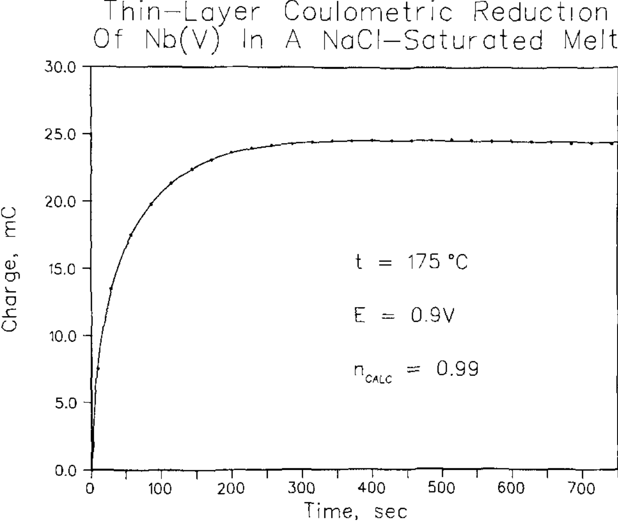

Fig. 4. Charge vs. time plot for the thin-layer coulometric reduction of Nb(V) in the NaCl-saturated chloroaluminate melt. Potential stepped from 1.5 to 0.9V vs. the Al(III)/Al reference electrode in the NaCl-saturated melt. OTE: Pt screen.

This reduction was studied spectroelectrochemically in an acidic melt ($AlCl_3$-NaCl 63-37 m/o) at 225°C, and the resulting spectra are shown in Fig. 5. The Nb(V) band at 300 nm disappears as the reduction is carried out, and no new bands are observed. The slight increase in absorbance seen at the longer wavelengths is probably due to the formation of a precipitate containing Nb(III) (14). Because this precipitate apparently was deposited on the screen OTE, it could be reoxidized completely to Nb(V), as indicated by the reappearance of the band at 300 nm. Thin-layer coulometry carried out simultaneously with spectral acquisition gave an n value of 2.2. Although this value deviates from the expected value of 2.0, it should be considered as a preliminary result because an exhaustive coulometric study of this system has not been undertaken.

Spectroelectrochemical Study of Sulfur Oxidation

The electrochemistry of sulfur in molten chloroaluminates is of considerable importance to the development of a molten salt battery using a sodium anode and positive oxidation states of sulfur as the cathode (18, 19); it has been investigated in both basic and acidic melts (20-22). Because sulfur can be oxidized to higher oxidation states in acidic melts, its chemistry in these melts is of greater importance to the battery work. In acidic $AlCl_3$-NaCl melts sulfur is oxidized in three steps, the final product being S(IV) as indicated by voltammetry and controlled-potential coulometry (22). Both Raman (23) and potentiometric (24, 25) studies have indicated that S(IV) is present as SCl_3^+.

We are using spectroelectrochemistry to study further the mechanism of the oxidation of sulfur in acidic chloroaluminates. By oxidizing elemental sulfur in the melt to S(IV), at least five intermediate oxidation states can be produced (24, 25). Several of these species have characteristic absorption maxima which can be used to ascertain the species present as a function of the potential applied to the OTE.

Elemental sulfur was dissolved in an acidic chloroaluminate melt ($AlCl_3$-NaCl 63-37 m/o); this solution was studied spectroelectrochemically at platinum and carbon OTE's at 225°C. Thin-layer coulometry was carried out on the first oxidation wave by holding the potential of a Pt OTE at +1.65V. N values ranging from 0.14 to 0.16 were obtained. These results agree with those obtained through exhaustive bulk coulometry (22). An n value of 0.125 would correspond to the formation of S_{16}^{2+} (or S_8^+), while an n value of 0.25 would indicate formation of S_8^{2+}. The intermediate value suggests that a mixture of these species is formed. The spectra shown in Fig. 6, obtained at a

Fig. 5. Spectra obtained during the reduction of Nb(V) in $AlCl_3$-NaCl (63-37 m/o) melt. Potential stepped from 1.5 to 0.9V vs. the Al(III)/Al reference electrode in the 63-37 melt. OTE: Pt screen; pathlength: 0.25 mm; Conc. Nb(V): 0.0036M.

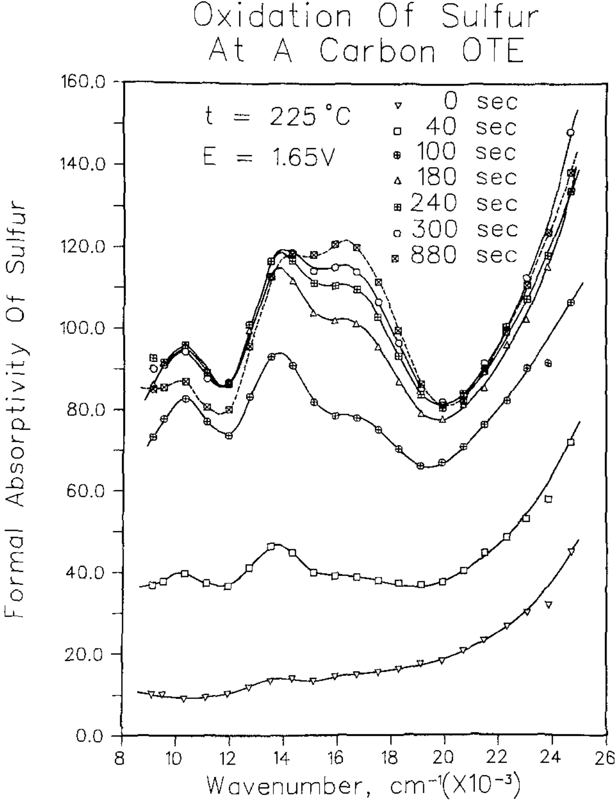

Fig. 6. Spectra obtained during the oxidation of sulfur at a glassy carbon OTE in the $AlCl_3$-NaCl (63-37 m/o) melt. Potential stepped from 1.3 to 1.65V vs. the Al(III)/Al reference electrode in the 63-37 melt. Conc. S: 0.013M.

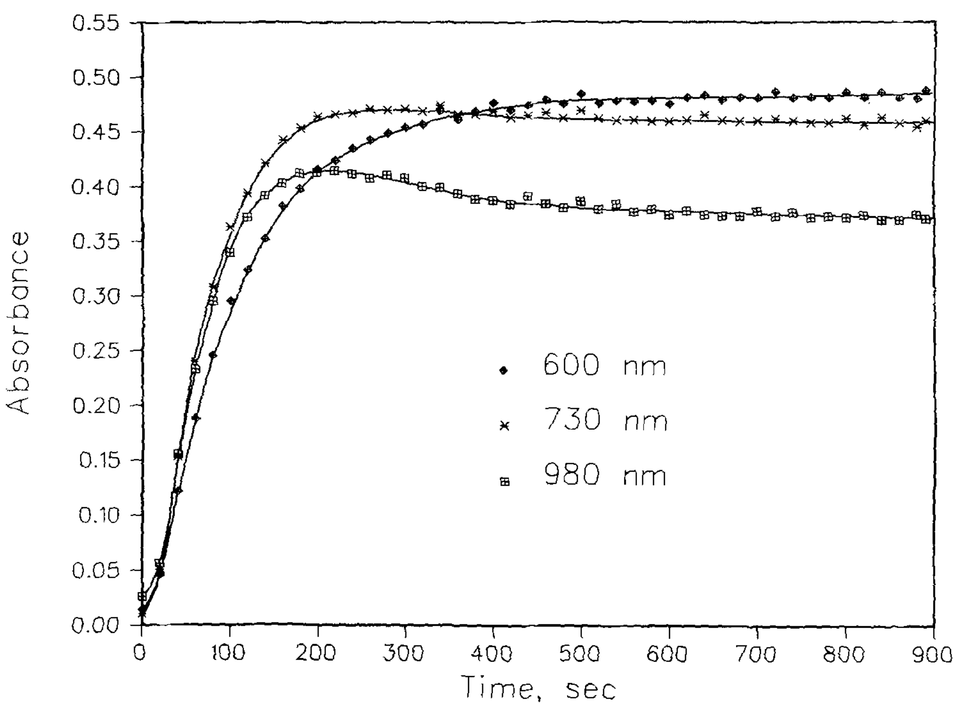

Fig. 7. Absorbance vs. time plots for the three absorbance bands shown in Fig. 6. Pathlength: 2.0 mm.

carbon OTE, substantiate this supposition. As the oxidation takes place, three absorption bands appear approximately simultaneously at 16,600 cm^{-1} (600 nm), 13,700 cm^{-1} (730 nm), and 10,200 cm^{-1} (980 nm). The latter two bands achieve a maximum absorbance after about 4 min and begin to decrease as the first band continues to increase. This can be seen clearly from the absorbance-time profiles illustrated in Fig. 7. According to previously published work (24, 25), it is reasonable to attribute the 600 nm band to S_8^{2+} and the 730 and 980 nm bands to S_{16}^{2+}. This first oxidation step then produces a mixture of S_{16}^{2+} (or S_8^{+}) and S_8^{2+}. Marassi *et al.* (22) have proposed mechanisms involving chemical reactions which could account for these results.

The spectra shown in Fig. 8 were obtained by stepping the potential of the carbon OTE from 1.65V (plateau of the first wave) to 1.85V (just past the plateau of the second wave). The band at 13,700 cm^{-1}, due to S_{16}^{2+} (or S_8^{+}) immediately vanishes while the band at 16,600 cm^{-1} (S_8^{2+}) initially increases. This band then slowly disappears as S_8^{2+} is oxidized to S(I). In a similar experiment carried out at a Pt screen OTE, but recording spectral data at shorter wavelengths, bands at *ca.* 26,300 cm^{-1} (380 nm) and $\sim$31,000 cm^{-1} (323 nm) appeared as the oxidation proceeded. At least one and perhaps both of these bands can be attributed to the formation of S(I) (as S_2^{2+}) (25). The third sulfur oxidation wave is not very interesting for spectroelectrochemical study because the S(IV) product does not exhibit any absorption in the visible region (25).

Conclusion

We have demonstrated that spectroelectrochemistry can be carried out successfully in melts using optically transparent electrodes. The correlation of the spectral data with the electrochemical results has proved very helpful in determining what species are formed during the reduction or oxidation, thereby yielding insight into the mechanisms of the electrochemical processes in melts.

ABSTRACT

The oxidation of a two-phase iron-copper alloy has been studied as an example of the behavior of multiphase systems with simple compositions of the component single phases. The alloy oxidizes more slowly than either of the pure metals, particularly iron, and the scale contains both components, copper being particularly accumulated close to the scale-gas interface. A deep region of internal oxidation is also present, where the iron-rich particles have been converted into FeO. Possible reasons for the observed reduction of the oxidation rate in comparison with pure iron are examined: by means of an approximate calculation based on the theory of the growth of multilayer scales it is concluded that a major fact is the thermodynamic destabilization of the fast growing wustite phase, due to the low iron activity at the alloy-scale interface. No particular effect of growth stresses, due to the anticipated differences in oxidation rate of the component phases, has been observed. Instead, in agreement with the observation that the scale composition is rather uniform laterally and shows the largest changes perpendicularly to the alloy surface, the two-phase nature of the alloy does not seem to exert a strong influence on the overall oxidation behavior.

During the high temperature oxidation of alloys the scales that form often contain a number of different phases, each of which may contain more than one alloy component. Thus, the ratio of the metals in the scale is different from their ratio in the alloy because the various components have different affinities for oxygen, and the rate of transport in the scale is different for each cation and in each phase. The composition of the scale may also vary with position due to these differing diffusivities. Some success has been achieved in attempts to correlate the theories of alloy oxidation kinetics with diffusional, structural, and compositional parameters of the metal oxides in systems in which a solid solution scale is formed (1-4). This paper continues that theme in attempting to analyze the behavior of the Fe-Cu alloys where the oxides of the constituent metals are virtually immiscible, and clearly the overall oxidation rate will depend heavily on the distribution of the various oxide phases in the scale. In addition, Fe and Cu are relatively immiscible in the metallic phase and large compositional changes in the alloy due to any preferential oxidation are therefore precluded even though there are considerable differences in stabilities between iron and copper oxides. Thus, some internal oxidation is anticipated.

There are also substantial differences in oxidation rate of two pure metals and, hence, presumably between the two constituent phases in the alloy. Originally, it was anticipated that this could give rise to complex growth stress development in the growing scale: this does not seem to be the case, as will be seen later.

Experimental

The alloy used in the present study was prepared by melting 99.998% Fe and 99.9996% Cu in a high frequency induction furnace and casting into a water-cooled mold. Analysis gave an average composition of 44.1 weight percent (w/o) Cu. The ingot was mechanically worked into a cylindrical shape and samples in the form of disks about 0.8 mm thick were cut from it. The disks were subsequently polished on SiC papers and were then annealed for 24 hr at 850°C in vacuo ($\simeq 10^{-5}$ Torr). Immediately prior to oxidation they were lightly re-abraded on 6/0 emery paper to remove the tarnish film produced during the annealing process.

Oxidation tests were performed in pure, dry oxygen at 760 Torr pressure under static conditions in a Mettler thermoanalyzer; weight gain was continuously recorded. At the end of the experiments the samples were cooled down in vacuo in the balance chamber; no further changes in weight were detected.

Cross sections of oxidized specimens were examined by standard methods of optical and electron microscopy. Concentration profiles were measured by an EDAX attachment to a JEOL SEM. Phases were identified by x-ray diffraction.

Results

Alloy microstructure.—Figure 1 shows the microstructure of the alloy after annealing: essentially the

Key words: two-phase alloy, iron-copper, oxidation.

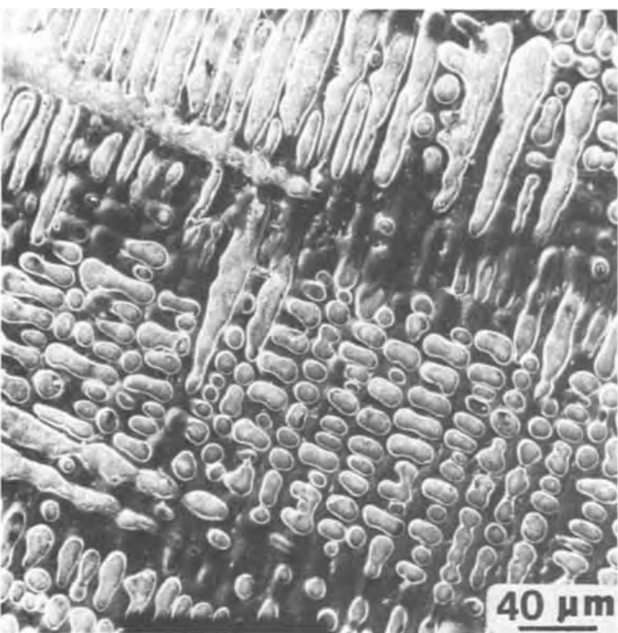

Fig. 1. Microstructure of the alloy

as-cast dendritic structure is maintained. The dendrites are the iron-rich phase which according to the phase diagram contains 5.81 w/o Cu; the copper-rich matrix contains 2.06 w/o Fe at 1000°C (5). The average size of the iron-rich phase particles is around 20-30 μm.

Kinetics.—Plots of squared weight gains per unit area *vs.* time are reported in Fig. 2 for the different temperatures (one individual curve for each T). They show that oxidation of this alloy follows, to a reasonable approximation, a parabolic rate law, especially if the complex nature of the alloy and the scale is considered. This is particularly true for relatively short reaction times (6 hr), with a scatter of K_p values of ±10% at 800°C and ±2% at the other temperatures. For longer times increasing deviations are observed,

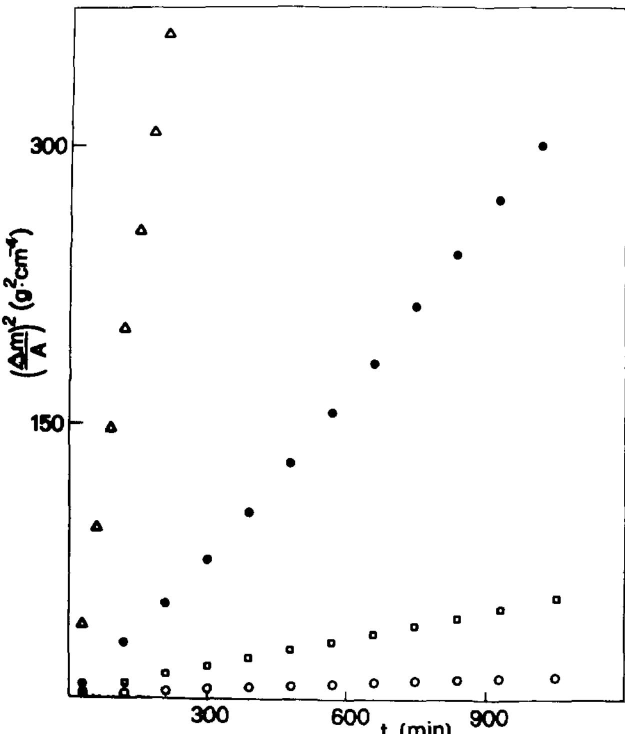

Fig. 2. Parabolic plot of the weight gain as a function of time: ○ 700°C, □ 800°C, ● 900°C, △ 1000°C.

Table I.

T (°C)	Parabolic rate constants (g^2 cm^{-4} sec^{-1}) Cu	Fe (8)	Alloy	$k_{Cu}/k_{all.}$	$k_{Fe}/k_{all.}$
700	1.72×10^{-9} (6)	6.0×10^{-9}	2.61×10^{-10}	6.6	23
800	5.53×10^{-9} (6)	5.7×10^{-8}	8.61×10^{-10}	6.4	66
900	2.80×10^{-8} (7)	2.5×10^{-7}	4.73×10^{-9}	5.9	53
1000	8.1×10^{-8} (7)	1.1×10^{-6}	$\sim 3.11 \times 10^{-8}$	2.6	35

the rate constant up to 18 hr showing on the average an increase with time at 900° and 1000°C and a decrease at 700°C; there is no definite trend at 800°C. Average values of the parabolic rate constant calculated for 6 hr oxidation are reported in Table I (g^2 cm^{-4} sec^{-1}).

A comparison of the alloy oxidation kinetic constants with those of the pure base metals (Table I) shows an improved resistance of the alloy to oxidation; the alloy oxidizes marginally more slowly than pure copper, but substantially more slowly than iron. The ratio between alloy and pure copper parabolic rate constants remains almost constant up to 900°C and then decreases sharply, whereas for a similar ratio between the alloy and iron a maximum is observed at 800°C.

Identification of scale products.—X-ray diffraction analysis of the scale still adherent to the alloy reveals the presence of CuO and two iron oxides (FeO and Fe_3O_4): sometimes also other lines are observed which can be attributed to a mixed oxide $CuFeO_2$ (delafossite). Although this compound is well known (9) and its x-ray diffraction pattern established (10), more recent studies (11) throw some doubts on its existence, a conclusion which is probably related to the instability of this compound under high oxygen pressures. In the scale examined in the present work, the mixed oxide is always present under an outer CuO layer and therefore can be stabilized by the relatively low oxygen potential at that location. Point microanalysis always gives a copper/iron molar ratio very close to that expected for this phase.

The distribution of the different phases in the scale can be found by a combined use of different techniques, such as observations under the optical microscope, the electron microscope in the backscattered

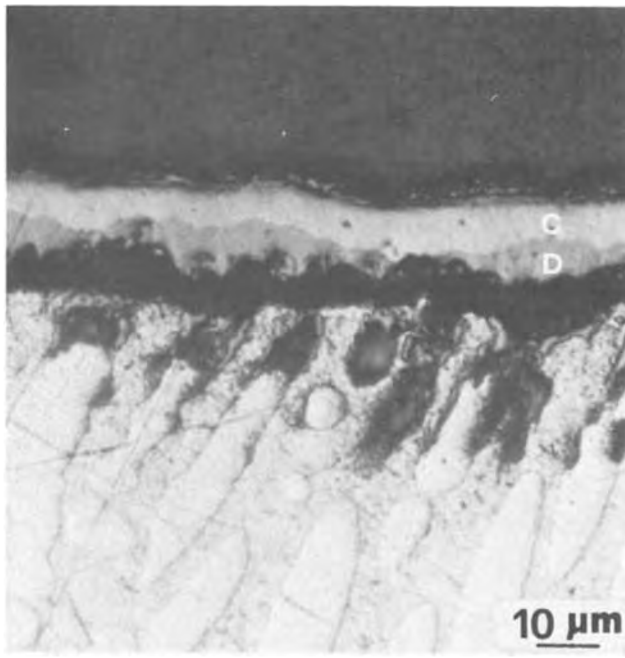

Fig. 3. Cross section of the scale formed on the alloy oxidized for 18 hr at 700°C, optical micrograph. C: Fe_3O_4; D: FeO.

electron-image mode which is sensitive to composition (BEI), and by the use of x-ray maps. The two iron oxides are clearly differentiated under optical observation, while copper oxide and the mixed oxide are very similar in appearance and can be distinguished from iron oxides only under very favorable conditions. BEI micrographs, on the other hand, do not differentiate between the iron oxides, but clearly show the differences between copper oxide (light gray), mixed oxide (intermediate gray), and the iron oxides (dark gray): this is confirmed by the corresponding x-ray maps and by point microanalysis performed in the various phases.

Scale microstructure and composition.—700°C.—The essential features of the scale formed at this temperature are independent of exposure time and are shown in Fig. 3 and 4. The outermost scale layer is primarily CuO; in many cases it becomes detached from the remainder of the scale, and also its thickness varies irregularly around the sample section. Quantitatively the Fe content is difficult to measure, because of the limited thickness of the layers; it appears to be quite low. Beneath this outer layer is a layer containing a light intermediate zone (Fe_3O_4) and an inner darker zone (FeO), although these differences are not detected in the BEI image of Fig. 4 as indicated earlier. In a

c. FeKα image

Fig. 4. Cross section of the scale formed on the alloy oxidized for 18 hr at 700°C.

few locations the magnetite phase appears to extend right up to the alloy/scale interface; normally it is separated from the alloy by an intervening FeO layer (Fig. 3). Point analysis of the Fe_3O_4 layer indicates a low solubility of Cu, 0.5 w/o Cu in Fe_3O_4.

The interface between the scale and the alloy is very undulating due to the preferential oxidation of the Fe-rich islands in the alloy; the Cu grains remain intact up to the scale/alloy interface and can even be incorporated unoxidized into the scale. The oxidation of the Fe-rich grains in the alloy completely encircles the unoxidized Cu grains, and these can extend up to half-way across the scale before they are converted to oxide.

800°C.—The scales formed at 800°C are similar in many aspects to those formed at 700°C, except for the appearance of an additional phase sometimes between the FeO and Fe_3O_4 layers, but more normally between the outer CuO layer and the underlying Fe_3O_4 phase; Fig. 5 and 6 show typical examples. Microanalysis identifies this phase as the mixed oxide $CuFeO_2$, referred to earlier. It appears as an intermediate shade of gray in the optical micrograph, Fig. 5, and more clearly in the BEI image and x-ray images of Fig. 6.

In the optical micrograph of Fig. 5, in which the various oxides of iron can be distinguished [FeO (dark), Fe_3O_4 (light)], it seems that FeO separates the magnetite layer from the alloy along much of the interface and is also formed within the Fe-rich grains of the alloy. However, where the mixed oxide $CuFeO_2$ forms below the magnetite, then this can extend up to the alloy surface. The numerous voids at and under the alloy/scale interface appear to be a result of scale pull-out during polishing. Finally, the outer CuO layer tends to vary in thickness around the sample section as observed at lower temperatures; generally however it is thicker.

At longer oxidation times, the mixed oxide appears to be largely confined to a region immediately below the outer CuO layer. In addition, FeO is mainly present only in the internally oxidized region and most of the iron in the outer scale is present as magnetite. Otherwise the scale morphology changes little with time.

It was possible to measure the Fe content of the outer CuO layer at this temperature and EPMA gave a value of 8-9 w/o. The solubility of Cu was around 0.75 w/o in the magnetite, but up to 2.5 w/o in the inner FeO layer.

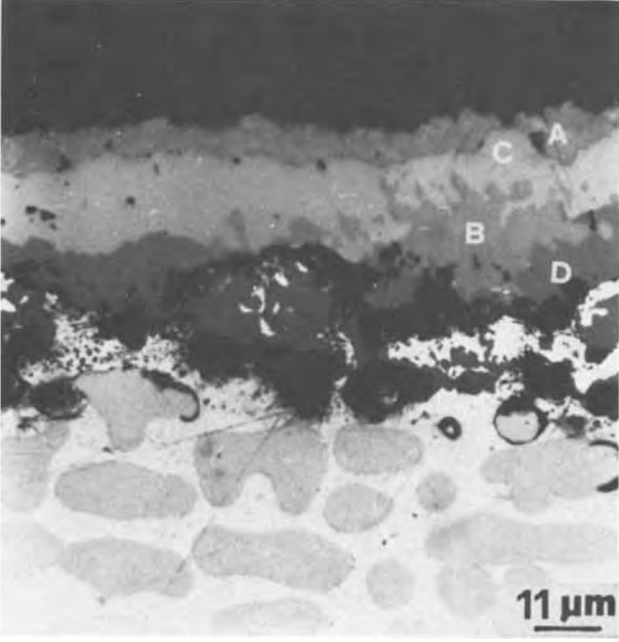

Fig. 5. Cross section of the scale formed on the alloy oxidized for 6 hr at 800°C, optical micrograph. A, CuO; B, $CuFeO_2$; C, Fe_3O_4; D, FeO.

900°C.—Figure 7 shows a typical scale cross section at 900°C enabling the four principal scale layers to be identified: outer CuO, a layer of $CuFeO_2$ or magnetite layer, and an inner wustite layer. In addition, as at the lower temperatures, there is a form of internal oxidation of the Fe islands within the alloy. After longer oxidation times, 18 hr, at this temperature, the outer CuO zone develops considerable porosity, which tends to be elongated in the growth direction and is shown in Fig. 8. The amount of Fe dissolved in this layer is about 7 w/o and the Cu concentration in the inner layers is 3.5 and 1.0 w/o in FeO and Fe_3O_4, respectively.

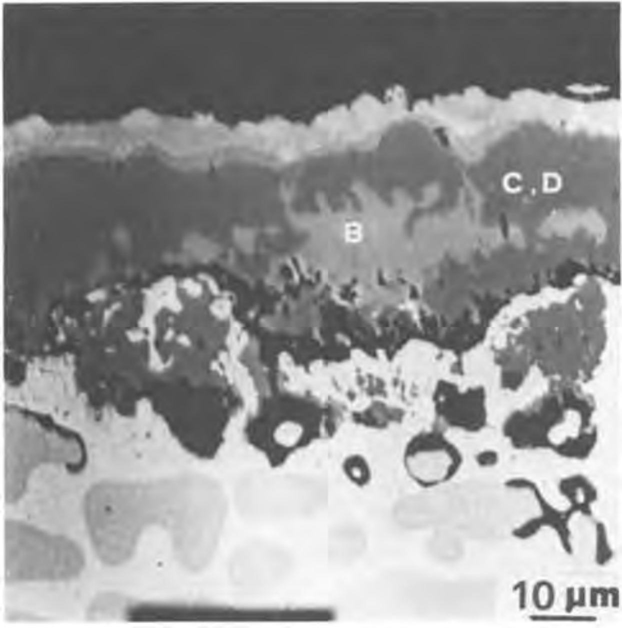
1000°C.—A distinctive feature of the scale present on the alloy at this temperature and not at the lower temperatures is the porosity which has developed in the outer CuO layer. Some of the porosity is clearly accentuated during metallographic preparation, but nevertheless a large portion of it is inherent. The pores are elongated in the growth direction and seem to initiate at the inside of this layer. In most locations the CuO layer is completely detached from the underlying scale. This is illustrated in Fig. 9 and 10. The accompanying x-ray maps also indicate the layer of mixed oxide, $CuFeO_2$, immediately below the outer CuO layer, and also the presence of this phase as elongated precipitates within the inner Fe-rich oxides, mainly FeO. At some positions an intermediate layer of Fe_3O_4 is also observed, formed inside the FeO layer, probably as a consequence of scale cracking, not evident in the micrograph. After 18 hr oxidation the scale structure is rather similar although internal oxidation of the Fe-rich phase of the alloy is very pronounced; Fig. 11 and 12. Surprisingly most of the internal oxide has been lost, presumably during metallographic preparation. Where the oxide does remain near to the alloy/scale interface, it is primarily FeO. Cu solubilities in Fe_3O_4 and FeO at this temperature were 2.5 and 8.0 w/o, respectively; Fe solubility in the CuO was not measurable using EPMA because of the high porosity.

Discussion

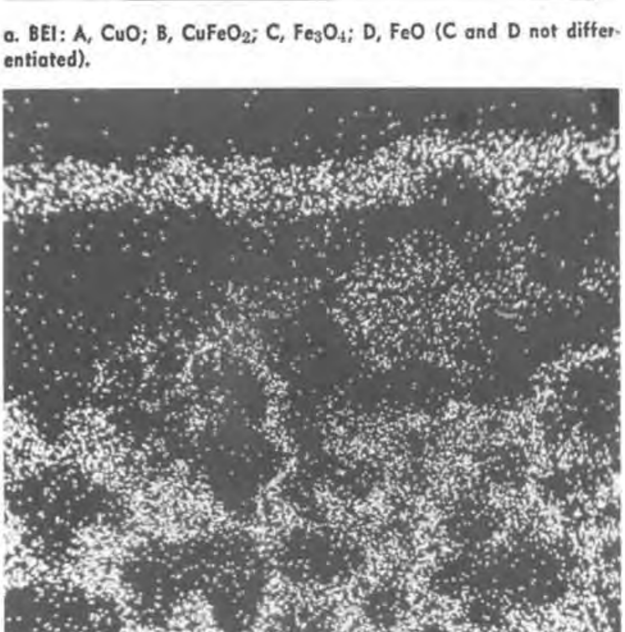
Although the scale structures described in the previous section are rather complex, they essentially consist of an outer layer of CuO, containing a small concentration of dissolved Fe, and inner layers of magnetite and wustite, both containing Cu in solution, whose concentration increases with increasing temperature. In particular the wustite layer, with the exception of samples oxidized at 1000°C, has a smaller relative thickness than in the oxidation of pure iron, where it amounts to about 0.95 of the entire scale from 700° to 1200°C (12). In addition, at the higher temperatures a layer of the compound oxide $CuFeO_2$ forms between the CuO and magnetite layers and as a precipitate within the magnetite. Beneath the scale there is a region of internal oxidation, having a thickness comparable to that of the external scale, and where the Fe-rich dendrites in the alloy have been oxidized to FeO.

The outer layer of CuO presumably formed in the early transient stages of oxidation (13) when on initial exposure of the alloy both alloy components will form their respective oxides. However, because of its higher relative affinity for oxygen, iron is eventually selectively oxidized from the alloy and continuous layers of magnetite and wustite will develop at the alloy/scale interface. In effect, the copper oxide is then cut off from its direct supply of Cu ions from the alloy, although there may be a reduced continuing flux of copper through the scale, since it is soluble in the iron oxides.

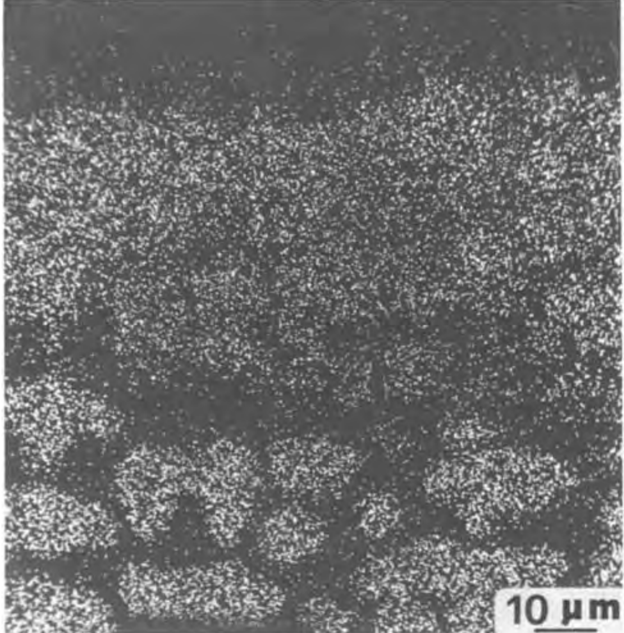
Below the outer CuO region the scale contains principally iron oxides. Magnetite is not stable, however,



a. BEI: A, CuO; B, $CuFeO_2$; C, Fe_3O_4; D, FeO (C and D not differentiated).



b. CuKα image



c. FeKα image

Fig. 6. Cross section of the scale formed on the alloy oxidized for 6 hr at 800°C.

in contact with CuO since the lowest value of the oxygen activity at the inner interface of CuO corresponds to the CuO/Cu_2O equilibrium and amounts of 5.88×10^{-3} at 700°C and to 0.374 at 1000°C, while the highest activity of oxygen at the outer interface of magnetite is much smaller, amounting to 2.85×10^{-6} at 700°C and to 2.62×10^{-3} at 1000°C. Therefore, the two phases must be separated by either Cu_2O or Fe_2O_3 or both. These compounds are never observed, however, either because CuO and magnetite are separated by an intervening layer of the mixed oxide $CuFeO_2$ formed by chemical interaction between copper oxide and iron oxide, as it occurs at high temperatures, or even because the effective thickness of these layers is too small to be detected.

In any case oxygen is supplied to the inner iron oxides from the outer CuO layer either directly or through the intermediate mixed oxide, producing an outward flux of copper in the CuO layer. At high temperatures the corresponding inward flux of vacancies through CuO is not completely incorporated into the underlying mixed oxide and can condense out in a porous region at the interface. Eventually the CuO layer may become completely detached and a dissociative-type mechanism for the supply of oxygen to the inner scale region can take over. An extreme situation of this kind would correspond to the formation of a continuous porous network in the outer layer, with oxygen being supplied directly from the gas phase to the inner scale regions. This seems particularly likely at 1000°C in view of the high porosity in CuO.

At the alloy/scale interface oxygen is supplied by partial dissociation of the scale and dissolves into the alloy. In view of the very large difference between the thermodynamic stability of the oxides of the two metals, iron is preferentially oxidized producing FeO, while copper cannot be oxidized due to the low oxygen potential established there, and the network of copper-rich grains remains relatively intact. As the scale grows and encroaches into the alloy, copper particles

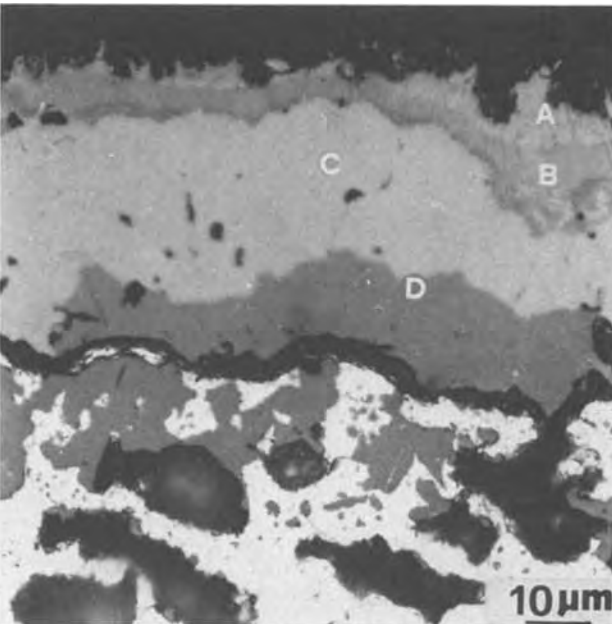


Fig. 7. Cross section of the scale formed on the alloy oxidized for 6 hr at 900°C, optical micrograph. A, CuO; B, $CuFeO_2$; C, Fe_3O_4; D, FeO.

are incorporated into it and are subsequently oxidized when exposed to a sufficiently high oxygen activity. Copper is oxidized in the scale mainly to $CuFeO_2$ which partly dissolves into the surrounding iron oxides and partly remains as isolated particles.

It is appropriate at this point to consider how the features of the scale formed on this alloy, reported above, would affect the overall oxidation rate, which at any temperature is smaller than for either of the pure metals. The reduction in rate in comparison with that of pure Fe is especially significant since the scale consists mainly of the oxides of Fe. Undoubtedly it is due to many concurrent effects in view of the complexity of the structure of the alloy and also of the scale. These are now considered individually.

The absence of an outer hematite layer should not have a great influence, since it grows rather slowly, even on pure iron. The reduction of the relative thickness of the wustite layer could instead have a marked effect, since this oxide has a large defect concentration and a correspondingly high cation diffusivity. The effect of this on the reaction kinetics has been discussed in greater detail in a study of the oxidation of an iron-rich monophase Fe-Cu alloy published elsewhere (14), which has a simpler scale composition, where it is shown that the reaction rate can be strongly decreased in this way. The situation of the two-phase alloy is more complex, however, not only because of the presence of CuO and the mixed oxide in the outer region of the scale, but also because the interface between FeO and Fe_3O_4 regions is often very irregular. Moreover from 700° to 900°C the wustite layer is even discontinuous, since at some positions magnetite reaches the scale interface, while at 1000°C a continuous thick layer of FeO is developed.

A rough estimate of the influence of this aspect of the scale structure on the scaling constant can be obtained by ignoring the presence of FeO and evaluating the growth rate expected in presence of magnetite alone. The rate constant for the direct formation of magnetite on an iron alloy having a metal activity at the alloy/scale interface corresponding to the equilibrium FeO/Fe_3O_4 and an oxygen activity at the outer magnetite interface as required for the equilibrium Fe_3O_4/Fe_2O_3 is one-fourth of the so-called third-kind rate constant for the magnetite growth (15), as shown in the Appendix. The latter has been calculated from the experimental results on the oxidation of iron and has been reported in an earlier paper (16). Unfortunately there was an error in the quoted value and the correct value is given as a function of temperature as (17)

$$k_p(Fe_3O_4) = 2.08 \exp(-40.8/RT)$$

Thus, the required rate constant $k' = k_p/4$ amounts to ($g^2\ cm^{-4}\ sec^{-1}$) 3.517×10^{-10} at 700°C, 2.517×10^{-9} at 800°C, 1.288×10^{-8} at 900°C and 5.097×10^{-8} at 1000°C. These values are somewhat higher than the experimental rate constant for this alloy, in spite of the presence of some FeO, particularly at 1000°C, in the scales. The presence of FeO should imply that the above calculated rate constants represent minimum values, and the other factors are presumably involved. In particular, the oxygen activity at the outer magnetite interface could be lower than that for the Fe_3O_4/Fe_2O_3 equilibrium as assumed above. Indeed, Fe_2O_3 is not observed in the scale. This situation would lead to a decrease of the rate constant for the growth of magnetite and thereby of the overall rate constant.

A contribution to the decrease of the scaling rate can also come from the dissolution of copper in iron oxides. In fact FeO, in spite of the large deviations from stoichiometry and the complex nature of its defects, is essentially a p-type semiconductor, so that the presence of copper, most probably in the form of Cu^+ ions owing to the low oxygen activity, should produce a decrease of the vacancy concentration and hence slow down the diffusion of iron. Actually large additions would be thought necessary for this effect due to the high concentration of native defects in FeO as compared to similar oxides like NiO or CoO (18): observations on the influence of Li_2O on the rate of formation of FeO (19) and on the rate of oxidation of Fe-Cr alloys (20) are in substantial agreement with this prediction, even if the effect is small. In addition, the presence of foreign ions in magnetite is known to produce a strong decrease of the iron mobility (21).

The two-phase alloy oxidizes more slowly even than the monophase iron-rich alloy, since the reduction factor of the parabolic rate constant with respect to iron for the latter system ranges from 4 to 9 according to the temperature (14), so that additional factors are operating to reduce the reaction rate further in this alloy. The main differences between the scale structure of the mono- and two-phase alloys are the absence of the outer layers of CuO and mixed oxide, the greater relative thickness of the FeO layer, except at 1000°C, and the absence of the internal oxidation region in the former system. In addition the copper concentration in the iron oxides is much larger for the two-phase alloy. All these aspects can affect the oxidation rate, but in view of the previous discussion the destabilization of wustite and copper dissolution in iron oxides seem to be the most important factors.

Possible stress effects associated with the development of different oxides growing at different rates on the alloy seem to be absent from this system. In fact, the scale appears compact and of uniform thickness and shows no lateral variations in structure or composition, at least none which can be directly associated with the two-phase structure of the alloy only. The thickness of the wustite layer sometimes shows large variations around the surface of the sample where at some positions it is confined to the internal oxidation region while in others it extends far into the scale. The relative uniformity of the scale structure is possibly related to the small grain size of the alloy, so that Cu-rich and Fe-rich regions in the alloy alternate frequently at the alloy/oxide interface and lateral diffusion is sufficiently rapid to even out these fluctuations: differences in the scale structure are in fact confined mainly in a direction perpendicular to the alloy surface rather than parallel to it.

Conclusions

The results obtained in this study on the oxidation of a two-phase alloy lead to the following conclusions.

1. The alloy oxidizes more slowly than the constituent pure metals, especially, Fe, at all temperatures in the range 700°-1000°C.

2. A number of factors are involved in the reduction in rate but that of particular importance is the partial destabilization of wustite due to a large decrease in the iron activity at the alloy/scale interface.

3. The inner regions of the scale contains mainly iron-rich oxides and the outer scale layer is CuO. This CuO layer is virtually cut off from the alloy after the initial transient stages. Porosity, more pronounced at 1000°C, develops between the outer CuO and Fe_3O_4 layers, as a result of an exchange reaction at that interface and the continued flux of copper through the outer CuO layer. This can lead to complete detachment of the outer layer and a dissociative-type mechanism.

4. Internal oxidation of the iron-rich phase in the alloy is always observed to a thickness comparable with that of the external scale. This also produces a depletion of iron in the surrounding Cu-rich matrix, as evidenced by the destabilization of FeO and the concomitant reduction in the relative thickness of the FeO layer in the scale in comparison with the oxide scales formed on pure Fe.

5. The two-phase nature of the alloy does not seem to have any particular effect on the scale properties. This is presumably related to the rather regular and closely spaced distribution of the two phases in the alloy. Certainly, stress development due to the accommodation within the scale of two phases oxidizing at different rates are not evident.

Acknowledgments

Thanks are due to Mr. M. Piazza for his help in the experimental part of this work.

APPENDIX

The relationship between the rate constant for the direct growth of magnetite on an iron alloy at a surface iron activity corresponding to the equilibrium FeO/Fe_3O_4 and an oxygen activity at the outer surface corresponding to the equilibrium Fe_3O_4/Fe_2O_3 and the rate constant of third kind for magnetite growth (15) is obtained as follows.

The systems to be considered are referred to as A and B and are schematized below

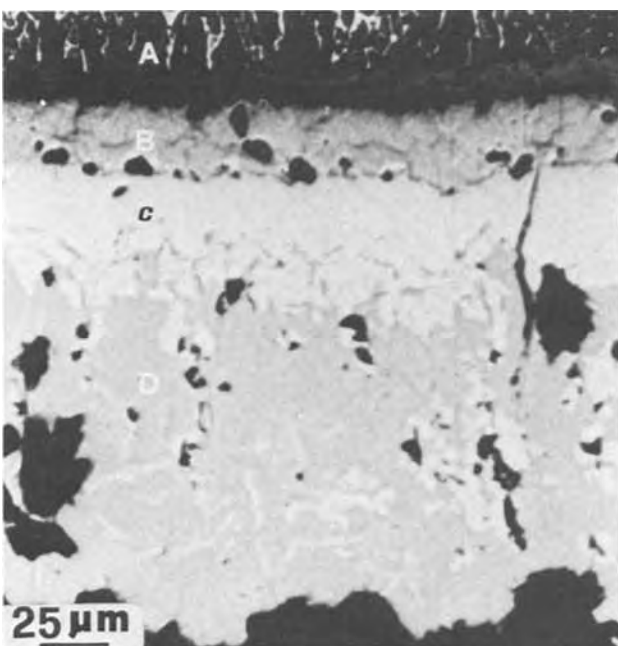

Fig. 11. Cross section of the scale formed on the alloy oxidized for 18 hr at 1000°C, optical micrograph. A, CuO; B, CuFeO$_2$; C, Fe$_3$O$_4$; D, FeO.

(A)		(B)	
O_2		O_2	
	II		II
Fe_3O_4		Fe_3O_4	
	I		I
Alloy		FeO	

The oxygen activity in the gas phase is assumed to correspond to the magnetite/hematite equilibrium in both cases, while the iron activity at the interface I corresponds to the equilibrium FeO/Fe$_3$O$_4$, so that FeO is completely destabilized in system A. If the oxidation rate is controlled by diffusion through the magnetite layer, the flux of iron ions J for both systems is related to the parabolic rate constant k_t (molecules cm^{-1} sec^{-1}) by (22)

$$\frac{J}{3} = \frac{dn}{dt} = \frac{k_t}{x} \qquad \text{[A-1]}$$

where dn is the number of Fe$_3$O$_4$ formula units formed in the time dt per unit area at the interface II by the reaction

$$3Fe + 2\,O_2 = Fe_3O_4 \qquad \text{[A-I]}$$

and x is the instantaneous thickness of the magnetite layer. For an exclusive cation diffusion in an oxide M_aO_b one has (23)

$$k_t = \frac{c_O}{a}\int_{a_O{}^i}^{a_O{}^e} D_M d\ln a_O \qquad \text{[A-2]}$$

The relationship between the weight of oxygen of the magnetite layer per unit area q, the corresponding number of moles n, and the thickness x are

$$q = \frac{4M(O)}{N_A}n = \frac{4dM(O)}{M(Fe_3O_4)}x \qquad \text{[A-3]}$$

(N_A = Avogadro's number, d = oxide density, M(O) = atomic weight of oxygen, M(Fe$_3$O$_4$) = molecular weight of magnetite). Deriving Eq. [A-3] with respect to t and using Eq. [A-3], [A-9], and [A-10] results in, the system A

$$\frac{dq(A)}{dt} = \frac{k(A)}{2q(A)} = \frac{4M(O)}{N_A}\frac{dn(A)}{dt}$$

$$= \frac{4M(O)}{N_A}\frac{k_t}{x(A)} = \frac{16dM^2(O)}{N_AM(Fe_3O_4)}\frac{k_t}{q(A)} \qquad \text{[A-4]}$$

or

$$k(A) = 16\frac{2dM^2(O)}{N_AM(Fe_3O_4)}k_t \qquad \text{[A-5]}$$

On the contrary, deriving Eq. [A-3] with respect to t and using Eq. [A-3], [A-9], and [A-13] results in the system B

$$\frac{dq(B)}{dt} = \frac{k(B)}{2q(B)} = \frac{4M(O)}{N_A}\frac{dn(B)}{dt}$$

$$= 4\frac{4M(O)}{N_A}\frac{k_t}{x(B)} = 4\frac{16dM^2(O)}{N_AM(Fe_3O_4)}\frac{k_t}{q(B)} \qquad \text{[A-6]}$$

or

$$k(B) = 64\frac{2dM^2(O)}{N_AM(Fe_3O_4)}k_t \qquad \text{[A-7]}$$

Comparing Eq. [A-5] and [A-7] gives finally

$$k(A) = k(B)/4 \qquad \text{[A-8]}$$

where D_M is the self-diffusion coefficient of the metal ions in the oxide, c_O the concentration of oxygen in the oxide (ions cm^{-3}), and $a_O{}^i$ and $a_O{}^e$ are the oxygen activities at the metal/scale and scale/gas interfaces, respectively.

If $a_O{}^i$ and $a_O{}^e$ are the same for the two systems, as assumed here, k_t will be the same in both, since D_M depends on a_O in the same way. However, in spite of the equality of k_t, the parabolic rate constants as functions of the weight of oxygen in magnetite per unit area for the two systems, defined by

$$q^2(A) = k(A)t \quad \text{and} \quad q^2(B) = k(B)t \qquad \text{[A-9]}$$

differ. In fact, for the system A Fe$_3$O$_4$ forms only at the interface II with the rate defined by Eq. [A-1] and controlled by the iron flux J in the form

$$\frac{dn(A)}{dt} = \frac{J}{3} = \frac{k_t}{x(A)} \qquad \text{[A-10]}$$

while in the system B Fe$_3$O$_4$ forms at the interface I by the reaction

$$4FeO = Fe_3O_4 + Fe \qquad \text{[A-II]}$$

creating the flux J diffusing through the magnetite layer and oxidized at the interface II according to reaction [A-1]. Reaction [A-II] requires however, that one formula unit of magnetite forms at the interface I for every Fe ion diffusing in magnetite. The rate of formation at the two interfaces are

$$\frac{dn(B)\,(II)}{dt} = \frac{J}{3} = \frac{k_t}{x(B)} \qquad \text{[A-11]}$$

and

$$\frac{dn(B)\,(I)}{dt} = 3\frac{J}{3} = 3\frac{k_t}{x(B)} \qquad \text{[A-12]}$$

and the overall rate of formation of magnetite results

$$\frac{dn(B)}{dt} = \frac{dn(B)\,(I)}{dt} + \frac{dn(B)\,(II)}{dt} = \frac{4}{3}J = 4\frac{k_t}{x(B)} \qquad \text{[A-13]}$$

Reversal of Relative Oxidation Rates of <111> and <100> Oriented Silicon Substrates at Low Oxygen Partial Pressures

S. I. Raider[1] and L. E. Forget

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Crystalline Si wafers oriented in the <100> and <111> planes were oxidized in ambients containing low oxygen partial pressures to examine the role played by oxidant pressure on relative oxidation rates. The grown oxide films were formed at temperatures between 850° and 1050°C and were less than 300Å thick. Substrates with <111> oriented surfaces are generally oxidized more readily than substrates with <100> orientations at the same oxidation temperature and oxidant pressure. However, a reversal in the relative oxidation rates of these crystalline Si substrates was observed at low oxygen partial pressures. This reversal was nearly independent of oxidation temperature and also of oxidant diluent gas. A qualitative model is proposed to account for these results.

Thermal growth of SiO_2 films on Si substrates in an oxygen ambient takes place at an SiO_2-Si interface (1) after oxygen is diffused to the substrate. The oxidation reaction occurs at the substrate and goes to completion in the partially oxidized transition region located between the crystalline substrate and the amorphous SiO_2 film. Oxygen reacts with accessible, nonoxidized Si-Si bonds to form siloxane groups. At a fixed temperature, the Si oxidation rate is altered by changes in the partial pressure of oxygen, p_{O_2} (1-4), in oxide film thickness, and in the crystalline substrate orientation (2, 5, 6).

Si oxidation rates are rate-controlled by the crystalline substrate surface orientation in the thin (<300Å) film thickness region. The oxidation rate within the interfacial reaction zone is dependent upon the oxygen concentration in this region. The oxygen concentration in this zone is directly proportional to the oxygen partial pressure in the oxidizing ambient (1, 7, 8).

The dependence of Si oxidation kinetics upon substrate orientation has been observed in the thin film range at temperatures below, but not at, 1200°C (2-6). At a given oxidation temperature and oxidant pressure, single crystal Si substrates with <111> oriented surfaces (2, 5, 6) generally oxidize more readily in oxygen and in water vapor ambients than substrates with <100> orientations. The number of accessible, nonoxidized Si-Si bonds at the substrate surface and within the SiO_2-Si transition regions is greater on <111> Si than on <100> Si (5, 9-11). As a consequence of this difference in observed oxidation kinetics at a constant p_{O_2} for substrates with <100> and <111> orientations, a relationship between thermal oxide growth rates and the accessible Si-Si bond concentration at the interface was proposed (5, 11).

Si oxidation kinetics in this thin film range are often approximated by linear growth. The linear rate constant, k_{lin}, for oxidation of <111> and <100> oriented Si decrease with p_{O_2} at 850°C and at 1000°C in O_2/N_2 ambients (2). At a given oxidation temperature, straight line plots of k_{lin} *vs.* p_{O_2} indicate a stronger pressure dependence on oxidation of <111> oriented substrates than on oxidation of <100> oriented substrates. The plots are not parallel but intersect at a nonzero value of p_{O_2}. The relative magnitudes of ln k_{lin}<111> and of ln k_{lin}<100> reverse when one extrapolates to low oxygen partial pressures.

[1] Present address: Thomas J. Watson Research Center, Yorktown Heights, New York 10598.

Key words: silicon, silicon dioxide, thermal oxidation, oxidation kinetics, pressure dependence.

Cabrera and Mott (12) have proposed a steric argument in which the order of increasing oxidation rates is the same as the density of decreasing atoms on the crystalline faces. This model predicts that the <100> face of Si should oxidize faster than the <111> face. Kamigaki and Itoh (13) have fit their Si oxidation rate data to the Cabrera-Mott oxidation equation for oxide films $\leq$200Å thick and $p_{O_2} \lesssim 10^{-2}$ atm. They have observed pressure-dependent reversals in relative oxidation rates of oriented Si substrates after oxidizing at 1100°C in O_2/N_2 ambients. Much of their data is obtained at O_2 pressures at which the N_2 diluent, which can react with Si (14, 15), may affect the Si oxidation kinetics.

The extent to which nitrogen interaction with Si alters the oxidation kinetics at low oxygen partial pressures is unknown. Nitridation reactions are known to occur at the SiO_2-Si interface provided that the oxidant concentration is sufficiently low (14, 15). In order to determine whether a reversal in oriented Si oxidation kinetics will occur in ambients free of nitrogen, oxidation kinetics of <111> and <100> oriented Si substrates at low p_{O_2} were examined in O_2/Ar, O_2/He, and O_2/N_2 ambients in this thin Si oxide growth range.

Experimental

Si single crystal wafers that were chem-mech polished, p or n-type, 1-2 Ω-cm, <100> and <111> oriented, were used in this investigation. They were cleaned in (*i*) NH_4OH, H_2O_2, H_2O (1:1:5) at 65°C, (*ii*) H_2O, (*iii*) HCl, H_2O_2, H_2O (1:1:5) at 65°C, (*iv*) H_2O, and (*v*) etched in HF:H_2O (1:1) followed by a (*vi*) deionized water rinse. In some cases, the wafers were subjected to a clean-up oxidation step. An SiO_2 film about 2000Å thick was first grown at 1050°C in dry oxygen and then removed by etching. This step was later discontinued since no difference in oxidation kinetics was detected as a result of its omission.

Oxidations were carried out at atmospheric pressure in furnaces containing single walled, high purity, fused silica tubes at temperatures of 850°-1050°C. Total gas flow velocities were 1-3 cm sec^{-1}. High purity nitrogen, argon, and helium gases with $<$ 2 ppm H_2O were used as diluents to reduce the oxidant partial pressures. The oxidant was generally dry O_2 ($<$ 2 ppm H_2O) but some experiments were performed using H_2O vapor as the oxidant by bubbling a fraction of the N_2 carrier gas through H_2O kept at 25°C. The water vapor content of the N_2 carrier gas

in the latter experiments was estimated (16) to be about 750 ppm and about 2000 ppm.

During oxidation, the wafers were vertically arranged on a quartz carrier with <100> and <111> oriented wafers symmetrically positioned. Several wafers with each orientation were oxidized at a given time. Positions of oriented wafers were often reversed to eliminate errors in oxide film thickness due to small gradients in temperature in the oxidation zone within the furnace tube. Wafers were warmed to temperature in the diluent gas and then oxidized for a desired length of time at a fixed oxidant partial pressure, p_{ox}.

Oxide film thickness was generally measured by ellipsometry at the center of each wafer after aligning the ellipsometer. All data points were measured in 2 zones at a wavelength of 5461Å and with an angle of incidence of 70.00°. In some cases, oxide film thicknesses were derived from x-ray photoelectron spectroscopy (XPS) intensity data and were compared with corresponding ellipsometric measurements.

Results

In Fig. 1, changes in oxide film thickness of <111> and <100> oriented Si substrates oxidized at 850° and 1050°C for 10 min intervals are plotted *vs.* oxygen partial pressures, p_{O_2}. The oxygen is diluted with nitrogen gas. At $p_{O_2} \sim 0.07$ atm, the <100> and <111> oriented substrates are oxidized at the same rates independent of oxidation temperature. At higher p_{O_2} values, the commonly observed orientation dependence occurs with <111> oriented substrates oxidizing faster than <100> oriented substrates. At lower p_{O_2}, this orientation dependence on oxidation rates is reversed.

N_2 gas interacts with Si at the SiO_2-Si interface when the oxygen concentration is low (14, 15). The reversal in relative oxidation rate of the two crystalline Si surfaces was reexamined at 1050°C with respect to diluent gas used in the oxidation ambient. Film thicknesses are given in Table I for <111> and <100> oriented substrates oxidized for 10 min intervals in ambients containing either N_2, Ar, or He with p_{O_2} ranging from 0.01 to 0.1 atm. A reversal in orientation dependence is detected for $p_{O_2} = 0.05$ to 0.1 atm for O_2/N_2 mixtures and at $p_{O_2} \sim 0.05$ atm for O_2/Ar or O_2/He mixtures.

In Fig. 2, thicknesses of oxide films on <111> and <100> oriented substrates formed at 1050°C are plotted *vs.* oxidation time with $p_{O_2} = 0.01$ atm in N_2, Ar, and He diluents. With each diluent, the oxide formed on the <100> oriented substrate is thicker than the oxide formed on the <111> oriented substrate. Small differences in film thickness are observed with change of diluent gas but these differences are likely to be associated with small experimental errors in mixing

Table I. Effect of diluent gas on Si oxide growth

Diluent gas	T (°C)	Substrate	d_{oxide} (Å) 0.5% O_2	1% O_2	5% O_2	10% O_2
N_2	850	<111>	16.2	19.0	22.0	25.8

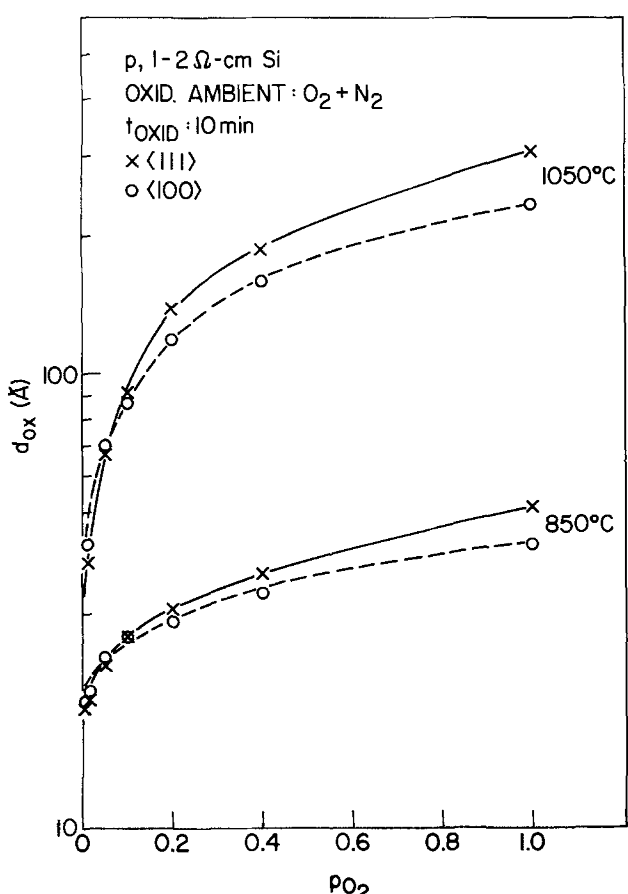

Fig. 1. The effect of O_2 partial pressure on SiO_2 film thickness after thermally oxidizing <100> and <111> oriented substrates for 10 min at 850° and 1050°C in O_2/N_2 mixtures.

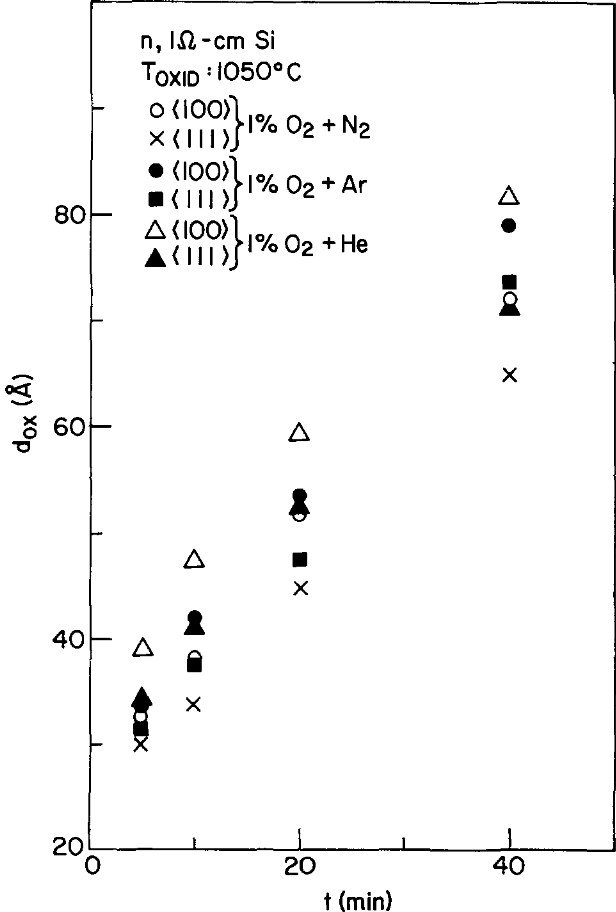

Fig. 2. The effect of change in oxygen ambient diluent at $p_{O_2} = 0.01$ atm on SiO_2 film growth at 1050°C on <100> and <111> oriented substrates.

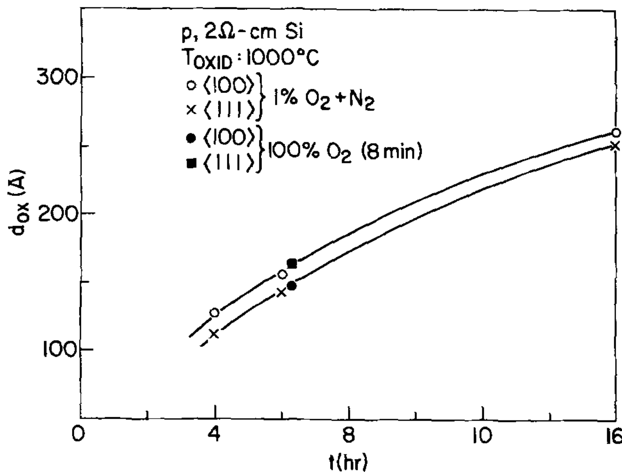

Fig. 3. Long-term Si oxidation of <100> and <111> oriented substrates at $p_{O_2} = 0.01$ atm and at an oxidation temperature of 1000°C compared with corresponding 8 min oxidation at $p_{O_2} = 1.0$ atm.

of the gases. From this comparison of oxidation rates in different diluent ambients, no evidence of N_2 reactivity with Si are apparent at oxygen partial pressures as low as 0.01 atm. However, as the oxygen partial pressure is decreased further, competition between the nitrogen reaction and the oxygen reaction with Si may complicate the oxidation kinetics.

In Fig. 3, thicknesses of oxide films on <111> and <100> oriented substrates formed at 1000°C are plotted *vs.* oxidation time with $p_{O_2} = 0.01$ atm in an N_2 diluent. Oxidation times are from 4 to 16 hr and yield film thicknesses in the 100-300Å range. Again, oxide films formed on <100> oriented substrates are thicker than the films formed on <111> oriented substrates. Changes in film thickness for oxides formed on <100> and <111> oriented substrates with $p_{O_2} = 0.01$ atm are summarized in Table II. Oxidation rates decrease with time indicating that the reaction has progressed beyond a linear oxidation range. After oxidation at $p_{O_2} = 0.01$ atm in an N_2 diluent for 10 min at 850°C, ellipsometric thickness measurements show oxide films on <100> oriented substrates to be 0.5-2Å thicker than oxides formed on <111> oriented substrates. XPS intensity measurements of Si 2p photoelectrons from the oxide film yield oxide film thickness data consistent with those obtained from the ellipsometric measurements.

Oxide films were also formed by oxidizing <111> and <100> oriented Si substrates in H_2O/N_2 mixtures at 850° and 1050°C. The N_2 stream was partially diverted and bubbled through deionized water at 25°C. In the first experiment, about 750 ppm of water vapor was added to the N_2 stream. In the second experiment, about 2000 ppm of water vapor was added to the N_2 stream. The water vapor oxidation results are illustrated in Fig. 4. After oxidation had occurred for 10 min at 850°C and at 1050°C, a reversal in the relative oxidation rates of <111> and <100> Si is ob-

served that is dependent upon the partial pressure of water vapor. At the low water vapor partial pressures, <100> Si is oxidized more rapidly than <111> Si.

Discussion

The <111> and <100> Si surfaces exhibit different dependencies upon oxidant partial pressure in the thin Si oxide film range. A consequence of this difference is that the relative oxidation rates of <111> and <100> oriented Si substrates reverse at $p_{O_2} < 0.1$ atm. The partial pressure of O_2 at which this reversal is observed is unaffected by change in diluent gas from N_2 to Ar to He. This reversal is only weakly affected by change in temperature from 850° to 1050°C. A similar reversal is observed in our preliminary oxidation studies with low water vapor partial pressures. Changes in the relative oxidation rates of <111> and <100> oriented Si surfaces are associated with changes in the partial pressure of the oxidant (O_2 or H_2O).

Other chemical reactions that are faster on <100> than on <111> Si surfaces have previously been observed. Addition of 10% HCl to an O_2 oxidizing ambient appears to alter the relative oxidation rates of <100> and <111> oriented Si substrates (17). The <111> surface is less chemically reactive when etched in wet ambients (18), but is more reactive when oxidized in water vapor. The chemistry affecting the relative reaction rates on these substrate orientations requires further clarification for the different reactions.

The pressure-dependent reversal in oxidation kinetics on Si substrates with different surface orientations are neither accounted for by comparison with Si-Si bond accessibility in the transition region (5, 11) nor by a steric argument proposed by Cabrera and Mott (12). These models can be fit to separate portions of the oxidation rate-p_{O_2} or -p_{H_2O} data. Neither model explains the observed dependence of the relative oxidation rates of the crystalline Si surfaces upon oxygen pressure.

The oxygen transported to the SiO_2-Si transition regions is determined by the oxygen partial pressure in the ambient. The ratio of Si-Si bond densities within the transition regions of <111> and <100> oriented substrates is expected to remain nearly constant during the oxidation process, particularly as p_{O_2} is decreased. Oxygen transport through an amorphous oxide film to the transition region is either totally independent of the substrate orientation or differs by a small, constant rate. The reversal in oxidation rates of the differently oriented substrates presumably occurs without significant change in the relative concentrations of either accessible Si-Si bonds or of oxidant at the transition regions. The observed oxidation kinetics, *i.e.*, the stronger dependence of oxidation rate with oxygen partial pressure of a <111> than a <100> oriented surface, are associated with differences in intrinsic properties of the two oriented substrates and are made visible by changes in transition region oxidant concentrations.

To account for the oxidation kinetics, the chemical environment of the partially oxidized transition region in which the oxidation reaction occurs must be considered. This region is a three-dimensional structure where Si-Si bonds are converted to siloxane (Si-O-Si) groups during oxidation. A volume change occurs upon oxidation in which the Si atom surface density in an oriented substrate is decreased by more than 50% when SiO_2 is formed. Greater than 50% of this transition to SiO_2 occurs within 2-3Å from the substrate (9, 10).

Despite the higher Si atom density on <111> Si than on <100> Si, the first transition region oxide layer appears to be less completely oxidized on <111> Si than on <100> Si substrates (9, 10). The transition region width between crystalline Si and SiO_2 is greater on <111> Si than on <100> Si. The estimated number of nonoxidized Si-Si bonds located within the transition regions are equivalent to 1-2 layers of Si substrate atoms. XPS studies of the SiO_2-Si interface (9, 10) indicate, within detection limits, that the composition and width of the transition regions of a given crystalline orientation are independent of the oxidation conditions (*e.g.*, oxidation temperature, oxygen partial pressure, oxide film thickness, etc.) for oxide films formed at temperatures $\leq 1050°C$. The dependence of transition region width on substrate orientation represents the different volume over which the two substrates convert Si into SiO_2 and suggests the possibility that oxidation of crystalline Si is occurring layer by layer.

The microscopic details of the interfacial Si oxidation reaction are not known. A multistep Si oxidation reaction has been proposed (19) in which oxygen initially reacts with and breaks Si-Si covalent bonds. A thermally activated reaction step follows in which siloxane groups form. The initial reaction between nonoxidized Si and oxygen depends upon their concentrations as reactants within the transition region. Since the oxygen concentration is significantly lower than the Si-Si bond concentration, the rate of this initial reaction is proportional to the oxidant concentration within the transition region and, therefore, to the oxidant partial pressure.

Formation of siloxane groups requires insertion of an oxygen atom between chemically bound Si atoms at the Si surface and within the transition region. Nonoxidized substrate Si atoms accessible to oxidant are primarily constrained by tetrahedral bonding to the crystalline substrate. These constraints are reduced for nonoxidized, or partially oxidized, Si atoms within the transition region. For oxidation to proceed, siloxane formation requires displacement of those Si substrate atoms at which reaction is occurring as well as of the neighboring lattice atoms (20). Completion of the reaction requires a reduction in the substrate lattice constraints that act to prevent the required volume expansion upon oxidation. This is accomplished by breaking of Si-Si covalent bonds at the substrate surface. The oxidation rate depends upon the local density of broken Si-Si bonds and is directly dependent upon the oxygen partial pressure. Oxidation is thus a cooperative phenomena involving several oxygen atoms. Synchrotron radiation studies indicate that the initial oxidation process on <111> oriented Si occurs about 2Å below the free Si surface (21). Subsurface oxidation can detach Si surface atoms from the substrate thereby lifting the lattice constraints for oxidation at a substrate surface.

Substrate lattice constraints cause oxidation at a crystalline Si surface to be anisotropic. Si-Si bonds perpendicular to the surface are readily oxidized whereas Si-Si bonds parallel to the surface are constrained by the crystal lattice. Oxidation is rate limited by the oxidation rate in the plane of the substrate. The kinetics of reaction on the two oriented Si surfaces are related to, but have different dependencies upon, the oxygen partial pressure. Three subsurface Si-Si bonds must be broken at a <111> substrate compared with two Si-Si bonds at a <100> surface. Nonoxidized Si-Si bonds at <111> surfaces, oriented primarily in the plane of the substrate surface, are accessible to the oxidant whereas Si-Si bonds at <100> substrate surfaces are directed in a more inclined direction to the substrate (5). The molecularity for oxidation of Si atoms in the plane of a <111> surface is higher than for oxidation of Si atoms in a <100> Si plane. As a consequence, there is a stronger dependence upon the oxygen pressure for <111> oxidation. At low p_{O_2}, this results in a reversal of the commonly observed relative oxidation rates of the crystalline substrate surfaces. As p_{O_2} is increased, the greater accessibility of nonoxidized Si-Si bonds at the <111> surface and the relatively high oxygen concentration at the interface cause the <111> oxidation rate to be higher than that for <100> Si. A strong dependence upon oxidation temperature in the range considered or upon diluent gas is not expected and is consistent with the experimentally obtained results.

Acknowledgments

Discussions with J. W. Matthews were of significant help in both formulating and clarifying our ideas concerning this work and are greatly appreciated. We thank the Divisional Editor, Prof. J. B. Wagner, Jr., for his patience and interest and thank R. A. Ghez, W. A. Pliskin, and J. A. VanVechten for helpful comments. R. Flitsch is gratefully acknowledged for the ESCA measurements.

The Growth and Characterization of Very Thin Silicon Dioxide Films

A. C. Adams, T. E. Smith, and C. C. Chang

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Very thin oxides (30-140Å) have been prepared by oxidizing silicon at 900°-1000°C at reduced pressure (0.25-2.0 Torr). The oxidation rate is parabolic. The oxides have been characterized by ellipsometry, infrared spectroscopy, Auger spectroscopy, etch rate variation, and breakdown voltages. The thin, low pressure oxides have properties similar to those of thicker oxides prepared at atmospheric pressure. The intrinsic breakdown fields are high (10-13 MV/cm) and distributed over a very narrow range. The ellipsometric, etch rate, and Auger data indicate a thin interfacial region <15Å thick, but such a region is not detected in the infrared spectra.

Very thin silicon dioxide films, in the range of 40-100Å, are being investigated for applications in several types of silicon devices. These thin oxides are usually prepared by oxidation of silicon with oxygen or steam at low temperatures (400°-800°C) (1, 2) or by oxidation at higher temperatures with the oxygen or stream diluted with an inert gas (3-5). Alternative methods for the oxidation of silicon to produce very thin films have used nitric oxide and hydrogen at 950°-1140°C (6); hot nitric acid (7); boiling water (8); and room temperature air (9, 10). Except for the oxidations with nitric oxide and hydrogen, these alternative methods produce maximum film thicknesses of only 20-40Å and thus are too thin for many device applications. Oxidations at reduced pressure have been reported (11, 12), but these oxidations have used specialized experimental equipment rather than furnaces suitable for device fabrication. In this paper, we describe the growth of thin (30-140Å) oxides at temperatures of 900°-1000°C in a furnace maintained at low pressure (0.25-2.0 Torr oxygen).

The very thin oxides described in this paper have been characterized by ellipsometry, infrared spectroscopy, Auger electron spectroscopy, etch rate determination, and electrical measurements. Thicker oxide films on silicon have been analyzed by many techniques. Much of this work, which has been recently summarized (13-15), has been directed at determining the thickness and composition of the interfacial region between the oxide and the silicon. The results tend to support a very thin interfacial region with a maximum thickness of <30Å and a composition that is silicon-rich, SiO_x where $x < 2$; however, other interpretations for the data have been suggested (13, 14, 16). The nature of the interface structure is relevant to the present work since the thicknesses of the oxides considered in this paper are comparable to some of the thicknesses proposed in the literature for the interfacial transition layer.

Electrical characterizations of oxide films have been reported (4, 17), and it has been suggested that oxides grown in dry oxygen may have an increased defect density caused by micropores in the oxide (17). Again, an alternative interpretation of the data has been suggested (18). In this paper, electrical, physical, and chemical data have been used to compare the very thin oxides grown at reduced pressure with thicker oxides grown at atmospheric pressure.

Experimental

The thin oxides are grown in a low pressure chemical vapor deposition reactor (19, 20). The oxidation takes place in an 11.5 cm diam quartz tube heated by a 3-zone furnace. Temperatures are uniform within ±0.5°C over the central 55 cm zone. The furnace has a capacity of 110 wafers. The reduced pressure is obtained with a Roots blower backed by a mechanical pump. Ultrahigh purity oxygen is metered through a calibrated flowmeter. The pressure is measured with a capacitance manometer.

Unless stated otherwise, the silicon substrates are 75 mm in diameter, 20 mils thick, (100) orientation, boron-doped, with a resistivity of 8-30 Ω-cm. The substrates are chemically etched on the back to reduce roughness and polished on the front surface to give a mirror finish. Prior to oxidation, the substrates are cleaned in a sequence of acidic and basic hydrogen peroxide solutions (21), etched in dilute hydrofluoric acid (100:1 H_2O:49%HF), rinsed in deionized water, and spun dry. The samples are loaded into the furnace in a nitrogen ambient and the furnace evacuated to 0.002 Torr for 15 min while thermal equilibrium is reached. The oxidation is started by admitting oxygen, and the pressure maintained by adjusting the oxygen

Key words: silicon oxidation, dielectrics, interfaces, integrated circuits.

flow. At the end of the oxidation, the furnace is evacuated to 0.002 Torr for 5 min and then backfilled to atmospheric pressure with nitrogen. The samples are removed from the hot zone in nitrogen and unloaded after cooling.

Several control oxidations have been performed by leaving samples in the furnace under vacuum (0.001-0.002 Torr) for 4 hr or under 2 Torr nitrogen for 4 hr. These samples have 25-27A of oxide after treatment. This small amount of oxidation may result from oxygen or water vapor introduced during loading, from impurities in the nitrogen, or from small leaks in the system.

The ellipsometer measurements are made with a Rudolph Model 43603-200E ellipsometer at an angle of incidence of 70.00° and a wavelength of 0.5461 μm. The instrument is aligned using standard procedures (22) and checked by making measurements on fused silica (23). Psi and delta are obtained from measurements made in two zones (24). The reported data are averages of at least two measurements per sample. The reproducibility is generally within ±0.02° for psi and ±0.05° for delta.

Infrared measurements are made with a Perkin-Elmer Model 580 spectrophotometer using an ordinate expansion of 5, 10, or 20×. Samples are cleaved and the oxide removed from one part by etching in dilute hydrofluoric acid. The resulting bare silicon is used in the reference beam. This procedure gives exact compensation for the substrate. Some spectra have been obtained using thicker silicon substrates (30 mils thick) polished on both sides. These spectra are complicated by interference fringes which are evident at the high ordinate expansions. The best data are obtained by using silicon substrates that are polished on the front and etched on the back to reduce roughness. Apparently the scattering from the back is large enough to eliminate the interference fringes but still small enough so that spectra can be measured.

The experimental procedure for the Auger analysis has been described previously (25). The initial analysis measures the contamination, if any, on the surface and in the film. The oxide thickness is determined using the chemically shifted silicon peaks, and the interface chemistry is examined utilizing ion-mill depth profiling. Etch rates are measured at 25°C using dilute hydrofluoric acid (100:1 H_2O:49%HF).

Samples are prepared for electrical measurements by evaporating 7000A of aluminum on the oxide and using standard photolithography and etching techniques to form dots with a 0.076 cm (30 mil) diameter. The oxide is removed from the back of the sample by etching and aluminum is evaporated for a back contact. The samples are not annealed after metallization. Two hundred measurements of the breakdown voltage are made for each sample. The measurements are made with the top aluminum dot biased negatively so the p-type silicon substrates are in accumulation. The breakdown is indicated by a current >10 μA.

Oxidation Kinetics

The oxidation rate at 953°C and 1.0 Torr oxygen has been determined by measuring the film thickness on 34 samples oxidized for different times (0.5-24 hr). Seven rate laws, all of which have been previously suggested to describe the oxidation of silicon to form very thin oxides, have been considered.

linear-parabolic $t = A_0 + A_1 d + A_2 d^2$

linear $t = A_0 + A_1 d$

parabolic $t = A_0 + A_1 d^2$

logarithmic $d = A_0 + A_1 \ln t$

inverse logarithmic $1/d = A_0 + A_1 \ln t$

variable power $d = A_0 t^{A_1}$

cubic $d = A_0 + A_1 t^{1/3}$

Table I. Coefficients for seven rate laws[a]

	A_0	A_1	A_2
Linear-parabolic	−1440	−184	8.47
Parabolic	−7630	7.25	
Linear	−42,800	1070	
Logarithmic	−154	22.6	
Inverse logarithmic	0.0721	−0.00562	
Variable power	2.20	0.342	
Cubic	−5.24	2.59	

[a] Thickness measured in A and times in sec; for oxidations at 953°C and 1.0 Torr oxygen.

where d is the oxide thickness, t is the oxidation time, and the A's are coefficients which are determined by linear least squares and are given in Table I for oxide thicknesses measured in angstroms and times measured in seconds.

Plots of thickness *vs.* time show that the linear and the logarithmic rate laws give a very poor fit to the data (Fig. 1). The remaining five rate laws are all much better (Fig. 2 and 3). The parabolic and linear-parabolic laws are almost identical except at very short times where the parabolic law overestimates the oxide thickness (Fig. 2). The inverse logarithmic law overestimates the thickness at long times, while the variable power law and the cubic law give fairly good fits for all times (Fig. 3).

The rate laws have been further evaluated by examining the residuals (the calculated thicknesses minus the measured thickness for each sample). The residuals are compared using four parameters: the range, the midspread, the median absolute deviation (mad), and the standard deviation, which are given in Table II. The residuals for the linear and the logarithmic laws are very large, agreeing with the poor fit observed graphically. The residuals for the other five laws are smaller showing better agreement between the experimental and predicted thicknesses. The rate laws in Table II have been ordered; the laws giving the best fit are listed first. It must be remembered that the linear-parabolic law has three adjustable co-

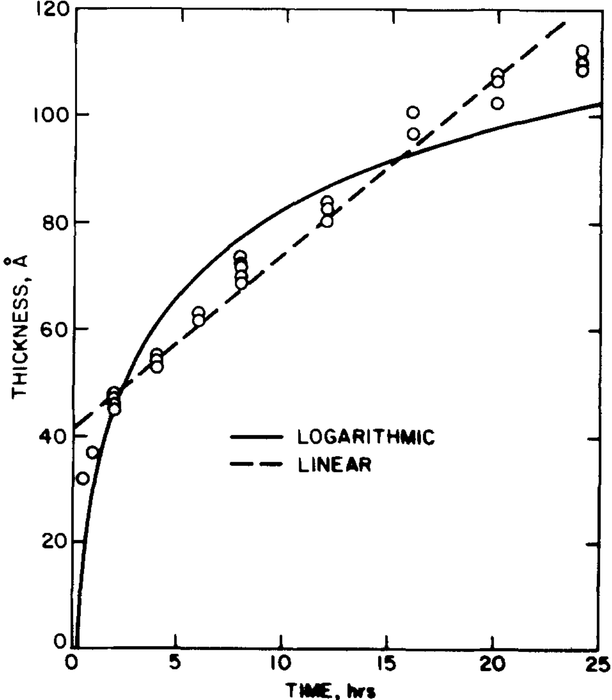

Fig. 1. Film thickness *vs.* oxidation time; the lines are calculated for the logarithmic and the linear rate laws.

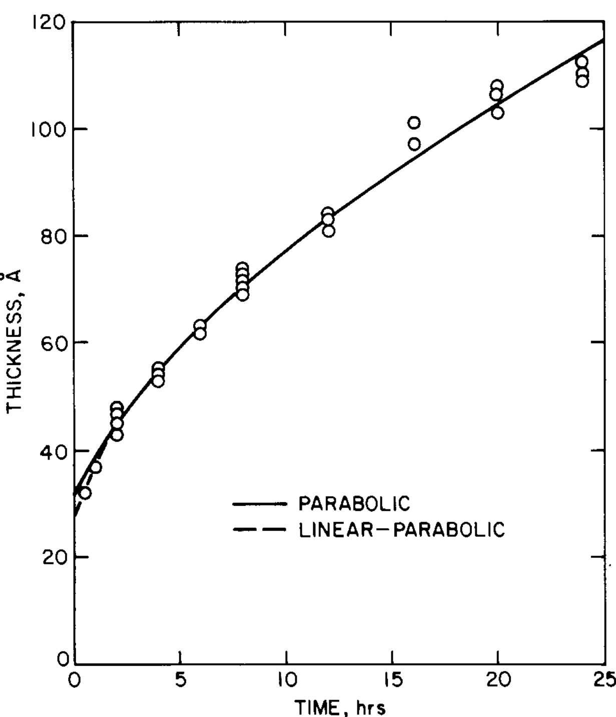

Fig. 2. Film thickness vs. oxidation time; the lines are calculated for the parabolic and the linear-parabolic rate laws.

efficients and the improvement observed with this law is due in part to the additional coefficient.

Previous work has described the oxidation of silicon at high temperature to form very thin oxides as following a linear (17), a linear-parabolic (11), or an inverse logarithmic rate law (4, 5). For the conditions used in this work, the rate is clearly not linear. The linear-parabolic law gives a negative linear rate constant (agreeing with previous work) (4, 5), but as discussed by others the determination of the linear rate constant is very difficult, especially when the oxidation is predominantly parabolic (11, 26). Also, calculation

Linear	19	5.0	6	3
Logarithmic	26	6.8	14	6

[a] Residuals are measured in Å.

of a negative linear rate constant is not justification for rejecting the parabolic rate law. Calculation of the parabolic rate constant from the least squares coefficients gives 0.12 $Å^2$/sec ($1/A_2$) for the linear-parabolic law and 0.14 $Å^2$/sec ($1/A_1$) for the parabolic growth.

Comparison of these rate constants with published values is difficult because of differences in oxidation conditions. Parabolic rate constants calculated from published data for oxidations at 953°C and 1.0 Torr oxygen, assuming a linear pressure dependence (12, 27), are given in Table III. The value measured in this work is near the middle of the published data extrapolated to 1.0 Torr.

Since a parabolic rate law implies that diffusion through the oxide is the rate-limiting step, the rate constant should be independent of substrate effects (27, 28). Experimentally determined parabolic rate constants for oxidations at 1.0 Torr oxygen are given in Table IV for different substrates. No variation is observed for different dopants, doping levels, or orientations. This is additional evidence for believing that the parabolic rate law is valid.

An inverse logarithmic law results if oxidation occurs by cation migration in a strong field caused by the potential difference between the silicon and absorbed oxygen (1, 31). This rate law has been used to describe the oxidation of silicon to form very thin oxides (1, 4, 5, 7); however, an upper temperature limit of 500°C has been estimated for inverse logarithmic growth. (1) In view of this temperature limitation it is unlikely that the inverse logarithmic law is valid for oxidations at 953°C, in spite of the fairly good empirical agreement shown in Fig. 3. As a further check, values for the potential difference can be calculated from the least squares coefficients (1). Assuming that the migrating silicon has a charge of plus four, and that the jump distance is 5Å, then the calculated potential is about 2V. This is about an order of magnitude larger than values observed for silicon oxidations at low temperatures (1) and observed for germanium oxidation (32). This large calculated potential also makes the inverse logarithmic law (cation migration in a strong potential field) unlikely.

Detailed models for silicon oxidation leading to the cubic or the variable power laws have not been devel-

Table III. Parabolic rate constants for oxidations at 953°C and 1.0 Torr oxygen

oped. However, it has been suggested that the variable power law may result if a reversible reaction occurs between the diffusing species and the oxide (12), and the cubic law may result for room temperature oxidations after very long times (33).

The best description for the oxidation kinetics at low pressure to form very thin oxides is provided by the parabolic rate law (or the linear-parabolic law with the parabolic term dominating). The parabolic rate constants agree with those observed for a variety of oxidation conditions. Difficulties exist for the remaining rate laws. Cation migration (inverse logarithmic growth) is unlikely at high temperatures; mechanisms leading to the variable power law and the cubic law have not been developed; and, the linear and logarithmic laws give a very poor fit to the data.

Oxide Characterization

Ellipsometry.—Although ellipsometry is a well-established technique for measuring the thickness and the refractive index of transparent films, there are limitations when the films are very thin. The measured values for the thickness and the refractive index of very thin films are strongly influenced by the choice of optical constants for the substrate and by the model of the interface structure (3, 34, 35). The procedure we have used to minimize these effects is similar to that described by van der Meulen (3). Briefly, the interface is assumed to be abrupt, so there are only five quantities that must be known or measured: the complex refractive index of the silicon substrate, n_{Si}-ik_{Si}; the complex refractive index of the film, n_F-ik_F; and the film thickness, d. These quantities are determined as follows. It is assumed that the film is nonabsorbing (the imaginary part of the film refractive index, k_F, is zero). The imaginary part of the silicon refractive index, k_{Si}, is obtained from optical transmission measurements and has a value of 0.031 at a wavelength of 0.5461 μm (23, 36). The value for the real part of the silicon refractive index, n_{Si}, is obtained using ellipsometric measurements from samples with very thin films ($d < 50$Å). The refractive index of the oxide film is calculated using samples containing thicker films ($d > 100$Å). Once the optical constants of the silicon substrate and the oxide film are known, the film thickness can be calculated for each sample. This procedure assumes that the optical constants are the same for all samples, and that the only sample variable is the film thickness.

This procedure is illustrated in Fig. 4 and 5. Values of the measured quantities, psi and delta, are shown in Fig. 4 for samples oxidized at 900°-1000°C to form very thin films ($d < 70$Å). The solid lines are calculated for different film thicknesses and different values for n_{Si} assuming that the film refractive index is 1.50. The average value for n_{Si} calculated from 28 samples with $d < 50$Å is 4.040; the standard deviation is 0.0022. No variation with oxidation temperature is observed. The complex refractive index for the silicon samples used in these experiments is taken as 4.040-0.031i. Data from samples with thicker films are shown in Fig. 5. The lines are calculated for different values for the film refractive index using 4.040-0.031i for the silicon substrate. The average value for the film refractive index

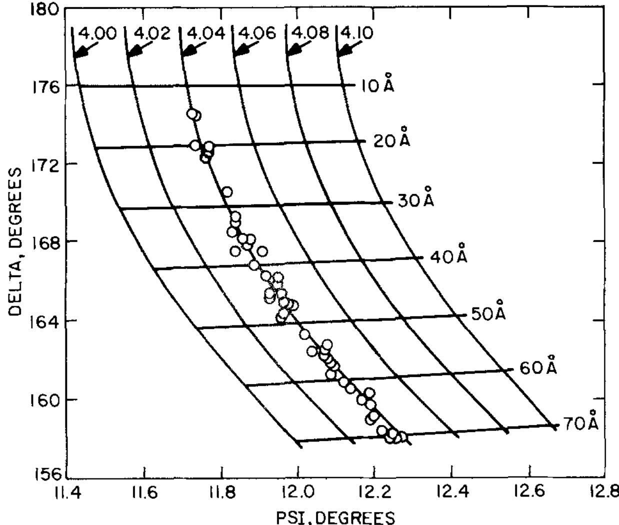

Fig. 4. Ellipsometric data for thin ($d < 70$Å) oxides; the lines are calculated for different values of n_{Si} and d assuming that $k_{Si} = 0.031$ and $n_F = 1.50$; the samples have been oxidized at 902°, 953°, and 999°C.

from 19 samples with thicknesses between 100 and 140Å is 1.55; the standard deviation is 0.063. The film thickness can be calculated for each sample using the average refractive index of 1.55.

The value for the silicon refractive index, 4.040-0.031i, is similar to reported values for etched silicon, approximately 4.05-0.028i (24, 37, 38) or 4.08-0.028i (3, 23, 39). Mechanisms for variations in n_{Si} have been proposed and invoke a thin layer at the silicon surface with optical properties different from bulk silicon (40). The value for the film refractive index is considerably higher than expected; oxide films usually have an index of 1.46 (24, 37-39). However, slightly higher values (1.47-1.48) have been reported (3, 23). Recent ellipsometric (34, 35), XPS (16), and Auger (15) data indicate an interfacial layer approximately 6Å thick (with an effective refractive index of about 2.8) be-

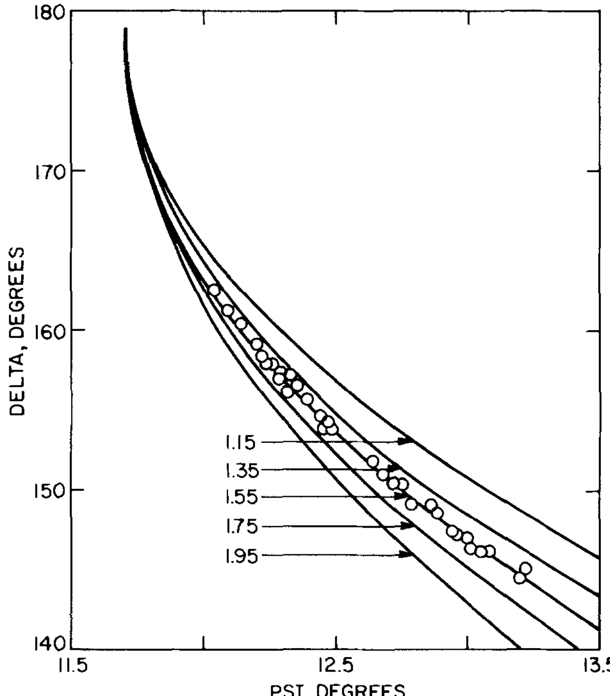

Fig. 5. Ellipsometric data for thicker (50Å < d < 140Å) oxides; the lines are calculated for different n_F assuming that the complex refractive index of Si is 4.040-0.031i; the samples have been oxidized at 902°, 953°, and 999°C.

tween the silicon substrate and the thermal oxide. If the ellipsometric data in Fig. 5 are recalculated using a similar interfacial layer, the refractive indexes for the oxide films are reduced to 1.460-1.465, in good agreement with the reported values.

Etch rates.—The etch rate of an oxide film is strongly dependent on the oxide composition and structure (41). In general, strain or porosity causes an increase in etch rate, while an oxygen deficiency (a silicon-rich film) causes the etch rate to decrease. Comparing the etch rate of the thin oxides with thicker oxides prepared by oxidation at atmospheric pressure provides information on the composition of the thin oxides. In addition, changes in etch rate with film thickness may indicate the presence of surface or interfacial layers.

Film thicknesses are shown *vs.* etch times in Fig. 6 for three samples etched at 25°C in dilute hydrofluoric acid (100:1 H_2O:49% HF). The solid points show the thicknesses measured after the samples become hydrophobic; the samples are hydrophilic for all other points. The average etch rate determined from the slopes is 25.6 Å/min. For comparison, samples of thermal oxide, approximately 1000Å thick, prepared by oxidation at 950°C in dry oxygen at atmospheric pressure have an etch rate of 25.3 Å/min. The similar etch rates show that both oxides have similar structure and composition. There is no indication of increased porosity in the thin, low pressure oxides.

The samples in Fig. 6 show a decrease in etch rate starting at 15-20Å. This may represent the beginning of an Si-rich interfacial layer. Such a layer is in good agreement with results obtained by other methods (16, 42). However, the decrease in etch rate may also result from an abrupt interface with a nonuniformly thick oxide, as has been suggested (13). If this is the case, the silicon surface starts to be exposed when the average film thickness is about 15Å. As etching continues, more of the surface becomes exposed causing an apparent decrease in etch rate.

Infrared spectra.—An infrared spectrum for a film 110Å thick is shown in Fig. 7. Since the spectrum is measured in transmission, through the silicon substrate, the total film thickness is assumed to be 220Å (110Å on the front and also on the back). The spectrum shows the three SiO_2 lattice absorptions at approximately 1080, 800, and 450 cm^{-1} (43). A small peak at 880 cm^{-1} is observed for most samples. This peak is also observed when clean silicon is placed in the sample and the reference beams, and is probably caused by slight differences in the incident angles for the sample and reference beams. Absorptions associated with OH or with SiH have not been observed (44, 45).

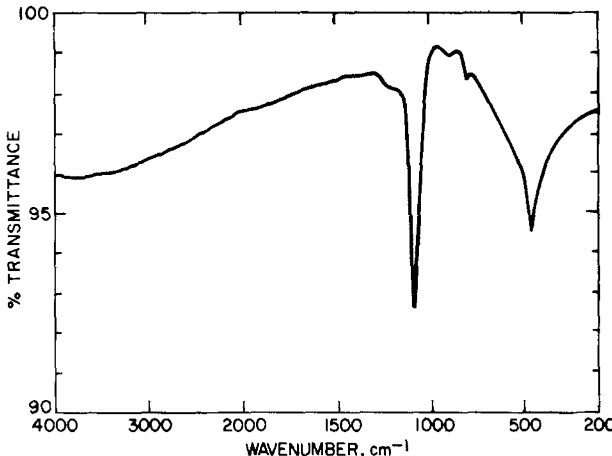

Fig. 7. Infrared spectrum for an oxide 110Å thick; the ordinate expansions is 10×.

The absorbance at 1080 cm^{-1} is plotted against the total film thickness (front and back) in Fig. 8. The solid points are measured from samples with oxide on the front and the back. The total film thickness is assumed to be twice the thickness measured on the front surface. The open points are measured from samples with the film removed from the back by etching in dilute hydrofluoric acid. For these samples the film thickness is the thickness measured for the front surface plus 10Å (the thickness of the native oxide on a silicon surface after etching, rinsing, and drying). The straight line is calculated by least squares assuming the Lambert-Bouguer law

$$A = 0.434\alpha(d - d_o)$$

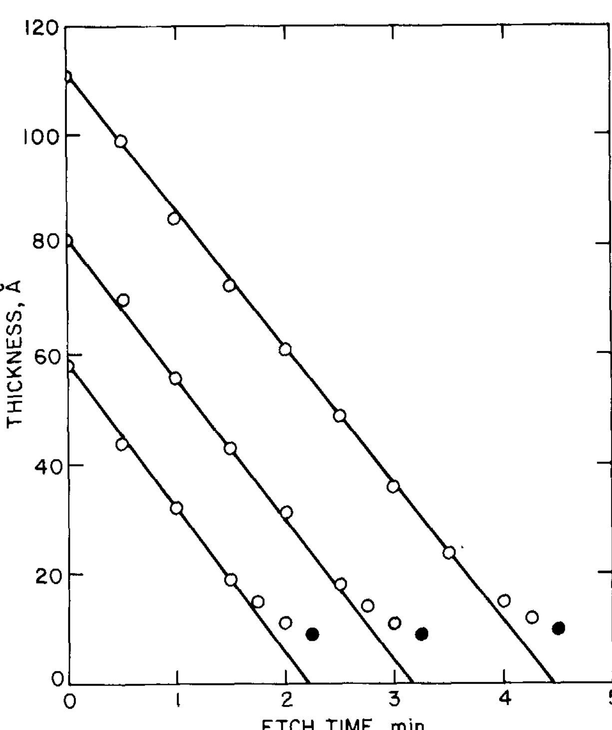

Fig. 6. Thickness vs. etch time for three samples oxidized at 953°C and 2.0 Torr.

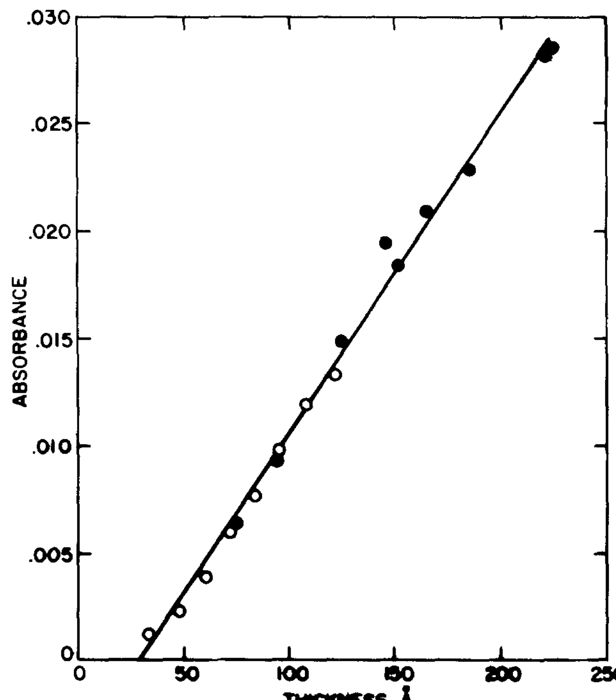

Fig. 8. Absorbance at 1080 cm^{-1} vs. the total oxide thickness; the samples have been oxidized at 902°, 953°, and 999°C.

where A is the absorbance, α is the apparent absorption coefficient, d is the total film thickness, and d_0 is the total oxide thickness on the silicon sample in the reference beam. The values for α and d_0 obtained from the least squares fit are 3.4×10^4 cm^{-1} and 19Å. The value of α is identical to values reported for much thicker oxide films: 3.3-3.7 $\times 10^4$ cm^{-1} (43, 46-48). The value for d_0 is also in very good agreement with experimental values. Film thicknesses measured on silicon wafers immediately after cleaning, rinsing, and drying range between 8 and 11Å, giving values for d_0 between 16 and 22Å.

The infrared spectra show no indication of an interfacial layer. Absorption peaks for spectra other than SiO_2 are not observed; in addition, there is no tendency for the absorption peaks to shift with film thickness. However, spectra of the interfacial layer will be canceled if the two samples (reference beam and sample beam) contain identical interfaces.

Auger analysis.—Three samples have been examined by Auger spectroscopy in combination with *in situ* ion-milling to provide depth information. All three samples have carbon on the surface; the amount of carbon is estimated at about 0.5Å. This is only slightly higher than for clean samples exposed to air (0.3Å) and probably represents contamination of the samples after oxidation. No other impurities are observed on the surface, and no impurities are observed within the film. The Auger spectra are essentially identical to spectra obtained from thicker thermal oxides grown at atmospheric pressure. Oxide thicknesses have been calculated from the chemically shifted Auger spectra (25) and are about 10Å less than the thicknesses measured by ellipsometry. A large part of this discrepancy can be explained by the existence of an interface layer containing mostly SiO. The chemical depth profiles at the silicon interface have been obtained and are essentially the same as those obtained from thermal oxides grown at atmospheric pressure. Based on the Auger, infrared, and etch rate data, we conclude that these very thin, low pressure oxides contain no detectable impurities and are essentially identical to much thicker thermal oxides.

Dielectric breakdown.—Breakdown measurements have been made on several samples with oxide thicknesses between 30 and 140Å. Representative results are shown in the histogram in Fig. 9 showing data for a sample with 93Å of oxide, and in the cumulative distribution plots in Fig. 10 showing data from three samples with oxide thicknesses of 56, 73, and 94Å. Several features are apparent from these figures.

Most breakdowns occur at high fields and within a very narrow range. Except for one sample 56Å thick (shown in Fig. 10), more than 75% of the breakdowns occur at fields between 11-13 MV/cm. One sample, 69Å thick, has more than 90% of the breakdowns between 11.6 and 12.2 MV/cm showing a very narrow distribution. The high fields and narrow distributions indicate an extremely uniform and homogeneous oxide (49). The distribution of intrinsic (high field) breakdowns is neither Gaussian nor log-normal (50), but there are insufficient data from the present samples to determine the actual distribution. The median breakdown fields are dependent on the oxide thickness (51). The observed breakdown fields are 10.5-11.0 MV/cm for oxides about 100Å thick; 11.5-12.0 MV/cm for oxides 75Å thick; and 12-13 MV/cm for 50Å oxides. The so-called secondary breakdowns (at fields of 1-3 MV/cm), believed to be caused by small crystalline regions in the amorphous oxide (52) are not observed. These secondary breakdowns are not expected since the samples have not been heated to high enough temperatures to cause crystallization.

Low field breakdowns, caused by structural defects such as pinholes or particulate contamination (the oxide samples are not prepared in a clean environment)

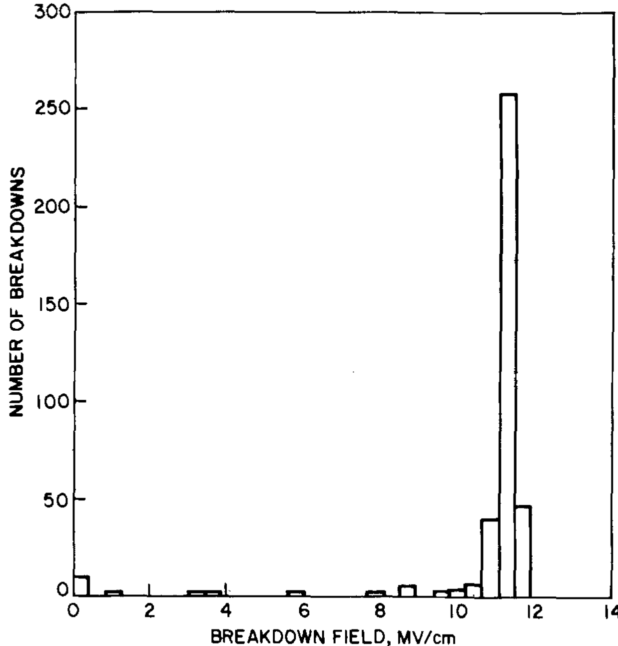

Fig. 9. Histogram showing breakdown fields for an oxide 93Å thick; the sample has been oxidized at 953°C and 2.0 Torr.

are observed for all samples. Between 1 and 30% of the breakdowns for each sample occur at fields less than 0.5 MV/cm. These low field breakdowns have a very strong (exponential) dependence on oxide thickness as shown in Fig. 11. The point at 150Å is taken from Ref. (17) for oxides prepared at atmospheric pressure.

Comparisons with oxides prepared at atmospheric pressure are difficult because of differences in oxide thickness. Data have been reported for samples 150Å thick prepared with dry oxygen and no postoxidation anneal; a maximum in the breakdown distribution occurs at about 9 MV/cm, but with the breakdowns ranging between 6 and 15 MV/cm, and with about 20% of the breakdowns occurring below 6.5 MV/cm (17). Samples prepared with steam are much better with the breakdowns occurring between 8 and 14 MV/cm (17). The thin low pressure oxides reported in this paper are comparable to the thicker steam oxides. The percent of intrinsic (high field) breakdowns for silicon oxidized in oxygen at atmospheric pressure is reported to decrease with decreasing thickness, and less than 30% of the breakdowns are intrinsic for oxides less

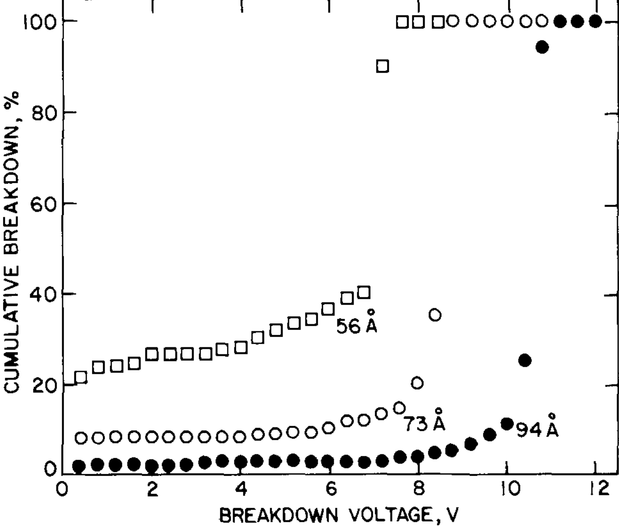

Fig. 10. Cumulative distribution plot showing breakdown voltages for three samples oxidized at 953°C and 2.0 Torr.

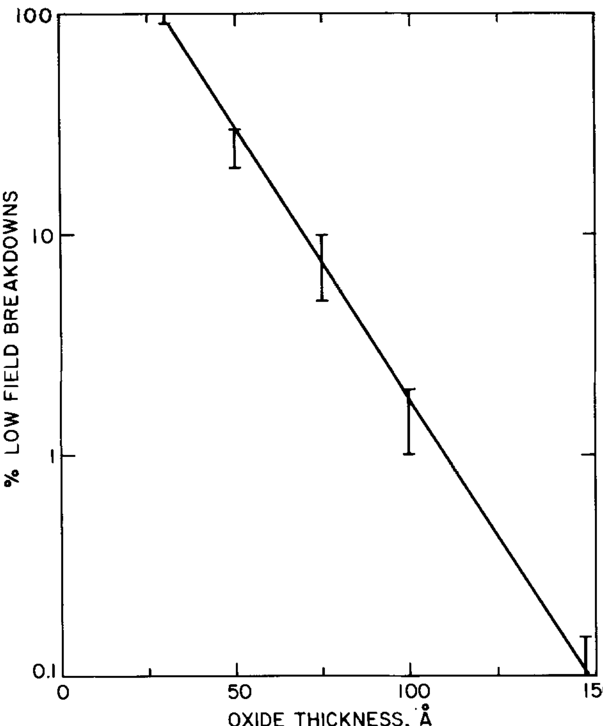

Fig. 11. The % low field breakdowns vs. oxide thickness; the point at 150Å is taken from Ref. (17) for an oxide prepared at atmospheric pressure.

than 200Å thick (49). As already stated, the low pressure oxides have a much higher percent of intrinsic breakdowns even though the films are very thin. The very narrow distribution, high breakdown fields, and high percent of intrinsic breakdowns observed for the present samples indicate that the very thin low pressure oxides are high quality, low porosity films and are more homogeneous than thicker samples oxidized at atmospheric pressure.

Capacitance-voltage measurements have been made on several samples. No attempt has been made to investigate the effects of oxide thickness or of processing parameters (annealing and cleaning) on the MOS properties. Typical values are: fixed charge, $1\text{-}5 \times 10^{11}$ cm^{-2}; mobile charge, $<2 \times 10^{10}$ cm^{-2}; fast state density at midgap, $4\text{-}6 \times 10^{10}$ cm^{-2} V^{-1}.

Summary and Conclusions

Silicon samples have been oxidized at 900°-1000°C using oxygen at reduced pressure (0.25-2.0 Torr) to give films 30-140Å thick. The growth of these very thin films is easily controlled because of the low oxidation rate. The low pressure oxidation follows the parabolic rate law (or the linear-parabolic law with the parabolic term dominating). The parabolic rate constants calculated for the reduced pressure oxidation are in good agreement with values extrapolated from atmospheric pressure. Other rate laws have been evaluated but are not as suitable as the parabolic law.

The very thin oxides have been characterized by infrared spectroscopy, Auger spectroscopy, etch rate variation, ellipsometry, and breakdown voltage. The film properties are independent of the oxidation temperature over the range studied. Auger spectroscopy shows a small amount of carbon on the oxide surface, which is only slightly higher than observed for typical oxidations at atmospheric pressure. No impurities are detected within the film. The infrared spectra have three absorptions due to the SiO_2 lattice; absorptions caused by SiH or OH are not observed. The absorbance at 1080 cm^{-1} is a linear function of the oxide thickness and agrees with values obtained from thicker samples. The infrared data show no indication of an interfacial region. The effective film refractive index, determined by ellipsometry, is high, 1.55. This high value may be caused by a thin interfacial layer with a high refractive index (34, 35). The etch rate (in dilute hydrofluoric acid) of the thin, low pressure oxides is identical to that of thicker oxides prepared at atmospheric pressure. The etch rates are uniform throughout the film, indicating a homogeneous oxide, except for a decrease in etch rate about 15Å from the silicon interface. This decrease may be caused by a silicon-rich interfacial layer. The distribution of breakdown voltages is characterized by high breakdown fields (10-13 MV/cm), a narrow range, and a high percent of intrinsic breakdowns, indicating a very uniform, homogeneous oxide. The percent of low field breakdowns (probably caused by pinholes or particulate contamination) increases exponentially with decreasing thickness; however, the percent of low field breakdowns may be reduced by oxidizing the samples in a cleaner environment. The chemical, physical, and electrical data indicate that the very thin oxides prepared at low pressure are very similar to thicker oxides prepared at atmospheric pressure.

Behavior of Phosphors under Low Voltage Cathode Ray Excitation

Kinichiro Narita, Akiyasu Kagami, and Yoshiyuki Mimura

Kasei Optonix, Limited, Odawara 250, Japan

ABSTRACT

The behavior of phosphors under low voltage (less than 100V) cathode ray excitation is investigated. A phosphor coated on an anode plate is excited by low voltage cathode rays from two line cathodes. Brightness increases as the distance between the anode and the cathodes decreases. Most phosphors used here show high brightness when mixed with conductive materials such as In_2O_3 or SnO_2. The smaller diameter of In_2O_3 mixed with Y_2O_2S:Eu, the lower added amount of In_2O_3 necessary for maximum brightness. ZnS:Cu,Al coated with SnO_2 shows maximum brightness when the added amount of $SnCl_4$ is 100 w/o and the sample is fired at 700°C. $(La_x,Lu_{1-x})InO_3$:Eu shows spectrum variations according to the change of x and Eu concentration. The peak wavelength of $LaInO_3$:Eu changes to longer wavelength when the phosphor is sulfurized into $LaInO_2S$:Eu, which is a similar phenomenon to that shown by Y_2O_3:Eu and sulfurized Y_2O_2S:Eu under conventional high voltage cathode ray excitation.

Currently, various display devices are being actively studied. Among them fluorescent display tubes (1), in which phosphors are excited by cathode rays of several tens of volts, are one of the best display devices and are widely used for hand or desk top calculators and other digital display applications. However the only emission color is bluish green, peaked at 520 nm, because only ZnO:Zn has been available for low voltage cathode ray tubes. Multi-color fluorescent tubes are needed for further development, for example, panel meters, flat television sets, and large area display devices. Phosphors for the tubes were first reported by Hiraki, Kagami, Hase, Narita, and Mimura in 1976. The phosphors were mixed with conductive materials such as ZnO or In_2O_3 to lower threshold voltage for emission (2). Nitta, Matsuoka, Tohda, Wasa, and Hayakawa reported on SnO_2:Eu. This phosphor shows 60 f-L at 20V without any conductive materials (3). Kukimoto, Oda, and Nakayama reported on ZnS and ZnSe activated by Cu or Ag together with Al. They used single crystals subjected to the Zn-extraction treatment (4).

However, there are few reports about other phosphors, the relation between brightness and applied voltage or current, and the luminescent mechanism under low voltage cathode ray excitation. In this paper the behavior of phosphors under low voltage excitation is reported.

Key words: inorganic, cathodoluminescence, phosphor.

Experimental

The apparatus for phosphor evaluation under low voltage cathode ray excitation is demountable. Eight anode plates (2×2 cm^2) coated with phosphors can be mounted on a ceramic disk. Two line cathodes are used for electron sources. The distance between the plate and the cathodes is variable. In operation, the anode voltage is applied to only one anode just below the cathodes thus preventing electrons from diverging. Evacuation is carried out by a rotary pump with trap and a noble pump (Nichiden-Varian). The phosphors are coated on the anode plates by the sedimentation method. Brightness is measured by a photometer (Pritchard). The emission spectrum and CIE chromaticity coordinates are obtained by a grating monochrometer, an optical multi-channel analyzer (OMA-Princeton Applied Research), a micro-computer, and a four color plotter (Yokogawa-Hewlett Packard). Figure 1 shows the block diagram. A synchroscope is used for a spectrum monitor. In order to

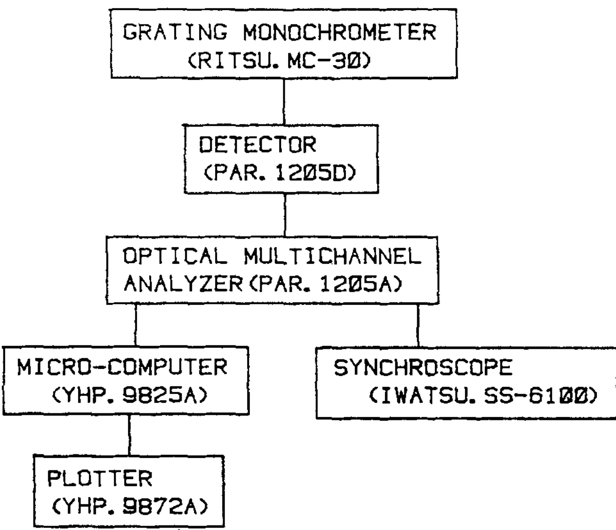

Fig. 1. Block diagram to obtain emission spectrum and CIE chromaticity. Synchroscope is used for a spectrum monitor.

measure the resistivity, phosphors are pressed into disks of 17.5 mm in diameter and 0.5 mm thick at a pressure of 200 kg/cm^2. The measurement is carried in the evacuated vessel at a pressure of 10^{-3} Torr.

Results and Discussion

Figure 2 shows brightness *vs.* applied voltage. The parameter is distance between an anode plate with a phosphor and the two line cathodes in mm. The phosphor used here is ZnO:Zn. These curves show that the brightness is more strongly dependent on the applied voltage and that the threshold voltage for emission goes down when the plate and the cathodes are closer. Figure 3 shows brightness (solid line) and anode current density (dotted line) *vs.* distance between electrodes in mm. These curves show that brightness and current density increase rapidly as the distance narrows. The density is three orders of magnitude higher than that of conventional high voltage cathode ray excitation. Anode-cathode diode characteristics in

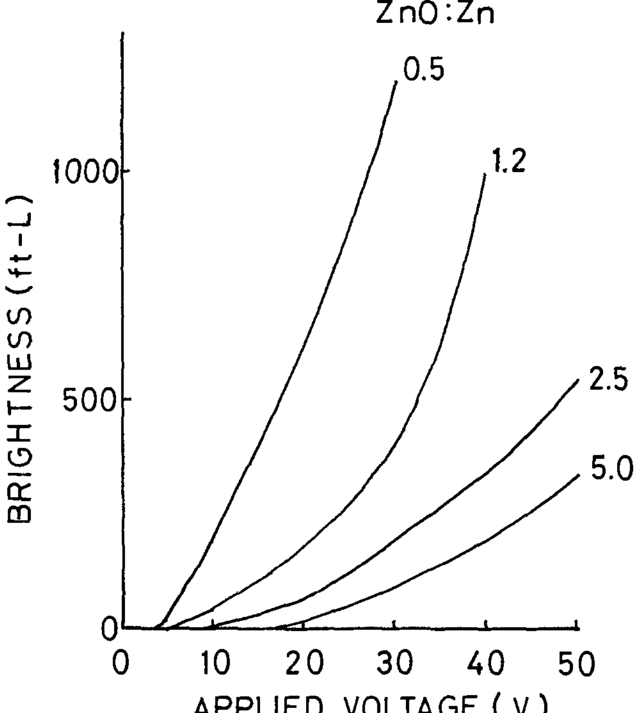

Fig. 2. Brightness *vs.* applied anode voltage. Parameter is distance between the anode and the cathodes in mm.

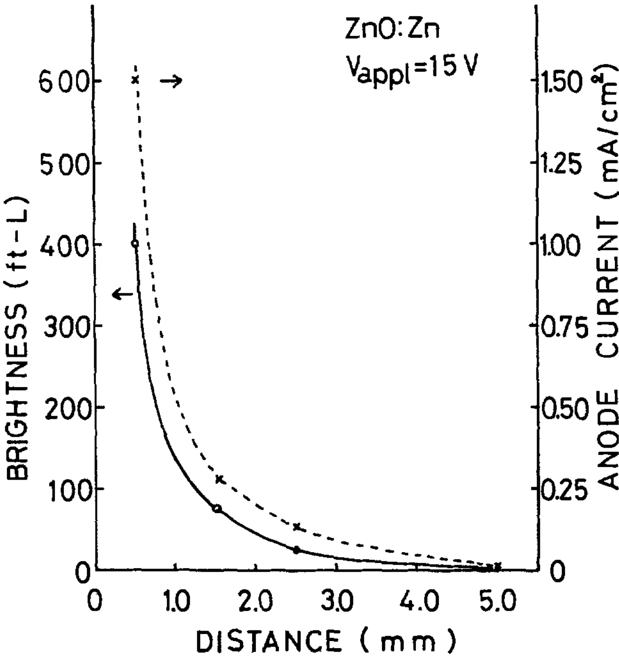

Fig. 3. Brightness and anode current *vs.* distance between electrodes. Applied anode voltage is 15V.

vacuum usually show $I = K \cdot V^{3/2} \cdot d^{-2}$ (I: current, K: constant, V: applied voltage, and d: distance between electrodes) because current is space charge limited. In this experiment, the power of V from a log-log plot (not shown here) is not 3/2 but 5/2. This difference seems to be due to the fact that the anode plate is coated with a phosphor, and so the current flows through the limited area at low voltage region (below 10V) and at large distances (above 3.0 mm), resulting in the fact that the phosphor emission is not uniform. In commercial tubes a mesh grid for the diffusion and the drawing of the current is placed between the cathode and the anode to get uniform phosphor emission. It may be said, however, that in this diode construction space charge limited current flows and the brightness depends largely on the current through the phosphor.

Phosphors generally have high resistivity (for example, 10^{13} $\Omega \cdot$ cm orders of magnitude in Y_2O_2S:Eu disk), so that under conventional high voltage cathode ray excitation the phosphor screen of television tubes is metal-backed to prevent charge-up. On the other hand certain phosphors with relatively low resistivity, for example, ZnO:Zn, SnO:Eu, and (Zn,Cd)S:Cu or Ag, emit brightly under low voltage cathode ray excitation. Some phosphors can also show high brightness when mixed with conductive materials such as ZnO, In_2O_3, or SnO_2. Figure 4 shows brightness *vs.* In_2O_3 content. The phosphor used here is Y_2O_2S:Eu, the particle diameter being 8 μm. The parameter is the diameter of the In_2O_3 conductive material. The curves show that the content for maximum brightness decreases as the diameter of In_2O_3 becomes smaller, and that the maximum brightness is nearly constant. Figure 5 shows brightness *vs.* applied voltage, in which the parameter is the diameter of Y_2O_2S:Eu. Mixture ratio of Y_2O_2S:Eu to In_2O_3 is 1.0. The brightness of 4 μm Y_2O_2S:Eu is much higher than that of 8 μm.

Figure 6 shows brightness *vs.* diameter ratio of ZnS:Cu,Al to In_2O_3. The parameter is the phosphor diameter. Curves in this figure also show that the mixture of the phosphor and the conductive material with small diameter can show higher brightness than that with large diameter, and that the mixture of a phosphor and a conductive material with the same diameter emits more brightly than that with different diameters. The penetration depth of electrons into

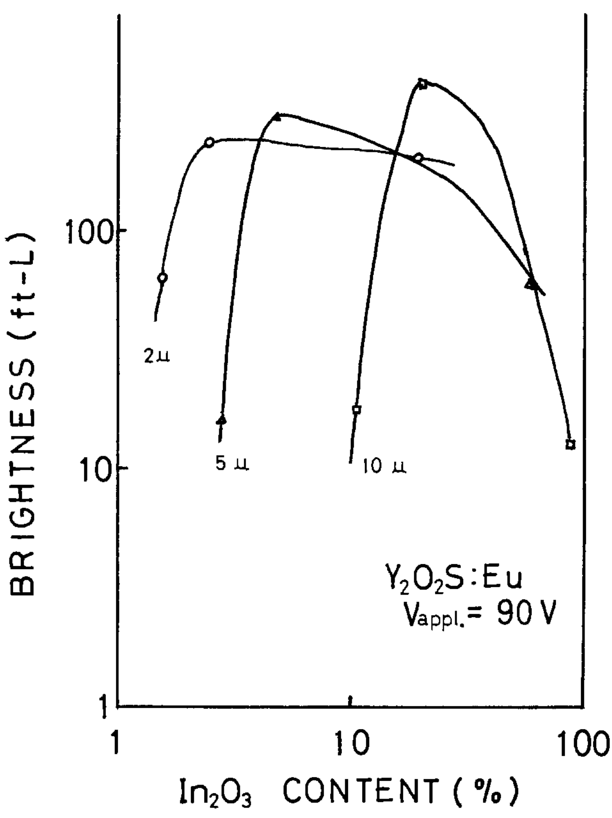

Fig. 4. Brightness vs. In_2O_3 content. Parameter is the diameter of Y_2O_2S:Eu. Applied anode voltage is 90V.

phosphors, according to Leverenz (5), Young (6), and Feldman (7), is less than a few tens of angstroms at 100V anode voltage. This shows that the phosphors preferred for low voltage cathode ray tubes should

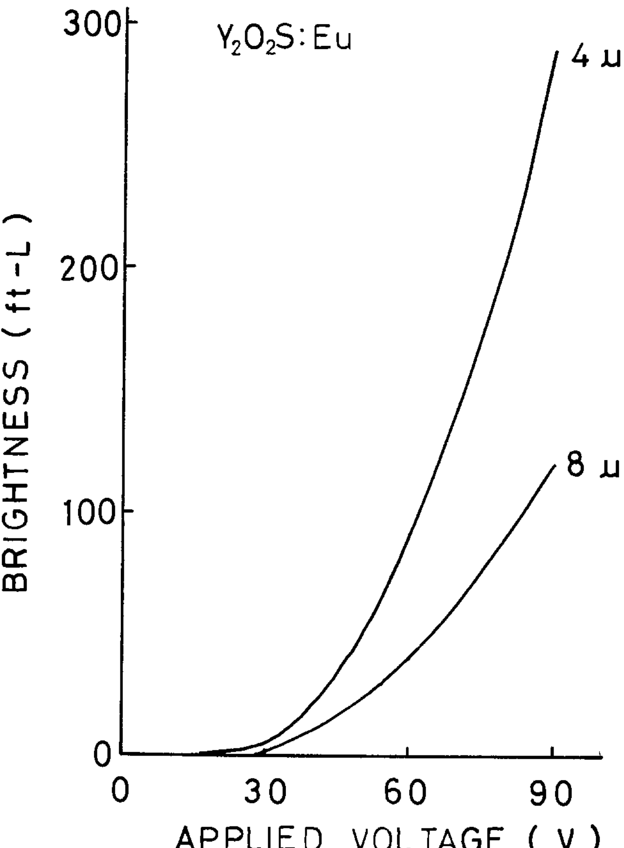

Fig. 5. Brightness vs. applied anode voltage. Parameter is the diameter of Y_2O_2S:Eu.

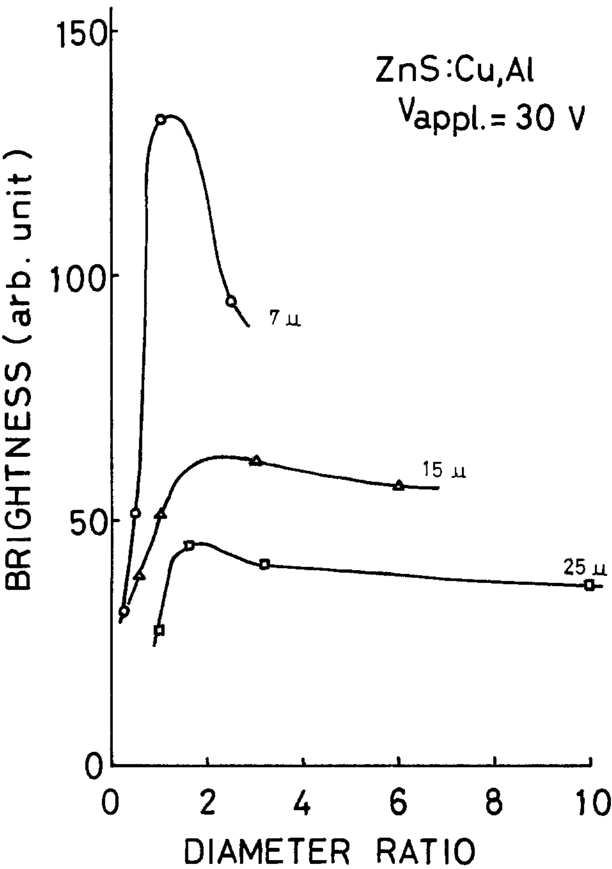

Fig. 6. Brightness vs. diameter ratio. The ratio is the diameter of ZnS:Cu,Al to that of In_2O_3. Parameter is the diameter of ZnS:Cu,Al.

be of small diameter in order to obtain large surface emitting area and thin and uniform to obtain high brightness. Furthermore, it can be said that the same small diameter is generally preferred for maximum brightness of settled powder screens.

Figure 7 shows brightness and anode current density *vs.* $SnCl_4$ content for conductively coated ZnS: Cu,Al. The phosphor is dipped in a solution containing $SnCl_4$ and then baked at 700°C for 10 min in air. This results in an SnO_2 coating on the phosphor. Maximum brightness is obtained at 100 weight percent (w/o) of $SnCl_4$, while the current continues to increase as the

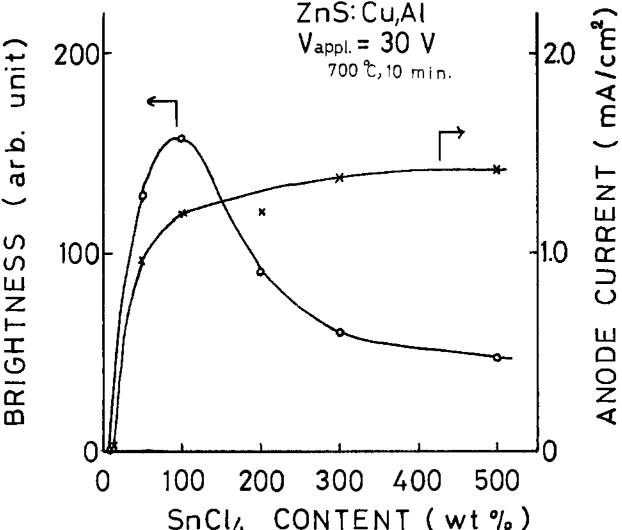

Fig. 7. Brightness vs. $SnCl_4$ content. ZnS:Cu,Al is dipped in $SnCl_4$ and fired at 700°C for 10 min in air. Applied anode voltage is 30V.

$SnCl_4$ content increases. This result shows that there is an optimum conductivity for maximum brightness under low voltage cathode ray excitation, and that any additional increase in conductivity is only effective to draw space charge limited current without excitation of the phosphor itself.

Most oxides including phosphors have generally very high resistivity, so that Y_2O_3:Eu is not as bright as Y_2O_2S:Eu under low voltage cathode ray excitation, even if In_2O_3 is added. But $(La_x,Lu_{1-x})InO_3$:Eu is a compound already containing In_2O_3. Hence it shows bright emission (see the spectra of Fig. 8) when it is mixed with In_2O_3. Curves 1, 2, 3, and 4 are for $x =$ 0.75, 0.50, 0.25, and 0.00, respectively. The intensity of the 610 nm peak increases as x decreases. This fact shows that $LaInO_3$ and $LuInO_3$ form a solid solution and the transition probability of Eu levels changes corresponding to the mixture ratio of La and Lu ions. Figure 9 shows the dependence of emission spectrum on Eu concentration in $LaInO_3$. An increase of Eu concentration from 2 mole percent (m/o) (curve 1) to 6 m/o (curve 2) decreases the intensity of the 550 nm subpeak. According to this spectral change the CIE chromaticity coordinates change from $x = 0.570$ and $y = 0.389$ to $x = 0.621$ and $y = 0.364$. This spectral change is also observed for Y_2O_2S:Eu under conventional high voltage cathode ray excitation, as is well known. Similar spectral change is also observed when the phosphor is fired at different temperatures, even if the Eu concentration is not changed. The subpeak is higher when the phosphor is fired at 1000°C than when fired at 1400°C, not shown here. This is due to the fact that Eu ions are introduced more effectively at 1400°C than at 1000°C, the effect similar to that of adding excess Eu.

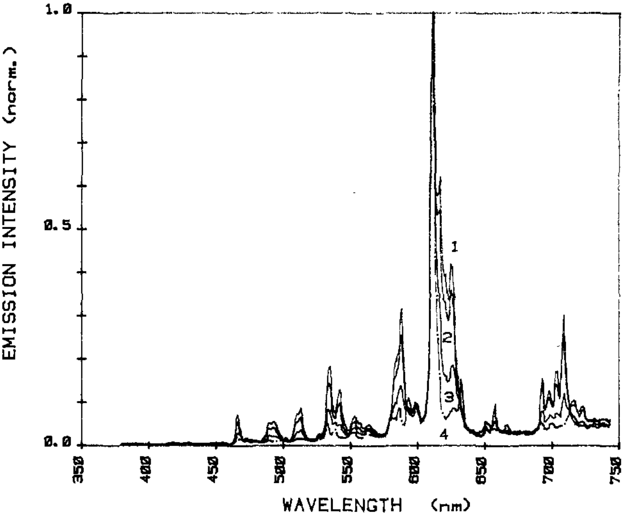

Fig. 8. Emission spectra of $(La_x, Lu_{1-x})InO_3$:Eu. Curves 1, 2, 3, and 4 are of x = 0.75, 0.50, 0.25, and 0.00, respectively.

Figure 10 shows the difference of spectra between $LaInO_3$:Eu (curve 1) and $LaInO_2S$:Eu (curve 2). The latter shows a main peak at longer wavelength than the former. The same relation exists between the spectrum of Y_2O_3:Eu and that of Y_2O_2S:Eu under conventional high voltage cathode ray excitation, as is well known.

Conclusion

In the case of low voltage (less than 100V) cathode ray luminescence, that which is produced by a phosphor coated on an anode and subjected to electron shower from line cathodes, the current through the phosphor strongly affects the brightness. Since the current is space charge limited, the high current density for high brightness is obtained with the lowering of the threshold voltage by narrowing the distance between the anode and the cathode. Experiments show that phosphors for fluorescent tubes should be of small diameter, a fact which can be explained using the electron range equations. The emission spectrum of $(La_x,Lu_{1-x})InO_3$:Eu varies according to x value and Eu concentration. The relation of the spectral change between $LaInO_3$:Eu and sulfurized LaO_2S:Eu under low voltage cathode ray excitation is the same as that between Y_2O_3:Eu and Y_2O_2S:Eu under conventional high voltage excitation.

Annealing Technique for LEC Grown Twin-Free InP Crystals

W. A. Bonner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

An *in situ*, postgrowth annealing technique for liquid encapsulated Czochralski (LEC) grown twin-free InP crystals is reported. The procedure described minimizes the effects of both growth-induced stress and that resulting from differential thermal contraction between the InP crystal and the B_2O_3 skin adhering to it after growth.

A systematic study and control of crystalline defects and growth related problems associated with InP substrate preparation has until recently been difficult due to the limited availability of constant quality twin-free InP crystals. A new liquid encapsulated Czochralski (LEC) growth technique which limits the rate of diameter enlargement while a nearly planar crystal-melt interface is maintained has essentially eliminated the problems related to twinning and polycrystalline growth (1). Using the apparatus employed in Ref. (1, 2), ~100g InP single crystals, (30 mm diam × ~80 mm long) of constant quality suitable for quaternary alloy device studies can be routinely grown. Twin-free crystals so grown, however, have been found to exhibit evidence of somewhat greater internal stress than previously observed in twinned crystals. In this paper, an *in situ*, postgrowth annealing technique is reported, which has been found effective in minimizing the effects of both growth-induced strain and that resulting from differential thermal contraction between the InP crystal and the B_2O_3 skin adhering to it after growth.

Experimental and Results

LEC growth of InP crystals is accomplished using an inert gas pressure of ~38 atm to prevent dissociation of the compound at the melting point and molten B_2O_3 as the encapsulant to seal the melt. As the crystal is pulled through the encapsulant layer a thin skin of B_2O_3 adheres to the boule surface. Differential thermal contraction between this B_2O_3 skin (1.5×10^{-5} °C^{-1}) (3) and the InP crystal (5.3×10^{-6} °C^{-1}) (4) during cooling can introduce mechanical strain as well as impede the relief of growth-induced stress unless properly annealed as discussed below.

Previous conventional procedures suggest, at the conclusion of growth, InP crystals be cooled without decreasing pressure in the growth chamber to prevent decomposition. Prior to the growth technique reported in Ref. (1), most InP "single" crystals contained twins which appear as a sequence of closely spaced parallel (111) planes. For crystals grown in a <111> direction, three geometrically similar (111) planes occur at 70.32° to the growth direction symmetrically spaced 120° apart.

Key words: semiconductors, crystal growth, III-V compounds.

Recent studies (1) have shown that if the rate of diameter enlargement is such that the angle the growing crystal makes with the <111> growth direction exceeds ~19.68 twins form which are parallel to the <111> surfaces expected at 19.68°. However, if the rate of diameter enlargement results in an angle less than 19.68° so (111) surfaces are avoided, initial twin formation is prevented. So limiting the rate of diameter enlargement while employing growth parameters which result in a nearly planar crystal melt interface reproducibly yields twin-free crystals.

An example of a typical, twinned, crystal is shown in Fig. 1. The surface of this crystal has been sandblasted using 3 μm alumina to produce a uniform matte finish and subsequently etched with concentrated HCl to reveal twins. Conventional cooling procedures alluded to above appear to have been sufficient to prevent strain in crystals of this morphology as stress relief can occur primarily through deformation twinning and slip.

Evidence for the presence of internal stress in twin-free InP crystals was the observation that crystals cooled prior to decreasing the pressure exhibit a greater tendency to crack during wafering.

Twin-free InP crystals (example shown in Fig. 2) cooled to room temperature while a pressure of 38 atm is maintained in the chamber show a rough and

Fig. 1. InP so-called "single" crystal showing <111> parallel twin planes.

Fig. 2. Surface feature typical of twin-free InP crystal cooled at 38 atm pressure.

mottled surface. It is a result of spalling of the B_2O_3 skin remaining on the crystal after growth. Spalling of the crystal surface also occurs due to the development of surface microcracks caused by differential thermal contraction and adhesion of the B_2O_3. A $\langle 111 \rangle$ slice through such a crystal is shown in Fig. 3, and reveals the extent to which surface damage can occur. Further, failure to relieve growth-induced strain causes cracking during wafering. Nominally, 15% of the wafers cut from twin-free crystals improperly annealed crack.

Figure 4 shows a twin-free crystal cooled at the same rate as that in Fig. 3, after the pressure was reduced to 1 atm. In contrast, the surface does not spall and is smooth and free of surface cracks. The B_2O_3 skin remaining on crystals annealed in this manner was also smooth and continuous. In the example shown the B_2O_3 has been removed by washing. Twin-free crystals so annealed show no tendency to crack during

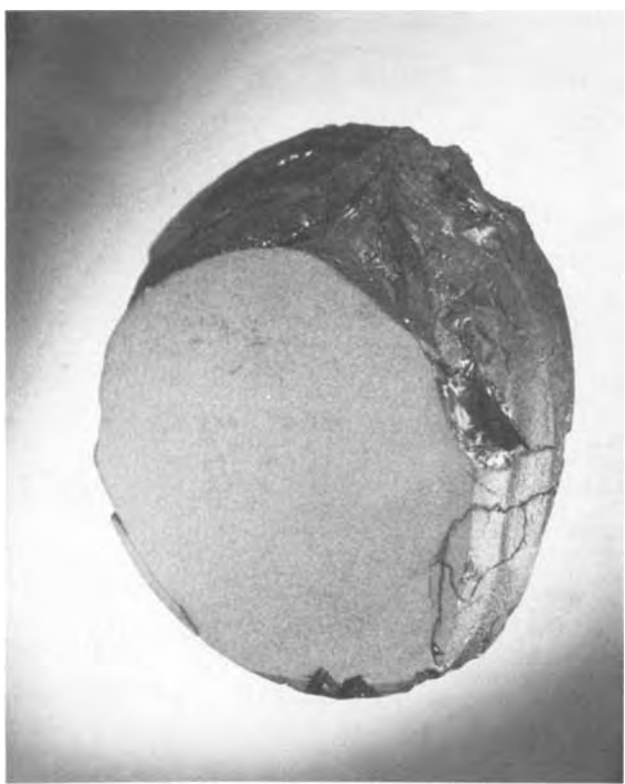

Fig. 3. $\langle 111 \rangle$ slice through twin-free InP boule cooled at 38 atm pressure, 5× showing extent to which surface damage can occur.

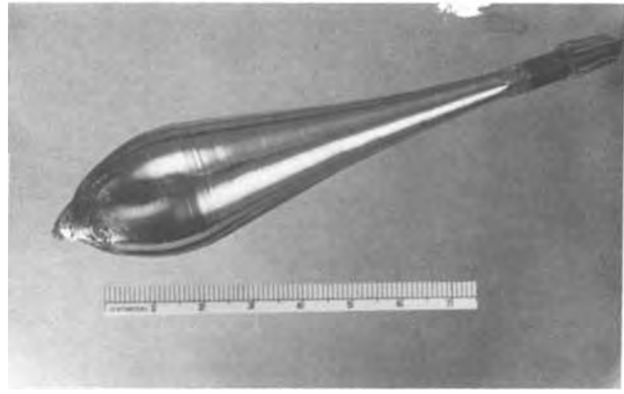

Fig. 4. Surface feature typical of twin-free InP crystal cooled at 1 atm pressure.

wafering, quaternary alloy devices prepared on substrates from these crystals exhibit less variability in device characteristics (5), and substrate cleavage is sharper and cleaner (6).

Growth-induced internal stress responsible for cracking can be relieved and strain prevented in twin-free crystals provided the temperature of the grown crystal is maintained sufficiently high so that the B_2O_3 skin remains somewhat fluid while the ambient pressure is gradually reduced. This is easily accomplished in our apparatus without the use of auxiliary after-heaters by proper positioning of the crystals above the crucible and maintaining rf power to the susceptor. In this regard, it is essential that the entire InP melt be extracted from the crucible during crystal growth, as material remaining in the crucible will decompose at the decreased pressure. Heating of the crystal then occurs by radiation and conduction by the inert gas atmosphere. Strain annealing is accomplished when the inert gas pressure is gradually decreased to 1 atm and the crystal subsequently cooled by decreasing power to the susceptor. The rate of pressure decrease is unimportant. In these studies approximately 1 atm/min was found convenient. Slower rates did not improve the final crystal quality. Cooling rates between 40°C/min and 2°C/min were examined. Qualitatively, stress relief appeared complete if rates 20°C/min or slower were used.

A temperature profile of the growth chamber at 38 atm and 1 atm are shown in Fig. 5. R-f power to the susceptor was maintained at the same level during crystal growth. The position of the crystal and crucible (susceptor) during annealing is indicated. Although a significant thermal gradient exists along the crystal length it has not been found detrimental.

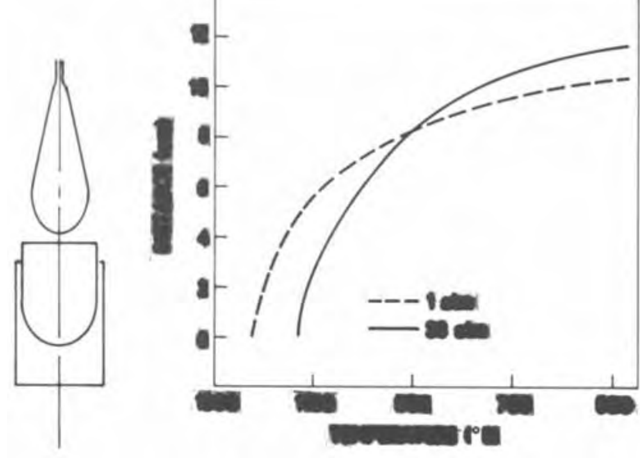

Fig. 5. Temperature profile of growth chamber for 38 atm and 1 atm pressure prior to cooling.

Discussion

In the case of twinned "single" crystals (Fig. 1), differential thermal contraction between InP and the B_2O_3 skin does not present a serious problem. The effects are manifested primarily in the rough surface texture due to spalling, surface cracks, and the formation of above average dislocations near the surface. A plot depicting typical dislocation densities, as revealed by etch pitting on (100) surfaces, for crystals cooled while at 38 atm and cooled after the pressure was reduced to 1 atm, is shown in Fig. 6. The (100) wafers were cut from twin-free crystals grown in a <111> direction. Although the density of dislocations is quite similar for the bulk of material the density near the surface is about ten times greater for crystals cooled prior to decreasing the chamber pressure. TEM studies by Mahajan (7) indicate some of the dislocations near the surface are slip generated.

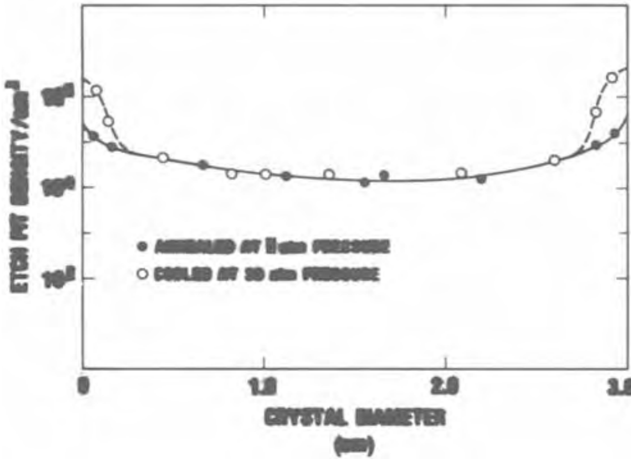

Fig. 6. Idealized plot of dislocation density across (100) InP wafers from crystals cooled at 38 atm and 1 atm.

No attempt has been made to measure the magnitude of the stresses due to differential thermal contraction. A smooth, continuous B_2O_3 skin has, however, been observed on twin-free InP crystals cooled prior to lowering the pressure provided very slow cooling rates ($<1°C/min$) were used. However, in such cases, the B_2O_3 skin and crystal surface decrepitate with some degree of violence upon simply touching or washing. Crystals annealed in this manner also crack severely during wafering, suggesting relief of growth-induced strain was restricted. It is apparent then that cooling of twin-free InP crystals at low ambient pressure in the growth chamber is essential in order to minimize the effects of growth-induced stress and prevent surface deformation resulting from differential thermal contraction of the encapsulant.

Epitaxial Growth of Cubic ZnS_xSe_{1-x} by Vapor Phase Transport

D. Etienne, L. Soonckindt, and G. Bougnot

Centre d'Etudes d'Electronique des Solides (associé au C.N.R.S.),

Université des Sciences et Techniques du Languedoc, 34060 Montpellier Cedex, France

ABSTRACT

Films of cubic ZnS_xSe_{1-x} have been grown epitaxially on cleaved CaF_2 substrates by vapor phase transport in flowing hydrogen and the conditions to obtain epitaxial deposits of these compounds have been determined. The effects of gas flow rates and both source and substrate temperatures on the composition x have been investigated. The composition dependence of the bandgap was determined by photovoltage measurements.

II-VI compound semiconductors and their alloys cover a wide range of electrical and optical properties which make them potentially useful for a variety of practical applications. These include luminescence, photoconductive, acoustoelectric properties and p-n junction light emitting diodes. Unfortunately, the synthesis of these materials is frequently complicated by the combination of high melting temperatures and dissociation pressures. However, many of the difficulties associated with these complications are minimized when vapor phase crystal growth methods are employed, primarily because of the low growth temperatures involved with this technique.

Among the different possible approaches to the vapor deposition of II-VI compounds, only open-tube flow methods offer the flexibility and control needed to prepare compounds or alloys, with widely varying composition, doping, and geometries.

For ZnSe, ZnS, the literature describes many methods dealing with the growth of ZnSe (1-5) or ZnS

Key words: chemical vapor deposition, semiconductors, electronics.

(6-9), but information on the zinc sulfoselenide system, however, is rather sketchy (4, 10-12) and the crystals obtained are reported to be inhomogeneous.

Recently a method has been developed (13) for growing ZnS_xSe_{1-x} boules with uniform composition and consisting in several grains, using the iodine vapor transport technique in a sealed ampul.

In a previous paper, we had briefly described the application of an open-tube system for the preparation of ZnS_xSe_{1-x} (14). In that system, deposition of epitaxial films of ZnS_xSe_{1-x} composition in the range $0 \leq x \leq 1$ was carried out on calcium fluoride (CaF_2) substrates by reaction of hydrogen with the compound in powdered form. In the present paper, we wish to give more details on the results thus obtained.

Growth Procedure

The growth apparatus previously described for ZnS and ZnSe (15, 16) was modified for growing ZnS_xSe_{1-x} by flowing H_2 over two independent sources (Fig. 1).

The reaction chamber consisted of a 30 mm inner diameter, 1m long quartz tube. It was positioned in a horizontal two-zone furnace which provided the temperature profile needed for the sources and for the epitaxial deposition.

The CaF_2 substrates (1×1 cm^2 area) were cleaved in a (111) plane, mechanically polished to a mirror-smooth finish and etched with a HCl-HNO_3 (1:1) solution. The operation of the system may be summarized as follows: the tube is first flushed with hydrogen, then the sources and deposition zone are brought to the required temperatures, and by means of a quartz push rod, the substrate is moved into the deposition zone and etched *in situ* in flowing H_2. The hydrogen flow and deposition is commenced when the temperature of the substrate is reasonably stable.

Growth times were between 1 and 8 hr, yielding films between 5 and 40 μm thick. At the end of the run the furnace was slowly cooled (100°C/hr) to room temperature in order to avoid cracks arising from the difference in the thermal expansion coefficients. This difference is one of the most important factors to be considered in selecting suitable substrate materials in addition to the room temperature lattice constant. In fact, CaF_2, in spite of its good lattice match (5.482Å for CaF_2, 5.6687Å and 5.4093Å for ZnSe and ZnS) shows a relatively large difference in the thermal expansion coefficients ($19 \cdot 10^{-6}$ °C^{-1} for CaF_2, $6.7 \cdot 10^{-6}$ °C^{-1} for ZnSe and ZnS at room temperature). The epitaxial deposition was carried out at a source temperature within the 800°-950°C range (usually 850°C for both ZnS and ZnSe sources), total hydrogen flow rates of about 100-300 cm^3 min^{-1}, and substrate temperatures within the 630°-780°C range. The linear velocity (defined as the ratio of the carrier gas flow rate to the cross section of the reaction tube) of the system depends on the flow rate over the two sources.

Theoretical Determination of Composition in ZnS_xSe_{1-x}

The composition x was determined by a simple formula, based on the thermodynamics of the equilibria.

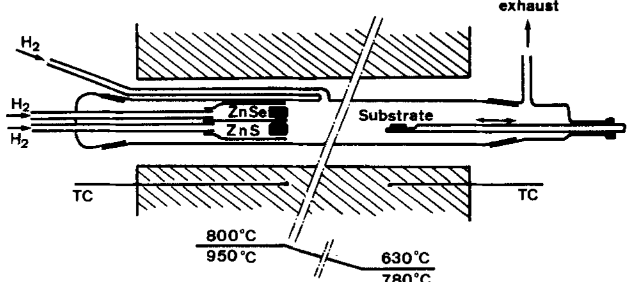

Fig. 1. ZnS_xSe_{1-x} vapor growth system: experimental arrangement and temperature profile during growth.

The mechanism for the ZnS_xSe_{1-x} formation involves six chemical reactions

$$Zn(g) + (1-x)\,H_2Se(g) + x\,H_2S(g) = ZnS_xSe_{1-x}(s) + H_2(g) \quad [1]$$

$$H_2(g) + 2Zn(g) = 2ZnH(g) \quad [2]$$

$$H_2(g) + \tfrac{1}{2}\,Se_2(g) = H_2Se(g) \quad [3]$$

$$H_2(g) + \tfrac{1}{2}\,S_2(g) = H_2S(g) \quad [4]$$

$$3Se_2(g) = Se_6(g) \quad [5]$$

$$4S_2(g) = S_8(g) \quad [6]$$

Equation [1] may be considered as the superposition of two chemical reactions due to hydrogen over two independent solid sources

$$ZnSe(s) + H_2(g) = Zn(g) + H_2Se(g)$$

$$ZnS(s) + H_2(g) = Zn(g) + H_2S(g)$$

Lever's principle (17) of resolution, which is based on Gibb's phase rule and which was improved by Hurle and Mullin (18) was used (19) for the determination of the equilibria constant K_p.

The values of the partial pressures are calculated for each chemical substance able to exist in a vapor state on the basis of a thermodynamical equilibrium between solid and vapor phase. If "p_j" represents the partial pressure of the gaseous species "j", and if "n_i" stands for the total number of atoms per unit volume of the constituent "i" in an elemental or compound form in the gaseous mixture at the output of the two sources, the equations enabling us to give an overall description of the system are:

The six relations between partial pressures corresponding to the chemical equilibria [1]-[6].

The constancy of the total pressure

$$P_o = \sum p_j \text{ with } P_o = 1 \text{ atm.}$$

The stoichiometry conservation

$$P_{Zn} + P_{ZnH} = 2P_{Se_2} + 6P_{Se_6} + P_{SeH_2} + P_{SH_2} + 2P_{S_2} + 8P_{S_8}$$

The concentration x in zinc sulfide in the vapor phase with source at temperature T_1, given by

$$\frac{x}{1-x} = \frac{n_s}{n_{Se}} = \frac{2P_{S_2} + 8P_{S_8} + P_{SH_2}}{2P_{Se_2} + 6P_{Se_6} + P_{SeH_2}}$$

From these conditions, the partial pressures of each gaseous species are calculated in all the range of temperature and composition (Fig. 2, 3).

One concludes that the main gaseous species are Zn, H_2Se, H_2S, and to a less extent, S_2, Se_2, and ZnH.

Let $\gamma = (D^oH_2)_{ZnS}/(D^oH_2)_{ZnSe}$, where $(D^oH_2)_{ZnS}$, $(D^oH_2)_{ZnSe}$ are, respectively, the hydrogen flow rates over the ZnS and ZnSe sources, as measured at room temperature.

At the source temperature T_1

$$\gamma \simeq \frac{(D_{H_2})_{ZnS}}{(D_{H_2})_{ZnSe}} = \frac{V_{ZnS}}{V_{ZnSe}}$$

V_{ZnS} and V_{ZnSe} are the linear velocities over the separate sources, $(D_{H_2})_{ZnS}$ and $(D_{H_2})_{ZnSe}$ the H_2 flow rate at T_1. Atomic fluxes leaving the sources regions are given by

$$J_i = N_i \cdot V_{ZnS \text{ or } ZnSe}, \text{ with } N_i = \sum_{j=1}^{j=m} \lambda_{ij} \frac{P_j}{RT_1}$$

N_i is the total number of "i" atoms over each source and λ_{ij} is the stoichiometric coefficient of the ith element in the jth specie. For the ZnS and ZnSe sources

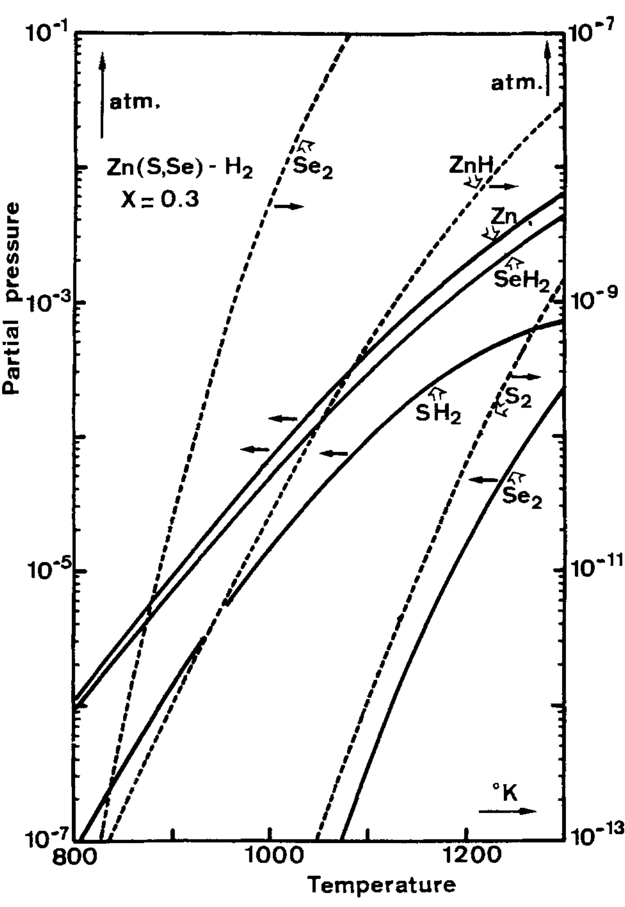

Fig. 2. Partial pressure in the system ZnS_xSe_{1-x}-H_2 as a function of temperature for $x = 0.3$.

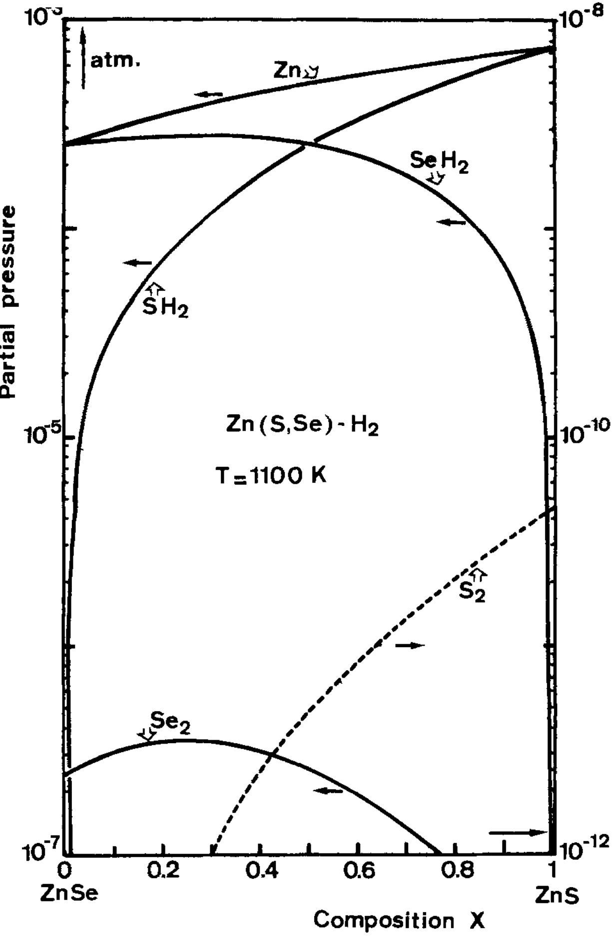

Fig. 3. Partial pressure in the system ZnS_xSe_{1-x}-H_2 as a function of composition x for $T = 1100°K$.

$$J_S = \frac{V_{ZnS}}{RT_1}\,[2P_{S_2} + P_{SH_2}]_{T_1/ZnS}$$

$$J_{Se} = \frac{V_{ZnSe}}{RT_1}\,[2P_{Se_2} + P_{SeH_2}]_{T_1/ZnSe}$$

$$= \frac{1}{\gamma}\cdot\frac{V_{ZnS}}{RT_1}\,[2P_{Se_2} + P_{SeH_2}]_{T_1/ZnSe}$$

where the partial pressures are now calculated in the systems ZnS/H_2 and $ZnSe/H_2$, separately considered at temperature T_1. Then, the composition x is determined by

$$\frac{x}{1-x} = \frac{J_S}{J_{Se}} = \gamma\cdot\frac{[2P_{S_2} + P_{H_2S}]_{T_1/ZnS}}{[2P_{Se_2} + P_{H_2Se}]_{T_1/ZnSe}} \quad [7]$$

So, it is possible to calculate the theoretical composition x, in terms of the ratio γ of the hydrogen flow rates over the ZnSe and ZnS sources and with variation of sources temperature T_1.

Experimental Results

Morphology and crystal structure.—The growth temperature is one of the important parameters which determine the crystal quality and morphology. The epitaxial quality of the individual films was evaluated primarily by means of microscopic studies of the film surfaces. These studies were initially checked against x-ray and electron diffraction results.

Figure 4a and b are photomicrographs of the as-grown surfaces of two $ZnS_xSe_{1=x}$ films, with various parameters. In both cases, the layers deposited di-

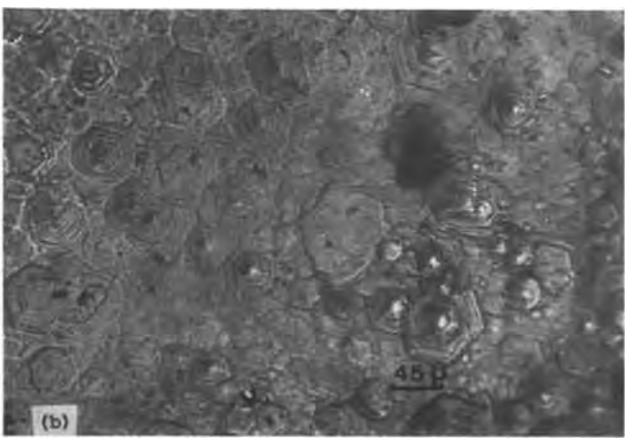

Fig. 4. Photomicrographs of ZnS_xSe_{1-x} layers grown on (111) CaF_2 substrates: (a) $x = 0.22$, source temperature 850°C, substrate temperature 780°C, $\gamma = 0.1$; (b) $x = 0.86$, source temperature 850°C, substrate temperature 730°C, $\gamma = 2$.

rectly on (111)-CaF_2 substrates showed well-defined microstructure, and revealed well-oriented triangular growth pattern, characteristic of the (111) epitaxy.

Reflection electron diffraction was used to determine the crystalline quality of the layers. The investigations give structural information about highly localized areas of the deposited layers. Figure 5 shows reflection electron diffraction patterns of the alloy layer with various composition and various growth temperatures. The diffraction pattern consists in strong spots which indicates a good crystalline structure. The alloy layers were single crystals with the some orientation as the substrate.

In some cases (substrate temperature $< 650°C$), the diffraction pattern indicates a good single crystal structure although the superimposed satellite spots do suggest the inclusion of structural defects such as twins or stacking faults. For substrate temperature of 630°C, the diffraction pattern shows so-called Debye rings; this indicates a polycrystalline structure. Figure 6 shows x-ray (CuKα) diffraction patterns from the films deposited on CaF_2 substrate. The layers investigated were between 5 and 15 μm thick and were not etched before the measurements. It shows only a reflection from the (111) planes. By using this growth method, ZnS, ZnSe, and $ZnS_xSe_{1=x}$ high quality films are obtained with high reproducibility and these x-ray diffractometer scans proved the results of the reflection electron diffraction.

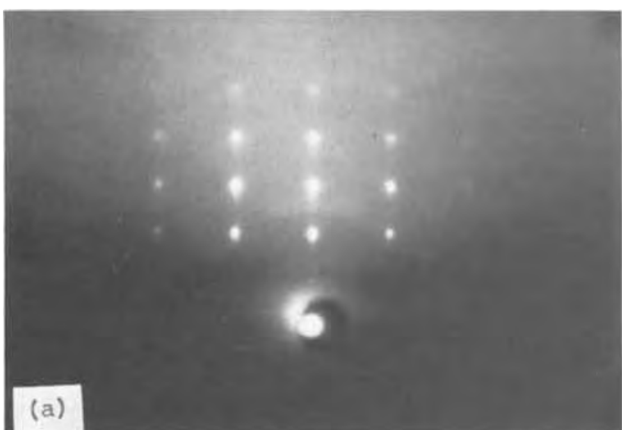
Results on the x variation.—Figure 7 shows the variation of composition x *vs.* the ratio γ for the same source temperature 850°C and for two substrate temperatures 730° and 780°C. It is possible, at a substrate temperature $T_2 = 730°C$, to obtain a composition x in the range $0 < x < 0.5$; with the temperature $T_2 = 780°C$, the composition range is $0.5 < x < 1$.

The composition x was determined from lattice-constant measurements on the basis of Vegard's law or by electron probe microanalyzer. The solid curves represent the theoretical variations of x, in function of γ, which were obtained from calculations using Eq. [7]. Good agreement is found with the experimental values, it confirms that the S content in the vapor phase is increasing with increasing flow over the ZnS source (high γ values).

With the source temperature T_1, the variation of composition x is shown on Fig. 8 for different substrate temperatures and different values of γ. The solid curves represent the theoretical values of x (Eq. [7]), and good agreement is found with the experimental values. We observe that a wide range of x values may be obtained by varying γ, but these x values are rather insensitive to the sources temperatures.

Figure 9 shows the variation of composition x with substrate temperature T_2. Such a variation is not expected from the theory; the composition x should depend only on T_1 and not on T_2, since from the equation of continuity, the concentration of ZnS must be the same at the source and substrate temperatures. This variation of composition x with T_2 can be explained by the nucleation on the wall of the reaction chamber. At high temperature, the Se is the first deposit experimentally observed, and at low temperature the S concentration is higher than the Se one. In this case the composition x is a function of the substrate temperature and the composition x decreases with the increasing of T_2. However, these experimental results show that the composition remains constant with the substrate temperature for two ranges of temperature. For $\gamma < 0.5$, the composition is constant with $T_2 > 750°C$, and for $T_2 < 750°C$ the composition is varying in function of T_2. The same results are observed for $T_2 < 750°C$ and $\gamma > 0.5$. In this range of temperature, the composition for different γ remains constant *vs.* T_2.

This result is consistent with the curve of Fig. 7. For $T_2 = 780°C$ ($T_2 > 750°C$), the composition is well defined and any variation occurs with the substrate temperature according to the theory. For $T_2 = 730°C$ ($T_2 < 750°C$), in the range $0.5 < \gamma < 4$, any influence of substrate temperature occurs.



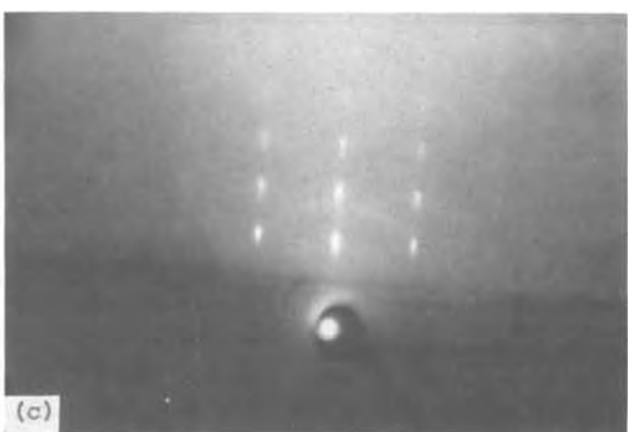


Fig. 5. Reflection electron diffraction pattern: (a) $x = 0.22$, substrate temperature 780°C, $\gamma = 0.1$; (b) $x = 0.6$, substrate temperature 730°C, $\gamma = 0.5$; (c) $x = 0.9$, substrate temperature 730°C, $\gamma = 2$.

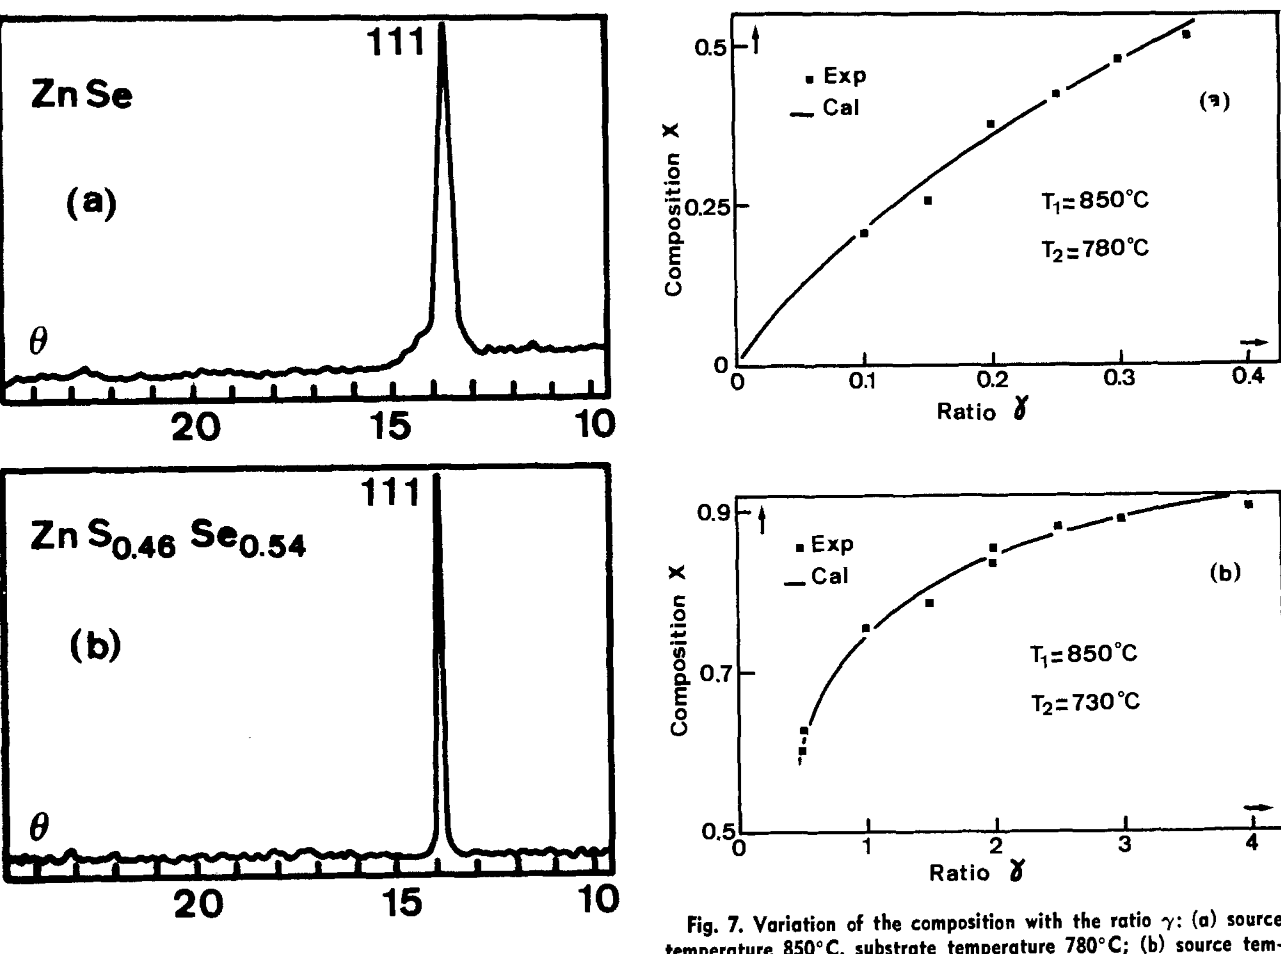

Fig. 6. X-ray diffraction scan: (a) ZnSe layer, substrate temperature 730°C; (b) $ZnS_{0.46}Se_{0.54}$ layer, substrate temperature 780°C, $\gamma = 0.3$; (c) ZnS layer, substrate temperature 750°C.

Electro-Optical Characterization of the Samples

Method of measurement.—The technique used is based on the Kelvin method (20). It consists in measuring the contact potential V_{cp} between the surface and a reference electrode. From the variation of V_{cp} it is possible to obtain the variation of the surface potential V_s. To increase the sensitivity of the systems, we used a wavelength modulation technique (21), so as to get directly the derivative $dV_{cp}/d\lambda = dV_s/d\lambda$ of the signal with respect to the wavelength. The measurement cell is a capacitance constituted by the sample in front of which a semitransparent electrode is placed parallel to the semiconductor surface, about 0.2 mm away. In series with the capacitance is a high input impedance amplifier. The illumination of the sample with pulsed radiation of energy $h\nu > E_c - E_v$ gives variations of dV_s of the barrier potential V_s. In the circuit then appears a pulsed current whose amplitude is proportional to dV_s.

Fig. 7. Variation of the composition with the ratio γ: (a) source temperature 850°C, substrate temperature 780°C; (b) source temperature 850°C, substrate temperature 730°C.

The method can be used over a wide temperature range and does not need any contact or evaporation of a semitransparent electrode on the sample. It does not require the measurement of the incident or reflected light intensity and any optical detector is not required for the measurement of $dV_{cp}/d\lambda$. The sensitivity is good and the signal-to-noise ratio is better than the field electroreflectance for the same conditions of surface states.

Experimental results.—The composition dependence of the fundamental bandgap at 300°K is given on Fig. 10. Our results fit with good approximation the quadratic expression in x

$$E_o(x)\text{eV} = 2.721 + 0.352x + 0.630x^2$$

given by Ebina *et al.* (11) from reflectivity measurements on cleaved single crystals. We have studied the variation of the fundamental bandgap with temperature on samples of different composition.

Figure 11 shows the wavelength modulated surface photovoltage spectra of zinc selenide epitaxial layers near the fundamental edge for different temperatures; the width of the curve at midheight is close to 35-40 meV.

The variations of the fundamental bandgap were studied on samples of composition $x = 0$; 0.4; 0.6; 1. Figure 12 shows this variation for zinc selenide and zinc sulfo-selenide epitaxial layers with $x = 0.4$. The variations are found to be linear in the temperature range studied. The values of the variation of the gap are listed on Table I.

Conclusion

The investigations carried out indicate that the technique described can be successfully used for obtaining

ABSTRACT

New data for the resistivity-dopant density relationship for phosphorus-doped silicon have been obtained for phosphorus densities between 10^{13} and 10^{20} cm^{-3} and temperatures of 296°K (23°C) and 300°K. For dopant densities less than 10^{18} cm^{-3}, results were calculated from resistivity and junction capacitance-voltage measurements on processed wafers. For more heavily doped material, data were obtained from Hall effect and resistivity measurements on specimens cut from bulk silicon slices. The results differ by 5-15% from the commonly used Irvin curve, always in the direction of lower dopant density for a given resistivity. For comparison with the electrical measurements, phosphorus densities were also obtained by neutron activation analysis and the photometric technique. The values from these methods were within 10% of the electrical results. Analytical fits were determined for the resistivity-dopant density product as a function of resistivity and dopant density for temperatures of 23°C and 300°K. Similar fits were obtained for the calculated electron mobility as a function of resistivity and electron density.

The conversion between resistivity and dopant density of silicon is widely used in the semiconductor industry. In device design, the calculation of various parameters such as breakdown voltage involves relating resistivity, which can be readily measured, to dopant density, which is the desired quantity but very difficult to measure directly. Applications using the conversion over many decades of dopant density include the calculation of the surface dopant density of a diffused layer from the sheet resistance-junction depth product and the determination of a dopant density profile from anodic oxidation/incremental sheet resistance measurements. Significant error in the results of these measurements occurs when incorrect expressions are used to relate resistivity and dopant density.

During the past decade, the most frequently used conversion curves for both n- and p-type silicon are those formulated by Caughey and Thomas (1) based on the curves of Irvin (2). Irvin's curve for n-type material includes measurements on silicon doped with arsenic, antimony, and phosphorus. More recently Baccarani and Ostoja (3) published a conversion for phosphorus-doped silicon which agrees with that of Irvin at low phosphorus densities but departs at high densities with a difference of 30% at 10^{20} cm^{-3}. This paper describes the results of a comprehensive redetermination of the resistivity-dopant density relationship for phosphorus-doped silicon. Differences of 5-15% from the n-type Irvin curve were found, always in the direction of lower dopant density for a given resistivity. A preliminary report on this work was presented earlier (4).

Electrical Measurements

For dopant densities of 10^{18} cm^{-3} or less, data were obtained from test structures fabricated on silicon slices. The resistivity was measured directly on planar four-probe square array structures described in detail elsewhere (5). A cross-sectional view of this structure is shown in Fig. 1. The dopant density was determined from capacitance-voltage (C-V) measurements (6) on p^+n junction diodes. These test structures and other diagnostic structures were assembled on microelectronic test patterns NBS-3 (7) and NBS-4 (8) which were prepared especially for this work.

The starting material, in both ingot and slice form, was obtained from several different suppliers and was selected for minimum resistivity gradients by mechanical four-probe measurements prior to fabrication of the test patterns by bipolar processing (9). The difference between center and half radius resistivity

Key words: electron mobility, Hall effect, neutron activation analysis, photometric technique, semiconductor.

values ranged from −3% to +7% with an average absolute difference of +2.5% for the material used in this study. The resistivity data obtained from the square array structures after processing agreed to within a few percent with the mechanical four-probe measurements prior to fabrication. Most of the results on high resistivity material were obtained on neutron transmutation doped silicon which was much more uniform than material doped by conventional techniques. Leakage current measurements were made on the processed wafers to verify the fabrication and to assure proper operation of the test structures.

The dopant density of the collector region was obtained by the junction C-V method (6) on the gated base-collector diode structure shown schematically in Fig. 2. This method gives the net dopant density, *i.e.*, the number of dopant atoms in excess of any compensating atoms. For the C-V measurements, the gate was biased at the flatband voltage which was determined from C_{min}-C_{max} measurements on an MOS capacitor structure on the test pattern (10). The dopant density calculated from the C-V method is sensitive to the value used for the diameter of the diode as the diameter enters as the fourth power. The diameters (nominally 432 μm) of several diodes were measured by a scanning interferometer (11). These results were then used as a calibration for determining from photomicrographs the diameters of other diodes from each processing run of wafers. The uncertainty in the diameter is estimated to be less than 1 μm. The base junction depth, used in the analysis of the C-V data, was measured by the groove and stain technique (12) with an estimated error of $\pm$0.1 μm.

Dopant density values were calculated from the C-V data pairs using a computer program which includes corrections for peripheral effects and for back depletion into the diffused base region (13). A fitting procedure (14) was incorporated into the program in which a Gaussian shape is assumed for the base diffusion near the junction, and the surface concentration of the diffusion and the background dopant density are adjusted to give a best fit to all the C-V data. The fitting procedure made it possible to obtain results on wafers with dopant densities greater than 10^{17} cm^{-3} which otherwise could not be measured because of compensation by the diffusion tail within the obtainable depletion depth. Errors in the dopant density due to uncertainties in the surface dopant density of the diffusion, junction depth, and random measurement error were examined in idealized data studies (14). Based on these studies, the errors caused by uncertainties in these parameters for the wafers in this work are expected to be less than 1%. In the calculations, a value of 11.7 (15) was used for the relative dielectric constant of silicon. For a few of the lightly doped wafers, it was not necessary to use the fitting procedure for reducing the C-V data to dopant density.

The square array resistivity results were corrected to 23°C and 300°K from the actual measurement temperatures using published coefficients (16). The C-V measurements were made at room temperature; no correction for temperature is required because the dopant is completely ionized in the depletion layer.

The procedure used for correlating the resistivity and dopant density values was slightly different for the two test patterns. On test pattern NBS-3, the one four-probe resistor structure on the pattern, which is repeated over the entire wafer, is located about 2.5 mm from the diode used for the dopant density measurements. In order to minimize the influence of resistivity variations over the wafer, the average of the resistivities measured on the two four-probe resistors on either side of the diode was taken as the resistivity corresponding to the dopant density at that diode site. On test pattern NBS-4, there are three four-probe resistor structures (with different collector pipe sizes for measuring a wide range of resistivities) located within 1.2 mm of the base-collector diode. On this pattern, an average resistivity was obtained from measurements on two or more of these structures for correlation with the dopant density determined from C-V measurements on the diode. Typically, for wafers fabricated with either test pattern, data were collected for six sites near the center of each wafer and the results averaged. Mobility values calculated for a small number of the wafers were judged significantly below those from other wafers with similar dopant densities. Data from these wafers were omitted from the analysis so that the curves would represent good material without compensation or other problems.

Fig. 2. Cross-sectional view of the base-collector diode used for the junction C-V measurements of dopant density.

For dopant densities greater than 10^{19} cm^{-3}, Hall effect and resistivity measurements were made on van der Pauw specimens ultrasonically cut from bulk silicon slices. The shape of the specimens is shown in Fig. 3. The measurements were made at controlled temperatures of 23°C and 300°K for a magnetic flux density of 0.6 *T* (6 kG) following standard procedures (17). The commercial Hall probe for measuring the flux density was calibrated using an NMR gaussmeter. The integrating digital voltmeter used for all the voltage measurements was calibrated using a standard voltage source and a standard cell. The standard resistors used for the determination of the current through the specimens were calibrated against other standard resistors with known values.

The electron density, n, was calculated from the expression $n = -r/qR_H$, where q is the electronic charge, R_H is the Hall coefficient, and r is the Hall scattering factor which is unity for heavily doped material. The Hall effect was not used for material

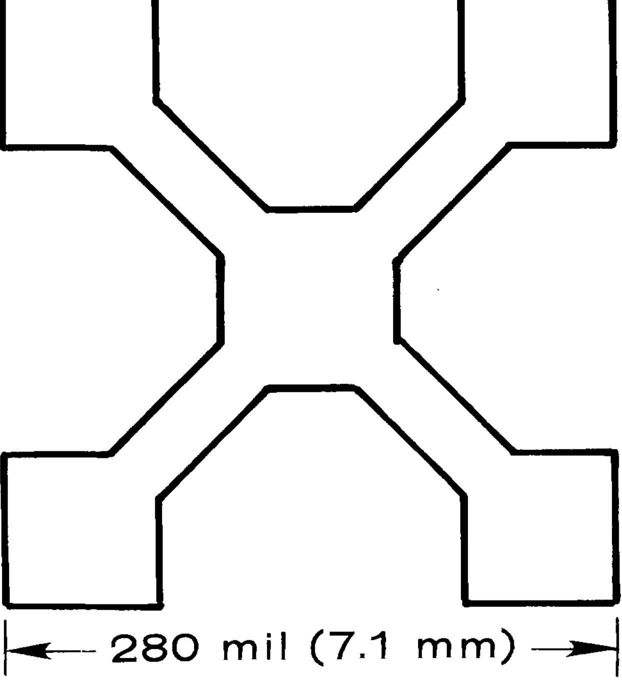

Fig. 3. Shape of van der Pauw specimens ultrasonically cut from bulk silicon slices.

doped less than 10^{19} cm^{-3} because of the unknown value of the Hall scattering factor.

Chemical Techniques

Chemical measurements of phosphorus density were made for comparison with the electrical data as a check on systematic errors and to determine the agreement between total and electrically active densities. The chemical techniques were also used for confirmation of the curve fit in the region between the Hall effect and C-V measurements.

Neutron activation analysis.[1]—Neutron activation analysis was used to determine the phosphorus content in about 20 silicon slices with phosphorus densities between 10^{15} and 10^{20} cm^{-3} (18). The majority of these slices were cut from ingots used for the other measurements. The slices and suitable phosphorus monitors were irradiated for 14 hr at a nominal flux of 1×10^{13} $n \cdot$cm$^{-2} \cdot$sec^{-1} in the Texas A&M reactor. After removal from the reactor, the slices were cleaned and placed on x-ray film to check the dopant uniformity by autoradiography. Using the autoradiograms as guides, a uniformly doped region about 2 cm square was scribed from the center of each slice for beta counting, and the specimens were dissolved in 1:3 HF:HNO_3. Three or four aliquots of the solution were dried on filter paper and counted for each slice. The monitors, $NH_4H_2PO_4$, were dissolved in deionized water and aliquots were pipetted onto filter paper for counting by the same method used for the slices. The samples were allowed to decay for either 17 or 21 days after irradiation before beta counting to decrease the considerable ^{31}Si activity. Gamma ray surveys during the decay period did not detect any major interferences. Half-life determinations ($T_{1/2}$ = 14.4 days) were made for positive identification of the ^{32}P isotope. Phosphorus counts from both the slices and monitors were corrected for background and decay over the counting time. The phosphorus concentrations in atoms/cm^3 were calculated from the weights of the samples counted and the ratios of the ^{32}P activity from slices and monitors.

Photometric technique.[2]—The photometric technique (19), also known as the colorimetric method, was used to analyze nine silicon slices with phosphorus densities from 2×10^{17} to 5×10^{19} cm^{-3}. The slices were dissolved in platinum dishes in nitric acid with the addition of small amounts of hydrofluoric acid. The solutions were diluted with perchloric acid and heated to evaporate the nitric and hydrofluoric acids. They were then diluted with water, reduced by heating with bisulfite, and the phosphorus color was developed by the successive addition of bismuth sulfate, ammonium molybdate, and ascorbic acid solutions. Spectrophotometric measurements were made in a 1 cm cell. For the smaller amounts of phosphorus, the phosphomolybdate complex was extracted into 10 ml of iso-butyl alcohol and the absorbance measured against synthetic standards which went through all steps of the procedure including the extraction part. Each dissolved slice was divided into at least two and sometimes three or four portions for analysis. For heavily doped material, individual values had a spread of less than 2%. At the lightly doped end, the spread increased to 10%. For two slices, additional phosphorus was added to the solution for one portion of each slice. The added phosphorus was deducted from the final result which was in excellent agreement with that from the unadulterated portions of each slice.

Results

Figure 4 is a graph of the product of resistivity and dopant density as a function of resistivity at

[1] Work performed under the direction of Dr. Joseph A. Keenan at Texas Instruments, Incorporated, Dallas, Texas.

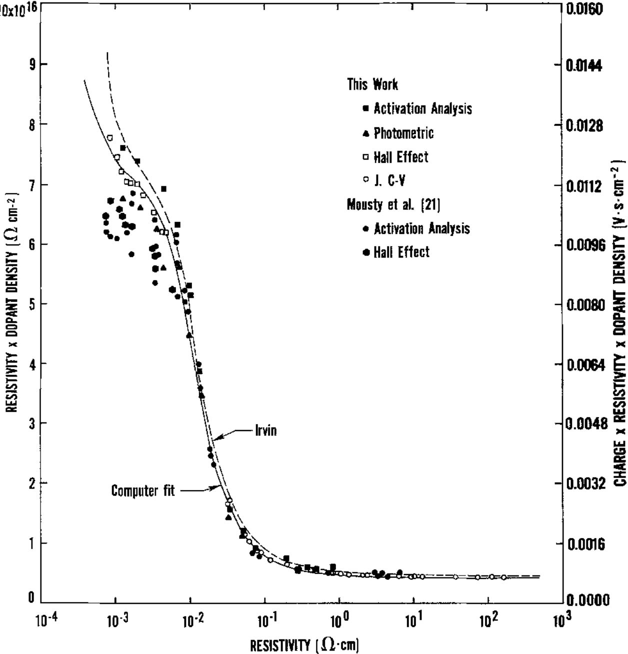

Fig. 4. Resistivity-dopant density product for phosphorus-doped silicon at 300°K. Results of this work are compared with those of Mousty et al. (21) and Irvin (2). Values of the $q\rho N$ product are on the right ordinate.

300°K. Since to the first approximation resistivity is inversely proportional to dopant density, a plot of the product allows deviations from this relationship to be seen, particularly for low resistivities where the product is large. As seen in Fig. 4, there is a systematic difference between the results from neutron activation analysis and those from the photometric technique. The data points from the Hall effect, which measures only electrically active phosphorus, lie between the two chemical techniques. Even though the chemical techniques are less sensitive for low dopant densities, the data from these techniques are in good agreement with the junction C-V results. A more detailed comparison of the chemical and electrical results is available elsewhere (20). The data of Mousty *et al.* (21), obtained from resistivity measurements and either neutron activation analysis or Hall effect for phosphorus density, are also plotted in Fig. 4. Their results are in reasonable agreement with this work except at the low resistivity end where differences are as large as 15%. Both the Irvin (2) curve and the computer fit to the data of this work are also shown in Fig. 4. Throughout the resistivity range the fit to the data presented here is displaced from the Irvin curve in the direction of lower dopant density for a given resistivity. The difference varies between 5 and 15% over the resistivity range with somewhat larger deviations below 1 Ω·cm than above.

Figure 5 is a graph of electron mobility at 300°K as a function of electron density. The junction C-V results of the present work were converted to electron density using the percent ionization calculations of Li and Thurber (22). For example, at a dopant density of 10^{18} cm^{-3} about 10% of the phosphorus atoms are not ionized in equilibrium but they are counted by the C-V method as all atoms are ionized in the depletion layer. Consequently, the dopant density measured by C-V must be reduced by the fraction of atoms not ionized to obtain the electron density before the carrier mobility is calculated. No such reduction is needed for results from Hall effect measurements as the Hall effect is a transport phenomenon for which equilibrium conditions exist. In addition, for heavily doped material, conduction is metallic-like and each dopant atom contributes an electron for conduction.

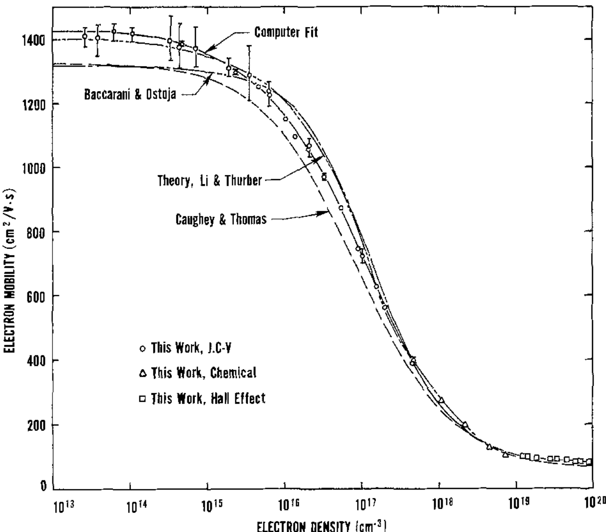

Fig. 5. Electron mobility as a function of electron density for phosphorus-doped silicon at 300°K. The junction C-V data have been corrected for deionization using the calculations of Li and Thurber (22). The error bars are the standard deviation in the individual mobility values for that wafer. When not shown, the error bars lie within the plotted symbol. Shown for comparison with the computer fit to the data are the mobility expressions of Caughey and Thomas (1), Baccarani and Ostoja (3), and the theoretical calculation of Li and Thurber (22).

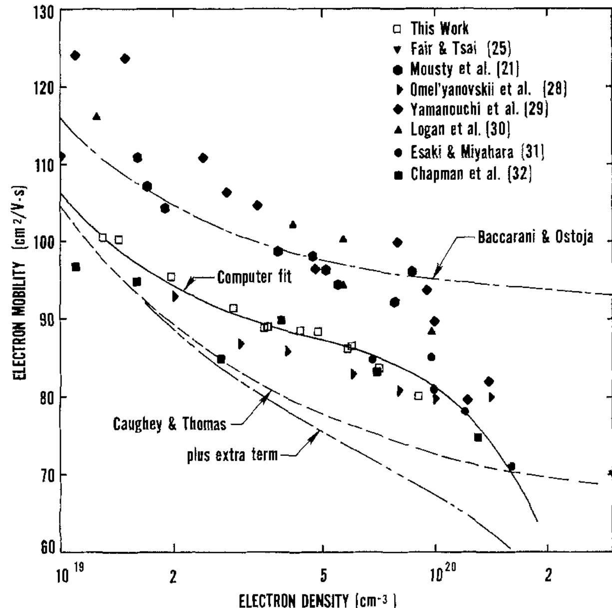

Fig. 6. Electron mobility determined from Hall effect measurements for electron densities greater than 10^{19} cm^{-3}. The computer fit to the data of this work lies between the mobility expressions of Caughey and Thomas (1) and Baccarani and Ostoja (3). The extra term in the modified Caughey and Thomas expression is given by Plunkett *et al.* (24).

The theoretical curve of Li and Thurber (22) in Fig. 5 is in good agreement with the experimental results. The Caughey and Thomas mobility expression for n-type silicon (1) gives significantly lower mobility at low electron density as shown in Fig. 5. The Caughey and Thomas expression is a fit to the Irvin curve with the assumption that the electron density equals the dopant density. This is true except for moderately doped material prior to the onset of metallic conduction at about 3×10^{18} cm^{-3}. For phosphorus densities greater than about 5×10^{19} cm^{-3}, the formation of phosphorus-vacancy pairs gives rise to electrically inactive atoms (23).

Also shown in Fig. 5 is the mobility expression of Baccarani and Ostoja (3) based on the data of Mousty *et al.* (21) with the assumption that electron and dopant densities are equal. For comparison with the other curves, the Baccarani and Ostoja expression has been corrected to 300°K since the Mousty data were taken at 23°C. At low dopant densities, the Baccarani and Ostoja curve is about 7% below the data of this work. In the range 10^{16} to 5×10^{17} cm^{-3}, their curve is parallel to, but about 5% above, the results of this work. At high dopant densities, the Baccarani and Ostoja curve gives values between 10 and 20% larger than those obtained in this work as is seen more clearly in Fig. 6.

For detailed comparison with the results of other workers, the electron mobility for densities greater than 10^{19} cm^{-3} is plotted in Fig. 6. All of the results shown were obtained by Hall effect and resistivity measurements with the assumption that the Hall scattering factor was unity. In this dopant range, the Caughey and Thomas curve is lower and the Baccarani and Ostoja curve is higher than the results of this work. The modification of the Caughey and Thomas expression shown in the figure consists of multiplying the constant μ_{min} by a term which decreases μ_{min} at high electron densities (24). The computer fit to the data, discussed in the next section, is also shown in Fig. 6.

With the exception of the data point of Fair and Tsai (25), all of the results in Fig. 6 were obtained on silicon doped during crystal growth. Recently Masetti and Solmi (26) have made extensive measurements on silicon heavily doped by thermal diffusion. Their mobility values obtained from incremental sheet resistance and Hall effect measurements are in good agreement with those of this work. They concluded, from a comparison of their data with those of Mousty *et al.*, that the mobility in diffused phosphorus-doped silicon is always lower than that in uniformly doped silicon for $n > 10^{19}$ cm^{-3}. However, when the results of Mosetti and Solmi are compared with those of this work, the conclusion is that the mobility is the same in diffused and uniformly doped silicon.

Computer Curve Fits

The curve fits of the data were done using the DATAPLOT language (27) for the nonlinear least squares fitting. The simplest expression which gave a fit of the same precision as the uncertainty in the experimental data was a third degree polynominal divided by a third degree polynominal. The equation for fitting the resistivity-dopant density product is of the form

$$\log_{10}(P/P_o) = \frac{A_0 + A_1X + A_2X^2 + A_3X^3}{1 + B_1X + B_2X^2 + B_3X^3} \quad [1]$$

with $P = q\rho N$ where q is the electronic charge, ρ is the resistivity, and N is the electrically active dopant density. The normalization factor, P_o, was taken equal to 1 V·sec/cm². Fits were made for both $X = \log_{10}(\rho/\rho_0)$ and $X = \log_{10}(N/N_0)$ with $\rho_0 = 1$ Ω·cm and $N_0 = 10^{16}$ cm^{-3}. With the use of these normalizing values, the magnitude of X is usually less than 4. This is better from a computational standpoint because the computation is much less sensitive to the number of significant figures retained for the coefficients.

The data used for the fits consisted of 26 points obtained from the *C-V* measurements, four points based on the photometric and NAA results, twelve points determined from the Hall effect measurements, two points from Esaki and Miyahara (31) at 1.2×10^{20} and 1.6×10^{20} cm^{-3}, and one point from Fair and Tsai (25) at 3×10^{20} cm^{-3}. The latter three points are shown in Fig. 6 and were included to increase the range of the fit at the high density end beyond that justified by the data of this work alone.

In addition, a point was added at $N = 1 \times 10^{12}$ cm^{-3} to improve the fit for calculating values in the low dopant density range. This point was taken equal to the average of the four lowest dopant density data points since the ρN product is essentially constant in this region. Also, the inclusion of this point helps insure that the fits as a function of $\log_{10}(\rho/\rho_0)$ and $\log_{10}(N/N_0)$ both give essentially the same calculated values in this region. All seven coefficients as determined by the fit are given in Table I for 23°C and 300°K. The approximate standard deviation is given for each coefficient and the residual standard deviation (R.S.D.) for the fit is listed in units of V·sec/cm^2. The R.S.D. is the square root of the quotient of the sum of the squared residuals divided by the number of degrees of freedom.

The plot of the data used for the curve fit, with the exception of the point at 10^{12} cm^{-3}, and the least squares fit of the $q\rho N$ product *vs.* N for 300°K are shown in Fig. 7. This figure clearly shows that the "min-max" expressions of Caughey and Thomas (1) are not suitable for this data as there is no plateau or maximum at high dopant densities. The curve obtained for the product as a function of resistivity is plotted in Fig. 4 along with the experimental data of this work and other results.

The two expressions, one a function of $\log_{10}(\rho/\rho_0)$ and the other a function of $\log_{10}(N/N_0)$, have a worst case self-consistency of 8% for all values of N (and corresponding values of ρ) within the range 1×10^{12} to 4×10^{20} cm^{-3}. That is, when the product $q\rho N$ is calculated for a given N, a ρ is derived which can be used in the $q\rho N$ *vs.* ρ expression to again calculate the product. The latter product will be within 8% of the former. The maximum difference occurs only in the low 10^{18} cm^{-3} range and elsewhere the fits are consistent within 4%. When the self-consistency is calculated starting with a given ρ, the fits have a maximum difference of 4% for resistivities from 2×10^{-4} to 3×10^3 Ω·cm.

Fits were also obtained for electron mobility as a function of both electron density, n, and resistivity. It was found that better and more self-consistent fits were possible if the data point at 3×10^{20} cm^{-3} were omitted. Otherwise the data used for the mobility fits corresponded to that used for the product fits. As mentioned previously, the percent ionization calculations of Li and Thurber (22) were used to obtain the electron density from the measured dopant density

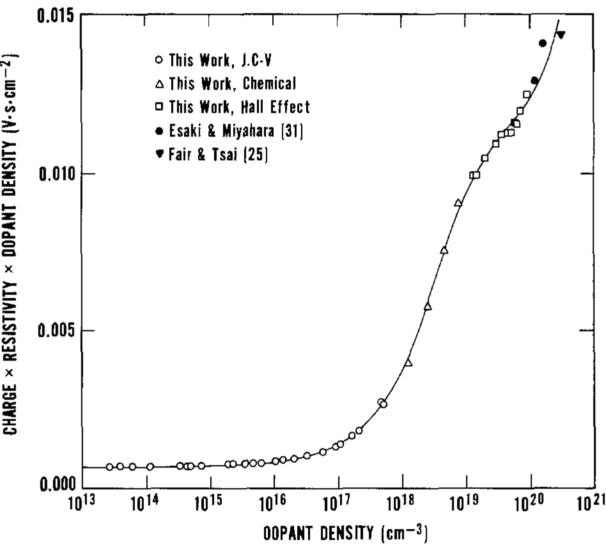

Fig. 7. Graph of the $q\rho N$ product as a function of N for 300°K. The curve is the least squares fit to the data.

prior to the computation of mobility. The expression for calculating the electron mobility is of the form

$$\log_{10}(\mu/\mu_0) = \frac{A_0 + A_1X + A_2X^2 + A_3X^3}{1 + B_1X + B_2X^2 + B_3X^3} \quad [2]$$

where μ is the mobility and $\mu_0 = 1$ cm^2/V·sec. As before, fits were made for both $X = \log_{10}(\rho/\rho_0)$ and $X = \log_{10}(n/n_0)$ for temperatures of 23°C and 300°K. Values for the coefficients are given in Table II. The plot of the mobility data and fitted curve as a function of resistivity for 300°K is given in Fig. 8. The fit of mobility *vs.* electron density is shown in Fig. 5 and 6 for comparison with experimental data. An expression of the form suggested by Mosetti and Solmi (26) was also tried for the mobility fits, but the percent residuals in the low mobility range were significantly larger than with Eq. [2], particularly for the fit as a function of resistivity.

The mobility fits are self-consistent within 6% for electron densities in the range 10^{12}-10^{20} cm^{-3}. The expressions rapidly diverge for densities greater than 2×10^{20} cm^{-3}. The fit as a function of resistivity is the better choice for approximating mobility values beyond the range of the fitted data. When the self-

consistency is calculated starting with a given resistivity, the fits have a maximum difference of 3% for resistivities from 6×10^{-4} to 10^{1} Ω·cm. Graphs showing the self-consistency and other details of the curve fitting will be included in a forthcoming NBS Special Publication on this work.

Conclusions

The relationship between resistivity and dopant density has been determined for phosphorus-doped silicon for densities between 10^{13} and 10^{20} cm^{-3}. The results differ from the n-type Irvin curve by 5-15%, always in the direction of lower dopant density for a given resistivity. The work is in agreement with the mobility curve of Baccarani and Ostoja in the 10^{15}-10^{18} cm^{-3} range but differences exist for lower and for higher doping levels. The phosphorus densities measured by neutron activation analysis and the photometric technique were within ±10% of those obtained from the electrical methods on the same crystals. Using a model convenient for engineering calculations, analytical fits were determined for the resistivity-dopant density data as a function of resistivity and dopant density for temperatures of 23°C and 300°K. Similar fits were obtained for the calculated electron mobility as a function of resistivity and electron density.

ABSTRACT

The parameters of high frequency transistors with implanted arsenic emitter and boron base were found to change significantly on annealing at temperatures between 600° and 900°C with a maximum change at about 700°C. The change can be interpreted as a decrease of boron concentration in the base and of the donor concentration gradient at the emitter-base junction. Determination of the concentration profiles by secondary ion mass spectrometry and by Rutherford backscattering spectrometry (RBS) showed that these decreases were due to enhanced diffusion of both arsenic and boron. Electron microscopy showed precipitation which was probably preceded by arsenic clustering, in agreement with RBS channeling results. These showed that the substitutional fraction of arsenic, which was between 95% and 98%, decreased by a few percent on annealing at 700°C. The enhanced diffusion is thought to be caused by vacancy generation by either one of two precipitation-induced processes: dissociation of As-vacancy complexes or growth of interstitial defects.

Implanted arsenic is now widely used as a donor-type impurity in silicon. For example, bipolar transistors are made with implanted boron base and arsenic emitter. After implantation the As and B are electrically activated by an appropriate heat-treatment around 1000°C. In a process which involved a subsequent annealing at 650°C, we found that the parameters of high frequency transistors with shallow As emitter (0.2 μm) and B base (0.35 μm) were drastically affected by this annealing. The current gain, for example, was greatly increased.

The effects of low temperature heat-treatments on Si with As diffused into it have been studied earlier. Osvenskii *et al.* (1) found interstitial dislocation loops by transmission electron microscopy on As-doped Si crystals which had been annealed at 800°C in vacuum after quenching from 1250°C. The loops were attributed to As precipitation. Schwenker *et al.* (2) found for As diffused at 1050° and 1100°C to a depth of 6-9 μm into Si that heat-treatment between 500° and 970°C in argon caused the sheet resistance to increase. Around 750°C this increase was maximum, being a factor of 2 at a surface concentration of 1.2×10^{21} cm^{-3} and less at lower concentrations. Transmission electron microscopy showed dark spots and interstitial hexagonal Frank dislocation loops. The effects on sheet resistance were ascribed to As clustering or vacancy-complex formation. An increase in sheet resistance due to heat-treatment between 500° and 800°C in vacuum was also found by Miyamoto *et al.* (3) who observed an increase of the lattice constant, which was supposed to be due to SiAs formation. Haskell *et al.* (4) studied Rutherford backscattering on As in Si and found from channeling that 90% to 95% of the As was on lattice sites. Heat-treatment between 650° and 900°C in argon increased the aligned As yield, showing As to be displaced from substitutional lattice sites. Shibayama *et al.* (5) observed an enhancement of both B and As diffusion in Si for As surface concentrations above about 10^{20} cm^{-3}, due to heat-treatment between 500° and 800°C in nitrogen. The effects were ascribed to As precipitation and subsequent vacancy generation.

All this previous work was carried out on Si with chemically deposited As. In the present paper we report a study on the effect of low temperature heat-treatment on the electrical parameters of high frequency transistors with shallow As emitter and B base both made by ion implantation. These effects are correlated with changes in the chemical As and B profiles as measured by secondary ion mass spectrometry (SIMS) and by Rutherford backscattering spectrometry (RBS) and with precipitation effects as studied by transmission electron microscopy (TEM) and by the RBS channeling technique.

Experimental Procedures

Electrical measurements were carried out on npn test transistors made in epitaxial N-type Si (3.3 μm, phosphorus 3×10^{15} cm^{-3}) grown on N$^+$-Si <100> wafers (10^{-2} Ω-cm). The base (65 $\times$ 65 μm) was made by B implantation (25 keV, dose 1.3×10^{14} cm^{-2}), followed by 40 min annealing at 950°C in dry N_2. Two emitters (4 $\times$ 32 μm) were made by As implantation (60 keV, dose 6.5×10^{15} cm^{-2}), followed by 12 min annealing at 990°C in dry N_2. In both cases the annealing was followed by fast cooling (pulling out of the furnace). The process yielded an emitter, with a sheet resistance of about 30Ω and a depth of 0.2 μm, and a base, with a sheet resistance of about 600Ω and a depth of 0.35 μm.

For the measurement of the As and B profiles and for the TEM observations two types of wafers were used. One series had had a treatment identical to that of the wafers in which transistors were grown, except for the masking operations (type I). The other series (type II) were N-type <100> Si, 1 Ω-cm (2-3 $\times 10^{15}$ cm^{-3} phosphorus) substrates without an epitaxial layer. These received two B implantations: 20-25 keV, dose 1.3×10^{14} cm^{-2} and a lower dose with 60 or 80 keV. The implantation was followed by annealing for 30 min at 875°C in dry N_2. Subsequently As was implanted at 60 keV, dose 10^{16} cm^{-2}, followed by annealing for 24 min at 990°C in dry N_2 and fast cooling. The implantation and annealing treatments are summarized in Table I. These standard treatments were given to all samples.

The effect of a low temperature heat-treatment was studied by an additional annealing in dry N_2 at a temperature between 500° and 1000°C. On the test transistors this treatment was carried out after opening of the contact windows, but before metallization.

SIMS profiles were determined with the CAMECA IMS 300 using a 5.5 keV, 1 μA, 60° incident O_2^+ pri-

mary beam. Oxygen gas was introduced into the sample chamber at a pressure of about 3×10^{-5} Torr, except for one arsenic profile, which was measured in the 10^{-7} Torr residual vacuum. The primary beam was rastered over 1.5×1.5 mm, leading to an erosion rate of about 5 Å/sec. Secondary ion acceptance was restricted by a 300 μm field aperture to the center of the sputtered crater. Signals monitored were $^{11}B^+$ and $^{75}As^+$, the latter with a target potential shift of typically 50V to minimize the contribution from Si_2O^+ at mass number 75. The boron and arsenic profiles were measured in separate runs at different sample locations. The secondary ion currents were converted into concentrations (accuracy $\pm 12\%$) via calibration from standard implants, and the depth scale was obtained by linear extrapolation from the final crater depth measured with a mechanical stylus instrument. The detection limit was determined by the 3 decades dynamical range. Uncertainties in crater depth determination are caused by curvature of the crater bottom (*i.e.*, nonuniform primary ion current density) and nonplanarity of the sample surface.

Arsenic profiles were also measured with RBS using the Van de Graaff accelerator at Philips Research Laboratories, Amsterdam, with 2 MeV He^+ ions and using a scattering angle of 170° and target angles between 0 and 65°. The detector resolution was 15 keV. Depth determination was done using published values of stopping cross sections (6). These are accurate to within a few percent. With channeling in <100> and <110> directions the same values were used as for a random direction. The number of arsenic atoms per square centimeter was determined from the area of the As peak and the height of the Si signal for scattering in a random direction. The concentration was then obtained from the number of counts per channel and the channel width (7). The accuracy of this determination is a few percent.

TEM observations were made using a Philips EM 400 or the high voltage microscope at the T.N.O., Apeldoorn, on samples that were wet-chemically thinned from the back.

Electrical Measurements

We measured the sheet resistance, R_b, of the base underneath the emitter and the current gain on the transistor, h_{FE}, as a function of the time of annealing at 700°C. The results are shown in Fig. 1, which shows a change of both parameters by an order of magnitude after 16 hr. Even relatively short annealing times had a strong effect. The ratio between h_{FE} and R_b remained constant.

The base sheet resistance is given by

$$R_b^{-1} = \int q\mu_p N_B dx \quad [1]$$

where μ_p is the hole mobility in the base, N_B is the acceptor concentration, and the integration is taken over the base. The current gain $h_{FE} = I_c/I_b$, where the collector current I_c is given by

$$I_c = \frac{A_e q n_{io}^2}{G_b} \exp(qV_{eb}/kT) \quad [2]$$

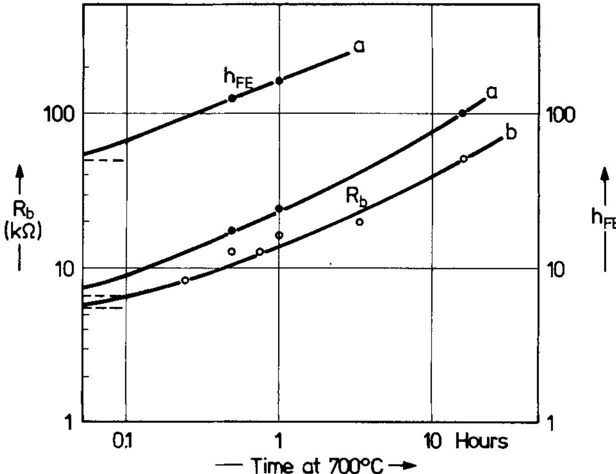

Fig. 1. Buried base sheet resistance R_b and current gain h_{FE} for two transistors (a and b) as a function of annealing time at 700°C. The values before annealing are indicated by broken lines.

and I_b is the base current. In Eq. [2] A_e is the emitter area, n_{io} is the intrinsic carrier concentration for low impurity concentrations, V_{eb} is the applied emitter-base voltage, and G_b is the Gummel number of the base. This is given by

$$G_b = \int \frac{N_B}{D_n} \left(\frac{n_{io}}{n_i}\right)^2 dx \quad [3]$$

where D_n is the diffusion coefficient for electrons in the base, n_i is the dope-dependent intrinsic carrier concentration, and the integration is carried out over the base (8). G_b can be derived from the I_c (V_{eb}) characteristics at low currents.

Figure 2 shows the dependence of h_{FE}, R_b, and G_b on the temperature of the additional heat-treatment at constant annealing time. It appears that h_{FE} and R_b are maximum after annealing at 700°C, while G_b is minimum at the same annealing temperature. It was found that the base current was not significantly affected by the annealing treatment, so that the change of h_{FE} is only caused by a change in I_c. For

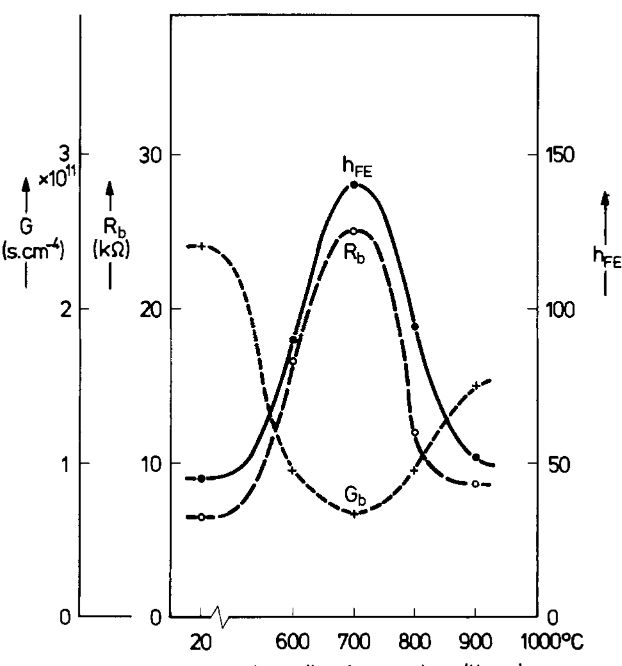

Fig. 2. Buried base sheet resistance R_b, current gain h_{FE}, and base Gummel number G_b as a function of annealing temperature (1 hr annealing).

constant base current h_{FE} is inversely proportional to G_b, according to Eq. [2]. This was also found experimentally. The fact that h_{FE} and R_b go through a maximum while G_b goes through a minimum strongly suggests that the total number of acceptors in the base is a minimum on annealing at 700°C, as follows from Eq. [1] and [3]. A rough estimate, using Eq. [3] and taking into account the dope dependence of D_n and n_i, gives for the integrated base impurity concentration $\int N_B dx$ a value of about 6×10^{12} cm^{-2} before annealing and about 2×10^{12} cm^{-2} after annealing at 700°C.

We also made measurements of the emitter-base capacitance and the cut-off frequency f_T, in order to investigate the annealing effect on the behavior of the impurity distribution in the junction region. As can be seen in Fig. 3, the capacitance C at $V_{eb} = 0$ changes by a factor of two, whereas the cut-off frequency hardly changes. These results may be interpreted in terms of a change of the impurity concentration gradient at the emitter-base junction, dN/dx. This can be calculated from the emitter-base capacitance C using the expression for a linear doping profile (9)

$$C^{-3} = \frac{12(V_g - V_{eb})A_e^{-3}}{qa\epsilon^2\epsilon_0^2} \qquad [4]$$

where V_g is the so called built-in gradient voltage and $a = dN/dx$, which can thus be derived from a C^{-3}-(V_{eb}) plot. This is the usual procedure for determining the impurity gradient in the emitter-base junction. This gradient is also shown in Fig. 3. We learned from numerical simulations that for steep arsenic-boron profiles the gradient so obtained may differ by a factor of up to 3 from the actual gradient. However, we think that the large variation of the slope of the C^{-3}-(V_{eb}) plots that we measured indicates a similar change in the impurity gradient.

The insensitivity of f_T on low temperature annealing may be explained by a rather long and constant collector delay time, which is not affected by annealing, and by the fact that the influence of the varying gradient on the charge storage in the emitter-base junction [the neutral charge capacitance (10, 11)] is partly compensated by the variation of the Gummel number.

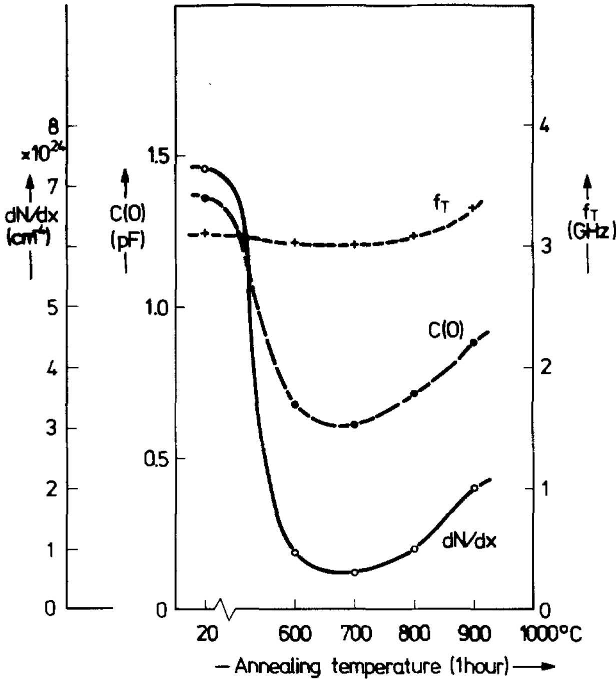

Fig. 3. Emitter-base capacitance at zero voltage $C(0)$, cut-off frequency f_T, and donor concentration gradient at the emitter-base junction dN/dx, as a function of annealing temperature (1 hr annealing).

Profiles

Type I wafers.—Boron profiles were measured with SIMS before and after low temperature annealing between 600° and 1000°C. Profiles as measured before and after annealing for 1 hr at 700° and 800°C are shown in Fig. 4. The boron concentrations in the profiles were equalized at the value at 500Å depth. This involved shifts of the order of 10% or less, which is within the accuracy of the concentration determination. The maximum in the boron concentration at about 850Å is a remainder of the implantation maximum. The minimum around 0.2 μm is likely to be located at the p-n junction. Because of the electric field at this junction, ionized boron is driven toward the N-type area and this causes a minimum in the boron concentration (12, 13). This provides a means of determining the depth of the p-n junction. The effect of annealing is much larger at 700° than at 800°C. The profile has shifted to greater depth. As the minimum in the profile is located at the p-n junction, this means that the arsenic profile has also shifted. We measured the location of the minimum d and also the location where the boron concentration had decreased to 3×10^{16} cm^{-3}, which is about the lower limit of boron detection, d^1, as a measure of the base-collector junction depth. Figure 5 shows the dependence of d and d^1 on annealing temperature. The curves are similar and exhibit a maximum at 700°C and a minimum between 800° and 900°C.

The integrated dopant concentration in the base is an important parameter, as was discussed in the previous section. Assuming the p-n junction to be situated at the boron minimum, we determined the value of the integrated boron concentration below the minimum in the profile, Q_B, which is approximately equal to $\int N_B dx$. The result is also shown in Fig. 5, where the value of Q_B, expressed as a fraction of the total boron density Q_o, measured on the same profile, is drawn as a function of annealing temperature. Q_B goes through a minimum at 700°C, in agreement with the electrical measurements. It can be seen from the difference between d and d^1, which has a more or less constant value of about 0.22 μm at most annealing temperatures,

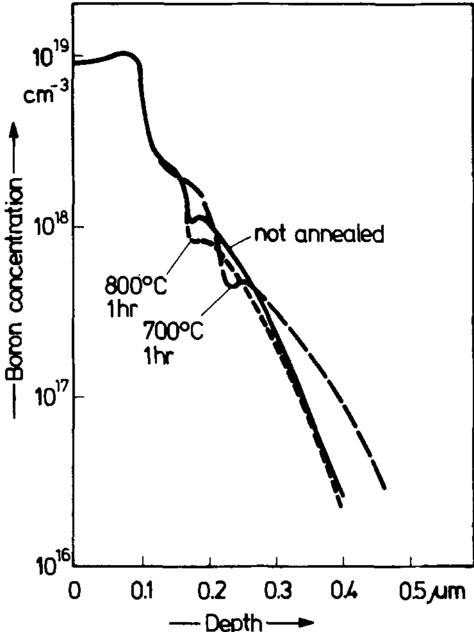

Fig. 4. Boron profiles as measured with SIMS on type I samples without additional annealing and annealed for 1 hr at 700°C and at 800°C.

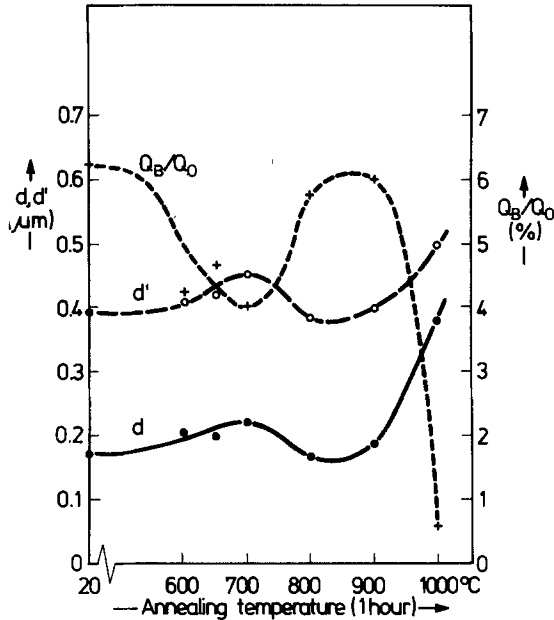

Fig. 5. Depth of the minimum in the boron profile, d, and of the boron concentration of 3×10^{16} cm^{-3}, d', and the boron density below the minimum Q_B, as related to the total boron density Q_o as a function of annealing temperature (1 hr annealing).

that the change in Q_B is not due to a smaller base width, but mainly to a lower boron concentration. The value of Q_B after 1 hr at 700°C is a factor of 1.5 smaller than that before annealing, which is about 8×10^{12} cm^{-2}.

The effect of annealing time at 700°C is shown in Fig. 6, where d is seen to increase and Q_B/Q_o is seen to decrease with time.

The values of d and d^1 and of Q_B/Q_o show some scatter. This is partly caused by the possible error in the depth determination in SIMS experiments, which is about 5%. Other possible causes of scatter are real differences between the samples owing to variations in, for example, temperature during implantation, dislocation density, and cooling rate after annealing. The results of measurements made on samples that were all cut from the same wafer are shown in Fig. 6 by open symbols.

Arsenic profiles were also determined with SIMS. Figure 7 shows the profile for a sample that had not undergone low temperature annealing. The profiles taken on samples annealed at various temperatures exhibited little difference. However, for these samples the uncertainty in the depth determination due to asymmetric sputter effects or samples that were not sufficiently flat, was about 8%. Therefore, it could not be shown that the minimum in the boron profile was indeed at the depth where As and B concentrations were equal. Other uncertainties are caused by the fact that the arsenic and boron profiles were measured on different sites.

Arsentic profiles as determined by RBS do not suffer from uncertainty in depth determination as caused by sputter etching. Figure 8 shows As profiles measured by RBS on samples before and after annealing at 700° and 800°C. The measurements show that after annealing a tail is found at concentrations below about 8×10^{19} cm^{-3}. The shift of the profile due to the annealing at 700°C is of the order of 300Å. The appearance of a tail means that after annealing the profile is less steep than before annealing. This causes a decrease

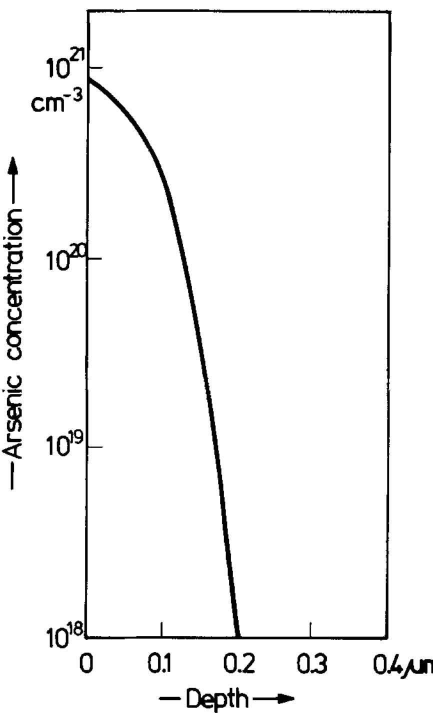

Fig. 7. Arsenic profile as measured with SIMS on a type I sample

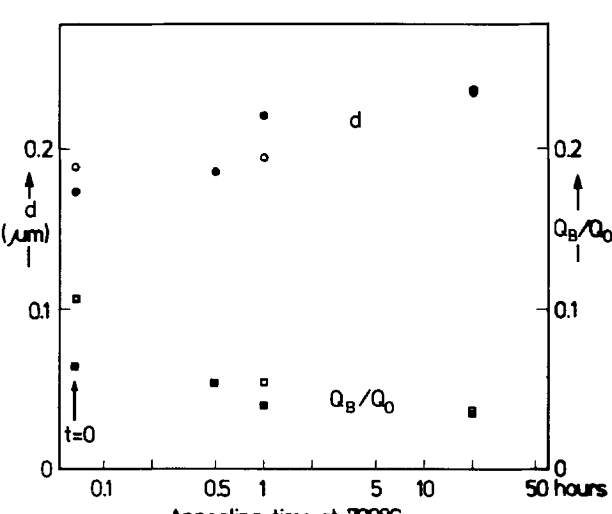

Fig. 6. d and Q_B/Q_o, as defined in Fig. 5, as a function of the time of annealing at 700°C. The open symbols correspond to measurements on one wafer.

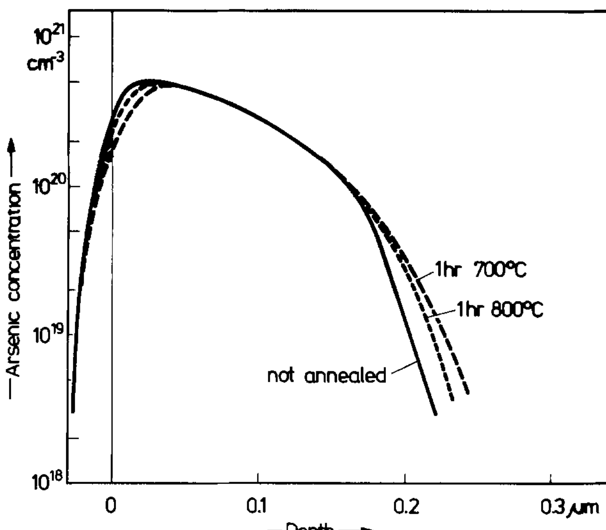

Fig. 8. The effect of an additional annealing treatment (1 hr at 700° and at 800°C) on arsenic profiles, as measured with RBS on type I samples.

of the impurity gradient at the p-n junction, as was also found by electrical measurements. The effect of annealing at 800°C is smaller than at 700°C, in qualitative agreement with the boron profiles.

Our results on the shift of As and B profiles are similar to those of Shibayama *et al.* (5) from electrical measurements. However, they found a maximum at a lower annealing temperature around 600°C.

Type II wafers.—Boron profiles were also measuered on type II wafers, where the profile is deeper than in type I wafers. They are shown in Fig. 9 for no low temperature annealing and annealing for 1 hr at 650° and 800°C on sample A (see Table I). Figure 10 shows profiles before and after annealing for 17.5 hr at 700°C on sample B (see Table I). Again, the minima in the boron concentration are found to shift on annealing at 650° and 700°C and less so at 800°C. They are also deeper than for type I wafers. The value of Q_B/Q_o decreases from 3.6% before annealing to 1.6% after annealing for 1 hr at 650°C for sample A and from 4.6% before annealing to 0.6% after annealing for 17.5 hr at 700°C for sample B.

Arsenic profiles were measured on sample B with the same annealing treatment using SIMS, as also shown in Fig. 10. The arsenic profile of the annealed sample was measured in vacuum. The shift of the As profile on annealing is larger than for type I wafers and is in agreement with the shift of the boron minimum. The uncertainty in the depth determination for both arsenic and boron was about 3%.

Transmission Electron Microscopy

Type I wafers were found to contain dislocations with density of about 10^8 cm^{-2}, as shown in Fig. 11. These may have originated as a result of implantation damage. From the number of extinction fringes at the edge of the crystal, it was found that they were located at about 0.3 μm below the surface. Annealing at temperatures between 600° and 800°C did not change the dislocation density and also no precipitates were found, when using the weak-beam technique (14) which set an upper limit to precipitate diameters of about 50Å.

The effect of annealing at various temperatures was also investigated on type II wafers. On sample B which was annealed for 18 hr at 700°C, rod-shaped defects were present as shown in Fig. 12. This type of defect has been reported to be associated with boron implantation and is probably of an interstitial type (15, 16). Also particles of about 100-200Å in diameter, as well as dislocation segments between particles, were observed. No defects were found on an unannealed sample.

On sample A no defects were seen before annealing and after annealing for 1 hr at 800°C, but extensive defect formation had occurred after annealing for 1 hr at 650°C. The micrograph is shown in Fig. 13. The annealing produced small defects, about 200Å in diameter which were too small to determine unambiguously whether they were precipitates or dislocation loops and a smaller number of precipitates between 400Å and 1500Å in diameter. Annealing at 700° produced similar precipitates but fewer than at 650°C. The micrograph also shows dislocation segments between some of the particles.

Assuming the composition of the precipitates to be SiAs and assuming that the contrast in the micrographs is caused entirely by the particle, thus neglecting the strain field of the precipitate, the densities of the larger precipitates at 650° and 700°C correspond to densities of about 10^{15} and 3×10^{14} As atoms/cm^2, respectively. If the strain field of the precipitates was taken into account, smaller densities would be obtained.

The results on sample A are in qualitative agreement with the change in electrical parameters and in the profiles, which is maximum after annealing around 700°C.

The main differences compared with sample B, which exhibited the rod-shaped defects, are the higher

boron implantation energies and the longer annealing time for sample B.

The absence of precipitates in type I wafers may be caused by the presence of dislocations, which may act as nucleation sites for very small precipitates.

Channeling

The fraction of As not on lattice sites f_{ns} was determined by RBS with the primary ion beam aligned in the <100> or the <110> direction (channeling). This can be calculated from the minimum backscattering yield related to the yield in a random direction x_{As} for As and x_{Si} for Si (7)

$$f_{ns} = \frac{x_{As} - x_{Si}}{1 - x_{Si}}$$

The values of x_{As} and x_{Si} were determined from the integrated yields in an interval 500-2000Å below the surface. This interval was based on the stopping cross section for the beam in a random direction. As the stopping cross section for perfectly aligned He ions is less than that for nonaligned particles by about 20% (7), this may introduce an error in the calculated values of x_{Si}, x_{As}, and f_{ns}. However, since we are mainly interested in the change of these quantities by annealing, we may neglect this error.

In the experiments the beam was aligned with the proper crystalline direction to give a minimum yield and the sample was then displaced in order to make the measurements on a nonirradiated spot. This was done to minimize As displacement by the ion beam (17). For each measurement this was carried out a number of times until subsequent measurements yielded approximately the same value of x_{As}.

Table II gives values of x_{Si} and f_{ns}, averaged over 2 to 4 measurements in which the spread was about 20%. For type I wafers the nonsubstitutional fraction of As, which was 5.1% in the <100> direction and 2.0% in the <110> direction, increased by about 2% on annealing at 700°C, corresponding to an As dose

Table II. RBS channeling results in two directions

	<100>		<110>	
	χ_{Si}* (%)	f_{ns}† (%)	χ_{Si}* (%)	f_{ns}† (%)
Type I				
Not annealed	3.7	5.1	2.2	2.0
1 hr 700°C	3.6	5.1	2.2	4.1
20 hr 700°C	3.5	6.5	2.2	4.1
Type II (sample B)				
Not annealed	3.8	2.6	2.1	2.3
17.5 hr 700°C	5.1	5.6	2.8	5.2

† f_{ns} = nonsubstitutional fraction of As.

of 1.3×10^{14} cm^{-2}. Table II also shows that for type II wafers (sample B) annealing at 700°C changed the values of f_{ns}, which were 2.6% in the <100> direction and 2.3% in the <110> direction, by about 3%, corresponding to an As dose of 3×10^{14} cm^{-2}. This is about a factor of 3 less than the maximum amount of precipitated arsenic obtained from TEM micrographs, assuming the contrast to be due completely to precipitate particles. As the strain field of these particles also causes contrast, a better agreement would be obtained between the two methods, if this were taken into account. These results show that most of the As is on substitutional lattice sites. The change that is observed on annealing is in agreement with earlier work by Haskell *et al.* (4) and is ascribed to precipitation.

There is a difference between type I and type II wafers, as regards the variation of χ_{Si} on annealing. It increases only for type II wafers. This is presumably caused by lattice defects introduced by precipitation. In type I wafers precipitation may have taken place on dislocations already present before the heat-treatment.

Discussion

The measurements on the As and B profiles have shown that low temperature annealing gives rise to a shift of these profiles to greater depths, which is maximum for annealing around 700°C. These results are in qualitative agreement with those of Shibayama *et al.* (5) on chemically deposited As and B, for which a maximum in the shift was found around 600°C. The shift of the profiles can be correlated with the change of electrical parameters. These were shown to be due to two effects, both of which were maximum after annealing at 700°C: a decrease of the total number of impurities in the base and a decrease of the impurity gradient at the emitter-base junction. The profile measurements indeed showed that the shifts led to such changes, although there is some discrepancy between the values of the chemical impurity density in the base Q_B, as measured with SIMS, and the carrier density $\int N_B dx$, as calculated from the Gummel number. For example, after 1 hr at 700°C Q_B has changed by about a factor of 1.5 and $\int N_B dx$ by a factor of 3.

We ascribe this discrepancy to the scatter in the measurements, to uncertainty in the values of D_n and n_i in Eq. [3], and to the fact that in electrical measurements the effective base width is determined by the depletion layers on either side of the base. These are wider at lower impurity concentrations, so that they extend further into the base after annealing. The fact that the buried base resistance changes by a factor of 10 on annealing for 16 hr at 700°C, but the boron density only by a factor of 2, can only partly be explained by the above-mentioned causes. Perhaps there are differences between the chemical profile, as measured by SIMS, and the electrical profile.

The question that remains is what causes the shift of the As and B profiles. In agreement with Shibayama's proposition, our TEM and RBS results support a mechanism of enhanced diffusion due to generation of point defects caused by precipitation of As. The number of precipitates as found by TEM, assuming them to be SiAs, corresponded reasonably well with the number of As atoms not on lattice sites, as determined with RBS. The number of precipitates was maximum around 650°C. This can be understood qualitatively from the phase diagram in Fig. 14, which shows the total and the electrically active As solubilities (18). The As solubility at the temperature at which the wafers were annealed after implantation, 990°C, is about 10^{21} cm^{-3}. Due to the relatively fast cooling to room temperature, most of the implanted As remains in solution (approximately 95-98%, according to RBS measurements). Since the solubility at room temperature is negligible, the As is in supersaturation. By subsequent annealing at a temperature, where diffusion is possible, the equilibrium situation can be restored by precipitation.

The rate of precipitation is the product of the nucleation rate and the growth rate. For homogeneous precipitation, the energy barrier that must be overcome to nucleate a precipitate is proportional to $\gamma^3/\Delta F_v^2$, where γ is the interface free energy per unit area between particle and matrix and ΔF_v is the bulk free energy change per unit volume on precipitation (19). This is to a first approximation proportional to the degree of undercooling and, therefore, the nucleation rate increases with the amount of undercooling, *i.e.*, with decreasing temperature. On the other hand, the growth rate is limited by diffusion and therefore decreases with decreasing temperature. So the precipitation rate will have a maximum at some intermediate temperature.

In the case of precipitation on dislocations the nucleation rate will be larger than with homogeneous precipitation and the temperature of maximum precipitation will be higher. This may have caused the precipitation rate in type II wafers to be maximum at a lower temperature than in type I wafers. In the latter case, the shift of the profiles was ideed maximum at a somewhat higher temperature. The absence of visible precipitation in type I wafers and the fact that the minimum yield of Si changed little on annealing could be related to very small precipitates on dislocations.

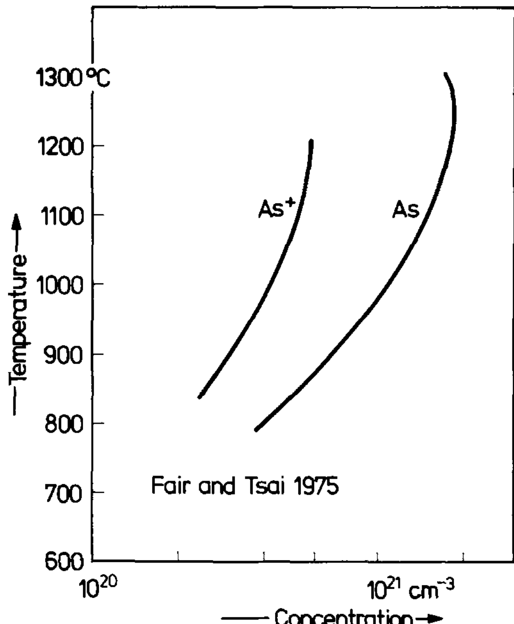

Fig. 14. Solid solubility of As in Si (As) and electrically active As concentration (As+) for implanted As as a function of diffusion temperature. After Fair and Tsai (18).

If the precipitation is diffusion limited, the As diffusion length should be large enough to reach the dislocations or the precipitation nuclei. From extrapolation of the values reported by Masters and Fairfield (20) for the diffusion coefficient of As in Si at concentrations between 10^{20} and 10^{21} cm^{-3} we find for the diffusion length in 1 hr at 700°C a value of the order of 10Å, which is much too low to provide a diffusion current for precipitation both in type I and in type II wafers. It is therefore likely that there is a first stage in the precipitation where As clustering occurs or small coherent precipitates are formed, too small to be observed in TEM. With these clusters or precipitates a very small interface energy and thus a small energy barrier for formation are associated. The formation of As_4Si clusters with As on Si lattice sites was earlier proposed by Hu (21) and evidence for cluster formation was presented by Chu and Masters (22). Formation of such clusters would not change f_{ns} significantly. If cluster of coherent precipitate formation gives rise to generation of point defects, then diffusion is enhanced and precipitation is speeded.

A shift of As profiles over a distance of the order of 300Å corresponds to a diffusion coefficient of about 3×10^{15} cm^2/sec, which is a factor of about 3×10^3 larger than the value at 700°C, obtained from extrapolation of high temperature values.

Enhanced diffusion of various elements in Si has also been obtained by radiation with protons (23, 24). This radiation probably generates lattice vacancies at a depth comparable to the proton range. The profiles acquire a tail by such treatment.

Since at low temperatures diffusion of As in Si probably takes place by a lattice vacancy mechanism (25), it is plausible to assume that the point defects generated by cluster formation or precipitation, are lattice vacancies. The fact that the atomic size of As is very similar to that of Si and the high degree of substitutionality of both Si and As show that a supersaturation of self-interstitials is unlikely.

Two mechanisms of vacancy generation by As clustering and precipitation may be active: dissociation of arsenic-vacancy complexes and the growth of interstitial defects.

Arsenic-vacancy complexes were first postulated by Schwenker *et al.* (2) to explain the fast conductivity change during low temperature annealing on samples that had been quenched from a high temperature and the difference between the electrically active and the total As concentrations. These complexes would presumably involve two arsenic atoms and a vacancy. RBS showed the atoms to be on lattice sites. This model was worked out by Fair and Weber (26) for chemically deposited and diffused As. Fair and Tsai (18) believed that this model was not true for ion-implanted As, because at not too high concentrations, maximum activation of As could be obtained in that case. However, the solubility of As^+ is still much lower than that of As and the RBS results show that here too most of the As is on lattice sites. Dissociation of arsenic-vacancy complexes, caused by As clustering and precipitation, gives rise to vacancy generation. These highly mobile vacancies will diffuse both toward the surface and into the bulk. Some of these vacancies will be available to enhance As and B diffusion. Since dislocations will trap some vacancies, the effects of enhanced diffusion may be somewhat larger in dislocation-free Si.

An alternative mechanism of vacancy generation is the growth of interstitial defects. These may be small interstitial dislocation loops as found earlier in transmission electron microscopy (1, 2). Also a climbing dislocation is a source of vacancies by the growth of the extra half-plane.

The rate-limiting step in the successive processes: clustering and precipitation-vacancy generation-As diffusion may be determined from the time dependence. In three-dimensional diffusion-limited precipitation the amount of impurity precipitated is initially proportional to t^n, with n depending on the shape of the precipitates, in general $n \geq 1$ (19). A simple one-dimensional diffusion has a $t^{1/2}$ time dependence. A plot of the increase of the buried base sheet resistance with annealing time gives a time dependence with $n \approx 0.55$, as can be deduced from Fig. 1. This suggests that the As diffusion is rate limiting. The shift of the boron minimum d with annealing time exhibits too much scatter for its time dependence to be determined, but Fig. 6 shows it to be sublinear.

The relatively large amount of scatter in d, Q_B/Q_o, and f_{ns} between different wafers may be due to various causes: variation of precipitation nucleation rate by variation of dislocation density, variation of cooling rate from 990°C and thus of the amount of As and vacancy supersaturation, and variations in temperature during implantation, which may cause variations of the profile (27).

The effect of low temperature treatment on diffusion of As is very similar to the same process with phosphorus where the increase of the base resistance and the change of the P and B profiles can be correlated. The effect is ascribed to dissociation of P-vacancy complexes (*E* centers) (28, 29).

Our results suggest that the base push-out effect that is sometimes observed with arsenic emitters (30) is related to the precipitation of arsenic.

Conclusions

1. Annealing at temperatures between 600° and 900°C changed the parameters of high frequency transistors with implanted arsenic emitter and boron base, with a maximum change at 700°C. The buried base resistance and the current gain increased, the base Gummel number, the donor concentration gradient at the emitter-base junction and the emitter-base capacitance decreased, and the cut-off frequency did not change. These changes are interpreted as a decrease of the boron concentration in the base and the donor concentration gradient at the emitter-base junction.
2. Arsenic and boron profiles as measured with SIMS or RBS indeed showed these effects by shifts of the profiles to greater depth.
3. TEM observations showed precipitation in dislocation-free material, but not in dislocated Si.
4. RBS channeling in <100> and <110> directions showed that the substitutional fraction of As, which was between about 95% and 98%, decreased by a few percent on annealing.
5. The results are explained in terms of arsenic clustering and precipitation causing vacancy generation and thus enhanced diffusion. Precipitation is maximum at about 700°C. At higher temperatures the supersaturation is too small and at lower temperatures the diffusion is too slow. Vacancy generation is assumed to be due to dissociation of arsenic-vacancy complexes or to growth of interstitial defects.

Photocurrent Spectroscopy of Interface States at a Semiconductor-Electrolyte Junction

by J.-N. Chazalviel

Laboratoire de Physique de la Matière Condensée, Groupe de Recherche du Centre National de la Recherche Scientifique, Ecole Polytechnique, 91128 Palaiseau, France

ABSTRACT

We have investigated the photocurrent induced by subbandgap light irradiation at the n-Si-aqueous electrolyte junction. The observed effect is shown to arise from optical processes involving interface states, and mainly from electron transitions from the filled interface states to the conduction band. The dependence of the photocurrent upon anodic voltage is accounted for quantitatively by considering the Schottky barrier lowering effect, already measured from the dark *I-V* characteristics. The dependence of the photocurrent upon photon energy enables us to extract a density of states curve for the occupied interface states. It suggests that these states are bound states on the semiconductor side, due to the coulomb potential of adsorbed ions. Complementary observations on oxidized and bandgap irradiated junctions are discussed and are found to fit well in the above picture.

Experimental evidence for the role of interface states at the semiconductor-electrolyte junction has been brought in many instances, mostly through capacitance and recombination studies (1, 2). These techniques however, hardly permit a systematic investigation of interface states through the semiconductor gap. A true spectroscopy of these states might rather be obtained by observing the photocurrent induced by subbandgap optical transitions between these levels and the semiconductor bands (3, 4). This technique however, suffers from two drawbacks: (*i*) the expected effects are rather small; (*ii*) larger effects may be present in the same photon energy range, for example onset of bandgap absorption, transitions involving deep levels in the bulk or the space charge region, and also thermal effects (5). We present here the results of an investigation of the photocurrent induced by subbandgap light at the n-silicon-aqueous electrolyte junction, where interface states are known to be present (2, 6). We show that they are indeed responsible for the observed effect and their energy distribution can be attained from the experimental data.

Experimental

The electrochemical cell was similar to a previously described one, allowing transient measurements when the sample is put into contact with the electrolyte (6). The optical arrangement is shown in Fig. 1. The design had to provide a maximum subbandgap light intensity, together with rigorous exclusion of bandgap light, because the investigated subbandgap signal can be very small and any parasitic bandgap light might obscure it because of the large associated photoelectrochemical current. The light source was a 250W tungsten lamp and the monochromator was single beam, 1:5 aperture, equipped with a 2 μm blazed grating. All the light from the output slit was focused onto the sample with an elliptical mirror. The sample was shaped as a Weierstrass sphere, to provide reliable concentration of the light on the small Si-electrolyte interface area. Rigorous exclusion of bandgap light was obtained by inserting an 8 mm thick pure silicon filter in the light path; this material was heated at 100°-200°C to increase slightly its cutoff wavelength (7). With this arrangement the light intensity on the sample was a few milliwatts for a typical 50 nm resolution and rejection of bandgap light was about 10^5. Additional filters were used to measure the weakest signals at wavelengths larger than 1.5 μm. The light was chopped at a typical frequency of 30 Hz and the small photocurrent was measured by using a standard three-electrode potentiostatic arrangement and a lock-in amplifier.

The minimum detectable photocurrent is limited by the background noise current I_N, which is due to the shotnoise fluctuations of the dark current I. This gives for a frequency interval $\Delta\nu$ (8)

$$\langle I_N^2 \rangle = 2\, Ie\Delta\nu$$

with $\Delta\nu \sim 1$ Hz and $I \sim 10^{-6}$A, this gives a minimum detectable signal $\sqrt{2\, Ie\Delta\nu} \sim 10^{-12}$A which corresponds to a quantum yield (number of detected electrons per incident photon) $\eta \sim 10^{-9}$. In practice for carefully prepared surfaces the sensitivity was indeed close to this theoretical limit but any defects left on the surface upon polishing were found to increase the noise drastically (flicker noise), due to localized avalanche breakdown near the defects.

The sample was cut from a dislocation-free single crystal doped with $N_D = 2.4 \times 10^{16}$ cm^{-3} phosphorus. This doping was chosen as a compromise to allow a small concentration of bulk defects, together with a thin space charge layer, in order to minimize the unwanted photocurrents that might arise from photoionization of traps in the bulk or the space charge region. The flat surface of the sample was prepared using the mechanochemical procedure described earlier (6) in order to obtain a defect-free surface. [111] and [100] surfaces were investigated and were found to give similar results. The electrolytes used were aqueous solutions of 1M HCl or 1M buffered KCl. As reported earlier (6) there is no evidence for anion adsorption on n-Si either with Cl^- or with the various 0.05M buffer anions.

Results and Discussion

The observed photocurrent is independent of the frequency of light chopping in the investigated 10-100 Hz range. This rules out thermal effects as the explanation for the effect (5). The effect, expressed as a quantum yield, is plotted in Fig. 2 as a function of photon energy for a fixed electrode potential $V = 1V_{SCE}$. The sharp rise around 1 eV corresponds to the onset of bandgap absorption and the associated large photocurrent. The change of slope near 0.95 eV indicates that the observed effect between 0.6 and 0.9 eV is of a different nature. This conclusion is further supported by

Key words: photoelectrodes, surface states, semiconductor electrochemistry.

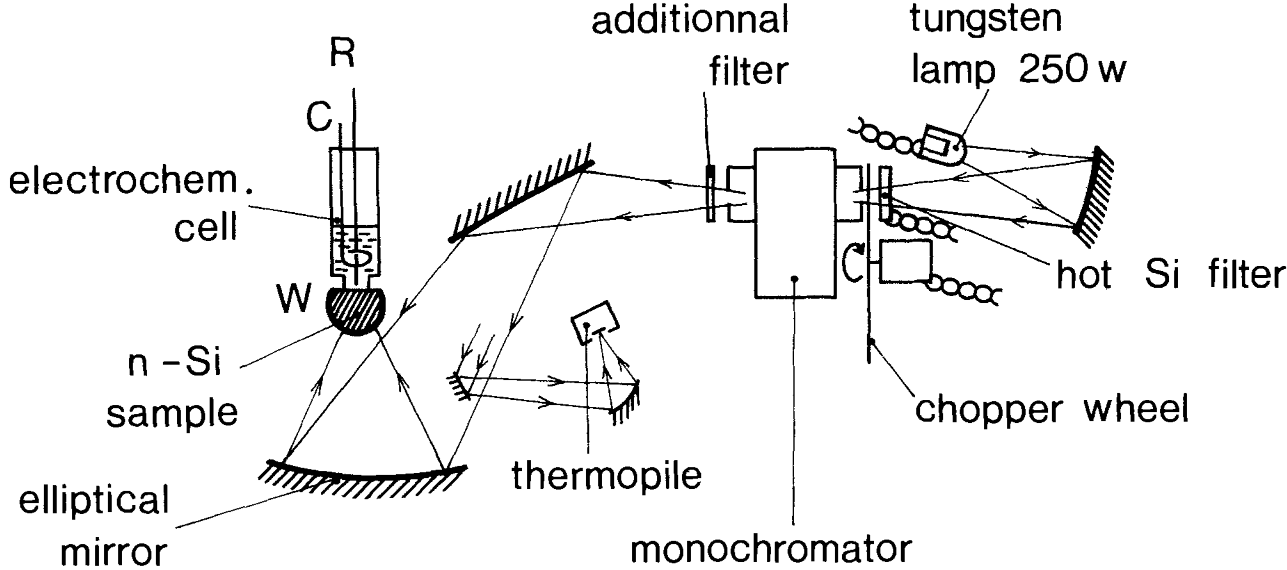

Fig. 1. Scheme of the optical arrangement (see text)

the dependence of the effect upon electrode potential, which shows a different behavior for $h\nu = 1$ eV and 0.8 eV, see Fig. 3. When pH is changed the bandgap effect remains the same, except for a trivial shift of the voltage scale (Nernst law) (6) but the subbandgap effect is found to increase by about a factor of 5 when going from pH = 0.1 to pH = 4.7. This large sensitivity of the subbandgap effect to pH is taken as marked evidence for a surface process.

One can imagine two elementary processes involving interface states (4); these processes are sketched as (a) and (b) in Fig. 4. Process (a) is electron excitation from the valence band into empty interface states; process (b) is electron excitation from occupied interface states into the conduction band (similar to internal photoemission in metal-semiconductor junctions). Whether the observed effect is due to process (a) or (b) can be tentatively answered on the basis of the model we have used previously to account for the dark I-V and C-V characteristics (6). According to this model, charge transport through the interface proceeds via two serial steps, also sketched in Fig. 4: step 1 electrochemical transfer from the electrolyte to the interface states and step 2 electron transfer from the interface states to the semiconductor bulk. Step 2 has been shown to proceed via thermal activation of the electrons over the Schottky barrier (6); although our understanding of step 1 is far less advanced one may think of it as an ionic transfer (*e.g.*, OH^- ions) through the Helmholtz layer and eventually the oxide layer created as the net result of the two steps. The associated overvoltages for 1 and 2 are, respectively, of the form (6)

$$\delta V_1 = (kT/\beta e)\ln(I/I_{ex}) \quad [1]$$

$$\delta V_2 = -(kT/e)\ln(1 - I/I_1) \quad [2]$$

where I_{ex} and I_1 are two constant currents, and $\beta \sim 0.2$. In the framework of this model, the effect of illumination is to provide an alternative pathway for step 1 [process (a)] or for step 2 [process(b)]. Since the total overvoltage is fixed and the two steps are in series, illumination may induce a new repartition of the overvoltage between steps 1 and 2. This effect is summarized in Fig. 5; the net result is that the photocurrent (a) associated with step 1 will be

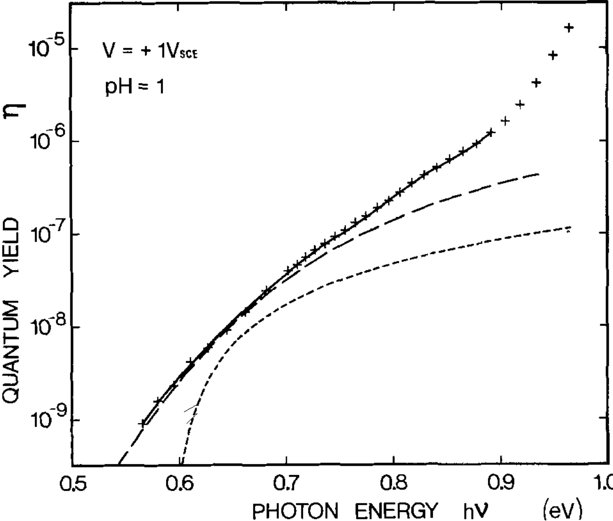

Fig. 2. Quantum yield as a function of photon energy. The points are experimental and the full curve is a fit with the energy distribution of interface states (see text). The fast increase of η near $h\nu = 0.95$ eV is due to the onset of bandgap transitions. The dotted curve is the expected yield from a single type of surface states at energy $E_C - 0.6$ and the dashed curve is for a constant density of surface states through the gap with $E_F = E_C - 0.6$ and $T = 297°K$.

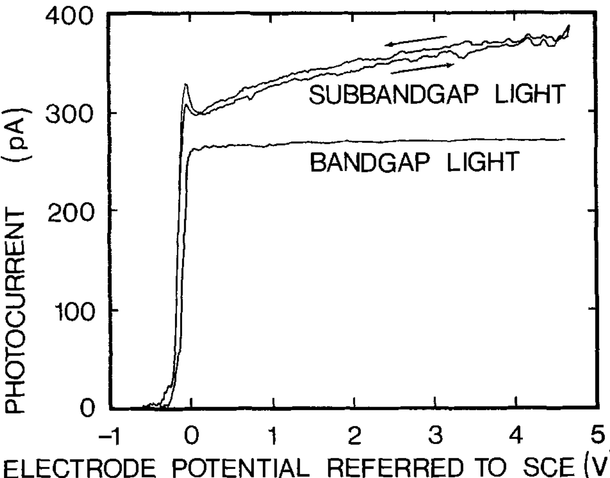

Fig. 3. Photocurrent as a function of electrode potential. Subbandgap light is $h\nu = 0.8$ eV, intensity $\sim 10^{-3}$W; bandgap light is $h\nu = 1.0$ eV, intensity $\sim 10^{-4}$W (vertical sensitivity is 10^2 times smaller). Notice the different shape of the two curves.

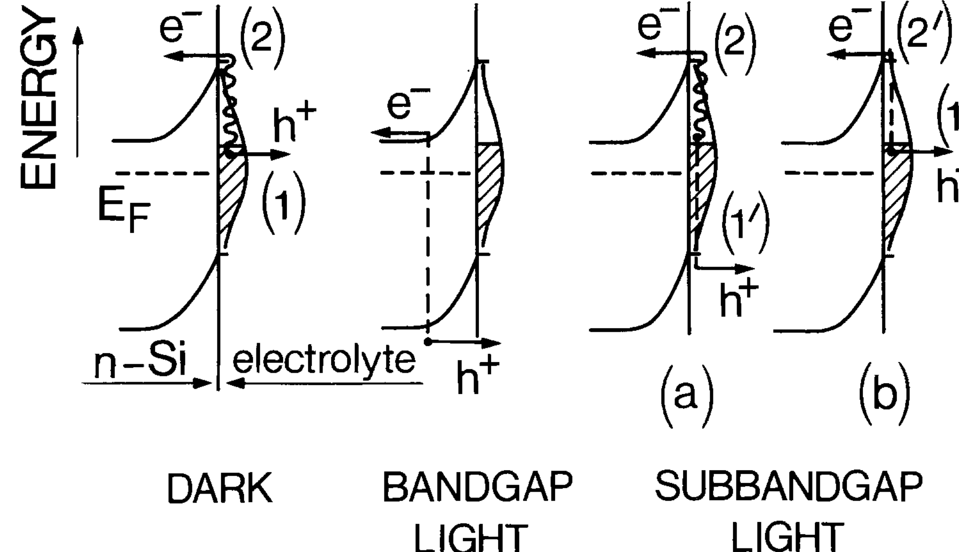

Fig. 4. Scheme for anodic current flow at the n-Si-electrolyte junction in the dark, with bandgap light, and with subbandgap light. The curve near the semiconductor surface schematizes the energy distribution of interface states and the hatched area is for the occupied ones. The dotted line is the bulk Fermi level. The vertical wiggly and dashed lines are for thermal excitation and light excitation, respectively. Steps 1 and 2 are the two steps for dark current from Ref. (6) (see text).

affected by a factor $R_1/(R_1 + R_2)$ and the photocurrent (b) by $R_2/(R_1 + R_2)$, where R_1 and R_2 are the differential resistances associated with step 1 and 2, respectively. In the anodic region the current reaches its limiting value and R_2 is orders of magnitude larger than R_1 so that process (a) should have a much smaller efficiency than (b) (in other terms, the relevant process will be that associated with the limiting step). For electrode potentials less anodic than a certain potential V_o, (6) step 2 is no more the limiting step, R_1 and R_2 are of comparable magnitude, and processes (a) and (b) may both participate in the photoeffect. A quantitative analysis of the data in Fig. 3 is however difficult in this region, because the band curvature gets small and the photoeffect (bandgap as well as subbandgap) subsequently decreases to zero. We will therefore limit our quantitative analysis to the strongly anodic region ($V > V_o$).

Effect of anodic voltage.—As Fig. 3 shows, the bandgap photoeffect is nearly independent of electrode potential through the anodic range; in contrast the subbandgap photoeffect appreciably increases with anodic voltage. This can be understood as a consequence of

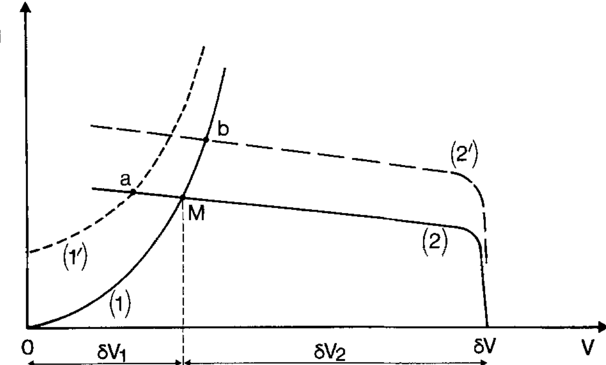

Fig. 5. Graphical discussion of processes (a) and (b) of Fig. 4. According to Ref. (6) the dark current flows through two serial steps. Here curve 1 is the *I-V* characteristic for step 1 and curve 2 is that for step 2; this last curve is plotted backwards starting from δ*V* so that the current for a given overpotential δ*V* is given by the ordinate of the intersect *M* of curves 1 and 2. In the presence of subbandgap light, process (a) enhances step 1 and curve 1 must be replaced by curve 1′ (upwards shift by $I_{ph}{}^a$). The new current is given by the ordinate of the intersect *a* of 1′ and 2. The current increase is seen to be much smaller than the initial $I_{ph}{}^a$. The effect on process (b) is similar: curve 2 is replaced by 2′ and M by b. The current increases are related to the inverse slopes of curves 1 and 2 at point M, *i.e.*, the differential resistances for processes 1 and 2 (see text).

Schottky barrier lowering: it has been previously deduced (6) from the dark-current characteristics that the Schottky barrier height ϕ_B decreases with anodic voltage V following the law

$$\phi_B = \phi_B{}^o - \Delta\phi_B = \phi_B{}^o - [2(V - V_{FB} - kT/e)\, eN_D/\epsilon\epsilon_o]^{1/2} ed \quad [3]$$

where $\Delta\phi_B$ is the barrier lowering, V_{FB} is the flatband potential, ϵ is the dielectric constant of silicon, N_D is the donor concentration, and $d \approx 13$Å (6). If the subbandgap photoeffect is due to process (b), decreasing the barrier height will result in enhancing the photocurrent I_{ph}; *i.e.*, to the first order in $\Delta\phi_B$

$$\Delta I_{ph} = \frac{\partial I_{ph}}{\partial \phi_B}(-\Delta\phi_B) \approx \frac{\partial I_{ph}}{\partial(h\nu)}\Delta\phi_B \quad [4]$$

where we have made the reasonable assumption that I_{ph} depends on ϕ_B only through the photon energy above threshold ($h\nu - \phi_B$). Since the quantity $\partial I_{ph}/\partial(h\nu)$ can be measured separately, Eq. [4] provides a good checkpoint for the above explanation of the dependence of I_{ph} upon V. Figure 6 shows I_{ph} plotted as a function of $\Delta\phi_B$, as given by Eq. [3], for typical experimental conditions. In spite of the 30% variation of I_{ph} the linear approximation (Eq. [4]) is well obeyed and the slope is in good agreement with the measured $\partial I_{ph}/\partial(h\nu)$ (see the dashed line in Fig. 6). As a further verification we have investigated the photoeffect in a sample with a smaller donor concentration $N_D = 1.8 \times 10^{15}$ cm^{-3}. Due to this smaller doping the barrier lowering effect was nearly four times smaller for this sample and the dependence of I_{ph} upon V was found to be reduced accordingly. This good agreement of the results with Eq. [4] gives a verification that the photoeffect in the anodic region is due to process (b) as process (a) would not give such a voltage dependence.

Effect of photon energy.—A typical dependence of the photocurrent I_{ph} *vs.* photon energy $h\nu$ is shown in **Fig.** 2. If a single type of interface state, at a well-defined energy E_t in the bandgap, were responsible for the photoeffect, one would expect for the photocurrent near threshold a dependence

$$I_{ph} \propto (h\nu + E_t - E_C)^\alpha \quad [5]$$

where E_C is conduction band energy. The most appropriate value for the exponent should be $\alpha = 3/2$.[1]

[1] The choice $\alpha = 3/2$ can be briefly justified as follows: the final density of states is that of the conduction band $[\propto (h\nu + E_t - E_C)^{1/2}]$ but the matrix element for the transition probability introduces a further factor $(h\nu + E_t - E_C)$ because a conduction band wavefunction has to fall to zero near the interface, hence the amplitude will be at most $\sim k_\perp a$ at a distance a from the surface, if $k_\perp$ is the normal component of the wavevector; this leads to the factor $k_\perp^2 \propto (h\nu + E_t - E_C)$ in the transition probability. The final α is therefore 1/2 + 1 = 3/2.

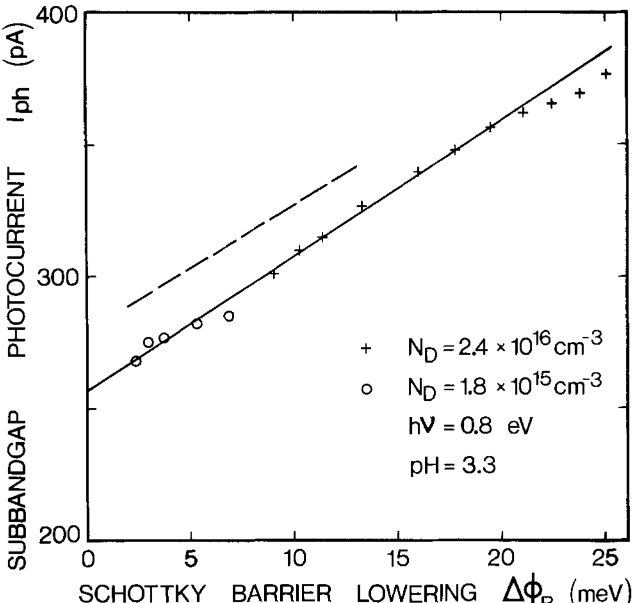

Fig. 6. Effect of barrier lowering on the photocurrent. The crosses represent the data of Fig. 3 ($pH = 3.3$; $N_D = 2.4 \times 10^{16}$ cm^{-3}; $h\nu = 0.8$ eV) plotted as a function of barrier lowering $\Delta\phi_B$, calculated from Eq. [3]. The full line has been drawn through the experimental points. The dashed line is the calculated slope, from Eq. [4] and the measured $\partial I_{ph}/\partial(h\nu)$. The circles are data from a sample with $N_D = 1.8 \times 10^{15}$ cm^{-3} (the vertical scale has been adjusted to the same extrapolated photocurrent at $\Delta\phi_B = 0$).

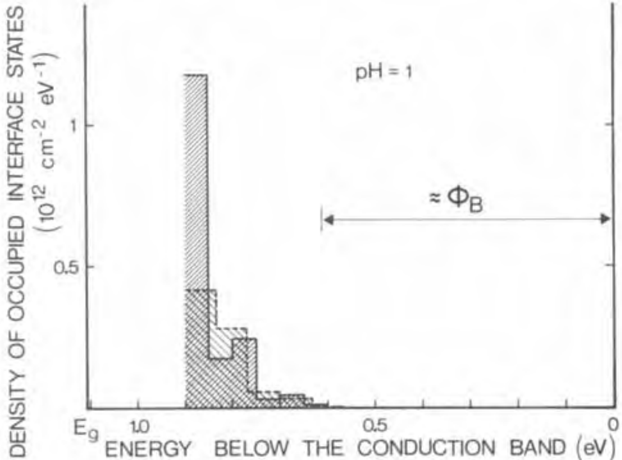

Fig. 7. Density of occupied interface states as deduced from the fit in Fig. 2. The vertical scale is only given as an order of magnitude; assuming a cross section $\sigma = \sigma_0[(h\nu - E_C + E_t)/E_g]^{3/2}$ with $\sigma_0 = 10^{-15}$ cm^2. The two curves are obtained from fits with two different meshes.

However the observed dependence cannot be fitted with Eq. [5] whatever the value given to α. The observed behavior is more suggestive of a broad energy distribution of surface states; if such is the case, then one expects

$$I_{ph} \propto \int_{E_V}^{E_0} g(E_t)\ (h\nu + E_t - E_C)^{\alpha}\ dE_t \qquad [6]$$

where E_V is valence band energy. We have tried to determine the distribution $g(E_t)$ by fitting the experimental data in Fig. 2 with Eq. [6]. The interface state energy distribution was taken as a histogram and the amplitudes of the histogram were used as the parameters for the fit. It was found that the $I_{ph}(h\nu)$ curve is not very sensitive to the details of the $g(E_t)$ distribution, and the cell for the histogram can hardly be taken smaller than 50 meV. A typical result for $g(E_t)$ is shown in Fig. 7. An exponent $\alpha = 3/2$ was assumed for Eq. [6] but values of α ranging between 1 and 2 yield very similar shapes for $g(E_t)$. The quantity $g(E_t)$ corresponds to the density of occupied states per unit energy interval and as expected goes to zero for $E_C - E_t \gtrsim \phi_B \approx 0.60$ eV. The most prominent feature of $g(E_t)$ is its increase near the valence bandedge; this feature may be somewhat exaggerated by matrix element effects that we do not consider here; however, this behavior is very similar to that reported from field effect data for the dry Si-SiO_2 interface (9). The interface states there have been attributed to localized states inside the semiconductor due to the coulomb potential of charged impurities in the oxide. With regard to our problem, this may suggest a synthetic picture for the anodic process: if, *e.g.*, OH^- ions are adsorbed onto the surface upon step 1, such localized states will result in the silicon. These, after being emptied via step 2, will be left with localized holes, allowing neutralization of the OH^- with formation of Si-OH bonds.

Effect of the oxide.—The effect of oxidation on the dark current I has been investigated earlier by using a transient technique (6). The same technique has been used here in the presence of chopped light, allowing in principle the separate recording of I and I_{ph} during the oxide growth. We have been able to measure I_{ph} in this way for bandgap photon energies. The effect of oxide growth is found to be much smaller than for the dark current: in the first minute the decay for I_{ph} is less than a factor of two, while for I it is more than one order of magnitude; and only at larger oxide thicknesses (for example after anodic oxidation under strong illumination) is the bandgap photocurrent drastically reduced. The same technique could not be applied to the measurement of the subbandgap photocurrent because it is a small effect and a lock-in detection is necessary; this makes transient measurements impossible, at least for times shorter than a few seconds. Recordings of the lock-in output for times between a few seconds and a few minutes seem to show that the decay of the subbandgap effect is intermediate between the large decay of the dark current and the small decay of the bandgap current.[2] No significant change of shape of the $I_{ph}(h\nu)$ curve was observed with time, so that the role of the oxide seems to be unessential and the measurements shown in Fig. 2 are thought to be representative of the oxide-free surface, within a scale factor of a few units.

An interesting point is the time evolution of the shape of the $I_{ph}(V)$ curves for the subbandgap effect. While the anodic photocurrent decreases a peak develops near V_0 after a few minutes (see Fig. 8) and slowly increases with oxide growth. We think this peak can be accounted for by an increase of process (a) in Fig. 4, due to the increase of the resistance R_1 associated with step 1 under the influence of the oxide. This peak exhibits about the same dependence upon $h\nu$ as the anodic photocurrent; this possibly implies that the distribution of empty surface states has a shape similar to the symmetric of Fig. 7 around midgap. We think this qualitative information is the most we can obtain from such strongly oxidized interfaces.

Effect of double illumination.—We have been looking for crossed effects between bandgap and subbandgap illumination. The subbandgap photocurrent is orders of magnitudes smaller than the dark current and therefore constitutes a negligible disturbance for the system, but the bandgap photocurrent can be very large and may affect the population of the interface states, thereby changing the subbandgap effect. A

[2] All these observations are consistent with the simple expectation that the deeper in energy is the hole created at the interface, the more easily will the resulting reaction take place, *i.e.*, the weaker is the effect of oxidation.

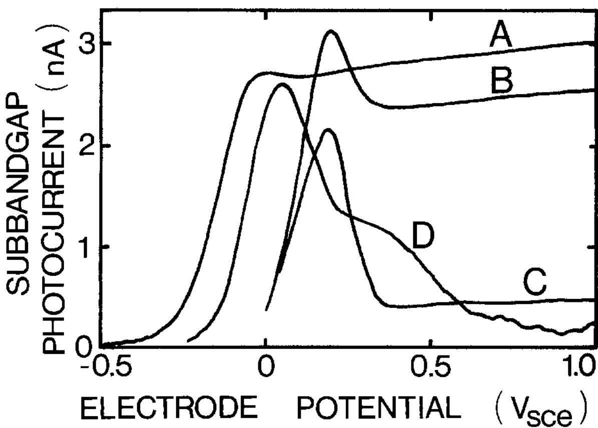

Fig. 8. Voltage dependence of the subbandgap photocurrent. Curve A: freshly immersed surface; curve B: oxidized surface (1 hr immersion); curve C: oxidized surface in the presence of bandgap light; curve D: surface with defects; the signal decrease correlates with avalanche breakdown; notice the associated increase of the noise. The anodic shift of curves B and C (and possibly D) relative to A is due to the large oxide thickness. pH = 3.3; $h\nu$ = 0.85 eV.

small 0.5W lamp was added to the experimental setup a few centimeters below the sample, allowing a small continuous bandgap irradiation. The corresponding bandgap photocurrent ($\approx$1 μA for a useful surface of ~1 mm^2) is found to decrease the subbandgap photocurrent, weakly (~10%) for a freshly immersed surface, but with increasing effectiveness as oxide is growing; after 30 min the subbandgap effect in the anodic region is almost completely quenched (~90%) by a bandgap photocurrent as small as 0.1 μA. In contrast the peak near V_0 attributed to process (a) is unaffected by bandgap irradiation.

These observations are quite consistent with our interpretation of the photocurrent: the main effect of bandgap irradiation is to create holes near the surface; instead of being directly transferred to the electrolyte, these holes will have some probability of being trapped on the occupied surface states, thereby decreasing their density and quenching process (b). The same detrimental influence of holes on the subbandgap photocurrent has been verified when holes are created by avalanche breakdown near surface defects (see Fig. 8). A thick oxide layer hinders hole transfer to solution and favors hole trapping, hence the increased quenching effect in the presence of oxide. On the other hand, the insensitivity of the peak near V_0 to these holes is not surprising, since this peak has been attributed to process (a), which should not be affected by hole trapping.

Conclusion

We have measured the photocurrent arising from subbandgap light irradiation of the n-Si-electrolyte junction. The measured effect is shown to arise from interface states and processes involving transitions to the conduction band and from the valence band are separately identified. The dependence of the photocurrent upon anodic voltage is accounted for quantitatively by the Schottky barrier lowering effect. The spectral dependence of the photoeffect allows us to deduce the energy distribution of the occupied interface states. The result suggests that these states are localized states on the semiconductor side, bound by the coulomb potential of adsorbed ions.

Electron Microscope Study of Annealed SiH_2^+ Implanted InP

J. J. Comer, D. Eirug Davies, and J. P. Lorenzo

Rome Air Development Center, Solid State Sciences Division, Hanscom Air Force Base, Massachusetts 01731

ABSTRACT

Transmission electron microscopy was used to characterize structural defects in annealed InP implanted both at room temperature and at 200°C with 10^{14} SiH_2^+/cm^2 at 150 keV. During implantation at room temperature an amorphous layer was formed to a depth of ~1850Å, whereas no such layer was formed on the specimen implanted at 200°C. Upon recrystallization of the amorphous layer at 650°C or higher shear dislocations were observed as well as loop structures up to 2000Å in diameter on {111} and {110} planes within that region. Smaller, interstitial loops were present on {110} planes throughout the implanted region. The specimens implanted at 200°C did not go through a recrystallization stage. Therefore, no shear dislocations were formed in this case. However, these specimens when annealed to 650°C or higher contained loops under 100Å in size. The structural differences observed between the room temperature and 200°C implants may account for the higher carrier mobility measured for the 200°C implant.

Structural damage resulting from ion implantation in elemental semiconductors such as silicon (1-5) and the III-V semiconductors, notably GaAs (6), has been studied extensively by transmission electron microscopy. A correlation was sometimes found between the extent of damage formed and the electrical behavior of the material after postimplantation annealing to obtain maximum electrical activity.

In ion implantation, damage results from displacement of atoms in the crystal lattice, causing the introduction of interstitial atoms and vacancy sites. When the specimen is annealed these defects aggregate to form dislocation loops. At high fluences, the damage may be severe enough to form an amorphous layer near the surface of the specimen. When this occurs, the postanneal temperature must be sufficiently high to bring about epitaxial regrowth of the layer. Earlier work on Si-implanted InP in which the substrate was heated to 200°C during the implantation suggested that an amorphous layer does not form under these conditions (7). The present work shows that, for room temperature implants, not only does an amorphous layer form at the surface but, also, that following post-implantation annealing the loop structures for these implants are much larger than the defects found in the hot implants under similar annealing conditions.

Whether the ion implantation method is used to form semi-insulating regions in InP or for conventional doping it is important to know the structural damage that occurs because of the effect it may have on device performance. To this end, transmission electron microscope studies were made of annealed InP implanted at room temperature and at 200°C. Defects formed under various annealing conditions have been characterized and the results of electrical measurements are presented to show how they may be affected by the defects.

Experimental

The InP used in these experiments was grown in these laboratories by the Czochralski encapsulation method and was doped with 10^{16} Fe/cm^3. Wafers were cut and polished to obtain specimens oriented 3° from the (001) plane. The concentration of grown-in dislocations was $\sim 10^4/cm^2$. Extreme care was exercised in handling the specimens because of the room temperature plasticity exhibited by the material (8, 9). Specimens were implanted with SiH_2^+ at room temperature or at 200°C. The fluence was 10^{14} $ions/cm^2$ at 150 keV. Postannealing was done isothermally in a PH_3/H_2 ambient to prevent deterioration of the InP surface (10). Anodic oxidation and stripping of the oxide layer was carried out on some specimens to obtain an estimate of the depth of the amorphous layer formed during the room temperature implant (11). Final thinning of the specimen for electron microscopy was done by the jet-etching method of Booker and Stickler (12) using 0.5% bromine in methanol for the solvent.

Specimens were examined in a JEM-100CX/ASID transmission electron microscope equipped with a ±60° goniometer and a ±45° tilting stage. The instrument was operated at 100 kV. All micrographs were printed with the emulsion side up. Kikuchi patterns were used to establish beam directions and diffracting vectors. Extensive use of stereomicrographs was made to determine loop planes or sense of tilt, and to measure distance of defects from the top or bottom surfaces of the specimen. To aid in these determinations, a 5Å thick layer of gold was evaporated onto the top or bottom surface for identification, and to establish a reference point for the measurements. The angle and direction of tilt was controlled by using Kikuchi patterns.

Results and Discussions

Room Temperature Implants

At a fluence of 10^{14} SiH_2^+/cm^2 at 150 keV an amorphous layer forms near the surface of the specimens. This layer was detected by both reflection electron diffraction and selected area diffraction. Similar amorphous layers have been reported for ion-implanted Si, Ge, and GaAs. They are derived from overlapping disordered zones in the crystal caused by atomic displacements (1-6, 13). An oxidation and stripping technique (11) was applied to the present specimens to remove from 100 to 750Å of material in each of several successive steps. After each step, the specimen was examined by reflection electron diffraction at 100 keV and electron channeling patterns at 20 kV. From these, it was estimated that the amorphous region extended to a depth of ~1850Å.

Recrystallization of the amorphous layer.—Some recrystallization of the amorphous layer occurred as the result of specimen heating caused by the electron beam during examination in the electron microscope. This was seen in the selected area diffraction mode where the diffuse rings, characteristic of the amorphous ma-

Key words: InP, ion implantation, transmission electron microscopy.

terial, gradually changed to sharp ring patterns showing some preferred orientation but no epitaxial regrowth. Other specimens were examined after annealing isothermally at temperatures ranging from 400° to 750°C for periods of 15 min. Although recrystallization occurs well below 400°C, epitaxial regrowth is not observed until the specimen is heated to 650°C or higher. Below 640°C, the recrystallized material was poorly oriented and the electron micrographs exhibited Moiré fringe patterns. Diffraction patterns contained "extra" spots due to double diffraction; streaking through the spots indicated the presence of thin platelets. A micrograph of material recrystallized at 600°C is shown in Fig. 1.

Dislocations associated with epitaxial regrowth.—Several examples of imperfect epitaxial recrystallization have been reported in the literature for ion-implanted Si and GaAs (3, 6, 13). Davidson and Booker (3) observed a dislocation network in annealed N^+ implanted Si which they believe formed at the interface between crystals of very slightly different lattice spacings resulting from the simultaneous recrystallization of two amorphous/crystalline interfaces on either side of a buried amorphous layer. They suggest that improper matching of the lattice could be due to varying impurity concentrations. In the present study, specimens annealed up to 650°C often contained regions where epitaxial regrowth was not complete. Contrast within these regions was different than in the surrounding epitaxially recrystallized material and Moiré fringes were observed. Some of these regions were present as islands within the epitaxially regrown material. While it is probable that the Moiré fringes are due to rotation of one lattice with respect to another identical one, this has not been proved. Therefore, the possibility that they are caused by slight differences in unit cell dimensions resulting from nonstoichiometric conditions cannot be ruled out. It is certain, however, that on heating to 700°C or higher no Moiré fringes remain and electron diffraction shows good epitaxial regrowth. Before this stage is reached, at 650°C or below, line dislocations extend from the poorly oriented material into the epitaxially regrown regions as shown in Fig. 2. Some of the dislocations are aligned along $\langle 110 \rangle$ directions. Where islands of incomplete epitaxial growth exist, as in Fig. 3, the dislocations spread out radially. Often these islands, which are sources of dislocations, were removed by preferential etching while thinning the specimen for electron microscopy. In all cases, the dislocations have Burgers vectors of the type $\bar{b} = a/2 \langle 110 \rangle$ inclined to the (001) specimen plane. A determination of the Burgers vectors of dislocation segments A and B is illustrated in Fig. 3. Segment A is out of contrast for $\bar{g} = 040$ and $\bar{g} = 1\bar{3}\bar{1}$ (Fig. 3c and 3e) but is in contrast for all other reflections. Applying the invisibility criterion for $\bar{g} \cdot \bar{b} = 0$, it was determined that $\bar{b} = \pm a/2$ [101] for this segment. Similarly, the Burgers vector of segment B which is out of contrast for $\bar{g} = \bar{4}00$ and $\bar{g} = \bar{3}1\bar{1}$ (Fig. 3d and 3f) was determined to be $\bar{b} = \pm a/2$ [011]. The depth of these dislocations was ~700Å below the surface, or within the region recrystallized from the amorphous state. Within the island are Moiré fringes, one set of which is shown in Fig. 3b.

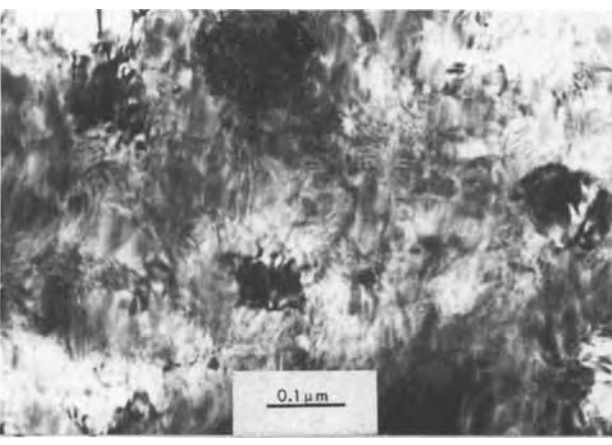

Fig. 1. Bright field electron micrograph illustrating a recrystallized amorphous layer after annealing at 600°C. Moiré fringes and other contrast effects are due to incomplete epitaxial regrowth.

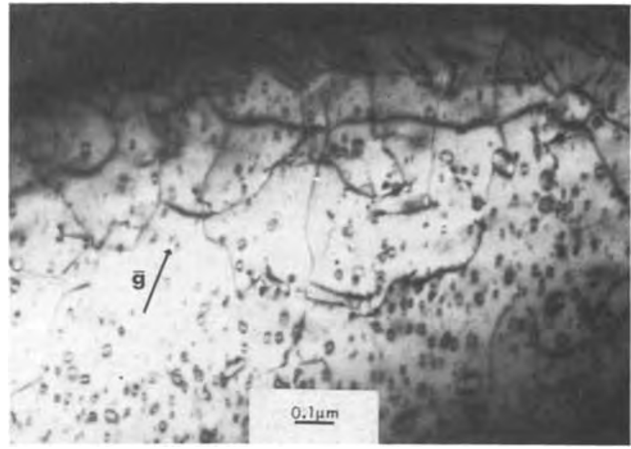

Fig. 2. This micrograph of a specimen annealed to 650°C shows regions of complete and incomplete epitaxial regrowth. The dislocations introduced at this stage have Burgers vectors of the type $a/2 \langle 110 \rangle$ inclined to the (001) plane of the specimen.

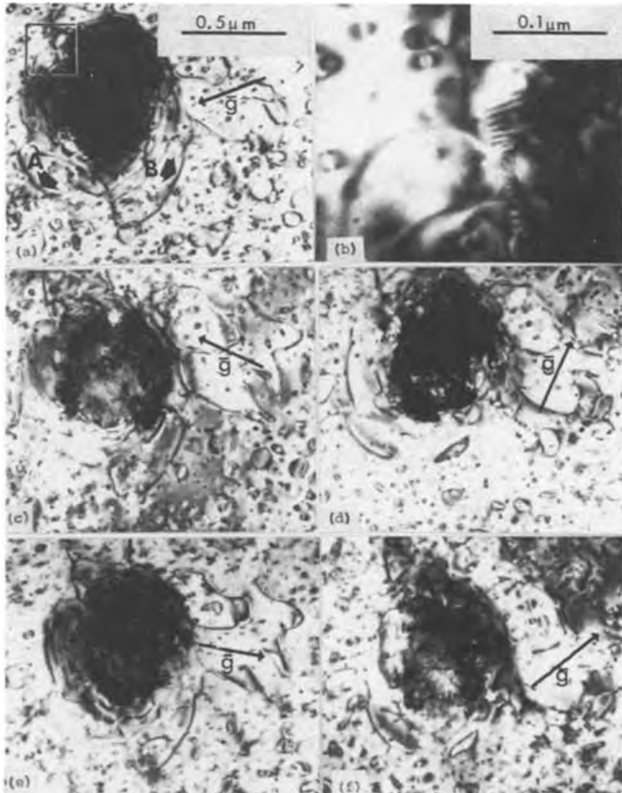

Fig. 3. Electron micrographs illustrating Burgers vectors determination of dislocations emitted from circular "islands" of poorly oriented regrown material. (a) $\bar{g} = 2\bar{2}0$; (b) enlargement of area within box in (a); (c) $\bar{g} = 040$; (d) $\bar{g} = \bar{4}00$; (e) $\bar{g} = 1\bar{3}\bar{1}$; and (f) $\bar{g} = \bar{3}1\bar{1}$. Beam directions were close to [001] for (a), (b), (c), and (f), and close to [$1\bar{1}4$] and [$\bar{1}14$] for (e) and (d).

Loop structures.—Half-loops were found in some specimens annealed at 650°C. In Fig. 4 the loop in the center of the field was found by stereomicroscopy to lie on the $(\bar{1}\bar{1}1)$ plane. It goes out of contrast when the diffracting vectors are $\bar{\mathbf{g}}$ = 400 or $3\bar{1}\bar{1}$ and is in contrast for the vectors $\bar{2}\bar{2}0$, 040, $\bar{2}20$, and $\bar{1}3\bar{1}$. From these observations, it was determined that $\bar{\mathbf{b}} = \pm a/2$ [011], with $\bar{\mathbf{b}}$ parallel to the loop plane. This is a shear loop containing both screw and 60° dislocation segments.

Other dislocation structures resulting from the recrystallization consist of large loops with meandering dislocations lines about 500-1000Å below the specimen surface. These loops, some of which are shown in Fig. 5, are not confined to a particular plane. An area of interest in Fig. 5 contains segments labeled A, B, and C. Points where the dislocation line rises sharply to the surface are shown by the arrows. In comparing images of the three segments for the operating reflections $\bar{2}\bar{2}0$, $13\bar{1}$, 400, and $2\bar{2}2$ (Fig. 5a-5d), loop A is out of contrast only for the $13\bar{1}$ reflection, B is out for the 400 and $2\bar{2}2$ reflections only, and C is out for $13\bar{1}$. From this, the Burgers vectors are found to be $\pm a/2$ [101], $\pm a/2$ [011], and $\pm a/2$ [101], respectively.

In a specimen annealed to 750°, shown in Fig. 6, the larger loops, 500-2000Å in diameter, lie on both {111} and {110} planes. These loops lie closer to the surface than the small loops which are uniformly dispersed throughout the specimen thickness. Intersecting loops on {111} planes share a common dislocation segment shown by the arrow in Fig. 6a. Stereomicroscopy shows that the loops are in a "butterfly" configuration with A on the $(\bar{1}\bar{1}1)$ and B on the (111) plane. Images were formed with the reflections $2\bar{2}0$, 220, 040, $2\bar{2}2$, $\bar{4}00$, and $\bar{3}1\bar{1}$. Since loop A is out of contrast only for the $\bar{4}00$ reflection, the Burgers vector is $\pm a/2$ $[0\bar{1}1]$. Loop B is out of contrast for 040 and $2\bar{2}2$, therefore $\bar{\mathbf{b}} = \pm a/2$ $[10\bar{1}]$. The shared dislocation segment is a screw type with $\bar{\mathbf{b}} = \pm a/2$ $[1\bar{1}0]$ and is out of contrast only for the 220 reflection. Similar results were obtained for other pairs of intersecting loops on {111} planes. The Burgers vector of loop A on the $(\bar{1}\bar{1}1)$ plane does not lie on the loop plane, whereas that of loop B on the (111) is parallel to the loop plane. Thus, A is a prismatic loop, and B is a glissile loop. The probable reaction between the two dislocations is: $a/2\ [10\bar{1}] + a/2\ [0\bar{1}1] = a/2\ [1\bar{1}0]$. The vector of this screw dislocation is parallel to the (001) specimen plane.

In Fig. 2-5 it is clear that many of the loops are under 500Å in diameter, and are uniformly distributed from top to bottom of the region of the specimen under examination. The concentration is $\sim 2 \times 10^{10}/\text{cm}^2$.

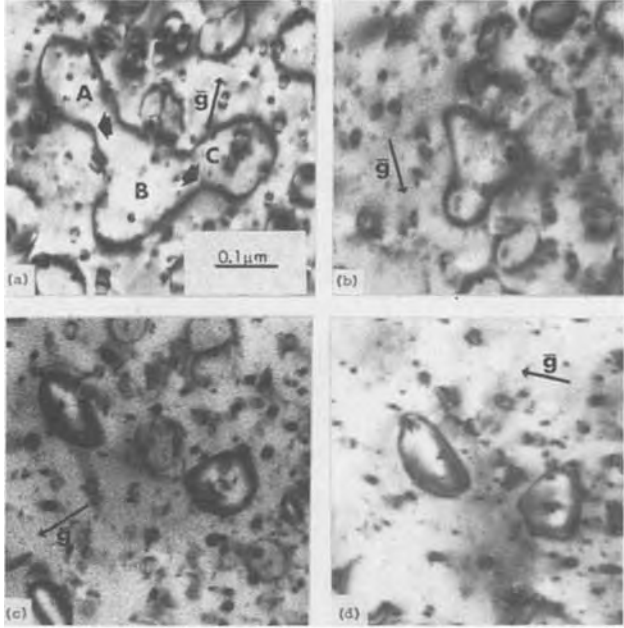

Fig. 5. Micrograph showing meandering loops in specimen annealed at 650°C. Segments A, B, and C are all in contrast for $\bar{\mathbf{g}} = \bar{2}\bar{2}0$ in (a). Other reflections are: (b) $\bar{\mathbf{g}} = 13\bar{1}$; (c) $\bar{\mathbf{g}}$ = 400; and (d) $\bar{\mathbf{g}} = 2\bar{2}2$. Beam directions are close to [001] for (a) and (c), and close to $[\bar{1}12]$ for (b) and (d). The dislocation line bends up sharply at points indicated by the arrows.

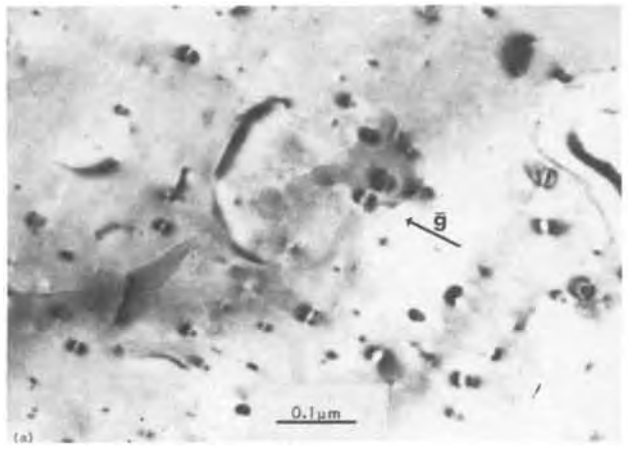
These loops form on annealing by aggregation of point defects. Unlike the larger loops associated with strain introduced by the recrystallization of the amorphous region, they lie mainly in {110} planes and are prismatic. The loops shown in Fig. 7 are all under 500Å except for the ones labeled A. These lie on the (101) plane, and the Burgers vector is $\bar{\mathbf{b}} = \pm a/2$ [101]. Smaller loops, B and C, on the $(1\bar{1}0)$ and (110) planes, have Burgers vectors of $\bar{\mathbf{b}} = a/2$ $[1\bar{1}0]$ and $\bar{\mathbf{b}} = \pm a/2$ [110].

Nature of loops.—Analyses were made to determine whether the prismatic loops were of the interstitial or vacancy type. The method used was that applied by Groves and Kelly to the analysis of loops in MgO (14). For the product $(\bar{\mathbf{g}} \cdot \bar{\mathbf{b}})s > 0$, where s is the deviation parameter, the loop exhibits outside contrast and for $(\bar{\mathbf{g}} \cdot \bar{\mathbf{b}})s < 0$ it exhibits inside contrast. In applying this method the sense of inclination of the loop was first determined by stereomicroscopy to establish the direc-



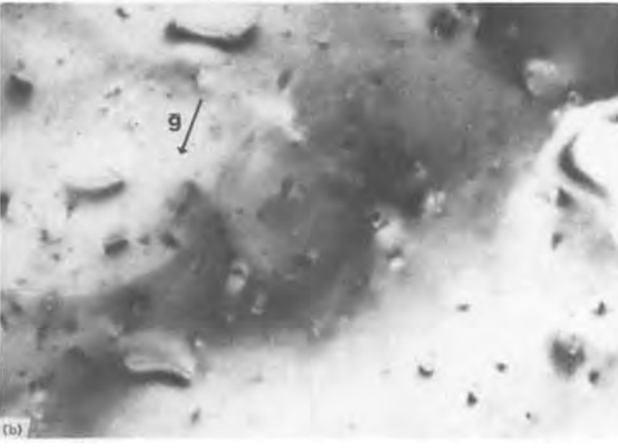


Fig. 4. Half-loop on (111) in contrast for $\bar{\mathbf{g}} = \bar{2}\bar{2}0$ in (a), and out of contrast for $\bar{\mathbf{g}} = 3\bar{1}1$ in (b)

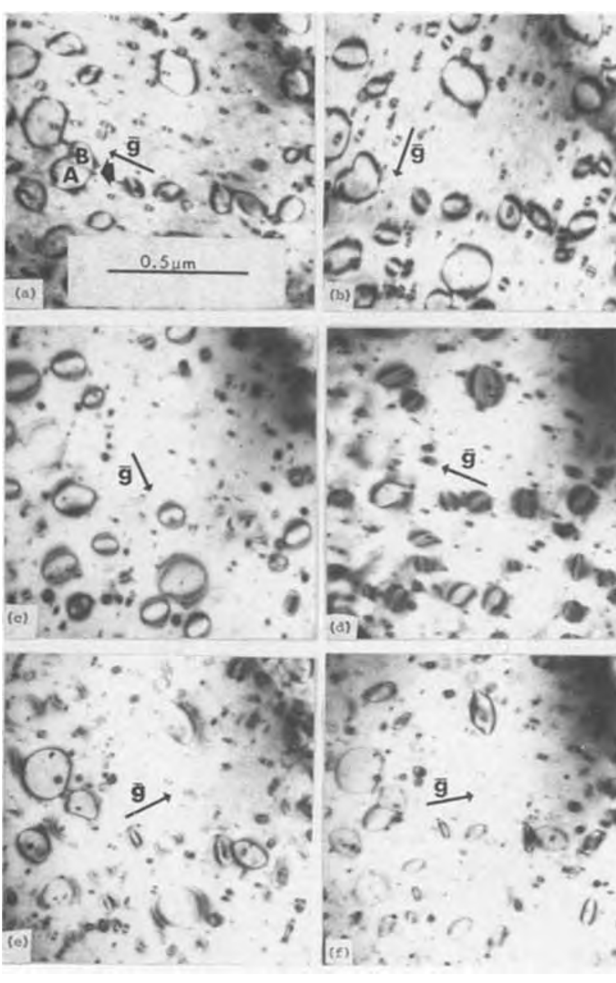

Fig. 6. Electron micrographs showing interaction between loop A on the $(\bar{1}\bar{1}1)$ plane and loop B on the (111) plane. The following diffracting vectors were used: (a) $\bar{g} = 2\bar{2}0$; (b) $\bar{g} = \bar{2}20$; (c) $\bar{g} = 040$; (d) $\bar{g} = 2\bar{2}2$; (e) $\bar{g} = \bar{4}00$, and (f) $\bar{g} = \bar{3}1\bar{1}$. Beam directions were close to [001] for (a), (b), (c), and (e) and were $[\bar{1}12]$ and $[\bar{1}14]$ for (d) and (f).

tion of $\bar{n}$, the upward-drawn normal to the loop. Then, images were obtained for $+\bar{g}$ and $-\bar{g}$ conditions while keeping $s > 0$. By noting whether the image exhibited outside or inside contrast the sense of $\bar{b}$ was determined. When $\bar{b}$ is in the same sense as that of the upward-drawn normal to the loop, $(\bar{n} \cdot \bar{b})$ is greater than

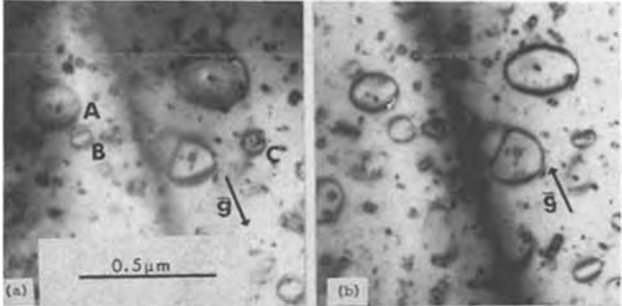

Fig. 8. Effect on loop size of tilting from $\bar{g} = 040$, $s > 0$ in (a) to $\bar{g} = 0\bar{4}0$, $s > 0$ in (b). Loops A and C shrink. Loop B expands.

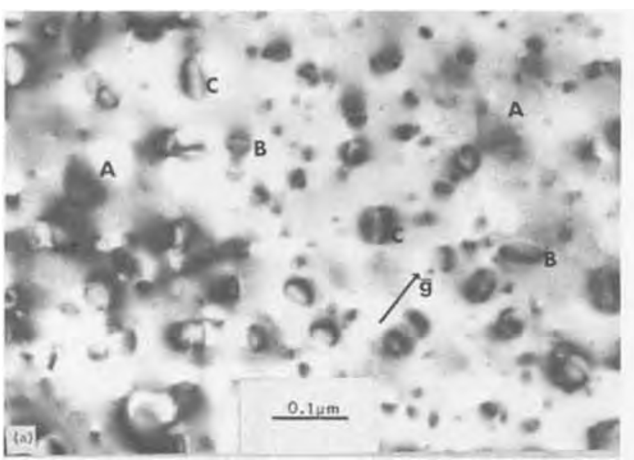
0 and the loop is interstitial in nature; if it is opposite in sense, the loop is of the vacancy type. In Fig. 8, loops A, B, and C were found by stereomicroscopy to lie on the (011), $(0\bar{1}1)$, and (011) planes and have Burgers vectors of $\pm a/2$ [011], $\pm a/2$ $[0\bar{1}1]$, and $\pm a/2$ [011]. In Table I the results obtained on imaging the layers with $\bar{g} = 040$ and $0\bar{4}0$ are summarized. The results indicate that the Burgers vectors are in the same upward direction as the loop normals and by definition are interstitial in nature. Similar results were obtained on other specimens annealed in the same manner.

Implants at 200°C

When the specimen was held at 200°C during the implantation no detectable amorphous layer formed. On annealing at 650°C the only defects found were "black spots," considered to be unresolved loops, and a few defects recognized as loops. The concentration of these defects was of the same order of magnitude as those for the room temperature implants. However, even after annealing at 750°C the average size of the defects was only 50-100Å in diameter as shown in Fig. 9 whereas loops above 2000Å in diameter were found in room temperature implants. A detailed analysis of the spots was not attempted. However, an estimate of the nature of the defects was made by applying a technique described by Wilkens (15). The bottom, or etched surface, of the specimen was coated with 5Å of evaporated gold so that it could be identified in stereomicrographs. Stereo pairs of micrographs were obtained using Kikuchi patterns to guide the tilting around a <220> axis, and to obtain accurate measurements of the tilt angle. Images of stereo pairs were obtained with a 220 reflection. A stereometer was used to measure the height of defects above the bottom surface so that those defects under 60Å in diameter lying between 0-100Å from the bottom could be selected for



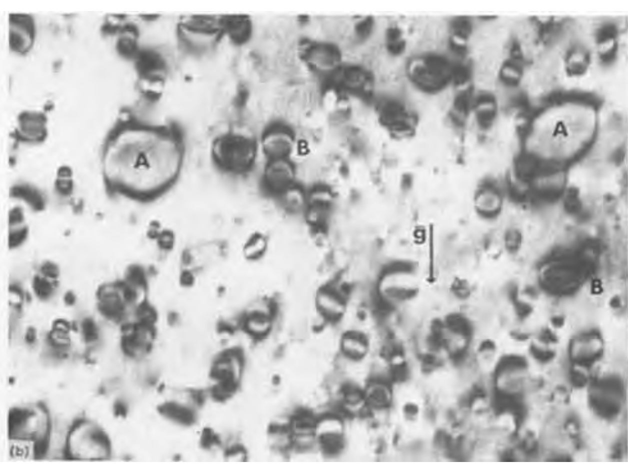


Fig. 7. Bright field micrographs of specimen annealed to 700°C showing loops on {110} planes derived from aggregation of point defects. Diffracting vectors are: (a) $\bar{g} = 0\bar{4}0$; and (b) $\bar{g} = \bar{2}20$. Loops A, B, and C lie on the (101), $(1\bar{1}0)$, and (110) planes, respectively.

Table I. Nature of prismatic loops on {110} planes

Loop	Loop plane	Loop contrast on changing from $\bar{g}$ = 040, s > 0 to g = $0\bar{4}0$, s > 0	Sign of n · b	Loop nature
A	(011)	Inside, (g · b)s < 0	>0	Interstitial
B	($0\bar{1}1$)	Outside, (g · b)s > 0	>0	Interstitial
C	(011)	Inside, (g · b)s < 0	>0	Interstitial

observation. For these defects, the direction of black-to-white contrast on positive prints made from micrographs under bright-field conditions pointed in the same direction as the $\bar{g}$ vector. This type of contrast is expected for interstitial defects where the distance of the defect is less than one-third of the extinction distance from the bottom of the specimen.

Effect of implantation temperature on carrier mobility.—The difference in the physical structure of the material is also reflected in the electrical properties. In some recent work with 1 MeV Si^+ implants into InP, it was shown that the electron mobility was greater by a factor of ~2 on implanting at 200°C rather than at room temperature (7). This applied after annealing at the temperatures ranging from 650° to 800°C. While measurements on lower energy implants are less extensive, the same appears to hold in this case as well. For 4 × 10^{14} Si^+ cm^{-2}, 200 keV implants at RT and 200°C, the corresponding sheet mobilities were 1130 and 860 cm^2/Vsec. This was after annealing to 750°C in a PH_3/H_2 ambient without encapsulation and where the active sheet carrier concentrations were 1.91 × 10^{14} cm^{-2} and 1.96 × 10^{14} cm^{-2}. Other similar concentration room temperature implants at 100 and 200 keV have yielded mobilities ranging from 500 to 740 cm^2/Vsec. The peak concentrations within such layers are ~10^{19} cm^{-3}. As similarly doped epitaxial layers yield mobilities ~1000 cm^2/Vsec, it is apparent that factors other than dopant impurity scattering again limits the mobility within room temperature implanted layers at these lower energies.

Summary and Conclusions

When InP is implanted with 10^{14} SiH_2^+ at room temperature at an energy of 150 keV an amorphous layer is formed near the surface to a depth of ~1850Å. However, similar implants into specimens at 200°C do not produce this layer.

For room temperature implants, epitaxial regrowth of the amorphous layer at ~650°C introduces shear dislocations generated at the interface between single crystal and poorly oriented material. These form closed loops about 500-100Å below the specimen surface. The dislocation line enclosing the loops meanders and does not lie in any particular plane. At 700°-750°C the larger loops are replaced by smaller ones, still over 500Å in diameter, lying on both {111} and {110} planes. Both prismatic and shear loops were found on the {111} planes. Interaction between two such loops results in the formation of a screw dislocation common to both loops. The Burgers vector was of the type $\bar{b}$ = a/2 <110> parallel to the (001) specimen plane. The other important defects observed first at 650° along with the shear dislocations were prismatic loops of an interstitial nature lying on {110} planes. These were mainly under 500Å in diameter and were uniformly dispersed throughout the depth of the region under examination. Their concentration was ~2 × 10^{10}/cm^2. These loops are believed to be formed by aggregation of point defects.

The specimen implanted at 200°C did not have to go through a recrystallization stage upon postannealing. Therefore, shear dislocations, as observed in the room temperature implants, were not formed. On annealing, damage resulting from the implantation appeared as black spots, some of which could be recognized as loops. These are believed to form by aggregation of point defects. The concentration of these defects was of the same order of magnitude as the loops found in the room temperature implants. The size of the loops, even after a 750°C anneal, was only 50-100Å in diameter. These defects also appear to be interstitial in nature.

That dislocations can affect the electrical properties of semiconductors has been known for some time (16), and recent papers by Booyens, Vermaak, and Proto (17, 18), and Esquivel, Sen, and Lin (19) have discussed the electrical anisotropy of α and β dislocations in III-V compounds as they affect carrier mobility. In the present case, an increase in electrical carrier mobility by a factor ~1.3 was demonstrated for hot implants at 150-200 keV and, earlier, an increase by a factor of ~2 (7) for 1 MeV implants. From these results, we conclude that the reduction in structural damage observed for the high temperature implants may account in part for the increase in carrier mobility.

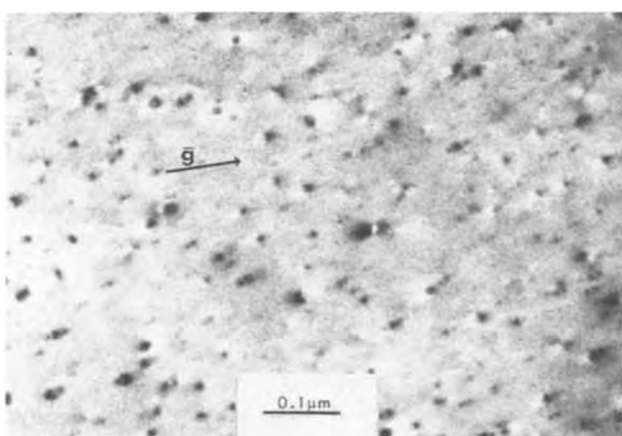

Fig. 9. Black-white contrast of defects in specimen implanted at at 200° and annealed at 750°C. Defect concentration is 4 × 10^{10}/cm^2. Grainy background is from evaporated gold film.

ABSTRACT

The study was carried out on the gas adsorption and the $\alpha \rightarrow \beta$ phase transition in metal phthalocyanine (Pc) crystals at different degrees of purity. The uptake of NH_3, O_2, or H_2S on CuPc crystals decreased remarkably with the degree of purification, but the uptake of HCl did not change. The $\alpha \rightarrow \beta$ phase transition of CuPc crystals was accelerated by purifying, and it was considerably affected by the ambient gases in the low purity crystal, and hardly at all affected in the high purity crystal. The $\alpha \rightarrow \beta$ phase transition of ZnPc crystals in NH_3 gas began upon decomposition of the NH_3-ZnPc addition complex (near 220°C) which formed readily at 25°C. The results of NiPc crystals were mostly similar to that of CuPc crystals.

The phase transition phenomenon in metal phthalocyanine (Pc) crystals has been extensively investigated, since the crystals are used as organic semiconductors exhibiting different properties due to crystallographic modification (1-3).

The dependence of some properties of metal Pc crystals on impurity presence is still an open question because of the difficulty in obtaining the high purity crystals in spite of purification by combined procedures of vacuum sublimation, acid washing, and extraction by organic solvents (3-7). Recently, Kiryukhin *et al.* (6) and Sadaoka *et al.* (7) reported the dependence of electrical conductivity of CuPc crystals on crystal purity. Also Sakaguchi *et al.* (8) observed the $\alpha \rightarrow \beta$ phase transition in CuPc crystals to be appreciably affected by chemisorption of ambient gases on the crystal.

In the present work, we report a study on gas adsorption and the $\alpha \rightarrow \beta$ phase transition in CuPc crystals at different degrees of purity. Similar examinations are reported for ZnPc and NiPc crystals.

Experimental

Materials.—Commercial β-CuPc crystals[1] (supplied by Toyo Ink Manufacturing Company, Limited) were pretreated by washing with sulfuric acid [2 weight percent (w/o)] and NaOH aqueous solution (2 w/o), and followed by washing with pure water (deionized and distilled), then the crystals were vacuum dried and ground; this is our source sample A. This source sample A was further purified by extraction with organic solvents and by vauum sublimation; the details are given in Table I. Sample B (α-CuPc) was prepared by recrystallization from concentrated sulfuric acid solution using source sample A followed by washing successively in pure water, NH_4OH (2 w/o), and pure water; then the residue was vacuum dried for 2 hr at 110°C and ground (200 mesh through). Sample C was purified by Soxhlet extraction with methyl alcohol (MeOH). Samples D, E, and F were purified by repeated consecutive Soxhlet extractions with dimethylformamide (DMF) and MeOH, and sublimation *in vacuo* (10^{-3} mm Hg at 480°C); each sample was further subjected to similar recrystallization process as for sample B. α-ZnPc and α-NiPc crystals (supplied by Eastman Kodak Company) were prepared by a similar pretreatment as sample F. In the highest purity sample F, the high pure α-ZnPc, and the high pure α-NiPc, no organic impurity was detected by gas chromatographic and liquid chromatographic analyses, and the total amount of the foreign metals did not exceed 15 ppm according to atomic absorption spectrometry.

The reagents (DMF, MeOH, sulfuric acid, aqueous ammonia) used in these experiments were guaranteed reagent grade (supplied by Junsei Chemical Company, Limited).

The gases used for the adsorption and the heating atmosphere of phase transition reaction were prepared as follows: high purity He was further purified by passage through a glass tube containing the molecular sieve 5A at −196°C; high purity HCl, H_2S, and NH_3 were further purified by vacuum distillation using both Dry Ice-alcohol and liquid O_2 baths; O_2 was prepared by evaporation of pure liquid O_2.

Apparatus.—The apparatus used for heat-treatment and adsorption measurements in various ambient gases and BET surface area measurements was of the static

* All samples are transformed into α-form crystal.

type constructed of borosilicate glass. The system dead space was ~100 ml. The sample chamber was protected from mercury and grease contamination by presence of cold trap (0°C).

Procedure.—(a) Gas adsorption.—The weighed sample (2.0g), after preliminary evacuation at 25°C for 1 hr, was further evacuated under high vacuum at 250°C for 1 hr. The adsorbate gas (initial pressure: 100 mm Hg, *i.e.*, 5.2×10^2 μmole) was then admitted to the sample. The surface area of each sample was determined by BET method using N_2 as adsorbing gas at −196°C. The uptake of gases (NH_3, O_2, H_2S, HCl) by all metal Pc crystals was irreversible under the present experimental conditions, *i.e.*, these gases were sorbed on the crystals.

(b) Phase transition.—The sample (1.0g) was heated at 200° ~ 300°C for 1 hr in various gases (1 atm) after evacuating under high vacuum for 1 hr at 25°C. The time interval required to reach the heating temperature was 20 min in all cases. After heating the sample was rapidly cooled at the rate of about 50°C/min. The x-ray powder diffraction pattern of each heated sample was obtained using Cu(Ni)Kα radiation, and the β-form content was determined by the method reported by Suito *et al.* (9). The rate of the α → β phase transition of metal Pc crystals during heating in various gases was determined by using an apparatus which enabled simultaneous measurement of high temperature x-ray diffraction and differential thermal analysis (DTA) (Rigaku Denki Company, Limited).

Results

The sorption characteristics of various gases on sample B are shown in Fig. 1. The lower initial uptake of O_2 is in striking contrast to HCl and NH_3 sorption.

The sorption characteristics of NH_3 on each α-CuPc crystal (samples B ~ F) of varying purity are shown in Fig. 2. The uptake of NH_3 decreased considerably with the purity.

The sorption characteristics of various gases on the highest purity crystal, sample F, are shown in Fig. 3. The uptake of HCl with time is in striking contrast to NH_3, H_2S, O_2.

The effect of the ambient gases on the α → β phase transition in samples B and F at different temperatures is given in Fig. 4. The noticeable effect of the ambient gas on the transition is evident for sample B whereas for the highest purity sample F the effect of the gas is barely discernible. It was reported by Takahashi (10) that the transition temperature in air was at 250° ~ 300°C. It is noteworthy that in the most pure crystal, the phase transition was least affected by the sorption of HCl, nevertheless the crystal sorbed HCl gas readily.

The ambient gas phase transition effect on samples B and F in NH_3, O_2, and He was examined in more detail[2] by using simultaneous high temperature x-ray diffraction and DTA as shown in Fig. 5 and 6. The temperature for α → β conversion (intersection of α and β line intensities) in sample B decreases in the order O_2 > He > NH_3 whereas no such order is recognizable in sample F; these results are consistent with Fig. 4. In the case of heating sample F in O_2, the diffraction peaks characteristic of β-form crystals disappeared near 300°C with the simultaneous increase in exothermicity on the DTA curve; these results are in direct contrast to sample B heated in O_2. We interpret these results to indicate that sample F is more reactive

[2] HCl and H_2S gases were not included because of corrosive action on instrument.

than sample B in an oxidizing atmosphere at 300°C. For comparison purposes, we examined two other commercially available CuPc crystals[3] (Eastman Kodak Company, Tokyo Kasei Industrial Company) and we obtained similar results.

Parallel experiments carried out on the high purity α-ZnPc and α-NiPc crystals obtained using the purification procedure detailed for sample F gave the results shown in Fig. 7. In view of the high sorption for NH_3 on α-ZnPc crystals it was desirable to extend the study of gas sorption (NH_3, O_2, He) on α-ZnPc crystals by simultaneous high temperature x-ray diffraction and DTA; the curves are presented in Fig. 8. He and O_2 presence show no effect on the characteristic peak height of α-ZnPc crystals up to 220°C at which temperature a slight rise in diffraction peak intensity and weak endotherm is observed. On the other hand, the presence of NH_3 on α-ZnPc affects an immediate disappearance of α-ZnPc diffraction peak and appearance of a high diffraction peak at a lower angle with a

[3] The data for the impurity contained in these commercial CuPc crystals was similar to that of the CuPc crystal supplied by Toyo Ink Manufacturing Company, Limited.

simultaneous exothermic effect on the DTA curve. The characteristic features of the assumed NH_3-ZnPc addition complex disappeared at 220°C followed by the reappearance of the α-ZnPc peak and the onset of $\alpha \rightarrow \beta$ phase transition which is almost complete at 350°C. The endotherm at 320°C is attributed to a recrystallization or sintering effect. The effects of ambient gases on the initial and final temperatures of the phase transition in α-ZnPc crystals showed a similar trend to sample F.

The results of the phase transition study on the α-NiPc crystals using the same method did not follow the pattern of behavior in α-ZnPc crystals, but were similar to that of the highest purity sample F.

Discussion

The impurities present in CuPc crystals are interpreted to be bound as a complex or some stable configuration because the impurities resisted extraction by normal procedures (*cf.* Table I and Fig. 2). As shown in Fig. 2, the high purity CuPc crystals did not exhibit the sorption capacity for NH_3, but the low purity CuPc crystal complex showed an increased ability for gas sorption. Steinbach *et al.* (11) pointed out that the enhanced gas sorption ability of the complex must result from the change of electron density of the Cu atom in the CuPc molecule due to the strong interaction of π electron between the CuPc molecule and incorporated impurities.

In the case of O_2 sorption, the slight initial increase of O_2 uptake reflects a net effect resulting from generation of volatile products from the oxidized surface, *i.e.*, surface cleansing action. The subsequent O_2 uptake is enhanced by surface oxide layer.

Because of its highly ionic polar character HCl would be expected to be sorbed not only on the Cu atom but also on the edge benzene group in CuPc molecule as shown by Shigemitsu (13). Accordingly, the sorption ability of HCl should not be affected by the purity of the crystals (Fig. 3).

The phase transition in sample B was promoted by NH_3 or HCl, but inhibited by O_2 or H_2S exhibited an inhibiting effect in comparison with He or vacuum. These results suggest that the sorbed gas affects the intermolecular force within the CuPc crystal. That is, the intermolecular force of CuPc crystals would be weakened by the sorption of NH_3 or HCl and strengthened by the sorption of O_2 or H_2S. Accordingly, the rate of phase transition with negligible gas sorption on sample F, except for HCl was similar in all ambient gases (Fig. 4); HCl would not be expected to be as effective on the phase transition of sample F even if it were taken up by sample F. Furthermore, the phase transition in highest purity sample F occurred at lower temperatures than in sample B since the stabilizing effect due to bound impurities in the CuPc crystal was absent. The negligible effect of ambient gas on the phase transition temperature for sample F, is consistent with this fact.

The result that the high sorption of NH_3 was instantaneous on the high purity α-ZnPc crystal is attributed to the formation of NH_3-ZnPc complex (Fig. 8). This interpretation is supported by x-ray diffraction pattern and DTA thermal peaks along with the parallel formation of the n-hexylamine complex of ZnPc crystal as reported by Kobayashi *et al.* (14).

The basis for NH_3-metal Pc complex formation in ZnPc crystal only might be found in the character of divalent zinc ion to adopt a tetrahedral configuration by use of sp^3 hybrid orbitals, but the details must await further work.

The Nucleation of CVD Silicon on SiO_2 and Si_3N_4 Substrates

II. The SiH_2Cl_2-H_2-N_2 System

W. A. P. Claassen and J. Bloem*

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

A description is given of nucleation experiments with silicon on SiO_2 and Si_3N_4 substrates in the SiH_2Cl_2-H_2-N_2 system, performed at temperatures between 800° and 1100°C. The saturation cluster densities were determined for different mixtures as a function of temperature and could be varied between 10^5-10^{10} cm^{-2}. A reaction scheme is proposed in which silicon adatoms reach a steady-state concentration before nucleation occurs. Comparison of the experimental data with existing nucleation theories gives approximate values for the size of the critical cluster. A strong adsorption of atomic hydrogen, especially on SiO_2 surfaces, may explain the substantial differences in nucleation on SiO_2 and Si_3N_4 surfaces at temperatures below 1000°C.

Polycrystalline silicon layers are finding extensive application in the fabrication of integrated circuits, *e.g.*, as gate material in MOS (metal-oxide-silicon) field effect transistors (1). For this purpose CVD with SiH_4 as input gas is most widely used, but chlorosilanes too, such as $SiHCl_3$ and $SiCl_4$ and recently SiH_2Cl_2, are becoming increasingly important as starting materials for the deposition of silicon layers (2). Reports of nucleation experiments with silicon on amorphous, polycrystalline, and monocrystalline substrates are relatively scarce. The present authors discussed such experiments in a previous paper dealing with nucleation of silicon on SiO_2 and Si_3N_4 substrates in the SiH_4-HCl-H_2 system (3). The present paper deals with nucleation in the SiH_2Cl_2-H_2-N_2 system on SiO_2 and Si_3N_4 substrates. The experimental results are described and compared with existing nucleation theories.

Experimental

The nucleation experiments were performed in a horizontal rf heated reactor, consisting of a rectangular air-cooled fused silica tube, provided with a pyrographite-coated carbon susceptor covered with a thin layer of silicon. Nucleation of silicon was performed on silicon slices (wafer 0.5 in. square) covered with an amorphous 1500Å thick LP-CVD SiO_2 or Si_3N_4 layer. The effective cross section of the reactor tube was about 11 cm^2. The gas system was provided with automatic mass flow controllers for the hydrogen and nitrogen carrier gas and the SiH_2Cl_2 source. Some experiments were performed with $SiHCl_3$, in which case the input concentrations were controlled by passing a flow of hydrogen, monitored by means of an automatic mass flow controller, through a bubbler filled with $SiHCl_3$ at a constant temperature. The carrier gas was purified; both water vapor and oxygen concentrations were below 1 ppm. The slices were cleaned prior to a deposition experiment in an H_2SO_4-H_2O_2 mixture followed by rinsing in water of ultrahigh purity. After spin drying, the slices were further cleaned in the reactor tube with 0.2 volume percent (v/o) HCl in hydrogen at 1000°C for 5 min. After this, the reactor was purged by a hydrogen flow, while the substrate temperature was brought to the desired nucleation temperature. Prior to deposition the reactor was flushed with the particular H_2-N_2 mixture, which is also used during the nucleation experiment for about 5 min. During the nucleation experiment the H_2-N_2 mixture loaded with SiH_2Cl_2 was passed over the slices. In order to obtain stable gas flow conditions a room temperature gas velocity of about 60 cm/sec was chosen. The temperature of the slices was measured with an optical pyrometer focused on the surface of an uncoated silicon slice, and the values were corrected for the emissivity of silicon and the absorption and reflection of the system. After termination of the experiment the substrates were cooled without SiH_2Cl_2 addition and inspected at room temperature. The density of the nuclei formed was determined from either SEM or TEM photomicrographs.

Experimental Results

A series of short depositions was carried out with different concentrations of SiH_2Cl_2 in H_2, N_2, or mixtures of H_2 and N_2 at temperatures between 800° and 1100°C. As in the SiH_4-HCl-H_2 system (3), it was

* Electrochemical Society Active Member.

Key words: polysilicon, nucleation, CVD.

found that after an incubation period the density of stable clusters very quickly reached a saturation density of nuclei with respect to exposure time. After this period the clusters merely increased in size until coalescence occurred. The existing clusters showed a very narrow size distribution, from which it may be concluded that the clusters are formed in a very short period of time.

Nucleation on an SiO_2 substrate.—The experimentally observed saturation densities of Si clusters in the SiH_2Cl_2-H_2-N_2 system have been collected in Table I. In Fig. 1 the saturation densities of silicon clusters on SiO_2 substrates at 1000°C are plotted for 0.1 v/o SiH_2Cl_2 for some H_2-N_2 mixtures, the latter expressed as $p_{H_2}/(p_{H_2} + p_{N_2})$. The highest saturation density can be observed for pure nitrogen, while the introduction of hydrogen strongly reduces the saturation density of Si clusters on SiO_2 substrates. Figure 2 gives a plot of the saturation density of nuclei *vs.* the reciprocal temperature in the temperature region 925°-1100°C (with the exception of nitrogen, where results at 800°C are also given). For nitrogen the formation process is barely a function of temperature. If hydrogen is added to the mixture the temperature dependence of the formation process increases with increasing hydrogen concentrations. Figure 3 shows photomicrographs of nucleations on SiO_2 substrates at 1000°C, for an input concentration of 0.1 v/o SiH_2Cl_2 in pure H_2 (a) and pure N_2 (b).

It is shown below that the experimental data on saturation densities of nuclei (N_S) on an SiO_2 substrate at 1100°C as a function of gas phase composition can be described by

$$N_s = \frac{A p_{SiH_2Cl_2}(b)}{1 + B p_{H_2}^{1/2}} \quad [1]$$

where $p_{SiH_2Cl_2}(b)$ is the input concentration of SiH_2Cl_2 and A and B are constants. For $Bp_{H_2}^{1/2} > 1$ a plot of $\log\,[N_s/p_{SiH_2Cl_2}(b)]$ *vs.* $\log\,(p_{H_2})$ should show a linear dependence, as indicated in Fig. 4. For temperatures below 1100°C the tangent in Fig. 4 differs from ½ for high hydrogen pressures. In this figure the points at p_{H_2} around 10^{-3} represent the saturation densities of nuclei for the SiH_2Cl_2-N_2 system (no hydrogen added). As described later, in a nitrogen medium SiH_2Cl_2 decomposes almost completely in the gas phase to $SiCl_2$ and H_2. This means that an input concentration of 0.1 v/o SiH_2Cl_2 gives $p_{H_2} \cong 10^{-3}$ bar.

Nucleation on an Si_3N_4 substrate: difference compared with an SiO_2 substrate.—Table II gives the experimental data for the saturation densities of stable clusters on Si_3N_4 substrates in the SiH_2Cl_2-H_2-N_2 system. Figure 1 also shows saturation densities of silicon clusters for Si_3N_4 substrates as a function of $p_{H_2}/(p_{H_2} + p_{N_2})$ at 1000°C. The difference between SiO_2 and Si_3N_4 substrates is remarkable. Introduction of hydrogen to the system reduces the saturation density of nuclei for the Si_3N_4 substrate, but for the SiO_2 substrate the variation is much stronger. In Fig. 5 saturation densities of nuclei on Si_3N_4 substrates are given for 0.1 v/o SiH_2Cl_2 in hydrogen and nitrogen as a function of temperature. As for the SiO_2 system (Fig. 2) the experiments in hydrogen give the lowest saturation density of nuclei and the strongest temperature dependence of the formation process. It appears that if the hydrogen content is very low there is hardly any difference between an SiO_2 and an Si_3N_4 substrate. The experimentally found expression for the saturation density of stable clusters (Eq. [1]) as a function of temperature and gas phase composition could also be used for Si_3N_4 substrates. In Fig. 6 $\log\,(N_s/p_{SiH_2Cl_2})$ *vs.* $\log\,(p_{H_2})$ is plotted at 1000°C for Si on Si_3N_4, giving a linear dependence between the two parameters. Further it can be observed that the tangent in this figure is smaller than ½, indicating that the assumption $Bp_{H_2}^{1/2} > 1$ is not acceptable in this case.

Nucleation of Si on SiO_2 and Si_3N_4 substrates: comparison of the SiH_2Cl_2-H_2 system with other silicon-containing compounds in hydrogen.—Figures 7 and 8 give saturation densities of silicon clusters for SiO_2 and Si_3N_4 substrates, respectively, as a function of temperature for SiH_4 (3), SiH_2Cl_2, and $SiHCl_3$ (all concentrations about 0.1 v/o) in hydrogen as a carrier gas. The difference in the saturation nucleus density between SiH_4 and SiH_2Cl_2 as the silicon-containing compounds for both substrates is remarkable. The saturation density of nuclei in the SiH_4-H_2 system increases with decreasing temperatures, whereas for the other systems the opposite occurs. On SiO_2 substrates $SiHCl_3$ behaves in much the same way as SiH_2Cl_2, whereas on Si_3N_4 substrates this is only true at high temperatures (Fig. 8).

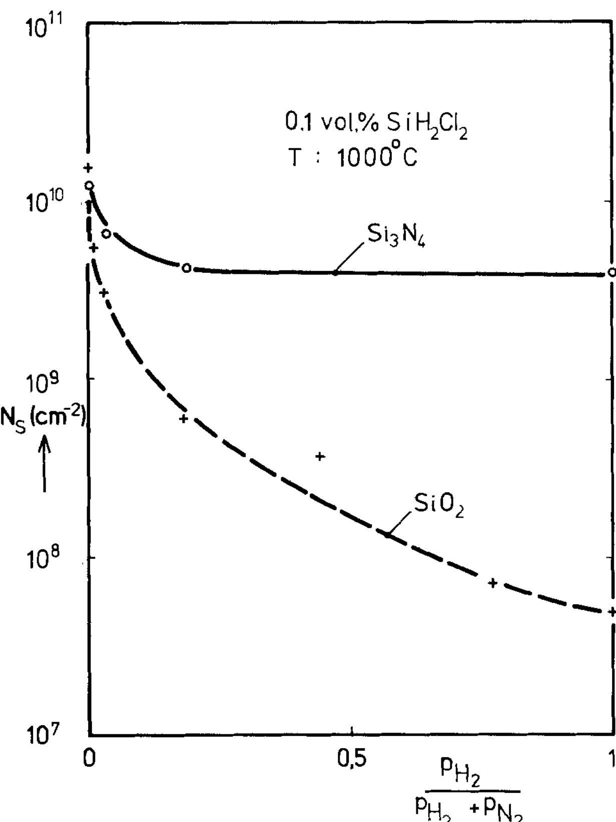

Fig. 1. The saturation nucleus density for some H_2-N_2 mixtures and 0.1 v/o SiH_2Cl_2 on SiO_2 and Si_3N_4 substrates at 1000°C.

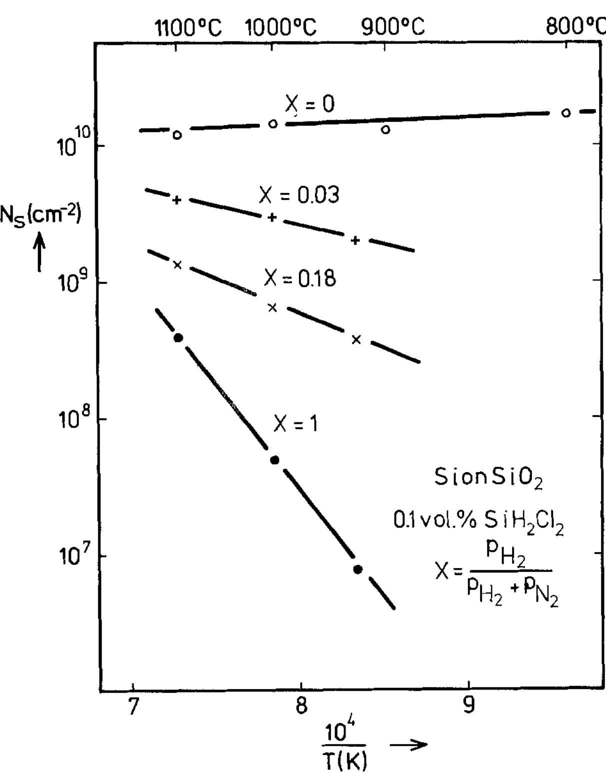

Fig. 2. The saturation nucleus density as a function of temperature on SiO_2 substrates for some H_2-N_2 mixtures and 0.1 v/o SiH_2Cl_2.

It was observed that the growth rate of silicon on silicon for a mixture of 0.1 v/o SiH_4 and 0.2 v/o HCl is almost equal to that of 0.1 v/o SiH_2Cl_2, both systems having hydrogen as a carrier gas and a temperature of 1000°C (4). It is therefore interesting to compare the saturation densities of nuclei on SiO_2 and Si_3N_4 substrates in the SiH_2Cl_2-H_2 system with the results of nucleation experiments in the SiH_4-HCl-H_2 system. In Fig. 9 saturation densities of silicon clusters are given for SiO_2 and Si_3N_4 substrates as a function of temperature for 0.1 v/o SiH_2Cl_2 and a mixture of 0.1 v/o SiH_4 and 0.2 v/o HCl (4), botn systems in a hydrogen medium. It can be observed on both substrates that for the SiH_2Cl_2-H_2 mixture the saturation density of nuclei decreases with decreasing temperature, whereas for the SiH_4-HCl-H_2 mixture the opposite occurs.

Discussion

Adatom concentration and surface coverage.—In order to arrive at an expression describing the adatom concentration of silicon on the substrate it would be very helpful to have thermochemical data of the Si-H-N-Cl system. With this in view thermochemical data of the Si-H-Cl and Si-N-Cl systems have been calculated for $Cl/H_2 = 10^{-3}$ and $Cl/N_2 = 10^{-3}$, respec-

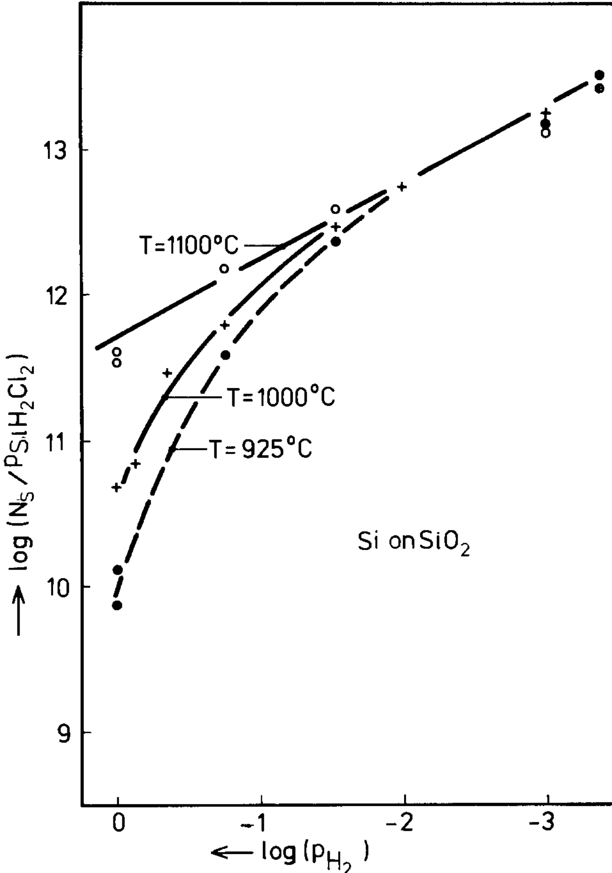

Fig. 4. The saturation nucleus density at 925°-1000°C and 1100°C for different mixtures of SiH_2Cl_2-H_2-N_2, expressed as log ($N_s/p_{SiH_2Cl_2}$) vs. log (p_{H_2}), on SiO_2 substrates.

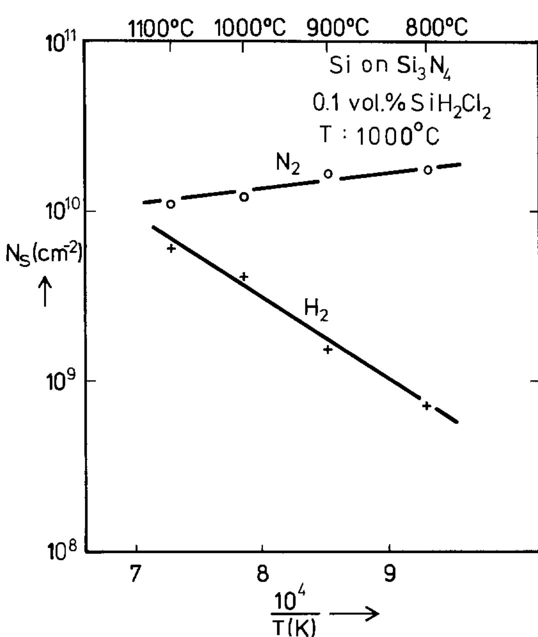

Fig. 5. The saturation nucleus density on Si_3N_4 substrates for 0.1 v/o SiH_2Cl_2 in pure H_2 (+) and pure N_2 (○) as a function of temperature.

tively, in the temperature range of 900°-1400°K, using the procedure reported by Van der Putte *et al.* [5] (Fig. 10). In equilibrium with solid silicon the most abundant species are H_2, HCl, $SiCl_2$, SiH_2Cl_2, $SiCl_4$, and $SiHCl_3$, in accordance with mass spectrometric analysis results reported by Ban and Gilbert (6). With the aid of thermochemical data a number of reactions that can take place on or near the substrate are sum-

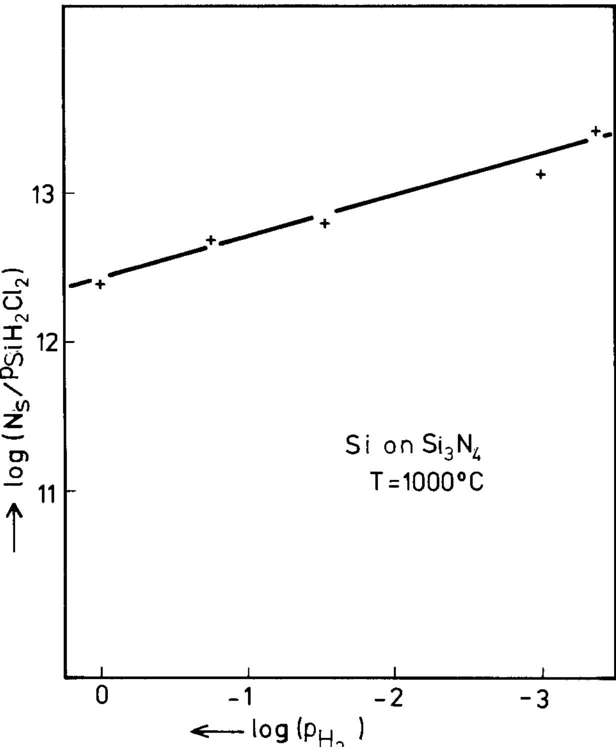

Fig. 6. Log ($N_s/p_{SiH_2Cl_2}$) vs. log (p_{H_2}) at 1000°C for Si on Si_3N_4.

marized in the Appendix. As discussed in the Appendix, reasonable assumptions could be made for the initial states of nucelation, leading to an expression for the silicon adatom concentration [A-15]

$$\frac{n_1}{n_0} = \frac{K_3 p_{SiCl_2}}{k_8(1 + K_3 p_{SiCl_2} + K_{10} p_{H_2}{}^{1/2})} \quad [2]$$

The dissociation of SiH_2Cl_2 to $SiCl_2$ and H_2 [A-1] followed by a very strong adsorption of $SiCl_2$ compared to SiH_2Cl_2 plays an important role in obtaining this expression. The decomposition parameter α of reaction [A-1] can be defined by

$$p_{SiH_2Cl_2} = (1 - \alpha) p_{SiH_2Cl_2}(b)$$

$$p_{SiCl_2} = \alpha p_{SiH_2Cl_2}(b) \quad [3]$$

where $p_{SiH_2Cl_2}(b)$ is the input concentration of SiH_2Cl_2. If the equilibrium partial pressure of $SiCl_2$ is much higher than that of SiH_2Cl_2 it can be assumed that the decomposition of SiH_2Cl_2 into $SiCl_2$ and H_2 is almost complete ($\alpha \cong 1$) (Fig. 10). For an H_2-N_2 mixture we obtain, by introducing the decomposition parameter α into Eq. [2]

$$\frac{n_1}{n_0} = \frac{A\alpha p_{SiH_2Cl_2}(b)}{(1 + K_3\alpha p_{SiH_2Cl_2}(b) + K_{10} p_{H_2}{}^{1/2})} \quad [4]$$

where $A = K_3/k_8$. Equation [4] for the silicon adatom concentration can also be used if no H_2 is added deliberately. In that case p_{H_2} is given by the equilibrium partial pressure of H_2 (proportional to $\alpha p_{SiH_2Cl_2}(b)$).

Interpretation of results.—The SiH_2Cl_2-H_2-N_2 system.—It was concluded that expressions given by Venables (3, 7) can be used to characterize the saturation density of stable clusters (N_s) in the present case where incomplete condensation of silicon has to be assumed. Because of the existence of an incubation period before the actual nucleation starts, it is thought probable that an equilibrium concentration of silicon adatoms can build up prior to the first nucleation. In this period, therefore, a strong incomplete condensation regime applies. For this situation the relevant expression given by Venables can be rewritten as

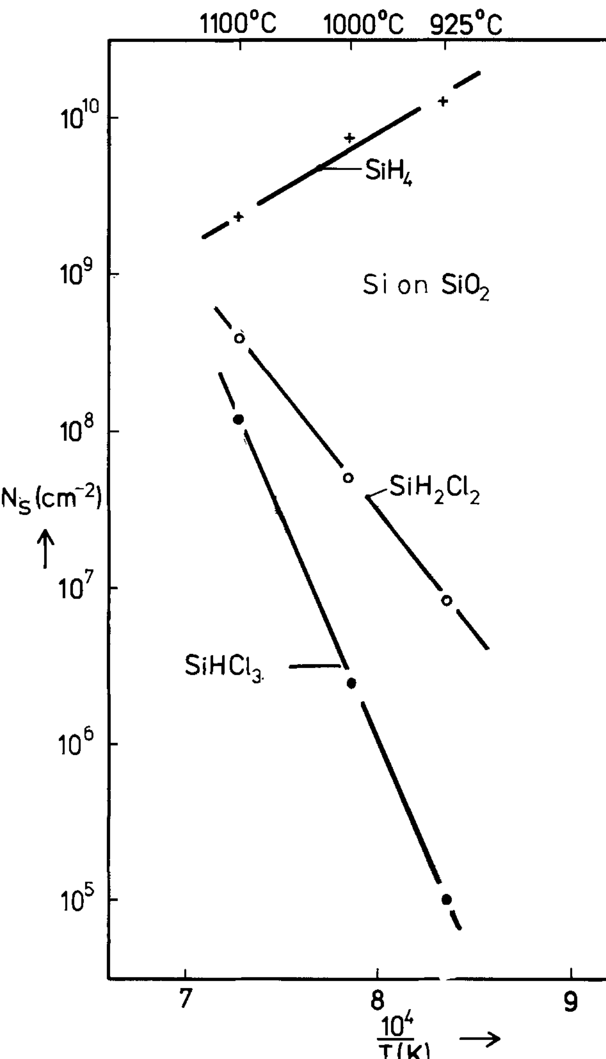

Fig. 7. Saturation densities on SiO_2 substrates as a function of temperature for SiH_4, SiH_2Cl_2, and $SiHCl_3$ (all concentrations about 0.1 v/o) in H_2 as a carrier gas.

$$\frac{N_s}{n_0} \cong \left(\frac{n_1}{n_0}\right)^{\frac{i+1}{2}} \exp\left[(E_i + E_m - E_d)/2kT\right] \quad [5]$$

where i is the number of atoms in the initial cluster, n_1 the monomer or adatom concentration, and n_0 denotes the number of surface sites ($\cong 10^{14}$ cm^{-2}). E_i is the heat of formation of a cluster consisting of i atoms, E_m is the activation energy for surface diffusion of mobile clusters, and E_d is the activation energy for surface diffusion of adatoms. As discussed above n_1/n_0 can be given as a first approximation by Eq. [4], leading to

$$\frac{N_s}{n_0} = \left\{\frac{A\alpha p_{SiH_2Cl_2}(b)}{(1 + K_3\alpha p_{SiH_2Cl_2}(b) + K_{10}p_{H_2}{}^{1/2})}\right\}^{\frac{i+1}{2}} \exp\left[(E_i + E_m - E_d)/2kT\right] \quad [6]$$

where A is a constant, α is the decomposition parameter, and $p_{SiH_2Cl_2}(b)$ is the input concentration of SiH_2Cl_2, the other parameters being as defined before (Eq. [5]).

Starting with the experiments done on SiO_2 substrates, it can be observed in Table I that N_s in the SiH_2Cl_2-H_2 system is almost proportional to $p_{SiH_2Cl_2}(b)$. It can thus be concluded that in Eq. [6] $K_3\alpha p_{SiH_2Cl_2}(b) < (1 + K_{10}p_{H_2}{}^{1/2})$, and moreover $i = 1$ for the temperature range between 925° and 1100°C. If $i = 1$ for

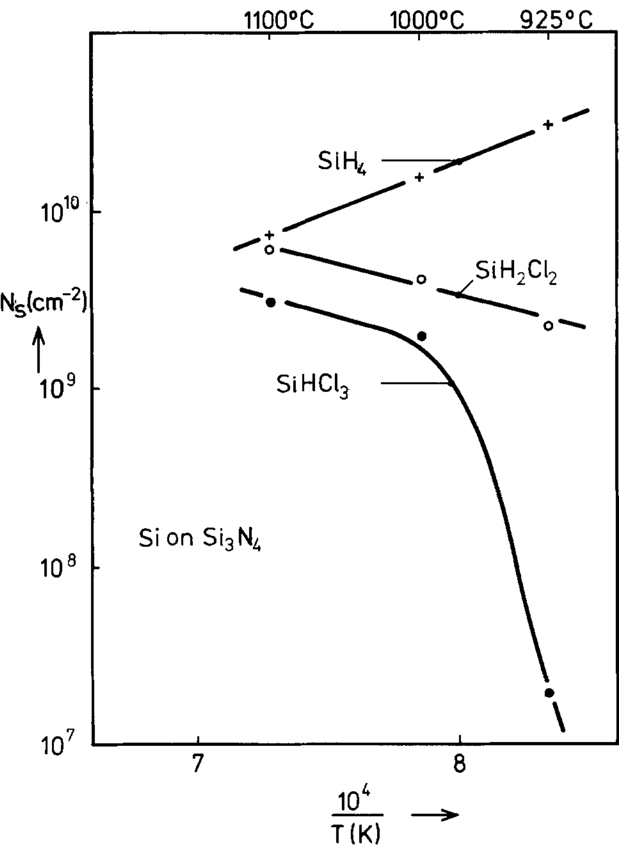

Fig. 8. Saturation densities on Si_3N_4 substrates for SiH_4, SiH_2Cl_2, and $SiHCl_3$ in H_2 as a carrier gas (all concentrations about 0.1 v/o) as a function of temperature.

the SiH_2Cl_2-H_2 system, it is acceptable that in all other cases where the saturation nucleus density is higher one will also have $i = 1$. If, furthermore, $K_3\alpha p_{SiH_2Cl_2}(b) < (1 + K_{10}p_{H_2}{}^{1/2})$ for all H_2-N_2 mixtures, we obtain, from Eq. [6], for a fixed temperature

$$\frac{N_s}{n_0} = \frac{A\alpha p_{SiH_2Cl_2}(b)}{1 + K_{10}p_{H_2}{}^{1/2}} \quad [7]$$

The experimental data given in Fig. 4 by plotting log $[N_s/p_{SiH_2Cl_2}(b)]$ vs. log (p_{H_2}) can now be analyzed. At 1100°C we observe a tangent which is almost ½ for all H_2-N_2 mixtures, from which it may be concluded that adsorption of atomic hydrogen plays an important role in nucleation kinetics on SiO_2 substrates ($K_{10}p_{H_2}{}^{1/2} > 1$). Equation [7] can be used for the SiH_2Cl_2-N_2 system by introducing the equilibrium partial pressure of H_2. This is done in Fig. 4, and the results show that α is close to unity in accordance with the thermochemical data in Fig. 10 [$p_{H_2} \cong p_{SiH_2Cl_2}(b)$]. At lower temperatures the tangent in Fig. 4 is only ½ for the lowest hydrogen pressures and the deviation from the slope ½ is strongest at 925°C. Especially at the lower temperatures the assumption $K_{10}p_{H_2}{}^{1/2} > [1 + K_3\alpha p_{SiH_2Cl_2}(b)]$ remains acceptable. For SiO_2 substrates an additional decrease in N_s then has to be found in a lower value of α.

At lower temperatures and the highest hydrogen pressures, therefore, hydrogen adsorption is no longer the only factor that determines the saturation density. According to Fig. 10, the dissociation of SiH_2Cl_2 into $SiCl_2$ and H_2 becomes more difficult under these experimental conditions, leading to the smaller value of α. If the decrease in saturation density is only caused by a decrease in α and if $\alpha \cong 1$ at 1100°C, we calculate an effective value of $\alpha = 10^{-2}$ at 925°C using Fig. 4.

For the Si_3N_4 substrates Eq. [6] can also describe the experimental data given in Fig. 1, 5, and 6. If we compare Fig. 2 and 5, where the saturation nucleus

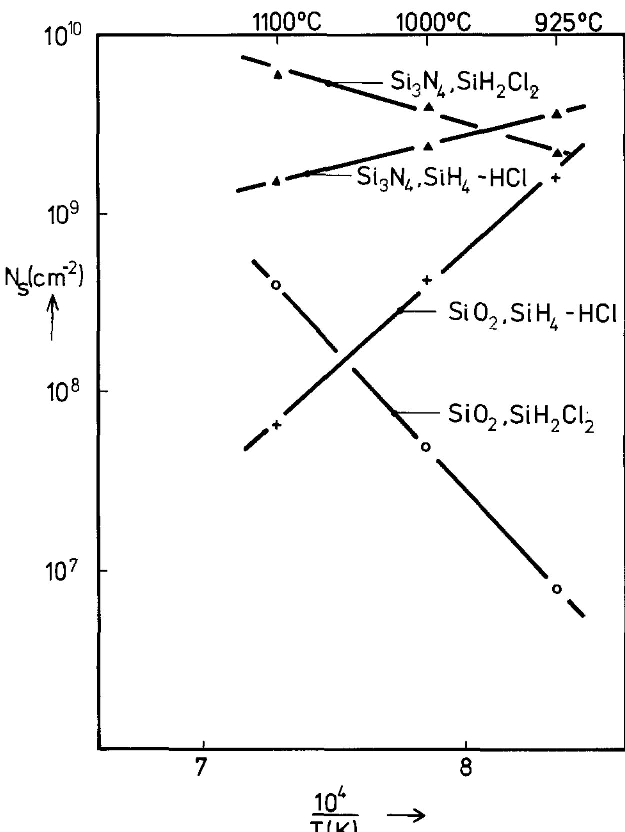

Fig. 9. Saturation nucleus densities on SiO_2 and Si_3N_4 substrates as a function of temperature for 0.1 v/o SiH_2Cl_2 and a mixture of 0.1 v/o SiH_4 and 0.2 v/o HCl.

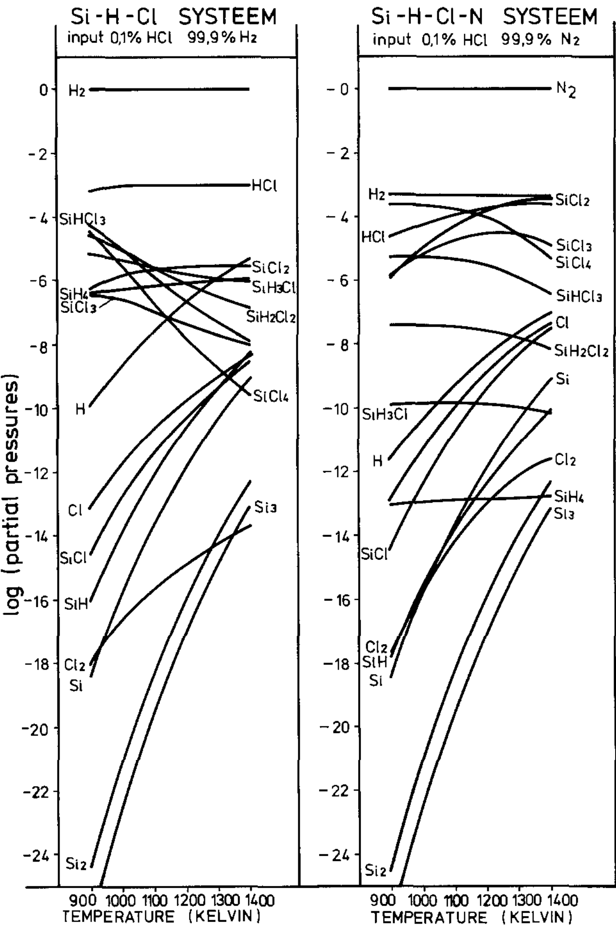

Fig. 10. Thermodynamic data for the Si-H-Cl and the Si-N-H-Cl systems as a function of temperature and an input of 0.1 v/o HCl.

density is plotted for hydrogen and nitrogen as a carrier gas, on SiO_2 and Si_3N_4 substrates, it can be observed that hydrogen adsorption on Si_3N_4 substrates could play a role, but to a lesser degree than on SiO_2 substrates. By plotting log $[N_s/p_{SiH_2Cl_2}(b)]$ *vs.* log (p_{H_2}) (Fig. 6) we observe that the tangent in this figure is less than ½ at 1000°C, leading to the conclusion that the assumption $K_{10}p_{H_2}{}^{1/2} > [1 + K_3\alpha p_{SiH_2Cl_2}(b)]$ is not acceptable in this case, adsorption of $SiCl_2$ thus cannot be neglected.

It may be concluded that the difference in saturation nucleus densities between SiO_2 and Si_3N_4 substrates in a hydrogen medium is caused by strong adsorption of atomic hydrogen, especially on SiO_2 substrates. According to the JANAF tables (8) the OH bond energy is stronger than the NH bond by about 20 kcal/mole. This difference in bond energy is sufficient to explain the experimental data.

Comparison between different silicon-containing compounds in an H_2 medium.—Figures 7 and 8 give saturation densities of silicon clusters for SiO_2 and Si_3N_4 substrates, respectively, for SiH_4, SiH_2Cl_2, and $SiHCl_3$ (all concentrations about 0.1 v/o) in hydrogen as a carrier gas. If we start with the SiO_2 substrate a remarkable difference between the SiH_4-H_2 and the SiH_2Cl_2-H_2 system is observed. As discussed above, the presence of hydrogen hampers the dissociation of SiH_2Cl_2, and moreover adsorption of atomic hydrogen on SiO_2 blocks the adsorption for silicon species, as a consequence of which the saturation density decreases with decreasing temperature. In the SiH_4-H_2 system, hydrogen adsorption does not determine nucleation kinetics in the temperature range under discussion. At temperatures below 900°C hydrogen adsorption also becomes important for SiH_4 on SiO_2 substrates, which results in a decrease of the saturation density with decreasing temperatures for the SiH_4-H_2 system as well (3). The $SiHCl_3$-H_2 system behaves like the SiH_2Cl_2 system, but shows a lower saturation nucleus density than the former system. Nucleation is more difficult than for the SiH_2Cl_2-H_2 system, probably because of a lower $SiCl_2$ concentration in the gas phase due to a smaller decomposition parameter. For Si_3N_4 substrates the difference between the SiH_2Cl_2-H_2 system and the SiH_4-H_2 system is smaller than for the SiO_2 substrates (Fig. 8). This can be understood because we have seen that hydrogen adsorption plays a less important role on Si_3N_4 substrates in the SiH_2Cl_2-H_2 system, and in the SiH_4-H_2 system hydrogen adsorption does not come into play. The strong decrease of the saturation density at temperatures below 1000°C in the $SiHCl_3$-H_2 system also has to be explained by a decrease of the $SiCl_2$ concentration in the gas phase.

Introduction of HCl to the SiH_4-H_2 system decreases the saturation nucleus density, but down to 900°C this density still increases with decreasing temperature (Fig. 9). In the SiH_4-HCl-H_2 system etching of Si adatoms by HCl occurs, whereas, in the SiH_2Cl_2-H_2 system as discussed in the Appendix hardly any free HCl is present before the onset of nucleation. The greater critical cluster size, which varies from 1 to approximately 4 for the SiH_4-HCl-H_2 system, could also be explained in terms of the etching of Si adatoms by HCl, giving $SiCl_2$ (3). The differences in nucleation on SiO_2 and Si_3N_4 substrates in the SiH_4-HCl-H_2 and SiH_2Cl_2 systems are ultimately traced back to the difference in the steady-state concentration of silicon adatoms on the substrates prior to the actual nucleation.

Conclusions

In an attempt to understand and be able to monitor the crystallite size of polycrystalline silicon layers we have studied the nucleation of silicon on various substrates for different silicon-containing compounds as a function of gas phase composition and tempera-

ture. Experiments with nucleation of silicon on SiO_2 and Si_3N_4 substrates were reported for the SiH_2Cl_2-H_2-N_2 system in the temperature range of 800°-1100°C. The differences and conformities between the SiH_4-H_2-HCl, $SiHCl_3$-H_2, and the SiH_2Cl_2-H_2 systems were also discussed. As far as the SiH_2Cl_2-H_2-N_2 system is concerned it is observed that the saturation nucleus densities on SiO_2 and Si_3N_4 substrates are almost the same for nitrogen as a carrier gas, and these densities are barely a function of temperature. Introduction of hydrogen strongly reduces the saturation nucleus density and this decrease is much stronger for SiO_2 than for Si_3N_4 substrates, resulting in a decrease of the saturation nucleus density with decreasing temperatures. Further the temperature dependence of the formation process increases with increasing hydrogen pressures. The experimental data can be explained from an analysis of the silicon adatom concentration on the surface as a function of gas phase composition and temperature. Application of an expression for the saturation nucleus density as obtained by Venables gives an indication of the size of the critical cluster, which seems to be 1 for all SiH_2Cl_2 mixtures under discussion. The differences between the SiH_4-H_2-HCl, the SiH_4-H_2, the $SiHCl_3$-H_2, and the SiH_2Cl_2-H_2 systems are remarkable. For $SiHCl_3$ and SiH_2Cl_2 the saturation density of silicon clusters decreases with decreasing temperature, whereas for the SiH_4-HCl-H_2 and SiH_4-H_2 systems the opposite occurs. Formation of $SiCl_2$ by dissociation of SiH_2Cl_2 or $SiHCl_3$ becomes more difficult at decreasing temperatures, leading to a smaller steady-state concentration of silicon adatoms at lower temperatures.

APPENDIX

Reaction Scheme for the SiH_2Cl_2-H_2-N_2 System

According to the thermochemical data in Fig. 10 the main processes which take place on or near the surface can be summarized as follows:

Supply of SiH_2Cl_2 by means of gas phase diffusion

$$SiH_2Cl_2(b) \xrightarrow{k_a} SiH_2Cl_2(g) \quad [A\text{-}0]$$

$SiH_2Cl_2(b)$ is the input concentration of SiH_2Cl_2 and $SiH_2Cl_2(g)$ the concentration of SiH_2Cl_2 near the surface.

Dissociation of SiH_2Cl_2 in the gas phase

$$SiH_2Cl_2(g) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SiCl_2(g) + H_2(g) \quad [A\text{-}1]$$

Adsorption of SiH_2Cl_2 and $SiCl_2$ on a free surface site (denoted by an asterisk) and dissociation of $SiH_2Cl_2^*$

$$* + SiH_2Cl_2(g) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} SiH_2Cl_2^* \quad [A\text{-}2]$$

$$* + SiCl_2(g) \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} SiCl_2^* \quad [A\text{-}3]$$

$$SiH_2Cl_2^* \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} SiCl_2^* + H_2(g) \quad [A\text{-}4]$$

Formation of Si adatoms on the surface

$$SiH_2Cl_2^* \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} Si^* + 2HCl(g) \quad [A\text{-}5]$$

$$SiCl_2^* + H_2(g) \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} Si^* + 2HCl(g) \quad [A\text{-}6]$$

Formation of stable silicon clusters by diffusion of Si adatoms on the surface

$$Si^* \xrightarrow{k_7} Si(s) \quad [A\text{-}7]$$

Reaction of Si adatoms with hydrogen

$$Si^* + H_2 \underset{k_{-8}}{\overset{k_8}{\rightleftharpoons}} SiH_2^* \quad [A\text{-}8]$$

Adsorption of hydrogen and chlorine

$$* + HCl(g) \underset{k_{-9}}{\overset{k_9}{\rightleftharpoons}} Cl^* + \tfrac{1}{2} H_2(g) \quad [A\text{-}9]$$

$$\tfrac{1}{2} H_2(g) + * \underset{k_{-10}}{\overset{k_{10}}{\rightleftharpoons}} H^* \quad [A\text{-}10]$$

Formation of chlorosilanes other than $SiCl_2$, such as $SiHCl_3$ and $SiCl_4$, can be left out of consideration, at least in the initial stage of nucleation, where practically no HCl is present. The notation (g) will only be used when comparison with bulk values of the vapor pressure is made.

The total number of reactions can be decreased by judging the various parameters in view of experimental results and thermochemical data. The following assumptions can be made:

Because hardly any HCl is present in the initial stage of nucleation, the back reaction k_{-5} and k_{-6} can be neglected and also [Cl*] can be treated as small.

Nucleation and growth experiments in the SiH_4-HCl-H_2 system lead to the conclusion that silicon adatoms [Si*] are needed to arrive at nucleation (3).

Gas phase dissociation of SiH_2Cl_2 to $SiCl_2$ and H_2 occurs at temperatures above 800°C. This is according to Smith and Sedwick (9) who performed *in situ* measurements using inelastic light scattering and obtained spectra of $SiCl_2$ in an rf heated reactor in the SiH_2Cl_2-H_2 system.

The nucleation starts via the adsorption of $SiCl_2$ or via adsorption of SiH_2Cl_2.

In order to discriminate between adsorption of SiH_2Cl_2 and $SiCl_2$ we have to notice that SiH_2Cl_2 is a fully coordinated molecule with four atoms bonded in a tetrahedral configuration. If SiH_2Cl_2 adsorbs without dissociation, then a peripheral hydrogen or chlorine atom has to come into contact with the surface. In the nonlinear $SiCl_2$ molecule the silicon atom is not sterically blocked from the surface of the substrate, and the presence of the unbonded electrons on the silicon greatly enhances its adsorption by interaction with the dangling bonds on the surface (10). It can therefore be concluded that the adsorption energy of SiH_2Cl_2 is much smaller than that of $SiCl_2$. This means that [A-2], [A-4], and [A-5] can be left out of consideration. With the above approximations the steady-state concentrations of [Si*] and [$SiCl_2$*] will be given by

$$n_1 = [Si^*] = \frac{k_6[SiCl_2^*]p_{H_2} + k_{-8}[SiH_2^*]}{k_7 + k_8 p_{H_2}} \quad [A\text{-}11]$$

$$[SiCl_2^*] = \frac{k_3 p_{SiCl_2}[*]}{k_{-3} + k_6 p_{H_2}} \quad [A\text{-}12]$$

As for the SiH_4-HCl-H_2 system (3) the nucleus density very quickly reaches a saturation density, with respect to exposure time, after an incubation period. On the basis of these experiments it was assumed that the time needed to attain the population of adatoms is small, giving a constant value of n_1 before nucleation occurs. This means that k_7 can be omitted until nucleation takes place. The second term in the nominator, the indirect formation of Si*, can be assumed to be small

compared to the first term and can be neglected. The silicon adatom concentration will be much smaller than the concentration of adsorbed $SiCl_2$ molecules, therefore, it can be assumed that $k_{-3} > k_6 p_{H_2}$. With these approximations one obtains.

$$n_1 = \frac{k_6 K_3 p_{SiCl_2}[*]}{k_8} \quad \text{[A-13]}$$

For the concentration of free surface sites we can write

$$[*] = n_0 - [Si^*] - [SiCl_2^*] - [H^*] - [SiH_2^*]$$

where n_0 is the total number of sites per unit area. With $[H^*] = K_{10} p_{H_2}^{1/2}[*]$; $K_{10} = k_{10}/k_{-10}$, $[SiCl_2^*] = K_3 p_{SiCl_2}[*]$; $K_3 = k_3/k_{-3}$ and $[Si^*]$, $[SiH_2^*] << [SiCl_2^*]$, this leads to

$$[*] = \frac{n_0}{(1 + K_3 p_{SiCl_2} + K_{10} p_{H_2}^{1/2})} \quad \text{[A-14]}$$

The silicon adatom concentration can now be given by

$$\frac{n_1}{n_0} = \frac{K_3 k_6 p_{SiCl_2}}{k_8(1 + K_3 p_{SiCl_2} + K_{10} p_{H_2}^{1/2})} \quad \text{[A-15]}$$

Growth of Epitaxial ZnO Thin Films by Organometallic Chemical Vapor Deposition

Chi Kwan Lau,* Shiban K. Tiku,* and K. M. Lakin

University of Southern California, Los Angeles, California 90007

ABSTRACT

Organometallic chemical vapor deposition of ZnO on sapphire, using the reaction of diethylzinc with H_2O/H_2, N_2O/N_2, and CO_2/H_2 oxidizing gas systems, has been studied. Epitaxial films have been achieved at temperatures of 400° and 730°C, respectively, in the first two systems. The films have been characterized using scanning electron microscopy (SEM), reflection electron diffraction (RED), and surface acoustic wave techniques.

ZnO is one of the most versatile and useful thin film materials for acoustoelectric, acousto-optic, electro-optic, and photoconductive device applications (1). The heteroepitaxial system, $(11\bar{2}0)$ ZnO//$(01\bar{1}2)$ Al_2O_3 with the c-axis of ZnO in the plane of the R-plane sapphire, is highly desirable for surface acoustic wave (SAW) device applications because of the high electromechanical coupling coefficient of ZnO and low acoustic wave propagation loss of sapphire. Furthermore, R-plane sapphire is the orientation used in silicon-on-sapphire (SOS) technology and for the growth of many III-V and II-VI compounds, implying the potential for integrating ZnO and semiconductor devices on a single substrate. Finally, substrates with good epitaxial quality surfaces are available commercially.

Growth methods.—RF sputtering is the most popular technique for ZnO thin film fabrication and recently planar magnetron sputtering has been successful in producing 5-10 micron thick films on glass substrates in an hours growth time (2, 3). These sputtered films have a tendency of growing with c-axis perpendicular to the substrate surface and only at very low growth rates (100 Å/min) and high substrate temperatures (~450°C) have $(11\bar{2}0)$ ZnO films on R-plane sapphire been achieved by sputtering (4). Growth of ZnO from the vapor phase has also been widely investigated. Most of the methods reported to date are essentially based on ZnO transport using the transport agents H_2/HCl (5) and H_2/H_2O (6) or controlled oxidation of zinc vapor. Growth rates of about 1.2 μm/min have been achieved at substrate temperatures around 775°C. However, because of the nucleation problems associated with the use of zinc vapor, film growth is nonuniform and nonreproducible. This problem can be solved by the introduction of a presputtered layer of ZnO on the substrate. Using this technique with the $ZnO/H_2O/O_2/H_2$ transport system, Ohnishi *et al.* (7) have grown films with excellent uniformity and surface finish. Growth rates of 1 μm/min were achieved at a rather high substrate temperature of 975°C. However, extensive corrosion of the quartzware takes place in all these transport systems. The corrosion problem has been mitigated by employing the reaction of zinc vapor and H_2O (8).

ZnO films grown by any of the vapor phase techniques show low resistivity, making postgrowth compensation necessary. Diffusion of lithium (and polishing to remove the damage due to etching by the lithium source) must be done before the films can be used for piezoelectric applications. Since the resistivity of ZnO films has been seen to increase in the presence of CO_2 (1), the Zn(v)/CO_2 reaction was recently investigated for the growth of ZnO films on sapphire (9). Here an as-grown resistivity of 10^6 Ω-cm resulted, but degraded on further process handling and exposure to the atmosphere.

Organometallic growth.—In recent years, the organometallic process for semiconductor thin film growth has received increasing attention, because of certain distinct advantages largely associated with the ease of handling the metal sources (10). Growth of compound

Key words: organometallic, CVD of ZnO, ZnO for SAW devices, ZnO thin films.

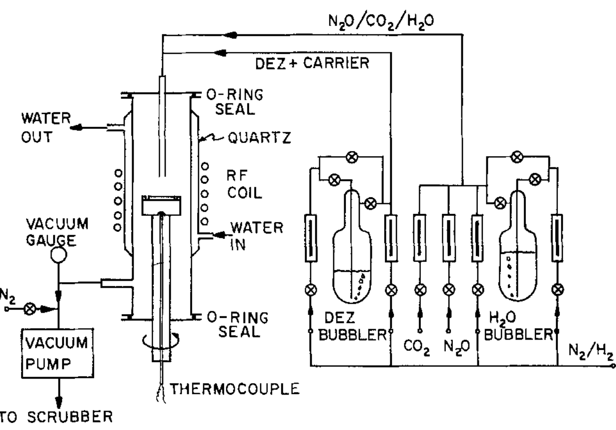
semiconductor films using organometallic reactions has been reviewed by Manasevit (11) and the heteroepitaxial growth has been successful for a number of III-V semiconductor materials on various oxide substrates (10). The successful growth of II-VI compounds based on zinc has been reported by Manasevit and Simpson (12). The only organometallic growth method reported for the deposition of ZnO is by the decomposition of zinc propionate and zinc acetyl-acetonate (13). Oriented films were obtained at extremely low growth rates (27 Å/min) on mica substrates.

In this paper, we report the results on the growth of ZnO thin films in R-plane sapphire, using the oxidation of diethylzinc, $(C_2H_5)_2Zn$ (DEZ), by the three oxidizing gas mixtures, H_2O/H_2, CO_2/H_2, and NO_2/N_2 (14). Hydrogen, which plays a dominant role in the growth process, was used as the carrier for the H_2O and CO_2 reaction systems and N_2 was used for the DEZ/N_2O system.

Experiment

Growth system.—Both horizontal and vertical quartz tube reactors were used in the present study as shown schematically in Fig. 1. The vertical gas flow system with substrate rotation proved to be advantageous in the DEZ/N_2O growth system, as more uniform films could be grown. In the case of the DEZ/H_2O reaction system, solid ZnO particles were formed on the inside walls of the injection tube. In the vertical geometry, these particles can be blown by the carrier gas onto the substrate, causing spurious growth problems. The horizontal growth system gave better quality films due to the absence of this problem. In both geometries the gas flow was at near normal incidence to the substrate surface. The temperature was monitored by a thermocouple with its tip placed inside a small hole in the susceptor. The injection tube-to-substrate distance was adjustable. The exhaust was connected to a scrubber through a rotary vacuum pump maintaining a pressure of about 400 Torr inside the reaction chamber.

The entire gas flow system for both the horizontal and the vertical reactors was assembled using stainless steel tubing, stainless steel bubblers for DEZ and deionized H_2O, and with provisions made for purging the system with nitrogen. The quartz reaction chamber is 40 mm ID, 40 cm long tube. The susceptors used were 30 mm diam graphite disks capable of holding 20 mm square substrates.



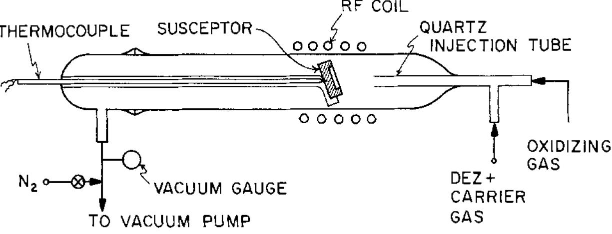


Fig. 1. Schematic diagram of the growth system used for ZnO, OM-CVD growth, (a, top) vertical geometry, (b, bottom) horizontal geometry.

Nitrogen gas was obtained directly from liquid nitrogen boil-off, and H_2, N_2O, and CO_2 were of four-nine purity. Electronic grade DEZ was chilled with melting ice to get better control over its flow rate. (The vapor pressure of DEZ at 20°C is 15 Torr.)

Substrate preparation.—R-plane sapphire (3.8 cm diam and 1.23 mm thick) of epitaxial surface quality was purchased from Union Carbide. A standard polishing and cleaning procedure consisted of Syton (Monsanto) polishing for 10 min followed by cleaning with trichloroethylene, acetone, and methanol. Deionized water was used for the final wash before the dry nitrogen blow-off.

Experimental procedure.—To start a growth run, the reactor was evacuated and the carrier gas was admitted. The preparatory sequence continued by heating the substrate to the deposition temperature, followed by introduction of the oxidizing gas. After about 5 min, growth was initiated by introduction of DEZ and continued for a specified time. After the growth run, the substrate was cooled slowly.

As-grown films were examined visually under an optical microscope and a small portion of the film was etched away with dilute HCl and the remaining film thickness measured across the etched step using a stylus-type profile meter (Dektak). Further physical characterization was carried out using SEM and RED.

Electrical characterization consisted of a four-point probe resistivity measurement followed by capacitance and electromechanical coupling coefficient measurements using a surface acoustic wave interdigital electrode transducer.

Results and Discussion

Reactions.—DEZ is an electron deficient compound with two vacant orbitals. The presence of these vacant orbitals available for bonding explains its high chemical reactivity. Thus, DEZ forms complexes easily with compounds containing free electron pairs. DEZ forms complexes at temperatures near ambient or higher with H_2O, CO_2, and N_2O (15). The reactions of interest in the present study are:

1. DEZ/H_2O/H_2 system (15)

At room temperature, in the gas stream

$$(C_2H_5)_2Zn + 2H_2O = Zn(OH)_2 + 2C_2H_6$$

At the surface at high temperature (400°C)

$$Zn(OH)_2 = ZnO + H_2O$$

$$ZnO + H_2 \rightleftharpoons Zn(V) + H_2O$$

2. DEZ/CO_2/H_2 system (16)

At 150°C, in the gas stream

$$(C_2H_5)_2Zn + 2CO_2 \rightarrow (C_2H_5COO)_2Zn$$

At high temperature, on the substrate (500°C)

$$(C_2H_5COO)_2Zn \rightarrow ZnO + \text{gaseous product}$$

$$ZnO + H_2 \rightleftharpoons Zn(V) + H_2O$$

3. DEZ/N_2O/N_2 system (15)

$$(C_2H_5)_2Zn + N_2O \xrightarrow{\text{low temp.}} \text{"complex"}$$

$$\text{"complex"} \xrightarrow{\sim 700°C} ZnO + \text{gaseous products}$$

Growth kinetics.—Because of the formation of organo-zinc complexes [or $Zn(OH)_2$ in the DEZ/H_2O system] at low temperature, it is necessary to keep the reactants separate until they are a short distance

Table I. Growth parameters and properties of ZnO films grown by OM-CVD

Process	Optimum growth temperature, °C	Growth rate, Å/min	Optimum gas flow rates, l/min H_2	N_2	DEZ	Oxidizing gas
DEZ/H_2O/H_2	400	300-850	2.7	—	0.015	H_2O = 0.02
DEZ/CO_2/H_2	500	300-500	2.5	—	0.015	CO_2 = 0.05
DEZ/N_2O/N_2	730	80-120	—	2.5	0.021	N_2O = 0.05

Reactor pressure: 400 Torr.

away from the substrate. Homogeneity of mixing and delivery of the reactants uniformly to the substrate is difficult to achieve. The reactor must be geometrically optimized to achieve growth uniformity and low pressure must be used in order to accelerate complex dissociation and removal of reaction products from the growth surface.

Table I shows the growth parameters for the three reaction systems. The rate of growth as a function of temperature (with all other parameters being constant and equal to the optimum values given in Table I) is shown in Fig. 2. The optimum temperatures for the three systems are 400°C for the H_2O/H_2, 500°C for the CO_2/H_2, and 730°C for the N_2O/N_2 process. The shapes of the curves indicate that the growth is kinetically controlled at low temperature because of the activation energy needed to dissociate $Zn(OH)_2$ or the complexes. At high temperatures, the growth rate drops due to thermodynamic factors, including the instability of ZnO in the presence of hydrogen. In addition, the growth rate was observed to decrease as the DEZ/oxidizing gas ratio was increased and at very high DEZ concentration growth stopped in all the three reaction systems. This indicated poisoning of the growth surface by excess complex molecules. Thus, the desorption of large organic species may be the rate-limiting step under such conditions. Figure 3 shows the dependence of the growth rate on the oxidizing gas flow rate with constant flow rates of other gases (equal to the optimum values of Table I). Maxima are observed in each case. Thus adsorption of H_2O, CO_2, and N_2O by the ZnO surface may also lead to a drop in the growth rate.

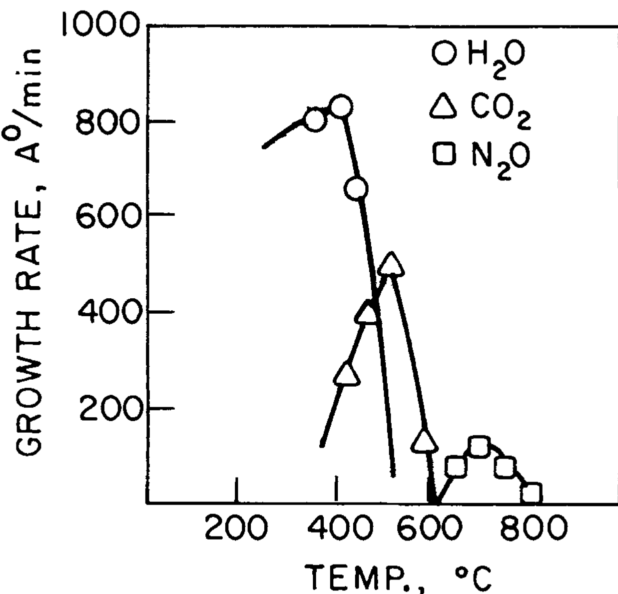

Fig. 2. Growth rate as a function of temperature, with other parameters constant at the optimum values given in Table I.

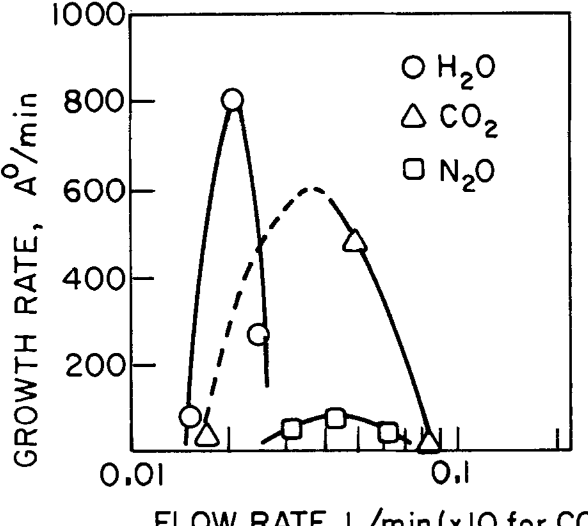

Fig. 3. Growth rate as a function of the flow rate of H_2O, CO_2, and N_2O (other parameters at their optimum values given in Table I).

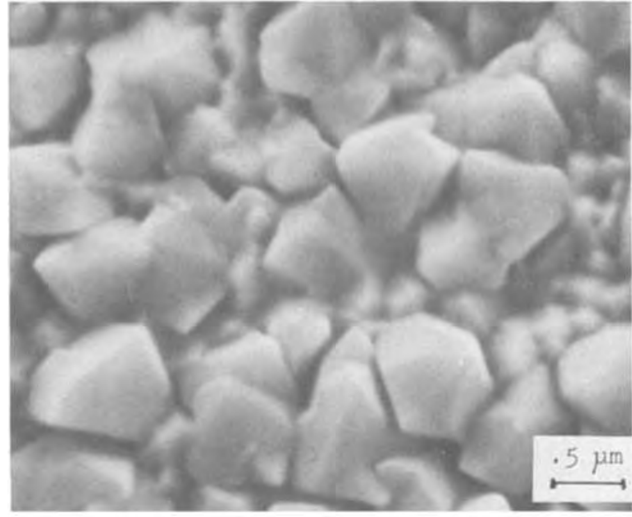
Growth morphology.—Films obtained with the DEZ/H_2O/H_2 process were pale white translucent with a rough surface. The SEM micrograph for a typical film, shown in Fig. 4, does not reveal any obvious



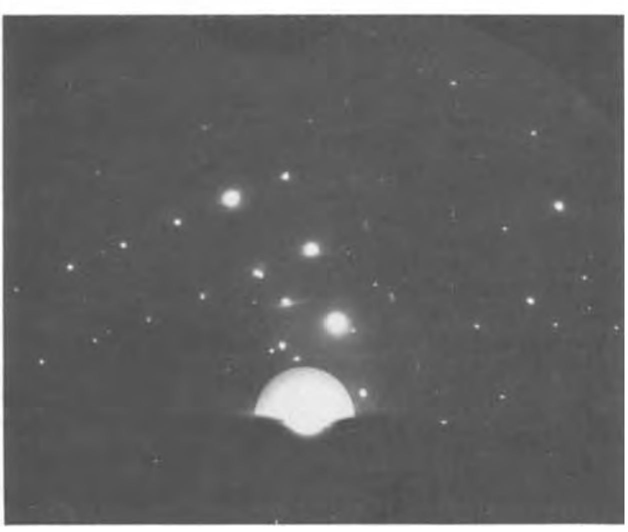


Fig. 4. SEM/RED for a 2 μm thick ZnO film grown at 400°C by the DEZ/H_2O/H_2 growth process.

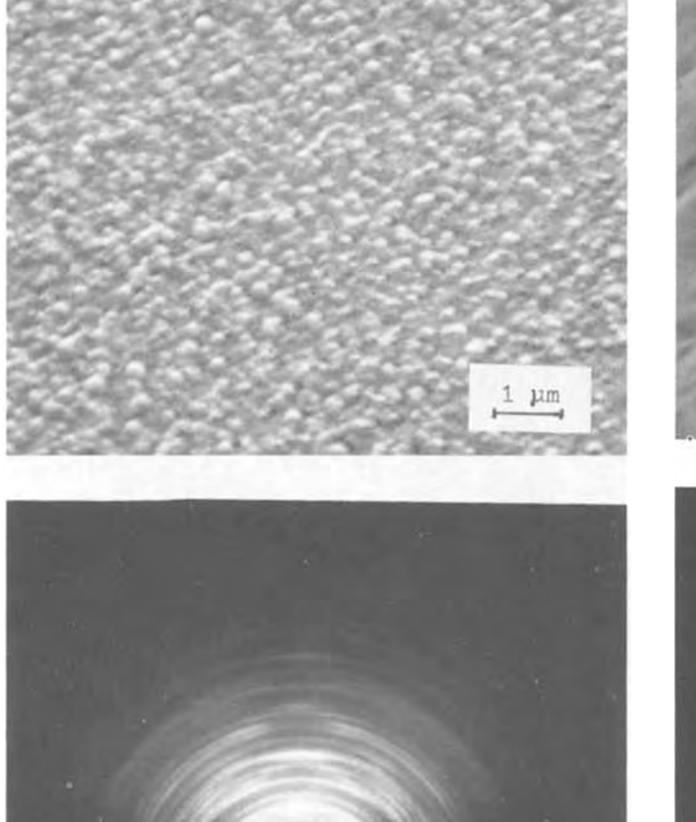

Fig. 5. SEM/RED for a 2 μm thick ZnO film grown at 500°C by the DEZ/CO_2/H_2 growth system.

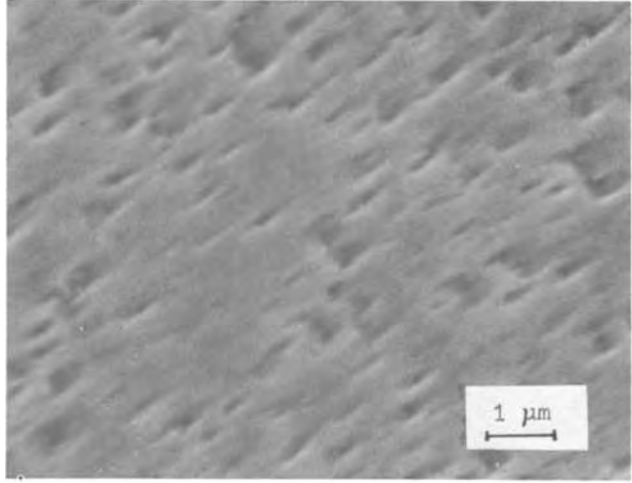
alignment of crystallites, although the RED confirms an oriented film. Films grown by the DEZ/CO_2/H_2 system were polycrystalline (Fig. 5). Films grown by the N_2O/N_2 process were transparent with very smooth surfaces and the SEM/RED data, Fig. 6, show that the crystallites are aligned along the c-axis of ZnO crystallites in the R-plane sapphire. ZnO has a marked tendency of growing fast along the c-axis and it appears that in the presence of H_2 any needles that are not in the growth plane become unstable. In the DEZ/N_2O/N_2 system, because of the absence of hydrogen, spurious growth can become important. Thus, if the arrival rate of the complex is increased by reducing the distance between the injection tube and the substrate, growth rate increases and spurious growth, with hexagonal needles growing out of the plane, results as shown in Fig. 7. Thus, the growth rates must remain low in order to retain epitaxy.

Electrical characterization.—Resistivity of the films was measured by the four-point probe method. The results are listed in Table II. Films grown by using CO_2 have a high resistivity of 10^6 Ω-cm and those grown by H_2O and N_2O reactions exhibit low resistivity. For SAW applications, a resistivity of greater than 10^6 Ω-cm is necessary. Lithium diffusion for increasing the resistivity was carried out for some films, by coating the film with Li_2CO_3 solution and heating them in air at 700°C for 12 hr. The film had to be polished after the diffusion to remove the surface damage due to the etching of Li_2CO_3.



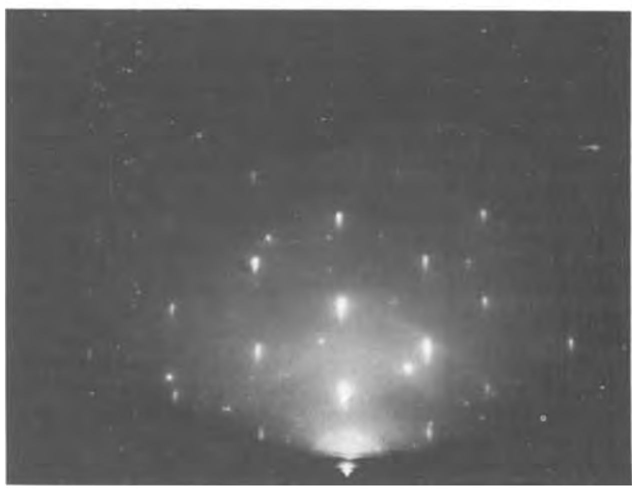


Fig. 6. SEM/RED for a 1.5 μm thick ZnO film grown at 730°C by the DEZ/N_2O/N_2 growth system.

Aluminum interdigital transducers (IDT) of 15 μm wavelength were fabricated on the film surface using the "lift-off" technique (17). The impedance of the IDT was then measured as a function of frequency using an HP8410 network analyzer. The SAW electromechanical coupling coefficient (K^2) for the c-axis propagating ZnO/Al_2O_3 structure was then calculated using the expression (18)

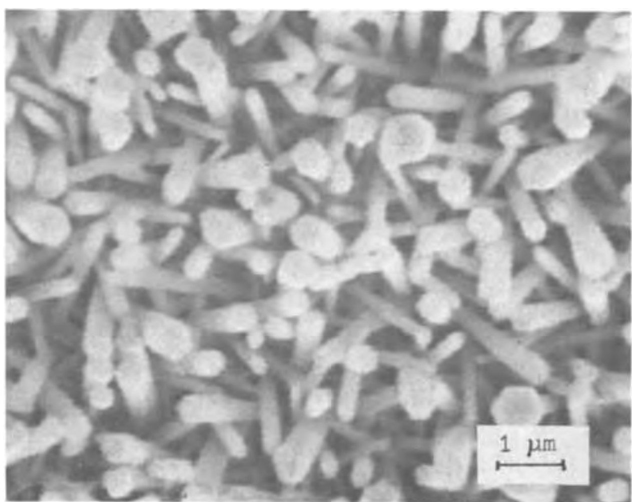

Fig. 7. SEM picture of film grown by the N_2O/N_2 process under high flux conditions, showing spurious growth.

Table II. Properties of ZnO films grown by OM-CVD

Process	Electrical resistivity, Ω-cm		SAW properties			
	As-grown	After Li diffusion	Film thickness,* μm	Resonant freq., MHz	t/λ	Coupling coef. K^2
$DEZ/H_2O/H_2$	1-10	$>10^6$	1.0	351.17	0.067	0.22%
$DEZ/N_2O/N_2$	10^2	$>10^6$	1.2	343.43	0.08	0.61%

* After polishing, the film thickness was uniform within ±0.1 μm over an area of 1 × 2 cm.

$$K^2 = \pi^2 f_o R_a C_s/2$$

where f_o = resonant frequency, R_a = radiation resistance, and C_s = capacitance/finger pair.

The coupling coefficient and other relevant parameters are tabulated in Table II. The films grown by the H_2O and N_2O reaction systems were found to be piezoelectric as expected from the RED data. The films grown by the CO_2 process were found to be of poor quality, and several attempts to measure the SAW properties were unsuccessful. For the $DEZ/N_2O/N_2$ process, a K^2 value of 0.61% at a thickness to wavelength ratio (t/λ) of 0.08 was determined which is better than the value obtained by Pizzarello using the $ZnO/HCl/H_2$ closed-space transport process (19), and is comparable to the theoretical value obtained by Lakin and Penunuri (20). The coupling coefficient for films grown by the $DEZ/H_2O/H_2$ process is lower (0.22% at $t/\lambda = 0.067$), but reasonable for a low growth temperature of 400°C.

Conclusion

The organometallic reaction systems using the reaction of DEZ with H_2O/H_2, CO_2/H_2, and N_2O/N_2 were investigated and these show promise as low temperature growth techniques for epitaxial ZnO thin films. The films were evaluated by SEM, RED, and by surface acoustic wave measurements. The films grown by the H_2O and N_2O reactions at temperatures of 400° and 730°C showed electromechanical coupling coefficients of 0.22% at a thickness to wavelength (t/λ) ratio of 0.067 and 0.61% at $t/\lambda = 0.08$, respectively.

Methods to increase the growth rate and the resistivity are under investigation.

Silicon Oxidation in Fluoride Solutions

Kenneth M. Sancier and Vijay Kapur*[,1]

SRI International, Menlo Park, California 94025

ABSTRACT

Silicon is produced in a NaF, Na_2SiF_6, and Na matrix when SiF_4 is reduced by metallic sodium. Hydrogen is evolved during acid leaching to separate the silicon from the accompanying reaction products, NaF and Na_2SiF_6. The hydrogen evolution reaction was studied under conditions simulating leaching conditions by making suspensions of the dry silicon powder in aqueous fluoride solutions. The mechanism for the hydrogen evolution is discussed in terms of spontaneous oxidation of silicon resulting from the cooperative effects of (*i*) elemental sodium in the silicon that reacts with water to remove a protective silica layer, leaving clean reactive silicon, and (*ii*) fluoride in solution that complexes with the oxidized silicon in solution and retards formation of a protective hydrous oxide gel.

A process for producing silicon has been developed at SRI International and is based on the reaction between sodium and silicon tetrafluoride

$$4Na + SiF_4 \rightarrow 4NaF + Si \quad [1]$$

The reaction is initiated at temperatures above 500°K and is highly exothermic. Reaction temperatures lower than 900°K favor formation of some sodium fluosilicate according to the reaction

$$2NaF + SiF_4 \rightarrow Na_2SiF_6 \quad [2]$$

The reaction product from the SiF_4-Na reaction is a solid mixture of Si, NaF, Na_2SiF_6, and, occasionally, unreacted sodium.

The silicon can be recovered from the reaction product mixture by aqueous leaching of the soluble NaF, Na_2SiF_6, and unreacted Na. Acidic solutions are used for leaching to neutralize unreacted sodium and to avoid the spontaneous oxidation of silicon that occurs rapidly in alkaline solutions

$$Si + 2H_2O \rightarrow SiO_2 + 2H_2 \quad [3]$$

$$Si + H_2O + 2\,OH^- \rightarrow SiO_3^{=} + 2H_2 \quad [4]$$

However, even when a strong acid solution is used for leaching, hydrogen evolution may continue for several days. In this paper we discuss the conditions under which hydrogen evolution occurs when silicon powder that is recovered by leaching is added to fluoride solutions to simulate additional leaching.

Experimental Details

Three types of silicon powder were used to study hydrogen evolution. Most of the experiments were performed with silicon that had been recovered by rapid leaching of the soluble fluoride salts from the SiF_4-Na reaction products and then dried. Typically, a 100g batch of the reaction products of the SiF_4-Na reaction was suspended in 4 liters of 1.2*N* H_2SO_4, agitated for 30 min, and then centrifuged. Eight successive leach-centrifuge steps requiring a total of about 4 hr were sufficient to decrease the fluoride ion concentration in the wash solution to less than $10^{-4}N$. The silicon was then washed with deionized water, dried at 380°K for 1 hr, and stored in a capped polyethylene bottle; in the following discussion this material is referred to as SRI silicon. The average particle diameter was 0.1 μm, as indicated by a measurement of surface area by the BET method. Some of the above reaction products were stored in a plastic bottle, and 122 days later the silicon was recovered by leaching.

[1] Present address: ARCO Solar, Chatsworth, California 91311.
Key words: silicon, silicon oxidation, fluoride, sodium.

Silicon produced by Union Carbide Company by pyrolysis of SiH_4 (with a particle diameter of 0.1 μm) and silicon obtained from Alfa Products (99.5% pure with a particle diameter of less than 44 μm) were also used.

To study hydrogen evolution, we added silicon powder to solutions that were similar to those used during leaching of the reaction products. Typically, 1.0g of silicon powder was added to 100 ml of solution containing H_2SO_4, NaF, or Na_2SiF_6 (Baker, reagent grade). The suspension was contained in a 125 ml plastic bottle that was capped and connected by tubing to an inverted graduated cylinder so that hydrogen gas could be collected by water displacement. The room temperature solubility of hydrogen in the water was neglected. The fluoride ion concentration of the suspension was measured with a fluoride ion-specific electrode (Orion).

The gas evolved from the SRI silicon-fluoride suspension was identified to be hydrogen by mass spectrometry. The SRI silicon was also examined by mass spectrometry at temperatures of up to 1070°K to determine if elemental sodium was present in the silicon.

Results

The SRI silicon powder used in the main part of the study was recovered by rapidly leaching reaction products which had been stored in air for approximately 30 days after the SiF_4-Na reaction was performed. Because gas evolution occurs during leaching, the leaching process was carried out as rapidly as possible to minimize loss of silicon by oxidation (*e.g.,* within 4 hr). Gas evolution studies were first made after the SRI silicon had been stored in a capped bottle for 7 days. The rate of hydrogen evolution increased with increasing the concentration of NaF in the suspension containing SRI silicon and 1.2*N* H_2SO_4, as shown in Fig. 1. The hydrogen evolution behavior of a suspension containing 0.060M NaF and 1.2*N* H_2SO_4 was remarkably similar to that containing water saturated with Na_2SiF_6 for which the fluoride ion concentration is comparable. In all cases, the rate of hydrogen evolution decreased with time. The percentage of silicon oxidized, as calculated from the amount of hydrogen evolved (reaction [3]), is indicated on the right-hand ordinate of Fig. 1.

Table I gives, as a function of solution composition, the initial rate of hydrogen evolution indicating that fluoride ions are required in the mechanism of hydrogen evolution.

The hydrogen evolution characteristics of the SRI silicon stored 7 days in air were essentially independent of *p*H in the range of −0.08 to 9.7 for solutions containing 0.60*N* NaF, as shown in Fig. 2. However, when this silicon was introduced into 1*N* NaOH, the rate of

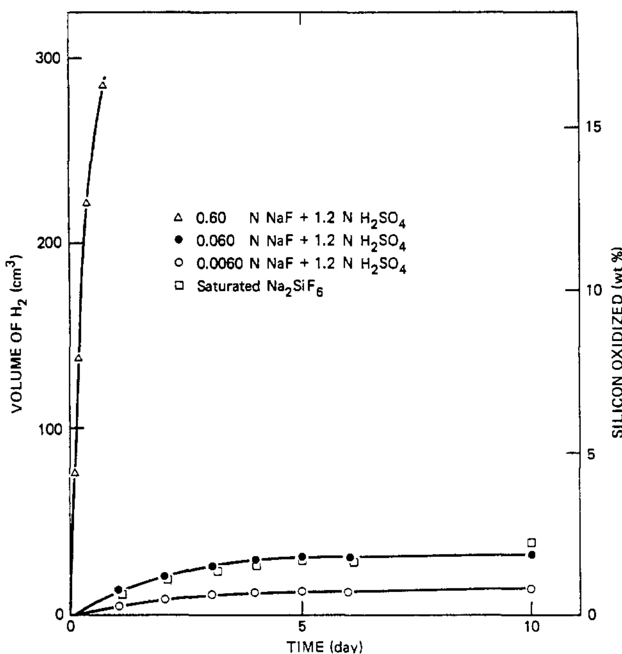

Fig. 1. Hydrogen evolved by SRI silicon in NaF solutions containing 1.2*N* H_2SO_4 and in water saturated with Na_2SiF_6. Si stored in air 7 days after recovery by leaching, then 1.0g Si added to 100 ml solutions containing a fluoride salt.

hydrogen evolution was 100 times greater than the highest rate observed in acid fluoride solutions.

The evolution rate of hydrogen from SRI silicon in an acid fluoride solution decreased with the storage time of the silicon powder in air (in capped plastic bottle) following leaching. This result is illustrated in Fig. 3 for a given sample of silicon powder that was stored for 7, 94, and 154 days before the hydrogen evolution measurement in a solution containing 0.60*N* NaF and 1.2*N* H_2SO_4. To determine whether a protective silicon oxide layer was inhibiting the hydrogen evolution, the 154-day-old sample (Fig. 3) was treated with 50% HF for 1 hr to remove surface silica. The hydrogen evolution behavior was again measured in a solution containing 0.60*N* NaF and 1.2*N* H_2SO_4 and was comparable to that originally observed for the 154-day-old sample before the HF treatment. This result shows that the decreased hydrogen evolution rate of aged silicon was not the result of a thick protective silicon oxide layer.

A sample of SRI silicon was also recovered by leaching the products of the SiF_4-Na reaction which had been stored for 122 days. The hydrogen evolution rate of this silicon powder was about the same as that of the 94-day-old silicon (Fig. 3). This result suggests that in silicon that is stored over a given period of time, similar chemical changes occur, either in the reaction products or in the dried silicon powder that is recovered by leaching.

Table I. Initial rate of hydrogen evolution from aqueous suspensions of SRI silicon[1]

Fluoride salt		H_2SO_4 concentration (*N*)	Fluoride ion concentration[2] (M)	Initial rate of H_2 evolution[3] (cm^3/min)
Salt	Concentration (M)

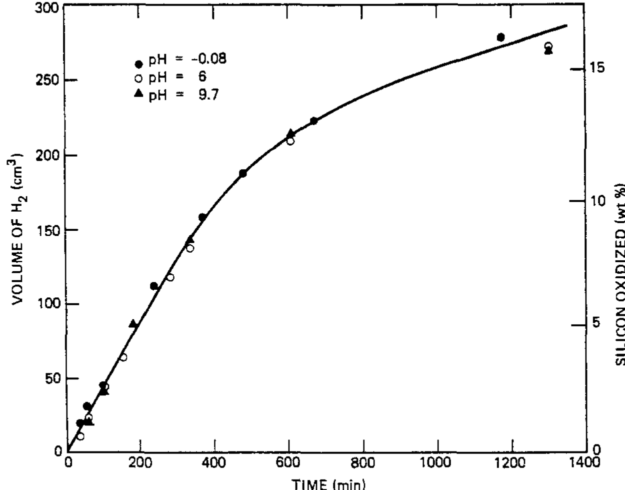

Fig. 2. Hydrogen evolved from reaction between SRI silicon powder and solutions containing 0.60*N* NaF at 20°C. Si stored in air 7 days after recovery by leaching, then 1.0g Si added to 100 ml of solution.

The results in Fig. 1 through 3 demonstrate that oxidation of the silicon can be appreciable in acid fluoride solutions, for example, at least 16 weight percent (w/o) per day. If the silicon is in continuous contact with such acid fluoride solutions for 8-10 days, 90 w/o of the silicon can be lost by oxidation.

When the other two silicon samples (nonfluoride process) were introduced separately into solutions containing 0.60*N* NaF and 1.2*N* H_2SO_4, the rate of gas evolution, presumed to be hydrogen but not analyzed, was much less than that for the SRI silicon. The Alfa Products silicon produced 11 cm^3 of gas in the first hour, and evolution then ceased over a monitoring period of 5 days. The Union Carbide silicon produced 44 cm^3 of gas slowly over a period of 5 days, and thereafter evolution ceased.

The SRI silicon contained 0.75 w/o sodium (by emission spectroscopy), part of which could be Na, NaF, or Na_2SiF_6 that was not completely removed by leaching. The SRI silicon that had been stored 154 days was examined by high temperature mass spectrometry. At sample temperatures above 575°K, the evolved gases contained sodium atoms, as indicated from the peak at mass 23 and the low appearance potential of 5.5 eV, in agreement with the reported value of 5.1 eV for sodium (2). Above a sample temperature of 650°K, SiF_4 molecules were detected in the gas, indicating that Na_2SiF_6 was present in the silicon. The mass spectrometric

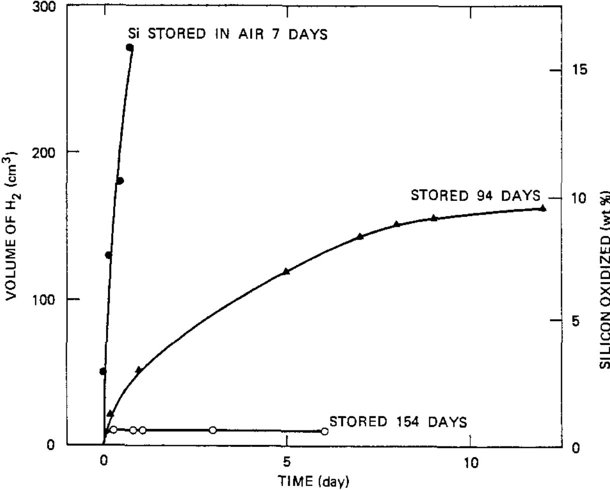

Fig. 3. Hydrogen evolved by SRI silicon powder in acid fluoride solution after storing silicon in air. 1.0g Si in 100 ml solution of 0.60*N* NaF and 1.2*N* H_2SO_4.

measurements indicated semiquantitatively that the amount of Na_2SiF_6 in the silicon was greater than that of the elemental sodium.

When the SiF_4-Na reaction is carried out so that the reaction products contain no unreacted sodium, hydrogen evolution is not observed when the reaction products are immersed in acid fluoride solutions.

Discussion

Hydrogen evolution is known to occur spontaneously when silicon is placed in a strongly alkaline solution, but such evolution has not been observed in acid solutions (3). The evidence discussed here indicates that the SRI silicon is oxidized by the combined effects of sodium in the silicon and high concentrations of fluoride in solution.

The high temperature mass spectroscopy measurements demonstrate that the elemental sodium was driven off from the SRI silicon. These sodium atoms could have originated either from metallic sodium or from sodium silicide. Sodium in the elemental state would be expected to appear in the gas phase at sample temperatures as low as 425°K (4). Although sodium silicide is reported to decompose significantly at temperatures greater than 675°K (5), vapor pressure data are unavailable. In the present discussion the term sodium refers either to the elemental form or to sodium silicide. It should be noted that the sodium atoms observed by high temperature mass spectroscopy could not arise from thermal decomposition of the Na_2SiF_6 impurity in the silicon since the products are SiF_4 and NaF, which is very stable thermally and would have an appearance potential much higher than that of Na.

Hydrogen evolved during simulated leaching did not originate solely from the reaction between sodium and water. If all the sodium in the sample (0.75 w/o by emission spectroscopy) was present as elemental sodium and reacted with water to produce hydrogen, the maximum amount of hydrogen would be about 8 cm^3 or about 3% of the greatest amount shown in Fig. 1.

The mechanism for hydrogen evolution by the SRI silicon in fluoride solutions should take into account the evidence that the rate of hydrogen evolution is related to (*i*) the presence of sodium in the silicon, (*ii*) the fluoride ion concentration, and (*iii*) the age of the silicon after preparation. We propose that a small amount of sodium is incorporated in the silicon, either dissolved in the silicon or trapped in a microporous structure resulting from sintering of small crystallites of silicon. When this sodium reacts with water, hydroxyl ions and hydrogen are produced, and these species can remove the protective surface oxide from the silicon: hydroxyl ions will dissolve silica and will react with silicon to produce more hydrogen. Also, some silica may be dislodged from the surface by the bubbling action of hydrogen evolution, especially in restricted volumes within the microporous structure. The role of sodium in hydrogen evolution is further supported by results from studies with reaction products containing no unreacted sodium, since upon leaching no hydrogen evolution is observed from those reaction products.

One explanation for a high, local alkalinity in the solution, even though the main solution may be strongly acid, is that the sodium reaction occurs in restricted volumes. For example, the reaction may occur in the microporous structure of silicon crystallites, where the diffusion rate of acid from the solution is small. The generation of hydrogen by reaction [4] can proceed only to the extent that sodium was originally present to produce the local alkaline environment. However, hydrogen evolution by reaction [3] will proceed with clean silicon without consuming hydroxyl ions. We believe that the role of the fluoride is to prevent a passivating layer from forming on the clean and reactive silicon in the restricted volumes. For example, when the solution near the silicon surface becomes neutral (*e.g.*, as acid diffuses into the microporous structure), silicic acid that results from silicon oxidation will tend to polymerize and form a passivating layer on the silicon. However, fluoride ions at sufficiently high concentration will probably complex with the silicic acid to form species such as $Si(OH)_3F^-$, and thus retard formation of a passivating layer. Eventually, enough acid will diffuse into the microporous structure to neutralize the local alkalinity produced by the sodium, and hydrogen evolution will cease.

The protective silicon oxide layer on the outermost surface of silicon may initially be removed by HF which is present in acid fluoride solutions. The dissolution rate of SiO_2 films on silicon is reported to be linearly dependent on the HF concentration (6). Indeed, we observed that the hydrogen evolution produced by SRI silicon is roughly linearly proportional to the HF concentration which is essentially equal to the NaF concentration in acid solutions (Table I). However, the mechanism for removal of the protective oxide layer on silicon by HF cannot apply when the pH of the solution is high enough ($pH > 5$) to completely hydrolyze the HF to F^- ions. Figure 2 shows that hydrogen evolution characteristics are the same for acid, neutral, and basic fluoride solutions, indicating that HF is not necessarily involved in the hydrogen evolution reaction. Therefore in neutral and basic solutions, F^- ions, rather than HF, must be the active fluoride species. However, fluoride species (HF or F^-) alone are insufficient to cause hydrogen evolution, as indicated for the 154-day-old silicon in Fig. 3. Therefore, the results shown in Fig. 2 support a hypothesis that some common reactive species is responsible for the hydrogen evolution. We suggest that this species is sodium in the silicon and that hydrogen is generated mostly by spontaneous oxidization of silicon by reaction [3].

The decrease in the hydrogen evolution rate with time (Fig. 1 and 2) suggests that a rate-limited process is occurring. First-order kinetics is suggested from the data on the 94-day-old silicon (Fig. 3) when we assume that the limiting amount of hydrogen evolved (175 cm^3) is proportional to some reactant, such as sodium in the silicon that maintains a high local pH. The data for the other two curves in Fig. 3 are inadequate to test for first-order kinetics. Alternatively, the rate-limiting process may be diffusion controlled, as suggested from the linear relationship obtained by replotting the data for the 7-day- and 94-day-old silicon in Fig. 3 according to the parabolic rate law, that is, hydrogen volume *vs.* square root of time. The data for the 154-day-old silicon are inadequate for this analysis. It is possible to account for a diffusion-controlled process in two ways: the sodium is dissolved in silicon and diffuses through the silicon to react with solution, or the sodium metal is trapped in the microporous structure of the silicon and the solution diffuses through this structure to reach the sodium.

To account for the decreased rate of hydrogen evolution that was observed after the SRI silicon was stored for extended periods of time (Fig. 3), we suggest that some water was adsorbed on the silicon or on NaOH resulting from partial Na oxidation. The adsorbed water will hydrolyze sodium fluosilicate, shown to be present in the SRI silicon; thus, weakly acidic products are produced, according to the equilibrium

$$SiF_6^{=} + 2H_2O \rightleftarrows 4H^+ + 6F^- + SiO_2 \qquad [5]$$

for which the equilibrium constant is $K_a = 10^{-26}$ (6, 7). Ultimately, if there is sufficient water and fluosilicate, the fluosilicate will completely neutralize the local alkaline regions due to sodium and NaOH that promote spontaneous oxidation of silicon. Subsequent exposure of such silicon to a fluoride solution will not result in

hydrogen evolution, such as in the case of the SRI silicon stored 154 days (Fig. 3).

The mechanism for evolution of the relatively small quantities of gas from aqueous suspensions of the other two silicon samples clearly cannot involve the sodium mechanism discussed above, since sodium was not used in producing these silicon samples. However in the case of the Union Carbide sample, the gas evolved could be due to hydrogen that was incorporated in the silicon during its production by thermal decomposition of SiH_4 to Si and H_2 and that was either attached to defect sites (8) or present as Si-H alloy (9).

Technical Notes

Modified Poly-Paraxylylene Coatings and Films with Improved Oxidation Resistance

T. E. Baker,* G. L. Fix, and J. S. Judge*

Raytheon Company, Sudbury, Massachusetts 01776

Many studies have been performed on the physical and chemical properties of poly-paraxylylene (2-5). [Parylene is the generic name for members of this well-known polymer series. (1).] Films of poly-paraxylylene which are produced by vapor phase polymerization are approved as a conformal coating for military electronic assemblies. Although the electrical and physical properties of these films are generally superior to spray applied epoxy or urethane conformal coatings, one inherent shortcoming is their oxidation resistance. The work which is reported in this paper deals specifically with improving the oxidation resistance of films which are produced from the dichloro-di-paraxylylene dimer (6). The techniques and chemistry involved, however, are easily applied to the other poly-paraxylylene polymers as well.

Experimental

The films utilized in this study were produced from dichloro-di-paraxylylene dimer which was obtained from Union Carbide. A Union Carbide Model No. 10C coater was used to produce polymeric films approximately 18 μm in thickness. In all instances the standard processing parameters and temperatures were employed. These conditions are described in detail elsewhere (5) and will not be reiterated here.

For this investigation two separate coating depositions were performed. In each instance 4 × 6 aluminum foil panels were employed as the coating substrates. The first deposition was conventional and was produced from 57g of dichloro-di-paraxylylene dimer. The total substrate area was 2320 cm². The second deposition was produced from a homogenous mixture of 21g of dichloro-di-paraxylylene dimer and 0.21g of a sterically hindered phenol, 4,4'-methylene-bis-(2,6-di-tert-butylphenol). The total substrate area was 970 cm².

Oxidative degradation of the polymer films was performed at 140°, 180°, and 200°C in a forced air oven. The relative degree of oxidation was monitored periodically by infrared spectroscopy. The infrared technique of monitoring the oxidation of a material is accomplished by measuring the absorbance intensity of the peak at 1700 cm^{-1}. This absorption peak can be attributed to the organic acid (—COOH) functionality which is formed by oxidative attack. This absorption is not present in either film initially. Its intensity is observed to monotonically increase as a function of time and temperature.

Results

Figure 1 shows the infrared absorption intensity of the 1700 cm^{-1} peak for both films. The data of this figure clearly illustrate that the addition of the antioxidant successfully prevents the oxidation of the polyparaxylylene polymer for more than 250 hr at 140°C.

* Electrochemical Society Active Member.
Key words: coatings, films, oxidation.

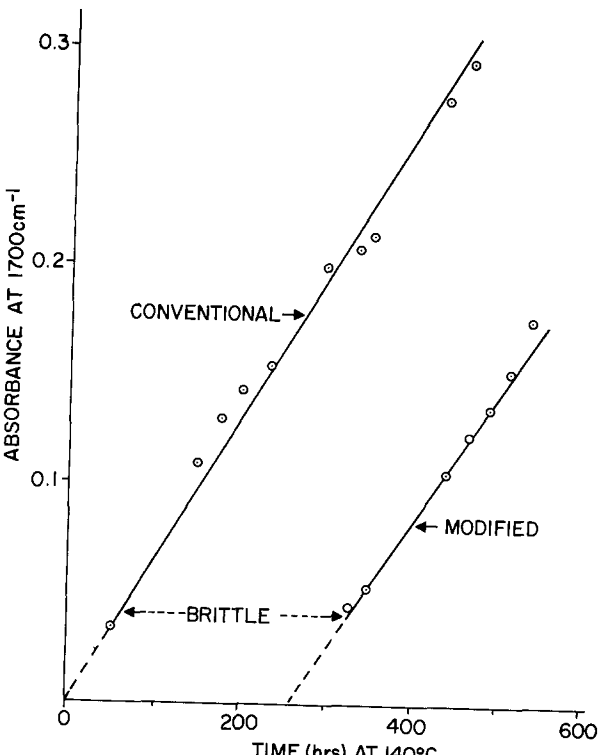

Fig. 1. Plot of absorbance at 1700 cm^{-1} as a function of time at 140°C for conventional and modified poly-paraxylylene films.

The oxidation of the conventional films is seen to be spontaneous. The point on each curve marked "brittle" is the point where the films failed to sustain a 180° bend test. This point corresponds to a peak intensity at 1700 cm^{-1} of 0.04 absorbance units. Similar testing at 180° and 200°C showed that the presence of the antioxidant inhibits oxidation for approximately 5 hr at 180°C and 1 hr at 200°C. Figure 1 also shows that once oxidation is initiated in the modified film the rate of degradation is comparable to that of conventional parylene C. This indicates that the antioxidant activity of the additive is finite and is consumed as a function of time and temperature. Once it is consumed the oxidative mechanisms for both films are identical.

Figure 2 is a plot of the log of the time required to embrittle the two films as a function of the reciprocal of the absolute temperature (°K). The difference between the two lines at any one temperature is the period of time over which the antioxidant effectively prevents degradation of the film. Table I lists some extrapolated values of the time required to embrittle the two films at lower temperatures.

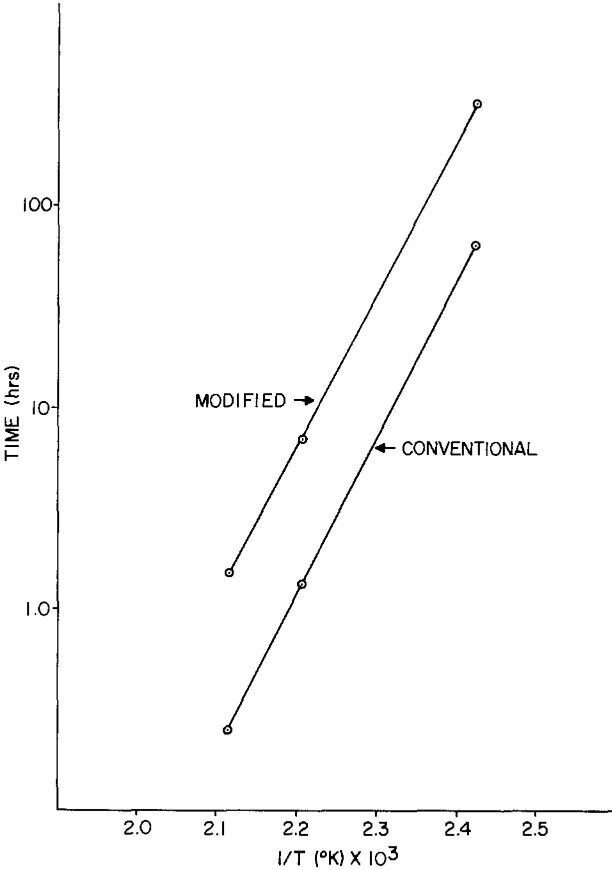

Fig. 2. Plot of the log of the time required to embrittle conventional and modified poly-paraxylylene films as a function of reciprocal absolute temperature.

Table I. Comparative service life of conventional and modified poly-paraxylylene films

SERVICE LIFE		
Temperature, °C	Conventional	Modified
80	11 yrs.	58 yrs.
90	1.5 yrs.	8 yrs.
100	10 mos.	55 mos.
115	42 days	250 days
150	22 hrs.	130 hrs.

Summary

Oxidation resistant poly-paraxylylene conformal coatings can easily be produced by incorporating an appropriate antioxidant material into the starting dimer. The resultant polymeric films exhibit greater than five times the service life of conventional unmodified films.

Analysis of Hydrogen Content in Plasma Silicon Nitride Film

Takeo Yoshimi, Hideo Sakai, and Keizo Tanaka

Computer Development Laboratories, Limited, Kodaira, Tokyo, Japan

Plasma-activated silicon nitride (P-SiN) films (1-7) are widely applied as final chip passivation films for silicon devices. It is important to control the hydrogen content, H_z, and the atomic ratio, Si/N, in the P-SiN film in order to obtain good mechanical properties, such as film stress and crack resistance, and electrical and optical properties. Both the H_z and the Si/N in the P-SiN film deposited by an SiH_4-NH_3 reaction are affected by various deposition parameters such as temperature, rf-power input for plasma activation, pressure, and reactant ratios, SiH_4/NH_3. In this work, composition of the H_z in the P-SiN film was performed by using a quadrupole mass analyzer (8) during high temperature annealing. The ratio, Si/N, in the P-SiN film was determined by Auger electron spectroscopy (AES) and electron spectroscopy for chemical analysis (ESCA) for various deposition conditions. From these measurements, film compositions, $Si_xN_yH_z$, of the P-SiN film, were determined.

Experimental and Results

The production of P-SiN film was carried out through reaction of SiH_4, NH_3, and N_2 mixtures in the plasma-activated reactor. The reactor design consisted of two parallel electrodes with one electrode connected to a 2 kW, 50 kHz rf power supply (9) and the other grounded. Conditions for the P-SiN film deposition were as follows: deposition temperature 130°-350°C, total gas flow 1200 ml/min, rf input power 250-800W, and pressure 0.2 Torr (0.27×10^2 Pa). The system for quadrupole mass analysis of the H_z in the P-SiN film is schematically shown in Fig. 1. A silica tube was 2 cm in inner diameter, 40 cm long, and the hot zone was 20 cm long. Film thickness of a sample deposited in the plasma-activated reactor was measured with a Talystep. The sample was put into the silica tube and evacuated to 1.3×10^{-4} Pa. The hydrogen content in the P-SiN film was measured in the annealing temperatures ranging from 400° to 900°C. The duration of heat-treatment in the quadrupole mass analysis was 20 min for temperatures of 400°, 500°, 600°, 700°, 800°, and 900°C, as shown in Fig. 2. The Si/N ratio was measured as a function of deposition temperature by AES and ESCA.

Key words: hydrogen content, quadrupole mass analysis, step coverage, crack resistance, protection film.

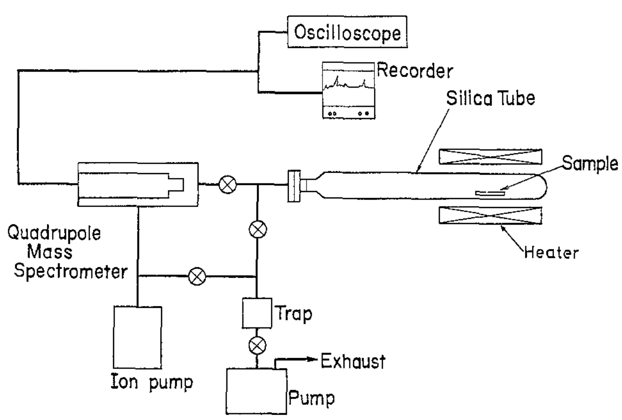

Fig. 1. System of quadrupole mass analyzer used for analysis of hydrogen content in P-SiN film.

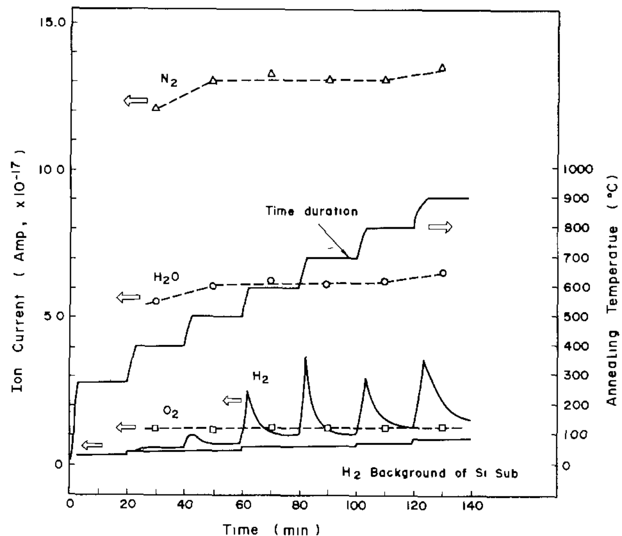

Fig. 2. Time duration for hydrogen content measurement with quadrupole mass analyzer.

The relationship between H_z and rf power is shown as a parameter of deposition temperature, 270°, 310°, and 350°C, in Fig. 3. The H_z obtained by annealing

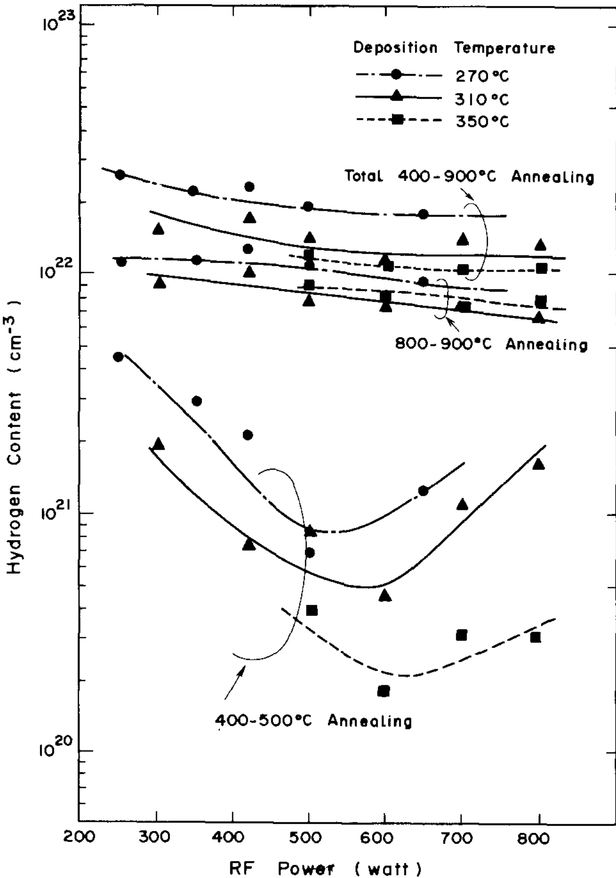

Fig. 3. Variation of hydrogen content with rf power

at 400°-500°C, was clearly a function of rf power. The total amount of hydrogen dissociated from the P-SiN film through the annealing temperature range, 400°-900°C, was about 1-3 $\times$ 10^{22} cm^{-3} at each deposition temperature and rf power 250-800W. The deposition temperature dependences of the H_z are shown in Fig. 4 at rf power of 420W. At lower annealing temperatures (400°-600°C), H_z was influenced strongly by the deposition temperature. When the P-SiN film was deposited at 305°C, the H_z was 1 $\times$ 10^{20} cm^{-3}, or approximately 10 times less than that obtained at a deposition temperature of 130°C. The total H_z obtained at annealing temperature decreased gradually with increasing deposition temperature.

An SiH_4 flow rate of 120-150 ml/min and an NH_3 flow rate of 150-350 ml/min had little effect on the H_z and the dependence of H_z on pressure, 0.1-0.4 Torr, was even less.

The quantitative technique of quadrupole mass analysis was useful and sensitive for the measurement of hydrogen content in the P-SiN film. The H_z was 3.6, 3.1, 2.8, and 2.0 $\times$ 10^{22} cm^{-3} for deposition temperatures of 130°, 220°, 270°, and 305°C, respectively. H_z removed by annealing until 900°C was 80-85% of total H_z included in the P-SiN film. The dependence on higher frequency (MHz) of the H_z was not investigated in the same deposition system.

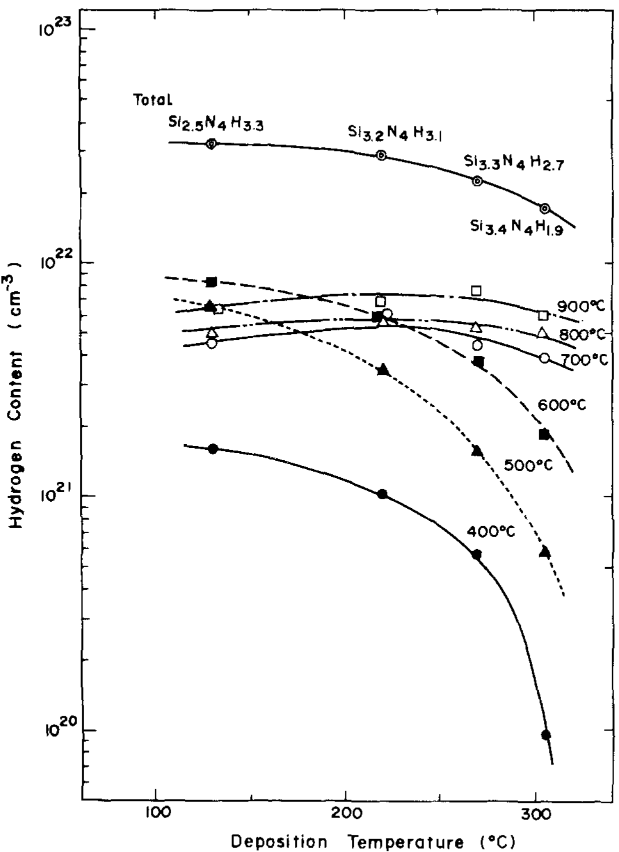

Fig. 4. Variation of hydrogen content with deposition temperature.

* Quadrupole mass analysis
** Auger electron spectroscopy and electron spectroscopy for chemical analysis
*** A composition of nitrogen, Ny, is normalized at 4.0.

The Si/N in the P-SiN film was determined from an integral spectrum, produced by computer from a differential spectrum. It is considered that the atomic ratio, Si/N, and the H_z affect characteristics on Si devices, such as resistivity and crack resistance. A summary of these results is shown in Table I. Hydrogen content was found at a concentration of about 1-4 $\times$ 10^{22} cm^{-3} in the P-SiN film deposited under the various deposition conditions, such as reactant ratio SiH_4/NH_3 = 0.50, pressure 0.20 Torr, rf power 250-800W, deposition temperature 130°-305°C, and an electrode spacing of 2 in. (5 cm). The film composition of the P-SiN film deposited at 305°C and 420W was $Si_{3.4}N_{4.0}H_{1.9}$, corresponding to 1.2 weight percent of hydrogen. P-SiN film should be deposited by higher deposition temperature to reduce the H_z.

Acknowledgments

Determination of the Diffusion Coefficient of Thallium in KCl Crystal by Electron Irradiation

K. Goswami, S. Chaudhuri, D. P. Banerjee, and A. Chaudhury

Department of Physics, Jadavpur University, Calcutta—700032, India

Thallium-doped ionic crystals are important for their application as detectors for ionizing radiations. The Tl atoms are usually incorporated into the crystal during growth from its melt and the product is known as phosphor. Phosphors can also be made by the process of thermal diffusion of Tl in alkalihalide crystals. Although a lot of work (1, 2) has accumulated on the diffusion phenomenon in solids, limited attention (3) has been applied to diffusion of Tl in alkalihalide crystals.

The incorporation of Tl atoms in the KCl lattice is found to create luminescent centers in the host crystal. For constant external conditions of excess Tl atoms at the crystal surface in equilibrium with an external vapor, the distribution is well described by a complementary error function (4). The luminescence yield under electron irradiation from successive depths of the activated crystal is related to the Tl penetration into the crystal and can be used to obtain information on the diffusion process in alkalihalide phosphors. If a solid is exposed to a volume of metal vapor having a uniform concentration N_0 atoms per unit volume, these atoms will diffuse into the solid medium following an equation (4)

$$N(x,t) \approx N_0\left(1 - \operatorname{erf}\frac{x}{2\sqrt{Dt}}\right) = N \operatorname{erfc}\frac{x}{2\sqrt{Dt}} \qquad [1]$$

When a KCl crystal is doped with Tl atoms, it becomes a phosphor. If it is assumed that the luminescence yield is linearly proportional to the concentration of Tl atoms in the host crystal the ratio $N(x, t)/N_0$ in Eq. [1] may be replaced by $L(x, t)/L_0$, where $L(x, t)$ is the luminescence yield due to Tl atoms as a function of the distance x from the surface, t is the period of heat-treatment, and L_0 is the yield from the surface. Equation [1] takes the form

$$\frac{L(x,t)}{L_0} \approx \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) \qquad [2]$$

An experimental determination of $L(x, t)/L_0$ as a function of x may lead to the evaluation of the diffusion coefficient D. The activation energy of diffusion (E) may also be estimated using an equation

$$D = D_0 \exp(-E/kT) \qquad [3]$$

Experimental

A block of cleaved KCl <100> crystal (Harshaw Chemical) and properly distilled thallium metal of known weight were put in a glass tube. The glass tube had two intercommunicating sections separated by a constriction to avoid direct contact between the sample and the metallic Tl. The tubes were sealed under vacuum, heated at diffusion temperatures for a period of 4 hr, and quenched to room temperature. Four such KCl samples were doped with Tl at four different temperatures, 573°, 623°, 673°, and 723°K. The time and other conditions for the doping process were kept the same in all the cases.

The doped crystals were inserted into an electron accelerator tube and irradiated with normally incident 5 keV electrons. Beam current was 0.5 μA cm^{-2}. The intensity of luminescence was measured by an RCA IP21 photomultiplier. All doped samples showed luminescence spectra under electron irradiation peaking at 3050 and 4750Å while no luminescence was detected in the case of pure KCl crystal. The diffusion of Tl was followed by measuring the intensity of luminescence at the surface of the specimen and at various depths along <100> direction by successive removal of surface layers.

Results and Discussion

The luminescence spectrum peaking at 4750Å at room temperature is in conformity with that of others (5, 6). The depth of Tl diffusion has been measured from luminescence yield observed under 5 keV electron irradiation. At such an energy (5 keV) the electron penetration is very low (less than 1 μm) and the observed luminescence is primarily due to doped atoms present in a shallow surface layer of the specimen. In the present experiment the Tl concentration had been sufficiently low and accordingly (7) the luminescence yield may be considered to be proportional to the number of atoms and the ratio $L(x, t)/L_0$ between the luminescence yields at a depth x and at the surface should be equal to $N(x, t)/N_0$ as assumed in Eq. [2]. The ratio of luminescence yields $L(x, t)/L_0$ is determined for different values of x shown in Table I.

The values of $y = x/2\sqrt{Dt}$ for various observed values of $L(x, t)/L_0$ are computed from the graphical solution of Eq. [2].

A graph between y and x is plotted in Fig. 1 for different temperatures of heat-treatment. The straight line plots passing through the origin support the conclusion that the complementary error function solution is valid in this case of vapor to solid phase diffusion. From the slope of the curve of Fig. 1 the values of the diffusion coefficient for different temperatures of doping have been determined and are also shown in Table I.

The values of the diffusion coefficient increase as the temperature of diffusion rises. A plot of $\log_{10} D$ *vs.* $1/T$ is shown in Fig. 2. The plot is a straight line satisfying the relation as stated in Eq. [3]. From the slope of the straight line (Fig. 2), the activation energy of diffusion is estimated and found to be

A Chemical Method for the Deposition of Thin Films of Bi_2Se_3

P. Pramanik, R. N. Bhattacharya, and A. Mondal

Department of Chemistry, Indian Institute of Technology, Kharagpur 721302, India

Thin film formation of selenide of Pb^{2+} by chemical deposition is a very well known process (1,2,3), but chemical methods of deposition of thin films of bismuth selenide have not yet been reported. This brief communication describes a chemical method for the deposition of Bi_2Se_3 thin films.

A sodium selenosulfate solution was prepared by refluxing 5g selenium powder with 12g of sodium sulfite (anhydrous) in 100ml of water for about 5 hours. It was cooled and kept overnight, since on cooling a little selenium separated out from the solution. It was then filtered to obtain a clear solution.

One gram of $Bi(NO_3)_3 \cdot 5H_2O$ was triturated with 10ml of triethanolamine and then 50ml of water was added to it. The resulting solution was continuously stirred till a nearly clear solution was obtained, which was then filtered.

Ten millilitre of the Bi^{3+} solution was taken in a glass beaker. To it 4ml of 0.65(M) NH_4OH and 10ml of the sodium selenosulfate solution were added and the volume was made upto 100ml with water. It was then poured into another glass beaker containing two cleaned glass slides, which were clamped vertically. It was kept at room temperature (30°C) for about two hours. Uniform films of Bi_2Se_3 were obtained on the glass substrates. They were then taken out, washed with water and dried in air. When the solution contained 2ml of hydrazine hydrate, the films had more metallic lustre and better electrical conductivity, but the deposition time was reduced to 30 minutes since on longer staying the films became brittle. The Bi_2Se_3 films were about 0.1 - 0.2 microns thick.

Key words: thin film, chemical deposition, bismuth selenide.

NH_4OH was added to slow down the formation of Bi_2Se_3 and to increase the adherence of it on the glass substrate.

X-ray diffraction data showed that the film deposited from the solution which was free of hydrazine hydrate contained traces of elemental selenium. Selenium deposition was due to atmospheric oxidation of Se^{2-}.

X-ray diffraction data in both the cases, with hydrazine hydrate and without hydrazine hydrate, showed distinct d-lines of Bi_2Se_3. Scanning electron microscopy showed that films contained random distribution of small crystallites shown in figures (1) and (2). Specific resistance of the film obtained from the solution without hydrazine hydrate was 2.4×10^5 ohm-cm. and that of the film obtained from the solution with hydrazine hydrate was 4.5×10^2 ohm-cm. Optical band-gap was found to be 1.15eV for the first case and 1.03eV for the second case, as shown in figure (3). All the films were photoconductive in nature. More detailed studies are in progress.

A Dry Etching Technique Using Electron Beam Resist-PBS

T. Yamazaki, Y. Watakabe, Y. Suzuki,* and H. Nakata

Mitsubishi Electric Corporation LSI Research and Development Laboratory 4-1 Mizuhara, Itami, Hyogo, Japan

The technology of electron beam lithography is of great importance for the fabrication of devices directly on silicon, and for the patterning of photomasks. Although electron beam resists such as PMMA, PBS and others have already been used for many experiments, the acceptance of these resists in the manufacturing enviroment has been very slow due to the uncertainties associated with processing of these materials.

Among the many electron beam resists, PBS has the best combination of resolution, sensitivity, and adhesion. The main limitation to PBS is its poor resistance to dry etching enviroments which attributed to plasma depolymerization which enhances the rate of film loss.

The purpose of this paper is to demonstrate a new technique of gas plasma etching of chromium photomask films using PBS. Figure 1 shows the etching resistance of PBS to the gas plasma enviroment for chromium photomask etching, together with other electron beam resists and AZ-1350. In this experiment, gas plasma etching was carried out in a barrel type plasma reactor, in which the gas plasma was generated by RF discharge at 13.56 MHz. The pressure in the reactor was maintained at 0.2 torr. and the RF power was kept at 240 W. The etching gas was a mixture of CCl_4, N_2, and O_2.

From Fig. 1, it is apparent that the loss rate of PBS is high compared with AZ-1350 or the electron beam resists COP and FMR. Since the etch rate of the chromium film is 50 Å/min. in this gas plasma condition and the loss rate of PBS film is 1140 Å/min., it would be necessary to use more than 14000 Å of PBS film for a 600 Å chromium film.

In a previous paper, we reported on the reversal gas plasma etching technique for chromium films using AZ-1350 (1). In this paper, in order to obtain fine patterns with an electron beam exposure technique, we have used PBS instead of AZ-1350 in the

* Present address; Computer Development Laboratories Limited, 4-1, Mizuhara, Itami, Hyogo, Japan

Key words; Gas Plasma, Photomask, Electron Beam Resist.

reversal gas plasma etching of chromium photomasks. Figure 2 shows photographs at different stages of the reversal plasma etching process where PBS was used as the patterning film.

The photomasks used in this experiment consisted of an anti-reflective chromium film, comprised of a chromium oxide film on a chromium film all deposited on a glass substrate. The thickness of the chromium oxide film and the chromium film were 200 Å and 600 Å, respectively. The photomask size was 4 x 4 inches. The chromium oxide film was deposited by resistance heating and the chromium film was deposited by flash evaporation. The PBS processing was the same as the one described by Bowden (2). The thickness of PBS films were 4000 Å, measured by a Talystep. An AES analysis of the chromium oxide film showed that tungsten impurities are included in the surface of the chromium oxide film. These impurities are assumed to be caused by evaporation of the tungsten boat during heating. The elemental concentration ratio of tungsten to chromium at the surface layer was 0.6 as determined by AES analysis.

As we described in the previous paper, in reversal gas plasma etching, a naturaly grown WO_3 layer in the surface of a chromium oxide film works as a masking layer for the gas plasma enviroment and the decomposed species of the resist film react with the WO_3 masking layer to remove it while the resist film is decomposing. PBS, which is very weak to the gas plasma enviroment, can be used as a patterning resist for reversal gas plasma etching if its decomposition time is long enough for the decomposed species to react with WO_3 masking layer. In the case of AZ-1350 which has high resistivity to the plasma enviroment, a long time is required to decompose all of the resist film. Accordingly, the decomposed species react with WO_3 near a photoresist pattern and make it difficult to control pattern widths precisely. In the case of a PBS film, as the decomposition of the film occurs quickly, the decomposed species can react with WO_3 layer just underneath the patterning film and sharp edged patterns can be obtained. Figure 3 shows an example of a photomask which was prepared by the reversal gas plasma etching, and demonstrates good edge profiles for minimum 2 μm line width.

In summary, a new gas plasma etching technique using the electron beam resist PBS, which is known as a very weak resist for dry etching enviroments, has been demonstrated. With this new technique, 2 μm line widths were obtained with chromium photomasks.

ACKNOWLEDGEMENT

The authors express their appreciation to Dr. Oka for his encouragement.

Radiation Damage Estimates and Control in Ion-Beam Lithography

K. F. Galloway*

National Bureau of Standards, Electron Devices Division, Washington, DC 20234

The purpose of this note is to present estimates of the radiation dose absorbed in critical device dielectric layers during the application of ion-beam lithography (IBL). Ion-beam lithography has been demonstrated as a technique providing submicrometer resolution with the capability of large throughput in work recently reported by Rensch et al. (1) and by Seliger and Sullivan (2). These estimates should facilitate the comparison of this technique with other techniques delivering a radiation dose to device structures during processing.

Device structures fabricated with x-ray or electron-beam lithographic techniques receive absorbed radiation doses in critical dielectric layers in excess of 1 Mrad(SiO_2) (3). This process-related radiation exposure may affect the ultimate reliability and radiation hardness of devices so fabricated (3,4,5). In fact, the radiation hardness of devices fabricated using x-ray lithography has been shown to be diminished even though the damage due to the lithography was apparently annealed out (5).

In order to arrive at the desired estimate for radiation dose due to IBL, a description of the behavior of an ion beam passing through multiple thin films is required. The technique of Bernstein and Kolodny (6) has been used to obtain such a description. Consider the schematic illustration of Fig. 1. ϕ_0 and E_0 are the incident fluence (ions/cm^2) and incident ion energy (keV) impinging on the layered film structure. ϕ_1 and E_1 are the fluence and <u>average</u> ion energy passing from film one into film two and so on. The number of ions stopped in any film is independent of the following films. Assuming the distribution to be Gaussian, the number of ions stopped in film one is found by integrating the ion density distribution

$$n(x_p) = \frac{\phi_0}{\phi_p\sqrt{2\pi}} \exp\left\{\frac{-(x_p - R_p)^2}{2\sigma_p^2}\right\}$$

over the film thickness using R_p (projected range) and σ_p (straggle) from the tabulated values for ion-film-energy combinations (7); x_p is measured along the direction of incidence of the beam. The fluence into film two (ϕ_1) is found by subtracting the number stopped in film one from ϕ_0. This procedure is then followed for each subsequent film. The increase in straggle as the ions pass

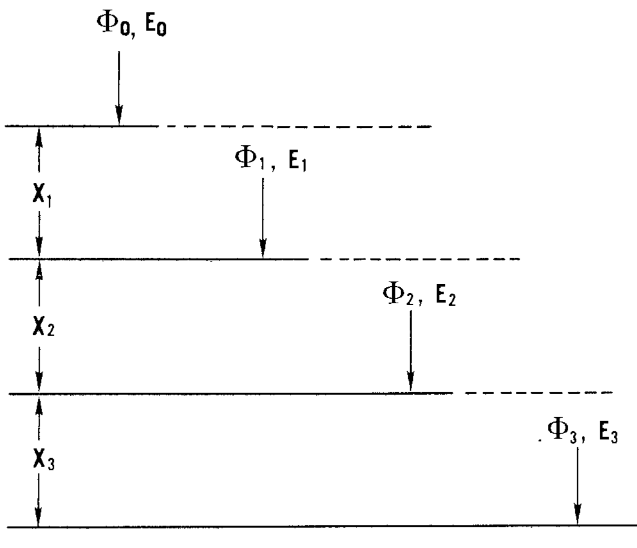

Fig. 1. Schematic illustration of three films of thickness x_1, x_2, and x_3, respectively, on a semi-infinite substrate with the ion fluence and average ion energy entering each film indicated.

through the several films has been ignored as have such subtleties as ion backscattering at film interfaces and the departures of the ion penetration distribution from a Gaussian due to higher order moments in the solution of the range equation. E_1, the average ion energy entering film two after passing through film one, is found using the tables (7) as follows:

1. Find R_p (E_0, film one), the projected range that the ion beam of energy E_0 would have in film one if the film were infinitely thick.

2. Subtract the thickness of film one, x_1, from R_p (E_0, film one).

3. If R_p (E_0, film one) $\leq x_1$, the ion beam is essentially stopped in film one and E_1 is approximately zero.

4. Otherwise, find E_1 as the energy required for an ion to have a range R_p (E_1, film one) = R_p (E_0, film one) - x_1.

This procedure for obtaining the average ion energy (6) is then repeatedly applied as the ions pass through each film in the layered structure.

Consider the application of the procedure discussed in the preceding paragraph to a structure where a silicon substrate is covered by a 0.05-μm thick film of silicon dioxide which is covered by a 1.0-μm thick film of aluminum metallization which is in turn covered with a 1.0-μm thick film of photoresist to be patterned by IBL. Since AZ11 is the only resist considered in the tables (7), its tabulated parameters were used; the estimates based on these parameters are expected to be typical of other resists. The average energy per ion deposited in the oxide layer is calculated as $E_2 - E_3$ (see Fig. 1), and using ϕ_2, the total energy deposited and the dose can be calculated. In the ion-energy regimes considered here, electronic interaction processes dominate possible nuclear interaction processes (7). Typical values of the ion beam parameters have been selected from the work of Rensch et al. (1). If E_0 is 200 keV and the incident ions are protons, $E_2 - E_3$ is 8 keV and $\phi_2 \sim \phi_1 \sim \phi_0$ for the structure considered. For ϕ_0 of 2 x $10^{13}/cm^2$, the radiation-absorbed dose in the silicon dioxide layer is approximately 220 Mrad(SiO_2).* If E_0 were 58 keV, the proton projected range in the aluminum film would be 0.8 μm, and the projected standard deviation would be 0.187 μm. Thus, the proton beam would be stopped in the aluminum film and there would be no absorbed dose in the oxide layer (ignoring beam straggle beyond a standard deviation, possible x-ray production, and secondary electrons).

If the aluminum film in the material configuration above is replaced by a 1.0-μm thick film of polysilicon, there are differences in radiation-absorbed dose in the oxide layer because of differences in the projected range for ions in polysilicon as compared to that for ions in aluminum. The radiation-absorbed dose in the silicon dioxide layer under the polysilicon film is approximately 200 Mrad(SiO_2) for a proton beam with an E_0 of 200 keV and a ϕ_0 of 2 x $10^{13}/cm^2$. If E_0 were 93 keV, the proton projected range in the polysilicon film would be 0.8 μm and the projected standard deviation would be 0.111 μm. If beam straggle beyond a standard deviation, possible x-ray production, and secondary electrons are ignored, there will no radiation-absorbed dose in the oxide film for proton beams with energy less than 93 keV.

If the aluminum or polysilicon represents the gate metallization of an MOS device, a positive resist and an etch-back process (plasma or ion etching) will probably be utilized. In this case, no ions will be inci-

* The SI unit for absorbed dose is the gray (Gy) in units of J/kg. One rad equals 1 x 10^{-2} Gy.

dent on the gate oxide layer. However, laterally scattered radiation might be expected to yield significant radiation exposures in the vicinity of the gate metallization edges.

The estimates presented here indicate that the radiation-absorbed dose in device oxide layers when applying ion-beam lithography can be substantial. It has been shown that annealing temperatures higher than 550°C are required to remove both the positive and neutral traps generated by ionizing radiation from the oxide layers (8). Also, it should be noted that the implantation of protons in device oxides has been suggested as a technique for advantageously tailoring device interface states (9). The estimates also indicate that by carefully matching the ion beam energy to the material configuration, the radiation-absorbed dose in critical oxide layers can be essentially eliminated. In general, this means operating with a beam energy which is as low as practicable after accounting for mask membrane penetration (1) and allowing for loss of resolution due to beam scattering and which is high enough to achieve uniform exposure and minimize lateral scattering in the resist. This ability to reduce the radiation-absorbed dose in the oxide is perhaps a significant advantage over electron-beam or x-ray lithography (3).

The one-electron quasireversible reduction of oxygen to superoxide ion, $O_2^{\bar{\cdot}}$, in aprotic solvents is well known (1-4).

$$O_2 + e^- \rightleftharpoons O_2^{\bar{\cdot}} \quad [1]$$

Superoxide ion has been shown to function as a base, nucleophile and reductant in reactions with organic compounds (5). It also possesses the enigmatic ability to act as an oxidizing agent toward certain organic compounds under conditions which appear thermodynamically unfavorable for it to do so (6). This property of $O_2^{\bar{\cdot}}$ is of considerable interest to workers studying the role of $O_2^{\bar{\cdot}}$ in biological systems. It is generally believed that the first step in these oxidations involves proton transfer from the substrate to $O_2^{\bar{\cdot}}$, according to Eq. [2] (6).

$$O_2^{\bar{\cdot}} + RH \rightarrow HO_2\cdot + R^- \quad [2]$$

Actual oxidation of the substrate is postulated to result from the reaction of $HO_2\cdot$ or O_2, the latter produced by the disproportionation reaction depicted in Eq. [3], with the substrate anion, R^- (6).

$$O_2^{\bar{\cdot}} + HO_2\cdot \rightleftharpoons O_2 + HO_2^- \quad [3]$$

Recent synthetic explorations of the reaction of $O_2^{\bar{\cdot}}$ with phenylenediamines, employing KO_2, resulted in the isolation of oxidation products, e.g., nitrosoanilines, nitroanilines, and diaminoazobenzenes (7, 8). On the basis of these products, the oxidation of phenylenediamine by $O_2^{\bar{\cdot}}$ was postulated to entail an initial hydrogen abstraction process in which a phenylenediamino radical intermediate, $RNH\cdot$, is formed (7).

$$O_2^{\bar{\cdot}} + RNH_2 \rightarrow HO_2^- + RNH\cdot \quad [4]$$

We wish to communicate electrochemical data concerning the reaction of electrogenerated $O_2^{\bar{\cdot}}$ with 2-phenylenediamine (2-PDA) which contributes to further understanding of the involvement of proton transfer in these reactions.

EXPERIMENTAL

Electrochemical experiments were carried out in N,N-dimethylformamide, DMF, (Burdick and Jackson) with a specified water content of 0.004%. The supporting electrolyte, tetra-n-butylammonium perchlorate, TBAP, was synthesized according to standard procedures and dried at 100°C in a vacuum for several days. The 2-phenylenediamine (Eastman) was recrystallized twice from chloroform and dried in a vacuum for 24 hrs. The cell and electrodes, electrochemical instrumentation, and experimental procedure are detailed in a companion publication (9).

RESULTS AND DISCUSSION

Cyclic voltammograms, corresponding to the process represented in Eq. [1], at a glassy carbon electrode in O_2 saturated DMF containing 0.1 *M* TBAP are shown in Fig. 1. In the presence of 2-PDA the $O_2^{\bar{\cdot}}$ reoxidation peak at -0.82 V in Fig. 1 is diminished, and peaks representing the oxidation of products are apparent. As shown in Table I, the cyclic voltammetric peak current ratio, i_p^a/i_p^c, for the $O_2/O_2^{\bar{\cdot}}$ electrode process is less than 1.0 in the presence of 2-PDA, but increases toward 1.0 as the scan rate, ν, is increased. Values of the voltammetric current function, $i_p^c/\nu^{1/2}$, for oxygen reduction given in Table I are the same within experimental error at each scan rate tested regardless of whether 2-PDA is added. The cyclic voltammetric data given in Table I for the $O_2/O_2^{\bar{\cdot}}$ process in the presence of 2-PDA match diagnostic criteria presented by Nicholson and Shain (10) for a charge transfer process followed by an irreversible chemical reaction, i.e., an EC mechanism.

Table I. Cyclic Voltammetric Data for the $O_2/O_2^{\bar{\cdot}}$ Electrode Reaction at 40.0°C.

ν (V/s)	i_p^a/i_p^c		$i_p^c/\nu^{1/2}$ (mA s$^{1/2}$/V$^{1/2}$)	
	O_2	O_2 + 2-PDA[1]	O_2	O_2 + 2-PDA[1]
0.02	1.00	0.58	2.1	2.2
0.05	1.00	0.73	2.0	2.0
0.10	1.01	0.80	1.9	1.9
0.20	1.02	0.87	1.8	1.8
0.50	1.00	0.90	1.7	1.6
1.00	1.03	0.92	1.6	1.5

[1]The concentration of 2-PDA was 0.1 *M*.

Key words: free radicals, organic, kinetics

Further indication of an EC mechanism was obtained using chronopotentiometry. Figure 2 shows a chronopotentiogram with current reversal for the process represented by Eq. [1] in oxygen saturated solutions with and without added 2-PDA. The reverse transition time, τ_r, for reoxidation of $O_2^{\cdot-}$ is decreased considerably in the solution containing 2-PDA and additional waves representing the oxidation of products are apparent. The ratio, τ_r/t_f, where t_f is the forward electrolysis time, is 0.3 for the oxygen reduction-reoxidation process without added 2-PDA but decreases to 0.1 when 2-PDA is added to the solution. Behavior of this nature can be attributed to an EC process (11).

These electrochemical data suggest that the reduction of O_2 in solutions containing 2-PDA involves a charge-transfer process to form $O_2^{\cdot-}$ followed by homogeneous irreversible chemical reactions in which $O_2^{\cdot-}$ attacks 2-PDA. The overall process appears complex, since both cyclic voltammograms and chronopotentiograms exhibit waves due to the oxidation of numerous products. Furthermore, the O_2 reduction process in the presence of 2-PDA involves the same number of electrons as the O_2 reduction process without added 2-PDA, since data for $i_p^c/v^{1/2}$ in the last two columns of Table I are virtually identical. Additional support for this conclusion is obtained from chronoamperometric experiments in which a potential step from 0 to -1.25 V was applied to the working electrode in O_2 saturated solvent and the resulting current was recorded as a function of time. Values of $it^{1/2}$ for the O_2 reduction process obtained from these experiments are shown in Table II. No significant increase in $it^{1/2}$ is evident for O_2 reduction in the presence of 2-PDA compared to $it^{1/2}$ for O_2 reduction without added 2-PDA.

Table II. Chronoamperometric Data for the Oxygen Reduction Process at 40.0°C

t (s)	$it^{1/2}$ ($mA\ s^{1/2}$)	
	O_2	O_2 + 2-PDA[1]
2.0	0.51	0.56
4.0	0.52	0.57
6.0	0.53	0.58
8.0	0.53	0.59
10.0	0.54	0.61
12.0	0.55	0.62

[1]The concentration of 2-PDA was 0.1 M.

If proton transfer from the phenylenediamine to $O_2^{\cdot-}$ were a significant step in the overall mechanism, whereby the organic substrate is oxidized, then it should be possible to observe the reduction of $HO_2\cdot$ produced by proton transfer to $O_2^{\cdot-}$. This process would be concurrent with the reduction of O_2 according to Eq. [5], since $HO_2\cdot$ is more readily reduced than O_2 (4).

$$HO_2\cdot + e^- \rightarrow HO_2^- \quad [5]$$

An overall reduction sequence represented by Eqs. [1], [2], and [5] should produce a voltammetric response indicative of an ECE process (12). In addition, O_2 produced by the reaction represented in Eq. [3] would also contribute to the initial O_2 reduction current (13). In any case, if proton transfer to O_2 by 2-PDA were a significant process, the reduction of O_2 in the presence of 2-PDA would involve more than one electron and both $i_p^c/v^{1/2}$ and $it^{1/2}$ would be enhanced. This response would be similar to that reported for the reaction of electrogenerated $O_2^{\cdot-}$ with proton donors, when $O_2^{\cdot-}$ is electrogenerated in the presence of acidic organic or inorganic substrates and course of its existence is followed electrochemically (4, 9, 14, 15). We also observed this behavior experimentally for the reduction of O_2 in the presence of ascorbic acid which is known to undergo net oxidation in the presence of $O_2^{\cdot-}$ (16).

The preliminary electrochemical data presented in this communication suggest that $O_2^{\cdot-}$ attacks 2-PDA via a pathway which circumvents an initial proton transfer step. Thus, proton transfer does not appear to be important in all cases for which net oxidation of an organic substrate by $O_2^{\cdot-}$ is reported. Our results appear consistent with a process involving Eqs. [1] and [4], although the overall mechanism may be complex. Further nonelectrochemical studies will be required to delineate the exact pathway by which these reactions take place.

Properties of Lead Dioxide Doped with Antimony

F. Caldara, A. Delmastro, G. Fracchia, and M. Maja*

Istituto di Elettrochimica, Politecnico di Torino, Torino, Italy

ABSTRACT

The effects of antimony on the electrocrystallization and on the electrochemical behavior of α and β lead dioxide were investigated by scanning electron microscopy, x-ray diffraction, and chemical analysis. Galvanostatic reduction tests in alkaline solutions were also performed. Antimony drastically modifies the crystal morphology of α lead dioxide and, up to a concentration of 0.2%, changes the O/Pb ratio by filling lattice vacancies. On β PbO_2, on the contrary, antimony does not seem to have any significant influence. The reduction tests on lead dioxide showed that the cathodic process occurs in a homogeneous system until the O/Pb ratio reaches a value depending on the dioxide allotropic form and on the antimony content. The O/Pb ratio of intermediate oxide increases from pure α PbO_2 (1.33) to Sb-doped β PbO_2 (1.65).

For many years the most relevant effects of antimony on the performance of lead acid batteries have been known (1-4). Antimony, which is present in the grids as an alloying element to improve mechanical properties and castability of lead alloys, dissolves in the electrolyte and then reacts with the active material.

On negative plates, antimony has a detrimental influence poisoning the sponge lead and inducing local electrochemical action which causes self-discharge. In addition the presence of antimony affects the charge efficiency. The increase of the amount of antimony on the sponge lead is partially avoided by stibine formation during charge periods.

For positive plates, some studies (5-9) have shown a different behavior of the plates with antimonial lead grids compared to those without antimony; there is evidence that antimony improves some properties of the positive active material.

Burbank (5) characterizing positive active material with SEM and x-ray diffraction, showed that antimony modifies the crystal size and habit of lead dioxide and promotes α PbO_2 formation. Ritchie and Burbank (6) examined the behavior of lead acid cells with pure and antimonial lead grids, concluding that cells with pure lead grids were losing slow discharge capacity more rapidly than the antimonial cells.

Antimony appears to act as an inhibitor for the growth of dioxide crystals or as a nucleating catalyst, thus reducing average crystal size.

Swets (7) suggested that the increase of α PbO_2 in the active material during the life of the batteries with antimonial lead grids is due to the formation of meta-antimonate. This compound, identified by x-ray diffraction, should passivate the dioxide during the discharge of the plates and should help the nucleation of α PbO_2 during the recharge period. Dawson (8) studied the chemical reaction involving solvated antimony ions in lead acid batteries and the adsorption of antimony on lead dioxide.

Maskalick (9) measured antimony adsorption on positive active material during accelerated life tests showing the buildup of a greater concentration in positive active material compared with the negative

Simon (10) showed another phenomenon directly related to antimony: the formation (when Sb_2O_3 is added during paste mixing) of acicular crystals, precursors of PbO_2 crystals. Recently Abdularim and Ismail (11) reported that the addition of Sb_2O_3 to positive active material enhances the capacity of positive plates.

The mode of influence of Sb on the morphology of positive active material is still not clear. Ritchie and Burbank (6) suggested that antimony in the form of pentavalent ions, according to the positive plate potential, could both enter the lead dioxide lattice, occupying Pb^{4+} positions, and be absorbed at growth sites on the lead dioxide crystal surface.

The present work concerns the effect of antimony on the properties and electrocrystallization of lead dioxide. For this purpose various samples of Sb-doped lead dioxide were prepared by electrolyzing plumbous salt solutions to which different quantities of antimony were added. The samples were analyzed to determine antimony concentration and the oxygen/metal atomic ratio (O/Pb). The semiconducting properties and the electrochemical characteristics of Sb-doped lead dioxide were also determined. These semiconducting properties were investigated by means of photoeffect measurements; the electrochemical characteristics were studied by analyzing the linear sweep voltammetry (LSV) curves traced during the reduction of the samples in alkaline solutions. The effect of antimony on the structure of lead dioxide was investigated using x-ray diffraction and scanning electron microscopy.

The effect of antimony on the reactivity of α and β PbO_2 was recently reported by Brenet (12) and coworkers. From galvanostatic reduction curves, traced in 8N H_2SO_4, $10^{-4}N$ Sb_2O_3 solution, these authors deduced an influence of antimony on the electrochemical reactivity of lead dioxide.

With regard to semiconducting properties, Mindt (13) investigated resistivity, Hall effect, and optical absorption of electrodeposited α and β PbO_2 and stated that the n-semiconduction of PbO_2 could be due to deviation from stoichiometry or to incorporation of hydrogen in the lattice.

* Electrochemical Society Active Member.
Key words: lead acid cell, electrocrystallization, photoeffects, lead dioxide reduction.

Other lead oxides (14) present semiconducting properties and clearly display photoconductivity in the visible region of the light spectrum.

Pavlov (15) studied the photoeffects on PbO_x formed on the lead and its photo-activation. Lyamina (16) evaluated the semiconducting properties of partially reduced PbO_2 by studying the dioxide behavior in a redox system concluding that there is an inhibition of the reduction processes.

Concerning dioxide reduction in alkaline solutions, Jones (17) and Glickman (18) observed, during galvanostatic reduction of lead anodically oxidized, two potential arrests on the voltage-time curves corresponding to the couples PbO_2/PbO and PbO/Pb. Ezerskii (19) showed that during dioxide reduction in hot concentrated alkaline solutions, at high current density ($i > 100$ mA/cm^2), Pb_3O_4 is formed by reaction of $HPbO_2^-$ ions with the PbO_2 layer. Lyamina (20, 21), in contrast to the previous results, found that the dioxide reduction proceeds in a homogeneous system until the O/Pb ratio reaches a value near 1.3, then lead formation begins to occur. Moreover, this author (20) pointed out that the process limiting the cathodic current is oxygen diffusion in the solid phase.

Chartier (22) traced potentiodynamic and galvanostatic curves for α and β PbO_2 reduction in dilute alkaline solutions and showed that lead dioxide passivates at a potential below PbO formation. From galvanostatic curves this author deduced also that the reduction mechanism of the two allotropic lead dioxide forms is different.

Carr and Hampson (23) studied α PbO_2 reduction by fast linear voltammetry and they observed two cathodic peaks at potentials corresponding to the reduction of α PbO_2 to PbO and PbO to Pb. The β PbO_2 reduction seems to be complicated by a transformation of β PbO_2 to α PbO_2 which occurs at the electrode surface.

Experimental

Anodic layers of α and β PbO_2 were electrodeposited on a gold substrate according to methods described in the literature (24). α PbO_2 was deposited at 30°C from a 2*N* KOH solution saturated with PbO at a current density of 10 mA/cm^2. β PbO_2 was obtained at 25°C from 0.15*N* $Pb(NO_3)_2$, 0.15*N* HNO_3 solution at a current density of 100 mA/cm^2. The nitric acid solution was also used to deposit mixtures of α and β PbO_2 which were analyzed by x-ray technique considering reflection lines from (111) plane for the α PbO_2 and from (110) plane for β PbO_2.

To obtain antimony-doped lead dioxide, Sb_2O_3 dissolved in KOH was added to the solution used to deposit lead dioxide. The concentration of trivalent antimony ions was in the range 0-100 ppm.

Some of the anodic deposit of pure and doped lead dioxide were finely ground, washed in 1M KOH or in 10% HNO_3 solution, rinsed in doubly distilled water, and analyzed to determine the O/Me ratio and the antimony amount. The O/Me ratio was determined by means of iodometric titration (25). This analytical technique was previously tested by measuring the O/Mn ratio for Mn_2O_3 samples prepared by calcining pure $MnCO_3$ at 700°C. The standard deviation of these measures was smaller than 0.01%. The antimony amount in the anodic deposit was determined by means of an atomic absorption technique.

The reduction of pure and doped lead dioxide was carried out in pure 1M and 5M KOH solutions at a temperature of 22°C. For this purpose linear sweep voltammetry (LSV) curves were traced with a low scan rate (200 μV/sec). During the reduction, the amount of charge required by the cathodic process was measured with an electronic integrator; the amount of charge and the current intensity were recorded *vs.* the electrode potential.

The working electrode, made of gold covered with lead dioxide layers 2-8 μm thick, had a surface area of 0.8 cm^2. The reference half-cell was an Hg/HgO electrode and the counterelectrode was a Pt foil. To determine the change of lead dioxide structure and the appearance of new phases during the cathodic processes, some reductions were interrupted at various electrode potential. Subsequently the partially reduced samples, rapidly removed from the cell, rinsed with water and dried with acetone, were analyzed by x-ray diffraction and were observed at the SEM.

To determine the effects induced by light on the electrochemical cathodic processes the working electrode was illuminated with a chopped (13 Hz) white light of a mercury lamp (OSRAM HBO-200) during the slow potentiodynamic reductions, and the photocurrents were detected by means of a lock-in amplifier.

Results and Discussion

Pure lead dioxide.—X-ray diffraction patterns of anodic layers showed that crystals are strongly oriented. α PbO_2 layers displayed a very very strong line from (200) plane ($d = 2.48$ nm) in agreement with literature data (26, 27). β PbO_2 layers, on the contrary, gave a strong line from (031) plane ($d = 1.486$ nm). In both cases the remaining lines were very weak or absent. The diffraction patterns recorded from finely ground anodic layers displayed the characteristic peaks, reported in ASTM cards (No. 11-549 and 25-447).

Concerning the O/Me ratio measurements, the results obtained by analyzing 50 samples, by iodometric technique, showed that lead dioxide has a chemical composition corresponding to $PbO_{1.87}$ for the α allotropic form and corresponding to $PbO_{1.92}$ for the β form. In Fig. 1 and 2 are represented the electron micrographs of both allotropic forms of electrodeposited lead dioxide.

Sb effect on the structure.—When α PbO_2 is deposited from solutions containing trivalent antimony ions, it can be observed that x-ray reflection lines from powdered samples are weakly shifted toward lower angles; this shift is particularly evident (0.05°) for the reflection lines from (110) and (111) plane when the antimony concentration in the electrolyte is greater than 60 ppm.

Small modifications seem to occur in the diffraction patterns of powdered β PbO_2 samples; only a slight broadening of the peaks can be observed. X-ray analysis of α and β mixtures codeposited showed that antimony favors α PbO_2 formation. The increase of α form has been about 20% when Sb concentration in the solution is 100 ppm and the α/β ratio for pure PbO_2 is 1.

Chemical analysis.—Chemical analysis showed that antimony concentration in the anodic deposits in-

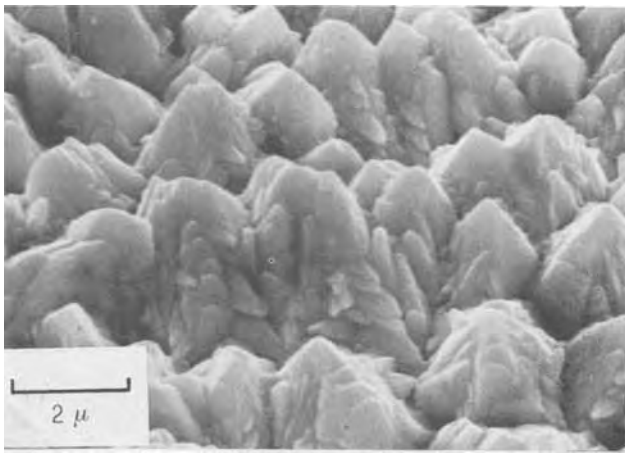

Fig. 1. SEM micrograph of pure α PbO_2 electrodeposited from 2*N* KOH saturated with PbO; $i_{dep} = 10$ mA/cm^2, $T = 30$°C.

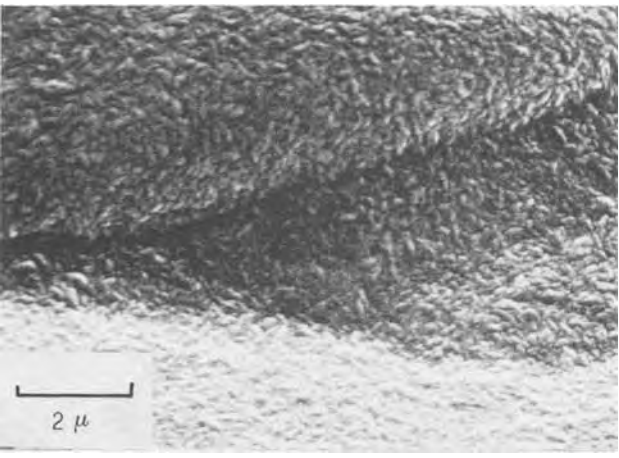

Fig. 2. SEM micrograph of pure β PbO_2 electrodeposited from 0.5M $Pb(NO_3)_2$ and 0.15M HNO_3; $i_{dep} = 100$ mA/cm², $T = 30$°C.

creases with increasing antimony content in the electrolyte, as reported in Fig. 3. It can be seen that antimony content in α PbO_2 is higher than in β PbO_2. In Fig. 3 the values of the O/Pb ratio are also reported.

As can be easily seen, the O/Pb ratio in the α lead dioxide increases markedly with increasing antimony content in the electrolyte, until the antimony concentration in the anodic layer reaches the value of 0.02%, corresponding to 40 ppm of antimony in the electrolyte. Above this value the O/Pb ratio reaches a constant value. On the other hand, antimony does not seem to change the O/Pb ratio in the β lead dioxide.

Considering that antimony pentavalent ions behave, with respect to iodometric analysis, as tetravalent lead ions, both oxidizing two equivalents of iodine, the Sb^{5+} substitution for Pb^{4+} does not modify the O/Me ratio of lead dioxide. Instead. this ratio is changed if

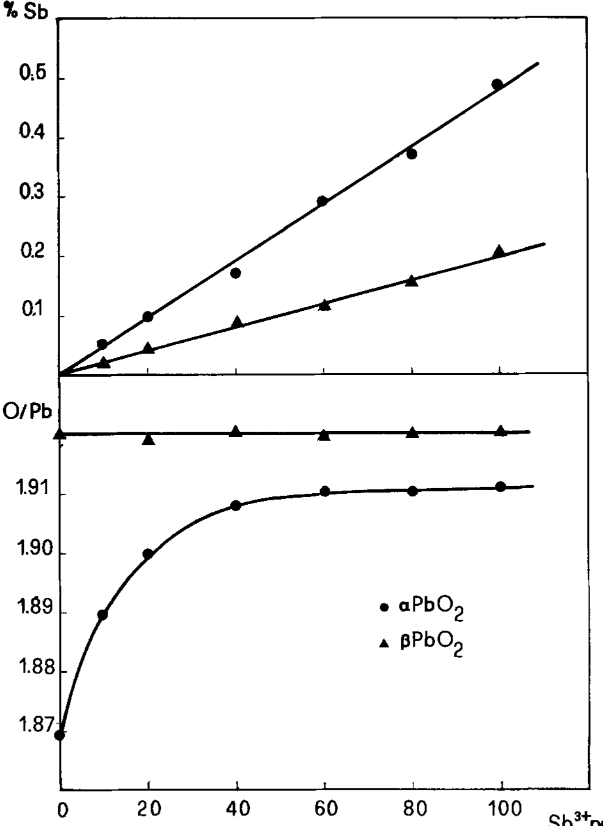

Fig. 3. Antimony content in the anodic deposits of α (●) and β (▲) PbO_2 (upper diagram), and O/Pb ratio (lower diagram) vs. antimony content in the electrolyte.

antimony fills lattice vacancies or substitutes divalent lead ions.

Antimony decreases the number of lattice defects (26) thus contributing to the growth of a more regular structure. This latter effect is outstanding because the observed O/Pb ratio is surprisingly greater than that one would expect from the introduction of small quantities of Sb in the PbO_2 lattice. From Fig. 3 it can also be deduced that for antimony concentration greater than 0.2% the O/Pb ratio increases no more and the Sb^{5+} enters the lattice by substituting tetravalent lead ions.

The greater solubility of antimony in αPbO_2 could explain the increasing amount of that allotropic form in the positive active material of lead acid cell with antimonial lead grids.

Effect of Sb on crystal habit.—When antimony is present in the α PbO_2 lattice, the crystal habit of the dioxide changes drastically. Comparing Fig. 1 with Fig. 4a and Fig. 4b with Fig. 4c, it appears clearly that antimony reduces the crystal size. Its influence is so relevant as to cause a change in the crystal morphology when the antimony amount in the dioxide is greater than 0.2%.

With increasing antimony amount, the crystal size becomes smaller and its surface energy increases until "soap bubble" forms can grow. The crystal size reduction is already apparent when, on the oxide surface, for about 20 lead ions there is one antimony ion. That seems in better agreement with the assumption of an influence of antimony on crystal growth rate, based on the adsorption, rather than an influence on the nucleation rate.

With regard to β PbO_2, for which the crystal size is already very small, antimony does not seem to have any influence. But a slight broadening of the peaks observed in the diffraction patterns could reveal that also for the β form there is a crystal size reduction. Moreover for both allotropic forms of lead dioxide it was observed that electrodeposition occurs with greater difficulty if the antimony concentration in the solution is greater than 100 ppm.

α PbO_2: reduction tests.—An LSV curve for the α PbO_2 reduction in 0.1N KOH solution is reported in Fig. 5. The curves in 0.1N KOH solutions show two main peaks. The first main peak appears at a potential of -170 mV (NHE) and it is preceded by a lower peak [$V = 140$ mV (NHE)] which appears as a shoulder if the scanning rate is greater than 50 μV/sec.

The second main peak is observed at about $V = -700$ mV (NHE) and it is followed by a lower peak or by a shoulder at $V = -900$ mV (NHE) before hydrogen evolution.

The values of the amount of charge measured during the reduction permitted calculation from the initial O/Pb ratio of the mean value of the reduction degree of lead dioxide, at various points on the LSV curves.

The mean O/Me ratio calculated according to the cathodic reaction

$$PbO_x + 2\delta e + \delta H_2O \rightarrow PbO_{x-\delta} + 2\delta OH^- \quad \delta \leq x \quad [1]$$

is also reported *vs.* the electrode potential in Fig. 5.

In this way it is possible to verify that the first main peak corresponds to the formation of an oxide having a composition near to that of Pb_3O_4, and the second main peak corresponds to a simultaneous formation of PbO and Pb. During the first lower peak, lead dioxide apparently reduces to $PbO_{1.8}$. The shoulder, which appears before hydrogen evolution, should correspond to lead formation from residual PbO.

If pure lead dioxide is reduced in 5N KOH solution, the voltammetric curves show only the first main peak. In this case the oxide dissolves completely in the electrolyte and the charge required for the reduction corresponds to PbO formation.

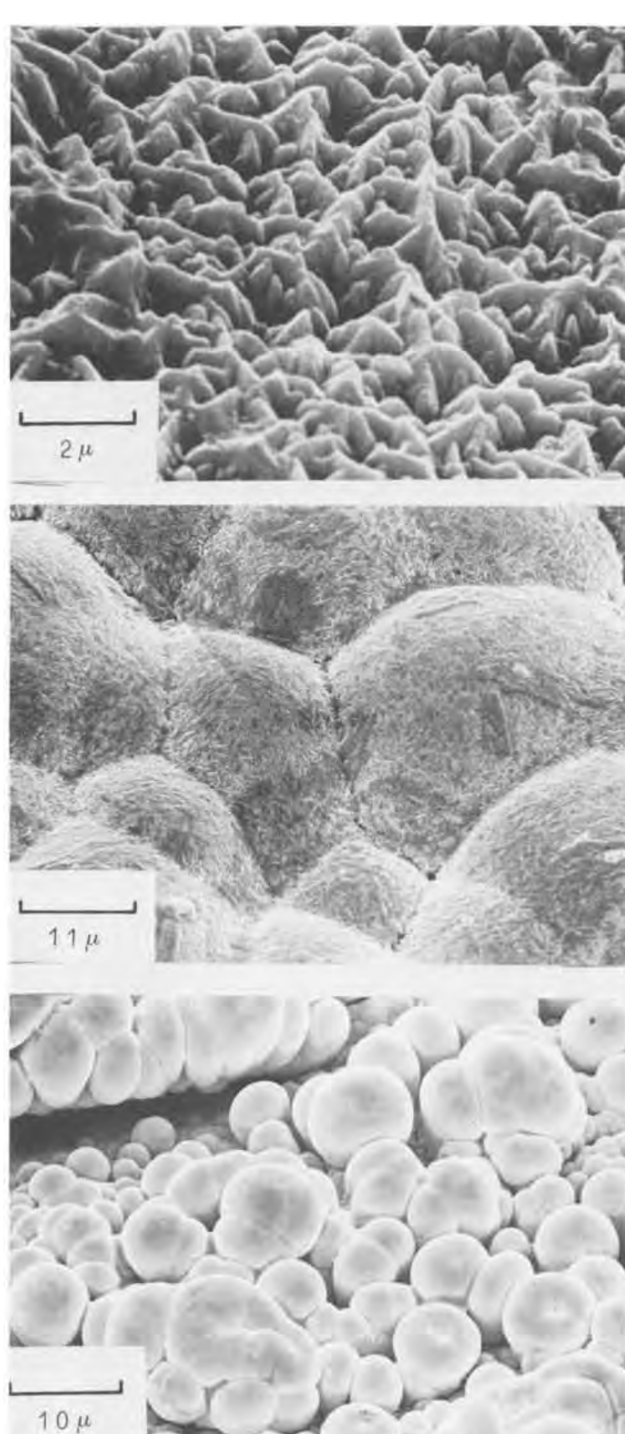

Fig. 4. SEM micrographs showing the effect of antimony on α PbO_2 morphology. Sb^{3+} concentration in the electrolyte: (a, top) 25 ppm, (b, center) 60 ppm, (c, bottom) 100 ppm.

When the lead dioxide is doped with antimony, some change in the LSV curves occurs. An example is reported in Fig. 6 which shows the curves referring to reduction in 0.1*N* KOH solution of α PbO_2 electrodeposited from a solution containing 100 ppm of Sb. It can be observed that the first main peak appears at a potential of 100 mV (NHE), the intermediate oxide has a composition near that of $PbO_{1.57}$, and the intensity of the second main peak, which appears at a potential of −700 mV (NHE), is very small.

In addition a third peak appears at a potential of −980 mV (NHE) before the lead peak [$V = -1150$ mV (NHE)], and hydrogen evolution begins when the O/Pb ratio is greater than one. The reduction tests

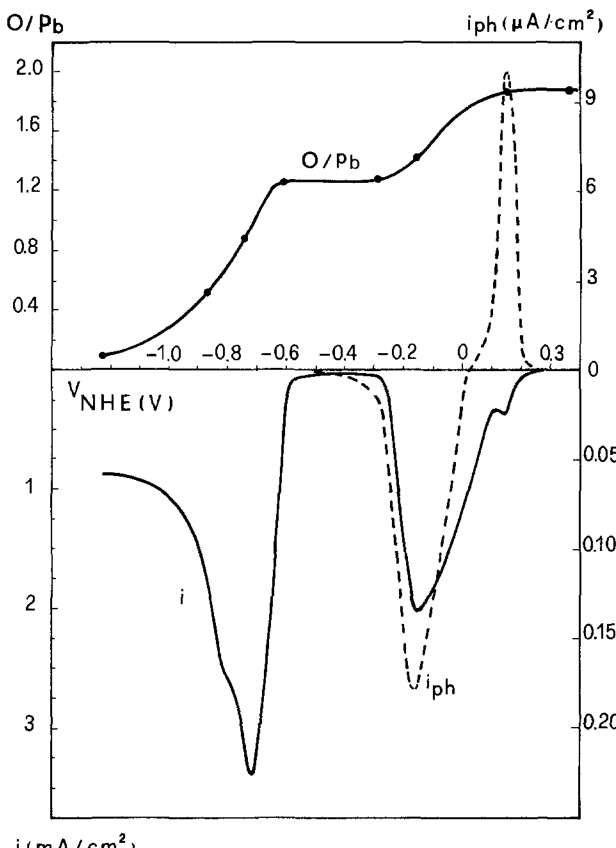

Fig. 5. Linear sweep voltammetry curve (full line), photocurrent intensity (dotted line), and O/Pb mean ratio (●) for α PbO_2 reduction in 0.1*N* KOH.

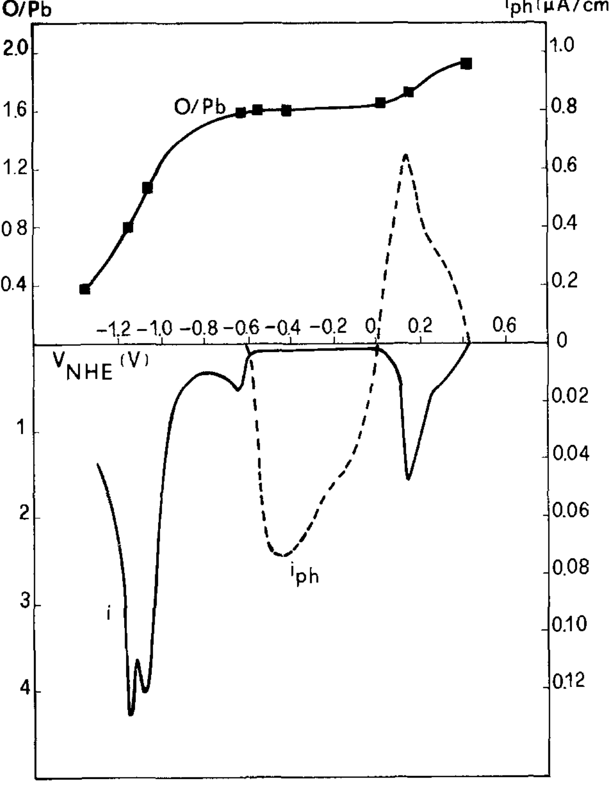

Fig. 6. Linear sweep voltammetry curve (full line), photocurrent intensity (dotted line), and O/Pb mean ratio (■) for α PbO_2 reduction in 0.1*N* KOH solution containing 100 ppm of Sb.

carried out in 5*N* KOH solutions showed that the oxide layer does not dissolve in the electrolyte and the

LSV curves display the peaks corresponding to PbO and Pb formation. The reductive dissolution appears more difficult and some areas of the electrode remain covered with partially reduced lead dioxide and metallic lead also at the end of the voltammetric curves.

The x-ray diffraction analysis and the SEM observations of the anodic layers partially reduced showed that the cathodic process occurs in the solid state. For an O/Pb ratio greater than 1.33, the diffraction patterns clearly show only one reflection line from (200) plane of PbO_2, the intensity of which decreases with decreasing the O/Pb ratio.

Moreover the background noise of the diffraction patterns and some very, very weak lines appear. These lines correspond to reflection from (211), (112), and (310) planes of Pb_3O_4, when the O/Pb ratio is near 1.33. When the O/Pb ratio is smaller than 1.1, a line corresponding to reflection from (111) plane of lead appears. The tests carried out with Sb-doped α lead dioxide show that the lead line appears when the O/Me ratio is close to 1.57.

The SEM observations of the electrode surface after partial reduction, some of which are shown in Fig. 7-10, are in good agreement with x-ray results. Moreover it can be seen that the crystal habit of lead dioxide is maintained during the reduction until lead and lead oxide appear at the same time. As Gourbonova pointed out (20), the reduction takes place in a homogeneous system.

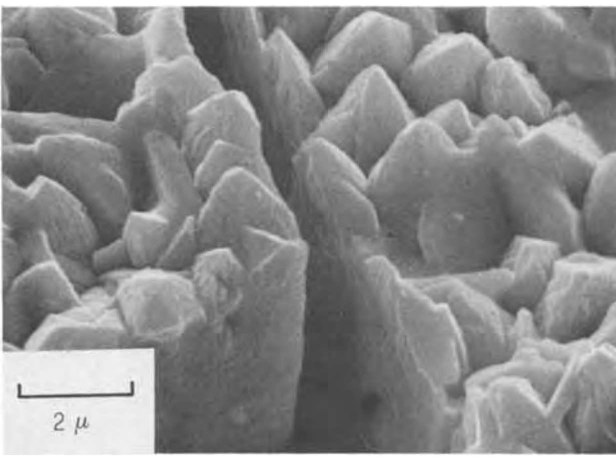

Fig. 7. SEM micrograph of α PbO_2 electrodeposited from 2N KOH saturated with PbO (i_{dep} = 10 mA/cm^2, T = 30°C) and reduced until $PbO_{1.33}$ in 0.1N KOH.

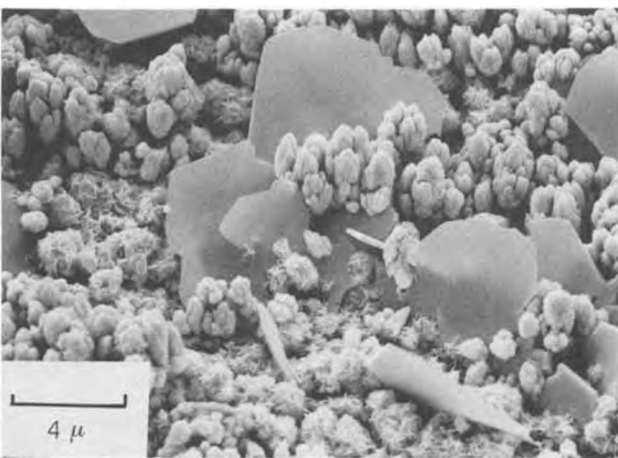

Fig. 8. SEM micrograph of α PbO_2 electrodeposited from KOH (pH > 14) saturated with PbO (i_{dep} = 10 mA/cm^2, T = 30°C) and reduced until $PbO_{0.8}$ in 0.1N KOH.

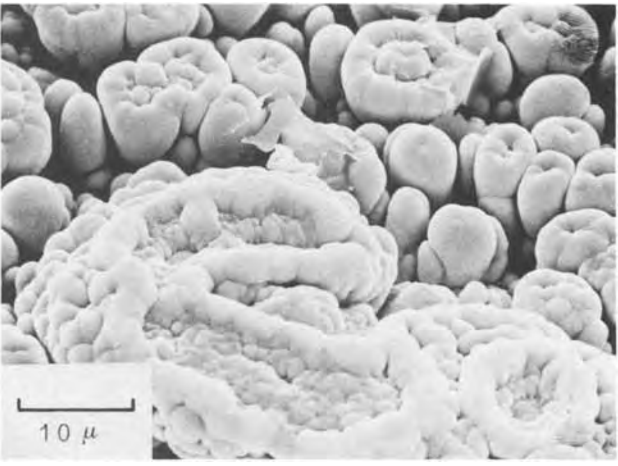

Fig. 9. SEM micrograph of α PbO_2 electrodeposited from KOH (pH > 14) saturated with PbO, containing 100 ppm of antimony (i_{dep} = 10 mA/cm^2) and reduced until $PbO_{1.48}$ in 0.1N KOH.

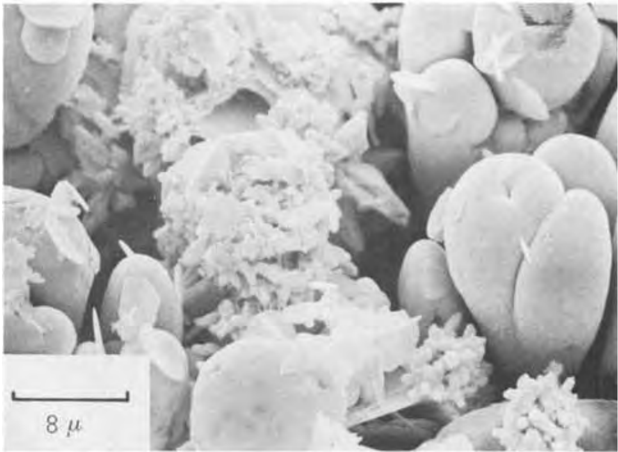

Fig. 10. SEM micrograph of α PbO_2 electrodeposited from KOH (pH > 14) saturated with PbO, containing 100 ppm of Sb (i_{dep} = 10 mA/cm^2, T = 30°C) and reduced until $PbO_{1.66}$ in 0.1N KOH.

Thus the cathodic process occurs by removal of oxygen ions from the dioxide lattice. Initially the process takes place at the oxide-solution interface where the electrons are available and Pb^{4+} ions can be reduced to Pb^{2+}. The oxygen, so released, reacts with the adsorbed water molecules to form hydroxide ions. In this way, a concentration gradient of oxygen ions and an opposite gradient of Pb^{2+} ions are set up in the oxide. Subsequently the reduction of Pb^{4+} ions takes place far from the oxide-solution interface, and oxygen ions released in the bulk of the oxide move toward the solution under the action of the diffusion gradient and of the electric field. In this condition the cathodic process includes the following three consecutive steps

$$PbO_2 + 2e \rightarrow PbO + O_{bulk}^{2-}$$
$$O_{bulk}^{2-} \rightarrow O_{surf.}^{2-} \quad [2]$$
$$O_{surf.}^{2-} + H_2O \rightarrow 2\,OH^-$$

The removal of oxygen from the dioxide lattice causes nonstoichiometric PbO_x oxide formation. The known stable PbO_x oxides are solid solutions having a composition in the range $PbO_{1.33}$-$PbO_{1.57}$ (28-29). Their solubility in alkaline solutions (30) is very small, decreasing from $PbO_{1.33}$ to $PbO_{1.57}$. Since the reduction tests, carried out in 5N KOH solutions, showed that the oxide layer dissolves quickly during the first main peak of LSV curves, we can suppose

that the reduction process initially causes, at the oxide-solution interface, a decreasing of the O/Pb ratio until this ratio reaches a value near one.

In 5*N* KOH solutions while the reduction of Pb^{4+} occurs in the solid state, PbO dissolution at the oxide-solution interface can take place. In dilute alkaline solutions a little dissolution of PbO can also occur because, owing to cathodic process, OH^- ions are formed at the oxide-electrolyte interface.

The $HPbO^{2-}$ ions, so formed, can hydrolyze where the local $HPbO^{2-}/OH^-$ ratio is greater than the equilibrium constant value for the PbO dissolution reaction. This clearly appears from the electron micrograph, Fig. 11, referring to a reduction carried out without stirring the solution to enhance the phenomenon. In this case PbO appears on the electrode surface, during the first main peak of the LSV curves, in the shape of platelets coming out from PbO_x crystals. The x-ray diffraction patterns do not display a strong line of this compound. It can be deduced that PbO hydrolyzes in amorphous form.

However in dilute alkaline solutions the PbO dissolution is a secondary process. In fact all the tests carried out with dioxide layers having different thickness (2-8 μm) showed, for the intermediate oxide, the same value of the above-mentioned O/Pb mean ratio. When the entire layer is reduced to PbO_x, the reduction process stops since PbO_x is a poor conductor. This is confirmed by some oxidation tests of the intermediate oxide. These tests showed that the electrode seems passivated and PbO_x is oxidized only if the electrode potential is greater than 550 mV (NHE). Moreover the SEM observations show that lead dioxide is subjected, during the reduction, to internal stresses which produce some cracks in the layer (Fig. 13). The crack formation can explain the presence on the LSV curves of the first lower peak. This peak should indicate when, on the electrode surface, the O/Pb ratio becomes one and cracks begin to form. The cracks explain also why PbO_x can still be reduced when the electrode potential reaches more negative values (3rd and 4th peak on LSV curves). The reduction begins to take place near the crack edges at substrate-oxide-electrolyte contact.

With regard to Sb-doped lead dioxide, it was observed that during the reduction in concentrated alkaline solutions the intermediate oxide does not dissolve in the electrolyte. From this behavior we can deduce that the O/Pb ratio, at the oxide surface, decreases only to 1.5. In these conditions, owing to greater conductivity of the intermediate oxide, the further reduction to form PbO and Pb can go on also by a reductive dissolution-precipitation mechanism. Moreover

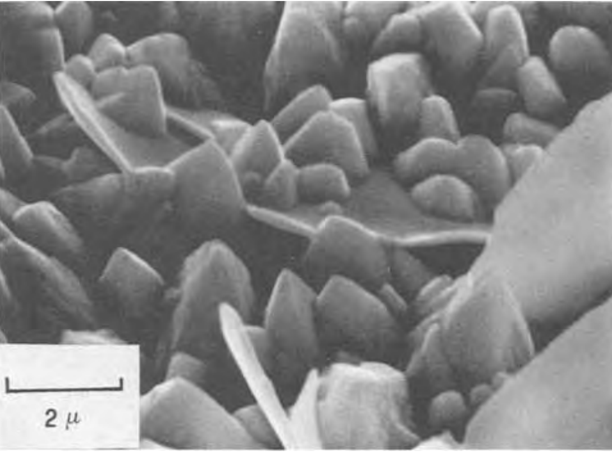

Fig. 11. SEM micrograph of α PbO_2 electrodeposited from 2*N* KOH saturated with PbO (i_{dep} = 10 mA/cm^2, T = 30°C) and reduced until $PbO_{1.33}$ (crystals) with some blades of PbO in 0.1*N* KOH.

the peak at V = −980 mV (NHE) on the LSV curves reveals that there are two paths for PbO formation perhaps corresponding to two areas with different Sb amount.

The previous discussion agrees with the conclusions by Rickert *et al.* (31, 32) referring to the electrochemical behavior of the PbO_2 electrode. In lead dioxide the values of chemical potential of lead and oxygen seem to vary within a wide range according to the electrode polarization. The corresponding change of stoichiometry is related to the change in the number of free electrons. Thus, lead dioxide can acquire semiconducting properties exhibiting n-type behavior. For this reason photoelectrochemical measurements are a useful tool for investigating lead dioxide electrodes.

Photoeffects on α PbO_2 electrodes.—The results of photocurrent measurements are also reported in Fig. 5 and 6. The anodic photocurrents appear when the reduction begins; later the photocurrents become cathodic and their intensity reaches a maximum value when $PbO_{1.33}$ forms. When Pb and PbO begin to form the photocurrents disappear.

With regard to Sb-doped PbO_2 the photocurrents are smaller and the cathodic ones reach a maximum when PbO appears. The effects induced by light confirm the proposed reduction mechanism.

The anodic photocurrent can be explained by supposing that light produces Pb^{4+} centers in the oxide which hinder the reduction according to a mechanism similar to that proposed by Pavlov (15) for the photoactivation of PbO to PbO_2. In the first stage of the reduction, a concentration gradient of Pb^{2+}, Pb^{4+}, and oxygen ions is set up in the oxide near the electrolyte. Under these conditions, owing to photon absorption, some electrons jump from the valence to the conduction band of the semiconducting oxide. The holes are captured by divalent lead ions while the electrons move, according to band bending, toward the bulk of the oxide. As a result, some tetravalent lead ions are created in the oxide near the solution, trapping the oxygen ions. In this way the oxygen ion migration is hindered. Thus light decreases the cathodic process rate and this influence is revealed as an anodic photocurrent.

Continuing the reduction, a thin layer of intermediate oxide is formed near the solution and the bands of semiconducting oxide are bent downward. That is due not only to a potential shift toward the cathodic direction but also to a change of the oxide composition. The intermediate oxides are poor electrical conductors and the cathodic potential tends to localize in a thin surface layer of the oxide near the solution.

In this condition, the light can promote the PbO_x photocomposition according to the mechanism proposed by Williams (33). It is known that $PbO_{1.33}$ is a photosensitive material (30) and its solution rate in KOH increases when the oxide is illuminated.

The photon absorption produces electrons and holes which are separated by the electric field. The electrons go toward the oxide-solution interface where they are available for the reaction

$$2(x-1)h + PbO_x + (x-1)H_2O \rightleftharpoons HPbO_2^- + (2x-3)OH^- + 2(x-1)h \quad [3]$$

The photoeffects disappear when the reduction process begins to occur at the substrate-oxide interface, as it has been supposed above.

The effect of antimony on the semiconducting properties of lead dioxide is revealed by the decrease of photocurrent intensity during the reduction. This also indicates a decrease in the number of lattice defects in the intermediate oxides.

β PbO_2 reduction test and photoeffects.—The LSV curves referring to β PbO_2 reduction in 0.1*N* KOH

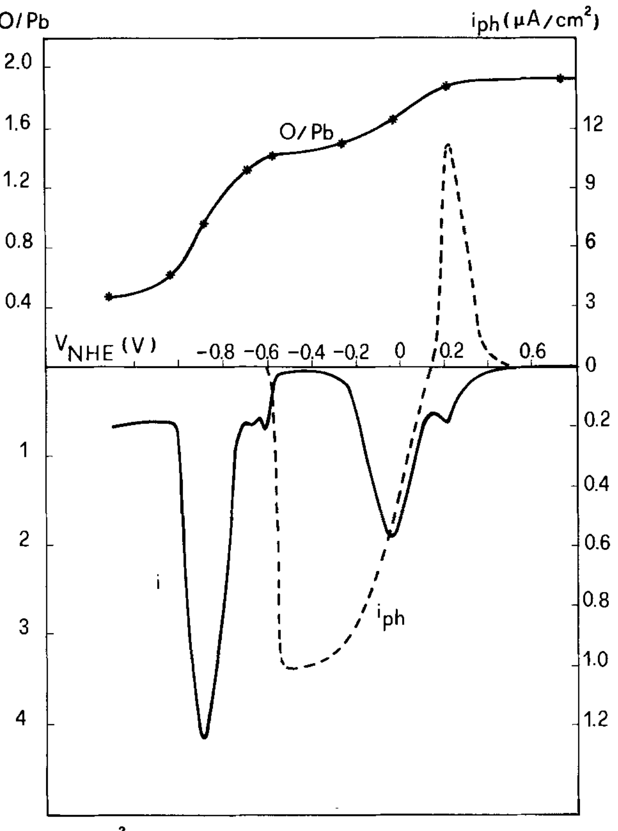

Fig. 12. Linear sweep voltammetry curve (full line), photocurrent intensity (dotted line), and O/Pb mean ratio (✲) for β PbO_2 reduction in 0.1N KOH.

solution present two main peaks, Fig. 12, which appear at $V = -50$ mV (NHE) and $V = -880$ mV (NHE), respectively. Each of these peaks is preceded by a lower peak at $V = 200$ mV (NHE) and at $V = -600$ mV (NHE). The intermediate oxide formed after the first main peak has a composition very close to that of $PbO_{1.57}$.

Antimony shifts the first peak toward positive values of the electrode potential as reported in Table I, where the potential of the first peak and the calculated O/Pb ratio for the initial and intermediate oxide are listed for pure and doped lead dioxide.

As it appears from the electron micrograph reported in Fig. 13, which refers to partially reduced lead dioxide, the cathodic process for the reduction of β PbO_2 in alkaline solution is similar to that of the α form; *i.e.*, the reduction takes place initially in a homogeneous system. The photocurrent measurements and the effect of antimony are in agreement with previous discussion concerning α PbO_2 reduction.

The most remarkable effect of antimony, as it is shown in Table I, concerns the O/Pb ratio value of intermediate oxide. The amount of charge required to form PbO_x increases from Sb-doped β PbO_2 to pure α PbO_2. The galvanostatic reduction curves confirm the above reported results as shown in Fig. 14. We can deduce from these curves the different amount of

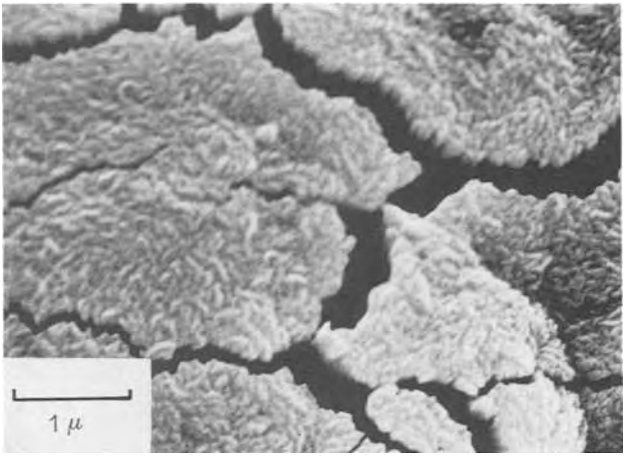

Fig. 13. SEM micrograph of β PbO_2 electrodeposited from 0.15M HNO_3 and 0.5M $Pb(NO_3)_2$ ($i_{dep} = 100$ mA/cm², $T = 30°C$) and reduced until $PbO_{1.5}$ in 0.1N KOH.

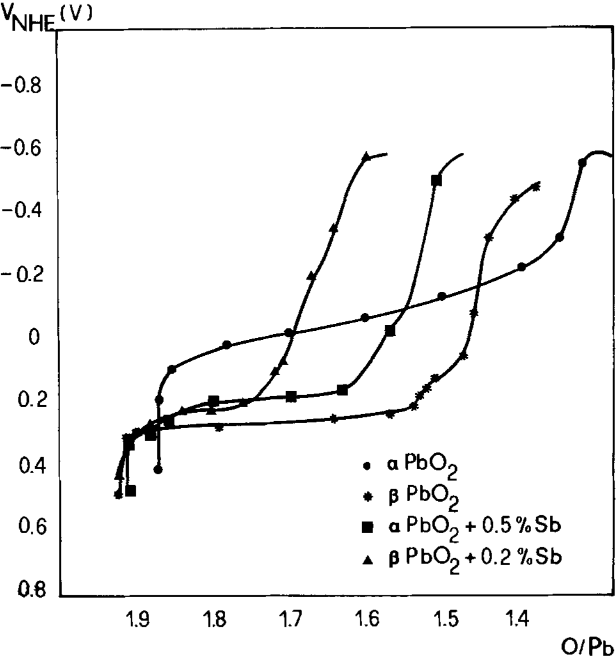

Fig. 14. Electrode potential vs. O/Pb ratio during the galvanostatic reductions of α and β lead dioxide with different Sb content.

charge required by the various lead dioxides to reach the PbO/Pb potential and also the different reducibilities of these dioxides.

In agreement with previous findings (22), the kinetics of reduction for the α and β allotropic form of lead dioxide seem to be different. By considering reaction [2], if oxygen transfer through the oxide-solution interface is faster than oxygen ion migration within the oxide, diffusion polarization sets up in the oxide. In this case, under galvanostatic condition the overpotential increases during the cathodic process.

Table I. Potential values of the first and second peak on voltammetric curves and O/Pb ratio for the initial and intermediate oxide obtained on pure and doped lead dioxide

Oxide	V_{NHE} (mV) (1st peak)	V_{NHE} (mV) (2nd peak)	$(O/Me)_{PbO_2}$	$(O/Me)_{PbO_x}$
Sb-doped β PbO_2 Sb 0.2%	320	140	1.92	1.65
Sb-doped α PbO_2 Sb 0.5%	280	100	1.91	1.57
β PbO_2	250	−20	1.91	1.50
α PbO_2	140	−170	1.87	1.33

From Fig. 14 it seems that α PbO_2 reduction is really controlled by oxygen migration in the oxide. On the contrary, under the same conditions the overpotential during the galvanostatic reduction of β PbO_2 is constant. Then we can imagine that the reaction is controlled by oxygen transfer from the oxide to the solution. The effect of antimony is to change the kinetic mechanism of α PbO_2 reduction by making it similar to that of β PbO_2. Further investigation is necessary to explain the different shape of the galvanostatic reduction curves, and this will be matter for further work.

Conclusions

Antimony enters the lattice of lead dioxide changing the morphology and the electrochemical behavior. Sb dissolution is greater in the α than in the β form. Sb, up to a concentration of 0.2%, fills the lattice vacancies of α PbO_2 and promotes more regular structure. As for β PbO_2, Sb^{5+} simply substitutes Pb^{4+} ions. The crystal size of α PbO_2 reduces by increasing the antimony content. The β PbO_2 crystal size apparently is not modified.

The greater solubility of antimony in α PbO_2 can explain the increase of this form in the lead acid cell with antimonial lead grids and the different performance of positive plates with respect to lead calcium grids.

The reduction of lead proceeds initially in a homogeneous system until lead dioxide is converted to PbO_x with $1.33 < x < 1.65$. The effect of antimony is particularly on the electrochemical reactivity of the dioxide, the O/Pb ratio of intermediate oxide, and PbO formation.

Safety Studies on Li/SO_2 Cells

IV. Investigations of Alternate Organic Electrolytes for Improved Safety

A. N. Dey* and R. W. Holmes

Duracell International, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The lithium reactivity of a variety of organic solvents and their mixtures was determined by measuring the exotherm initiation temperature of the organic solvents with Li using DTA. The least reactive solvent and mixtures were used to prepare electrolytes comprising 1M LiBr and 70% liquid SO_2 and the electrical conductivities of these electrolytes were measured at various temperatures. Eight electrolytes were found to have equivalent or better conductivities and significantly less reactivity towards Li compared to the state-of-the-art electrolyte comprising LiBr, acetonitrile, and SO_2. Some of the electrolytes showed a reduction in conductivity on storage.

Li/SO_2 organic electrolyte cells consisting of Li anode, porous carbon cathode, and LiBr-acetonitrile-liquid SO_2 electrolyte were demonstrated (1-5) to be an excellent power source for various military applications requiring high current drains, long shelf life, and exceptionally cold temperatures. Although the battery system was found (3) to be quite abuse resistant for a variety of abuse conditions, the object of this ongoing investigation was to improve the abuse resistance of the cells even further so that the cells are safe under all reasonable abuse conditions. We have shown earlier (6) that the reaction most responsible for initiating a thermal runaway was the exothermic reaction between the Li and the organic solvent, acetonitrile (AN), that may work on deep discharging an Li/SO_2 cell when almost all the SO_2 has been consumed. We have also shown by kinetic studies (7) that the above reaction may be mitigated by the addition of other less reactive solvents. As an extension of these studies it is of interest (*i*) to determine the optimum concentration of the additive solvent required for suppressing the Li-AN reaction, and (*ii*) to determine the electrical conductivity of the LiBr-SO_2 electrolytes made with the above solvent mixtures. Our objective is to develop the least reactive electrolytes that has an adequate conductivity for the applications of interest.

We have chosen to use the exotherm initiation temperature (defined as the temperature at which the Li-solvent reaction exotherm starts) as a measure of the Li-solvent reactivity. The higher the exotherm initiation temperature, the lower the reactivity and conversely. We measured the Li-solvent exotherm initiation temperature as a function of the organic solvent concentrations at a fixed heating rate using DTA and we determined the electrical conductivities of the electrolytes consisting of approximately 70% liquid SO_2, 1M LiBr, and the promising organic solvent mixtures selected from the above studies. The experimental details and the results are described in this paper.

Experimental

The Mettler TA2000 DTA system was used with the Nemonic crucibles. 20 μl of the solvents of interest were run wih 0.00029g Li disks at the 5.0°C/min heating rate. The resulting thermograms were interpreted as follows: the programmed temperature, T_p, was determined where the steepest slope of the Li-solvent reaction exotherm intersected the projected baseline. The exotherm initiation temperature was determined by subtracting the thermal lag of the sample crucible, ΔT_{LAG}, from the intersect temperature. Figure 1 shows the DTA thermogram at 5°C/min for two samples and the typical determination of the exotherm initiation temperature.

For the effort centering on the use of AN with an additive we generally used 5% (volume) additive and 95% AN. Promising solvent systems were studied in more detail by determining the exotherm initiation temperature at various additive concentrations.

The electrical conductivity of the electrolytes was measured with a high pressure conductivity cell, shown in Fig. 2. Pressurized SO_2 electrolytes were

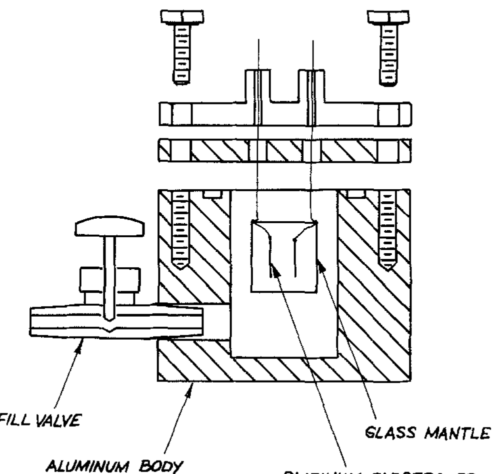

Fig. 2. High pressure conductivity cell

made up in 115 ml polypropylene cylinders fitted with polypropylene ball valves on each end and an additional three-way stainless steel valve on one end. Vacuum-dried LiBr and appropriate distilled solvents (except acetic anhydride) were introduced into the polypropylene electrolyte cylinder and SO_2 was condensed into the chilled cylinder through the three-way valve. The conductivity cell was filled with argon and then connected to the electrolyte filling station via the fill valve. At the filling station the conductivity cells were evacuated to facilitate the introduction of electrolyte which was introduced through the fill valve. The filled cells were equilibrated at various temperatures between −40° and 98°C. At thermal equilibrium, the solution resistances were measured with a GenRad GS1657 Digibridge at 1 kHz (0.3V rms maximum) and the series equivalent circuit was used.

All the solvents except PC, DME, BL, and dioxolane were used as received from Eastman Kodak. PC and BL were vacuum distilled over Li. Water content of AN was less than 0.01%.

Results and Discussion

Exotherm initiation temperature of Li and organic solvent.—The effect of a variety of organic solvents as additives on the exotherm initiation temperatures of Li + AN was determined by the method described above and are tabulated in Table I, in the code of ascending exotherm initiation temperature; the ternary mixtures are listed separately at the bottom of the table. The organic compounds and additives investigated include the following functional groups: alcohol, aldehyde. ketone, acetate, anhydride, amide, amine, carboxylic acid, carbonate, glycol, and sulfoxide. The exotherm initiation temperature of Li + AN varied from 25° to 50°C depending upon the condition of the surface of the lithium specimen, as discussed later.

The results in Table I show that the organic solvent additives in items numbering 1-17 had exotherm initiation temperatures below 50°C, and as seen these provide no reductions in the reactivity of Li with acetonitrile. Item 18, contained acrylonitrile, an impurity of AN, which had a negligible effect on the exotherm initiation temperature of Li + AN. Similarly items 19 through 27 were only marginally beneficial. Items 28 through 37 indicated a significant increase in the exotherm initiation temperature. The organic solvents involved are propylene carbonate (PC), butyrolactone (BL), acetic anhydride (AA), and methlyl formate (MF). Of these, methyl formate is known (8) to decompose in presence of moisture to form CO. Also, H_2 may form by a side reaction with Li. Both of these are flammable and would increase the internal pressure of the Li/SO_2 cells.

Table I. Chemical reactivity of solvent systems DTA at 5°C/min. 0.00029g Li + 20 μl of indicated solution

Item No.	Solution	Initiation temp (°C)

44	AN/PC/BL (90/5/5)	111

Note: PC, BL, and dioxolane were distilled.

The reactivity of dimethoxyethane (DME) and other ethers towards Li were investigated earlier using the activation energy method (7). The measurement of exotherm initiation temperatures of the above ether with Li verified our earlier findings that Li is very unreactive with ether but ethers do not suppress the Li + AN reaction when used as an additive, they enhance it. Compare the results of item 37 with items 2, 4, and 5 in Table I.

In the ternary mixture (item 42, Table I) AN/PC/DME(90/5/5), the exotherm initiation temperature is increased to 104°C, indicating that the tenacious protective film formed in the presence of PC is insoluble in DME, thus providing continued protection to Li in the presence of AN. Ethers therefore may be useful in certain ternary solvent systems.

In view of the excellent protection of Li by PC, we studied a few more ternary solvent systems and found (items 38 and 39, Table I) that neither PC nor BL could protect Li adequately in AN containing methanol (5%), which itself reacts with Li. We had included methanol in the hope of finding electrolytes with increased conductivity. The ternary mixtures consisting of two of the three "protective" solvents (*viz.* PC, BL, and AA) with AN, showed no beneficial synergistic effects (items 41, 43, 44, Table I).

For the more promising solvent systems, we determined the optimal concentrations of the additive solvent by measuring the exotherm initiation temperature as a function of the concentrations of the additive solvent. The effect of addition of PC and AA to AN on the exotherm initiation temperature is shown in Fig. 3. Note that the exotherm initiation temperature of Li + AN increases with addition of PC and AA from 50°C to approximately 110°C up to a concentration of 10% of PC and AA and then levels off.

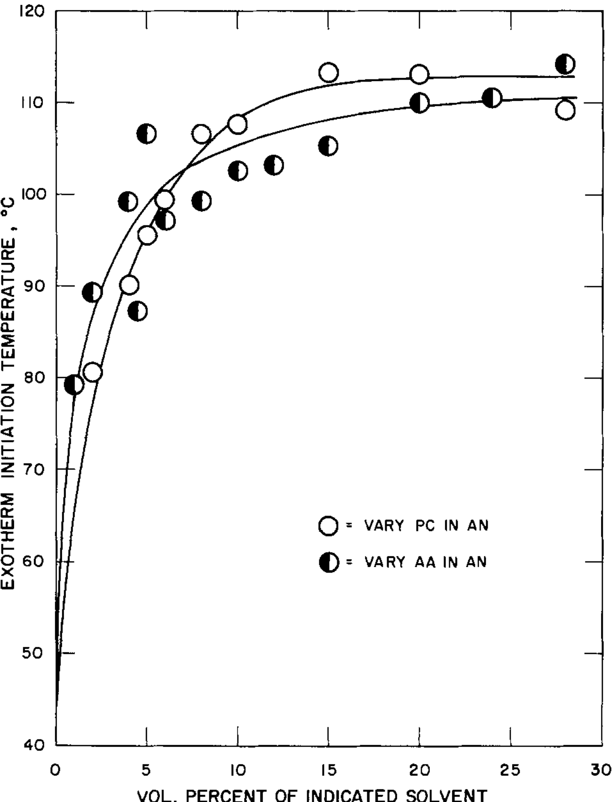

Fig. 3. Exotherm initiation temperature of Li + AN reaction as a function of the concentration of additive solvents, PC and AA.

Therefore, the optimal concentrations of PC and AA are about 10%.

We examined the ternary solvent system, AN/PC/DME, in the above manner. The results are shown in Fig. 4. In these experiments in one case, we started out with a mixture of 95% AN and 5% DME and determined the exotherm initiation temperature with Li as a function of the concentration of added PC. The addition of PC resulted in the increase of the exotherm initiation temperature from 50° to 110°C up to a concentration of approximately 10% of PC; no further increase in the exotherm initiation temperature occurred at higher concentrations of PC. In another case, we started out with a mixture of 95% AN and 5% PC and measured the exotherm initiation temperature as a function of the concentration of added DME. In this case, the exotherm initiation temperature started out at 100°C, as expected and remained unchanged with the addition of DME. This confirmed our earlier observation in regard to the level of protection of Li by DME in conjunction with AN. PC is the only "protective" solvent in this mixture.

We examined the AN + BL binary solvent systems as well and found that the data had great scatter as shown in Fig. 5. Despite the scatter, BL appears to effectively inhibit the Li + AN reaction as evidenced by the increase in the exotherm initiation temperature.

We have also studied the effect of SO_2 on the exotherm initiation temperature of Li + AN in order to determine the minimum amount of SO_2 needed to provide protection. We carried out these experiments on the Li disks as well as with Li powder. We also examined the effect of moisture (1%). The results are shown in Fig. 6. Note that the exotherm initiation temperature increases rapidly from 50° to over 150°C with the addition of 3-5% SO_2. Moisture of up to 1% does not appear to have a significant effect on the exotherm initiation temperature. However, Li powder was found to be considerably more reactive as evidenced by the lower exotherm initiation temperature compared to the Li disks.

It is interesting to note that the exotherm initiation temperature of Li + AN with 20% SO_2 was above 400°C. This is considerably higher than the exotherm initiation temperature of 180°C (6) of Li + SO_2 elec-

trolyte containing LiBr + AN. This lowering of exotherm initiation temperature indicates a possible catalytic effect of LiBr in promoting the Li + AN reaction. Similar catalysis of the Li-solvent reaction by salts such as $LiClO_4$ has been reported by others (9).

Based on the above studies, we selected sixteen SO_2 organic electrolytes all containing 70% SO_2 and 5-6% LiBr for further evaluations based on electrical conductivity.

Electrical conductivity.—The exact composition of the 16 electrolytes selected for conductivity studies are shown in Table II. The plots of the specific conductance *vs.* temperature of the various electrolytes are shown in Fig. 7. The electrolytes were ranked in order of decreasing conductivity and are listed in Table III. All but the last seven electrolytes had conductivities equal to or greater than the standard electrolyte containing AN. We rated the conductivity of the electrolyte containing BL as marginal since its specific conductance plot was within the variability of the specific conductance of standard electrolyte which showed a reduction of conductivity (25-30%) on storage at 72°C for a few days. Electrolytes 4 containing AN/BL(90/10) and 7 containing AN/PC/DME(95/10/5) had good conductivities when fresh, but the conductivities dropped considerably on storage for a few days at room temperature as shown in Fig. 8. The conductivity of electrolyte 7 dropped from $5.1 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ to $1.1 \times 10^{-2}\ \Omega^{-1}\ cm^{-1}$ on storage at 25°C for a week. The decrease of conductivity was accompanied by the salting out of an unknown white precipitate containing bromine and sulfur as determined by KEVEX (SEM). The x-ray diffraction indicated that the precipitate was a crystalline compound. The exact chemical formula is not known as yet.

Conclusions

Based on the chemical reactivity of the organic solvents and solvent mixtures towards Li as determined by the exotherm initiation temperature, we selected approximately 16 solvent systems for further evaluation based on their electrical conductivities in SO_2-LiBr containing electrolytes. We included a solvent system containing methanol in spite of its relatively high reactivity, in order to determine the contribu-

tion of highly polar solvents such as methanol on the conductivity. Based on the conductivity data, it is clear that there are at least 8 or 9 solvent systems with electrical conductivities superior or comparable to the standard electrolytes and having significantly lower reactivity towards Li than the standard electrolyte containing AN. Of these there are at least two or three solvent systems, as shown in Table III which do not contain any AN at all, and as such are the most suitable for improving the safety of the Li/SO_2 cells without any significant performance penalty.

Evaluation of High Temperature $LiAl/TiS_2$ Cells

Z. Tomczuk,* K. E. Anderson, D. R. Vissers,* and M. F. Roche*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The electrochemistry of the TiS_2 electrode of Li/TiS_2 cells in molten LiCl-KCl was found to be similar to that in room temperature cells. The emf curve for $Li_xTiS_2 (0 \leq x \leq 1)$ was nonlinear and could be treated in terms of a regular solution model. The effect of TiS_2 electrode thickness was investigated, and the results indicated that good utilization (~70%) could be obtained with thick (0.66 cm) TiS_2 electrodes. The performance of engineering-scale $LiAl/TiS_2$ cells (77-142 A-hr capacities) was investigated.

A variety of transition-metal sulfides (1-3) are used as positive electrode materials in high temperature (~400°C) cells. These cells employ molten LiCl-KCl as the electrolyte and Li-Al or Li-Si alloys as the negative electrode materials. The metal sulfides that have received the greatest attention are FeS and FeS_2 (4). However, recent studies of Whittingham (5-7) and others (8, 9) have shown that TiS_2 is an excellent positive electrode material for ambient temperature Li/TiS_2 cells, and, therefore, we have decided to evaluate the performance of TiS_2 cells with a molten LiCl-KCl electrolyte.

* Electrochemical Society Active Member.
Key words: cell, fused salt, emf.

The discharge mechanism of TiS_2 in the ambient temperature cells is different from that of iron sulfide in high temperature cells. The reaction of TiS_2 in ambient temperature cells is

$$xLi^+ + TiS_2 + xe^- \rightarrow Li_xTiS_2 \quad (0 \leq x \leq 1) \qquad [1]$$

The overall reactions of FeS and FeS_2 electrodes in high temperature cells are, respectively

$$FeS + 2Li^+ + 2e^- \rightarrow Li_2S + Fe \qquad [2]$$

$$FeS_2 + 4Li^+ + 4e^- \rightarrow 2Li_2S + Fe \qquad [3]$$

Reaction [1] involves a single phase intercalation process, while reactions [2] and [3] typically involve three phases.

To study the performance capabilities and the reaction mechanism of TiS_2 electrodes, we operated a variety of small (1-5 A-hr) LiAl (or Li)/LiCl-KCl/TiS_2 cells and examined the TiS_2 electrode products at various states of discharge. Based upon the favorable results obtained with these small-scale cells, we then tested engineering-scale cells (77-142 A-hr capacities) to evaluate the LiAl/TiS_2 system on a practical level.

Experimental

A total of 14 small cells were operated. The cells were of an open design described earlier (1), and were operated at temperatures of 375°-445°C in furnace wells located in helium-atmosphere glove boxes. The cell chemicals were LiCl-KCl electrolyte of eutectic composition from Lithcoa (Lithium Corporation of America), TiS_2 from Great Western Inorganic, Li from Lithcoa, and Li-Al [48 atomic percent (a/o)] from Kawecki-Berylco Industries. When lithium was used, the negative electrode consisted of a 5 cm^2 × 0.6 cm disk of Type 302 stainless steel Feltmetal[1] (90% porosity, 27 μm pore size) that had been wet with 1g (4 A-hr) of liquid lithium. When the lithium-aluminum alloy was used, the negative electrode was prepared by vibrating 12g (10 A-hr) of the alloy (−40 +140 mesh) into an iron Retimet[2] disk which was contained in a 1008 mild-steel cylinder (15.6 cm^2 × 0.7 cm deep). The Li-Al particles were retained in the cylinder by a stainless steel (−325 mesh) screen and zirconia cloth. The positive electrode was prepared by placing either a compressed TiS_2 pellet (65-75% theoretical density) or TiS_2 powder in a cylindrical cup of ATJ graphite. The cup opening was covered by either a PG-60 porous graphite diffusion barrier (0.63 cm thick) or by zirconia cloth and molybdenum screen (−70 mesh). The area of the positive electrodes was generally 5 cm^2, but for some tests the area was 11.4 cm^2. The electrode leads were iron (negative lead) and either carbon or molybdenum (positive lead). The electrodes and the electrolyte (~150g) were contained in an alumina beaker. Boron nitride cloth, which was impregnated with electrolyte, was used in some of the cells as an electrode separator; otherwise, the electrodes were separated by approximately 1 cm of molten salt.

The prismatic design of the engineering cells is shown in Fig. 1, and the cell components are listed in Table I. The cell construction is similar to that reported for Li-Al/LiCl-KCl/FeS_2 cells (10). The TiS_2 electrodes were prepared by cold pressing the TiS_2 (without electrolyte) onto a molybdenum current collector at 43 MPa to a density of 2.05 g/cm^3 (64% of theoretical). The Li-Al electrodes were prepared in a similar manner, but with small amounts (10g) of electrolyte added.

The cells were cycled at constant current using automatic cyclers that switched polarity at preselected voltage limits of 1.0V (discharge) and 2.2-2.3V (charge). The current densities employed during cycling ranged from 16 to 140 mA/cm^2. Both the current density and voltage were monitored using strip-chart recorders and digital voltmeters. After the cycling tests had been completed, the positive electrodes of small cells were examined by metallography, x-ray diffraction, and, in one case, by ESCA; the engineering cells were cross-sectioned and examined by metallography.

A special cell was constructed for the purpose of making emf measurements. It was a small cell identical in design to the small cells described above. The cell employed polarographic-grade LiCl-KCl electrolyte of eutectic composition (from Anderson Physics Laboratory), a compressed TiS_2 pellet (2.10g; 5 cm^2 × 0.6 cm) electrode, and an Li-Al electrode to which Al powder was added to make the final composition 42 a/o lithium. The cell was discharged to successively larger values of x (see Eq. [1]) and the open-circuit voltage was monitored with a Model 5330 Dana digital voltmeter. The time on open circuit was at least one-half hour for each emf measurement, although most measurements were made for periods in excess of 20 hr. Measurements for values of x near zero were made after first taper charging the cell at a low current density (1 mA/cm^2) to a voltage of 2.4V and then making measurements after small increments of discharge. The values of x

[b] Mild steel and molybdenum honeycomb were the negative and positive current collectors, respectively. Electrode enclosures were stainless steel frames and screens. Zirconia cloth was the particle retainer, and BN fabric was the separator.
[c] Weight of electrolyte required to fill cell is included.

The emf data from the high temperature and ambient temperature cells are compared in Fig. 4 with the model curves which were generated using Eq. [6]. The molar free energy changes for the cell reactions were obtained by integrating Eq. [6] were calculated from the ratio of the capacity discharged to the theoretical capacity of the TiS_2 electrode.

Results and Discussion

Typical discharge and charge data for a small Li/TiS_2 cell are shown in Fig. 2; the utilization of the TiS_2 was 100% at a current density of 98 mA/cm^2. These data show that TiS_2 has rate capabilities that are comparable to FeS and FeS_2 in LiCl-KCl electrolyte (1). Equivalent utilizations of TiS_2 in ambient temperature cells were obtained at current densities below 10 mA/cm^2 (5). The above data were obtained for a cell having an unpressed TiS_2 electrode of relatively low capacity density, 50 mA-hr/cm^2. Because higher electrode loadings are required in a practical cell, another cell with a pellet TiS_2 electrode having a capacity density of 200 mA/cm^2 (4.2g TiS_2, 5 cm^2 $\times$ 0.4 cm, ~65% theoretical density) was cycled. The utilization of this positive electrode was again high, 97% at 98 mA/cm^2, and the voltage curve at a current density of 98 mA/cm^2 was nearly identical to that of the previous cell (see lowest curve in Fig. 2).

The shapes of the discharge curves in Fig. 2 are similar to those observed in ambient temperature cells (5, 8, 9). This finding suggests that the reaction mechanism is the same (*i.e.*, intercalation) for both cell types. An x-ray diffraction examination was conducted on the positive electrode materials obtained from five cells operated between $0 \leq x \leq 1$ (see Eq. [1]). These examinations showed that the electrode materials had lattice parameters that were in excellent agreement with those reported by Whittingham for Li_xTiS_2 (3). An ESCA examination of the $LiTiS_2$ showed the presence of Ti^{+3}, which is consistent with the formation of $LiTiS_2$. These results show that the reaction mechanism is intercalation in the high temperature cell.

Three small cells having LiAl negative electrodes and pelletized TiS_2 positive electrodes were used to evaluate the effect of TiS_2 electrode thickness on the performance of LiAl/TiS_2 cells. These cells had positive electrode thicknesses of 0.20, 0.40, and 0.66 cm and were cycled at various current densities. The results, summarized in Table II, indicated that good utilization (~70%) can be obtained with thick (0.66 cm) TiS_2 electrodes and that the utilization decreases only slightly with increasing current densities. The voltage curves from these tests were similar to those shown in Fig. 2, but were ~0.3V lower because Li-Al is ~0.3V less anodic than Li at these temperatures (11). These tests show that the LiAl/TiS_2 cell should achieve an acceptable capacity density at the high electrode loadings required in engineering-scale cells.

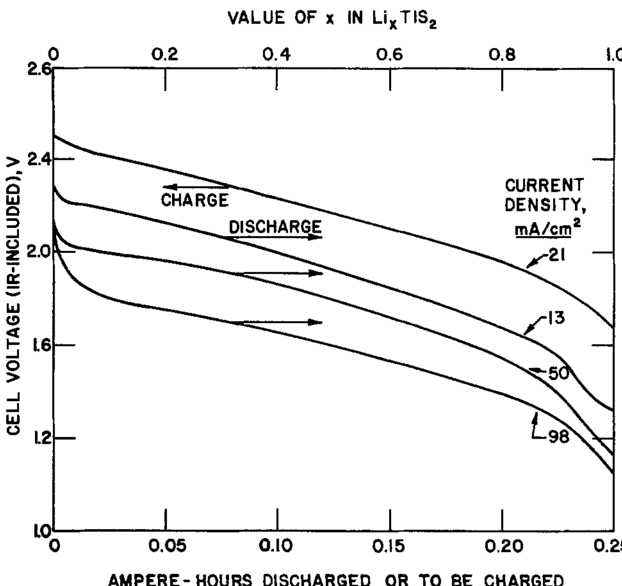

Fig. 2. Performance of Li/TiS_2 cell at 420°C (all discharges preceded by 21 mA/cm^2 changes).

Voltage *vs.* current-density data for a small Li/TiS_2 cell,[3] using 15 sec current pulses, are shown in Fig. 3 for three temperatures. Peak power densities calculated from these curves were 0.55, 0.47, and 0.40 W/cm^2 at 457°, 428°, and 382°C, respectively. These data compare favorably with the earlier power data for Li/FeS_2 cells (1). However, the data for the TiS_2 system showed a slight temperature dependence and are nonlinear, whereas the data for the FeS_2 system did not. Further study will be required to resolve these differences.

Owing to the excellent performance of the small cells, we decided to test three engineering cells. The performance results for these cells are summarized in Table III. The best achieved capacities were obtained at approximately the 10 hr rate and were 90 A-hr (specific energy 54 W-hr/kg) for cell DK-52, 61 A-hr (54 W-hr/kg) for cell TiSp1, and 52 A-hr (67 W-hr/kg) for cell TiSp2. These specific energies are approximately equal to those of similarly constructed Li-Al/FeS cells (12). Since a specific energy of 90-100 W-hr/kg has been achieved in LiAl/FeS cells of a more advanced design (12), we believe that, with further development, the Li-Al/TiS_2 cell will also achieve 90-100 W-hr/kg.

The cycle life of the Li-Al/TiS_2 engineering cells was limited to less than 20 cycles by various mechanical failures, as determined by the post-test metallographic examinations. In one case, for example, the cell failure was a result of penetration of the separator by the molybdenum honeycomb current collector; this caused a short circuit. The ultimate cycle life of improved engineering cells is expected, however, to be high, as the small scale cells were cycled in some cases to 200 cycles without any signs of failure. (The coulombic efficiencies of the laboratory cells and the engineering cells, in their early cycles, were greater than 95%.)

The above results showed that the kinetics of the high temperature Li-Al/TiS_2 system were satisfac-

[3] The cell had a pellet TiS_2 electrode (3.75g, 4.5 cm $\times$ 0.4 cm, 200 mA-hr/cm^2).

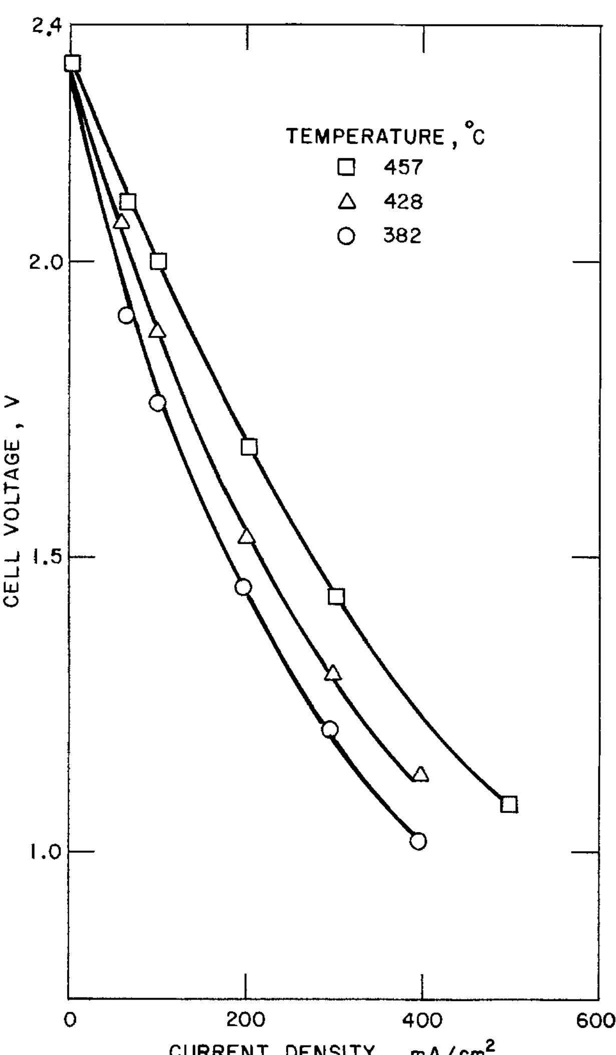

Fig. 3. Voltage *vs.* current density data for an Li/TiS_2 cell

tory, and that, with further development, a system having high specific energy and cycle life could be developed. To determine the theoretical specific energy of the high temperature cell, we measured its emf.

The emf data for the $Li\text{-}Al/TiS_2$ cell at 431°C are given in Table IV. This emf, like that for the ambient temperature cell (3) decreases with increasing values of x. Winn *et al.* (8) have noted that the essential features of the emf curve for the ambient temperature cell could be reproduced by a relatively simple interaction model; however, no details of this model were given. We found that the emf data in Table IV and the emf data for the ambient temperature cell can be satisfactorily reproduced by a regular solution model (13) in which the positive electrode, Li_xTiS_2 is treated as a solution of x moles of $LiTiS_2$ in $(1 - x)$ moles of TiS_2. The regular solution model leads to the following equations for the activity coefficients, γ

$$RT \ln \gamma_{LiTiS_2} = k(1 - x)^2 \qquad [4]$$

[1] Value of x in Li_xTiS_2.

$$RT \ln \gamma_{TiS_2} = kx^2 \qquad [5]$$

where k is an interaction parameter. These equations, when combined with the Nernst equation, yield the following emf equation

$$E = E_m + \frac{RT}{\mathbf{F}} \ln \left(\frac{1 - x}{x} \right) - \frac{k}{\mathbf{F}} (1 - 2x) \qquad [6]$$

where E_m is the voltage at $x = 0.5$. The values of E_m and $k/\mathbf{F}$ were found by plotting

$$E - \frac{RT}{\mathbf{F}} \ln \left(\frac{1 - x}{x} \right) \textit{ vs. } x$$

The values for the high temperature $Li\text{-}Al/TiS_2$ cell were 1.80 and − 0.214V, respectively, while those for the ambient temperature Li/TiS_2 cells were 2.22 and − 0.181V, respectively. The fairly close agreement of the $k/\mathbf{F}$ values indicates that the behavior of the system is reasonably consistent with the regular solution model, which requires that k be temperature independent, or nearly so (13).

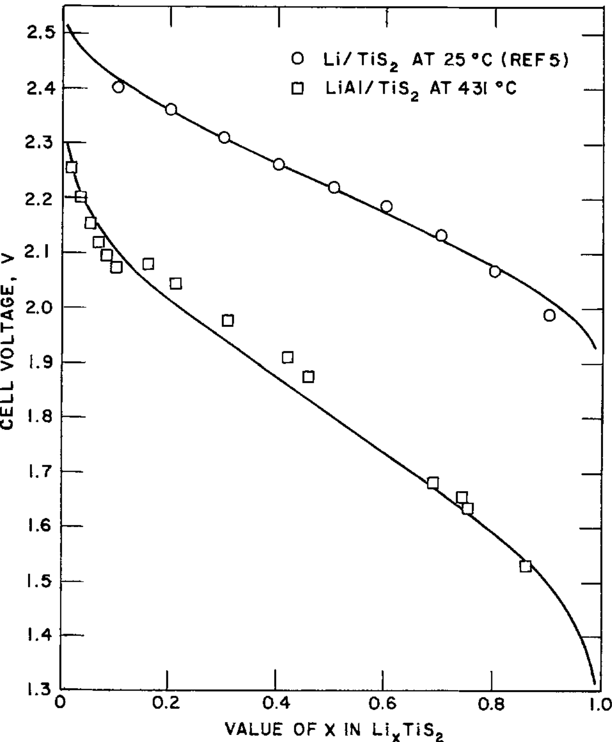

Fig. 4. Emf *vs.* composition for Li/TiS_2 cell based on regular solution model.

$$\Delta G = -\mathbf{F}\int_0^1 E dx \qquad [7]$$
$$= -\mathbf{F}E_m$$

Thus, ΔG is -174 kJ (-41.66 cal) for the Li-Al/TiS_2 cell at 431°C and is -214 kJ (-51.2 kcal) for the Li/TiS_2 cell at 25°C. The theoretical specific energies of these cells are 331 and 500 W-hr/kg, respectively. The relatively large difference in specific energies is due to the use of Li-Al which has a higher equivalent weight and is less anodic than lithium. Because of technical problems with the use of liquid lithium in high temperature cells, solid lithium alloys are preferred (14).

Although we have employed a regular solution model to treat the emf of the Li/TiS_2 cell for values of $x \leq 1$, others (15, 16) have employed emf equations that vary linearly with x for other cells (Na/TaS_2 and Li/TaS_2) that also operate by an intercalation reaction. Thus, the regular solution model is not always applicable to intercalation reactions.

Continued discharge of the LiAl/TiS_2 cell to cutoff voltages below those normally used (1V *vs.* Li-Al) yielded voltage plateaus having an emf of 0.86 and 0.4V. The length of the plateau at 0.86V was approximately one-half that necessary to form $LiTiS_2$. The constant emf obtained on this plateau suggests a two-phase region between $LiTiS_2$ and perhaps Li_2TiS_2, which has been recently reported as forming in room temperature cells (17). However, in the high temperature cell, Li_2TiS_2 is not likely to have formed because the overall TiS_2 electrode composition at the end of the plateau is equivalent to $Li_{1.5}TiS_2$. We did not determine the full length of the 0.4V plateau, but the electrode reaction must involve three phases, since lithium sulfide and some other sulfide of titanium, not identified, were found in the electrode by x-ray diffraction.

Conclusions

These experiments indicate that the electrochemistry of the TiS_2 electrode in high temperature Li-Al/TiS_2 cells is similar to that observed in ambient temperature Li/TiS_2 cells. However, the performance capability of the high temperature cell was considerably better, as the cell could be cycled at current densities a factor of 10 greater than could be used in ambient temperature cells. The engineering test results suggest that, with further development, the LiAl/TiS_2 system should achieve a performance comparable to the lithium-aluminum/iron sulfide system. The emf curves of the TiS_2 cells could be reproduced using a regular solution model.

Safety Studies on Li/SO_2 Cells

V. Effect of Design Variables on the Abuse Resistance of Hermetic D Cells

A. N. Dey
Duracell International, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The effect of cell design variables such as stoichiometric ratios of $Li:SO_2$, electrode area, electrolyte salt, SO_2 content of the electrolyte, etc. on the abuse resistance of the hermetic Li/SO_2 D cells on force-discharge, especially at −30°C at a current of 2A, was evaluated. Both the $Li:SO_2$ ratio and the current density of operation were found to be important design parameters from the safety standpoint. Lithium-limited cell designs were found to be safer than the lithium-rich cell designs for a given current density of operation.

In the study of intrinsic abuse resistance of Li/SO_2 cells, we have pursued two approaches: (*i*) A causative approach involving the identification of chemical and/or electrochemical reactions occurring during use and abuse of Li/SO_2 cells, that are responsible for unsafe behavior and the development of possible ways of quenching these reactions for increased safety, and (*ii*) an empirical approach involving the construction and testing of D size hermetic Li/SO_2 cells made with several design modifications for increased abuse resistance.

The former approach involving DTA of Li/SO_2 cell constituents was pursued separately and the results are reported elsewhere (1). The latter approach has been pursued in this paper. The empirical approach involved the construction and abuse testing of hermetic D cells according to twelve different designs which included the following cell construction variables: (*i*) electrode area (moderate rate and high rate); (*ii*) electrode thickness; (*iii*) SO_2 content in the electrolyte (70% and 80%); (*iv*) organic solvent in the electrolyte (AN, PC + AN); and (*v*) electrolyte salt (LiBr, $LiAsF_6$).

The details of the twelve selected cell designs incorporating the above variables are shown in Table I. A major variable, shown earlier (2) to have significant impact on the safety, is the stoichiometric ratio of $Li:SO_2$ which was varied in the cell designs by varying the thickness of Li and the SO_2 content of the electrolyte. We showed earlier (1) from the DTA studies of the Li/SO_2 cell constituents that the exothermic reaction between Li and AN (in the absence of SO_2) which occurs at room temperature is a major cause of hazardous behavior of cells on force-discharge, that may be encountered by individual cells in a series connected multi-cell battery. The presence of SO_2 prevents the Li + AN exothermic reaction from occurring at room temperature. Therefore, the starting stoichiometric ratio of $Li:SO_2$ is important since the cell discharge results in the consumption of Li and SO_2 is according to the reaction

$$2Li + 2SO_2 \rightarrow Li_2S_2O_4 \quad [1]$$

and depending upon the initial $Li:SO_2$ ratio, the cells may end up with either Li and AN, or only AN or SO_2 and AN (assuming 100% utilization of Li and SO_2), as shown in the cell reaction trajectories I, II, and III in Fig. 1. According to the earlier studies (1, 2), the latter two conditions are more desirable from a safety standpoint.

The main objective of this program is to establish the dependence of the cell performance and cell safety on the cell composition and design; so that

an optimum cell design can be developed with respect to both the cell performance and the safety. The underlying assumption is that the electrical performance can be traded for an increased abuse resistance (safety) and our objective is to optimize this tradeoff.

Experimental

State-of-the-art hermetic Li/SO_2 D cells were made by winding the Li anode and the carbon cathode of appropriate lengths and thicknesses according to the twelve different designs specified in Table I. Porous polypropylene separators were used in-between the anode and the cathode layers. The cells were filled with appropriate electrolytes and were tested as follows: (*i*) capacity test at various loads at ambient temperature, and (*ii*) abuse test on constant current (2A) discharge and reversal at −30°C.

Both the voltage and the wall temperature of the cells were monitored during the latter tests. The abuse resistance of the cells was determined by examining the cells visually after the test and photographically recording the condition of the cell.

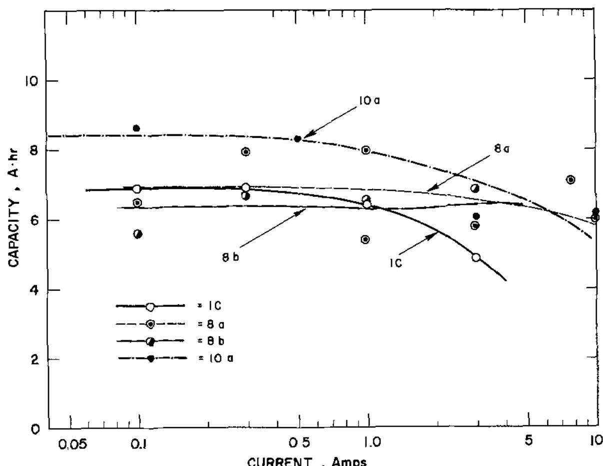

Fig. 4. Capacity-rate characteristics of Li/SO_2 D cells of type 1c, 8a, 8b, and 10a.

Results and Discussion

Capacity-rate characteristics.—The capacity-rate characteristics of the D cells of the twelve types are shown in Fig. 2, 3, and 4. Note that the maximum capacity of the D cells of type 1a, 1a', 2a, 1b, 1c, 1g, and 2g is approximately 7 A-hr whereas the maximum capacity of the D cells of type 3a and 3g is approximately 10 A-hr. Considering the fact that the stoichiometric capacity of SO_2, based on reaction [1], is approximately 10-11 A-hr (Table I) for all the cell types, the low capacity of the D cells of type 1a, 1a', 2a, 1b, 1c, 1g, and 2g indicate that these cells are lithium anode limited. The stoichiometric capacity of Li for these latter types of cells varied from 9.2 to 9.9 A-hr thus giving rise to lithium utilization efficiencies of 70-76%. This indicates that the so-called lithium-limited cells must contain excess unused Li at the end of the low current discharge. The amount of excess Li remained varied from 2.2 to 2.9 A-hr whereas the amount of excess SO_2 varied from 3 to 4.4 A-hr for the D cells of type 1a, 1a', 2a, 1b, 1c, 1g, and 2g. In contrast, the D cells of type 3a and 3g are cathode and/or SO_2 limited; the utilization of SO_2 based on reaction [1] was 90-100%. Thus there was virtually no SO_2 left at the end of the low current discharge of the D cells of type 3a and 3g. The amount of excess Li left was approximately 1.5 A-hr.

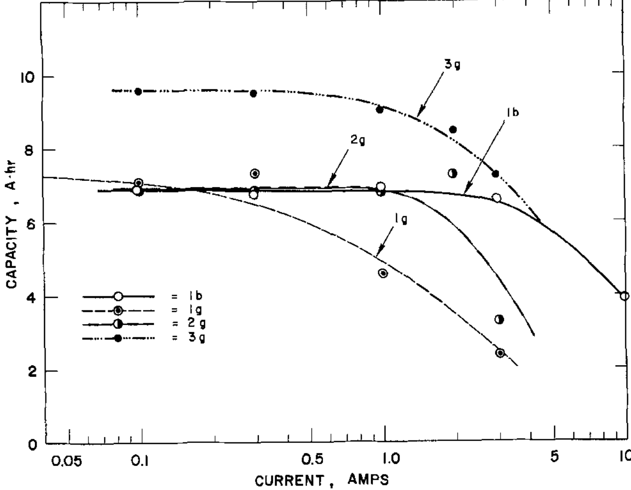

Fig. 2. Capacity-rate characteristics of Li/SO_2 D cells of type 1b, 1g, 2g, and 3g.

The type of electrode configuration, *viz.* exterior cathode *vs.* interior cathode does not appear to have any effect on the capacity-rate characteristics of the cells. D cells of type 1g appear to be an exception in that the rate capability of this group of cells is quite poor.

The effect of the electrolyte variables such as $LiAsF_6$ salt on the capacity-rate characteristics of the cells at ambient temperature does not appear to be very significant. The rate capability of the cells with 80% SO_2 appears to be marginally lower than the standard.

The capacity penalty of the D cells of type 1a, 1a′, 2a, 1b, and 1c compared to 3a and 3g is significant at low rates (0.1-1.0A), but insignificant at high rates (2-10A).

The addition of PC (1c) appears to lower the rate capability of the cell somewhat.

Constant current (2A) discharge and reversal at −30°C.—We tested six cells from each type of D cells under this condition. Typical voltage and temperature profiles of the cells of type 1a are shown in Fig. 5. Simplified qualitative voltage profiles of all types of D cells on 2A discharge and reversal at −30°C are shown in Fig. 6.

In general the cell wall temperature changed with the cell voltage in approximately a mirror image fashion indicating that the cell heating was due to the cell polarization. The most rapid cell heating occurred at the point where the cell experienced deep reversal towards the end of the test. This was the point where venting and/or fire and explosion occurred. We define this point as the "trigger point." We did not see any spontaneous cell heating after the completion of the test leading to a venting and/or fire. Whatever happened, happened at this trigger point. There are several instances when neither venting nor explosion occurred even at the trigger point.

The cell voltage reflects primarily the potential of the cathode since the Li anode potential remains constant throughout the discharge because of its high exchange current. This is demonstrated by discharging a D cell with an Li reference electrode as shown in Fig. 7. The electrochemical reactions occurring in the cell up to the zero volt result in the formation of Li salts according to reaction [1] (primarily $Li_2S_2O_4$ and possibly others), and the consumption primarily of Li and SO_2. These reactions may be viewed as deactivating processes which reduce the amount of active materials such as Li which can initiate and/or propagate a combustive and/or explosive process. The electrochemical reactions occurring below zero volt result in the formation of active materials such as Li on the cathode. This Li may spontaneously alloy (3) with the Al grid of the cathode or may be in a very active form to initiate and/or propagate a fire and/or an explosion.

Based on the above analysis, the voltage profiles of the D cells of the various types can be grouped into four different classes, as shown in Fig. 6. The voltage profiles of D cells of type 1a, 1a′, 2a and 1c, and 2g belong to class I. The class I voltage profile has a plateau above 2V and a stepwise decline to zero volt followed by an immediate deep reversal corresponding to the trigger point. The deep reversal occurs because of the consumption and/or disconnection of the Li anode which does not have a current collector. The interval between the zero volt and the deep reversal is very small indicating very little or no formation of active form of Li on the cathode. Consequently, the cells did not exhibit explosion or fire at the trigger point; only venting occurred. The amount of SO_2 consumed up to zero volt was approximately 7-8 A-hr which meant that there was 2-3 A-hr of SO_2 still left at the trigger point to cool the cell sufficiently on venting. The cells exhibiting this type of voltage profile had excellent abuse resistance on 2A reversal at −30°C. It should be noted

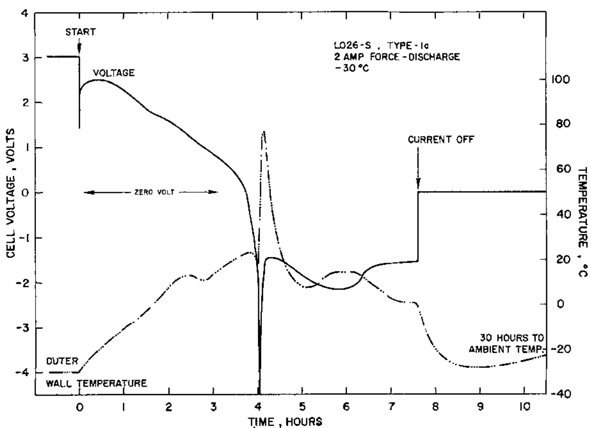

Fig. 5. Typical voltage and temperature profiles of Li/SO₂ D cell of type 1a on 2A discharge and force-discharge at −30°C.

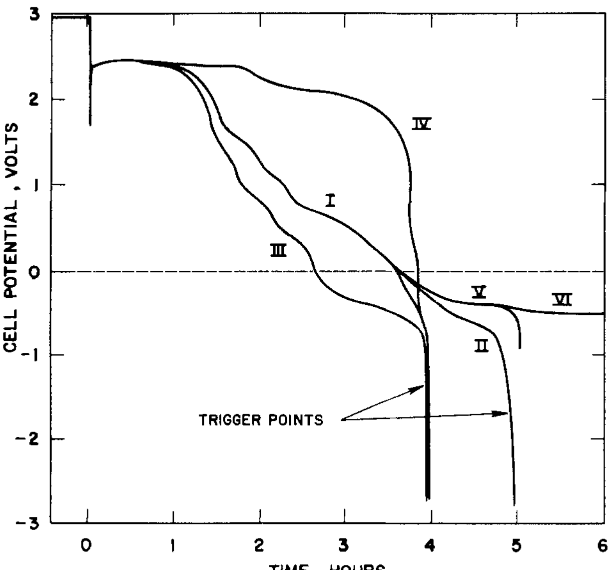

Fig. 6. Classification of voltage profiles of D cells of various types on 2A discharge and force-discharge at −30°C.

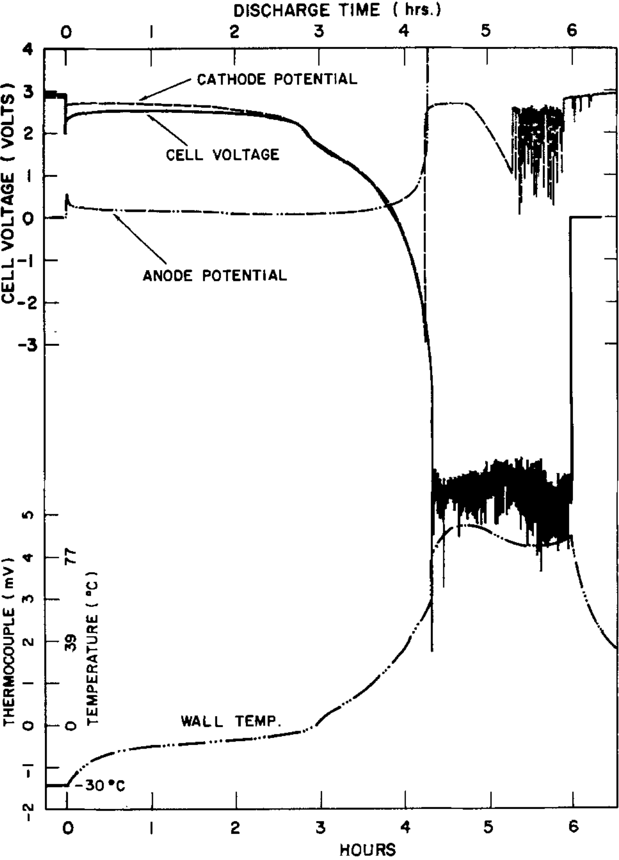

Fig. 7. Cell voltage, individual electrode potential (vs. Li reference), and temperature profiles of Li/SO₂ D cell of type 1a on 2A discharge and force-discharge at −30°C.

that for a given current and temperature the amount of Li and the anode design determines the trigger point; the carbon cathode and the electrolyte composition determines the time to zero volt. For a safe cell the interval between the above two must be as close to zero as possible; also the stoichiometric amount (A-hr) of SO_2 must be higher than the capacity up to zero volt to ensure excess SO_2 at the trigger point.

The class II voltage profile is very similar to class I profile except that the cell voltage lingers below zero volt quite a bit longer prior to the trigger point. The above analysis conforms to the observed explosion and fire of the D cells of type 3a and 3g whose voltage profiles on reversal belong to class II. The interval between zero volt and the trigger point of these cells was 1 hr (2 A-hr) or more thus resulting in the formation of significant amounts of active forms of Li on the cathode which caught fire at the trigger point. This was because the anode had excess Li which made the time to trigger point much longer.

The voltage profiles of D cells of type 1g belongs to class III, where although the stoichiometric amount of Li was the same as in 1a, 1a′, 2a, 1c, and 2g, the poor performance of the cathode resulted in the increase of the interval between the zero volt and the trigger point and the consequent unsafe behavior at the trigger point.

The voltage profiles of D cells of type 1b was quite exceptional and belongs to class IV. This is very similar to class I except that the cell voltage remains at a relatively high level prior to reaching zero volt and the immediate deep reversal at the trigger point. These cells were also safe on 2A reversal at −30°C, since there was no chance of lithium deposition on the cathode. The higher operating voltage of this type of cell gives them a longer useful life to a given cutoff voltage. These cells have $LiAsF_6$ salt as the electrolyte.

The voltage profiles of D cells of type 8a and 8b belong to class V. This is very similar to class II except that the trigger point is very shallow and the voltage drop was insufficient to cause any appreciable cell heating. There was no venting or explosion on force-discharge. This was due to the higher (50%) electrode area of these cells compared to the cells of general type 1, 2, or 3. Accordingly, the current density of operation at 2A was 50% lower in these cells than the others.

The voltage profiles of D cells of type 10a belong to class VI and the cells do not reach the trigger point during the test since the Li content of these cells was far in excess of the others. Furthermore, the current density of operation at 2A is also 50% lower than the other cells. None of the cells of this type vented or exploded on 2A force-discharge at −30°C in spite of high Li:SO_2 ratio.

The above results indicate that the abuse resistance of D cells on constant current reversals at −30°C depends on (*i*) the absence of lithium deposition on the cathode prior to the exhaustion of Li on the anode (trigger point), (*ii*) the availability of excess SO_2 at the trigger point, and (*iii*) the low current density of operation.

There was no dramatic effect of the addition of PC on the abuse resistance of the cells of type 1c since the cells contained excess SO_2. The effect of current density on the abuse resistance of D cells was further evaluated by testing D cells of type 1a and 2a on force-discharge at currents of 0.5A and 3.0A at −30°C. The typical voltage and temperature profiles of D cells of type 1a on 0.5A and 3.0A tests at −30°C are shown in Fig. 8 and 9, respectively. While the cells did not vent on 0.5A force-discharge, the cells vented, some violently, on 3A force-discharge. Note that at 0.5A test (Fig. 8) the capacity between the zero volt and the deep reversal (trigger point) was insignificant, whereas at 3.0A test, the capacity was sufficiently significant to cause the unsafe behavior. The D cells of type 2a behaved similarly and showed no venting on 0.5A test and venting (some violently) on 3.0A test.

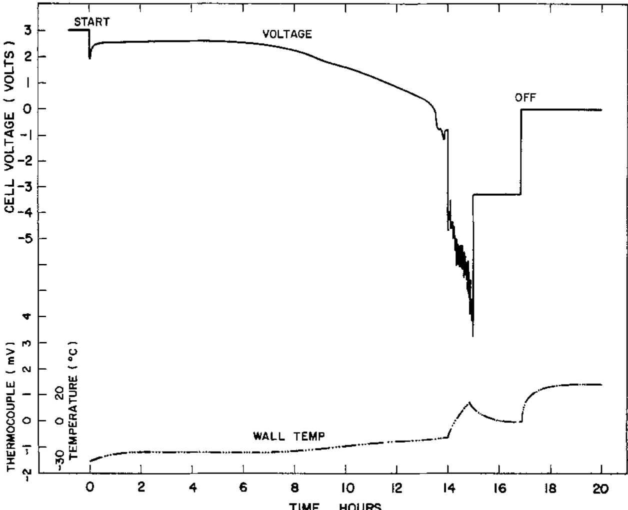

Fig. 8. Voltage and temperature profiles of D cells of type 1a on 0.5A discharge and force-discharge at −30°C.

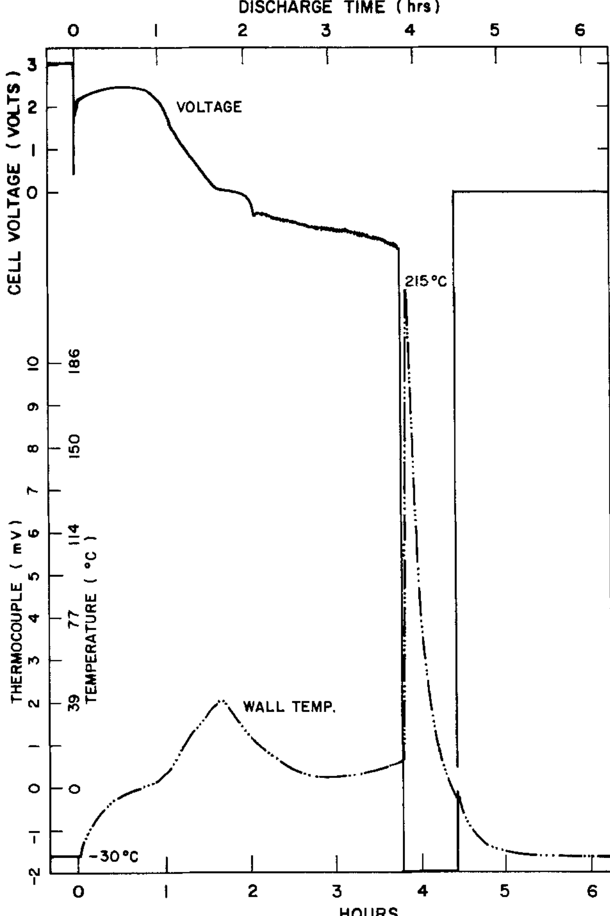

Fig. 9. Voltage and temperature profiles of D cells of type 1a on 3A discharge and force-discharge at −30°C.

Conclusions

The Li:SO_2 ratio was found to be an important parameter affecting the safety of the Li/SO_2 cells, and the lithium-limited cell designs were found to be safer than the lithium-rich cell designs. Furthermore, the high rate D cells having a higher rate capability were found to be safe under a 2A force-discharge at −30°C with a larger Li:SO_2 ratio. The abuse re-

sistance of the cells appears to depend markedly on the current (current density) of the abusive discharge. The cells which were found to be safe on 2A force-discharge became unsafe on 3A force-discharge. It should be possible, therefore, for any given abuse, to design cells capable of tolerating that abuse with impunity, provided we know how to construct truly high rate cells.

The importance of the stoichiometric ratio of Li:SO_2 in a cell in determining the safety on reversal is only applicable when both Li and SO_2 are utilized efficiently. Whereas the Li electrode is inherently efficient at high current densities provided there is electrical continuity, the efficiency of the carbon cathode depends on the current density and the current distribution in the cell, as well as on the cathode fabrication process. Assuming that the latter is kept invariant, the importance of Li:SO_2 stoichiometric ratio is valid up to a limiting current density of operation. At higher current densities the cathode may polarize prematurely leading to Li deposition in the cathode prior to the exhaustion of Li anode. This deposited Li is very active towards AN and may lead to an unsafe situation.

ABSTRACT

The mechanism of formation of the protective layer on commercial Cu-9.4Ni-1.7Fe alloy in aerated 3.4 weight percent NaCl solution at room temperature was investigated for various times up to 191 days. The weight of the sample, the weight of the corrosion product layer, and the anodic and cathodic polarization curves were measured before and after the corrosion periods. Results of these experiments show that the decrease in the overall corrosion rate by formation of the protective layer is due mainly to a decrease in the oxygen reduction rate and only slightly to a decrease in the metal dissolution rate. They indicate that to a large degree, if not entirely, the location of the oxygen reduction reaction is the surface of a thin, strongly adherent inner layer which is in contact with electrolyte as a result of the porous nature of the much thicker outer layer. The rate-determining step of this reaction was found to be the transport of electrons through the inner layer, which increases in thickness according to the parabolic law. The results futher show that the (modest) decrease in the anodic reaction during open-circuit corrosion is due entirely to the porous outer layer.

The commercial Cu-9.4Ni-1.7Fe alloy (CDA 706) has been used successfully as condenser tubes in saline environments. It is generally believed that this corrosion resistant alloy is protected by the films developed on its surface in seawater. The effect of minor Fe additions is to improve the corrosion resistance of Cu-Ni alloys (1-4) with, however, some accompanying loss of ductility at room temperature (5). Stewart and LaQue (2) found that the alloy with Fe in solid solution (solutionized) was more corrosion resistant than the alloy containing Fe precipitates, in agreement with Swartzendruber and Bennet (4).

Key words: marine corrosion, polarization, condenser tubes, protective films, oxygen reduction.

Room temperature anodic polarization curves over a limited potential range have been determined for this alloy in aqueous NaCl solution by several investigators (6-8). The curves exhibit a sharply increasing rate of anodic dissolution with increase in electrode potential. Ijsseling and Kroughman (9) investigated cathodic polarization curves on the uncorroded and precorroded (protected by corrosion products) samples in seawater. They found the cathodic reaction to be more highly polarized the longer the corrosion periods, confirming earlier results by North and Pryor (6), who also observed the same for anodic polarization. Thus, the presence of the film retards both the cathodic and anodic reaction and, hence, the overall reaction.

The purpose of this paper is to investigate the corrosion of commercial (solutionized) Cu-9.4Ni-1.7 Fe alloy in aerated 3.4 weight percent (w/o) NaCl

aqueous solution at room temperature 23° ± 3°C. Following the procedures of Wagner and Traud (10), the mechanism of the corrosion process in the presence and absence of a protective corrosion-product layer is determined from the individual anodic and cathodic polarization curves. Anodic and cathodic polarization curves were determined after different periods of corrosion and for various conditions and amounts of the protective film on the sample.

Experimental

Materials and specimen preparation.—The composition and mechanical properties of the Cu-9.4Ni-1.7Fe alloy sheet material (0.17 cm thick) in the solutionized condition (850°C for 30 min, water quench), are given in Tables I and II, respectively. Specimens (0.17 × 1.5 × 2.5 cm) were cut from the master sheet and polished successively down to 600 grit. The samples were then immersed in deaerated 10 volume percent (v/o) H_2SO_4 for 10 min to remove the air-formed oxide. This was followed by degreasing in 50 v/o acetone-benzene mixture with ultrasonic surface cleaner for 10 min and finally rinsing in a methanol solution and drying in a desiccator for 25 hr. The electrolyte used throughout this work was 3.4 w/o NaCl.

Weight loss under open-circuit corrosion conditions.—Open-circuit corrosion tests were always run using duplicate specimens which were suspended in a 1 liter beaker by glass hooks through holes in the corners of the specimens. The specimens were weighed and their thickness measured before immersion. Each pair was allowed to corrode for varying lengths of time, *i.e.*, 1, 2, 12, and 24 hr; and 2, 3, 5, 10, 30, and 191 days at room temperature. The solutions were changed weekly. At the end of a run, the specimen was removed from the solution, rinsed with distilled water, dried, and weighed. One of the two specimens was analyzed by ESCA (XPS), Auger electron spectroscopy, and/or x-ray diffraction (11). The other specimen was immersed in deaerated 15 v/o H_2SO_4 for 2 hr to dissolve the corrosion products. This was followed by rinsing with distilled water, drying with hot air, and weighing. An identical noncorroded sample treated similarly gave no detectable weight loss indicating that the deaerated sulfuric acid treatment did not attack the alloy itself. From the first and third, and the second and third weighings, the weight loss of the sample due to metal oxidation and the weight of the corrosion-produced layers were determined, respectively.

Polarization measurements. — Current-potential curves were obtained on fresh and corroded samples using an Aardvark potentiostat (Model V) and a Honeywell chart recorder (Electronic 193). The electrochemical cell includes a saturated calomel reference electrode (SCE), a working alloy disk (1.35 cm diam) electrode, an auxiliary electrode (Cu wire or carbon rod), and a gas disperser. These were arranged in a beaker containing 300 ml electrolyte (pH adjusted with NaOH to 8). A Cu wire covered with an acrylic plastic sleeve was soldered to the top (back side) of the disk. The sleeve end and back side of the disk were shielded from the electrolyte by cold mount, such that only the (bottom) disk surface was exposed to the electrolyte. This surface was abraded, as above. Anodic and cathodic polarization curves were obtained on these samples after periods of open-circuit corrosion, in some cases following stripping of the corrosion product with tape. The electrode was immersed in the electrolyte and the gas flowed (either prepurified nitrogen or air) for 30 min before measurements were started. All potentials are reported *vs.* the standard hydrogen electrode (SHE).

Anodic polarization curves were measured on the 0, 5, 10, 15, and 191 day corroded samples. The surface films were formed by the method described in the weight-loss measurements. The corroded specimens at the completion of their open-circuit exposure were immediately transferred to the electrochemical test cell. Measurements were taken at various potential scanning rates in the range of 45-545 mV (SHE) as follows: (*i*) high scanning rate (75 mV min^{-1}), (*ii*) low scanning rate (1.5 mV min^{-1}), (*iii*) manual stepping of the potential by 10 or 20 mV steps and allowing the current to reach a steady value before the next potential step, and (*iv*) direct immersion of a fresh sample at each of the following potentials: 145, 170, 245, 320, 345, 445 mV (SHE).

The cathodic polarization curves were measured potentiostatically by stepping the potential 20 or 50 mV over the range of 45 to −455 mV (SHE). The current was measured after 10 min at each potential. Though quasi-stationary currents were obtained by this time, some of the current was due to reduction of the oxide films. The amount of film reduction was obtained by measuring the cathodic polarization curves on the 30 day precorroded specimen with nitrogen gas bubbling through the cell.

In order to assess the roles of electronic resistance of the corrosion-product layer and/or the catalytic nature of the corrosion-product surfaces, some specimens were coated with the electrocatalyst Pd in the following manner: (*i*) The specimen surface (fresh, corroded or corroded and stripped) was dried thoroughly. (*ii*) A few drops of 0.5% of Pallamerse solution (Technic Incorporated, Chicago, Illinois) was placed on the whole area of the specimen surface. (*iii*) After 5 min, the excess Pallamerse solution was removed with tissue paper and air dried.

Other samples in the corroded but not stripped condition were coated with another electrocatalyst,[3] Pt, by sputtering Pt on the corrosion-product surface.

Results and Discussion

Corrosion and film growth rates.—Figure 1a is a plot of the weight of the solid corrosion product layer (film) and of the overall weight loss *vs.* time of immersion of the sample in aerated solution under free corrosion conditions. Figure 1b shows the variation of the average corrosion rate with time. Note that film weight refers to the compounds $Cu_2(OH)_3Cl$, Cu_2O, and possibly others (11), and consequently the weight of the metal included in forming the film is less than the film weight. On the other hand, the overall weight loss and corrosion rate refer to metal.

[3] The exchange current density of oxygen reduction is about one order of magnitude greater on Pd than on Pt (12).

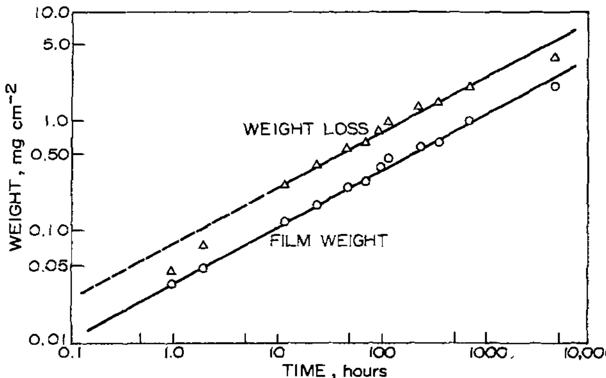

Fig. 1a. Time variations of film weight and total weight loss of the Cu-Ni alloy in the 3.4 w/o NaCl solution.

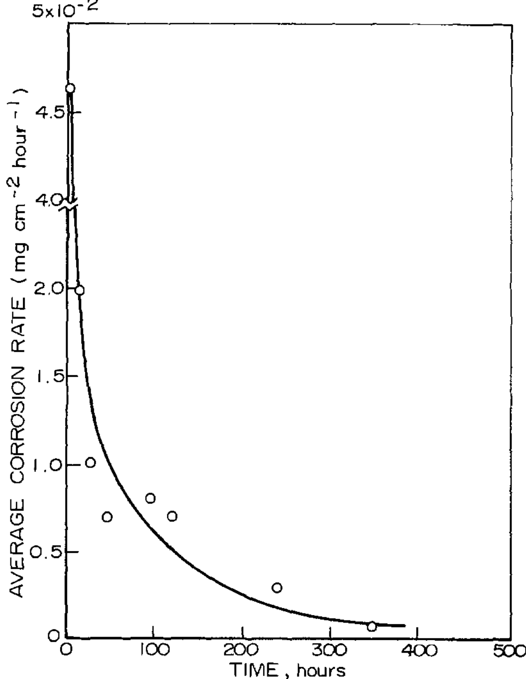

Fig. 1b. Time variation of the average corrosion rate of the alloy, *i.e.*, weight loss rate.

This shows that, at all times, only a fraction of the metal ions resulting from the corrosion reaction are present in the solid corrosion product. The corrosion rate of the alloy (Fig. 1b) decreases with time of immersion; the most pronounced rate-of-decrease being at shorter times. This has been attributed to the protective effect of the corrosion product layer on the limiting corrosion process.

The weight of the film per unit area is taken as a measure of its thickness, with the solid line representing the least squares correlation of the data points (all except the last one which shows the most deviation; about 25% lower than predicted by the correlation). The slope of the straight film line in Fig. 1a is 0.51 and the correlation coefficient is 0.995. Thus

$$WF = 3.5 \times 10^{-2}\, t^{0.51} \qquad 1 < t < 1000 \text{ hr} \qquad [1]$$

where WF is the weight of the film in mg cm^{-2} of alloy surface area, and t is the time of free corrosion in hours. This parabolic relation indicates that the growth of the film follows a transport-limited mechanism. The above correlation applies for at least 1000 hr (42 days); the film weight for the one datum point at >1000 hr is lower than that obtained by extrapolation.

The variation of the overall weight loss with time is more complex than that of the film weight. The parabolic rate law is closely approximated in the 10-1000 hr period. Even at short times, however, the slope is closer to one-half than to unity, *i.e.*, closer to parabolic than to linear-law behavior. During this initial period the film appears to undergo substantial change, both in composition and in structure, as reported in Part II of this series (11).

The solution pH was initially 7.5, increased to 8.0 within a day, and increased more gradually thereafter to 8.1 after one week.[4] The open-circuit corrosion potential varied with time, starting out at about 65 mV (SHE) and drifting to about −10 mV by 48 hr.

Anodic polarization measurements.—Figure 2 shows the effect of potential scan rate on the anodic current-potential curves. While the low scan rate (1.5 mV min^{-1}) gives nearly steady-state behavior, the high scan rates, typical of many previous studies, $\gtrsim$ 300 mV min^{-1} (6-8), give quite different results at potentials beyond the Tafel region. The maximum and minimum currents in the 1.5 mV min^{-1} curve are reproducible, but are not observed using the fast scan rate for determining the polarization curve. The time to reach a steady-state current is relatively long, *e.g.*, > 60 min at 345 mV (insert in Fig. 2). The decrease of current with time at 345 mV is consistent with the formation and thickening of a protective layer. In the Tafel region shorter times are required consistent with the establishment of stable Cl^- and $CuCl_2^-$ ion profiles in the solution boundary layer as discussed below.

The steady-state anodic current-potential curves were also measured on precorroded specimens (for times up to 191 days), Fig. 3. A current peak was always observed, at around 200 mV, for the alloy

[4] Buffered solutions were not used because of their effect on the anodic polarization behavior (Fig. 6).

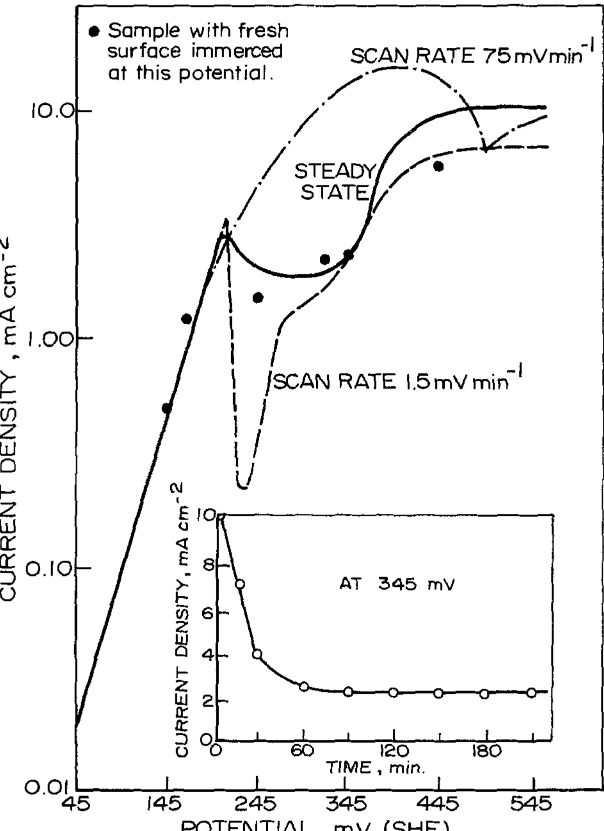

Fig. 2. Effect of potential scanning rate on the anodic polarization curves of the alloy in deaerated 3.4 w/o NaCl solution. Insert: anodic current *vs.* time behavior of the alloy in deaerated 3.4 w/o NaCl solution at 345 mV (SHE).

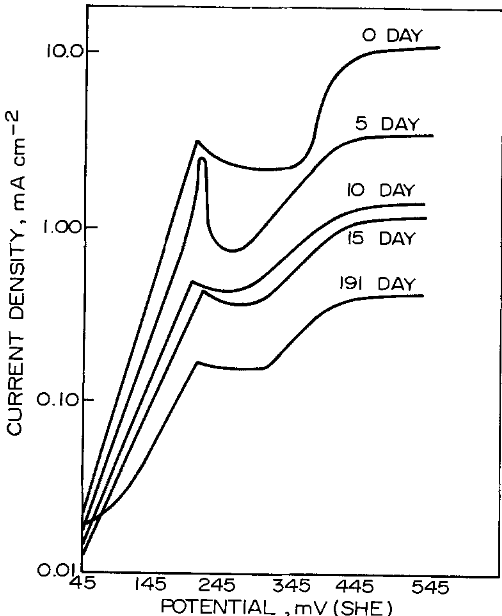

Fig. 3. Anodic polarization curves of the Cu-Ni alloy after various periods of free corrosion.

in different stages of protective film formation. The corrosion product layer restricts the anodic current at any given potential; the decrease is greater the longer the free-corrosion period. The decrease in current is rather large at high anodic potentials, but is small near the corrosion potential compared to the decrease in corrosion rate shown in Fig. 1b.

The curves of Fig. 2 and 3 can be divided into three regions: (*i*) Linear E-log i or Tafel region extending from 45 to 200 mV. (*ii*) Passivation region extending from 200 to 325 mV. This, more appropriately, may be labeled brightening region in view of the relatively high currents of 1-2 mA cm^{-2} (13). Results for pure Cu are compared with those for Cu-Ni in Fig. 4. Since both pure Cu and Cu-Ni alloy show a brightening region, Cu-rich reaction product, seemingly CuCl or $Cu_2(OH)_3Cl$ (11) may be responsible for the brightening effect. (*iii*) "Transpassive" region extending above 325 mV. CuCl and $Cu_2(OH)_3Cl$ were detected on the sample in this potential region by x-ray diffraction (11).

Kinetics of anodic dissolution in the Tafel region.—The Tafel slope, $dE/d \log i$, on the pure Cu surface is 60 mV for both the zero and 5 day corroded samples (Fig. 4). A Tafel slope of 60 mV (at room temperature) can be readily attributed to a one-electron transfer reaction, with diffusion of a reactant or product in the aqueous phase being the rate-determining step (14-17). Thus, if

$$Cu + 2Cl^- \rightarrow CuCl_2^- + e^- \quad [2]$$

is the predominant anodic dissolution reaction in the Tafel region, as has been suggested (8, 14, 16, 18), transport of Cl^- to, or of $CuCl_2^-$ away from, the surface is the rate-determining step.

The Tafel slope obtained on the fresh Cu-Ni surface is 70 mV per current decade, and the open-circuit corrosion potential is about 10 mV more noble for the alloy than for pure copper, with both values varying somewhat with time. Reaction [2] may also be one of the anodic dissolution reactions for the alloy. The greater polarization of the alloy compared to pure copper may be due to various causes. A thin (10Å thick) NiO layer has been shown by ESCA to cover the air-exposed surface of Cu-10Ni (19). The Tafel slope increases with the length of the open-circuit corrosion period, being 70, 75, 100, 110, and 120 mV per current decade for the 0, 5, 10, 15, and 191 day exposure, respectively (Fig. 3).

Effect of the loosely adherent surface layer.—Figure 5 shows the E-log i relations on the following specimens: zero day corroded specimen, 10 day corroded specimens with the surface in the wet and the dry conditions, and 10 day precorroded specimens after the film has been stripped with tape. The stripped film has been identified by x-ray diffraction as $Cu_2(OH)_3Cl$ (11). The 10 day stripped specimens gave the same Tafel line as the fresh specimens. This indicates that transport through the outer por-

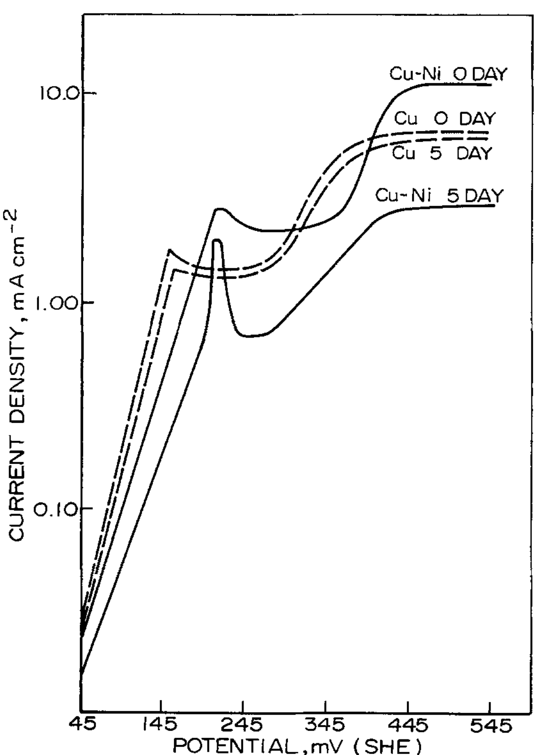

Fig. 4. Anodic polarization curves of pure Cu and Cu-Ni alloy after 5 days of free corrosion.

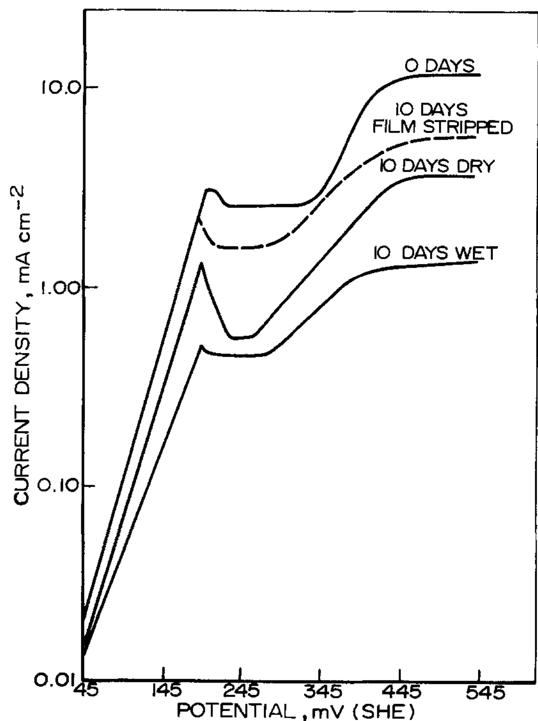

Fig. 5. Effect of the corrosion-product layer on the anodic polarization curves of the alloy precorroded for various lengths of time.

ous layer (probably Cl^- or $CuCl_2^-$ diffusing through electrolyte within the pores) is responsible for the (modest) decrease of the anodic reaction rate in the Tafel region, and that the underlying adherent layer is not a hindrance in the Tafel region to the anodic dissolution reaction or the transport of Cu^+ ions (and presumably Ni^{++} and Fe^{++} ions) through it. The polarization curves also show that the dried surface scale is less protective than the nondried one. This may be attributed to cracking and/or flaking of the loosely adherent film on drying.

Effect of some buffers on the passive current.—It has been found that under free corrosion conditions the pH of the solution changes from 7.5 to 8 in the first day and then levels off becoming 8.1 after a week. Since the measured pH refers to the overall electrolyte, it suggests that there is a considerable local increase in pH to even higher values near the corroding surface. The most likely source of OH^- will be the reduction of oxygen at the corroding alloy surface according to the reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \quad [3]$$

In order to minimize the effect of these pH variations on the corrosion process, it would be necessary to corrode the specimen in buffered solutions. However, the effect of the anions of the buffer on the anodic dissolution reaction is significant. Figure 6 shows the anodic E-log i relations in several buffer solutions which are all 3.4 w/o NaCl. The lower currents obtained in the passive region with borate and phosphate buffers, and the higher currents obtained with ammonia buffers, can be readily correlated to the solubilities of their respective Cu salts. Furthermore, copper gives a stable Cu-ammonia complex which would explain the higher currents obtainable in the Tafel region.

Cathodic polarization measurements.—Oxygen transfer in the aqueous phase.—Figure 7 shows the effect of air-stirring rate on the cathodic E-log i curves of specimens with freshly prepared surfaces. The well-defined diffusion-limiting currents show clearly that for the alloy in the starting condition oxygen

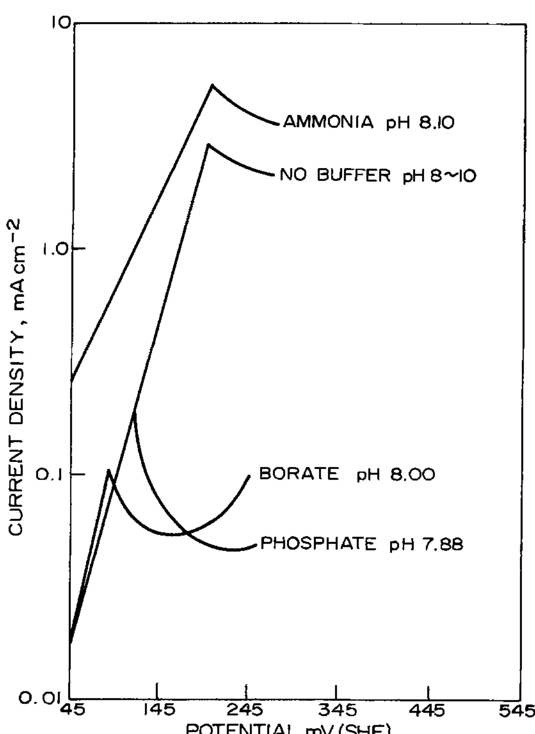

Fig. 6. Effect of different buffers on the anodic polarization curves of the alloy.

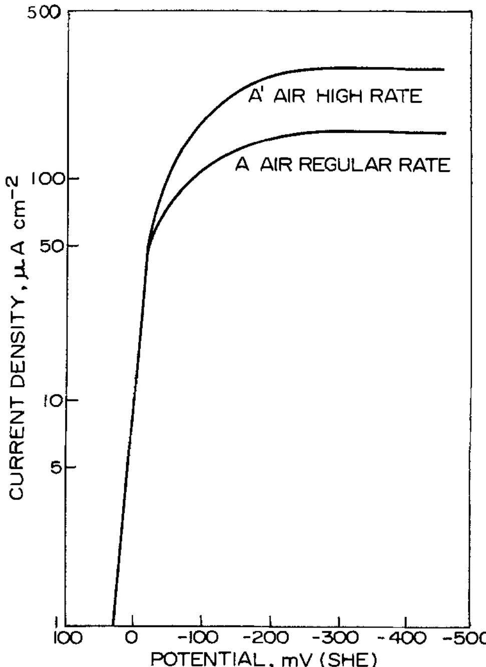

Fig. 7. Effect of stirring on the oxygen reduction rate on fresh alloy surfaces.

reduction is the predominant cathodic reaction, see reaction [3]. Since these limiting currents are an order of magnitude (or more) higher than the currents obtainable on the precorroded samples, it is concluded that, in the latter case, reasons other than transport of oxygen through the diffusion boundary layer are responsible for the reduced corrosion current. Nor is transfer of dissolved oxygen in the porous, corrosion-product layer likely to be the slow step responsible for the reduced corrosion rate brought about by the corrosion-product layer. This is supported by two other observations: (*i*) the thickness of the porous layer (1 μm) is very small compared to the thickness of the diffusion boundary layer, and (*ii*) the observations in Fig. 8 and below. Consequently, it follows that oxygen was not depleted inside the pores of the corrosion product layer during the open-circuit corrosion experiments.

Effect and location of the electron transfer step.—Figure 8 shows that the corrosion product layer at a rather advanced stage of development causes a substantial decrease in the rate of the oxygen reduction reaction. Clearly, this reaction, at potentials near the corrosion potential, is much more affected by the corrosion product than is the anodic reaction, Fig. 3, 8, and 9; hence, oxygen reduction may be projected as the more important reaction in determining the overall corrosion rate in the presence of the corrosion product (protective) layer.

Figure 8 also shows the effect of the adherent (thin) and detachable (thick) layers of the corrosion product on the kinetics of oxygen reduction. Stripping of the corrosion product with tape causes little (*e.g.*, curves E and F in Fig. 8) or no difference (see the conditions of curve D) in the oxygen reduction rate. These results suggest for a well-developed protective layer that oxygen reduction occurs at the interface (fracture plane) between a porous detachable outer, and an adherent thin inner, layer. This interface supports much lower oxygen reduction currents compared to the fresh alloy surface. The extent of this decrease increases with immersion time at open circuit (*i.e.*, the inner layer becomes more of a hindrance to the cathodic reaction and, hence, more protective against corrosion), as shown by comparing curves D and F.

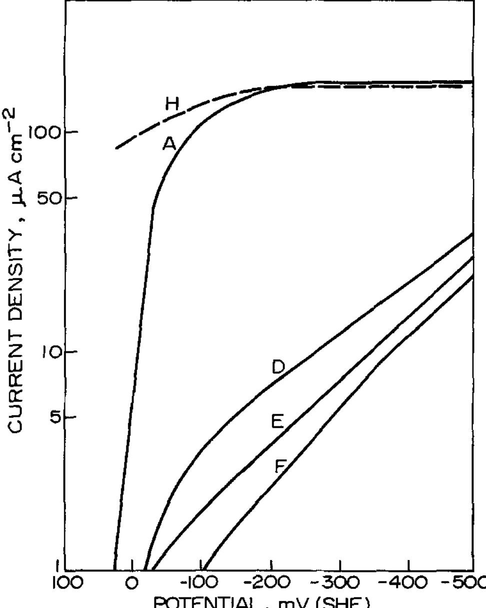

Fig. 8. Effect of the adherent (thin) corrosion-product layer and of the detachable (thick) layer on the current potential relations for oxygen reduction. Curve A, fresh surface; curve D, 10 day corroded with or without stripping detachable layer; curve E, 30 day corroded and stripped; curve F, 30 day corroded; curve H, Pd deposit on 10 or 30 day corroded samples after stripping.

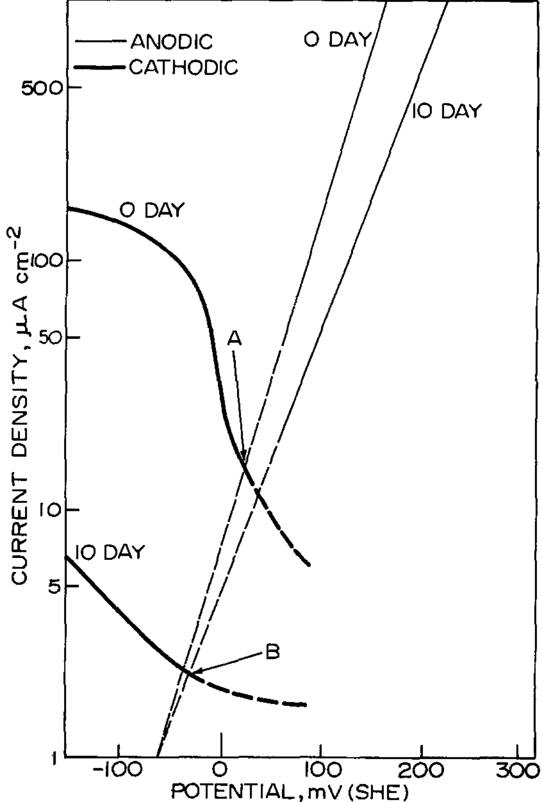

Fig. 9. Superposition of the anodic (Fig. 3) and cathodic (Fig. 8) polarization curves near the corrosion potential of zero day (A) and 10 day (B) corroded samples.

This decrease in the O_2-reduction current is likely due to a lack of electrons at the interface because of a high electronic resistivity of the adherent layer, as is discussed next.

Mechanism of open-circuit corrosion.—Let us consider what happens when copper is heated in air at 1273°K. A dense layer of solid cuprous oxide forms on the copper surface. At the Cu/Cu_2O interface, copper ions and electrons form (anodic reaction) and both migrate through the Cu_2O layer toward the outer surface where formation of oxygen ions occurs by the (cathodic) reduction of oxygen gas. This is a somewhat different process than is usually discussed during aqueous corrosion of metals, *i.e.*, that the electrons which form at the anodic site move through the metal to the cathodic site where they are consumed by the cathodic reaction. The latter situation (only) is generally referred to as a local cell (corrosion) process.

In the present experiments, the open-circuit aqueous corrosion of Cu-Ni specimens which are covered with a well-developed protective corrosion-product layer, is like the oxidation of copper at elevated temperatures. Cu^{+} (Ni^{++} and Fe^{++}) ions and electrons form at the alloy/oxide interface and both migrate through the (inner) oxide layer, Fig. 10a. At the inner oxide/outer oxide interface, reduction of oxygen occurs and the cations enter the aqueous phase or form the porous outer layer (accompanied by oxidation to the plus two state in the case of copper ions). The outer layer provides some hinderance to the anodic reaction (Tafel region of Fig. 5) and thus provides a (small) contribution of anodic control (as compared to the much larger contribution of the inner layer to cathodic control) of the overall corrosion process (Fig. 9).

The rate-determining step (rds) for the reduction of oxygen is electronic conductance through the inner oxide layer. Identification of a transport process through the inner layer as the rds, coupled with the finding that the overall film thickness increases according to the parabolic law (Fig. 1), establishes that the inner layer also thickens according to the parabolic rate law. It also follows for these conditions that, in addition to a flux of cations arriving at the inner oxide/outer oxide interface given by the parabolic rate law, the ratio of cations which enter the aqueous solution to those which participate in the formation of the outer porous layer is fixed.[5] The rds for the less important (from the point of view of reducing the rate of the overall corrosion process) anodic reaction is the diffusion of cations through (probably the aqueous phase of) the porous structure

[5] This ratio may be partly established by the greater tendency of one component(s) of the alloy to participate in formation of the outer film (*e.g.*, Ni and Fe) than another (Cu), as is shown in Part II of this series.

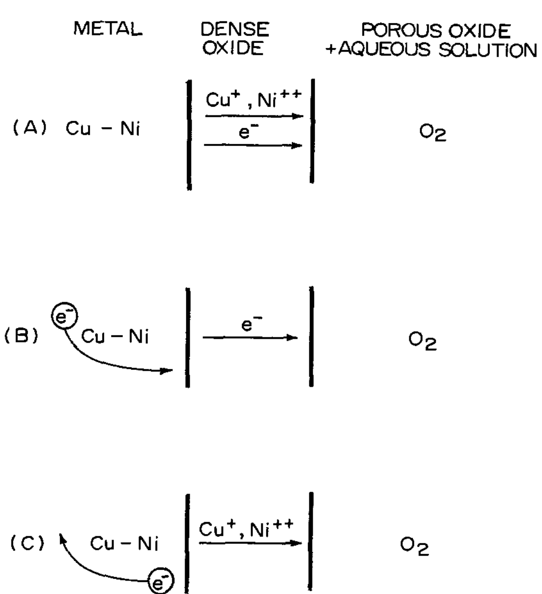

Fig. 10. Schematic of the transport processes in the reaction product during (a) open-circuit corrosion, (b) cathodic polarization (oxygen reduction), and (c) anodic polarization (metal dissolution).

of the outer layer. Only these rds can be rationalized with all of the experimental observations as follows:

Weight loss data.—The rate of metal oxidation and of thickening of the solid reaction product follow the parabolic rate law (Fig. 1a). Hence, transport through the reaction product layer essentially determines the overall corrosion rate.

Oxygen reduction kinetics.—The significant decrease in oxygen reduction rate in going from a fresh to a reaction-product covered Cu-Ni surface during cathodic polarization (Fig. 8) indicates that electron transport through the oxide is difficult. This follows since oxygen reduction during cathodic polarization requires only the transport of electrons through the reaction product layer (Fig. 10b). When the same low rate was observed after stripping away the outer porous layer, the inner (dense) reaction product layer was identified as the actual barrier for transport of the electrons from anodic to cathodic sites.

Metal oxidation kinetics.—There is no reduction in alloy dissolution rate (in the Tafel region) in going from a fresh Cu-Ni surface to one covered only with the thin inner layer (Fig. 5). Since only cation diffusion through the reaction product layer is involved during anodic polarization in oxygen-free solution (Fig. 10c), this result indicates that cation transport through the inner layer is relatively fast. Cation transport through the outer layer, on the other hand, is a (small) hindrance to the anodic reaction in the Tafel region (Fig. 5).

Pd-covered oxide layer.—When Pd was electrodeposited on the inner layer the oxygen reduction rate during cathodic polarization increased (significantly) to that of a fresh Cu-Ni surface (Fig. 8). This is consistent with the formation of a palladium short circuit through the dense oxide layer, thereby providing a metallic conductor for the electrons. The Pd is envisioned to have penetrated the inner layer during electrodeposition along a crack in the oxide or along the specimen edge. A similar result was obtained for an analogous experiment using platinum.

This result is also significant in that it rules out any possibility that either cation or oxygen ion transport is important, since their transport requires an ionic, not metallic conductor. Another function of the palladium or platinum is to increase the rate of Eq. [3] since these metals are excellent catalysts for the oxygen reduction reaction (12). However, in view of a shortage of electrons at the cathodic sites, consistent with electron transfer through the inner layer as the rds, the rate of Eq. [3] increases in the presence of Pd or Pt seemingly due to an increase in electronic conductance, rather than due to an increased catalytic nature of the cathodic site.

Conclusions

The results of the corrosion rate and polarization studies on commercial Cu-9.4Ni-1.7Fe alloy in 3.4 w/o NaCl solution at room temperature show that (*i*) the corrosion-product layer is composed of a thin adherent inner layer, and a much thicker, porous outer layer which can be easily removed by tape; (*ii*) the cathodic half-cell reaction, which is oxygen reduction, is more polarized than the anodic reaction in the presence of this layer and, hence, is more important in controlling the rate of the corrosion process; (*iii*) the inner and the outer corrosion product layers both thicken during the first 1000 hr of their formation in accord with the parabolic rate law; (*iv*) the weight loss, which is the sum of metal oxidized to solid corrosion product and to soluble ions in the aqueous phase, also follows the parabolic rate law during most of this period; and (*v*) transport of oxygen through the aqueous-solution boundary layer and through the electrolyte within the porous outer layer is more than adequate to maintain the relatively slow oxygen reduction rate which is determined by the transport rate of electrons across the inner layer.

On the Mechanism of Corrosion of Cu-9.4Ni-1.7Fe Alloy in Air Saturated Aqueous NaCl Solution

II. Composition of the Protective Surface Layer

ABSTRACT

The formation of protective layers on Cu-9.4Ni-1.7Fe alloy in air-saturated, aqueous 3.4 weight percent NaCl solution, both under natural corrosion and under potentiostatic conditions, has been studied by ESCA (XPS), SEM, and x-ray diffraction. It was concluded that the protective film formed under open-circuit corrosion conditions has the following features: (*i*) is comprised of a relatively thick outer layer, mainly $Cu_2(OH)_3Cl$, and an inner thin layer containing appreciable chloride, oxygen, and copper, and some nickel, (*ii*) is rich in chloride throughout the film with a maximum concentration along a plane located within the inner layer near the inner layer/outer layer interface, (*iii*) is relatively poor in Ni and Fe in the inner layer compared to levels in the outer layer, and (*iv*) has, in early stages of growth, an outer surface consisting of a cuprous (probably Cu_2O) compound which with time gives way to a carbonate and finally to a cupric ($Cu_2(OH)_3Cl$) compound. The transition in Cl, Fe, Cu, and Ni concentrations is sharply confined to the interface region between the thin inner and thick porous outer layers. The thin inner layer is mainly responsible for the good corrosion resistance of the alloy according to electrochemical results reported in Part I of this series.

In Part I of this series (1) the mechanism of corrosion and of protective layer formation on solutionized (850°C, 30 min, W.Q.) Cu-9.4Ni-1.7Fe alloy in air-saturated, aqueous NaCl solution at 23° ± 3°C is examined by well-established polarization methods and by special electrochemical tests designed to identify the rate-determining step. It was found that samples containing the protective layer exhibited a much increased cathodic polarization and a marginally increased anodic polarization compared to samples without the free-corrosion-grown protective layer. This tended to support the view that a much reduced rate of the cathodic reaction (oxygen reduction) is mainly responsible for the good corrosion resistance of the Cu-Ni alloys in seawater. The corrosion product which was responsible for the high cathodic polarization was shown to be in the region of the metal/oxide interface and to remain adherent after the bulk of the corrosion-product layer was stripped with tape. An adherent layer of this type is well suited for chemical analysis with the surface-sensitive techniques of x-ray photoelectron spectroscopy, XPS (also known as ESCA) (2), or Auger electron spectroscopy (3). Such analyses are reported herein and are augmented by x-ray diffraction examination of the corrosion-product layer.

The material which can be removed by tape has, in the vicinity of the corrosion potential, a modest influence on the rate of the anodic reaction, and little or no effect on the rate of the cathodic reaction (1). However, its composition, structure, and chronological sequence of formation are important for an improved understanding of the mechanism of formation of the underlying protective layer. Structural and compositional analyses of such films on cupronickel alloys have been conducted by several investigators (4-8). The presence of Cu_2O and $Cu_2(OH)_3Cl$ as major components, in amounts which vary with temperature (4) and flow velocity of the solution (6, 8), has been revealed by x-ray diffraction. North and Pryor (4) based an explanation of the protective behavior on the electronic and ionic resistance of a defective form of Cu_2O inner layer. Ijsseling (6) showed that the total concentration of iron and nickel was at its highest in the interface region between the inner and outer layer, and it would follow that a discrete layer could be of importance in determining corrosion resistance.

Experimental

The corrosion system is the same as described in Part I of this series (1), where the specimen preparations and arrangements for open-circuit and polarization experiments and procedures are also given. X-ray diffraction, SEM, and ESCA analyses of the corrosion products formed during the open-circuit (corrosion) tests were done on one of two (duplicate) samples immersed for varying lengths of time; weight change data were obtained from the other sample of each pair (1).

X-ray diffraction examination.—X-ray diffraction examination of samples after the open-circuit corrosion periods were performed by placing a sample (5 × 5 mm), carefully cut from the corroded sample, in a Debye-Scherrer camera at an angle of about 8° to the x-ray beam, in order to increase the path length of the x-rays in the sample.

In the case of the anodically polarized samples the corrosion product films were scraped off with a knife, and the resulting powder was utilized for the x-ray diffraction analysis. Corrosion products which become detached and dispersed throughout the solution during anodic polarization were also gathered, rinsed with water, dried, and then analyzed as above.

XPS (ESCA) studies.—Samples (6 × 6 mm), cut from the corrosion test coupons taking care to avoid handling the faces to be examined, were mounted in batches of five on the probe of the XPS spectrometer and examined with AlKα radiation. The heights and areas of the principal peaks of the elements Cl, C, O, Cu, Fe, and Ni were obtained using a computer-based

data acquisition system (V. G. Datasystems Limited, England). In addition, survey scans covering the binding energy range 0-1000 eV were taken from each sample. Individual peaks could be obtained to an accuracy of ±0.2 eV from the computer display. Values obtained in this way, corrected the reference levels of $Cu2p_{3/2}$ = 932.8 eV (10) or C_{1s} = 285 eV (10), are quoted in the text where appropriate for the identification of bonding state. Cupric compounds are readily recognized by the presence of the shake-up satellite (Fig. 1). Analyses in all cases were corrected, using relative sensitivity factors based on those published by Jorgenson and Berthou (9) and normalized to 100 atom percent excluding carbon, which in most cases was merely present as a surface contaminant. The analysis so obtained is a surface-weighted mean with about 70% of the signal obtained from the top 1 nm.

The outer surfaces of samples exposed to the test solution for 12 hr, 1, 3, 5, and 10 days were examined in order to establish the chronological order in which new phases appeared on the surface. This was found to be the period of corrosion activity necessary to develop the underlying protective film (1). The samples were examined prior to ion etching since ion etching is known to alter valence states, in particular cupric ions are always transformed to the cuprous state (11). The adsorbed film on these samples will reduce slightly the intensity of low kinetic energy peaks, such as copper, with respect to those of high energy, such as chloride, but not to an extent which would warrant ion etching.

Information relating to the distribution in depth of the phases within the reaction product layer was obtained using samples exposed separately for 5 days. For these studies, the visible corrosion product was removed using tape and both the fractured material remaining on the metal substrate and that adhering to the tape were subjected to detailed analysis. Ion beam etching was used sequentially with XPS analysis after initial examination in order to obtain the direction of concentration gradients in the region of the fracture. An ion current of 10 μA and a beam energy of 8 keV was used. The etch rate so obtained was of the order of 0.02 nm sec^{-1}.

Because of an overlap between the $Fe2p_{3/2}$ photoelectron peak and a prominent copper Auger line, the presence of Fe in the region of the interface had to be confirmed using Auger electron spectroscopy. In this case the surface film was stripped from a 5 day test sample using indium foil. Auger analysis of the fracture surface was, however, only possible on the substrate side because of problems associated with electrostatic charging of the stripped material.

Results

X-ray diffraction analysis.—The x-ray diffraction results on (corroded) samples immersed more than 5 days indicate that the corrosion product is mainly $Cu_2(OH)_3Cl$ and contains much less Cu_2O; d-spacings are shown in Table I. Samples immersed less than 5 days exhibited only Cu-Ni diffraction lines, indicating insufficient oxide thickness (<<1 μm). The loosely adherent film on the 30 day corroded sample (stripped with double-face tape) showed only $Cu_2(OH)_3Cl$. Tables II-IV show the identity of reaction products formed during anodic polarization of the Cu-Ni alloy at potentials more noble than the Tafel region (labeled brightening region in Part I).

Surface analysis.—Figure 1 shows wide scan (1000 eV) spectra obtained from the outer surface of the 0.5, 1, 3, 5, and 10 day samples. The lack of a shake-up satellite (12) on the copper 2p peaks at 0.5 and 1 day shows this element to be metallic or in the cuprous form; the Cu LMN peak position (917.0 eV) shows it to be cuprous (12). At 3 days and after, the

presence of a satellite shows the surface film to be entirely in the cupric form. There is also a marked increase in the chloride peak, first noted in the 3 day spectrum (Fig. 1). Both the nickel and sodium signals are negligible on these samples while, after correction for charging, the oxygen peak is entirely in the position (531 eV) usually ascribed to OH^- ion (13) (Fig. 1). Thus, the analyses would be consistent with the presence of cuprous oxide, having perhaps a hydrated surface, at 12 hr and of basic cupric chloride at 3 days and after. The sample exposed for 1 day was the first which showed the visible corrosion product that covered subsequent samples. At 1 day the film covered one-third to one-half of the surface; it appeared to start at an edge and grow laterally over the surface. Analysis of this filmed region showed copper to be in the cupric form, unlike the bright half which remained in the cuprous state, Fig. 2. However, the transition in valence state did not coincide with the pickup of chloride ion, since there was very little present, even on the discolored half of the 1 day specimen (Fig. 2).

Both the oxygen and carbon signals obtained from a scan of the 1 day specimen, which included both halves, show prominent shoulders (Fig. 3a and 3b). Separate spectra from the filmed and unfilmed areas show that the high energy shoulders for both elements are uniquely found on the tarnished half, on which they form a major part of the signal. One possible reason for this unusual observation is that the filmed and unfilmed areas of the specimen were electrostatically charged relative to each other. Thus, care was taken to reference the position of the carbon signal on the unfilmed half to the cuprous position and on the filmed half to the cupric position (using Cu(II) $2p_{3/2} = 934.4$ obtained from laboratory standards). This procedure confirmed the carbon 1s position to be 285.0 eV on the unfilmed material and 288.0 eV on the filmed material. The equivalent oxygen positions are 531.3 and 534 eV, respectively. A similar procedure applied to the single carbon and oxygen

peaks on the 3 and 5 day specimens fully accounted for the observed shift in terms of electrostatic charging. Nickel ions are only present to a trivial extent in the 12 hr, 1 day (bright), and 5 and 10 day surfaces. However, they are prominent in the spectra from the filmed half of the 1 day sample and from the 3 day sample (Fig. 1c). The composition of the outer surface based on the above analysis and individual peak intensities is plotted as a function of corrosion time in Fig. 4. Also shown are some likely compounds containing the identified elements at the various stages of dissolution.

Interface analysis, 5 day samples.—The analyses obtained from the fracture surface of the stripped substrates of the 5 day samples are given in Table V. These give the relative proportions of Cu, Ni, Fe, and Cl only; oxygen and carbon are excluded because of the different behavior of adsorbed gases in the XPS and AES spectrometers. The high Ni content in three of the samples in Table V appears to be associated with reaction product characteristic of the stripped side of the fracture surface rather than that on the substrate side (Table VI and Fig. 5). Sample 3, on the other hand, was repeatedly stripped prior to analysis and showed a lower Ni level. Results in Table V,

furthermore, show a high concentration of chloride ions and a low concentration of iron. After ion etching (Table VI) the iron level is not detectable in the substrate side and much higher in the stripped material. Conversely, chlorine is much lower in the stripped material. These results, coupled with about 1 nm resolution (in the absence of ion etching), indicate a very sharp change of the iron and chloride contents along the plane separating the material which can be stripped from the sample from that which cannot. Nickel and copper similarly exhibit sharp concentration gradients along this plane. An ion etch profile obtained by XPS from the matching surfaces of sample 3 of Table V is given in Fig. 5. Comparing matching values in the plane of fracture (*i.e.*, before ion etching) one observes the mentioned sharp composition changes across the fracture plane for Cl, Fe, Cu, and Ni, and that whereas the phase which is stripped away is enriched in nickel and iron, the adherent reaction product on the substrate side of the fracture plane contains mainly Cu and some Ni with the Cu:Ni ratio the same as that of the bulk alloy. The chloride content of the reaction product, furthermore, is a maximum along a plane located within the inner layer near the fracture plane itself. Thus, it appears that the thin inner and thick porous outer layers are distinctly different reaction product phases.

Metallographic examination.—SEM examination of the outer surface at different stages of film formation is shown in Fig. 6. The corrosion product is easily recognizable by tarnish colors in less than 1 hr (Table VII) and appears porous and discontinuous by one day. After 5 days, it is more compact. After stripping, the substrate appears metallic with some

locations still covered with reaction product. This is consistent with the ESCA results which show a high Cl concentration on the substrate side of the fracture plane. The corrosion product adhering to the tape had a greenish hue.

Discussion

The results presented above provide a chronological sequence of the phases appearing on the outer surface of the test pieces and a structural sequence of some of the compositions found in the thick corrosion product. Because of the shallow depth of analysis, the chronological sequence is important as an indicator of the direction of chemical reactions with the environment such as hydrolysis or oxidation at different times of exposure. Similarly the structural sequence provides analyses close to interfaces in the hierarchy. Each series of analyses must be supplemented with the bulk analyses for a full picture of the surface processes.

Table VII. Color changes of the Cu-Ni alloy during immersion in the 3.4 w/o NaCl solution at room temperature

48 hr	Shiny tan and dull tan areas
72 hr	Dull tan
96 hr	Dull tan

Early stages of protective layer formation.—The chronological sequence for the appearance of copper compounds at the corrosion product/bulk solution interface shows that by 3 days, cuprous oxide has transformed to basic cupric chloride, paratacamite. The basic chloride is clearly the stable product, as evidenced by the diffraction patterns of long-term test pieces and the SEM observation of clusters of crystals growing into rafts, which, after about 3 days, cover the whole of the surface. In the initial transient period cuprous oxide was present over the whole specimen surface for 12 hr and remained on some areas for over a day which is a surprisingly long time in a well-aerated solution. Although the cuprous oxide was probably generated in the first place during preparation and subsequent air exposure, XPS analysis has been shown to be quite capable of detecting progressive changes in the air-formed film as it equilibrates with water, *e.g.*, on stainless steel changes are observed within 10 min of exposure to pure water (14). The longevity of cuprous oxide as the surface phase probably is due mostly to an activated step in the nucleation of cupric compounds and, particularly, of the stable basic chloride. This is in accord with the observation that nucleation of cupric compounds starts first at an edge and moves across the surface as a front.

The identity of the first precipitate of cupric material remains to some extent uncertain. Examination of the 1 day spectrum in detail reveals no possible anions, other than carbon and oxygen, on the part of the specimen which returned a strong cupric signal. The carbon peak at 288 eV could arise from an unusual quirk of electrostatic charging but this seems unlikely. It

would require an organic contaminant on the surface to have charged relative to the cupric phase on this sample, whereas it does not charge relative to either the thin cuprous oxide phase at shorter times or to the thick cupric, paratacamite phase at longer times. An alternative possibility is that the first cupric precipitate is the basic carbonate, malachite, $CuCO_3Cu(OH)_2$. The position of the carbon peak in sodium carbonate is 289.6 eV, but the binding energy could be lower in a less strongly ionic compound or in a poorly oriented surface compound. The formation of a carbonate as first precipitate in a chloride-rich environment may arise from the nucleation difficulties of the chloride, or because the necessary thermodynamic conditions exist as a brief transient. Bianchi and Longhi (15) have provided a diagram giving the stability ranges of $Cu_2(OH)_3Cl$ and $CuCO_3Cu(OH)_2$ as a function of the *p*H value and the total inorganic carbon content of the solution. Maximum stability occurs at a *p*H of about 7.5, where approximately 2.5×10^{-3} g-at/liter of carbon is required to enter the stability field of malachite. While they show that this is reached in many natural seawaters, it seems unlikely that it could have been reached in the aerated sodium chloride solutions used in this study. Furthermore, the movement of *p*H toward a value of 8, as recorded during the exposure (1), would tend to move that part of the surface supporting the oxygen reduction reaction (Eq. [3] in Part I) away from a carbonate stability field and ensure that any such deposit had only a transient existence. Pourbaix (16), discussing behavior in natural waters, also indicates the basic carbonates to have only a transient existence at anodic sites because of a shift in *p*H to lower values due to hydrolysis reactions. Thus, a carbonate could have a prolonged life, although its appearance probably arises only because of its preferred nucleation as a surface phase.

The copper spectrum from the tarnished half of the 1 day specimen contains both cupric and cuprous (or copper) components. The appearance, Fig. 2, of very strong nickel (II) signals, coupled with the lack of evidence for the diffusion of nickel ions through an air-formed cuprous oxide film at room temperature (17), indicates that the underlying cuprous oxide has undergone modification during the course of precipitation of the cupric compound. This is supported by evidence which was obtained at a later stage of the film formation and is presented in Part I of this series (1) that cations diffuse readily through the inner layer and only slightly less so through the outer layer. Again, because of the almost total lack of chloride ions in the film during its early stage of formation, we presume the nickel to be present primarily as $Ni(OH)_2$, which is known to be the preferred surface phase on nickel in humid conditions (18). It is noticeable that the cuprous spectrum on the bright half remains identical to that found after 12 hr. Thus the nucleation of the cupric phase on one part of the surface does not result in modification of the cuprous oxide over a large area.

The developed protective layer.—Turning to the sequential analyses carried out on the specimen immersed for 5 days we find two important results: (*i*) the layer removed by use of adhesive tape included the corrosion product layer enriched in iron and nickel, which other authors have reported to be important for the good corrosion resistance of cupronickel alloys (4); (*ii*) the layer remaining adherent to the substrate was not enriched in iron and nickel but contained the highest concentrations of chloride ions found in any part of the film. It is this adherent layer which was identified in Part I to be primarily responsible for protection (1).

The analytical results (*i*) and (*ii*) taken together with the finding reported in Part I, that mechanical removal of the visible corrosion product caused the anodic polarization curve in the Tafel region to revert to the polarization curve found without prior exposure, indicate some resistance to cation transport through the thick porous outer layer. These data are, on the one hand, consistent with Popplewell *et al.'s* (5) conclusion that the thick porous outer layer offers a resistance to the corrosion reaction, but, on the other hand, inconsistent with their view that this film is the primary source of protection. Furthermore, the underlying adherent layer is not simply a defective form of cuprous oxide as found by these authors since it is very highly enriched in chloride and contains nickel. This is important since the inner layer is mainly responsible for the good corrosion resistance of the alloy. The latter is a result of its poor electronic conductivity as shown in Part I, thereby restricting the oxygen reduction reaction (1).

Ion beam profiling results show that the high chloride level in the inner layer is not present as an adsorbed monolayer, but is a layer extending over several tens of nanometers. It is not possible to say whether the material *in situ* is in the cuprous or cupric form, because of its ready interconversion by air oxidation in the one direction and by ion etching in the other. However, the high chloride content remains closer to Pourbaix's description of residual layers formed on copper covered with paratacamite than to Popplewell's presumption of cuprous oxide inner layers.

Although Cu and Cl are in the approximate mole ratio of 1:1 in a part of the inner layer near the inner/outer layer interface, Fig. 5, CuCl is usually associated with nonprotective, rather than protective, layers, such as form at the bottom of pits in copper (16) and in the brightening region in this work, Table II. Furthermore, other elements are present in the inner layer, in particular, much oxygen (Table VI) and Ni, so that the nature of the inner layer remains partly unresolved. CuCl, itself, is stable at *p*H $\lesssim$ 4 for the conditions reported here (16), and, if present, would be evidence that the *p*H in electrolyte within the porous layer is in this range. It is not clear, however, that the *p*H should be lower in the porous structure, since the hydrolysis reaction which is expected to occur at anodic sites and the oxygen reduction reaction which occurs at the cathodic sites (1) shift the *p*H in opposite directions. No evidence was found on the freely corroded samples of the $Ni(OH)_2$ layer formed as a passivating layer at high anodic potentials (19), see also Table IV.

In general the analyses are in good accord with the dynamic view of the nature of corrosion in NaCl solutions expressed by Popplewell *et al.* The outer composition is close to that required for paratacamite, considered to be back deposited by a continuous process of dissolution and precipitation. This covers an intermediate zone enriched in the oxides or hydroxy oxides of iron and nickel, which have enriched because of greater Cu ion solubility in the aqueous phase. To this we now add the finding of an innermost layer, rich in chloride and possessing a high cationic and low electronic conductivity, the latter of which controls its rate of formation and to very large degree the overall corrosion rate.

Conclusions

1. The chronological sequence of results suggests that the stable outer phase of basic copper chloride ($Cu_2(OH)_3Cl$, paratacamite, was identified by x-ray diffraction) is formed early in the film formation process by a reconstitution of the initial cuprous oxide phase with involvement of a transient carbonate phase.

2. During the transition period (1-3 days) oxidized nickel is visible in the spectrum obtained from the reaction-product surface. A nickel oxide phase would normally underlie the cuprous oxide (17), and

its appearance in an analysis having such a shallow depth of penetration means that the growing cupric phase is forming as isolated nuclei on or within a mixed cuprous/nickel oxide/hydroxide layer.

3. SEM micrographs reveal a porous, discontinuous reaction product, particularly for the 1 and 5 day samples (Fig. 6a-d), consistent with the conclusion in 2.

4. After 5 days the cupric compound outer layer covers the entire surface, but it is highly enriched in nickel and iron on the substrate side of the layer. This thick, porous layer is responsible for the (relatively small) contribution of anodic control to the overall corrosion rate.

5. The inner layer (that which cannot be removed by stripping) associated with strong cathodic control of the overall reaction is not selectively enriched in either iron or nickel, but does contain the greatest concentration of chloride, about equal to that of copper near the inner/outer layer interface, found in any part of the corrosion product structure and a Cu:Ni ratio which is the same as in the bulk alloy.

6. The strongly protective nature of the inner layer arises from its low electronic conductivity which thereby restricts the rate of cathodic reduction of oxygen at the inner layer/outer layer interface, according to electrochemical experiments in Part I of this series (1). The electrochemical data also show that the inner layer is highly permeable to Cu, Ni, and Fe ions.

The Nature of Anodic Films on Nickel and Single Phase Nickel-Molybdenum Alloys

V. Mitrovic-Scepanovic and M. B. Ives

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

The decay of potential after anodization at a passive potential has been followed for a series of nickel-molybdenum alloys and the observations used to speculate on the effects of molybdenum alloying additives on the nature of the passivating films formed on nickel in $0.15N$ Na_2SO_4 at a pH of 2.8. It is concluded that small quantities (<5 w/o) of molybdenum causes considerable defectiveness to passive films, decreasing their stability. It is proposed that at higher alloy levels, but levels which do not produce a two-phase alloy, a mixed oxide $(Mo^{4+}, Mo^{6+})_xO_y$ is produced along with a much less stable defective NiO.

Whenever a passivated metal or alloy is subjected to an environment which tends to dissolve the surface film which maintains passivity, it has been found instructive to follow the potential with time as it tends towards the equilibrium open-circuit potential of the metal/electrolyte system. The decay curves invariably show a structure represented by arrests at characteristic potentials which may sometimes be related to redox potentials for the appropriate species existing in the passivating film (1-3). The application of the open-circuit potential decay technique to films formed on nickel in sulfate solutions by MacDougall and Cohen (4-6) has, however, shown that potential arrests may also be related to the presence of regions

Key words: potential, anodization, passivation.

of defective film and not necessarily different phase oxides.

The potential decay technique has been applied to the study of passive films on nickel and on single phase nickel-molybdenum alloys in an attempt to elucidate the manner in which molybdenum changes the structure and properties of passive films formed on nickel in aqueous sulfate solutions.

Experimental

The electrochemical studies were carried out in a cylindrical cell with a working volume of approximately 200 ml. Alloy specimens were fixed in a Teflon holder which fitted snugly into one arm of the cell providing a constant relative position with a Luggin capillary and connected to a saturated calomel electrode (SCE) by an agar/Na_2SO_4 salt bridge. Two inlets for nitrogen were provided both above and below the electrolyte surface.

Electrolyte solution was supplied to the cell from a storage vessel with a capacity of approximately 4 liters, which was kept under a stream of purified nitrogen. Deaeration of all solutions was performed for a minimum of 48 hr prior to each experimental run. Pure nitrogen[1] was further purified by passing it over copper wool at 450°C, cooled in a coiled glass water column, and dried by passing through silica gel, anhydrous $CaSO_4$, and a molecular sieve.

All experiments were performed in 0.15*N* Na_2SO_4 solution prepared from ultrapure Na_2SO_4.[2] The *p*H of the solution was adjusted with conc H_2SO_4 to *p*H = 2.7-2.8. Oxygen dissolved in the solution was removed by prolonged bubbling with purified nitrogen. The *p*H of the solution was checked before each experimental run by means of a *p*H-meter (Fisher Acumet 140).

Electrical measurements were performed using a potentiostat (Wenking 70HC3), a digital multimeter, and a two-pen potentiometric recorder provided with an integrating facility.

The electrode geometry in the cell is dictated primarily by the need to establish a symmetric electric field at the working electrodes. By using a platinum gauze counterelectrode with an area more than 20 times that of the working electrode, the dimensions of the working electrode can be varied over a wide range as also can its position, thus improving the flexibility of measurement and comparison between samples.

Samples were prepared of nickel and nickel-molybdenum alloys containing 1, 3, 5, 10, and 15 weight percent (w/o) Mo. The nickel samples were prepared from "low oxygen" material received as cold-rolled sheets prepared from refined cathode material, containing typically a maximum of 15 ppm carbon. The analysis of the pure nickel is given in Table I. The alloys were prepared from 99.9% nickel and 99% molybdenum. Qualitative spectrographic analysis of the base metals used in the preparation of the alloys is given in Table II. All the alloys are known to be single phase alloys in the nickel-molybdenum system (7). Samples were cut from sheets rolled from arc-melted buttons, heat-treated in accordance with the schedules noted in Table III under a vacuum of 10^{-5} Torr. These heat-treatments produced average grain sizes of approximately 0.02-0.04 mm.

Samples with surface areas ranging from 0.25 to 0.5 cm^2 were attached to tin-coated copper wires on the back surface and mounted in epoxy resin, such that only one face was exposed for polishing. This assembly fitted snugly into a Teflon holder. Samples were mechanically polished to 1 μm diamond polish following which they were ultrasonically degreased in acetone and electropolished. Electropolishing was performed

immediately before each experimental run in ice-cooled 60 volume percent H_2SO_4 at a current density of 0.1 A/cm^2 for 1 min.

Specimens were washed immediately after electropolishing with double-distilled water and transferred to the cell, where they were cathodically polarized at −2V for 10 min, in the absence of nitrogen bubbling to avoid the possibility of the deposition of impurities (8). The conditions for appropriate cathodic reduction were established from the behavior of pure nickel in the active region during subsequent potentiostatic polarization. The active dissolution peak at the active-passive transition was found to increase with decreasing potential of cathodic reduction. Cathodic reduction carried out at potentials more negative than −2V did not cause any further change in the active dissolution peak and consequently, −2V was adopted as the cathodic polarization practice. The Ni-Mo alloy were also subjected to the same cathodic reduction even though there is some possibility of hydrogen production and absorption which has been ignored in this investigation, but may well affect the detailed potential decay characteristics.

Anodic potentiostatic curves were obtained in 50 mV steps made at 2 min intervals, starting from −600 mV. Moderate nitrogen bubbling was introduced after the current polarity changed from negative to positive. Polarization at fixed potentials in the passive

region was performed by stepping the potential from −600 mV to the desired value. The potential decay curves were recorded by switching the potentiostat off after anodic polarization at a potential in the passive region for certain periods of time.

Specimens were routinely checked by optical metallographic examination to ensure that localized attack at grain boundaries (indicating possible segregation effects during sample preparation) or due to crevice attack at the sample edges have been avoided. Results from samples exhibiting such attack were always discarded.

"Surface reactivity" measurements (5) were performed in order to determine relative activity of the surface after a time on the open circuit. When a metal electrode is directly subjected to a potential in the passive region after the cathodic pretreatment, the amount of charge consumed during the formation of a steady-state film, Q_0, can be considered as the amount of charge needed for film formation on a "clean" surface. If, however, the film were formed under the same conditions (potential and time of anodization) but starting with a surface not completely film-free, the charge consumed, Q, would be less than in the former case. The ratio $Q/Q_0 \times 100\%$ can be defined as surface reactivity, R_s, since a film-free surface would be 100% active. The surface reactivity was measured after different elapsed times on open circuit by stepping the potential back to the value at which the film had been previously grown. Conclusions on the stability of film coverages can be made on the basis of such results.

All potential data reported here are referred to the saturated calomel electrode. Both change of current with time during anodic oxidation and change of potential with time during open-circuit potential decay were followed by the chart recorder. For all experiments the curves presented here are the record of particular experimental runs, but are typical for the given conditions. Potentiostatic polarization measurements were reproducible to within ± 5% in the active region. The maximum scatter in the potential decay measurements was ± 10 mV.

Results and Discussion

Polarization Characteristics of Ni and Ni-Mo Alloys

The anodic potentiostatic polarization behavior of Ni and Ni-Mo alloys was investigated first in order to determine the potential range of passivity. The results are given in Fig. 1 and 2. Although the passivation behavior will not be discussed in detail here, it is worth observing that (*i*) the 1% and 3% Mo alloys do not show ability to completely passivate, exhibiting two narrow "passive" regions. (*ii*) The passivation current and potential do not show any trend with moybdenum content. The current increases

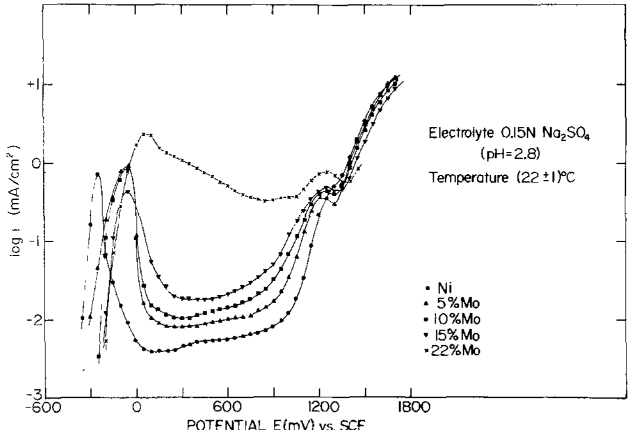

Fig. 2. Anodic potentiostatic polarization of nickel and single phase nickel-higher molybdenum alloys.

and then decreases with increasing molybdenum content, the passivating potential being shifted 200 mV in the positive direction with respect to that of pure Ni for all the alloys. (*iii*) The current density in the passive region increases monotonically with Mo content.

The observed behavior indicates a negative effect of molybdenum on the corrosion resistance of Ni and a significant difference in anodic polarization behavior between the alloys low and high in molybdenum. Similar observations were reported by Greene (9) and Tachibana and Ives (10).

Potential Decay and Surface Reactivity Measurements

Pure Ni.—Open-circuit potential decay and surface reactivity measurements were performed so that the effect of two variables could be studied: anodization potential and time (Fig. 3, 4, 5). All decay profiles show an abrupt change of potential (a "spike") at approximately −300 mV which appears after times which depend on the potential and time of anodization. The decay time elapsed before the spike, t_s, is longer for higher potentials and longer times of film formation. The surface reactivity was estimated at t_s and (t_s + 10 min) (labeled R_s and R_s', respectively).

All decay curves, except those for electropolished nickel, also exhibit well-resolved potential arrests (Fig. 5). The characteristic potential plateaus occur close to −150 and −200 mV. Polarization at +800 mV brings out an additional arrest at approximately −10 mV. However, none of these potential arrests corresponds to the redox potentials of nickel oxides (Table IV) which should appear in the experimentally observed potential region.

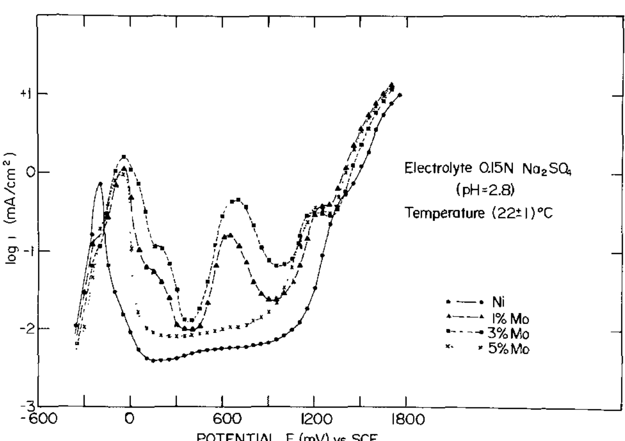

Fig. 1. Anodic potentiostatic polarization of nickel and nickel-low molybdenum alloys.

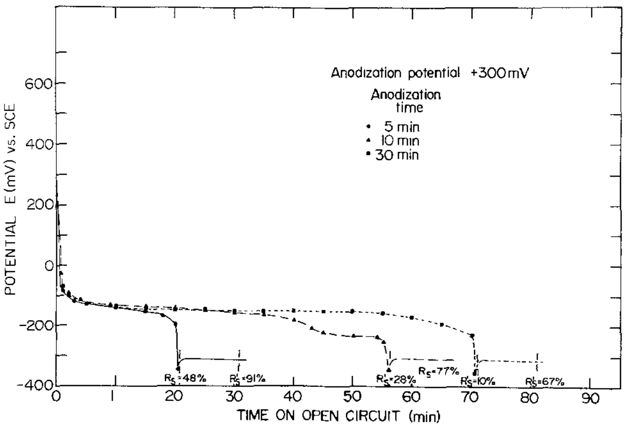

Fig. 3. Effect of anodization time at a fixed potential of +300 mV (SCE) on open-circuit potential decay of nickel.

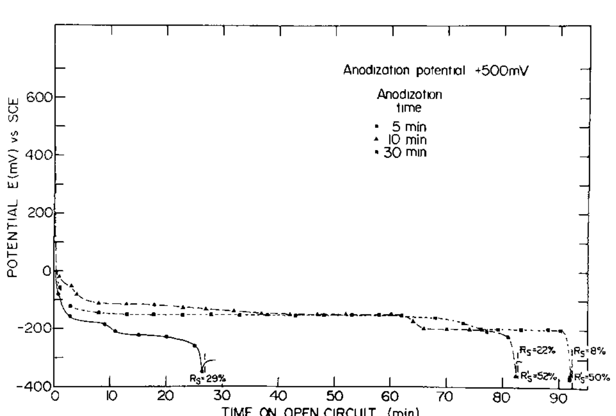

Fig. 4. Effect of anodization time at a fixed potential of +500 mV (SCE) on open-circuit decay of nickel.

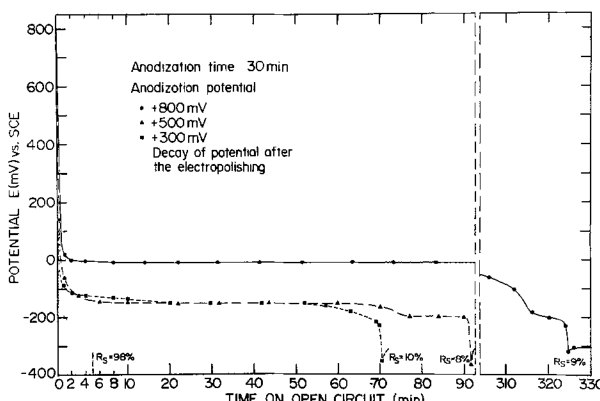

Fig. 5. Effect of anodization potential on open-circuit potential decay of nickel.

The potential spike at −300 mV is close to the equilibrium potential of a Ni/NiO electrode, suggesting it is NiO which is present on the anodized Ni under these experimental conditions, in agreement with the observations of MacDougall and Cohen (6). The other potential arrests could be explained in terms of a defective NiO which covers a part of the surface, the remainder being covered with stoichiometric NiO. The structure of the decay curve of electropolished nickel (Fig. 5) suggests the same type of oxide coverage, probably formed due to air exposure after electropolishing, but being much thinner than that formed by polarization at a potential in the passive region. Surface reactivity measurements suggest that prior to the spike only a relatively small fraction of defective film is susceptible to dissolution. After the potential shift to −300 mV, the (t_s + 10 min) values indicate that the surface reactivity increases rapidly. It appears that the oxide is removed quickly from the surface once the potential reaches −300 mV, perhaps by the process of undermining (6).

Ni-Mo alloys.—The open-circuit behavior and surface reactivity measurements made on the Ni-Mo alloys are shown in Fig. 6-10. The corresponding results for nickel are also given for comparison. Surface reactivities were estimated after different times at open circuit (dotted vertical lines on the decay curves).

Table IV. Equilibrium potentials of Ni and Mo oxides calculated for the electrolyte of pH = 2.8 with respect to SCE (mV)

Ni/NiO	−299.4	Mo/MoO$_2$	−479.5
NiO/Ni$_3$O$_4$	+489.5	Mo/MoO$_3$	−339.5
NiO/Ni$_2$O$_3$	+624.5	MoO$_2$/MoO$_3$	−87.5
Ni$_3$O$_4$/Ni$_2$O$_3$	+897.5		

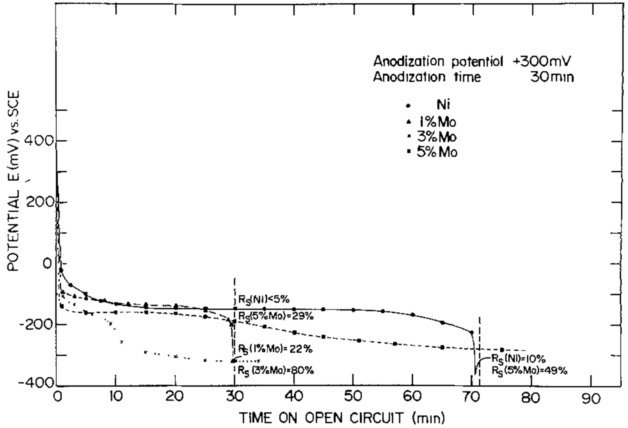

Fig. 6. Open-circuit potential decay of nickel-molybdenum alloys anodized at +300 mV (SCE) for 30 min.

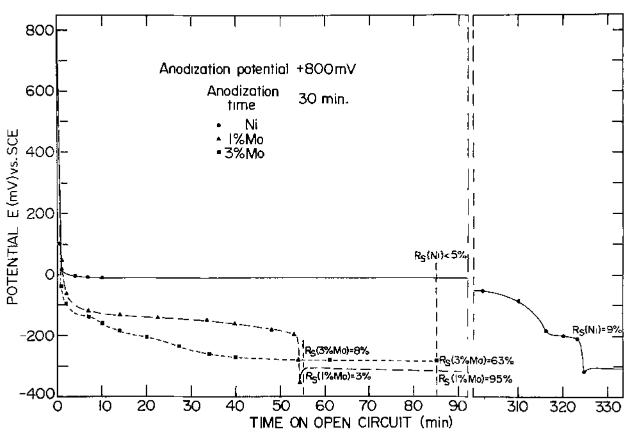

Fig. 7. Open-circuit potential decay of nickel-molybdenum alloys anodized at +800 mV (SCE) for 30 min.

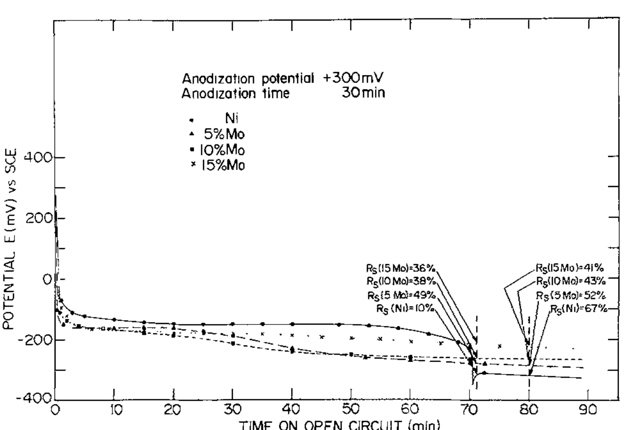

Fig. 8. Open-circuit potential decay of nickel-molybdenum alloys anodized at +300 mV (SCE) for 30 min.

The decay profiles and surface reactivity measurements may be summarized as follows: (*i*) only the 1% Mo alloy shows the potential spike characteristic of Ni, t_s being much smaller however, and depending on the conditions of film formation. (*ii*) The 3% Mo alloy shows a faster decay of potential than the 1% Mo alloy for which the surface reactivity measurements indicate that the oxide coverage on the 3% Mo alloy is the least stable of any of pure Ni, 1% Mo, and 3% Mo alloys. It appears that small amounts of molybdenum markedly affect the stability of the anodic film (Fig. 6, 7). (*iii*) Films formed on higher Mo alloys are less stable than NiO within the period t_s, but are more stable than nickel at longer times (Fig. 8, 9, 10).

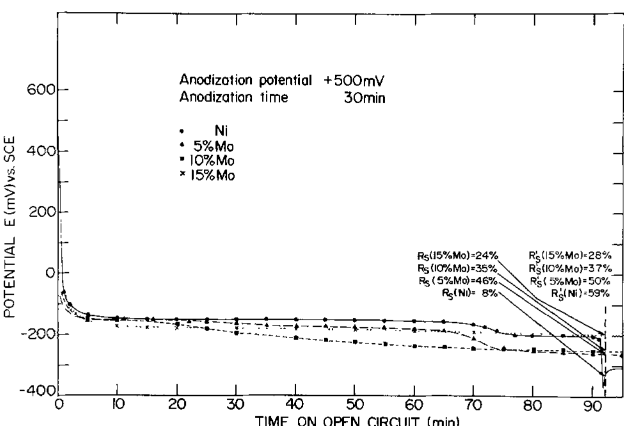

Fig. 9. Open-circuit potential decay of nickel-molybdenum alloys anodized at +500 mV (SCE) for 30 min.

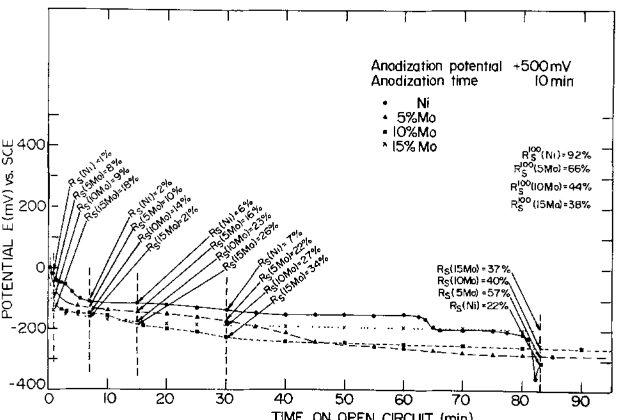

Fig. 10. Open-circuit potential decay of nickel-molybdenum alloys anodized at +500 mV (SCE) for 10 min. [R_S^{100}-surface reactivity measured after 102 min on open circuit.]

The above observations suggest that anodic films formed on the alloys low in Mo differ from those formed on alloys with higher Mo content. The effect of Mo content on the potential of the arrest at ~ -150 mV, the one in common for all the alloys, is summarized by a set of "inverse rate curves" in Fig. 11. It can be seen that the arrest at ~ -150 mV is shifted to a more positive potential for 1% Mo and to more negative potentials for 5, 10, and 15% Mo alloys. The potential decay of 3% Mo alloy occurs very quickly, so that the corresponding potential arrest is relatively poorly resolved (Fig. 6). Open-circuit behavior does not give any indication of the presence of MoO_2 and MoO_3 on the surface (Table IV).

In general the potential of a metal immersed in a conducting solution is that of either a single oxidation-reduction process or of a mixed potential of several redox reactions. In the absence of electrode reactions involving hydrogen or oxygen it may be assumed that the potential of the metal specimen is determined by some redox reaction involving the metal and/or the surface film. The simplest approach is to assume the arrest exhibited on the potential decay curves to be the equilibrium potentials of the surface oxides present (3).

In these studies more than one potential arrest has been observed for both pure nickel and the nickel molybdenum alloys. In addition, an abrupt change of potential appears consistent with the observations on nickel by MacDougall and Cohen (5).

Comparison of the observed arrests with the expected equilibrium potentials (Table IV) shows no correlation with any arrest except for the nickel "spike" at -300 mV, suggesting that the passive film on nickel is NiO. The nature of the other potential

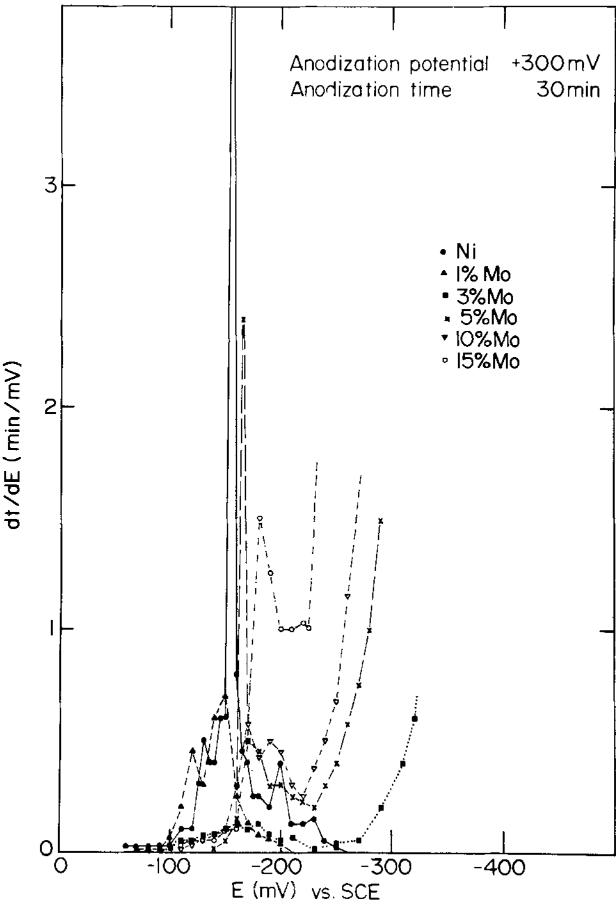

Fig. 11. Inverse rate curves constructed from potential decay data following anodization at +300 mV (SCE) for 30 min.

arrests could have a variety of origins most of which require the concept of defective oxide film. It is most likely that such films have regions of varying defectiveness and/or composition and the corresponding arrest potentials should probably therefore be considered as mixed potentials corresponding to the phases currently reacting with the solution. If the surface is mostly covered with stoichiometric NiO, the defective oxide could control the open-circuit potential if its exchange current were significantly high.

Considering the behavior of anodized nickel one could suppose that each potential arrest corresponds to a particular degree of imperfection of nickel oxide. The difference in potential $\Delta\epsilon$ between the arrest and the Ni/NiO potential would give an estimate of the excess free energy, ΔG, from the simple relationship $\Delta G = 2\mathbf{F}\Delta\epsilon$, where $\mathbf{F} = 96.5$ kC.

NiO is a metal deficit oxide, so that each potential arrest might be thought of as the equilibrium potential of $Ni/(NiO)_{def}$. Defective NiO would be an oxide with a definite concentration of point defects (Ni-vacancies) associated with each potential plateau. The atom fraction of vacancies which could contribute to the observed ΔG range from 0.08 for the arrest at -200 mV to 0.24 for the arrest at -10 mV as shown in Fig. 5. Such large defect concentrations are difficult to rationalize and suggest other causes for some of the observed potential arrests.

It is, however, interesting to note that recent data (11) provide evidence for the influence of oxygen on the position of the lowest potential arrest (-200 mV): it is shifted towards more positive potentials in the presence of oxygen. The defect equation $\frac{1}{2} O_2 \rightarrow O_O^* + V_{Ni}'' + 2h^\circ$ implies that concentration of vacancies increases with increasing oxygen concentration

$$K = \frac{[V_{Ni}''][h^\circ]^2}{P_{O_2}^{1/2}} = \frac{4[V_{Ni}'']^3}{P_{O_2}^{1/2}}$$

where $[V_{Ni}'']$ denotes the concentration of negatively charged nickel vacancies and $[h^\circ]$ the concentration of positive holes in the structure of the nickel oxide. Since

$$[V_{Ni}''] = \frac{1}{2}[h^\circ]$$

then

$$[V_{Ni}''] = \left(\frac{k}{4}\right)^{1/3} P_{O_2}^{1/6}$$

which supports the assumption of nonstoichiometry.

The open-circuit behavior of nickel could also be interpreted in terms of other types of imperfection. The films could be strained or cracked and porous so that the estimated energies, ΔG, could represent strain energy and/or surface energy, but these would be excessive.

The behavior of low Mo alloys might be considered to be a consequence of doping nickel oxide with molybdenum, resulting in a higher concentration of defective sites more susceptible to dissolution. The shift of the arrest potential for 1% Mo alloy to a more positive value would be consistent with this conclusion, since a higher concentration of defects would correspond to a more positive potential arrest. The thermodynamic stabilities of oxides possibly present in the film suggest the existence of Mo-oxides as separate phases rather than as solutions of molybdenum in NiO, after some critical content of Mo is reached (probably between 3 and 5% Mo).

Pozdeeva *et al.* (12) have studied the electrochemical behavior of all the oxides of molybdenum and their results permit one to assume a mixed oxide phase of the type $(Mo^{4+}, Mo^{6+})_xO_y$ which could be present in the films on the higher Mo alloys, due to its much higher thermodynamic stability.

The amount of charge consumed for film formation (Table V) indicates that the steady-state film thickness increases with increased molybdenum content of the alloy, if 100% current efficiency is assumed. This would support the assumption of a Mo enrichment of the film. Tachibana and Ives (10) reported enrichment of the film in Mo on the basis of solution analysis. When the alloy film breaks down, the NiO phase probably dissolves first, leaving a surface covered mostly with a mixed Ni-Mo oxide. The surface reactivity data are in agreement with this conclusion; the films on the 5, 10, and 15% Mo alloys are only slowly removed from the surface, and are much more stable than NiO at longer dissolution times. The fact that surface reactivity for these alloys increases faster than that for Ni for $t < t_s$ and slower at longer times could also indicate that the film on the alloys breaks down much faster at open circuit than does the film on nickel. Once the film breaks down, its removal involves active metal dissolution from oxide-free (or defective) areas and a cathodic reaction, such as hydrogen evolution on the remaining oxide-covered surface. The effect of molybdenum then might be such that (*i*) it increases the polarization associated with the active metal dissolution (by decreasing the exchange current density) which leads to a slower rate of oxide undermining, compared to that on pure nickel after t_s; and/or (*ii*) the cathodic reaction might be slowed down with resulting decrease of metal dissolution and a corresponding lower rate of reactivation after t_s. Moreover, it is possible that the amount of bare surface after the spike is much higher for the alloys and, since the undermining is probably under cathodic control, the surface reactivity should increase more slowly

Any further elucidation of a nature of films formed on nickel and nickel molybdenum alloys in these solutions must now be provided by other than purely electrochemical measurements. To this end, it is planned to perform additional chemical analysis of the solutions following anodic dissolution, and also to initiate studies of the structure and composition of surface films using physical surface analysis techniques.

ABSTRACT

Ellipsometry and Auger electron spectroscopy (AES) were applied in order to elucidate the state and composition of chromium surfaces in deaerated 0.15M H_3PO_4 (pH 1.55), 0.15M NaH_2PO_4 (pH 4.38), and borate (pH 6.48 and 8.42) solutions. The cathodic reduction of chromium at −1.19V (HESS) for 15 min in 0.15M NaH_2PO_4 (pH 4.38) solution gives a good reproducible bare surface whose refractive index N_s is 4.35-4.15*i*. The refractive index of the passive film formed on chromium for 1 hr at constant potential in the passive region is 1.80-(0.0 ∼ 0.20)*i*, independent of the film thickness. In the case of pH 6.48 and 8.42 solutions the film thickness obtained ellipsometrically is in good agreement with that obtained coulometrically. The thickness (0.3 ∼ 2.0 nm) of passive films increases linearly with increasing anodic potential and becomes smaller in the solution of the higher pH. The quantitative Auger analysis reveals that the average composition in depth of the passive film is nearly equal to Cr_2O_3 and that only the uppermost surface is hydrated.

Chromium is the most beneficial alloying element for improving the corrosion resistance of iron-base alloys. Recently surface analytical techniques such as Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS) have revealed that chromium is enriched in passive films formed on stainless steels (1, 2). The high corrosion resistance of stainless steels is mainly attributed to the chromium enrichment in passive films. Numerous studies (3-8) concerning the passivity of chromium have been undertaken in relation to the corrosion resistance of iron-chromium alloys. No clear information, however, has been obtained on the state and composition of chromium surfaces passivated in aqueous solutions.

In the present study, ellipsometry combined with electrochemical measurements was applied to throw light onto the passivation of chromium surfaces in aqueous solutions. Furthermore, the chromium surfaces after passivation were quantitatively analyzed by means of AES and ellipsometry.

Experimental

Specimen and electrolyte solution.—A zone-refined polycrystalline chromium lump (purity > 99.9%) was machined to plates (0.2 × 1.0 × 2.0 cm), vacuum annealed for 30 min at 873°K, and cooled gradually to room temperature. Further, the specimen was polished with emery paper, finally polished with α-Al_2O_3 abrasives (0.05 μm), and washed with a mixture of methanol and acetone using an ultrasonic technique. The electrolyte solutions used were 0.15M H_3PO_4 (pH 1.55), 0.15M NaH_2PO_4 (pH 4.38), and boric acid-sodium borate (pH 6.48 and 8.42) solutions, which were completely deaerated in solution reservoirs by purified nitrogen gas before introduction into an electrolytic cell.

* Electrochemical Society Active Member.

Key words: ellipsometry, Auger analysis, passive film, chromium.

Ellipsometry and electrochemical measurement.—The ellipsometer used was of the horizontal type with a compensator placed on the side of incident beam and a mercury arc lamp (546.1 nm) with an interference filter as a light source. An electrolytic cell with two optical-glass windows was used for simultaneous measurements of ellipsometry and electrochemical polarization. The details of ellipsometer and electrolytic cell are described elsewhere (9). The specimen in the cell was first cathodically reduced in different electrolyte solutions to obtain a bare surface which was used as an optical reference plane. After cathodic reduction, the electrolyte solution was renewed and the specimen was passivated potentiostatically at a desired anodic potential for 1 hr. The ellipsometric and coulometric measurements were simultaneously conducted with respect to the passivated surfaces of the specimen. The amount of chromium ion dissolved into the electrolyte solutions during cathodic reduction and passivation of the specimen was measured by colorimetry (diphenylcarbazide method). The measurements were carried out at a constant temperature of 298° ± 0.1°K. The electrode potential of the specimen was referred to a hydrogen electrode in the same solution (HESS).

AES measurement.—After passivation, the specimen was rapidly washed with doubly distilled water and dried with a jet of nitrogen gas. The specimen was set on a sample holder in the Auger chamber (PHI, 540A), which was evacuated to a vacuum better than 2.7 × 10^{-7} Pa, and then Auger spectra of the specimen surface were taken by using a primary electron beam (2 kV, 40 μA) with a diameter of about 50 μm and a modulation amplitude of 4V at a frequency of 30 kHz.

Results and Discussion

Cathodic reduction of chromium in strongly acidic solutions (6, 10) has frequently been employed to ob-

tain a bare surface without films. This procedure, however, gives rise to a significant dissolution of chromium substrate producing a rough surface which is not suitable for ellipsometer measurements. In the present study, therefore, potentiostatic cathodic reduction of the specimen in 0.15M NaH_2PO_4 (pH 4.38) solution was tentatively conducted to obtain an optically flat surface without films. It was eventually found that potentiostatic cathodic reduction of the specimen at −1.19V (HESS) for 15 min in 0.15M NaH_2PO_4 (pH 4.38) gave a good reproducible surface without films.

Figure 1 shows the measured values of two ellipsometer reading, P and A for a number of specimens cathodically reduced at −1.19V (HESS) for 15 min in 0.15M NaH_2PO_4 (pH 4.38) solution. In Fig. 1, the computed P-A grid for a bare substrate of varied refractive indexes ($N = n - ik$) is superimposed on the measured values. It appears that all the experimental P-A values are located within a limited region of the computed grid with n ranging from 4.2 to 4.5 and k from 4.0 to 4.4. An average value of complex refractive index N_s for the cathodically reduced chromium surface, is determined to be $N_s = 4.35 - 4.15i$, which is in good agreement with that ($N_s = 4.17 - 5.19i$) obtained by Genshaw and Sirohi (10).

Anodic oxidation of chromium.—The stationary anodic polarization curves of chromium obtained after 1 hr of anodic oxidation at constant potential in 0.15M H_3PO_4 (pH 1.55), 0.15M NaH_2PO_4 (pH 4.38), and boric acid-sodium borate (pH 6.48 and 8.42) solutions are shown in Fig. 2. The transpassive dissolution of chromium proceeds at anodic potentials higher than 1.10V (HESS) in all solutions studied. The total amount of electric charge passed Q_T($C \cdot m^{-2}$) and the amount of chromium dissolved into the solutions W_D($mg \cdot m^{-2}$) during 1 hr of anodic oxidation are plotted *vs.* anodic potential E_{HESS} in Fig. 3. The value of W_D in the passive region is negligibly small so that Q_T in the passive region is equal to the amount of electric charge required for film formation Q_F. The results in Fig. 3 indicate that the thickness of the passive film increases linearly with increasing anodic potential.

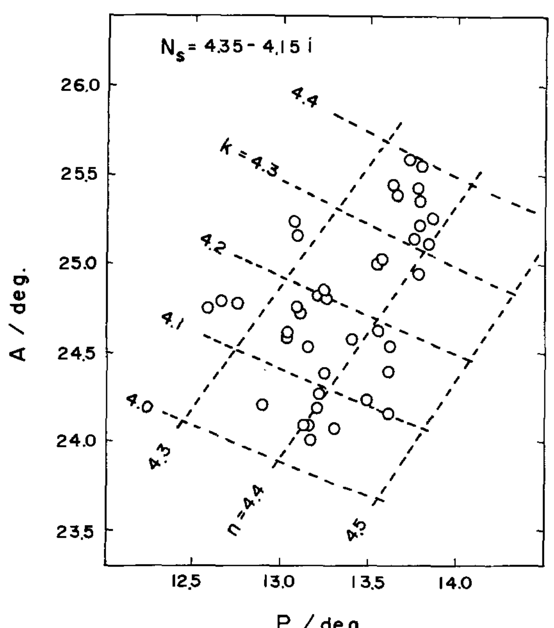

Fig. 1. Two ellipsometer readings, *P* and *A*, experimentally obtained for a number of chromium surfaces cathodicaly reduced at −1.19V (HESS) for 15 min in 0.15M NaH_2PO_4 (pH 4.38) solution. Dashed lines show a computed *P-A* grid for a bare substrate of various refractive indexes ($N_s = n - ik$).

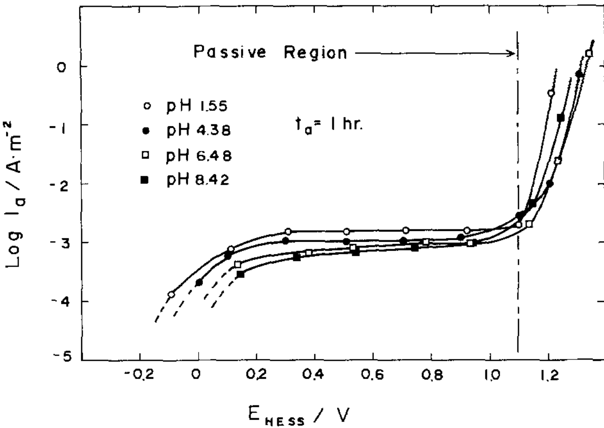

Fig. 2. Stationary anodic polarization curves of chromium obtained after 1 hr of anodic oxidation at constant potential in 0.15M H_3PO_4 (pH 1.55), 0.15M NaH_2PO_4 (pH 4.38), and boric acid-sodium borate (pH 6.48 and 8.42) solutions.

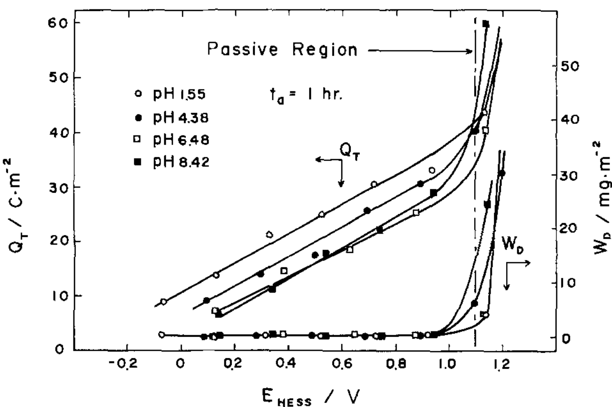

Fig. 3. Total amount of electric charge passed Q_T and amount of chromium dissolved into solutions W_D duriing 1 hr of anodic oxidation at constant potential E_{HESS}.

Figure 4 shows the pair-values of P and A observed after 1 hr oxidation at constant potential, the values being referred to P_o and A_o of the bare chromium surface. From a linear relationship observed between δP and δA in the passive region, it is suggested that the passive film on chromium consists of a single layer, the refractive index of which is constant, independent of potential (and hence of thickness), although slightly dependent on the solution pH. Theoretical computation for a film having a constant refractive index and increasing thickness leads to a linear re-

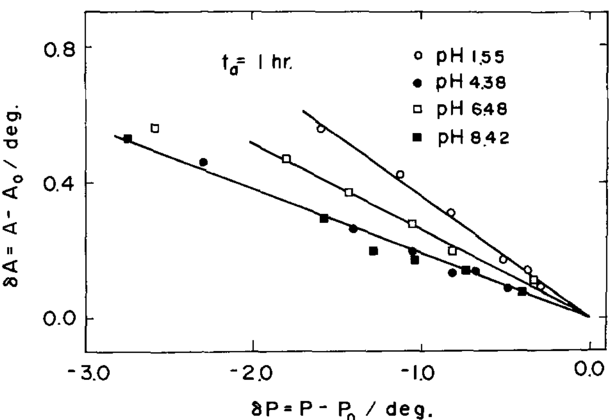

Fig. 4. Two ellipsometer readings *P* and *A* observed for chromium surfaces passivated at constant potential for 1 hr in solutions of different pH values, δP and δA being referred to P_o and A_o for the bare surface.

lationship between δP and δA. The refractive index of the passive film can be evaluated by comparing the experimental values of δP and δA for a growing film with the computed values for various refractive indexes and thicknesses. The refractive indexes ($N_f = n - ik$) of the passive films thus obtained, are $1.80 - 0.0i$ for the solution of pH 1.55, $1.80 - 0.15i$ for the solution of pH 6.48, and $1.80-0.20i$ for the solutions of pH 4.38 and 8.42.

Once the refractive index of the film is determined, the film thickness L_f can be computed as a function of either δP or δA. Figure 5 shows the film thickness computed as a function of δP for surface films on chromium with three different refractive indexes. The film thickness for certain experimental values of δP in Fig. 4 can be obtained from the relation between L_f and δP shown in Fig. 5. The thickness thus obtained for the passive film formed on chromium is plotted as a function of anodic potential in Fig. 6. Figure 7 shows the film thickness calculated coulometrically from the values of Q_F in Fig. 3, assuming that the passive film consists of Cr_2O_3. In the case of pH 6.48 and 8.42 solutions, the film thickness obtained ellipsometrically is in good agreement with that obtained coulometrically. In the case of pH 1.55 and 4.38 solutions, the agreement between the film thickness obtained ellipsometrically and coulometrically is not satisfactory probably because of the surface roughening in acid solution.

Composition of passive film.—Figure 8 shows the Auger spectra of chromium anodically oxidized at +0.71V (HESS) for 1 hr in 0.15M NaH_2PO_4 (pH 4.38) solution. The Auger peaks of P (120 eV) and C (272 eV) as well as the main peaks of Cr (529 eV) and O (510 eV) were observed for the passivated chromium surface. For the quantitative analysis of the passive film on chromium, it is necessary to separate the pure Auger peak of Cr (529 eV) from the overlapped peaks of Cr (529 eV) and O (510 eV). In the present study, separation of the pure Auger peak of Cr (529 eV) was accomplished by subtracting the pure Auger peak of O (510 eV), observed with an Fe_2O_3 film on iron, from the overlapped peaks of Cr (529 eV) and O (510 eV), assuming that the shape of O (510 eV) peak is the same for both Fe_2O_3 and Cr_2O_3 films. The justification of this method has been verified by Frankenthal and Thompson (11). The Auger peak-to-peak height ratio of O (510 eV) to Cr (529 eV), H_O/H_{Cr}, thus obtained is plotted *vs.* the film thickness obtained ellipsometrically in Fig. 9. The value of H_O/H_{Cr} increases with increasing film thickness.

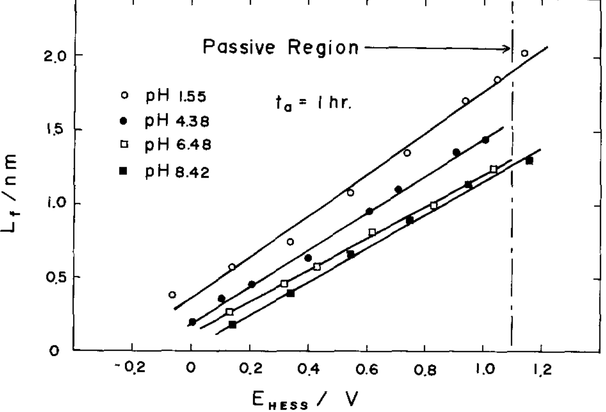

Fig. 6. Film thickness L_f obtained ellipsometrically as a function of anodic potential E_{HESS}.

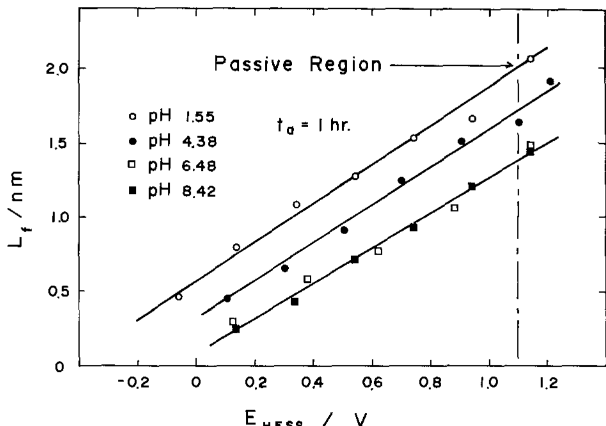

Fig. 7. Film thickness L_f obtained coulometrically as a function of anodic potential E_{HESS}.

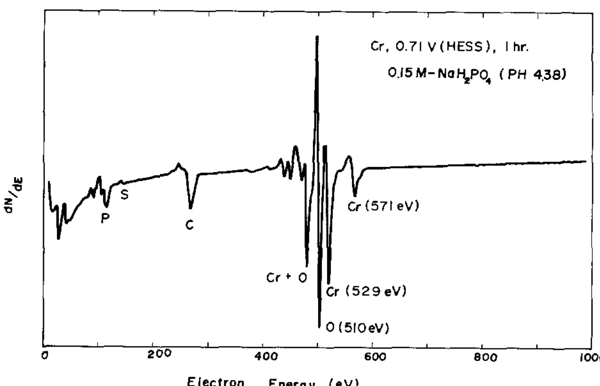

Fig. 8. Auger spectra of chromium anodically oxidized at +0.71V (HESS) for 1 hr in 0.15M NaH_2PO_4 (pH 4.38) solution.

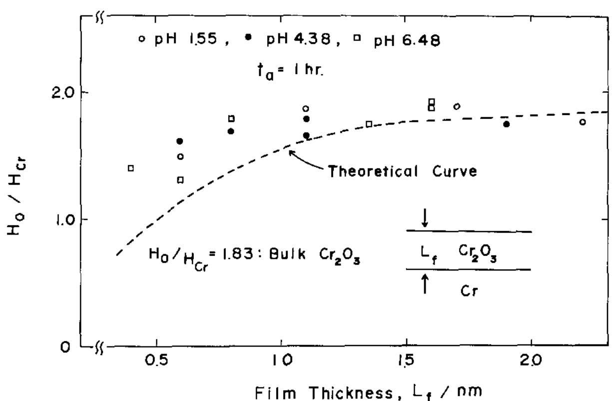

Fig. 9. Auger peak to peak height ratio H_O/H_{Cr} vs. film thickness L_f obtained ellipsometrically. Dashed line shows a theoretical curve for a single layer of Cr_2O_3.

For determination of the composition of passive films from the value of H_O/H_{Cr}, the contribution of chromium substrate for the total Auger peak-to-peak height of chromium must be taken into account, because the escape depth (0.8 nm) of Auger electrons of Cr (529 eV) is the same order of magnitude as the film thickness. The Auger peak-to-peak heights of Cr (529 eV) and O (510 eV), H_{Cr} and H_O, are given by

$$H_{Cr} = \alpha_{Cr} n_{Cr}^f \sum_{i=1}^{i=l} e^{-k(i-1)d} + \alpha_{Cr} n_{Cr}^b \sum_{i=l+1}^{i=\infty} e^{-k(i-1)d} \quad [1]$$

$$H_O = \alpha_O n_O^f \sum_{i=1}^{i=l} e^{-k(i-1)d} \quad [2]$$

where α_{Cr} and α_O are the sensitivity coefficients of chromium and oxygen atoms, n_{Cr}^f and n_O^f the atomic densities of chromium and oxygen in the passive film, n_{Cr}^b the atomic density of chromium in the substrate, l the number of surface atomic layers in the passive film, d the thickness of surface monolayer, and k the attenuation coefficient per unit length of Auger electrons of chromium or oxygen. In Eq. [1] and [2], it is assumed that both n_{Cr}^f and n_O^f are uniform in depth up to the film/substrate interface. Further, the attenuation coefficient k is given (12) by

$$k = \frac{1}{\lambda_I \cos\theta_1} + \frac{1}{\lambda_p \cos\theta_2} \quad [3]$$

where λ_I is the escape depth of Auger electrons of chromium or oxygen λ_p the mean free path of primary electron in the specimen, θ_1 the acceptance angle of Auger electrons in the CMA, and θ_2 the incidence angle of primary electrons to the specimen measured from the normal direction. As previously reported elsewhere (13), the value of k was determined as 2.36 nm^{-1} by substituting the reasonable values of $\lambda_{Cr} = \lambda_O = 0.8$ nm, $\lambda_p = 3.0$ nm, $\theta_1 = 42°$, and $\theta_2 = 60°$ into Eq. [3]. The sensitivity coefficient ratio of oxygen to chromium α_O/α_{Cr} was determined as 1.22 from the Auger results (14) of an α-Cr_2O_3 film which was prepared by dry oxidation of chromium in the air for 15 min at 873°K. Assuming that the passive film on chromium consists of Cr_2O_3 and that the monolayer thickness is 0.3 nm (13), the values of $d = 0.3$ nm, $n_O^f/n_{Cr}^f = 1.5$ and $n_{Cr}^f/n_{Cr}^b = 0.5$ are obtained for the calculation of H_O/H_{Cr} as a function of film thickness, using Eq. [1] and [2].

The dashed curve in Fig. 9 shows the relation between the value of H_O/H_{Cr} thus calculated and the film thickness. The experimental value of H_O/H_{Cr} exceeds slightly the theoretical curve of Cr_2O_3 (dashed curve), revealing that the average composition of passive film in depth is nearly equal to Cr_2O_3. The deviation of experimental value from the theoretical curve, however, increases with decreasing film thickness. The XPS study (15) by Bouyssoux *et al.* showed that only the uppermost surface of the passive film on chromium is hydrated. The increasing deviation of the experimental value of H_O/H_{Cr} from the theoretical curve with decreasing film thickness can be attributed to the presence of a hydrated layer localized in the uppermost part of the surface film. The results of quantitative Auger analysis for the passive films on chromium are consistent with those obtained by ellipsometry and coulometry.

Conclusion

Ellipsometry combined with electrochemical measurements was applied to elucidate the state and composition of chromium surfaces passivated in deaerated 0.15M H_3PO_4 (pH 1.55, 0.15M NaH_2PO_4 (pH 4.38), and boric acid-sodium borate (pH 6.48 and 8.42) solutions. Furthermore, quantitative Auger analysis was performed on the chromium surfaces after 1 hr passivation, by taking the escape depth of Auger electrons and the film thickness obtained ellipsometrically into account. The following conclusions were drawn:

1. The cathodic reduction of chromium at −1.19V (HESS) for 15 min in 0.15M NaH_2PO_4 (pH 4.38) solution gives a good reproducible bare surface whose refractive index N_s is 4.35-4.15i.
2. The refractive index N_f of the passive film formed on chromium for 1 hr at constant potential in the passive region is 1.80-(0.0 ∼ 0.20)i, independent of the film thickness. In the case of pH 6.48 and 8.42 solutions, the film thickness obtained ellipsometrically is in good agreement with that obtained coulometrically, assuming that the passive film consists of a single layer of Cr_2O_3.
3. The thickness (0.3-2.0 nm) of passive films increases linearly with increasing anodic potential. The thickness of passive film formed at the same anodic potential (HESS) becomes smaller in the solution of the higher pH.
4. The Auger analysis reveals that the average composition in depth of the passive film is nearly equal to Cr_2O_3 and that only the uppermost surface is hydrated.

ABSTRACT

The $Pb\text{-}H_2O\text{-}SO_4$ Pourbaix diagram was investigated by examining potentiostatically oxidized lead samples using Raman and infrared spectroscopy. In 0.1M sulfate solutions surface film compositions were not in complete agreement with predictions of the calculated potential-pH diagram. The Pourbaix diagram did not predict the formation of PbO under any conditions; however, spectra indicated the presence of the oxide at certain potentials in acid and neutral solutions and at all potentials above the immunity region in basic solutions. Spectroscopic identification of insoluble surface species was in agreement with potentiodynamic polarization curves.

Laser Raman spectroscopy can unambiguously identify the compounds present in aqueous corrosion product films on metal surfaces. It can be used to analyze insoluble surface layers *in situ* without removing a metal sample from the corrosive solution with which it is reacting (1-3). The ability to identify surface species without changing the environment makes this technique ideal for experimental confirmation of theoretical Pourbaix diagrams, which identify the lowest energy species for any given set of conditions.

In situ Raman spectroscopy, in combination with the complementary technique, reflection-absorption infrared spectroscopy, has been used to study the Pourbaix diagrams for the $Pb\text{-}H_2O$ and $Pb\text{-}H_2O\text{-}Cl$ systems (1, 2). Potentiostatic exposures of lead electrodes were conducted in buffer solutions and the resulting surface films were analyzed spectroscopically. The compounds comprising the surface corrosion product films were only in partial agreement with Pourbaix diagram predictions, and reasons for these differences were discussed. In the present research simple, unbuffered solutions were used for electrochemical exposures to find if experimental results would be closer to those predicted by thermodynamics if the solutions did not contain the extra dissolved species of the buffer systems used previously.

The behavior of lead in sulfate solutions has been studied extensively due to the widespread use of lead-acid storage batteries. For this reason, the preponderance of experimental work has involved the reactions of lead with sulfuric acid, and very little research on lead in neutral or basic sulfate solutions has been conducted. Pourbaix diagrams for lead in aqueous sulfate solutions have been calculated (4-6). Some efforts have been made to verify the theoretical predictions experimentally, although experimental sulfate exposures have been confined to the acid and neutral regions of the diagram (4, 7). The present report describes infrared and Raman spectroscopic results from systematic exposure of lead samples in 0.1M sulfate solutions under conditions covering a large part of the Pourbaix diagram.

Experimental

Raman spectra were recorded with a Spex Industries Model 1401 double monochromator using a photon counting detection system. A Coherent Radiation Laboratories Model CR-3 argon ion laser was used as the excitation source. Both the 488.0 and 514.5 nm wavelength laser lines were used. Additional details are contained in previous reports (1-2).

Infrared reflection-absorption spectra were obtained with a Wilks Scientific Corporation Model 9 multiple specular reflection attachment in both the sample and reference beams of Perkin-Elmer Model 521 infrared spectrophotometer equipped with a grating polarizer. Details of the special electrochemical cell and instrumentation used for controlled potential sample exposures are contained in a previous report (1).

Lead foil (1.6 mm thick) supplied by Alfa Products, Incorporated, at greater than 99% purity was used for this investigation. It was cut into 2.8 × 5.7 cm rectangles to fit the sample holder of the electrochemical cell. This size was also required for the infrared reflection attachment. Prior to placing a lead sample in solution, it was immersed in warm, concentrated ammonium acetate solution for 5 min to dissolve the surface layer, leaving a clean, silvery sample. The clean lead sample was washed with distilled water and immediately placed in the exposure solution.

The three solutions used were made from reagent grade compounds. The acid solution was 0.1M H_2SO_4. The neutral solution chosen was 0.1M K_2SO_4 which has a pH of approximately 6.5, and for exposure in basic solution, a solution of 0.1M K_2SO_4 and 0.004M KOH, giving an approximate pH of 11, was used.

The electrochemical cell filled with solution was purged with dry nitrogen for 30 min before and throughout the controlled potential exposures. The potential of the lead working electrode was held constant relative to the saturated calomel reference electrode by a Wenking Model LT73 potentiostat for periods ranging from ¼ to 21 hr. Upon completion of an exposure period, an *in situ* Raman spectrum was recorded. The sample was then removed from the cell, washed thoroughly with distilled water, and allowed to dry in air. The dry sample was returned to the Raman spectrometer for examination and then analyzed by the infrared spectrophotometer.

Some exposures were conducted on lead films which were vapor deposited onto gold substrates on glass microscope slides. These samples allowed the lead to be completely oxidized leaving a nonreacted gold mirror substrate. The approximate thickness of oxidized lead films on such samples was measured by a Talystep-1 stylus-type profile instrument.

Results and Discussion

The Pourbaix diagram for the lead-water-sulfate system was calculated using the relationships used by Ruetschi and Angstadt (4) but employing more recent values for the free energy of formation of some species (8). The newer thermodynamic data, summarized in Table I, caused only small changes in the positions of the $PbO \cdot PbSO_4$ equilibria lines. A sulfate ion activity of 0.1 was used for the calculations resulting in the Pourbaix diagram shown in Fig. 1.

Electrochemical exposures were carried out in solutions of the desired *p*H which were 0.1M in sulfate. The solutions used gave *p*H values of approximately 1, 6.5, and 11 to allow observation of the reactions of lead over a wide portion of the Pourbaix diagram. Measurement of solution *p*H before and after potentiostatic exposures showed that the *p*H remained fairly constant, *i.e.*, it did not change by more than 0.6 after as long as 24 hr.

In order to provide an experimental basis for choosing exposure potentials, potentiodynamic polarization curves were recorded for lead in the three solutions selected for exposures. Polarization curves were recorded with a relatively slowly changing potential of 40 mV/min to allow the formation of a relatively thick oxidation product film, as would be encountered in potentiostatic oxidation.

The polarization curves are shown in Fig. 2. They are rather similar, each has a strong wave at approximately −0.25V (*vs.* NHE) as its major feature. These waves mark the transition from reduction to oxidation, *i.e.*, the upper limit of the immunity region. In accordance with the Pourbaix diagram, the potential of such a transition decreases as *p*H increases. The oxidative wave was observed at −0.23V in *p*H 1, −0.27V in *p*H 6.5, and −0.30V in *p*H 11 solution. The positions of these waves are in general agreement with the Pb to $PbSO_4$ and Pb to $PbO \cdot PbSO_4$ transitions of the Pourbaix diagram.

Table I. Free energy data used to calculate the lead-water-sulfate Pourbaix diagram

Species	Standard free energy of formation (cal/mole)	
	NBS (8)	Ruetschi and Angstadt (4)
SO_4^{2-}	−177,970	−177,340
HSO_4^-	−180,690	−179,940
H_2O	−56,690	−56,690
Pb_3O_4	−143,700	−147,600
Pb_2O_3	−98,417	−98,417
α-PbO_2	−51,940	−51,940
β-PbO_2	−52,340	−52,340
$PbSO_4$	−194,360	−193,890
$PbO \cdot PbSO_4$	−246,700	−243,200
$3PbO \cdot PbSO_4 \cdot H_2O$	−397,300	−397,300
$5PbO \cdot 2H_2O$	−336,350	−336,350
PbO	−45,050	−45,050

Potentials used for lead exposures were chosen so that at least one was located in each region of the theoretical Pourbaix diagram and in all potential regions where the polarization curves indicated the possible formation of different species. The exposure conditions selected and the resulting spectra obtained from these potentiostatic oxidations are summarized in Table II.

pH 1 exposures.—In the 0.1M H_2SO_4 solutions used to attain acidic conditions, lead is stable at low potentials, but it is oxidized to lead sulfate at higher potentials (4, 9, 10). After formation of a surface sulfate film thick enough to hinder reactions of lead with solution species, layers of PbO or basic lead sulfates develop under the sulfate film at potentials of +0.32V and higher (4, 9, 11). Although the formation of underlying oxide layers was not considered in the calculation of the Pourbaix diagram, the very weak wave at +0.34V on the *p*H 1 polarization curve may indicate the commencement of formation of another compound beneath the sulfate film.

Potentiostatic exposures of lead in 0.1M sulfuric acid formed surface films whose compositions agreed well with x-ray diffraction work by Pavlov and

Iordanov (11). Raman and infrared spectroscopic results indicate three ranges of potential: immunity, lead sulfate, and a lead sulfate-lead monoxide region.

At potentials below −0.26V, lead appeared to be immune to oxidation. An insoluble surface layer was not detected by *in situ* Raman spectroscopy, samples remained clean and shiny, and current flow was in the reducing direction. Previous reports show the lack of Raman spectra for PbO (1, 2). Thus if PbO were formed on the surface, none could be detected by *in situ* Raman spectroscopy. When samples exposed in this region were washed and allowed to dry, a nonuniform, light gray surface coating appeared. Infrared spectra identified the surface layer composition as lead sulfate and orthorhombic PbO. Raman spectra of dry sample surfaces confirmed this finding but showed that the sulfate and oxide were not found together but were occupying separate parts of the sample surface. The appearance of these compounds probably results from precipitation of dissolved lead compounds after removal of the applied potential (2). In the generally reducing conditions of this region, it is unlikely that any lead would be directly oxidized at the electrode surface during the potentiostatic exposure. The formation of PbO and lead sulfate is probably a result of the sample removal, washing, and drying process.

At potentials higher than the −0.23V wave of the polarization curve, net current flow was in the oxidizing direction and spectra showed that lead sulfate was formed. Oxidation at −0.26 and −0.02V resulted in $PbSO_4$ films.

Exposure at potentials higher than the wave at +0.34V gave surface films identified as tetragonal PbO and $PbSO_4$, in agreement with the findings of earlier research (11, 12). A Raman spectrum of the film in this potential region is compared with one of a purely $PbSO_4$ film and with the spectrum of reagent grade $PbSO_4$ powder in Fig. 3.

It was not possible to measure the relative amounts of PbO and $PbSO_4$ in the surface films from their spectra; just as it is impossible to measure film thickness. However, observation of strong tetragonal PbO spectra gave an indication of the thickness of films analyzed by these techniques. Ruetschi (9) developed a model for the $PbO/PbSO_4$ two-phase film formed by oxidation of lead in sulfuric acid solutions. He assumed that a surface film with a thickness on the order of a micron was needed before any underlying tetragonal PbO could form (4). Electrochemical measurements and calculations based on ion diffusivity in the films determined that a 24 hr exposure of lead in 4.2M H_2SO_4 in the range of +0.2-+1.1V would give a film consisting of 1 micron of lead sulfate covering 1 micron of tetragonal PbO. The ability to record strong spectra of the underlying layer of PbO gives indication that Raman and infrared spectroscopy can examine the entirety of films with thicknesses on the order of a micron.

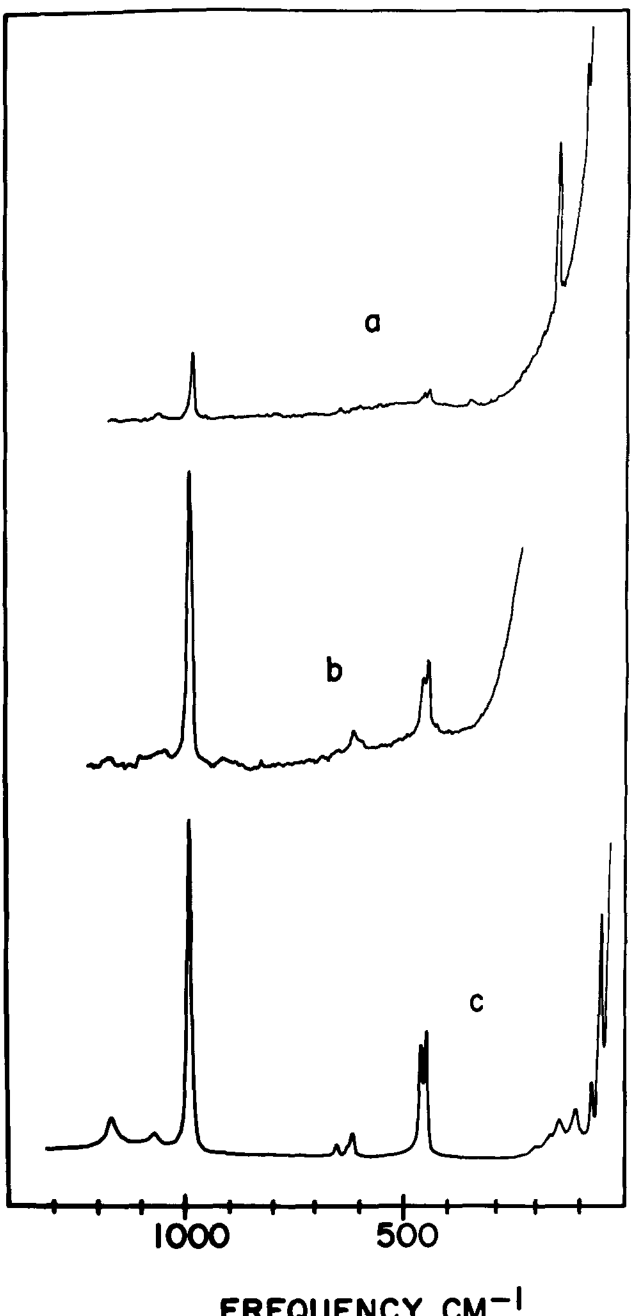

Fig. 3. Raman spectra of (a) lead in 0.1M H_2SO_4 after 20 hr at +0.80V, (b) lead in 0.1M H_2SO_4 after 18 hr at −0.26V, (c) $PbSO_4$ powder.

pH 6.5 exposures.—The lead-water-sulfate Pourbaix diagram predicts that in a pH 6.5, 0.1M sulfate solution lead should be stable at potentials below −0.3V, PbO_2 should form above +0.9V, and $PbSO_4$ should be found at potentials in between. The lower transition was observed in the polarization curve for lead in the 0.1M K_2SO_4 solution used, but the transition to PbO_2 was not observed. The polarization curve shows a weak wave at +0.06V which does not correspond to any feature of the Pourbaix diagram.

Potentiostatic exposures resulted in films with compositions which were in better agreement with the polarization curve than with the Pourbaix diagram. Exposure at potentials below the −0.27V wave resulted in immunity. Current flow was in the reducing direction, the surface remained clean and shiny, and no spectra were obtained in solution or in air. Higher potentials resulted in oxidation of the lead electrode and formation of insoluble surface films. Films consisted of lead sulfate up to +0.24V and, above that, tetragonal PbO covered the sample surfaces.

The formation of lead sulfate was in agreement with the Pourbaix diagram, but the $PbSO_4$ gave slightly different spectra from the sulfates examined previously. As shown in Fig. 4, the sulfate film gave an exceptionally strong 451 cm^{-1} Raman band, the band associated with the O-S-O bending vibration (13). Infrared reflection spectra also had a sharp band at 451 cm^{-1} as shown in Fig. 5. Such a vibration is not infrared active in normal sulfate compounds. The unusual intensity of the 451 cm^{-1} band is assumed to be due to a distortion of the normal lead sulfate lattice.

The broad wave at +0.06V is near the potential where film composition changed from lead sulfate to tetragonal PbO, and it may be due to such a transition. Lead monoxide films were black in color and gave no evidence of the presence of sulfate. The transition from sulfate to PbO was not considered in cal-

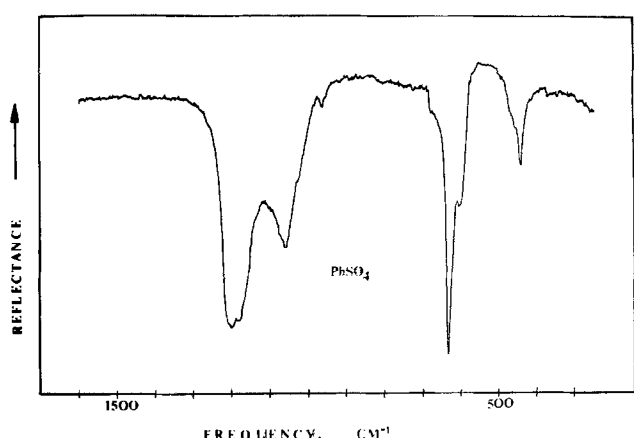

Fig. 5. Infrared reflection spectra obtained from lead exposed in 0.1M sulfuric acid, pH = 0.9, at 0.80V NHE for 20.5 hr (a) parallel polarization, (b) perpendicular polarization.

culating the Pourbaix diagram, since this reaction was not anticipated. No waves were observed at higher potentials and spectra did not indicate a change to the PbO_2 predicted by the Pourbaix diagram.

pH 11 exposures.—Oxidation of lead at a pH of 11 was predicted to form a basic lead sulfate, $PbO \cdot PbSO_4$, at potentials between −0.45 and +0.50V and PbO_2 at higher potentials. The solution used, 0.1M K_2SO_4 with enough KOH added to make the initial pH 11, resulted in a polarization curve with only one clear oxidation feature. The experimentally observed wave, or group of waves, at approximately −0.30V represents the transition from lead stability to the formation of an oxidized species. The oxidative change seen above +0.80V in Fig. 2 could represent a transition to a higher oxidation state, but it is probably due to the decomposition of water to evolve oxygen.

Potentiostatic exposures were conducted throughout the potential range where water is stable. As expected, exposure at low potentials gave extremely low current flow in the reducing direction, and no Raman bands were observed. Lead is immune to oxidation below the −0.30V wave of the polarization curve.

All exposures at higher potentials resulted in the formation of tetragonal PbO surface films. An oxidation at −0.34V, a potential higher than the first lobe of the oxidative wave, resulted in a film which gave a strong tetragonal PbO spectrum. Although the wave at −0.30V seems to be made up of three separate waves, all exposures at potentials above −0.45V, where the current recorded in the polarization curve first became oxidative, formed tetragonal PbO.

Although the composition of the films was identified as PbO, Raman spectra recorded in solution were somewhat misleading. *In situ* spectra, as shown in Fig. 6, contained the strong bands of tetragonal PbO but also the 980 cm^{-1} band characteristic of the SO_4 symmetric stretching vibration and a broad band in the 450 cm^{-1} region. Except for the broadness of the 450 cm^{-1} band, these spectra look like a mixture of PbO and $PbSO_4$. Upon washing the samples thoroughly, however, those bands characteristic of sulfate disappeared. Dry sample spectra indicated only tetragonal PbO. The sulfate bands, which can be distinguished from those of $PbSO_4$ by the broad 450 cm^{-1} band (lead sulfate has two sharp bands in that region, at 439 and 451 cm^{-1}), are due to the sulfate of the solution. The bulk sulfate solution gave the same sulfate spectrum. The change in the spectrum caused by washing the samples was evidence that spectra of both wet

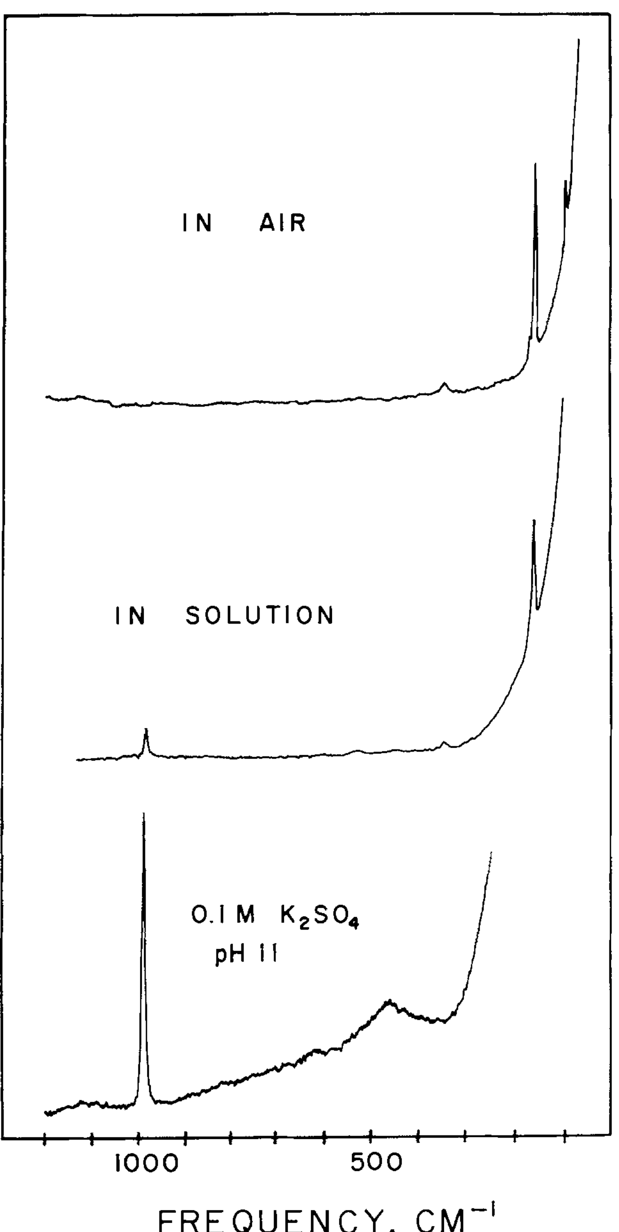

Fig. 6. Raman spectra of lead exposed to pH 11, 0.1M sulfate solution for 18.5 hr at −0.34V recorded with the sample in solution and, after washing, in air; and the Raman spectrum of the pH 11, 0.1M sulfate solution.

and dry samples are needed to distinguish solution or adsorbed species from those compounds which were actually part of an insoluble surface film.

The possibility that the surface layer might consist of $PbO \cdot PbSO_4$ as predicted by the Pourbaix diagram calculations was investigated. Although spectra of the sample surfaces identified tetragonal PbO, Raman spectra of the basic sulfate are not available for comparison. Infrared reflection spectra confirmed that tetragonal PbO was the compound present. Comparison with published infrared spectra of $PbO \cdot PbSO_4$ (14) indicated that this compound was not present.

The oxidation currents recorded during potentiostatic exposures and potentiodynamic polarization curve measurements confirmed that lead sulfate forms more protective surface films than does PbO. In 0.1M sulfate solutions, all of which had approximately the same conductivity and ionic strength, conditions which caused the formation of PbO resulted in net current flow 5-10 times greater than that observed when $PbSO_4$ was formed. The smallest differences were noted in pH 6.5 exposures, a pH near the minimum of PbO solubility (15), but even in those conditions oxide films allowed measurably higher current flow than sulfate films. The ability of sulfates to form an insoluble, passivating film on lead is well known.

Film thickness.—Potentiostatic oxidation of vapor-deposited lead samples was conducted so that the thickness of the resulting films could be measured and their spectra recorded. While films of organic compounds on silver mirrors have shown that Raman spectra of films as thin as 50Å can be recorded (16, 17) and infrared spectra of oxide layers as thin as 10Å have been reported (18), the minimum detectable film thickness varies widely with the composition of a thin film.

A lead sulfate film, measured to be 2140 ± 60Å thick, was formed by oxidation at +0.80V in 0.1M H_2SO_4 for 15 min. The Raman spectrum in Fig. 7 shows that the strong sulfate bands are clearly visible. The infrared spectrum of the same sample, shown in Fig. 8, is an excellent lead sulfate spectrum. Exposure of solid lead electrodes under identical conditions formed a film which consisted of both $PbSO_4$ and tetragonal PbO, but the vapor-deposited sample showed no trace of PbO. Presumably the thin sulfate film was not thick enough to provide the diffusion barrier necessary to allow formation of an underlying PbO layer (19).

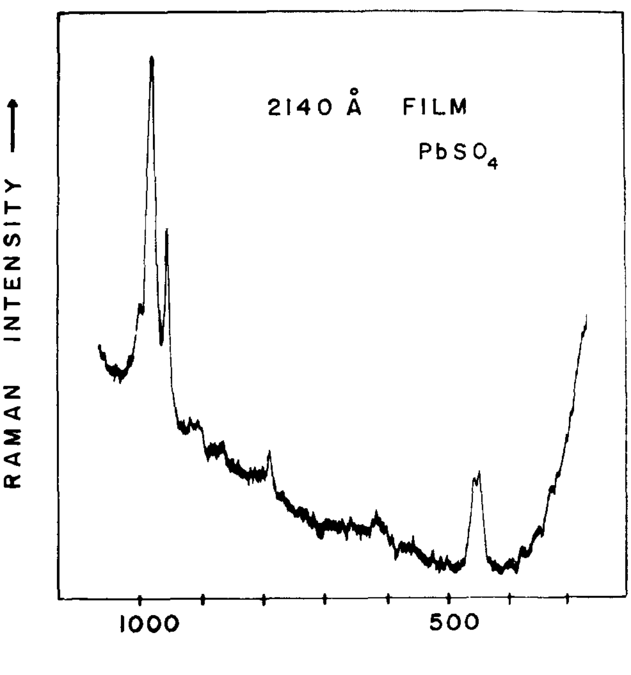

Fig. 7. Raman spectrum of a 2140Å thick film of $PbSO_4$ made from a vapor-deposited lead sample by exposure at +0.80V for 15 min in 0.1M H_2SO_4. The features at 790 and 920 cm^{-1} are grating ghosts.

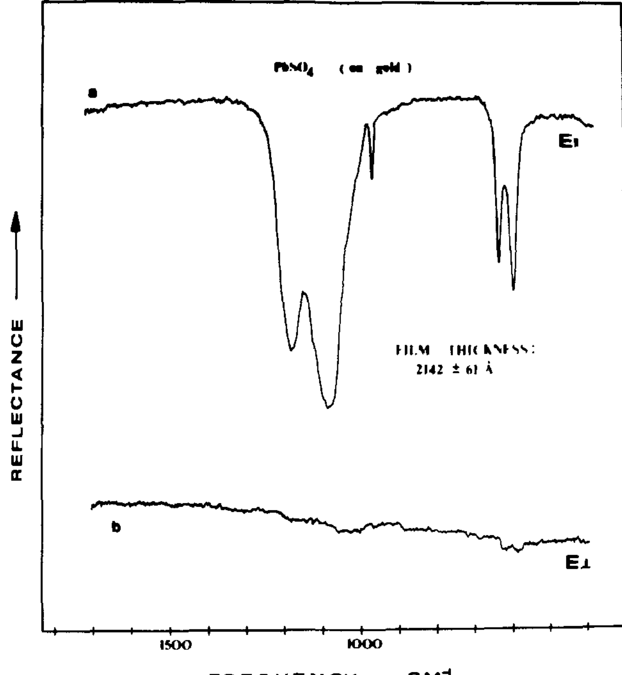

Fig. 8. Infrared reflection-absorption spectra of a 2140Å thick $PbSO_4$ film made from a vapor-deposited lead sample. The two spectra were recorded with two different polarizations of the infrared beam. For thin films only light with its electric vector parallel to the plane of incidence interacts with the surface species.

It is estimated that a lead sulfate film approximately one-tenth of the 2140Å thickness would still give spectra with signal to noise ratios of two or more, the ratio considered necessary for observation of a band. Films as thin as 200Å should be identifiable by Raman and infrared spectroscopy with very little difficulty. Single spectrometer scans were used to record all spectra. Greater sensitivity to very thin films could be achieved by averaging the results of multiple scans. Signal averaging of more than one scan of the spectral region of interest would increase the signal to noise ratio observed and reduce the minimum detectable thickness (20).

Conclusions

In situ Raman spectroscopy and reflection-absorption infrared spectroscopy can conclusively identify the compounds present in thin corrosion product films on metal surfaces. Using these techniques, the Pourbaix diagram for lead in 0.1M sulfate solutions was examined and the surface species observed showed only partial agreement with predictions based on thermodynamic equilibria. Spectroscopic analysis of surface films during and after potentiostatic exposure in sulfate solutions was in excellent agreement with potentiodynamic polarization curves but the oxides and sulfates frequently formed were not those predicted in the Pourbaix diagram. The major difference was that tetragonal PbO was found experimentally in neutral and basic solutions and $PbO \cdot PbSO_4$, the compound predicted to be stable under such conditions, was not.

It has been shown that spectra of sample surfaces in solution and after drying are both needed to distinguish between spectral features due to solution species and those from compounds comprising insoluble surface films, just as they are both needed to determine if changes occur when samples are removed from solution. Measurement and estimation of film thicknesses

have shown that the Raman and infrared techniques can identify components in films as thin as 200Å and analyze the entirety of films as thick as 1 micron.

The Electrolyte-Silicon Interface; Anodic Dissolution and Carrier Concentration Profiling

C. D. Sharpe and P. Lilley

Electrical Engineering Laboratories, The University of Manchester, Manchester, M13 9PL, England

ABSTRACT

The electrical behavior of the NaF:H_2SO_4 electrolyte-silicon interface has been investigated. *I-V*, *C-V*, and anodic dissolution phenomena are discussed in relation to the feasibility of using the interface for the determination of carrier concentration profiles in silicon structures; specimen electrochemical profiles are presented and compared with corresponding spreading resistance profiles.

The object of the work described here was to establish the feasibility of measuring carrier concentration profiles of epitaxial silicon structures, with minimal restriction on the range of carrier concentration and depth, by the electrochemical capacitance-voltage technique (1); conventional *C-V* profiling is limited in depth by dielectric breakdown and, as for resistivity techniques, deep profiles require etch or angle lapping procedures.

The electrolyte-semiconductor interface includes a space charge region within the semiconductor surface adjacent to the electrolyte (2), and for certain overpotentials the interface approximates to a Schottky barrier. Recently *C-V* characterization of such a barrier, involving a GaAs electrode, has been combined with anodic dissolution of the semiconductor to yield semicontinuous carrier concentration profiles (1); an automated system is commercially available for profiling this compound.[1] In the case of silicon, Pham *et al.* have reported capacitance-depth profiles for shallow ion-implanted layers (3); a different measurement technique was used and the conversion factor relating capacitance and carrier concentration could not be established.

We have applied the basic measurement principles used for GaAs, namely simultaneous dissolution and *C-V* analysis, to semiconducting n-type silicon; the problem being to establish an electrolyte and suitable operating potentials for (*i*) smooth and flat dissolution to depths in excess of 20 microns, and (*ii*) interface conditions approximating to a Schottky barrier, such that overall interface capacitance is given by

$$C = A\ (\epsilon\epsilon_0 nq/2V)^{1/2} \qquad [1]$$

where A is the interface area, and n the carrier concentration in the semiconductor at a distance W_D from the interface equal to the depletion width; the equation

$$W_D = \epsilon\epsilon_0 A/C \qquad [2]$$

yields the depletion width.

To produce a carrier concentration profile, the dissolution depth W_R must be added to W_D. The dissolution current is integrated, to yield W_R by the Faraday relation

$$W_R = \frac{M}{DANF}\int I dt \qquad [3]$$

where M and D are the molecular weight and density of the semiconductor, and N is an empirical number representing the electronic charge passing through the external circuit per molecule of semiconductor liberated.

Experimental Arrangement

The electrochemical cell included a silicon anode, carbon cathode, saturated calomel reference, and platinum (capacitance) electrodes. The silicon slice was

Key words: interfaces, electrolyte, semiconductors.

[1] Polaron Equipment, Limited, Watford, England.

held against the exterior wall of the cell, via a Teflon sealing ring, by a spring-loaded plunger; twin antimony-doped gold wires were incorporated in the plunger and gave low resistance (~ 10Ω) back-contacts to high doped material following a short 30V, 50 Hz pulse across them. Anodic dissolution was confined to an area A (~ 0.1 cm^2) defined by the sealing ring. The SCE reference electrode was linked to the electrolyte in the vicinity of the silicon surface by a salt bridge and a fine capillary, the potential of the silicon electrode (cell potential) being measured by a high impedance differential amplifier connected between the second back-contact and the reference electrode. Potentiostatic control was achieved by comparing the cell potential with a reference voltage (variable), the error signal changing the current accordingly.

Illumination, necessary for n-type semiconductor dissolution, was provided by a 150W tungsten halogen lamp, via a copper sulfate infrared filter and short light pipe. Capacitance measurements were made with a Wayne-Kerr "Autobalance" bridge (1.5 kHz), a.c. coupled to the silicon and to the platinum electrode near the silicon surface. Both C-V and I-V characteristics of the silicon electrode were obtained dynamically, by ramping the reference voltage. A computed "best fit" to the C^{-2}-V information was used to obtain carrier concentration. The system was not fully automated, unlike the Post Office apparatus for GaAs (1) (which uses a two-frequency technique for increased resolution); for the purpose of this feasibility study an automated system was undesirable, tending to mask the detailed nature of the interface.

Electrolyte.—The criteria governing choice of electrolyte for an electrochemical profiling system are:

1. The C-V characteristic of the semiconductor-electrolyte interface must correspond to that of the space charge layer, *i.e.*, effects due to Guoy and Helmholtz capacitance, and to surface states on the semiconductor, should be negligible. In practice, the former can be satisfied by using a concentrated electrolyte (> 0.1M).
2. The etched surface should be (a), smooth and (b), flat. If these criteria are not satisfied, errors are introduced into the profiles due to the averaging of depth information and consequent uncertainty in carrier concentration, particularly in the region of junctions. Similarly, gassing at the silicon electrode must be minimized.
3. The electrolyte should give a dissolution rate > 1 μm/hr, to achieve profiles in a reasonable time.

The characteristics of several electrolytes interfaced with Si have been investigated; sodium fluoride/sulfuric acid has to a large extent satisfied the above criteria.

Experimental Results

Anodic V-I characteristics of the Si-H_2SO_4/NaF system.—For all specimens the dark rest potential was −0.45 ± 0.1V (relative to SCE) and photopotentials were −70 mV for n-type and 150 mV for p-type Si. Anodic V-I characteristics, obtained by scanning the cell voltage at a rate of 400 sec/V in the anodic direction, show a saturation current for both p- and n-type silicon. Figure 1 illustrates the effect of increasing fluoride content on the V-I characteristics of p-type silicon (0.01 Ω cm). 0.05M sulfuric acid alone produced an approximately linear V-log I characteristic, the high Tafel slope (~ 0.725 V/decade) indicating that current was controlled neither by carrier supply nor reaction rate; rather, it was suggestive of current limitation by an oxide film at the interface, through which electrolyte ions must travel to reach the silicon surface. Small concentrations of sodium fluoride changed the characteristic to one with a slope tending to 60 mV/decade at low current, and caused the appearance of a well-defined peak in the current. As the NaF content was increased, the near exponential low current

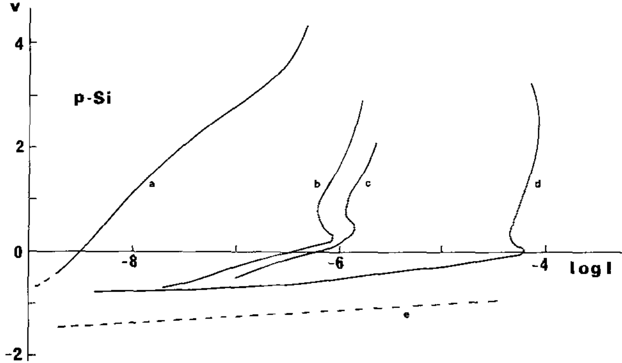

Fig. 1. The effects of increasing fluoride concentration on the V-I characteristics of the p-Si: NaF/H_2SO_4 interface (a) 0.05M H_2SO_4, (b) 0.05M H_2SO_4/0.05M NaF, (c) 0.05M H_2SO_4/0.1M NaF, (d)0.05M H_2SO_4/0.2M NaF. ---- (e) represents a slope of 60 mV/ decade.

region extended and approached 10^{-4}A at 0.2M concentration (a current level indicating a reasonable dissolution rate). Current levels below the peak were little affected by acid concentration, whereas above the peak, current increased with acid content.

As expected, illumination of the p-type electrode caused virtually no change in current; holes for dissolution being in plentiful supply. Illumination of low doped n-type Si, caused a large increase in current, due to increased hole concentration at the surface, whereas the behavior of heavily doped n-type silicon was characterized by a large dark current; such currents have been observed by Meek (4) for the Si-HF system.

Gas evolution was observed at both n- and p-type Si electrodes under anodic bias, reaching a maximum at or near the current peak. Although diminishing at higher voltage, evolution of gas continued at a slow rate even at 2V overpotential (bubbles noticeable on the surface after a period of several minutes).

Anodic dissolution of n-type silicon.—Currents below the saturation region gave a pitted etch, together with traces of a dark film, [as noted by Uhlir (5) and others] which in some cases changed appearance after removal from the solution, finally resembling a dust on the surface. Samples etched in the current saturation region were considerably smoother, particularly under strong illumination, electrolytes with the higher acid content giving the smoothest etches, with few pits or spikes on the surfaces; however it was apparent that electrolytes with a high sodium fluoride content gave flatter etched surfaces in terms of gross uniformity over the whole of the exposed area. The 1M NaF: 0.05M H_2SO_4 electrolyte has been found to be a reasonable compromise and was used for the remaining experiments to be described, although deep etches (> 10 μm) left a pronounced slope in one quadrant of the etched area (recently this problem has been overcome by pulsating the electrolyte near the Si electrode, a technique similar to jet etching generally used to improve the flatness of chemically etched pits).

A detailed discussion on the electrode reaction and transport kinetics is not appropriate in this paper. However two experimental observations, (*i*) that deep etched surfaces were nonplanar and (*ii*) that stirring increased the dissolution rate, leads us to suggest the mass transport in the electrolyte, in the vicinity of the Si electrode, plays an important role in the dissolution process.

The dissolution valence N has been estimated to be 3.50 ± 0.3 (by weight loss measurements on epitaxial n-type material) for the "standard" cell condition used for dissolution (cell potential 1.0V, 0.05M H_2SO_4 + 1M NaF). This value has been used to establish profiles, irrespective of doping level and type. Recent work by Arita (6) has shown that for HF electrolyte/silicon the

dissolution valence is dependent on carrier concentration and type, in addition to illumination and current levels, varying over a range $2 < N < 4$. We are carrying out a corresponding investigation for the NaF: H_2SO_4 electrolyte, and intend to include the effects of crystallographic orientation on dissolution.

C-V characteristics for n-type silicon.—*C-V* graphs were obtained by scanning the cell potential between 0 and −0.6V at rate of 20 sec V^{-1}, about 10 sec after illumination was removed. The fast sweep rate, relative to that used for *V-I* plots, was preferable for two reasons. Firstly, the technique depends upon a 1:1 relationship between change in cell potential ΔV, and change in semiconductor space charge potential $\Delta\phi_S$; a change in Helmholtz potential drop $\Delta\phi_H$ would distort this relationship. Since processes occurring in the Helmholtz layer are considerably slower than the relaxation time of carriers in the space charge region, $\Delta\phi_H$ is reduced by a fast change in cell potential. It would have been preferable to use a much faster rate than 20 sec V^{-1}; this figure represents a compromise between the above considerations and the response time of the measurement system (capacitance bridge and X-Y recorder). Secondly, it is important to minimize dark dissolution, in the case of n-type material, as this generally results in a pitted surface, particularly on heavily doped specimens.

The *C-V* data obtained from low doped n-type material was found to yield either inaccurate or ambiguous values for carrier concentration. Consider the C^{-2}-V plot of Fig. 2(a). The data is a reasonable fit to the Schottky function with carrier concentration $n = 1.0 \times 10^{16}$ cm^{-3} which, although the result was obtained from an encouragingly linear C^{-2}-V plot, indicates a large error when compared with a quoted value of 4.5×10^{15} cm^{-3} for this specimen. In some cases, particularly at or close to the original surface of the sample, a well-defined "hump" appeared in the *C-V* curves (Fig. 3) being most pronounced at the original surface, and diminishing with dissolution depth; the C^{-2}-V plot, corresponding to a dissolved depth of ~ 0.5 μm, shows two distinct slopes (Fig. 3). In other cases, although no definite hump in the *C-V* plot existed, two (or more) straight lines could be drawn through the C^{-2}-V data; again this could occur at the surface or in the bulk of a layer. Figure 2(b) shows C^{-2}-V results for which this phenomenon was particularly well defined (the steeper slope corresponds to a carrier concentration n of 8.6×10^{15}: the shallower slope giving $n = 2.5 \times 10^{16}$; these are to be compared with a spreading resistance result corresponding to 1.2×10^{16} cm^{-3}).

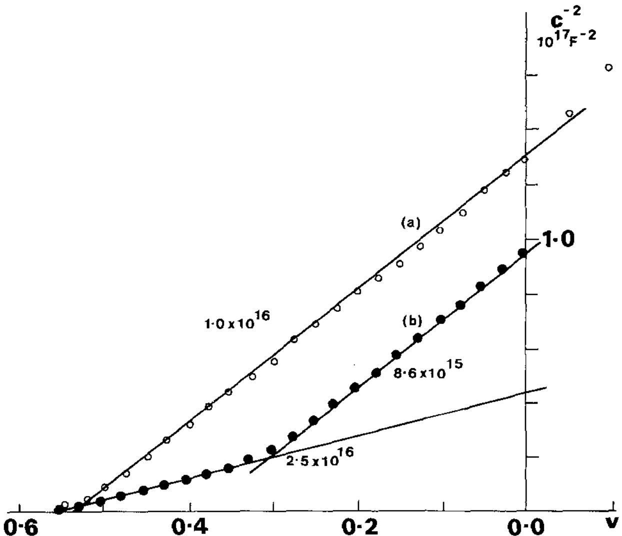

Fig. 2. *C-V* data and Schottky function best fit for two low doped silicon specimens, (a) quoted as 4.5×10^{15} cm^{-3}, (b) spreading resistance estimate 1.2×10^{16} cm^{-3}.

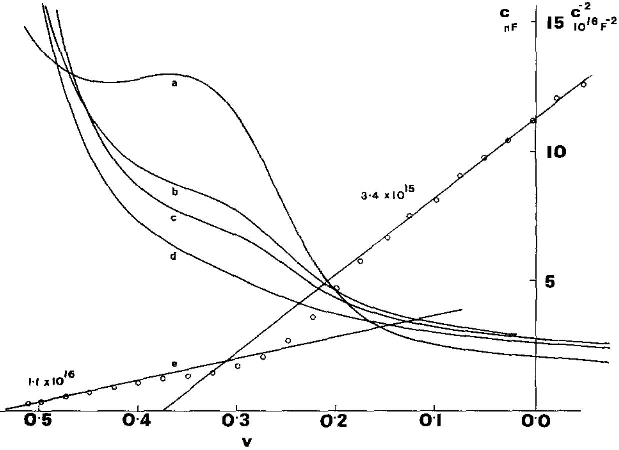

Fig. 3. *C-V* data from a low doped specimen at depths of (a) 0.0, (b) 0.05, (c) 1.5, (d) 3.5 microns, and C^{-2}-V plot at 0.5 microns, ($N = 2.5 \times 10^{15}$ cm^{-3} from spreading resistance).

In contrast, the C^{-2}-V plots from highly doped material were usually linear, and gave values for carrier concentration in close agreement with those obtained from spreading resistance. Generally, high doped material did not provide the extensive problems associated with low doped material. A phenomenon related to this, is the difference in apparent flatband potential between high and low doped material; Dewald (7) reported a similar effect, both in magnitude and direction, for the ZnO electrode, and attributed the phenomenon to a change in metal-semiconductor (back contact) potential. This variation in flatband potential appears somewhat anomalous, since any shift in metal semiconductor contact potential should be balanced by an equal and opposite change in semiconductor-electrolyte contact potential, as the cell potential is not a function of Fermi level (8).

Generally, in the case of highly doped n-type silicon, the electrochemical result for carrier concentration was slightly lower than that obtained from spreading resistance measurement, this in contrast to the situation at low doping levels, where the electrochemical result was substantially higher. Ambridge and Faktor (9) noted a difference between resistivity measurements and electrochemical results on low doped GaAs. They attributed the differences to the presence of deep traps in the material. Under strong reverse bias (during anodic dissolution) the Fermi level may fall below such levels causing ionization of the traps. The space charge is then that due to both uncompensated donor atoms and ionized trap states. If the traps have long relaxation times, a measurement of the *C-V* characteristic performed almost immediately after dissolution is interrupted (as was the practice here) would show a Schottky curve corresponding to concentration $n' = n + N_t$, where N_t is the trap concentration. If however, the system was left at the equilibrium potential (low reverse bias, in the present case) for some time in the dark following dissolution, then the trap states could be neutralized by recombining electrons. A subsequent measurement of the *C-V* characteristic would therefore be expected to correspond to the "true" carrier concentration. This has been observed to be the case; a sample left at rest potential in the dark for 10 min following dissolution resulted in a value of $n = 2.4 \times 10^{15}$ cm^{-3} for a specimen quoted as 2.5×10^{15} cm^{-3}.

In some case, particularly on low doped material but not exclusively so, the C^{-2}-V plots gave two parallel linear regions, suggesting a shift in potential distribution at the interface during the voltage sweep, which can be attributed to (*i*) a distinct fast surface state and/or (*ii*) a shift in Helmholtz region potential drop. Since it is unlikely that the surface state charge density is comparable with the space charge

density at high doping levels, it is suggested that the potential shift has origins primarily in the electrolyte side of the interface (*i.e.*, the Helmholtz region). This is a very tentative explanation and it is important to note that a fast space-charge modulation technique (such as used in the gallium arsenide profiler) for determination of *C-V* data would be expected to exclude most of the effects due to the Helmholtz region potential change; though it might not exclude the effects of fast surface states, if such exist.

Profiling.—**Profiling conditions for silicon, using the** H_2SO_4/NaF electrolyte were: (*i*) a dissolution cell potential of 1.0V, (*ii*) *C-V* characteristics taken 10-15 sec after dissolution and illumination terminated, (*iii*) cell potential scanned at 20 sec/V in the cathodic direction, over a range 0.0 to −0.6V, to obtain a *C-V* characteristic. Investigation of *C-V* characteristics taken throughout single epitaxial layers indicated that consistent values for the carrier concentration could be obtained from the slope of the C^{-2}-*V* graphs at −0.45V (relative to the SCE); although, as shown in the previous section, yielding excessive values for low doped material, this slope was used for the feasibility study, which also involved profiling multi-epitaxial structures.

A profile of a uniformly doped low resistivity substrate wafer is shown in Fig. 4(a); for depths to about 10 μm the measured values of carrier concentration are in close agreement with those obtained from spreading resistance, whereas at greater depths the uncertainty of the measured value increases due to excessive nonlinearity of the C^{-2}-*V* graphs. This problem was found to be associated with material crystallizing from the solution in the vicinity of the silicon electrode (x-ray fluorescence spectra indicated the deposit to be Na_2SiF_6); furthermore, slow gas evolution at the interface over long periods of time (hours) used for deep dissolution caused the formation of bubbles on the silicon electrode. Recently we have found that pulsating the electrolyte in the vicinity of the silicon electrode, at about 10 sec intervals, solves the deep dissolution problems.

One example of an epitaxial silicon structure profiled as described above (without pulsation) is shown in Fig. 4(b). The corresponding spreading resistance profile is also given for comparison; this clearly shows the large error at the low doping levels.

Recent investigation of *G-V* (shunt conductance-voltage) characteristics of the interface over the range of voltage used for the *C-V* characteristics has shown that in the region of −0.45V the shunt conductance is changing rapidly with voltage (Fig. 5) whereas at

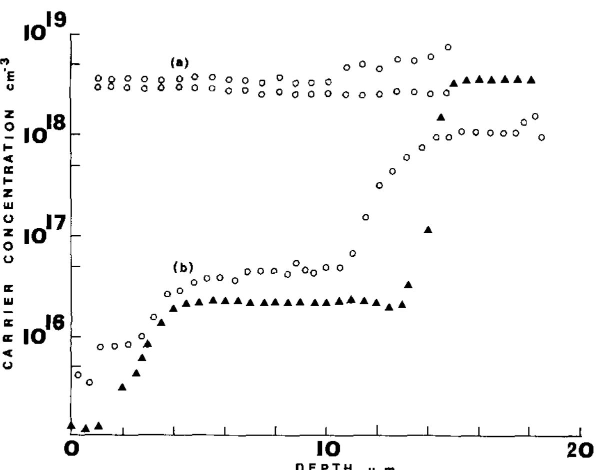

Fig. 4. Electrochemical carrier concentration profile of (a) uniformly doped silicon wafer (quoted as 3 × 10^{18} cm^{-3}), and (b) of a multi-epi wafer; experimental values (○) taken from C^{-2}-V plots with −0.6 < V < 0.0V. The triangles (▲) represent the corresponding profile from spreading resistance.

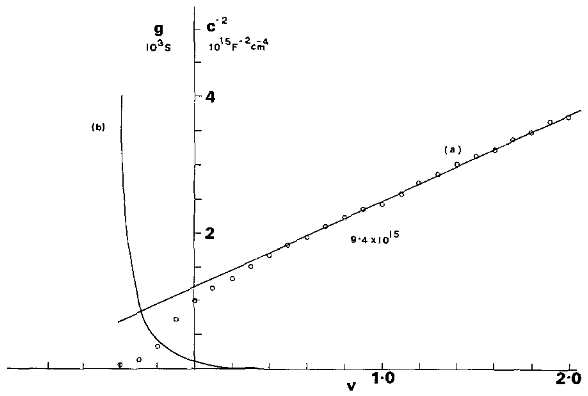

Fig. 5. (a) C^{-2}-V, and (b) G-V plots over a large voltage range −0.5 < V < 2.0V for low doped silicon quoted as 1.2 × 10^{16} cm^{-3}.

potentials > 0.0V the *G-V* characteristics are generally flat, the conductance being negligible (this may well be associated with a recombination current due to traps in the surface region, as discussed earlier). It became clear that detailed *C-V* characteristics were required at more positive cell potentials—the bridge quoted was unsuitable for this range of capacitance, and investigations were carried out on a Post Office plotter suitably modified for our cell configuration. Figure 5 shows a C^{-2}-*V* plot for the low doped specimen quoted as 1.2 × 10^{16} cm^{-3}; the trend towards lower estimates of carrier concentration as cell voltage approached zero continued into the positive region, finally giving close agreement with spreading resistance measurements.

Electrochemical profiles have been taken with a pulsated electrolyte and cell potential of + 1.0V, using the two-frequency automated facility of the Post Office plotter (10); an example is shown in Fig. 6 along with a corresponding profile obtained from spreading resistance measurements, and indicates close agreement over a wide range of carrier concentration.

Conclusion

An investigation of *I-V*, *G-V*, and *C-V* characteristics of the silicon:H_2SO_4/NaF interface has shown that certain cell potentials can be used for deep dissolution and carrier concentration measurements. To obtain meaningful estimates of carrier concentration, ranging over several orders of magnitude, *C-V* measurements should be taken with the depleted surface heavily (> 1V) reverse biased. In that way we have

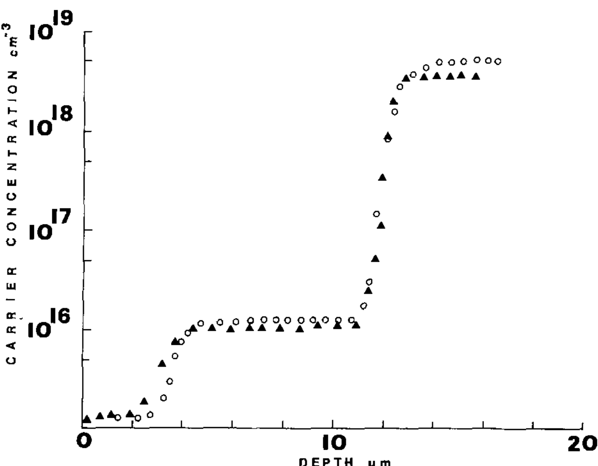

Fig. 6. Electrochemical profile of a multi-epitaxial silicon structure, taken by the Post Office Semiconductor Plotter, at a cell voltage of 1.0V, using pulsated NaF/H_2SO_4 electrolyte.

shown that it is possible to profile n-type silicon structures (10). The technique also appears to be suitable for p-type silicon structures, for which the conventional mercury probe *C-V* technique presents problems due to an inherently low barrier height. One of the most useful application areas has been found to be that of ion implantation, complimenting other (comparatively expensive) systems such as SIMS.

Faradaic Processes at the Ir/Ir Oxide Electrode

S. Gottesfeld*[,1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Faradaic reactions at the Ir/Ir oxide electrode provide information on the energy levels and the nature of electronic states in the electrochromic oxide. The rate of carrier injection and transport is found to depend strongly on the distribution of electronic levels in the oxide film and in the electrolyte. Conclusions can be drawn on the mechanism of charge injection and transport during electrochromic transients under small and large potential perturbations.

The electrochromic reaction in anodic iridium oxide (1-4) as well as rhodium oxide (5) films has been described recently. The anodic iridium oxide film exhibits a strong increase in light absorption (coloration) under anodic applied potentials in aqueous solutions and is reversibly bleached under cathodic applied potentials. Such reactions involve double ejection or injection of electrons and protons during the anodic or cathodic half-cycles, respectively (2). The kinetics depend, in principle, on the interfacial transfer and bulk transport of both electrons and protons through the oxide layer. Recent a-c impedance studies of the oxide-covered iridium electrode in acid solutions (6) showed that, for small potential perturbations ($\Delta V \sim 1$ mV), transport through the film is rate-controlling in the reversible charging process and the apparent conductance of the film (per unit area), $G_{a.c.}$, increases exponentially with the applied d-c bias. For an Ir oxide film with an ellipsometrically determined thickness of 1500Å (7), $G_{a.c.}$ changes from $<10^{-2}\ \Omega^{-1}\ cm^{-2}$ for the completely bleached form at $V < 0.4V_{SCE}$ up to $10^2\ \Omega^{-1}\ cm^{-2}$ for the colored form at $V = 1.0V_{SCE}$ (6). In an attempt to resolve the contribution of electron transfer and transport (ETR) to the total impedance in the electrochromic process, the faradaic reactions of some redox couples were examined at a rotating-disk (RDE) oxide-covered iridium electrode. Such reactions require only ETR through the film with no coupled ionic transfer or transport. Since these tests are conducted with the electrode immersed in the aqueous electrolyte, they reflect the properties of the unmodified active hydrous form of the electrochromic oxide film.

Results and Discussion

Figure 1 shows the current-potential curves for the $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ couple obtained at the bare and at the oxide-covered iridium RDE in acid solutions. The oxide layer was grown to a thickness of *ca.* 1500Å in a separate cell containing $0.5M\ H_2SO_4$, by the potential multipulsing technique described elsewhere

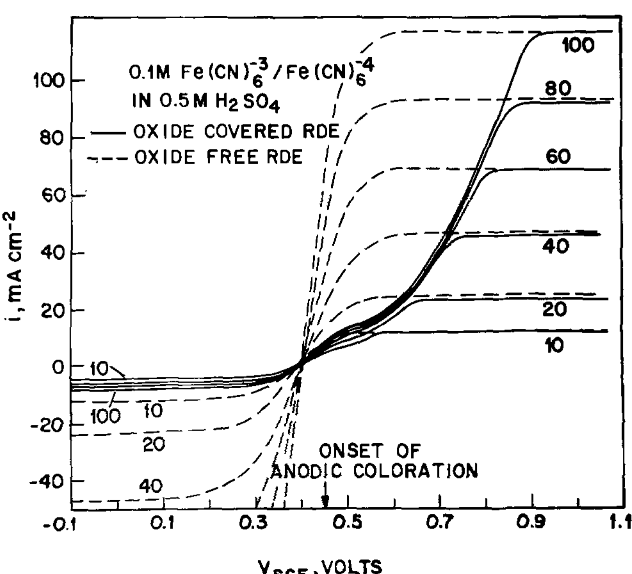

Fig. 1. Current-potential curves obtained at the Ir and the Ir/Ir oxide RDE with the $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ in acid solutions. Scan rate —5 mV sec^{-1}. The square root of the rotational speed is designated in (rpm)$^{1/2}$.

(2). The behavior of the redox couple at the bare RDE was regular (Fig. 1), exhibiting anodic and cathodic limiting currents directly proportional to the respective concentrations and also to $\omega^{1/2}$ up to $\omega = 10{,}000$ rpm. In the voltammograms obtained at the oxide-covered RDE three potential regions can be clearly distinguished in Fig. 1: At $V < 0.5V_{SCE}$ the limiting currents, i_L, in both the cathodic and anodic faradaic processes are "blocked," *i.e.*, much lower than those obtained at the "bare" RDE. On the other hand, at $V > 0.9V_{SCE}$ the values of i_L obtained at the oxide-covered RDE are practically equal to those measured at the metal RDE for ω up to 10,000 rpm. The gradual transition of the film from a blocking to a nonblocking layer occurs in the intermediate potential range of 0.5-$0.9V_{SCE}$. The onset of this transition coincides with the onset of anodic coloration. [The potential of the early anodic peak in the Ir oxide voltammogram (1) was chosen to designate the coloration onset in Fig. 1 and 2.] This coincidence demonstrates that the rate of ETR through the film increases in this case significantly with coloration. At $V > 0.9V_{SCE}$, where the oxide is strongly colored, charge exchange with the ferrocyanide ions occurs at the oxide-electrolyte interface and the high rate of ETR through the films allows bulk diffusion-controlled oxidation currents at bulk concentrations higher than 0.1M. On the other hand, the limiting currents in the blocking region at $V < 0.4V_{SCE}$ are not proportional to $\omega^{1/2}$ as expected for bulk diffusion-controlled currents, but rather converge upon a saturation level $i_{L,SAT}$ at high ω, as shown in Fig. 1. $i_{L,SAT}$ was found to be proportional to the bulk concentration and inversely proportional to film thickness. These results suggest that the current in the blocking region is limited by diffusion through the oxide film. The diffusing species may be the ferricyanide and ferrocyanide ions, which diffuse from solution through a pore network or through pinholes in the film, while the charge-transfer takes place at the metal substrate. The rate of the reactions of the ferri- or ferrocyanide ions at the bleached oxide in acid solutions is thus limited by ionic transport through pores in the film.

In contrast to the case presented in Fig. 1, high faradaic reduction rates were monitored at the bleached form of the oxide when redox couples with a higher oxidizing power (relative to that of the pH-dependent Ir couple) were employed. This behavior was found for the reduction of ceric ions in sulfuric acid solutions and for the reduction of the ferricyanide ion in alkaline solutions. In both cases there was no detectable difference between limiting reduction currents measured at the metal RDE and at the RDE covered with the bleached form of the oxide. The case of $Fe(CN)_6^{-3}$ reduction in 0.1M KOH is shown in Fig. 2.

The results of Fig. 1 and 2 demonstrate that the rate of ETR through the bleached film depends strongly

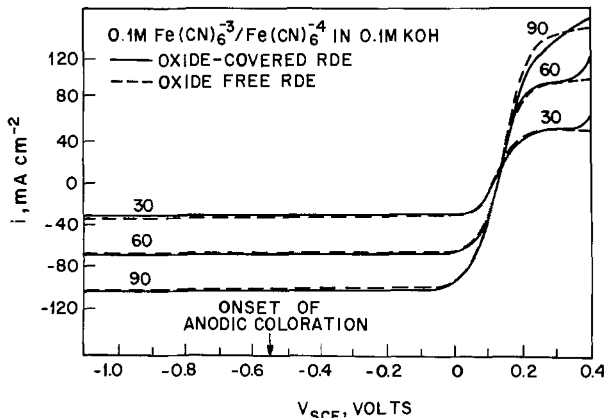

Fig. 2. Same as Fig. 1, in 0.1M KOH

on the relative positions of the electron energy levels in solution and in the oxide. Such a dependence, which was found before in many cases for semiconducting or insulating electrode materials (8), may serve as a source of information on the energy distribution and on the nature of electronic states in the oxide film. A schematic diagram of electronic states in the oxide in the relevant energy region, as suggested by the results of the ETR measurements, is given in Fig. 3. The basic features of this diagram are: (*i*) all the electronic states in the oxide which lie below (anodic to) the potential of the main current peak in the cyclic voltammogram ($E_p = 0.7V_{SCE}$ in 0.5M H_2SO_4 and $-0.35V_{SCE}$ in 0.1M KOH) belong to a band of extended states. This is most probably a metal-oxygen d-π^* band, as proposed by Rogers *et al.* (9) for IrO_2 and identified by XPS measurements on pressed-powder IrO_2 samples (10). In the colored form these are the highest occupied electronic levels and the band is partially filled as in IrO_2 (9), allowing fast carrier transport through the colored oxide. (*ii*) During bleaching higher levels are gradually occupied, the band is filled, and the Fermi level in the oxide, $E_{F,OX}$, is shifted to more cathodic potentials, (higher electron energies). The density of the last levels which are occupied in the cathodic bleaching process, *e.g.*, at $V < 0.6V_{SCE}$ in acid, is small, and their associated mobility is low as expected in a disordered solid for electronic states located close to a bandedge or in the bandgap (11). The fine-grained microcrystalline structure reported for anodic Ir oxide from x-ray diffraction measurements (12) suggests that the electronic structure of the colored form may be indeed related to that of crystalline IrO_2 (9), with modifications due to some loss of long-range order. In IrO_2 a complete

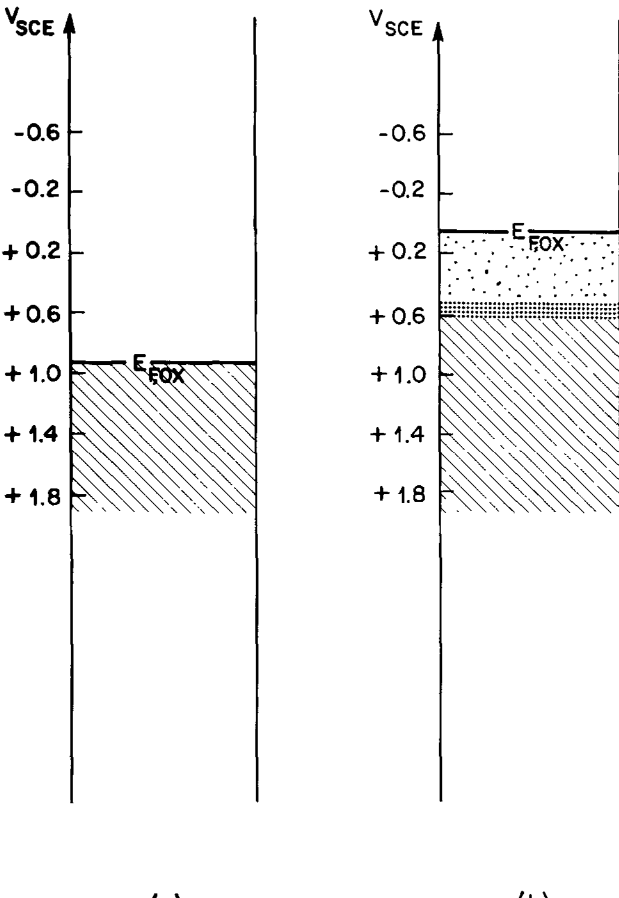

Fig. 3. Occupation of electronic levels in the colored (a) and in the bleached (b) forms of the Ir oxide electrochromic film. The hatched region designates occupied states in a band. The dotted region designates occupied states of lower densities and mobilities, located near the bandedge and in the bandgap.

filling of the d-π^* band is expected when one extra electron is added per Ir atom, *i.e.*, when the formal oxidation state is lowered from IV to III (9). The assumption that bleaching involves only the filling of unoccupied levels with no accompanying variations of band structure may be an oversimplification, since the protons injected into the oxide during bleaching may, for example, split-off levels from the d-π^* band to form a separate narrow band of localized states near $E_{F,OX}$. However, even according to the simple diagram in Fig. 3 it is possible to see why the states near $E_{F,OX}$ in the bleached film may be less dense and more localized, while the deeper states may still be forming a band associated with a higher mobility.

The results obtained for faradaic reductions at the bleached form of the oxide can be now understood in terms of the schematic diagrams in Fig. 3: when E_{Redox} is close to $E_{F,OX}$, charge injection has to take place at an energy level where the density of states in the bleached oxide is small and the mobility is low. Hence, low rates of both charge-injection at the oxide-electrolyte interface and charge transport through the bulk of the oxide are expected. This seems to be the situation for the reduction of $Fe(CN)_6^{-3}$ at the bleached oxide in acid solutions [see Fig. 4(a)]. If, on the other hand, the energy difference E_{Redox}-$E_{F,OX}$ is sufficiently large, holes can be injected into the lower lying more extended occupied electronic levels in the oxide. The density of states and the mobility in the band are higher and, therefore, the rates of both hole injection and hole transport through the bleached oxide are significantly enhanced. This is demonstrated schematically for the reduction of Ce^{+4} in acid in Fig. 4(b) and for the reduction of $Fe(CN)^{-3}$ in 0.1M KOH in Fig. 4(c). It is easy to see that the "hot hole" transport mode depicted in Fig. 4(b) and 4(c) requires that the hole trapping time in the bleached film be much longer than L/v, where L is film thickness and v the hole velocity in the band. A significant effect of trapping could not be detected even for films 10,000Å thick, at which the same unaltered diffusion-controlled currents were still recorded for the reduction of Ce^{+4}.

Optical measurements showed that the Ir oxide film was maintained in its bleached form in the presence of a stirred 0.1M Ce^{+4}/Ce^{+3} acid solution when subjected to potentials more cathodic than $0V_{SCE}$, *i.e.*, that the Fermi level in the oxide is determined by the potential applied to the metal. This means that high rates of hole injection and transport are indeed observed through the bleached film (Fig. 2), and that under the strong nonequilibrium conditions imposed the large potential drop is located in a narrow region at the oxide-electrolyte interface as assumed in Fig. 4, allowing hole-injection into the lower lying levels in the bleached oxide.

The corrosion of the oxide during these hole injection processes was checked and found to be negligible during the short times required to record the current-potential curves. This is not very surprising considering that hole injection occurs into a d-band which has a relatively minor role in the bonding in this oxide (13), and that the oxide was kept under cathodic applied potentials during the measurement.

The faster ETR observed through the bleached film under strong nonequilibrium conditions may be significant in the mechanism of the electrochromic process: a high rate of charge transport is expected through the bleached form of the oxide at the onset of the coloration process, in spite of the low a-c conductance of the film, provided a large anodic perturbation, *e.g.*, a pulse of $1V_{SCE}$ in acid is applied. Under these conditions the rate of anodic coloration will be determined by the higher rates of injection and transport via lower lying extended states. This is shown in Fig. 5(a), which demonstrates hole-injection from the colored region of the film adjacent to the metal to the bleached part of the film adjacent to the solution following an anodic pulse. (This form of color gradient in the film is expected if the rate of electron transport is lower than that of proton transport.) Since $G_{a.c.}$ is measured at small perturbations, the low conductance obtained for the bleached form (6) is apparently due to the low density and mobility of states near $E_{F,OX}$, as demonstrated in Fig. 5(b). Comparison of Fig. 5(a) and (b) elucidates the lack of a unique correspondence between large and small signal measurements, as noted before (6).

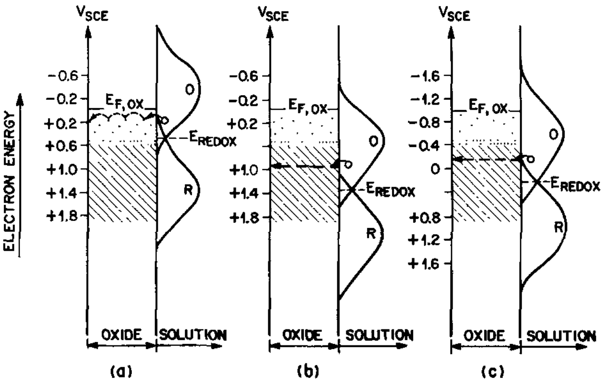

Fig. 4. Schematic electron energy diagram for the bleached oxide film and the redox couples in solution. Case (a) depicts the relative positions of electronic levels for $Fe(CN)_6^{-3}$ reduction in acid. Cases (b) and (c) describe the relative positions for Ce^{+4} reduction (in acid) and for $Fe(CN)_6^{-3}$ reduction in 0.1M KOH, respectively.

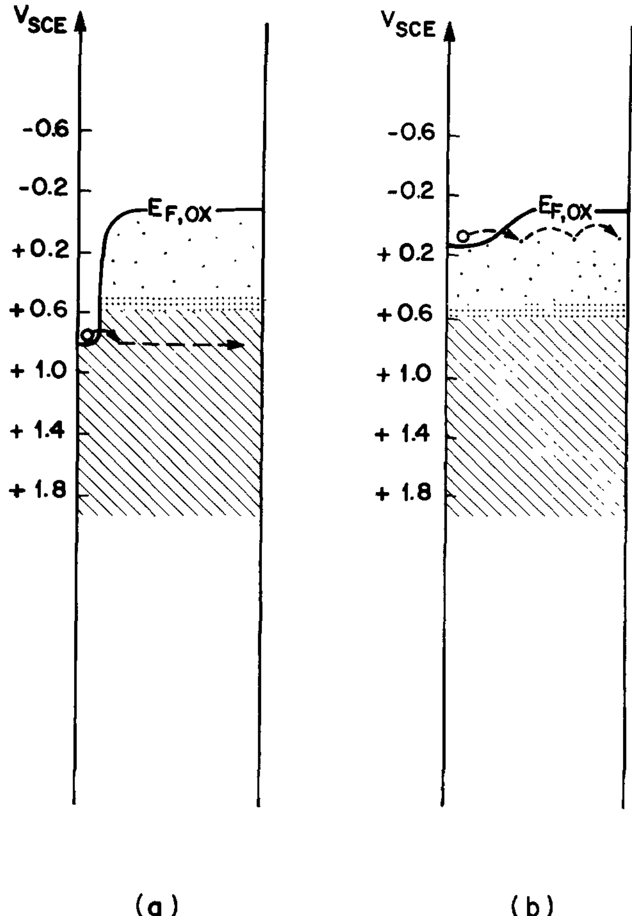

Fig. 5. Part (a) describes conditions for fast hole transport through lower levels in the bleached oxide during a coloration transient under large anodic perturbations. Part (b) describes the slower transport expected during a coloration transient under small anodic perturbations.

Anodic Etching of Defects in P-Type Silicon

H. Föll

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A new etching technique for p-type Si has been developed which combines the advantages of chemical etching and EBIC. The method is electrochemical in nature and the silicon sample is biased as the anode in an electrochemical cell. The etching behavior of defects is governed by the magnitude of the applied voltage. At low voltages only electronically active defects are etched and the etching pattern corresponds to an EBIC image of the same area. At higher voltages all defects are etched and the etching behavior resembles chemical etching. The method offers considerable advantages as compared to EBIC and chemical etching.

Preferential chemical etching of defects in Si crystals with special chemical solutions ("etches") has been the most important technique for revealing defects in crystalline Si. An etching solution based on the HF-CrO_3 system which was first introduced by Sirtl and Adler (1) has been widely used in its original form or in modified versions (2-4) but etches based on the HF-HNO_3 system are also used (5, 6).

Despite the widespread use of these etches, it is not understood exactly how they work, *i.e.*, why, under certain circumstances, they attack certain defects with an etching rate different from that of the perfect crystal. This is illustrated, *e.g.*, by the remarkable difference in the etching behavior of the Sirtl-, Secco-, and Seiter-etch (1, 2, 4), all of which are based on the HF-CrO_3 system: whereas Sirtl etch works best on {111} planes and not on {100} planes, the Seiter etch is sensitive to all crystal planes except the {111} plane. Finally, the Secco etch works on all crystal planes.

This lack of universality of most etches is no major drawback for the purpose of defect delineation in single crystals of Si because the crystal orientation and the kinds of defects which might be present usually are known. Thus the proper etch can be chosen and fine-tuned to the specific application without major problems [see Ref. (7) for an example].

The situation has changed with the advent of polycrystalline Si for photovoltaic applications in recent years. Neither the orientation of various grains nor the nature of defects to be expected is known: all kinds of dislocations, stacking faults, low- and high-angle grain boundaries, and precipitates of impurities may be present simultaneously. Application of standard etching procedures thus may leave defects undetected or give different responses in different grains. Moreover, the response of grain boundaries to the various etches is not known.

Chemical etching gives information about the presence of certain defects, but no information about their electronic activity. Because the latter is the most interesting property of defects with respect to photovoltaics, additional experimental methods such as scanning microscopy in the electron-beam induced current (EBIC) mode have to be employed if electronic properties are to be studied.

This paper proposes a new etching method for p-type silicon which is based on electrochemical methods. It exploits the difference between the electrochemical potential of defects and the silicon matrix. Therefore, etching features can be related to electronic properties of defects. The same information about defects as obtained in EBIC measurements can be derived, making this method especially suited for the evaluation of polycrystalline Si. The method can be easily extended to all kinds of p-type Si crystals and possibly to other semiconductors.

Background: Electrochemistry of Silicon

If Si is anodically biased in an electrochemical cell and a suitable electrolyte is used, it will dissolve with a rate proportional to the current density (8-10). It has been shown that the dissolution process requires holes, therefore only p-type Si will dissolve anodically with ease. The silicon-electrolyte interface behaves in

Key words: etching, dejects, crystals.

many respects like a Schottky diode which is forwardly biased for p-type Si and reversely biased for n-type Si. Consequently, even with a rather high voltage applied to the electrochemical cell, n-type Si will not dissolve rapidly and the current density will be small (corresponding to the leakage current of a reversely biased diode). A space-charge region is built up at the Si-electrolyte interface and any defects present in this layer which are able to generate holes, may locally enhance the current density and thus the etching rate. This effect is known to provide a valuable tool for etching "electronically active" defects and has already been mentioned by Turner (8). Anodic etching of n-type GaAs has indeed been used for some time for defect detection and was shown to offer considerable advantages over chemical etching (11-13), but not until recently was it applied to the characterization of defects in n-type Si (14).

Anodic etching of defects in p-type semiconductors has not been attempted so far. Since holes are the majority carriers in this case, no influence of defects on the current density was expected. Moreover, a layer of so-called porous Si (8, 15) is frequently formed on the etched surface and this was believed to mask possible preferential etching of defects (14). While this is true for bias voltages larger than a few volts, it will be shown in this paper that at low bias voltages a very pronounced etching of defects occurs. In this case the silicon half-cell is operated around or below the threshold voltage for current flow in the forward direction (in the diode picture of the half-cell) and the presence of defects can substantially alter the current-voltage characteristic of the Si-electrolyte "diode." Moreover, the etching rate for a given defect is very sensitive to changes in the applied voltage and it is different for defects with different electronic properties. Therefore, by varying the applied voltage it is possible to probe the specimen for defects with different electronic activities.

Experimental

A very simple experimental setup was used for the present work. The electrolytic cell consisted of a plastic beaker, and a Pt wire was used as the cathode of the system. The solution was agitated by a magnetic stirrer and etching was usually performed at room temperature in the dark. No reference electrodes were used and measurements of currents and voltages were made with typical (low impedance) laboratory instruments.

The specimens used were polycrystalline silicon obtained by unidirectional solidification (16) with a resistivity of ~10-20 Ωcm and silicon ribbons (17) with a resistivity of ~1-2 Ωcm. The specimens were mounted on a metal stick and the back side contact was made by a drop of liquid Ga-In alloy. A good back side contact was found to be essential; earlier experiments using carbon- or silver-paste yielded irreproducible results. The specimen holder and the edges of the specimen were then covered with wax so that only the surface of the specimen was exposed to the electrolyte. The electrolyte was HF [49%] diluted with a 50:50 mixture of distilled water and absolute ethanol so that the HF concentration was typically 1-10%. If water alone was used as a dilutant, the etching was often inhomogeneous and spotty in appearance, probably because of wetting problems. A constant voltage power supply was used and the voltage applied ranged from −0.5 to +20V. The small negative voltages still biased the silicon anodically because the built-in voltage of the Pt-Si cell was around 0.7V.

Some of the specimens were subjected to electron-beam induced current (EBIC) measurements in a scanning electron microscope (18). The Schottky contact necessary to apply this technique was made by evaporating 40-50 nm of Ti on the carefully cleaned sample surface.

Results

General observations.—The open-circuit voltage of the Pt-HF [5%]-Si system is about 0.7V; the silicon electrode is the positive terminal of the cell. A typical current-voltage curve is shown in Fig. 1 for poly-Si. Preferential etching of defects can be achieved in the region between −0.7 and ~2V. Figure 2 shows an example to illustrate the etching quality. The poly-Si specimen was etched ~40 min at 0V bias voltage (short-circuited cell); the current density was ~1.3 mA/cm^2 and ~3 μm of Si was removed during etching. Dislocations and grain boundaries are clearly visible; the dislocation etch pits are usually round or elliptical and can be very extended for dislocations running nearly parallel to the surface. Any surface damage is also revealed because only the top layer of the crystal was removed.

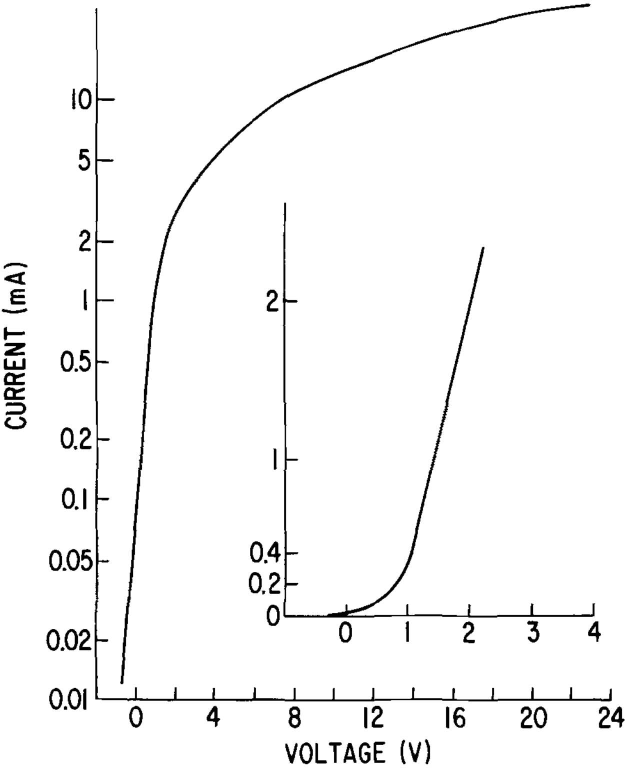

Fig. 1. Current-voltage characteristic for poly-Si in 5% HF. The inset shows the current-voltage characteristic for small voltages on a linear scale.

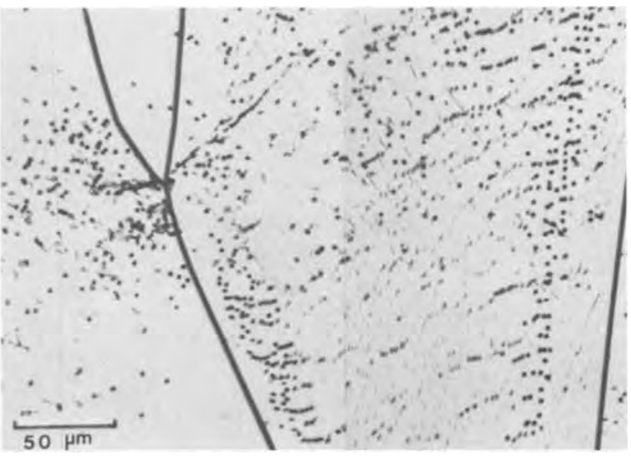

Fig. 2. Example of anodically etched poly-Si (40 min at 0V bias)

If a positive voltage >2V is applied, only grain boundaries are revealed (Fig. 3). If the voltage is further increased, electro-polishing will eventually begin (around 15V, *e.g.*, for poly-Si in a 5% HF solution) and the surface appears to be structureless.

The voltage regions within which these characteristic features are observed depend somewhat on the HF concentration and on the resistivity of the samples. Higher HF concentrations and lower resistivities tend to shift the "critical" voltages to higher values.

It is important to note that grain boundaries may be visible after etching (including purely chemical etching) for two unrelated reasons: they may be preferentially etched, *i.e.*, a groove is formed (Fig. 4a) or they may be outlined as a step between two grains because the etching rate in the two grains was different (Fig. 4b). In general, a mixture between groove and step will prevail (Fig. 4c). It is only when an etch groove is formed that the boundary can be considered to be truly etched. It is not always possible to distinguish between the three cases but a decision can frequently be made if the etch pattern is sufficiently developed and a microscope with interference or Nomarski contrast is used at moderate magnifications (~200-800×).

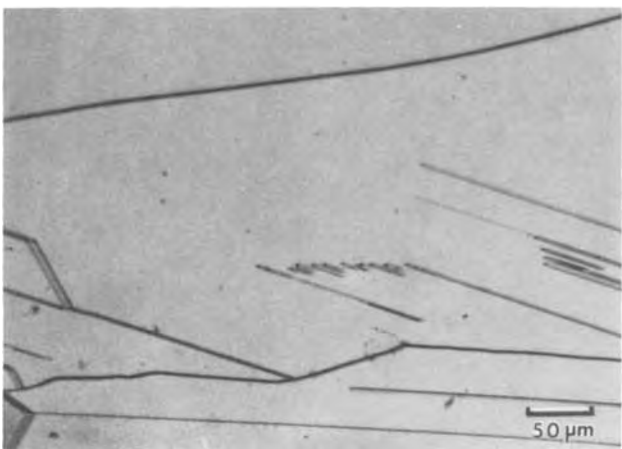

Fig. 3. Example of anodically etched poly-Si (1 min at 5V bias voltage).

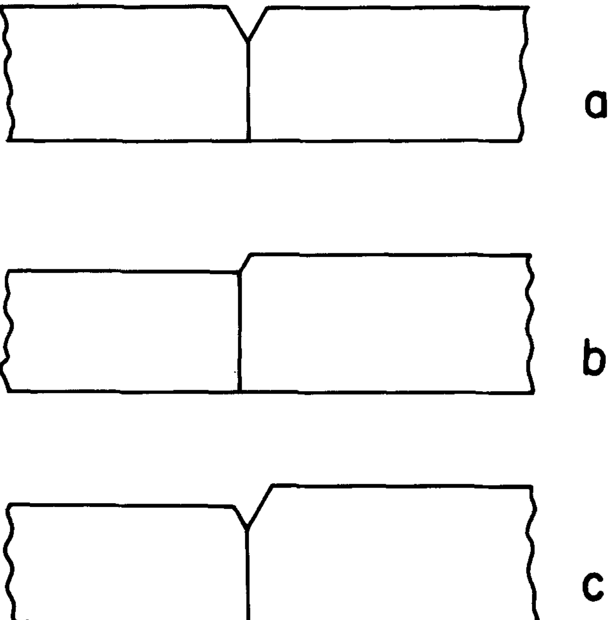

Fig. 4. Schematic outline of possible etching features at grain boundaries.

At low voltages the silicon surface is always covered with a thin layer of so-called porous Si (8, 15). This film mostly appears as a homogeneous layer displaying bright interference colors. Grains with different orientations may be outlined distinctly by this film because they appear in different colors due to a different film thickness. The etch pattern is visible through this film; it is however advantageous to remove it by transferring the specimen to a 1% solution of HF and by applying a voltage of ~7V for 1-2 min. This treatment will always remove the colored layer without changing the etching pattern as has been ascertained in numerous cases. Other methods for removing the porous silicon layer are mentioned in Ref. (15) and may work as well, although they have not been tried in this case. Sometimes, particularly at very low or negative bias voltages, a rough-looking brownish surface appears instead of the colored film. This film could not be completely removed by the above treatment and the surface remains somewhat rough and covered with many small pits. This can be disturbing but does not seriously interfere with the defect etching pattern.

The voltage dependence of preferential etching.—In the low voltage region (−0.7-~2V) the etching behavior of defects is strongly voltage dependent. Figure 5 shows directly neighboring parts of a silicon ribbon etched at 0V (Fig. 5a), −0.4V (Fig. 5b), and +0.5V (Fig. 5c) for 10, 20, and 5 min, respectively. Whereas it is safe to say that the nature and spatial distribution of defects did not change considerably in those parts of the sample probed at the three different voltages, the etching patterns look quite different. Especially if a small negative voltage is applied to the silicon electrode (in order to reduce the open-circuit voltage) many of the (twin) boundaries which were etched at 0 and +0.5V are no longer revealed. Dislocations, however, are still preferentially etched and their density and distribution in Fig. 5b corresponds perfectly to those in Fig. 5a and c. Etching at 0 and +0.5V produces similar patterns but dislocations running nearly parallel to the specimen surface are better revealed at +0.5V than at 0V. These dislocations are also etched quite nicely in Fig. 5b. They are shorter, however, because in this case only ~0.4 μm of Si has been removed as compared to ~2.1 μm at 0V and ~1.4 μm at +0.5V. The sensitivity of the preferential etching, *i.e.*, the ratio between the etch-pit size and the amount of silicon which was dissolved, decreases with increasing voltage. At a voltage of

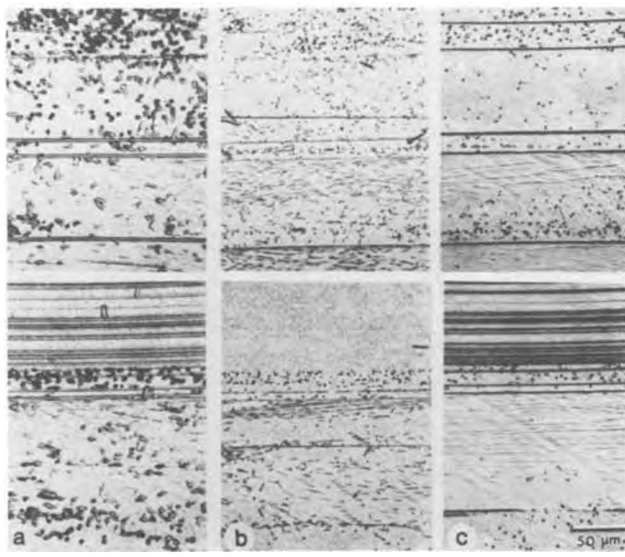

Fig. 5. Anodically etched Si-ribbon at (a) +0.5V, (b) 0V, and (c) −0.4V.

Fig. 6. Si ribbon etched at 5V. In (a) dislocation etch pits are still visible whereas in a neighboring area dislocations are no longer revealed.

5V only steps at grain boundaries are left. Figure 6a shows an intermediate case: pronounced steps have been formed at the boundaries but dislocations are only revealed as very small pits. In neighboring grains dislocations are no longer etched at all, showing that the changeover is somewhat orientation dependent (Fig. 6b).

Geometrically shaped etch pits [as found, *e.g.*, with Sirtl (1) or Wright (3) etch] have never been observed, indicating that etching occurs on all crystallographic planes with comparable etching rates.

Comparison with chemical etching and EBIC.—Figure 7 shows the same area of a poly-Si sample anodically etched at −0.4V (Fig. 7a), +0.4V (Fig. 7b), and with Sirtl etch (Fig. 7c). Although more spectacular examples could have been chosen, these pictures demonstrate several points: (*i*) Sirtl etch did not attack all the twin boundaries present, whereas anodic etching does. (*ii*) Although the etch-pit patterns for dislocations seem to correlate fairly well between Fig. 7a-c (allowing for unavoidable changes in the distribution because several microns of the surface had to be removed between successive etching steps) there are differences: Fig. 7a shows that dislocations are present in the outermost twin boundary which are missing in Fig. 7b and which are only poorly resolved in Fig. 7c. This may indicate that the etching properties of dislocations depend on their type. (*iii*) In Fig. 7a the colored layer has not been completely removed; it can be seen that it does not interfere with the observation of the etching pattern. (*iv*) The EBIC picture of the same area (Fig. 7d) corresponds better to Fig. 7a than to Fig. 7b and c.

Similar behavior can be observed for Si ribbons. Figure 8 shows a Sirtl-etched area next to an anodically etched one. With one exception the twin boundaries are not visible in the anodically etched part of the sample.

Secco-etched samples may show a better correlation to anodically etched ones because dislocations on all crystal planes are revealed. With respect to boundaries it appears to work similar to Sirtl etch. Interestingly, Secco etch applied to ribbons sometimes left a rough surface full of small pits very similar to the rough surface sometimes obtained with anodic etching.

It has been shown that twin boundaries, especially coherent twin boundaries in Si ribbons, often do not significantly influence the electronic properties of the crystal, *e.g.*, the carrier collection efficiency of a solar cell (19). Because twin boundaries can be made to disappear completely in anodic etching there seems to be a correlation between their electrical activity in solar cells and their anodic etching behavior. Both ribbon and poly-Si samples were therefore subjected to a test of the electrical activity of their defects using a scanning microscope in the EBIC mode. Figures 9 and 10 show some results, another example was already given in Fig. 7. The correspondence between the EBIC pictures and the anodic etching pictures is one-to-one for a negative bias voltage of the sample. This has been observed in many more cases than can be shown here. It is particularly interesting that the few twin boundaries out of a whole bundle which show electrical activity in EBIC are also revealed in the anodic etching whereas the electrically inactive twin boundaries appear only at higher etching voltages. Figures 9 and 10 show that the etch pattern is much clearer than the EBIC picture thus allowing a more detailed interpretation of the electrically active defects.

Discussion

Enhanced dissolution rate of defects.—The dissolution rate of a given area of Si is proportional to the current passing through it, *i.e.*, the current density.

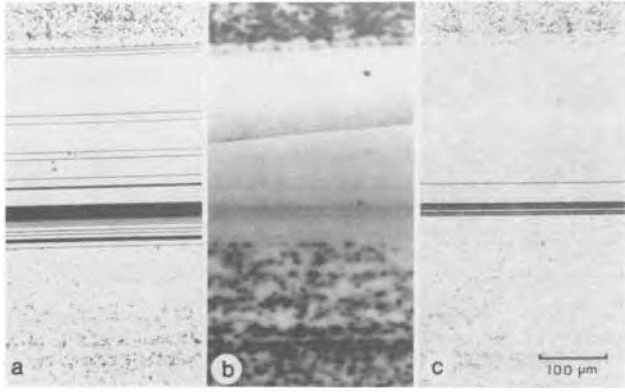

Fig. 10. Comparison between anodic etching at +0.5V (a), EBIC (b), and anodic etching at −0.4V (c) in ribbon-Si.

Preferential etching of defects thus requires higher current densities at the intersection of defect and surface as compared to the undisturbed surface. The current density at a given voltage depends on several factors; the most important ones are the resistance of the electrolyte, the generation and transfer of charge at the silicon-electrolyte interface, and the bulk properties of the silicon.

At high voltages the current density is limited by the resistance of the electrolyte only and practically does not depend on any specific interface or bulk properties of the silicon. The current density across the interface is governed by the HF concentration, thus electropolishing will occur.

At intermediate voltage ranges pronouncedly different etching rates are observed for different surface orientations. This demonstrates that surface properties are dominating the current density in this voltage region. This is in general agreement with the observation that the holes required for the dissolution process are generated in the near-surface regions rather than in the bulk of the Si (9). This is in contrast to Ge where holes from the bulk are diffusing to the interface. The concentration of holes generated near the surface is related to the bulk concentration and their flow across the interface is not inhibited since the band-bending introduced by the applied voltage favors the flow of current.

At very low or negative applied voltages the bulk concentration of holes (and the surface concentration related to it) is no longer important. This is demonstrated by the fact that the potential current curves for p- and n-type Si are almost identical for small applied voltages, *i.e.*, for small overpotentials (15). The current density for n-type Si of low overpotentials can be even higher than that of p-type Si (15), indicating a possible surface inversion-layer. Thus it appears that not the availability of holes but their transport across the interface is rate determining. In other words, potential barriers between hole states in the semiconductor and in the electrolyte may exist, making current flow difficult. Defects may introduce additional transition possibilities for holes to the electrolyte.

A full understanding of the current-potential curves of semiconductors with and without defects requires a sophisticated theory which is beyond the scope of this paper. Phenomenologically, the difference in etching rates for defects and for perfect material can be described by appropriately chosen voltage-current characteristics. From the limited number of experiments performed so far a rough idea of these characteristics can be derived; this is shown in Fig. 11. Comparing these curves to characteristics given in (15), it is clear that defected areas in p-type Si behave as p^+-type Si. In other words, defects in p-type Si behave like p^+-type material; this is in accordance with the general view of the electronic properties of defects in Si, *cf.* various papers given in Ref. (20).

Dislocations and grain boundaries other than twin related boundaries appear to be etched under most conditions although they may show some voltage dependence as illustrated in Fig. 7. Thus they are strongly electronically active and this is related to the states in the bandgap introduced by them (20, 21). Most twin boundaries, on the other hand, are not etched at small negative voltages. This may indicate that no electronic states in the bandgap are associated with them. However, the fact that they are preferen-

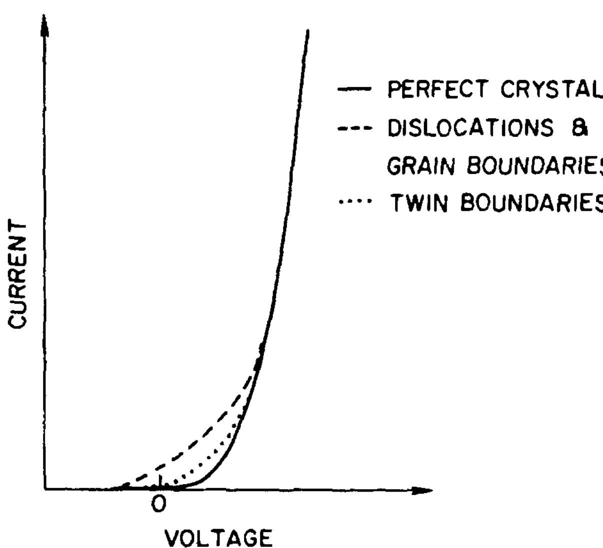

Fig. 11. Tentative current-voltage curves for various defects

tially etched at small positive voltages [scanning electron microscopy showed that true etch grooves and not steps were formed (Fig. 12)] indicates that they do influence the electronic structure of the semiconductor to some extent. This might be due to a change in the surface states around the twin boundaries rather than to states in the bandgap. It may also explain why chemical etching usually does attack twin boundaries and stacking faults (which are closely related defects) although these defects do not have an appreciable strain field or electrical (bulk) activity and cannot always be assumed to be decorated with impurities.

The correspondence between EBIC and anodic etching at negative voltages is striking, even for fine details. This indicates that anodic etching essentially probes the same properties of the defects as EBIC does, namely their ability to act as carrier recombination or generation centers. Of particular interest here is the observation that certain twin boundaries may be electronically active while others are not. This was attributed to the presence of dislocations in these boundaries (17) but this could not be confirmed in the present work.

Chemically etched specimens looked similar to specimens etched anodically at a certain voltage. It appears that Secco etch corresponds roughly to anodic etching at ~0-1V and Sirtl etch to somewhat higher voltages. Since chemical etching is also an electrochemical reaction, the present experiments may lead to a better understanding of their operation.

Some remarks on the applicability of the method.— Anodic etching offers a simple and elegant way to obtain defect information about defects in Si which usually would require EBIC and chemical etching. It has considerable advantages compared to EBIC, the setup and the preparation is simple as compared to the rather complex specimen preparation and equipment needed for EBIC. The resolution is much better for anodic etching and large areas can be etched and inspected in a short time. On the other hand, EBIC is nondestructive and can be made quantitative whereas anodic etching requires the dissolution of a thin surface layer ($\lesssim 1$ μm) and is as yet not quantitative.

Anodic etching can replace chemical etching if the correct voltage is chosen. The sensitivity seems to be better than that of most chemical etches and there is no ambiguity about the selectivity of the etching with respect to certain surface orientations or certain defects.

It is important to note that the method is not restricted to p-type Si; n-type Si can be anodically etched in much the same way as was already demonstrated in Ref. (14). Moreover, the method very likely can be applied to any semiconductor if a suitable electrolyte can be found. This might be difficult, but certainly it is less so than the development of a chemical etch.

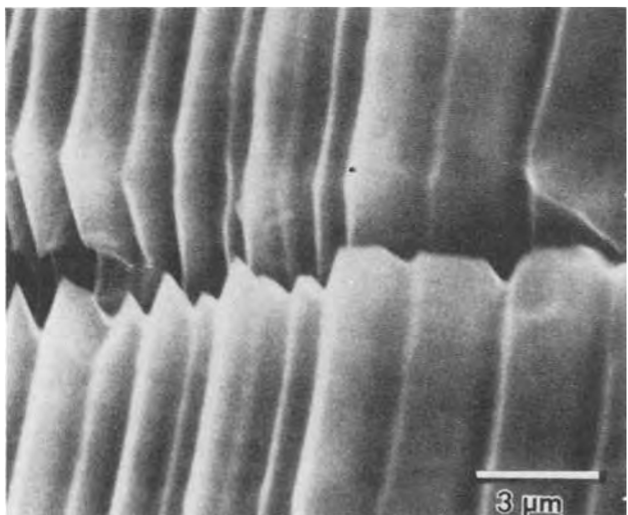

Fig. 12. SEM picture of etch-grooves at twin boundaries crossing a scratch-mark in ribbon Si after anodic etching at +0.5V.

It is felt that the method could be made quantitative if a better theoretical understanding of the basic process could be achieved and if quantitative experimental results could be supplied. The latter would involve precise measurements of the Si-potential-current relationship rather than simple voltage-current characteristics and should also define the role of the resistivity of the Si.

Conclusions

1. Defects in p-type Si can be etched anodically and their etching behavior depends on the applied voltage.
2. At very low potentials only defects are etched which would be classified as "electrically active" by EBIC.
3. At somewhat higher potentials the etching is similar to chemical etching but is more sensitive and free of ambiguities.
4. Anodic etching has the potential to develop into a powerful technique for defect characterization in many semiconductors for both p- and n-type and can widely replace EBIC and chemical etching.

Applications of a Low Noise Potentiostat in Electrochemical Measurements

Ugo Bertocci*

National Bureau of Standards, Chemical Stability and Corrosion Division, Washington, D.C. 20234

ABSTRACT

Measurements on two electrochemical systems, copper in copper sulfate and aluminum in boric acid/tetraborate buffer, have been carried out by recording the amplitude spectrum of the fluctuations in the current density. For these measurements, a low noise potentiostat developed and built at NBS was employed. In the case of copper, the current spectra are found to be the deterministic response of the electrode to the noise voltage generated by the potentiostat. The electrode characteristics for charge-transfer and for diffusion could be obtained from the impedance plots derived from the measurements when the level of the applied signal was of the order of 10^{-7}V. In the case of aluminum, the deterministic response observed in the absence of pitting gave way to random fluctuations in the current in conditions leading to pitting. It is shown that the onset of pit formation can be detected from noise measurements. The significance of the information obtained in electrochemical noise measurements is briefly discussed.

The study of random fluctuations in current and potential of electrodes, usually known as electrochemical noise, is receiving increasing attention, and interesting applications are being envisaged in the field of corrosion (1). In these studies, it is often necessary to detect and measure very low amplitude signals, and it is therefore very important to reduce the noise generated by the measuring instruments. Since in most electrochemical studies it is desirable to control the electrode potential, a low noise potentiostat is a particularly useful device (2).

Elsewhere (3), the circuit and performance of a potentiostat designed and built at NBS have been described. The purpose of this communication is to report on measurements carried out on some electrochemical cells, taking advantage of the characteristics of such a potentiostat. These measurements are not restricted to the detection of noise, but concern also the observation of the current response to very small voltage signals.

Experimental Procedures

The measurements were carried out with the apparatus shown schematically in Fig. 1. All the instruments inside the dot-dashed enclosure are battery operated, and the enclosure represents electromagnetic shielding as well as some protection from mechanical vibrations. The potentiostat provides for a low noise d-c control voltage and for the measurement of the d-c current. A built-in a-c amplifier is employed for the detection of the fluctuations in the current in the frequency range approximately between 0.1 Hz and 2 kHz. The cell is provided with two reference electrodes, a low impedance one, which is used as a sensor for the potentiostat and for the measurement of the voltage noise, and a second one, often an SCE, employed for the monitoring of the d-c electrode potential. The values of the d-c voltage and current are recorded on a two-channel recorder.

* Electrochemical Society Active Member.

Key words: aluminum, copper, impedance measurements, pitting, potentiostat.

An additional voltage signal can be added to the d-c control voltage. In this work, the superimposed voltage consisted of a constant amplitude, swept frequency signal, sweeping linearly over a factor of ten. The repetition rate was slightly less than the time of acquisition of a spectrum by the spectrum analyzer.

The frequency analysis of the output signal, either the current or the electrode potential, depending on the position of the switch shown in Fig. 1, was carried out by a spectrum analyzer with a frequency resolution of 1/200 of the range. In the 50 Hz range, for example, the spectrum consisted of 200 values at intervals of 0.25 Hz. The acquisition time for one spectrum is equal to one period at the lowest frequency, that is, 4 sec for the range mentioned above.

The input waveform to the spectrum analyzer as well as the instantaneous and average spectra were observed continuously on the oscilloscope. Average spectra were then recorded on an X-Y recorder, either on a linear or on a logarithmic scale.

The time involved in acquiring the average spectra in the low frequency ranges can be considerable. In the 5 Hz range each spectrum requires 40 sec so that for an average over 64 spectra the acquisition time is of the order of 40 min.

Experimental Results

The results presented here concern two quite different electrode systems, one having low and the other high resistance to the faradaic current. As a low impedance system, the reaction between Cu metal and a 0.5 mole/liter $CuSO_4$ + 0.1 mole/liter H_2SO_4 solution was examined. Figure 2 and 3 show the voltage and current spectra, respectively. The reference electrode was also copper, and the data were taken in conditions of zero d-c current. The spectra were also taken when a swept frequency signal was added to the d-c control voltage. The amplitude of the signal as shown in Fig. 2 was about 10-100 times the background noise but never larger than about 2 μV. Figure 3 shows the current response with and without the superimposed voltage signal.

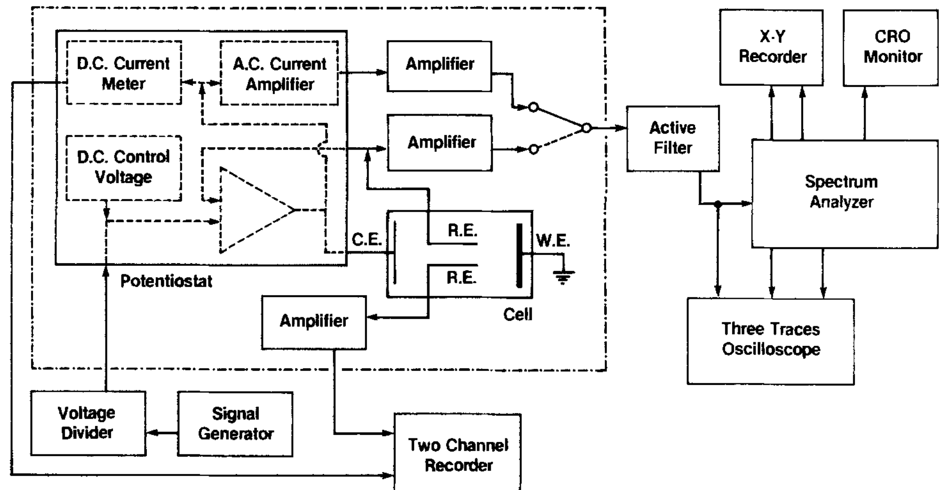

Fig. 1. Experimental circuit for the recording of current and voltage spectra under potentiostatic conditions.

The impedance of the electrode |Z| can be obtained as the ratio of voltage to the current at every frequency, and the results are shown in Fig. 4. These ratios were calculated after subtracting from each value the instrumental noise, which had been previously measured (3). For the voltage, the instrumental noise is less than 10^{-8} V/$\sqrt{\text{Hz}}$ above 8 Hz and for the current it is equivalent to $3 \cdot 10^{-11}$ A/$\sqrt{\text{Hz}}$ above 1 Hz. The points in Fig. 4 obtained with and without the superimposed voltage signal are very close. This is because the electrode impedance is rather small, and therefore the instrumental noise in the current density data is small compared with the recorded value of the current. The increased signal-to-noise ratio obtained by a larger voltage signal has little effect on the accuracy of the results.

The results have been fitted to an equivalent circuit (shown in the inset in Fig. 4). The line drawn in Fig. 4 shows |Z| as calculated from this circuit, using the following values: ohmic drop resistance $R_\Omega = 5\Omega$, charge-transfer resistance $R_{ct} = 15\Omega$, equivalent to an exchange current i_o for the rate-determining step (4) $Cu^{++} + e^- \rightleftarrows Cu^+$ of 0.42 mA/cm^2; double layer capacitance $C = 35$ μF/cm^2.

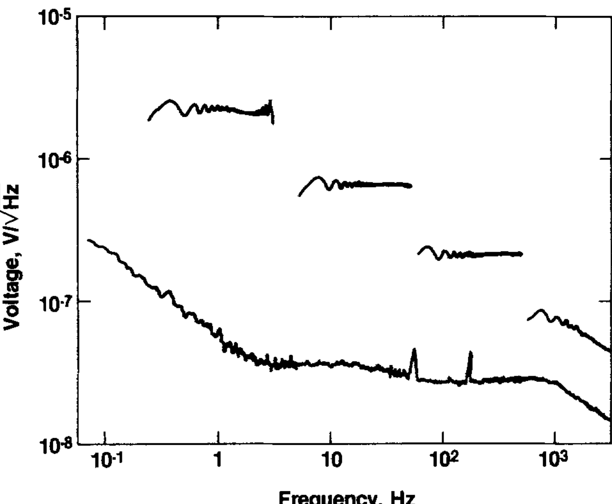

Fig. 2. Voltage spectra recorded under potentiostatic conditions ($I_{dc} = 0$) on Cu in 0.5 mole/liter $CuSO_4$ + 0.1 mole/liter H_2SO_4. The four segments are the swept frequency signal superimposed to the d-c control voltage.

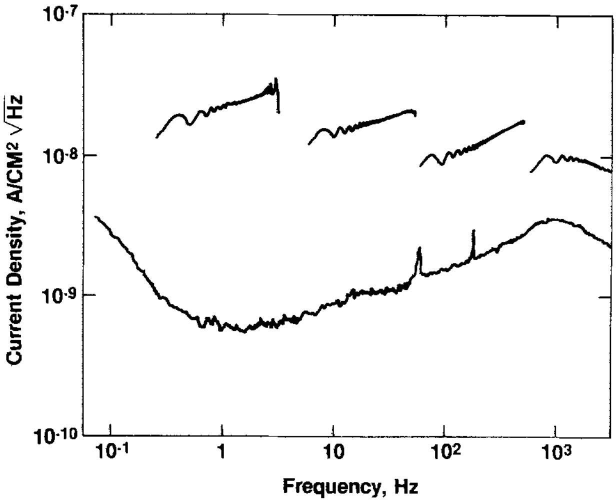

Fig. 3. Current spectra recorded under potentiostatic conditions ($I_{dc} = 0$) on Cu in 0.5 mole/liter $CuSO_4$ + 0.1 mole/liter H_2SO_4. The four segments are the current response to the swept frequency signal shown in Fig. 2.

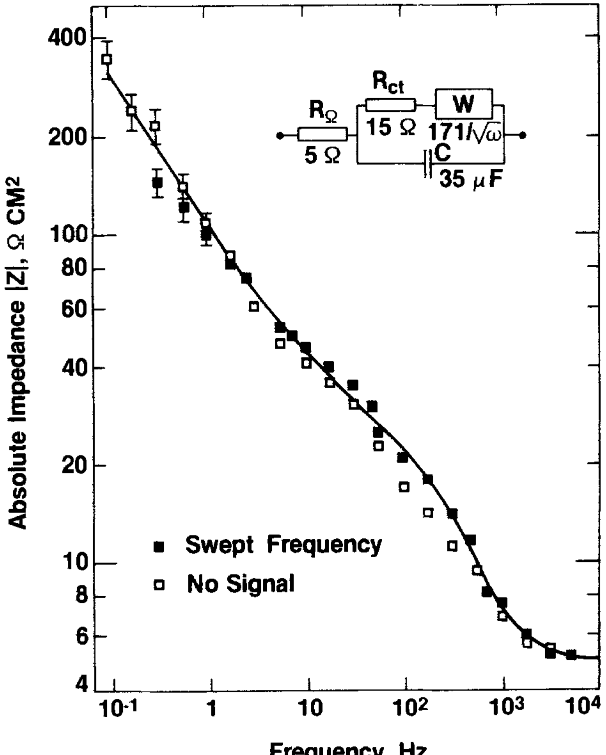

Fig. 4. Absolute impedance |Z| vs. frequency for Cu in 0.5 mole/liter $CuSO_4$ + 0.1 mole/liter H_2SO_4 obtained from current and voltage spectra. Solid line calculated for circuit shown.

Since one of the species involved in the rate-determining step, Cu^+, is present only in low concentrations, a significant Warburg impedance is present at low frequencies. The value of the Warburg impedance

$$W = \frac{RT}{z^2F^2(Cu^+)\sqrt{2\omega D_{Cu^+}}}$$

was calculated choosing $D_{Cu^+} = 1.38 \cdot 10^{-5}$ cm²/sec and $Cu^+ = 2.9 \cdot 10^{-4}$ mole/liter. Most of these values are in excellent agreement with the literature; for instance, the exchange density (5) and the diffusion coefficient of Cu^+ (6). The Cu^+ concentration that gives the best fit is about 80% larger than that calculated from the reaction

$$Cu^{++} + Cu = 2Cu^+$$

whose equilibrium constant is $7 \cdot 10^{-4}$ (6, 7), and taking the activity coefficient of 0.5 mole/liter $CuSO_4$ as 0.062 (8). The value of the Cu^+ concentration affects the magnitude of the Warburg impedance and therefore that of $|Z|$ only at low frequencies, where the reliability of the experimental points, as shown by the error bars in Fig. 4, is not as good as at higher frequencies.

The second system examined was 6061 aluminum in a 1:1 mixture of saturated H_3BO_3 and $Na_2B_4O_7$ with and without addition of 0.05M NaCl. The current and voltage spectra in the solution not containing chlorides are as given in Fig. 5.

In the chloride-containing solution, which is known to cause pitting if the potential is raised approximately above -700 ± 50 mV *vs.* SCE (9), the current spectra obtained below and at the pitting potential are reported in Fig. 6 together with the voltage spectrum. During the recording of the spectra, the d-c current was about 10 μA/cm² cathodic at -800 mV, while at -650 mV, it became anodic, increasing slowly to about 50 μA/cm².

The impedance plots for this system are given in Fig. 7. Here again the onset of pitting is marked by a fundamental change in the impedance plot up to 1 kHz.

Discussion

The results shown for the $Cu/CuSO_4$ electrode indicate that random fluctuations in electrode characteristics are so low that they do not affect significantly the current response to the broadband noise voltage signal. For this reason, the impedance plot shown in Fig. 4 can be accounted for satisfactorily by the deterministic response of the circuit drawn, from which reliable values concerning the kinetics of the electrode can be obtained. Therefore, although the intrinsic noise of the control voltage is still too large in this case for the detection of random processes at the electrode, good measurements can be carried out even for signals below 0.1 μV, detecting currents in the nA range.

In the case of aluminum in boric/borate solution, when pitting does not occur, random current fluctuations are below the limits of detection, and the electrode response is largely that of a capacitor of about 0.3 μF/cm². The data of Fig. 7 seem to indicate a larger capacitance in chloride containing solution, where thinning of the film can occur (10). Above the pitting potential, the noise current increases more than two orders of magnitude, and the impedance plot in Fig. 7

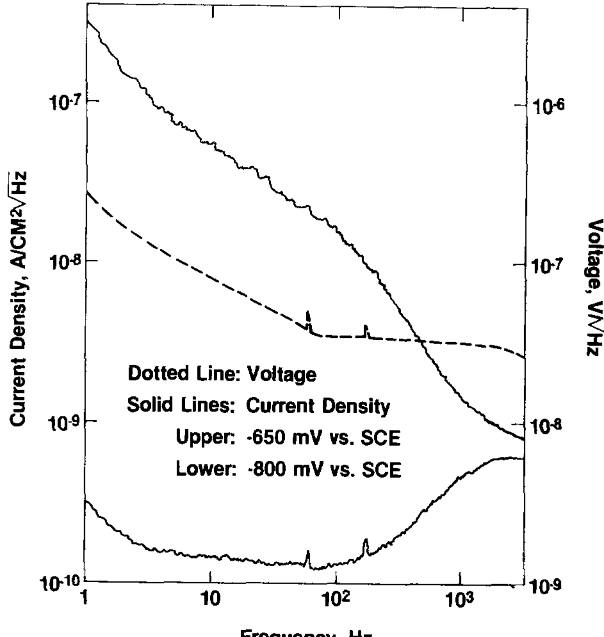

Fig. 6. Current and voltage spectra recorded under potentiostatic conditions below and at the pitting potential on Al in $H_3BO_3{:}Na_2B_4O_7$ + 0.05 mole/liter NaCl.

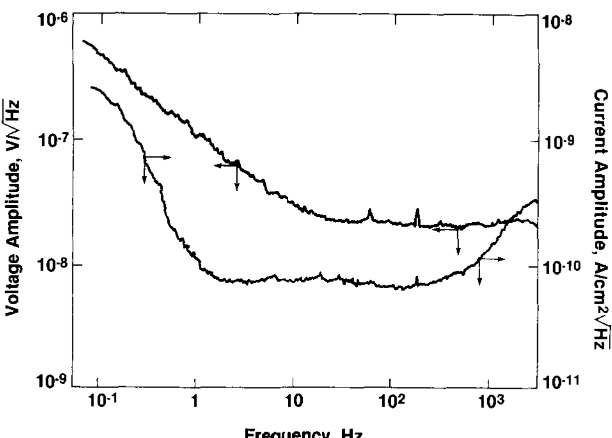

Fig. 5. Current and voltage spectra recorded in potentiostatic conditions ($E = -320$ mV *vs.* SCE) on Al in $H_3BO_3{:}Na_2B_4O_7$ solution.

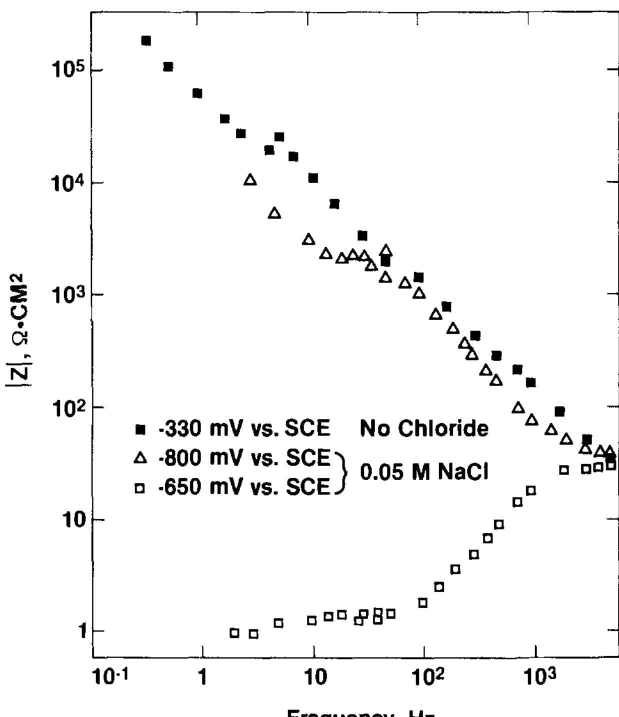

Fig. 7. Absolute impedance $|Z|$ *vs.* frequency for Al in $H_3BO_3{:}Na_2B_4O_7$ with and without chloride added.

cannot be explained other than as caused by random fluctuations of the electrode current, independently of the voltage signal applied.

The detection of this current noise is a good indication of the beginning of pitting, and the large fluctuations are probably due to hydrogen evolution from the pits (11). The onset of the large current noise has shown to be reproducible within a range of 10-20 mV.

The noise current observed is the sum of several contributions since the fluctuations of the control voltage interact with the random variations of the electrode resistance and capacitance causing intermodulation terms. These terms are, however, much smaller than the contributions due to the fluctuations of the d-c current, which are independent of the control voltage noise. Since the d-c current, upon pitting, increases to several $\mu A/cm^2$, the noise current observed can be accounted for by oscillations of the order of a few percent of the average d-c current.

It is more difficult to estimate the possible contribution of fluctuations in the double layer capacitance; they can be caused by changes in surface area as well as changes in the thickness of the protecting film, a more likely case for Al in neutral solution. The current generated is

$$i_c = (E - E_{zc}) \frac{dC}{dt}$$

where E_{zc} is the potential of zero charge. If the capacitance varies by a fraction k at angular frequency ω, that is

$$C = C_o(1 + k \sin \omega t)$$

the current at that frequency is

$$i_c = (E - E_{zc}) \omega C_o k \cos \omega t$$

The potential of zero charge for Al is at about -0.75V *vs.* SCE (12), therefore $|E - E_{zc}|$ can be estimated to be of the order of 0.1 ± 0.2V. Since $C_o \simeq 0.3$ $\mu F/cm^2$, for $k = 1$, the rms value of the capacitative noise current would be about $1.3 \cdot 10^{-7}$A at 1 Hz and 100 times larger at 100 Hz. Since the experimental value of the current decreases with frequency and is about 10^{-8}A at 100 Hz, it is safe to conclude that the higher frequency fluctuations of the capacitance are very small, but it is not possible to assign the noise observed unambiguously to variations in the faradaic rather than in the capacitative current.

The results presented show that reduction of the instrumental noise is essential for the study of random fluctuations and that it can be quite useful in all circumstances, allowing measurements with very little perturbation of the systems under investigation. The fact that deterministic measurements can be done using the almost white noise in the control voltage (13) has, however, important implications for a proper understanding of the current spectra when "noise" measurements are attempted. Only in electrochemical systems where the data cannot be explained by assigning constant values to the components of the equivalent circuit is it appropriate to describe the signal observed as electrochemical noise.

Electroless Gold Plating on III-V Compound Crystals

L. A. D'Asaro, S. Nakahara, and Y. Okinaka

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Electroless gold plating in an alkaline bath containing potassium borohydride as the reducing agent has been found to produce tightly adherent plated films on GaAs, $Al_xGa_{1-x}As$, GaP, and InP. In this process, the substrate is activated in an acidified solution of palladium chloride prior to plating. The same process applied to Si or Ge produces poorly adherent films. A transmission electron microscope study of activated GaAs and Si surfaces revealed markedly different morphology and distribution of Pd grains on these two substrates. The adhesion of the subsequently plated electroless gold is discussed in terms of these observations and a model involving atomic interactions at interfaces.

An electroless (autocatalytic) gold plating process utilizing potassium borohydride as the reducing agent has been previously described (1) and used for plating on noble metals such as Pd, Pt, Rh, or Au, or on active metals such as Cu and its alloys (2). The noble metals catalyze the plating reaction, and this fact has led to a method of activating certain metallic surfaces, such as tantalum. An activator solution for that purpose was developed by DeAngelo, *et al.* (3), using acidified palladium chloride containing HF and acetic acid. The HF removes oxide from the surface, allowing activation of the freshly cleaned surface *in situ.* We have found that treatment in similar solutions will induce electroless gold plating on a variety of III-V compound crystals. Comparisons of the electroless gold films (about 1 μm thick) plated by this method with evaporated films of Cr-Au or Ti-Pt-Au indicate that the electroless gold is more tightly adherent, more reproducible, and less expensive to prepare than the evaporated films. These films pass the "Scotch tape test" and cannot be removed by rubbing or scratching with a metal point.

It is shown in this paper that the activation with the $PdCl_2$-containing solution involves the reduction of Pd^{2+} ions to metallic Pd by galvanic displacement. With this activation mechanism one can easily imagine that the overall adhesion of the subsequently plated electroless gold layer will be influenced by the adhesion of the catalyst to the substrate. In fact, there are substrates to which electroless gold adheres poorly. An example is silicon activated by the same process as is used for GaAs. In order to obtain insight into the difference in adhesion on different semiconductor substrates, the morphology and distribution of the Pd catalyst on the substrates were studied using a transmission electron microscope (TEM). The results will be discussed in relation to the mechanism of catalyst deposition. A model involving atomic interactions at various interfaces is presented to explain the observed strong adherence of electroless gold to the III-V compounds.

Solution Preparation and Plating Procedure

In the procedures described here, the plating bath was held constant. The bath composition is given in Appendix 1 (2). We have found that it is convenient to prepare a 5× concentrated solution for storage. It is important to avoid organic contaminants in the water to obtain good results.

The activator solution was modified somewhat for each III-V compound as a result of empirical tests. The preparation of the activator for GaAs and $Al_xGa_{1-x}As$ is given in Appendix 2 (3).

The adherence of gold film is strongly dependent on the cleaning procedures which should therefore be made as stringent as possible. We have used an HCl rinse on chemically polished surfaces followed by rf plasma cleaning to remove traces of organic contaminants.

The plating procedure consisted of activation for at least 1 min (longer time when plating is nonuniform) followed by rinse in distilled deionized water, and immersion in the plating bath held at 70°C. It is essential to supply agitation to the sample in the bath in order to obtain uniform and rapid plating (2). A typical plating rate was 1 μm in 40 min in the present conditions.

A useful technique to insure uniform plating is to inspect the sample after 10 or 15 min and reactive if any spots are unplated. The sample will then plate everywhere, unless contamination is present.

The plating proceeds equally rapidly on n-type, p-type, or semi-insulating crystals, on crystals containing p-n junctions, and on crystals where noble metals are bonded to the surface. Details for each III-V compound are as follows

1. GaAs and $Al_xGa_{1-x}As$—The procedure is as described above. Various compositions of $Al_xGa_{1-x}As$ were plated, with the largest $x = 0.4$.
2. GaP—The acetic acid was omitted from the activator.
3. InP—The activator was modified by omitting acetic acid and adding 5 times the normal HF. It was necessary to heat the activator to 50°C and immerse the InP wafers for 2 min in order to obtain satisfactory plating.

In cases where contamination is present, modification of the activator bath to higher fluoride ion concentration and/or higher activation temperature will usually enable plating.

Photoresist Masking

Masking with negative photoresist is useful for producing patterns of electroless gold. An example of a masked pattern formed on the back of a GaAs metal epitaxy Schottky field effect transistor (MESFET) is shown in Fig. 1.

TEM Observation of Activated GaAs and Si

Sample preparation.—The substrates used in this study were (110) GaAs and (111) Si. Annealed OFHC copper was used for comparison. In order to compare the surface structures of the same specimen before and after activation, thin foil TEM specimens were used as substrates. Galium arsenide foils were prepared by first mechanically polishing a 3 mm disk which had been ultrasonically cut out of a (110) wafer, to a thickness of about 50 μm, and then thinning down further by ion milling. Thin foils of Si were obtained by chemically etching the sample in a solution prepared by mixing 100 ml of conc HNO_3 and 140 ml of glacial acetic acid (4). Copper foils

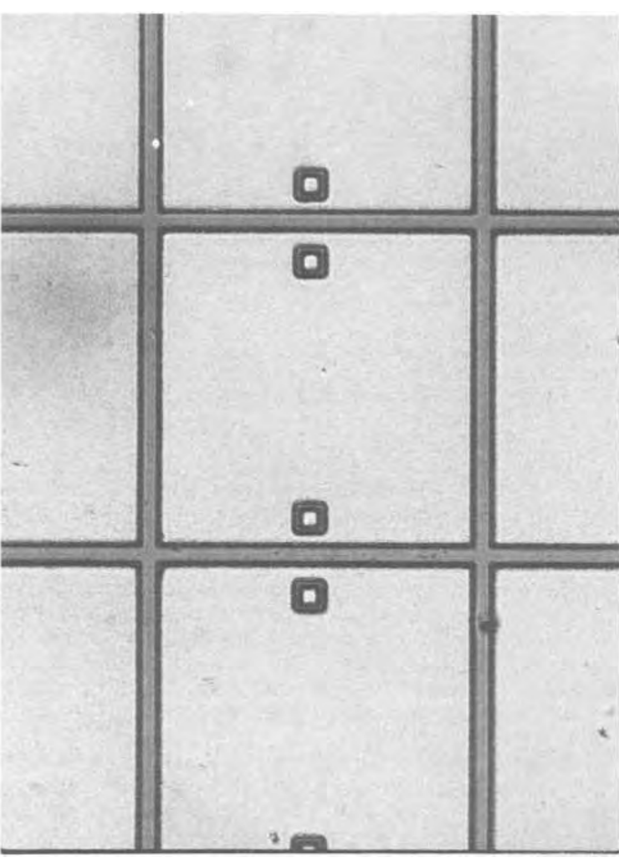

Fig. 1. Bonding pads formed by electroless gold plating through a photoresist mask on the back of a wafer of GaAs MESFET's. The pad dimensions are 500 μm square. The small squares are alignment marks.

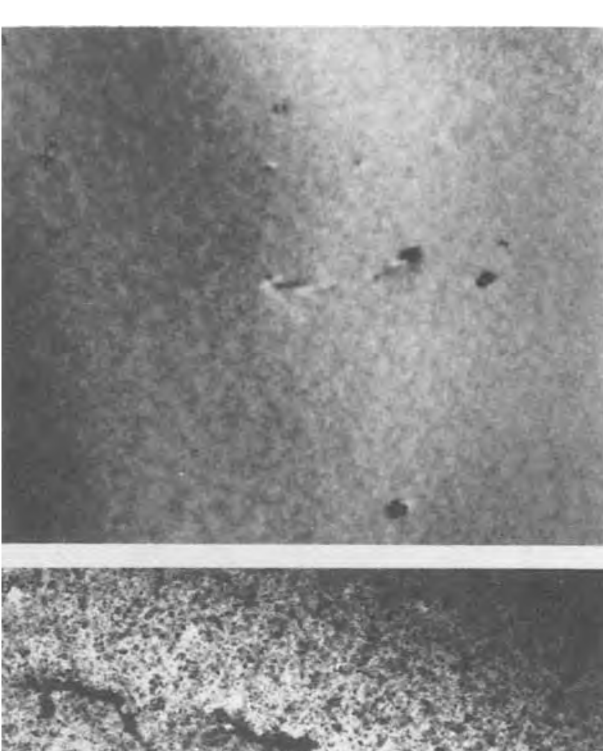
were prepared by electropolishing an annealed sheet in a mixture of 2 parts methanol and 1 part conc HNO_3 at dry ice temperature.

Transmission electron micrographs were taken with a JEM 200 electron microscope operated at 200 kV.

TEM results.—The two TEM micrographs (a) and (b) shown in Fig. 2 compare the structures of (110) GaAs foils before and after activation, respectively. It is seen in Fig. 2(b) that a high density of small "dark" particles has grown on the top and bottom surfaces of the foil upon activation. The particle density has been determined to be $(1 \sim 2) \times 10^{12}/cm^2$. An electron diffraction analysis identified these particles as metallic palladium (see Table I). Appreciable etching of GaAs in the activator solution is also indicated by the presence of large "white" holes shown in Fig. 2(b). In order to measure the size of the palladium particles, a dark-field micrograph was taken using a portion of (111) Pd diffraction ring (see Fig. 3). The bright spots represent the images of individual Pd grains measuring 50-100A. Furthermore, these Pd grains are randomly oriented without any epitaxial relationship to the (110) GaAs substrate. This randomness is indicated by the continuous diffraction rings of Pd grains as shown in Fig. 4. From the size and density of Pd grains, the surface coverage can be calculated to be about 75-85%.

Figure 5 shows a TEM micrograph of an activated (111) Si foil. A large number of round particles are seen to have grown with a smaller density and coverage than those on GaAs. Electron diffraction analysis revealed that these particles also consist of grains of metallic Pd (see Table I). The morphology and distribution of the particles are, however, markedly different from those on activated GaAs substrate (see Fig. 2). Substrate etching appeared to be less on Si than on GaAs. In order to compare the particle



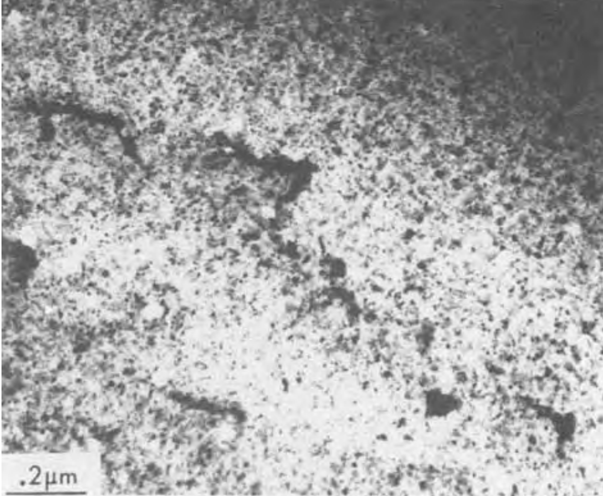


Fig. 2. TEM micrographs of (110) GaAs foils (a) before and (b) after activation. Fine Pd grains are seen to be uniformly distributed on surface. Dark linear features indicate regions containing closely grown Pd grains at the surface steps.

size and distribution at the same magnification, a part of the area in Fig. 5(a) taken at a slightly higher magnification is shown in Fig. 5(b). It is seen that each particle measuring 500-2000A, in fact, consists of smaller grains (~100A) and the particle shape resembles that of spherulites in polymer crystals (5). These hemispherical particles were distributed nonuniformly over the substrate with a density of $\sim 1 \times 10^{10}/cm^2$. An image taken using the high-resolution defocus contrast technique (6) revealed that these spherulite particles contain pores along their radial direction. The particle morphology can be best described as spongy sphere and hemisphere (Fig. 6). The electron diffraction pattern is shown in Fig. 7. The Pd rings are not as continuous as those found with activated GaAs (Fig. 4). This discontinuity is a primary indication of the nonuniform distribution of Pd grains.

Electroless gold plating on copper does not require an activation step because an initial layer of gold is formed as a result of a galvanic displacement reaction, and this layer was previously found to serve as the catalyst for the initial deposition of electroless gold (7). Nevertheless, the surface of copper treated in the activating solution was examined for comparison with the semiconductor substrates. A TEM micrograph of an activated copper foil is shown in Fig. 8. The growth of needle-shaped crystals is noted. From electron diffraction analysis these crystals were

found to be cuprous oxide (Cu_2O) rather than metallic palladium (see Table I). This result is of interest because it shows that metallic palladium, which undoubtedly forms, does not adhere to the copper surface under the conditions of this experiment. The formation of metallic palladium is indicated by the appearance of finely dispersed black particles during the activation treatment in conjunction with the consideration of electrochemical potentials involved. The nonadherence of metallic palladium on copper is attributed to the stability of Cu_2O on copper and the more favorable nucleation in the solution phase than on Cu_2O or copper. Undercutting may also be responsible. It should be noted that the Cu_2O needles did not result from air oxidation of copper; the air-oxide is known to grow epitaxially in the form of cubes. The Cu_2O needles must be the product of oxidation of copper by palladium ions.

Discussion of TEM results.—Before the morphology and adhesion of palladium particles can be considered, it is instructive to discuss the mechanism of chemical reactions leading to the nucleation and growth of metallic palladium. The activator solution contains excess HCl which serves to dissolve $PdCl_2$ by complexing it to form $PdCl_4^{2-}$. The deposition of metallic palladium from this species occurs according to the reaction

$$PdCl_4^{2-} + 2e^- = Pd + 4Cl^- \quad (E° = 0.62V) \quad (8) \quad [1]$$

The required electrons must be supplied by the substrate. In the case of GaAs[1] the following reactions

[1] The ionicity of the Ga-As bond is estimated to be only 5-10% (9), which may be ignored for the purpose of the present discussion.

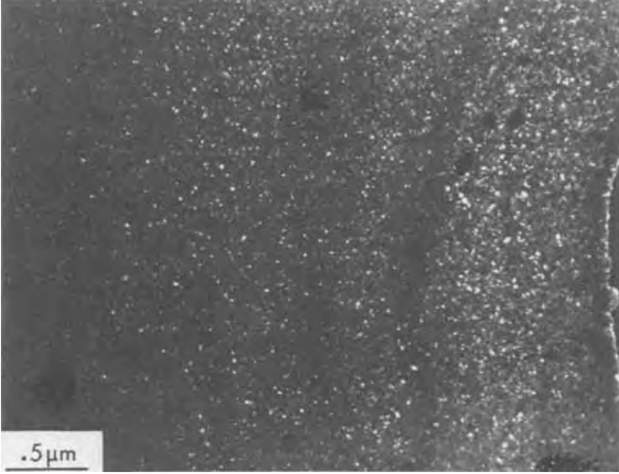

Fig. 3. Dark-field TEM micrograph corresponding to Fig. 2(b), taken from a portion of a (111) Pd diffraction ring. Bright spots indicate finely distributed Pd grains grown on activated (110) GaAs foil.

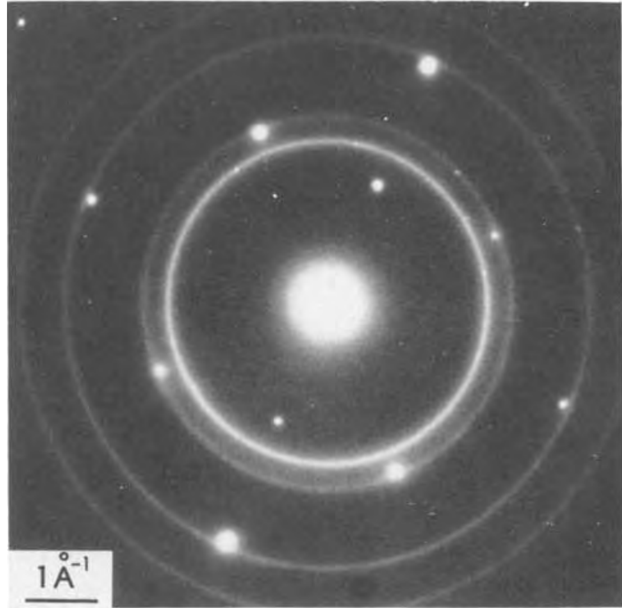

Fig. 4. Electron diffraction pattern from activated (110) GaAs foil. The continuous rings originate from finely distributed Pd grains, whereas the spots result from single crystal (110) GaAs.

may proceed from right to left

$$Ga^{3+} + 3e^- = Ga \ (E^\circ = -0.54V) \quad [2]$$

$$HAsO_2 + 3H^+ + 3e^- = As + 2H_2O \ (E^\circ = 0.248V) \quad [3]$$

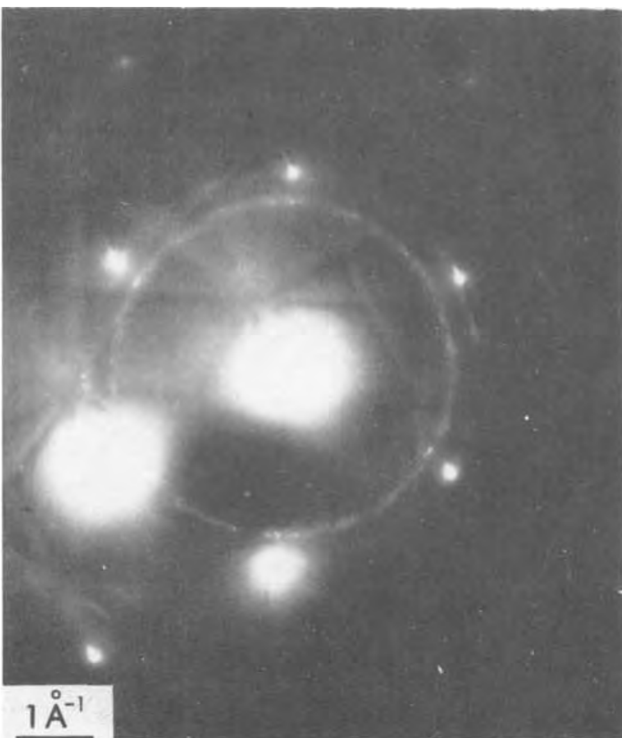

Fig. 7. Electron diffraction pattern from activated (111) Si. The rings are from Pd grains; the spots are from (111) Si. The discontinuity in the rings indicates that Pd grains are not uniformly distributed over the Si surface.

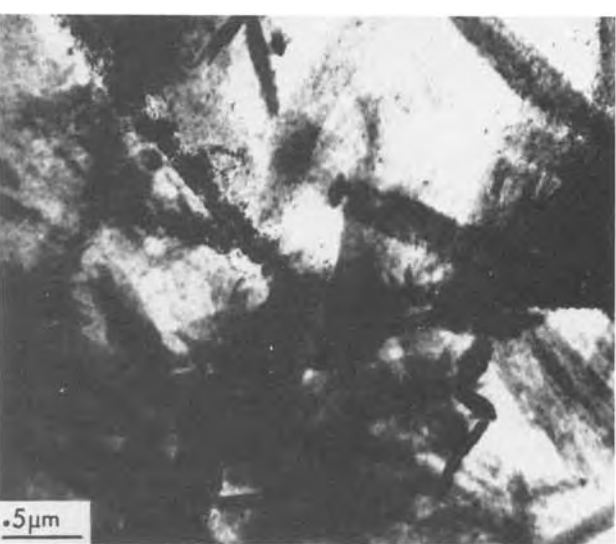

Fig. 8. Needles of copper oxide (Cu_2O) grown on activated copper foil.

$$H_3AsO_4 + 5H^+ + 5e^- = As + 4H_2O \ (E^\circ = 0.377V) \quad [4]$$

The relevance of these reactions was inferred from the predominance diagram for GaAs recently published by Park and Barber (10). The values of E° indicate that both Ga and As may be oxidized by $PdCl_4^{2-}$. For Si in the presence of F^-, the relevant oxidation will be the reverse of the following reaction

$$SiF_6^{2-} + 4e^- = Si + 6F^- \ (E^\circ = -1.2V) \quad [5]$$

For Cu in the presence of Cl^-,[2] the corresponding reactions are

$$CuCl + e^- = Cu + Cl^- \ (E^\circ = +0.137V) \quad [6]$$

$$CuCl_2^- + e^- = Cu + 2Cl^- \ (E^\circ = +0.067V) \quad [7]$$

Comparison of these E° values with the value for reaction [1] indicates the thermodynamic possibility for the formation of Pd metal by galvanic displacement in all cases. Based on the above considerations and the experimental results, we conclude that the metallic palladium particles observed were formed as a result of galvanic displacement.

We shall now consider why metallic Pd thus formed give rise to different morphologies depending on the substrate. A galvanic displacement reaction can be considered as a mixed potential reaction consisting of cathodic and anodic half-reactions in much the same way as a corrosion reaction. At any instant during the reaction, then, cathodic and anodic sites must be distributed side by side on a microscopic scale on the substrate surface. Palladium will deposit at the cathodic sites, while substrate oxidation (dissolution) will take place at the anodic sites. The deposition of palladium will involve nucleation and growth as in conventional electrodeposition processes. The uniform distribution of very small Pd grains observed on GaAs indicates that nucleation is highly promoted on this substrate. On the other hand, the morphology observed on Si indicates that after the initial nucleation took place on the relatively small number of cathodic sites, further nucleation occurred preferentially on the already existing palladium particles rather than directly on the substrate, thus resulting in the formation of the spherulite particles. It is generally recognized (12) that for any metal deposition systems a strong atom-to-surface interaction will result in the formation of a high density of nuclei while a weak interaction will give widely spaced nuclei. The observed high density of Pd nuclei

[2] F^- forms only a very weak complex with Cu (11).

grown on GaAs, therefore, indicates that there is a strong interaction at the interface between Pd and GaAs. The observation with Si, on the other hand, indicates a much weaker interaction. The nature of the atom-to-surface interaction will be discussed later. The manner in which electroless gold deposition progresses on a substrate only partially covered with discrete Pd catalyst particles can be depicted as follows. Immediately after the substrate is placed in the electroless plating bath, gold begins to nucleate on Pd and to grow in all directions. The growth of gold in the lateral direction results in coalescence of adjacent particles and eventually in the formation of a continuous layer of gold. The thickness of this layer continues to grow indefinitely because of the autocatalytic nature of the process. The adherence of the gold film formed in this manner must depend on adherent interactions at three different interfaces: (*i*) Pd/substrate, (*ii*) Au/Pd, and (*iii*) Au/substrate in the regions between Pd catalyst sites.

Pd/substrate interface.—As already discussed, the microscopic observations indicate that a strong interaction exists between Pd and GaAs, while the interaction between Pd and Si is weak. The binary phase diagram for Pd-Ga (13) shows that Ga has a significant solubility at room temperature in Pd. Also, Pd forms intermetallic compounds with Ga (and other Group IIIA elements). On the other hand, Pd and Si have no mutual solubility according to the phase diagram of this system (13). Intermetallic compounds are known, but if formed, these are ineffective in promoting adherence of the electroless gold.

Au/Pd interface.—The adhesion of electroless gold to evaporated or sputtered Pd films or to bulk Pd metal has previously been shown to be extremely strong regardless of the surface roughness (1), and thus the adherence of electroless gold to Pd catalyst particles is expected to be strong on both GaAs and Si.

Au/substrate interface.—The phase diagrams (13) again show significant solubilities of Au in Ga and other Group IIIA elements and possibilities of the formation of intermetallic compounds. There is independent evidence showing that evaporated gold reacts chemically with GaAs at room temperature (14). On the other hand, no evidence is found for room temperature chemical interaction between Au and Si. Hence the bonding of Au to Si at room temperature can be expected to be weak. In the case of GaAs it is not expected that the Au/substrate interface plays a major role in determining the overall adhesion because of the high Pd coverage (~80%) of the substrate. Nevertheless, the expected strong interaction between Au and GaAs certainly should reinforce the overall adhesion. For Si the lack of chemical interaction with Au in conjunction with the low Pd coverage seems decisively responsible for the poor overall adhesion observed.

From the analysis of the model consisting of three interfaces presented above, it is concluded that the strong adhesion of electroless gold to GaAs and other III-V semiconductors is due to the favorable situation at all three component interfaces.

Finally, it is of interest to mention that the adherence of electroless gold on Pd-activated germanium was found to be as poor as for Si. This result is also consistent with the expected lack of chemical interaction at room temperature, as inferred from the corresponding phase diagram.

Summary and Conclusions

A range of III-V compounds can be electroless gold plated if appropriate activation is used. The films, about 1 μm thick, are tightly adherent as judged by scratching with a sharp metal point and pulling with "Scotch tape."

The activation of GaAs, Si, and Cu by the activator containing HCl, HF, and acetic acid was studied using TEM. It was shown that metallic Pd forms on GaAs and Si by galvanic displacement, while on Cu only Cu_2O was observed. On GaAs, grains of Pd measuring 5-100A are uniformly and densely distributed $[(1 \sim 2) \times 10^{12}/cm^2]$ so that they cover ~80% of the surface, whereas on Si these grains form large agglomerates (500-2000A) which are distributed with large separation (~1000A). These differences in morphology and distribution of Pd grains were discussed in relation to the difference in surface-to-Pd atom interaction. The strong adherence of electroless gold to Pd-activated GaAs and other III-V compounds and the weak adherence to Si (and Ge) can be explained using a model based on atomic interaction at three component interfaces: Pd/substrate, Au/Pd, and Au/substrate.

These results indicate that electroless gold plating can be usefully applied to a variety of III-V compound devices where pure, soft gold is required. In a recent application, via-connections on GaAs MESFET's were plated (15). We believe that other III-V compounds than those reported here could also be electroless gold plated using suitable modifications of the process.

APPENDIX 1

Plating Solution

			5 X conc. (g/liter)
$KAu(CN)_2$	0.003M	(0.864 g/liter)	4.3
KOH	0.2M	(11.2 g/liter)	56.0
KCN	0.1M	(6.5 g/liter)	32.5
KBH_4	0.2M	(10.8 g/liter)	54.0

To make 5 X concentrate:

1. Dissolve KOH in 500 ml of H_2O. Add KBH_4 and stir until dissolved.
2. Dissove KCN in 200 ml of H_2O in a volumetric flask. Add $KAu(CN)_2$ and stir until dissolved.
3. Add solution 1 to solution 2 in a volumetric flask and make up to volume with distilled H_2O. Filter through a filter paper. Store in a Teflon or polypropylene bottle. Do not close tightly because the solution liberates hydrogen slowly during storage.

APPENDIX 2

Activator Solution

Dissolve 0.3g $PdCl_2$ in 9 ml conc. HCl and dilute it with 9 ml H_2O. Add this mixture to 864 ml glacial acetic acid; then add 18 ml HF(49%) and mix.

Electrowinning of Silicon from K_2SiF_6-Molten Fluoride Systems

Gopalakrishna M. Rao,* Dennis Elwell,* and Robert S. Feigelson

Center for Materials Research, Stanford Univerity, Stanford, California 94305

ABSTRACT

The electrowinning of silicon from solutions of K_2SiF_6 in fluoride melts at 745°C has been achieved. Electrolysis close to the deposition potential gave dense, coherent, and well-adherent deposits. Up to 3 mm thick films were grown using a K_2SiF_6 concentration of 4-6 m/o. The polycrystalline silicon has a columnar structure with grain size up to 100 μm. The morphology of the electrodeposited silicon onto silver substrates and its dependence on the deposition parameters is discussed. The purity of the deposits is substantially higher than that previously reported for electrodeposited silicon.

The availability, low toxicity, and high degree of technological development make silicon the most likely material to be used in terrestrial solar cells. The cost of silicon solar cells is still too high, however, for economic energy production, and the cost of pure elemental silicon is itself a major problem in achieving the cost objective of \$100-300 per peak kW by 2000 (1). Electrowinning is, in principle, a very attractive process for production of elemental silicon since it allows direct, single-stage production from some source material. The process can be operated at relatively low temperatures in comparison with those which involve molten silicon, and can yield a product which is substantially lower in impurity concentration than the source material.

The electrodeposition of silicon was first reported in 1854 (2) but there have been relatively few systematic studies reported in the literature. The most detailed investigation to date has probably been that of Monnier *et al.* (3, 4), who showed that silicon of 99.99% purity could be produced in a two-stage winning and refining process. Their deposits were, however, apparently powdery and incoherent and required subsequent separation from entrapped solvent. Cohen *et al.* (5-7) in our laboratory showed that single crystal epitaxial layers could be electrodeposited from solutions of K_2SiF_6 in a KF/LiF eutectic and that continuous films could be produced by electrorefining using a dissolving silicon anode.

The objective of the present study was to electrowin high purity silicon, in bulk form or as films with large grain size, from an inexpensive source. The morphology of the polycrystalline silicon films produced and their dependence on the electrodeposition conditions is discussed. A preliminary report of this investigation has been presented previously (8).

Key words: polycrystalline silicon, electrocrystallization, semiconductor, solar cell.

Experimental

The apparatus used in this investigation was similar to that reported by De Mattei *et al.* (9), except that silica tubes were used to electrically insulate the electrode leads from the top flange. The nickel leads were fixed into the silica tubes using a low vapor pressure epoxy cement. The tubes were replaced after several experiments when devitrification was evident.

Potassium fluorosilicate was chosen as the source of silicon because of the large number of successful silicon and silicide depositions using this material (2-8). Fluorosilicic acid is a by-product of phosphate fertilizer manufacture and has at present no useful application, so that fluorosilicates are an inexpensive source of silicon. The potassium salt has the lowest volatility and material of 99% purity was obtained commercially (Alfa Ventron).

The solvent used was the ternary LiF/NaF/KF eutectic "Flinak" (mp 459°C) or the binary LiF/KF eutectic (mp 492°C). These solvents have the advantages of high conductivity, low viscosity, high decomposition voltage, and high solubility for oxides which tend to form on the electrode surfaces. LiF of 99.5% purity, NaF of 99% purity, and 99-99.5% KF were used in this investigation. These anhydrous materials were mixed and dried first under vacuum at 200°C and then under flowing argon for several hours prior to fusion. The argon was purified by passing it over titanium chips at 650°C. After cooling the fused solvent, K_2SiF_6 was added and the resulting solution was purified by pre-electrolysis for 12-24 hr under conditions similar to those used for deposition but at a substantially higher potential and current density.

Electrodeposition of silicon was performed at 745° ± 10°C in a two- or three-electrode configuration with the melt contained in a vitreous carbon crucible. After graphite, niobium, and nickel had been tried

in preliminary experiments, silver was selected as the cathode material because of its low reactivity with silicon. Graphite was found to be unsuitable as an anode material because it reacts and tends to disintegrate. Platinum was therefore used both as anode and reference electrode. Electrodes were ultrasonically cleaned in ethanol prior to use. Voltammetry and electrolysis at constant current or potential were carried out using a potentiostat/programmer and the charge passed was measured with a coulometer.

Salts adhering to the deposit were removed by digesting in hot distilled water for about 12 hr followed by ultrasonic cleaning in water, then ethanol, for about 15 min.

The morphology of the deposits was investigated by scanning electron microscopy and optical microscopy. The samples were analyzed for impurities by x-ray, electron microprobe, and emission spectrographic analysis.

Results

Morphology.—A major aim of this investigation was to determine the conditions for the deposition of inclusion-free, coherent layers of uniform thickness. Initial studies were made using K_2SiF_6 concentrations from 0.5 to 2.5 mole percent (m/o) in the two-electrode configuration and a typical cyclic voltammogram for a 1 m/o solution at 750°C is shown in Fig. 1. Deposition potentials extrapolated from linear regions of current-voltage plots for graphite, nickel, niobium, and silver are listed in Table I. Silicon is highly reactive at 750°C and only in the case of silver was the reaction between the deposit and the substrate found to be negligible.

Cell voltages above −2V *vs.* Pt and corresponding current densities above 20 mA cm^{-2} were found to result in very nonuniform powdery or dendritic deposits on top of a thin, coherent layer about 2 μm thick. Reducing the deposition potential to −1.9V was found to give coherent and strongly adherent deposits. Figure 2 shows a typical sample of about 20 μm thickness which was deposited at a constant potential and the current density was 3.9 mA cm^{-2} with a total charge passed of 208 C cm^{-2}. The average grain size is about 16 μm. A similar deposit at a constant current of 3.2 mA cm^{-2} is shown in Fig. 3 and 4. The measured potential was about −1.95V *vs.* Pt and the total charge passed was 514 C cm^{-2}. The cross section demonstrates that the deposit is free from inclusions but also shows the irregularity in the thickness.

It was found possible to deposit reproducibly coherent, well-adherent films of about 50 μm average thickness using a cell potential of −1.88 ± 0.02V *vs.* Pt with current densities of 2-13 mA cm^{-2} depending on the solute concentration. The current efficiency

Table I. Deposition potentials extrapolated from linear regions of current-voltage plots

Substrate	Deposition potential (V)	Remarks
Graphite	−0.75 ± 0.1 (*vs.* graphite)	No identifiable deposit
Nickel	−1.26 ± 0.01 (*vs.* graphite)	Powdery deposit—mainly nickel silicides
Niobium	−1.45 ± 0.05 (*vs.* graphite)	Powdery deposit—mainly niobium silicides
Silver	−1.96 ± 0.03 (*vs.* platinum)	Dense, coherent, and well-adherent silicon

was normally 35-50% and the grain size up to 60 μm on top of an initial layer of 8-14 μm average grain size.

Attempts were made to deposit relatively thick layers at these low current densities. Figure 5 shows the result of prolonged electrolysis at −1.90 ± 0.02V *vs.* Pt over two days (2945 C cm^{-2} charge), at current densities in the range from 4 to 12 mA cm^{-2}. The deposit was 2 mm in thickness but a cross section (Fig. 6) shows that there was a very high concentration of fluoride inclusions trapped between grains. A surprising feature of this experiment is that the inclusion concentration is rather high even during the early stages of growth, but the deterioration in the later stages is severe.

Since thick, inclusion-free layers could not be electrodeposited from the dilute solutions used, the K_2SiF_6 solute concentration was increased to 4-6 m/o in subsequent investigations. In addition, a three-electrode arrangement was introduced since in principle this gives better control over the deposition rate. Although boron nitride compartmented metal/metal ion (*e.g.*, Ni/Ni^{2+}) and the hazardous fluorine reference cells have been used (10), a platinum foil pseudo-

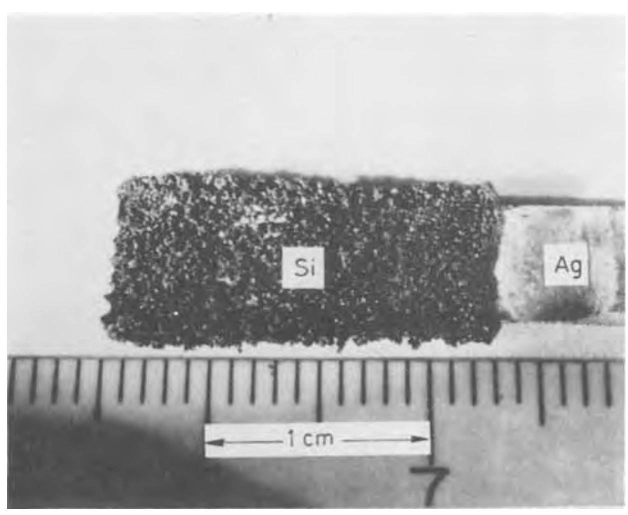

Fig. 5. General view of thick deposit plated at constant cell potential of −1.9V vs. Pt at 750°C, the K_2SiF_6 concentration ~2.5 m/o.

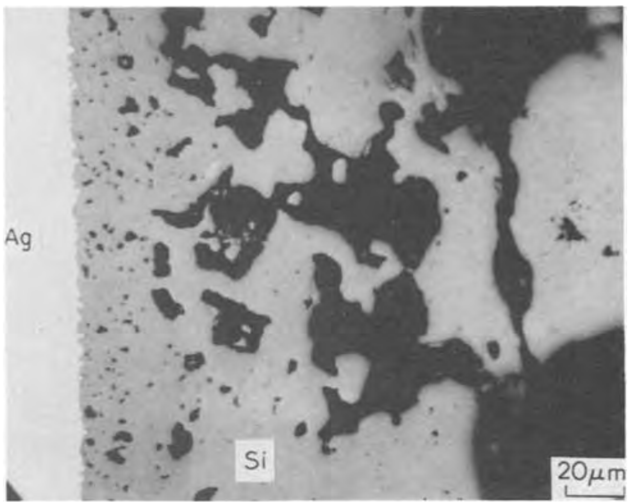

Fig. 6. Cross-sectional view of silicon, electrodepositing conditions same as in Fig. 5.

reference electrode was preferred in this study because of its simplicity. The measured deposition potential against a Pt reference electrode was found to be −0.74 ± 0.03V. However, variations by as much as 0.10V were observed in a few experiments. These variations may be due to changes in electrode separation or to small changes in electrode surface structure, or to the inherent uncertainties in the determination of deposition potential (11). The deposition potential was therefore determined prior to each electrodeposition experiment.

Well-adherent, inclusion-free deposits up to 3 mm in thickness were found possible using applied potentials in the vicinity of the deposition potential (Table II). The corresponding current density was from 10 to 60 mA cm^{-2} and the efficiency was from 35 to 70%. Figure 7 shows a typical example of a deposit plated at −0.75V *vs.* Pt for about four days (total charge 12,890 C cm^{-2}). The cross section of this deposit at the silver-silicon interface is shown in Fig. 8. With the exception of a few cracks introduced either during cooling or mounting, the deposits are substantially coherent; the wedge shape of Fig. 7 is an end effect and is characteristic of the small samples currently prepared.

Figure 9 shows the grain structure of a typical deposit as revealed by an HNO_3/HF etch. Growth is columnar with a grain size up to 100 μm, the grain size increasing with increasing thickness of the deposit as is usual for electrodeposits from aqueous solutions without complexing agents (12). Grain orientation has not yet been studied in detail but a columnar structure might be advantageous for the direct use of polycrystalline films in solar cells.

Purity.—As mentioned earlier, starting materials were of 99-99.5% purity and were not given any purification treatment apart from pre-electrolysis. This latter procedure is expected to remove from the

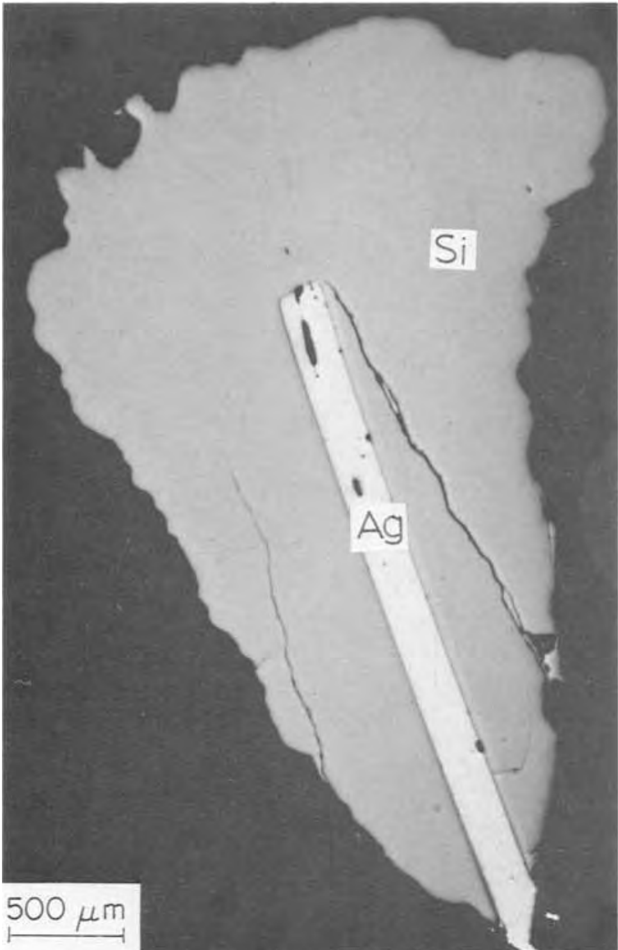

Fig. 7. Micrograph of silicon, deposited at constant cathodic potential of −0.75V vs. Pt at 746°C, the K_2SiF_6 concentration ~5 m/o.

solution those impurities which deposit at lower potentials than silicon. Impurities with a higher deposition potential than that used for subsequent electrodeposits should remain in solution. This idealized situation rarely occurs in practice since co-deposition tends effectively to reduce differences in deposition potentials between individual elements. An additional factor to be considered is that normal segregation of impurities is expected to depend upon the morphology of the deposit, and also on the grain size.

The increase in impurity concentration in irregular deposits at higher potentials was confirmed by analysis of highly dendritic films. These showed 2-20% of Li,

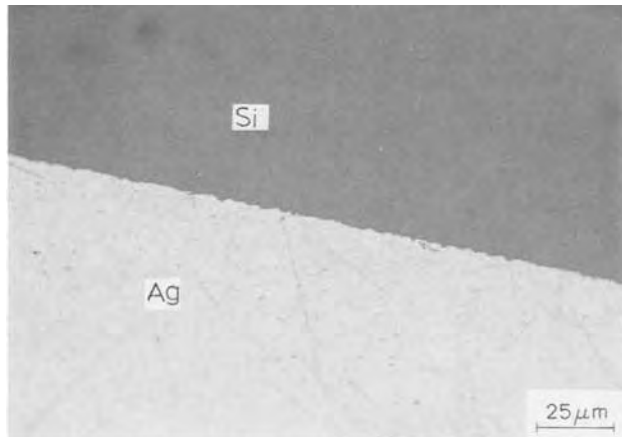

Fig. 8. Micrograph of silicon-silver interface of the deposit in Fig. 7.

Fig. 9. Micrograph of etched silicon surface of the deposit plated at constant cathodic potential of −0.74V vs. Pt at 747°C, the K_2SiF_6 concentration ~4 m/o.

presumably as inclusions of LiF, together with about 2% of other impurities, mainly Al, Cr, and Fe with traces of B, Cu, Mg, and Ni.

When deposits were made at potential close to the deposition potential, the impurity concentration was reduced to typically about 200 ppm of Al, B, Cr, Fe, Mg, and Ni. The best electrodeposits, however, showed only 10 ppm of total impurity (2 ppm B, 5 ppm Cr, 0.6 ppm Cu, 0.3 ppm Pt, and 1 ppm Ag). This material appears to be the highest purity silicon to be prepared by electrodeposition to date, since the best material previously reported is that of Monnier *et al.* (3, 4) with 99.99% purity.

The thicker inclusion-free deposits were sometimes found to contain 0.01-0.1% of Cr and Fe. These deposits require a period of several days of electrolysis during which fluoride vapor or anodically liberated fluorine can attack the Inconel atmosphere tube and produce transition metal fluorides. These may be transported to the melt via the vapor phase and result in the transition metal contamination. Microprobe analysis of the reacted scales on the furnace wall indicated a Cr-rich phase instead of normal Ni-rich Inconel 600. Such a Cr-rich surface film formation upon aqueous oxidation of Inconel 600 even at 300°C was demonstrated recently by McIntyre *et al.* (13). This source of contamination can clearly be eliminated by the use of an alternative furnace design with an internal graphite element and water-cooled stainless steel jacket. However the 99.999% pure material was produced as thick deposits.

Discussion and Conclusions

Reproducible deposits of silicon onto silver have been obtained by the electrolysis of K_2SiF_6-fluoride systems at 745°C and conditions have been determined for the deposition of inclusion-free and well-adherent layers. Although silicon has been deposited previously from fluoride melts, the present experiments appear to be the first in which electrowinning of silicon gave coherent deposits up to 3 mm in thickness.

The powdery deposits at high potentials and the spongy or dendritic deposits on prolonged electrolysis of dilute K_2SiF_6 solutions at the deposition potential could be explained in terms of a secondary reaction between alkali metal deposited by the primary deposition as observed by Dodero (14)

$$4K + Si^{4+} \rightleftarrows Si + 4K^+$$

No evidence for electrodeposition of potassium was observed in our system and this is considered unlikely in view of the large difference in deposition potential between alkali metals and silicon. Dodero used very high depositional potentials and so the primary elec-

trodeposition of alkali metals was to be expected in his experiments.

The noncoherent deposits may also be explained in terms of a secondary reaction between the deposited silicon and the melt

$$Si + Si^{4+} \rightleftharpoons 2Si^{2+}$$

Dissolution of silicon has been observed when wafers were held in contact with the melt in the absence of an applied potential. However this does not necessarily imply that disproportionation occurs under the conditions of deposition, and it is difficult to understand how this effect can explain the major improvement in morphology on increasing the solute concentration.

It appears likely that polynuclear complexes are present in the solution and that these may have a strong influence on the deposition process. Complexes such as $Mo_2Cl_9^{3-}$ (15) in alkali chloride melts and $U_2O_4^{3-}$ in perchlorate solutions (16) are formed when the concentrations of $MoCl_3$ and uranyl ions, respectively, are increased. Compounds of structure Si_nF_{2n+2} are known to exist, and both Si_3F_8 and Si_4F_8 have been isolated (17). It is suggested that a slow chemical step involving dissociation of a polynuclear complex precedes the electron-transfer reaction and that this dissociation step is rate controlling and favors the deposition of coherent films. Further study is required before this postulate can be confirmed, but we believe that it is important to determine the rate-controlling step in the silicon deposition reaction.

The purity of the best deposits is good in comparison with the starting materials and indicates that the single stage electropurification process is effective. Since the solvent phase is reusable, high purity alkali metal fluorides can be used reducing the initial impurity content in the melt. Improved furnace design to eliminate high temperature reactions between fluoride vapors and Inconel 600 should lead to the deposition of "solar cell" grade material as either thin or thick films in a single step.

Thick films have a columnar structure of relatively large grain size as is required of the deposited material is to be used directly for solar cell fabrication. The power required to deposit 1 kg of silicon is about 16 kW-hr plus the cost of maintaining the melt at 745°C. In large scale plants, joule heating from the deposition current is adequate to maintain temperatures of this order, so that we believe that electrodeposition has the potential to yield silicon of adequate purity for solar cells at about $1 per kg. Silver is clearly too expensive a material for use on a large scale but the substrates could be reused if bulk silicon were stripped from the cathode after deposition. Alternatively a 20-100 μm coating on a cheap substrate would be sufficient in a process to produce thin film solar cells directly using this method.

Formation of Oxide Films at Platinum Anodes in Alkaline Solutions

I. Question of Kinetics and Mechanisms

A. Damjanovic,* L.-S. R. Yeh,* and James F. Wolf

Allied Chemical Corporation, Corporate Research Center, Morristown, New Jersey 07960

ABSTRACT

The kinetics of growth of anodic oxide films at platinum electrodes was determined in 1M KOH solutions at room temperature using linear potential sweep and galvanostatic charging techniques. Irrespective of the mode or rate of growth, the same oxide film forms at potentials anodic to 1.0V *vs.* RHE. Oxygen initially adsorbed at prereduced electrodes at potentials below 1.0V is used at higher potentials for the film formation. The rate equation for the growth in alkaline solutions has the same general form as in acid solutions. Growth proceeds according to the model of high field assisted formation of ions at the metal/oxide interface (first step) and their migration through the oxide phase (second step). The exchange current density for the growth in alkaline solutions is, however, significantly higher, about 10^3 times, than in acid solutions. This is not expected for the proposed model of growth with either the first or the second step as rate determining.

In acid solutions, an oxide film grows over platinum electrodes at potentials above about 1.0V *vs.* RHE according to (1-4)

$$i = i_o \exp\left[\frac{\alpha(V - V_o)}{d}\right] \quad [1]$$

where α and i_o are constants independent of pH, V_o is a parameter that changes with pH, and d is the thickness of the oxide film equal to rq. Factor r converts charge density q into thickness. This equation describes the formation of the film irrespective of the mode or rate of growth, *e.g.*, irrespective of whether the film grows galvanostatically, potentiostatically, or potentiodynamically (4). The physical model of the growth is that of the high field, $(V - V_o)/d$, assisted formation of ions at the metal/oxide interface (the first reaction step) and their migration in the field through the oxide film (the second reaction step). Kinetic data of growth appears to be compatible with the first step as rate determining (5, 6).

No similar study was found in the literature on kinetics and mechanisms of formation of anodic films at platinum in alkaline solutions. This is surprising in view of the role platinum plays as an electrocatalyst in alkaline solutions. For, whenever an electrode is covered by a thin anodic film, no meaningful analysis of kinetics, mechanism, or electrocatalysis of an electrochemical reaction can be made unless the properties of the film, including its thickness, are first known. Recent studies of oxygen evolution illustrate this (7-8).

To determine if an oxide film forms according to the same model of growth in alkaline as in acid solutions, we examined the kinetics of film formation at platinum in alkaline solutions.

Experimental

The experimental procedure was the same as described previously (4-6, 9). Two series of experiments were carried out in 1M KOH solutions saturated at room temperature with either O_2 or N_2. In the first series, the potentiodynamic technique was used to examine the buildup of anodic films. A linear potential sweep was applied to a polished disk electrode (0.33 cm²) which was initially prereduced at a potential just before hydrogen evolution (~0.2V *vs.* RHE). In a few experiments, the starting potential of the sweep was set in an N_2-saturated solution at 0.65V *vs.* RHE (~−0.4V *vs.* SCE), and the anodic and cathodic branches of the sweep were recorded. For most of the experiments, the starting potential was set at the rest potential in O_2-saturated solutions (~0.95V *vs.* RHE). Currents for different rates of potential sweeps, S, were followed with time either with an oscilloscope or an X-Y recorder.

In the second series of experiments, the galvanostatic technique was used. A constant current was applied to a prereduced electrode starting from the rest potential in O_2-saturated solutions and the potential was recorded with time.

Potentiodynamic Formation of Oxide Films

Asymmetry of the i-V traces.—A typical potentiodynamic i-V trace in an N_2-saturated solution is shown in Fig. 1. It is similar to those reported in acid and alkaline solutions for the same potential region [cf. Ref. (4, 10-15)]. The similarity of the traces in acid and alkaline solutions suggests that the same processes control the anodic film formation and their reduction in both solutions [*e.g.*, Ref. (10-17)].

As in acid solutions, a current plateau appears at potentials above about 0.95V *vs.* RHE. Following the initial adsorption stage at lower potentials, an anodic film of few monolayers is formed in the plateau region (4, 13, 17). If similar processes control the

Key words: platinum anodic films, anodic oxide growth.

formation of films both in acid and alkaline solutions, then the film in alkaline solutions, too, is an oxide phase [cf. Ref. (3, 15)].

On the reversal of the potential scan, a cathodic peak for the film reduction is observed at potentials negative to those of the anodic scan in the plateau region. This asymmetry of current traces in the anodic and cathodic scans is a general characteristic of i-V profiles in acid and alkaline solutions. It is a consequence of the diametrically different mechanisms that must hold for the anodic formation and cathodic reduction of oxide films (18). According to the model of high field assisted growth, only an oxide film of uniform thickness can grow. The model itself, however, precludes any possibility that the reduction of the oxide film can occur according to the same mechanism. Not only is the uniform reduction of an oxide film precluded, but the reduction cannot be completed by the action of a simple mechanism. This is because any point on the oxide film at which the reduction is randomly initiated must become a "weak" point that will dissolve preferentially due to the locally increased field (now in the opposite direction). When a pit in the oxide phase, which is formed in this initial process, reaches the surface of the metal itself, lateral reduction of the oxide film along the metal surface is an easy alternative process for further rapid reduction. The overall process is therefore a reversed nucleation and growth process and should lead to a current peak rather than to a plateau [cf. Ref. (16, 18)].

Analysis of the i-V traces in the plateau region.— If a unique relationship exists between current density, potential, and film thickness during the growth of oxide films in the plateau region, *i.e.*, if

$$i = i(V, q) \qquad [2]$$

the following analysis of the i-V profiles, originally suggested by Harris for the growth of films in acid solutions (4), can be made. Taking V as an independent variable, differentiation gives

$$\frac{di}{dV} \equiv \left(\frac{\partial i}{\partial V}\right)_q + \left(\frac{\partial i}{\partial q}\right)_V \frac{dq}{dV} \qquad [3]$$

which, with the identity

$$\left(\frac{\partial i}{\partial q}\right)_V = -\left(\frac{\partial i}{\partial V}\right)_q \left(\frac{\partial V}{\partial q}\right)_i \qquad [4]$$

transforms to

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q \left[1 - \left(\frac{\partial V}{\partial q}\right)_i \Big/ \frac{dV}{dq}\right] \qquad [5]$$

Now, since

$$\frac{dV}{dq} = \frac{dV}{dt} \Big/ \frac{dq}{dt} \equiv \frac{S}{i} \qquad [6]$$

Eq. [5] can be rewritten in the form (4)

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q \left[1 - i\left(\frac{\partial V}{\partial q}\right)_i /S\right] \qquad [7]$$

This equation, which is independent of a model or mechanism of anodic film growth, shows that as the potential increases current density may in principle either increase, remain constant, or even decrease depending on the relative values of the terms in the brackets.

When i remains constant during the potential scan, as in the plateau region, the following condition must be satisfied (4)

$$i_S = \left[\left(\frac{\partial V}{\partial q}\right)_{i_S}\right]^{-1} S \qquad [8]$$

Here, i_S is the current density in the plateau region for a given scan rate, S. From Eq. [8], i_S is either exactly proportional to S, *i.e.*, $(\partial V/\partial q)_{i_S}$ = const. $\neq f(S)$, or i_S increases either faster or less rapidly with S than required by the proportionality, *i.e.*, $(\partial V/\partial q)_{i_S} = f(S) \neq$ const.

With i_S obtained from i-V profiles such as that in Fig. 1, log i_S is plotted *vs.* log S in Fig. 2. A nearly linear relationship with a slope close to one is observed. This can lead to the conclusion that $(\partial V/\partial q)_i$ = const. $\neq f(S)$. However, for the proportionality, the slope should be equal to one. The proportionality is indicated in Fig. 2 with two lines drawn close to the experimental points. The deviation from linearity is now evident. It is a consequence of the change of $(\partial V/\partial q)_{i_S}$ with S. It indicates that i_S increases less rapidly with S than required by the proportionality, *i.e.*, $(\partial V/\partial q)_{i_S}$ increases with S and hence also with i_S. A more sensitive check is a plot of S/i_S against S (4). Clearly, S/i_S is not constant, but is an increasing function of log S (cf. Fig. 3). Whether i_S is proportional to S or not depends, of course, on the mechanism of film formation. Suppose that the film formation is described by an equation of the form

$$i = i(\alpha V - \beta q) \qquad [9]$$

where α and β are constants. Since from Eq. [9]

$$\left(\frac{\partial V}{\partial q}\right)_i = \frac{\beta}{\alpha} = \text{const.} \qquad [10]$$

it follows from Eq. [6] and [8] that in the plateau region

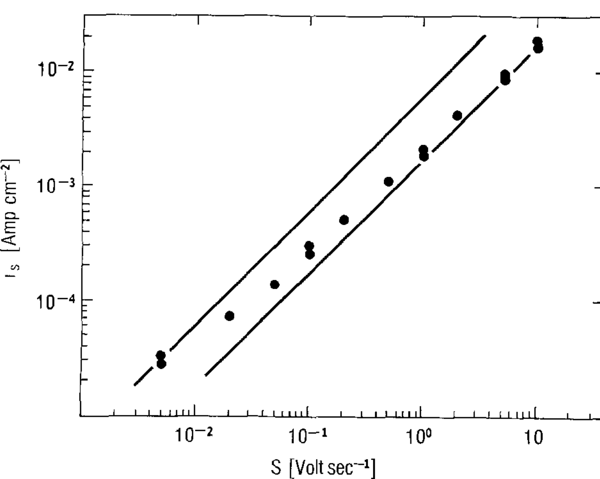

Fig. 2. Variation of anodic plateau current density with potential scan rates. Current density not corrected for the roughness of electrode surface.

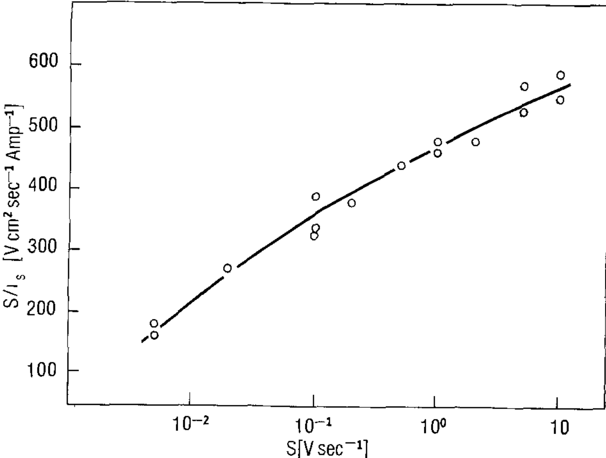

Fig. 3. Ratio of scan rate to plateau current density as function of scan rate from Fig. 2.

$$\frac{S}{i_S} = \left(\frac{\partial V}{\partial q}\right)_{i_S} = \frac{\beta}{\alpha} = \text{const.} \neq f(S) \quad [11]$$

Equation [9], therefore, describes a process of growth for which S/i_S = constant, *i.e.*, the process for which i_S increases linearly with S [c.f. Ref. (10, 15)]. Since present experiments show that $S/i_S = f(S) \neq$ const., any mechanism for film formation leading to a rate equation of the form of Eq. [9] does not represent the formation of an anodic film in the plateau region. This analysis eliminates, for example, any mechanism that leads to a rate equation of the form

$$i = i_o \exp(\alpha V - \beta q) \quad [12]$$

Such an equation can describe the buildup of adsorbed oxygen films at anodes under Temkin conditions of adsorption. This analysis illustrates how, on the basis of the quasi-linear dependence of i_S on S with the slope close to one, an incorrect conclusion can be reached regarding the rate equation and the mechanism of film formation.

Rate equation for oxide growth.—What is the form of the rate equation that satisfies condition [8] and can this equation be derived from the potentiodynamic data alone? An equation such as [1], that describes the growth of oxide films in acid solutions, would, for instance, satisfy this condition, *e.g.*

$$\left(\frac{\partial V}{\partial q}\right)_{i_S} = \frac{S}{i_S} = \frac{1}{\alpha} \ln \frac{i_S}{i_o} = f(i) \neq \text{const.} \quad [13]$$

Whether the potentiodynamic data in alkaline solutions follow this relationship can be checked by plotting S/i_S *vs.* log i_S. It is clear from Fig. 4 that $(\partial V/\partial q)_i$ depends strongly on log i_S. It is, however, not so clear if the dependence is linear as it should be to satisfy Eq. [13]. It may be noted that the condition [8] does not itself require linearity. Apparently, present potentiodynamic data are not sensitive enough for this test. It will be shown later from galvanostatic data that $(\partial V/\partial q)_i$ does change linearly with log i. This dependence is indicated in Fig. 4 by the broken line.

If instead of Eq. [2] one writes $V = V(i, q)$ and takes i as an independent variable, then

$$\frac{dV}{di} = \left(\frac{\partial V}{\partial i}\right)_q + \left(\frac{\partial V}{\partial q}\right)_i \frac{dq}{di} \quad [14]$$

Now, $(\partial V/\partial q)_i$ can be obtained from data in Fig. 4 using Eq. [13]. Since a linear dependence of $(\partial V/\partial q)_i$ on log i_S is indicated in the figure, we can take for this dependence the analytical expression given by Eq. [13]. $(\partial V/\partial i)_q$ can be obtained from the i-V data at different S. For instance, contours of constant q, obtained by integration along any single i-V profile from a suitable starting point, *e.g.*, from A in Fig. 1, can be superimposed over i-V contours and then the $(\partial V/\partial i)_q$ evaluated along such contours. It is, therefore, possible to determine the rate equation from the potentiodynamic data alone providing analytical expressions can be derived both for $(\partial V/\partial \ln i)_q$ and for $(\partial V/\partial q)_i$ dependence. Since the plot of S/i_S *vs.* log i_S indicates that an equation similar to [1] can describe the growth under potentiodynamic conditions, it is convenient to examine $V = V(\ln i, q)$ instead of $V = V(i, q)$ and to rearrange Eq. [14] accordingly. If Eq. [1] is valid also for growth in alkaline solutions, then $(\partial V/\partial \ln i)_q$ should be equal to q/α and Eq. [14] can be integrated. Unfortunately, as in the case of $(\partial V/\partial q)_i$ the potentiodynamic data are not accurate enough to allow an analytical expression for $(\partial V/\partial \ln i)_q$ to be determined.

Galvanostatic Formation of Oxide Films

Constant current charging curves.—In a series of experiments a constant current was applied to an initially prereduced electrode starting from the rest potential in oxygen-saturated solutions. Under these conditions, a rest potential was established in a few minutes. In Fig. 5, galvanostatic charging curves are reproduced from a photograph of an oscilloscope storage screen (Tektronix, 7623A) for 3×10^{-5}, 3×10^{-4}, 3×10^{-3}, and 3×10^{-2} A/cm². Time scales on the scope were adjusted to represent charge density, q.

At all current densities, the potential after an initial short, steep, and nonlinear rise increased nearly linearly with charge density. The linear region was followed by a potential "plateau." In the plateau region, the potential, however, was not constant; it continued to increase with time but much slower than in the linear region. Using a rotating ring-disk electrode it was shown that O_2 does not evolve in the linear region. It starts to evolve in the plateau region and soon becomes the predominant reaction (Fig. 6). In the linear region, therefore, the current is used almost entirely for forming an anodic film (except for a small part used for charging the double layer).

The most significant feature of the linear V-q traces is that the $(\partial V/\partial q)_i$ slopes increase linearly with the logarithm of applied current density, *i.e.*

$$\left(\frac{\partial V}{\partial q}\right)_i = f(i) = c' \log i + b$$
$$= c \ln(i/i_o) \quad [15]$$

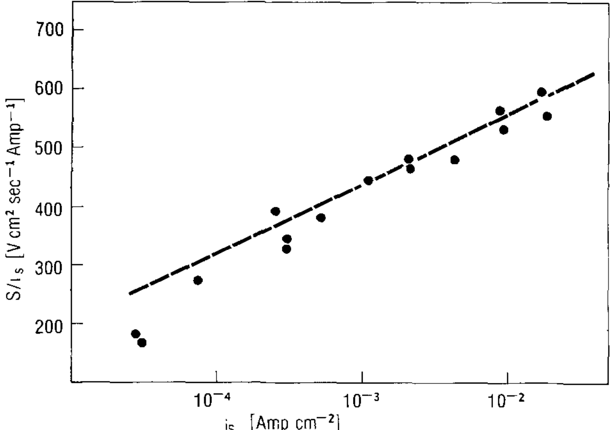

Fig. 4. Ratio of scan rate to plateau current density as function of plateau current density.

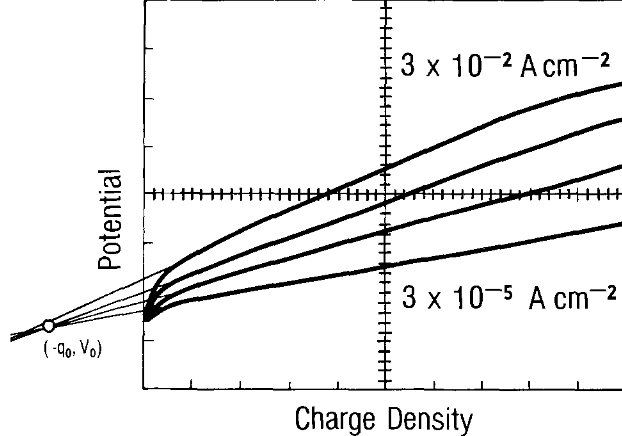

Fig. 5. Galvanostatic charging curves at various current densities. Charge density: 150 μC cm⁻² per division. Potential: 0.2V per division. Data are not corrected for the roughness of electrode surface.

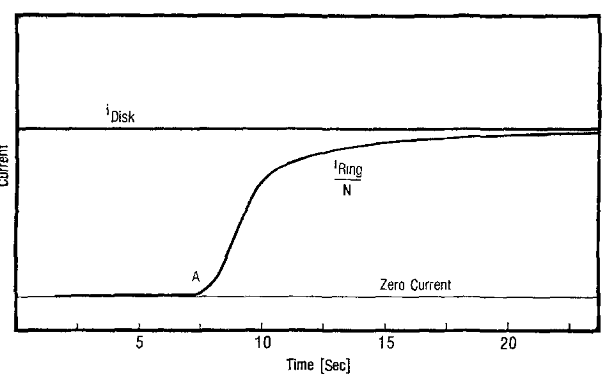

Fig. 6. The ring current for reduction of oxygen after correction for the collection efficiency. Constant current of 10^{-4}A was applied to the Pt disk electrode (area 0.49 cm^2).

This is shown in Fig. 7. The slope of this relationship is given by the constant c' ($=2.3c$), *i.e.*

$$\frac{\partial^2 V}{\partial q\, \partial \ln i} = c[=52\ \mathrm{VC^{-1}\,cm^2}] \quad [16]$$

Parameter b is the value of $\partial V/\partial q$ at $\log i = 0$. It is approximately equal to 800 VC^{-1} cm^2. Here, neither b nor c is corrected for the roughness of the electrode surface. Constant i_o is the exchange current density for the growth (see below); $i_o = \exp(-b/c)$, *i.e.*, it is equal to 1.3×10^{-7} A cm^{-2} when corrected for the roughness of the electrode surface ($RF = 1.6$).

The linearity of the $(\partial V/\partial q)_i$ *vs.* $\log i$ extends for four decades of the current densities used in this work. This is possible only when the same mechanism of growth holds for a wide range of growth rates. A similar relationship has been observed for the anodic oxide film formation in acid solutions (3, 9).

Returning now to Eq. [13] and Fig. 4, the galvanostatic $(\partial V/\partial q)_i$ data agree reasonably well with the potentiodynamic S/i_S data, particularly at high current densities. The deviation of S/i_S from linearity at low current densities is perhaps due to an experimental error in the potentiodynamic data rather than to any change in the mechanism of film formation. Evidently, the same film forms at platinum anodes irrespective of the mode of growth.

The second significant feature of the galvanostatic data is that the extrapolated V-q traces for various constant current densities intercept at the same potential, $V_o = 0.94$V *vs.* RHE and at the same negative value of charge density, $-q_o \sim -260\ \mu C\ cm^{-2}$ (cf. Fig. 5). Following the same discussion as in case of growth of anodic films in acid solutions (3, 9), it can be shown that V_o is related to the potential at which an oxide film would initiate and grow at zero field with the rate equal to the exchange current density i_o (cf., Eq. [1]). V_o is not necessarily equal to the potential from which a constant current is applied, *e.g.*, to the rest potential in O_2-saturated solutions, V_R. The negative charge density is related to the oxygen adsorbed at electrodes prior to the application of a constant anodic current (9).

Since V-q traces at different current densities all intercept in extrapolation at the same point ($\sim q_o$, V_o), the linear dependence for any given current density is given by (6)

$$V - V_o = (q + q_o) f(\log i) = (q + q_o)\left(\frac{\partial V}{\partial q}\right)_i \quad [17]$$

or, with Eq. [15], by

$$V - V_o = c(q + q_o)\ln(i/i_o) \quad [18]$$

Here, the constants c and i_o have the same significance as in Eq. [15]. The rate Eq. [18] can be rearranged to the more familiar form

$$i = i_o \exp\frac{V - V_o}{c(q + q_o)} \quad [19]$$

that can now be compared with the rate Eq. [1] for the growth in acid solutions.

Returning to Fig. 5, the dependence of the potential on current density at any constant q can be graphically determined. This is shown in Fig. 8. From the separation of the Tafel lines at any constant current density it follows, as expected from Eq. [19], that $(\partial V/\partial \log i)_q$ is a linear function of q, *i.e.*

$$\left(\frac{\partial V}{\partial \ln i}\right)_q = f(q) = a(q + q_o) \quad [20]$$

Constant a is found to be equal to 55 VC^{-1} cm^2. It should be equal to c (cf. Eq. [18]) if $V = V(\ln i, q)$. Rate Eq. [19] can be obtained also from Eq. [15] and [20] using [14]. It can be concluded, therefore, that a rate equation of the same form as in acid solutions describes the growth of anodic films above 1.0V *vs.* RHE in alkaline solutions.

Initial adsorption.—In this study, before a constant anodic current was applied to the test electrode, the electrode was cathodically prereduced at a potential just short of hydrogen evolution and then allowed to reach its rest potential, V_R, in O_2-saturated solutions. Under these conditions, the coverage with oxygen at V_R, expressed as charge density, is (19) about 200 $\mu C\ cm^{-2}$ (not corrected for electrode roughness). As in acid solutions, the extrapolated charge

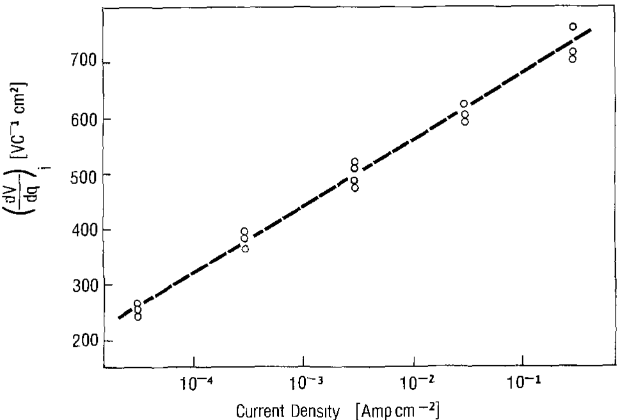

Fig. 7. Slopes of galvanostatic charging curves at various constant current densities. Data are not corrected for the roughness of electrode surface.

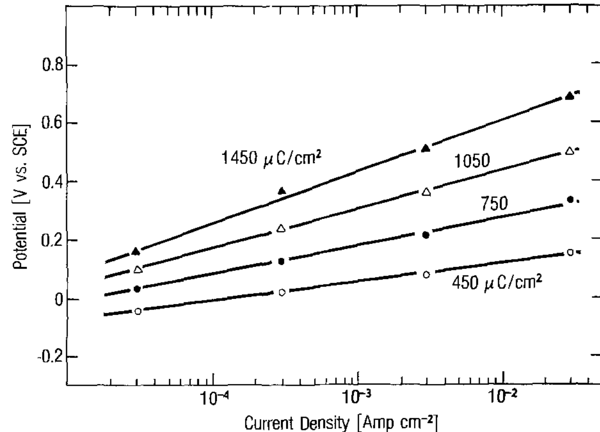

Fig. 8. Tafel slopes for oxide growth at constant thicknesses of oxide films.

density q_o in Fig. 5 was identified with the adsorbed oxygen at oxide free electrodes at the rest (or starting) potential (9).

Though no evidence regarding the nature of the anodic film in alkaline solutions is available from ellipsometric, electron diffraction, or spectroscopic studies, it is taken here that the film is an oxide phase rather than an adsorbed oxygen layer. The following evidence supports this view. First, the rate equation for anodic film formation has the same form as the rate equation for the growth of anodic oxide films under the influence of a high field within oxide films. A rate equation of the same form normally does not describe an adsorption process. For an adsorption process and intermediate coverages, an equation of the form of Eq. [12] rather than [19] is expected (11, 15). Second, the similarity of the kinetic data in acid and alkaline solutions suggests that the nature of the films is the same in both solutions. In acid solutions, ellipsometry and other techniques have shown that the film is an oxide phase (20-22). Third, total charge density in the formation of the anodic film at the end of the linear region at 3×10^{-4} A cm^{-2} is about 1800 $\mu C\ cm^{-2}$ (cf. Fig. 5 and 6). This charge density already includes the density q_o equivalent to oxygen initially adsorbed at electrodes. However, immediately following the linear region, in the plateau region, a substantial part of the current is still being used for film formation. In Fig. 6, integration of i_{disk}-i_{ring} shows that beyond the linear region, which ends at point A in Fig. 5, the film continues to grow an additional 30-35% for the same period of time it grew in the linear region. Total charge density for the film formation is, therefore, at least 2400 $\mu C\ cm^{-2}$. This coverage is not corrected for the roughness of the electrode surface. The roughness factor was determined in N_2-saturated 1M KOH solution by capacitance measurements in the "polarizable" region. Taking the capacitance of an ideal surface to be 16 $\mu F\ cm^{-2}$, RF is calculated to be 1.6. The total charge density for the anodic film formation is then about 1500 $\mu C\ cm^{-2}$. This coverage is too high to be accounted for in terms of adsorption. Fourth, in the case of adsorption, the desorption process is expected to occur by the same mechanism as the adsorption process though in reverse direction. A symmetry of the i-V anodic and cathodic profiles in potentiodynamic experiments, or of the V-t traces in galvanostatic experiments, should then be observed. Such a symmetry has been observed by Conway and co-workers (12, 23), but only when the upper potential limit of a potential sweep is below a potential at which an oxide phase is formed. Once an oxide film had been initiated, an asymmetry in the V-i profiles develops. All the evidence, therefore, points toward the formation of an oxide film at potentials above about 1.0V *vs.* RHE. Of course, adsorption at least up to the level of q_o always precedes oxide film formation (9, 13).

Because the linear V-q dependences for different current densities intercept in extrapolation at $(-q_o, V_o)$, and because q_o is identified as the coverage with oxygen before the application of a constant current, it follows that in the process of anodic film formation initially adsorbed oxygen is almost entirely used for the formation of the oxide film. Further, because the linearity is established soon after the current is applied, the adsorbed oxygen is used for oxide formation during the very early stages of growth upon the application of a constant current. Coverage with adsorbed oxygen, or $OH^{\cdot}$, over the oxide surface must, therefore, be fairly low. In acid solutions, this coverage has been determined by Vetter and Schultze (2) to be only about 0.02-0.03. It is necessary, therefore, to add q_o to q ($= it$) in Eq. [19]. Writing

$$q_T = q_o + it = q_o + q \qquad [21]$$

the rate Eq. [19] becomes

$$i = i_o \exp \frac{V - V_o}{c q_T} \qquad [22]$$

This is equivalent to shifting the origin of the coordinate V-q system from (O, V_o) to $(-q_o, V_o)$.

Analysis of the rate equation.—For the model of the high field assisted growth of anodic oxide films with the potential barrier at the metal/oxide interface as the rate-determining step (the Cabrera-Mott mechanism), the following rate equation has been derived [*e.g.*, Ref. (18)]

$$i = zeN\nu \exp\left[-\frac{W}{RT}\right] \exp\left[\frac{ze\lambda(V - V_o)}{dkT}\right]$$

$$= i_o \exp\left[\frac{\alpha \Delta V_{of}}{d}\right] \qquad [23]$$

Here, N is the density of metal ions in the metal surface, ν is their vibrational frequency, ze is the charge of the migrating ion, λ is the half-jump distance, and W is the activation energy. ΔV_{of} is the potential difference across the oxide film and d is the thickness of the film such that $\Delta V_{of}/d$ is the electric field within the film.

Comparison of Eq. [21] and [22] gives

$$\alpha = \frac{ze\lambda}{kT} = \frac{r}{c} \qquad [24]$$

This relationship allows the product $z\lambda$ to be determined from experimental parameters and hence a check to be made regarding the validity of the model for anodic film formation in alkaline solutions. For anodic film formation in acid solutions, r is calculated to be 9×10^3 Å C^{-1} cm^2 (3). With the same factor for alkaline solutions and with $c = 83$ VC^{-1} cm^2 when corrected for the roughness of the electrode surface, α and $z\lambda$ are respectively equal to 108 Å V^{-1} and 2.8Å. Were z equal to 1, *i.e.*, were Pt^+ a migrating species, which is improbable, the half-jump distance would be quite high, 2.8Å. For $z = 2$, *i.e.*, for a divalent cation as the migrating species, such as in $Pt(OH)_2$, $\lambda = 1.4$Å. This is a reasonable value for the half-jump distance. A similar value for the half-jump distance, $\lambda = 2$Å, was reported for the growth in acid solutions (3). The agreement is satisfactory and provides additional support for the hypothesis that the same mechanism of growth controls the formation of anodic films and that the same oxide phase is formed both in acid and in alkaline solutions.

The exchange current density.—Difficulties arise, however, when the exchange current densities, i_o's, for growths in acid and alkaline solutions are compared and analyzed. In acid solutions, $i_o = 2 \times 10^{-10}$ A cm^{-2}, whereas in 1M KOH solution it is 1.3×10^{-7} A cm^{-2} (see above).

The exchange current density according to Eq. [23] is given by

$$i_o = N\nu ze \exp\left[\frac{-W}{RT}\right] \qquad [25]$$

For the process at the metal/oxide interface as the rate-determining step, *i.e.*, for the Cabrera-Mott model of growth, N, ν, z, and W should all be independent of the conditions in solution or at the oxide/solution interface. Hence, i_o, should be the same both in acid and in alkaline solutions. The observed difference in i_o's would then, in general, indicate a different rate-determining step for the growth in alkaline solutions.

If N is the only parameter that is responsible for the observed difference in i_o's, its value in alkaline solutions (1M KOH) should be 10^3 times higher than in acid solutions. In acid solutions, N has been determined from a temperature study to be closely equal to the density of atoms in the metal surface (5, 6).

In general, N in alkaline solutions can only be equal to or less than N in acid solutions. Hence, the observed difference in i_0's cannot be accounted for in terms of N alone. If W is responsible for the observed difference in i_0's, then W for the growth in alkaline solutions should be about 4 kcal/mole lower than W ($\sim$ 25 kcal/mole) in acid solutions. Present data do not provide any clue whether W or N, or both, change from acid to alkaline solutions. However, both for the first and for the second step as rate determining, no solution effect on either W or N is expected.

The observed difference in i_0's cannot be accounted for with the same model of growth but with the second step as rate determining in alkaline solutions. For the second step to become rate determining, its activation energy should increase over that for the process at the metal/oxide interface rather than decrease. However, a decrease is indicated by the higher value of i_0 in alkaline solutions.

In a following paper, the kinetics of film formation is determined at different temperatures and N and W are evaluated and correlated to the possible rate-determining steps.

Formation of Oxide Films at Platinum Anodes in Alkaline Solutions

II. Temperature Study

A. Damjanovic,* L.-S. R. Yeh,* and James F. Wolf

Allied Chemical Corporation, Corporate Research Center, Morristown, New Jersey 07960

ABSTRACT

The kinetics of growth of oxide films at platinum anodes in 1M KOH solution is determined at different temperatures using the galvanostatic charging technique. The growth of the oxide film at potentials above about 1.0V *vs.* RHE follows the model of high field assisted formation of ions at the metal/oxide interface and their migration within the oxide film. The activation energy and preexponential factor are determined as 18.5 kcal/mole and 10^{13} cm^{-2}, respectively. These parameters differ significantly from the respective values reported for the growth in acid solutions. Comparison of the growth kinetics in acid and alkaline solutions leads to a serious difficulty. Neither the process of ion formation at the metal/oxide interface, nor the process of ion migration through the oxide phase as the rate-determining step, can account for the growth kinetics in alkaline solutions, unless it is assumed that different oxide phases form in acid and alkaline solutions. This is, however, an unlikely assumption.

It is shown in a preceding paper (1) that at platinum in alkaline solutions an anodic oxide film grows above about 1.0V *vs.* RHE according to

$$i = i_o \exp\left[\frac{V - V_o}{cq_T}\right] = i_o \exp\left[\frac{\Delta V_{of}}{cq_T}\right] \quad [1]$$

where q_T, when corrected for the roughness of the electrode surface [$RF = 1.6$ (1)], represents the thickness of the oxide film expressed in C cm^{-2} and $\Delta V_{of}/(rq_T)$ is the electric field within the growing oxide phase. Factor r converts charge density into thickness. V_o is the potential at which an oxide film would grow without the accelerating effect of the field with a rate equal to the exchange current density i_o [cf. Ref. (1)]. A rate equation of the same form was observed also for anodic growth in acid solutions (2-5). Evidently, the rate equations for growth in both acid and alkaline solutions, considered independently of each other, obey the formalism of the well-known model of the high field assisted formation of oxide films (6, 7). For this model, the following rate equation has been derived (6, 8)

$$i = N\nu ze \exp\left[\frac{-W}{kT}\right] \exp\left[\frac{ze\lambda\Delta V_{of}}{kTd}\right] = i_o \exp\left[\frac{\alpha\Delta V_{of}}{rq}\right] \quad [2]$$

Meanings of the various parameters are given in the preceding paper (1). There is, however, a significant difference in i_o's in acid (2×10^{-10} A cm^{-2}) and alkaline (1.3×10^{-7} A cm^{-2}) solutions. As discussed in the preceding paper, this difference cannot be accounted for by the model with the suggested rate-determining steps.

In order for the significance of the observed difference in i_o's to be appreciated, it is helpful to analyze briefly the meanings of various parameters in the rate equation. Parameter α is defined by

$$\alpha = \frac{ze\lambda}{kT}\left(=\frac{r}{c}\right) \quad [3]$$

with ze being the charge of the ions that migrate across the metal/oxide interface and through the oxide phase, and λ their half-jump distance. Both in acid and alkaline solutions it was determined that $z = 2$. In acid solutions, λ is close to 2Å, while in alkaline solutions it is close to 1.4Å. This is only a minor and perhaps insignificant difference which may, at least partially, be due to uncertainty in the determinations of the roughness factors in these two solutions. The agreement indicates that the same oxide phase forms in both solutions and that Pt^{++} is the most likely species migrating in the process of growth.

V_o in 1M alkaline solutions is about 800 mV more negative than in 1M H_2SO_4 when both are referred to a pH-independent reference electrode. This difference is, however, expected. In acid solutions V_o decreases about 60 mV as the pH increases for one unit (9). If the same dependence holds over the entire pH range, this will account for the observed difference in V_o. Though Eq. [2] does not explicitly predict such a dependence, it is not contrary to the model. V_o is related to the critical field in the metal/solution double layer which is just sufficient to pull metal ions from their positions in the surface lattice and place them over the metal surface. This field, however, depends on pH in a similar way as does the potential of zero charge (9). Neither α (through z) nor V_o is expected to affect the exchange current density.

The exchange current density is given by

$$i_o = N\nu ze \exp\left[\frac{-W}{kT}\right] \quad [4]$$

Only two parameters, N and W, can be responsible for the observed difference in the exchange current densities. Both parameters, however, will depend on the rate-determining step. Two variations of the model, or different rate-determining steps, have been suggested [cf. Ref. (1, 6-8)]. According to the first variation, the Cabrera-Mott mechanism of growth (6), the first reaction step, *i.e.*, the process of formation of ions at the metal/oxide film interface, is rate determining. For this step, the preexponential factor N

* Electrochemical Society Active Member.

Key words: platinum oxide films, anodic film formation.

should be closely equal to the density of atoms in the metal surface, N_s. According to the second variation, the Verwey mechanism of growth (7), the second reaction step, *i.e.*, the process of ion migration from one to an adjacent interstitial position within the oxide phase, is rate determining. For this step, the factor N should be equal to the density of the interstitial cations in a reaction plane within the oxide phase, N_i. Then, N_i should be less than N_s by a few orders of magnitude. Factor N for either of these two rate-determining steps, however, is not expected to depend on the conditions in solution, specifically on pH. Similarly, W for the same rate-determining step should not depend on the conditions in solution, *i.e.*, on pH. Of course, W will change with the rate-determining step. Now, factor N for the growth in acid solutions has already reached the maximum possible value, *i.e.*, $N_s = 10^{15}\ \mathrm{cm^{-2}}$ (10, 11). It is difficult to visualize any reaction step in the model for which N would be higher than N_s. For the growth in alkaline solutions, therefore, N is expected to be either equal to or less than N_s, *i.e.*

$$N_{\mathrm{alk}} \leq N_{\mathrm{acid}} = N_s \qquad [5]$$

But, if N for the growth in alkaline solutions is equal to or less than N_s, then, considering N only, the exchange current density in alkaline solutions should be either equal to or less than the exchange current density in acid solutions, rather than higher as observed. Since

$$(i_o)_{\mathrm{alk}} >> (i_o)_{\mathrm{acid}} \qquad [6]$$

it would appear that the activation energy, W, for the growth in alkaline solutions should be substantially lower than the activation energy in acid solutions. But why should the activation energy change at all?

An objective of this study is to evaluate N and W in alkaline solutions and correlate them to the corresponding parameters in acid solutions and rate-determining steps.

Results and Discussion

Galvanostatic charging curves.—In 1M KOH solutions at different temperatures, 1°, 22°, and 45°C, V-q dependencies are determined galvanostatically for various current densities. The experimental procedure is the same as in previous studies (1, 9). In Fig. 1, V-q traces at 45°C for 3×10^{-5}, 3×10^{-4}, 3×10^{-3}, and 3×10^{-2} A cm^{-2} are reproduced from an oscilloscope storage screen. Evidently, general shapes of these traces are similar to those previously reported for room (22°C) temperature [cf. Fig. 5 in Ref. (1)]. In Fig. 2, V-q traces for the same current density,

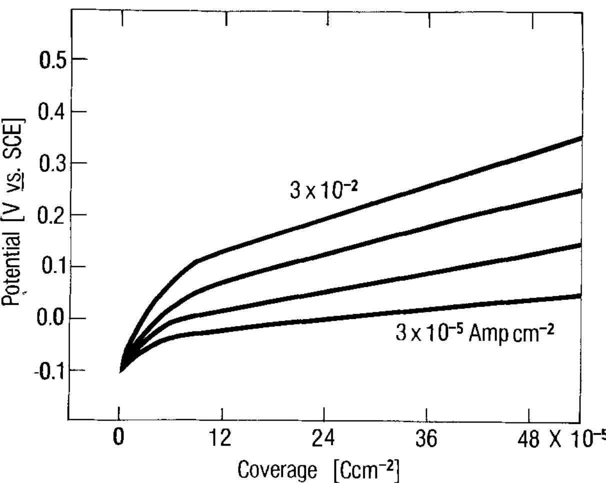

Fig. 1. Potential-charge density reationships for 3×10^{-5}, 3×10^{-4}, 3×10^{-3}, and 3×10^{-2} A cm^{-2}. Temperature 45°C. Data not corrected for *RF*.

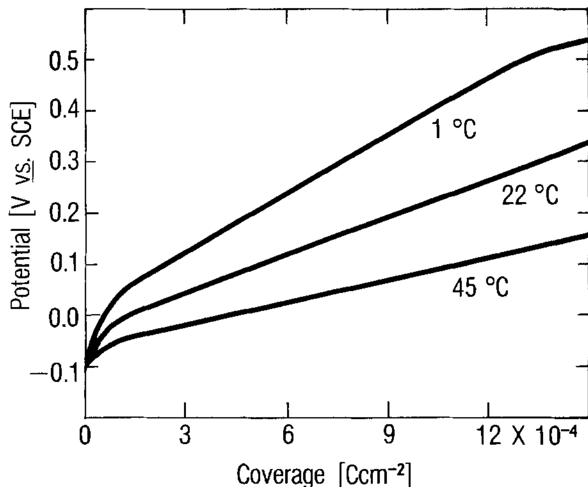

Fig. 2. Potential-charge density relationships for 3×10^{-5} A cm^{-2} at 1°, 22°, and 45°C. Data not corrected for *RF*.

3×10^{-5} A cm^{-2}, are shown for the three temperatures. From Fig. 1 and 2, and other data, plots $(\partial V/\partial q)_{i,T}$ *vs.* log i are constructed for each temperature. They are shown in Fig. 3. These plots, which are linear at all temperatures, show the same basic features as the plots for the anodic oxide growth at different temperatures in acid solutions [cf. Fig. 2 in Ref. (11)]. They are used here to evaluate N and W.

For the suggested model of growth, irrespective of the rate-determining step, the slopes of $(\partial V/\partial q)_i$ *vs.* log i should increase with temperature according to (cf. Eq. [1] and [2])

$$\frac{\partial^2 V}{\partial q\, \partial \log i} = 2.3c(T) = \frac{2.3r}{\alpha} = \frac{2.3rRT}{z\mathbf{F}\lambda} \qquad [7]$$

Parameters α and $z\lambda$ can be determined from measurements at room temperature only. They are respectively equal to 108 Å V^{-1} and 2.8Å. If λ does not change in the narrow range of temperature in the present study, then $c(T)$, or the slopes of the plots of $\partial V/\partial q$ *vs.* log i, should increase with temperature according to Eq. [7]. It is evident from Fig. 4 that $c(T)$ does change linearly with temperature. The slope of $c(T)$ *vs.* T is about 0.3 V Å^{-1} °C^{-1}, and this is in accordance with the analysis of α from the data at room temperature. Temperature study, therefore, provides an additional confirmation for the proposed model of growth.

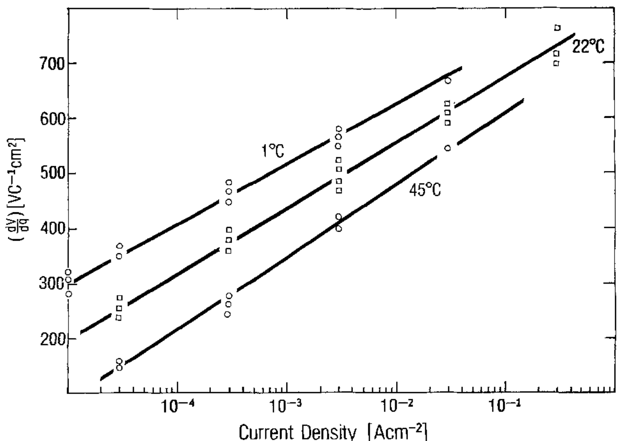

Fig. 3. The characteristic $\partial V/\partial q$ vs. log i plots at different temperatures. Data not corrected for *RF*.

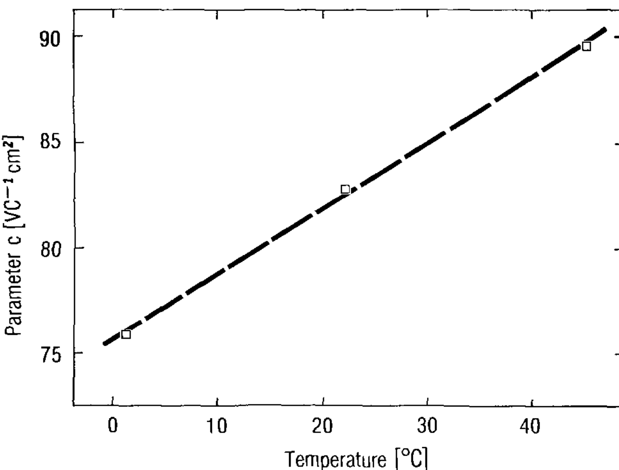

Fig. 4. Slopes from Fig. 3 plotted against temperature. Slopes are corrected for *RF* [= 1.6 (1)].

The exchange current density, activation energy, and frequency factor N.—From Eq. [1] it follows that

$$\left(\frac{\Delta V}{\Delta q}\right)_T = 2.3c(T) \log i - 2.3c(T) \log i_o \quad [8]$$

From here, the exchange current density can be calculated for any given temperature, *e.g.*, with the known value of $c(T)$ and the value of $(\Delta V/\Delta q)_T$ extrapolated to $i = 1$ A cm^{-2}. In Fig. 5, i_o is plotted against reciprocal temperature. At all temperatures, i_o in alkaline solutions is substantially higher than i_o in acid solutions (2×10^{-10} A cm^{-2}); for instance, 800 times at room temperature. The activation energy is now calculated from this plot using the relationship (cf. Eq. [4])

$$W = -2.3R \frac{d \log i_o}{d(1/T)} \quad [9]$$

It is 18.5 kcal/mole^{-1}.

The activation energy in alkaline solutions is, therefore, significantly lower than the activation energy in acid solutions previously determined to be 25 kcal mole^{-1} (11). This difference in the activation energies alone would increase i_o in alkaline solutions at room temperature over i_o in acid solution by about 9×10^4. Since at room temperature $i_{o,alk} \approx 800 i_{o,acid}$, it follows that the activation energy is not the only factor affecting the change of i_o in alkaline solutions. The preexponential factor, too, must change from acid to alkaline solution; N must be at least 100 times less than the same factor in acid solutions. From Eq. [4], N can now be obtained; it is about 1.5×10^{13}, *i.e.*, it is indeed significantly less than observed in acid solutions ($\sim 1 \times 10^{15}$ cm^{-2}).

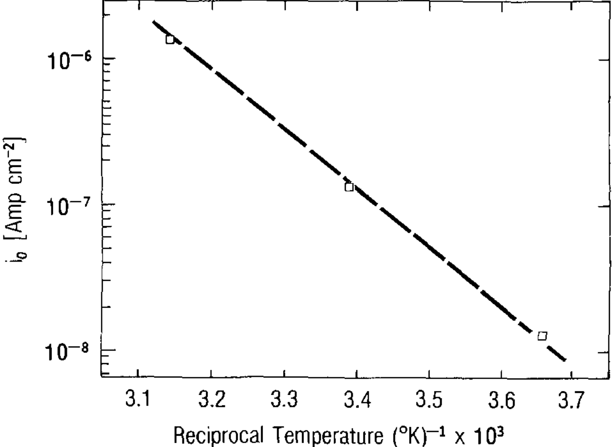

Fig. 5. Exchange current density vs. 1/*T*. Current densities are corrected for *RF*.

Comparison of growth kinetics in acid and alkaline solutions.—This study shows that both W and N differ from the corresponding parameters in acid solutions. At first sight, the difference in both W and N would indicate that in alkaline solutions the rate-determining step is different from that suggested for the growth in acid solutions. Since N for the growth in acid solutions is close to 10^{15} cm^{-2}, *i.e.*, close to the density of surface sites, it was suggested (10, 11) that the formation of ions at the metal/oxide interface is the rate-determining step. For alkaline solutions, then, the second reaction step, *i.e.*, the process of migration of ions within the oxide phase, would be expected to be the rate-determining step. This interpretation would then formally account for the observed changes both in W and N. It is difficult, however, to understand why the rate-determining step should change from acid to alkaline solutions and why, in alkaline solutions, W for the second step should become higher than for the first step. N is certainly expected to be less for the second step as rate determining. However, for the second step, N still appears to be too high. It would require the concentration of interstitial cations in the oxide phase to be about 1%.

The real difficulty in the interpretation of the kinetic data arises when W for the growth in alkaline solutions is compared with that in acid solutions. For instance, if one assumes that the process of ion formation at the metal/oxide interface is the rate-determining step in acid, but not in alkaline solutions, then why should W for this step change and become, in alkaline solutions, even less than W for the second step, particularly since, as suggested, the same oxide phase forms in both solutions? Activation energy for the first step should not at all depend on the conditions in solutions. Further, if the process of cation migration through the oxide phase is rate determining in alkaline solutions, then why should the process within the oxide phase become slower than the same process in acid solutions? For, the process of ion migration through the oxide phase is also not expected to be affected by the conditions in solutions.

A modified picture regarding the mechanism of growth in both solutions will, however, emerge and this difficulty will disappear once the present temperature study is complemented with the study of pH dependence of growth in alkaline solutions. This will be discussed in the next paper. It will be shown that, though the same basic model of growth is still valid, neither of the reaction steps discussed in this and previous papers is rate determining, certainly not in alkaline and most probably not in acid solutions.

Manuscript received Nov. 5, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by the Allied Chemical Corporation.

ABSTRACT

Precise definitions are given of three thermodynamic parameters which characterize the water-electrolysis reaction: the enthalpic voltage, the higher-heating-value voltage, and the thermoneutral voltage. Expressions are derived for these parameters and for the reversible potential, as functions of temperature between 25° and 250°C, and of pressure between 1 and 100 atm. Heat losses due to radiation, convection, and conduction are also considered, and a thermal-balance voltage is defined; representative values are calculated. Electrical-energy efficiency is related to the characteristic parameters, and thermodynamic limitations on its value are discussed.

Although hydrogen production by the electrolysis of water has been practiced for over a hundred years, this technique has been receiving special prominence in recent years because of its potential role in the energy economy. A substantial effort is being devoted to the problem of minimizing the energy requirements of the electrolytic process. This requires a two-pronged approach. Firstly, an attempt is made to reduce or eliminate internal energy losses, such as those arising from the electrode overvoltages and ohmic-resistance. Secondly, a choice is made of the optimum operating conditions for the electrolysis: the temperature, the pressure and, in the case of aqueous water electrolysis, the concentration of the electrolyte.

In present commercial water electrolyzers, electrical-energy efficiency is limited by the internal energy losses; cooling water is normally required to remove excess heat. However, technical advances now being made promise to reduce these losses to the point where efficiency will be limited instead by the requirement that sufficient heat be generated internally to maintain the electrolyte temperature. This latter limitation relates to the energy balance around the electrolyzer cell, and it can be calculated from thermodynamics. In fact, the ultimate limitations on the energy requirements of the electrolytic process are thermodynamic.

Although one might think that the calculation of the values of the relevant thermodynamic parameters for various operating conditions would be a relatively straightforward matter, serious errors have crept into the literature and have led to a considerable amount of confusion. The present examination of the thermodynamics of water electrolysis has been undertaken for this reason. Consideration is given primarily to aqueous water electrolysis using KOH as the electrolyte. However, many of the considerations are also applicable to the case of solid electrolytes.

* Electrochemical Society Active Member.

Key words: electrolysis, hydrogen, reversible potential energy efficiency.

Energy Requirements for an Ideal Electrolysis Cell

In examining the thermodynamics of the electrolytic process, it is convenient to consider an "ideal" electrolysis cell, consisting of a reversible hydrogen electrode and a reversible oxygen electrode immersed in a solution of potassium hydroxide of molality m at a total pressure of p atm and maintained at a temperature T°K or t°C by means of a thermostat. The hydrogen and oxygen in contact with the reversible electrodes are assumed to be "wet," in the sense of containing water vapor in equilibrium with the water in the KOH solution.

Calculations will be made using one of the following two sets of assumptions: (*i*) hydrogen, oxygen, and water vapor are ideal gases and the first two form ideal binary gaseous solutions with the third; and (*ii*) the individual gases are not ideal but the two binary gaseous solutions are. In either case the partial pressure of water vapor in each of the wet gases will be equal to p_w, the aqueous vapor pressure of the KOH solution. Thus $p = p_w + p_{hy} = p_w + p_{ox}$.

The continuous production of hydrogen and oxygen would require addition of reagent water in the amount of $[1 + 1.5p_w/(p - p_w)]$ moles per mole of hydrogen produced. The products of the process would consist of one mole of hydrogen mixed with $p_w/(p - p_w)$ moles of water vapor at a total pressure p, and 0.5 mole of oxygen mixed with $0.5p_w/(p - p_w)$ moles of water vapor, also at a total pressure p.

The total energy required per mole of hydrogen produced would be made up of electrical energy plus heat energy removed from the thermostat. It can be defined in terms of an enthalpy change, ΔH, with the value of ΔH being expressed in terms of the enthalpies of the three phases concerned

$$\Delta H = H(\text{wet hydrogen}) + H(\text{wet oxygen}) - H(\text{reagent water}) \quad [1]$$

The enthalpies of the two gaseous solutions can be

expressed in terms of the partial molar enthalpies of the components[1]

$$H(\text{wet hydrogen}) = [\bar{H}_{hy} + (p_w/(p - p_w))\bar{H}_{w(g)}]_{t,p} \quad [2]$$

$$H(\text{wet oxygen}) = 0.5[\bar{H}_{ox} + (p_w/(p - p_w))\bar{H}_{w(g)}]_{t,p} \quad [3]$$

The enthalpy of the reagent water can be expressed in terms of the molar enthalpy of liquid water. If this is supplied at t°C and p atm then[2]

$$H(\text{reagent water}) = [1 + 1.5p_w/(p - p_w)]\tilde{H}_{w(l),t,p} \quad [4]$$

The enthalpy change defined by Eq. [1]-[4] is clearly equal to the minimum amount of energy that would be required, per mole of hydrogen, to produce wet hydrogen and wet oxygen on a continuous basis using as the feedwater liquid water at the temperature and pressure of the electrolysis.

If the electrolysis is conducted at a temperature $t > 25$°C and a pressure $p > 1$ atm, the total energy requirement must include the amount of energy required to heat the feedwater from 25° to t°C and to increase its pressure from 1 to p atm, namely[3] $[1 + 1.5p_w/(p - p_w)]\ [\tilde{H}_{t,p} - \tilde{H}^\circ_{25}]_{w(l)}$. The total energy can be expressed either in terms of energy units (joules or calories) or as a voltage, using the conversion factor $n\mathbf{F} = 192973\text{J mole}^{-1}\ \text{V}^{-1} = 46122 \text{ cal mole}^{-1}\ \text{V}^{-1}$. When expressed as a voltage it will be called the thermoneutral voltage, in keeping with the practice of a number of authors, and given the symbol V_{tn}. Rearranging terms, $n\mathbf{F}V_{tn}$ may be written as the sum of three terms

$$n\mathbf{F}V_{tn} = [\bar{H}_{hy} + 0.5\bar{H}_{ox} - \tilde{H}_{w(l)}]_{t,p} + \Phi[\langle\bar{H}_{w(g)}\rangle - \tilde{H}_{w(l)}]_{t,p} + [1 + \Phi][\tilde{H}_{t,p} - \tilde{H}^\circ_{25}]_{w(l)} \quad [5]$$

where

$$\Phi = 1.5p_w/(p - p_w) \quad [6]$$

and $\langle\bar{H}_{w(g)}\rangle$ is a weighted average of the partial molar enthalpies of water in wet hydrogen and wet oxygen gases

$$\langle\bar{H}_{w(g)}\rangle = \frac{1}{1.5}\left[(\partial H/\partial n_{w(g)})_{n_{hy}} + 0.5(\partial H/\partial n_{w(g)})_{n_{ox}}\right]$$

The calculation of accurate values of V_{tn} at various temperatures and pressures is a matter of some importance. However, it is usually sufficient to simplify the calculation by making either of the two sets of assumptions referred to above. On the basis of set (i), the chemical potentials of the three gases can be expressed in the form

$$\mu_i = \tilde{G}^\circ_i + RT\ln p_i \quad [7]$$

where the first term on the right-hand side is the molar free energy of the pure component as an ideal gas at 1 atm pressure, and p_i is its partial pressure in the gaseous solution. Partial molar enthalpies are related to chemical potentials by the expression

$$\bar{H}_i = \mu_i - T\partial\mu_i/\partial T \quad [8]$$

Substitution of Eq. [7] into Eq. [8] demonstrates that, in this case, the partial molar enthalpy is equal to the molar enthalpy of the pure component as an ideal gas at 1 atm pressure and t°C

$$\bar{H}_i = \tilde{G}^\circ_i - T\partial\tilde{G}^\circ_i/\partial T = \tilde{G}^\circ_i + T\tilde{S}^\circ_i = \tilde{H}^\circ_i \quad [9]$$

Equation [5] can then be written

$$n\mathbf{F}V_{tn} = [\tilde{H}^\circ_{hy} + 0.5\tilde{H}^\circ_{ox} - \tilde{H}_{w(l),p}]_t + \Phi[\tilde{H}^\circ_{w(g)} - \tilde{H}_{w(l),p}]_t + [1 + \Phi][\tilde{H}_{t,p} - \tilde{H}^\circ_{25}]_{w(l)} \quad [10]$$

It is clear from Eq. [10] that if the gases and their solutions were ideal then an increase in the pressure at which the electrolysis takes place would have no effect on the thermoneutral voltage, except for the quite minor influence of pressure on the enthalpy of liquid water and on p_w. Unfortunately, a number of authors engaged in water-electrolysis research who, for simplicity, have assumed gas ideality, have come to a quite different conclusion (1-4). As the result, thermoneutral voltages calculated by them are in error by an amount of the order of 90 mV for a cell operating at 120°C and 35 atm pressure.

The effect of pressure on the enthalpy of any phase is determined by the relation

$$\partial H/\partial p = V - T\partial V/\partial T \quad [11]$$

The error appears to have arisen through the neglect of the second term on the right of Eq. [11] which, for an ideal gas, exactly cancels the first. The error in calculating the enthalpy of one mole of H_2 plus 0.5 mole of O_2 at a pressure of p atm from its value at 1 atm would be $1.5RT \ln p/n\mathbf{F}$ V. For 120°C and 35 atm this is approximately 90 mV.

The set of assumptions (ii) is somewhat less "ideal" than set (i) used above, in that none of the individual gases is ideal but the binary solutions of wet gases are. In this case the chemical potential of a component i in one of the gaseous solutions would be equal to the molar free energy of that component as a pure gas at the pressure p_i, namely $\tilde{G}_{i,p_i}$. Thus, in view of Eq. [8]

$$\bar{H}_{i,p} = \tilde{G}_{i,p_i} - T\partial\tilde{G}_{i,p_i}/\partial T = \tilde{G}_{i,p_i} + T\tilde{S}_{i,p_i} = \tilde{H}_{i,p_i} \quad [12]$$

and the thermoneutral voltage may be written

$$n\mathbf{F}V_{tn} = [\tilde{H}_{hy} + 0.5\tilde{H}_{ox} - \tilde{H}_{w(l)}]_{t,p-p_w} - [\tilde{H}_p - \tilde{H}_{p-p_w}]_{w(l),t} + \Phi[\tilde{H}_{w(g),p_w} - \tilde{H}_{w(l),p}]_t + [1 + \Phi][\tilde{H}_{t,p} - \tilde{H}^\circ_{25}]_{w(l)} \quad [13]$$

The first of the four terms in Eq. [13] can be seen to be the negative of the molar enthalpy of formation of liquid water at t°C and $p - p_w$ atm; it can be written $-\Delta\tilde{H}_f[H_2O(l)]_{t,p-p_w}$. The second term will be very small; it is the increase in enthalpy on isothermally compressing liquid water from $p - p_w$ to p atm. The third term is the energy required to evaporate the water that is carried off with the evolved gases at t°C. The last term is the energy required to heat and compress the feedwater from 25°C and 1 atm to t°C and p atm.

It should be noted that as the total pressure is increased at constant temperature the mole fraction of water vapor in the wet gases, p_w/p will get smaller

[1] $\bar{H}_i$ denotes the partial molar enthalpy of component i, $(\partial H/\partial n_i)_{n_j}$.

[2] $\tilde{H}_i$ denotes the molar enthalpy of component i, H_i/n_i.

[3] It is assumed in all calculations in this paper that water fed to electrolyzers for water decomposition, and to replace the water carried off as vapor with the product gases, has a temperature of 25°C. In fact, this water comes from two sources in some electrolyzer designs: condensate returned from gas coolers or scrubbers, and make-up water added from an external source at the ambient temperature. These two streams can be at different temperatures, both of them different from 25°C. This can be accounted for in a straightforward manner in the detailed calculations, although the effect on derived values of the characteristic voltages is small for representative operating conditions.

and the validity of Eq. [12] will be improved. The quantity Φ will tend toward zero and the difference between p and $p - p_w$ can be neglected. The expression for $n\mathbf{F}V_{tn}$ given by Eq. [5] will tend toward the limiting expression

$$n\mathbf{F}V_{tn} \rightarrow \Delta\tilde{H}_{t,p} + [\tilde{H}_{t,p} - \tilde{H}^\circ_{25}]_{w(l)} \text{ as } p/p_w \rightarrow \infty \quad [14]$$

in which $\Delta\tilde{H}_{t,p}$ is a convenient expression for $-\Delta\tilde{H}_f[H_2O(l)]_{t,p}$.

Since $\Delta\tilde{H}_{t,p}$ is the negative of the enthalpy of formation of liquid water from the elements at t and p, the quantity $\Delta\tilde{H}_{t,p}/n\mathbf{F}$ will be called the enthalpic voltage $V_{t,p}$. The quantity $\{\Delta\tilde{H}_{t,p} + [\tilde{H}_{t,p} - H^\circ_{25}]_{w(l)}\}/n\mathbf{F}$ will be called the higher-heating-value voltage and given the symbol V_{HHV}. The relation [13] can then be written

$$n\mathbf{F}V_{tn} = n\mathbf{F}V_{HHV} + \Phi[\tilde{H}_{w(g),t,pw} - \tilde{H}^\circ_{w(l),25}] \quad [15]$$

where V_{HHV} is evaluated at the pressure $(p - p_w)$.

The Effect of Temperature and Pressure on the Enthalpy of Formation of Water; The Enthalpic Voltage

Since the enthalpy of formation of liquid water is a negative quantity, we will deal with the positive quantity $\Delta\tilde{H}_{t,p}$. Its evaluation is most easily effected in two steps, starting with the value $\Delta\tilde{H}^\circ_{25} = 2.85840 \times 10^5$ J/mole obtained from the JANAF tables (5)

$$\Delta\tilde{H}_{t,p} - \Delta\tilde{H}^\circ_{25} = [\Delta\tilde{H}^\circ_t - \Delta\tilde{H}^\circ_{25}] + [\Delta\tilde{H}_{t,p} - \Delta\tilde{H}^\circ_t] \quad [16]$$

where

$$\Delta\tilde{H}^\circ_t - \Delta\tilde{H}^\circ_{25} = [\tilde{H}^\circ_t - \tilde{H}^\circ_{25}]_{hy} + 0.5\,[\tilde{H}^\circ_t - \tilde{H}^\circ_{25}]_{ox} - [\tilde{H}^\circ_t - \tilde{H}^\circ_{25}]_{w(l)} \quad [17]$$

and

$$\Delta\tilde{H}_{t,p} - \Delta\tilde{H}^\circ_t = [\tilde{H}_{t,p} - \tilde{H}^\circ_t]_{hy} + 0.5[\tilde{H}_{t,p} - \tilde{H}^\circ_t]_{ox} - [\tilde{H}_{t,p} - \tilde{H}^\circ_t]_{w(l)} \quad [18]$$

The effect of temperature on $\Delta\tilde{H}^\circ$.—$(\tilde{H}^\circ_t - \tilde{H}^\circ_{25})$ is reported as a function of temperature for hydrogen and oxygen gases in the JANAF tables (5). Data covering the temperature range $25°C \leq t \leq 327°C$ for one mole of hydrogen plus one-half mole of oxygen were fitted to the expression $-1087.4 + 43.472t + 2.940 \times 10^{-3}\, t^2$ J, where t is the temperature in °C. The average deviation of this expression from the JANAF data at 25°, 26.8°, 126.8°, and 326.8°C was 0.8J. The enthalpy of liquid water at 1 atm pressure was interpolated from the Steam tables (6). Data for temperatures above 100°C were theoretical, calculated using the fundamental equation of Keenan *et al.*

Values of $(\Delta\tilde{H}^\circ_t - \Delta\tilde{H}^\circ_{25})$ (Eq. [17]) were derived at 20°C intervals between 25° and 250°C, and were fitted by the method of least squares with the expression

$$\Delta\tilde{H}^\circ_t - \Delta\tilde{H}^\circ_{25} = 730.68 - 28.752t - 0.01898t^2 \quad [19]$$

where units are J/mole of water. The corresponding expression for the enthalpic voltage $\Delta\tilde{H}^\circ_t/n\mathbf{F} = V^\circ_t$ is[4]

$$V^\circ_t = 1.4850 - 1.490 \times 10^{-4}t - 9.84 \times 10^{-8}t^2 \text{ V} \quad [20]$$

This expression is drawn as the bottom curve in Fig. 1. It is in approximate agreement with predictions based on $\Delta\tilde{H}^\circ_t$ values reported by Wicks and Block (7) for temperatures up to 100°C, but predicts lower values at higher temperatures.

The value of V°_t decreases significantly with rising electrolyte temperature, from 1.4812V at 25°C to 1.4416V at 250°C. An earlier result for V°_t erroneously showed it to increase with increasing temperature (8).

The effect of pressure on $\Delta\tilde{H}_t$.—The effect of pressure on enthalpy is given by Eq. [11], and hence for each of the three phases involved in the expression for $\Delta\tilde{H}_t$ there will be a relation of the form

$$\tilde{H}_{t,p_2} - \tilde{H}_{t,p_1} = \int_{p_1}^{p_2} (\tilde{V} - T\partial\tilde{V}/\partial T)\,dp \quad [21]$$

In the case of hydrogen and oxygen the value of the integral in [21] is nonzero only because of the nonideality of the two gases.

The equations of state for hydrogen and oxygen gases are conveniently represented by the modified Virial equation of the form

$$\frac{p\tilde{V}}{RT} = 1 + B'p + C'p^2 + \ldots \quad [22]$$

where R is the gas constant. Substitution in Eq. [21] gives

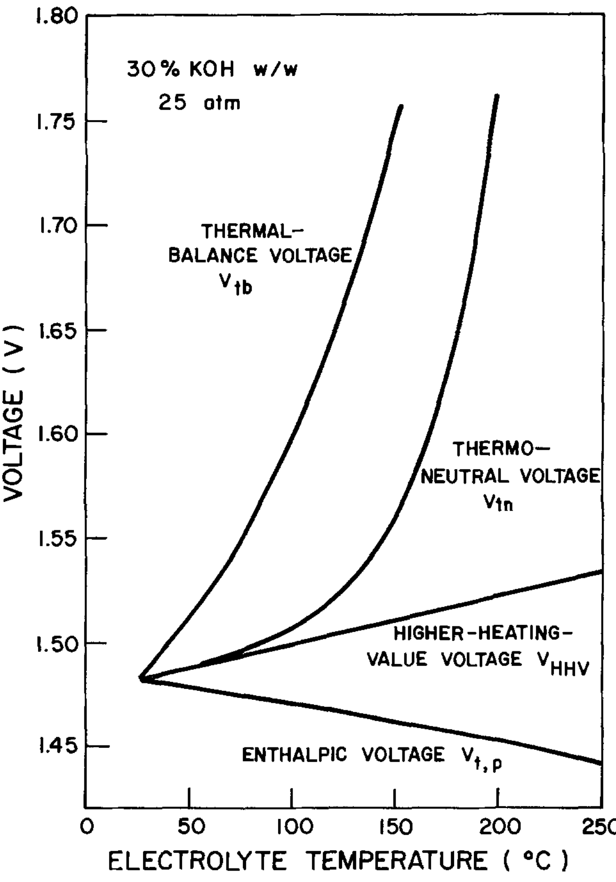

Fig. 1. Variation of the principle voltage parameters of a water electrolyzer with temperature, for representative operating conditions. The contribution V_{rc} of radiation and convection to the thermal-balance voltage is calculated assuming an electrolyzer surface area of 0.1 m²/kA, and a surface emissivity of 0.8.

[4] Because of the nonideality of hydrogen and oxygen gases, $\Delta\tilde{H}_{t,p=1}$ is not equal to $\Delta\tilde{H}^\circ_t$, and the corresponding voltage differs slightly (by a maximum of 15 μV) from the value calculated for V°_t using Eq. [20]; see Table I.

$$\tilde{H}_{t,p_2} - \tilde{H}_{t,p_1} = RT^2 \int_{p_1}^{p_2} \left(\frac{\partial B'}{\partial T} + p \frac{\partial C'}{\partial T} + \ldots \right) dp \quad [23]$$

Values of the coefficients B', C', . . . of the modified Virial equation are not normally provided, and must be derived from coefficients B, C, . . . of the standard Virial equation

$$\frac{p\tilde{V}}{RT} = 1 + B/\tilde{V} + C/\tilde{V}^2 + \ldots \quad [24]$$

The two sets of parameters can be shown to be related through the expressions

$$B' = B/RT \quad [25]$$

and

$$C' = (C - B^2)/(RT)^2 \quad [26]$$

These results are substituted in Eq. [23] to express the pressure dependence of the enthalpy of a nonideal gas in terms of known quantities[5]

$$\tilde{H}_{t,p} = \tilde{H}^\circ_t + \left(B - T\frac{\partial B}{\partial T} \right) p + \frac{C - B^2 - \frac{1}{2} T \left(\frac{\partial C}{\partial T} - 2B\frac{\partial B}{\partial T} \right)}{RT} p^2 + \ldots \quad [27]$$

Virial-coefficient data for hydrogen and oxygen are plotted against linearizing functions of temperature in Fig. 2 and 3, respectively. The data are taken from critical compilations by Dymond and Smith (9), and by Sengers *et al.* (10), and the temperature functions were suggested by the work of Goodwin *et al.* (11). The data for both gases are well represented between 25° and 250°C by the expressions

$$B = b_1 + b_2/T \quad [28]$$

and

$$C = c_1 + c_2/T^{1/2} \quad [29]$$

where values of the coefficients are indicated in the figures. Substituting these expressions, Eq. [27] can be written

$$\tilde{H}_{t,p} - \tilde{H}^\circ_t = (b_1 + 2b_2/T)p + \left(c_1 + \frac{1.25c_2}{T^{1/2}} - [b_1 + 2b_2/T]B \right) p^2/RT \quad [30]$$

The first term on the right of Eq. [30] dominates, so that portion of $\Delta\tilde{H}_{t,p}$ relating to the product gases varies roughly linearly with pressure.

To complete the calculation of $\Delta\tilde{H}_{t,p} - \Delta\tilde{H}^\circ_t$, values of $\tilde{H}_{t,p} - \tilde{H}^\circ_t$ for pure liquid water were obtained from the Steam Tables (6). The pressure dependence of the enthalpic voltage expressed as $(\Delta\tilde{H}_{t,p} - \Delta\tilde{H}^\circ_t)/nF$, in millivolts, is given in Table I for a range of temperatures and pressures. It is apparent from this table that the pressure dependence of the enthalpic voltage is very small over the temperature and pressure range of interest.

[5] The enthalpy of the gases in their standard state is evaluated by setting $p = 0$, since real gases approach ideality at zero pressure, and the enthalpy of an ideal gas is independent of pressure.

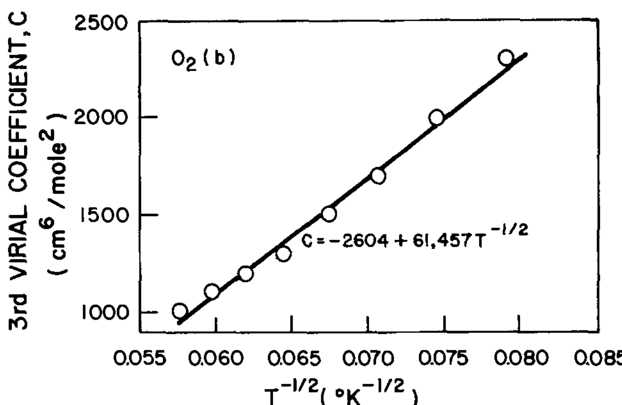

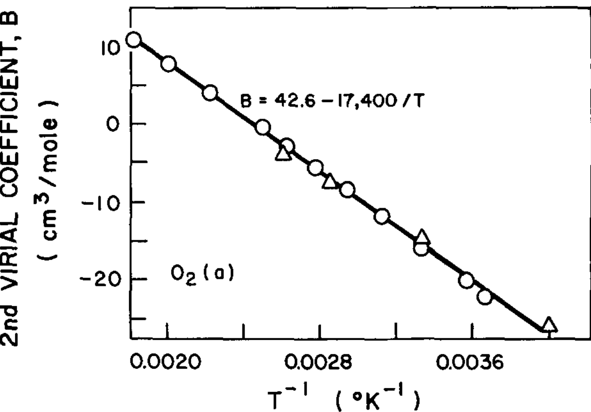

Fig. 3. Virial coefficient data for oxygen gas

The Higher-Heating-Value Voltage

As shown by Eq. [19], $\Delta\tilde{H}^\circ_t < \Delta\tilde{H}^\circ_{25}$ for $t > 25$°C. However, to heat the reagent water from 25° to t°C requires $(\tilde{H}^\circ_t - \tilde{H}^\circ_{25})_{w(l)}$ J/mole at 1 atm pressure. The total corresponding energy requirement per mole of hydrogen produced, expressed as a voltage, is

Table I. Pressure dependence of the enthalpic voltage*

$(V_{t,p} - V°_t) = (\Delta\tilde{H}_{t,p} - \Delta\tilde{H}°_t)/n\mathbf{F}$ (mV)

t (°C)	p = 1 atm	25 atm	50 atm	75 atm	100 atm
25	−0.0152	−0.578	−1.143	−1.686	−2.208
100	−0.0078	−0.354	−0.694	−1.018	−1.320
200	(−0.0015)	−0.121	−0.242	−0.342	−0.439
250	(+0.0008)	(+0.041)	+0.083	+0.125	+0.167

* Bracketed values are theoretical only; liquid water would not exist under these conditions.

the higher-heating-value voltage, $V°_{HHV,t}$, and is defined by the equation

$$V°_{HHV,t} = V°_t + (\tilde{H}°_t - \tilde{H}°_{25})_{w(l)}/n\mathbf{F} \quad [31]$$

Values of $V°_t$ given by [20], together with values of $(\tilde{H}°_t - \tilde{H}°_{25})_{w(l)}$ obtained from the Steam tables (6), yield the equation

$$V°_{HHV,t} = 1.4756 + 2.252 \times 10^{-4}t + 1.52 \times 10^{-8}t^2 \quad [32]$$

This expression is plotted in Fig. 1.

For a pressure of p atm we can write

$$n\mathbf{F}V_{HHV,t,p} = (\tilde{H}_{t,p})_{hy} + 0.5(\tilde{H}_{t,p})_{ox} - (\tilde{H}°_{25})_{w(l)} \quad [33]$$

The pressure dependence of the higher-heating-value voltage can then be expressed as

$$V_{HHV,t,p} - V°_{HHV,t} = [(\tilde{H}_{t,p} - \tilde{H}°_t)_{hy} + 0.5(\tilde{H}_{t,p} - \tilde{H}°_t)_{ox}]/n\mathbf{F} \quad [34]$$

Representative values of the quantity defined by Eq. [34] are recorded in Table II. It should be noted that they differ from zero solely because of the deviations of the two gases from ideality, and that they differ from the corresponding data in Table I by the omission of the term $(\tilde{H}_{t,p} - \tilde{H}°_t)_{w(l)}/n\mathbf{F}$.

The Thermoneutral Voltage

Within the limitations implied by the validity of Eq. [12] for wet hydrogen and wet oxygen, the thermoneutral voltage can be expressed by Eq. [15], where V_{HHV} is evaluated for the pressure $p - p_w$. As indicated by Table II, the effect of pressure on V_{HHV} is quite small. We will, therefore, drop the distinction between p and $p - p_w$ and write

$$n\mathbf{F}V_{tn} = n\mathbf{F}V_{HHV} + \Phi[\tilde{H}_{w(g),t,p_w} - \tilde{H}°_{w(l),25}] \quad [35]$$

where V_{HHV} is evaluated at t and p.

The quantity Φ is defined by Eq. [6]. For any given value of the total pressure p, values of Φ can be calculated provided p_w, the vapor pressure of the KOH solution, is known. Values of p_w at various temperatures and concentrations were obtained from the International Critical Tables (12) and fitted to the equation

$$\ln p_w = 0.01621 - 0.1380m + 0.1933m^{1/2} + 1.024 \ln p_w^* \quad [36]$$

Table II. Pressure dependence of the higher-heating-value potential

$(V_{HHV,t,p} - V°_{HHV,t})$ (mV)

t (°C)	p = 1 atm	25 atm	50 atm	75 atm	100 atm
25	−0.0152	−0.370	−0.720	−1.048	−1.354
100	−0.0078	−0.185	−0.350	−0.497	−0.624
200	−0.0015	−0.031	−0.050	−0.057	−0.051
250	+0.0008	+0.023	+0.056	+0.098	+0.149

The vapor pressure of pure water, p_w^*, can be obtained from, for instance, the Handbook of Chemistry and Physics (13) or can be calculated with an error of less than 1% over the range 25°-250°C using the relation

$$\ln p_w^* = 37.04 - 6276/T - 3.416 \ln T \quad [37]$$

The quantity $[\tilde{H}_{w(g),t,p_w} - \tilde{H}°_{w(l),25}]$ in the second term of Eq. [35] may be approximated by $[\tilde{H}_{w(g),t,p_w^*} - \tilde{H}°_{w(l),25}]$, values of which can be obtained from Steam tables (6). $\tilde{H}_{w(g),t,p_w}$ is the molar enthalpy of steam at t°C and at the pressure p_w equal to the vapor pressure of water over the KOH solution. This pressure will be less than the vapor pressure of pure water, p_w^*, at t°C. However, the molar enthalpy of water vapor at p_w^* will differ from that at p_w only because of deviations from ideal-gas behavior. The corrections can be calculated in the same way as they were for hydrogen and oxygen, but in view of the fact that they will be smaller than the errors in Φ arising through uncertainties in p_w it was not considered worthwhile to prepare a table of corrections. One calculation, made for a 30% w/w solution of KOH ($m = 7.64$) at 150°C and a total pressure $p = 10$ atm, gave $p_w = 2.34$ atm, $p_w^* = 4.70$ atm, and a correction, $\Phi[\tilde{H}_{p_w} - \tilde{H}_{p_w^*}]_{w(g),150}$ equal to 32 J mole^{-1} or 0.17 mV. This value was calculated using van der Waal's constants for water vapor (13).

The expression for the thermoneutral voltage may then be written

$$n\mathbf{F}V_{tn} = n\mathbf{F}V_{HHV} + \Phi Y \quad [38]$$

where, for simplicity, $[\tilde{H}_{w(g),t,p_w^*} - \tilde{H}°_{w(l),25}]$ is given the symbol Y. This quantity depends only on the temperature, and can be represented within 0.02% by the equation

$$Y = 42960 + 40.762t - 0.06682t^2 \text{ J mole}^{-1} \quad [39]$$

over the temperature range $25°C \leq t \leq 220°C$.

Values of V_{tn} calculated from Eq. [38] (using [32], [36], [37], and [39]) are plotted in Fig. 1 for a 30% w/w solution of KOH and a total pressure of 25 atm. The rapid increase of V_{tn} with temperature, as compared to the relatively modest increase of V_{HHV}, occurs because of the rapid increase with temperature of the amount of water vapor that is carried off with the hydrogen and oxygen. The quantity Y does not increase very strongly with temperature, but Φ does. The quantity Φ decreases with increasing total pressure p, and, as shown by Fig. 4, this causes V_{tn} to decrease with increasing pressure. As noted in Eq. [14], V_{tn} approaches V_{HHV} asymptotically as $p \rightarrow \infty$.

The designation "thermoneutral voltage" has been used previously in water-electrolyzer literature, although without a clear definition. Numerous authors (14-17) have reproduced a curve which originated with Gregory (18), which shows what is identified as the thermoneutral voltage to increase weakly with increasing temperature. Absolute values were between the curves drawn in Fig. 1 for the enthalpic and higher-heating-value voltages. Thus the earlier result must be considered to be an approximation to these quantities, which do not include the unavoidable energy requirements of water evaporation.

The Efficiency of a Water Electrolyzer

In discussing the efficiency of a real electrolyzer which is operating with an observed voltage V_{obs}, it is convenient to think of a black box into which water at 25°C and 1 atm pressure is fed together with energy in the amount $n\mathbf{F}V_{obs}$, and out of which comes wet hydrogen and wet oxygen together with waste energy in the form of radiation, convection, and conduction. These waste-energy terms can be grouped

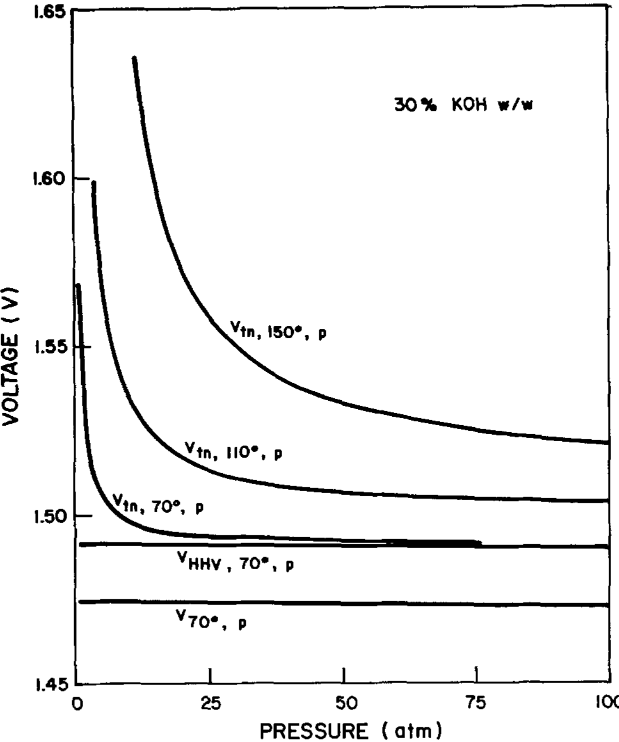

Fig. 4. Variation of the thermoneutral voltage with total pressure for three representative electrolyte temperatures. The enthalpic and high-heating-value voltages are indicated at 70°C.

together and defined as Q J/mole of hydrogen produced.[6] Since energy is conserved

$$n\mathbf{F}V_{obs} = H(\text{wet hydrogen})_{t,p} + H(\text{wet oxygen})_{t,p} - H(\text{feed water})_{25,1\text{ atm}} + Q = n\mathbf{F}V_{tn} + Q \quad [40]$$

Within the accuracy implied by the use of Eq. [38]

$$n\mathbf{F}V_{obs} = n\mathbf{F}V_{HHV} + \Phi Y + Q \quad [41]$$

The useful output from the expenditure of $n\mathbf{F}V_{obs}$ J is usually considered to be the energy equivalent to the higher-heating value of the product hydrogen, represented by the term $n\mathbf{F}V_{HHV}$. It is customary, then, to define the electrical-energy efficiency of an electrolyzer as η, where

$$\eta = V_{HHV}/V_{obs} \quad [42]$$

This definition of efficiency has become widely accepted, in spite of the fact that it would never be possible to recover the full higher heating value of hydrogen in an energy application. Nevertheless, a uniform basis for comparison is required. The use of V_{HHV} has the strong advantage that it is a thermodynamic quantity, whose value is independent of the way in which the product gases are subsequently treated or used. The efficiency with which the heat content of the product gases can be transformed into useful energy in a particular application can then be analyzed as a separate issue.

As an example of efficiency calculation, it follows from Eq. [32] that the value of V°_{HHV} at 100°C is 1.4983V. Using Table II, the value of V_{HHV} at 100°C and 50 atm is $1.4983 - 0.350 \times 10^{-3} = 1.4980$V. The electrical energy efficiency of an electrolyzer operating at 1.750V at this temperature and pressure would then be $1.4980/1.750 = 85.6\%$. It is interesting to note that if the pressure dependence of V_{HHV} had been calculated by the method of neglecting the second term in Eq. [11] (1-4), the calculated value of V_{HHV} would have been $1.4983 + 0.0944 = 1.5925$V, and the efficiency η of an electrolyzer operating at 1.750V at 100°C and 50 atm would have been calculated to be 91.0%.

[6] Q will, of course, depend on the electrolyzer and its operating conditions, including the current.

The enthalpic voltage ($V_{t,p}$), the higher-heating-value voltage (V_{HHV}) and the thermoneutral voltage (V_{tn}) are thermodynamic state functions, depending only on the temperature and pressure of the electrolyzer and, in the case of V_{tn}, on the concentration of the KOH electrolyte. In particular, they are quite independent of the magnitude of the electrolyzing current,which determines the rate of production of hydrogen. On the other hand, the net energy losses due to radiation, convection, and conduction usually manifest themselves as a power loss of, say P_QW or P_Q J/sec. For an electrolysis current of I amp the rate of production of hydrogen would be $I/n\mathbf{F}$ moles/sec. The energy loss per mole of hydrogen produced, the quantity Q in Eq. [40] and [41], would then be given by

$$Q = n\mathbf{F}P_Q/I \text{ J mole}^{-1} \quad [43]$$

It can also be expressed as a voltage

$$V_Q = Q/n\mathbf{F} = P_Q/I \quad [44]$$

It is evident from Eq. [40] that if V_{tn} can be calculated, then V_Q can be obtained by subtracting V_{tn} from V_{obs}

$$V_{obs} = V_{tn} + V_Q \quad [45]$$

The Thermal-Balance Voltage

It should be noted that if cooling water is used to remove heat from the electrolyzer this will make a positive contribution to V_Q; if heat has to be supplied to the electrolyzer in order to maintain its temperature at t°C then this will make a negative contribution to V_Q. The latter situation would arise if the energy dissipation in the electrolyzer represented by overvoltages and ohmic-resistance losses were not sufficient to raise $n\mathbf{F}V_{obs}$ to a value large enough to exceed $n\mathbf{F}V_{tn}$ by enough to supply the energy losses from radiation and convection.

It follows from these considerations that if the operating conditions of an electrolytic cell, including the temperature, pressure, KOH concentration, and current, were such that V_{obs} was equal to $V_{tn} + V_{rad} + V_{conv}$ then separate heating or cooling of the cell would not be required. That particular value of V_{obs} would be the thermal-balance voltage V_{tb}

$$V_{tb} = V_{tn} + V_{rad} + V_{conv}$$

or

$$V_{tb} = V_{tn} + V_{rc} \quad [46]$$

where $V_{rad} + V_{conv} = V_{rc}$.

It should be noted that V_{tb} is not a thermodynamic state function because neither V_{rad} nor V_{conv} is a state function. Nevertheless, an estimate of the magnitude of both of the latter two quantities can be made.

The radiation loss can be estimated using the well-known fourth-power law of radiation

$$P_{rad} = A\epsilon\sigma(T^4 - T_a^4) \quad [47]$$

where A is the radiating area, ϵ is its emissivity, σ is the Stefan-Boltzmann constant, 5.67×10^{-8}W m^{-2} deg^{-4}, and T_a is the ambient temperature. As an example, consider a cell operating at the temperature $T = 373.2$°K with the ambient temperature $T_a = 298.2$°K. Suppose that the emissivity is 0.8 and the area of the radiating surface is 0.1 m^2 per kA of current passing through the cell. The heat loss by radiation would be 52.1W per kA, corresponding to $V_{rad} = 52.1$ mV.

It is also possible to make an estimate of the heat loss by convection, using an expression taken from Perry (19)

$$P_{conv} = 1.77A(T - T_a)^{1.25}\text{W} \quad [48]$$

Using the same values of T, T_a, and A as before, P_{conv} per kA would be 39.1W, and V_{conv} would be equal to 39.1 mV. V_{rc} would then be 91.2 mV.

It is evident from Eq. [47], [48], and [44] that for fixed operating and ambient temperatures, V_{rad} and V_{conv} are inversely proportional to the electrolyzing current for any particular electrolyzer. This effect has been noted previously (20).

In Fig. 1 values of the thermal-balance voltage V_{tb}, defined by Eq. [46], are plotted as a function of temperature for an electrolyzer operating at 25 atm total pressure, using a 30% KOH electrolyte and having the area and emissivity referred to above. At 150°C and 25 atm, V_{tb} is 1.743V. Operation below this voltage would require input of heat from an external source. Under these conditions, V_{HHV} is 1.510V. Thus the energy efficiency of an electrolyzer operating at V_{tb} would be 1.510/1.743 = 86.6%. If the cell were perfectly insulated V_{tb} would be equal to V_{tn}, and the efficiency for operation at the thermal-balance voltage would be 96.8%.

The value of the thermal-balance voltage represents a limitation on the maximum electrical-energy efficiency which can be achieved in an electrolyzer, if a supplementary source of heat is not available to maintain the temperature. These limitations are particularly onerous for high operating temperatures and modest pressures. Kunstreich's group has given the first systematic attention to this problem, proposing energy recovery from gas driers as an essential component of efficient high temperature electrolysis systems (1, 2).

As has been noted by many authors, it is possible for the electrical efficiency of a water electrolyzer, as defined by Eq. [42], to exceed 100%. In terms of the present discussion such a situation implies that energy release internal to the electrolyzer (from electrode overvoltages and resistive losses) is so low that energy input by conduction must exceed the difference between V_{tb} and V_{HHV}.

Dependence of the Thermal-Balance Voltage on Pressure and Electrolyte Concentration

As indicated by Eq. [46], the thermal-balance voltage can be calculated from a knowledge of the thermoneutral voltage, V_{tn}, which is a state function depending only on the temperature, the pressure, and the concentration of the electrolyte, and of the value of V_{rc}, which depends on the electrolyzer and its operating conditions, including current. The value of V_{rc} can be estimated, for example, by using Eq. [47] and [48]. It can also be estimated by subtracting V_{tn} from V_{obs} to get V_Q, using Eq. [45], and then subtracting from V_Q the contribution (positive or negative) made by external cooling or heating other than by radiation and convection. If the electrolyzer were perfectly insulated, then V_{rc} would be equal to zero and V_{tb} would be equal to V_{tn}. In view of these considerations the dependence of the thermoneutral voltage on pressure and electrolyte concentration is illustrated in Fig. 4 and 5.

In Fig. 4 values of the thermoneutral voltage for 30% w/w KOH are plotted as a function of pressure for three representative electrolyte temperatures. In addition, values of the enthalpic and the higher-heating-value voltages at 70°C are plotted. The slight decreases in the values of these latter quantities with increasing pressure were calculated using linear interpolation of the data in Tables I and II. As a result of the rapid decrease in the quantity Φ [$= 1.5p_w/(p - p_w)$] with increasing total pressure, V_{tn} approaches V_{HHV} at high pressures. This is illustrated quite clearly by the data for 70°C. It should be noted that the curves in Fig. 4 are substantially different from the results reported by Kunstreich *et al.* (1, 2) for comparable conditions.

Figure 5 illustrates the dependence of the thermoneutral voltage on electrolyte concentration for various operating temperatures at a total pressure of 5 atm. The rapid decrease in V_{tn} with increasing concentration of electrolyte, particularly at the higher temperatures, arises because of the strong dependence of the vapor pressure on electrolyte concentration, and the even stronger dependence of the quantity Φ. For example, at 130°C the vapor pressure over a 45% solution of KOH is only about 34% of that over a 20% solution; the value of Φ is about 22% of that for the weaker solution.

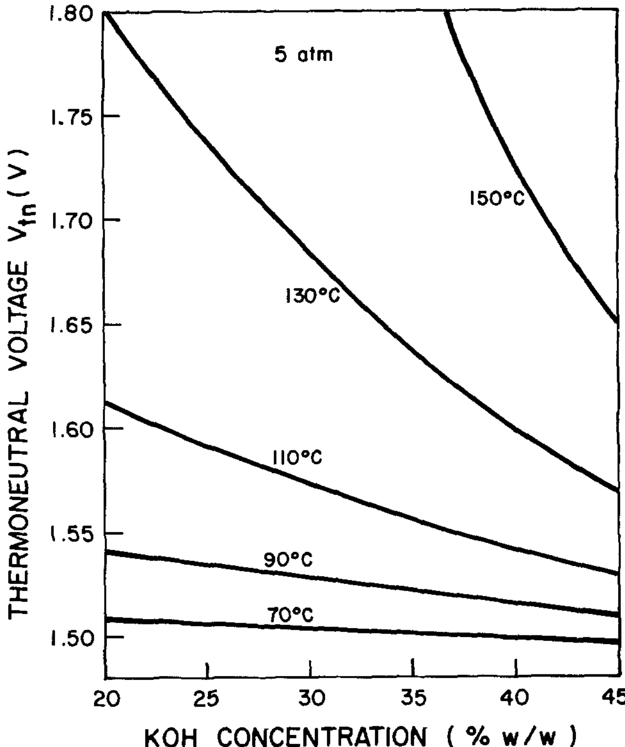

Fig. 5. Dependence of the thermoneutral voltage on concentration of the KOH electrolyte for representative temperatures.

The Reversible Potential

In the course of developing expressions for $V_{t,p}$, V_{HHV}, and V_{tn} it was convenient to consider an imaginary electrolytic cell immersed in a thermostat at temperature t°C with reversible electrodes, one of which was in contact with wet hydrogen, the other with wet oxygen, the whole being at a pressure of p atm. The emf of such a cell would be the so-called reversible potential, E_{rev}, where

$$nFE_{rev,t,p} = -\Delta G_{t,p} = \mu_{hy} + 0.5\mu_{ox} - \mu_{w(soln)} \quad [49]$$

in which μ_{hy} is the chemical potential of hydrogen in the gaseous solution of hydrogen and water vapor, μ_{ox} is the chemical potential of oxygen in the gaseous solution of oxygen and water vapor, and $\mu_{w(soln)}$ is the chemical potential of water in the electrolyte.

If, as has been assumed, the water in each of the gaseous solutions is in equilibrium with the water in the electrolyte, then $\mu_{w(soln)}$ will be equal to $\mu_{w(g)}$, the chemical potential of water in either of the two gaseous solutions. To simplify the development it will be assumed that the gaseous solutions are ideal and that the individual pure gases are also ideal. In this case Eq. [7] would apply and Eq. [49] can be written

$$nFE_{rev,t,p} = [\tilde{G}^\circ_{hy} + 0.5\,\tilde{G}^\circ_{ox} - \tilde{G}^\circ_{w(g)}]_t + RT \ln [(p - p_w)^{1.5}/p_w] \quad [50]$$

The first term in square brackets is the negative of the standard free energy of formation of gaseous water at t°C. This can be expressed in terms of the negative of the standard free energy of formation of

liquid water by obtaining a relation between $\tilde{G}^\circ_{w(g)}$ and $\tilde{G}^\circ_{w(l)}$.

For pure liquid water in equilibrium with its vapor at a pressure of p_w^* atm

$$[\tilde{G}_{w(l)}]_{p_w^*} = [\tilde{G}_{w(g)}]_{p_w^*} \quad [51]$$

If the vapor can be considered as an ideal gas, Eq. [51] may be expanded as

$$\tilde{G}^\circ_{w(l)} + \int_1^{p_w^*} \tilde{V}_{w(l)}\, dp = \tilde{G}^\circ_{w(g)} + RT \ln p_w^* \quad [52]$$

The value of the integral in Eq. [52] is zero at 100°C, negative below 100°C, and positive above; expressed in terms of a voltage by dividing by $n\mathbf{F}$, its absolute value is less than 10 μV at 25°C and less than 1 mV at 250°C. Dropping the integral and substituting for $\tilde{G}^\circ_{w(g)}$ in Eq. [50]

$$n\mathbf{F}E_{rev,t,p} = n\mathbf{F}E^\circ_{rev,t} + RT \ln [(p - p_w)^{1.5} p_w^*/p_w] \quad [53]$$

where

$$n\mathbf{F}E^\circ_{rev,t} = [\tilde{G}^\circ_{hy} + 0.5\,\tilde{G}^\circ_{ox} - \tilde{G}^\circ_{w(l)}]_t$$

$$= -\Delta\tilde{G}^\circ_f [H_2O(l)]_t \quad [54]$$

The value of the standard free energy of formation of liquid water at 25°C is −56 690.2 cal (21) and so the value of $E^\circ_{rev,25}$ is equal to 1.2291V.

In developing the expressions for the enthalpic voltage and the higher-heating-value voltage, corrections arising as a result of the nonideality of the individual gases were evaluated and tabulated in Tables I and II. Analogous corrections to E_{rev} are not made in this paper; although this could be done in a fairly straightforward manner. Instead of using Eq. [7] in derivation of the expression for $E_{rev,t,p}$ (Eq. [50]), the molar free energy of a gas i at pressure p would be written

$$\tilde{G}_i = \tilde{G}^\circ_i + RT [(\ln p_i + B'p_i + C'p_i^2/2 + \ldots)] \quad [55]$$

in which B' and C' are the second and third virial coefficients defined previously.

In examining the effect of temperature on the reversible potential, the coefficient of RT in Eq. [53] can be evaluated with the aid of Eq. [36] and [37]. Also, in view of the thermodynamic relation

$$\partial(G/T)/\partial T = -(H/T^2) \quad [56]$$

it follows that

$$\partial(E^\circ_{rev,t}/T)/\partial T = -(V^\circ_t/T^2) \quad [57]$$

where V°_t is given by Eq. [20]. After integration and rearrangement $E^\circ_{rev,t}$ is given by the expression

$$E^\circ_{rev,t} = 1.5184 - 1.5421 \times 10^{-3}T + 9.523 \times 10^{-5}T \ln T + 9.84 \times 10^{-8}T^2 \quad [58]$$

E°_{rev} decreases with increasing temperature in an almost linear fashion, as shown in Fig. 6. In the same figure values of E_{rev} are plotted for a total pressure of 25 atm and a 30% KOH electrolyte.

It is interesting to compare the values of E_{rev} and V_{tn} for this pressure and electrolyte concentration and for the same temperature, say 100°C. The values of E_{rev} and V_{tn} are 1.2522 and 1.5070V, respectively. The amount of electrical energy required per mole of hydrogen produced in an ideal electrolyzer having no overvoltages and no ohmic-resistance losses would be $n\mathbf{F}E_{rev}$. The balance of the energy required for the chemical process, 0.2548 $n\mathbf{F}$ or 49,170J, together with any energy required to cover losses through radiation

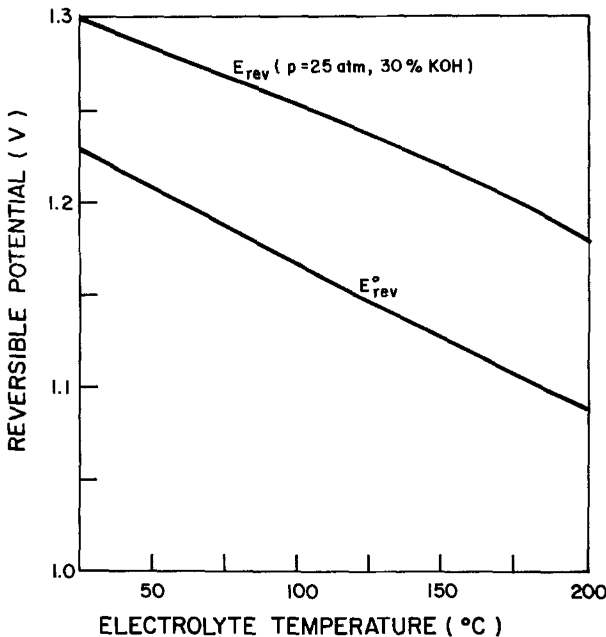

Fig. 6. Dependence of the reversible potential on electrolyte temperature, under standard conditions, and for 30% w/w KOH electrolyte at 25 atm pressure.

and convection, could, in principle, be supplied as heat. The value of V_{obs} for the cell would be 1.2522V. Since V_{HHV} for these conditions is 1.4981V, the electrical efficiency of the cell would be 1.4981/1.2522 = 119.6%.

Acknowledgments

We are indebted to Mr. A. Hufnagl whose energy-balance analyses of advanced water-electrolyzer designs prompted the calculations reported here, as well as to Professor R. Aziz of the University of Waterloo and Dr. G. Kell of the National Research Council of Canada who assisted in critical evaluation of thermodynamic data for hydrogen, oxygen, and water.

Gold Passivation in Aqueous Alkaline Cyanide

D. W. Kirk,* F. R. Foulkes,* and W. F. Graydon

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

The behavior of gold electrodes in alkaline cyanide solution was studied using potentiostatic and potentiodynamic techniques. The results showed that the three anodic current peaks found in both steady-state and potential sweep experiments resulted from passivation of the gold cyanide dissolution reaction

$$Au + 2CN^- \rightarrow Au(CN)_2^- + e^-$$

Potential pH measurements showed that the passivating reactions were dependent on the hydroxyl ion concentration. The potentials at which passivation occurred closely corresponded to the formation potentials of gold oxide and suboxide surface species. It was concluded that the most anodic dissolution reaction (peak 3) was passivated by the formation of gold (III) oxide. The less anodic gold dissolution peaks, peaks 1 and 2, were passivated by the formation of gold (I) hydroxide according to

$$Au + OH^- \rightarrow AuOH + e^-$$

From the remarkable similarity between the location of the gold dissolution peak in alkaline cyanide solution and the location of the oxide and suboxide peaks in cyanide-free alkaline solution, it was concluded that peaks 1 and 2 corresponded to gold dissolution and subsequent passivation predominantly on the (100) and (111) crystal planes, respectively; whereas peak 3 corresponds to gold dissolution and subsequent passivation over the complete electrode surface.

Gold displays a complex anodic behavior in aqueous alkaline cyanide solutions. Potentiostatic (1-3) and slow potential sweep measurements (1) have shown the presence of three peaks in the anodic potential profile. These three peaks have been identified with a gold dissolution process (1). The electron stoichiometry of the dissolution process has been measured and shown to be unity for each of the three peak regions (4). The dissolution process in each peak region has been shown to follow the reaction sequence

$$Au + CN^- \rightleftarrows AuCN_{ads}^- \quad [1]$$

$$AuCN_{ads}^- \rightleftarrows AuCN_{ads} + e^- \quad [2]$$

$$AuCN_{ads} + CN^- \rightleftarrows Au(CN)_2^- \quad [3]$$

The rate-determining step has been identified for each of the peak regions (1, 5).

* Electrochemical Society Active Member.

Key words: metals, electrode, passivity, dissolution.

There have been several attempts made to explain the origin of the peaks. Cathro and Koch (2) suggested that the formation of basic cyanide films anodic of peaks 1 and 2 caused the passivation of these peaks. Later, MacArthur (6) questioned the formation of the basic cyanide films and suggested that the reaction mechanism and not passivation was the cause of peak 1. Peak 1 was identified by MacArthur with a charge transfer reaction followed by a chemical reaction mechanism in which the chemical reaction is rate determining and the surface intermediate interferes with the charge transfer reaction. Peak 2 was not separated from peak 3 in MacArthur's work and was not identified.

In a more recent paper by Eisenmann (3), the formation of peaks 1 and 2 was said to be the result of diffusion limitation of the cyanide ion. Our own work (1) on the anodic behavior of gold indicated that the formation of passivating surface films was

the cause of the peaks, although the nature of these films was not determined.

Knowledge of the electrochemical reactions of gold in alkaline cyanide is important for the development of electrolytic processing of industrial gold liquors. Although it is generally agreed (1-3, 14) that the peak 3 reaction is passivated by the formation of gold (III) oxide, the cause of the formation of the other peaks has not been explained satisfactorily. Therefore work was carried out to investigate the process of peak formation in potentiostatic and potentiodynamic measurements on gold in alkaline cyanide solutions.

Experimental Section

The equipment consisted of a Wenking potentiostat (Model 70TS1) and voltage scan generator (Model VSG72). The potential sweep measurements were recorded with a Hewlett-Packard Model 70004Bx4 recorder for slow sweep rates, and a Tektronics Model 5113 dual beam storage oscilloscope for fast sweep rates.

Gold electrodes (99.99% purity) were used for both working and counterelectrodes in a Pyrex cell. The working electrode was a gold wire 0.0381 cm in diam. The counterelectrode consisted of 2 gold foil sheets (each 1.6 cm^2) set 1.25 cm to either side of the working electrode and contained in glass fritted tubes. The reference electrode was a saturated calomel electrode.[1] The cell configuration has been described previously (1, 7).

The surface area of the electrode was determined from potential scan measurements using the linear relation between the current peak height and the square root of the voltage scan rate for the oxidation of $Fe(CN)_6^{-4}$. The relation given by Nicholson and Shain (8) is

$$\frac{i_p}{nFAC_oD_o\frac{nFv^{1/2}}{RT}} = 0.4463$$

where C_o is the concentration of $Fe(CN)_6^{-4}$ (mole $\cdot$ cm^{-3}), D_o is the diffusion coefficient of $Fe(CN)_6^{-4}$ ($cm^2 \cdot sec^{-1}$), i_p is the peak current (A), A is the area (cm^2), n is the number of electrons transferred in the oxidation, v is the scan rate ($Vsec^{-1}$), and $\mathbf{F}$, R, and and T have their usual meanings.

Solutions prepared from analytical grade reagents and doubly distilled water were deoxygenated by bubbling with oxygen-free nitrogen.

A standard pretreatment of the gold electrode was necessary to achieve reproducibility in the voltage scans. The electrode was first heated to redness in air, then etched in hot aqua regia for 10 sec, then washed in doubly distilled water and dried. It was immediately given a further treatment consisting of a 5 min reduction period in the electrolyte at $-1.2V$.

Results and Discussion

A typical single sweep potential profile is shown in Fig. 1 for gold in 0.1M KOH + 0.1M KCN at a sweep rate of 1.0 $mV \cdot sec^{-1}$. For the anodic sweep direction there are three current peaks, labeled peak 1, peak 2, and peak 3. The reaction in each of these peak regions has been shown to be a one electron transfer process (4) following the reaction sequence [1], [2], and [3] (1,5). The current peaks in the potential scan represent the rate of gold dissolution in alkaline cyanide under the given experimental conditions. The fact that the dissolution rate does not increase monotonically or reach a plateau with increase in potential suggests that the surface may become partially passivated during the potential sweep by the formation of either nonreactive or slowly reactive surface species.

[1] All potentials in this work are reported *vs.* the saturated calomel electrode.

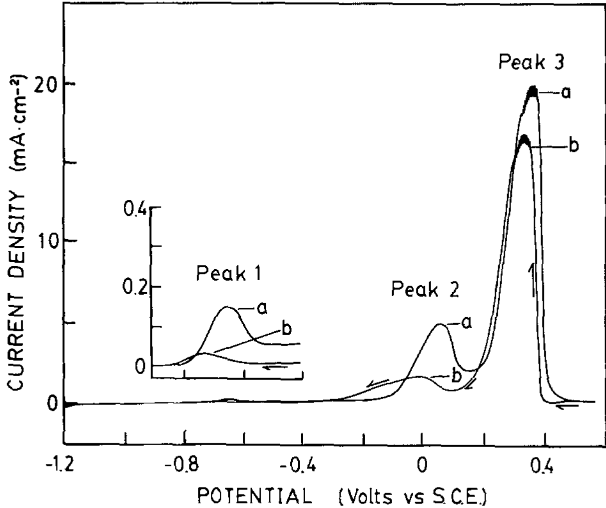

Fig. 1. Single sweep potential profile in aqueous alkaline cyanide: 0.1M KOH + 0.1M KCN; sweep rate = 1.0 mV $\cdot$ sec^{-1}; initial potential = $-1.2V$; temperature = 23.5°C. a) anodic scan, b) cathodic scan.

The current maximum measured in the region of peak 3 can be seen to be unstable. This current instability, which is observed in both the anodic and cathodic sweep directions, is typical of a phenomenon known as periodic oxidation (9-12). In most cases, this type of oscillation or current variation has been found to be the result of two competing reactions, one of which involves dissolution and the other passivation. The dissolution reaction is believed to undermine the passivating layer, causing the collapse of the passivated surface and resulting in the exposure of fresh surface. This process ceases when the passivating layer has completely covered the surface of the electrode.

In the case of the peak 3 cyanide reaction, the passivating species is the gold (III) oxide, which is thermodynamically stable at these potentials. Without cyanide present, the oxidation and reduction peak of the gold (III) oxide species easily can be observed near the potential of peak 3 (1, 6). In alkaline cyanide solutions, the competing dissolution reaction is the gold dissolution reaction via sequence [1], [2], and [3].

The cathodic scan of gold in alkaline cyanide solutions has received very little attention in the literature. The single sweep profile shown in Fig. 1 reveals several interesting features in the cathodic portion of the scan. Although the sweep is in the cathodic direction, there are multiple anodic current peaks in the profile. This behavior is not commmon in potential sweep or cyclic sweep expermiments, but is very significant. The first small cathodic current peak (~0.42V) in the cathodic scan is associated with the start of the reduction of the gold (III) oxide. Once sufficient oxide has been reduced, the anodic reaction recommences. The cathodic reduction peak will be discussed in greater detail later. The first anodic current maximum in the cathodic scan is very similar to that of peak 3 in the anodic scan and must correspond to the same anodic dissolution reaction. As the potential becomes more negative during the cathodic scan, the rate of gold dissolution decreases in the fashion of a normal faradaic reaction. An arrest in the current decrease occurs at about +0.15V, after which an anodic current increase again takes place, This second anodic current increase may reasonably be associated with the anodic reaction at peak 2, since it is in the same potential region. The arrest and second anodic current increase strongly suggest that the reaction at peak 2 is blocked by the formation of a passivating layer during the anodic scan, and that the

reduction of this passivating layer during the cathodic scan (at $\simeq +0.15V$) allows the anodic dissolution reaction to recommence. A cathodic peak indicating the presence of a reducible species would be expected only if the magnitude of the cathodic reaction was greater than that of the competing anodic reaction.

The continuation of the cathodic scan from peak 2 in Fig. 1 shows that the current remains anodic, but decreases with potential. From the inset in Fig. 1 it can be seen that a third anodic increase takes place in the peak 1 region. Although the peak 1 reaction is weak at these potentials, it is clear that the behavior of the gold electrode in this region is very similar to that observed for the peak 2 and peak 3 regions. The reduction of a passivating species (at $\simeq -0.6V$) would allow the anodic dissolution reaction to recommence.

Thus the cathodic scan in Fig. 1 is consistent with the proposal that the anodic current peaks are the result of a dissolution reaction which is blocked by the formation of passivating surface species.

The effect of the extent of the sweep range is shown in Fig. 2. The range of the potential sweep was varied from 0.06 to 0.5V past peak 3. When the anodic sweep extent was just sufficient to cause the passivation of peak 3 (curve 1), the cathodic scan revealed almost complete reversibility of the peak 3 reaction. However, with greater potential scan ranges, the reversibility of the peak 3 reaction decreased (curves 2, 3, and 4). When the extent of the potential sweep exceeds +0.8V (curve 4), little or no evidence of the peak 3 reaction can be seen on the cathodic sweep. The thickness of the oxide may increase with oxidation time and the nature of the oxide may change with increase in oxidation potential. Either phenomenon could account for the progressive decrease of anodic current in the cathodic scan in Fig. 2.

Figure 3 shows the effect of varying the sweep rate for a fixed sweep range. At sweep rates of 1 $Vsec^{-1}$, peak 2 is no longer distinct from peak 3 in the anodic scan. In the cathodic scan, the cathodic reduction peak of the gold (III) oxide is more readily observed. Thus at the faster sweep rates, the gold (III) oxide reduction reaction is more readily separated from the anodic dissolution reaction. By holding the potential at the end of the anodic scan for various times, then performing the cathodic scan at 1 $Vsec^{-1}$, the change in the oxide buildup can be estimated. This change can be seen in Fig. 4. The magnitude of the reduction peak increases with the time held at the end of the anodic sweep, although a limiting value is reached after approximately 2 min (see insert). This limiting value in the 0.1M KOH + 0.1M KCN electrolyte corresponds to approximately 75% coverage with an Au^{+3} monolayer. Under conditions more favorable to the oxide formation (increased hydroxide concentration, 1.0M), the limiting value was achieved more rapidly (<1 min) and was higher, corresponding to 100% coverage of a monolayer of Au^{+3} oxide. The lower values in the 0.1M KOH + 0.1M KCN may simply reflect a greater proportion of the anodic dissolution reaction in the measurements. There is evidence in Fig. 4 that the cathodic oxide reduction reaction is not completely separated from the anodic dissolution reaction. The tail of the reduction peak from −0.1 to −0.3V becomes anodic, indicating that the anodic process dominates for this region and obscures a portion of the reduction peak, thereby yielding lower apparent values of oxide coverage. These data support the theory that gold (III) oxide passivates the peak 3 cyanide reaction. The presence of cyanide in solution appears to limit the oxide growth

[2] The theoretical monolayer coverage was calculated using an atomic density of 1.15×10^{15} atoms $\cdot$ cm^{-2} (7) based on the average of the atomic density of the three crystal planes (100), (110), and (111).

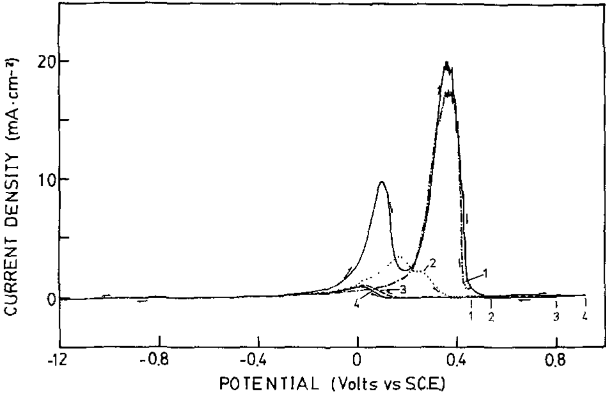

Fig. 2. Effect of potential scan range on single sweep potential profile in aqueous alkaline cyanide: 0.1M KOH + 0.1M KCN; sweep rate = 10 mV · sec^{-1}; initial potential = −1.2V; temperature = 19.8°C. Sweep extent: curve 1, +0.46V; curve 2, +0.54V; curve 3, +0.80V; curve 4, +0.92V.

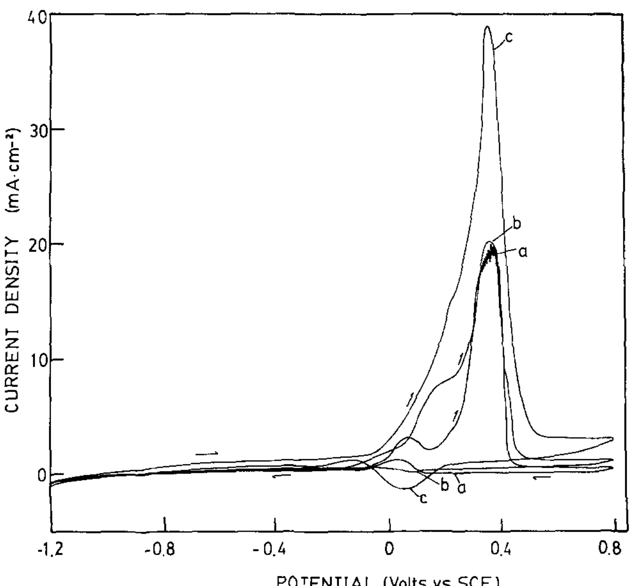

Fig. 3. Effect of sweep rate on single sweep potential profile in aqueous alkaline cyanide: 0.1M KOH + 0.1M KCN; initial potential = −1.2V; temperature = 22.3°C. Sweep rate: a, 10 mV · sec^{-1}; b, 100 mV · sec^{-1}; c, 1.0 $Vsec^{-1}$.

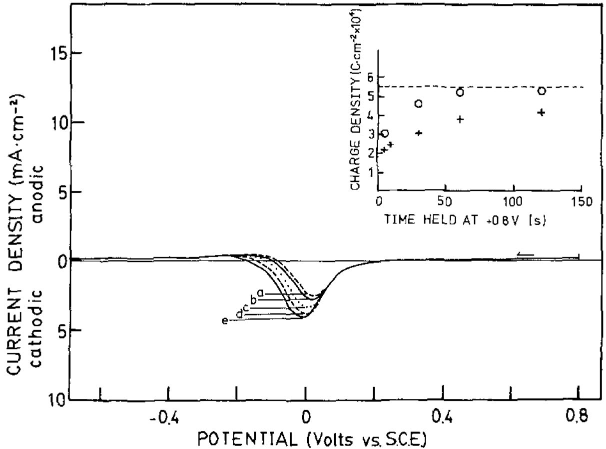

Fig. 4. Cathodic single sweep potential profile after holding electrode potential at +0.8V in aqueous alkaline cyanide: 0.1M KOH + 0.1M KCN; sweep rate = 1.0 $Vsec^{-1}$; temperature = 22.8°C. Holding time: a, 5 sec; b, 10 sec; c, 30 sec; d, 60 sec; e, 20 sec. Insert shows total charge for cathodic currents during run. Dotted line indicates charge required for reduction of an Au^{+3} monolayer. +: measurements from curves a, b, c, d, and e; ○: measurements from similar runs in 1.0M KOH + 0.1M KCN.

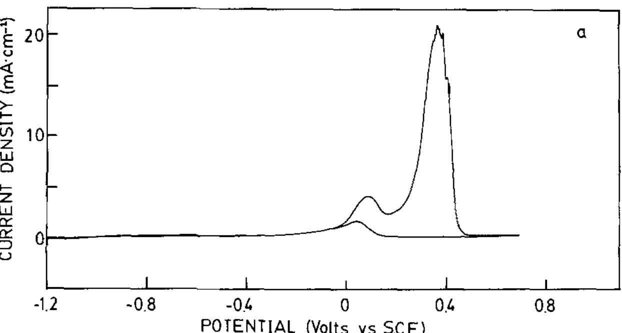
to about a monolayer. In alkaline solutions without cyanide, multilayer oxide formation does take place (7). It is clear in the cathodic scans in Fig. 2 that when the extent of the potential scan is small (curve 1), the oxide layer is either incomplete or does not have time to rearrange to form a more stable layer (13) and the reduction is relatively easy, allowing the anodic reaction to recommence. For greater scan ranges (curve 4), the oxide layer is more complete or more stable and the reduction of this oxide layer may occur at more cathodic potentials. This effect can be seen in the shift of cathodic reduction peak potential with increase in oxidation time in Fig. 4. A more complete or more stable oxide would also take longer to reduce and thus the potential may pass the peak 3 region in the cathodic scan before the oxide is removed (curve 4, Fig. 2).

By stopping the potential sweep at the anodic peak potential on the cathodic sweep, it can be seen that, given sufficient time, the oxide reduction can take place at that potential. Shown in Fig. 5b is the current-time behavior of a gold electrode after an anodic sweep to +0.70V and a cathodic sweep back to +0.38V. Figure 5a shows the single sweep profile without the hold at +0.38V *vs.* SCE. The single sweep profile of Fig. 5a shows that in the cathodic sweep the anodic reaction would not be observed until a potential of +0.13V. By holding the potential at +0.38V,



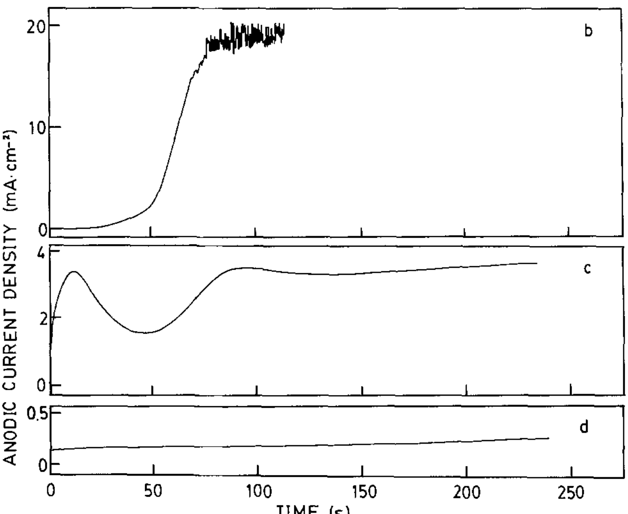


Fig. 5. Anodic recovery behavior of a gold electrode in aqueous alkaline cyanide after passivation: 0.1M KOH + 0.1M KCN; temperature = 22.3°C. a) single sweep potential profile: sweep rate = 10 mV · sec^{-1}. b) current-time behavior at peak 3 after passivation by a single potential sweep as in 5a except that the potential was stopped and held at +0.38V in the cathodic sweep. c) current-time behavior at peak 2 after passivation by a single potential sweep to +0.2V. The potential was stopped and held at +0.1V during the cathodic sweep. d) current-time behavior at peak 1 after passivation by a single potential sweep to −0.4V. The potential was stopped and held at −0.62V during the cathodic sweep.

the steady-state dissolution rate of peak 3 is achieved in about 90 sec. This represents the time required to reduce the oxide from full surface coverage to the steady-state coverage at +0.38V. The oscillation in the steady-state current at +0.38V can be observed easily in Fig. 5b. This instability, as noted earlier, appears to be the result of the inability of the gold (III) oxide reaction to dominate and passivate the surface at this potential.

The nature of the passivating layer for peak 2 may also be examined by measuring the recovery time of the anodic reaction after passivation. Potential scans were carried out in which the potential was stopped in the passivation region of peak 2 (+0.2V), then returned to a potential at the peak value (+0.1V). A current-time curve after the potential sweep is shown in Fig. 5c. It is clear from this figure that the passivation is not complete for peak 2 and that the anodic recovery begins immediately. However, the time required to reach the steady-state anodic dissolution rate is longer than that required for peak 3 recovery. In addition, it can be seen that the steady-state value is not reached in a monotonic fashion. This transient behavior is believed to be related to the dark film formation which is observed in the peak 2 region. This dark film, which has been reported in earlier works, (1, 2), has not yet been identified. The film does not seem to be the passivating layer, since the anodic reaction proceeds despite its formation. The film may, however, cause an increase in the effective surface area and hence cause a temporarily high anodic dissolution rate. The measurement of the surface area of an electrode held at peak 2 (+0.1V) for 5 min revealed that the area increased by about 26% as a result of the film formation. This area increase is sufficient to cause the current "overshoot" in the current-time behavior observed in Fig. 5c. Despite this added feature, the recovery behavior is consistent with that expected for a reaction which has been blocked by the formation of a passivating film.

The recovery time of the anodic reaction in the peak 1 region also was studied. After an anodic scan to −0.40V, the cathodic potential scan was stopped at a value of −0.62V in the cathodic leg of the scan. The current-time profile was then recorded and is shown in Fig. 5d. In this profile, the current slowly returns to its steady-state level. This slow return is partly the result of the slow rate of reaction of the cyanide reaction at this potential.

It is clear that the formation of intermediates during the dissolution reaction could cause peaks in the potential scans if the rate of reaction was dependent on either the diffusion of the reactants forming the intermediate or the diffusion of the products of the intermediate. In either case, however, steady-state measurements would show limiting current plateaus and not current peaks. In earlier works (1-3), steady-state measurements have shown potential-current profiles which have three peaks, and not three current plateaus. It is unlikely, therefore, that the passivating species is a reaction intermediate in the dissolution process. The formation of the gold (III) oxide species does passivate the reaction at the peak 3 region. Thus one might expect that if lower valence oxides could form, they might also be able to passivate the cyanide reaction. Recently it has been shown (7) that lower valence oxides may be found in alkaline solutions at potentials cathodic of the gold (III) oxide potential. In three different potential regions, distinct hydroxide-gold reactions were found. These reactions, identified by current peaks found in fast potential sweep profiles in potassium hydroxide solutions, were the result of monolayer hydroxide adsorption on the gold surface via the reaction

$$Au + OH^- \rightarrow AuOH_{ads} + e^- \quad [4]$$

The three potential regions where the current peaks were found were labeled peaks A, B, and C and were from −1.2 to −0.7V, −0.7 to −0.3V, and −0.3 to +0.2V, respectively.

In Fig. 6, a single anodic potential sweep profile is shown for gold in 0.1M KCN + 0.1M KOH. The potentials of formation of the gold hydroxide species at peaks A, B, and C, corrected for these *p*H conditions, are indicated. The potential regions indicated for peaks A, B, and C are the 95% confidence limits of the peak maxima for the data presented in Ref. (7). Peaks B and C were not found to shift with sweep rate, hence the potentials for a sweep rate of 1 $mV \cdot sec^{-1}$ are directly available from the potential-*p*H diagram [Fig. 5 in Ref. (7)]. Peak A, however, was shown to behave irreversibly with a potential shift of +0.053V per decade of increasing sweep rate. Direct extrapolation of the peak potential measured at 1 $Vsec^{-1}$ in the earlier work to 1 $mV \cdot sec^{-1}$ in this work is not advisable since the reaction may not remain irreversible at slow sweep rates (15). Therefore the "reversible" potential of peak A obtained using $\left(\frac{Ep \text{ cathodic} + Ep \text{ anodic}}{2} \right)$ (16) was used to indicate the formation potential of peak A. Direct measurement of the peak formation potentials at a sweep rate of 1 $mV \cdot sec^{-1}$ is not possible because the small number of coulombs required to complete the reactions is obscured by the background current. The potential of formation of the gold (III) oxide (peak D), which is found in the solution without cyanide, is also shown.

As can be seen from Fig. 6, gold (III) oxide is formed just anodic of the peak 3 cyanide reaction. Thus, it is clear that the buildup of the oxide on the surface is the cause of the termination of the cyanide reaction. The oxide layer has been shown to be passive in potassium hydroxide solutions (7), and the variation of the current near the peak is the result of the competition between the passivation and anodic dissolution reactions as discussed earlier.

It can also be seen from the figure that the formation of the hydroxide adsorption peak C coincides with the minimum between the cyanide reactions of peak 2 and peak 3, and is anodic of peak 2. This is the region in which the formation of a passivating film would be expected in order to account for the decrease in the cyanide reaction at peak 2. The hydroxide adsorption peak C has been shown to be passive (7). Thus it is reasonable to associate the formation of the adsorbed hydroxide layer of peak C with the passivating surface species of the peak 2 cyanide reaction.

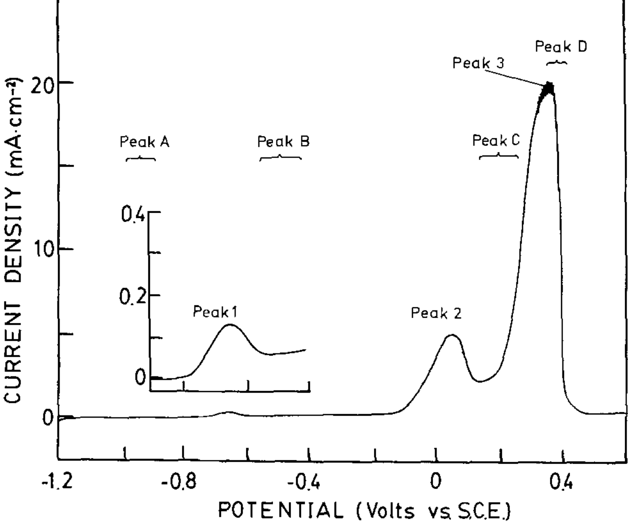

Fig. 6. Comparison of peaks in alkaline and alkaline cyanide electrolytes: anodic single sweep potential profile: 0.1M KOH + 0.1M KCN; sweep rate = 1.0 $mV \cdot sec^{-1}$; temperature = 23.5°C; potential ranges of peaks A, B, and C represent 95% confidence limits for peak potentials at this sweep rate.

From Fig. 6 it can also be seen that the formation of the adsorbed hydroxide species at peak B is anodic of the cyanide reaction of peak 1, and is approximately at −0.5V. This is the region in which the formation of a passivating film would be expected in order to account for the decrease in the cyanide reaction at peak 1. The hydroxide adsorption peak B has been shown to be passive (7), and it is reasonable to associate the formation of the adsorbed hydroxide layer of peak B with the passivating surface species of the peak 1 cyanide reaction.

If the passivation reaction involves the hydroxyl ion, then the potential of formation of the hydroxide species may be shifted by altering the concentration of the hydroxyl ion in the solution. This would then change the peak potential of the cyanide reaction because passivation would be either advanced or retarded. The change of cyanide peak potential with hydroxide concentration is shown in Fig. 7. The earlier results of Cathro and Koch are also shown in the figure. The change of peak potential with hydroxide concentration for both peaks 1 and 3 is approximately −0.06 V/decade, while peak 2 does not appear to shift over the hydroxide concentration range 10^{-3} to 1M. In the case of the peak 3 passivation, the theoretical potential of formation of the gold (III) oxide decreases linearly at the rate of 0.059V per tenfold increase in hydroxide concentration. This is in good agreement with the measured cathodic shift of 0.063V per tenfold increase in hydroxide concentration for the peak 3 cyanide reaction.

In the case of peaks 1 and 2, passivation, via reaction [4], would be expected to cause the cyanide peak to shift cathodically at the rate of 0.059V per tenfold increase in hydroxide concentration. The measured cathodic shift of 0.057V per tenfold increase in hydroxide concentration for peak 1 is in good agreement with the theoretical value. The potential at peak 2, however, does not show any change for concentrations above 10^{-3}M KOH. Despite the lack of potential shift of peak 2, the concentration of hydroxide does affect the rate of reaction in the peak 2 region. In Ref. (1) (Fig. 7), the rate of dissolution was shown to decrease with increase in hydroxide concentration. This effect was greatest for changes in hydroxide concentration above 10^{-2}M. From these data it appears that the $AuOH_{ads}^-$ species may have a significant concentration at the surface in the peak 2 region. By using the data presented in Ref. (1), it is possible to model the hydroxide adsorption isotherm and estimate the coverage of $AuOH_{ads}^-$ on the surface. The details are given in the Appendix and show that, even for concentrations of hydroxide as low as 10^{-3}M, the surface coverage of the $AuOH_{ads}^-$ species could be 48%. As a result of the relatively high surface coverage of the $AuOH_{ads}^-$ species in the region of peak 2, it is necessary to consider the formation of $AuOH_{ads}$ in a two stage reaction

$$Au + OH^- \rightarrow AuOH_{ads}^- \quad [5]$$

$$AuOH_{ads}^- \rightarrow AuOH_{ads} + e^- \quad [6]$$

The reversible potential of formation of $AuOH_{ads}$ can be seen to depend on the concentration of the $AuOH_{ads}^-$ species via the relation

$$\Delta\phi_e = \Delta\phi_e^\circ + \frac{RT}{\mathbf{F}} \ln \frac{a_{AuOH_{ads}}}{a_{AuOH_{ads}^-}} \quad [7]$$

From the adsorption data, the concentration of $AuOH_{ads}^-$ is relatively high for hydroxide concentrations above 10^{-3}M. If the activities of the two sur-

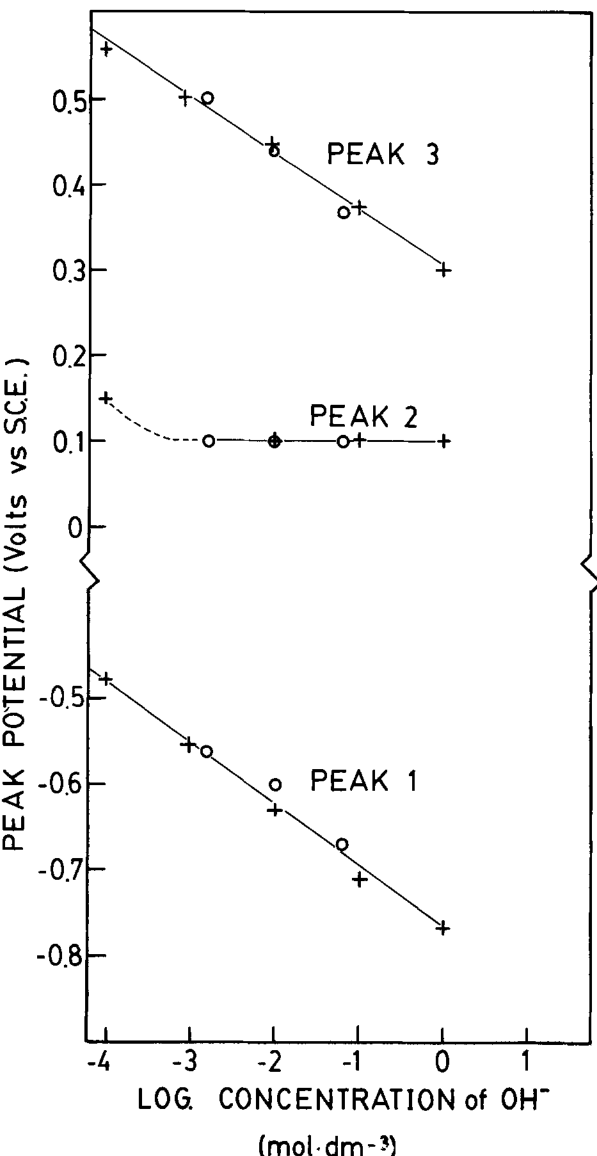

Fig. 7. Effect of hydroxide concentration on peak potentials in aqueous alkaline cyanide: free cyanide concentration = 0.1M; temperature = 23°C. +, data from this work; ○, data from Cathro and Koch (2).

face species $AuOH_{ads}$ and $AuOH_{ads}^-$ remain approximately constant for bulk hydroxide concentrations greater than 10^{-3}M, then $\Delta\phi_e$, the potential of formation, will remain constant. Under these conditions, the passivation of peak 2 would not shift with changing hydroxide concentration. For lower hydroxide concentrations ($<10^{-3}$M), the formation of the $AuOH_{ads}$ should become dependent on the hydroxide concentration in the bulk solution and a potential shift of -0.059V per tenfold increase in hydroxide concentration would be expected. As can be seen in Fig. 7, the peak 2 potential for the 10^{-4}M concentration is shifted from the 0.1V value. For lower pH values, buffering is required. Although it is not known what effect the buffering ions will have on the adsorption of hydroxide ions, an anodic potential shift of the passivation would be expected with a decrease in hydroxide concentration.

A potassium phosphate buffering system was used to lower the *p*H. Sufficient potassium cyanide was dissolved in the solution to set the free cyanide ion concentration at 0.1M despite the formation of undissociated hydrocyanic acid via the reaction

$$CN^- + H_2O \rightleftharpoons HCN + OH^- \quad [8]$$

Very slow sweep rates (0.1 mV · sec^{-1}) were used so that the passivation reactions could still take place despite the reduced hydroxide concentration. The results showed that from *p*H 10-7.8, peak 2 shifted in the anodic direction at the rate of 0.065 ± 0.010 (95% confidence) V per *p*H unit. This value agrees favorably with the theoretical value of 0.059V per *p*H unit. As a result of the anodic potential shift with decrease in *p*H the peak 3 cyanide reaction begins to obscure the passivation of the peak 2 reaction to the extent that peak 2 appears to be only a shoulder of the peak 3 reaction. Potential scans in the buffered solutions (*p*H $\leq$ 10) appear to be more complex than in those of high alkalinity. Multiple peak formation is observed in these solutions. Since several new species are present in the buffered solutions (HCN, $PO_4^{\equiv}$, $HPO_4^{=}$, $H_2PO_4^-$, H_3PO_4) it is not clear whether these species may be contributing to the complexity of the potential scans. Despite these new features in the potential scans, it is clear that the passivation of the peak 2 cyanide reaction is affected by the hydroxyl ion. In addition, the model for the hydroxide adsorption phenomenon presented in the Appendix is consistent with both the earlier findings (1) that the dissolution rate decreased linearly with log [OH^-] and with the potential-*p*H behavior of peak 2 in this work.

It is clear that the hydroxyl ion is involved with the passivation of the cyanide reactions and that the oxide formation potentials occur just anodic of the cyanide peaks. Therefore, it is reasonable to associate the passivation of the cyanide reactions at peaks 1 and 2 with the formation of the adsorbed hydroxide species indicated by peaks B and C as shown in Fig. 6. The passivation of the cyanide reaction at peak 3 is the result of the formation of gold (III) oxide indicated by peak D.

The linking of the passivation of peaks 1 and 2 with the species identified at peaks B and C in alkaline solutions has interesting consequences. The passivating species formed at peaks B and C were shown to be the result of monolayer hydroxide adsorption on distinct crystal planes (7). This would then explain why the same dissolution reaction sequence was indicated for peaks 1 and 2. Peak C was identified with hydroxide adsorption on the (111) gold crystal plane. Thus, if the peak C reaction is the cause of the passivation of the peak 2 cyanide reaction, then the peak 2 cyanide reaction must occur predominantly on the (111) crystal plane. Peak B was identified with the monolayer hydroxide adsorption on the (100) crystal plane. By similar reasoning, the peak 1 cyanide reaction should occur predominantly on the (100) crystal plane. Thus the same dissolution reaction sequence would be found for peaks 1 and 2. After peak C in alkaline solutions, the surface is predicted (7) to have complete coverage of adsorbed hydroxide. Thus the cyanide reaction at peak 3 which is anodic of peak C must take place despite the hydroxide coverage. As a result of the reaction proceeding in spite of the hydroxide coverage, the hydroxide concentration should not affect the peak 3 cyanide reaction rate. This is indeed the case. In Fig. 5 of Ref. (1), the concentration of the hydroxide ion was shown to have no effect on the gold dissolution rate at peak 3 over the concentration range 10^{-3} to 1M. From the data presented, it is clear that the gold oxide and suboxide reactions can provide an explanation for the complex behavior of gold in alkaline cyanide solutions.

The effect of the peak A hydroxide adsorption reaction on the cyanide dissolution reaction has not yet been discussed, although it is likely that the blockage of the (110) crystal plane may simply prevent reaction from occurring on that plane until the peak 3 region.

Summary

The results of this work indicate clearly that the three anodic current peaks found in potentiostatic and potentiodynamic profiles for alkaline cyanide solutions are the result of passivation of the active gold surface. That the various passivation species are gold hydroxides, was shown by the hydroxyl ion dependence measurements. Passivation potentials correspond closely to the formation potentials of gold oxide and suboxide species.

The most anodic dissolution peak for the cyanide dissolution is passivated by the formation of gold (III) oxide. The more cathodic peaks are subject to passivation by hydroxide adsorption on various crystal planes to form a gold (I) surface species. These various dissolution and passivation phenomena are illustrated in the schematic representation of the anodic behavior of gold in alkaline cyanide solution shown in Fig. 8.

APPENDIX

Calculation of an isotherm for hydroxide adsorption on gold in the region of peak 2 (+0.1V) in aqueous alkaline cyanide

From Ref. (1), Fig. 7, the following data are obtained

Table IA. The effect of hydroxide concentration on the dissolution rate of gold at peak 2 (+0.1V)

Dissolution rate ($mg \cdot m^{-2} \cdot sec^{-1}$)	Concentration of $[OH^-]$ ($mole \cdot dm^{-3}$)	Current density* ($A \cdot m^{-2}$)
25	1.0	12.2
42	0.1	20.6
62	0.01	30.4
77	0.001	37.7

$[CN] = 0.05m$

* The current density is calculated by converting the dissolution rate to $mole \cdot m^{-2} \cdot sec^{-1}$, then by noting that the dissolution reaction is a one-electron transfer process (1), multiplication by 96,489 c/mole gives current density ($A \cdot m^{-2}$).

In Ref. (1), step [2] was shown to be the rate-determining step in the dissolution sequence [1], [2], and [3] in the region of peak 2. The theoretical reaction rate for step [2] was shown to be

$$\vec{i} = \frac{\vec{k}_1\vec{k}_2(1-\theta'')[CN^-]}{\overleftarrow{k}_1 + \vec{k}_1[CN^-]} \exp\left(\frac{\beta \mathbf{F} \Delta\phi}{RT}\right) \quad [A\text{-}1]$$

where $\overleftarrow{k}_i$, $\vec{k}_i$ are the partial electrochemical rate constants, θ'' is the surface coverage by $AuOH_{ads}^-$, β is the symmetry factor of the rds, $\Delta\phi$ is the electrode potential, $\vec{i}$ is the reaction rate expressed as current density, and **F**, R, T, have their usual meanings.

For constant potential and constant cyanide concentration this expression reduces to

$$i = K(1-\theta'') \quad [A\text{-}2]$$

where K is the constant $\frac{\vec{k}_1\vec{k}_2[CN^-]}{\overleftarrow{k}_1 + \vec{k}_1[CN^-]} \exp\left(\frac{\beta \mathbf{F} \Delta\phi}{RT}\right)$

It is clear from Table IA that an increase in the concentration of hydroxide causes a decrease in the dissolution rate. A plot of current density *vs.* log $[OH^-]$ in Fig. A-1 shows that $i \propto \log [OH^-]$.

Using linear regression the relationship can be found to be

$$i = 12.28 - 8.63 \log [OH^-] \quad [A\text{-}3]$$

As a consequence of the similarity between Eq. [A-2] and [A-3] it is reasonable to assume that $\theta'' \propto \log [OH^-]$. Furthermore if the concentration of the surface species $AuOH_{ads}^-$ is assumed to be $\simeq 0$ for a concentration of $[OH^-] = 10^{-7}M$, then

$$\theta'' = \frac{7 + \log [OH^-]}{8.42}$$

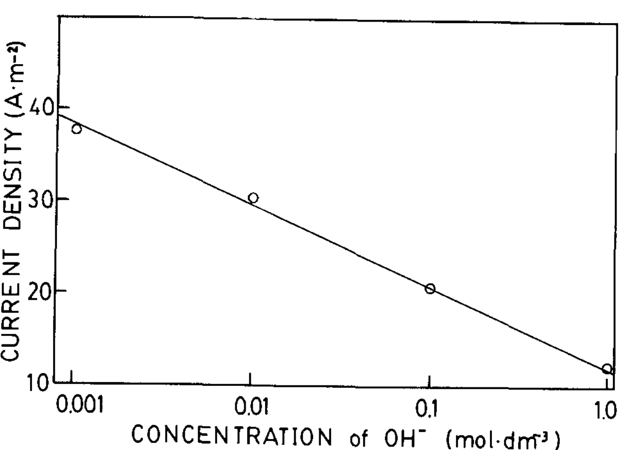

Fig. A-1. Effect of hydroxide concentration on the dissolution rate of gold in aqueous alkaline cyanide: temperature = 23.5°C; 0.05M $[CN^-]$. Data from Fig. 7, Ref. (1).

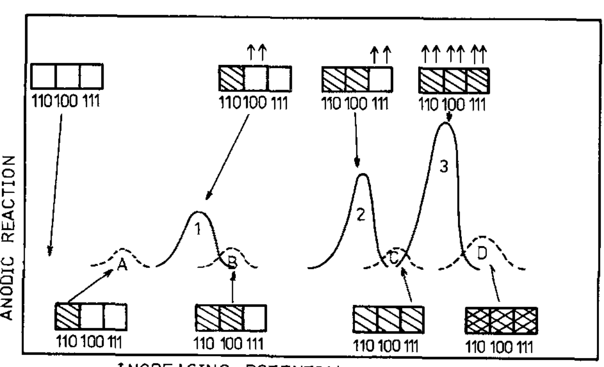

Fig. 8. A schematic representation of the anodic behavior of gold in aqueous alkaline cyanide. bare Au; Au dissolving; OH covered; Au_2O_3 covered. ——— reaction in alkaline cyanide solution, - - - - - - reaction in cyanide-free alkaline solution. The numbers refer to the crystal planes involved in the reactions.

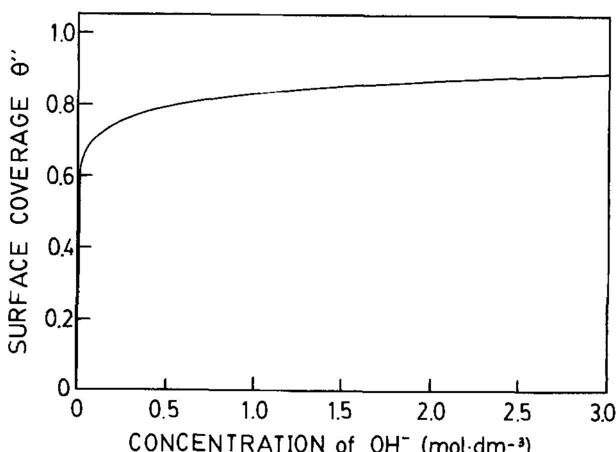

Fig. A-2. Surface coverage (θ'') of $AuOH_{ads}^-$ *vs.* concentration of hydroxide for the adsorption isotherm $\theta'' = 7 + \log [OH^-]/8.42$.

This relationship has been plotted in Fig. A-2. From this isotherm the coverage of the gold by $AuOH_{ads}^-$ at $[OH^-] = 10^{-3}M$ is about 48%.

From Fig. A-2 it can be seen that at concentrations $> 10^{-3}M$ KOH the surface concentration of $AuOH_{ads}^-$ remains relatively constant.

Models for the Photoelectrolytic Decomposition of Water at Semiconducting Oxide Anodes

J. M. Kowalski,* K. H. Johnson, and H. L. Tuller**

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Surface states at semiconducting TiO_2/electrolyte interfaces are believed to play an important role in charge transfer and thereby the efficiency of photoelectrochemical processes at such interfaces. Theoretical calculations were therefore performed using the SCF-Xα-SW method to determine the position and character of surface states at various characteristic interfaces. At the TiO_2/water interface, antibonding surface states were found which when occupied would explain the experimentally observed dissociation of water into hydroxyl groups at n-type semiconducting TiO_2 surfaces. Similarly, antibonding surface states were found at the TiO_2/OH^- interface which when occupied would tend to destabilize the OH bond. A likely mechanism for the dissociation of water and decomposition of certain photoanodes in photoelectrochemical cells based on the above results is presented. The effects of surface reconstruction at heavily reduced TiO_2 surfaces on the validity of our calculations are also discussed.

The present fuel shortage has stimulated much research concerning the production of hydrogen gas by the photoelectrolysis of water on semiconductor electrode surfaces. To date, only a few semiconducting oxides, including titanium dioxide and some perovskites, have been shown to remain inert in cell operation and decompose water. In all cases surface states at the electrode-electrolyte interface are believed to play an important role in the charge transfer process and thereby the overall efficiency of such cells (1, 2). Little is known, however, concerning the source of these surface states and the manner in which they assist the photoelectrolytic process. In the following, SCF-Xα-SW calculations are presented which serve to clarify some of these issues.

The catalytic behavior of a surface often depends on its ability to interact electronically with the adsorbate. The determination of the electronic structure of the surface perturbed by the chemisorbed species may, therefore, provide a basis for understanding charge transfer catalysis. In order to understand the electronic interaction between water and a TiO_2 surface, cluster molecular-orbital calculations were performed using the self-consistent-field-Xα-scattered wave (SCF-Xα-SW) method (3). This technique is based on the combined use of the Xα density-functional approximation to electron-electron exchange and correlation and the multiple-scattered-wave method of solving Schrödinger's equation. Details of the technique, including computational procedure, and previous applications are described in Ref. (3). The SCF-Xα-SW method was chosen over the conventional Hartree-Fock self-consistent-field linear-combination-of-atomic orbitals (HF SCF-LCAO) method since the former is less laborious and costly in computer time and leads to a more reliable description of electronic structure (3). Molecular orbital methods were chosen over band theory since it offers a more appropriate description of local interactions and chemical bonding.

Previous SCF-Xα-SW studies (4) have shown that the local electronic structure of bulk TiO_2 (rutile) can be realistically modeled in terms of a $(TiO_6)^{8-}$ cluster, yielding results in good agreement with measured photoemission and optical absorption spectra. In the same manner, the chemisorption of H_2O on a titanium dioxide surface can be modeled by the combination of a TiO_2 surface cluster and an adsorbed H_2O molecule. In the remainder of this paper, results for the clean, water-chemisorbed, and OH^--chemisorbed surfaces are presented and compared with recently measured photoemission spectra. With these results, a possible mechanism is suggested for the dissociation of water in the photoelectrochemical cell.

Results of Calculations

Figure 1(a) shows the schematic energy level diagram for "bulk" TiO_2 as calculated by the SCF-Xα-SW method along with those for the free oxygen and titanium atoms. Only the Ti3d and O2p levels are shown since they are the only ones involved in bonding on this energy scale. One observes that the titanium 3d level splits into the antibonding e_g* and t_{2g}* levels which represent the conduction band of bulk TiO_2. The valence band is composed mainly of oxygen bonding and nonbonding 2p character and lies approximately 3 eV below the conduction band.

Clean surfaces.—The simplest model for the clean (110) titanium dioxide surface is the $(TiO_5)^{6-}$ cluster which consists of a slightly distorted and truncated octahedron in which a titanium atom is surrounded by five nearest neighbor oxygen atoms. These slight distortions are ignored in our analysis to simplify calculations. Furthermore, since this is nearly the same local environment of a titanium atom in the perovskite structure, this cluster also represents the (100) active surface site of $SrTiO_3$. The charge on the cluster is chosen such that the valencies of the atoms sum to zero. This simulates charge transfer with neighboring titanium atoms in the solid.

The calculated energy levels for the $(TiO_5)^{6-}$ surface cluster are shown in Fig. 1(b). Here the 3d levels split further due to the lower symmetry near the surface. Since the cluster method does not correctly treat the Madelung constant, the resultant energy levels are only on a relative scale and must be aligned with the absolute scale. This is usually done by choosing a nonbonding level and aligning it with that of the free atom, since nonbonding levels are not expected to shift much upon bonding. The diagrams are aligned using the O2p nonbonding level, which lies at the top of the valence band.

The splitting of the t_{2g}* and e_g* levels in the surface cluster results in the d_{yz}* and d_{xz}* states extending into the energy gap. These bandgap surface states are simply due to the truncation of the lattice. In the intrinsic material, only levels to the top of the valence band are filled while these bandgap surface states are empty. If the material is made n-type, however, these surface states become occupied.

Similar calculations were performed for the $(TiO_4)^{4-}$ cluster, which represents the oxygen deficient (001) surface. The resultant energy level diagram shown in Fig. 1(c) reveals that the d levels are further split by the reduced symmetry of this surface. A new characteristic surface state, designated by d_{z^2}*, is generated at this surface.

Surface clusters with chemisorbed water.—To study the interaction of water with a TiO_2 surface, calculations for both surface clusters were extended to include a chemisorbed water molecule. The resultant energy diagrams for both surfaces are largely a superposition of those for the separated clean surfaces and H_2O molecule.

The electronic structure of the $(TiO_5)^{6-}H_2O$ cluster is shown in Fig. 2, along with that for the clean surface and that for the H_2O molecule. The figures are aligned such that the oxygen 2p nonbonding levels coincide, which is the top of the valence band for the surface clusters and the b_1 level for the water molecule. The a_1* and b_2* water levels are normally empty and lie about 5 eV above the filled b_1 level. Although the a_1* and b_2* levels of water are traditionally viewed as corresponding to "Rydberg orbitals," they have significant antibonding character which increases through the interaction with TiO_2 d orbitals discussed below. In the $(TiO_5)^{6-}H_2O$ cluster, the water valence levels are still identifiable (mixing very little with the TiO_2 valence band) and are pulled down almost uniformly in energy. The a_1 level does, however, shift more to tighter binding energy and bonds more with titanium than the b_1 and b_2 levels. This suggests that water is chemisorbed onto the surface as an intact molecule and bonds to the surface through the a_1 orbital. The antibonding a_1* and b_2* water levels are also pulled down in energy but mix more strongly with the TiO_2 3d levels. These states, normally unoccupied in the intrinsic material could, however, become filled if the material were made n-type by reduction or doping.

Photoemission data of Henrich (5) for water chemisorbed on annealed (110) TiO_2 and (100) $SrTiO_3$ surfaces show the H_2O levels displaced uniformly about 2 eV below the top of the valence band with the a_1 orbital shifting more to tighter binding energies, in agreement with our calculations. This suggests nondissociative water chemisorption on the annealed surface. Our calculations however predict a larger shift for the water levels of about 4 eV. This discrepancy

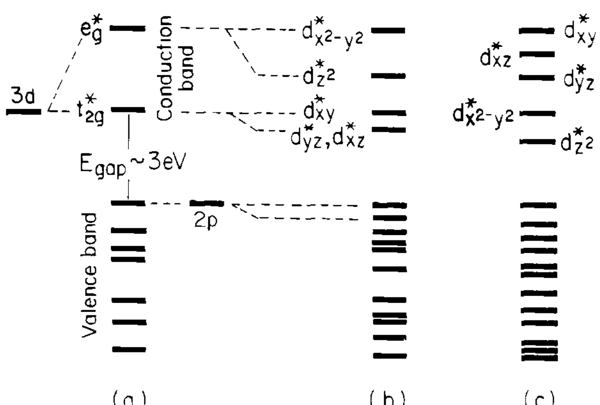

Fig. 1. (a) Energy level diagrams of bulk TiO_2 and the free titanium and oxygen atoms, (b) energy levels for the clean (110) TiO_2 and (100) $SrTiO_3$ surface modeled by the $(TiO_5)^{6-}$ cluster, or (c) the $(TiO_4)^{4-}$ cluster.

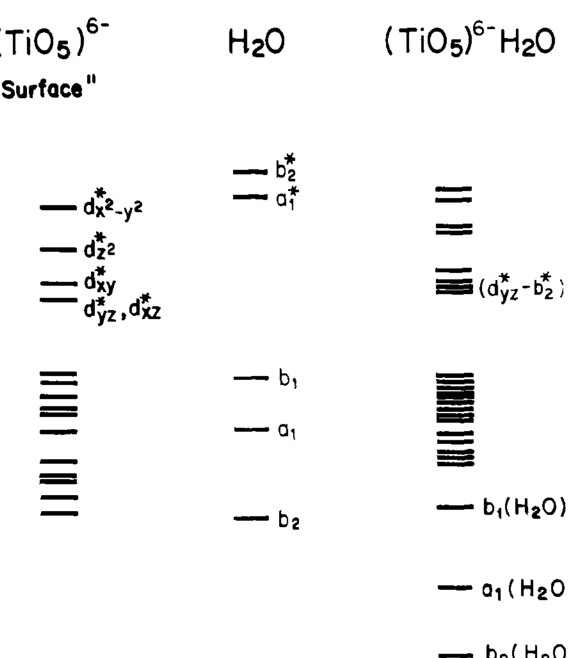

Fig. 2. Calculated energy levels for the $(TiO_5)^{6-}$, H_2O, and $(TiO_5)^{6-}$ H_2O clusters representing the clean TiO_2 surface, the water molecule, and the water chemisorbed surface.

may be due to the short bonding distance between the surface and the H_2O molecule chosen for the calculation. The bonding distance between the surface titanium atom and the water oxygen atom may very well be greater than the bulk Ti-O bond length of 1.94Å chosen. A larger value would have the effect of lowering the attraction between the surface and the water molecule, thereby lessening the perturbation on the H_2O molecule.

Lo, Chung, and Somarjai (2) likewise conclude on the basis of their photoemission studies that water molecules chemisorbed on stoichiometric TiO_2 surfaces remain undissociated. On the other hand, for surfaces reduced by heating to above 800°C or by argon bombardment, they obtained evidence for the existence of dissociated water in the form of hydroxyl groups. We later show that dissociation of water molecules on reduced surfaces of TiO_2 can be explained by considering the destabilizing effects that occupation of the $d_{yz}^* - b_2^*$ antibonding states have on the stability of the H_2O molecule.

Surface clusters with adsorbed OH radicals.—As a simple model for the TiO_2-electrolyte interface in a photoelectrochemical cell, the $(TiO_5)^{6-}OH^-$ and $(TiO_4)^{4-}OH^-$ clusters were chosen to represent the local electronic interaction between the titanium dioxide surface and basic electrolyte. The resultant energy levels are a superposition of those for the clean surfaces and the OH^- ion, with some mixing. The results for the $(TiO_5)^{6-}OH^-$ cluster are shown in Fig. 3 along with the energy levels of the OH radical and clean surface cluster. Again the diagrams are aligned at the nonbonding oxygen 2p level, which is the filled π level for the OH^- ion. The π and σ OH^- levels appear to remain relatively unperturbed upon chemisorption, but the antibonding σ^* and π^* levels are pulled far down in energy to interact with TiO_2 d levels resulting in additional surface states within the bandgap. In the next section these states will be shown to play a potentially important role in the photoelectrolytic decomposition of water.

Discussion

As a result of our calculations we have been able to predict the relative positions of surface states generated at TiO_2-vacuum, -H_2O, and -OH^- interfaces as well as the character of these states. It should be noted that the absorbate itself has a strong influence on the position, character, and number of surface states that exist at a given interface. In the following we consider the consequences that occupation of these surface states have on water dissociation and photoelectrolysis and compare these predictions with experimental evidence.

Clean surfaces.—A number of investigators have recently studied the surface electron structure of TiO_2 by ultraviolet photoemission spectroscopy (UPS), low-energy-electron diffraction (LEED), and Auger electron spectroscopy (AES). Henrich *et al.* (6) observed a UPS peak at about 2.5 eV above the bottom of the valence band for annealed TiO_2 surfaces which they attributed to surface defect states. This peak increased by more than a factor of 10 under argon-ion bombardment which was shown to result in the formation of Ti^{3+} ions at the surface (6). Lo *et al.* (2) observed similar absorption peaks which were sensitive to annealing and Ar bombardment treatments. Both studies are consistent with our calculations which indicate the existence of normally empty surface states which become occupied upon reduction of the surface resulting in the formation of Ti^{3+} ions. Subsequent exposure of the surface to oxygen results in a sharp decrease in the emission peak indicating a reversible depopulation of the Ti-like surface states.

Water dissociation.—In investigating the chemisorption of water on variously treated TiO_2 surfaces by photoemission (UPS), Lo *et al.* (2) discovered that whereas water is adsorbed as an intact molecule on oxidized TiO_2 surfaces, it appears to dissociate on reduced surfaces leaving behind $(OH)^-$ molecules adsorbed on the surface. Henrich *et al.* (5) observed similar results for argon bombarded (110) TiO_2 surfaces upon exposure of up to 10 liters H_2O.

Since existence of Ti^{3+} ions at the surface appears to be critical in determining the manner in which water molecules adsorb on the surface we examine the consequences of surface state occupation on bonding between TiO_2 and adsorbed water molecules.

Reduction of the TiO_2 surface by argon bombardment or annealing in hydrogen should result in occupation of the d_{yz}^*-b_2^* levels of the TiO_2-H_2O interface (see Fig. 2). The contour diagrams for these orbitals are shown in Fig. 4. The d_{yz}^* orbital is antibonding between the titanium 3d and oxygen 2p levels; this is revealed by opposite signs in the overlapping lobes between the titanium and oxygen. In the diagrams, the lobes are shrunken in size and are not shown as overlapping for clarity. The sign inside the lobes represents the phase of the wave-function: overlapping

Fig. 3. Calculated energy levels for the clean TiO_2 surface, the OH^- ion, and the OH^- chemisorbed surface.

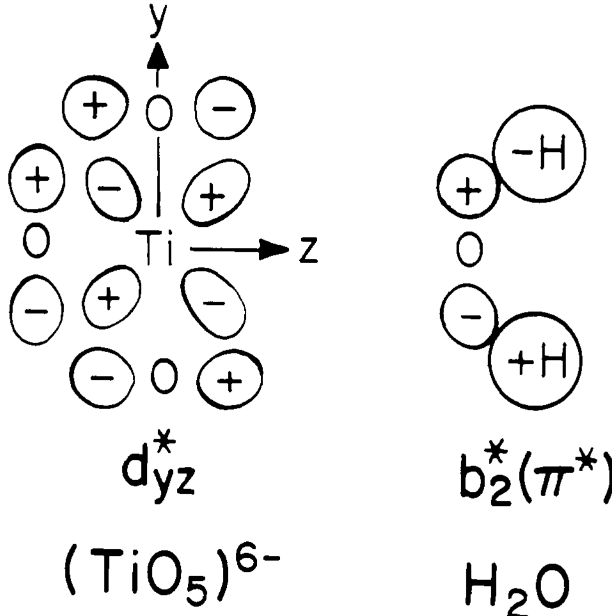

Fig. 4. Contour diagrams of the d_{yz}^* and b_2^* antibonding orbitals before mixing in the $(TiO_5)^{6-}H_2O$ cluster.

lobes of the same sign signify bonding. When the d_{yz}* and b_2* orbitals mix, the titanium d lobes and the oxygen 2p lobe (of H_2O) overlap in a bonding fashion as do the oxygen 2p lobes (of the lattice) and the hydrogen lobe. When the d_{yz}*-b_2* orbital is occupied, as it is in the bombarded TiO_2 surface with chemisorbed water, bonding between the titanium d and oxygen 2p (of H_2O) and the surface oxygen 2p and hydrogen orbitals will be strengthened; the OH bonding within the water molecule will be weakened since the overlapping orbitals have opposite phase. Thus, a plausible mechanism exists for the break up of chemisorbed water into OH radicals on the surface if and only if the surface states with antibonding character are occupied as they are in reduced TiO_2. Similar results are also obtained for the $(TiO_4)^{4-}$-H_2O cluster.

Photoelectrolytic decomposition of water.—When n-type photoanodes such as TiO_2 or $SrTiO_3$ are immersed in liquid electrolytes and are illuminated with bandgap light, oxygen gas (O_2) is known to be released (7). This process of oxygen evolution has been modeled assuming that a Schottky barrier is formed at the solid liquid interface at which electron-hole pairs are formed during illumination. The built-in space-charge field is then believed to cause the photogenerated holes to be swept towards the interface while the electrons are swept away from the interface towards the platinum counterelectrode. The OH^- ions adsorbed at the interface are now believed to lose their electrons to the semiconductor valence band via surface states (1) producing oxygen by the reaction

$$OH^- + 2h^+ \rightarrow \tfrac{1}{2} O_2\uparrow + H^+$$

Because the energy of the electrons associated with the OH^- ions (commonly referred to as the OH^-/O_2 redox level) lies considerably above the semiconductor valence band in energy, direct charge transfer is highly unlikely. The existence of surface states nearly degenerate with the OH^-/O_2 level would, however, exhibit the high tunneling probabilities necessary for efficient charge transfer across the interface. Although such surface states are believed to play an important role in photoelectrolysis, little is now known concerning their identity.

Examining again the energy levels for the $(TiO_5)^{6-}$-OH^- cluster, we find that the states labeled d_{xy}*, d_{yz}*-π*, and d_{z^2}*-σ* lie within the bandgap. Since the TiO_2 anodes used for photoelectrolysis are n-type with a Fermi level near the bottom of the conduction band, these levels have a high probability of being occupied, and therefore, may be viewed as representing one possible surface state configuration. Recent surface photocurrent spectroscopy data of Mavroides *et al.* (1) for reduced $SrTiO_3$ operating in an electrolytic cell with basic electrolytic, support the occupation of bandgap surface states in this energy range.

To explain the observed O_2 gas released from the semiconductor surface according to the proposed equation above, one must first show a mechanism for splitting the O-H bond in the OH radical. In general, bonds are broken by occupying antibonding orbitals or by depopulating bonding orbitals. The $(TiO_5)^{6-}$-OH^- results show the top valence level to be mainly of OH^--π character. Under illumination in the electrochemical cell, this state would most probably be depopulated. However, since it is a nonbonding O2p level, it does not bond with hydrogen so its depopulation would not be expected to destabilize the OH bond. On the other hand, the occupation of antibonding orbitals may lead to destabilization of the O-H bond.

If we consider the lowest antibonding orbital, d_{xy}*, we observe that it does not mix with the OH^- orbital due to symmetry conservation and thus contains no OH^- character. Similarly, examination of the contour map of the d_{yz}*-π* orbital in Fig. 5(a) shows that no OH breakup is expected since the π* orbital contains no H bonding.

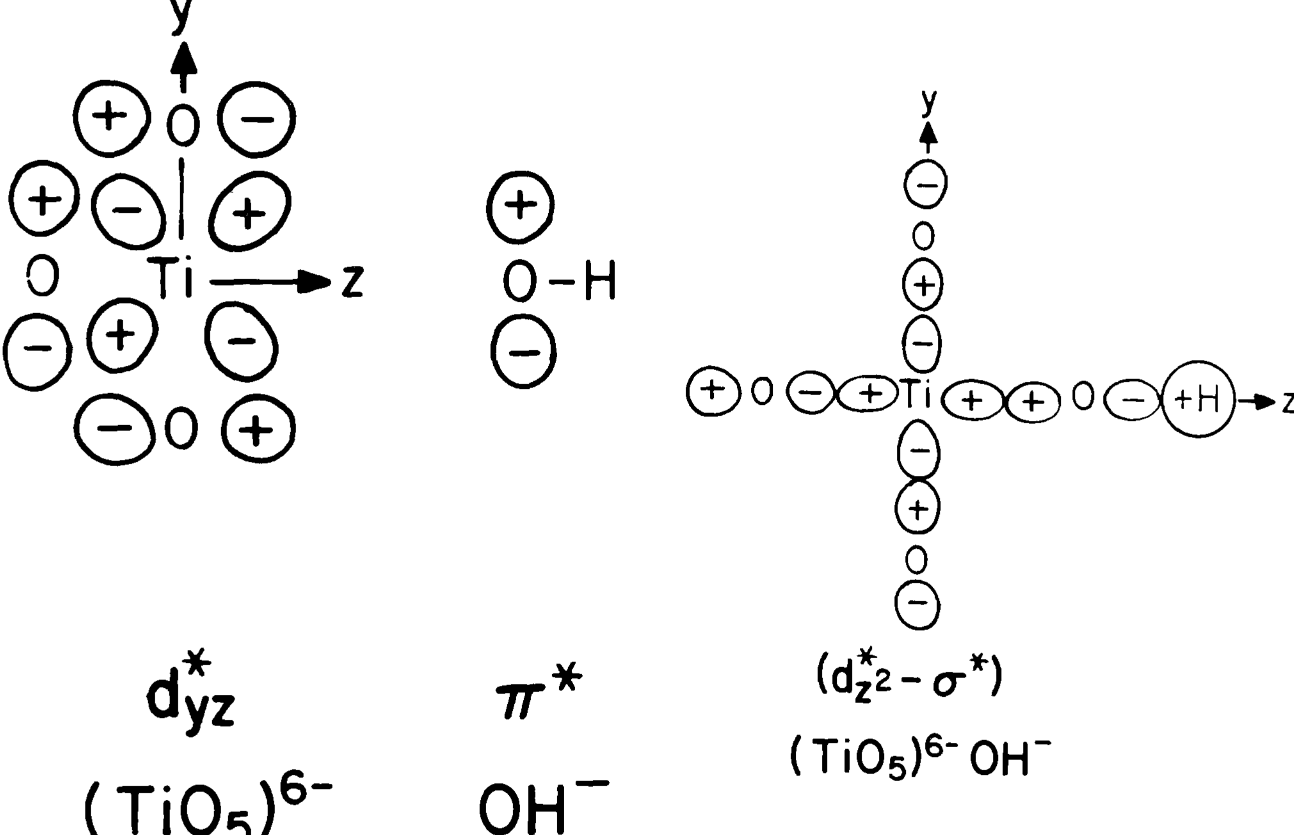

Fig. 5. (a, left) Contour diagram of the antibonding d_{yz}* and π* orbitals for the $(TiO_5)^{6-}$ OH^- cluster; (b, right) contour diagram of the antibonding d_{z^2}* and σ* orbitals for the $(TiO_5)^{6-}$ OH^- cluster.

Occupation of the $d_{z^2}*$-$\sigma*$ orbital would, however, tend to destabilize the O-H bond since the $\sigma*$ orbital is antibonding between the oxygen and hydrogen. Occupation of the $d_{z^2}*$-$\sigma*$ orbital would also tend to promote bonding between the Ti atom and the oxygen atom of the OH^- ion since their wavefunctions are in-phase. Thus occupation of the $d_{z^2}*$-$\sigma*$ orbital would provide a mechanism for breaking the O-H bond, while leaving the O of OH bonded to the surface.

Other antibonding states higher in energy on the $(TiO_5)^{6-}OH^-$ energy diagram also contain some $\sigma*$ character, though not as much as the $d_{z^2}*$-$\sigma*$ level (*i.e.*, less mixing between the d* and $\sigma*$ orbitals). For this reason, occupation of the $d_{z^2}*$-$\sigma*$ orbital is expected to be, in large part, responsible for splitting the O-H bond, although higher states may contribute to some extent.

The contour diagram of the $d_{z^2}*$-$\sigma*$ orbital [Fig. 5(b)] shows the oxygen atom of the OH radical to be more strongly bonded to the Ti atom than the oxygen atoms of the lattice (which are antibonding with respect to the Ti atom). This suggests that the observed O_2 gas released from the oxide surface during photoelectrolysis may originate from the lattice. Oxygen atoms leaving the surface layer would thereby create vacancies which might then be occupied in turn by oxygen ions originating with the adsorbed OH^- ions.

The possibility suggested above that surface oxygen ions may be released preferentially from TiO_2 surfaces during illumination, might explain their relative stability to photodecomposition. For nonoxide electrodes, regeneration of the lost surface anions from the adsorbed OH^- ions would not be possible and might therefore explain their propensity to decompose under illumination.

Extension of Calculations

The above calculations have been performed using the simplest models possible to represent the ideal clean TiO_2 surface interacting with adsorbed species. A major simplification made in our calculations was to assume that the n-type TiO_2 and $SrTiO_3$ surfaces differed from the stoichiometric (annealed) surfaces only by the occupation of the bandgap states. Both Henrich *et al.* (6) and Lo *et al.* (2) report, however, that argon-bombarded surfaces and highly reduced (oxygen deficient) surfaces become disordered and show a succession of different surface-defect phases depending on the degree of reduction. In fact, extensive bombardment on the TiO_2 surface results in the formation of a different compound, Ti_2O_3, on the surface. Similar phenomena are known to occur in bulk TiO_2 upon reduction. A whole range of closely spaced intermediate compounds are formed related to the parent rutile structure by a series of "shear" transformations in which planes of oxygen ions are removed from the lattice resulting in modified Ti-Ti bond lengths and reduced symmetry (8).

Such structural transformations are not believed to occur in TiO_2 or the perovskite titanates made "n-type" by virtue of doping rather than by creation of oxygen deficiency. Consequently, our calculations should be more directly applicable to such surfaces. On the other hand, since similar photoelectrolytic response has been observed for both reduced and doped samples, the implication exists that models presented above are at least qualitatively correct in either case.

Recent studies by Subbarao *et al.* (9) on TiO_{2-x} and $TiO_{2-x}F_x$ showed that the fluorine-doped TiO_2 exhibited a different spectral response than reduced TiO_2. This difference was characterized by a greater sensitivity to longer wavelengths and generation of higher photocurrent with the fluorine-doped material. Similar studies by Kowalski and Tuller (10) on reduced and Nb-doped $BaTiO_3$ showed the doped material to exhibit much enhanced photocurrents under similar conditions.

The above results are consistent with the expectation that the reduced surfaces will possess surface states with different character and at different energies than the surface states calculated here which are more characteristic of the doped materials. Further work is underway to determine whether surfaces with Ti_2O_3 character can explain the differences in photoresponse observed for the two types of surfaces.

O_2 Electrocatalysis on Thin Film Metallic Oxide Electrodes with the Delafossite Structure

P. F. Carcia,* R. D. Shannon, P. E. Bierstedt, and R. B. Flippen

E. I. du Pont de Nemours and Company, Central Research and Development Department, Experimental Station, Wilmington, Delaware 19898

ABSTRACT

Thin film electrodes of $PtCoO_2$, $PdCoO_2$, $PdRhO_2$, and $PdCrO_2$ delafossite-type oxides are good electrocatalysts for O_2 reduction and O_2 evolution in NaOH. O_2 reduction activity correlates with the noble metal cation (Pt > Pd), while O_2 evolution activity correlates with the transition metal cation (Co > Rh > Cr). Electrodes were prepared by rf sputtering from metal alloy targets. The as-sputtered films are amorphous. The delafossite phase forms on annealing in air or O_2 at 700°-850°C. Thin films are metallic with $\rho \sim 10^{-4}$ Ω-cm.

The current interest in O_2 electrocatalysis is motivated by the potential for energy applications. For example, an improved O_2 reduction electrode would increase the electrical power output of fuel cells (1), making them more attractive for electric power generation. The efficiency for H_2 production from H_2O electrolysis would also be improved by a better O_2 anode (2). In the chlor-alkali industry, which annually consumes ~$1 billion in energy (3), an O_2 reduction cathode instead of the H_2 evolving cathode could reduce the voltage for brine electrolysis by as much as 1V (a savings of ~ 1/3).

In this paper we discuss O_2 electrocatalysis on thin film electrodes with delafossite structure (4). Noble metal delafossites, $PdCoO_2$, $PdCrO_2$, $PdRhO_2$, and $PtCoO_2$, are interesting electrode candidates because they are excellent metallic conductors and allow investigation of specific cation effects of both a noble metal and a transition metal in the same compound. We report for the first time their activity for O_2 reduction and O_2 evolution in NaOH.

Experimental

Thin film preparation.—Thin films were prepared by rf sputtering in a commercial system (Materials Research Corporation SEM-8620) and by subsequently annealing the films. The sputtering targets were arc-melted buttons (*e.g.*, PdCo) which had been remelted several times to insure homogeneity. The 3/8 in. diam buttons were Ag-epoxied to a 1/4 in. diam Cu rod threaded into an H_2O-cooled backing plate, which was shielded from sputtering by a grounded adapter plate. The sputtering was done in various partial pressures of O_2 and Ar; substrates were Al_2O_3 and Pt or Pd foils. The sputtering power was ~200W, which gave deposition rates of ~150 Å/min. Annealing was done overnight in a box furnace in air or O_2 at 700°-850°C.

Characterization.—Films were routinely characterized by x-ray diffraction. Some were also examined by scanning electron microscopy (SEM), electron spectroscopy for chemical analysis (ESCA), and x-ray microprobe analysis. Four-probe electrical resistivity measurements from 300° to 4.2°K were made for films on Al_2O_3 substrates. Film thicknesses were determined from a fractured edge by SEM.

Electrochemical measurements.—Measurement of O_2 reduction and evolution was made potentiostatically by slowly sweeping a PAR (Princeton Applied Research) 173 Potentiostat with a triangular waveform from a PAR 175 programmed source. The cell was a single compartment. The measured *IR* corrections were negligible. Electrolytes were made with reagent grade NaOH and triply-distilled H_2O. The reference electrode was a dynamic hydrogen electrode (DHE) (5) brought close to the working electrode surface with a glass capillary. The auxiliary electrode was a 2 cm² Au or Pt foil. Thin film electrodes were Pd or Pt foils coated on both sides with 3-5 μm of the delafossite phase. Electrical connection was made with a Pd or Pt wire previously welded to the foil. Relative electrochemical surface areas were estimated from capacitances measured by a low frequency (10 Hz) impedance (6) or a transient technique (7).

Results

The delafossite structure is indicated in Fig. 1 for $PtCoO_2$. It consists of alternating layers of Pt and Co atoms. The platinum atoms are linearly coordinated with two oxygen atoms and the cobalt atoms are octahedrally coordinated by oxygen atoms. Each platinum atom in the plane is coordinated hexagonally by other platinum atoms.

The fact that these noble metal delafossites could be prepared by sputtering and annealing of the thin films

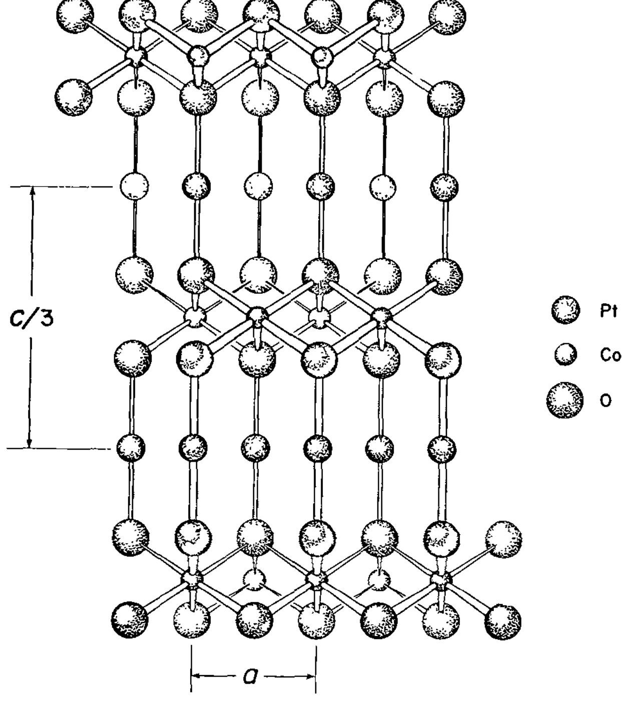

Fig. 1. $PtCoO_2$ (delafossite) structure

* Electrochemical Society Active Member.

Key words: films, electrodes, catalysis, sputtering.

Table I. Synthesis conditions and cell dimensions of delafossite-type oxide thin films

	$P_{(Ar)}$(mTorr)	$P_{(O_2)}$(mTorr)	T_A (°C)	a (A)	c (A)
$PtCoO_2$	20	1	700	2.827	17.84
$PdCoO_2$	20	1	700-725	2.830	17.75
$PdRhO_2$	20	0.1	750	3.028	18.08
$PdCrO_2$	20	0.1	800-850	2.929	18.10

is novel. Previous syntheses have used solid-state reactions, metathesis, high pressure, and hydrothermal methods (8, 9).

Table I summarizes the optimum sputtering pressures, the 16 hr annealing temperatures, and cell dimensions found for these phases. The films were either annealed in air or in a low stream of O_2.

Initially, the sputtered films are amorphous to x-rays. It is possible that oxygen is incorporated in the films, disordering the alloy which would form with only Ar as the sputtering gas. $PdRhO_2$ and $PdCrO_2$ required a lower O_2 partial pressure during sputtering; otherwise, annealing produced only the binary oxides plus some noble metal product. These same products were also obtained in all preparations where annealing was done under high O_2 flow rates. Once the binary oxides are produced, they do not readily react to form the delafossite phase.

The annealed films are nearly single phase by x-ray diffraction for the Co-containing oxides. Free Pt in $PtCoO_2$ and Pd or PdO in $PdCoO_2$ is usually <1%. In some $PdCrO_2$ and $PdRhO_2$ films, which must be annealed close to the decomposition temperature, PdO or Pd levels are sometimes higher (~5%). For many of the films, x-ray data indicate a high degree of preferred orientation, the plane of the film being perpendicular to the c-axis. Cell dimensions of the delafossite-type oxides given in Table I agree well with those in Ref. (8).

We examined the surface of a $PtCoO_2$ and a $PdCoO_2$ thin film on Al_2O_3 by ESCA using a du Pont 650B Spectrometer. Figure 2 shows the photoelectron spectra for Pt 4f and Co 2p photoelectrons in $PtCoO_2$. Table II compares the Pt 4f binding energies of $PtCoO_2$ to those of Pt metal and its oxides. The energies are charge corrected to the O 1s peak at 531.6 eV.

The Pt sample was a bright foil, α-PtO_2 was a commercial grade obtained from Engelhard Industries, and the preparation of β-PtO_2 has previously been described (10). Binding energies for PtO were taken from the literature (11). From these data, we conclude that the formal valence of Pt at the surface of the $PtCoO_2$ thin film is +1. Both the lack of a definite shakeup satellite structure in the Co 2p spectra of $PtCoO_2$ and the Co photoelectron binding energies are consistent with accepted ESCA interpretations (12, 13) for low spin Co^{3+}. These oxidation states, Pt(I) and Co(III), at the surface of the $PtCoO_2$ thin film are the same as found for powder samples (8). The same oxidation states were also found (ESCA) for a thin film of $PdCoO_2$. *i.e.*, Pd(I) and Co(III).

Electron microprobe analysis[1] of the $PtCoO_2$ film showed that both Pt and Co were distributed evenly with no apparent segregation effects at 500× magnification. Quantitative Pt and Co analysis for three separate areas gave a Pt:Co ratio of 1.003 with 65.46% Pt and 19.72% Co. These values are 4% lower than the calculated values of 68.3% and 20.6% for Pt and Co, respectively, in $PtCoO_2$. The measured values would give a composition $Pt_{0.72}Co_{0.72}O_2$. This is close to $Pt_{0.8}Co_{0.8}O_2$, a nonstoichiometric delafossite phase previously prepared by Shannon *et al.* (8). However, the Pt(II) oxidation state of this phase is not consistent with monovalent Pt found at the surface of the films by ESCA. The lower values may instead result from the rough surface of the film. A number of cracks extend to the Al_2O_3 substrate and thus may reduce the total x-ray fluorescence. The composition, $Pt_{1.0}Co_{1.0}O_2$, is consistent with the Pt:Co ratio of 1.0 and the oxidation states from ESCA.

[1] Microprobe analysis was performed by Micron Incorporated, Wilmington, Delaware 19807.

Table II. Photoelectron binding energies for Pt and Pt oxide surfaces

	Pt		Co	
	4f 5/2	4f 7/2	2p 1/2	2p 3/2
Pt	74.3 eV	71.1 eV	—	—
$PtCoO_2$ (film)	75.7	72.2	795.4 eV	780.5 eV
PtO	76.6	73.3	—	—

α-PtO_2	78.6	75.3	—	—

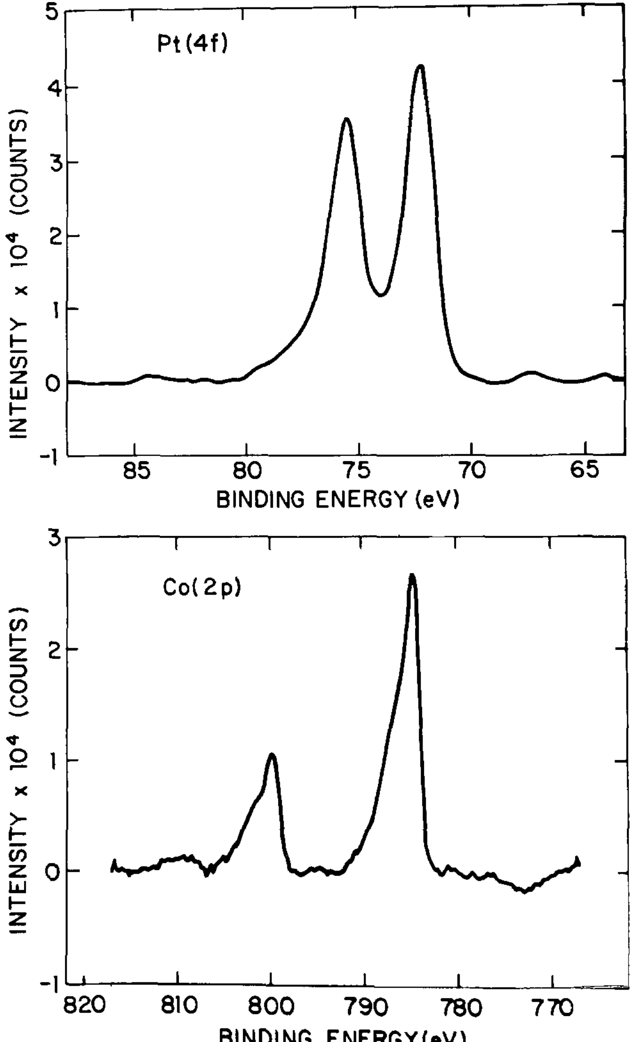

Fig. 2. Photoelectron spectra for Pt and Co in $PtCoO_2$

Scanning electron micrographs of $PtCoO_2$, $PdCoO_2$, and $PdRhO_2$ thin film surfaces on Al_2O_3 substrates are shown in Fig. 3. $PtCoO_2$ and $PdCoO_2$ have "mud-crack" surfaces. Thin films of $PdCrO_2$, not shown, show similar morphology. The $PdRhO_2$ films are, however, denser. All films have large grains, 5-10 μm. We measured the (BET) surface area of a $PtCoO_2$ thin film on smooth Pt by Kr physisorption. The surface area was ~10 m^2/g which corresponds to a surface roughness of ~200×. The capacitance measured for the same film was 3.6 mF which corresponds to an electrochemical surface roughness of 40-80× if we assume that 1 cm^2 is equivalent to 20-40 μF of capacitance. Similarly obtained electrochemical surface roughness for $PdCoO_2$ and $PdCrO_2$ thin films were within a factor of 2× that of $PtCoO_2$ films, while the denser $PdRhO_2$ film has smaller surface roughness.

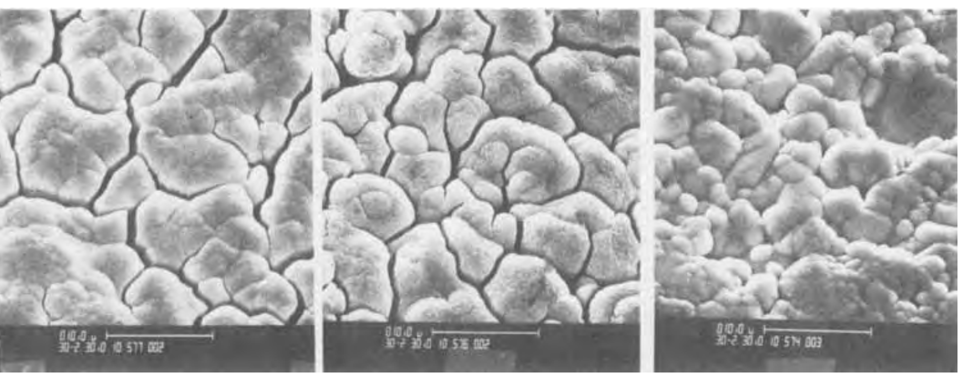

Fig. 3. 3000× magnification, scanning electron micrographs of (a, left) $PtCoO_2$, (b, middle) $PbCoO_2$, and (c, right) $PdRhO_2$ thin films on Al_2O_3.

Figure 4 shows the temperature dependence of resistivity for the thin film delafossites. The positive temperature coefficients indicate metallic conductivity with resistivities of ~10^{-4} Ω-cm at 300°K for all films. The resistivities for $PdRhO_2$ and $PdCrO_2$ had not been previously measured, but metallic conductivity was predicted from a one-electron band model (8). The resistivity for the $PtCoO_2$ films is considerably higher than for a single crystal (8), but nearly the same as for polycrystalline $PtCoO_2$ prepared in our laboratory. The contribution to resistance from grain boundaries likely accounts for the higher resistance of the thin film and polycrystalline samples.

Figure 5 shows the current-voltage characteristic for thin film $PtCoO_2$ in 0.1*N* NaOH. We swept the voltage at 0.1 mV/sec from the open-circuit value to 0.8 V/DHE, and then swept back to near the open-circuit voltage. We obtained data in the same way for $PdCoO_2$, $PdRhO_2$, and $PdCrO_2$ between the open-circuit voltage and a lower limit ~0.75 V/DHE. The current-voltage curves swept in opposite directions are within 10 mV over most of the current range. The Tafel regions are linear and at least two decades wide. The limiting current (I_L) in 0.1*N* NaOH is ~2 mA, the same for all electrodes. Currents in O_2-saturated electrolytes are >100× those in N_2, confirming O_2 reduction activity.

Table III compares O_2-reduction current densities at E = 0.9 V/DHE, Tafel slopes (b), and open-circuit

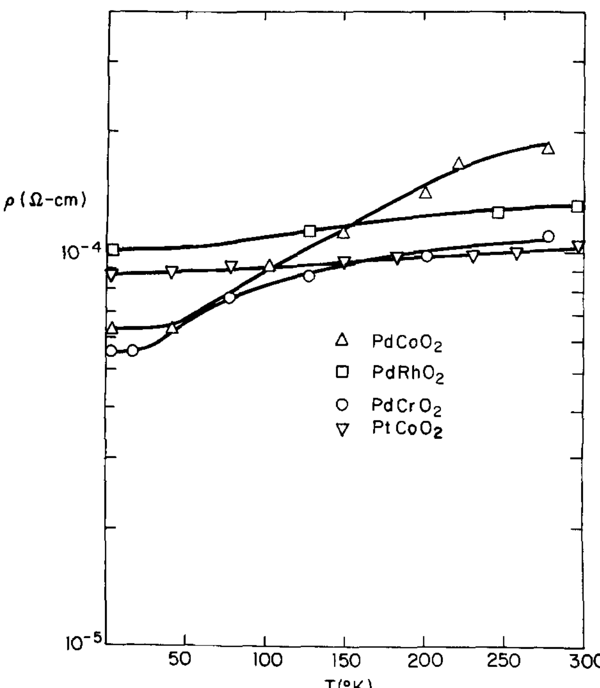

Fig. 4. Resistivity vs. temperature for the thin film oxides

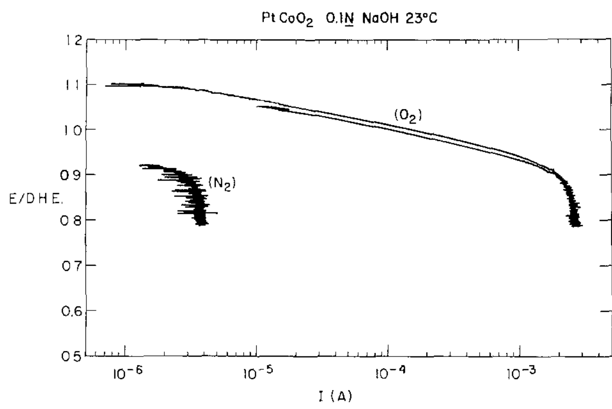

Fig. 5. O_2 reduction current vs. potential for thin film electrode of $PtCoO_2$ in 0.1*N* NaOH taken at sweep rate 0.1 mV/sec.

voltages ($E_{o.c.}$) for the oxides from these sweep experiments. It also includes data obtained in the same way for smooth Pt and Pd electrodes. Current densities are all based on geometric areas, and the data represent the average values measured for at least two different electrodes of each oxide.

$PtCoO_2$ has the highest O_2 reduction current density, ~10× that for the Pd oxides. $PtCoO_2$ also has the highest open cell potential. $PdCoO_2$, $PdCrO_2$, and $PdRhO_2$ have approximately the same current density, 10^{-4} A/cm², and nearly the same Tafel slope, b ~ 45 mV, which is different than for $PtCoO_2$, b ~ 60 mV. Since the capacitance-determined surface areas for the oxides only differ by ~2×, we conclude that the O_2 reduction activity correlates with the noble metal cation, Pt > Pd, and is nearly independent of the transition metal cation in Pd oxides.

Because of their larger surface roughness, the oxides have higher current densities than either smooth Pt or Pd. If we use the BET surface roughness (~200×) for $PtCoO_2$ and assume a roughness ~1.5× for smooth Pt, the current density of $PtCoO_2$ is approximately half that of Pt. But they have approximately equal current densities if we use the surface roughness for $PtCoO_2$ from capacitance data.

Table III. O_2 reduction activity in 0.1*N* NaOH at 23°C

	$E_{o.c.}$† (V/DHE)*	i at 0.9 V/DHE* (μA/cm²)	b (mV)
$PtCoO_2$	1.09	1900	58
$PdCoO_2$	1.00	150	43
$PdCrO_2$	1.01	85	47
$PdRhO_2$	1.00	75	43
Pt (smooth)	1.02	25	65
Pd (smooth)	1.00	20	40

† $E_{o.c.}$ = open-circuit voltage in O_2-saturated 0.1*N* NaOH.
* DHE = dynamic hydrogen reference electrode.

To further study the influence of the noble metal on oxygen reduction activity, we synthesized thin films with compositions intermediate to $PtCoO_2$ and $PdCoO_2$. This was done by simultaneously sputtering from a PdCo and a PtCo target, spaced ~25 mm apart. Al_2O_3 substrates were placed underneath and between the targets. Scanning electron micrographs show that all films have the same "mud-crack" morphology of $PtCoO_2$ and $PdCoO_2$ films shown in Fig. 2.

Electrochemical measurements were only made on single phase materials (x-ray diffraction). Electrical contact for electrochemical measurements was made in the plane of films at one end of the Al_2O_3 substrate by a thin gold foil strip, welded to a gold wire and clamped to the film between two planar sections of a holder of Teflon.

$PtCoO_2$ and $PdCoO_2$ are isostructural with nearly identical lattice dimension. We can distinguish them by x-ray diffraction since the 003 diffracted peak is twice as strong for $PtCoO_2$ as for $PdCoO_2$. The normalized 003 peak intensities were 29, 11, and 6 from the Pt-rich to Pd-rich end of the (Pt, Pd) CoO_2 series.

Table IV gives (Pt, Pd) CoO_2 film compositions from electron microprobe analysis. The composition is close to "$A_{1.0}B_{1.0}O_2$" for the Pd-rich film, but is closer to "$A_{0.8}B_{0.8}O_2$" for the Pt-rich film, as was observed for $PtCoO_2$. (To confirm whether this nonstoichiometric effect in Pt-oxides and mixed Pt-rich oxides is real and not an artifact of the rough thin film surfaces, we must characterize these films further.)

The O_2 reduction current densities are higher for these three mixed oxides (Table IV) than for $PdCoO_2$ (Table III). The oxide with intermediate Pt concentration (Pt/Pd = 0.54) has the highest current density. However, its electrochemical area, estimated by capacitance, is 2× higher than for the other films (2.5 mF for Pt/Pd = 0.54 compared to 1.3 mF for Pt/Pd = 0.34 and 1.2). A thickness gradient for films on substrates between targets probably causes these surface area differences. If we normalize for this, then higher O_2 reduction current correlates with higher Pt/Pd ratio. This is consistent with the higher activity measured for $PtCoO_2$ than $PdCoO_2$.

The Tafel slopes for mixed oxides are intermediate to those of the end member compositions. It seems plausible to us that O_2 reduction on mixed oxides proceeds by a combination of rate-determining steps that are the same as for $PtCoO_2$ and $PdCoO_2$.

We have also studied O_2 evolution for these oxides. The current densities were measured by sweeping the electrodes at 10 mV/sec with negligible hysteresis between 1.2 and 1.8 V/DHE in 1*N* NaOH at 23°C. Figures 6 and 7 summarize O_2 evolution currents from sweeping experiments for the oxides and smooth Pt and Pd. Prior to O_2 evolution sweeps, Pt and Pd electrodes were preanodized at 10 mA for 3 min to form stable oxide surfaces. For consistency the delafossite electrodes were identically preconditioned. In contrast to O_2 reduction, O_2 evolution activity is strongly dependent on the transition metal, Co > Rh > Cr. Figure 7 highlights differences in potential for O_2 evolution at $I = 5$ mA.

One of the $PtCoO_2$ electrodes was tested galvanostatically for ~30 hr at 5 mA. Initially, the potential was 1.58V. After 30 hr, it increased to 1.68 V/DHE. X-ray diffraction of this film showed ~10% Pt not

Table IV. O_2 reduction activity of (Pt, Pd)CoO_2 in 0.1*N* NaOH at 23°C

	Pt/Pd	i^* at 0.9 V/DHE ($\mu A/cm^2$)	b (mV)
$Pt_{0.42}Pd_{0.35}Co_{0.51}O_2$	1.2	772	52
$Pt_{0.31}Pd_{0.57}Co_{0.[illegible]9}O_2$	0.54	968	50
$Pt_{0.25}Pd_{0.73}Co_{0.93}O_2$	0.34	312	53

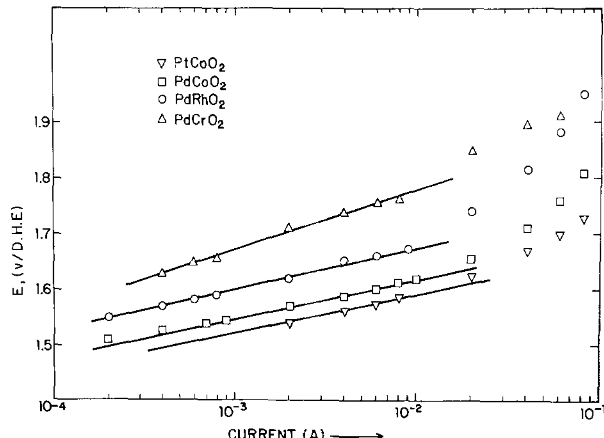

Fig. 6. O_2 evolution current vs. potential for thin film oxide electrodes obtained at 10 mV/sec in 1*N* NaOH at 23°C.

initially present. It is likely, therefore, that some decomposition to Pt occurred and is responsible for the higher overpotential.

Discussion

Oxygen reduction necessarily involves oxygen adsorption as the first step (14, 15); but little is known about the nature and distribution of atoms which would be potential adsorption sites at the surface of complex oxides in solutions, especially under the influence of oxidizing potentials. However, it seems reasonable to assume that at potentials >0.7 V/DHE, the surfaces of $PtCoO_2$ would consist of $O^=$ or OH^- ions bonded to either Co^{3+} or Pt^+ ions. Although t_{2g} orbitals of Co III LS, in the center of the CoO_6 octahedral face, point in the 001 direction, these orbitals are filled and would not allow the possibility of bond formation. However, surface oxygen vacancies or Co III HS at the surface would allow the possibilities of adsorption sites for O_2 in the Co layer. Oxygen vacancies have been proposed to take part in the oxygen reduction mechanism on perovskite oxides such as $LaNiO_3$ (16) and $Nd_{1-x}Sr_xCoO_3$ (17), but neither the presence of oxygen vacancies nor Co III HS in delafossite-type oxides has been demonstrated.

As noted earlier, our electrochemical data show that the O_2 reduction activity on the delafossites is high,

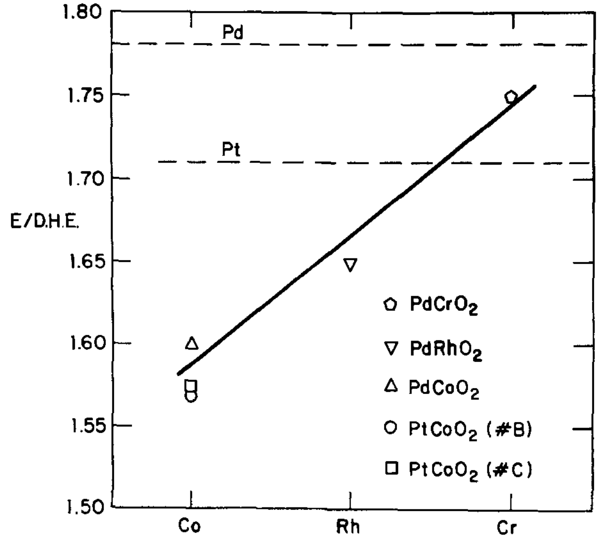

Fig. 7. Potential for O_2 evolution at $I = 5$ mA vs. transition metal cation in thin film oxide electrodes. Data obtained from sweep experiments at 10 mV/sec.

and correlates with the noble metal (Pt > Pd), but in $PdMO_2$ is nearly independent of the transition metal (Co ~ Cr ~ Rh). A possible explanation for the relative insensitivity of the $PdMO_2$ to the transition metal ion in O_2 reduction is that these ions are all remarkably similar, *i.e.*, all are strongly stabilized in an octahedral crystal field with d^3 (Cr^{3+}) and low spin d^6 (Rh^{3+}, Co^{3+}) electron configurations. Bonding of O_2 to these sites is either sterically hindered, or in the case of an anion vacancy, too strong to be effective for reduction to H_2O.

Furthermore, to our knowledge, high O_2 reduction activity has never before been observed on an oxide electrocatalyst containing either Rh^{3+} or Cr^{3+}. The high activity on Co-oxides is frequently correlated with Co^{2+} or high spin Co^{3+} as in Co-chelates (18) and $La_{1-x}Sr_xCoO_3$ (19), respectively.

Therefore, most of the O_2 reduction likely occurs on noble metal sites, and the transition metal contributes little to the overall activity. Pt atoms, in contrast to Co atoms, have O neighbors oriented only along the c-axis. Crystal surfaces 100 and 110 which contain Pt distances in $PtCoO_2$ of 2.83Å are comparable to those in Pt metal of 2.77Å. These short distances might allow "side-on" O_2 adsorption and a mechanism similar to that on Pt metal. Furthermore, even the 001 oxygen layers are probably not strongly bonded to Pt (ΔF_f for PtO_2 is -19 kcal/mole compared to -60 kcal/mole for Co_3O_4). Thus, these O atoms might be stripped off in solution at potentials for oxygen reduction creating even more Pt atoms for bonding with O_2 molecules. Similar crystallographic and thermodynamic arguments can be made for $PdCoO_2$, $PdCrO_2$, and $PdRhO_2$. In support of this view, the Tafel slopes appear to reflect Pt-like and Pd-like character. The slope is $\sim RT/\mathbf{F}$ for $PtCoO_2$ and $\sim 2\,RT/3\mathbf{F}$ for the Pd delafossites. These are the same slopes observed for O_2 reduction on Pt and Pd electrodes in alkaline electrolytes (20).

The analogy with Pt and Pd cannot be carried too far, however, because the noble metal atoms and molecular orbitals available for adsorption in $PtCoO_2$ and $PdMO_2$ with formally Pt(I) and Pd(I), will be different than those in Pt and Pd metals. Indeed, Pt and Pd have roughly the same O_2-reduction activity measured at 0.9 V/DHE in contrast to the higher activity for $PtCoO_2$ than $PdMO_2$. Further, the open-cell potential for $PtCoO_2$ is higher than is normally observed for Pt in alkaline electrolytes. We ruled out the possibility that the activity differences are due to a larger $PtCoO_2$ surface area which we accounted for. The capacitance of $PtCoO_2$ electrodes is larger, but is less than $2\times$ that for $PdCoO_2$, much smaller than the $10\times$ difference in their O_2 reduction currents. Further experimental and theoretical work is thus needed to explain the O_2 reduction activity of these materials.

In O_2 evolution, the activity in delafossite-type oxides correlates with the transition metal (Co > Rh > Cr), and is nearly independent of the noble metal (Pd ~ Pt). For metals, the highest activities occur for those whose oxides are also good electrical conductors, *e.g.*, RuO_2 and IrO_2 (21). This would seem reasonable, particularly if the rate-determining step involves an electron transfer as suggested by O'Grady *et al.* (15). Pt and Pd, whose surfaces are necessarily covered with an oxide at O_2 evolution potentials, have low activity. This correlates with poor conductivity in PtO_2 ($\rho \sim 10^6$ Ω-cm) and PdO ($\rho \sim 10^2$ Ω-cm) (22). If the noble metal planes of the delafossites are also oxide covered, their specific contribution to O_2 evolution may be low. It is not surprising then that the experimental results correlate with the transition metal cation. Intuitively, the negative hydroxyls should be attracted to the trivalent cations making these the most likely adsorption sites. The results are also correlated with those of Miles *et al.* (23) who found that Cr oxide electrodes have much lower electrocatalytic activity for oxygen evolution than either Co or Rh oxide electrodes. Furthermore, there are several examples (24, 25) of Co-oxides with low overpotential for O_2 evolution and recently Burke (26) has observed high O_2 evolution activity on an oxidized surface of Rh.

Acknowledgments

We would like to thank H. A. Selz for assistance with the sputtering experiments, D. J. Jones and P. R. Spring for the electrochemical measurements, J. F. Whitney for assistance with x-ray diffraction, M. L. Van Kavelaar for the SEM photographs, and R. J. Bouchard for helpful discussions and review of the manuscript.

Manuscript submitted Dec. 4, 1979; revised manuscript received April 11, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1981 JOURNAL. All discussions for the June 1981 Discussion Section should be submitted by Feb. 1, 1981.

Publication costs of this article were assisted by E. I. du Pont de Nemours and Company.

Electron Transfer and Axial Coordination Reactions of Cobalt Tetra(Aminophenyl)Porphyrins Covalently Bonded to Carbon Electrodes

Colleen P. Jester,[1] Roy D. Rocklin,* and Royce W. Murray

Kenan Laboratories of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

Electrochemistry of tetra(aminophenyl)porphyrin covalently attached to glassy carbon and then cobalt-metallated, was investigated in DMSO and CH_3CN solvents in the presence of pyridine. Shifts in formal potential were used to measure complex stability constants and coordination number for the pyridine complexes of the immobilized metalloporphyrin. Unusually slow electrochemistry of the Co(III/II) reaction was also studied by cyclic voltammetry and by reflectance spectroelectrochemistry. It is proposed that coordination of cobalt by surface carboxylate groups causes extraordinarily slow electron transfer for the Co(III/II) step.

This laboratory has in previous reports (1-3) described the covalent immobilization of tetrakis(p-aminophenyl)porphyrin, (p-NH_2)$_4$TPP, on glassy carbon electrodes by the reaction sequence

$$\text{glassy carbon} \xrightarrow[\text{or } O_2 \text{ plasma}]{O_2,} , \xrightarrow{SOCl_2} C\!-\!C(=O)Cl \xrightarrow{(NH_2)_4TPP} C\!-\!C(=O)(NH)_x(NH_2)_{4-x}TPP \quad \mathbf{I} \qquad [1]$$

The number of amine bonds formed to the surface was determined by x-ray photoelectron spectroscopy, XPS, to be two, on the average (2). The surface porphyrin I can be metallated *in situ* with first row transition elements such as Fe and Co (1-3). All these immobilized species exhibit electron transfer reactions with the carbon electrode with formal potentials $E_{surf}^{\circ\prime}$ near those of their unattached molecular analogs (4).

It is well known (5) that metalloporphyrins immobilized within the framework of biological macromolecules can exhibit special chemistry associated with proximity of axially coordinating ligands attached to the framework or with steric restrictions imposed by the framework on the axial coordination of otherwise potent ligands. Inasmuch as some analogies between the circumstances of biological macromolecular and electrode immobilization can be envisioned, a better understanding of the axial coordination chemistry of metalloporphyrins prepared from structure I was of interest. With this in mind, a further study of the cobalt-metallated form of structure I, C/∼Co(NH_2)$_4$TPP, in contact with solutions containing the ligand pyridine, has been carried out and is described here. Results are also given for the monoamine tetraphenylporphyrin, C/∼Co(NH_2)TPP. Of interest was how the coordination number of axially bound pyridine depends on the oxidation state of the immobilized cobalt porphyrin and its complex stability constants. A base of comparative electrochemical data for the interaction of pyridine with dissolved cobalt tetraphenylporphyrin is available (6-8). Also of interest was a better understanding of the previously noted (2) abnormally small electrochemical surface wave for reduction of immobilized C/∼Co(III)(NH_2)$_4$TPP as compared to C/∼Co(II)(NH_2)$_4$TPP.

Experimental

Immobilization.—Glassy carbon electrodes (Atomergic Chemetals Corporation, Plainview, New York, Grade V10-50, 3-4 mm diam) with freshly polished ends were oxidized *in vacuo* at *ca.* 400°C for 1 hr or in an rf plasma (9) chamber at *ca.* 200 mTorr O_2 and 5W for 30 min. Lower background currents were observed with plasma-oxidized electrodes. The oxidized electrodes were refluxed in *ca.* 2 ml freshly distilled $SOCl_2$ in 15 ml of sodium dried toluene for 1 hr, briefly rinsed with dry toluene, and refluxed for 3 hr in a hot solution of *ca.* 1 mg of (NH_2)$_4$TPP or (NH_2)TPP porphyrin in 15 ml of dry toluene. Thorough rinses with dry toluene and reagent grade methanol were used to remove adsorbed porphyrin. The immobilized porphyrins were metallated by refluxing the air-dried electrodes in a solution of *ca.* 0.5g of $CoCl_2$ in 20-30 ml CH_3CN followed by washing with CH_3CN. The electrodes were mounted for electrochemical experiments in a cylinder of heat-shrinkable Teflon, leaving the cylinder end exposed. Cobalt metallation was ordinarily complete as indicated by the absence of electrochemical waves for residual-free base.

Electrochemistry.—Electrochemical experiments were carried out in dimethylsulfoxide (DMSO) and acetonitrile solvents predried over molecular sieves and containing 0.1*M* Et_4NClO_4 supporting electrolyte and various concentrations of pyridine ligand. The solutions were degassed with N_2 presaturated with vapor of a pyridine/solvent mixture identical to that in the electrochemical cell. The pyridine had been distilled and stored over molecular sieves.

The electrochemical cell was conventional, with a Luggin capillary to the NaCl-saturated calomel reference electrode (SSCE). To ascertain that junction potential effects at the Luggin tip were unimportant as the pyridine concentration was varied over a wide range, the formal potential of the ferrocene/ferricenium couple was measured as a function of [Py]. Its potential was constant, $+0.496 \pm 0.006$V *vs.* SSCE.

Electrochemical equipment was a Princeton Applied Research Model 174 as potentiostat for cyclic voltammetry and differential pulse voltammetry with a locally designed triangular wave generator (10) as signal source for the former. A freshly prepared electrode was first inspected by cyclic voltammetry, then volt-

ammograms were determined at a series of [Py] with differential pulse voltammetry, whose application to immobilized electrode reactants has been described by Brown and Anson (11). $E_{surf}^{\circ\prime}$ is the average of the potentials for current peaks observed on cathodic and anodic-going scans. The differential pulse experiment allowed accurate determination of peak potentials even at the very slow potential scan rates desirable for $E_{surf}^{\circ\prime}$ measurements.

Chemicals.—Tetrakis(p-aminophenyl)porphyrin, $(NH_2)_4TPP$, and mono(p-amino)-tetraphenylporphyrin, $(NH_2)TPP$, were prepared as previously (2, 3) and generously supplied by C. M. Elliott (Stanford University), respectively. Cobalt tetraphenylporphyrin (Man-Win Chemicals, Washington, D.C.) was used as received.

Determination of x in reaction [1].—The dangling amine groups remaining on the immobilized porphyrin in reaction [1] were coupled to 3,5-dinitro-benzoyl chloride and the relative XPS N 1s band intensities for nitro and porphyrin nitrogens determined as described previously (2). This measurement was carried out on electrodes prior to metallation and also on electrodes after cobalt insertion. XPS spectra were obtained with a du Pont Model 650B Electron Spectrometer with the assistance of Dr. M. Umaña.

Results and Discussion

Some general characteristics of the cyclic voltammetry of tetra(p-aminophenyl)porphyrin attached to carbon as in Eq. [1] and then cobalt metallated, $C/\!\!\sim\!Co(NH_2)_4TPP$, and of its monoamine analog, $C/\!\!\sim\!Co(NH_2)TPP$, are illustrated by Fig. 1-3. In both DMSO and CH_3CN solvents, the Co(III/II) and Co(II/I) porphyrin reactions occur at potentials similar to the $E^{\circ\prime}$ values for unattached CoTPP (+0.12 and −0.82V *vs.* SSCE in DMSO), typical of modified electrodes (3, 4). The voltammograms in DMSO and CH_3CN are unusual however, in that in the absence of added pyridine ligand (Fig. 1A, 2A), the Co(III/II) wave is typically only 1-5% as large as the Co(II/I) wave. When pyridine is added (compare Fig. 1A, 1B), and for $C/\!\!\sim\!Co(NH_2)TPP$ as compared to $C/\!\!\sim\!Co(NH_2)_4TPP$ (compare Fig. 1A, 2B), the Co(III/II) wave is enhanced, but remains < 1:1 in relation to the Co(II/I) step. Voltammetry of $C/\!\!\sim\!Co(NH_2)_4TPP$ in pyridine as solvent is similar to that in >1*M* solutions of pyridine in DMSO.

The cathodic Co(II/I) wave in both DMSO ($E^{\circ\prime}$ = −0.87V *vs.* SSCE) and CH_3CN ($E^{\circ\prime}$ = −0.87V *vs.* SSCE) exhibits an irreversible prewave whose definition varies from electrode to electrode (Fig. 1A, 3A),

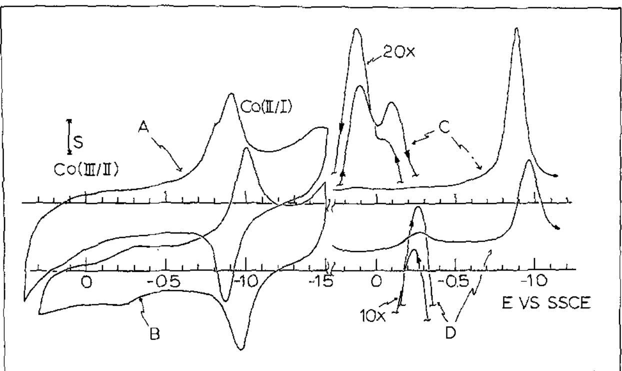

Fig. 1. Cyclic voltammetry at 100 mV/sec of 6 × 10^{-10} mole/cm² $C/\!\!\sim\!Co(NH_2)_4TPP$ in DMSO (curve A) and in 3.47*M* pyridine in DMSO (curve B). Differential pulse voltammetry (2 mV/sec scan rate, 0.5 sec/cycle, 25 mV modulation) of 5.7 × 10^{-10} mole/cm² $C/\!\!\sim\!Co(NH_2)_4TPP$ in DMSO (curve C) and in 3.47M pyridine in DMSO (curve D). S = 13.8 μA/cm² (curves A, B); 27.6 μA/cm² (curves C, D). Insets are Co(III/II) DPV responses of curves C and D amplified as indicated for precise measurement of E_{peak}.

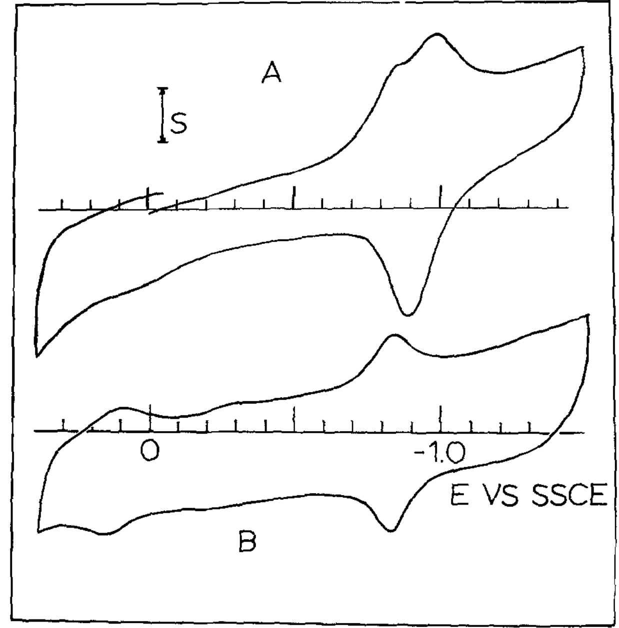

Fig. 2. Cyclic voltammetry at 100 mV/sec of 1.1 × 10^{-9} mole/cm² $C/\!\!\sim\!Co(NH_2)_4TPP$ in CH_3CN (curve A) and of 3.2 × 10^{-10} mole/cm² $C/\!\!\sim\!Co(NH_2)TPP$ in DMSO (curve B). S = 27.6 μA/cm² (curve A); 2.8 μA/cm² (curve B).

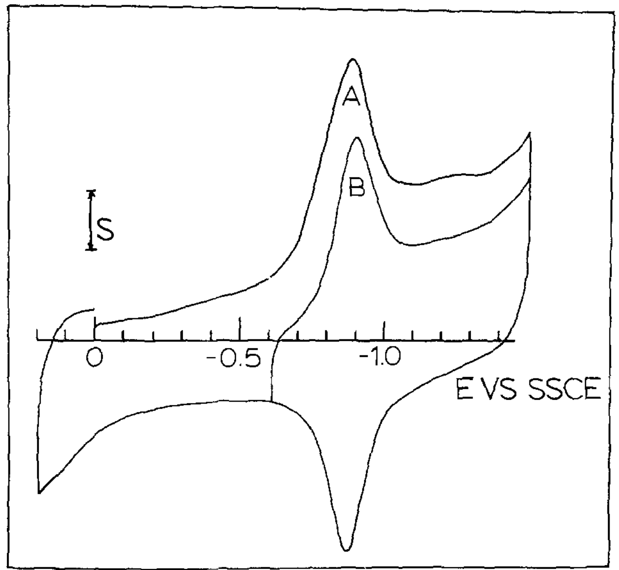

Fig. 3. Cyclic voltammetry at 100 mV/sec of $C/\!\!\sim\!Co(NH_2)_4TPP$ in DMSO. Curve A: potential scan after potentiostatting at 0V for *ca.* 1 min, Q_{cath}/Q_{anod} ≈ 1.38; curve B: steady-state scan between −0.6 and −1.5V *vs.* SSCE, Q_{cath}/Q_{anod} = 1.02.

and which has no anodic counterpart. If the potential scanning region is restricted (Fig. 3B) or if the electrode is prepotentiostatted at −0.4V for a few minutes, the cathodic prewave is largely eliminated.

From these general observations it seems that only a fraction of the immobilized metalloporphyrin population undergoes the Co(III/II) reaction at its reversible potential, but that most if not all of the Co(II/I) reaction proceeds normally especially if the electrode is prepotentiostatted as described above. We will return to this point after considering the axial ligation properties as deduced from the reversible Co(III/II) sites and the Co(II/I) reaction.

Coordination with pyridine.—Theory for the shift in reversible redox potential of an electrode immobilized metal complex caused by a change in coordination has not been discussed previously. It is formally similar to

the conventional solution relations, replacing solution concentrations by surface excess Γ (moles/cm²). We will assume that $r_O = r_R$ for the surface interaction terms (11). Thus for the reactions of C/∼Co(NH₂)₄-TPP

$$\text{C/∼Co(III)(NH}_2)_4\text{TPP} + e^- \rightleftharpoons \text{C/∼Co(II)(NH}_2)_4\text{TPP} \quad [2]$$

$$\text{C/∼Co(II)(NH}_2)_4\text{TPP} + e^- \rightleftharpoons \text{C/∼Co(I)(NH}_2)_4\text{TPP} \quad [3]$$

the reversible potentials in the absence of pyridine are

$$E = E_{\text{surf(III/II)}}^{\circ\prime} - 0.059 \log [\Gamma_{\text{Co(II)}}/\Gamma_{\text{Co(III)}}] \quad [4]$$

$$E = E_{\text{surf(II/I)}}^{\circ\prime} - 0.059 \log [\Gamma_{\text{Co(I)}}/\Gamma_{\text{Co(II)}}] \quad [5]$$

and after addition of pyridine generating the equilibria

$$\text{C/∼Co(III)(NH}_2)_4\text{TPP} + m\,\text{Py} \overset{K_{\text{III}}}{\rightleftharpoons} \text{C/∼Co(III)(NH}_2)_4\text{TPP(Py)}_m \quad [6]$$

$$\text{C/∼Co(II)(NH}_2)_4\text{TPP} + p\,\text{Py} \overset{K_{\text{II}}}{\rightleftharpoons} \text{C/∼Co(II)(NH}_2)_4\text{TPP(Py)}_p \quad [7]$$

we obtain

$$E_{\text{surf/complx(III/II)}}^{\circ\prime} = E_{\text{surf/(III/II)}}^{\circ\prime} - 0.059 \log [K_{\text{III}}/K_{\text{II}}] - 0.059(m - p) \log [\text{Py}] \quad [8]$$

$$E_{\text{surf/complx(II/I)}}^{\circ\prime} = E_{\text{surf(II/I)}}^{\circ\prime} - 0.059 \log [K_{\text{II}}] - 0.059(p) \log [\text{Py}] \quad [9]$$

Measurement of $E_{\text{surf/complx}}^{\circ\prime}$ as a function of [Py] yields p [the number of pyridine axially coordinated to Co(II)] and K_{II} from Eq. [9] and thence m [the number of axially coordinated pyridines for Co(III)] and K_{III} from Eq. [8]. These values depend on solvent since solvent coordinates competitively with pyridine.

To accurately measure peak potentials for the Co(III/II) and Co(II/I) waves, differential pulse voltammetry produces sharply defined waves at the slow potential scan rates desirable to ensure Nernstian charge transfer equilibrium for reactions. Also, the small Co(III/II) wave, detected with difficulty by cyclic voltammetry is easily seen (Fig. 1) in the DPV experiment. $E^{\circ\prime}$ was taken as the average of E_{peak} negative and positive-going potential sweeps (see Fig. 1C, 1D insets). Table I shows that DPV peak potential separations (ΔE_p) are small, with differences between the Co(III/II) and Co(II/I) steps and between C/∼Co(NH₂)₄TPP and C/∼Co(NH₂)TPP. In DMSO, a spurious wave at −0.10V (Fig. 1C), which disappears when a small concentration (2 mM) of pyridine is added, is thought to arise via adventitious ligands such as trace water. The potential of the more positive wave is taken as $E_{\text{surf(III/II)}}^{\circ\prime}$, +0.124V *vs.* SSCE.

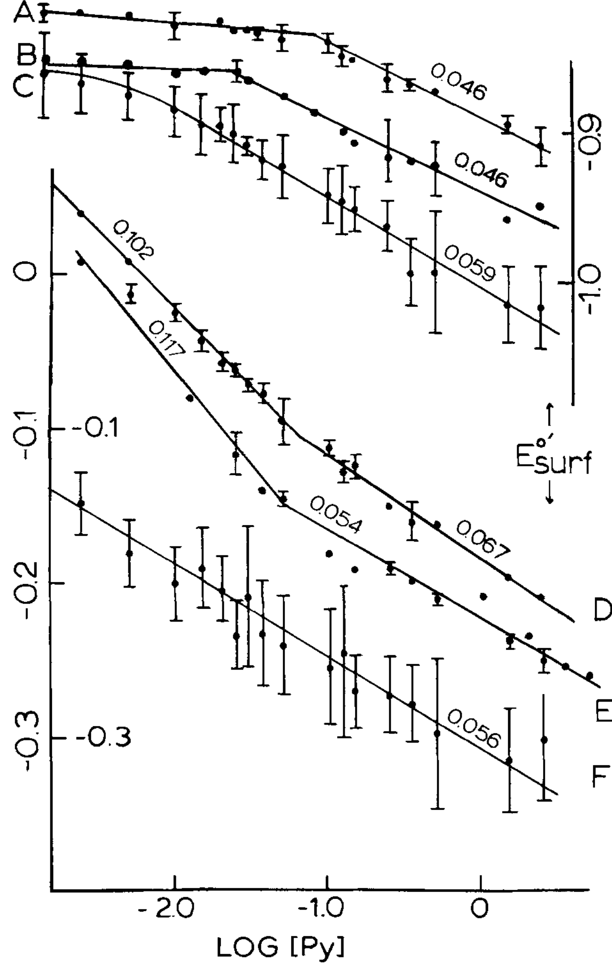

Fig. 4. Formal potential $E_{\text{surf}}^{\circ\prime}$ (average of E_{peak} of positive and negative DPV sweeps) as a function of log[Py]. Curves A, B, C are Co(II/I) wave, curves D, E, F are Co(III/II) wave. Curves A, D: C/∼Co(NH₂)TPP in DMSO; curves B, E: C/∼Co(NH₂)₄TPP in DMSO; curves C, F: C/∼Co(NH₂)₄TPP in CH₃CN. Numbers by curves are least squares slopes.

Data for $E_{\text{surf}}^{\circ\prime}$ as a function of [Py] are displayed in Fig. 4. Results for different experiments are overlaid. The potential becomes more negative as pyridine is added, since the Co(III) state is more stabilized by pyridine coordination than the Co(II) state. In DMSO, clearly defined changes in slope for both C/∼Co-(NH₂)₄TPP and C/∼Co(NH₂)TPP occur at [Py] ∼ 0.05*M* and the slopes are approximate multiples of 0.059. At low [Py], $m - p$ for the Co(III/II) reaction is for both porphyrins near two and p for (Co(II/I) is zero. At these concentrations, both axial sites on C/∼Co(III)(NH₂)₄TPP and C/∼Co(III)(NH₂)TPP are occupied by pyridine, and these are both displaced upon reduction to C/∼Co(II)TPP. At high [Py], we

Table I. Stability constants[a] for complexation of pyridine by immobilized cobalt aminotetraphenylporphyrins

Solvent	Porphyrin	Log K_{III}	Log K_{II}	$E_{\text{surf}}^{\circ\prime}$ III,II[b]	$E_{\text{surf}}^{\circ\prime}$ II,I[b]	ΔE_{peak},[c] mV III,II	ΔE_{peak},[c] mV II,I

[f] Ref. (20).

find $m - p = 1$, so only one of the two initially present pyridines becomes displaced in C/~Co(II)TPP, the second being lost upon reduction to C/~Co(I)TPP.

Acetonitrile is a less strongly coordinating solvent and so it is not surprising that Fig. 4 shows that only one pyridine is dissociated upon reduction to C/~Co(II)TPP, over the entire range of [Py]. As before, the second pyridine is lost upon further reduction to C/~Co(I)TPP. The data from different determinations in acetonitrile show greater scatter than in DMSO; the weaker ligand CH_3CN probably allows greater coordinative interference from impurity ligands such as water.

These results are summarized in the reactions

In DMSO, at [Py] < 0.05*M*

$$C/\sim Co(III)(NH_2)_4TPP(Py)_2 + e^- \rightarrow C/\sim Co(II)(NH_2)_4TPP(DMSO) + 2Py \quad [10]$$

In DMSO at [Py] > 0.05*M*, and in CH_3CN

$$C/\sim Co(III)(NH_2)_4TPP(Py)_2 + e^- \rightarrow C/\sim Co(II)(NH_2)_4TPP(Py) + Py \quad [11]$$

$$C/\sim Co(II)(NH_2)_4TPP(Py) + e^- \rightarrow C/\sim Co(I)(NH_2)_4TPP + Py \quad [12]$$

Reactions [10]-[12] for immobilized cobalt porphyrin are consistent with previous electrochemical information on solutions of cobalt porphyrin (6, 7). In structural studies of cobalt porphyrins (12-16), Co(III) is generally six coordinate (two axial ligands), Co(II) is generally five coordinate, and square pyramidal with the metal displaced 0.1-0.2Å out of the plane of the porphyrin ring, and Co(I) is four coordinate (no or very weak axial ligation). The data of Fig. 4 for all cases, show six coordinate Co(III), *i.e.*, C/~Co(III)-$(NH_2)_4TPP(Py)_2$, at most one pyridine coordinated to Co(II), and overall dissociation of two pyridines upon complete reduction of Co(III) to Co(I). Similar results for axial coordination of pyridine in solutions of CoTPP in DMSO and propionitrile solvents were reported by Davis (6). In DMSO, Kadish and co-workers (7) reported an additional reduction wave at intermediate [Py] which we did not observe for the immobilized cobalt porphyrins.

Stability constants for Eq. [6] and [7] calculated using Eq. [8] and [9] are summarized in Table I. Except for K_{III} for C/~Co(III)$(NH_2)_4$TPP, which is notably larger, K_{III} and K_{II} agree fairly well with the values cited by Kadish (7) for solutions of CoTPP in DMSO. K_{III} and K_{II} are larger in the less coordinating acetonitrile solvent, consistent with coordination number results in Fig. 4, and in good agreement with results in propionitrile (6).

Aspects of surface binding and the Co(III/II) reaction.—The above results show that the axial coordination numbers and stability constants for the reversibly reacting C/~Co$(NH_2)_4$TPP and C/~Co(NH_2)TPP are little different from that for solutions of CoTPP. However, we have also observed that only a small fraction of the total immobilized cobalt porphyrin population seems to react at the reversible Co(III/II). Associated with this effect is the appearance of a prewave of the Co(II/I) wave (Fig. 1A, 2A, 3A). The combined charge of this prewave and the Co(II/I) wave, Q_{cath}, relative to that of the subsequent Co(I/II) wave, Q_{anod}, as shown for C/~Co$(NH_2)_4$TPP in DMSO in Table II, depends upon the potential scanning history of the electrode. On a fresh electrode, Q_{cath}/Q_{anod} is nearly 2/1. This value drops upon succeeding potential scans, especially for continuous scanning, and falls to 1.02 if the potential scan is restricted to the vicinity of the Co(II/I) wave. The value of Q_{cath}/Q_{anod} which is observed after brief potentiostatting at 0V especially increases if pyridine is present since the reversible Co(III/II) potential is then more negative than 0V.

The strong implication of this behavior is that immobilized Co(III) porphyrin which does not react in the small, reversible Co(III/II) wave, reacts as the prewave of the Co(II/I) wave. The electron transfer rate for this "slow Co(III) porphyrin" must be very slow. Further, the overlap of the "slow Co(III/II)" wave (the prewave) and the reversible Co(II/I) wave suggests that the onset of the latter catalyzes the former, perhaps through generation of some Co(I) sites from the reversibly reacting Co(III/II) population.

To observe the slow Co(III/II) reaction by a different method, we have conducted reflectance spectroelectrochemistry on the same porphyrin system attached to Pt electrodes using organosilane chemistry

$$Pt-OSi(CH_3)(CH_2)_3C(=O)Cl \xrightarrow[2.\ CoCl_2]{1.\ (NH_2)_4TPP} Pt-OSi(CH_3)(CH_2)_3C(=O)NH)_y-(NH_2)_{4-y}TPP(Co) \quad [13]$$

II

As shown in Fig. 5, voltammetry of the silane-bound cobalt porphyrin, II is similar to that seen on glassy carbon, *i.e.*, an abnormally small Co(III/II) wave and a prewave to the Co(II/I) reaction. Reflectance spectra taken (*in situ*, acquisition time *ca.* 15 sec) with the surface II potentiostatted at +0.4, −0.4, −1.1, −0.4, and +0.4V *vs.* SSCE in DMSO are shown in the figure. Details of the reflectance experiment are given elsewhere (17). The +0.4V spectrum (curve a) should correspond to the Co(III) state, and its 452 nm λ_{max} is in good agreement with the 450 nm value obtained for a solution of Co(III)$(NH_2)_4$TPP in DMSO in an optically transparent thin layer electrochemical cell (17). When the potential is changed to −0.4V, appropriate for the Co(II) state, a spectral change commences (curves b, c, d), but this is very slow; even after 10 min there is only a 3 nm shift in λ_{max}. In contrast, changing the applied potental to −1.1V is accompanied by an immediate change of the reflectance spectrum to that of Co(I) as shown in Fig. 5, curve e. Likewise, return of the potential to −0.4 immediately results in a Co(II) porphyrin spectrum (curve f) with λ_{max} = 435 nm (the corresponding solution value is 433 nm). Finally, return of the potential to +0.4V *vs.* SSCE also restores the Co(III) spectrum (curve g),; the Co(II/III) spectral change occurs much more rapidly than that for the Co(III/II) reaction. These

Curve a: potential applied to +0.4V vs. SSCE; curve b: after ca. 30 sec at −0.4V; curve c: after ca. 1 min at −0.4V; curve d: after ca. 10 min at −0.4V; curve e: after ca. 30 sec at −1.1V; curve F: after ca. 30 sec at −0.4V; curve g: after ca. 1 min at +0.4V.

spectral results confirm the extraordinarily slow Co(III/II) electrochemistry, and also indicate that the reversible potential for the "slow Co(III/II)" species is more positive than −0.4V.

To verify the absence of artifacts in our solutions, cyclic voltammetry of unattached Co(III)TPPCl in DMSO solution was reexamined at glassy carbon electrodes. The Co(III/II) wave is indeed fully developed (with $i_p/v^{1/2}$ = constant for v = 0.05-0.2 V/sec) as compared to the Co(II/I) wave as shown in Fig. 6.

We propose that the slow electron transfer in the "slow Co(III/II)" species involves an axial coordination effect, in which a potent ligand X axially binds to one axial side of the immobilized C/~Co(III)$(NH_2)_4$TPP, leaving the other side open to coordination by solvent or pyridine. Thus, in DMSO containing [Py] > 0.05M, a small population of C/~Co$(NH_2)_4$TPP is not coordinated by X at all and undergoes reaction [11] at the reversible potential as found in Fig. 4, whereas most of the immobilized metalloporphyrin undergoes a very slow electron transfer from the electrode or a faster one from neighbor Co(I) sites according to the reaction

$$\text{C/\sim Co(III)(NH}_2)_4\text{TPP(Py)(X)} + e \rightarrow \text{C/\sim Co(II)(NH}_2)_4\text{TPP(Py)} + \text{X} \quad [14]$$

In Eq. [14], X becomes dissociated rather than pyridine as attested by the results of Fig. 4 (i.e., p = 1). The Co(II) product of both Eq. [11] and [14] thereafter undergo the expected Co(II/I) reaction [12].

Intervention of ligand X in the electrochemistry of C/~Co$(NH_2)_4$TPP is supported by several experimental results. First, we expect that to some extent X should be displaced by added ligands, with an associated increase in the magnitude of the reversible Co(III/II) wave. Figure 1 shows that indeed the reversible Co(III/II) wave is enhanced in the presence of added pyridine, i.e., a larger proportion of the porphyrin reacts as in Eq. [11] rather than Eq. [14]. Secondly, a sterically small, hard ligand such as chloride produces a similar effect as shown in Fig. 7. A large excess of chloride both attenuates the prewave and enhances the reversible Co(III/II) wave which in the case of C/~Co(NH_2)TPP (curve d) exhibits a charge nearly equal now to that of the Co(II/I) wave, suggesting nearly complete replacement of X by chloride.

Whatever X is, it has the property of being stably bound (competes well with large excess of pyridine) and of dramatically slowing the electron transfer for

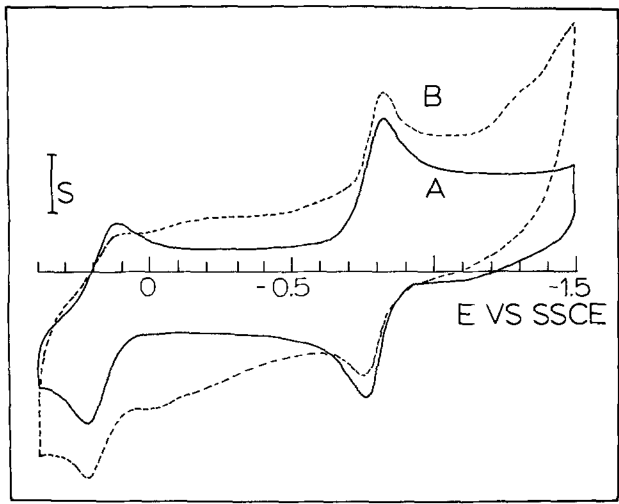

Fig. 6. Cyclic voltammograms at 100 mV/sec of a 0.4 mM solution of cobalt tetraphenylporphyrin in DMSO (curve A) with 0.4M tetraethylammonium benzoate added (curve B). S = 27.6 μA/cm^2.

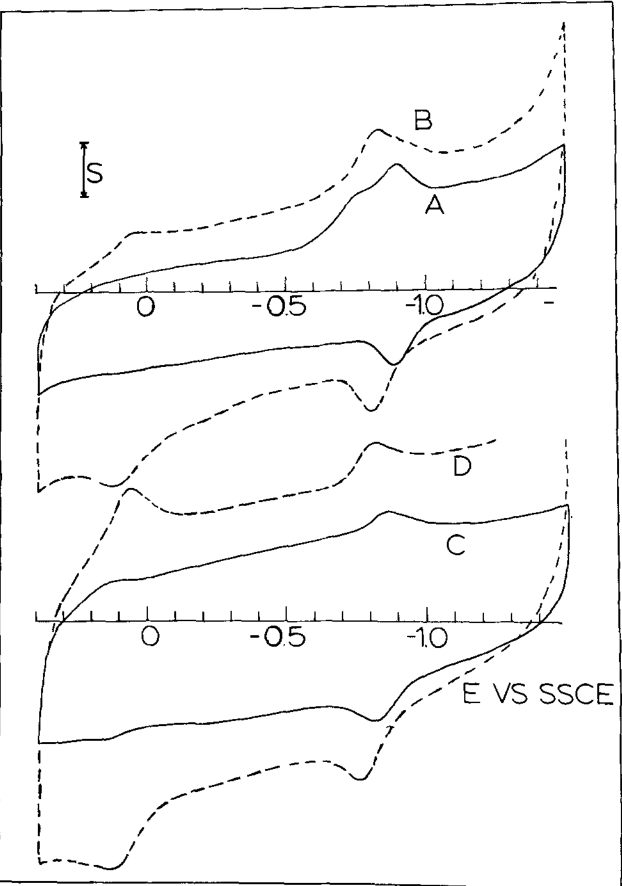

Fig. 7. Cyclic voltammograms at 100 mV/sec in DMSO of 2.2×10^{-10} mole/cm^2 C/~Co$(NH_2)_4$TPP (curve A) with excess tetraethylammonium chloride added (curve B), and of 6.2×10^{-10} mole/cm^2 C/~Co(NH_2)TPP (curve C) with excess $Et_4N^+Cl^-$ added (curve D). S = 13.8 μA/cm^2 (curves A, B); 55.5 μA/cm^2 (curves C, D).

the Co(III/II) reaction. We must consider **X** as being either a trace constituent of the solvent-electrolyte system contacting the electrode, or a chemical functionality which is attached to the surface molecular framework. For some time we suspected that traces of dioxygen in the solvent might coordinate to the cobalt porphyrin. In aqueous acid, immobilized C/~Co$(NH_2)_4$TPP does catalyze dioxygen reduction, at potentials suggesting H_2O_2 as product, and with eventual deactivation of the porphyrin. Also, deliberately added small amounts of dioxygen in DMSO and CH_3CN enhance current at the potential of the prewave. Scrupulous degassing, however, neither eliminates the prewave nor restores the Co(III/II) wave to a normal magnitude. We do not have satisfying evidence for the involvement of dioxygen and propose instead that **X** is a ligand constituent of the surface itself.

Immobilized ligands on surfaces I and II include dangling amine functionalities of $(NH_2)_4$TPP which did not couple to the surface acid chloride groups, and carboxylic acid groups which are eventual hydrolytic products of the latter. The dangling amine groups can be investigated by the amidization reaction

$$\text{C/\sim CONH)}_x(\text{NH}_2)_{4-x}\text{TPP} \xrightarrow[\text{ClCOPh(NO}_2)_2]{} \text{C/\sim CONH)}_x\text{TPP(NH}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—C}_6\text{H}_3(\text{NO}_2)_2)_{4-x} \quad [15]$$

by measuring the relative intensities of the x-ray photoelectron N 1s spectral bands for the nitro groups and for the overlapping porphyrin plus amide nitrogens as we have earlier described (2). For unmetallated porphyrin, we redetermined $4 - x$ as 1.85 ± 0.28, in agreement with the earlier result from which we concluded that an average of two amide bonds formed between each $(NH_2)_4$TPP and the carbon surface. In a new experiment, the porphyrin was metallated with cobalt prior to reaction [15]; the result was again $4 - x = 1.82 \pm 0.54$ (average of three measurements). Thus, cobalt does not change the number of dangling amines with the implication that such amines are not pre-empted from reaction [15] by axial coordination to cobalt. Also cobalt-metallated electrodes still exhibit small Co(III/II) waves after reaction [15]. Finally, neighbor amine donors should not be possible on C/~Co(NH_2)TPP surfaces, which exhibit the "slow Co(III/II)" effect, albeit to a lesser degree (Fig. 2B, 7C).

The second surface ligand model, in which **X** is a carboxylate function of the glassy carbon lattice which centrally underlies C/~Co$(NH_2)_4$TPP sites and coordinates axially with the cobalt from the electrode side of the porphyrin ring, is thought to be a stronger possibility. Since carboxylate groupings on glassy carbon occur with sufficient surface density to permit two groups to fall into register with an amide bond to (on the average) two amine sites on each porphyrin, it is therefore plausible that many axial porphyrin sites should also achieve a register with a third carboxylic acid surface group. On surface II, there is of course a large population of dangling carboxylic acid groups not consumed by the amide bonding reaction but still attached by the silane linkage to the Pt electrode.

Figure 6B shows a cyclic voltammogram of unattached CoTPP in the presence of a 10^2-fold excess of benzoate ion (a molecular analog of a graphite carboxylate edge site). The Co(III/II) wave is split. A diminished solvent-coordinated Co(III/II)TPP wave remains visible and so the stability constant for benzoate coordination is small. A diffuse, second Co(III/II)TPP wave with large ΔE_p is seen at more negative potentials. This behavior shows that benzoate coordination by itself retards the electron transfer rate for the Co(III/II) reaction.

In six coordinate Co(III)TPP complexes, the low spin Co(III) lies in the plane of the four porphyrin nitrogens (12, 18). In five coordinate Co(II)TPP, on the other hand, the usual cobalt coordination geometry is square pyramidal with the low spin Co(II) protruding from the porphyrin plane toward the axial ligand by 0.1-0.2Å (12, 13, 19) or more. Thus reduction of Co(III) in Eq. [11] and [14] is accompanied by an adjustment of the metal site geometry as well as loss of one axial ligand. To the extent that the rate of electron transfer depends on either or both of these events, and it is likely that it does, involvement of a ligand **X** which is affixed indirectly to the porphyrin itself (via the surface) could cause severe constraints on the electron transfer rate. Neither the proposed **X**, carboxylate groups, or the Co$(NH_2)_4$TPP, attached as they are to the surface, have unrestricted motion on the surface, especially relative to one another. The mobility of C/~Co(NH_2)TPP should be greater than that of C/~Co$(NH_2)_4$TPP, being attached by one amide bond rather than two, and correspondingly Co/~Co(NH_2)TPP exhibits prewave and small Co(III)/II) wave effects less pronounced than for C/~Co$(NH_2)_4$TPP.

The above model of the axial ligand **X** as carboxylate groups attached to surfaces I and II, while consistent with the available experimental results, is nonetheless admittedly speculative. The evidence for some interfering ligand **X** is strong, but we have no direct, only circumstantial evidence identifying **X** as carboxylate. Precedent for our model is found, however, in a prior proposal by Kuwana and co-workers (21) that carbon surface oxides can axially bind to and induce the adsorption of cobalt tetrapyridylporphyrin from aqueous acid.

Anodic Photocurrents at Silver Electrodes in Halide Solutions

M. A. Butler*

Sandia Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

Enhanced anodic photocurrents are observed at silver electrodes when the electrolyte contains halide ions. The potential behavior of this effect suggests the formation of a silver halide surface layer. This surface layer then enhances the photocurrent by reducing the back-reaction at the electrode surface. Considerable structure is observed in the photocurrent as a function of photon energy. This structure is related to the electronic structure of the surface film. These kinds of measurements appear to be a promising technique for studying films on metal electrodes such as might occur in corrosion or passivation processes.

Photocurrents at metal electrodes have been studied for a number of years. Both cathodic and anodic currents have been observed and attributed to photoemission processes and photoinduced surface reactions. A number of good reviews have been written on the subject (1, 2).

In this paper, we discuss anodic photocurrents at silver electrodes and the effects of adding halide ions to the electrolyte. Anodic photocurrents at silver electrodes have been observed previously (3). We observe that the addition of halide ions to the electrolyte greatly enhances these anodic photocurrents when the electrode is positive of some potential, E_0, or has recently been at a potential positive of E_0. With Cl^- ions in solution there is a hysteresis in the enhancement effect about E_0. As the potential is scanned in a positive direction, there is no enhancement until after E_0 is passed. If the potential is then scanned in a negative direction, the enhancement persists to potentials negative to E_0. This hysteresis in the enhancement of the anodic photocurrent suggests growth of a surface layer. Formation of this layer and its removal would take time and thus would give a hysteretic effect. From the value of E_0 we have identified this layer as AgCl. The corresponding behavior with appropriate shift in E_0 is observed with Br^- ions in solution. The structure observed in the spectral response will be discussed in terms of the electronic structure of the surface.

The experimental apparatus consisted of a Schoeffel 500W xenon lamp and high intensity monochromator. The monochromatic light is modulated with a PAR chopper at 13.6 Hz before being incident upon a three-electrode electrochemical cell with quartz windows. The silver electrodes are nominally 99.99% pure, polycrystalline foils, which are etched in aqua regia diluted 1:5 and rinsed in distilled water. This procedure is not essential as the enhancement effect is not very sensitive to electrode preparation procedures. The electrolytes are reagent grade with no additional purification. The potential of the Ag electrode is controlled by a PAR Model 173 potentiostat. The output of the potentiostat goes into a PAR Model 124A lock-in amplifier and the photoresponse is detected at the chopping frequency. By scanning the wavelength of the incident light a spectral response curve is produced such as shown in Fig. 1. The cutoff at short wavelengths is due to a loss of light intensity.

Both spectra in Fig. 1 are taken at the same potential +0.1V (SCE). As can be seen spectrum (B) shows a strong photoresponse while spectrum (A) shows negligible photoresponse. The difference between these two measurements is that the electrode was biased to a more positive potential, +0.15V (SCE), for 10 min before spectrum (B) was taken at +0.1V (SCE). This illustrates hysteresis in the photoresponse and suggests chemical modification of the Ag surface. For a $2 \times 10^{-3}M$ KCl electrolyte the reaction (4)

$$Ag + Cl^- \rightarrow AgCl + e^- \quad [1]$$

occurs at a potential of +0.14V (SCE), which suggests the growth of an AgCl layer on the silver electrode surface. For our silver electrodes 10 min at +0.15V (SCE) corresponds to growth of a film ~400Å thick. We believe that the enhancement effect arises from the growth of this surface layer. Previous experiments to

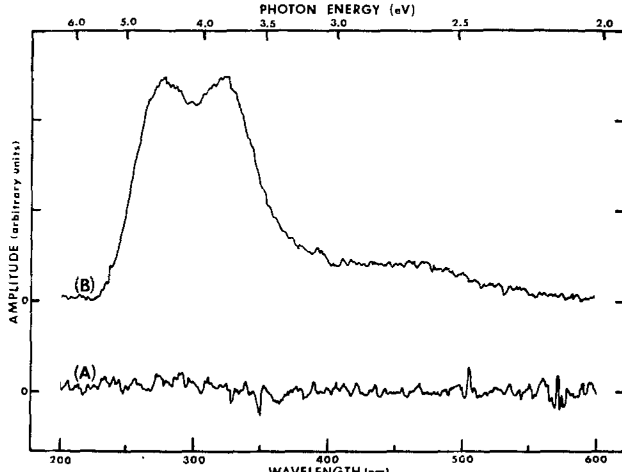

Fig. 1. The spectral response uncorrected for light intensity of an Ag electrode in 2M H_2SO_4 with $2 \times 10^{-3}M$ KCl electrolyte. Spectrum (A) is taken at +0.1V (SCE) and spectrum (B) at +0.1V (SCE) after being at +0.15V (SCE) for 10 min. The sensitivity in spectrum (A) is ten times greater than in spectrum (B).

Key words: electrolyte, films, surfaces.

observe the effects of Cl^- ions on photocurrents at Pt and Au electrodes did not show significant enhancement effects (5). This is because the potential was always negative of the potential for formation of platinum and gold chlorides.

Photoemission of electrons from a metal electrode into an aqueous electrolyte is another example of internal photoemission (6). The electrolyte may be considered an amorphous semiconductor (7) and the electron is photoemitted into the empty conduction band [see Fig. 2(a)]. Thus, all metals show the same threshold for photoemission into aqueous electrolytes (2). Conversely, anodic photocurrents may arise from emission of photoexcited holes into the valence band of the aqueous electrolyte [see Fig. 2(a)], although this interpretation of anodic photocurrents is still subject to some controversy (8).

The magnitude of the photoemitted currents is determined by a number of factors. The amorphous nature of the aqueous electrolyte suggests considerable scattering and indeed the range of photoemitted electrons is observed (9) to be 20-30Å. At such a distance from the metal surface, back reactions on the electrode surface are highly likely. For electron emission the back reaction can be reduced by a suitable choice of scavenger in the electrolyte (2). A good scavenger for holes has not yet been found. The net observed photocurrent is the difference between the photoemission and back-reaction currents.

Although the morphology of our films is not known and undoubtably is not simple, we will assume for purposes of analysis a uniform surface layer. Then the energy level diagram is as shown in Fig. 2(b). The light is incident through the electrolyte and can cause photoexcitation at various depths in the surface layer structure. For photons of energy less than the silver halide bandgap, internal photoemission from the silver into the silver halide will be observed. The transport of the photoexcited electron or hole in the silver halide will depend on trap sites and the electric field in the halide layer. The actual character and composition of this layer is complex because ionic conduction of the Ag^+ ion is expected at room temperature (10). An excess of Ag^+ ions in the layer may be a source of traps for any photoexcited electrons. At the interface with the electrolyte, the photoexcited charge carriers will cause an electrochemical reaction to take place, probably relating to decomposition of the AgCl. The only requirement is that the electron-driven electrochemical reactions have redox potentials below the conduction band and the hole-driven electrochemical reactions have redox potentials above the valence band. For electrons which reach this interface a possible reaction is the reverse of that given in Eq. [1]. For holes we may speculate that the following reaction is possible

$$2AgCl + 2h \rightarrow 2Ag^+ + Cl_2 \quad [2]$$

since the standard potential is +1.4V (SCE) and the valence bandedge occurs at +2.3V (SCE) for AgCl. At any given photon energy the net photocurrent observed is the sum of electron and hole currents.

For photons with energy larger than the bandgap of the silver halide we expect additional excitations across the bandgap in the halide layer. Again the disposition of these photoexcited carriers will depend on trapping and the electric fields in the surface layer.

The magnitude of the photocurrents observed for such a surface layer structure should be different than for the bare metal electrode. For any electron or hole which reaches the electrolyte and reacts to form some charged species in solution, the back reaction will be drastically reduced. A number of factors contribute to this effect. Most important, an electron or hole which reacts with the electrolyte must lose energy equal to the difference between the relevant redox potential and the appropriate bandedge. Thus, the halide layer creates a potential barrier on the order of 1 eV which must be overcome for the back reaction to occur.

Some information about the electronic structure of the surface may be obtained by examining the spectral response curves. The yield curves for Ag:AgCl and Ag:AgBr are shown, respectively, in Fig. 3 and 4. We see that for these anodic photocurrents, considerable structure exists in the yield curves. It does not

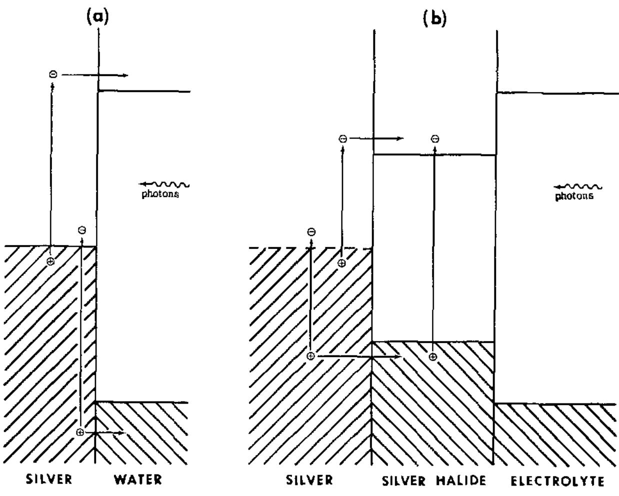

Fig. 2. The energy level diagram for the silver electrode with and without a silver halide layer on the surface. (a) The excitations for electron and hole photoemission from silver into water considered as an amorphous semiconductor. (b) The photoexcitation processes from silver into the silver halide layer and within the silver halide layer. At the surface of the electrolyte, the excited carriers react to form some unknown species in the electrolyte.

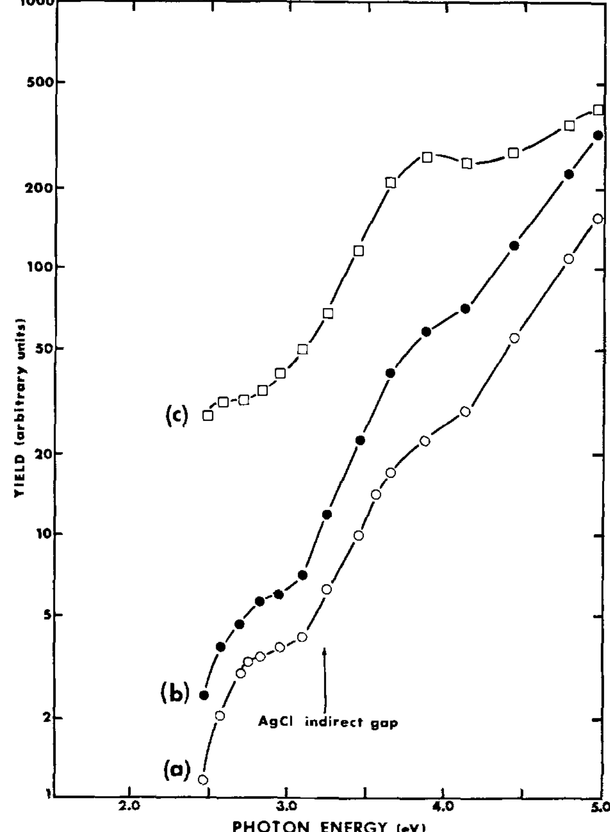

Fig. 3. The spectral response curves, corrected for light intensity, for an AgCl layer on an Ag electrode at +0.1V (SCE). The layer thickness is on the order of 500Å and varies from (a) to (c) with increasing thickness. The bandgap of silver chloride is indicated.

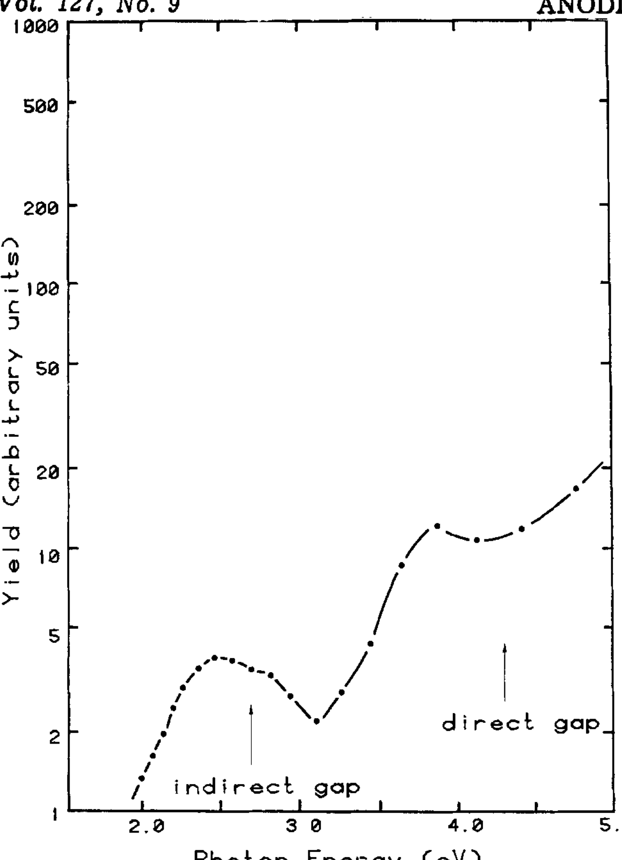

Fig. 4. The spectral response curve, corrected for light intensity, for an AgBr layer on an Ag electrode at 0.0V (SCE). Both the indirect and direct bandgaps of AgBr are indicated.

appear that this structure correlates with the known bandgaps of the halide layers.

For a clean Ag metal electrode a peak is sometimes observed in the yield spectrum due to surface roughness which allows optical excitation of surface plasmons (3). These surface excitations can result in generation of excess excited holes and electrons near the electrode surface which can then result in photoanodic or photocathodic currents depending on the electrode potential (3). Such a surface plasmon should exist at the Ag:Ag halide interface and will occur at a photon energy given by (11)

$$\epsilon_1(h\nu_{sp}) = -\epsilon_d \quad [3]$$

were ϵ_1 is the dielectric constant of Ag (12) and ϵ_d the dielectric constant of the halide film (13). If the interface is sufficiently rough to allow the photons to couple to this plasmon, we would expect structure in the yield spectra at 3.2 eV for both AgCl layers and AgBr layers. From Fig. 3 and 4, we see that dips occur in the photoanodic current which would correspond to the surface plasmon contributing a photocathode component to the current. Considering the potentials at which these spectra were taken, this is consistent with the observations in Ref. (3).

While one would normally expect a yield curve to be a monotonically increasing function, there appears to be a peak in both the AgBr and AgCl data at about 3.8 eV. The common nature of this peak to both halides suggests that it is a feature of the silver rather than specifically the halide layer. A peak at this energy has been previously identified as the excitation of a longitudinal volume plasmon which then decays into single particle excitations which contribute to the photoemission current (14). While excitation of this plasmon required p-polarized light and in our experiment the light was incident normal to the surface, the polycrystalline nature of the electrode and its rough surface would make excitation of this plasmon possible. Whether such an excitation should contribute an anodic or cathodic component to the photocurrent will depend on potential, relative lifetime of photoexcited holes and electrons, and other factors. Thus, it is not clear that it should exhibit the same sign as the surface plasmon effect since the excitation mechanism is different in the two cases. The observation of this peak suggests the possibility of a very rough halide layer on the surface where the underlying silver is sufficiently exposed to the electrolyte to allow direct photoemission without influence of the halide layer.

For photon energies below the bandgap of the halide and the threshold for photoemission into the electrolyte, we still see a contribution to the yield curve. This is attributed to internal hole photoemission from the Ag into the Ag halide followed by a reaction at the silver halide surface. This hypothesis is best explored by analyzing the thresholds of the yield curves. In Fig. 5, we show Fowler plots for two examples of chloride ion and one of bromide ion in solution. Whether $Y^{0.5}$ should be plotted rather than $Y^{0.4}$ is still an unsettled question relating to shielding of the photoemitted electron charge by ions in the electrolyte (1). Since our data do not cover a sufficient range to differentiate these two behaviors, we use the form we believe to be correct. Note that for the chloride example, a shift in potential of the Ag electrode is reflected in a corresponding shift in the photocurrent threshold. This suggests that the additional potential is dropped across the Ag:Ag halide interface and not in the Ag halide layer or at the Ag halide:electrolyte interface. This behavior is not typical of conventional metal-semiconductor junctions and arises because of the unique properties of the silver halides.

This interface is a blocking junction for electronic conduction since the Fermi level of Ag is in the bandgap of the silver halide (see Fig. 2). However, the

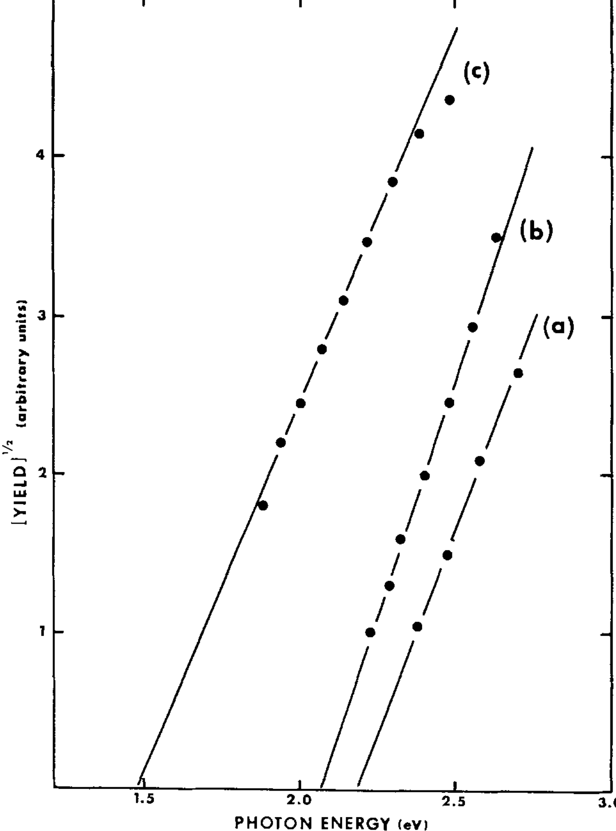

Fig. 5. Fowler plots for anodic photocurrents on a silver electrode. The potentials and halide on concentrations are: (a) 0.1V (SCE) 2 × 10^{-3}M KCl, (b) 0.2V (SCE) 5 × 10^{-5}M KCl, and (c) 0.0V (SCE) 2 × 10^{-3}M KBr. The threshold energies are: (a) 2.18 eV, (b) 2.07 eV, and (c) 1.48 eV.

silver halides are also Ag^+ ion conductors at room temperature with a conductivity for polycrystalline (AgBr) of about (15) 10^{-5} $(\Omega\text{-cm})^{-1}$. Our halide layers are estimated from measurements of total charge used in growing the layers to be $\lesssim 10^3$Å thick. Thus, they would have a resistance for a 1 cm^2 sample of about 1Ω. Since the d-c currents flowing when the photoresponse measurements are made are at most 10^{-4} A/cm^2, we would expect at most a voltage drop across the halide layer of ~0.1 mV. Thus, the film cannot support a potential drop of any size.

The electrochemical reaction which results in transport of Ag^+ ions across the Ag:Ag halide interface is one for which the exchange current density at room temperature is quite small ($\ll 10^{-6}$ A/cm^2) (16). Thus, it could support a considerable overpotential. We believe that the shift in the photocurrent threshold in Fig. 5 for the two AgCl layers is evidence for this overpotential.

The indirect bandgap of AgCl is 3.25 eV (17). Internal photoemission of electrons from Ag into AgCl was observed previously (18) to have a threshold of 1.1 eV at low temperature. At these temperatures, the ionic conduction is frozen out and the major part of the applied potential will be dropped across the AgCl. Thus, we would expect the threshold for hole photoemission, with little or no potential drop across the Ag:AgCl interface, to be at ~2.15 eV. This is in reasonable agreement with the thresholds that we observe.

An important question to ask is why the Fermi level in the Ag occurs ~1.1 eV below the conduction band of the AgCl. For conventional metal:electrolyte interfaces at equilibrium we expect the Fermi level in the metal to be pinned at the redox level in the electrolyte. If AgCl is considered as an electrolyte then a similar argument can be made. The Fermi level in the Ag must be pinned at the electrochemical reaction potential for

$$Ag^+(AgCl) + e^- \leftrightarrow Ag(\text{metal}) \qquad [4]$$

otherwise considerable current will be flowing across the interface. This concept of equilization of electrochemical potentials may be relevant to the determination of barrier heights at other semiconductor-metal interfaces.

For the AgBr layer the bandgap is smaller, 2.68 eV (17). The threshold for electron emission has not been measured but we would expect it to be similar to that for AgCl, since the Ag^+ ion transfer reaction

$$Ag^+(AgBr) + e^- \leftrightarrow Ag(\text{metal}) \qquad [5]$$

should occur at a similar electrochemical potential to the transfer reaction at the Ag:AgCl interface. Thus, the hole photoemission threshold should decrease approximately the same amount as the bandgap decreases or to about 1.5 eV. This is in reasonable agreement with the measured threshold of 1.48V, since overpotentials of a few tenths of a volt are possible at the Ag:AgBr interface.

These results for AgCl and AgBr films on silver electrodes illustrate the sensitivity of this technique to the films. Drastic changes in the spectral response of these electrodes are observed. The potential for the onset of enhanced photocurrents identifies the surface reaction taking place and thus the chemical nature of the surface film. The spectral response of these electrodes gives considerable information about the electronic structure of the surface as illustrated by the data. The photoresponse of electrodes appears to be one of the most promising techniques for examining solid-liquid interfaces and should find useful application for studying corrosion and passivation processes.

A Thermodynamic Theory of Dissolution Potential and Further Tests of the Theory

R. P. Rastogi and S. A. Kahn[1]

Department of Chemistry, Gorakhpur University, Gorakhpur, U.P. India

ABSTRACT

A theory of dissolution potential of electrolytes has been developed on the basis of the thermodynamics of irreversible processes. The theory is found to be in agreement with the available experimental data. In order to provide further tests of the theory, the diffusion and dissolution potentials of KI in dimethylformamide-water mixtures and of KCl in KCl-HCl aqueous solutions have also been measured. The sign of diffusion potential and dissolution potential are found to be the same in the former case, in conformity with the predictions of the theory. The measurements of dissolution potential of KCl in KCl-HCl aqueous solutions further confirm the theory. Although the dissolution potential of KCl in water alone is negative, it is positive in aqueous KCl-HCl mixtures.

The phenomenon of dissolution and precipitation potential was discovered by Rastogi, Dass, and Batra (1) in 1961. Comprehensive studies of these potentials have been reported by Rastogi and co-workers (2-5). They have explained the development of these potentials on the basis of unequal mobilities of anions and cations. It has been postulated by these workers that the precipitation potential develops due to a difference in the rate of attachment of cations and anions during crystallization, and dissolution potential develops due to a difference in the rate of detachment of cations and anions during dissolution. In the light of this mechanism Rastogi, Shukla, and Bhagat (4) could explain the sign and magnitude of precipitation and dissolution potentials in a large number of cases.

Recently Girdhar and co-workers (8, 9) have studied the precipitation and dissolution potentials of a number of electrolytes in aqueous medium. They have tried to explain the development of these potentials on the basis of a solvation mechanism (8, 10).

Ibl *et al.* (6, 7) have recently reported studies on crystallization and dissolution potentials using single crystals. They have tried to explain the phenomenon in terms of a "corrosion" model based on the difference in the kinetics of the dissolution of cations and anions.

More intensive studies are necessary in order to have a clear picture of the phenomenon and hence the present investigation was undertaken. In this communication an attempt has been made to develop a theory of dissolution potential on the basis of the thermodynamics of irreversible processes. It is found that the theory gives a satisfactory explanation of the observed facts.

In order to have a sensitive check of the theory measurements of the following quantities can be made.

(*i*) Diffusion potential and dissolution potential of a number of electrolytes in solvents in which $(U_+^{\circ} - U_-^{\circ})$ may have different signs, where U_+° and U_-° are the ionic mobilities of cations and anions, respectively.

(*ii*) Diffusion potential and dissolution potential of an electrolyte in a mixture of solvents in which $(U_+^{\circ} - U_-^{\circ})$ may change sign with change in composition.

(*iii*) Diffusion and dissolution potential of KCl in KCl-HCl aqueous solutions in which $(U_{K^+}^{\circ} - U_{Cl^-}^{\circ})$ can be very large (15).

Measurements of type (*i*) have been reported by Rastogi, Shukla, and Bhagat (4) and Vishnu, Khan, and Jahan (13). Thermodynamic theory is found to be in accord with their findings. Experimental data of type (*ii*) and (*iii*) are reported in this communication. The results are striking and confirm the underlying hypothesis of the thermodynamic theory.

Thermodynamic Theory of Dissolution Potential

The physics of dissolution potential can be understood from the schematic diagram given in Fig. (1). When a platinum electrode loaded with the crystals of an electrolyte (α-phase) is introduced into the solvent, dissolution starts immediately. Ions detach from the surface of the crystal and a narrow zone of high concentration is set up in its vicinity. We shall call it β-phase for convenience. From the kinetics of dissolution it has been found that the process of dissolution is diffusion controlled and the crystal maintains a state of near saturation in the liquid film adjacent to it (14). The justification of the existence of β-phase is further provided by the fact that the phase potential is a reality. In the steady state the rate at which ions become detached from the crystal surface is equal to the rate at which they diffuse away from the liquid film (β-phase) adjacent to the surface of the crystal. The concentration of the electrolyte in the β-phase would vary with time but we shall assume that at a particular instant a steady concentration is attained. The ions diffuse away from β-phase and go into the bulk of the solvent, where a concentration gradient is set up. We shall call it as δ-phase for convenience.

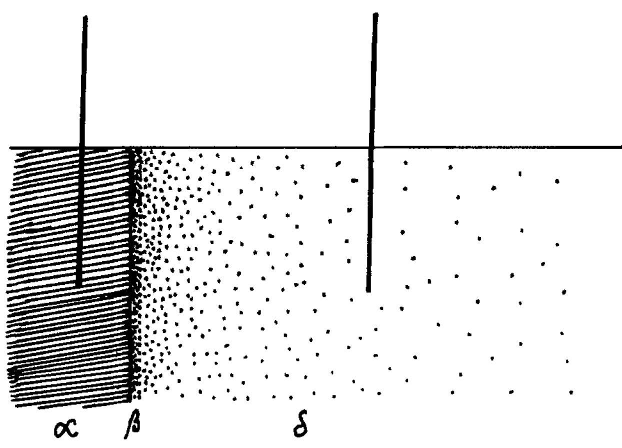

Fig. 1. Schematic diagram of dissolution cell

[1] Present address: Chemistry Department, St. Andrew's College, Gorakhpur, India.

Key words: thermodynamics, dissolution, potential.

Thus the above system comprises a discontinuous system involving α- and β-phases and a continuous system involving δ-phase. We use the terms "continuous" and "discontinuous" as they are understood in the terminology of irreversible thermodynamics. It should be noted that such a combined system has not been examined from the viewpoint of nonequilibrium thermodynamics so far. We present below a formal treatment of such a system.

The total entropy of the system would be given by the equation

$$TdS = TdS^{\alpha} + TdS^{\beta} + TdS^{\delta} \quad [1]$$

where dS^{α}, dS^{β}, and dS^{δ} are the entropy changes for the three sub-systems.

The Gibbs equation for the sub-systems α and β would be given by

$$TdS^{\alpha} = dU^{\alpha} + PdV^{\alpha} - \sum_{i=1,2} (\mu_i^{\alpha} + e_i\phi^{\alpha})dM_i^{\alpha} - \frac{2\gamma}{\rho r}dM^{\alpha} \quad [2]$$

$$TdS^{\beta} = dU^{\beta} + PdV^{\beta} - \sum_{i=1,2} (\mu_i^{\beta} + e_i\phi^{\beta})dM_i^{\beta} \quad [3]$$

where μ_i^{α} = chemical potential of component i in the phase α, e_i = the charge carried by i, ϕ^{α} = electrical potential of phase α, dM_i^{α} = change of mass of component i in phase α, γ = surface energy at α-β interface, ρ = density , r = radius, and M = molecular weight. The terms with β suffix have similar meaning in β-phase.

Thus from Eq. [1], [2], and [3] we get

$$TdS = dU^{\alpha} + PdV^{\alpha} - \sum_{i=1,2} (\mu_i^{\alpha} + e_i\phi^{\alpha})dM_i^{\alpha} - \frac{2\gamma}{\rho r}dM^{\alpha} + dU^{\beta} + PdV^{\beta} - \sum_{i=1,2} (\mu_i^{\beta} + e_i\phi^{\beta})dM_i^{\beta} + TdS^{\delta} \quad [4]$$

Thus,

$$T\frac{dS}{dt} = \frac{dQ^{\alpha,\beta}}{dt} - \sum_{i=1,2} (\mu_i^{\alpha} + e_i\phi^{\alpha})\frac{dM_i^{\alpha}}{dt} - \sum_{i=1,2} (\mu_i^{\beta} + e_i\phi^{\beta})\frac{dM_i^{\beta}}{dt} - \frac{2\gamma}{\rho r}\frac{dM^{\alpha}}{dt} - T\frac{dS^{\delta}}{dt} \quad [5]$$

Now putting

$$-\frac{dM_i^{\alpha}}{dt} = \frac{dM_i^{\beta}}{dt} = J_i \quad [6]$$

$$\frac{dM^{\alpha}}{dt} = J_c \quad [7]$$

$$-\frac{2\gamma}{\rho r} = J_c \quad [8]$$

$$S^{\delta} = sM \quad [9]$$

where s = specific entropy of the phase δ and M = total mass of the phase δ we write Eq. [5] as

$$T\frac{dS}{dt} = \frac{dQ^{\alpha,\beta}}{dt} + \sum_{i=1,2} J_i(\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + J_cX_c + TM\frac{ds}{dt} \quad [10]$$

Using the results of irreversible thermodynamics of continuous processes (11), we get

$$T\frac{ds}{dt} = \frac{1}{\rho}\left[-\text{div}\left(J_q^{\delta} - \sum \mu_i^{\delta}J_i^{\delta}\right) + \sum J_i^{\delta}X_i^{\delta}\right] \quad [11]$$

where J_i^{δ} = mass of the component i flowing per unit area per unit time across β-δ interface. μ_i^{δ} = chemical potential of the component i in the δ-phase. And

$$X_i^{\delta} = e_i \text{ grad } \phi^{\delta} + \text{grad } \mu_i^{\delta} \quad [12]$$

Now if A is the area of β-δ interface and the mass flowing per unit area per unit time from phase β to the phase δ is the same all along the interface

$$J_i = AJ_i^{\delta} \quad [13]$$

Using Eq. [10] and [11] we get

$$T\frac{dS}{dt} = \frac{dQ^{\alpha,\beta}}{dt} + \sum_{i=1,2} J_i(\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + J_cX_c + \frac{M}{\rho}\left[-\text{div}\left(J_q^{\delta} - \frac{1}{A}\sum \mu_i^{\delta}J_i\right) + \frac{1}{A}\sum J_iX_i^{\delta}\right] \quad [14]$$

Or

$$T\frac{dS}{dt} = \left[\frac{dQ^{\alpha,\beta}}{dt} - \frac{M}{\rho}\text{div}\left(J_q^{\delta} - \frac{1}{A}\sum \mu_i^{\delta}J_i\right)\right] + \sum_{i=1,2} J_i[(\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + 1X_i^{\delta}] + J_cX_c \quad [15]$$

When we consider the gradient along the x-axis to be uniform, Eq. [12] yields

$$X_i^{\delta}\int_{x=0}^{x=1} dx = e_i\int_{\phi_0}^{\phi_1} d\phi^{\delta} + \int_{\mu(\text{sat})}^{\mu(\text{soln.})} d\mu^{\delta}$$

or

$$1X_i^{\delta} = e_i\Delta\phi^{\delta} + \Delta\mu_i^{\delta} \quad [16]$$

Thus from Eq. [15] and [16] we get

$$T\frac{dS}{dt} = \left[\frac{dQ^{\alpha,\beta}}{dt} - \frac{M}{\rho}\text{div}\left(J_q^{\delta} - \frac{1}{A}\sum \mu_i^{\delta}J_i\right)\right] + \sum_{i=1,2} J_i[(\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + (e_i\Delta\phi^{\delta} + \Delta\mu_i^{\delta})] + J_cX_c \quad [17]$$

Hence from Eq. [17] we find

$$\sigma = \sum_{i=1,2} J_i[(\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + (e_i\Delta\phi^{\delta} + \Delta\mu_i^{\delta})] + J_cX_c \quad [18]$$

Or

$$\sigma = \sum_{i=1,2} J_ix_i + J_cX_c \quad [19]$$

where

$$x_i = ([\Delta\mu_i^{\alpha,\beta} + e_i\Delta\phi^{\alpha,\beta}) + (e_i\Delta\phi^{\delta} + \Delta\mu_i^{\delta})] \quad [20]$$

Thus flux-force equations will be given by

$$J_1 = L_{11}x_1 + L_{12}x_2 \quad [21]$$

$$J_2 = L_{21}x_1 + L_{22}x_2 \quad [22]$$

The current I flowing through the system would be given by

$$I = (e_1J_1 + e_2J_2) \quad [23]$$

Since we measure the potential when $I = 0$, we get from Eq. [23], [22], and [21]

$$l_1x_1 + l_2x_2 = 0 \quad [24]$$

where

$$l_1 = e_1L_{11} + e_2L_{22} \quad [25]$$

$$l_2 = e_1L_{12} + e_2L_{22} \quad [26]$$

From Eq. [20] and [24] we get

$$l_1[(\Delta\mu_1^{\alpha,\beta} + e_1\Delta\phi^{\alpha,\beta}) + (e_1\Delta\phi^{\delta} + \Delta\mu_1^{\delta})] + l_2[(\Delta\mu_2^{\alpha,\beta} + e_2\Delta\phi^{\alpha,\beta}) + (e_2\Delta\phi^{\delta} + \Delta\mu_2^{\delta})] = 0 \quad [27]$$

Therefore

$$-(\Delta\phi^{\alpha,\beta} + \Delta\phi^{\delta}) = \frac{l_1}{e_1 l_1 + e_2 l_2}\Delta\mu_1^{\alpha,\beta} + \frac{l_2}{e_1 l_1 + e_2 l_2}\Delta\mu_2^{\alpha,\beta} + \frac{l_1}{e_1 l_1 + e_2 l_2}\Delta\mu_1^{\delta} + \frac{l_2}{e_1 l_1 + e_2 l_2}\Delta\mu_2^{\delta} \quad [28]$$

Using Onsager reciprocal relation

$$L_{12} = L_{21}$$

it can be easily proved that

$$\left(\frac{t_1}{e_1}\right)_{\Delta\mu_1=0,\Delta\mu_2=0} = \frac{l_1}{e_1 l_1 + e_2 l_2} \quad [29]$$

$$\left(\frac{t_2}{e_2}\right)_{\Delta\mu_1=0,\Delta\mu_2=0} = \frac{l_2}{e_1 l_1 + e_2 l_2} \quad [30]$$

where t_1 and t_2 are effective transport numbers. Thus from Eq. [28], [29], and [30] we get

$$-(\Delta\phi^{\alpha,\beta} + \Delta\phi^{\delta}) = \left[\frac{t_1}{e_1}\Delta\mu_1^{\alpha,\beta} + \frac{t_2}{e_2}\Delta\mu_2^{\alpha,\beta}\right] + \left[\frac{t_1}{e_1}\Delta\mu_1^{\delta} + \frac{t_2}{e_2}\Delta\mu_2^{\delta}\right] \quad [31]$$

There are two terms on the right side of Eq. [31]. Let us denote them as $(\Delta\phi)_{\mathrm{I}}$ and $(\Delta\phi)_{\mathrm{II}}$ for convenience. Thus we get

$$(\Delta\phi)_{\mathrm{I}} = \frac{t_1}{e_1}\Delta\mu_1^{\alpha,\beta} + \frac{t_2}{e_2}\Delta\mu_2^{\alpha,\beta} \quad [32]$$

$$(\Delta\phi)_{\mathrm{II}} = \frac{t_1}{e_1}\Delta\mu_1^{\delta} + \frac{t_2}{e_2}\Delta\mu_2^{\delta} \quad [33]$$

The right-hand side of Eq. [33] is the well-known equation for the diffusion potential. In terms of activity and mobility it is given by

$$(\phi\Delta)_{\mathrm{II}} = (\Delta\phi)_{\mathrm{Diff}} = -\frac{RT}{\mathbf{F}}\left(\frac{U^+ - U^-}{U^+ + U^-}\right)\ln\frac{a^{\delta}}{a^{\beta}} \quad [34]$$

where it has been supposed that

$$\frac{a_1^{\delta}}{a_1^{\beta}} = \frac{a_2^{\delta}}{a_2^{\beta}} = \frac{a^{\delta}}{a^{\beta}} \quad [35]$$

for uni-univalent electrolytes.

From Eq. [32] we have

$$(\Delta\phi)_{\mathrm{I}} = \frac{t_1}{\mathbf{F}}(\mu_1^{\alpha} - \mu_1^{\beta}) - \frac{t_2}{\mathbf{F}}(\mu_2^{\alpha} - \mu_2^{\beta}) \quad [36]$$

where

$$e_1 = -e_2 = \mathbf{F}$$

The chemical potentials in α and β phases are given by

$$\mu_i^{\alpha} = \mu_i^{0(S)} + RT\ln a_i^{(s)} \quad [37]$$

$$\mu_i^{\beta} = \mu_i^{0} + RT\ln a_i^{\beta} \quad [38]$$

where $\mu_i^{0(S)}$ and μ_i^0 are the standard chemical potentials in solid and solution, respectively. Further $a_i^{(s)}$ is the activity of the component i in solid phase α, which will be equal to unity, and a_i^{β} is the activity of component i in the liquid phase β.

Thus from Eq. [36], [37], and [38] we get

$$\mathbf{F}(\Delta\phi)_{\mathrm{I}} = [t_1\{\mu_1^{o(s)} - \mu_1^{o} - RT\ln a_1^{(\mathrm{sat'd})}\} - t_2\{\mu_2^{o(s)} - \mu_2^{o} - RT\ln a_2^{(\mathrm{sat'd})}\}] + RT\left[t_1\ln\frac{a_1^{(\mathrm{sat'd})}}{a_1^{\beta}} - t_2\ln\frac{a_2^{(\mathrm{sat'd})}}{a_2^{\beta}}\right] \quad [40]$$

where $a_1^{(\mathrm{sat'd})}$ and $a_2^{(\mathrm{sat'd})}$ denote the activities of ions 1 and 2 in the saturated solution. If $(\Delta\phi)_{\mathrm{Phase}}$ denotes the phase potential, it can be easily shown (12) that

$$\mu_1^{o(s)} - \mu_1^{o} - RT\ln a_1^{(\mathrm{sat'd})} = -\mathbf{F}(\Delta\phi)_{\mathrm{Phase}} \quad [41]$$

$$\mu_2^{o(s)} - \mu_2^{o} - RT\ln a_2^{(\mathrm{sat'd})} = +\mathbf{F}(\Delta\phi)_{\mathrm{Phase}} \quad [42]$$

where 1 denotes cation and 2 denotes anion. Hence from Eq. [40], [41], and [42] we get

$$\mathbf{F}(\Delta\phi)_{\mathrm{I}} = -\mathbf{F}(t_1 + t_2)(\Delta\phi)_{\mathrm{Phase}} - RT(t_1 - t_2)\ln\frac{a^{\beta}}{a^{(\mathrm{sat'd})}} \quad [43]$$

where we have supposed that

$$\frac{a_1^{(\mathrm{sat'd})}}{a_1^{\beta}} = \frac{a_1^{(\mathrm{sat'd})}}{a_2^{\beta}} = \frac{a^{(\mathrm{sat'd})}}{a^{\beta}} \quad [44]$$

As

$$(t_1 + t_2) = 1$$

and

$$(t_1 - t_2) = \frac{U^+ - U^-}{U^+ + U^-}$$

we get from Eq. [43]

$$(\Delta\phi)_{\mathrm{I}} = -(\Delta\phi)_{\mathrm{Phase}} - \frac{RT}{\mathbf{F}}\left(\frac{U^+ - U^-}{U^+ + U^-}\right)\ln\frac{a^{\beta}}{a^{(\mathrm{sat'd})}} \quad [45]^2$$

The second term on the right side of Eq. [45] denotes the dissolution potential. The crystal dissolves while $a^{\beta}/a^{(\mathrm{sat'd})} < 1$. When the ratio becomes equal to unity dissolution stops.

Thus $(\Delta\phi)_{\mathrm{Diss}}$ is given by

$$(\Delta\phi)_{\mathrm{Diss}} = -\frac{RT}{\mathbf{F}}\left(\frac{U^+ - U^-}{U^+ + U^-}\right)\ln\frac{a^{\beta}}{a^{(\mathrm{sat'd})}} \quad [46]$$

Thus from Eq. [31], [34], [44], and [45] we find that the observed dissolution potential would be given by

$$(\Delta\phi)_{\mathrm{Observed}} = (\Delta\phi)_{\mathrm{Phase}} + (\Delta\phi)_{\mathrm{Diss}} + (\Delta\phi)_{\mathrm{Diff}} \quad [47]$$

where the first, second, and third terms of Eq. [47] have already been defined by Eq. [41], [42], [46], and [34], respectively.

Experimental

Materials

B.D.H. chemicals (AR grade) were used without further purification. The specific conductivity of the DMF used as $1.95 \times 10^{-6}\ \Omega^{-1}\ \mathrm{cm}^{-1}$. Platinum electrodes fused in Pyrex glass tubes were welded to copper wire in order to avoid electrical contacts through mercury which might form unsuspected secondary cells. Coaxial cables were used which are unaffected by stray external fields. The platinum electrodes were thoroughly cleaned by boiling in nitric acid and then by heating in a flame before each experiment. The experiments were performed as described earlier (4).

Potentials were recorded with the help of a Lindemann Quadrant Electrometer. All parts of the experimental circuits were properly insulated. In order to avoid electrical disturbances, additional stabilizers were introduced into the circuit of electrometer mains.

Measurement of dissolution potential.—The dissolution potential was measured with the following cell

Pt | KI(Crystals) ¦¦ DMF | Pt

Two bare platinum electrodes were introduced in the dissolution cell containing the solvent and asymmetry potential was recorded between them. It was minimized as far as possible by a proper adjustment of electrical contacts and cleaning of electrodes once

[2] It should be noted that U^+ and U^- in Eq. [45] are the mobilities of the cations and anions at the crystal interface. However, these would be equivalent to ionic mobilities.

again if necessary. A uniform thick layer of the salt was deposited on one of the electrodes by controlled crystallization from a solution of the salt saturated at 75°C. The electrode loaded with the crystals of the salt was mechanically dipped in the dissolution cell. The potential thus generated was recorded as a function of time. The asymmetry potential was checked once again. The actual dissolution potential was determined by taking the asymmetry potential into account. Dissolution potentials of KI in various dimethylformamide-water compositions and those of KCl in aqueous KCl-HCl solutions were measured.

Measurement of diffusion potential.—The apparent diffusion potential was determined with the help of the following cell

Pt | Saturated solution of KI in DMF ⋮ Pure DMF | Pt

The experimental setup for the measurement of apparent diffusion potential was similar to that of Rastogi and Shukla (4). The buildup and decay of apparent diffusion potential was recorded.

Measurement of phase potential.—The phase potential, which is the potential difference arising from an electrical double layer developed at the liquid-crystal interface as a result of the dynamic equilibrium of ion migration from the crystal phase to the liquid phase and vice versa, was determined with the help of following cell

Pt | KI(Crystals) ⋮ Saturated solution of KI in DMF | Pt

A uniform thick layer of the salt was deposited on a platinum electrode by controlled crystallization from a saturated solution of the salt at 75°C. The electrode loaded with the crystals was mechanically dipped in a cell filled with the saturated solution of the salt.

The phase potential was measured with reference to the potential of another bare platinum electrode dipping in the above saturated solution. The asymmetry potential existing between the two platinum electrodes was taken into account in order to determine the phase potential. The potential difference was measured electrostatically by means of the electrometer.

Comparison with the experimental data.—Equations [46] and [47] are in general agreement with the available experimental data. These equations predict that (*i*) the sign of dissolution potential should depend on the sign $(U^+ - U^-)$ for an electrolyte, (*ii*) the magnitude of $(\Delta\phi)_{\text{Diss}}$ should be directly proportional to the magnitude of $\frac{U^+ - U^-}{U^+ + U^-}$, and (*iii*) the decay of observed dissolution potential with time should be similar to that observed in case of diffusion potential. The signs of the true dissolution potentials of alkali halides in acetone (4), formamide (4), and DMF (13) are in agreement with the first prediction. The experimental data reported by Rastogi, Shukla, and Bhagat (4) are in accord with the second prediction. The decay experiments on dissolution potential made by Rastogi *et al.* (3, 4), Girdhar *et al.* (9, 10), and Vishnu, Khan, and Jahan (13) are in agreement with the third prediction.

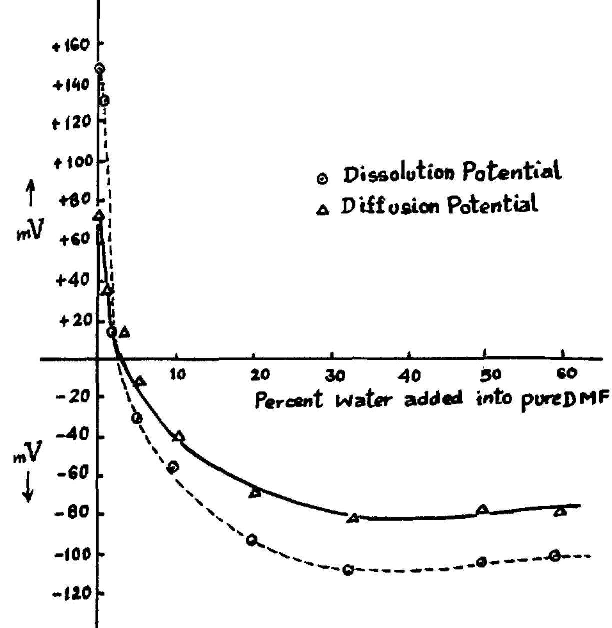

Fig. 2. Dissolution and diffusion potential of KI in DMF + H_2O mixtures.

The effect of temperature and concentration can also be predicted from Eq. [46]. These effects will be similar to those observed in case of diffusion potential. The experimental results of Rastogi and co-workers, and those of Girdhar and co-workers are once again in agreement with the theory.

The theory developed in the section "Thermodynamic Theory of Dissolution Potential" is also in agreement with the data reported in this communication.

The dissolution potential measured at various DMF-water compositions are given in Table I. The true dissolution potential was calculated from Eq. [47,] i.e.

True dissolution potential = observed dissolution potential
—diffusion potential
—phase potential

Results reported in Table I and plotted in Fig. 2 show that the sign of diffusion potential of KI in DMF-water mixtures exactly matches the sign of the dissolution potential of KI in the same solvent medium. From Eq. [34] and [46] we observe that the sign of both the diffusion potential and dissolution potential would depend upon the difference of the mobilities of cations and anions. Hence, according to the theory the sign of diffusion and dissolution potentials should match, and this is confirmed by the experimental data.

Results reported in Table II provide another strong confirmation of the thermodynamic theory of dissolution potential. Experiments on the dissolution potential of KCl in the aqueous KCl-HCl mixtures show that, whereas in pure water the dissolution potential is negative, it assumes positive values when HCl is added. This is understandable since the transport number of Cl^- is much greater than that of K^+ in the system. Accordingly Cl^- leaves the lattice much faster, making it positively charged. The diffusion potential and dissolution potential of KCl in

Table II. Dissolution potential of KCl-HCl aqueous solutions

Medium	t_{H^+}	t_{K^+}	t_{Cl^-}	Diff. pot. (mV)	Phase pot. (mV)	Obs. diss. pot. (mV)	True diss. (mV)
Cond. H_2O	—	0.4906	0.5094	-73 ± 3	-25 ± 1	-197 ± 3	-99 ± 7
0.075M HCl + 0.025M HCl	0.7456	0.0503	0.2041	-131 ± 3	-26 ± 1	-19 ± 1	$+138 \pm 5$
0.05M + 0.05M KCl	0.6198	0.1242	0.2560	-66 ± 3	-26 ± 1	-82 ± 3	$+174 \pm 7$
0.25M HCl + 0.075M KCl	0.4109	0.2477	0.3414	-33 ± 1	-23 ± 1	$+92 \pm 3$	$+148 \pm 5$

the aqueous KCl-HCl mixtures do not have the same sign (Table II), since the former is determined by the transport numbers of H^+, K^+, and Cl^- ions, and the latter is determined by the transport numbers of K^+ and Cl^- ions only.

Anodic Dissolution of Gold in Aqueous Alkaline Cyanide Solutions at Low Overpotentials

D. W. Kirk* and F. R. Foulkes*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

Potentiodynamic and potentiostatic methods were used to study the anodic dissolution of gold in aqueous alkaline cyanide at low overpotentials (in the region of -0.65 *vs.* SCE). The effect of cyanide and hydroxide concentration on the anodic dissolution rate at -0.65V *vs.* SCE was determined from weight loss measurements. The variation of the potential sweep profile with sweep rate and stirring rate was determined and Tafel parameters were measured. The steady-state gold dissolution was shown to follow the sequence

$$Au + CN^- \rightleftharpoons AuCN^-_{ads}$$

$$AuCN^-_{ads} \xrightarrow{\text{slow}} AuCN_{ads} + e^-$$

$$AuCN_{ads} + CN^- \rightleftharpoons Au(CN)_2^-$$

in which the second step is the rate-determining step. Measurements at sweep rates > 20 mV $\cdot$ sec^{-1} revealed various aspects of the reaction sequence which helped to reconcile conflicting statements found in the literature regarding the reaction mechanism.

Although the alkaline cyanide medium has been used extensively for the processing of gold, the basic electrochemical reactions of gold in this medium are not yet fully understood. In particular some confusion still exists concerning the anodic dissolution process at low overpotentials. In an earlier paper (1) the anodic dissolution of gold in aqueous alkaline cyanide was studied for a wide potential range (-0.9 to $+0.8$V[1]). Three current peaks found in potential sweep measurements were shown to be the result of a gold dis-

* Electrochemical Society Active Member.

Key words: anode, dissolution, kinetics, metals.

[1] All potentials are reported *vs.* the saturated calomel electrode.

solution process. The electron stoichiometry of the reaction in each of the regions was identified and indicated that $n = 0.85$, 0.95, and 1.05 for peaks 1 (−0.9 to −0.6V), 2 (−0.1 to +0.15V), and 3 (+0.2 to +0.38V), respectively. Later it was shown (2) that when competing chemical dissolution was taken into account, the n values became 1 for each of the three peaks.

A single reaction scheme

$$Au + CN^- \rightleftharpoons Au\,CN^-_{ads} \quad [1]$$

$$Au\,CN^-_{ads} \rightleftharpoons Au\,CN_{ads} + e^- \quad [2]$$

$$Au\,CN_{ads} + CN^- \rightleftharpoons Au(CN)_2^- \quad [3]$$

was shown to account for the reaction at the three peaks. The rate-determining steps for the dissolution process in the regions of peak 2 and peak 3 were identified. There is general agreement (1, 3-5) that the dissolution of gold in the region of peak 1 proceeds via the reaction sequence [1], [2], and [3], although in two cases (3, 4) the steps [1] and [2] have been combined. However, these studies do not all predict the same rate-determining step, hence the limiting step is still uncertain for the peak 1 region. MacArthur (3) used cyclic voltammetry and galvanostatic transients to study the process and concluded that step [3] was the rate-determining step. Cathro and Koch (4) used potentiostatic and galvanostatic methods and reported that

$$Au + CN^- \rightarrow Au\,CN_{ads} + e^- \quad [4]$$

was the rate-determining step. Eisenmann (5), using steady-state and relaxation methods with a rotating disk electrode, reported that step [2] was the rate-determining step. As a result of the discrepancies in the reported rate-determining step it was apparent that additional data were needed to clarify the dissolution process in the peak 1 region.

Experimental Methods

Solutions, prepared from analytical grade reagents and doubly distilled water were deoxygenated by bubbling with oxygen-free nitrogen gas for at least 30 min before an experiment. In experiments for which no stirring rate is reported the nitrogen gas was passed over the electrolyte during the measurements. Gold foil electrodes (>99.99% purity) were used for both the working and counterelectrodes. The reference electrode was a saturated calomel electrode. A Luggin capillary, housing the reference electrode, was positioned with the 0.1 cm diam capillary tip located 0.17 cm from the electrode. This configuration has been shown to distort the current density at the point of measurement by less than 1% (6-8). Because the maximum IR-drop for peak 1 was only 0.3 mV, the data were not corrected for IR-drop. Details of the cell and electronic equipment have been given in Ref. (1). Gold dissolution rates were determined from weight losses and electrode surface areas. Each experimental run was continued for a sufficient time to allow a minimum weight loss of 200 μg, which was measured using a semimicro balance with an accuracy of ±10 μg. The longest run was 2 hr. The surface area of the electrode was determined from potential scan measurements, using the linear relation between the current peak and the square root of the voltage scan rate for the oxidation of $Fe(CN)_6^{-4}$. This relationship has been given by Nicholson and Shain (9). A standard electrode pretreatment was necessary to achieve reproducibility. The electrode was first heated to redness in air, then etched for 10 sec in hot aqua regia, washed in doubly distilled water, dried, and weighed. It was immediately given a further treatment consisting of a 5 min reduction period in the electrolyte at −1.2V. This latter pretreatment was found to improve the reproducibility of the potentiodynamic measurements but did not affect the measured weight of the electrode. At the end of an experiment, the electrode was thoroughly washed in doubly distilled water, dried, and weighed.

Results and Discussion

The effect of cyanide and hydroxide concentration on the dissolution rate for the reaction at peak 1 was studied using six levels of cyanide and three levels of hydroxide. The results shown in Fig. 1 demonstrate that, for low cyanide concentrations (<0.2M), the dissolution rate is linear with cyanide concentration, and that the dissolution rate decreases with increasing hydroxide concentration.

The potential sweep rate dependence of the reaction at peak 1 is shown in Fig. 2. The peak current decreases with an increase in sweep rate, (v), and at sweep rates faster than 2 $mV \cdot sec^{-1}$, a new peak (1a) appears. This new peak begins to dominate for sweep rates ≥ 10 $mV \cdot sec^{-1}$. Therefore, two different peaks, and possibly two different mechanisms, may be studied, depending on the range of sweep rate employed. Indeed, the Tafel slope for sweep rates of 0.5 and 1.0 $mV \cdot sec^{-1}$ (peak 1) was found to be 0.12 ± 0.01 V/decade, while at 20 $mV \cdot sec^{-1}$, Tafel slopes of 0.36 ± 0.01 V/decade for peak 1 and 0.06 ± 0.01 V/decade

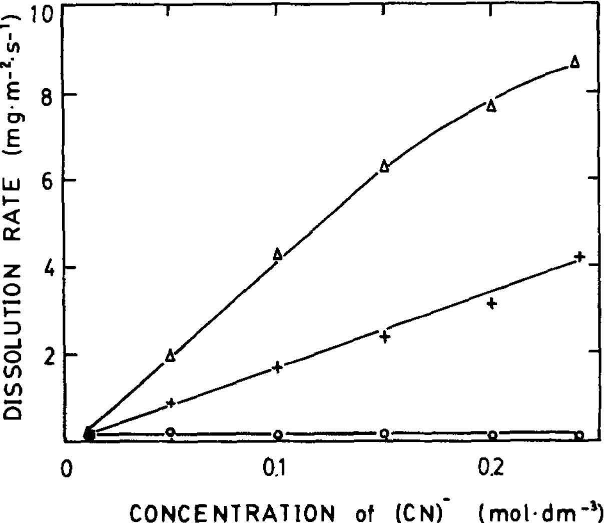

Fig. 1. Dependence of dissolution rate on free-cyanide and hydroxide concentration for peak 1(−0.65V vs. SCE); ○, 1.0M KOH; +, 0.1M KOH; △, 0.01M KOH; temperature = 23.5°C.

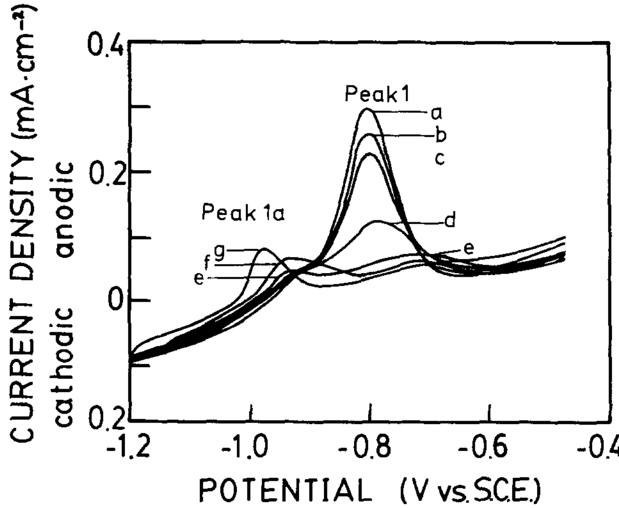

Fig. 2. Dependence of anodic single sweep profile on sweep rate for the region of peak 1: 1.0M KOH + 0.1M KCN; a) $v = 0.1$ $mV \cdot sec^{-1}$; b) $v = 0.2$ $mV \cdot sec^{-1}$; c) $v = 0.5$ $mV \cdot sec^{-1}$; d) $v = 1.0$ $mV \cdot sec^{-1}$; e) $v = 2.0$ $mV \cdot sec^{-1}$; f) $v = 10$ $mV \cdot sec^{-1}$; g) $v = 100$ $mV \cdot sec^{-1}$; temperature = 23.3°C.

for peak 1a were measured. At 100 mV·sec^{-1} no Tafel region was found. Some caution must be exercised in interpreting Tafel data from potential sweep measurements since the Tafel equation applies to steady-state conditions. The measurements for the slow sweep rates of 0.5 and 1.0 mV·sec^{-1} safely can be assumed to be at steady state since the slope was unchanged for either sweep rate. While the steady-state condition may not strictly apply to the measurements at 20 mV·sec^{-1}, it appears that the Tafel slope parameter increases with sweep rate. The Tafel slope for peak 1a at 20 mV·sec^{-1} would be valid if the reaction for this peak is sufficiently rapid to achieve steady-state conditions during the potential sweep. Typical sets of data for these measurements are shown in Fig. 3. Since measurements taken using different potential sweep rates yield different Tafel parameters, some of the discrepancy found in the literature for the rate-determining step for the initial cyanidization reaction may be understood.

Cathro and Koch (4) reported a Tafel slope of 0.13 V/decade for peak 1 from steady-state measurements. More recent measurements by Eisenmann (5) using steady-state current potential measurements with a rotating gold disk electrode in 0.1M KCN + 0.01M KOH electrolyte can be shown to yield a Tafel value of 0.11 V/decade. Both these values compare favorably with the measured Tafel slope of 0.12 ± 0.01 V/decade obtained in this work for the slow sweep measurements.

MacArthur (3), who used potential sweep measurements with sweep rates greater than 40 mV·sec^{-1}, reported a rate-determining step (step 3) which would theoretically yield a Tafel value of 0.059 V/decade.[2] This value is within the experimental limits for that found for peak 1a in this work (0.06 ± 0.01 V/decade) for sweep rates of 20 mV·sec^{-1}.

The reaction scheme [1], [2], [3] presented earlier can account for the reaction at peak 1 since, for steady-state measurements (or very slow scan measurements), step [2] has a theoretical Tafel value of 0.12 V/decade.[2] In addition, step [2] theoretically should show a linear dependence on cyanide concentration for low cyanide concentration, and the rate of dissolution should decrease with increase in hydroxide concentration (1). This behavior is observed for the steady-state dissolution reaction in the region of peak 1, as shown in Fig. 1.

Since step [2] does not directly involve the reaction with the cyanide in the solution, stirring rate would be expected to have little effect. At a sweep rate of 1 mV·sec^{-1} no stirring rate dependence is found for peak 1 (see Fig. 4a). Therefore, although the rate-

[2] See Appendix for derivation of theoretical Tafel slopes.

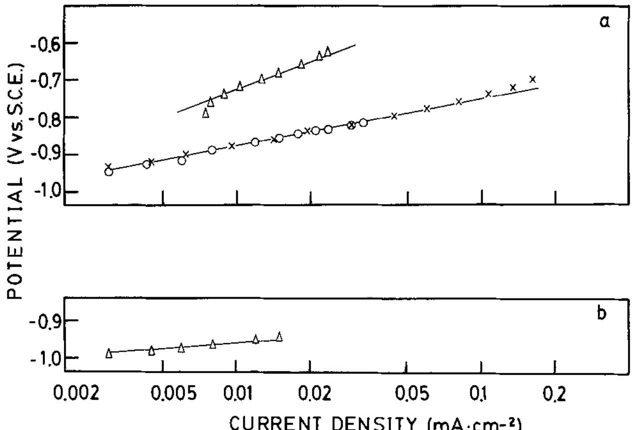

Fig. 3. Typical data for Tafel slopes in the potential region −1.2 to −0.6V at various sweep rates (temperature = 23.5°C, electrolyte 0.1M KOH + 0.1M KCN. a) Peak 1: ○—0.5 mV · sec^{-1}; ×—1.0 mV · sec^{-1}; △—20 mV · sec^{-1}. b) Peak 1a: △—20 mV · sec^{-1}.

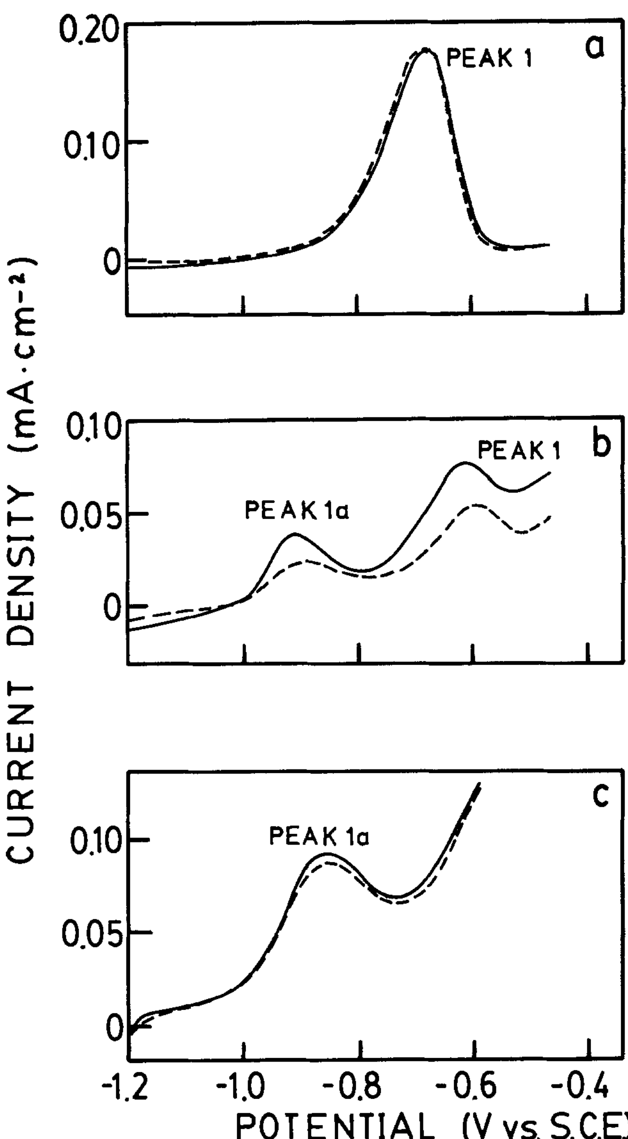

Fig. 4. Effect of stirring on the reaction in the region of peak 1: electrolyte 0.1M KOH + 0.1M KCN, temperature = 23.5°C. a) v = 1.0 mV · sec^{-1}; b) v = 20 mV · sec^{-1}; c) v = 100 mV · sec^{-1}. ——— electrolyte well stirred; - - - - - - electrolyte unstirred.

determining step [4] proposed by Cathro and Koch correctly predicts the measured Tafel slope, the reaction does not account for the lack of dependence on the stirring rate. Thus the complete reaction sequence [1], [2], and [3], in which the adsorption of the cyanide species is considered, is necessary to model the dissolution process. The Tafel slope and the lack of stirring-rate dependence show that step [2] is the rate-determining step. This rate-determining step is in agreement with that proposed by Eisenmann (5) who had also used steady-state measurements. The variation of the potential sweep profile with sweep rate can yield information about the reaction mechanism. The decrease in the height of peak 1 with increase in sweep rate (Fig. 2) indicates that the reaction rate of the rate-determining step (step 2) is slow relative to these sweep rates. Therefore, the extent of reaction 2 is decreased by increase in sweep rate. As the extent of this reaction is decreased, the previous stage (step 1) should become important. Thus the measured Tafel parameter for peak 1 is larger at 20 mV·sec^{-1} and reflects the contribution of step [1] which has a theoretical Tafel slope of ∞. In addition, stirring rate would affect step [1]; therefore stirring rate should start to influence peak 1 at the faster sweep rates, as observed in Fig. 4b.

In contrast, the behavior of peak 1a shows that as the sweep rate increases the peak current also increases. This behavior is typical for fast electrochemical reactions such as adsorption reactions (10, 11). For a kinetically fast adsorption process the amount of charge passed during a single potential sweep remains constant regardless of sweep rate and therefore as the measurement time is decreased the peak size is correspondingly increased. Although the analysis of reactions where both adsorption and diffusion are important is difficult, it has been shown that when adsorption of either the products or reactants of a reaction occurs, then linear scan voltammetry can give rise to the formation of pre-peaks or post-peaks. This type of phenomenon has been discussed by several workers (12-14). Although the exact behavior of the adsorption peak depends on the type of adsorption and the free energy of the bonding process, the effect of strong adsorption of the product of the reaction most closely resembles peak 1a behavior. For the reaction sequence (12) given below the effect of sweep rate on the potential profile for the case of strong product adsorption is shown in Fig. 5

$$R_{soln} \rightleftharpoons R_{ads}$$

$$R_{ads} \rightleftharpoons O_{ads} + ne^-$$

$$O_{ads} \rightleftharpoons O_{soln}$$

where O is the oxidized species and R is the reduced species.

This is the behavior of peak 1a shown in Fig. 2. Since peak 1a begins to dominate the potential sweep profile for sweep rates greater than 20 $mV \cdot sec^{-1}$ and since peak 1a appears to be related to the adsorption of the product of the reaction [1], [2], and [3], one would expect the final step in the reaction (step [3]) and the subsequent diffusion of the product to characterize the reaction process at these sweep rates.

It is evident therefore that electrochemical measurements taken at sweep rates above 20 mV/sec might reflect the desorption of the $Au(CN)_2^-$ species from the electrode surface. The Tafel parameter measured in this work for peak 1a at 20 $mV \cdot sec^{-1}$ was 0 06 V/decade and corresponds to the theoretical value of 0.059 V/decade for step [3]. This is in agreement with the rate-determining step reported by MacArthur who used potentiodynamic methods with sweep rates greater than 40 mV/sec. Step [3] theoretically should show a dependence on stirring rate (1) as would the desorption of the product. In Fig. 4 at 20 $mV \cdot sec^{-1}$ it can be seen that stirring rate does increase the peak 1a size. However, at 100 $mV \cdot sec^{-1}$, little or no stirring rate dependence is found. This is probably the consequence of insufficient transfer of reactants or products through the boundary layer to be influenced by bulk stirring, at this sweep rate. Thus the behavior of gold in aqueous alkaline cyanide at low overpotentials

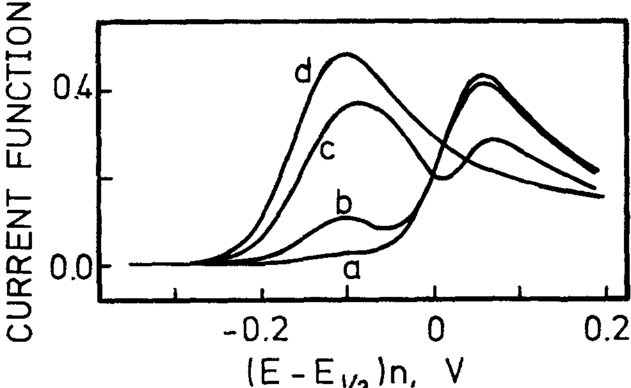

Fig. 5. Theoretical variation of potential sweep profile with sweep rate for product strongly adsorbed. From Ref. (9). Relative scan rates: a, 1; b, 25; c, 625; d, 2500.

is consistent with the reaction scheme [1], [2], and [3] with step [2] limiting the steady-state dissolution rate. Potentiodynamic measurements at sweep rates of 20 $mV \cdot sec^{-1}$ reflect effects attributable to the slow kinetics of step [2]. Therefore it appears that some of the discrepancy found in the literature for the reported rate-determining step is a result of the different measurement techniques. The slow scan or steady-state methods show that the rate of dissolution is controlled by step [2]. At sweep rates greater than 20 $mV \cdot sec^{-1}$ the potential sweep profile measurements suggest that the adsorption of the product of the reaction dominates the measurements.

Conclusions

1. The dissolution rate of gold in aqueous alkaline cyanide was found to increase linearly with increase in cyanide concentration (<0.20M) and decrease in hydroxide concentration at low overpotentials (−0.65V *vs.* SCE).

2. Tafel parameters from slow potential sweep measurements ($\leq$ 1.0 $mV \cdot sec^{-1}$) and the lack of variation of the potential sweep profile with stirring rate demonstrate that step [2] is the rate-determining step for the anodic steady-state dissoluion of gold at low overpotentials.

3. The formation of peak 1a at sweep rates $\geq$ 20 $mV \cdot sec^{-1}$ appears to be the result of product adsorption. The potentiodynamic behavior of peak 1a, the measured Tafel parameter at 20 $mV \cdot sec^{-1}$, and the stirring rate dependence indicate that step [3] dominates the process at these sweep rates. This agrees with the rate-determining step reported by MacArthur for fast (> 40 $mV \cdot sec^{-1}$) potential sweep measurements.

4. The variation in the reported rate-determining step for the anodic dissolution of gold resulted in one study (4) because the adsorption and electrochemical charge transfer steps were combined, and, although the combined step correctly predicted the observed Tafel parameter, it did not predict the observed lack of stirring rate dependence of the potential sweep profile. In the other study (3), measurements taken at sweep rates > 20 $mV \cdot sec^{-1}$ reflected the limitations of the kinetics of the reaction process under those conditions but do not necessarily apply to the steady-state process.

APPENDIX

Tafel Parameters

Reaction scheme: Anodic

[1] $Au + CN^- \rightleftharpoons AuCN^-_{ads}$

[2] $AuCN^-_{ads} \rightleftharpoons AuCN_{ads} + e^-$

[3] $AuCN_{ads} + CN^- \rightleftharpoons Au(CN)_2^-$

Cathodic:

$$Au(CN)_2^- \rightleftharpoons AuCN_{ads} + CN^- \quad [A\text{-}1]$$

$$AuCN_{ads} + e^- \rightleftharpoons AuCN^-_{ads} \quad [A\text{-}2]$$

$$AuCN^-_{ads} \rightleftharpoons Au + CN^- \quad [A\text{-}3]$$

$$\text{overall:} \quad Au(CN)_2^- + e \rightarrow Au + 2CN^-$$

Using $\alpha_{anodic} = n - \vec{\gamma}/\nu - r\beta'$ derived by Bockris (15)

from the generalized Butler-Volmer equation for the cathodic reaction, the following is obtained

rds	n	$\vec{\gamma}$	ν	r	β'	α_B	b_A
[A-1]	1	0	1	0	—	1	0.059
[A-2]	1	0	1	1	0.5	0.5	0.118
[A-3]	1	1	1	0	—	0	∞

where n = number of electrons transformed per unit act of the overall reaction, $\vec{\gamma}$ = number of electrons transferred before the rate-determining step, ν = number of times the rate-determining step occurs per unit act of the overall reaction, $r = 1$ for a rate-determining step with an electron transfer and $= 0$ for a rate-determining step without an electron transfer, β' = symmetry factor (usually assumed to be $\simeq 0.5$) for the rate-determining step, α_A = anodic transfer coefficient, and b_A = Tafel slope for anodic reaction.

From the table, if [A-1] is rds, $b = \infty$ V/decade; if [A-2] is rds, $b = 0.118$ V/decade; if [A-3] is rds, $b = 0.059$ V/decade.

For the mechanism presented by MacArthur and Cathro and Koch

$$[4]\quad Au + CN^- \rightleftharpoons AuCN_{ads} + e^-$$

$$[3]\quad AuCN_{ads} + CN^- \rightleftharpoons Au(CN)_2^-$$

Following the same procedure as above, if [4] is rds, then $b = 0.118$ V/decade; if [3] is rds, then $b = 0.059$ V/decade.

The Influence of Water on the Ni(II)/Ni(Hg) Electrode Process in Molten $LiNO_3$-KNO_3 Eutectic

David G. Lovering* and Richard M. Oblath[1]

Chemistry and Metallurgy Department, Royal Military College of Science, Shrivenham, Swindon SN6 8LA, England

ABSTRACT

D-C, pulse, differential pulse, and linear sweep polarographic methods have been used to characterize the Ni(II)/Ni(Hg) reduction as a function of water content in the $LiNO_3$-KNO_3 eutectic melt at 145°C. For very small concentrations of water added to the anhydrous melt, anodic shifts were observed in the Ni(II) polarographic wave. This was accompanied by changes in the kinetic shape parameter, αn_a. At higher water concentrations cathodic shifts occurred in the half-wave potentials and the waves became irreversible. These effects are attributed to dramatic changes in the coordination of the Ni(II) ion, especially the initial cleavage of the bidentate nitrate rings, rather than to adsorption of water molecules at the interface or catalytic acceleration of the reduction.

The interaction of water with molten salts is of interest and importance for both technological (1) and theoretical reasons. Surprisingly, the electroactivity of water itself, dissolved in nitrate melts is still not fully comprehended (2), in spite of a number of studies spanning more than twenty years (3-9). Few investigations (10-17) have been carried out in the experimentally difficult regime between aqueous melts and anhydrous molten salts; of these, only a small number have been concerned with the influence of water, per se, on electrode processes in nitrate melts.

Polarographic methods are suitable for monitoring electrode processes in aqueous melts (12) and low melting nitrate eutectics (18). In this investigation, the effect of small, controlled additions of water on the Ni(II)/Ni(Hg) electroreduction in anhydrous mol-

Key words: fused salts, water, polarography, reduction.

ten $LiNO_3$-KNO_3 at 145°C during the initial hydration stages has been studied. The small, highly polarizing Ni(II) ion is particularly sensitive to the water content of the medium, both in aqueous (19) as well as molten systems (10, 13), being wholly irreversibly reduced in the former, but apparently completely reversibly reduced in anhydrous nitrate melts (10, 18). In $Ca(NO_3)_2 \cdot 4H_2O$ + 46 mole percent (m/o) KNO_3, $LiNO_3 \cdot 3H_2O$, and $Ca(NO_3)_2 \cdot 4D_2O$ aqueous melts the reduction is also substantially irreversible, while in $CaCl_2 \cdot 6H_2O$ and $MgCl_2 \cdot 6H_2O$ it appears to be reversible (13). Furthermore, both diffusion data (18) and spectroscopic measurements (20-22) indicate that Ni(II) ions are complexed by nitrate ions in anhydrous nitrate melts; these species are reduced at half-wave potentials, $E_{1/2}$, close to the theoretical standard electrode potential (10, 18, 23) unlike the behavior of hexaquo-nickelate(II) complexes which predominate in aqueous environments (19). Moreover, coordinating aquo-ligands are not significantly displaced until the water content is reduced well beyond that in aqueous melts (13). In contrast, considerable cathodic $E_{1/2}$ shifts can be observed (13) when a solution of Cd(II) ions in $Ca(NO_3)_2 \cdot 4H_2O$ + 56 m/o KNO_3 is titrated with water, indicating that nitrate-water substitution reactions are still occurring for the Cd(II) ion within this concentration regime.

The surprising effects observed in this work for the Ni(II)/Ni(Hg) reaction upon addition of water to the melt precluded the calculation of aquo-nickelate(II) stability constants, since unusual shifts in $E_{1/2}$ occurred. In order to explain certain aspects of the present results, the Pb(II)/Pb(Hg) and Tl(I)/Tl(Hg) electroreductions were also monitored under similar conditions.

Experimental

The experimental equipment and procedures have been described in detail elsewhere (24). Pyrex glass cells incorporating electrodes, gas inlet/outlet, and entry facilities either attached to sliding glass tubes through a Pyrex cell head or passing directly through a p.t.f.e. cell head via "O"-ring seals were used. The assembly was thermostatted in an heated aluminum block to ± 0.1°C; visual observation and magnetic stirring facilities were provided.

Two straight-sided Pyrex dropping mercury electrodes, DME's, having m.t. products of 9.17 mg and 4.80 mg and a Radiometer hanging mercury drop electrode, HMDE, Type 958B at a fixed area of 0.0235 cm^2 were employed throughout. Mercury pool counter-electrodes and Ag/Ag(I) in melt /// asbestos wick, reference electrodes were used.

All equipment and materials were stored, assembled, and/or handled in the dry box prior to experimental work. Salts were of analytical grade from B.D.H. and ($LiNO_3$) Alfa Ventron, with the exception of the anhydrous $Ni(NO_3)_2$ prepared from N_2O_5 and kindly supplied by B. O. Field, City University. Mercury was of "polarographic grade" from Belgrave (Mercury) Limited, dried and used only once.

Water contents > 1.8 × 10^{-1}m were introduced directly into the sealed cell via a neoprene septum and microlitre syringe. Equilibration with known water vapor pressures monitored by M.K.S. Baratron equipment was employed for lower water concentrations. Henry's law was adopted for calculating the precise concentration of water dissolved in the melt (24).

A PAR 174A polarographic analyzer, with 174/170 drop timer, 175 programmer, Bryans xy/t 25000 chart recorder, and Datalab DL 905 transient recorder were utilized for monitoring d.c., normal pulse, differential pulse, and fast linear sweep polarograms.

Results

D-C polarograms for Ni(II), Pb(II), and Ti(I) at low concentrations, were regular sigmoidal-shaped when corrected for residual current, in the anhydrous $LiNO_3$-KNO_3 melt (24). Plots according to the Heyrovsky-Ilkovic equation, H.I.E., were linear, having $E_{1/2}$ intercepts of −560 mV, −652 mV, and −816 mV *vs.* Ag/Ag(I), 10^{-3}m reference electrode, and slopes of 45.4, 42.8, and 83.0 mV, respectively. Diffusion coefficients, D, calculated through the Ilkovic equation [see Ref. (12) and (18) for discussion of applicability] from limiting currents were 2.25 × 10^{-7} cm^2 sec^{-1}, 9.3 × 10^{-7} cm^2 sec^{-1}, and 8.3 × 10^{-7} cm^2 sec^{-1}, respectively. In some cases $E_{1/2}$ values and slopes, and, in each case, D values may be compared with tabulated values from the literature for similar melts (18, 24); no new or major departures from previous determinations are evident.

Interestingly, this most recent and precise evaluation of the H.I.E. slope leads to a value of $\alpha n_a = 1.83$ for the Ni(II)/Ni(Hg) reaction, *i.e.*, the process is less than wholly reversible in the classical sense, when determined in this pseudo-steady state manner. This is in agreement with the evidence of a square-wave polarographic study (25), but not other workers (10, 18, 23). In the former case (25), wave asymetry was ascribed to traces of water (vide infra), although large amounts of KCl were also present in the melt. In another case (18), polarograms were constructed from true, point-by-point, steady-state measurements.

Normal pulse and differential pulse polarograms, (d.p.p.'s), for the Ni(II) reduction were also of regular shape (24); values for $E_{1/2}$ and D were coincident with d-c polarographic determinations. Wave analysis for normal pulse polarograms indicated $\alpha n_a = 1.86$. The peak potential of d.p.p.'s was −555 mV *vs.* Ref. [≡ −557.5 mV for $E_{1/2}$ (26)] and their half-peak width was 82.5 mV compared with a theoretical value (27) of 63.4 mV for a totally reversible process; pulse amplitudes were 5 mV.

Typical linear sweep voltammograms for the nickel ion reduction at the HMDE are shown in Fig. 1(a); peak currents, i_p, were a linear function of Ni(II) concentrations (0.4-2.8 × 10^{-3}m) for sweep rates, ν, between 0.1 to 10 V sec^{-1}. Curvature in the i_p *vs.* $\nu^{1/2}$ plots, shown in Fig. 1(b), confirms the Ni(II)/Ni(Hg) electroreduction as "quasi-reversible" (28-29). Differences between the peak potential, E_p, and half-peak potential, $E_{p/2}$ are tabulated in Table I for various sweep rates and enable the values of αn_a to be evaluated according to (29, 30)

$$E_p - E_{p/2} = -1.857 \frac{RT}{\alpha n_a \mathbf{F}}$$

Values for the ratio $\Delta E_p/\Delta \log \nu$. determined between sweep rates in the range 0.1-10 V sec^{-1}, were ~ −13 compared with − 30/n for a classically irreversible process (29).

When very small amounts of water were added to the melt, the d-c polarograms were initially shifted in the anodic direction. As the water content was raised above ~ 5 × 10^{-3}m this shift reverted to the cath-

(b) i_p vs. $v^{1/2}$ for linear sweep polarograms at (a), except larger range of data points for sweep rate and concentrations of Ni(II): (i) 2.8 × 10^{-3}m (ii) 1.72 × 10^{-3}m (iii) 0.45m, with linear extrapolation shown as broken line.

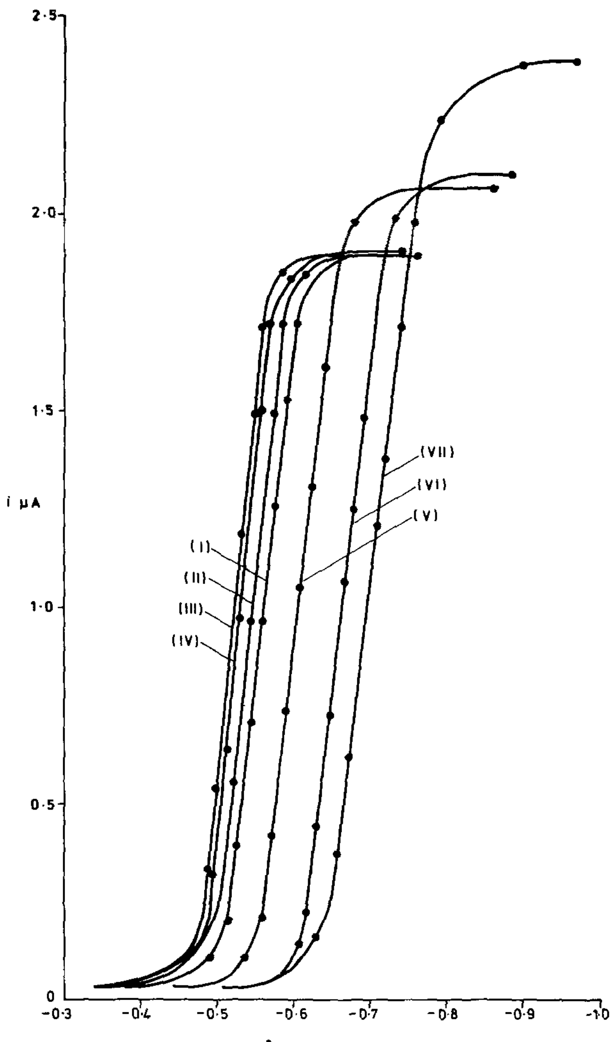

Fig. 2. Effect of water additions on the d-c polarograms for the Ni(II)/Ni(Hg) reduction in $LiNO_3$-KNO_3 eutectic melt at 145°C: Ni(II) concentration 8.35 × 10^{-4}m, water concentration, molal (i) 0, (ii) 2.25 × 10^{-3}, (iii) 4.5 × 10^{-3}, (iv) 1.8 × 10^{-2}, (v) 0.89, (vi) 1.74, (vii) 3.36. Capillary m.t. product = 4.80 mg.

odic direction, *i.e.*, that normally expected on the basis of the formation of more stable aquo complexes. Figure 2 shows the relevant d-c polarograms; corresponding $E_{1/2}$ shifts, wave shapes, and mean diffusion coefficients are given in Table II. Notably, the value of αn_a increases sharply from 1.83 to the totally reversible value of 2.0 at a water content of 4.5 × 10^{-3}m before falling again to only 1.35 at 3.36m H_2O, *i.e.*, approaching the totally irreversible behavior familiar in noncomplexing aqueous media (19). Plots of the Ni(II) reduction half-wave potential as a function of water concentration are shown in Fig. 3; the gap in data collection between ~ 3 × 10^{-2}m to ~ 4 × 10^{-1}m H_2O corresponds to the changeover in method of introducing water into the cell, although the inset and main figure suggest that this is not a region of crucial importance in this case. Virtually coincident plots result from the pulse polarographic data (24).

Table II. D-C polarographic data for the Ni(II/Ni(Hg) reduction in $LiNO_3$-KNO_3 eutectic at 145°C containing 8.35 × 10^{-4}m Ni^{2+} (concentration in anhydrous melts)

The values for the half-wave potentials ($E_{1/2}$) and αn_a were obtained from Heyrovsky-Ilkovic equation plots.

In order to further assess the kinetic effect of water additions on the electrode process suggested by the d-c polarographic data, fast linear sweep polarograms were recorded both as a function of sweep rate and water content of the melt. Some typical analyses for a sweep rate of 10 V sec^{-1} are compared with d-c polarographic data in Table III.

Using (30)

$$E_p = -1.14\frac{RT}{\alpha n_a \mathbf{F}} + \frac{RT}{\alpha n_a \mathbf{F}} \ln\left\{\frac{k^\circ_{fh}}{D^{1/2}}\right\} - \frac{RT}{2\alpha n_a \mathbf{F}} \ln \alpha n_a v$$

and

$$k_s = k^\circ_{fh} \exp \cdot \left\{\frac{-\alpha n_a \mathbf{F} E^\circ}{RT}\right\}$$

values of the standard rate constant, k_s, were estimated

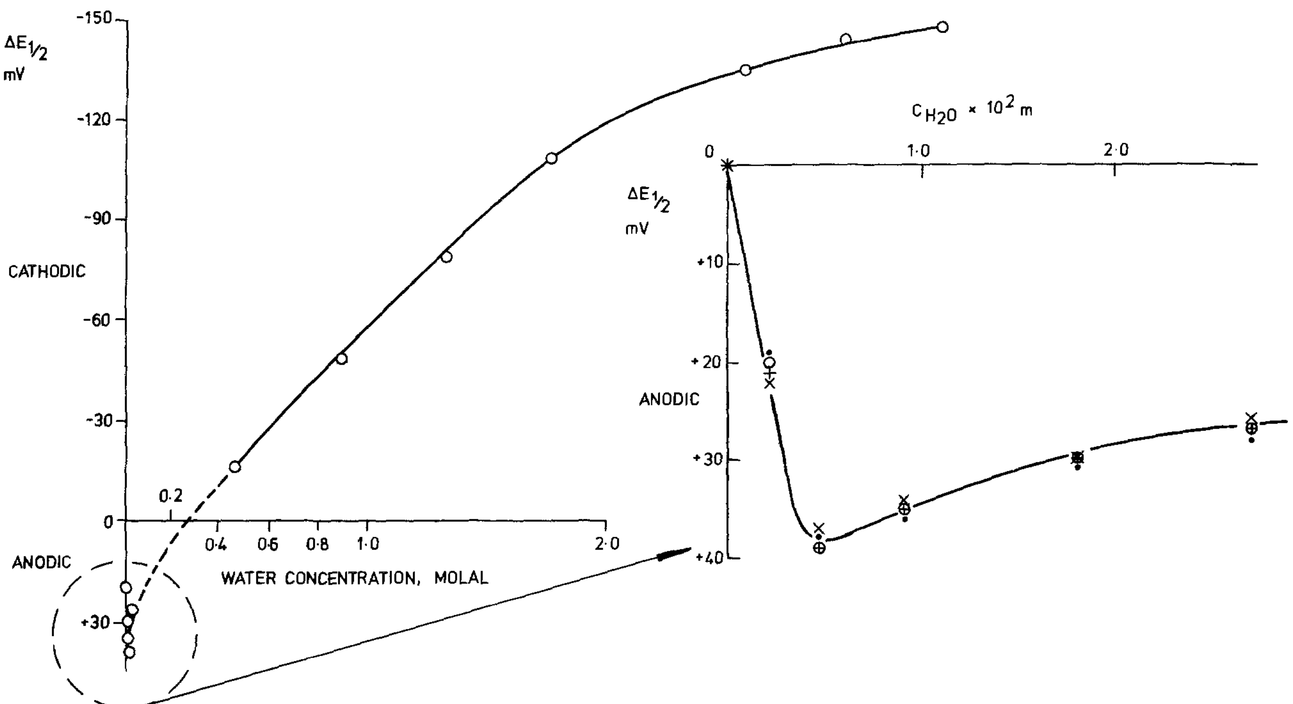

Fig. 3. Effect of water additions on the half-wave potential for the Ni(II)/Ni(Hg) reduction in $LiNO_3$-KNO_3 eutectic melt at 145°C. Initial concentrations of Ni(II): ×, 6.73 × 10^{-4}m; +, 7.83 × 10^{-4}m; ○, 8.35 × 10^{-4}m; ·, 1.07 × 10^{-4}m.

at each half-wave potential (equated to $E°$) for the various water concentrations. These values were fully corrected for the variation in melt density[2] (which affects the diffusion coefficient) and for the shifts in $E_{1/2}$; lack of data precluded these corrections in the earlier study (10), whose results are compared with the present ones in Fig. 4. The importance of these corrections may be gauged by examining their (10) third data point, for example, at ~ 0.175 mole fraction of water for which the actual density[2] of the melt would be ~ 1.90 g ml^{-1}, the viscosity[2] ~ 11½ cp, and $E_{1/2}$ ~ −0.83V *vs.* their ref. compared with ~ 1.99 g ml^{-1}, ~ 21½ cp, and ~ −0.70V in the completely anhydrous system.

Discussion

A number of features of the present study are surprising and in conflict with earlier reports. First and most importantly, the anodic $E_{1/2}$ shifts (Fig. 3) for the Ni(II)/Ni(Hg) reaction at very low water concentrations in the melt are unexpected. Anodic shifts for

[2] We thank Professor P. Claes and his colleagues of Louvain University for the provision of density and viscosity data prior to publication.

centration, *i.e.*, large decreases in the water content of the system. In the present case the formation of more stable aquo-complexes in the bulk melt, which must occur to a certain extent, is evidently eclipsed by an overlying factor. Liquid junction potentials arising from slight cell asymmetry during water additions were eliminated as a possible cause of the anodic shift by making simultaneous additions of water to both the main cell and reference electrode compartments: no additional changes in $E_{1/2}$ were evident. Neither could the $E_{1/2}$ shifts be caused by bulk structural changes in the melt at such low water concentrations (14, 16). Furthermore, it seems unlikely that very small additions of water could significantly change the gross structure of the electrical double layer (10, 11) and thereby affect the reduction potential. Nevertheless in order to affirm the latter contention. experiments were carried out under the same conditions using Pb(II) and Tl(I) ions as depolarizers in place of Ni(II). The Pb(II) ion is relatively large, exerts a weak field, is rarely specifically adsorbed at most electrodes, and being a nontransition metal ion of low polarizing power is only weakly solvated or complexed in most oxyanionic media. Indeed, both the half-wave potential of -652 mV *vs.* ref. and the value of $\alpha n_a = 1.94$ for the Pb(II)/Pb(Hg) reduction in the melt were invariant over the range of water concentrations 0-3.36m. Moreover, such changes as were observed in the diffusion coefficient could be attributed almost entirely to viscosity changes in the solvent, as shown in Table IV. The faster diffusion rate of the Pb(II) ion as compared to the Ni(II) ion is also consistent with the latter being extensively coordinated (18, 20-22), (vide infra).

The Tl(I) ion is also a large, weak field species of low polarizing power, but unlike Pb(II) (and Ni(II)) ions is frequently adsorbed at electrode interfaces from dilute solution. Adsorption behavior is generally manifested as a maximum in polarographic waves, and these did appear in the present work at concentrations $\geqq 1.12 \times 10^{-3}$m. Initially, polarograms were recorded for the Tl(I)/Tl(Hg) reduction over a range of water concentrations 0-1.74m at depolarizer concentrations $< 10^{-3}$m. Polarographic maxima were always absent and again the values of $E_{1/2} = -816$ mV *vs.* ref. and $\alpha n_a = 1.0$ were unaffected by the presence or absence of water; the variation of the diffusion coefficient was wholly accounted for in terms of viscosity changes (Table IV). However, in order to better probe the electrode/melt interface for possible direct interference by dissolved water molecules, polarograms for Tl(I) were also recorded at higher depolarizer concentrations $\sim 4 \times 10^{-3}$m, *i.e.*, in the range where maxima were clearly evident. The peak current at the maximum was then compared to the post-maximum diffusion-limited current (to eliminate viscosity effects) over the same range of water contents: this ratio remained constant at 1.2. Hence, there seems to be no evidence that small, (or even quite large!) amounts of water present in the melt significantly influences these polarographic reduction processes at the interphasial level. This conclusion would seem to be at variance either directly (19) or indirectly (10) with previous contentions, although Eriksrud has recently indicated (31) that charge-transfer rather than diffuse-layer effects might be responsible for the medium effect observed for Co(II) and Ni(II) (19) reductions.

Intuitively, it might be thought that very small quantities of water in the melt could dissociate and subsequently catalyze the reduction of Ni(II) ions; both temperature and entropy considerations would favor such a mechanism. The position of the Ni(II) polarographic wave in nitrate melts certainly resembles the catalytic prewave reported for aqueous environments in the presence of strongly complexing ligands (32). Moreover, any second wave (32) would be obscured by the onset of the nitrate ion reduction in the melt. Additionally, low apparent polarographic diffusion currents for Ni(II) ions in nitrate melts might be held to support this notion. Nevertheless, both the dielectric constant of the medium together with all previous evperimental evidence (4, 8, 11, 13-17) firmly argue against even the slightest dissociation of water molecules in nitrate melts, especially at low concentrations. Since the earliest investigation (23), there has never been any indication that the observable polarogram for Ni(II) in nitrate melts is other than a normal, diffusion-controlled wave (10, 18, 25); in this work, wave analysis responded to all the usual criteria identifying the polarographic wave as such. Furthermore, the evidence of the Pb(II)/Pb(Hg) and Tl(I)/Tl(Hg) reductions provides no support for catalytic involvement by water either. The fact that the fully corrected standard rate constant, k_s, for the Ni(II)/Ni(Hg) reduction varies comparatively little from the anhydrous melt up to water concentrations of $\sim$3m. also detracts from any catalytic scheme. The invariance of k_s in the presence of nitric acid (10), which would suppress hydrolysis, seems to eliminate this line of approach.

The variation in the value of αn_a with water concentration perhaps provides the best clue as to why anodic shifts are initially observed for the Ni(II) half-wave potential. Most probably changes in the structure of the diffusing species, which occur as water is added to the anhydrous system, best account for the experimental facts and concur with Eriksrud's reasoning (31).

According to the spectroscopic evidence, Ni(II) ions in nitrate melts are substantially coordinated by bidentate nitrate ions with ligand numbers of three (20, 22) or four (21), probably in an octahedral complex. The known chemistry (33) of anhydrous nitrate compounds emphasizes the extreme susceptibility of bidentate linkages to hydrolysis. Consequently ring opening may reasonably be assumed as the first stage in the hydration displacement equilibrium for the

Table IV. Variation of diffusion coefficients, viscosities,[2] and Stokes-Einstein equation quotients for dissolved Ni(II), Pb(II), and Tl(I) ions in molten, eutectic $LiNO_3$-KNO_3 at 145°C with added water (0-3.36 m)

Ni(II) ion in the melt. At the lowest concentrations, the change from bidentate nitrate ligands to monodentate nitrate and water ligands necessarily increases the ligand number. The thermodynamic consequences for the diffusing particles are most profound. There will be a sharp entropy decrease in the system due to the "loss" of the extra water ligand, and the complex will be somewhat destabilized (*i.e.,* lability increased) by an "inverse chelate effect." While this need not affect the rate of reduction of the Ni(II) species, it must affect the transfer coefficient for the process since this reflects the shape of the potential energy functions during the initial stages of ion desolvation prior to discharge. Furthermore, additional destabilization may occur as a result of "trans effect" labilization of other ligands. Thus, the partially substituted, mixed aquo-nitrato-nickelate(II) complex may more readily pass through the desolvation steps and lead to the appearance of classically reversible polarograms. The simultaneous sharpening of the polarographic wave may then account for the net anodic shift of $E_{1/2}$. Second order thermodynamic effects (not influencing reduction kinetics directly), include favorable enthalpy changes resulting from relief of steric ring-strain in the bidentate nitrate ions, and an increase in translational entropy arising from ring scission. Ligand rearrangement, homogeneous ligand exchange, and an enhanced statistical probability of ligand substitution constitute additional features complicating the initial ion hydration phase and are best studied, per se, by spectroscopy.

As the water content of the melt is increased beyond 10 millimolal, $E_{1/2}$ shifts revert to the cathodic direction, signaling the steady, step-wise formation of more stable aquo-complexes. At the same time, the polarographic wave becomes progressively less reversible, until at 3m in water it more closely resembles the wave obtained in aqueous media.

The near constancy of the $D\eta$ product, with varying water content, for all three ions is shown in Table IV. It provides an interestingly unique case of the apparent applicability of the Stokes-Einstein equation in molten salts; unlike previous examples, the medium, rather than the ion (34) is varying here. These results indicate that the approximate size and extent of interaction of each ion or complex with the surrounding medium is little changed whether or not the entity itself is undergoing substitutional modification. Clearly, bridged or polynuclear entities are not involved even as intermediates. Moreover, if all three ions are assumed six coordinate, Pb(II) and Tl(I) are assumed uncomplexed and unsolvated to a first approximation, then using Shannon and Prewitt (35) effective ionic radii, the $D \cdot \eta \cdot r$ products for Pb(II), Tl(I), and Ni(II) $(NO_3)_3^-$ in the anhydrous melt are sensibly comparable at 21.3, 24.1, and 19.8, respectively, in g cm^2 sec^{-2} $\times$ 10^{-16} units, when a radius of 1.93Å is taken for the nitrate ion (34). Notwithstanding these sweeping assumptions, perhaps the trend of the $D\eta$ product for Pb(II) suggests that the bare ion does acquire an aquo ligand at the highest water concentration.

Unfortunately, the initial complications in the hydration equilibria for the Ni(II) ion, manifested by the change in direction of $E_{1/2}$ shifts, the variation in αn_a values together with the continuously varying viscosity and density of the melt, preclude calculation of either formation constants or $\bar{n}_{max}$ for the aquo complexes formed. Nevertheless, a simplistic approach can be adopted to estimate the range in which the primary coordination sphere of the Ni(II) ion becomes substantially substituted with water molecules. The "associated radius" of the nickel nitrate complex in the anhydrous melt will be (34) 4.56Å, while that for the nickel aquo complex (regardless of structure or ligand number) will be 3.48Å, if $r_{NO_3^-} = 1.93$Å, $r_{H_2O} = 1.39$Å (34), and $r_{Ni(II)} = 0.7$Å (34). Ignoring consequential changes in the interaction of the diffusing particles with the medium, the diffusion coefficient of the nickel aquo complex will be approximately 0.295×10^{-6} cm^2 sec^{-1} in proportion to the associated radii. If this value is then multiplied by the appropriate melt viscosity for each experimental water concentration employed in Table IV, when $D\eta \simeq 4.4 \times 10^{-8}$ g cm sec^{-2} the value so calculated coincides with that experimentally observed, *i.e.* at ~ 1m in water. Such an elementary derivation makes many assumptions concerning the transport process and fails to account for the stepwise nature of the association equilibrium indicated by the $\Delta E_{1/2}$ *vs.* water concentration plot. However, the Ni(II) ion appears to be essentially coordinated by water molecules at the relatively dilute water concentration ~ 1m [*cf.* Cd(II) ions (34)].

Evidently many complicated factors may be involved in the initial hydration of transition metal ions in molten salts. A complete and quantitative treatment remains elusive; polarization forces between all the ions in the melt have also been conveniently ignored. However, in any Li-containing melt, the highly polarizing Li^+ ion must be considered a competitor for water molecules present. This competition may not be particularly effective compared to the field exerted by Ni(II) ions, but any attempt to quantify this conjecture, whether or not the Born equation is invoked, seems hazardous at present.

Conclusions

Polarographic studies of the Ni(II)/Ni(Hg) reduction in the $LiNO_3$-KNO_3 eutectic melt at 145°C illustrate some rather unusual electrochemical effects which occur during the initial stages of ion hydration. Apparently, the consequences of adding very small amounts of water to the anhydrous system cause no important changes either in the electrode/melt interface or in the overall transport behavior of the diffusing species. Such changes as do occur seem to alter the shape of the energy barriers for reduction rather than the overall rate for the process. This probably arises from changes in the nature of the diffusing entity, in this case an increase in ligand number arising from the disruption of bidentate nitrate bonds coordinating the Ni(II) ion with the incorporation of aquo ligands into a mixed ligand complex. The most profound electrochemical consequences, namely anodic shifting of the polarographic wave and an increase in the apparent reversibility, are dramatically sharp at extremely low levels of water. In view of the variable degree of dryness of, especially, $LiNO_3$-containing melts employed by previous workers, previous conclusions may need reviewing particularly where transition metal ions are involved. The roles of such thermodynamic and kinetic factors as have been discussed here could usefully be examined with respect to the highly concentrated aqueous electrolytes that are employed in industrial electrochemical devices and processes. Apart from parallel spectroscopic investigations, these studies need to be extended to other molten systems, other transition metal ions [especially Co(II)] and to be conducted over a wide range of temperatures using additional transient techniques in order to gain a better insight into the initial hydration of ions.

Hydrogen Peroxide as an Intermediate in Electrocatalytic Reduction of Oxygen. A New Method for the Determination of Rate Constants

F. van den Brink, E. Barendrecht,* and W. Visscher

Laboratory for Electrochemistry, University of Technology, 5600 MB Eindhoven, The Netherlands

ABSTRACT

On most electrocatalysts H_2O_2 is an intermediate in the electroreduction of oxygen. H_2O_2 can decompose either chemically or electrochemically and in assessing the performance of the electrocatalyst it is crucial to distinguish between these reaction paths. A simple method is proposed to determine whether or not the chemical path is followed.

For the electrochemical reduction of oxygen a general scheme of reactions can be given as in Fig. 1. Whether the reduction of oxygen to water will follow the direct path 1 or the consecutive path 2-3, or both these paths in parallel, is determined by the electrocatalytic properties of the electrode which are also critical for the further reaction of H_2O_2: electrochemical reduction (reaction 3) and/or chemical decomposition (reaction 4).

With the introduction of the rotating ring-disk electrode technique it became possible to distinguish between the consecutive and parallel pathways (1-4). Here, the disk current is measured at various potentials and rotation frequencies, while simultaneously the ring current is measured at a potential at which hydrogen peroxide is oxidized quantitatively. Several methods have been proposed to analyze the data obtained from these experiments; these methods have been reviewed by Pleskov and Filinovskii (5), while Wroblowa (6) has added a general criterion for distinguishing between the parallel and consecutive pathway. These analyses show that, in principle, only four (combinations) of the five rate constants in the general scheme can be obtained.

A problem which remains to be solved is that of the fate of the hydrogen peroxide, produced by reactor 2 in Fig. 1: H_2O_2 can be either reduced electrochemically (reaction 3) or chemically decomposed (reaction 4). Moreover, the solution of this problem is of vital importance in the evaluation of the performance of electrocatalysts for the oxygen electrode, since reaction 4 involves no net electron transfer and is

* Electrochemical Society Active Member.
Key words: electrocatalysts, reduction, decomposition.

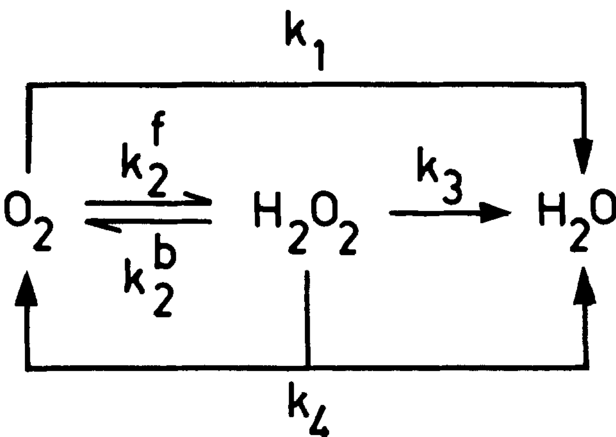

Fig. 1. Scheme of reactions for reduction of oxygen

electrochemically wholly unproductive. In this paper we will present a simple method to determine the rate constant of reaction 4, so that, in principle, it becomes possible to calculate all five individual rate constants of Fig. 1.

Theory

In the ring-disk electrode (RRDE) experiment, referred to in the introduction, sets of disk currents (I_D) and limiting ring currents (I_R) are obtained as functions of rotation frequency (ω) and disk potential, E_D. These data are analyzed by plotting at constant E_D according to (5)

$$-N_o I_D/I_R = A + B/\sqrt{\omega} \quad [1]$$

and

$$-N_o(I_{D,lim}^{H_2O} - I_D)/I_R = C + D\sqrt{\omega} \quad [2]$$

where $I_{D,lim}^{H_2O}$ is the limiting current at the disk for the reduction of oxygen to water and N_o is the RRDE's collection efficiency (7). A, B, C, and D are functions of the five rate constants, from which k_1, k_2^f, $2k_2^b + k_4$, and $2k_3 + k_4$ can be obtained (5).

We wish to point out that the value of k_4 can be found in many practical cases by measuring ring currents in a solution containing only H_2O_2 and no O_2, while the disk current is kept zero.

Relations between currents and rotation frequencies in H_2O_2 containing solutions have been derived by Bagotskii (1). From his equations the combinations $2k_2^b + k_4$, $2k_3 + k_4$, and $k_2^f - k_3$ can be obtained. A further extension of this method was given by Tarasevich and Radyushkina (8) who applied Bagotskii's equations under the condition that $I_D = 0$. They, again, found k_1, k_2^f, $2k_2^b + k_4$ (describing the rate with which H_2O_2 gives O_2), and $2k_3 + k_4$ (describing the rate with which H_2O_2 gives H_2O). We will show that they lost valuable information, *viz.*, that obtained from the value of the disk's open-circuit potential, by substituting the zero current condition ($I_D = 0$) only in Bagotskii's resulting equations (1).

In a solution containing hydrogen peroxide, but no oxygen, the hydrogen peroxide will react electrochemically (reactions 2 and 3) and chemically (reaction 4), giving oxygen and/or water; oxygen may react further (reactions 1 and 2). The quantities of formed oxygen and of decomposed hydrogen peroxide can be determined by measuring the anodic and cathodic limiting currents on the ring electrode. If, moreover, the disk current is zero, the net amount of oxygen formed by the electrochemical reaction is known if the ratio of the rates of production and of consumption of O_2 by the electrochemical reactions, *i.e.*, $k_2^b - k_3/2k_1 + k_2^f$ is known at the disk's rest-potential. This means that the amount of oxygen formed by reaction 4 can be found, *i.e.*, that the value of k_4 can be determined.

Thus, on the disk electrode

$$\left.\begin{array}{ll} H_2O_2 + 2H^+ + 2e^- \xrightarrow{k_3} 2H_2O & \text{with } I_3 \\ H_2O_2 \underset{k_2^b}{\overset{k_2^f}{\rightleftharpoons}} O_2 + 2H^+ + 2e^- & \text{with } I_2 \\ O_2 + 4H^+ + 4e^- \xrightarrow{k_1} 2H_2O & \text{with } I_1 \\ H_2O_2 \xrightarrow{k_4} \tfrac{1}{2} O_2 + H_2O & \end{array}\right\} \text{with } I_1 + I_2 + I_3 = I_D = 0$$

The assumptions are that reaction 4 is potential independent, that the pertinent reactions are first order in O_2 or in H_2O_2, and that adsorption to and desorption from the electrocatalyst of O_2 and H_2O_2 are fast.

On the ring electrode the anodic limiting current is $I_{R,lim}^a$ for the reaction

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-$$

and $I_{R,lim}^c$ the cathodic limiting current for the reactions

$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O$$

and

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

At the disk we have the mass balances, for hydrogen peroxide

$$\gamma_2\sqrt{\omega}(c_2^s - c_2^o) = (k_{2,r}^b + k_{3,r} + k_4)c_2^o - k_{2,r}^f c_1^o \quad [3]$$

and for oxygen

$$\gamma_1\sqrt{\omega}c_1^o = (k_{2,r}^b + \tfrac{1}{2} k_4)c_2^o - (k_{1,r} + k_{2,r}^f)c_1^o \quad [4]$$

Because of the zero current condition

$$\frac{I_D}{2\mathbf{F}A} = (k_{2,r}^b - k_{3,r})c_2^o - (2k_{1,r} + k_{2,r}^f)c_1^o = 0 \quad [5]$$

where the c's are the concentrations of O_2 (subscript 1) and of H_2O_2 (subscript 2). The superscripts o and s on the c's denote the electrode surface and the bulk of the solution, respectively ,while a subscript r is attached to k_1, k_2^f, k_2^b, and k_3 because the disk electrode is at its rest potential. Further, $\gamma\sqrt{\omega} = 0.62D^{2/3}\nu^{-1/6}\sqrt{\omega}$ is the rate constant for diffusion and A the disk area.

At the ring we have the limiting currents

cathodic

$$-\frac{I_{R,lim}^c}{N_o A\mathbf{F}} = 4\gamma_1\sqrt{\omega}\,c_1^o - 2k_4c_2^o + \frac{\beta^{2/3}}{N_o A\mathbf{F}} I_{D,lim}^{H_2O_2} \quad [6]$$

anodic

$$\frac{I_{R,lim}^a}{N_o A\mathbf{F}} = -2k_4c_2^o + \frac{\beta^{2/3}}{N_o A\mathbf{F}} I_{D,lim}^{H_2O_2} \quad [7]$$

where $I_{D,lim}^{H_2O_2}$ is the absolute value of the limiting current at the disk for the oxidation of H_2O_2 to O_2 and $\beta^{2/3}$ is a geometrical factor, defining the shielding factor $(1 - N_o\beta^{-2/3})$ of the RRDE (7).

Elimination of c_1^o and c_2^o between the sets of Eq. [3], [4], and [6], and [3], [4], and [7], respectively, together with the condition [5] gives

$$\frac{I_{R,lim}^c}{2N_oA\mathbf{F}c_2^s} = \frac{k_4}{1+K} - \left(\frac{K}{1+K} + \frac{\beta^{2/3}}{N_o}\right)\gamma_2\sqrt{\omega} \quad [8]$$

and

$$\frac{-I_{R,lim}^a}{2N_oA\mathbf{F}c_2^s} = \frac{k_4}{1+K} - \frac{\beta^{2/3}}{N_o}\gamma_2\sqrt{\omega} \quad [9]$$

where

$$K = \frac{2\gamma_1}{\gamma_2}\frac{k_{2,r}^b - k_{3,r}}{2k_{1,r} + k_{2,r}^f}$$

The pseudo constant k can be obtained by extrapolation of the values for the k's found with Eq. [1] and [2] to the rest potential at each rotation frequency.

If we may assume that the rest potential will not vary strongly with the RRDE's rotation frequency, K will be a constant. Then the plots of the limiting ring currents *vs.* $\sqrt{\omega}$ will give straight lines. Two limiting cases can be considered (Fig. 2). First $K << 1$, *i.e.*, H_2O_2 is, electrochemically, much less reactive than O_2 at the disk electrode. Therefore the anodic and cathodic limiting ring currents become equal, while reaction 4 is responsible for extra shielding of the ring current by the disk electrode. The second case $K >> 1$, *i.e.*, H_2O_2 is electrochemically more reactive. O_2 formed on the disk diffuses away, thereby increasing the cathodic limiting ring current. Now the influence of reaction 4 is much less than in the first case, because of the low H_2O_2 concentration near the disk surface. In Fig. 2, schematic diagrams are given for these two cases.

In general, by plotting $I_{R,lim}{}^a$ *vs.* $\sqrt{\omega}$, or, more precisely, $(1 + K)I_{R,lim}{}^a$ *vs.* $(1 + K)\sqrt{\omega}$ (Eq. [9]), $c_2{}^s$ can be found. Then k_4 can be calculated at each value of ω from

$$k_4 = (1 + K)\left[\frac{I_{R,lim}{}^c}{2N_oAFc_2{}^s} + \left(\frac{K}{1+K} + \frac{\beta^{2/3}}{N_o}\right)\gamma_2\sqrt{\omega}\right] \quad [10a]$$

$$= (1 + K)\left[\frac{-I_{R,lim}{}^a}{2N_oAFc_2{}^s} + \frac{\beta^{2/3}}{N_o}\gamma_2\sqrt{\omega}\right] \quad [10b]$$

The results can be averaged to give a final value of k_4. Alternatively, k_4 can be determined from the intercepts of $(1 + K)\ I_{R,lim}{}^c/2N_oAFc_2{}^s$ and $-(1 + K)\ I_{R,lim}{}^a/2N_oAFc_2{}^s$ *vs.* $(1 + K)\gamma_2\sqrt{\omega}$. The resulting value of k_4 is then subtracted from $2k_2{}^b + k_4$ and $2k_3 + k_4$, obtained from Eq. [1] and [2], to give the separate values for all five rate constants at each potential for which ring and disk currents are available.

Experimental

As an example, an experiment according to the line of reasoning described above was carried out, using an RRDE with an Au disk and a Pt ring in 1M KOH at 298°K. The construction of the RRDE was as described before (9). Its dimensions were such that $A = 51.5 \times 10^{-6}$ m^2, $N_o = 0.1437$, and $\beta = 0.1515$ (as calculated from the radii $r_{10} = 4.047$ mm, $r_{20} = 4.260$ mm, and $r_{30} = 4.437$ mm). A standard electrochemical cell was used, with a reversible hydrogen electrode (RHE) as reference and a platinum wire as counter-electrode. The Pt ring was slightly platinized (5×10^{-6} mole·m^{-2}). The measurements were carried out using a Tacussel bipotentiostat, Type BIPAD.

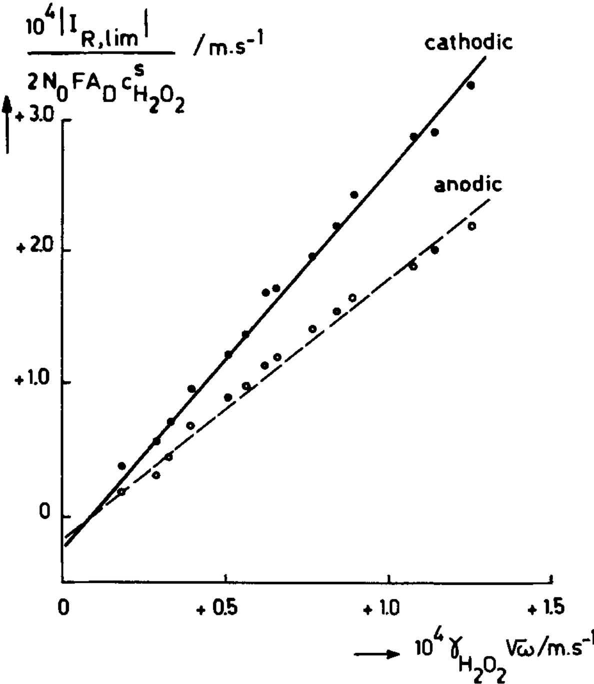

Fig. 3. Limiting ring currents *vs.* $\sqrt{\omega}$; for an Au/Pt-RRDE in 1*N* KOH at 298°K, plotted according to Eq. [8] and [9]. a = anodic, c = cathodic.

The KOH solution (prepared with p.a. quality KOH and doubly distilled water) was purified by preelectrolysis, made oxygen-free, and kept in Ar atmosphere. Hydrogen peroxide was added[1] and anodic and cathodic limiting currents at the ring were measured while the disk current was zero. To avoid poisoning of the ring by the stabilizer from the H_2O_2 solution used, the currents were measured by cyclic voltammetry with scan rates of 100-500 mV·sec^{-1}. The rest potential at the disk was measured to be 889 mV *vs.* a reversible hydrogen electrode in the same solution and was independent of the rotation frequency. Therefore it was possible to obtain the H_2O_2 concentration from a $I_{R,lim}{}^a$ *vs.* $\sqrt{\omega}$-plot. The slope of this plot gave $c_2{}^s = 5.3$ mM, which value was verified by titration with $KMnO_4$. The results, plotted as $I_{R,lim}/2N_oAFc_2{}^s$ *vs.* $\gamma_2\sqrt{\omega}$, are given in Fig. 3. The

[1] Brocacef, 30% v/w, Ph. Eur.

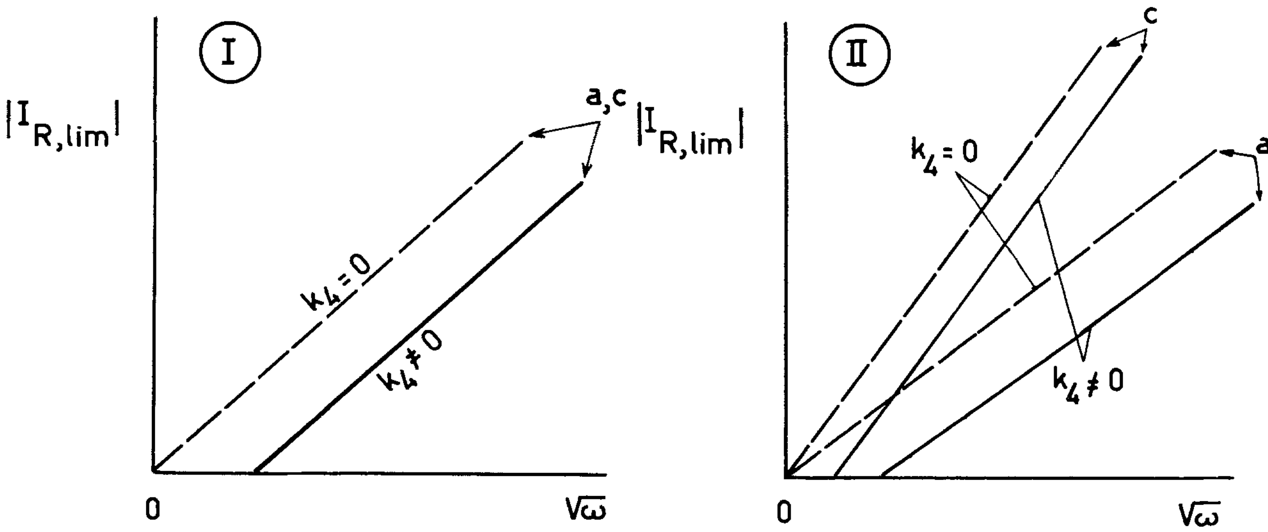

Fig. 2. Limiting cases of Eq. [8] and [9] (arbitary units). I: $K << 1$; II: $K >> 1$; a = anodic; c = cathodic limiting current; - - - for $k_4 = 0$; —— for $k_4 \neq 0$.

slope of the anodic branch is calculated to be 1.98 ± 0.06, in very good agreement with the theoretical value of

$$\frac{\beta^{2/3}}{N_o} = 1.978$$

From the slope of the cathodic branch (2.89 ± 0.07), the value of $K = 10.1$ can be calculated. This means that H_2O_2 is, electrochemically approximately five times more reactive at a gold electrode than O_2.

The intercepts of the anodic and cathodic branches are, respectively, -0.12×10^{-4} msec^{-1} and -0.17×10^{-4} msec^{-1}. This gives, by application of Eq. [8] and [9], $k_4 = (1.6 \pm 0.3) \times 10^{-4}$ msec^{-1}. Calculation according to Eq. [10] gives $k_4 = (1.6 \pm 0.2) \times 10^{-4}$ msec^{-1}.

Conclusion

As shown in the introduction, there are two nodal points in the scheme of reactions for O_2 reduction where a distinction is to be made between possible paths. The first is where oxygen can give either H_2O or H_2O_2. Here, RRDE experiments in O_2-containing solutions enable us to make the distinction. The second is where hydrogen peroxide can react either electrochemically or chemically. The method proposed here makes it possible to determine whether or not H_2O_2 decomposes chemically. In those cases where it may be assumed that k_4 does not depend on the disk electrode potential, it is even possible to calculate the magnitude of k_4. This assumption is valid as long as the catalytic properties of the electrode surface for the decomposition of H_2O_2 do not change significantly when the electrode potential is changed from the rest potential.

Furthermore, the method described here is simpler than that given recently by Appleby and Savy (10). They use an RRDE with a pyrolytic graphite ring, at which H_2O_2 is stable, to find k_4. This means that they need two different RRDE's, one to find k_1, k_2^f, k_2^b, and k_3 in oxygen-containing solutions and another one for use in solutions containing H_2O_2 to find k_4.

Transient and Failure Analyses of the Porous Zinc Electrode

I. Theoretical

W. G. Sunu*,[1] and D. N. Bennion*,[2]

School of Engineering and Applied Sciences, University of California, Los Angeles, California 90024

ABSTRACT

A mathematical model which describes the transient behavior of porous zinc electrodes has been developed on the basis of concentrated ternary electrolyte theory. The model predicts the current distribution, potentials in the solution, concentrations of hydroxide ion and zincate ion, porosity, and volume fractions of zinc and zinc oxide as a function of time and position perpendicular to the surface of the electrode. Numerical techniques were used to predict zinc electrode behavior during galvanostatic operation of the cell with and without a membrane. During discharge of the cell without a membrane, much of the discharge product, zincate ions, are lost into the counterelectrode compartment. For the cell with a membrane, this zincate loss is effectively restricted, but the utilization of zinc is severely limited by depletion of hydroxide ions within the zinc electrode compartment. In both cases, the reaction profiles are highly nonuniform and the reaction zone, located near the electrode surface, is very thin. This highly nonuniform reaction distribution accentuates the failure due to electrolyte depletion in the interior of the porous electrode, resulting in the low discharge capacity. On repeated cycling, the difference in anodic and cathodic reaction distribution causes the redistribution of solid zinc and zinc oxide species.

The zinc electrode has been commonly used as a negative electrode in primary cells such as Leclanché dry cells and alkaline zinc manganese dioxide cell. It also has received considerable attention, during the last decade, as a negative plate in secondary batteries, *e.g.*, zinc-nickel, zinc-silver oxide, zinc-bromine, and zinc-chlorine cells. The use of zinc electrodes in secondary batteries is attractive because of its availability, its low cost, and its ability to deliver high energy and power density. However, secondary batteries using zinc electrodes have poor cycle life, limited by zinc electrode failure. Any improvements on the cycle life of the alkaline zinc electrode can be applicable to its use in Zn-NiOOH or Zn-AgO rechargeable batteries, which are potential systems for use in electric vehicle propulsion or aerospace.

Failure of the zinc electrode can be attributed to a variety of causes. Two major causes of failure are zinc dendrite formation and shape change. The zinc dendrites which are formed during charge penetrate the separator and cause short circuits to the counterelectrode. Much of the work to date on improving zinc electrode behavior during charge has been associated with zinc deposit morphology, deposit adherency, and mechanism of dendrite growth (1-5). These studies have suggested that the use of low charge rate, pulse charging. and metallic or organic additives have some beneficial effects on preventing the formation of dendritic zinc deposits. The detrimental dendrite penetration, however, has been successfully reduced by use of an appropriate membrane material (6) such as commercially available grafted polyethylene ion exchange membrane.

Another failure known as shape change is the redistribution of solid zinc species over the electrode surface during cycling, which eventually decreases the effective surface area and thus cell capacity of the zinc electrode. Previous investigators (7-9) have indicated that the solid species moves from the top and sides to the bottom and center of the zinc electrode during cycling and that loose packing, compared to tight packing, of the cell promotes more rapid redistribution of zinc.

A mechanism based on gravitational effects has been proposed (10), but this mechanism is not consistent with the fact that shape change is independent of cell orientation. Other investigators (7, 9, 11) suggested concentration cell effects as a mechanism of shape change. McBreen (7) has suggested that a concentration cell is generated by the difference in the current distribution during charge and discharge. Recently, Choi *et al.* (12, 13) have proposed that the main reason for the shape change is the concentration cell caused by the difference in the convective flow pattern during cycling, *i.e.*, flow of supersaturated zincate solution toward the zinc electrode center during discharge and flow of unsaturated zincate solution toward the electrode edge or solution reservoir during charge. They confirmed that sealing or tight packing of the cell, preventing convection, successfully eliminated the shape change.

The simple approaches mentioned above have been effective in extending cycle life, but the resulting cycle life appears still to be limited by other factors. Initial loss of cell capacity as well as rapid decrease in cell capacity with continued cycling were observed even for the sealed cells for which chemical analysis for the zinc species confirmed no shape change (13). This indicates that there are further reasons for cell failure to be explained and minimized in order to gain further cycle improvements. The first step towards disclosing other failure modes and mechanism is to understand and be able to predict the zinc behavior within the porous electrode.

Various mathematical models have been proposed to describe the behavior of porous electrodes as summarized by Newman and Tiedemann (14). Winsel (15) described battery discharge by considering a single pore electrode of constant porosity and uniform concentration. Newman and Tobias (16) included the effects of a matrix resistance and concentration changes in their steady-state analysis of a

Key words: porous zinc electrodes, mathematical modeling, current distribution, failure mechanism.

one-dimensional, homogeneous mixture model. An attempt to consider structural changes in the pores was initiated by Alkire *et al.* (17). Dunning *et al.* (18) proposed a mathematical model which predicted discharge and cycling behavior of an Ag/AgCl electrode in NaCl solution. Recently, Gu *et al.* (19) extended the model of Dunning *et al.* to include surface diffusion of the adsorbed complex ion and realistic active surface area based on their experimental measurements. Simonsson (20, 21) applied his model to predict the failure mode of the positive electrode of the lead-acid battery. He showed that the discharge of the positive lead dioxide electrode at high current load failed by the severe depletion of sulfuric acid at the pore mouth, while Gidaspow and Baker (22) emphasized the pore plugging as a major cause of discharge failure.

In the present work, a mathematical model is developed to describe the transient behavior of the porous zinc electrode on the basis of concentrated ternary electrolyte theory. The discharge product ZnO is highly soluble in KOH solution, resulting in the potassium hydroxide-potassium zincate-water ternary mixture. It was also reported that the solution near the discharging zinc surface could become supersaturated with zincate (23). Therefore, fundamental equations developed for describing the concentrated ternary solution (24) were applied to the present model.

The model presented here consists of Ohm's law in the solution phase, Ohm's law in the matrix phase, kinetic rate expression, conservation of charge, and conservation equations of OH^- ion, zincate ion, water, and solid species. The effect of local mass transfer between the electrode active surface and the bulk solution in the pores, changes in porosity, variations of active surface area, and convection arising from the difference in molar volumes of reactants and products were included. The effect of the membrane separator and the solution reservoir on the zinc electrode performance was also included in the model to predict mathematically behavior under conditions similar to a practical battery system. The results of the numerical solution were used to suggest certain modes of failure and performance limitations of the zinc electrode.

The Mathematical Model

Zinc electrode reaction.—The process occurring in the zinc electrode in alkaline solution has been described by a dissolution-precipitation mechanism (25, 26)

$$Zn + 4\,OH^- \leftrightarrow Zn(OH)_4^{=} + 2e^- \quad [A]$$

$$Zn(OH)_4^{=} \leftrightarrow ZnO + 2\,OH^- + H_2O \quad [B]$$

Discharge of the zinc electrode produces supersaturated zincate solution by electrochemical reaction [A], from which ZnO precipitates by a chemical reaction [B]. The reverse process occurs during charge. Previous investigators (26, 27) have attempted to determine the rate of the precipitation reaction. However, values of rate constants are not precisely known. The kinetic mechanism of reaction [A] has been studied in alkaline media using both zinc amalgam electrodes (28-30) and pure solid zinc electrodes (31-34). The mechanism proposed by Bockris *et al.* (34) was considered in the present work to estimate kinetic parameters

$$Zn + OH^- \leftrightarrow Zn(OH) + e^- \quad [C]$$

$$Zn(OH) + OH^- \leftrightarrow Zn(OH)_2^- \quad [D]$$

$$Zn(OH)_2^- + OH^- \leftrightarrow Zn(OH)_3^- + e^- \quad [E]$$

$$Zn(OH)_3^- + OH^- \leftrightarrow Zn(OH)_4^{=} \quad [F]$$

where reaction step [E] is the rate-controlling step.

In a concentrated KOH solution saturated with ZnO, it is possible for the following complexes of zinc species to be present as intermediate compounds: Zn^{++}, $Zn(OH)^+$, $Zn(OH)_2$, $Zn(OH)_3^-$, $Zn(OH)_4^{=}$ . . . $Zn(OH)_n^{2-n}$. Based on the equilibrium constants reported by Butler (35), Boden *et al.* (36) concluded that the only species present to any appreciable extent in KOH solution was $Zn(OH)_4^{=}$ ion. Other workers (37-39) also confirmed that the predominant species was zincate ion. Therefore, in the present work, the electrolytic solution was considered as a four component system containing K^+, OH^-, $Zn(OH)_4^{=}$, and H_2O.

Description of the model.—A one-dimensional mathematical model of a porous zinc electrode has been proposed which predicts OH^- concentration c_3, $Zn(OH)_4^{=}$ concentration c_2, superficial current density in the solution i_2, transfer current density j, porosity ϵ, superficial volume average velocity v, potential in the solution ϕ_2, and potentials in the matrix ϕ_1, as a function of time and position perpendicular to the electrode surface. The geometric feature of the model is quite similar to that of previous studies (16, 19). A backing plate is located at $x = 0$ and the membrane or boundary layer at $x = L$. The porous electrode is treated as a homogeneous mixture of ionically conducting solution phase and an electrically conducting matrix phase. The solid matrix might contain zinc, ZnO, and inert conducting materials (*e.g.*, graphite) or any combination of the three.

The macroscopic averaging technique (14, 40) was applied to the present model by disregarding the actual geometric details of the pores. For example, consider c_i as the concentration of species i averaged over the volume of solution in the pores. Then the superficial concentration, averaged over the unit volume of the electrode, is ϵc_i where ϵ is the porosity of the electrode. If N_i is defined by the superficial flux based on the unit cross-sectional area of the electrode, N_i/ϵ represents the flux through the unit area of solution phase in the pores. Similarly, v/ϵ is the velocity in the solution phase if v is a superficial bulk fluid velocity.

With these average quantities (N_i/ϵ, i_2/ϵ, and v/ϵ), transport equations developed for the concentrated ternary solution (24) were applied to the present four component system on the basis of reaction mechanism [A] and [B]. The results are written as

$$\frac{N_2}{\nu_{2A}} = -D_{AA}\epsilon^{1+t}\frac{dc_A}{dx} - D_{AB}\epsilon^{1+t}\frac{dc_B}{dx} + \frac{t_2}{z_2\nu_{2A}\mathbf{F}}i_2 + c_A v \quad [1]$$

$$\frac{N_3}{\nu_{3B}} = -D_{BA}\epsilon^{1+t}\frac{dc_A}{dx} - D_{BB}\epsilon^{1+t}\frac{dc_B}{dx} + \frac{t_3}{z_3\nu_{3B}\mathbf{F}}i_2 + c_B v \quad [2]$$

$$N_o = D_{OA}\epsilon^{1+t}\frac{dc_A}{dx} + D_{OB}\epsilon^{1+t}\frac{dc_B}{dx} + c_o v \quad [3]$$

where

$$\left.\begin{aligned} D_{ij} &= (D_{ij})^\circ - D_{oj}(c_i/c_o) && ;\ i,j = A,B \\ D_{oj} &= \sum_k c_o\overline{V}_k(D_{kj})^\circ && ;\ j,k = A,B \\ t_i &= (t_i)^\circ - z_i c_i t_o && ;\ i = 1,2,3 \\ t_o &= \frac{\overline{V}_1(t_1)^\circ}{z_1} + \frac{\overline{V}_2(t_2)^\circ}{z_2} + \frac{\overline{V}_3(t_3)^\circ}{z_3} \end{aligned}\right\} \quad [4]$$

where subscripts 1, 2, 3, A, B, and o represent K^+ ion, $Zn(OH)_4^{=}$ ion, OH^- ion, potassium zincate, potassium hydroxide, and water, respectively, N_i is the flux of species i, $\overline{V}_i$ is the partial molar volume of species i, c_i is the concentration of species i, z_i is the charge number of species i, i_2 is the current density

in the solution phase, t is the tortuosity factor, and v is the volume average velocity. The diffusion coefficients D_{ij}(i,j = A,B) and the transference numbers t_i(i = 1,2,3) are defined with respect to the volume average velocity v, while those with superscripts "o" are referred to the solvent reference velocity v_o. The ν_{ij} is the number of ionic species i per molecule of electrolyte "j."

Electroneutrality requires $z_1\nu_{1A} + z_2\nu_{2A} = 0$, $z_1\nu_{1B} + z_3\nu_{3B} = 0$, and $z_1c_1 + z_2c_2 + z_3c_3 = 0$. For the solvent velocity reference frame, the parameters D_{OA}, D_{OB}, and t_o disappear from the above equations. The parameters D_{ij}, t_i, and v should be replaced with $(D_{ij})^o$, $(t_i)^o$, and v_o, respectively, to represent the flux equations referred to the solvent velocity v_o. The effective diffusion coefficients $D_{ij}\epsilon^{1+t}$ account for the tortuosity correction. Schofield and Dakshinamurti (41) have suggested that the effective diffusion coefficients are proportional to $\epsilon^{1.5}$ (or $t = 0.5$). The parameter t_o was taken as zero (or $t_i = t_i^o$) by definition [see Ref. (24)].

Ohm's law in the solution phase.—A modified Ohm's law applied to the ternary electrolyte solution is given by the following equation

$$i_2 = -\kappa\epsilon^{1+t}\frac{d\phi_2}{dx} - \frac{\kappa\epsilon^{1+t}}{n\mathbf{F}}\left(\frac{s_2}{\nu_{2A}} + \frac{nt_2}{z_2\nu_{2A}} - \frac{s_o}{c_o}c_A\right)\frac{d\mu_A}{dx} - \frac{\kappa\epsilon^{1+t}}{n\mathbf{F}}\left(\frac{s_3}{\nu_{3B}} + \frac{nt_3}{z_3\nu_{3B}} - \frac{s_o}{c_o}c_B\right)\frac{d\mu_B}{dx} \quad [5]$$

where ϕ_2 is the potential of a reference electrode of the same kind as the working electrode placed in the bulk solution within the pores of the porous electrode, κ is the conductivity of solution at concentration c_i, and μ_i is the chemical potential of species i. The s_i is the stoichiometric coefficient of species i for the electrode reaction given by

$$\sum_i s_i M_i^{z_i} = ne^- \quad [6]$$

where M_i is the symbol representing the chemical formula of species i, z_i is the charge number of species i, and n is the number of electrons transferred by the electrode reaction.

The effective solution conductivity corrected for tortuosity is represented by $\kappa\epsilon^{1+t}$. Meredith and Tobias (42) and Gagnon (43) suggested t as 0.5, while $t = 2$ was observed by Ksenzhek *et al.* (44). Simonsson (20) and Romanova and Selitsky (45) observed an effective conductivity which was only one-tenth of the conductivity of the free electrolytic solution. They attributed this large reduction to the gas generated in the pores.

Redox electrochemical rate expression.—The rate of charge transfer reaction [A] at the solid-solution interface and the conservation of charge can be represented by the following equation

$$j = \frac{1}{a_m}\left(\frac{di_2}{dx}\right) = i_o^o\left(\frac{c_{2s}}{c_{2r}}\right)^\gamma\left(\frac{c_{3s}}{c_{3r}}\right)^\zeta\left(e^{\frac{\alpha_a\mathbf{F}}{RT}(\phi_1-\phi_{2s})} - e^{-\frac{\alpha_c\mathbf{F}}{RT}(\phi_1-\phi_{2s})}\right) \quad [7]$$

where α_a and α_c are the effective anodic and cathodic transfer coefficients, respectively, j is the local transfer current per unit area of active zinc surface which acts as active sites for reaction (A), i_o^o is the exchange current density evaluated at reference concentrations c_{2r} and c_{3r}, γ and ζ are the orders of dependence of the exchange current density on zincate and hydroxide concentrations, respectively, ϕ_1 is the potential of the matrix phase, ϕ_{2s} is the potential of the reference electrode of the same kind as the working electrode located just outside the double layer, a_m is the solid-solution interface area per unit volume of electrode which acts as active sites for reaction [A]. The transfer current j was related to the gradient of the current density i_2 by the charge conservation equation.

The concentration of zincate ion (c_{2s}) and hydroxide ion (c_{3s}) at the reacting metal surface can be determined from the following equations

$$\frac{di_2}{dx} = -\frac{n\mathbf{F}}{s_2}ak_A(c_{2s} - c_2) \quad [8]$$

$$\frac{di_2}{dx} = -\frac{n\mathbf{F}}{s_3}ak_B(c_{3s} - c_3) \quad [9]$$

where a is the solid-solution interface area per unit volume of the electrode and k_i is the mass transfer coefficient of species i transferring from the bulk solution in the pores to the reaction sites which are active for charge transfer reaction [A] or vice versa.

The potential at the metal surface, ϕ_{2s}, was assumed to be the same as the potential of the bulk solution in the pores, ϕ_2. The mass transfer coefficients k_A and k_B and the active surface area a_m change with time and the state of charge. True values of these parameters are difficult to determine. Consequently, the mathematical forms described in Appendix B were assumed in this work. The constants γ, ζ, α_a, and α_c, corresponding to the reaction mechanism of Bockris *et al.* (34), are 0.75, 0, 1.5, and 0.5, respectively. The exchange current density, i_o^o, reported by previous investigators (29, 31, 34, 46) has values in the range of 10-300 mA/cm^2.

Species conservation equation.—The use of appropriate averaging quantities yields the following conservation equation

$$\frac{\partial\epsilon c_i}{\partial t} = -\frac{dN_i}{dx} + R_i \quad [10]$$

where R_i represents production or consumption of species i due to the electrode reaction. During discharge, zincate ion is produced by charge transfer reaction [A] and consumed by precipitation reaction [B]. On the other hand, hydroxide ion is consumed by reaction [A] and produced by reaction [B]. The reaction source term R_i can be written as

$$R_i = -\frac{s_i}{n\mathbf{F}}\frac{di_2}{dx} + s_{i*}ak_{s*}(c_2 - c_{2e}) \quad [11]$$

where k_{s*}, during discharge, is defined by the rate constant combining mass transfer of zincate ions from bulk solution in the pores to the reaction sites with chemical rate constant for precipitation of ZnO, c_{2e} is the equilibrium or saturation concentration of zincate ion at the solid-solution interface which is active for reaction [B], and s_i and s_{i*} are the stoichiometric coefficients of species i for the reaction [A] and for the reaction [B], respectively, defined by Eq. [6]. Substitution of Eq. [11] into Eq. [10] yields

$$\frac{\partial\epsilon c_2}{\partial t} = -\frac{dN_2}{dx} + \frac{1}{n\mathbf{F}}\frac{di_2}{dx} - ak_{s*}(c_2 - c_{2e}) \quad [12]$$

$$\frac{\partial\epsilon c_3}{\partial t} = -\frac{dN_3}{dx} - \frac{4}{n\mathbf{F}}\frac{di_2}{dx} + 2ak_{s*}(c_2 - c_{2e}) \quad [13]$$

$$\frac{\partial\epsilon c_o}{\partial t} = -\frac{dN_o}{dx} + ak_{s*}(c_2 - c_{2e}) \quad [14]$$

where $s_2 = -s_{2*} = -1$, $s_3 = 4$, $s_{3*} = -2$, $s_o = 0$, and $s_{o*} = -1$ have been substituted.

Overall conservation equation.—The porosity of the electrode will increase as zinc dissolves and decrease as ZnO precipitates. A material balance on the solid species shows how the porosity varies with time as

$$\frac{\partial \epsilon}{\partial t} = \frac{1}{n\mathbf{F}} \sum_i \overline{V}_i s_i \frac{di_2}{dx} + \sum_i \overline{V}_i s_{i*} a k_{s*} (c_2 - c_{2e}) \quad [15]$$

where $\overline{V}_i$ is the partial molar volume of species i and the species i represents the solid species, namely, zinc and ZnO.

Similarly, a material balance on the ionic species leads to the following electrolyte continuity equation

$$\frac{\partial \epsilon}{\partial t} + \frac{dv}{dx} = -\left(\frac{\overline{V}_A t_2}{z_2 \nu_{2A}} + \frac{\overline{V}_B t_3}{z_3 \nu_{3B}} + \frac{\overline{V}_A s_2}{n \nu_{2A}} + \frac{\overline{V}_B s_3}{n \nu_{3B}} + \frac{\overline{V}_o s_o}{n}\right) \frac{di_2}{\mathbf{F} dx} - a k_{s*} \left(\frac{s_{2*} \overline{V}_A}{\nu_{2A}} + \frac{s_{3*} \overline{V}_B}{\nu_{3B}} + \overline{V}_o s_{o*}\right) (c_2 - c_{2e}) \quad [16]$$

This equation is obtained by adding Eq. [12], [13], and [14] which have been multiplied by $\overline{V}_A/\nu_{2A}$, $\overline{V}_B/\nu_{3B}$, and $\overline{V}_o$, respectively, and using the relations of $c_A \overline{V}_A + c_B \overline{V}_B + c_o \overline{V}_o = 1$, $\overline{V}_A D_{AA} + \overline{V}_B D_{BA} - \overline{V}_o D_{OA} = 0$, and $\overline{V}_A D_{AB} + \overline{V}_B D_{BB} - \overline{V}_o D_{OB} = 0$. The last two relations for D_{OA} and D_{OB} can be derived from Eq. [4].

From Eq. [15] and [16], the convective bulk flow motion in the porous electrode can be described by the following overall continuity equation

$$\frac{dv}{dx} = -\frac{1}{n\mathbf{F}} \left[\overline{V}_{Zn} + 4\overline{V}_B - \overline{V}_A - 2\left(\frac{t_2 \overline{V}_A}{\nu_{1A}} + \frac{t_3 \overline{V}_B}{\nu_{1B}}\right)\right] \frac{di_2}{dx} + a k_{s*} [\overline{V}_{ZnO} + \overline{V}_o + 2\overline{V}_B - \overline{V}_A] (c_2 - c_{2e}) \quad [17]$$

The second bracket term is the volume change of reaction [B]. The first bracket term represents the volume change of reaction [A], *i.e.*, $(t_2 \overline{V}_A/\nu_{1A} + t_3 \overline{V}_B/\nu_{1B}) = \overline{V}_1$, if the transference number t_o, defined in Eq. [4], is chosen as zero.

Ohm's law in the solid matrix.—Ohm's law in the solid matrix can be written as

$$i_1 = I - i_2 = -\sigma \epsilon_m \frac{d\phi_1}{dx} \quad [18]$$

where ϕ_1 is the potential of the solid matrix and ϵ_m is the volume of conducting material per unit volume of the electrode (not necessarily equal to $1 - \epsilon$). The superficial current density in the solid phase i_1 and that in the solution phase i_2 are related to the total applied current density I as $i_1 + i_2 = I$. The conductivity of the solid matrix is approximated by

$$\sigma = \sigma_{Zn} (\epsilon_{Zn})^{t^*} + \sigma_{ZnO} (\epsilon_{ZnO})^{t^*} + \sigma_I (\epsilon_I)^{t^*} \quad [19]$$

where σ_{Zn}, σ_{ZnO}, and σ_I are the conductivities of the zinc metal, zinc oxide, and inert material in the pure solid phase, respectively, and ϵ_{Zn}, ϵ_{ZnO}, and ϵ_I are the volume fractions of the corresponding solid species.

Computation procedures.—The six equations; two second-order equations [12] and [13] and four first-order equations [5], [7], [17], and [18]; form a set of nonlinear coupled differential equations. The six unknown variables are i_2, ϕ_2, c_2, c_3, v, and ϕ_1, which are functions of time and position. The six equations can be solved by use of a numerical technique with the following initial and boundary conditions.

Initial conditions at time = 0 are

$$c_2 = c_{2o}, \quad c_3 = c_{3o}, \quad v = 0 \quad [20]$$

For the other variables, the following approximate equations were solved to estimate the initial profiles of i_2, ϕ_1, and ϕ_2

$$\left.\begin{aligned} i_2 &= -\kappa \epsilon^{1+t} \frac{d\phi_2}{dx} = -\kappa_e \frac{d\phi_2}{dx} \\ \frac{di_2}{dx} &= a_m i_o{}^o \frac{(\alpha_a + \alpha_c)\mathbf{F}}{RT} (\phi_1 - \phi_2) = R_e (\phi_1 - \phi_2) \\ i_1 &= I - i_2 = -\sigma \epsilon_m \frac{d\phi_1}{dx} = -\sigma_e \frac{d\phi_1}{dx} \end{aligned}\right\} \quad [21]$$

The solution of Eq. [21] becomes as follows, *e.g.*, for current distribution

$$\frac{di_2}{dy} = \frac{IQ}{\kappa_e + \sigma_e} \left[\sigma_e \frac{\cosh Qy}{\sinh Q} + \kappa_e \frac{\cosh Q(1-y)}{\sinh Q}\right]; \quad Q = L\sqrt{R_e\left(\frac{1}{\kappa_e} + \frac{1}{\sigma_e}\right)} \quad [22]$$

where y is the dimensionless distance from the backing plate (x/L); L is the electrode thickness.

The boundary conditions at $x = 0$ are as follows

$$\frac{d\phi_2}{dx} = 0 \ (\text{or } i_2 = 0), \quad \frac{dc_2}{dx} = 0, \quad \frac{dc_3}{dx} = 0, \quad v = 0, \quad \phi_1 = 0 \quad [23]$$

The boundary conditions at $x = L$ are

$$\left.\begin{aligned} i_2 &= I \\ \frac{\partial (Vc_i)}{\partial t} &= A(N_i)_L - A(N_i)_m; \quad i = 2, 3 \end{aligned}\right\} \quad [24]$$

where I is the applied current density, A is the cross-sectional area of the electrode, and V is the volume of the solution reservoir located between the electrode surface and the membrane. The $(N_i)_L$ and $(N_i)_m$ represent fluxes of species i across the boundary $x = L$ and across the membrane, respectively. If a solution reservoir is absent (*i.e.*, $V = 0$), the above boundary conditions simply represent the conservation of fluxes at the boundary, *i.e.*, $(N_2)_L = (N_2)_m$ and $(N_3)_L = (N_3)_m$.

The fluxes $(N_2)_L$ and $(N_3)_L$ are Eq. [1] and [2], applied to the boundary $x = L$, respectively. The fluxes $(N_2)_m$ and $(N_3)_m$ are written as

$$\left.\begin{aligned} \frac{(N_2)_m}{\nu_{2A}} &= \frac{(D_{AA})_m}{d} (c_{2L} - c_{2o}) + \frac{(t_2)_m}{z_2 \nu_{2A} \mathbf{F}} I + c_{2m} v_m \\ \frac{(N_3)_m}{\nu_{3B}} &= \frac{(D_{BB})_m}{d} (c_{3L} - c_{3o}) + \frac{(t_3)_m}{z_3 \nu_{3B} \mathbf{F}} I + c_{3m} v_m \end{aligned}\right\} \quad [25]$$

where d is the thickness of the membrane and subscripts "m", "L", and "o" represent values taken at the membrane, reservoir solution, and the counter-electrode compartment, respectively.

The six equations were linearized about a trial solution, put into finite difference forms, and solved by the numerical technique developed by Newman (47) subject to the initial conditions [20] and [21] and the boundary conditions [23] through [25]. The Crank-Nicolson implicit method (48) was used for averaging time derivatives in Eq. [12] and [13]. The resulting six finite difference equations are correct to second order, h^2 and $(\Delta t)^2$, where h and Δt are the mesh sizes of distance and time. The convergence criterion used was 10^{-5} which is defined by the ratio of the difference between the two successive solutions to the present solution. The details of the numerical procedures as well as the computer program have been described by Sunu (49). The physical and chemical parameters used for numerical calculations are summarized in Appendix A. The numerical calculations

were carried out in double precision using an IBM 360/91 computer.

Result

The mathematical model described in the previous section was solved under the following conditions; the initial solution of 8M KOH – 0.66M $K_2Zn(OH)_4$ and the electrode initially composed of 40% void volume, 50% zinc, and 10% ZnO by volume ($\epsilon = 0.4$, $\epsilon_{Zn} = 0.5$, $\epsilon_{ZnO} = 0.1$, and $\epsilon_I = 0$). The total capacity of this electrode estimated from the amount of zinc is 17.6 A-min and corresponds to a discharge for 352 min at 50 mA/cm^2. This capacity is referred to as "100% depth of discharge" or as "100% utilization" througout this paper. The capacity equivalent to the hydroxide ions of the pore solution is only 1.03 A-min or 5.85% utilization. This number is surprisingly small. Three boundary cases were considered using the parameters shown in Table I. They include the type I membrane boundary (second column), solution boundary (third column), and type II membrane boundary which is equivalent to the use of one layer of RAI P2291 cation exchange membrane. The results on discharge are shown in Fig. 1 to 5 and those on cycling are summarized in Fig. 6 and 7.

Figure 1 shows how concentrations of KOH (top curves) and potassium zincate (bottom curves) vary with time during discharge. Initial concentration was shown by dotted lines. After 1 min polarization, hydroxide concentration decreases to 7.6M, a value averaged over the entire pore solution, and zincate becomes supersaturated (curve A). On further discharge, hydroxide concentration drops rather slowly because a large amount of hydroxide ions which are transferring from the counterelectrode also participate in the electrode reaction. For example, at 30% depth of discharge (or 5.28 A-min), only 0.43 A-min is corresponding to the decrease of OH^- concentration of pore solution from 8M to 4.7M, and the remaining 4.85 A-min is resulting from the hydroxide ions supplied from the counterelectrode compartment. This indicates that the membrane affects significantly the utilization of active zinc particularly of the cell having a limited amount of electrolyte. Equilibrium concentration of zincate decreases with KOH concentration and therefore zincate concentration also decreases as discharge continues. However, there is always some degree of supersaturation with a maximum being located near the electrode face.

The effect of the membrane is clearly shown in Fig. 2 where profiles of KOH concentration obtained with three types of boundaries are presented. The average KOH concentration obtained after 10% depth of discharge was 7.5M for the solution boundary, 5.3M for the type I membrane boundary, and 2M for the type II membrane boundary. A similar calculation showed that a cell with two layers of type II (RAI P2291 cation exchange) membrane was completely depleted of hydroxide ions after only 8% depth of discharge. Clearly, discharge of the cell having a type II membrane as a separator could fail due to KOH depletion.

Table I. Transport parameters applied to the various boundary layers

	Type I membrane boundary	Solution boundary	Type II membrane (RAI P2291)*
$(t_1)_m$	0.5	0.23	0.5
$(t_2)_m$	0.0	0.05	0.0
$(t_3)_m$	0.5	0.72	0.5
$(D_{AA})_m$ (cm^2/sec)	2.5×10^{-8}	6.0×10^{-6}	1.0×10^{-8}
$(D_{BB})_m$ (cm^2/sec)	2.5×10^{-7}	2.0×10^{-5}	7.5×10^{-8}
d (cm)	0.0025	0.005	0.0025
$(L_{AA})_m$ (cm/sec)	1.0×10^{-5}	0.0012	4.0×10^{-6}
$(L_{BB})_m$ (cm/sec)	1.0×10^{-4}	0.004	3.0×10^{-5}

* Transport parameters for RAI P2291 membrane were taken from the data of Sinha and Bennion (50). The parameter $(L_{ii})_m$ is defined by $(D_{ii})_m/d$ (refer to Eq. [25]).

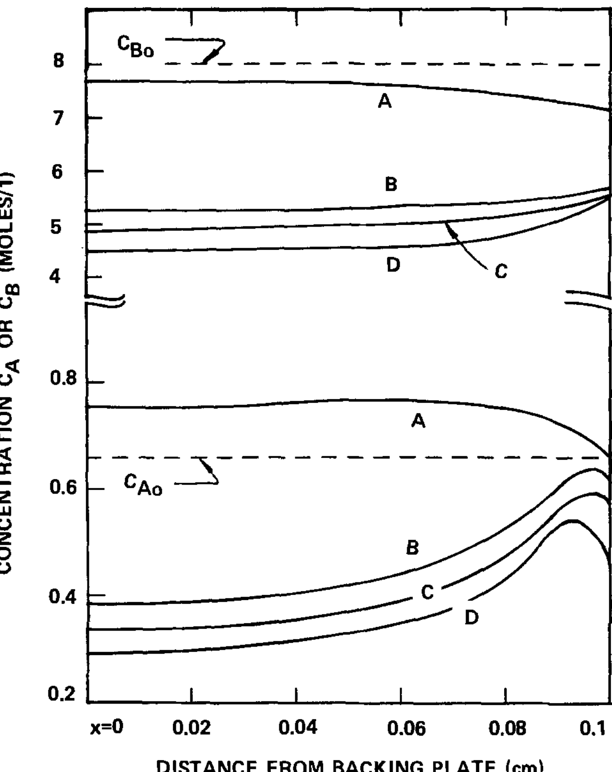

Fig. 1. Concentration profiles during constant current discharge for type I membrane boundary (I = 50 mA/cm^2, A for 1 min polarization and B, C, and D for 10%, 20%, and 30% depth of discharge, respectively).

The charge transfer current, j (mA/cm^2), is plotted as a function of distance in Fig. 3. Initially, the reaction distribution is shown as curve A, having a maximum at the face of the electrode. As discharge continues to 10% depth, KOH concentration, porosity, and therefore the conductivity of the solution decreases. This effect shifts the reaction toward the front face

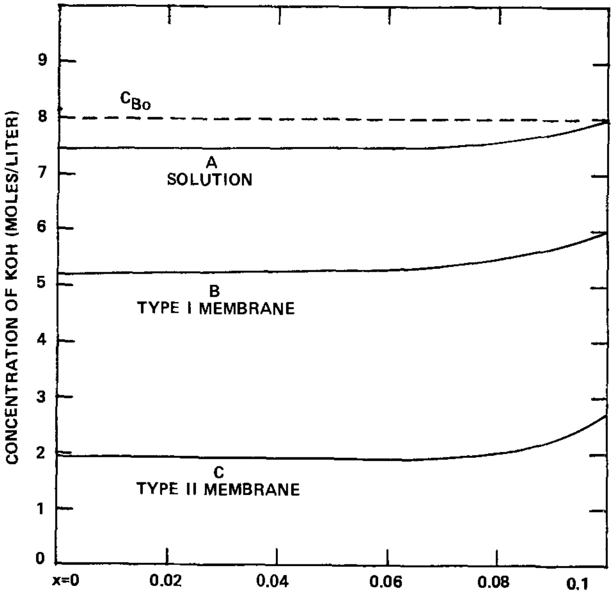

Fig. 2. Profiles of KOH concentration after 10% depth of discharge (I = 50 mA/cm^2 and A, B, and C for solution boundary, type I membrane boundary, and type II membrane boundary, respectively).

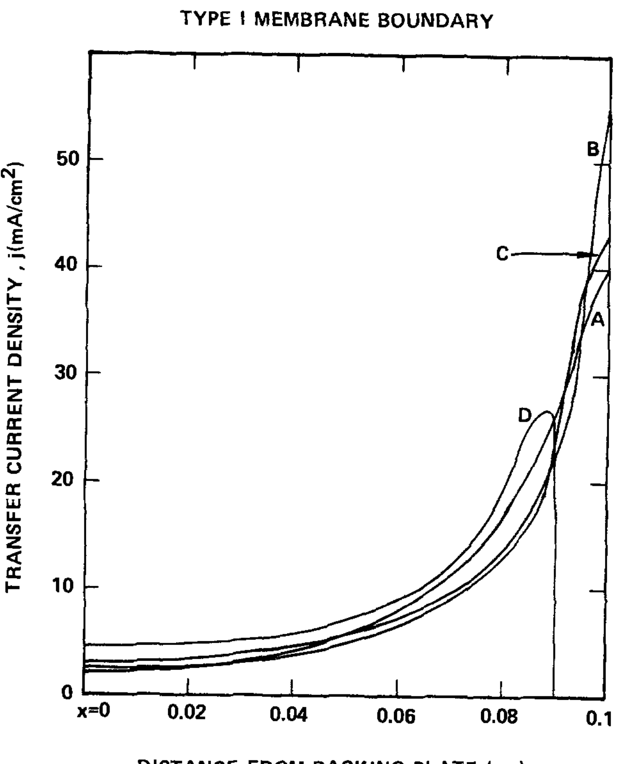

Fig. 3. Distribution of local charge transfer current, j (mA/cm²), for type I membrane boundary (I = 50 mA/cm², L = 0.1 cm, and A, B, C, and D represent 0%, 10%, 20%, and 40% depth of discharge, respectively).

and the reaction profile becomes less uniform as shown in curve B. When the electrode is discharged further beyond 20% depth, the reaction at the electrode face starts decreasing due to the depleted active zinc metal (curve C). After 40% depth of discharge, all the zinc near the front face is used up as shown in curve D. The overpotentials rose substantially when only 40% of the initial zinc metal was utilized. The reaction profile is highly nonuniform and the effective reaction zone moves step by step from the face of the electrode toward the backing plate. Similar trends were obtained with the other two boundaries.

The distribution of solid zinc and ZnO, in terms of volume fractions, is plotted in Fig. 4 for the type I membrane and in Fig. 5 for the solution boundary. The total amount of zinc dissolution into zincate at a specified time, *i.e.*, the integrated area between the dotted line denoted by $(\epsilon_{Zn})_o$ and the curve ϵ_{Zn} at time t, are the same for both cases. However, the total amount of ZnO precipitated, *i.e.*, the integrated area of ZnO profiles, is smaller for the solution case than for the membrane case. For example, after 40% depth of discharge, the amount of precipitated ZnO obtained from Fig. 4 and 5 are 95% and 55%, respectively. of the total amount of the zinc consumed during the same period of 141 min. The missing zinc oxide is lost into the counterelectrode compartment as a soluble species, zincate ion, before precipitation occurs.

The electrode initially composed of 40% liquid filled pores, 50% zinc, and 10% ZnO by volume was cycled numerically with a constant current density of 50 mA/cm². Each cycle consisted of 20% depth of discharge and 20% depth of charge. The current distribution predicted during one cycle is presented in Fig. 6 for the type I membrane case. It shows that current distribution becomes more uniform on charging than on discharging, in particular, near the beginning of charge (curve A). When charge starts, the solid-solution interfacial area near the electrode face contains mainly the area of ZnO precipitates and a very small

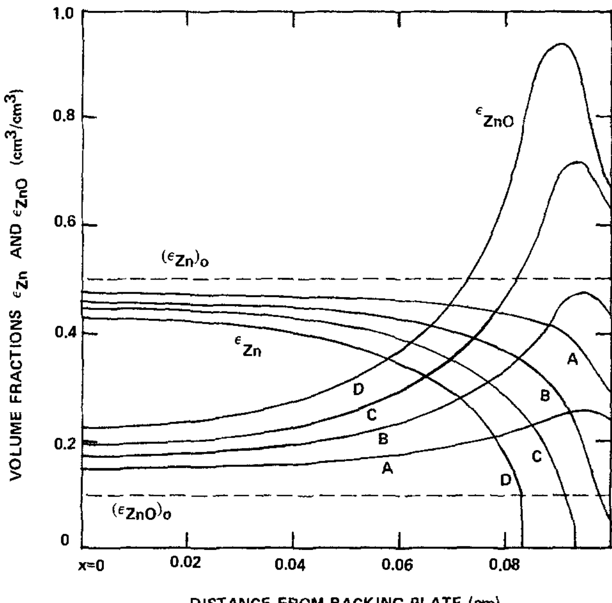

Fig. 4. Distribution of Zn and ZnO plotted as volume fractions for type I membrane boundary (I = 50 mA/cm², and A, B, C, and D represent 10%, 20%, 30%, and 40% depth of discharge, respectively).

active zinc area (see curves B of Fig. 4). This reduced zinc area at the electrode face prohibits the transfer reaction on charge and shifts the reaction toward the backing plate, resulting in curve A. If sufficient amount of zinc forms and serves as nucleation sites for further zinc deposition reaction, current distribution which is similar in shape to that of discharge will result (curves B and C).

In Fig. 7, the volume fractions of zinc and zinc oxide during two cycles are plotted as a function of the distance from the backing plate. After each complete cycling, the solid zinc species (Zn and ZnO) have not reformed in their original positions. This is due to the difference in the current distribution during discharge and charge. The redistribution of zinc and zinc oxide becomes less uniform as cycling continues. Numerical predictions obtained with a cell having no membrane

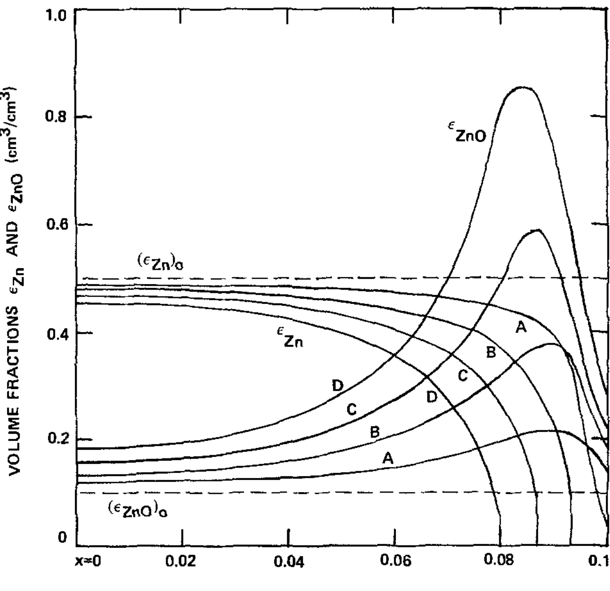

Fig. 5. Distribution of Zn and ZnO plotted as volume fractions for solution boundary (I = 50 mA/cm², and A, B, C, and D represent 10%, 20%, 30%, and 40% depth of discharge, respectively).

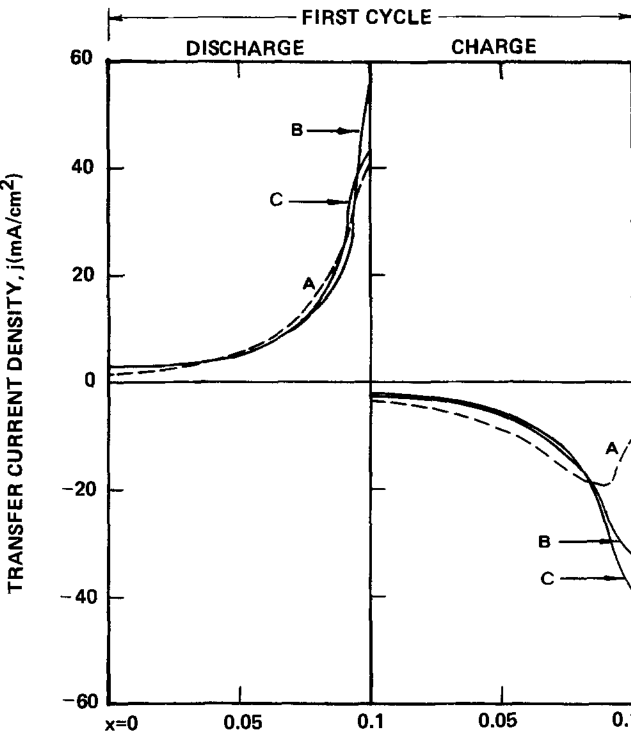

Fig. 6. Distribution of local charge transfer current density, j (mA/cm^2), during the first cycle for type I membrane boundary ($I = 50$ mA/cm^2, $L = 0.1$ cm, and A, B, and C represent 0%, 10%, and 20% depth of discharge or charge, respectively).

showed greater degree of redistribution of solid species (49).

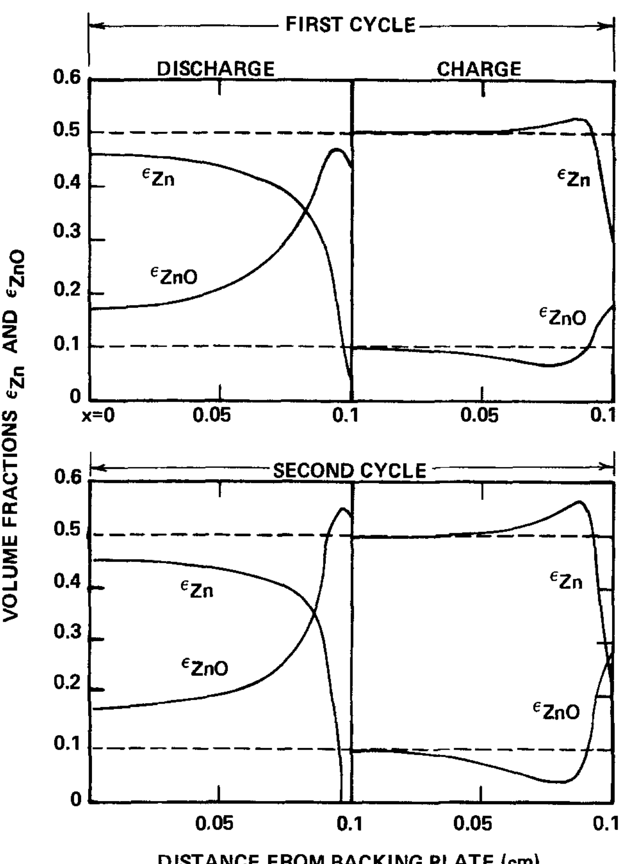

Fig. 7. Distribution of Zn and ZnO plotted as volume fractions during two cycles for type I membrane boundary ($I = 50$ mA/cm^2, $L = 0.1$ cm, $\epsilon_o = 0.4$, $(\epsilon_{Zn})_o = 0.5$, $(\epsilon_{ZnO})_o = 0.1$).

Discussion

Failure during discharge.—Zinc electrode behavior occurring during discharge has been predicted by a mathematical model. The model predicts that discharge of the zinc electrode having a porosity of 0.4 and one layer of type I membrane could fail after only 40% utilization due to the decrease in pore size (blockage of the first kind) as shown in Fig. 4. The primary effect of the decreased pore size is, as in the lead positive electrode (20), the restricted diffusion of electrolytes into the interior of the porous electrode, causing electrolyte depletion at the reaction sites. If the porosity falls below a certain limit, the resistance across the pore solution rises substantially and serves as a factor in limiting further utilization.

The model predicts that the reaction distribution is highly nonuniform, and the effective reaction zone is very thin (Fig. 3). The reaction distribution or the penetration depth has been characterized by certain dimensionless parameters (14). In the case of uniform concentration and low activation polarization, two parameters, σ_e/κ_e and Q of Eq. [22], could determine the shape of distribution. The reaction distribution becomes less uniform as the parameter Q increases. The ratio σ_e/κ_e determines the shape of distribution curves, namely, the position having a maximum utilization. Maximum utilization would occur at the electrode face for $\sigma_e > \kappa_e$ and at the backing plate for $\kappa_e > \sigma_e$. Concentration polarization and the decrease of pore size have an effect of increasing the effective resistance of pore solution and thus promoting the degree of nonuniformity. This effect was illustrated in Fig. 3 (compare curves A and B). This nonuniform reaction distribution will accelerate the failure due to pore plugging at the electrode surface. The zinc metal near the backing plate serves simply as an inert matrix and does not contribute to the cell capacity.

The loss of ZnO species into the counterelectrode compartment during discharge was very large for cells without a membrane (see Fig. 5), while for the cell with a membrane (Fig. 4), mass transfer of zincate ion into the counterelectrode compartment was restricted. However, KOH concentration was depleted significantly during discharge of a cell having one layer of RAI P2291 cation exchange membrane as was predicted in Fig. 2 (curve C). With two layers of RAI P2291 membrane, only 8% utilization resulted in the complete depletion of hydroxide ions inside the zinc electrode compartment (54).

Discharge failure mentioned above could be interpreted by a single process, *i.e.*, the limited mass transfer of soluble species to and from the dissolving zinc surfaces. For the planar zinc electrode, discharge failure has been interpreted as a phenomenon called "passivation" which was described by a limited diffusion of product species, zincate ions, away from the dissolving surfaces (51-53). Discharge of the porous electrode involves more complicated and interrelated phenomena, and therefore it appears to be valuable to divide the limiting process into several sub-mechanisms having more precise meaning, *i.e.*, passivation, pore plugging, and depletion of electrolyte. Each mechanism is defined as follows.

Consider a test electrode compartment which contains solution inside the porous electrode (designated as "pore solution"), and solution outside the pores but within that compartment ("reservoir solution"). Solution outside the test electrode compartment on the other side of the membrane separator which is usually contained in the counterelectrode compartment is denoted by "external solution." Discharge of the porous electrode may fail in three ways:

(*i*) If the reservoir solution is severely depleted of hydroxide ions due to the limited transfer of OH^- ions across the membrane, then the pore solution is also depleted of electrolyte KOH, as was predicted with a cell having one layer of RAI P2291 membrane (curve

C of Fig. 2). This causes passivation at the active zinc surfaces due to a decrease in solubility of ZnO and a rapid increase in the rate of ZnO precipitation, in addition to increased resistance losses. This phenomenon is defined as the electrolyte depletion. To reduce this effect, sufficient amount of electrolytes should be provided in the solution reservoir. Proper choice of the membrane, which leads to a maximal supply of OH^- ions from the counterelectrode compartment and also a minimal chance for zinc dendrite penetration, is also important.

(*ii*) The reservoir solution could retain the electrolyte concentration at a fairly constant level throughout the discharging process, provided that the reservoir has a large volume. But the pore solution still can be depleted of electrolyte due to the limited mass transfer across the reaction zone located near either side of the electrode surfaces, which has smaller pores. The consequences will be the depletion of electrolytes at discharging zinc surfaces, resulting in passivation. This is defined as pore plugging and can be eliminated by using high porosity electrodes. Discharge failure predicted with the solution boundary and type I membrane boundary are attributed to pore plugging (see Fig. 4 and 5).

(*iii*) Even if the KOH concentration of the pore solution as well as the reservoir solution remains appreciably high, passivation could occur by the physical blocking of the active zinc surface by a precipitated ZnO film, which forms due to the depleted hydroxide ion or due to the excess zincate at the zinc surface. This phenomenon is defined as passivation, having the same meaning as was used for planar electrodes. Passivation of this type could occur under very high current load. Electrodes with high active surface area and with uniform current distribution would reduce local transfer current density and thus the chance for passivation.
